The small size of the nanowire devices with 1D electronic transport necessitates a full quantum kinetic simulation approach such as the nonequilibrium Green's function formalism (NEGF) as described below. In the presence of Schottky barriers, few-electron charging effects of quasibound electrons may emerge which are beyond the scope of the commonly employed mean field approximation of the Coulomb interaction (e.g., self-consistent Hartree potential), requiring a many-body (e.g., multiconfigurational) approach.

Channel Electrostatics

Within the channel region of the NWFET, the Coulomb interaction between charges (such as electrons or ionized dopants) is screened due to image charge effects within the surrounding metallic gate electrode. The resulting electrostatic potential $V(x)$ (along the nanowire channel direction) can be modeled by a one-dimensional (1D) modified Poisson equation [7, 12]

$$\frac{\partial^2}{\partial x^2}V(x) - \frac{1}{\lambda^2}V(x) = -\frac{1}{\epsilon_0\epsilon_{ch}S}\rho(x) - \frac{1}{\lambda^2}V_{gs} \tag{6}$$

where λ is the effective screening length (see chapter above), V_{gs} denotes the gate-source voltage, $\rho(x)$ is the 1D total charge density (electrons, holes, and ionized dopants), and $S = \pi d_{ch}^2/4$ is the channel cross-sectional area.

As an analytical solution of the modified Poisson equation for fixed potential boundary conditions, one obtains

$$V(x) = \frac{1}{\epsilon_0\epsilon_{ch}S}\int dx' v(x,x')\ \rho(x') + V_{ext}(x) \tag{7}$$

with the so-called Coulomb Green's function

$$v(x,x') = \frac{\lambda}{2}e^{-\frac{|x-x'|}{\lambda}} + v_{bc}(x,x') \tag{8}$$

which contains a fixed-potential boundary condition term

$$v_{\mathrm{bc}}(x,x') = -\frac{\lambda}{2}e^{-\frac{x+x'}{\lambda}} + \frac{\lambda}{2}e^{-\frac{L}{\lambda}}\left(\frac{\cosh\left(\frac{x-x'}{\lambda}\right)}{\sinh\left(\frac{L}{\lambda}\right)} - \frac{\cosh\left(\frac{x+x'}{\lambda}\right)}{\sinh\left(\frac{L}{\lambda}\right)}\right) \tag{9}$$

stemming from screening effects due to metallic source and drain contacts at the outer ends of the channel (where v must vanish).

The electrostatic control of the FET as a function of the contact potentials V_{gs}, V_{ds} is solely contained within the potential term

$$V_{\mathrm{ext}}(x) = \frac{\sinh\left(\frac{x}{\lambda}\right)}{\sinh\left(\frac{L}{\lambda}\right)}V_{\mathrm{ds}} + \frac{1}{\lambda^2}\int dx' v(x,x')\,V_{\mathrm{gs}} \tag{10}$$

Quantum Kinetic Transport Simulation

On a fundamental level, the nonequlilbrium quantum mechanical state (preparation) of the whole interacting many-electron system of the nanodevice is completely described by its many-body statistical operator. For numerical simulation approaches of realistic nanodevices with a large number of basis states (as opposed to overidealized few-site models), however, this quantity exhibits an expontially scaling, numerically unfeasible number of matrix elements. Therefore, it is reasonable to consider temporal and spatial correlation functions of ordered field operators of the electronic system, so-called real-time Green's functions $G(x_1, t_1; x_2, t_2; \ldots)$, since those quantities can be employed directly for the calculation of relevant physical observables such as charge density and electrical current. It turns out that one can derive a closed set of integrodifferential equations (Dyson equation) for these Green's functions, without the necessity of a detailed knowledge about the full many-body statistical operator. For the numerical evaluation of these equations, approximation and reduction schemes are still required, assuming typical application-relevant conditions for device operation. This concept constitutes the basis for the nonequilibrium Green's function formalism (NEGF) for the quantum kinetic simulation of realistic nanoelectronic devices [13–17].

Within a numerical description of the nanoelectronic system, a suitable single-particle basis has to be chosen for a numerical representation of operators in terms of matrix elements. For the description of heterostructures of nanodevices layer by layer in real space (as opposed to approaches in momentum space), a tight binding representation of spatially localized basis wave functions is advantageous [18, 19]. Here, the single-particle ON basis functions ϕ_j (x, σ) are characterized by a multi-index j, which includes the unit cell site (localized position), orbital, and spin. Within the resulting Hamiltonian, transitions between states j, k are described by so-called hopping matrix elements t_{jk}. Typically, in the case of a thin nanowire, only the lowest radial sub-band within the nanowire needs to be considered, and thus, the NWFET channel can be treated as a 1D chain of localized states.

Within the NEGF approach for the simulation of stationary electronic transport in NWFETs, the two-point real-time Green's functions G^r ("retarded") and $G^<$ ("lesser") are typically considered, defined as

$$\begin{aligned} G^r_{jk}(t) &= -i\Theta(t)\left\langle\left\{c_j(t), c_k^\dagger(0)\right\}\right\rangle \\ G^<_{jk}(t) &= i\left\langle c_k^\dagger(0)c_j(t)\right\rangle \end{aligned} \tag{11}$$

where $c_k^\dagger$ and c_j denote the creation and annihilation operator for state j, respectively. Under nonequilibrium conditions, G^r and $G^<$ are independent, containing information about the electron dynamics (energy spectra, etc.) and the electron kinetics (level occupation, particle transport, etc.), respectively. For a stationary case, G depends on the time difference t only, and in turn, the time variable t can be Fourier transformed into an energy variable E. Consequently, G^r and $G^<$ are numerically represented as energy-dependent single-particle matrices.

G obeys the Dyson equation, which can be written as a set of coupled matrix equations (with E variable omitted for brevity) for G^r and $G^<$:

$$\begin{aligned} G^r &= G^{r0} + G^{r0}\sum{}^r G^r \\ G^< &= (1 + G^r\sum{}^r)G^{<0}(\sum{}^a G^a + 1) + G^r\sum{}^< G^a \end{aligned} \tag{12}$$

where $\sum$ is the so-called self-energy, which is an energy-dependent matrix, and $G^a = G^{r\dagger}$, $\sum{}^a = \sum{}^{r\dagger}$. $\sum$ incorporates all aspects of the system that are not contained within the unperturbed Green's function G^0. Typically, $\sum$ accounts for the Coulomb interaction, contact coupling (to source and drain for particle injection), scattering, etc. Consequently, G^0 has a very simple analytical form of a noninteracting, decoupled single-particle problem:

$$G^{r0}(E) = \frac{1}{E - H_{10} + i\epsilon} \quad (\epsilon \to 0+) \tag{13}$$

whereas $\sum$ becomes very complex and requires suitable approximation schemes for numerically feasible implementations.

From $G^<$, the single-particle density matrix

$$\rho_1 = \frac{1}{2\pi}\int dE \frac{1}{i} G^<(E) \tag{14}$$

can be calculated easily. In turn, all required single-particle expectation values, such as the electron charge density ρ_e and the drain current I_d, can be computed directly from ρ_1:

$$\rho_e(x,\sigma) = -e\sum_{j,k} \phi_j^*(x,\sigma)\ \ \phi_k(x,\sigma)\ \ \rho_{1kj} \tag{15}$$

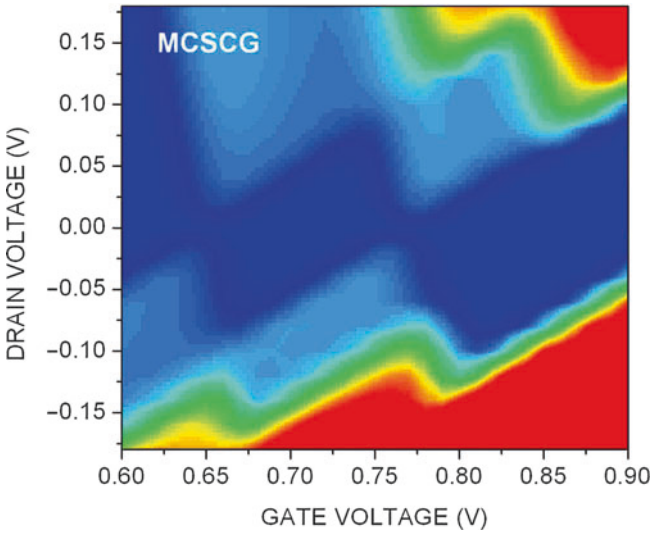
$$I_d = -\frac{e}{\hbar} \sum_{\substack{j,k \\ x_j \le x_d, \\ x_k > x_d}} 2Im\Big(t_{jk}\ \ \rho_{1kj}\Big) \tag{16}$$

As an approximation under application-relevant conditions (e.g., temperatures well above the relevant Kondo temperature of the nanosystem), the self-energy $\sum$ can be assumed to be of a decoupled form, written as a sum of independent contributions due to contact coupling, Coulomb interaction etc. Then, the retarded self-energy term $\sum_c$ due to source and drain contact coupling, for example, reads as

$$\sum{}^r_{cjk}(E) = \sum_{p,q\in c} t_{cjp} G^{r0}_{cpq}(E) t_{cqk} \tag{17}$$

and the self-energy term $\sum_{ee}$ for the Coulomb interaction in static (i.e., E-independent) mean field approximation (here Hartree-Fock), for example, reads as

$$\sum{}^r_{eeml}[\rho_1] = \sum_{j,k} \big(V_{mjkl} - V_{jmkl}\big)\rho_{1_{kj}} \tag{18}$$



with Coulomb matrix elements V_{mjkl} of the screened Coulomb interaction within the channel obtained from the Coulomb Green's function $v(x,x')$ (see chapter above):

$$\begin{aligned} V_{mjkl} = \ & \frac{e^2}{\epsilon_0\epsilon_{ch}S}\sum_{\sigma,\sigma'}\int dx \int dx'\ \ v(x,x') \\ & \times \phi_m^*(x,\sigma)\,\phi_j^*(x',\sigma')\phi_k(x',\sigma')\phi_l(x,\sigma) \end{aligned} \tag{19}$$

Within the considered approximation scheme, analytical expressions for $\sum^<$ can derived from the $\sum^r$ expressions above. One has to note that $\sum_{ee}$ above depends on ρ_1 which, in turn, results from $G^<$. In combination with the Dyson equation, therefore, a self-consistency problem results that has to be solved iteratively.

Few-Electron Charging Effects and Many-Body Aspects

Under certain conditions, charging effects of individual electrons (or holes) may become visible in the IV characteristics of the nanodevice. For example, so-called Coulomb diamonds (see e.g., Fig. 4) can emerge within the $I_d(V_{gs}, V_{ds})$ diagram, representing regions of suppressed current I_d due to a finite energy ΔE which is required to add a single additional electron to the system.

Nanowire FET Simulations Based on the Nonequilibrium Green's Function Formalism,
Fig. 4 Simulated drain current with Coulomb diamonds for an InGaAs NWFET with Schottky contacts, $L = 20$ nm, $d_{ch} = 4$ nm, $d_{ox} = 10$ nm at $T = 77$ K [21]

Such few-electron charging effects require the existence of resonantly trapped electronic states which are quasibound due to a weak coupling to the external contacts (e.g., due to Schottky barriers or potential wells in heterostructures). The energy gap due to Coulomb repulsion reads as $\Delta E_C = e^2/C^*$, where C^* denotes the effective capacitance of the system. Analogous, the single-particle quantization energy gap reads as $\Delta E_L \propto \hbar^2/\left(m^* L^2\right)$, which is due to the spatial confinement ($\propto L$) of quasibound electronic states. In general, the observed voltage regions of suppressed current (diamond-like shaped) are a result of the combination of both effects, Coulomb repulsion and level quantization due to confinement, resembling a finite total energy gap ΔE that has to be overcome to add an additional electron to the system. As a criterion for the visibility of this energy gap, the thermal energy $k_B T$ and the level broadening $\Gamma_c = i\left(\sum_c^r - \sum_c^{r\dagger}\right)$ (as a measure of the coupling strength to the contacts) must be small compared to ΔE, leading to the transport regime of so-called single-electron tunneling (SET). One has to note that under application-relevant conditions (above the Kondo temperature of the coupled system of contacts and trapped, interacting states), correlation effects associated with the contacts can be neglected (justifying the approximation of a decoupled self-energy form, see chapter above).

Experimentally as well as numerically, Coulomb blockade effects can be employed to determine effective capacitances C^* from the sizes of the observed Coulomb diamonds, providing valuable information about the nanowire channel.

Unfortunately, the simulation of few-electron Coulomb charging is beyond the scope of the commonly employed static mean field approximation (e.g., Hartree or Hartree-Fock), making a many-body approach to the interacting few-electron system mandatory. Due to the numerically unfeasible Fock space dimension of a realistic NWFET device (with a large number of single-particle basis states), numerical approximation schemes are required. In order to include few-electron Coulomb charging effects of resonantly trapped electrons within the framework of NEGF in a numerically feasible manner, for example, a multiconfigurational ansatz can be employed [20, 21]. The main idea is to write the Green's functions as a weighted mixture over a reduced set of relevant many-body states (so-called configurations) k of relevant quasibound electronic states:

$$\overline{G} = \sum_{\kappa} w_\kappa G[\hat{\rho}_\kappa] \tag{20}$$

where $\hat{\rho}_\kappa$ is the many-body statistical operator corresponding to the system being in

configuration κ. Note that the number of configurations grows exponentially with the number of relevant single-particle states. Relevant single-particle states are defined as those natural orbitals (i.e., eigenstates of ρ_1) that exhibit occupation fluctuations and are quasibound (i.e., weakly coupled), thus being responsible for few-electron charging effects (leading to Coulomb diamonds in the IV characteristics, etc.). This approach, hence, considers a voltage- and parameter-adaptive relevant Fock subspace which can be handled numerically (as compared to the full Fock space of the whole nanowire system). The determination of the relevant natural orbitals and the many-body configuration weights w_κ can be embedded self-consistently within the NEGF algorithm, leading to the so-called multiconfigurational self-consistent Green's function (MCSCG) approach for the inclusion of few-electron Coulomb charging effects (see, e.g., Fig. 4) within the numerical framework of NEGF-based device simulators [20, 21].

Synonyms

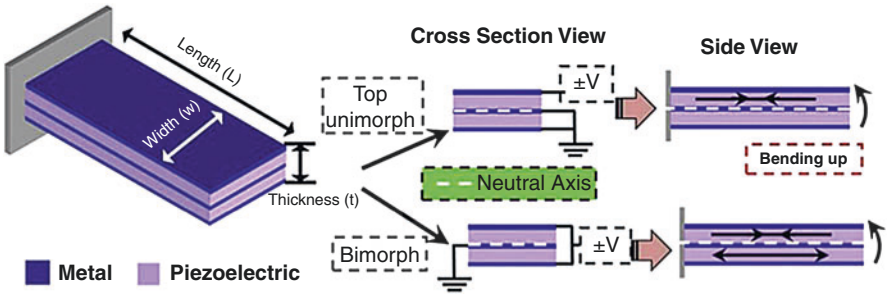
Dual-beam piezoelectric switches; Piezoelectric switches

Definition

NEMS Piezoelectric Switches are defined as mechanical switches that use piezoelectric actuation for switching and employ ultrathin or nanopiezoelectric films for realizing these switches.

Background and Motivation

MEMS switches were first demonstrated in 1979 [1]. Since then lot of research activities have focused on their development and optimization. MEMS switches have traditionally provided a multitude of advantages like higher isolation, lower insertion loss, very low power consumption, and better linearity when compared to traditional transistor/FET and pin diodes [2]. Most of the switch development till date has been done for applications in the Radio Frequency MicroElectroMechanical Systems (RF MEMS) domain. The main aim in this case is to use mechanical relays for switching on and off various components in RF architectures and also to facilitate the functioning of reconfigurable systems. More recently, there has been growing interest in the development of low voltage mechanical computing platforms using MEMS switches and reconfigurable mechanical RF front-ends. RF MEMS switches with their favorable on and off characteristics are ideal for such applications.



Various actuation methods can be employed for achieving switching, such as electrostatic [3–12], piezoelectric [13–23], electromagnetic [24], thermal [25], and electrothermal [26]. Out of these methods, electrostatic actuation has been the most commonly and widely used actuation method. However, it suffers from inherent disadvantages due to its nonlinear mechanism, which transduction methods like piezoelectric actuation have the ability to overcome.

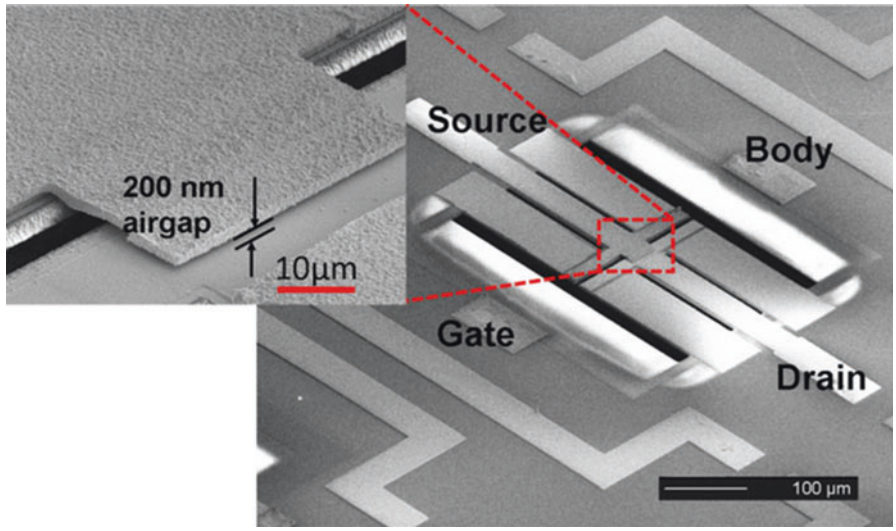
Piezoelectricity, as a phenomenon, was discovered in 1880 by Pierre Curie and Jacques Curie (the Curie brothers). It is simply characterized by the accumulation of charge in certain materials upon the application of mechanical stress. The converse piezoelectric effect also exists, which makes it a reversible process. In the converse piezoelectric effect, an applied electric field can lead to the generation of a mechanical force, thereby causing the film to strain. This converse effect was not predicted by the Curie brothers initially and was predicted by Gabriel Lippmann in 1881. It was later confirmed experimentally by the Curie brothers. The piezoelectric effect is a linear electromechanical interaction between the electrical and mechanical variables in crystalline and polycrystalline materials. For a material to exhibit this phenomenon its crystal structure needs to possess some asymmetry, so materials with inversion symmetry do not exhibit this property.

This linear interaction can be defined using a set of coupled equations between the strain (S) (6×1 matrix), compliance (s) (6×6 matrix), stress (T) (6×1 matrix), electric field $(\vec{E})$ (3×1 matrix), piezoelectric coefficients (d) (3×6 matrix), permittivity (ε) (3×3 matrix), and electric charge density displacement (D) (3×1 matrix).

$$\begin{aligned}[S] &= \left[s^E\right][T] + \left[d^t\right]\left[\vec{E}\right][D] \\ &= [d][T] + \left[\varepsilon^T\right]\left[\vec{E}\right] \end{aligned} \quad (1)$$

Implementation of piezoelectric actuation using the converse piezoelectric effect necessitates the presence of two electrodes that sandwich

NEMS Piezoelectric Switches, Fig. 1 Schematic representation of the piezoelectric actuator (showing the length (L), width (w), and thickness (t) of the actuator) made of two piezoelectric layers and three metal layers illustrating the two common topologies used for actuation, i.e., the unimorph (using one layer of piezoelectric material for actuation) and bimorph (using two layer of piezoelectric material for actuation)



the piezoelectric material to apply an electric field across it. For in plane stretching and consequently bending operation, the d_{31} piezo-coefficient is conventionally used in c-axis oriented, hexagonal materials such as AlN. In this case, an electric field applied across the film thickness generates an in-plane strain through the equivalent d_{31}piezo-coefficient. In a multilayered beam, this strain can be tailored to generate a bending moment about the neutral axis of the composite beam. This moment deflects the beam out-of-plane, i.e., vertically, and this motion is used to open and close an air gap in a mechanical switch. There are two commonly used configurations for implementing piezoelectric actuation, namely, unimorph and bimorph, shown in Fig. 1. In the unimorph configuration [27], there is only one operational piezoelectric layer. A unimorph actuator has both active and passive layers. The passive layers are used for offsetting the neutral axis so that the piezoelectric force can generate a moment about it. In the bimorph configuration [28] there are two active piezoelectric layers, which are simultaneously actuated. The electrodes sandwiching the actuator are properly designed and routed so that the two layers provide for additive bending moments and generate a greater deflection per volt than in the unimorph case, for a given piezoelectric layer thickness.

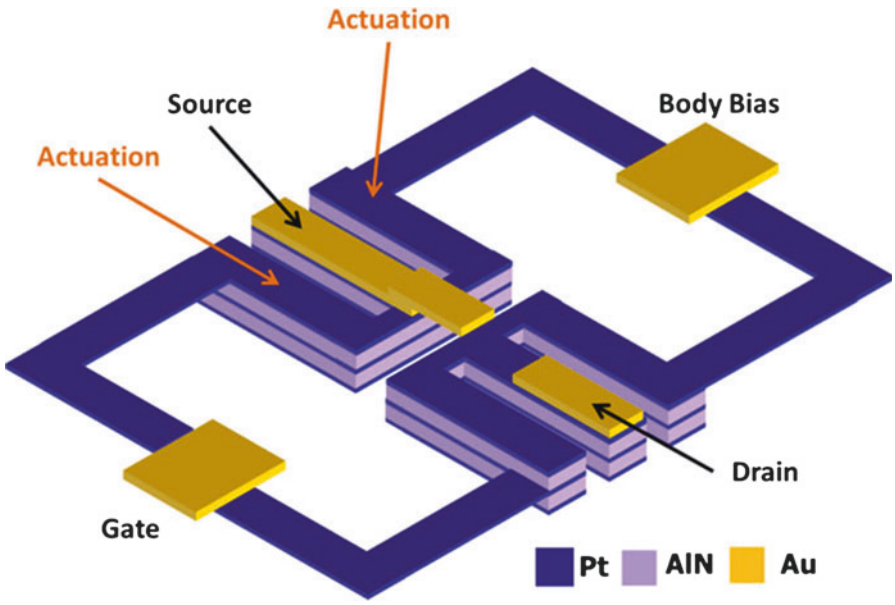
Majority of the piezoelectric switches made till date have employed either Lead Zirconate Titanate (PZT) or Aluminum Nitride (AlN) as their functional material. When compared to PZT, AlN has the advantage of being compatible with CMOS processes and foundries (by being lead free), exhibits a lower leakage current for comparable film thicknesses and has a lower dielectric constant, which ultimately translates to reduced power consumption for a given actuator dimension. PZT does exhibit a higher piezoelectric coefficient than AlN, but repeatability of high-quality PZT films has been known to be a challenge. This, along with the need to pole PZT post deposition (in the sol–gel process) has been the major reason why none of the prominent examples of PZT switches employ bimorph actuation, whereas this can be easily achieved when using AlN. Unlike PZT, AlN is easy to fabricate and has shown preservation of piezoelectric coefficients when scaled from thick (1 μm) to thin (100 nm) films [29]. Another unique advantage that AlN-based devices have over PZT-based devices is the ability of easy integration with the already well-established AlN-based contour-mode resonator technology [30–33]. With this integration new classes of transceivers that will use single-chip multifrequency and highly reconfigurable systems capable of low power and low loss operation can be realized.

AlN-Based Dual-Beam Piezoelectric RF MEMS Switch

RF MEMS Switch

The AlN-based MEMS switch described herein utilizes a novel dual-beam design, i.e., it consists of two symmetric, released beams that face each

NEMS Piezoelectric Switches, Fig. 2 A SEM of a fabricated three-finger AlN MEMS switch with a zoomed-in view of the planarized nano-air gap (~200 nm). Single gate and body terminals are created by appropriate electrode routing



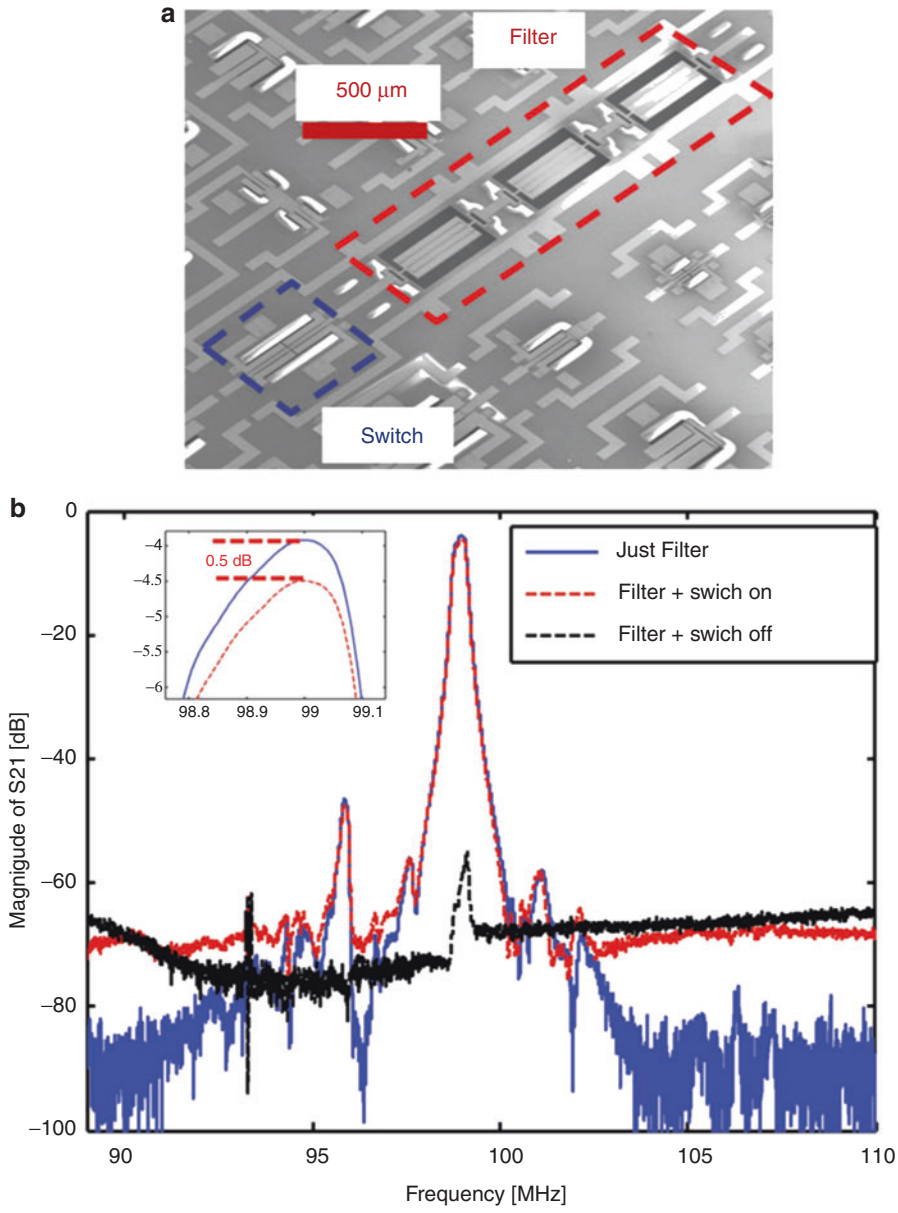
other and move in opposing directions (with respect to each other) with the same two inputs. Figure 2 shows an SEM of a dual-beam switch and the two inputs (i.e., the body and the gate) that are required for the switch to function. The reason for implementing such a design is the presence of residual stress in released multilayered structures. Residual stresses in MEMS and NEMS devices are unwarranted effects that result from the fabrication processes that occur at elevated temperatures. The residual stresses affect the structural reliability and the performance of the system. The deflection induced by residual stresses can cause significant variation in threshold voltages and can lead to a normally closed switch, and, in extreme cases, the release can lead to large deflections rendering the switch inoperable. Therefore, it is essential to overcome this effect in MEMS switches. The dual-beam design helps reducing the impact of this and is introduced primarily because of the need to fabricate switches immune to these residual stresses.

In the dual-beam mechanism employed, both beams can be actuated simultaneously, thus giving: (1) low actuation voltage (halved, as compared to just one beam moving the whole gap), (2) high contact forces (3) active pull-off to open the switch, and (4) faster switching times (as each beam has to move only half the gap). The nano-gap, shown in the zoomed-in view in Fig. 2, is what enables the switch to achieve both good contact forces and isolation.

The three-finger dual-beam switch design used for implementing piezoelectric devices was inherited from the initial RF switch development [21]. This topology comprises of using two symmetric released beams facing each other. Each of these two beams is made of three separate fingers (hence the three-finger design), the two outer fingers are used for actuation and the central finger is employed solely for carrying the signal from the source to the drain as to avoid any gate to source/drain overlap (Fig. 3). The actuators are made up of two layers of AlN, so this design helps in realizing bimorph actuation in piezoelectric switches.

Integration with Contour-Mode Technology

As mentioned earlier, one of the biggest advantages of developing an AlN-based RF MEMS switch was the ability to integrate it with the already proven contour-mode technology to



NEMS Piezoelectric Switches, Fig. 3 Schematic representation of the piezoelectric switch, showing the three-finger dual-beam design. The two pads are used to apply the gate and body-bias voltages and are properly connected to the layers of either actuator so that they actuate both the beams simultaneously

form switchable frequency control elements. This monolithic integration has the potential to tremendously impact the size and power efficiency of RF front-ends by drastically reducing parasitics and off-state leakage. Figure 4a shows an SEM of the monolithically integrated third order AlN contour-mode technology filter along with an AlN switch. Figure 4b shows the frequency response of the filter when it has been switched on and off. An attenuation of >50 dB was measured between the on and off states of the filter. The measurements also show the performance of the filter without the switch. The inset in Fig. 4b shows a zoomed-in view of the difference in insertion loss of the filter with the switch and without the switch, at the filter's center frequency (~99 MHz). The presence of the switch in the measuring path introduces a low loss in the performance of the filter, by increasing the insertion loss by ~0.5 dB.

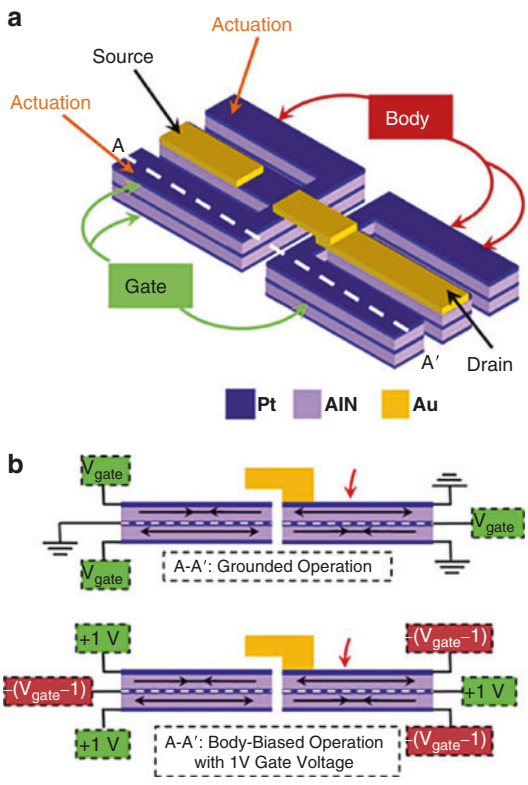
Such integration of switches and frequency control components has the potential to enable new reconfigurable RF architectures based on massive arrays of multifrequency AlN contour-mode resonators and filters.

MEMS/NEMS Switch-Based Logic Using Body-Biasing

MEMS switches can also be easily employed for computing applications. Scaling of CMOS technology to the nano-regime is facing issues with power consumption and reduction of threshold voltages. For overcoming these challenges the International Technology Roadmap for Semiconductors (ITRS) has recognized the development of technologies, like nanomechanical computing based on NEMS switches, as a possible solution for future electronic transistor replacement. Unlike transistors, MEMS/NEMS switches do not suffer from the drawback of passive power loss as they usually have an air gap instead of the physical channel between the source and the drain. Therefore, they can be used for developing efficient low power computing devices. AlN-based switches have been used to implement a unique MEMS switch actuation methodology, i.e., the body-biased actuation, which has enabled low voltage demonstration of basic logic-building blocks. These switches can be referred to as

NEMS Piezoelectric Switches, Fig. 4 (**a**) SEM of a monolithically integrated RF MEMS switch with a contour-mode filter. (**b**) Shows the experimental results of a switchable AlN filter effectively being turned on and off by an AlN RF MEMS switch. The switch introduces low loss and enables a single-chip switchable filter bank solution

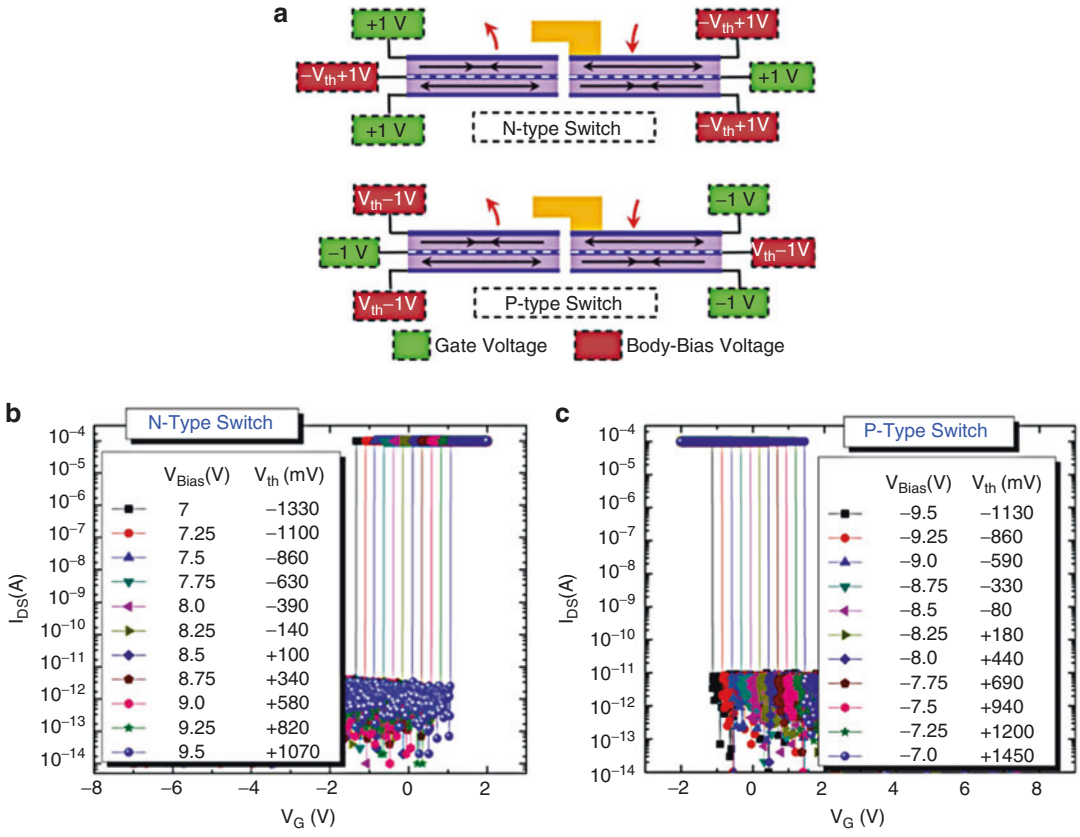
piezoelectric mechanical transistors (MTs) as they use mechanical transduction to achieve the function that is traditionally carried out by electronic transistors.



Body-Biased Actuation

As mentioned earlier, piezoelectric actuation necessitates the presence of two actuation electrodes that sandwich the piezoelectric material

and create an electric field across it. It is this electric field across the piezoelectric film, which generates the strain that leads to actuation. A body bias, in the present context, stands for a constant and floating voltage applied to one of the actuation electrodes. Traditionally, the actuators are operated by applying a voltage (V_{gate}) to the gate terminal, which is greater in magnitude than the threshold voltage (V_{th}) of the device, i.e., $V_{gate} > V_{th}$. This mode of actuation is referred to as the "grounded" mode of actuation, since the body terminal of the device is grounded, shown in Fig. 5b. Instead, in the "body-biased" mode of operation, the previously grounded electrode is biased to a constant voltage (V_{bias}) close in magnitude (but opposite in polarity) to the threshold voltage so that a lower gate voltage can be used to open and close the switch. In Fig. 5, the body-biased mode of actuation is explained schematically using a cross-section of a three-finger dual-beam switch [19, 20]. Figure 5b presents a scenario where the gate voltage of the MT is reduced from V_{gate} to 1 V by using a body-bias voltage of $-(V_{gate}-1)$. This new and lower threshold voltage leads to a smaller swing voltage, which effectively lowers the energy required for actuation. From a mechanical perspective, body-biasing can be explained as preloading (prebending) of the beams that form the actuators. Effectively, body-biasing corresponds to the reduction of the air gap between the two contacting surfaces and translates into the ability of tuning the device threshold voltage by modulating the size of the initial contact gap.



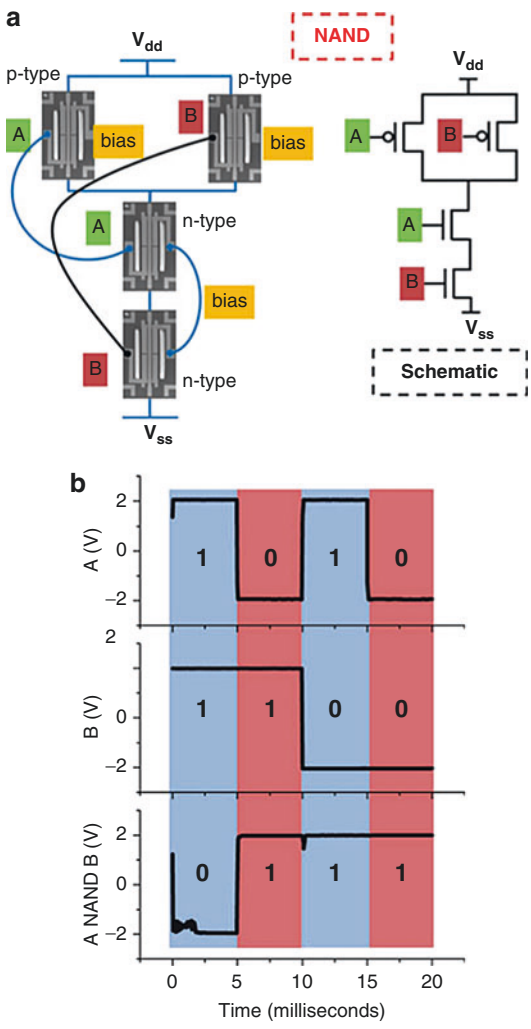
By using the body-biased mode of actuation, the threshold voltage of a piezoelectric switch can be tailored to be any value. The same switch can have a negative or positive threshold voltage, as shown in Fig. 6. The major aim of this technique is to reduce the threshold voltage in magnitude (as low as 1–20 mV), which can be easily achieved by body-baising.

The absence of a doped channel in the MT renders the classification of n- or p-type devices ambiguous. Moreover, this provides the MT with an unparalleled ability to choose or vary the nature of a switch on the basis of need, i.e., the same switch can be made into an n- or p-like device

NEMS Piezoelectric Switches, Fig. 5 (**a**) 3D schematic of a three-finger dual-beam AlN switch highlighting the source, drain, gate, and body terminals. It also shows the A–A′ cross-section used to illustrate the body-biasing method. (**b**) Schematic representation of the principle of operation of an AlN MEMS switch in grounded and body-biased mode of operation. By applying a bias to the body terminal $[-(V_{gate}-1)]$ V, the same effective potential required to close the switch is applied across the AlN layer with a lowered gate voltage of 1 V (1 V is used here as an example, but, theoretically, any value is possible thanks to the extreme linearity of the body-bias technique in a piezoelectric AlN film). This effectively reduces the dynamic energy required for every switching operation. The gold tip is not present along the A–A′ cross-section, but is drawn here to aid the understanding of the mechanism of device operation

(in analogy to p-type and n-type CMOS) without any change in design or fabrication by simply switching the polarity of the body-bias and applying it to the opposing actuating electrode set (as shown in Fig. 6a). For the switch to be actuated, the magnitude and direction of the electric field in the piezoelectric material has to be preserved. The polarity and value of the potential on any particular electrode is inconsequential.

NEMS Piezoelectric Switches, Fig. 6 (**a**) Schematic representation of the complementary operation made possible in piezoelectric switches by using the body-biasing method. By changing the polarity of the body-bias and the electrodes to which it is applied, the nature of the switch (p- or n-like) can be modified without any alteration to its layout design or fabrication. (**b**, **c**) Experimental data verifying that the switch threshold voltage (V_{th}) can be tuned by varying the value of the body bias. This data show that the body-bias technique enables the implementation of variable threshold voltages on the same die and in the same process. The current measurement was limited to a maximum value of 100 μA



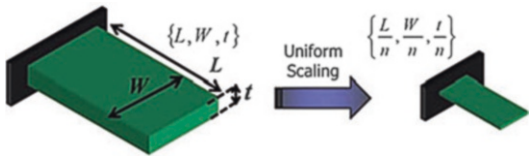
The subthreshold slope has been measured to be <1 mV/dec as the actuation of these structures is not limited by thermal noise. This gives these switches with body-bias the ability to lose nearly no power when they are in standby.

An Agilent B1500A Semiconductor Parameter Analyzer was used for measuring the switch threshold voltage as a function of body bias applied to the MT. Figure 6b, c illustrate the results of 11 successive scans, each, on a 200 × 200 μm^2 device, showing the change in the threshold voltage (V_{th}) as the body-bias (V_{bias}) is increased with a 250 mV step per scan, both for an n-like and a p-like MT. Equivalent to an n-type CMOS transistor, the MT can be made to operate as a depletion or enhancement mode device depending on the value of the body-bias. The absolute value of the body-bias voltages were the same for both the scan sets. Good agreement between threshold values for corresponding positive and negative body-bias values was observed, but small differences in the magnitude of the threshold voltage (10–120 mV) between the n-and p-like cases were recorded and can be attributed to subtle changes in the adhesive forces due to the evolution of the contact. These data conclusively show that, by using body-biasing the same switch can be made to behave either as an n-like switch or as a p-like switch.

Logic-Building Blocks Using MEMS/NEMS Switches

For initial demonstration of mechanical logic achieved by AlN MTs the logic circuit layout was adopted directly from traditional CMOS design and mechanical transistors were used to simply replace the CMOS transistors. This approach was used to implement and validate the ability of realizing low swing voltage dynamically operated complementary piezoelectric logic circuits via body-biasing.

These three-finger dual-beam AlN MEMS switches have been able to demonstrate logic elements like inverters, NAND, and NOR gates. The key factors that have enabled this low voltage demonstration are the use of thin AlN films (250 nm) and of the body-biasing technique. Two AlN MEMS switches were used to demonstrate a low voltage digital inverter using body-biased AlN switches capable of fast switching (~220 ns). The mechanical inverter formed was tested at 100 Hz with a ± 1.5 V (square input wave) voltage swing. The NAND and NOR structures were formed by wire-bonding four separate switches in the desired configuration. The mechanical NAND was formed by using AlN mechanical switches with one input at 100 Hz and the other at 50 Hz with a ± 2 V voltage swing, as shown in Fig. 7a. The experimental results and superimposed equivalent truth table for the dynamic testing of a single cycle of a mechanical NAND gate is shown in Fig. 7b.



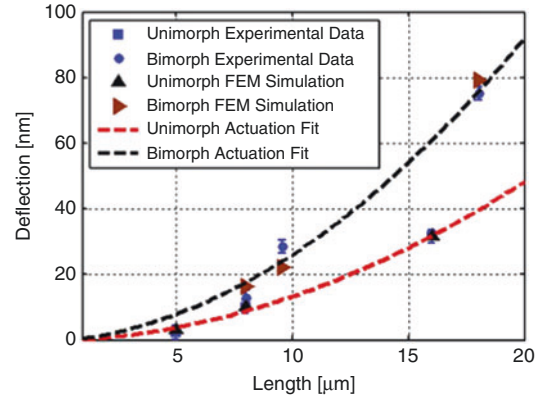
NEMS Piezoelectric Switches, Fig. 7 (**a**) Schematic representation of the switch layout showing the wiring that was required to form the NAND gate. The electronic schematic of a conventional NAND is also shown to illustrate the similarities between the two implementations. (**b**) Experimental data for one cycle of operation of a NAND gate made using mechanical switches and its corresponding truth table. This implementation was achieved with a ± 2 V swing

AlN Device Scaling and Nano-Actuator Development

The necessity to miniaturize the MT and improve device density, scaling of AlN MTs has to be investigated and projected. The results of an analysis of how dimensional scaling affects various important actuator parameters such as displacement, δ_E, resonance frequency, f_n, contact force, Fc, gap size, g, as well as the energy consumption, $(En)_E$, and power consumption, P_E, of a simple logic gate is show in Table 1. The analysis was carried out assuming uniform scaling of the actuator (Fig. 8), i.e., scaling of all the dimensions of the actuator together by the same factor. The other assumption of this study was the use of constant electric field, i.e., the magnitude of the electric field in the piezoelectric was kept constant throughout the scaling process. From the prospective of energy and power consumed the advantages of scaling are amply visible in the table. It is interesting to note the similarities to CMOS

NEMS Piezoelectric Switches, Table 1 Scaling factors for constant-field scaling of piezoelectric MTs. Scaling factor: k

Property	Relation to independent variables (L, w, t, V)	Constant-field scaling
Displacement (∂_E)	$\propto \frac{L^2}{t}$	$\propto \frac{1}{k^1}$
Contact force (F_C)	$\propto \frac{wt^2}{L}$	$\propto \frac{t}{k^2}$
Resonance frequency (f_n)	$\propto \frac{t}{L^2}$	$\propto k^1$
Gap (g)	$\propto \frac{L^2}{t}$	$\propto \frac{1}{k^1}$
Body-bias voltage	$\propto \frac{L^2}{t}$	$\propto \frac{1}{k_1}$
Energy $(En)_E$	$\propto wV$	$\propto \frac{1}{k^3}$
Power (P_E)	$\propto \frac{w_W}{L}$	$\propto \frac{1}{k^2}$



NEMS Piezoelectric Switches, Fig. 8 3D schematic showing uniform scaling as has been proposed for the mechanical transistors. All the dimensions of the actuator should be scaled by the same factor

scaling. The scaling of the channel length and the thickness of the gate oxide are effectively analogous to the scaling of the actuator length and the piezoelectric film thickness. As for CMOS scaling, MT scaling also leads to a linear increase in speed and quadratic reduction in power.

In the past, the biggest hurdle in the scaling of piezoelectric transduction to the nanoscale has been the degradation of piezoelectric properties due to limited orientation in thin films and increases in internal stresses (cracking and excessive deformations in released structures). With better control over the deposition parameters and extensive process development ultrathin AlN films have been successfully developed and demonstrated [34–36].

Nanoactuators have been developed to study the effect of scaling (to the nano-regime) on the piezoelectric properties of AlN. The films were successfully scaled down to the thickness of

NEMS Piezoelectric Switches, Fig. 9 Results of deflection testing of beams of different lengths with unimorph actuation (single layer) and bimorph actuation (double layer) at 4 V and their agreement with FEM analysis. The *dashed line* shows the square dependence that exists analytically between tip displacement and beam length

100 nm, and actuators as well as switches were fabricated using them. DC voltage-induced nanobeam deflections of six beams of different lengths (5–18 μm) under unimorph and bimorph actuation at 4 V are shown in Fig. 9. The measurements were made by a Zygo optical profilometer. Both layers of AlN have been individually actuated and the deflection measurement for each individual layer and both the layers actuated together closely match the FEM predictions (using COMSOL). This matching with FEM analysis verifies the dependence of vertical displacement on the square of the beam length as predicted by conventional Euler beam-bending equations. These deflection measurements along with analytical solutions for the deflection of piezoelectric unimorph and bimorph beams [37] were used for extracting the d_{31} piezoelectric coefficient of the ultrathin AlN film. The extracted experimental d_{31} is within 5 % of the theoretical value of the piezoelectric coefficient.

Finally, the successful scaling of the AlN film led to the demonstration of an AlN piezoelectric nanoswitch that employed 100 nm thick AlN films. These switches validate the use of the body-biasing technique at the nanoscale. As the thickness of the films has been scaled to the nano-dimensions the body-bias voltages have been lowered to <6 V and a better control over the

actuator motion has been demonstrated. This enhanced control over switching translates into a threshold voltage of ~1 mV and the ability to potentially operate with supply voltages of few 10 s of mV.

These demonstrations, both in the RF domain as well as in the field of mechanical computing, clearly show the scalability and the potential that this piezoelectric mechanical switch/MT technology possesses. Given continued effort this can lead to development of low power highly integrated RF and computing systems.

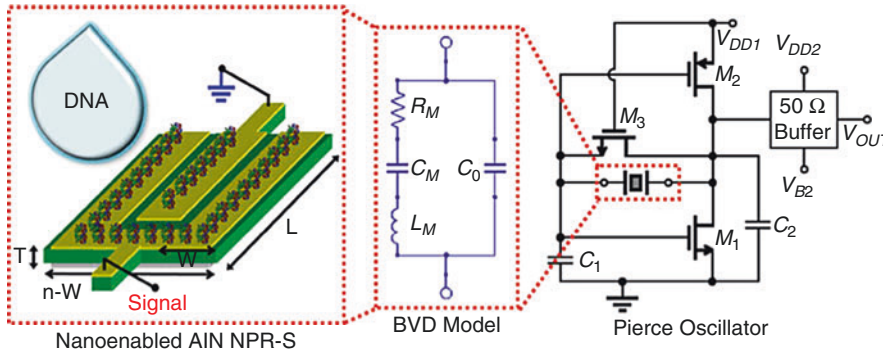
Definition

Nanoelectromechanical System (NEMS) Chemical Sensors are devices that combine electrical and mechanical functionalities at the nanoscale for the detection of minute concentrations of target gaseous compounds in the environment. A NEMS Resonant Chemical Sensor is composed of three fundamental elements: an electrically driven nanomechanical resonator (NEMS resonator), a chemical interactive material (CIM) deposited on

the surface of the NEMS resonator, and a readout system. The natural resonance frequency of the nanomechanical resonator is highly sensitive to variations in the device mass per unit area. Therefore, any small amount of mass per unit area loaded on the nanomechanical resonator will produce a relatively large shift in the natural resonance frequency of the device. The smaller is the mass per unit area of the mechanical resonator itself, the larger is the shift in resonance frequency for a given amount of mass per unit area loaded on the device surface. Therefore, an ultraminiaturized (nano) mechanical resonator, with an extremely low mass per unit area, is ultrasensitive to mass loading per unit area. When the sensor is exposed to a certain concentration of a target gaseous compound, a number of gas molecules per unit area (mass per unit area), depending on the affinity between the CIM and the target gas, are absorbed by the CIM on the NEMS resonator surface causing a shift in its natural resonance frequency. Since a specific amount of mass per unit area is absorbed by the CIM for a given concentration of gas in the environment and a specific shift in resonance frequency is caused by a given amount of mass per unit area loaded on the NEMS resonator, it is possible to quantitatively detect the concentration of the target gas by monitoring the natural resonance frequency of the NEMS resonator. The resonance frequency of the NEMS resonator is monitored over time and converted into an electrical signal by the readout system. The fundamental performances of a NEMS resonant chemical sensor are expressed in terms of limit of detection (LOD), response time, and selectivity. The LOD is the smallest amount of adsorbed mass per unit area (hence minimum gas concentration given a certain CIM) that can be resolved by the sensor. This quantity is inversely proportional to the resonator sensitivity to mass loading per unit area and directly proportional to the frequency fluctuations induced by the noise generated in the resonator and in the readout system. Therefore, a nanomechanical resonator characterized by a very large sensitivity to mass loading per unit area and a very low noise is the best candidate for the implementation of a high performance NEMS resonant chemical sensor. Response time and selectivity are instead determined by the chemical and physical properties of the CIM employed.



Main Text

In recent years, the demand for highly miniaturized sensor arrays capable of selectively detecting extremely small concentrations (part per trillion, ppt) of multiple gaseous analytes has steadily grown. The necessity to detect such small concentrations requires reliably measuring extremely small variations in the sensor output signal. In this perspective, gravimetric sensors, such as Quartz Crystal Microbalances (QCMs), have a significant advantage over other sensor technologies (conductance-based sensors, Chem-FET, or optical sensors) since they use frequency as the output variable, which is one of the physical quantities that can be monitored with the highest accuracy [1].

Nevertheless, smart, compact, portable, and low cost electronic noses for multiple gas detection cannot be implemented with bulky and unintegrable QCMs. Even if QCMs have been successfully employed as gravimetric sensors, thanks to their extremely high quality factors, which permit to obtain limits of mass detection in the order of few nanograms, their relatively large volume and their inability to be directly integrated on silicon render them unattractive for the fabrication of sensor arrays composed of a large number of mechanical elements.

In response to this growing demand for miniaturization, the use of microelectromechanical (MEMS) and nanoelectromechanical (NEMS) resonators for sensing applications has been extensively explored. The scaling of the device dimensions enables the fabrication of ultrasensitive nanomechanical gravimetric sensors that can be arranged in single-chip arrays capable of selectively detecting extremely small concentrations (ppb-ppt) of multiple gaseous analytes.

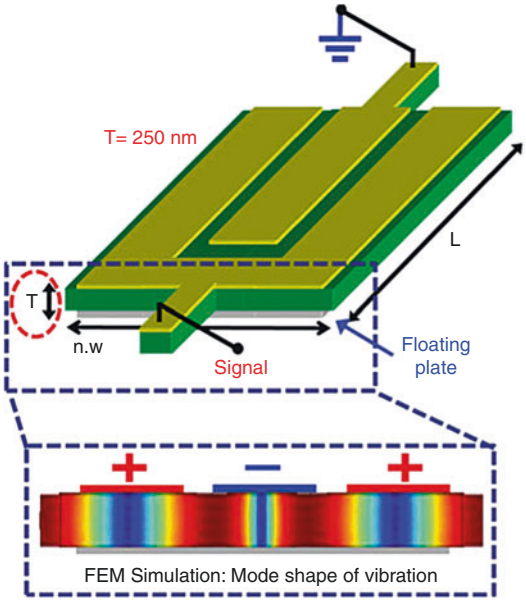
Different MEMS/NEMS resonator technologies based on electrostatic or piezoelectric

NEMS Resonant Chemical Sensors, Fig. 1 Schematic representation of the fabricated nanoenabled AlN NPR-S connected in a self-sustained oscillator loop (Pierce oscillator). The butterworth van dyke (*BVD*) model is used to describe the resonator behavior

transduction [2, 3] or piezoresistive displacement transduction [4] have been proposed. In particular, NEMS resonators have been exploited as transducers for the realization of extremely sensitive gravimetric sensors. Sub-attogram mass resolution has been demonstrated in NEMS cantilevers [4], thanks to the minuscule mass and the relatively high quality factor (Q). Nevertheless the greatly reduced dimensions of these devices render their transduction extremely difficult and require the use of cumbersome, complex, and power-inefficient readout techniques.

In this perspective, optimal sensor performance is attained by synthesizing a transducer that occupies a large area (which facilitates efficient transduction) and is very thin (which allows fabricating low mass devices with ultrahigh sensitivity). Suspended membranes with thickness in the nanometer range are therefore desirable. Flexural plates (instead of beams) are a good compromise [5], but higher frequencies and power handling are achieved in bulk mode acoustic resonators [3, 6].

A particularly representative example of high performance bulk mode acoustic NEMS resonant sensors that will be described here involves exciting high frequencies bulk acoustic waves in a piezoelectric nano-plate (thickness 250 nm) made of Aluminum Nitride (AlN). Such AlN Piezoelectric Nano-Plate Resonant Sensor (NPR-S) technology is not only characterized by high values of sensitivity, due to the reduced mass and high frequency of operation of the nanomechanical resonant element, but it is also associated with low noise performance, due to the combination of high quality factor, Q, and power handling capability of the bulk acoustic wave NEMS resonators. In addition, the AlN nanoplate composing the NPR-S can be efficiently actuated and sensed piezoelectrically on-chip solving the fundamental transduction issues associated with electrostatically transduced NEMS resonators and enabling the use of compact and low power CMOS circuits for electronic readout (Fig. 1). The sensor affinity for the adsorption of volatile organic chemicals such as 2,6 dinitrotoluene is enhanced by functionalizing the top gold electrode of the device with a thiol-terminated single stranded DNA sequence (Thiol – 5′ CTT CTG TCT TGA TGT TTG TCA AAC 3′) and the ability to detect concentrations in the ppt range is demonstrated. Thanks to the unique combination of extremely important features such as high sensitivity, low noise, efficient transduction, small form factor, and CMOS integration capability, the NPR-S represents one of the most suitable technologies to devise high performance portable gas sensors arrays that can be easily incorporated in wireless devices and sensor networks for distributed environmental or personal health monitoring.



NEMS Resonant Chemical Sensor Design

The fundamental metrics that need to be considered for the design of high performance NEMS

resonant chemical sensors are expressed in terms of limit of detection (LOD), response time, and selectivity. The LOD is the smallest amount of adsorbed mass per unit area (hence minimum gas concentration given a certain chemical interactive material, CIM) that can be resolved by the sensor. This quantity is inversely proportional to the resonator sensitivity to mass loading per unit area and directly proportional to the frequency fluctuations induced by the noise generated in the resonator and in the readout system. Therefore, a nanomechanical resonator characterized by a very large sensitivity to mass loading per unit area and a very low noise is the best candidate for the implementation of a high performance NEMS resonant chemical sensor. Response time and selectivity are instead determined by the chemical and physical properties of the CIM employed. A particularly representative example of high performance NEMS resonant chemical sensor design is given by the Aluminum Nitride (AlN) Nano-Plate Resonant Sensor (NPR-S) technology, which will be described in details herein.

The Aluminum Nitride (AlN) Nano-Plate Resonant Sensor (NPR-S) technology involves exciting a high frequency contour-extensional mode of vibration (Fig. 2) in piezoelectric nano-plates (thickness 250 nm) made out of AlN. The capability to excite higher order contour-extensional mode of vibration in micro-scale AlN plates has been demonstrated by the AlN Contour-Mode resonator (CMR) technology [3, 7, 8]. High performance AlN Contour-Mode resonators in the very high frequency (VHF), ultrahigh frequency (UHF), and superhigh frequency (SHF) range (20–10 GHz) and quality factors, *Qs*, between 1,000 and 3,000 have been reported [7–9]. Piezoelectric sensing and actuation of these devices have been successfully employed in the MEMS domain. While the scaling into the nano-domain of the AlN CMR core technology has been exploited for the implementation of AlN Nano-Plate Resonators with unique performances in sensing applications [10–15].

The reduced mass of the mechanical resonator along with the high quality factor values and the power handling capabilities make the AlN NPR-S technology capable of achieving unprecedented values of limit of detection to mass per unit area in the order of zg/μm^2.

NEMS Resonant Chemical Sensors, Fig. 2 Schematic representation of an AlN Nano-Plate Resonator. The *inset* shows a 2-D FEM simulation of the device mode of vibration

An AlN NPR-S is composed of an AlN nano-plate sandwiched between two metal electrodes (Fig. 2). When an AC voltage is applied across the thickness (*T*) of the device, a contour-extensional mode of vibration is excited through the equivalent d_{31} piezoelectric coefficient of AlN. Given the equivalent mass density, ρ_{eq}, and Young's modulus, E_{eq}, of the material stack (AlN and metal electrodes) that forms the resonator, the center frequency, f_0, of this laterally vibrating mechanical structure is univocally set by the period, *W*, of the metal electrode patterned on the AlN plate and can be approximately expressed as in Eq. 1.

$$f_0 = \frac{1}{W}\sqrt{\frac{E_{eq}}{\rho_{eq}}} \tag{1}$$

The other two geometrical dimensions, thickness, *T*, and length, *L*, set the equivalent electrical impedance of the resonator [3] and can be

designed independently of the desired resonance frequency.

The sensitivity to mass per unit area of an AlN NPR-S loaded on its top surface can be expressed as in Eq. 2 [10, 16].

$$S = -\frac{f_0}{2\rho_{eq}T} \tag{2}$$

It is worth noting that the resonance frequency, f_0, and the thickness, T, of the AlN NPR-S are two independent variables while for QCMs they are intrinsically coupled and cannot be set independently from one another. This is an important and unique advantage of AlN NPR-S. In fact, it permits to set the frequency of operation of these devices according to the specifications of the desired application and independently obtain the required value of mass sensitivity by scaling the device thickness.

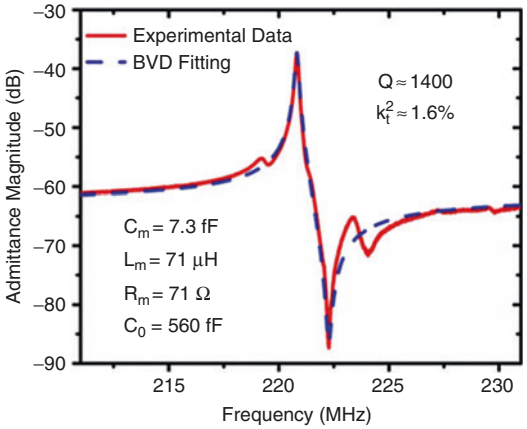
Nevertheless, the mass sensitivity of the device cannot be considered the only important parameter for the design of a high performance gravimetric sensor. In fact, the limit of detection, *LOD*, of the sensor (smallest amount of adsorbed mass per unit area that can be resolved) is defined as in Eq. 3:

$$LOD = \frac{\Delta f_{\min}}{S} \tag{3}$$

where $\Delta f_{\min}$ indicates the minimum frequency shift detectable by the sensor readout. Thus, the performance of the sensor can be improved by reducing the thickness, T, of the AlN layer up to the limit at which the smallest value of the ratio, $\Delta f_{\min}/f_0$, is preserved. For example, $\Delta f_{\min}/f_0$ comparable to thicker films and as low as 9×10^{-8} has been attained for a nanoscaled device.

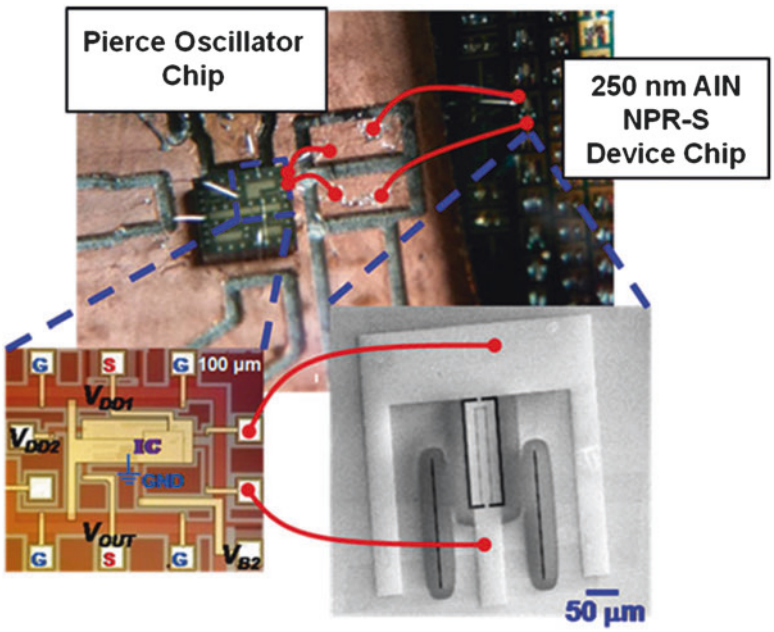
Another crucial aspect directly related to the scaling of the device is the complexity, size, and power efficiency of the required sensor readout. In particular, the ability to connect the nanoelectromechanical resonator to a self-sustained oscillator loop for direct frequency readout greatly simplifies the design of multiplexed sensor platforms involving large arrays of resonant devices. Self-sustained, high performance, Pierce-like oscillator circuits based on thick film (2–3 μm) AlN Contour-Mode MEMS Resonator (CMR) have been demonstrated [17]. The primary power loss in these oscillator circuits is due to the motional resistance, *Rm*, of the resonator [17], whose value is inversely proportional to the device figure of merit, $k_t^2 \cdot Q$ [17], where k_t^2 represents the device electromechanical coupling and Q its quality factor. Therefore, the $k_t^2 \cdot Q$ product of the AlN NPR-S needs to be maintained sufficiently large (>10) to be able to connect it to a compact and low power self-sustained oscillator circuit for direct frequency readout.

A particular device design that proves the scaling advantages of the AlN NPR-S technology consists of a 220 MHz ($W = 15$ μm) AlN resonant nano-plate whose thickness was set to be, $T = 250$ nm, in order to improve the sensitivity of the resonant sensor.



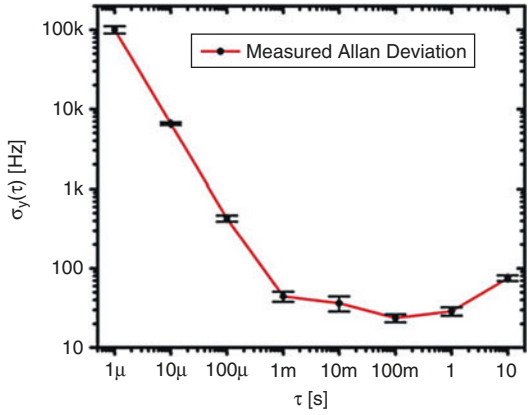
The oscillator circuit topology used as readout for this 250-nm-thick AlN NPR-S is described in more detail in [17]. Briefly, the circuit (Fig. 1) consists of a Pierce oscillator implemented by means of a CMOS inverter biased in its active region. Transistors M1 and M2 form the CMOS inverter while transistor M3 acts as a large resistor to provide biasing in the active region of M1 and M2.

Being functionalization another important aspect in the design of a resonant sensor, an interface layer between the CIM and the VOC has to be selected. In the case of this 250-nm-thick ALN NPR-s, the top gold (Au) electrode was chosen and used to attach thiolated single stranded DNA (HS-ss-DNA) sequences [18]. The capability of single stranded DNA to selectively enhance the adsorption of volatile organic compounds such as dimethyl-methylphosphonate (DMMP, a stimulant for nerve agent sarin) and 2,6 dinitrotoluene (DNT, a stimulant for explosive vapors) has been recently demonstrated [16]. Therefore, in order to enhance the sensor affinity for the adsorption of volatile organic chemicals, the top gold electrode of the AlN NPR-S device was directly functionalized with a thiol-terminated ss-DNA sequence. The capability of employing CIMs with increased effective adsorbing area based on single wall carbon nanotubes (SWNTs) directly



grown on the top surface of a micro-scale CMR and functionalized by DNA strands has also been demonstrated [16].

NEMS Resonant Chemical Sensor Performance



The performances of NEMS resonant chemicals sensor can be fully characterized by performing three sets of experiments: (1) Open loop measurements (i.e., frequency response of the nanomechanical resonator in Fig. 3) are performed to extract the device sensitivity to mass loading and extract the electromechanical parameters of the NEMS resonator [10]. (2) The NEMS resonator is then connected to a self-sustained oscillator circuit (Fig. 4) for direct frequency readout and closed-loop characterization of the resonant sensor performance in terms of noise and power consumption is performed. (3) Finally the sensor is exposed to different concentrations of the target gaseous compounds to verify detection capability. For the ss-DNA-functionalized 250-nm AlN NPR-S described herein, an open loop measurement (frequency response) was first performed and the sensitivity to mass loading was extracted to be approximately 41.6 KHz·μm^2/fg [10]. Despite the device volume reduction, high Q (~1,400 in air) and high k_t^2 (~1.6 %) were attained (Fig. 3) enabling the direct wire bonding of the AlN NPR-S to an oscillator circuit chip fabricated in the ON Semiconductor 0.5 μm CMOS process. The 220 MHz oscillator used a 1.67 V supply voltage and 300 μA of biasing current, which give a total power consumption of 501 μW.

NEMS Resonant Chemical Sensors, Fig. 5 Measured Allan deviation of the 220 MHz oscillator

NEMS Resonant Chemical Sensors, Fig. 6 Sensor response to 5 % DNT vapor pressure before and after DNA functionalization

In order to estimate the noise limited minimum frequency shift (Δf_{min}) detectable by the readout of a NEMS resonant chemical sensor, the short-term frequency stability of the oscillator output signal is characterized by measuring its Allan deviation, $\sigma_Y(\tau)$, [19]. The measured values of Allan deviation for the 220 MHz AlN NPR-S described here are reported in Fig. 5. The minimum value of Allan deviation recorded is approximately 20 Hz and it is achieved for a gate time, τ, of 100 ms. Therefore, considering a minimum detectable frequency shift, Δf_{min}, of 20 Hz, a limit of detection of mass per unit area of about 481 zg/μm^2 can be estimated. This translates to an extrapolated limit of detection for DNT concentrations of about 15 part per trillion (ppt) [20].

The detection capability of a NEMS resonant chemical sensor is finally tested by exposing the device to known concentrations of a target analyte and monitoring the respective frequency shifts of the oscillator output signal. The ss-DNA-functionalized AlN NPR-S in example was exposed to DNT vapor (generated by bubbling method [10]). The improved affinity of the AlN NPR-S to the DNT vapor, due to ss-DNA functionalization (Fig. 6), enabled the detection of very minute analyte concentrations. The measured sensor response for different concentrations of DNT, ranging between 0.2 % and 1 % of the saturated vapor pressure, is reported in Fig. 7. Considering that the DNT saturated vapor pressure at room temperature is equal to 5.67×10^{-4} Torr [20], a concentration of DNT as low as 1.5 ppb was detected by the fabricated nanoenabled AlN NPR-S prototype.

Definition

Nonlinear NEMS resonators are nanoelectromechanical system resonators that operate at excitation levels exceeding their linear range. Parametric NEMS resonators are NEMS resonators that are actuated parametrically, i.e., by means of modulating a system parameter at a rate proportional to the resonance frequency.

Introduction: Nonlinearity in NEMS

One of the astonishing examples of miniaturization in recent decades involves the development of micro- and nanoelectromechanical systems (MEMS and NEMS) – tiny moving structures with the sizes down to few atoms across [1]. An important subclass of already diverse field of MEMS and NEMS involves resonant electromechanical systems, which have already shown an unprecedented performance in their ability to sense important physical parameters, probe or manipulate the surfaces of materials, and provide accurate timing reference.

Much of the work in this area has revolved around characteristics of single devices operating in their linear regime. Not only has there been very little progress made on sensor arrays, despite their continuously expressed outstanding potential, but also individual device limitations have been poorly understood, due to the unique nonlinear properties at the nanometer scale. An extensive effort to understand and harness rich nonlinear dynamics of NEMS and MEMS resonators has recently been undertaken by a number of researchers with remarkable results. Thorough understanding of the nonlinear properties is crucial to evaluating the limitations of any practical device's performance. Moreover, the detailed knowledge of nonlinearities led to the development of methods for reducing its detrimental effects and enabled performance enhancement beyond what was considered possible. Besides practical benefits, unique nonlinear properties of NEMS provided an outstanding platform for analyzing complex nonlinear dynamical systems. This entry gives a brief overview of notable findings stemmed from the exploration of nonlinear dynamics in NEMS resonators.

Geometrical shapes, vibration modes, and source materials of miniaturized mechanical resonators vary greatly across the growing diverse field. Each example can be characterized by one or multiple potential sources of nonlinearity. The physical origins of nonlinearity can be divided into three classes:

1. *Material nonlinearity.* The Hooke's law is no longer linear if material stress exceeds linear elasticity range of the structural material. This can be the dominant source in bulk mode resonators [2].
2. *Transduction nonlinearity.* There are several ways transducer can cause nonlinearity. They include readout signal being nonlinear

function of the displacement [3] and the physical nature of the transducer exerting nonlinear force on the resonator [4].

3. *Geometric nonlinearity.* The large vibration displacement distorts mode shape or significant mass displacement occurs in multiple dimensions (*kinetic nonlinearity*), so that the approximation of linear elastic restoring force is invalid. This source is typically dominant in standard NEMS resonators such as beams [5] and cantilevers [6].

Each of the listed sources of nonlinearity is important in certain applications. This entry primarily focuses on nanomechanical systems. Their sizes are typically so small that practical displacements are comparable with dimensional scale; therefore, geometric nonlinearity usually prevails. The transduction nonlinearity is also occasionally important depending on chosen readout mechanism. Thus material nonlinearities rarely play a significant role.

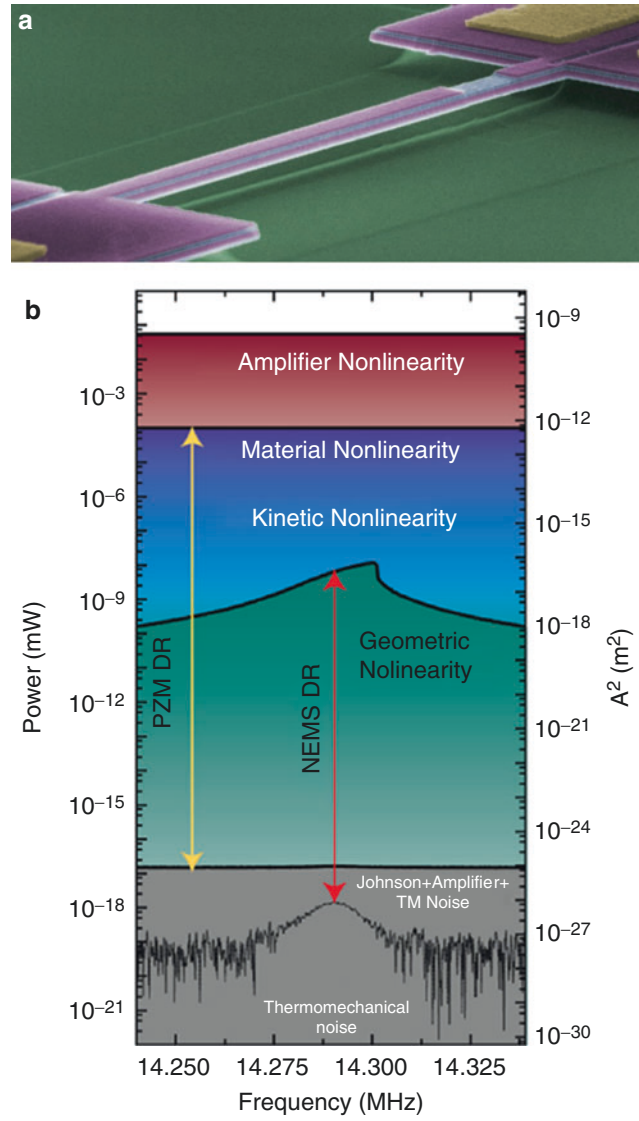
A widespread example of nonlinear nanomechanical system is a doubly clamped beam – a small rectangular mechanical bar with rigid supports on both sides. The nonlinear properties of its flexural out of plane resonant modes are well understood. An example of such system, described in [7], is shown in Fig. 1a. The linear ranges for each relevant physical mechanism are illustrated in Fig. 1b.

Regardless of the origin of nonlinearity, the first correction manifests itself as a next-order nonlinear term in the equation of motion of conventional resonator. The resonator's dynamics is then described by the following expression:

$$m\ddot{x} + \frac{m\omega_0}{Q}\dot{x} + kx + \alpha x^3 = F(t), \qquad (1)$$

where the first three terms on the left-hand side represent regular linear resonator and the fourth term is effectively an elastic restoring force that is proportional to the cube of the displacement (also known as the *Duffing nonlinearity*).

The solution for Eq. 1 can be expressed in an implicit form as a modified Lorentzian:



$$x_0 = \frac{F_0}{2m\omega_0^2} \frac{1}{\sqrt{\left(\frac{\omega-\omega_0}{\omega_0} - \frac{3}{8}\frac{\alpha}{m\omega_0^2}x_0^2\right) + \frac{1}{4Q^2}}}. \qquad (2)$$

One obvious consequence of the Duffing nonlinearity, evident from this expression, is frequency pulling. The additional term in the brackets in denominator implies that the effective resonance frequency shifts as the amplitude of motion increases. Another important outcome of nonlinear term is the presence of bistability – indeed Eq. 2 is implicit allowing for several amplitudes of motion to exist for specific drive parameters (amplitude F_0 and frequency ω_0 of the driving force).

Nonlinear Dynamics Experiments: Single Device

NEMS nonlinear properties enabled large number of researchers to perform a variety of experiments, resulting in expanded knowledge of nonlinear systems in general. Their findings illustrated the potential of NEMS resonators as tools for studying discrete nonlinear systems.

As the magnitude of the driving force is increased, bistability manifests itself in the appearance of hysteretic behavior [8]. For certain drive conditions, there exist two stable resonator states represented by two different amplitudes of vibration. The stable state of resonator is then determined by how current drive conditions were attained. If on the other hand the system drive condition is set quickly compared to a period of oscillation, then time dependent dynamical equation has to be considered in order to determine the final state. If the new drive allows for two solutions, then the initial condition of the resonator will determine which stable state to settle. Indeed if the initial amplitude and frequency are close to one of the possible final solutions, then it is natural to settle there. This situation is typically described as the initial condition of the resonator being located within the basin of attraction for this particular stable solution. Nonlinear

Nonlinear and Parametric NEMS Resonators, Fig. 1 (**a**) An SEM image of a doubly clamped beam described in [7]. (**b**) An illustration for the linear ranges of relevant nonlinear mechanisms (Reprinted with a permission from Nano Letters 2013 13 (4), 1622–1626. Copyright 2013. American Chemical Society)

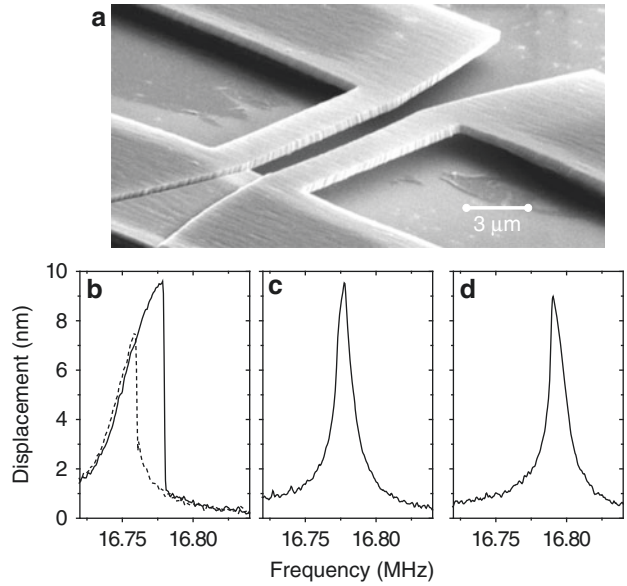
nanomechanical resonator serves as a great platform to conduct the experimental investigation of basins of attraction by perturbing the system and observing the final stable state.

One such experiment, performed by Kozinsky et al. [9], employed nanowire-based nonlinear mechanical resonator to systematically probe the basins of attraction with a very high precision. The experiment benefited from the fact that the relevant time scale per data point, $\sim Q/f_0$, was very short for high-frequency nanoscale devices. This enabled taking many data points before the parameters of the system significantly drifted. The authors observed the separatrix, a border between the two basins of attraction, change shape for varying drive strength, so that one of the basins became progressively smaller and eventually disappeared. The mapped basins of attraction showed a good agreement with theory. However, the observed separatrix was blurred due to ambient fluctuations, including residual noise in the drive system, which caused uncertainty in the preparation of an initial state close to the separatrix.

Such uncertainty gives rise to important physical phenomenon – noise-induced transitions. Ever present noise in any nonlinear system can

cause a spontaneous jump between states. A number of researchers investigated this phenomenon in detail in nonlinear NEMS resonators. In the experiments by Aldridge and Cleland [10], the authors introduced external noise source and varied its intensity. As a result they observed significant modification of hysteretic behavior. Particularly, spontaneous transitions occurred in the vicinity of bifurcation points. Subsequent increase in noise intensity eventually led to blurring of hysteresis width and ultimately to a complete its complete disappearance. In another work by Unterreithmeier et al. [11], the researchers were able to map basins of attraction and observed spontaneous transitions between two stable solutions by means of applying pulsed drive of a given duration, properly chosen to alter the state of the nonlinear resonator.

Since the nonlinear regime is readily accessible in nanoscale devices, the details of dynamical behavior are now increasingly important for proper engineering of any NEMS-based application. Traditionally the understanding of nonlinear properties was used to estimate the dynamic range in order to determine the limits of NEMS performance in linear regime. Recent research, however, has demonstrated that thorough understanding of nonlinear dynamics and incorporating it into a NEMS-based system enables performance enhancement beyond what previously considered possible.



One example of such application involves development of a self-sustained oscillators for time keeping or frequency source applications – a vital component of virtually any application. **In its most basic form, an oscillator consists of a resonator driven on resonance, through feedback, to create a periodic signal sustained by a static energy source**. Since the appearance of quartz-crystal-based oscillators, very few additional conceptual innovations have been introduced: quartz crystal resonators (their frequency-determining elements) operate at the highest possible signal to noise ratio in order to minimize the phase noise – which represents the sideband power spectral density at a given offset frequency, normalized by the oscillator's signal power – an important figure of merit characterizing the performance of an oscillator. The resonator's vibration is kept within *linear* regime; this results in the phase noise that is inversely proportional to the oscillator carrier power. An effort to replace ubiquitous quartz-crystal-based resonator with microfabricated NEMS or MEMS device will potentially lead to a dramatic reduction in size, cost, and power consumption. However, the size miniaturization necessarily leads to a decrease in maximum energy the nanoscale mechanical oscillator can store while remaining in linear harmonic regime. Smaller output power leads to performance degradation. Villanueva et al. [12] showed that these conventional performance limitations could be surpassed if nonlinear dynamics is considered.

The authors analyzed all the contributions to the phase noise in an oscillator based on a *nonlinear* resonator. They discovered the existence of a special region in the parameter space, above the nonlinear threshold, where the dominant contributions to the phase noise are suppressed. As a result the authors demonstrated a phase noise performance beyond the conventional limitations of linear regime. This experiment demonstrated that nonlinear dynamics can be used to improve performance of a practical application, and NEMS-based resonator is a perfect platform to realize that.

Nonlinear Dynamics Experiments: Multiple Devices

A simple increase in complexity of the dynamical system is achieved by considering multiple interacting nonlinear resonators. A relatively simple system of two nonlinear nanomechanical resonators strongly coupled by linear elastic force was theoretically modeled and experimentally studied by the authors of Karabalin et al. [13].

Despite its simplicity this two-resonator system demonstrated inherently rich dynamics, including the tuning of the nonlinearity of one mode by the other, the onset of spontaneous amplitude modulation oscillations, and the first strong evidence for deterministic chaos in nanoscale mechanical systems.

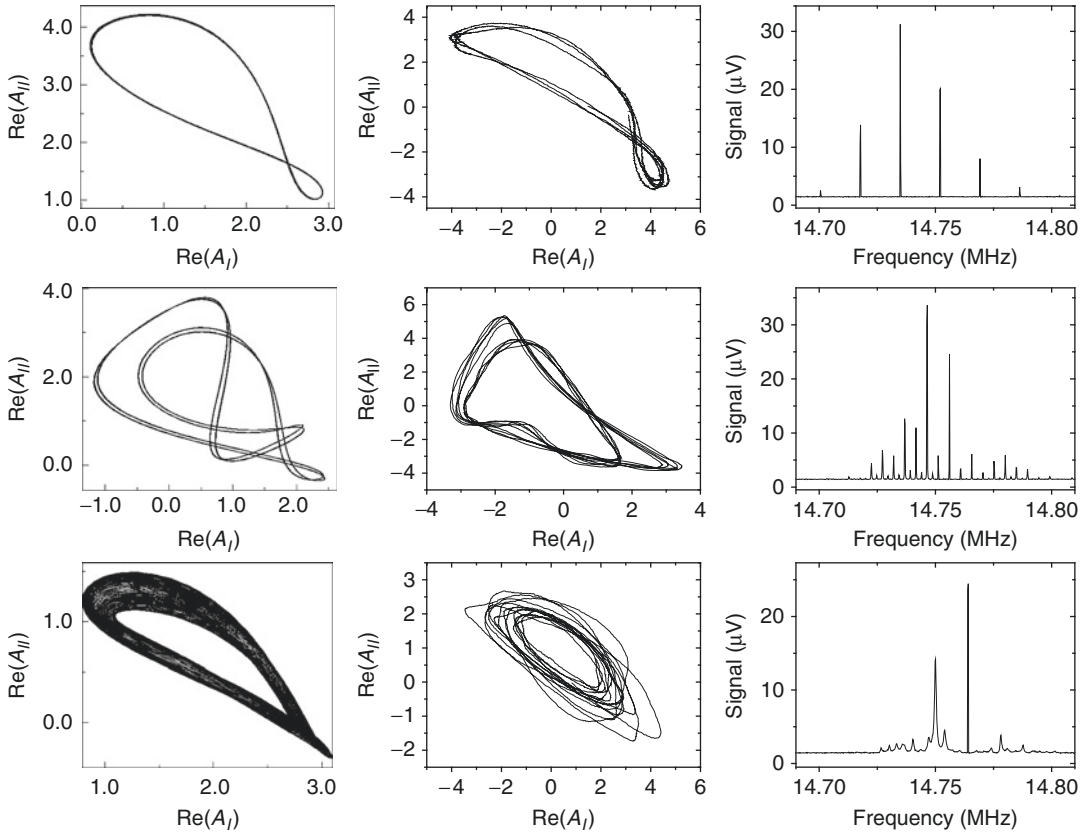
Nonlinear and Parametric NEMS Resonators, Fig. 2 (**a**) An SEM micrograph of two strongly coupled doubly clamped beams, which shared a ledge etched into an insulating layer. Individual electrical connections to the beams were provided. Frequency sweeps of the first mode response for increasing amplitudes of the second mode: the light line in (**b**) is a downward sweep, showing the hysteresis and amplitude jumps. There are no hysteretic jumps for (**c**) and (**d**), so the downward sweeps are not shown (Reprinted with a permission from Phys. Rev. B 79, 165309, 2009. Copyright 2009. American Physical Society)

Two nanomechanical resonators shown in Fig. 2a were linked via a ledge which acted as a strong elastic spring. Two coupled resonators could be reduced to two independent resonant modes, each being a mixture of vibrations from each beam. The authors of [13] have shown that a weak Duffing nonlinearity characteristic of each doubly clamped beam introduced nonlinear coupling terms for the two resonant modes. The multitude of remarkable physical phenomena arising from these simple terms were experimentally investigated and theoretically modeled by the authors.

In the case of a single resonator with a cubic nonlinearity, the peak frequency would effectively shift proportionally to the displacement squared. In two nonlinear coupled resonators, the frequency of one mode changed proportionally to the displacement of the other mode. Such system could therefore be useful as a displacement detector for quantum nondemolition measurements – an important application for nanoelectromechanical systems [14].

The authors further demonstrated that not only resonance frequency but also the nonlinear coefficient of each resonance could be controlled by the vibration state of the other resonance. When the coupling was strong enough, the minimum value of the effective nonlinear coefficient could be negative. In this case the resonance curve tilted to the left – a softening nonlinearity, as opposed to the usual case for hardening nonlinearity typically exhibited by doubly clamped beams, where the peak leaned to the right. It also meant that at some critical value (involving the drive strength and frequency of the second mode), the nonlinear coefficient vanished. Experimental results illustrating this effect are shown in Fig. 2b–d; here the first mode was driven at twice the critical strength. The plots show the shape of the resonance peak for three values of the drive frequency of the second mode. In panel (b), the amplitude A_{II} of the second mode was low, and the first mode spectral response had regular (hardening) nonlinear Duffing shape that leans to the right. For larger A_{II} as in (c), the first mode resonance

peak shape assumed a form close to a Lorentzian – that is, with little apparent nonlinearity. For even larger A_{II} as in (d), the sign of the effective Duffing coefficient became slightly negative, causing the spectral response peak to lean to the left, characteristic of a softening nonlinearity. This quenching of the nonlinearity can be used to enhance dynamic range of nanomechanical devices.

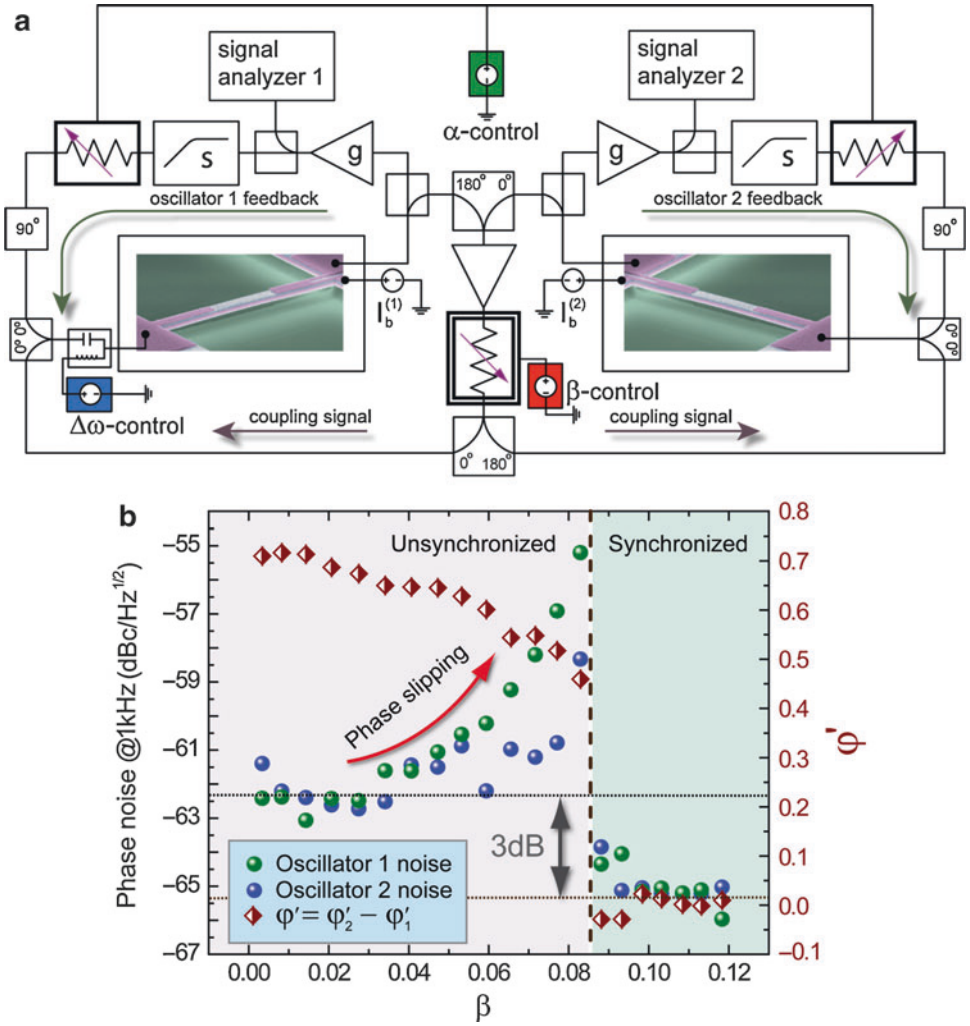


When the drive level of the first mode was increased to an extent comparable to the second mode, a variety of new effects were observed. The dynamical behavior in this case is more complex, as the response of the first mode becomes large enough to cause transitions in the second mode response through the nonlinear coupling. It turned out that for the drive frequencies near the transition points, the fast (about 17 MHz) oscillating response becomes amplitude modulated with a slow frequency of about 10–20 kHz. The theoretical simulations show that the frequency for the amplitude modulation was determined by the linewidth. The dynamics could be intuitively understood as follows: when the first mode was in its lower state and the second mode in its upper state, the first mode switched to the upper state; this caused the second mode to drop to the lower mode. In this condition the second mode became unstable in its lower solution branch and jumped to the upper state, kicking the first mode down to its lower state – thus restarting an oscillatory cycle. As a result the system reached a dynamical equilibrium where the two modes periodically transfer energy between one another.

Examples of simulated and measured amplitude modulation dynamics for three different sets of drive parameters are shown in Fig. 3. The first column shows examples of numerically calculated phase portraits of $\mathrm{Re}A_{\mathrm{II}}$ (real part of the amplitude of second mode) versus $\mathrm{Re}A_{\mathrm{I}}$ (real part of the amplitude of second mode). Phase portraits measured experimentally are shown in the second column. Frequency domain spectrum analysis is shown in the third column. The top row of Fig. 3 shows a relatively simple example where the motion is periodic but the trajectory nonetheless forms a small figure-eight loop. The spectrum of the measured mechanical signal also shows satellite peaks reflecting the anharmonic amplitude modulation.

As the parameters of the system were changed, period doubling or quadrupling in the amplitude modulation was observed. In this case the phase trajectory took two or four revolutions to complete the cycle [15]. An example of period quadrupling is shown in the middle row of Fig. 3. The complicated loop structures were visible in both theoretical and experimental trajectories, and the spectrum revealed amplitude modulation peaks at frequencies that corresponded to double and quadruple periods. Period-doubling transitions are often associated with chaotic dynamics, and indeed chaos in the coupled nanomechanical systems is shown in bottom row of Fig. 3. The broadband components of the spectrum (evident in the shoulders present in amplitude modulation peaks) provided clear evidence for the presence of chaotic dynamics in the experiment. Further illustration was the fact that the phase portrait trajectory did not form a closed loop. The theoretical model showed a similar behavior.

The realization of a large number of resonators performing useful application has long been one of the goals of NEMS research effort. One obvious benefit from employment of multiple NEMS resonators is hypothetical possibility to increase the signal to noise ratio, since the coherently summed signal grows faster than incoherently added noise. Thus the system could achieve not only high sensitivity and small form factor of NEMS, but also stability strong signal level of MEMS and larger mechanical devices. In order to achieve this goal, the resonators have to be synchronized, which turns out to be a challenging obstacle. An important work by Matheny et al. [16] demonstrated that nonlinear dynamics can be used as a tool to synchronize coupled oscillators and thus improve frequency stability of the system.



In this work the authors built two self-sustained oscillators out of two mechanically isolated NEMS resonators. The oscillators' natural linear frequencies did not exactly match due to fabrication uncertainties unavoidable at miniscule device dimensions. In this case the synchronization could occur if there existed a frequency

Nonlinear and Parametric NEMS Resonators, Fig. 3 Complex dynamics of two strongly coupled nanomechanical resonators. The three rows correspond to different input parameters (drive frequencies and amplitudes). The first column shows the theoretical calculation of the phase portrait, the second shows its experimental measurement, and the third column shows the corresponding experimental power spectrum of the optical measurement near one of the drive frequencies (Reprinted with a permission from Phys. Rev. B 79 165309, 2009. Copyright 2009. American Physical Society)

tuning mechanism that could be controlled by oscillator motion parameters and interaction. The anharmonicity arising from mechanical nonlinearity provided convenient method able to achieve synchronization under certain conditions [17]. The authors theoretically modeled this system and carefully mapped the parameter space where synchronization occurs. They calculated that stronger coupling strengths were needed for further separation in original frequencies. The authors devised a highly controllable coupling where the electric readout signal from one of the oscillators was directly fed into feedback loop of another oscillator and vice versa. The schematic of their setup is shown in Fig. 4a. The introduction of a cascade of amplifiers and phase shifters enabled the authors to control not only the strength but also the physical nature of interaction.

The synchronization was experimentally observed and carefully studied. A number of important dependencies characteristic of synchronization were measured, thus unequivocally demonstrating a true synchronization in nanomechanical systems for the first time. Thorough experimental work was performed by sweeping control parameters such as initial frequency separation and coupling strength. The experimental results were in remarkable agreement with theoretical predictions.

Nonlinear and Parametric NEMS Resonators, Fig. 4 (**a**) Simplified circuit schematic of the experiment. The NEMS resonators employed were selected to be as identical as possible. Each NEMS resonator (colored SEM micrograph) was embedded in two feedback loops: one was used for creating self-sustained oscillations in each resonator and the other for implementing coupling between the two oscillators. Three control knobs: α for nonlinear coefficient, β for coupling strength, and Δω for frequency offset are shown in the schematic. (**b**) Oscillator phase noise at 1 kHz offset from carrier frequency and oscillator frequency difference (right axis) as coupling is increased. At the value of coupling β = 0.086, the oscillator frequency difference goes to zero, and the phase noise for both oscillators decreases by 3 dB, i.e., corresponding to reducing the phase noise by half (Reprinted with a permission from Phys. Rev. Lett. 112, 014101, 2014. Copyright 2014. American Physical Society)

Finally, the authors explored the behavior of phase noise of the oscillators as it approached synchronization. Figure 4b shows the phase noise of both oscillators as a function of coupling strength. A theoretically predicted drop by 3 dB corresponding to a phase noise reduction by half is evident from the plot. This work showed the potential of nonlinear dynamics at the nanoscale scale. All of the components in the experiment could be realized in CMOS, implying that large-scale networks could be built using the standard semiconductor manufacturing techniques and electronically tested with state-of-the-art signal-processing capabilities. The flexibility of this system permitted high level of coupling control in completely random networks. The demonstrated

phase noise reduction in synchronized oscillators can pave the way toward enabling sensors and frequency sources based on arrays of nanomechanical devices.

Parametric Resonance

Another interesting fundamentally nonlinear effect that can be observed and exploited with nanoelectromechanical systems is parametric resonance. This phenomenon is useful for sensing applications because it provides an opportunity to amplify the signal in mechanical domain prior to applying electrical transduction. This reduces the often difficult challenge of optimally transducing signals from nanoscale mechanical devices into the realm of macroscopic electrical circuits. Parametric resonance is also valuable as a tool to study interesting dynamics in variety of systems ranging from quantum optics to plasma physics. In nano- and microscale mechanical systems, it has attracted significant attention for uses in applications and fundamental research. This section introduces the basic physics of a NEMS parametric resonance system using a specific realization with piezoelectric nanoelectromechanical system and describes an important experiment which explores parametric resonance as a means for building a self-sustained oscillator.

The simplest parametric amplification scheme involves periodic modulation of the spring constant of the system at twice its fundamental resonance frequency. Modulation of the tensile stress of a nanomechanical doubly clamped beam results in tuning of its resonance frequency. Calculating the displacement of the central point of the beam as a single degree-of-freedom harmonic oscillator of effective mass m, spring constant k, and quality factor Q with Duffing nonlinearity, we obtain the following equation of motion:

$$m\,\ddot{x} + \frac{m\omega_0}{Q}\,\dot{x} + \left(k + k_p \cos\left(\omega_p t\right)\right)x + \alpha x^3 = F_0 \cos\left(\omega t + \phi\right), \tag{3}$$

where k_p is a "parametric drive strength," i.e., amplitude of the spring constant modulation. The parametric modulation is performed at twice the resonance frequency, leading to a vibrational amplitude gain given by [8]:

$$G = \frac{A_{\text{pump on}}}{A_{\text{pump off}}} = \left[\frac{\cos^2\left(\phi + \frac{\pi}{4}\right)}{\left(1 + \frac{k_p}{k_t}\right)^2} + \frac{\sin^2\left(\phi + \frac{\pi}{4}\right)}{\left(1 - \frac{k_p}{k_t}\right)^2}\right]^{\frac{1}{2}}, \tag{4}$$

where k_t is the threshold parametric pumping force $2k/Q$. The second term in this equation diverges as k_p approaches k_t; thus significant vibrational amplitude gain can be obtained, provided the appropriate phase relationship between the parametric modulation and driving force.

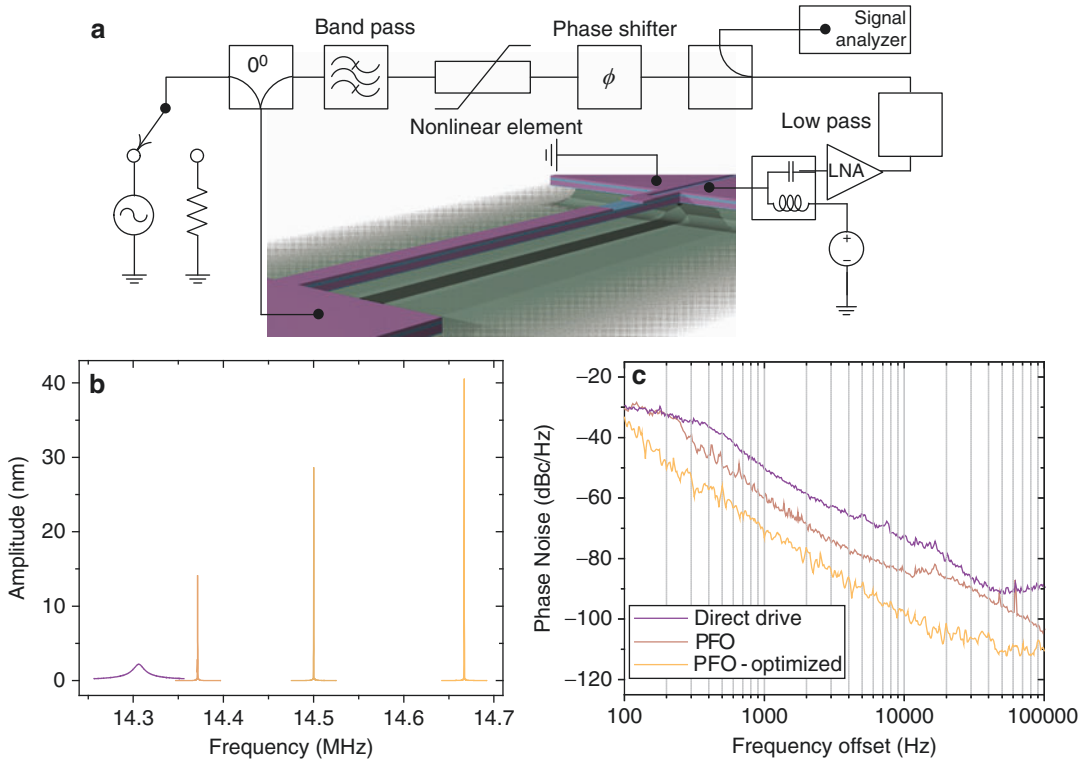
Piezoelectricity is a well-known phenomenon that directly converts electric fields into mechanical strain. Therefore it presents a convenient method to induce internal stress and thus change effective stiffness. In the experiment by Karabalin et al. [18], a set of doubly clamped beams were fabricated on the same chip. An active piezoelectric layer was sandwiched between the two conducting layers. When a voltage was applied between top and bottom conducting layers, the anisotropic piezoelectric coupling of the material caused longitudinal tensile strain to develop in the intermediate insulating layer. Doubly clamped boundary conditions converted the strain to stress, which either stiffened or softened the beam, thereby changing its resonance frequency.

Due to the remarkable efficiency of the piezoelectric stress tuning mechanism, the realization of parametric resonance could be implemented at very high frequencies with the NEMS devices. When the resonator is parametrically pumped at twice the characteristic frequency, a significant amplitude enhancement was observed consistent with theoretical prediction for parametric gain given in Eq. 4.

When the pumping force exceeded the threshold, the amount of energy delivered to the system became larger than the amount lost to dissipative phenomena. In this situation, in the absence of any

coherent driving signal, the resonator executed spontaneous oscillations close to its characteristic resonance frequency. The behavior of such dynamical system was described in detail in [8]. This interesting physical phenomenon was used to build a novel self-sustained oscillator paradigm in the work by Villanueva et al. [19]. The authors described and demonstrated an alternative to the canonical oscillator topology, namely, a new architecture based on nonresonant *parametric* feedback. A feedback loop in this work possessed a quadratic transfer function to apply parametric excitation at twice the resonant frequency (as opposed to "direct drive" at its resonant frequency).

The authors discovered many advantages of this generalized *parametric feedback oscillator* (PFO) technique, both from fundamental and technological points of view. Among them were (a) circumventing the need to satisfy the conventional "Barkhausen" oscillation conditions, thus enabling a wider variety of resonators to be used for oscillator circuits; (b) obtaining an unprecedented level of control of the resonator's nonlinear characteristics, enabling access to higher amplitudes of operation; (c) realizing a wider range of frequency tunability; and (d) obtaining substantial improvement in frequency stability of the oscillator, compared with that of conventional, direct-drive implementations.



The PFO concept was demonstrated using piezoelectric NEMS, where active piezoelectric layer (AlN) was sandwiched between two conducting layers (molybdenum). The out-of-plane resonator motion was detected using the time-varying, strain-induced resistance changes in a piezometallic (Mo) loop patterned at one end of the beam. Actuation was obtained by applying an AC voltage to an electrode that covers most of the beam's length; this induces longitudinal strain by means of the inverse piezoelectric effect. This time-varying strain could be used to actuate the beam either directly or parametrically.

The schematic of the setup is shown in Fig. 5a. The motional signal was first amplified and filtered to suppress high-frequency noise and higher harmonics ($>f$). Subsequently, the signal was delayed by a voltage-controlled phase shifter (ϕ) and then passed through a nonlinear element optimized to generate a *2f* signal with amplitude proportional to the square of the resonator motion. This frequency-doubled waveform was properly filtered and applied to a resonator actuation port thus inducing a resonator response at f – that is, parametric oscillation – provided the *2f* drive level exceeds the parametric threshold. Unlike traditional oscillator behavior, zero amplitude is a stable solution for our feedback system. This makes it necessary to initiate resonator motion by an external "start-up" source. However, after oscillations commence, the start-up drive can be removed and stable oscillations at f will persist, sustained only by the parametric feedback at *2f*.

Given that the frequency of the feedback (*2f*) and output signal (f) were well separated, cross talk was minimal for the operation of the parametric feedback oscillator; this eliminated a traditional obstacle for oscillators based on small-scale mechanical devices: for miniaturized electromechanical resonators, the output electrical signal was usually dominated by the feedthrough of the actuation voltage. In those conditions it was very challenging to attain an oscillation that used the mechanical resonator as the frequency-determining element.

When the feedback gain was sufficient to parametrically excite the resonator, then aforementioned parametric oscillation criterion was satisfied. The authors observed the inception of oscillation and carefully characterized it by capturing the power spectrum and comparing this to the open-loop resonator frequency response. Figure 5b shows the spectral response of the oscillator for three different values of phase delay, each incremented by 10°. Figure 5b also shows, for comparison, the open-loop resonator response at typical drive in linear regime. The extended tuning range was a direct consequence of parametric feedback, consistent with the theoretical model developed by the authors. This wide frequency range could be useful for applications requiring voltage-controlled oscillators and for the potential synchronization of coupled oscillators described in earlier section.

To characterize and quantify the performance of the parametric feedback oscillator, the authors

Nonlinear and Parametric NEMS Resonators, Fig. 5 (**a**) Schematic diagram of the generalized feedback system. The signal from the resonator was amplified and filtered at high frequencies to eliminate higher harmonics and noise. After an externally controlled (ϕ) phase delay was applied, the signal was passed through a nonlinear element followed by a bandpass filter to ultimately generate a signal at *2f*. This signal was applied to the actuation port of the beam through a power combiner that allowed simultaneous feedback and a direct drive with an external source, which was necessary to initiate the oscillations. Once the self-sustaining state had been reached, the source could be disconnected and the motion persisted. (**b**) Comparison between the open-loop response (*purple*) and the PFO power spectrum (*orange*). Three PFO traces are shown, each for a different value of ϕ (separated by 10°). (**c**) Phase noise measurements of the PFO in both a standard case and at the optimum phase value, showing a reduction of the noise. For comparison, the phase noise of a standard direct-drive oscillator is shown for the same oscillator energy, indicating higher phase noise than PFO over most of the frequency range (Reprinted with a permission from Nano Lett., 2011, 11 (11), pp 5054–5059. Copyright 2011. American Chemical Society)

measured its phase noise. A baseline comparison using separately constructed conventional feedback loop oscillator with direct drive at *f*, using the same active components, was provided. Frequency stability comparisons between this direct-drive oscillator and the prototype PFO, for operation at identical energies, were shown in Fig. 5c. The authors observed that the frequency stability of the PFO was significantly improved compared to that of the traditional oscillator topology. This provided direct evidence of suppression of the effects of phase noise in the feedback electronics. An additional enhancement was observed within the special region close to the mode coupling, where the phase noise was reduced by an additional 15 dB. This suppression was consistent with the theoretical model developed by the authors.

This section clearly demonstrates that parametric resonance is a unique dynamical system that could provide not only interesting insights into the deeper understanding in the field of nonlinear dynamics but also used to enhance performance of long-sought applications of nanoscale electromechanical systems.

Conclusions

A rapidly growing field of NEMS resonator has already shown remarkable progress in developing methodologies in the realm of sensing. NEMS resonators are increasingly employed for a variety of sensing applications including detection of mass, gas, biomolecules, and force – and they have demonstrated unprecedented resolution. The most responsive of these devices are based on frequency-shift sensing, where a stimulus to be measured induces a change in the resonant frequency of the NEMS. The development of NEMS-based self-sustained oscillators is not only promising for frequency control applications but also for miniaturizing the footprint of the whole sensor system. A stable NEMS oscillator element, co-integrated with a few active transistors, would represent the most compact sensing "pixel" achievable.

Today, an appreciable gap remains between many research demonstrations obtained in the laboratory and their translation to realization of reliable commercial applications – however, this gulf is closing quickly. Nonlinear processes are just beginning to be explored to assist in this process. There are enormous potential advantages that can be realized by nonlinear dynamics in nanoelectromechanical systems; among these are intrinsically noiseless amplification, suppression of noise mechanisms, synchronization of arrays of oscillators, and creation of novel types of nonlinear oscillators.

Meanwhile, NEMS resonators are increasingly providing an excellent testing bed for fundamental research that involves the detailed study of nonlinear dynamics; such efforts have potential applications to, and benefits for, many fields of endeavor. These nonlinear dynamical systems provide an opportunity to observe many interesting physical phenomena – among which are multiple, coexisting mechanical states, parametric resonance, noise-induced transition, chaos, and synchronization. It is anticipated that this research could have broad impact on fields as diverse as neuroscience, network theory, and frequency control.

Definition

Nonlinear optics (NLO) studies the behavior of light in *nonlinear media*, whose dielectric polarization (***P***) responds nonlinearly to the electric field (***E***) of the light. In general, such nonlinear behavior is observed under highly intense light beams. Several fundamental properties of materials such as nonlinear absorption, nonlinear refraction, harmonic generation, etc., can be probed using NLO spectroscopy.

The field of nonlinear optics (NLO) emerged into prominence more than three decades ago with the development of the laser. These milestone discoveries have not only generated much interest in laser science but also set the stage for future work in nonlinear optics. In recent years, the discovery of various nanoscale materials such as fullerenes, carbon nanotubes, and metallic and other semiconducting nanostructures has allowed nonlinear spectroscopy to progress towards technological applications, and the focus has been on the discovery of materials with higher photonic functionalities and better performance [1, 2]. Knowledge of electronic transitions is essential in understanding the linear and nonlinear optical properties of nanomaterials. Many spectroscopic techniques such as optical absorption, photoluminescence, photoacoustics, and x-ray photoelectron spectroscopy are often employed for the investigation of energy levels in nanostructures. More significantly, estimation of the nonlinear interaction of light with nanostructures helps one to probe the higher electronic levels, which are not easily accessible otherwise.

In nanostructures, quantum confinement effects and surface plasmon resonance (SPR), in tandem with other crucial factors like morphology, particle size, and chemical environment, can lead to interesting changes in nonlinear properties with many promising applications such as ultrafast optical switching, optical limiting, passive mode locking, frequency up-conversion lasing, optical data storage, multiphoton-based laser microscopy, etc. Interestingly, various nanomaterials exhibit distinct intensity-dependent nonlinear responses for laser excitation that depends on parameters such as laser wavelength, pulse duration, and repetition rate [2]. The physical basis of observed nonlinear optical responses in nanostructures is briefly elucidated in the

following sections along with an outline for various experimental techniques used for probing their photophysical properties with special reference to the optical limiting application. Optical limiters are materials which are transparent at lower incident fluences, but attenuate light considerably at higher fluences; thus protecting eye and photosensors from damage due to intense optical sources. Various nanostructures are promising as efficient and broadband optical limiters when compared to conventional materials like organic chromophores and dyes [1, 2]

Nonlinear Optical Processes

In general, the response of a material medium (which is lossless and dispersionless) to input light can be described in terms of the electric polarization $\boldsymbol{P}$ [1], which is usually expanded in a Taylor series in the electric field amplitude $\boldsymbol{E}$ as

$$\boldsymbol{P}=\chi^{(1)}\boldsymbol{E}+\chi^{(2)}\boldsymbol{EE}+\chi^{(3)}\boldsymbol{EEE} \tag{1}$$

where $\boldsymbol{\chi^{(n)}}$ are the susceptibility tensors of order n. Far away from a material resonance, the susceptibilities are predominantly real and the material response is instantaneous, but as resonances are approached, the susceptibilities will become complex, with relatively slower responses. The first term, $\boldsymbol{\chi^{(1)}}$, is responsible for linear absorption and refraction, while the remaining terms are associated with different light-induced nonlinear effects. Second-order nonlinear effects due to $\boldsymbol{\chi^{(2)}}$ are present only in noncentrosymmetric materials, and these include second harmonic generation and other three-wave mixing processes, optical rectification, and the electro-optic Pockels effect. Nonlinear optical effects involving the third-order susceptibility $\boldsymbol{\chi^{(3)}}$ include phenomena such as third harmonic generation and four-wave mixing processes, the electro-optic Kerr effect, two-photon absorption, and Raman amplification.

For a nonlinear optical medium, the refractive index and absorption coefficient will be functions of the incident light intensity. For an isotropic centrosymmetric material (where the lowest order nonlinearity is cubic), the intensity-dependent nonlinear refractive index is given by [1–4]

$$n = n_0 + n_2 I \tag{2}$$

and the intensity-dependent nonlinear absorption coefficient is given by

$$\alpha = \alpha_0 + \beta I \tag{3}$$

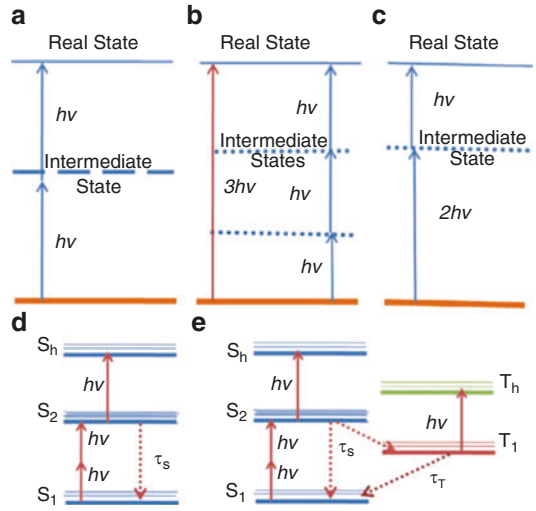
where n_2 is the nonlinear refractive index coefficient, and β is the nonlinear absorption coefficient. n_0 and α_0 are the linear refractive index and linear absorption coefficient, respectively. I is the intensity of the incident light which is proportional to $\boldsymbol{E}^2$. The third-order nonlinear susceptibility can be very generally written as

$$\chi^{(3)} = \chi^{(3)}_{(R)} + \chi^{(3)}_{I} \tag{4}$$

where the real part $\chi^{(3)}_{(R)}$ accounts for effects that are transient and consume no energy (like the optical Kerr effect, molecular orientation, electrostriction, etc.). The imaginary part $\chi^{(3)}_{I}$ accounts for processes that involve losses such as two-photon absorption. Thus, $\chi^{(3)}$ (both the real and imaginary parts) serves as a figure of merit for investigating potential novel materials for photonic applications.

It may be noted that ultrafast laser pulse excitation (typically in the femtoseconds regime) provides a way to measure pure-electronic nonlinearities exclusively. To observe longer timescale processes such as excited state absorption and thermal lensing, longer laser pulses (typically in the nanosecond regime) are used.

Nonlinear Refraction (NLR)



The dominant physical mechanism driving nonlinear refraction in a given medium can vary depending on the material, optical wavelength, irradiance, timescale of the light-matter interaction, and/or geometry. In addition to bound electronic nonlinearities, which are instantaneous, effects like intramolecular motion, molecular reorientation, electrostriction, induced population

change, and photothermal effects may become responsible for nonlinear refractive index in a medium. Depending on the sign (positive or negative) and magnitude of the value of "n_2" in Eq. 2, a laser beam passing through the nonlinear medium may be self-focused or defocused. Such focusing (or defocusing) arising from the real part of the third-order nonlinear susceptibility ($\chi^{(3)}_{(R)}$) is known as the optical Kerr effect (Kerr lens effect). The instantaneous nature of Kerr lensing is used in several applications including optical switching and laser mode-locking, especially in the ultrafast regime. At very high intensities, the optical Kerr effect may tend to saturate. For relatively shorter optical pulses with very high intensity, electronic nonlinearities may, on the other hand, lead to self-steepening and supercontinuum generation effects.

Nonlinear refraction can also occur due to thermal effects (usually referred to as thermal lensing), which typically build up with a relatively long response time of a few milliseconds. Thermal nonlinearity can be dominant for continuous-wave (CW) laser excitation and significant for nanosecond laser pulse excitation. The variation of the refractive index with temperature can be described mathematically as $\tilde{n} = n_o + (dn/dT)\tilde{T}_0$, where n_o is the linear refractive index, $\tilde{T}_0$ is the laser-induced change in temperature, and dn/dT, the temperature-dependent refractive index. The thermal nonlinear index of refraction can be determined using a closed aperture Z-scan measurement, employing either the thermal lens model (TLM) or Sheik-Bahae's formalism [3] for analysis.

Nonlinear Absorption

Nonlinear absorption refers to the change in the transmittance of a material as a function of input light fluence (given in units of J/m^2) [1]. As given above, the nonlinear absorption coefficient of a third-order nonlinear medium can be written as $\alpha = \alpha_0 + \beta I$, where β is the nonlinear coefficient of absorption. Far away from a material resonance, β usually reduces to the two-photon absorption coefficient. However, near a material resonance, two-step phenomena like excited state absorption (ESA) and free carrier absorption (FCA) may also contribute to nonlinear absorption. Such phenomena are collectively referred to as reverse saturable absorption (RSA). An overview of these phenomena is given below.

Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 1 Various nonlinear absorption schemes involving 2PA, 3PA and ESA processes. (**a**) depicts an ESA process while (**b**) shows 3PA and (**c**) shows 2PA. The dotted lines represent virtual state and *solid lines* represent real state. (**d**) and (**e**) show three- and five- level ESA models respectively, which have been extensively used in literature (see Ref. [1] for details). (**a**) 2PA virtual intermediate state (*dashed line*). (**b**) 3PA virtual intermediate state (*dotted line*). (**c**) ESA real intermediate state (*dotted line*)

Multiphoton Absorption

Many semiconducting and metallic nanomaterials exhibit multiphoton absorption (MPA). In this discussion, MPA is limited to two- and three-photon absorption (2PA and 3PA, respectively) processes. 2PA involves the simultaneous absorption of two photons to promote an electron from an initial state to a final state through a virtual intermediate level (Fig. 1). 3PA has a lower transition probability and involves three photons and two intermediate states. Since the intermediate level is virtual, energy need be conserved only in the final state. In contrast to reverse saturable absorption, MPA is an instantaneous process occurring in femtosecond timescales. The mechanism of 2PA can be viewed as analogous to a

three-level RSA process where the lifetime of the intermediate state approaches zero and the ground state absorption is extremely low (high linear transparency). Two- and three-photon-absorption-based nanomaterials can be used for applications like frequency conversion lasing, optical limiting, pulse stabilization, and reshaping [1].

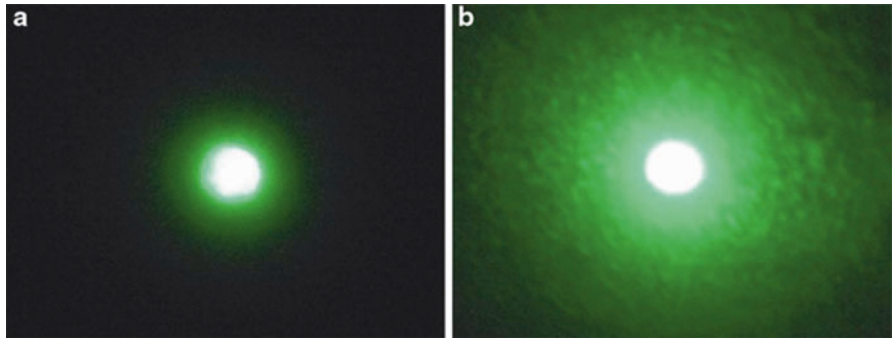
Excited State Absorption

In systems like C_{60}, the excited state absorption (ESA) cross section is greater than the ground state absorption cross section, which can lead to an enhanced absorption at higher input intensities. Typically, the ESA process is much stronger than 2PA, and to indicate the collective contribution of 2PA and ESA, the term "effective 2PA" is sometimes used in literature. When excited with nanosecond laser pulses, which are relatively long compared to typical excited state lifetimes of nonfluorescent materials, ESA will contribute significantly to nonlinear absorption. For instance, the effective 2PA cross section of a medium measured under nanosecond (ns) pulse excitation has been found to be about two orders of magnitude larger than the intrinsic 2PA cross section measured under femtosecond (fs) excitation [5]. In the case of intrinsic 2PA, the nonlinear absorption coefficient (β) is independent of the input intensity, but in the case of effective 2PA, the nonlinear absorption coefficient (β_{eff}) varies with input intensity. Relevant examples are discussed in section "Experimental Methods". Another interesting case is that of TPA-induced ESA, where a strong 2PA process considerably increases molecular populations in an excited state, which then absorbs another photon by an ESA process.

Free Carrier Absorption

In semiconducting materials, charge carriers are generated by one-photon as well as two-photon excitations. These electrons or holes can be excited to still higher or lower states in the conduction or valence bands by absorbing additional photons. Such carrier-assisted nonlinear absorption processes are known as "free carrier absorption," which is analogous to excited state absorption in molecular systems [2]. One difference is that free carrier absorption processes are usually independent of the input laser pulse width (assuming shorter timescales for carrier diffusion and recombination). In addition, they are insensitive to particle size and geometry and can be found in both solids and nanoparticle dispersions covering a broad range of temporal and wavelength ranges.

Induced Thermal Scattering



An important mechanism by which laser light transmitted through a medium suffers losses, particularly in the nanosecond excitation regime, is induced thermal scattering (ITS). Processes including the formation of microplasma and solvent microbubbles, and thermally induced local refractive index gradients lead to ITS [4]. Since the formation of thermal scattering centers takes several nanoseconds, these phenomena generally do not affect the transmission of ultrafast laser pulses through the medium. Mechanistically, ITS leads to a spatial redistribution of the incident beam (as shown in Fig. 2), resulting in spatial intensity modulation, which can be efficiently used for optical limiting if appropriate geometries are employed [2, 4].

Experimental Methods

In order to evaluate the contribution of various intensity-dependent nonlinear processes in any material, different methods such as second harmonic generation, four-wave mixing, ellipse rotation, nonlinear interferometry, and Z-scan are often employed [1, 2]. In recent years, Z-scan and four-wave mixing methods have been extensively adopted and applied by various research groups across the world to evaluate the nonlinear optical properties of various bulk and nanostructured materials.

Four-Wave Mixing

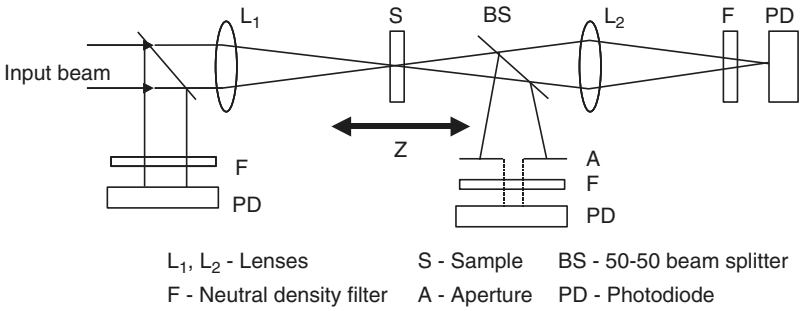
Four-wave mixing (FWM) is a phase-sensitive nonlinear effect arising from third-order optical nonlinearity. The concept of three optical fields interacting to produce a fourth optical field is central to the description of all four-wave mixing processes. Along with Z-scan, this is one of the

Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 2 Panel (**a**) shows the transverse profile of the incident laser beam, while panel (**b**) shows the beam profile of the scattered beam after traversing through the sample [6]

most widely used techniques to measure the third-order susceptibility $\chi^{(3)}$ of materials [2, 3]. In a dielectric medium, when two light beams are present, each beam independently polarizes the dielectric. The interference between polarized fields then results in harmonics at the sum and difference frequencies. When a third field is incident on the dielectric, it too drives the polarization and will beat with both the other input fields as well as the sum and difference frequencies. This beating with the sum and difference frequencies gives rise to the fourth field in four-wave mixing.

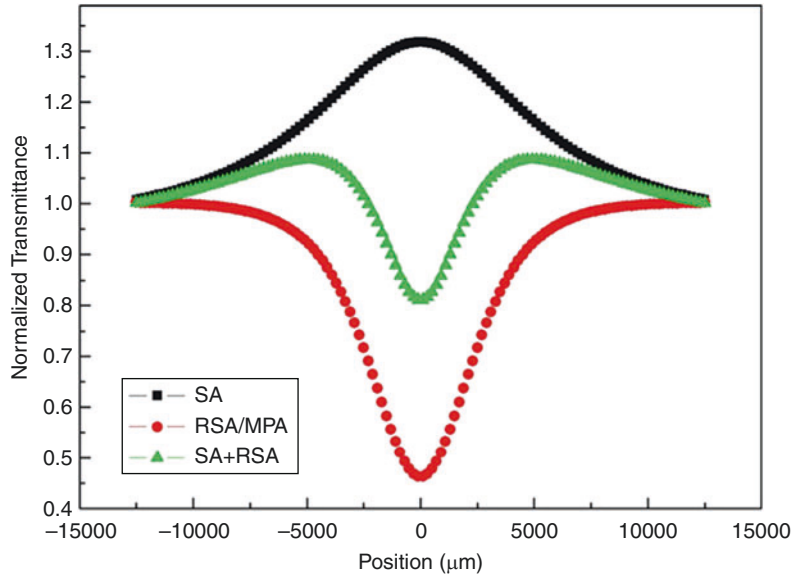
The FWM process is essentially of two types: nondegenerate and degenerate (DFWM). In the former, the optical excitation sources are of different wavelengths, while in the latter, their wavelengths are identical. The strength of the fourth beam is dependent on a coupling constant that is proportional to the effective $\chi^{(3)}$, and hence, measurement of the observed signal will yield information about the $\chi^{(3)}$ tensor components of the medium. Furthermore, DFWM can be employed in the backward (phase conjugate) and BOXCARS configurations, with the choice being made through consideration of the experimental conditions and requirements. In the backward geometry, two waves travel in the backward direction and two travel in the forward direction, whereas in the BOXCARS geometry, all the four waves travel in the forward direction. Using different polarizations for the three beams, all the components of the $\chi^{(3)}$ tensor can be measured. In terms of the intensity-dependent refractive index, the DFWM process is considered to be the interference of two input beams leading to a spatial periodicity resulting in the formation of a grating from which the third beam scatters, generating the fourth wave.

FWM can be used to probe either one-photon resonances or two-photon resonances in a material by measuring the resonant enhancement as one or more of the frequencies are tuned. By tuning the frequencies to multiple resonances in the material, excited state cross sections, lifetimes, and line widths can be measured. One of the main disadvantages of FWM is its sensitivity to alignment, requiring all three coherent beams to simultaneously overlap within the sample in space and time.



Z-Scan

The Z-scan technique is a sensitive and simple method employed to measure nonlinear absorption and nonlinear refraction. It has been used extensively to study the optical nonlinearity of various materials like semiconductors, nanocrystals, semiconductor-doped glasses, liquid crystals, organic materials, and biomaterials. Introduced by Sheik-Bahae et al. [3] in the early 1990s, this widely used technique has many advantages over other nonlinear spectroscopic methods. In a typical Z-scan, the light-induced change in transmittance (ΔT) of a medium due to optical nonlinearity is measured as a function of input light energy density (fluence) or intensity. A continuous variation of the input fluence is



achieved by translating the sample under study through the focal region of a focused laser beam (the sample position is taken as z with $z = 0$ being the focal point for the incident laser beam, hence the name "*Z*-scan"). Consequent increase and decrease of the intensity incident at the sample position lead to wave front distortions (created by nonlinear optical effects in the sample). There are two types of Z-scan techniques, namely, the "closed aperture" Z-scan and the "open aperture" Z-scan.

In the closed aperture Z-scan, which is used for studying nonlinear refraction (NLR), the transmitted beam is passed through an aperture placed in the far field and then measured by a detector, for different values of sample position z. When the medium is far before the focal plane, no self-lensing occurs. As the medium approaches the focal plane, the high intensity begins to induce a lensing effect in the medium. For a negative nonlinearity, this lens tends to collimate the beam, thereby increasing the transmittance through the aperture. At the focal plane, even though the intensity is highest, the influence of the induced lens is minimized, resulting in a transmittance comparable to the linear transmittance. This is similar to placing a thin lens at the focus of a beam; this results in a minimal effect on the far field beam pattern. As the sample is translated beyond the focal plane, the negative lens tends to increase the beam divergence, resulting in a decrease in the aperture transmittance. As the medium is translated still farther from focus, the intensity again becomes weak enough that the induced lensing is negligible. This sequence results in a change in transmittance with a characteristic peak followed by a valley, which is symmetric about the focal plane ($z = 0$). For a positive nonlinearity, the pattern consists of a valley followed by a peak. Thus, a simple Z-scan experiment can give both the sign and magnitude of the optical nonlinearity in a material. In both these cases, a purely refractive nonlinearity is considered, assuming that no absorptive nonlinearities are present. The sensitivity to nonlinear refraction results from the vital role played by aperture A (Fig. 3). If aperture A is removed, then the *Z*-scan is sensitive only to nonlinear absorption (NLA), and this configuration is commonly referred to as the open aperture Z-scan. The absorptive nonlinearity will be a maximum at the focal plane, where the intensity is highest. Thus, the open aperture scheme is employed to characterize materials that exhibit NLA, such as excited state absorption (ESA), two-photon absorption (TPA), saturable absorption (SA), etc.

Even though closed aperture Z-scan is used to study only NLR, in practice, the closed aperture Z-scan curve may contain a contribution from NLA also, depending on the sample. To obtain the NLR coefficient in such a case, it is sufficient to normalize the closed aperture data using the open aperture data before analysis. Although the open aperture Z-scan technique is adequate to detect the presence of nonlinear absorptive effects, it cannot singularly identify the nature of an absorptive nonlinearity. For example, at the outset, it cannot differentiate a 2PA signature from a two-step excitation signature. Figure 4 shows typical Z-scan curves simulated for the MPA, SA, and RSA processes. The Z-scan curves for SA (peak) and RSA (valley) have shapes, which are complementary to each other. It should be noted that the Z-scan curves for RSA and MPA

Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 3 A conventional Z-scan layout for simultaneous open aperture and closed aperture measurement

Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures,
Fig. 4 Simulated Z-scan curves for the saturable absorption (*SA*), reverse saturable absorption (*RSA*), and multiphoton absorption (*MPA*) processes

look very similar to each other. To confirm the exact nature of the process, it is often necessary to know the linear absorption properties of the sample from a linear absorption spectrum taken using a spectrophotometer. Z-scans performed using ultrafast laser pulses (where RSA effects are a minimum) will also be instructive in this regard.

A recent variation in the Z-scan technique is the white-light continuum Z-scan, where a supercontinuum is used as the light source for doing the Z-scan experiment. The "supercontinuum" is an intense, ultrafast, broadband light pulse, with wavelengths spanning the UV to the near IR region, generated when an ultrafast laser pulse is passed through certain transparent NLO media like heavy water. Conversion of the spectrally narrow pump pulse into the resultant broad spectrum involves the interplay of self-phase modulation and self-focusing of the pulse, due to an intensity-dependent refractive index of the medium. Since the typical supercontinuum spectrum covers the whole visible range, it appears white, and hence it is also known as a "white-light continuum." In the conventional Z-scan technique, nonlinearity can be measured only for one wavelength in one measurement. To determine the spectral dispersion of the nonlinearity, a tunable laser source has to be used, and separate Z-scans need to be done at all the required wavelengths. Obviously, this approach is time consuming and tedious. The idea of using a strong white-light continuum (WLC) as the light source to measure the dispersion of the nonlinearity in a single Z-scan experiment was therefore proposed by Van Stryland's group [7]. Their "WLC Z-scan" allows for rapid, broadband characterization of degenerate NLA and NLR.

Nonlinear Optical Properties of Nanomaterials

Nonlinear optical measurements in low-dimensional materials continue to draw considerable attention since the nonlinear behavior of the complex refractive indices lead to unique optical phenomena [1–3, 7]. Furthermore, the quantum confined nature of the charge carriers, surface effects, and sharp density of states in low-dimensional materials such as nanoparticles, nanowires, nanotubes, and nanorods introduces various new fundamental physical phenomena that can influence the NLO properties. For example, surface effects can lead to ferromagnetic behavior in nanostructured ZnO whereas bulk ZnO is diamagnetic [8], and a semimetal to semiconductor transition occurs in the low dimensional

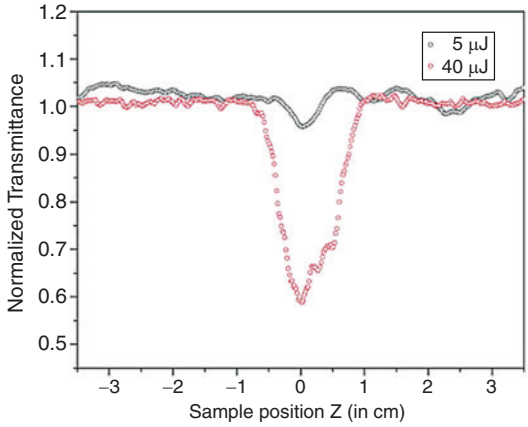
forms of bismuth due to quantum confinement effects. Hence, one may utilize these interesting properties of nanostructures to tailor new materials for NLO applications. For example, optical switching, saturable absorption, and optical limiting properties of one-dimensional nanostructures have shown considerable promise compared to bulk materials. In this section, several interesting NLO phenomena which can be observed in various nanostructures using the *Z*-scan technique are discussed. Although the discussion is limited to the *Z*-scan technique, various experimental techniques used for probing the NLO properties of popular nanostructures are summarized in Table 1.

Carbon Nanotubes



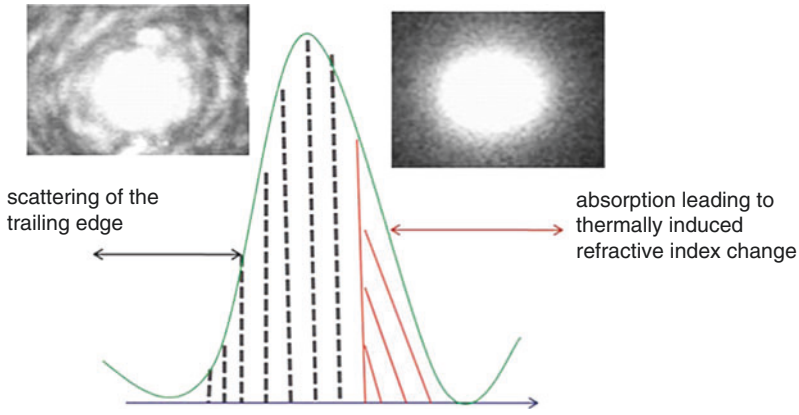
One-dimensional carbon nanotubes (CNTs) have revolutionized various fields of science and technology since their optical and electrical properties allow one to selectively modify and tailor nanotube properties for specific applications. Initial reports on the nonlinear optical limiting performance of multiwalled carbon nanotubes (MWNTs) highlighted the superior performance of nanotubes compared to corresponding properties of C_{60} and carbon black dispersions. Subsequently, it spurred interest in investigating NLO properties of functionalized CNT-based novel nanomaterials. Moreover, the broadband optical absorption profile of carbon nanotubes provides a unique advantage over other optical materials including fullerenes. Theoretical predictions by Margulis et al. claimed that the third-order nonlinear optical susceptibility for MWNTs exceeds that of fullerene molecules by two orders of magnitude [13]. Such enhancement in third-order NLO values arises from the combined effect of π-electron transitions, which are dominant over interband/intraband transitions. Thus, the modification of the π-electron cloud via functionalization or doping provides an efficient means for engineering novel materials with high nonlinear optical susceptibility.

The optical limiting performance of MWNTs at 532-nm excitation wavelength with a 7-ns pulsewidth from a second harmonic generator of a high-power Nd:YAG system (quanta systems) is depicted in Fig. 5. The laser excitation was used in the conventional open aperture *Z*-scan setup (as described in section "Experimental Methods"). Optical limiting response was studied by varying parameters such as the solvent used for nanotube suspension and the incident energy. The MWNTs were suspended in solvents such as deionized water, 2-propanol, and ethanol using sonication (for about ~10 min).

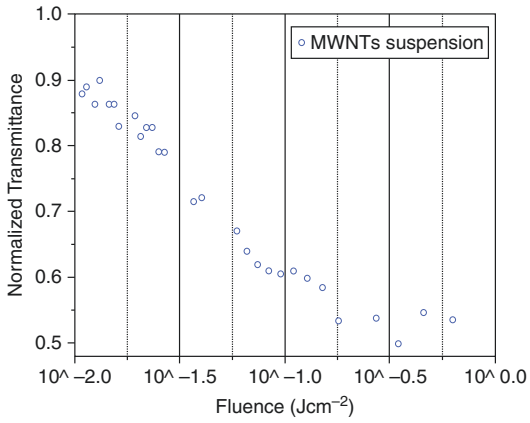
The transmittance curves of MWNT suspensions, as shown in Fig. 5, at different energies indicated improved limiting at higher energies. As expected, in the case of higher energies, early onset of limiting was observed (greater width of

transmittance curve at 40 μJ). The main mechanism responsible for the observed optical response is nonlinear-induced scattering, which was evident as the MWNTs suspension translated across the focal plane in the Z-scan experiment. The observed NLO response of MWNTs arises due to "microbubble" or "microplasma" formation that leads to the observed nonlinear scattering [4].

The leading edge of the pulse is absorbed by the MWNTs and is nonradiatively transferred to the surrounding medium within a few nanoseconds, which causes thermal inhomogeneities in the suspension centered around the nanotubes. Depending on the fluence (F_o) and thermo-optic coefficient (dn/dT), a local change in the temperature results in a local refractive index gradient (Δn) since $\Delta n = (dn/dT)(F0\ \alpha/2\rho C_v)$, where α is absorption coefficient, ρ is the density, and C_v is the specific heat of the sample [14]. The trailing edge of the optical pulse, therefore, "sees" a nonuniform optical medium of scatterers created by the leading edge of the pulse. Thus, the trailing edge gets scattered leading to a spatial redistribution of pulse energy (as shown in Fig. 6)

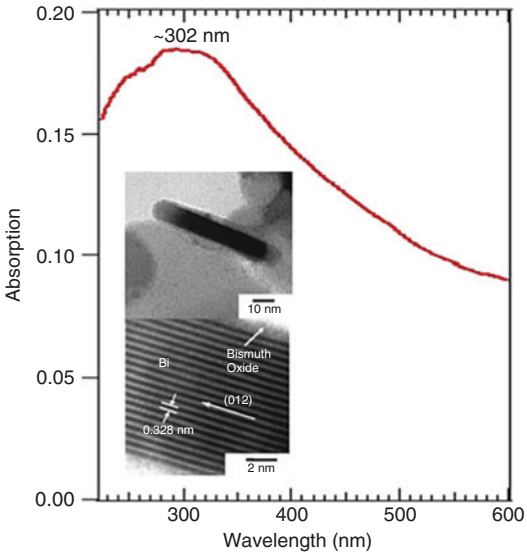


Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 5 Open aperture Z-scan signal for MWNTs suspensions dispersed in water and excited at two different incident energies, 5 μJ and 40 μJ; $\lambda_{excitation} = 532$ nm



Since the thermodynamical parameters of the solvent media surrounding the nanotubes play a crucial role in the formation of a scattering center, the optical limiting response was also found to be solvent dependent [9]. The threshold fluence for optical limiting (at which the transmittance falls to 50 % its initial value) for MWNTs was determined to be ~0.5 J cm^{-2} (Fig. 7).

Bi Nanorods



Bismuth is a semimetal in its bulk form and can be prepared in several different nanostructured forms, including thin films, nanowires, nanorods, and quantum dots [15]. Bi is an attractive material for studying how nanostructuring can alter the optical properties of metals. For example, because

Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 6 Scheme of nonlinear scattering or induced scattering leading to spatial redistribution of the beam as the intense laser pulse interacts with the MWNTs. The *right inset* shows the mm size laser spot before incidence, and the *left inset* shows the visible scattering after incidence

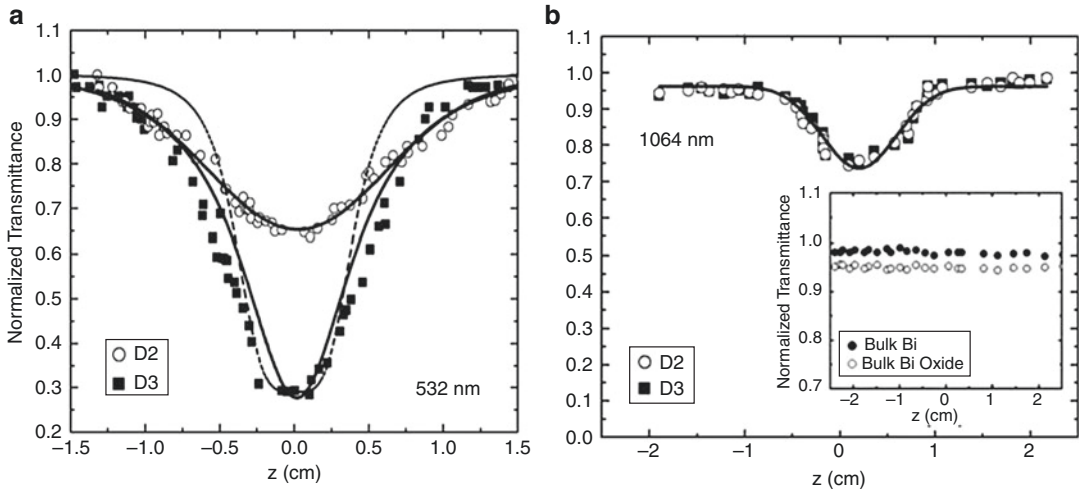
of the small effective mass components (in the anisotropic effective mass tensor) of Bi, quantum confinement effects are observed in nanowires with diameters as large as 40 nm at low temperature (77 K) [15]. In addition, since the mean free path is long in bismuth (∼250 nm at room temperature), the finite size effects in a Bi crystal are more pronounced. These effects, which are observed in the tens of nanometers range in Bi, occur in other metals only at much smaller length scales and, thus, are likely to be more difficult to probe experimentally. Therefore, understanding these effects in bismuth can assist in the prediction of the optical properties of other nanostructured materials.

A semimetal to semiconductor transition was predicted in the low-dimensional forms of bismuth due to quantum confinement effects. When such a transition occurs, it is expected that several material properties undergo a radical change. For example, the thermoelectric figure of merit is poor in bulk Bi due to nearly equal and opposite contributions from electrons and holes, but is high, ∼2, in small-diameter Bi nanowires. Similar enhancements in NLO properties were also observed for Bi nanorods [16].

Figure 8 shows the transmission electron microscope (TEM) images for Bi NRs synthesized using pulsed vaporization techniques [16]. Unlike bulk Bi, bismuth nanoparticles and nanorods exhibit a broad surface plasmon (SP) peak at ∼281 and ∼302 nm (4.4 and 4.1 eV), respectively. When irradiated by 532 nm (2.33 eV) laser pulses (pulse width ∼7 ns), Bi NRs can absorb energy via interband and intraband transitions, free carrier absorption, and two-photon excitation. The presence of the SP peak makes the absorption a "near-resonant" process. When Bi NRs are suspended in any solvent, the absorbed energy is transferred to the surrounding medium through nonradiative de-excitation, resulting in localized heating and thus scattering centers. In the case of a Z-scan experiment, the leading edge of the pulse creates these scattering centers and the trailing edge of the pulse gets scattered (see Fig. 6). Such a mechanism has been observed for other nanostructured systems such as SWNTs and MWNTs (see section "Carbon Nanotubes").

Previously, Sivaramakrishnan et al. used visible and IR laser pulses from a Nd:YAG laser (quanta system, 7 ns, 10 Hz), at both 532 and

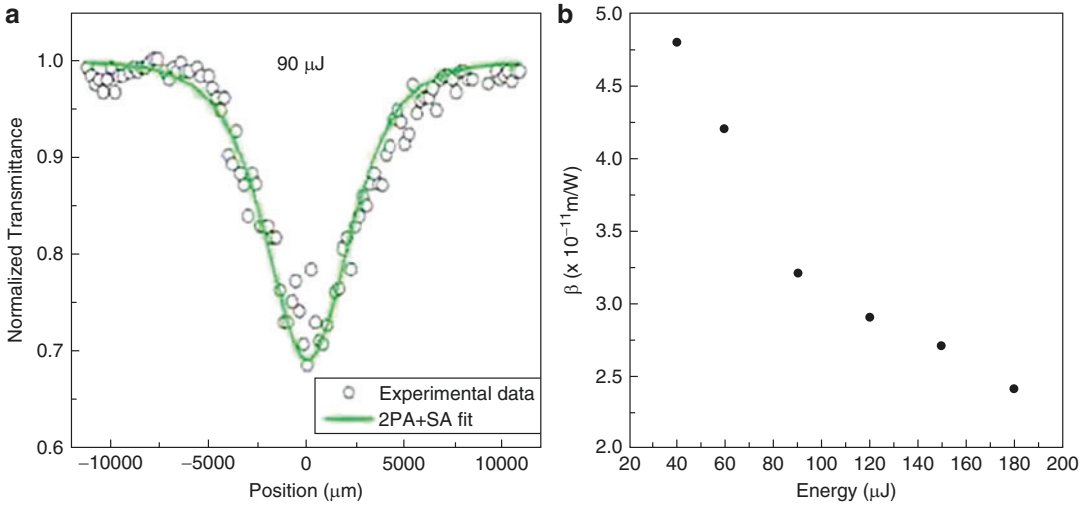


Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 9 Schematic of the experimental setup used for the NLO studies of Bi nanorods. A combination of lenses (*L1–L4*), beam splitters (*BS1*) and (*BS2*), neutral density filters (*NDFs*), aperture A, and detectors (*D1–D3*) are used to measure contributions to optical limiting from the scattered and unscattered components. Bi nanorod suspension is positioned at S and translated through $z = 0$

1,064 nm, to measure the optical limiting performance of Bi nanorod suspensions by the Z-scan technique at room temperature [17]. In order to separate the contributions of NLA and NLS, a modified Z-scan setup (Fig. 9) proposed by Jourdrier et al. was employed. In the modified setup, the beam is split 50:50 (using BS2) to reach two detectors D2 and D3 in order to measure the transmittance T of the sample with detector D1 as a reference. A "2" wide lens (L4) collects light from both the scattered and unscattered parts making D2 insensitive to transmittance changes due to spatial redistribution. This ensures that the collection efficiency is ~90 %. Thus, D2 records changes in transmittance solely due to absorptive effects, and the nonlinear extinction coefficient measured by the Z-scan curve is only due to contributions from NLA. On the other hand, D3 detects only the unscattered part since aperture (A) can be adjusted to prevent the scattered part from reaching D3. Therefore, D3 records a reduced transmittance due to NLS and NLA, unlike the case of D2. The Z-scan curves for the Bi nanorods suspended in chloroform (linear optical transmittance of 60 %) in a 1-mm cuvette made of fused silica (under a 55-μJ, 532-nm, 7-ns excitation) are shown in Fig. 10.

Figure 10a shows the Z-scan curves recorded by detectors D2 (NLA alone) and D3 (NLA and NLS). The depth of the valley in the Z-scan curve is a direct measure of the extent of optical limiting and is different in the D2 and D3 curves with dips of 0.65 and 0.25, respectively. Since D2 records the contribution due to NLA alone and the D3 curve also has contributions from NLS, it is clear that NLS induced by NLA makes a significant contribution to the total extinction. In fact, the contribution of NLS to optical limiting is greater than that due to NLA. Interestingly, in the case of 1,064-nm excitation (55 μJ, 7 ns), the D2 and D3 curves overlap (Fig. 10b), and the minimum transmittance is ~0.75 in both the cases. Thus, NLS is absent at 1,064 nm, and only NLA makes a contribution to the total extinction observed at this wavelength. At 532 nm, however, both NLA and NLS are responsible for the observed optical limiting unlike the 1,064-nm case. This is very unlike the behavior of carbon black and SWNT/MWNT suspensions, where NLS dominates at both 532- and 1,064-nm excitations (see section "Carbon Nanotubes").

As shown in Fig. 8, Bi nanorods used in this study contain a native oxide layer. Z-scan experiments performed using 532-nm excitation on



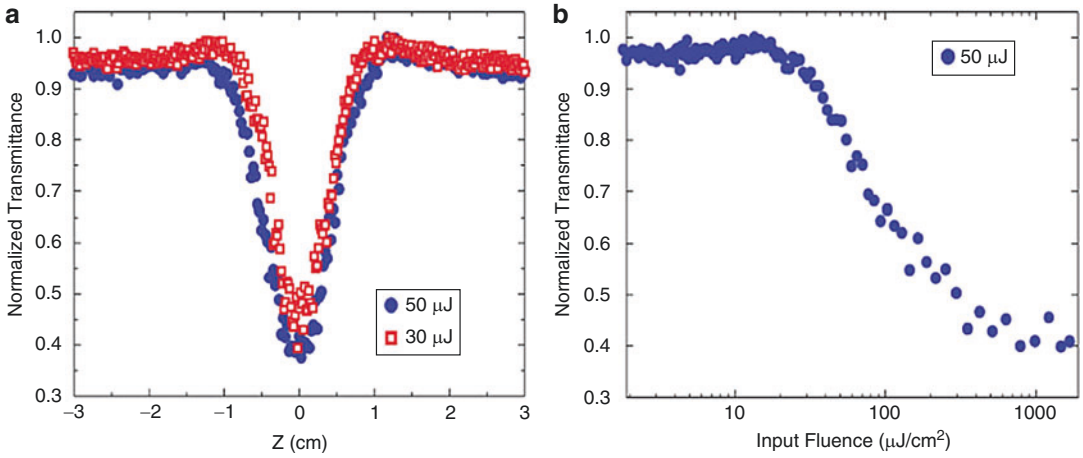
Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 10 (**a**) Normalized transmittance measured at 532-nm excitation by detectors D3 (nonlinear absorption and scattering) and D2 (nonlinear absorption only) for an input energy of 55 μJ. The minimum transmittance recorded by D3 is less than that of D2 as it has contributions due to both scattering and absorption. (**b**) Same as in (**a**) using the 1,064-nm excitation for an input energy of 55 μJ. The *overlapping curves* suggest that nonlinear scattering is absent when excited with 1,064 nm in contrast to the 532-nm case

bulk Bi and bulk Bi_2O_3 did not display any nonlinearity (inset in Fig. 10b).

However, ball-milled Bi_2O_3 powder exhibited strong nonlinearity when excited at a higher fluence (90 μJ; Fig. 11a). Similar to the case of Bi nanorods, the predominant cause for such nonlinearity was found to be two-photon absorption (2PA). Additionally, the saturation of the ground state absorption was also observed for ball-milled Bi_2O_3 samples. Thus an effective nonlinear absorption coefficient $\alpha(I)$, given by $\propto (I) = \frac{\alpha_0}{1 + \frac{I}{I_S}} + \beta I$ was considered for the fitting of the data shown in Fig. 11a, where I_S is the saturation intensity (intensity at which the linear absorption drops to half its original value) and β is the 2PA coefficient. Since Bi nanorods posses a high surface area (hence more of a surface oxide layer), it is possible that the nonlinear response discussed in Fig. 10 arises from the native surface oxide layer rather than core Bi nanorods. Furthermore, in Bi_2O_3, the numerically calculated β's were found to be decreasing with increasing energy as shown in Fig. 11b. The falloff of β with increasing intensity is a consequence of reverse saturation absorption arising from a sequential 2PA [2]. Thus, the contribution of the native Bi_2O_3 layer to the nonlinear properties of Bi nanorods cannot be ruled out despite the absence of any nonlinearity in bulk forms of Bi and Bi_2O_3.

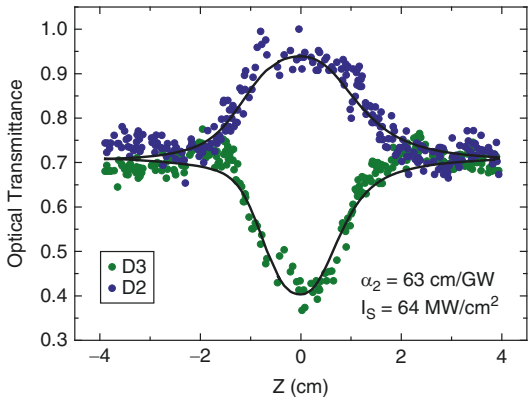
Surface-Modified NiS_2 Nanoparticles

Photonic nanoparticle systems have attracted considerable attention due to a wide variety of NLO applications such as optical limiting, saturable absorption, second harmonic generation, two-photon absorption, all-optical control, and holographic storage control. Typically, such systems are designed with a view of enhancing one of the nonlinear optical properties over their bulk counterparts. Previously, it was shown that nanomaterials (such as surface-modified NiS_2) can also be engineered to deliver systems displaying more complex behavior involving the interplay of two or more nonlinear phenomena [17]. If in such systems, two competing mechanisms operate simultaneously, however, the stronger dominates the weaker. Decoupling them in a single experiment is not straightforward. This section discusses the case of complete quantitative characterization in a single experiment of two *simultaneous* but *contrary* optical transmission



Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 11 (**a**) *Z*-scan data from ball-milled Bi_2O_3 samples obtained with 532-nm, 7-ns pulses. (**b**) The variation of 2 PA coefficients as a function of incident laser energy

phenomena – optical limiting and saturable absorption in surface-modified NiS_2 nanoparticle suspensions by employing a modified *Z*-scan method as in the case of Bi nanorods (Fig. 9). Capping with dimethylglyoxime (DMG) results in the surface modification of the nanoparticles and exhibits a spectral feature essential for the saturable absorption.



NiS_2 nanoparticles were suspended in an appropriate amount of 2-propanol so that the sample held in a 1-mm-wide fused silica cuvette would have a linear transmittance of 80 % at 532-nm wavelength. The second harmonic of a Q-switched Nd: YAG laser (532 nm) of pulse width 7 ns at 10-Hz repetition was used in the *Z*-scan studies employing a converging lens with a focal length of 20 cm. The *Z-scan curve* and transmittance as a function of input fluence are shown in Fig. 12a. It is clearly evident from Fig. 12b that the optical transmittance falls as intensity increases, exhibiting an *optical limiting* behavior. A transmission of 50 % (which is the threshold fluence for optical limiting) is reached at 300 μJ/cm^2. Such optical limiting in NiS_2 occurs due to the intensity-dependent scattering that is also visible to the naked eye.

Figure 13 shows the *Z*-scan curves (with the set up shown in Fig. 9) from detectors D2 (•) and D3 (•) for NiS_2 nanoparticles suspended in 2-propanol. The *Z*-scan curve due to detector D2 (•) shows an upward *peak* indicative of the saturation of absorption. The transmittance of the sample increases as it is brought closer to the focus of the *Z*-scan lens. This is in sharp contrast to the studies on Bi nanorods discussed earlier where the corresponding curve is a *valley* indicating that nonlinear absorption increases with intensity and transmission falls with intensity (Fig. 10). Saturable absorption observed in this case is similar to the behavior of rhodamine B under similar experimental conditions [6].

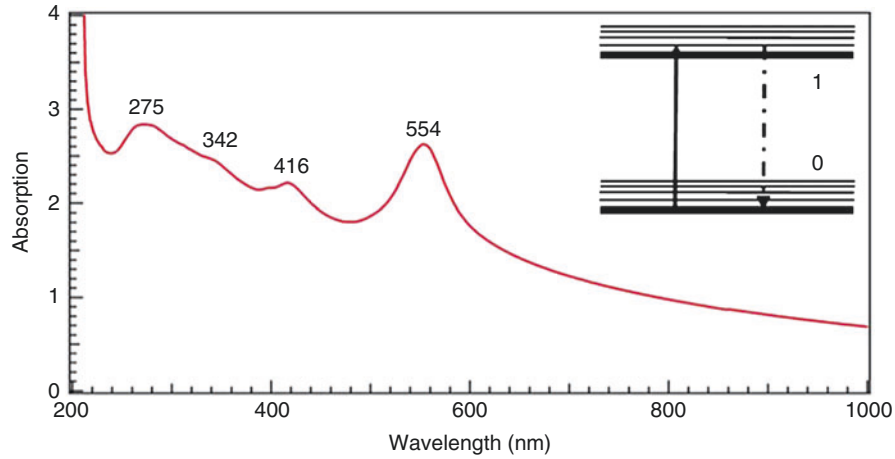
Furthermore, in Fig. 13, the Z-scan curve of detector D3 (•) which records intensity-dependent transmittance due to both absorption and scattering shows a typical optical limiting valley. Closer observation reveals that both the fall in transmittance due to optical limiting (•) and the rise in transmittance (•) due to saturable absorption are at a z-position of 1.75 cm with respect to the focal point ($z = 0$). Thus, the two effects are simultaneous and not sequential as has been observed in other experiments on nanoparticles systems [18]. The sequential occurrence of saturable absorption followed by an optical limiting behavior is indicative of excited state absorption.

Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 12 (**a**) Z-scan curves for nickel sulfide nanoparticles in 2-propanol and (**b**) the corresponding plot of optical transmission as a function of input fluence

Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 13 Z-scan curves of detector D3 (•) and D2 (•). While D3 measures the contribution of both nonlinear scattering and nonlinear absorption, D2 gives a measure of the intensity-dependent absorption alone

The UV–vis absorption spectrum for NiS_2 nanoparticles shows a strong absorption at ~554 nm (Fig. 14). Under 532-nm excitation, the nanoparticles are excited from the ground state (labeled "0") to a higher state (labeled "1") as shown in the *inset* in Fig. 14. As the intensity of the exciting laser pulse is increased to a maximum of 200 MW/cm^2, most of the nanoparticles occupy the excited state. As the ground state is bleached, the system becomes increasingly transparent to the incident laser pulse at 532 nm, resulting in a saturation of absorption and the consequent *Z*-scan curve.

The intensity-dependent absorption coefficient for a two-level system is given by [2]:



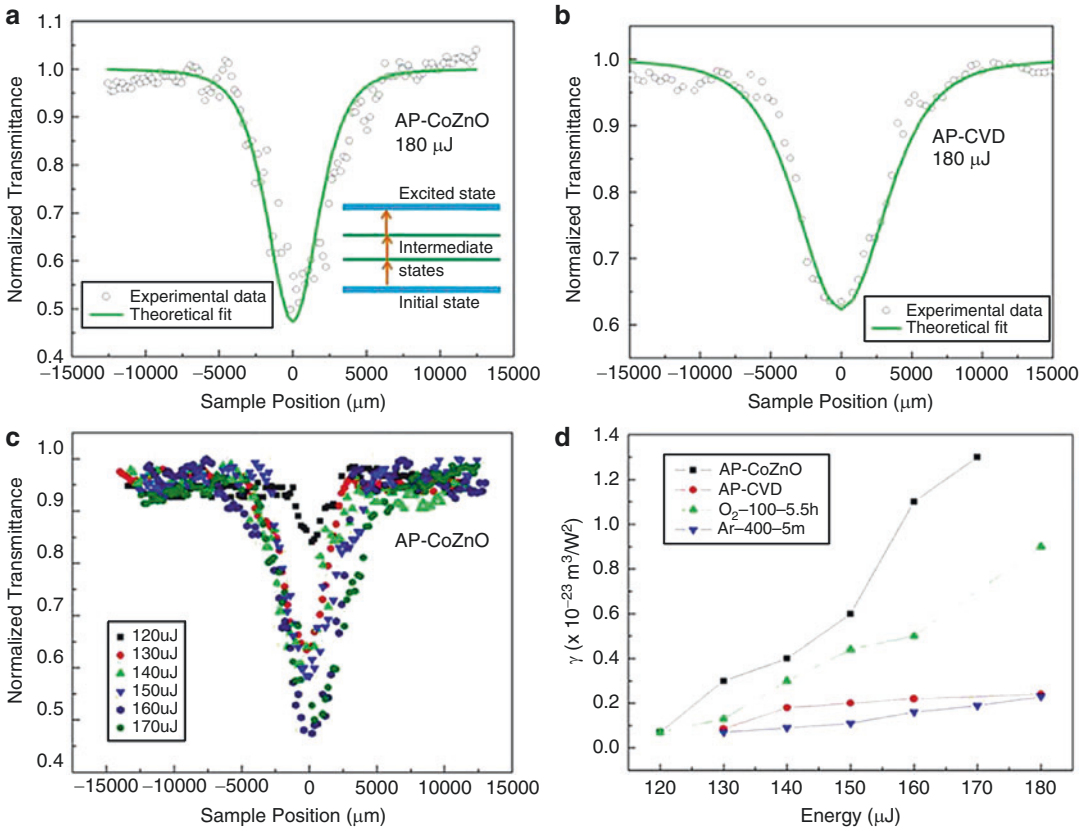
$$\alpha_{SA}(I) = \frac{\alpha_0}{1 + \frac{I}{I_s}} \tag{5}$$

where α_0 is the absorption coefficient, I is the intensity of the laser beam, and I_S the saturation intensity. This explains the upper curve in Fig. 13. The bottom curve can be understood in terms of simultaneous nonlinear intensity-dependent scattering that occurs due to energy transfer from nonradiative decay of excited states, as explained earlier in discussions of MWNT and Bi nanorod systems.

A complete description of the *Z*-scan experiment requires that both the saturable absorption and optical extinction due to nonlinear scattering be taken into account. Thus, in the similar lines of Venkatram et al. [18], we use the following equation describing these two concomitant processes:

$$\frac{dI}{dz} - \left[\alpha_0 + \alpha_2 I + \frac{\alpha_0}{1 + \frac{I}{I_s}}\right] I \tag{6}$$

N



Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 14 UV-Visible spectrum of NiS_2 nanoparticles in 2-propanol. *Inset* is a schematic of the excited manifold for saturable absorption as explained in the text

In the above equation, α_2 is the nonlinear scattering coefficient. The value of I_S and α_2 can be extracted from numerical fitting of data to this propagation. Here, the fourth-order Runge–Kutta method is used to solve the equation while finding the best fit for both parameters [6]. As mentioned earlier, the *Z*-scan curve of D2 is purely due to absorptive effects. The equation is first solved setting $\alpha_2 = 0$ so as to obtain a value for *IS* which in this case is 64 MW/cm^2. This value of *Is* is much smaller than the incident intensity at the focal point (at both 30 μJ and 50 μJ), eventually favoring the domination of nonlinear scattering following the absorption of a faction of the leading part of the incident pulse. Thereafter, the value of α_2 was obtained by using this value of I_S in the complete equation and finding the best fit to the Z-scan curve from detector D3. The nonlinear scattering coefficient, α_2, was found to be 63 cm/GW.

ZnO Nanostructures

Among the metal oxides, ZnO is a remarkable wide bandgap (3.37 eV in bulk) II–VI semiconductor. Its high exciton binding energy (60 meV) allows efficient exciton emission even at room temperature. As a consequence of its noncentrosymmetric crystal structure, ZnO is expected to have nonzero second-order susceptibility. Although many properties of bulk and nanostructured ZnO have been well studied, there is still a lack of understanding in the relationship between the density of defects, dopant level, synthesis conditions, and the observed optical and magnetic properties. In nanostructures, a fairly high surface state density significantly modifies or alters the chemical and physical properties, which can be reflected in optical measurements. NLO properties of different forms of pristine ZnO, such as single crystals, thin films, nanolayers, and nanowires, have been previously reported. It is also very important to understand the NLO properties of transition metal (TM)-doped ZnO nanostructures due to their ferromagnetic ordering at room temperature and importance in spintronic applications. An extensive study of NLO properties of TM-doped ZnO nanostructures can lead to a better understanding of the impact of surface states.

In earlier studies of the origin of ferromagnetism (FM) in pristine micro- and nanostructured ZnO, Podila et al. observed the changes in magnetic properties with varying crystallinity. They attributed the FM to the presence of surface states [8]. The presence of such surface states in pristine and Co-doped ZnO nanostructures (denoted as AP-CVD and AP-CoZnO) can be confirmed using the open aperture Z-scan. It is worth noting

Nonlinear Optical Absorption and Induced Thermal Scattering Studies in Organic and Inorganic Nanostructures, Fig. 15 (**a**) Z-scan data for AP-CoZnO samples fitted to a three-photon absorption (*3PA*) equation. *Inset* is a schematic depicting effective 3PA. When the intermediate states are virtual, the effect is genuine 3PA, but when they are real, it is an effective 3PA arising mostly from excited state absorption. (**b**) Z-Scan data for pristine ZnO samples fitted to a 3PA equation. (**c**) Z-scan data for AP-CoZnO samples at different incident laser energies. (**d**) Variation of the 3PA coefficient (γ) as a function of the incident laser pulse energy for AP-CVD, AP-CoZnO, O_2-100-5.5 h and Ar-400-5 m samples

that, except when excited by ultrafast laser pulses, ΔT strongly depends on the excited state population density. In view of this, the nonlinear transmission of the ZnO samples was measured in the nanosecond excitation regime using linearly polarized 5-ns optical pulses from a Q-switched frequency-doubled Nd:YAG laser operating at 532 nm. The Z-scan data obtained for AP-CoZnO and AP-CVD samples (Fig. 15a, b, respectively) were found to be best-fit numerically by a three-photon absorption (3PA) process model. It is instructive to note that, compared to the 2PA process described in Eq. 7, the nonlinear absorption coefficient α in the presence of 3PA is given by

$$\alpha(I) = \alpha_o + \gamma I^2 \tag{7}$$

In the above equation, I is the intensity of the laser, α_o the unsaturated linear absorption coefficient, and γ the 3PA coefficient. The value of γ was obtained by fitting the Z-scan curve to the 3PA propagation equation, given by

$$\frac{dI}{dz} = -\alpha_o I - \gamma I^3 \tag{8}$$

with z' being the propagation distance within the sample.

The values of γ numerically obtained from the fits indicated that nonlinear absorption in the

present case arises not only from genuine 3PA but also from "effective" three-photon nonlinearity [1]. Such effective 3PA originates from sequential excited state absorption as shown in the inset of Fig. 15a. In the case of genuine three-photon absorption (3PA), where the transition states involved are virtual, the 3PA coefficient (γ) is a constant and is independent of the incident laser fluence. All genuine ground state absorption coefficients (such as 2PA or 3PA) are dependent on the ground state population N since the absorption coefficient is obtained by multiplying the corresponding absorption cross section (σ) by N. The absorption cross section is a microscopic parameter, independent of N that characterizes the average two-photon/three-photon absorbability per molecule. However, the change in γ will be evident only when there is a substantial change in the ground state population due to absorption. Therefore, if the absorptions are weak, then the coefficients can be considered to be almost constant, since there is a negligible change in N. Genuine 2PA and 3PA are usually very weak phenomena, and, hence, the corresponding coefficients can be considered as material constants at a given wavelength and concentration. But strong excited state absorptions (ESA) during an effective 3PA deplete the ground state population significantly so that the absorption coefficient is no longer a constant. Hence a change in γ with respect to the incident laser intensity can help confirm the presence of surface states in the forbidden gap of ZnO.

Both two-photon absorption and/or sequential absorption of two photons at 532 nm (2.33 eV; inset Fig. 15a) will result in a real terminal level which is above the lowest excitonic state that lies around 363 nm (3.4 eV) for ZnO, and another one-photon absorption to go from this level to the band edge. Figure 15c, d show the variation of γ for AP-CoZnO, AP-CVD, and AP-CVD samples annealed in O_2 (Ar) for 5.5 h (5 min) at 100 °C (400 °C)−O_2-100-5.5 h and Ar-400-5 m, respectively – as a function of incident laser energy. While γ remains almost constant with input energy in AP-CVD, there is a pronounced increase in γ with incident energy in AP-CoZnO and O_2-100-5.5 h samples. Moreover, the 3PA coefficient (and, hence, the optical limiting efficiency) for AP-CoZnO samples is obviously higher than that of pristine ZnO. These observations concur with the enhancement seen in the magnetic moment of AP-CoZnO and O_2-100-5.5 h samples and indicate the presence of enhanced surface state density due to Co atoms in the ZnO lattice. Thus, the increase of γ with the incident laser energy confirms effective 3 PA due to the existence of a wide range of surface states in AP-CoZnO and O_2-100-5.5 h samples. Furthermore, the lowest γ values and a constant trend with input fluence were observed for Ar-400-5 m samples indicating the absence of any surface states. An enhanced surface state density in AP-CoZnO due to Co doping results in stronger FM and better optical limiting compared to pristine ZnO nanostructures [19].

Conclusion

In the preceding sections, the reader is introduced to optical nonlinearities and given an overview of various methods used for nonlinear optical characterization with emphasis on the *Z*-scan technique. The chapter discusses in detail the NLO properties of various nanostructures, such as carbon nanotubes, bismuth nanorods, NiS_2 nanoparticles, and ZnO nanowires, studied using the Z-scan. In the case of MWNTs and Bi nanorods, nonlinear scattering is found to play a major role in determining the nonlinear transmission. The simultaneous onset of two different nonlinear processes (saturable absorption and nonlinear scattering) was observed in NiS_2 nanoparticles. In pristine and doped ZnO nanostructures, the intensity dependence of the 3PA coefficient could be used to confirm the presence of intermediate states. These studies indicate that organic as well as inorganic nanostructures are excellent candidates for nonlinear optical transmission with potential strategic applications, including optical power limiting.

Parametrically excited nonlinear MEMS resonators

Definition

Nonlinear MEMS resonators excited by parametric excitation so its effective impedance is periodically modified by time-varying drive parameters

Background, Benefits, and Applications

In the rich context of physical and engineering disciplines, the first decade of systematic study on the nonlinear problems and parametrically excited systems dates back to the mid-nineteenth

century, with the work of Mathieu [1], Rayleigh [2], Stoker [3], and Nayfeh [4] as important landmarks. Owing to the use of a considerable amount of exemplary nonlinear problems, the forerunners provided intuitive concepts, such as self-excited systems, forced oscillations, parametric pump, and nonlinear restoring force, and backed them up with rigorous theorems. Recent work on the parametric resonance, especially in the context of resonant microelectromechanical systems (MEMSs), investigates the utility and advantage of exploiting parametric excitation in the areas of gravimetric [5] and chemical [6] sensing, inertial sensing [7], scanning tunneling microscopy [8], closed-loop servo [9], and scanning micromirrors [10].

A second-order mechanical system is typically excited into resonance using harmonic excitation – a time-varying excitation force whose frequency tracks the natural frequency of the system being driven. A system is excited parametrically when its effective impedance is periodically modified by time-varying parameters, such as a periodic driving force. For example, a pendulum can be "pumped" into parametric resonance when its rotational moment of inertia changes twice as fast as the pendulum's natural frequency. One could more intuitively picture a kid on a swing where periodic variation in the center of mass could lead to larger-amplitude rotational motion, if the variation in length is at a frequency that is twice of the swing's natural frequency.

One of the well-known benefits of the nonlinear parametric resonance is the bifurcation phenomenon, in which a directional sweep of drive frequency or phase creates amplitude "jump" in the region around twice the natural frequency. The bifurcation occurs in a system that exhibits bistability. A bistable system has two degenerated steady states. Perhaps the simplest bistable system is a binary bit which has "0" and "1" states. A state transition between "0" and "1" is analogous to the bifurcation phenomenon in MEMS. In the context of the MEMS parametric resonator, a sharp jump in the mechanical displacement amplitude from zero to a nonzero value could take place at a so-called "bifurcation frequency." The frequency at which the jump happens usually depends upon the direction of the parameter sweep, providing a hysteretic effect. Detecting this sharp jump therefore enables sensitive detection of changes in the resonant frequency, which can either be triggered by a change in mass [5] or stress that modifies the suspension spring constant.

Great resolution can be achieved given the bistable nature at the bifurcation point. With this capability, the class of nonlinear resonator becomes a good candidate for highly sensitive mass (i.e., gravimetric) and stress detector. Typically, the parametric resonance frequency links directly to the system's natural frequency, with a proportional constant that can be calculated through the perturbation theory introduced later in the text. Correlating the bifurcation frequency with the vibratory mass [5], one could measure the frequency shift on the sharp boundary of the bifurcation to determine the ultrasmall mass change. Unlike a harmonic-mode resonant mass sensor, the parametric-mode gravimetric detector is more immune to the amplitude noise [11] because the bifurcation response retains its sharpness in the presence of the intentionally injected detection noise. The prior demonstration of attogram mass sensitivity [12] through frequency resolution enhancement in a parametrically excited mass sensor offers motivation for parametric control [9], which is potentially capable of providing extremely sensitive detection of mass change.

Given ample design consideration, certain kinds of mechanical nonlinearity combined with electrostatic/piezoelectric/electromagnetic parametric drive give rise to flat and large-amplitude response over relatively wide-frequency ranges that are potentially useful in making manufacturable resonant devices. For devices with mismatched resonant modes, wideband frequency response makes mode matching possible and avoids the need for frequency tuning, example of which includes matched-mode gyroscope design in the presence of process mismatch [7]. Parametric resonance in MEMS finds further applications in effective Q enhancement through noise squeezing [13] and signal parametric amplification [14], parasitic signal reduction, and mechanical

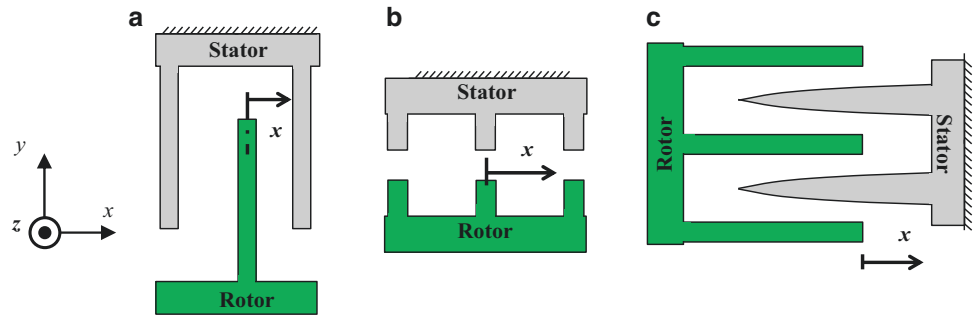
modulation [15]. Certain classes of nonlinear MEMSs can induce chaos behavior [16] with a particular set of oscillator parameters and could be potentially used for random number generation and signal encryption.

Parametric Excitation

Interdisciplinary nature of the MEMS inherently adopts various distinctive transduction mechanisms for parametric excitation, such as electrostatic, electromagnetic, piezoelectric, and optical actuations. In electrostatically driven resonant MEMS, the most effective time-varying parameter arises from tailored electrostatic actuators that introduce an equivalent electrostatic stiffness that varies with the excitation voltage. Turner and collaborators [8] experimentally measured five parametric resonant modes in a torsional oscillator excited through comb-drive levitation and observed that the parametric resonance occurs near the drive frequencies of $2\omega_r/n$, where ω_r is the natural resonant frequency and n is an integer larger or equal to 1. In most parametrically excited engineering electromechanical systems, the principal parametric resonance ($n = 1$) occurring at twice the natural frequency ($2\omega_r$) can be experimentally observed.

Fundamental difference between the parametric and harmonic resonators is the way they are excited. The harmonic resonator usually has a time-invariant mechanical spring constant, with an external drive that is sinusoidal in time t and independent of the displacement x. At harmonic resonance, the drive frequency tracks the natural frequency of the system. Parametric excitation, on the other hand, arises when the force applied on a MEMS resonator is not only a function of the time but also a function of the displacement of the resonator [17], creating time-varying impedance for the nonlinear system. The combined effective stiffness of the MEMS is periodically modulated by the parametric drive. Research literature is ripe with examples of exciting parametric resonance with a drive whose frequency doubles the natural frequency of the system. With proper designs, a parametric MEMS resonator can be excited into either harmonic or parametric mode with an appropriate selection of the driving electrode and the actuation condition – drive frequency and amplitude.

Electrostatic Parametric Excitation



In an electrostatically excited parametric MEMS, the electrostatic force drives the parametric resonator at an electrical frequency, ω_d, which creates a time-varying displacement-dependent spring constant, k_{eff}. Parametric resonance conditions are satisfied when the periodic variation of k_{eff} is at twice the natural frequency, i.e., $\omega_d = 2\omega_r$. A typical sinusoidally varying electrostatic parametric force, F_p, can be expressed as

$$F_p(t,x) = -\left(\gamma_1 x + \gamma_3 x^3\right)\ \left[V_{dc}^2 + V_{ac}^2 \cos\left(2\omega_r t\right)\right] \tag{1}$$

where t is time, x is the displacement of the mass, and V_{dc} and V_{ac} are the DC and AC components of the voltage applied on an electrostatic drive comb that is designed to create a voltage-controlled linear spring constant, γ_1, along with a cubic-displacement nonlinearity, γ_3.

Electrostatic parametric excitation in Eq. 1 is generated with several tailored electromechanical drive topologies. Combined direct and parametric drive can be generated through variable-gap electrostatic transduction. A simple example is a parallel-plate capacitive voltage-force transducer (Fig. 1a), which provides a direct excitation (i.e., constant force) and a linear softening electrostatic spring constant (i.e., γ_1 in Eq. 1), for sufficiently small displacement relative to the gap. Large displacement motion introduces higher-order forcing terms including the cubic spring constant (i.e., γ_3 in Eq. 1) that are usually avoided in this type of transducer design.

In parametric resonant MEMS, it is necessary to identify a parametric drive that provides pure parametric excitation, examples of which include tailored electrostatic comb drives. A well-known example is the non-interdigitated finger (NIF) comb drive [18, 19] (Fig. 1b), which is widely used to provide a well-defined voltage-controlled spring constant. The NIF comb drive is

Nonlinear Parametric MEMS, Fig. 1 Representative examples of electrostatic parametric transduction: (**a**) parallel-plate drive, (**b**) NIF, and (**c**) shaped-finger comb. *x* indicates the direction of motion

constrained to move in a direction orthogonal to the finger length (labeled in *x*) and makes use of the fringing electric field generated between nonoverlapping comb fingers. As the rotor moves away from the stator in $+x$ direction, electric field distribution is modified, and a retention force applies to the rotor in $-x$ direction whose magnitude is proportional to *x*. Both the linear and cubic stiffness can be independently tuned by the ratio of the finger width to its pitch [20] so the parametric response can be adjusted accordingly. The maximum displacement in this NIF design is limited to $\pm 1/2$ of the comb pitch (usually on the order of 1 1 μm mu;m for a typical MEMS NIF resonator). Necessary nonlinearity required to excite the parametric resonance imposes this constraint.

In the interest of extending the displacement range, an electrostatic "shaped-finger" comb is synthesized [21] to provide a large stroke with a small design footprint. It utilizes a nonlinearly varying electrode gap (Fig. 1c) between rotor and stator to provide the necessary electrostatic stiffness for exciting larger-stroke parametric resonance (usually on the order of 10 μm), which is a constraint partly by the length of the comb fingers and partly by the fabrication tolerance. Similar to the constant-gap parallel-moving straight-finger capacitive comb (the same comb as Fig. 1a but moves in *y*), the shaped-finger comb moves laterally in the plane of the wafer and parallel to the finger length, allowing sufficient clearance for large displacement motion. The shaped-finger comb concept was originally introduced by Hirano [22] to achieve a smaller gap between electrodes beyond the fabrication constraints. Later analytic study and experimental validation of the shaped-finger focus on its tuning dynamics, in which the electrode shape is tailored to provide specific electrostatic linear stiffness [23] and to further generate parametric drive [21]. For a resonator that utilizes the shaped-finger comb, separate linear displacement sensing combs can be included to electronically measure the parametric resonance in these large-stroke systems.

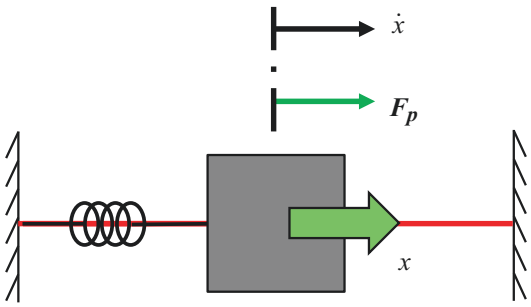
Other Parametric Excitation Mechanisms

Other parametric excitation mechanisms have also been adopted as alternative approaches to introduce time-varying excitation via parametric drives. In piezoelectric parametric excitation [6, 24], applying a periodic voltage to an external shear piezoelectric element modulates the total effective stiffness, which is equivalent to applying a periodic base excitation to a resonant device. In electromagnetic parametric excitation [14, 25, 26], the alternation of the polarity of the current and the magnetic field could generate direct or parametric Lorentz force excitation to a MEMS device with current-carrying metal traces that are exposed in a magnetic field. Thermal effect introduced by a laser beam [27] can also modify the time-varying impedance of the silicon disk oscillator, creating parametric amplification effect with proper selection of the optical pumped drive phase.

Parametric Resonance via Electrostatic Excitation

The second-order ordinary differential equation describing a nonlinear mass-spring-damper system is

$$m\ \ddot{x} + b\ \dot{x} + k_1 x + k_3 x^3 = F_p(t, x) \qquad (2)$$



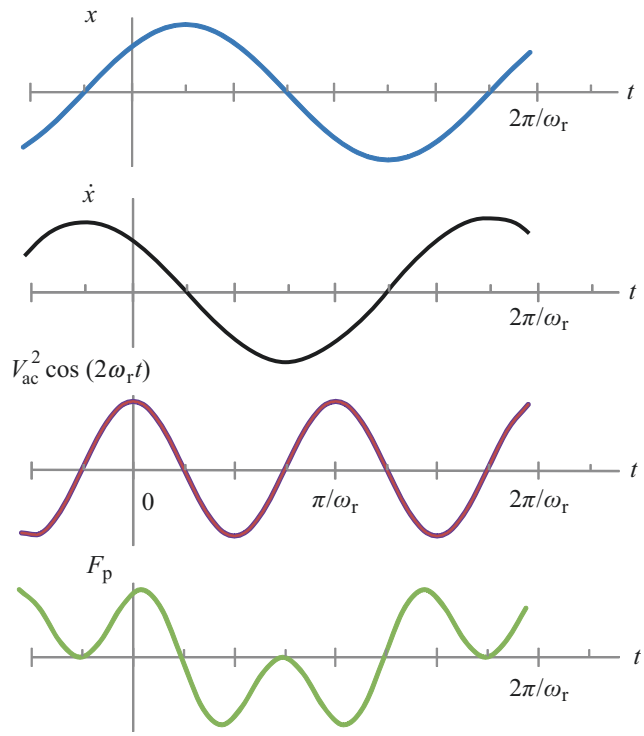
where m is mass, b is the damping coefficient, $\dot{x}$ is the first derivative of x with respect to time t, and k_1 and k_3 are linear and cubic mechanical spring constants (stiffness), respectively. Spring topology and composing beam dimensions set the mechanical stiffness and intentionally introduce essential nonlinearity to the nonlinear system. Substituting the electrostatic parametric force in Eq. 1 into Eq. 2 and rearranging terms yield a nonlinear Mathieu equation:

$$m\ \ddot{x} + b\ \dot{x} + \left(k_1 + \gamma_1 V_{dc}^2\right)x + \left(k_3 + \gamma_3 V_{dc}^2\right)x^3 = -\left(\gamma_1 x + \gamma_3 x^3\right)\ V_{ac}^2 \cos\left(2\omega_r t\right) \qquad (3)$$

Conceptual Example

A conceptual example of parametric excitation is shown in Fig. 2. A block material suspended by a mechanical spring experiences an electrostatic parametric excitation in the form of Eq. 1. Simplifying Eq. 1 by enforcing $V_{dc} = 0$ and $\gamma_3 = 0$, Eq. 1 can be rewritten as

$$F_p = -\gamma_1 x\ V_{ac}^2 \cos\left(2\omega_r t\right) \qquad (4)$$



Nonlinear Parametric MEMS, Fig. 2 A block material suspended by a mechanical spring experiences a parametric excitation in the form of Eq. 1

The waveforms of the displacement, x, velocity, $\dot{x}$, the square of the parametric voltage, $V_{ac}^2 \cos(2\omega_r t)$, and parametric force, F_p, are plotted in Fig. 3. The applied parametric force is always in the same direction of the velocity, pumping energy of electric origin into the system at a rate equal to twice the system's natural frequency.

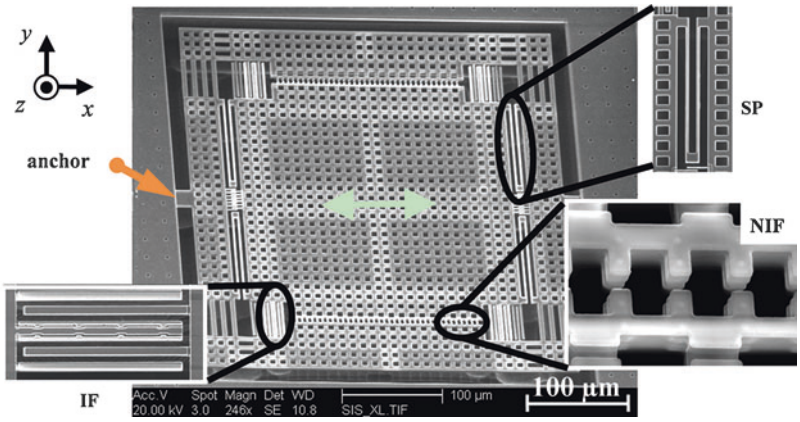
Quantitative Description

A trivial solution to the nonlinear Mathieu Eq. 3 is $x = 0$. At $x = 0$, the damping force, $b\dot{x}$, and the inertial force, $m\ddot{x}$, are both zero valued. Thus the spring force, $k_1 x + k_3 x^3$, is only driven by the parametric force F_p Eq. 1, which is generated by a symmetric drive design with no net force applied when the displacement is zero (as illustrated in Fig. 3). However, with air damping and the associated thermomechanical noise, a very small but nonzero displacement on the order of 10 fm/rtHz is present, and as a result, the electrostatically excited parametric force Eq. 1 is no longer zero and is proportional to the displacement. In a second-order mechanical system, this force exerted on a moving mass acts like a spring. And the applied voltage controls the associated "electrostatic spring constant." The total effective spring constant is a combination of both the mechanical spring constant and the electrostatic spring constant.

Upon application of the parametric drive voltage, the total effective spring constant of the mass-spring-damper system periodically increases (hardens) or decreases (softens). Parametric resonance commences when the parametric excitation and the velocity of the resonator are in phase. For principal parametric resonance at $2\omega_r$, the effective spring constant is modified twice within one period of the oscillation by the time-varying pump voltage. The system establishes parametric resonant amplification and its oscillation amplitude grows exponentially. The exponential growth is limited by the mechanical and electrostatic nonlinearities, controllable by the parametric drive voltage. The pumped displacement amplitude and phase are strong functions [19] of the system parameters such as the vibrating mass, mechanical spring constant, and electrostatic spring constant of the parametric drive.

Nonlinear Parametric MEMS, Fig. 3 The waveforms of the displacement, x, velocity, $\dot{x}$, parametric voltage square, $V_{ac}^2 \cos(2\omega_r t)$, and parametric force, F_p, for the conceptual example in Fig. 2

Nonlinear Mathieu Equation and Analytic Solutions



The governing nonlinear Mathieu Eq. 3 is in the form of a second-order differential equation with a cubic-displacement term and an oscillating excitation, whose exact solution is difficult to solve analytically. Perturbation techniques [17] provide a mathematical approach to find an estimated solution. Quantitative descriptions of MEMS parametric resonance have been extensively studied in [18] and [19] by solving Eq. 3 with perturbation techniques. The perturbation approach starts with normalizing Eq. 3 into a general, nondimensionalized form. It then finds the steady-state solutions, i.e., equilibria, using the various mathematical approaches such as the method of averaging and the method of multiple scales [17]. To determine the stability of steady-state solutions, the normalized equation is linearized locally around these equilibria. The system state is allowed to move along these linearized approximations by a small amount to determine the stability of each solution. Stability is often an interesting topic to study as it reveals if the associated steady-state solution is physically realizable.

Nonlinear Mathieu Equation

In electrostatically excited MEMS applications, the Mathieu equation describes a mass-spring-damper system with linear and cubic mechanical stiffness coefficients, driven by an electrostatic force that is not only a function of time but also of the displacement. The nonlinear Mathieu Eq. 3 may be written into a more general form:

$$m\ \ddot{x} + b\ \dot{x} + k_1 x + k_3 x^3 = F_p(t,x) = -\left(\gamma_1 x + \gamma_3 x^3\right)\ V^2. \tag{5}$$

Taking a CMOS-MEMS non-interdigitated comb finger (NIF) resonator described in Fig. 4 as an example, the perforated mass is suspended by four sets of mechanical springs. The sources of damping are usually dominated by the Couette damping of the suspended mass interacting with the underlying substrate, as well as Stokes

Nonlinear Parametric MEMS, Fig. 4 SEM of a CMOS-MEMS nonlinear parametric resonator that moves in x, with zoom-in view of NIF for parametric excitation, interdigitated finger (*IF*) for sensing and self-testing, and the spring (*SP*) for mechanical suspension

damping of the plate, and the squeeze-film damping between the gaps of any interdigitated comb fingers that are used for the capacitive velocity sensing and self-testing. The electrostatic parametric force, F_p, is an odd function of the displacement x. And this force is balanced when the displacement is zero (i.e., $F_p = 0$ when $x = 0$), usually attributed to a symmetric electrode design (i.e., drive combs located on both sides of the resonating mass, as shown on Fig. 4).

Applying a voltage in the form of

$$V(t) = \sqrt{V_{dc}^2 + V_{ac}^2 \cos(\omega_d t)}, \tag{6}$$

across the parametric excitation comb fingers provides a DC forcing term and an AC forcing term with a single frequency component ω_d [28] that decouples the parametric and direct harmonic excitation (i.e., AC term of the parametric force has only one frequency component, which can be used to excite pure parametric resonance).

Applying Eq. 6 on a parametric drive, (e.g., a NIF comb (Fig. 1b) or a shaped-finger comb (Fig. 1c)) generates a nonlinear parametric force in the form of Eq. 1. For the special case of a linear parametric force (i.e., $\gamma_3 = 0$),

$$F_p(t,x) = -\gamma_1 \left[V_{dc}^2 + V_{ac}^2 \cos(\omega_d t)\right] x. \tag{7}$$

Neglecting the mechanical cubic nonlinearity, $k_3 x$, and substituting Eq. 7 into Eq. 5 yield the linear Mathieu equation:

$$m\ \ddot{x} + b\ \dot{x} + \left(k_1 + \gamma_1 V_{dc}^2\right)x = -\gamma_1 V_{ac}^2 \cos(\omega_d t)x. \tag{8}$$

The resonant frequency of the linear Mathieu equation is thus

$$f_r = \frac{1}{2\pi}\sqrt{\frac{k_1 + \gamma_1 V_{dc}^2}{m}}. \tag{9}$$

With the inclusion of the nonlinear terms, γ_3 and k_3, a generalized form of the nonlinear Mathieu equation in Eq. 5 can be derived, which requires special treatments described in the following text.

N

Normalization

In general, perturbation approach starts with a nondimensionalization process, which is used to rewrite the nonlinear Mathieu Eq. 3 into a normalized form so its solutions can be universally applied given the variation in the design parameters:

$$\ddot{s} + \varepsilon\mu\dot{s} + s(\delta + 2\varepsilon\cos 2T) + \varepsilon s^3(\delta_3 + r_3\cos 2T) = 0 \tag{10}$$

where the dimensionless displacement is

$$s = \frac{x}{x_0} \tag{11}$$

and x_0 is the "characteristic displacement" chosen for a specific comb design. For example, x_0 may

be the comb finger pitch (center-to-center distance between electrodes in Fig. 1b) for a NIF resonator or the maximum stroke of a lateral comb resonator (Fig. 1c). The dimensionless time is

$$T = \frac{\omega_d t}{2}, \tag{12}$$

and for principle parametric resonance, $\omega_d = 2\omega_r$. The dimensionless linear parametric electromechanical stiffness, ε, is

$$\varepsilon = \frac{2\gamma_1 {V_{ac}}^2}{m\omega_d^2}. \tag{13a}$$

The dimensionless damping, μ, is

$$\mu = \frac{2b}{\varepsilon m \omega_d}. \tag{13b}$$

The dimensionless linear mechanical stiffness, δ, is

$$\delta = \frac{4\left(k_1 + \gamma_1 {V_{dc}}^2\right)}{m\omega_d^2}. \tag{13c}$$

The dimensionless cubic mechanical stiffness, δ_3, is

$$\delta_3 = \frac{2\left(k_3 + \gamma_3 V_{dc}^2\right)x_0^2}{\gamma_1 V_{ac}^2}. \tag{13d}$$

The dimensionless cubic parametric electromechanical stiffness, r_3, is

$$r_3 = \frac{2\gamma_3 x_0^2}{\gamma_1}. \tag{13e}$$

The relative magnitude of these dimensionless parameters represents their contribution to the parametric response.

Steady-State Solutions

The perturbation method typically starts with finding the steady-state solutions and linearizes the normalized equation about its solutions. An asymptotic expansion deriving the Jacobian matrix of the system is often used to determine the stability of each solution. To arrive at the steady-state solution, an assumed normalized solution

$$s(T) = A(T)\cos\left[\Omega T + B(T)\right] \tag{14}$$

and its normalized time derivative

$$\dot{s}(T) = -A(T)\Omega\sin[\Omega T + B(T)] \tag{15}$$

are imposed to rewrite the normalized Mathieu equation into two coupled equations in the amplitude, A, and phase, B, state-space model. The dimensionless mechanical frequency in Eq. 14 and Eq. 15 is defined as

$$\Omega \triangleq \frac{\omega_d}{2\omega_r}. \tag{16}$$

A combination of single harmonics are derived by plugging Eqs. 14 and 15 into Eq. 10 and rewriting the equation. These harmonics are integrated to keep only the time-invariant components and to discard the fast-varying transients [17–19]. This averaging method yields the first derivative of amplitude and phase:

$$\dot{A} = \frac{1}{8}x_0\,\varepsilon A\left[-4\mu + \left(4 + r_3 A^2\right)\sin\left(2B\right)\right] \tag{17}$$

$$\dot{B} = \frac{1}{8}\varepsilon\left[3A^2\delta_3 - 8\omega_1 + \left(4 + 2r_3 A^2\right)\cos\left(2B\right)\right] \tag{18}$$

where a "detuning parameter," ω_1, is defined such that

$$\Omega = 1 + \varepsilon\omega_1. \tag{19}$$

The quantity $\varepsilon\omega_1$ measures the closeness of the parametric excitation frequency, ω_d, to the predicted parametric resonance occurring around twice the natural frequency $2\omega_r$. The averaged model Eqs. 17 and 18 is used to obtain the steady-state response and the corresponding stability.

In weakly damped systems, one steady-state trivial (zero) and three steady-state nontrivial responses [19] are derived by setting $\dot{A} = 0$ and $\dot{B} = 0$:

$$\alpha_1 = \pm 2x_0\sqrt{\frac{1+2\omega_1}{3\delta_3 - 2r_3}} \tag{20a}$$

$$\beta_1 = \pm\pi\left(n+\frac{1}{2}\right), \text{ where } n = 0,\ 1,\ 2,\ \ldots \tag{20b}$$

$$\alpha_2 = \pm 2x_0\sqrt{\frac{-1+2\omega_1}{3\delta_3 + 2r_3}} \tag{20c}$$

$$\beta_2 = \pm n\pi, \text{ where } n = 0,\ 1,\ 2,\ \ldots \tag{20d}$$

$$\alpha_3 = \pm x_0\sqrt{-\frac{4}{r_3}} \tag{20e}$$

$$\beta_3 = \pm\frac{1}{2}\arccos\left(-\frac{3\delta_3}{r_3} - 2\omega_1\right) \tag{20f}$$

$$\alpha_4 = 0 \tag{20g}$$

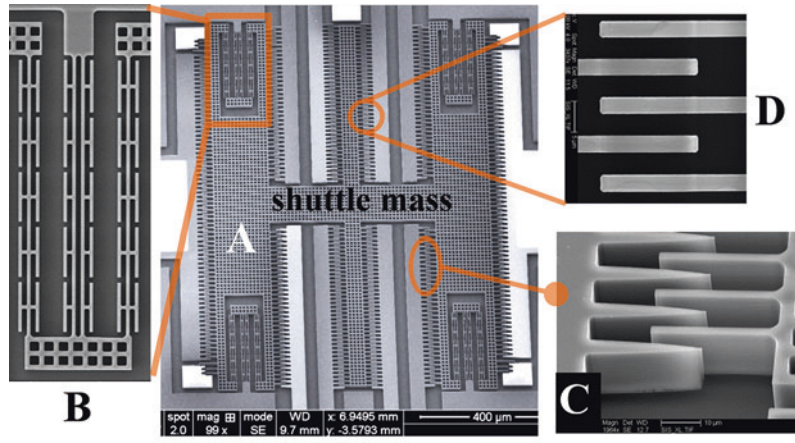
$$\beta_4 = \pm\frac{1}{2}\arccos(2\omega_1) \tag{20h}$$

where α_i and β_i are the dimensional steady-state amplitude and phase solutions, respectively. Dimensional steady-state solutions are sometimes written in the amplitude and phase pair $[\alpha_i\ \beta_i]^T$, where $i = 1, 2, 3$, and 4.

Frequency Response

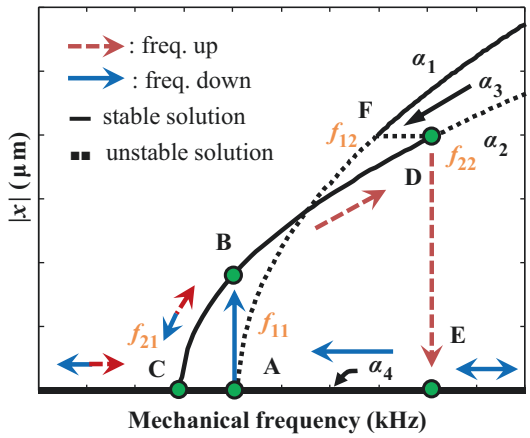
Electrically driven parametric resonance commences around the excitation frequency of $\omega_d \cong 2\omega_r$. With Eqs. 16, 19, and 20a-h, four denormalized (dimensional) mechanical responses are

$$x(t) = \alpha_i \cos\left[\left(1+\varepsilon\omega_{1,\ ij}\right)\omega_r t + \beta_i(t)\right] \tag{21}$$



where $i = \{1, 2, 3, 4\}$ denotes the i^{th} steady-state solution and $j = \{1, 2\}$ for $i = \{1, 2, 3\}$ denotes the j^{th} bifurcation frequency, determined by the stability analysis. The stability of the steady-state amplitude in Eq. 20a, c, e, g was extensively studied in [18], which determines the combination of frequency and phase that trigger the bistable jump. The generalized stability analysis uses the determinant of the Jacobian matrix of Eqs. 17 and 18 to derive the "boundaries" between the stable and unstable solution branches. The resulting boundaries are expressed in terms of the "detuning parameter" $\omega_{1,ij}$. In electrostatically driven parametric MEMS, the dimensional electrical excitation frequencies that give rise to bifurcation are

$$f_{\text{elec}} = f_{ij} = 2f_r\left(1+\varepsilon\omega_{1,\ ij}\right). \tag{22}$$



The bifurcation frequencies link to the observable system parameters such as the parametric excitation voltages and frequencies.

Using a fabricated shaped-finger comb parametric resonator [21] shown in Fig. 5 as an example, the shuttle mass (A) suspended by four sets of folded springs (B) is driven parametrically by the shaped-finger comb (C), and its motion is sensed with the straight-finger combs (D). Four denormalized steady-state amplitudes α_i and the corresponding denormalized bifurcation frequencies f_{ij} are plotted in Fig. 6 against the mechanical frequency (the frequency of the displacement).

The dimensional bifurcation frequencies are summarized in Table 1. Each of the solutions α_1 and α_2 has three branches of different stability properties, indicated on the figure with solid (stable branch) and dash (unstable branch) lines. Specifically, the steady-state solutions a_1 and a_2 are separated by the bifurcation frequencies (i.e., points A, F, C, and D) into different regions with well-defined stability. These bifurcation frequencies are labeled f_{ij}. The third solution α_3 is an unstable constant solution, and the fourth solution (zero displacement solution) α_4 is always stable in steady state, but it is not practical between points A and C, because noise will trigger a jump to a_2. The frequencies f_{11} and f_{21} are called "pitchfork" bifurcation frequencies, and f_{12} and f_{22} are called the "saddle-node" bifurcation frequencies. Two "pitchfork" bifurcation frequencies spread out symmetrically on the frequency axis corresponding to $\omega_{1,i1} = \pm 0.5$, where $i = 1,2$.

Nonlinear Parametric MEMS, Fig. 5 SEM of a silicon-on-insulator-MEMS shaped-finger comb parametric resonator suspended by folded springs

Nonlinear Parametric MEMS, Fig. 6 Steady-state frequency response of the folded-flexure shaped-finger comb parametric resonator demonstrating overall hardening nonlinearity

Nonlinear Parametric MEMS, Table 1 The dimensional bifurcation frequencies of the parametric MEMS resonator

Symbol	Physical interpretation
f_{11}	Pitchfork bifurcation from zero solution to the unstable region of α_1
f_{12}	Saddle-node bifurcation of α_1 to α_3
f_{21}	Pitchfork bifurcation where stable branch of α_2 annihilates into the zero solution
f_{22}	Saddle-node bifurcation of α_2 to α_3

In Fig. 6, the nonzero solutions emanating from the bifurcation points f_{11} and f_{21} emerge when the amplitude solutions are real valued.

The sign of the combined nonlinearity $(3\delta_3 \pm 2r_3)$ in Eq. 20a, c determines the direction of the bending. For the shaped-finger comb resonator in Fig. 5, the amplitude solutions a_1 and a_2 bend to the right, indicative of "cubic hardening" nonlinearity. The resonant amplitude is limited by the cubic stiffness nonlinearity. The resonator maintains resonating state along the nonzero solution curves. The type of nonlinearity can vary from spring hardening as in Fig. 6 to mixed nonlinearity [18] and further to spring softening [19].

The parametric frequency response may be measured by chirping (i.e., sweeping) the excitation frequency with time in the region near twice the natural frequency. For most values of the drive frequency, the system is not stimulated and the motion is near $x = 0$. After passing the bifurcation frequency, the system establishes automatic parametric resonance, which builds oscillation amplitude that would grow without bound if not for damping and nonlinearity in the system.

Hysteresis and Bifurcation Behavior

Figure 6 also reveals another aspect of parametric response – hysteresis effect. To the right of the "pitchfork" bifurcation point f_{21}, the "bending" of

the curve results in multivalued solutions at the same excitation frequency. Depending on the initial condition, the response amplitude could home on one of the three solution branches α_1, α_2, and α_4. The system always lands on the stable branches, whereas the unstable branches are not physically realizable in steady state.

In an open loop system, for a decreasing frequency sweep, the resonator displacement follows zero solution with a very small motion created by the thermomechanical noise, until reaching the bifurcation frequency f_{11} of solution α_1 where the stable zero solution intersects with the parametric unstable region of α_1 (point A). At point A, solution α_1 is unstable, while α_2 is stable. With the presence of small Brownian motion, the system jumps from the zero solution to the stable region of α_2 (blue line from A to B) as soon as its trajectory passes through the bifurcation frequency f_{11}. The jump amplitude a_{tran} is defined as the amplitude difference between B and A. At the "pitchfork" bifurcation A, $\omega_{1,11} = -0.5$. Corresponding to the frequency down-sweep, the bifurcation frequency and the jump amplitude are

$$f_{11} = 2f_r\left(1+\varepsilon\omega_{1,11}\right) \cong 2f_{r0}\sqrt{1+\frac{\gamma_1 V_{\text{dc}}^2}{k_1}}\left(1-\frac{\gamma_1 V_{\text{ac}}^2}{4k_1}\right) \tag{23}$$

$$a_{\text{tran}} = a_2|_{f=f_{11}} = 2\sqrt{\frac{\gamma_1 V_{\text{ac}}^2}{-\left(3k_3+3\gamma_3 V_{\text{dc}}^2+2\gamma_3 V_{\text{ac}}^2\right)}} \tag{24}$$

where $f_{r0} = (1/2\pi)\sqrt{k_1/m}$ is the natural frequency and the rest of the terms are independent of mass m. In a practical nonlinear system, the magnitude of the perturbation parameter ε is very small. Thus the exact bifurcation frequency Eq. 23 is very close to twice the natural frequency, providing guidance to experimental search of the bifurcation set points. In Eq. 23, V_{dc} provides an electrostatic tuning effect that shifts the location of the bifurcation. Both the location of the bifurcation and the width of the nonzero solution region can be modified by V_{ac}. In the case of extremely small V_{ac}, solutions α_1 and α_2 pinch and converge, making it difficult to search for the bifurcation because of the very small jump step. After the sharp jump from A to B, the amplitude gradually decreases to zero by following the stable branch of the solution a_2 from B to the "pitchfork" bifurcation point C.

On the other hand, for a slowly increasing frequency sweep, parametric resonance builds up after C. The displacement follows the stable solution branch of α_2 and keeps increasing until meeting a "saddle-node bifurcation" point D, where the stable and unstable branches of solution α_2 meet. The amplitude instantaneously drops from point D to the zero solution (point E). Corresponding to the frequency up-sweep, the bifurcation frequency is

$$f_{22} = 2f_{r0}\sqrt{1+\frac{\gamma_1 V_{\text{dc}}^2}{k_1}}\left[1-\frac{\gamma_1 V_{\text{ac}}^2}{4k_1}-\frac{3\left(k_3+\gamma_3 V_{\text{dc}}^2\right)\gamma_1}{4k_1\gamma_3}\right]. \tag{25}$$

Other than the natural frequency, f_{r0}, all other terms in Eq. 25 are independent of mass. The bifurcation frequency and the resonance amplitude depend heavily on the combined linearity and nonlinearity inherent in the nonlinear MEMS and are both tunable with applied parametric excitation voltages. Measuring shifts in the bifurcation frequencies Eq. 23 and Eq. 25 detects very small changes in resonant mass. Instantaneous "jump" transition from near-zero to high displacement (or the other way around) at the bifurcation frequencies improves the sensitivity of the associated parametric mass detector.

On-Chip Flow Cytometry

Flow cytometry is an analysis technique used to discriminate cells and other microscopic particles suspended in a liquid. Cells pass in rapid succession through a detection region where their properties are measured individually. Embedding such a system on the surface of a chip using microfluidics allows one to handle smaller sample volumes and less reagents (typically picoliter to nanoliter). The sensing is generally performed by optical or electrical detection means, preferably with micro-optic elements or microelectrodes placed around or within the fluidic channels.

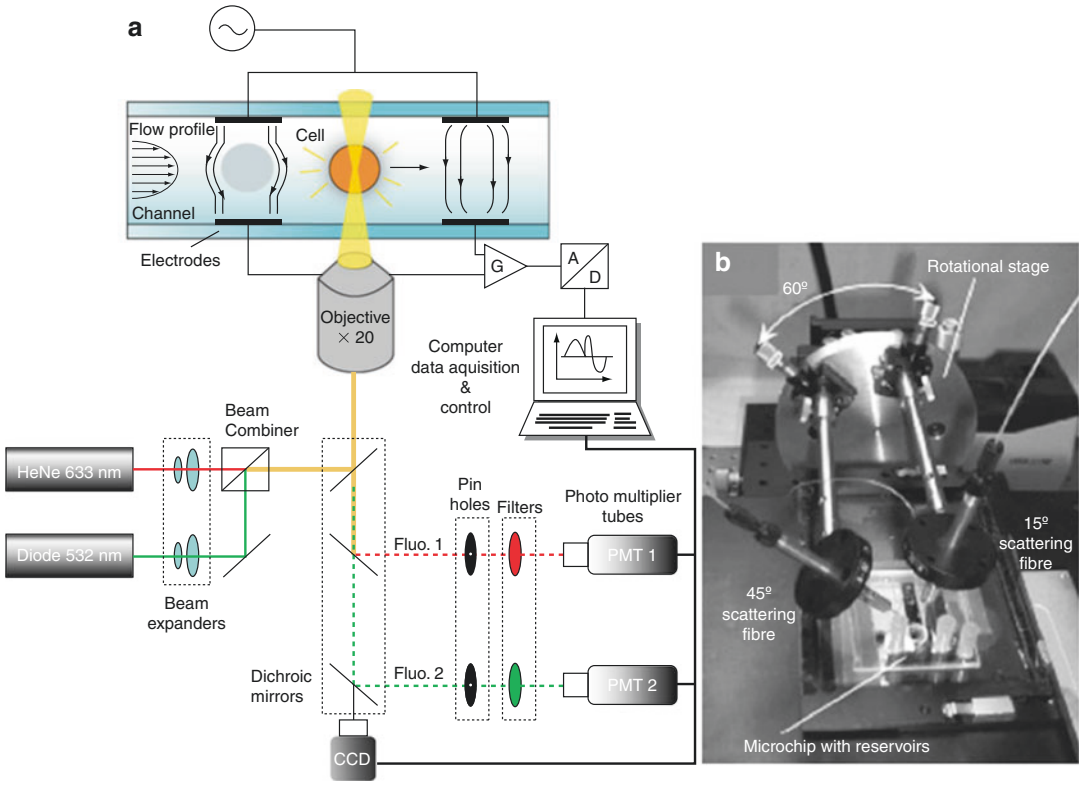
On-chip flow cytometers may also be co-integrated with a cell-sorting module to obtain purified sample subpopulations, or simply be used to enumerate cell types.

Overview

Coulter counters and fluorescence-activated cell sorters provide rapid high-quality cell analysis and sorting, but are traditionally relatively expensive laboratory-scale machines, requiring corresponding operator expertise and real estate. In view of the emergence of an ever greater number of point-of-care (POC) applications and integration of complicated protocols into easy-to-handle devices, a considerable effort has been made to reduce the footprint of cell analyzers and sorters to chip size. This has given rise to the field of micro-flow cytometry.

Introduction

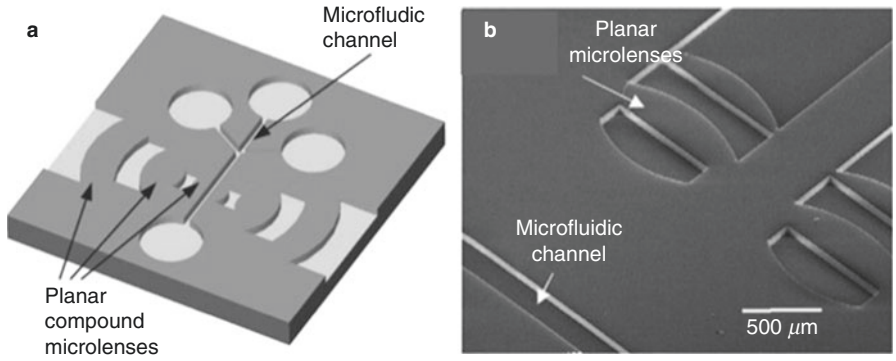


A number of on-chip impedance and dielectrophoretic force spectroscopy as well as optical techniques are presented here. Some of these techniques are currently being developed for use in point-of-care (POC) diagnostic applications and cell counting and separation devices for use in hematology, oncology, and toxicology. Cellular properties such as cell antigen expression, cell size, cell-cycle progression, and apoptosis can all be measured. To detect these properties, flow cytometry can either make use of specific labels (e.g., fluorescently conjugated antibodies) or assess intrinsic cell properties such as light scatter or impedance. This latter case has become an area of intense research in recent years with a number of label-free techniques being realized through the use of novel microfluidic technologies. Label-based analysis is currently the gold standard due to the high specificity and sensitivity achieved through the use of fluorescent probes coupled with molecular recognition elements (monoclonal antibodies, DNA intercalators). For POC applications, the major drawbacks of the cell labeling procedures are the requirement for multiple off-chip preprocessing steps and the extra cost of the label.

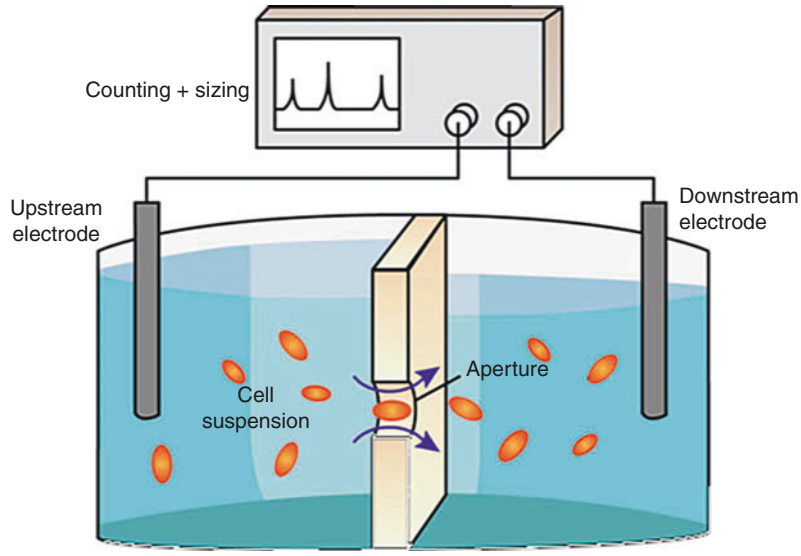
Electrical techniques, such as dielectrophoresis or impedance analysis, are generally used in settings where cell labeling is either not needed, or incompatible with the application. Major examples include cell sizing and discrimination, viability or osmotic response measurement in toxicity, and drug response screening as well as detection of intracellular infectious agents such as malaria.

Electrical and optical measurements can be combined onto a single platform thus extending the multiparameter analysis capabilities of such devices and allow powerful new analysis paradigms. Such combined measurements have been used for many years in hematology analyzers but have only recently been demonstrated in microfluidic cytometers, where they are expected to lead to the development of highly refined analysis and sorting instruments. Validation that the impedance and dielectric properties of cells correlate with cell type has been demonstrated through the use of such simultaneous electro-optical measurements.

Optical Detection



Commercial flow cytometers utilize bulky free-space optical components and allow interrogation, detection, and identification of cells and other particles (e.g., polymer beads, viruses) based on both fluorescence and light-scattering criteria. Such "traditional" optical detection techniques have been widely used with microfluidic devices [1, 2]. However, optical alignment is a problem, with such systems requiring mechanically stable mounting of the microfluidic device and the optical components. Optical benches are typically used to allow and maintain accurate alignment of the light paths. Figure 1a shows schematically the optical elements (e.g., lasers, filters, mirrors, lenses, and photo detectors) in a three-color fluoresence confocal detection setup, as used for the simultaneous optical and impedance detection of cells flowing in a microfluidic impedance cytometer. Figure 1b shows a photograph of a multi-angle light scatter detection setup, using optical fibers mounted at a number of fixed angles,



On-Chip Flow Cytometry, Fig. 1 Examples of external optical detection setups used with microfluidic flow cytometers. (**a**) Schematic of a combined impedance and optical detection system as used for blood analysis. (**b**) The use of optical fibers for multi-angle light scatter measurements from a microfluidic chip [2]

allowing analysis of the scatter properties of individual particles flowing in liquid suspension along a glass capillary [2].

The introduction of integrated optical elements into microfluidic chips is essential for the realization of robust, portable, and cheap handheld diagnostic devices. Integrated optics allows a reduction in the size, complexity, and cost of microfluidic devices. Optical alignment issues are avoided as these are now carried out at the design stage. The optical components are produced using the same microfabrication and lithographic techniques used to form the microfluidic channels. Waveguides can be used to precisely deliver excitation light and collect both scattering and fluorescence. One common method of incorporating integrated waveguides into microfabricated flow cytometers is to insert optical fibers into prefabricated aligned groves [3]. One end of the fiber is connected to the light source or detector, and the other end can be inserted directly into the device. Such setups are efficient at guiding light with little attenuation; however, they typically use commercially available optical fibers that impose geometrical limitations on the device and also limit their focusing and light collection capabilities. Photolithography has been used to make well-defined waveguides and lenses out of optically transparent photoresists such as SU-8 [1]. Buried waveguides have been fabricated directly onto silicon wafers in a variety of materials, such as silicon dioxide [2] and doped glassess [3]. These integrated waveguides typically have an attenuation at least five orders of magnitude greater than that of optical fibers necessitating their use in short segments. Figure 2 shows an example of a planar integrated optical system formed in SU-8. The optical elements and microfluidic channel were produced using photolithography.

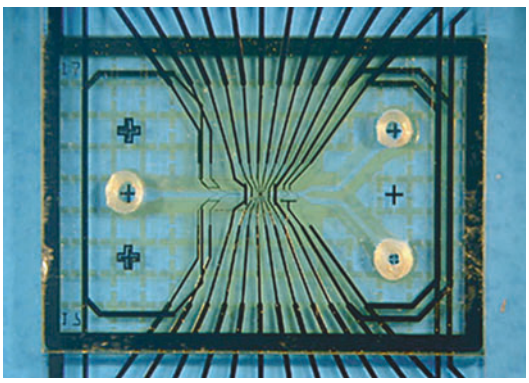
On-Chip Flow Cytometry, Fig. 3 Coulter counter principle. Cells are drawn through a small aperture, modifying the current as they pass, allowing them to be accurately counted and sized

Electrical Detection

The Coulter method of sizing and counting particles is based on measurable changes in electrical resistance produced by the cells or particles passing through a small aperture (see Fig. 3). The current, induced through two large electrodes placed upstream and downstream, is concentrated within the aperture representing the sensing area. The measured voltage pulse height is proportional to the volume of the particle. Several thousand particles per second can be individually counted and sized. In addition, a metering device is used to draw a known volume of the particle suspension through the aperture; a count of the number of pulses can then yield the concentration of particles in the sample.

On-Chip Examples

The first microCoulter devices were presented by Larsen et al. [5] and Koch et al. [6, 7]. These systems were microfabricated in silicon and use microfluidic sheath flows and filter structures. The first reports of on-chip cell measurements were published later by Fuller et al. on granulocytes [8], Larsen et al. on somatic cells using a simple silicon aperture [9], and Gawad et al. on erythrocytes using a coplanar electrode geometry [10]. Historically, the microCoulter technique

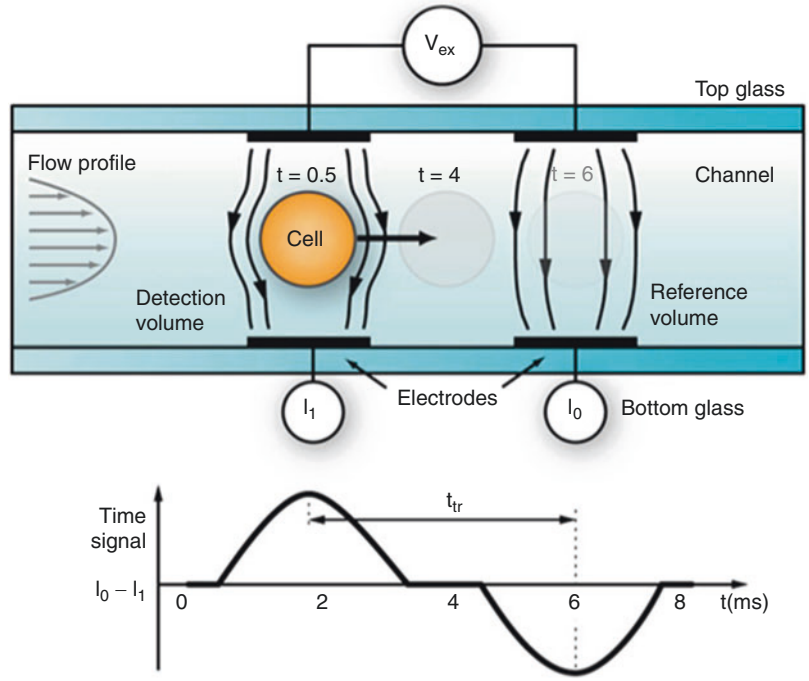


carries out cell sizing at a single measurement frequency, generally at low frequency or DC. Measurements at multiple frequencies in the kHz and MHz range enhance detection of additional attributes of the cell, such as membrane capacitance and intracellular conductivity.

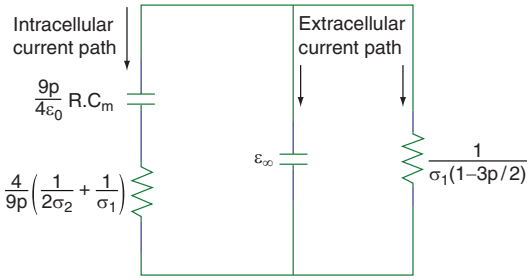
Chip Fabrication

On-chip integration of microfluidics and microelectrode patterns can be produced using relatively simple lithography techniques on a glass wafer. For example, the chip shown in Fig. 4 is fabricated as follows: a lift-off process is used to define metal electrodes, the microfluidic network is then produced on top of the electrodes in polymer [11]. Individual chips are released from the wafer by dicing and reversibly sealed by a molded PDMS block containing fluidic ports or embedded liquid reservoirs. More complex techniques to achieve electrodes patterned on top and bottom of a microchannel have also been presented in order to produce localized electric field (Fig. 4) [12, 13]. The full device is mounted into a custom-made fluidic and electrical interface. The thickness of the polymer layer defines the height the channels and can be adjusted to according to the necessities of each application; for cell work channel dimensions are typically 20–40 μm.

Cell Impedance Spectroscopy



For cell impedance spectroscopy, the excitation frequency range is typically from DC to about 50 MHz. At DC or low frequency the induced ionic current flows around the cell giving a measure of cell size; at higher frequencies (1–10 MHz) the membrane polarizes in response to the applied field giving a measure of the cell membrane properties, at yet higher frequencies (>30 MHz) the current crosses the membrane such that the intracellular properties of the cell are reflected in the current measurement.



On-Chip Flow Cytometry, Fig. 4 Microfabricated fluidic chip with embedded platinum microelectrodes for dielectric spectroscopy and cell sorting

Collecting significant information using this technique in a microfludic channel has been performed by using micrometer-sized electrodes, slightly larger than the cell itself, patterned on the channel walls. One set of electrodes is used to apply an electric field in a section of the channel while a separate set of electrodes, generally placed on the opposite side of the channel measure the current continuously. As the cell passes between the electrodes a current pulse is measured (Fig. 5). A differential measurement is typically used with one pair of electrodes measuring the current change due to the passing cell and the second pair of electrodes measure the suspending media. Subtracting these two measurements considerably eases further current amplification and allows for rejection of common mode interference. Furthermore, shielding, grounding, and band pass filtering using lock-in techniques are necessary to yield high sensitivity. For impedance spectroscopy, two or more excitation frequencies may be applied simultaneously in order to sense each cell at the different frequencies.

An electrical model of the cell impedance is very useful for understanding the impedance response function. A simple equivalent electric circuit was proposed by Schwan [14] for a single shell model representing the cell membrane capacitance and cytoplasm using a parallel and series arrangement of capacitors and resistors (Fig. 6). This circuit gives a simple representation of the behavior of this type of particle: For excitation frequencies lower than the membrane characteristic frequency, the current lines are surrounding an essentially insulating particle; at higher frequencies, the current gradually enters the cytoplasm as the membrane capacitance is considered as shorted. The left path in the figure represents the current path through the cell

On-Chip Flow Cytometry, Fig. 5 Impedance detection principle and the resulting differential current signal from a passing cell. The detection and reference volumes are inherently switched as the cell passes through each. The cell speed in the measurement channel is computed by measuring the transit time t_{tr} separating the two peaks. The bottom electrode is kept at a virtual ground potential

On-Chip Flow Cytometry, Fig. 6 Equivalent circuit for the Maxwell–Wagner dispersion due to RC charging of the cell membrane. The parameters σ_2 conductivity of the cytoplasm (Sm^{-1}), σ_1 conductivity of the extracellular fluid, Cm specific membrane capacitance (Fm^{-2}), *R* cell radius (m), p = volume fraction of cells in suspension [10]

interior. A more detailed explanation on the circuit models has been published by the authors [15].

This model was originally developed for analysis of bulk cell suspensions but is also valid in the case of a single cell measurement, with the added advantage that the measured particle volume is directly expressed by the single particle volume to detection volume fraction rather than simply representing an average volume of an unknown number of particles.

Cell position within the electric field does also have an important influence on the measured pulse shape and magnitude. By comparing impedance values at different frequencies, an opacity value independent of cell position can be obtained, giving access to some cell properties. Accurate cell sizing requires alignment of the cells on a given flow line, which can be achieved through the use of sheath flows. Microfluidics also allow the use of novel particle focusing modalities such as inertial forces (arising from Dean flows), and dielectrophoretic, ultrasonic, optical, and magnetic forces, which have all been demonstrated.

Cell Dielectrophoresis

For on-chip flow cytometry, cell manipulation in liquids is of primary importance. Cell alignment and cell sorting are preeminent examples. A versatile and established on-chip cell manipulation method is dielectrophoresis.

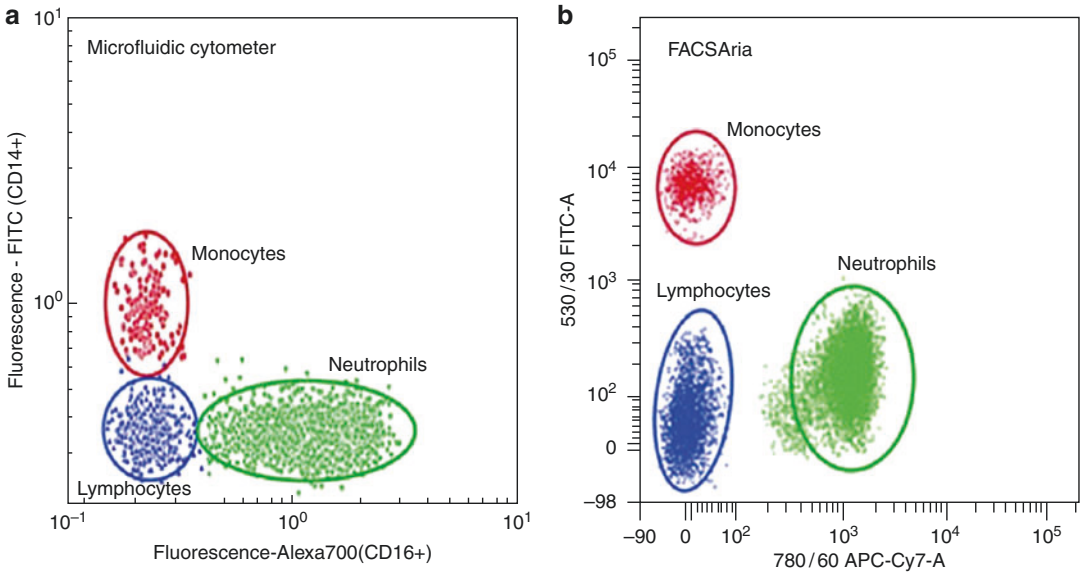
A dielectric particle such as a cell gets polarized when subjected to an electric field due to an induced dipole moment. When the induced dipole moment of a cell interacts with a nonuniform

electric field, a net movement of the cell is produced. If at a specific frequency, the cell is more polarizable than the surrounding medium, the cell will be attracted toward regions of high field strength (positive dielectrophoresis, pDEP). Conversely, the cell will be repelled from the high electric field region if it is less polarizable than the medium (negative dielectrophoresis, nDEP).

The mathematical expression for the dielectric force for a spherical particle is given by:

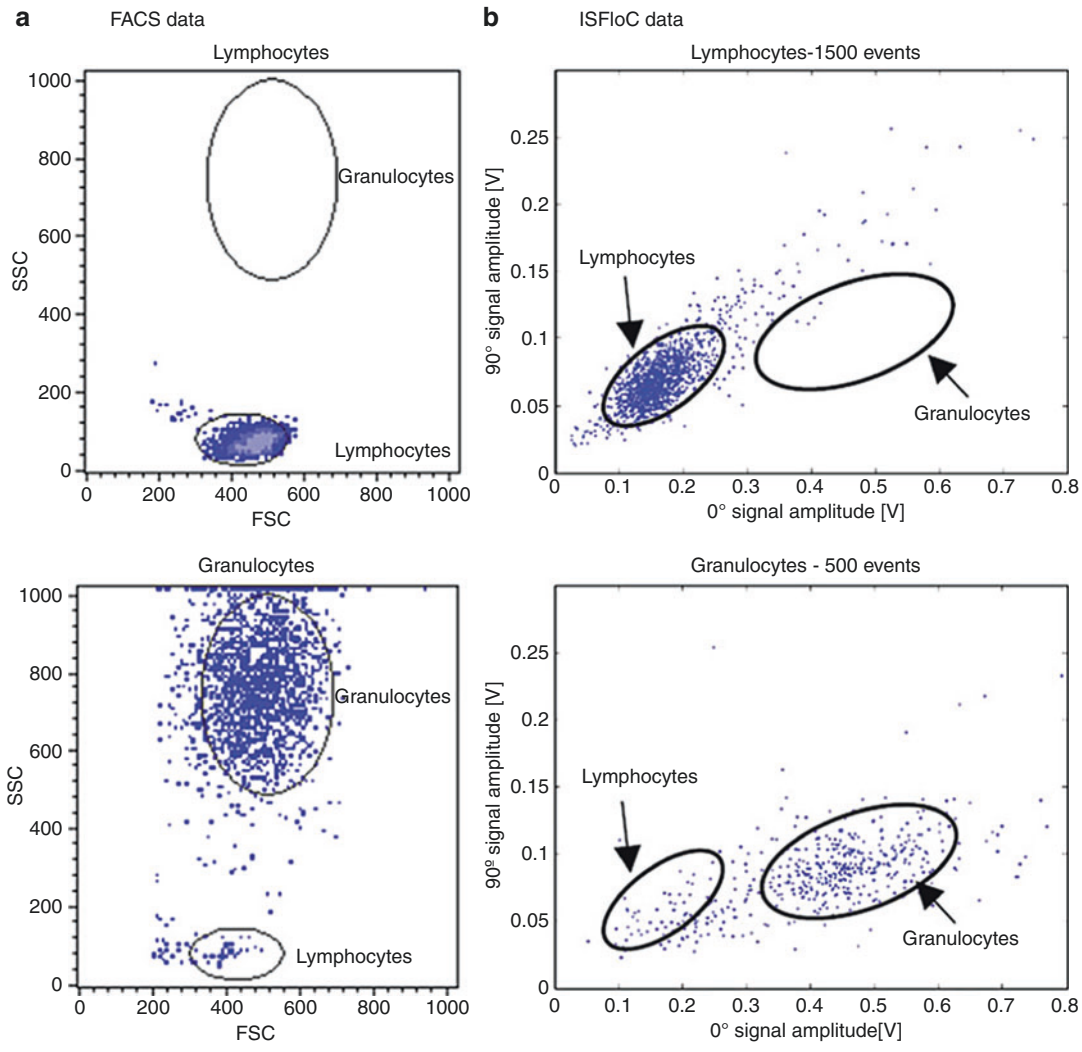
$$F_{\mathrm{DEP}} = \langle (P \cdot \nabla) E \rangle = \frac{3\pi}{2} \varepsilon_m V \cdot \mathrm{Re}(f_{\mathrm{CM}}) \nabla |E_{\mathrm{rms}}|^2 \quad (1)$$

where P is the dipole moment, V is the volume of the cell with a radius r, ε_m is the permittivity of the medium, f_{CM} is the Clausius–Mossotti factor. The Clausius–Mossotti factor quantifies the dipole moment induced in a suspended particle relative to the dipole moment that would be induced in an equivalent volume of suspension medium:



$$f_{\mathrm{CM}}(\omega) = \frac{\tilde{\varepsilon}_p - \tilde{\varepsilon}_m}{\tilde{\varepsilon}_p + 2 \cdot \tilde{\varepsilon}_m} \quad (2)$$

where $\tilde{\varepsilon}_p$ and $\tilde{\varepsilon}_m$ are the complex permittivity of the particles or cells and the medium respectively. Positive DEP will occur for positive values of $\mathrm{Re}(f_{\mathrm{CM}})$, nDEP for negative values, whereas a zero value of (f_{CM}) characterizes the crossover frequency.

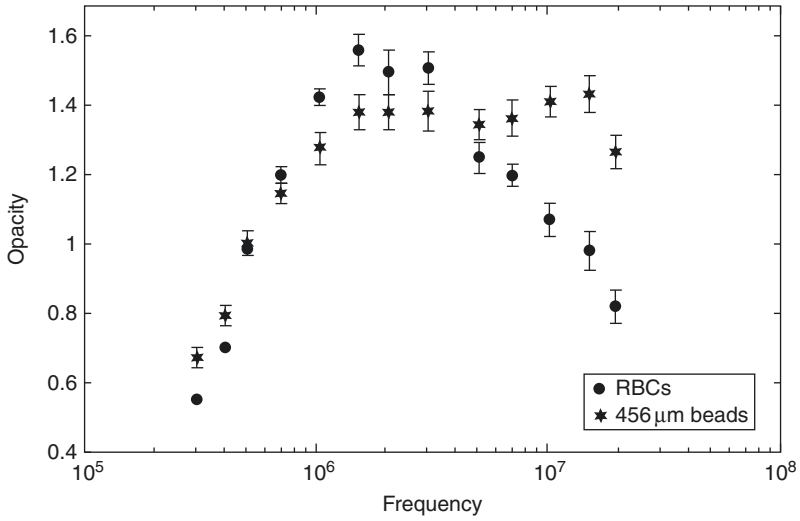


Applications

On-Chip Optical Cell Analysis

Optical detection has been used widely for detection and analysis in lab-on-a-chip devices. A number of highly sensitive flow cytometer devices have been demonstrated in the literature. Figure 7 shows typical data from one such device and compares the data obtained from the microfluidic device with that from a commercial flow cytometer (BD FACSAria). Whole blood was fluorescently labeled (anti-CD14-FITC and anti-CD16-Alexa700) and treated with saponin/formic acid to lyse erythrocytes, this sample was then analyzed using both the microfluidic chip device and a commercial flow cytometer. All the events were triggered on the forward scatter signal, cell populations identified and colored

On-Chip Flow Cytometry, Fig. 7 Scatter plots showing data obtained from blood samples measured using (**a**) microfluidic chip flow cytometer and (**b**) commercial flow cytometer FACSAria



On-Chip Flow Cytometry, Fig. 8 Scatter plots of FACS sorted lymphocytes (*top row*) and granulocytes (*bottom row*). (**a**) Forward (*FSC*) vs. side scatter (*SSC*) data as measured by a FACS instrument. The population of granulocytes is relatively smaller and contaminated with lymphocytes. (FACS measurement courtesy of P. Batard) (**b**) The same populations measured by on-chip impedance cytometry at 1.7 MHz showing the in-phase and out-of-phase signal

according to their fluorescence signal. The data show that both systems can clearly resolve the three major cell populations found in human blood (i.e., neutrophils, monocytes, and lymphocytes).

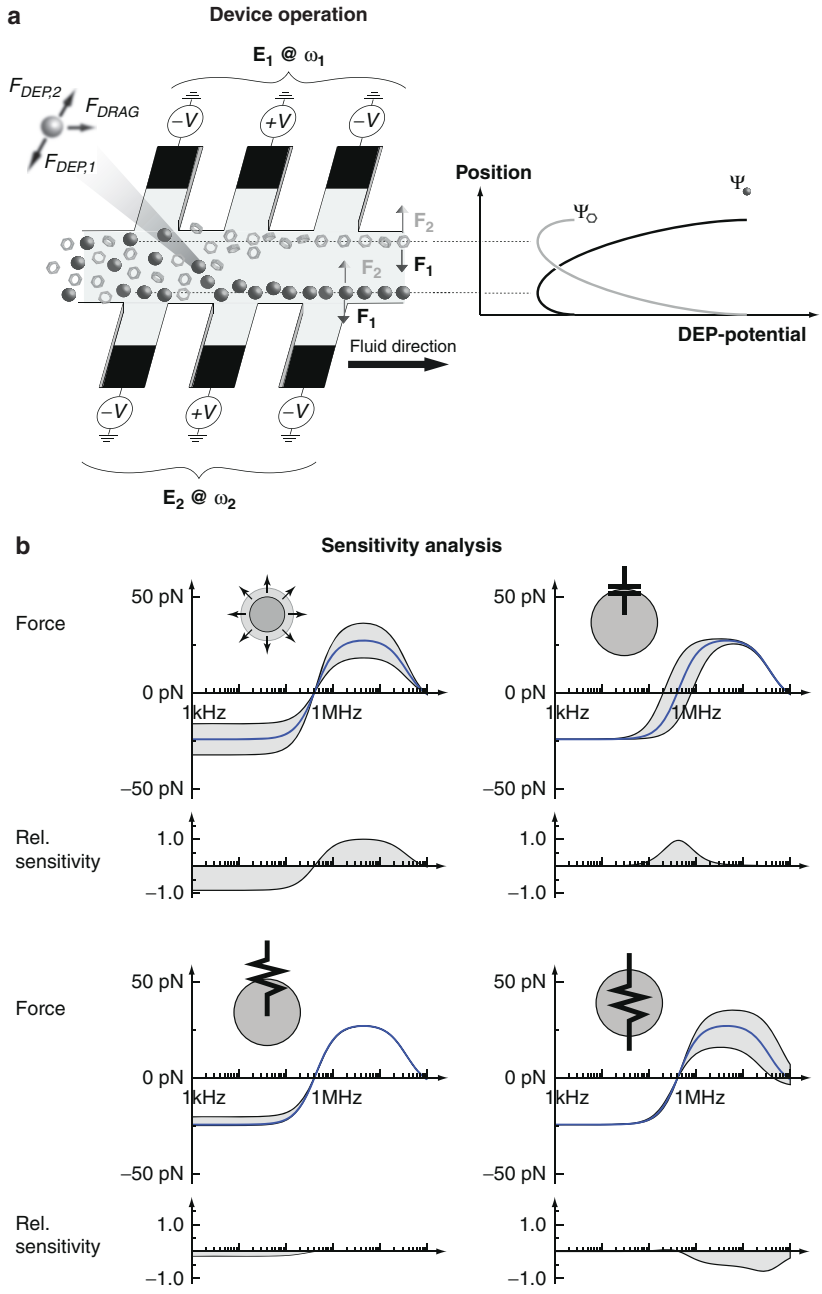
On-Chip Cell Impedance Spectroscopy

One of the most common applications of cytometry is in hematology analysis for the counting of white blood cells is of particular interest. Blood counts are routinely used to inform in clinical diagnostics and are performed by a range of diagnostic instruments. The example, shown in Fig. 8, makes use of the impedance cytometry chip shown in Fig. 4; human white blood cells are presorted with a FACS instrument (BD, FACSVantage SE) based on fluorescence and scattering. The sorted lymphocyte and granulocyte populations were measured a second time both in the FACS and in the microfabricated

On-Chip Flow Cytometry, Fig. 9 Opacity measurement of RBCs and polystyrene beads in the 300 kHz–20 MHz range. The RBCs show a ®-dispersion near 3 MHz, while the beads have a flat spectrum

cytometer. The granulocyte sample still contains a small amount of the more numerous lymphocytes. Differences in the measured electrical properties between those two cell populations are quite significant and allow clear discrimination using amplitude and phase information retrieved at a single frequency (see Fig. 8).

The above measurement is relatively easy due to the fact that the two cell populations are quite different in size. In order to differentiate between different types of particles of the similar size it is necessary to use several frequencies simultaneously. An example of this is shown below where red blood cells 4–6 µm in diameter are measured along with polystyrene beads of similar dimensions.

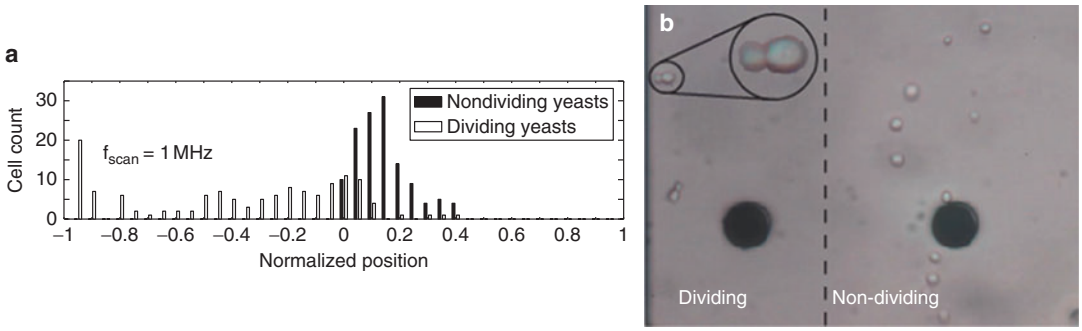


The measured opacity (ratio of high-frequency signal to a fixed low-frequency signal) of a specific cell population is determined using a population averaged frequency sweep technique where two discrete frequencies are employed simultaneously. The low reference frequency is kept constant (500 kHz) while the second frequency is used for the sweep. The ratio of the acquired data pulse height is taken for those two frequencies. This method efficiently suppresses size and position dependence of the measured data. The data shown in Fig. 9 shows a clear difference in the mid- to high-frequency range between the polystyrene beads and the red blood cells (RBCs).

Dielectrophoretic Sorting Device

A sorting device co-integrated on the same chip as one of the above examples could use the acquired real-time data that could be used to sort selected cells to a separated outlet port on the chip. Simple dielectrophoretic sorting devices can be used to modify the trajectory of a cell or particle in flow.

The following application example shows how dielectrophoretic forces may also be used to sort and characterize cells based on cell-cycle stage. The continuous cell-sorting microdevice is based on the opposition of a combination of several dielectrophoretic forces at multiple frequencies that discriminates between cell types according to their dielectric properties, such as the membrane permittivity and the cytoplasm conductivity.



Electric fields are generated by an array of electrodes located in both sidewalls of a main flow channel (Fig. 10a). Cells with different dielectric response experience different force magnitudes and are therefore continuously focused to different equilibrium positions in the flow channel, thus allowing label-free sorting. For cell-sorting purposes, two low-frequency signals (in the range 50–150 kHz), one from each side of the flow channel, focus the cells toward the channel midline, where the force potential minimum is located. For the actual separation, a high-frequency signal (typically in the MHz range) is

On-Chip Flow Cytometry, Fig. 10 (**a**) Principle of the cell-sorting device using multifrequency dielectrophoresis; the illustration shows a case where signals at two frequencies applied from the two liquid electrode arrays are sufficient to differentiate the cells. In many practical cases, including sorting of infected and noninfected red blood cells, three different frequencies are used so that on one side a linear combination of signals at different frequencies is acting on the particles. This configuration of signals takes advantage of the sensitivity of the high-frequency signals while ensuring a total nDEP force which stops cells from being drawn into the electrodes. (**b**) Influence on the different model parameters (1. volume fraction, 2. membrane conductivity, 3. membrane capacitance, 4. cytosol resistivity) on the dielectrophoretic force

superimposed from one of these electrode arrays. The strategy uses the same inherent electrical properties as those that give rise to the impedance differences measured in cells as described above: At low frequency, all cells experience a similar, repulsive force, so that they can be focused toward the channel midline. The high-frequency signal probes cell membrane capacitance and cell interior, and therefore shifts the equilibrium position for cells of different dielectric responses.

Like impedance spectroscopy, the dielectrophoretic force is sensitive to different cellular changes in different frequency windows (Fig. 10b). Since both techniques are

On-Chip Flow Cytometry, Fig. 11 Separation of yeast cells in division. The 1 MHz signal exerts relatively stronger pDEP on cells in division compared to normal yeast cells due to the lower crossover frequency. A subpopulation of cells in division is more attracted to the *left side* than the average, probably related to the stage in the cell division cycle

fundamentally dependent on the Clausius–Mossotti factor, they are generally sensitive to identical changes in similar frequency windows.

Sorting of biological samples using dielectrophoresis is generally based on changes in cell physiology due to the conductivity gradient between intracellular and extracellular space. However, cell morphology also has an influence on the dielectrophoretic properties. A good example where cell physiology and cell morphology are tightly coupled is cell division in budding yeast. When a suspension of yeast cells undergoing active division is injected into a miniaturized dielectrophoretic sorter; low-frequency focusing signals (100 kHz) in combination with a high-frequency discriminating signal at 1 MHz force dividing yeast cells to equilibrium positions on flow lines substantially shifted toward the high-frequency side of the flow channel (Fig. 11). This sorting effect is consistent with known dielectric properties of yeast cells in division [16]: The globally elongated shape due to bud growth increases cell polarizability and thus enhances pDEP as the cells progress through mitoses. However, when the neck closes after anaphase, the effect disappears by a progressive shift of the associated dispersion to lower and lower frequency, causing the pair to behave electrically like two individual single yeast cells. Therefore, the dielectrophoretic cell sorter using multiple-frequency dielectrophoresis is able to characterize and synchronize a yeast cell culture based on the different polarization mechanisms of cells that are associated to their cell-cycle phases [17].

Future Directions

Point-of-care devices based on on-chip flow cytometry are currently emerging. Miniaturization and integration is paramount to lowering the costs and skill levels required to carry out a given analysis. Small chip-based cell analysis devices are expected to be increasingly used to monitor different disease states and physiological functions. Potential applications with large markets include detection of circulating tumor cells (responsible for metastasis), blood analysis for quantification of physiological and immunological function. Such medical devices need to provide an extremely simple user interface and will contain all the necessary chemicals such as labels and buffers in an integrated form. Microfluidics is the key enabling technology, which will allow such devices to be developed.

Aside from the medical diagnostic applications, the small size of the on-chip format will enable continuous monitoring of cells in bioreactors or Petri dishes allowing cell population analysis in addition to the physical and chemical parameters usually measured (e.g., pH, dissolved oxygen, temperature, or glucose concentration). These technologies will lead to advances in the control and monitoring for industrial and laboratory-scale applications.

At a more fundamental level, optical measurements and electrical characterization and actuation are the main physical principles employed in on-chip flow cytometry. However, a series of other physical and chemical phenomena may be used for characterization and sorting, and potentially be integrated along with existing on-chip flow cytometric methods: acoustic deflection and acoustic impedance measurement, deterministic size-dependent displacement by micro- and nanostructured obstacles, cell-surface affinity, gravitational sedimentation rates, magnetic properties or probes, diffusion, etc.

Optoelectronic properties

Definition

The *electronic properties* are a set of parameters and representations that fully describe the state and behavior of electrons in the material. For example, the electronic band structure [1], which describes the state of the electrons in terms of their energy, E, and momentum, $\boldsymbol{k}$, is such a representation. The electronic properties are, in turn, strongly coupled with the electric properties such as electrical conductivity and dielectric response, and with the *optical properties* such as refractive index, damping constant, absorbance, etc. – which describe the response of the material to the electromagnetic radiation.

Nanostructures are portions of a material where at least one spatial dimension is at the nanoscale – as defined below. Nanoparticles, nanowires, and thin films are nanostructures. In nanoparticles, all three spatial directions are at the nanoscale, and therefore electrons are confined to a zero-dimensional space. Analogously, nanowires have two nanoscale dimensions, leading to a confinement of the electrons to a one-dimensional space. Thin films have one nanoscale dimension and electrons are confined to a two-dimensional space. *Nanostructured materials*, i.e., bulk solids presenting a morphology at the nanoscale, shall also be considered here. Electronic, electric, and optical properties in nanostructures and nanostructured can be markedly different than in bulk materials, mainly due to the effect of quantum confinement of electrons in one or more spatial dimensions.

It is important to note that there is not a uniquely defined size threshold below which a material can be considered nanometric: Nanoscale effects emerge at sometimes markedly different scales for different properties. Therefore the "nanoscale" is well defined only once the property under investigation has been specified.

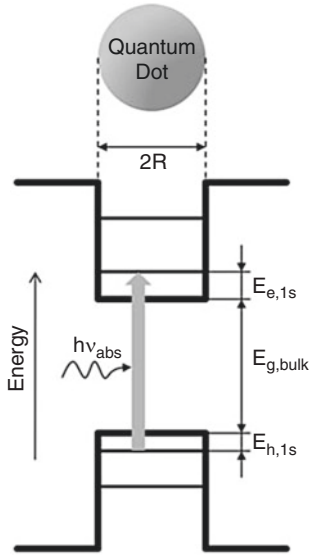
Optical and Electronic Properties, Fig. 1 Density of states for 0-D, 1-D, and 2-D nanostructures. All show a degree of discretization. The density of states 0-D is essentially a set of Dirac delta functions. The density of states of 1-D structures reflects the presence of a number of discrete sub-bands, each following the $E^{-1/2}$ behavior typical of the one-dimensional density of states. Analogously, the density of states of 2-D structures shows sub-bands with the constant behavior typical of the two-dimensional density of states. The *thinner line* shows the $E^{1/2}$ functional form typical of bulk materials

Electronic Structure in Nanostructures

Quantum confinement of the electrons, associated to a size reduction to the nanometric scale in one or more spatial directions, leads to a dramatic change in the electron density of states [2], as sketched in Fig. 1. Qualitative understanding can be obtained from the classic electron-in-a-box model: The main features are the formation of a

Optical and Electronic Properties, Fig. 2 Colloidal suspensions of CdSe nanocrystals showing a change of the absorption properties associated to a change of the nanocrystal size (Photo credit Michele Pianigiani)

set of electronic states at discrete energy values, and the fact that the spacing between such discrete states widens as the quantum confinement increases (i.e., the size of the box reduces). The details of such discretization depend on the number of spatial directions that have been confined. This behavior has a number of consequences on the properties of the nanostructures. For instance, concerning the optical properties, the size dependence on the separation of the electronic states leads to size-dependent absorption and emission properties. Concerning the electronic properties, widening of the separation between electronic states can lead to metal-to-semiconductor or to semiconductor-to-insulator transitions, such as in the classic cases of Bi and Si nanowires, respectively. Along with quantum confinement, another important general phenomenon is s*cattering of electrons at surfaces and interfaces*, which is most relevant for the electrical and thermal conductivity in nanowires and thin films. This shall be discussed in the relevant sections below.



Key Nanostructures and Relevant Optical and Electronic Properties

Most of the scientific and technological interest for the optical and electronic properties of nanostructures is associated to semiconductors and metals, which will be the focus of this entry. Molecules and molecular optoelectronics shall not be considered here. All optical and electronic properties could in principle be analyzed for each kind of nanostructure. However, only a selection of the most relevant ones, from the scientific or technological point of view, is presented here for each class of structures.

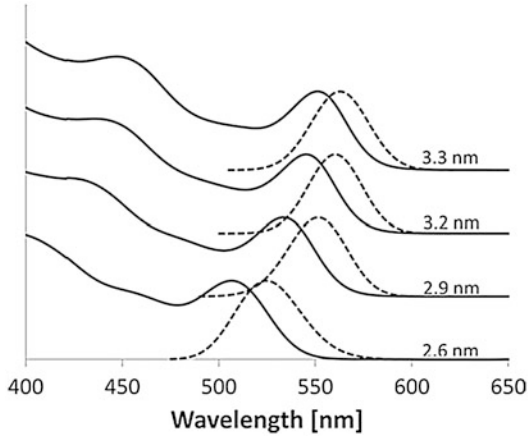
Zero-Dimensional Nanostructures: Nanoparticles

A number of techniques have been developed to form nanoparticles of all kinds of materials both in the amorphous and the crystalline phase, including self-assembly from deposition of highly mismatched epitaxial films, aerosol methods, and colloidal syntheses. One of the main reasons for the strong interest that this class of nanostructures has generated over the past two decades is associated to the peculiar optical properties shown in particular by crystalline nanoparticles (nanocrystals, NCs) of metals and semiconductors. In particular, great interest arises because of the fine tunability of such properties in the visible and near-infrared range of the spectrum (Fig. 2).

Semiconductor NCs, also known as *quantum dots (QDs)* or *artificial atoms* [3], owe their characteristic optical properties to the peculiar, atom-like electronic structure illustrated in Fig. 1. As mentioned above, a limited number of electrons are strongly confined within the QD, leading to the emergence of quantum effects. For semiconductors, a good rule of thumb is that the quantum effects typical of NCs start emerging when the

Optical and Electronic Properties, Fig. 3 Schematic of a spherical quantum dot with radius R and of the associated potential profile along any diameter of the sphere. The energy states for electrons and holes are discrete and can be described by the particle-in-a-box model, where the effective masses are used. The *gray arrow* represents the first available exciton state, which in first approximation corresponds to the onset of optical absorption

crystal is smaller than the Bohr radius, aB, of the bulk exciton:



$$a_B = \frac{\hbar^2 \varepsilon}{e^2}\left(\frac{1}{m_e^*} + \frac{1}{m_e^*}\right)$$

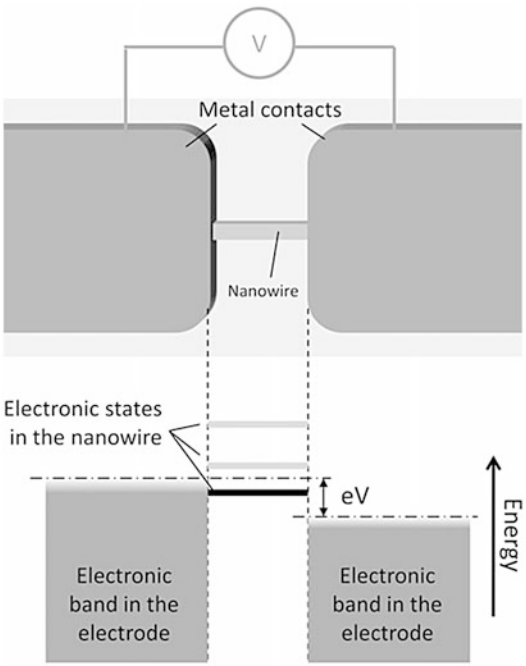
Here ħ is the reduced Plank's constant, e the charge of the electron, ε the dielectric constant of the nanoparticle, m^* the effective mass of the electrons and of the holes. In first approximation, the energy structure of a QD and its surrounding environment can be described as sketched in Fig. 3, so that electronic states in the QD are essentially discrete and are quite well described by a simple approach based on the classic analysis of the electron-in-a-box analysis. Therefore, the separation between the highest occupied state and the lowest unoccupied state (also known as the *apparent bandgap* of the quantum dot or the *first exciton state*) is simply given by the following equation [4]:

$$E_{g,\mathrm{dot}} = E_{g,\mathrm{bulk}} + \frac{h^2}{8R^2}\left(\frac{1}{m_e^*} + \frac{1}{m_e^*}\right) - 1.8\frac{e^2}{\varepsilon R}$$

Here h is Plank's constant and R the radius of the nanoparticle. The second and third terms are the energies $E_{e,1s}$ and $E_{h,1s}$ associated to the confinement of the electrons and holes, respectively, calculated as particles in a box. The fourth term accounts for the Coulomb interaction. The *absorption* spectrum of QDs (Fig. 4) is characterized by a sharp absorption edge corresponding to $E_{g,\mathrm{dot}}$ and by a series of less evident peaks reflecting the higher energy exciton states available in the dot. Perhaps the feature of more practical interest in this equation is that it establishes a correlation between the size and the absorption spectrum of NCs. This correlation is found to be quite accurate in some size ranges, so that in principle, it could be used to determine the size of NCs by simply measuring the absorption spectrum. In practice, due to additional effects that are not captured in this simple model, empirical correlations are normally established for different materials by comparing the position of the first absorption peak and the size of nanocrystals as measured from a large number of TEM images. More accurate models based on the effective mass approximation account for the detailed electronic structure [5] and can predict experimental data to excellent accuracy.

Emission of QDs is shown in the photoluminescence (PL) spectra in Fig. 4, characterized by the strong band corresponding to the lowest available energy transition. The photoluminescence is strongly affected by the quality of the NC's surface: Passivation of surface defects by capping the NC with organic ligands (typically aliphatic monocarboxylates, phosphines, thiols) or better with a shell of a larger bandgap semiconductor can lead to quantum yields exceeding 0.9 in the best scenarios. A reduction of the quantum yield of an ensemble of quantum dots is also due to the phenomenon of *blinking*: Emission of a single QDs is intermittent, with dark-bright periods oscillating over a wide range of timescales, up to minutes. The mechanisms underlying blinking are still matter of debate in the scientific community,

Optical and Electronic Properties, Fig. 4 Typical absorption (*solid line*) and photoluminescence (*dashed line*) spectra of quantum dots. This example shows four CdSe nanocrystals with a radius ranging from 2.6 to 3.3 nm (Data courtesy of Luca Cozzarini)



but seem to be associated to the formation of a single delocalized charge carrier within the NC, which can be excited via a non-radiative Auger process (dark phase). This is then followed by a radiative recombination of the carrier (bright phase).

Interestingly, the emission peak occurs at a markedly lower energy than the first absorption peak (Fig. 4). This phenomenon, known as *Stokes shift*, can be explained by observing that in nanocrystals, the valence band – which is normally degenerated in the bulk – splits into a number of states due to strong electron–hole exchange coupling and internal crystal field. The consequence is that the single transition predicted by the electron-in-a-box model is in fact a set of exciton states. Absorption can only occur at exciton states higher than the lowest (dark exciton) because of selection rules associated to the angular momentum, while emission from the lowest state can occur after the state becomes populated via thermalization from higher energy states. The Stokes shift enables a number of interesting applications, such as the possibility of efficiently tailoring the spectrum of a given source of illumination by absorption of unwanted spectrum ranges and re-emission within selected ranges – without incurring in the phenomenon of self-absorption.

Metal NCs are, too, characterized by a strong correlation between size and maximum of the absorption spectrum: Just as for the case of semiconductors, a size reduction leads to a blue shift of the absorption peak. However, in the case of metallic NCs, the absorption is dominated by an entirely different mechanism than in semiconductors, as it is associated to a surface plasmon resonance [4] (due to the interaction between the mobile electron cloud and the fixed atom nuclei in the nanocrystal). For metallic particles that are not too much smaller than the wavelength of the incident radiation, the dependence of the plasmonic resonance on the particle size is governed by Mie's theory [4], which relies on the solution of Maxwell's equations for small metallic spheres interacting with an electromagnetic wave. For particles smaller than about a tenth of the wavelength, the blue shift observed experimentally when decreasing the particle size can only be explained by taking into account quantum effects. In nanocrystalline metals, very high absorption coefficients ($\sim 10^9\,M^{-1}\,cm^{-1}$) are observed, mainly due to the enhancement of the absorption cross-section by the coupling between the plasmon and the polarization modes of the nanoparticle (plasmon-polariton resonance). Moreover, for metal NCs such as gold, silver, and copper, the surface plasmonic resonance occurs in the visible range, leading to interesting applications of such NCs for example as very effective dyes. It is worth mentioning that metal NCs have a wealth of applications as chemical and biological catalysts; however, as this is not the subject of this entry, these applications shall not be discussed here.

One-Dimensional Nanostructures: Nanowires

One of the most interesting phenomena occurring in one-dimensional nanostructures is associated with charge transport. A short nanowire (shorter than the typical mean free path of the material) connecting two bulk electrodes subject to an electrical bias does not behave as it would be expected by just applying the electrical properties of the corresponding material; rather, a quantized conduction behavior independent of the material is observed. A qualitative but powerful argument to

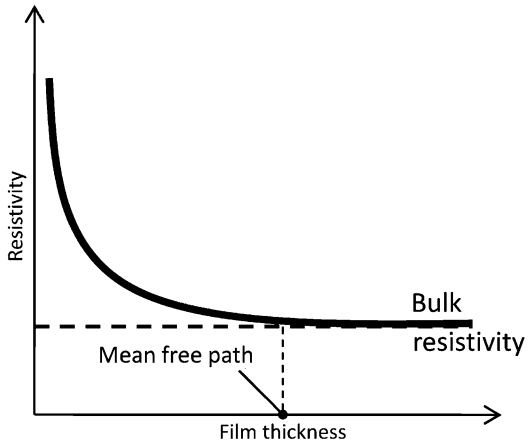
Optical and Electronic Properties, Fig. 5 (*Top*) Schematic of a possible arrangement for assessing the conductance of a short nanowire. (*Bottom*) Energy band diagram of the system. Due to the bias *V* applied to the electrodes, the Fermi levels are offset by *eV*. Only the electron states of the nanowire that fall within this range can contribute to electron transport from one electrode to the other. In the sketch, only one electronic state is available (shown in *black*), and the conductance is $G0 = 2e_2/h$. As the thickness of the nanowire increases, more modes might be included in the useful range *eV*, and the overall conductance will be enhanced by a quantum G_0 for each additional mode

demonstrate this is based on the idea that – as shown above for any nanostructure – the states of the nanowire are discrete, and only a limited number of such states will be comprised within the energy interval between the Fermi levels of the two biased electrodes and therefore available to carry charge carriers (Fig. 5). By carrying out this argument quantitatively, one obtains, for N available quantum states [4] within the nanochannel, a conductance of $G = N\,G_0$, where G_0 is the quantum conductance:

$$G_0 = \frac{2e^2}{h}$$

The inverse of G_0 is $R_L = h/2e_2 = 12.9\ k\Omega$ and is known as the Landauer resistance. Here e is the charge of the electron and h is Plank's constant. There are two remarkable observations: First, the Landauer resistance does not depend on the material and is in principle an universal constant (although a more detailed analysis would reveal a weak dependence on it [6]). Second, as the length of the channel is less than the mean free path of the electrons, no scattering is involved, so no energy is dissipated as a result of the transport mechanism illustrated here. In other words, the Landauer resistance is not to be intended as a classic dissipative resistance, rather as the ratio between the bias applied to the bulk electrodes and the current intended as probability of charge transport. The quantum conductance has been confirmed by quite striking experiments on carbon nanotubes and on short metal nanowires. In the latter, for example, the width of the nanochannel was thinned continuously while the current was measured. The conductance showed a perfectly discrete behavior, changing by multiples of G_0, thus reflecting the progressive reduction of the number of available states in the channel.

When the nanowires are longer than the mean free path of the charge carriers, transport is not controlled by quantum effects. However, for thin nanowires, conductivity can be governed by another important nanoscopic effect associated to surface scattering. As this mechanism has been studied first and most extensively for the case of thin films, the reader is referred to the following section for more detail.



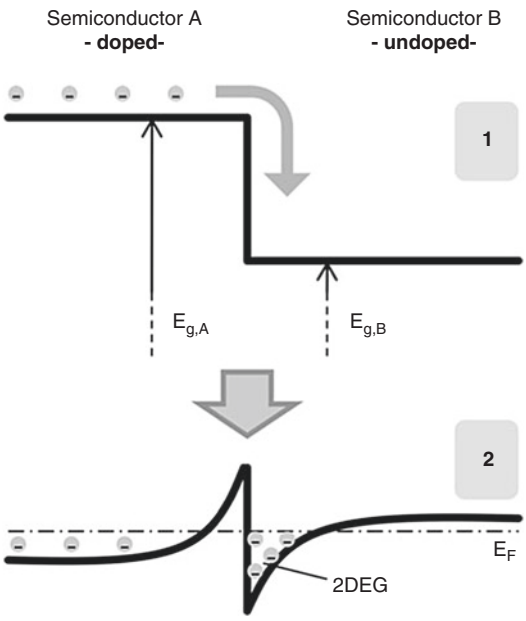
The optical behavior of nanowires is qualitatively analogous to the case of nanocrystals as discussed in the previous section: The main considerations on the size dependence of the discrete electronic states and therefore of the optical transitions still hold, and will not be discussed further.

Carbon nanotubes (CNTs) are another important class of one-dimensional nanostructures [7]. The optoelectronic properties of CNTs are governed by their chirality: One can imagine to obtain a CNT by folding a graphene sheet (a single graphite layer), and the direction of wrapping determines whether the structure has a semiconducting or metallic behavior. For

semiconductor CNTs, the bandgap is also determined by the chirality and the diameter of the tube. Due to the nearly perfect structure over great lengths, metallic CNTs can carry extremely high current densities (exceeding 10^9 A/cm^2). Large-scale applications, however, are currently limited by the lack of industrial techniques for producing CNTs of the desired kind in a controlled way.

Two-Dimensional Nanostructures: Thin Films

Electron transport in thin films and, as mentioned in the previous section, in nanowires can be affected by *surface scattering* [8]. This phenomenon arises when the film thickness is smaller than the carrier mean free path, and leads to a sharp resistivity increase with respect to the bulk value, as sketched in Fig. 6. This behavior can be modeled in principle by assuming that there is a certain degree of inelastic scattering of the charge carriers at the surface, i.e., the carrier velocity after a collision at the interface is partially or entirely uncorrelated with the velocity prior to the collision. This essentially classical model, first proposed by Thompson and later modified to include a degree of elastic scattering, predicts that the ratio between the bulk and the film resistivity (ρ_0 and ρ_f, respectively) is:



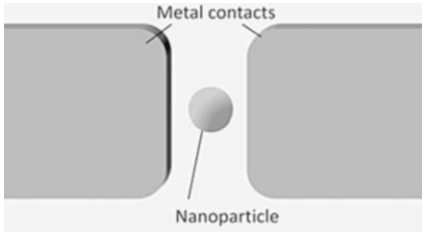
Optical and Electronic Properties, Fig. 6 Sketch of a film's resistivity as a function of the film thickness. Once the thickness of the film becomes comparable with the mean free path of the charge carriers, the resistivity departs from the constant bulk value and rapidly increases

$$\frac{\rho_0}{\rho_f} = \frac{3d}{4\lambda_0}(1+2P)\left(1\mathrm{n}\frac{\lambda_0}{d} + 0.423\right)$$

where P is the fraction of elastic scattering at the surface, d is the film thickness, and $\lambda 0$ is the mean free path. Fuchs and Sondheimer later included quantum effects. A number of difficulties, however, prevent these simple models to be of use in many practical situations, as P is a rather difficult parameter to quantify a priori, grain boundary scattering is not taken into account, and the film microstructure changes with the thickness.

Modern techniques such as Atomic Layer Deposition (ALD), Metal-Organic Chemical Vapor Deposition (MO-CVD), and mainly Molecular Beam Epitaxy (MBE) enable deposition of high-quality nanoscale films with atomic-scale precision. Heterostructures formed by layers of different materials can be deposited, making it possible to freely design novel electronic structures. Known as "bandgap engineering"; this approach has led, over the past 30 years, to remarkable scientific discoveries and technical achievements both in the field of electronics and optics. Only two of the fundamental building blocks that have enabled such tremendous progress in these fields are described here: the quantum well for optics, and the 2-D electron gas for electronics.

A *quantum well* can be fabricated by sandwiching a low-bandgap thin film between two layers of a high-bandgap "barrier" material [2]. The valence and conduction band profiles along the through-thickness direction of the heterostructure have essentially the same features shown in Fig. 3 for a quantum dot (of course, in accord to Fig. 1, the overall density of states is different for the two cases). Along this direction the electrons can be confined within the well, and once again the optical emission can be predicted by assuming that the electronic states are described by the electron-in-a-box model – as long as the confinement potential provided by the barrier is strong enough to resemble an infinite potential. Modern LEDs and semiconductor lasers are based on quantum well structures.



Optical and Electronic Properties, Fig. 7 Conduction band profile of a modulation doped heterostructure: A highly doped semiconductor *A* is placed in contact with an undoped semiconductor *B* whose conduction band lies at a lower energy than the conduction band of semiconductor *A*. (*Top*) An imaginary instant before electrons reach equilibrium. Some electrons statistically migrate from A to B. (*Bottom*) While electrons migrate from *A* to *B*, a potential builds up that would tend to push the electrons back to *A*. However, the conduction band offset determined by the choice of the two materials prevents the electrons to migrate back: The result is that excess electrons are trapped within a thin, two-dimensional layer near the interface (two-dimensional electron gas, 2DEG)

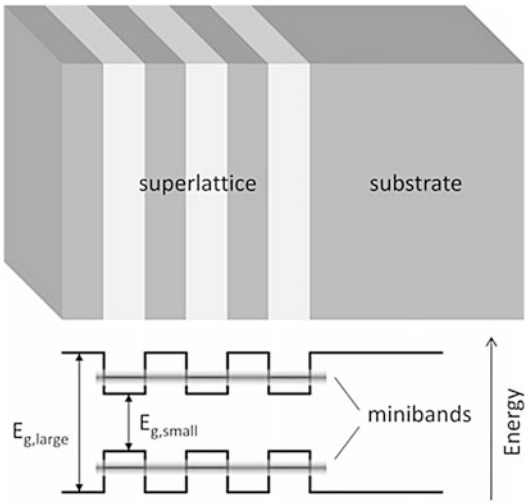
Another important thin film system is the *modulation doped heterostructure* [2]. The associated band profile is depicted in Fig. 7. Because of the initial band alignment, electrons from the highly doped region migrate to the undoped layer, and are confined in proximity of the interface due to the local electric field that naturally arises as the consequence of the electron migration. A *two-dimensional electron gas* (*2DEG*) is thus formed, i.e., a thin layer where a high number of electrons are confined. Most importantly, extremely high electron mobility is preserved thanks to the low doping level in this region. This peculiar 2D nanostructure is widely exploited in the fabrication of most modern high performance electronic devices. From a more fundamental perspective, it is interesting to report that in 2DEGs a *quantized Hall resistance* can be observed: $R_H = h/n\ e_2$, where $n = 1, 2, 3, \ldots$ Note that the quantum of Hall resistance is exactly twice the Landauer resistance observed in short nanowires.

Three-Dimensional Nanostructured Materials

Nanostructured materials are bulk materials characterized by having a relevant structure at the nanoscale, and are often obtained by combining nanostructures such as nanoparticles, nanowires, and thin films. *Large-scale assemblies of 1-D nanostructures*, such as self-assembled quantum dot arrays, colloidal close-packed solids, or assemblies of molecules, fall under this category. A number of mechanisms are relevant for understanding the optical and electronic properties of such assemblies, and will be described in the following.

Concerning the *optical properties* of assemblies of *weakly interacting* 1-D nanostructures [9] such as nanocrystals (NCs), dipolar interaction has an important role, as it can induce permanent polarization of the NCs and lead to ferroelectric and antiferroelectric phases in the assembly. Moreover, interaction between dipoles leads to enhanced absorption in the far IR range. Another relevant mechanism in arrays of weakly interacting NCs is Long Range Resonance Transfer (LRRT), where a transition dipole is transferred from an excited NC to one in its ground state. Due to the weak coupling, the transition rate is much slower than the absorption and relaxation processes. As a result, the absorption spectra of the close-packed NC solids in the optical region are essentially identical to those of the dispersed NCs. On the other hand, the photoluminescence (PL) spectrum is affected by LRRT: The energy transfer always occurs from smaller to larger NCs (the inverse process is not allowed as the smaller particle is transparent to the low-energy transitions that the larger NC can produce), so the emission of larger particles is enhanced. The result is that in weakly coupled NC solids, where there always is a certain spread of the size distribution, the PL is red-shifted with respect to the corresponding PL of dispersed NCs. As the coupling strength increases, e.g., due to a reduced

Optical and Electronic Properties, Fig. 8 Sketch of a system for observing and quantifying the Coulomb blockade mechanism



interparticle distance, both PL and absorption redshift as they converge to the optical behavior of the bulk.

Two peculiar mechanisms that are relevant for *charge transport* in large-scale assemblies of 1-D nanostructures are the Coulomb blockade and resonant tunneling [4]. These mechanisms, however, are best understood by first considering one single nanoparticle placed within a narrow gap between two electrodes, as in Fig. 8. The *Coulomb blockade* occurs when the electrical resistance between one electrode and the nanoparticle exceeds h/e^2 (two times the Landauer resistance): In this case, charge tends to accumulate on the particle when bias is applied to the electrodes, and no current flows in the structure until enough voltage has been applied to add one additional charge. By considering simple electrostatic arguments, it can be shown that the voltage required to add a single electron to a spherical particle with a radius of few nanometers is of the order of tens or hundreds of millivolts. Therefore, even at room temperature, the I-V characteristic of such a system shows a staircase-like behavior. Single Electron Transistors, SET, exploit this peculiar mechanism by using a third electrode to independently control the nanoparticle potential, thus enabling tuning or sensing the current at the finest, electron-level scale. If the coupling between the electrodes and the nanoparticle is stronger (i.e., the resistance between the electrodes and the nanoparticle is less than h/e^2), there is no charge accumulation on the particle and *resonant tunneling* occurs, where it can be shown [4] that transmission between the two electrodes is greatly enhanced with respect to normal vacuum tunneling.

Coulomb blockade and resonant tunneling are important elements in determining the electrical conduction regimes in arrays of NCs [9]. For example, in weak coupling conditions, the electric behavior of a metal NC array can been shown to be nonlinear and characterized by a conduction gap, i.e., a voltage threshold below which no current flows – in analogy with the Coulomb blockade. The strength of the coupling can be modified by simply engineering the distance between NCs (for example, in colloidal solids, the distance can be controlled by selecting the length of the organic molecules that serve as capping of the NCs). By using this approach, it is possible to control a transition between an insulator-like phase (weak coupling) to a highly conductive phase (strong coupling). Finally, high conductivity in weakly coupled NC assemblies can also be obtained by optical excitation (*photoconductivity*). For a given bias, the photocurrent increases linearly with the optical excitation intensity.

Three-dimensional arrays of small particles (mainly colloidal crystals, i.e., assemblies obtained from colloidal suspensions) are the subject of a number of studies due to their peculiar optical properties. Particularly interesting is the possibility of creating materials with *optical bandgaps* – i.e., materials that do not propagate light within a certain wavelength range – or, by exploiting higher-order effects, even materials with a negative refractive index [10]. A number of applications can be devised for these structures in the field of nonlinear optics; however at this time, no relevant devices have been realized.

Superlattices are another class of nanostructured materials, typically formed by an alternating sequence of large-bandgap and small-bandgap semiconducting thin films [2]. Such a structure and the associated electronic band profile are illustrated in Fig. 9. If the layer thickness is smaller than the mean free path, carriers can travel – without scattering – between one well to the other. The carrier mobility is very high, such that these structures are currently exploited in a number of high-frequency electronic devices. The periodic structure at the nanoscale produces electronic "minibands" (the simplest cases can be

Optical and Electronic Properties, Fig. 9 (*Top*) Schematic of a thin film heterostructure forming a superlattice. The layers are only a few nanometers thick. (*Bottom*) Energy band structure showing a series of periodically spaced potential wells. A set of *minibands* arises

analyzed by the Kronig-Penney model n), leading to finely tunable optical properties that are commonly exploited in optoelectronic devices such as semiconductor lasers. Finally, superlattices make it possible to observe the *Bloch oscillations*, a fundamental phenomenon predicted for any ideal periodic structure. This leads to a nonlinear, oscillating I-V characteristic with regions of negative differential resistance and can be exploited for fabricating solid-state switches and oscillators.

Nano-scale structuring

Definition

Nanostructured coatings are functional materials with nanoscale structuring, that is, having a characteristic dimension, in at least one direction, lower than 100 nm. Their family comprises coatings with mean size of the grains and foreign-phase

inclusions smaller than 100 nm, multilayer systems composed of the layers thinner than 100 nm, and composites with dispersed nanoparticles.

The size effect in mechanical nanostructured coatings allows obtaining hardness, toughness, friction and wear, and corrosion resistance enhanced compared to traditional hard coatings.

Optical nanostructured coatings are functional materials which allow the modification of optical properties of bilayer or multilayer structures. The classical optics effects and quantum effects, for example, electron confinement in low-dimensional systems, are present in such structures.

Overview

The first decade of the twenty-first century passed under the keywords like nanoscience, nanotechnology, and nanomaterials. Some nanomaterials were, however, known to people much earlier. The examples are: soot which is nothing but nanocrystalline graphite powder and the films of gold obtained from Faraday's "ruby fluids" (colloidal gold). It was R. F. Feynman, who first in 1959 drew the world's attention to the nanoscale (*nano* in Greek means a dwarf). In half a century since Feynman claimed "There's plenty of room at the bottom" nanoscience has evolved into a revolutionary area of research and technology, and started playing a magnificent role in rapidly growing industry.

The very concept of *nanotechnology* comes from Norio Taniguchi who, in the paper published in 1974, defined it as "the processing of separation, consolidation and deformation of materials by one atom or by one molecule." This definition was spread by K. E. Drexler in his books "Engines of Creation: The Coming Era of Nanotechnology" (1986) and "Nanosystems" (1992). Drexler described nanotechnology as technology based on manipulation of single atoms and molecules. At present a very general definition is accepted according to which nanotechnology is all what one does in nanoscale [1]. The description as above was given by R. E. Smalley awarded the 1996 Nobel Prize for the discovery of fullerenes.

The term *nanomaterials* refers to a particular family of "materials" comprising clusters of three to about thousand of atoms, single stable molecules like fullerenes or nanotubes, nanosize monocrystals and their superlattices, phases composed of nanosize crystallites (grains) and thin films of the thicknesses not exceeding 100 nm. The scale at which nanomaterials are characterized lies between that of interest to condensed matter physicists and chemists.

Specifying, the nanomaterials may be defined as those complying the *dimensional condition* according to which one of the characteristic dimensions (at least in one direction, for example, layer thickness or grain diameter or the dimension of the constituent phase) is lower than 100 nm. This characteristic size-parameter of the nanomaterials is somewhat arbitrary (some sources give 1,000 nm instead of 100 nm and some also give 1 nm as lower limit) but that is the size which determines the unusual properties of nanomaterials. The material properties can change totally if the size-parameter goes below characteristic critical value.

A significant improvement in the properties of nanomaterials compared to bulk materials of the same chemical composition (by factors about 3–5 times but in some cases even 100 up to 1,000 times) is associated just with the small dimension. The nanosize grains have much greater surface to volume ratio than micro-grains and large fraction of their volume should be regarded as surface phase of the properties drastically different from those of the solid. For example, the 1 nm thick interfacial boundary of the 5 nm (diameter) grain takes about 50 % by volume. The surface and interfacial phases have also significant impact on remarkable behavior of mono- and multilayers.

Besides the surface effects, also the phenomena occurring inside the nanosize particles and within the thin layers may be governed by different rules than those formulated for bulk materials. For example, lower friction of nanoparticles may be connected with discrete vibrational modes of the spacing increasing with decreasing particle size.

High efficiency of the material may be reached not only thanks to its low external dimension but

also by tailoring the nano-level internal shape (nano-scale structuring). Such materials are called *nanostructured* ones. They satisfy *structural condition* according to which a way of joining of nanoparticles (or nanolayers in multilayer system) into the bulk must preserve their nanostructured nature and characteristic nanometer dimension of the building blocks (lower than 100 nm). The family of nanostructured materials comprises: the solids and coatings with mean size of the grains and foreign inclusions smaller than 100 nm, the multilayer systems composed of the layers thinner than 100 nm as well as composites (layers and solids) with dispersed nanoparticles. All they exhibit unique properties unachievable in traditional bulk solid.

A technologically important part of nanostructured materials encompasses functional *nanostructured coatings* which may be metal, ceramic or polymer ones or their combinations. The potential benefits of such coatings include mechanical, optical, magnetic, thermal, and electrical properties. Thanks to the present-day deposition techniques (like PVD, CVD, ALD, or electrodeposition), which permit refining the coatings' internal structure at the nanometer scale with simultaneous precise control of chemical composition and impurities level, the nanostructured coatings have become of increasing interest to researchers involved in materials science and surface engineering.

By engineering the coatings at the nanometer level, it is possible to obtain materials of particular optical absorption spectrum. Because linear and nonlinear optical properties are determined by particle–particle interactions some additional low energy bands may appear in the absorption spectrum of nanostructured coatings. This is why they are currently present in optical telecommunication displays and various illumination technologies. They can also be used as components of laser diodes and plasma displays. The technologies based on optical nanostructured coatings have also a great impact on development of conventional energy, especially photovoltaics.

A strong interest is also directed to nanostructured coatings for mechanical applications, where high hardness, toughness, wear and corrosion resistance and low friction are required. Although conventional layers provide some improvement of mechanical properties of the substrate they do not meet all high requirements of modern technologies (including machinery, car and aircraft industry, space exploration or medical tools).

Below, some key topics related to the nanostructured coatings for optical and mechanical applications and to the methods of formation of such coatings are provided. A special stress is given to the coatings which are good candidates as the commercial materials for future large-scale manufacturing.

Optical Coatings

The main stream of the nanostructured coatings technology concerns the production of optical coatings for high-quality products such as *mirrors* and *filters* for high-power *lasers*, and narrow band filters for analysis and communication. The technologies related with optical nanostructured layers have a great impact on development of *nonconventional energy. Solar cell* industry requires permanent increase in modules efficiency, so very important are thin film technologies dedicated to *photovoltaics*.

Photovoltaic Applications

One of the main reasons of huge development of plasma assisted CVD systems is the thin film photovoltaic industry. Commercial production of thin film devices is related with amorphous silicon technology started in the second half of the 1970s [2]. Several features make amorphous silicon–based alloys attractive PV materials. These are: high optical absorption coefficient, low-temperature-deposition process, tunable optical gap in the region where high energy conversion efficiencies are expected. CVD *amorphous silicon*–based materials can be easily doped to get both p- and n-type conductivity. The present single junction a-Si:H commercial solar cells are based on p-i-n technology. The production of cells on glass involves *transparent conducting oxide* (TCO) technologies and Plasma Assisted Chemical Vapor Deposition (PACVD) formation

methods (deposition of p-type layer of boron doped silicon/silicon carbide alloy, intrinsic a-Si:H, phosphorus doped n-type layer, and metal back electrode). CVD methods open the possibility of a tandem a-Si:H cell with a-SiGe:H layer production.

PACVD techniques implemented in thin film solar cells: Silicon due to its availability and environmental sustainability is the main photovoltaic material. Wafer-based silicon technology has had about 70 % of market shares. In 2005, the annual production of thin-film modules reached 100 MW. Typical deposition process for large area substrates mass production is PACVD.

The most promising are microcrystalline/amorphous "micromorph" silicon solar cells (Neuchatel) of record stable efficiency 10 % where the nanotechnology is implemented [3]. The authors proposed the use of textured front and back contacts and intermediate reflectivity layer (IRL). "Micromorph" modules efficiency is about 9 %. The commercialization of such concept was done by Kaneka Corporation giving PV modules of superior light absorption per nominal Watt power. Future increase in conversion efficiency requires proper light scattering at textured interfaces and IRL between the individual cells. High-frequency PACVD enables the preparation of SiO_x IRL of refractive index lower than 1.7 from CO_2 + SiH_4 gas mixture. Flexible tandem n-i-p micromorph solar cell architecture consists of front low pressure CVD (LPCVD) ZnO, a-SiH (PACVD) top cell, asymmetric intermediate reflector (LPCVD-ZnO), μ-Si:H bottom cell, and ZnO/Ag back reflector.

Cadmium telluride solar cells show high performance and relatively low production costs [4]. CdTe is a direct gap semiconductor (1.45 eV). It converts solar energy to electricity more efficiently than indirect band gap materials. The CdTe/CdS solar cells are present in PV market and the production leaders (e.g., First Solar) observed rapidly increasing market. Key technologies for large area CdTe thin film solar cells are CBD/CSS chemical bath deposition and close space sublimation. The application of high-resistivity SnO_2 layer between conducting SnO_2/CdS films in the cell architecture causes the increase in solar cell efficiency. There are some reports on production of resistive (10^3 Ω cm) SnO_2 films by the use of PACVD from $SnCl_4$ and O_2 reagents. The reaction

$$SnCl_4 + O_2 \rightarrow SnO_2 + 2Cl_2$$

takes place at 120–200 °C and SnO_2 amorphous film grows. In next solar cell manufacturing CSS process steps at high temperature (500 °C) amorphous SnO_2 structure changes its form to crystalline. The temperature of solar cell processing is higher than PACVD, SnO_2 layers exhibit crystalline structure, and optical absorption edge moves into higher energy values.

The use of CVD antireflection coatings for improvement of bulk solar cells: PACVD is the method commonly used in fabrication of *antireflective* and *passivating* coatings in crystalline and polycrystalline silicon solar cell technology [5]. One of the steps in manufacturing crystalline silicon solar cells is low-cost deposition of an antireflection coating. The role of such layer is the reduction of reflection and surface/bulk defects passivation. The promising candidate for this aim is hydrogenated silicon nitride produced at low temperatures from SiH_4 + NH_3 gas mixture. Two other materials SiO_2 and TiO_x can be produced by thermal CVD but the former has too low refractive index and latter does not passivate the silicon. The formation of silicon nitride by atmospheric pressure CVD (APCVD) from silane and ammonia mixture is possible at 700–1,000 °C. The use of low pressure LPCVD (0.1 mbar) process from dichlorosilane and ammonia can be performed at 750 °C. Only PACVD technology of silicon nitride is attractive for electronic industry due to low-temperature coating preparation.

In 1981, a-SiN_x:H PACVD technology was transferred from microelectronics industry to photovoltaics (ASE GmbH) and Kyocera used commercially PACVD silicon nitride in crystalline silicon solar cells. Nowadays direct PACVD methods of high frequency or low frequency are widely used in industrial applications. Usually the deposition of antireflective coatings is processed in batch reactors, where achieving of hundreds of

silicon wafers with a-SiN_x:H layers per hour is possible. PACVD systems, the inline technology developed by the Japanese manufacturer Shimadzu, are applied in which the antireflection coating based on silicon nitride guaranteeing excellent surface passivation is produced at 1,147 wafers per hour.

Other amorphous silicon–based alloys like a-Si:C:H [6] and a-Si:C:N:H can be used as antireflective coatings for silicon solar cells. On the basis of the spectral dependence of the reflectivity $R(\lambda)$ (total or specular), the effective reflectivity (R_{eff}) could be calculated from:

$$R_{eff} = \frac{\int R(\lambda)N(\lambda)d\lambda}{\int N(\lambda)d\lambda} \quad (1)$$

where $N(\lambda)$ presents the *AM1.5* standard solar spectrum. The integration was performed over the spectral range from 400 to 1,100 nm. For a-Si:C:H films obtained by PACVD from the gas mixture of the composition $[CH_4]/[CH_4 + SiH_4] = 0.23$ on multicrystalline silicon Si substrates $R_{eff} = 5.9$ % was reached.

For reduction of the front surface reflectance several researchers have used porous silicon layers as antireflective coatings. The refractive index depends on its porosity and morphology. Strong surface recombination due to roughness occurs after the formation of porous silicon onto the emitter in silicon solar cell. PACVD deposited SiO_x films on porous silicon surface provides chemical stability, passivation, low reflectivity, and improvement of electrical properties of solar cell [7].

Solar Cell Nanotechnology: The improvement in solar cell efficiency requires the implementation of new nanostructured materials. Quantum dot–based solar cells could be effective and nonexpensive alternative to bulk silicon concept. The absorption spectrum may be larger and better explored by size control of QDs. Second generation solar cells with QDs have been based on single junction concept. In third generation photovoltaics the cells architectures with QD absorbers in tandem multijunction configuration are used [8].

Semiconductor Nanocrystals

Semiconductor nanocrystals are the zero-dimensional objects. Due to electron confinement nanocrystals have discrete energy spectra dependent on their size. The electronic and optical properties may be tailored. Nanocrystals of energy gap of 1.8 eV may be tuned to 3 eV by decreasing the dimensions from 11.5 to 1.2 nm (CdSe nanocrystals). MBE is a widely used technique for producing two-dimensional quantum wells, superlattices, and three dimensionally confined islands with dimensions below 10 nm. Another method is chemical synthesis of controlled homogeneous nucleation, high-temperature inorganic precipitation in molten glasses, and moderate temperature metal-organic reactions. Numerous theoretical descriptions of electronic structure of nanocrystals are given: electron in the box model, finite well effects, Coulomb interactions, confinement-induced mixing of valence subbands, etc. The applications of sized controlled spectral properties find a place in lasers, emitting light devices, solar cells, and switching devices.

MOCVD (metal-organic CVD) can be applied to grow ZnO quantum dots (QDs). ZnO due to good optical and electrical properties is one of the attractive materials [9]. The band gap is 3.36 at room temperature and it makes the material transparent. After the doping, ZnO reveals higher conductivity and is suitable for electrodes applications. ZnO QDs indicate exciton effect and are the candidates for construction of blue and UV devices like LED and lasers. Among the chemical methods MOCVD conducted at elevated temperatures 350–500 °C in diethylzinc (DEZn), oxygen and argon carrier gas enables the preparation of ZnO QDs. The dimensions of QDs of 10 nm increase and the density decreases with increasing process temperature.

PACVD deposited nanocrystalline silicon (nc-Si) is the material for electronics applications in solar cells, TFT transistors. nc-Si-based solar cells show higher stability and higher efficiencies than a-Si:H ones. TFTs with nc-Si active layer revealed high electron mobility and high performance. Technology conditions influenced the optical properties and grain structure of this

material. SiO_x films grown by PACVD after annealing at temperature above 1,200 °C reveal nc-Si embedded in SiO_2. This material exhibits nonlinear optical properties. Real and imaginary parts of third order susceptibility $\chi^{(3)}$ exhibit nonlinearity. The nonlinear absorption depends on light intensity and $\chi^{(3)}$ decreases when the size of nanocrystals increases [10].

Nanoscaled Si_3N_4 may be obtained by means of various techniques: nitridation process, a-SiN_x:H nanopowder nitridation, CVD, and the most advantageous PACVD. Low temperature PACVD process and possibility of fast deposition are useful for nanocrystals and nanowires synthesis on large area substrates.

Photorefractive semiconductor structures exhibit nonlinear optical properties. Nonlinear optical devices in nanometer scale change their optical properties in response to light intensity and can be used to perform dynamic holography under low light intensity. Low-dimensional systems could enhance optical properties and electronic transport in comparison to bulk materials. High density of deep levels provides semi-insulating conductive character. Defect traps could store photogenerated carriers. The traps produce electric fields and modified optical properties. Low light intensity information in photorefractive materials is stored in the form of trapped charges. The potential application of photorefractive materials is the storage capacity. Due to progress in magnetic and semiconductor technologies no storage system based on holography was developed [11].

Nanostructured Coatings for Mechanical Applications

Nanostructured coatings provide a new generation of functional materials with high potential for significant improvement of the properties of mechanical parts. They include various types of coatings: nano-grain phases, nano-multilayers, and nanocomposites [12] with high operational parameters reached thanks to the size effect. The unusual mechanical properties make the nanostructured coatings a perspective choice instead of traditional ways to enhance the strength, wear and corrosion resistance and service life of any mechanical component. The coatings with tailored internal shape may soon replace currently used protective hard layers and may be competitive to other methods allowing the modification of the existing surface (like carburizing, nitriding, oxidation, or hybrid combination of various techniques).

The application of nanostructured coatings to protect mechanical components is also an attractive alternative to bulk nanostructured materials. The main idea is to bridge the benefits of unique mechanical properties of nanostructured bulk materials (like hardness and strength) and the synergism of the properties which may be obtained in the layer–substrate system.

Mechanical Behavior

The complexity of mechanical behavior of the functional coating, strictly coating–substrate system, depends on many factors. Firstly the bond between the coating and the substrate must be strong enough and free of internal stresses. Secondly, the coating processing or any other surface treatment cannot lower the substrate operational parameters. Finally the coating should obviously have the properties for which it was designed, including resistance to wear and corrosion, low friction, high hardness, and enhanced chemical and thermal stabilities.

A generally accepted model explaining why the hardness, ductility, and strength of nanostructured coatings differ from those of conventional ones is often reduced to small slip distance in nanosize grains and attributed to dislocation activity and enhanced stress relaxation at the grain boundaries. The grain boundary is more disordered than the grain inside and act as an aggregation of pinning points which control dislocation propagation. It consequently prevents the dislocation movement in a continuous slip plane increasing material strength and rising elasticity limit.

The description of increased strength of nanostructured materials and coatings is usually based on the empirical Hall–Petch equation according to which a *yield strength* σ_y of the grained material increases when the grain size goes down:

$$\sigma_y = \sigma_0 + \frac{k}{\sqrt{d}} \quad (2)$$

σ_0 in the above equation is a stress above which dislocation movement starts and *ky* is the strengthening coefficient – both are constant to each material.

Strength testing of bulk and layer materials, including nanostructured ones, is usually confined to hardness measurements and the dependence between grain size and the hardness is described with the Hall–Petch formula. Unfortunately it does not comply all cases. Many results show that the strength and hardness of nano-grain materials and thin coatings fall down below the value predicted by *Carlson and Wronski* [2]. The grain of the diameter lower than 10 nm houses one or two dislocations and its plastic deformation is mostly due to grain boundary processes. Because of hindered dislocation pile-up the grain boundary diffusion does not occur. In such case a release of the stresses takes place via grain boundary sliding which effects to a decrease of the strength. There is a limit of strengthening (not provided by Carlson and Wronski [2]) – infinitely strong materials do not exist.

In the nanostructured materials of broad grain size dispersion (or different sizes of the inclusions), various phenomena may occur side by side. This means that when the mechanisms responsible for the deformation or even destruction of the coating are analyzed not only the mean grain size but also the related distribution should be taken into account. The nanostructured coatings (and in general nanomaterials) of similar size grains will exhibit greater flow stress than the coating containing the grains having the same mean size but more dispersed.

Various approaches have been proposed, next to the Hall–Petch approach, to predict a dependence between the strength (or hardness) and grain size and calculate the lower *d* limit. Some of them are based on the concept of dislocations generated during deformation at the grain boundaries. The others introduce multi-phase model with hard grain boundary and soft grain interior. Those and some other models applicable to nanostructured metals have been reviewed in Weertman [13]. Our knowledge concerning more complex systems like covalent-ionic ceramic materials remains very limited.

Yet another case is represented by amorphous coatings in which a nucleation of cracks is suppressed. It may seem that such coatings should be the best candidates for tough protection. It is not so because amorphous materials are brittle – the crack propagation throughout amorphous structure is easy. The best way to prevent crack propagation is to introduce reinforcing particles into amorphous matrix. Their size should be equal to the width of shear stresses at the localized structure defects. As far as the toughness is concerned, nanostructured coatings designed as amorphous composites with embedded nanosize crystallites are very attractive ones.

Hardness of the coating is not only an indicator of its strength but is also considered as a consequential factor in the designing the coatings of high *work and corrosion resistance*. Strictly, an interplay of hardness and ductility has crucial meaning in this case. Hard coatings improve wear resistance but they lower ductility and increase a probability of brittle failure. Otherwise, the high ductility allows greater plastic deformation at minimized risk of the particles breaking and delamination. Too high ductility causes abrasion danger. As a result, hardness and strength from one side and ductility from the other are antagonists and the well-designed coating should have high hardness (*H*) and low Young (elastic) modulus (*E*) (high *H/E* ratio).

The reports concerning elastic behavior (and ductility) of nanostructured materials are somewhat ambiguous. Most of them, however, confirm a substantial decrease in *Young modulus* of the materials of small grains and attribute it with a presence of the pores (like in foams). In the case of dense materials, only fine nanostructures with the grains of the diameter below 100 nm show clear reducing of Young modulus.

Wear resistance and tribological properties of the coatings may not be considered beyond friction. As a rule, in friction description, adhesive interactions between working surfaces should be considered. Referring to the structure at atomic level one can say that the best way of friction

reduction is to terminate dangling bonds. Such effect is observed when comparing friction of diamond-like carbon (DLC) with much lower friction of hydrogenated DLC. More generally, hydrogen passivation of the surface layer allows friction reduction. The friction may also be regarded via a conversion of the energy of reciprocal (translational) motion of two working surfaces into vibrational energy. Such approach allows modeling friction of nanocrystalline and composite coatings. Vibrational modes of small systems are discrete which impedes phonon damping. As a consequence one observes lower friction of the particles of smaller sizes (e.g., grains or reinforcements in composites). Friction occurs when the inverse of phonon-life time is higher than the vibrational mode spacing. The last one increases with decreasing size. In very low size limit there is no friction.

The size effect in thin layers and multilayer systems amounts to the problem of layer thickness. Like in nanosize grain materials, it is a presence of linear defects (dislocations) which determines the mechanical properties of the single layer and the layers in multilayer coatings. A critical thickness of such layers can be determined. Below this thickness misfitting dislocations may develop causing a degradation of the mechanical characteristic. According to Freud-Nix theory the critical thickness may be evaluated from the condition that the work of dislocation creation be equal to the strain energy recovered from the system.

Regardless of the coating properties (not only mechanical ones but also optical, electrical, etc.) a fundamental problem which has to be overcome in the coating engineering refers to the strength of the bond between the coating and the substrate. Only good adhesion allows rising the synergism of the properties in the coating–substrate system. The strength of the bond of the coating to the substrate is given by a stress needed to delaminate the layer from the substrate and is proportional to intrinsic toughness: $\gamma_{SV} + \gamma_{CV} - \gamma_{SC}$. Its value equals the change in the surface energy γ when the substrate–coatings interface (SC) separates into the substrate–vapor (SV) and coating–vapor (CV) surfaces. The highest values of intrinsic toughness may be achieved by a formation of diffusive layers.

Examples

The nanostructured coatings are good candidates for machining and wear-resistant applications and may effectively compete with the traditional protective coatings like oxides, carbides, and nitrides. The benefits in general include higher strength and hardness, higher ductility and toughness, improved wear and corrosion resistance, and improved tribological properties but lower elastic modulus and friction. The nanostructured coatings have relatively low thermal expansion coefficient followed by high thermal and chemical stability. Operational parameters of any nanostructured coating depend on the type of the structure (nanocrystalline, composite, or multilayer) and on the characteristic size (average grain size, grain-size distribution, layer thickness, and sizes of reinforcing particles). Furthermore, they clearly depend on the chemical composition of the phases present in the structure as well as on the impurities and segregation – both influencing the phenomena at the interfaces and grain boundaries.

Below, some representative examples of nanostructured coatings which can find large-scale applications in mechanical components are reviewed. The review is based mainly on Refs. [14–19].

Nanostructured ceramic alumina Al_2O_3 and alumina-titania Al_2O_3-13 % TiO_2 ceramic coatings exhibit micro-hardness about 15–30 % higher than that of the conventional ones. Their wear resistance is significantly improved, especially under a high wear load. The particularly increased wear resistance has dense coatings free of pores and microstructure defects. The addition of nanosize alumina dispersions results in an increase in the fracture toughness and thermal shock. The alumina coatings may be deposited with application of plasma spray technique. The structure contains partially melted nanosize Al_2O_3 particles trapped between the fully melted coarser Al_2O_3 grains of micrometer size. The dense coatings can be formed at high powers. An additional

enhancement of the properties is achieved by addition of TiO_2. The structure of sprayed Al_2O_3–TiO_2 coatings typically contains the regions of two kinds. The first ones may be described as fully melted regions formed mainly by nano-size grains of c-Al_2O_3 with dissolved Ti^{+4}. The second are unmelted/partially melted nanostructured regions – different than the conventional coating of lamellar structure. The nanostructured Al_2O_3–TiO_2 coatings have been used on the main propulsion shaft in ships.

Titanium dioxide TiO_2 is a chemically stable, relatively hard, and nontoxic material. It exhibits good biocompatibility, raised mechanical performance, high stability, and is nonabsorbable by the human body. The TiO_2 coatings may be effectively produced with variety of methods, like metal-organic CVD, ALD, or sputtering. The stable layers may even be 4 nm thick. The coatings deposited with thermal spray process exhibit nano-size structure with characteristic semi-molten nanostructured TiO_2 particles. The embedded nanoparticles act as crack arresters, improving the crack resistance and hardness of the conventional coating. The titania coatings are seen as a new generation of the coatings for enhancing the performance of long-lasting implants and other biomedical devices.

The nanostructured TiN coatings may be among other fabricated by means of reactive plasma spraying of micrometer titanium powders in the atmosphere. Such coatings contain not only TiN but also Ti_3N phases. They are of lamellar structure – typical for spraying. The grains have columnar shape of the sizes ranging from 60 to 120 nm. The nanostructured TiN coatings are characterized by higher bonding strength and better fracture toughness than those with greater grains. Both TiN and TiO_2 coatings are known for their low chemical reactivity, high hardness and wear and corrosion resistance. Thanks to this they are used for protecting various surfaces. Similar properties to TiN have been found in chromium nitride CrN. It can be obtained in the form of extremely hard, inert, thin layer applicable to precision metal parts.

The fusion of the properties of TiN and TiO_2 may be combined by formatting multilayer nitrided/oxided coatings. The surface layer modified with glow discharge oxynitriding is composed from nanocrystalline and columnar grains of the TiN phase. Addition of oxygen at the end of the process allows formation of a thin layer with inclusions of TiO_2 nanograins and small amount of amorphous phase. Such layers exhibit high corrosion resistance and can be successfully used as coatings on NiTi alloys in biomaterial for orthopedic and dental applications.

Very promising operational parameters have been found in nanostructured coatings of the chemical composition based on Ti, Cu, and N and deposited via reactive cathodic arc ion plating. The received structure consists of one hard and one soft phases. The film hardness, elastic modulus, and residual stress depend on the copper content. For example, the hardness slightly increases when the copper content rises until approximately 1.0 at. %. Further increase of the Cu content (up to about 1.5 at.%) causes rapid increase of the hardness up to a maximum value of approximately 42 GPa. This is approximately 1.5 times higher than the value for the pure TiN film. The highest elastic modulus (of the order of 400 GPa) has been measured for the films with 1.5 at.% Cu. The enhancement of the properties is explained by the reduction of the grain size due to Cu addition.

Titanium Carbide (TiC) is a hard ceramic material of excellent tribological wear properties. The CVD coating based on TiC provides very promising properties making them outstanding candidates for mechanical applications. Titanium carbo-nitride (TiCN) coatings offer slightly higher hardness compared to TiN and slightly lower friction coefficient. It may be used to enhance abrasive wear resistance. It exhibits a complex structure consisting of TiN and TiC bonds in a crystalline matrix – no TiCN molecule exists. TiCN may be deposited in multilayer or graded form by various PVD methods. TiC may also be applied in the form of nanocomposite nc-TiC/a-C(H) coatings (obtained for example by magnetron sputtering). The typical structure of such composite consists of TiC nanocrystallites (2 nm) with volumetric fraction of about 0.3. These nanocrystallites are embedded in

amorphous carbon matrix. Small size of the TiC particles and their relatively low fraction ensure highly homogeneous nanolevel structure. The coatings exhibit low friction, high toughness and wear resistance, and characteristic self-lubrication.

WC-Co coatings are of the great importance with respect to their extra high wear resistance. Nanostructured WC-Co coatings are much denser than conventional ones. In these coatings, nanometer size particles of WC are distributed evenly in the cobalt-rich phase. Though partial decarburization of WC may occur, nanostructured WC-Co has friction coefficient by about 20 % lower than traditional coating. It is followed by increased hardness, fracture toughness, and wear resistance.

Nanocrystalline and nanostructured carbon coatings may be produced in various forms mainly with a use of CVD techniques. Nanocrystalline diamond films can provide very smooth coatings having high hardness and other properties of polycrystalline diamond films. The other structure forms include simple shapes or fibbers, powders, whiskers, and components with complex shapes and surface morphologies coated on various substrates. Ordered and disordered graphite and nano-porous carbon may be formed depending on the processing conditions. These carbon forms can serve as good tribological coatings of low friction coefficient for preservation of various tools or as intermediate thin films for further CVD deposition of diamond. Carbon coatings may be modified by addition of other elements. Addition of hydrogen and formation of hydrogenated structure dramatically lowers friction (thanks to H-terminated bonds). Silicon or nitrogen addition allows obtaining nanocrystalline silicon carbide or nonstoichiometric amorphous carbon nitride layers (with nitrogen content up to 30 at.%) of high hardness and wear resistance. When both are in the structure one obtains $SiC_xN_y(H)$ layers which join the properties of hard SiC and more ductile Si_3N_4. They may be produced with PACVD technique as the uniform ones (e.g., on metals in medical applications) or in graded form as $C:N/SiC_xN_y$ (to enhance properties of polymer surfaces).

Technologies

The properties of the nanostructured coatings may be manipulated at the processing stage on condition that the technology and processing conditions be carefully designed. It is obvious that a spectrum of the properties and hence applications of nanostructured coatings and materials may be enlarged thanks to recent advances in the respective technologies [20]. The techniques applied in the processing of nanostructured coatings which allow fabrication on the commercial scale include:

- Physical Vapor Deposition (PVD) and Chemical Vapor Deposition (CVD)
- Mechanical alloying/milling
- Crystallization of amorphous alloys
- Glow discharge
- Electrodeposition
- Sol–gel
- Hybrid methods applying multidisciplinary techniques

The above methods comprise both top-down techniques, from macroscale to nanoscale, and conversely bottom-up by assembly of atoms.

The CVD methods allow obtaining covalent and ionic-covalent layers of complex composition both for optical and mechanical applications. Actually the metal coatings are seldom produced in this way. CVD makes use of homogeneous (in gaseous phase) and heterogeneous (at the solid–gas interface) chemical reactions. The gaseous precursor is introduced to the reactor by convection and then it diffuses perpendicularly to the substrate surface. Although CVD may be developed in various solutions, Plasma Assisted CVD (PACVD) and Remote Plasma-Assisted CVD (RPACVD) in which plasma is a medium enhancing chemical synthesis seem to be the most promising ones. The use of plasma allows reducing processing temperature which is often critical for some applications (e.g., when polymer is used as a substrate or in the production of semiconductors). In RPACVD, the substrate is removed from the plasma region and the temperature of the substrate may not be higher than room temperature. Plasma may be generated by radio (13.56 MHz;

RFCVD) or microwaves (2.45 GHz; MWCVD) or with application of DC voltage (DC-plasma CVD). PACVD is widely used in nanofabrication of epitaxial, amorphous, monocrystalline, and nanocrystalline thin layers and multilayer and composite coatings. It also allows obtaining gradient layers with the chemical composition changing perpendicularly to the surface. The materials include various forms of carbon (diamond like carbon DLC, hydrogenated DLC, carbon fibers, nanofibers, and nanotubes), the compounds like silicon carbide SiC, carbon nitride CN(H) and oxynitride CNO, titanium nitride TiN, and titanium dioxide TiO_2, or nanocomposites like Mo/Al_2O_3 – mostly for mechanical (and biomedical) applications. A variety of optical coatings may also be deposited with CVD, for example: high refractive silicon nitride, amorphous silicon, or hydrogenated silicon.

Chemical composition may be particularly well tailored when metal-organic CVD (MOCVD) is applied. High-quality thin films may be deposited with flame-based Combustion Chemical Vapor Deposition (CCVD). This technique allows formation of the nanocrystalline thin coatings with given orientation (including epitaxial coatings) as well as nonporous layers.

Atomic Layer Deposition (ALD) is a CVD technique in which the precursor materials are separated during reaction. The precursors react with a surface in a sequential manner, one-at-a-time. This method is likely to have the greatest potential to produce very thin dense layers with precisely controlled chemical composition and atomic structure, for example: oxides (Al_2O_3, TiO_2, ZnO), metal nitrides (TiN, NbN, WN), and pure metals (Ru, Pt).

Like CVD also PVD methods offer great possibilities to produce nanostructured coatings, especially for cutting tools and parts of machinery. The PVD methods may be developed as magnetron sputtering, arc evaporation, and pulsed laser ablation. Magnetron sputtering is the most common PVD technique. It makes use of atomization of the precursor material by energetic bombardment of its surface by ions or neutral particles. There are almost no restrictions in the target materials. Single or multi-elemental targets may be applied, including pure metals and ceramics (semiconductors and isolators). In arc evaporation, a material is evaporated from the cathode target with electric field. The process begins with high-current striking followed by an increase of a localized temperature at the cathode spot to very high values (above 10,000 °C) and vaporization.

The removal (ablation) of atoms from the bulk material in Pulsed Laser Deposition (PLD) is done by vaporization upon laser irradiation. Pulsed Laser Deposition (PLD) is a reliable but rather expensive coating technique that is applied to deposit defined films with complex stoichiometry. The most common hard coatings available by PVD are nitrides: TiN, CrN, TiCN, and TiAlN. The properties of these coatings can be much improved not only by the addition of other elements (like V, Y, or Cr) but also by the development of nanostructure. Multilayers (TiN/C–N, MoS_2 with Cr) and nanocomposite coatings may be formed. Disadvantage of PVD methods, limiting applications, may be relatively low (physical) adsorption of the coatings to the substrate. Thus an effort is directed to the formation of transition diffusion layer. Some solution is supplied by Hybrid Physical-Chemical Vapor Deposition (HPCVD).

Besides CVD and PVD methods there are developed some other techniques applicable in the manufacturing of nanostructured coatings. Ceramic coatings (and particularly thin films) can be deposited with solgel method in which a sol of the precursor is subjected to gelation and densification. The method is particularly useful in fabrication of homogeneous multicomponent coatings. Hybrid coatings can be obtained via introducing a different phase into the sol. With application of post-synthesis treatment it is possible to obtain nanostructured oxides, carbides, or nitrides. Solgel deposition ensures high structure control, also at nanolevel scale. In particular, the nanocrystalline layers of known porosity may be prepared (e.g., TiO_2 thin films). Nanostructured metal coatings can be deposited by electrolytic and electroless plating methods. In electrodeposition porosity-free metallic (pure metals and alloys) amorphous of nano-grain coatings may be produced (e.g., Pd, Ni). The deposition from

an electrolyte solution takes place on conductive substrate. Unlike electrodeposition, electrical conductors are not required as substrates in electroless deposition. Depending on processing conditions and composition the grain sizes may range between 2 and 100 nm.

Mechanical alloying and milling are the methods most often used for commercial scale. Attritor milling is used to manufacture large quantities (in kilogram per batch) of micrometer-size particles with nanostructure grains. Mechanical alloying is a ball-milling process in which blended powders are welded and fractured to achieve alloying at the atomic level. One of the purposes of these techniques is to produce powders suitable for thermal spraying: of given composition, tailored grain size, and distribution.

Thermal spraying methods (like atmospheric plasma spraying APS, high-velocity oxy-fuel thermal spraying HVOF, detonation gun (D-gun) spraying arc spraying AS and flame spraying FS) allow producing metallic, nonmetallic, and ceramic coatings via spraying molten solid particles from a thermal source onto a substrate. The structure of the formed coating depends on the shape of the sprayed particles. The method has been successfully applied in the deposition of 316-stainless steel nanostructured coating or nanocomposite and Cr_3C_2–NiCr and WC-Co cermet coatings.

Summary

Nanostructured coatings offer a great potential to serve as functional materials in many applications. In particular, they may be used in optical technologies, like laser or photovoltaic devices, and to protect components of machinery and tools. These two applications may be introduced on a large scale which make nanostructured coatings manufacturing an important industry with significant economical impact. Reliable coatings are needed to prevent wear and corrosion, to improve durability and frictions of the working component parts used both in commercial and advanced applications (like biomedical ones). They can also enhance yielding of optical devices, like solar cells. Functional nanostructured coatings may be produced thanks to the present-day development of modern technologies applicable on industrial scale. Further development of industry with the implementation of nanostructures becomes one of the key problems in the twenty-first century.

Unresolved problems comprise our still limited understanding of the mechanisms responsible for the size effect. The accepted theories, like the Hall–Petch approach, do not give full explanation of the enhancement of the properties as the characteristic size goes below 100 nm.

Optical Frequency Magnetic Dipole Transitions

Sinan Karaveli and Rashid Zia
School of Engineering, Brown University, Providence, RI, USA

Synonyms

Magnetic dipole emitters; Magnetic dipole transitions

Definition

Optical frequency magnetic dipole transitions are processes in which the magnetic field of electromagnetic radiation mediates a change in electronic states via the absorption or emission of a photon.

Overview

Nanoscale fabrication has enabled dramatic developments in the field of optical metamaterials, which in turn have expanded both the range of materials and phenomena available for future photonic devices. For example, researchers have used patterned metal nanostructures, including split-ring resonators and paired nanorods, as building blocks to engineer metamaterials with significant magnetic permeabilities at optical frequencies [1]. Whereas metamaterials research explores the artificial magnetic resonances supported by man-made structures, this entry describes the naturally occurring magnetic dipole transitions in atomic systems.

Based on a comparison of dipole moments in the Bohr model of hydrogen, it is often assumed that magnetic dipole transitions can be neglected at optical frequencies. Arguments in the literature contrast the approximate electric dipole moment ea_0 (where e is the electron charge and a_0 is the Bohr radius) with the Bohr magneton $\mu_B = \alpha e a_0/2$ (where α is the fine-structure constant). In CGS

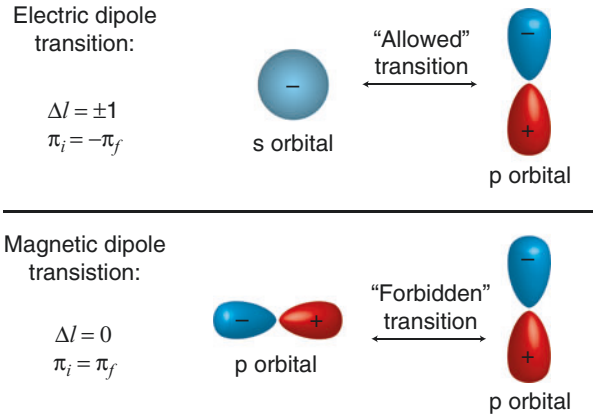
units, the Bohr magneton is smaller than the approximate electric dipole moment by half the fine-structure constant α, which itself is approximately 1/137. As the transition strength depends on the square of the dipole moment, it would appear that magnetic dipole transitions should be $\sim 10^5$ times weaker than electric dipole transitions.

However, the precise quantum mechanical transition strength depends on the specific electronic structure. In systems where electric dipole transitions are weak or not allowed, magnetic dipole transitions can be significant. In fact, magnetic dipole emission is observed everyday from Lanthanide ions such as trivalent Europium (Eu^{3+}), a common phosphor in fluorescent lighting. Magnetic dipole emission is also significant in the 1,550 nm line of trivalent Erbium (Er^{3+}), the gain source for Erbium-doped fiber amplifiers in telecommunication networks. With the growing interest in optical frequency magnetic resonances and magnetic light-matter interactions, magnetic dipole transitions are also finding new applications in experimental nano-optics and active nanophotonic devices.

Optical Transitions and the Multipole Expansion

In describing the way that light is absorbed or emitted by an atom or molecule, it is often convenient to expand light-matter interactions into multipolar transitions, e.g., electric dipole, magnetic dipole, electric quadrupole, etc. These transitions can be formally derived by a multipolar expansion of the interaction Hamiltonian [2] as follows:

$$\hat{H}_{\text{int}} = -\vec{p}\,.\,\vec{E} - \vec{m}\cdot\vec{B} - \left[\overleftrightarrow{Q}\,\nabla\right]\cdot\vec{E} - \ldots$$



where each term is associated with a different multipolar moment of the electronic charge distribution, e.g., the electric dipole moment $\vec{p}$, the magnetic dipole moment $\vec{m}$, and the electric quadrupole moment Q. This equation shows that the electric dipole moment interacts with the electric field $\vec{E}$, while the magnetic dipole moment interacts with the magnetic field $\vec{B}$. Higher-order terms, such as the electric quadrupole, interact with spatial derivatives of the electric and magnetic fields. Since the magnetic field is related to the curl of the electric field, the magnetic dipole and electric quadrupole terms are often grouped together as terms that depend on the spatial variation of $\vec{E}$.

Electric Dipole Approximation and the Parity Selection Rule

In terms of the electronic states which they connect, electric and magnetic dipole transitions are readily distinguished by the parity selection rule [3, 4]. Since the size of the electron wave function (on the order of angstroms) is much smaller than the wavelength of visible light (λ = 300–700 nm), it is generally fair to assume that the electron sees electromagnetic radiation as a time-varying but spatially uniform field. This is known as the electric dipole approximation, where the spatial variation of the electric field is neglected such that $\vec{E}\,(r,t) \equiv \vec{E}_0 \exp\left(\left(\vec{k}\cdot\vec{r} - \omega t\right)\right) \simeq \vec{E}_0 \exp(-i\omega t)$ and is equivalent to retaining only the first constant term in the Taylor expansion of $\exp\left(i\,\vec{k}\cdot\vec{r}\right) = 1 + i\,\vec{k}\cdot\vec{r} + \frac{\left(\vec{k}\cdot\vec{r}\right)^2}{2!} + \frac{\left(i\vec{k}\cdot\vec{r}\right)^3}{3!} + \ldots.$

In such a spatially uniform electric field, the electron will experience a time-varying force $\vec{F} = -e\vec{E}_0 \exp(-i\omega t)$ that can push or pull it along one axis. This interaction can thus mediate the interorbital transition from a symmetric $1s$ orbital to an antisymmetric $2p$ orbital, as shown in Fig. 1. However, it cannot mediate intra-orbital transitions between electronic wave functions with the same symmetry, e.g., $1s \rightarrow 2s$ or $2p_x \rightarrow 2p_z$. In the electric dipole approximation, the initial and final states of a transition must have different parities. This is known as the parity selection rule for electric dipole allowed transitions. For single-electron wave functions, this rule implies that there must be a change in the orbital quantum number l [3, 4]: $\Delta l = l_{\text{final}} - l_{\text{initial}} = \pm 1$.

When electric dipole transitions are weak or not allowed, higher-order "forbidden" processes such as magnetic dipole and electric quadrupole transitions must be considered. These processes

Optical Frequency Magnetic Dipole Transitions,
Fig. 1 Examples of single-electron dipole transitions. Unlike interorbital electric dipole transitions that occur between electronic states of differing parity, magnetic dipole transitions are intra-orbital transitions between electronic states of the same parity

Optical Frequency Magnetic Dipole Transitions, Table 1 Selection rules for pure LS coupling

Electric dipole transition	Magnetic dipole transition	Electric quadrupole transition
$\Delta L = 0, \pm 1 (0 \nleftrightarrow 0)$	$\Delta L = 0$	$\Delta L = 0, \pm 1, \pm 2 (0 \nleftrightarrow 0, 0 \nleftrightarrow 1)$
$\Delta S = 0$	$\Delta S = 0$	$\Delta S = 0$
$\Delta J = 0, \pm 1 (0 \nleftrightarrow 0)$	$\Delta J = 0, \pm 1 (0 \nleftrightarrow 0)$	$\Delta J = 0, \pm 1, \pm 2 \left(0 \nleftrightarrow 0, 0 \nleftrightarrow 1, \frac{1}{2} \nleftrightarrow \frac{1}{2}\right)$
Change of parity $\Pi_f = -\Pi_i$	*Parity conserved* $\Pi_f = \Pi_i$	*Parity conserved* $\Pi_f = \Pi_i$

are mediated by spatial variations in the electric field. Through the Lorentz Force $\vec{F} = -e\left(\vec{v} \times \vec{B}\right)$ and gradients to the Coulomb Force $\vec{F} = -e\,\vec{E}$, spatial variations in $\vec{E}$ can produce torque and thus drive rotational transitions such as $2px \rightarrow 2pz$, as shown in Fig. 1. For these transitions, the initial and final states have the same parity. For single-electron wave functions, this implies that the orbital quantum number l remains constant [4]: $\Delta l = 0$.

Table 1 shows the selection rules for multielectron configurations in pure *LS* coupling, where the electron wave functions are described in Russell–Saunders notation by their total orbital angular momentum L, total spin angular momentum S, and total angular momentum J [3].

Calculating Line Strengths, Emission Rates, and Oscillator Strengths

To determine the likelihood of magnetic dipole absorption or emission, one must first model the electronic states and then calculate the quantum mechanical matrix element for the magnetic dipole operator $\hat{H}_{MD} = \mu_B\left(\hat{L} + 2|\hat{S}\right)$ [3, 4]. The square of this matrix element is called the magnetic dipole line strength S_{MD}:

$$S_{\mathrm{MD}}(\psi_1, \psi_2) \equiv \left|\left\langle \psi_1 \middle| \hat{H}_{\mathrm{MD}} \middle| \psi_2 \right\rangle\right|^2$$

In SI units,the Bohr magneton is defined as $\mu_B = e\hbar/(2m_e)$ in units of A $\mathrm{m}^2 = (\mathrm{J/T})$. Thus, the line strength for a magnetic dipole transition is in units of $(\mathrm{J/T})^2$, whereas the line strength for an electric dipole transition is in units of $(\mathrm{C\ m})^2$. To make a direct comparison between electric and magnetic transitions, the line strength must be converted into a transition probability or oscillator strength.

The transition probability for spontaneous emission (also known as the Einstein A coefficient) from the upper state ψ_2 to the lower state ψ_1 may be calculated, in units of inverse seconds, from the magnetic dipole line strength as follows [4, 5]:

$$A_{\mathrm{MD},2\rightarrow 1} = \frac{16\pi^3\mu_0}{3h}\left(\frac{n}{\lambda}\right)^3 \frac{S_{\mathrm{MD}}(\psi_1, \psi_2)}{g^2}$$

O

where all terms are in SI units, μ_0 is the permeability of vacuum, n is the refractive index of the host medium, λ is the free-space wavelength, and g_2 is the degeneracy of the initial upper state. (Note that this equation explicitly includes the n^3 dependence of magnetic dipole emission in an isotropic dielectric medium [6].)

The line strength may also be related to the oscillator strength f, a dimensionless quantity often used to compare absorption lines. (The oscillator strength is defined as the ratio of the absorption likelihood for a given transition to that of a single-electron classical harmonic oscillator.) The oscillator strength for the magnetic dipole transition from the lower state ψ_1 to the upper state ψ_2 can be calculated as follows [6, 7]:

$$f_{\mathrm{MD},\,1\to2} = \frac{8\pi^2 m_e}{3he^2c}\left(\frac{n}{\lambda}\right)\frac{S_{\mathrm{MD}}(\psi_1,\psi_2)}{g_1}$$

where all terms are in SI units, and where g_1 is the degeneracy of the initial lower state.

As an overview of such calculations, the following provides a brief example for the 588 nm magnetic dipole transition in Eu^{3+} between the $^5D_0$ ($L = 2$, $S = 2$, $J = 0$) and $^7F_1$ ($L = 3$, $S = 3$, $J = 1$) levels. (This magnetic dipole line is clearly observable in the emission of fluorescent lights.) Based on the selection rules for pure LS coupling in Table 1, it would appear that this transition ($\Delta L = 1$, $\Delta S = 1$, $\Delta J = 1$) should not be allowed. However, it is important to note that the electronic states of most Lanthanide ions are generally described by the *intermediate coupling* configuration of N valence electrons in the $4f$ orbital [5–8]. (Since neither the spin-orbit nor Coulombic interactions dominate, the electronic eigenvectors must be found by diagonalizing the sum of the spin-orbit and Coulombic Hamiltonian matrices. For Lanthanide ions, this is often done in the LS basis by mixing terms of the same J value, with the mixed levels named according to the dominant LSJ component.) Analysis of experimental spectra can be combined with group theory calculations (Racah algebra) to expand the free-ion wave function $|4f^N\psi_J\rangle$ into a basis set of LS coupling levels $|4f^N\alpha SLJ\rangle$ as follows [5–8]:

$$\left|4f^N\psi_J\right\rangle = \sum_{\alpha,S,L} C(\alpha,S,L)\left|4f^N\alpha SLJ\right\rangle$$

where $C(\alpha, S, L)$ is the intermediate coupling coefficient, S is the total spin angular momentum, L is the total orbital angular momentum, J is the total angular momentum, and the term α includes all other quantum numbers required to describe the levels. To emphasize the mixed nature of these levels, brackets are sometimes used around the LS term in naming the dominant component; this notation also emphasizes that the J value outside the bracket is still a good quantum number. For example, the $[^5D]_0$ level in the intermediate coupling of the $4f^6$ configuration of Eu^{3+} includes significant ^5D and ^7F terms, while the $[^7F]_1$ level includes ^7F, ^5P, ^5D, and ^5F terms [9]:

$$\begin{aligned}\left|\left[^5\mathrm{D}\right]_0\right\rangle = {} & -0.2381\left|^7\mathrm{F}_0\right\rangle \\ & -0.1969\left|^5\mathrm{D}_0\right\rangle + 0.6893 \\ & \times\left|^5\mathrm{D}'_0\right\rangle - 0.539\left|^5\mathrm{D}''_0\right\rangle\end{aligned}$$

$$\begin{aligned}\left|\left[^7\mathrm{D}\right]_1\right\rangle = {} & 0.9742\left|^7\mathrm{F}_1\right\rangle - 0.0027\left|^5\mathrm{P}_1\right\rangle + 0.0052 \\ & \times\left|^5\mathrm{D}_1\right\rangle + 0.1472\left|^5\mathrm{D}'_1\right\rangle - 0.1645\left|^5\mathrm{D}''_1\right\rangle \\ & + 0.0263\left|^5\mathrm{F}_1\right\rangle + 0.0162\left|^5F'_1\right\rangle\end{aligned}$$

where the prime terms on the right-hand side are used to denote levels with different Racah parameters (W, U).

To calculate the line strength between these levels, the contributions from each LS basis term to the transition matrix element must be summed and then squared [5, 8]:

$$\begin{aligned}S_{\mathrm{MD}} &\equiv \left|\left\langle f^N\psi_{J'}\middle|\hat{H}_{\mathrm{MD}}\middle|f^N\psi_J\right\rangle\right|^2 \\ &= \left|\sum_{\alpha'S'L',\,\alpha SL} C(\alpha',S',L')C(\alpha,S,L)\left\langle 4f^N\alpha',S',L'J'\middle|\hat{H}_{\mathrm{MD}}\middle|4f^N\alpha SLJ\right\rangle\right|^2\end{aligned}$$

In the *LS* basis, the only nonzero matrix elements in the summation will be those transitions which obey the magnetic dipole selection rules ($\Delta L = 0$, $\Delta S = 0$, $\Delta J = 0, \pm 1$). For the example case of Eu^{3+}, this means that the line strength can be expressed in terms of just two matrix elements [8]:

$$S_{MD}\left(Eu^{3+}:{}^7F_1 \leftrightarrow {}^5D_0\right) \equiv \left|\left\langle [{}^7F]_1 \middle| \hat{H}_{MD} \middle| [{}^5D]_0 \right\rangle\right|^2 = \left|-0.2320\langle {}^7F_1|\hat{H}_{MD}|{}^7F_0\rangle + 0.1891\langle {}^5D_1|\hat{H}_{MD}|{}^5D_0\rangle\right|$$

where the ^5D contribution in the above expression has been simplified to include all Racah terms, (i.e., $0.1891 = -0.1969 \times 0.0052 + 0.6893 \times 0.1472 + 0.539 \times 0.1645$).

The magnetic dipole matrix element between pure *LS* terms, $^{2S+1}L_J$ and $^{2S+1}L_{J'}$, can be explicitly calculated for the three allowed cases ($J' = J - 1$, $J' = J$, and $J' = J + 1$) as follows [5, 7, 8]:

$$\left\langle {}^{2S+1}L_J \middle| \hat{H}_{MD} \middle| {}^{2S+1}L_{J-1} \right\rangle = (-\mu_B) \times \sqrt{\frac{(S+L+J+1)(S+L+1-J)(S-L+J)(L-S+J)}{4J}}$$

$$\left\langle {}^{2S+1}L_J \middle| \hat{H}_{MD} \middle| {}^{2S+1}L_J \right\rangle = (-\mu_B) \times \sqrt{J(J+1)(2J+1)} \left(1 + \frac{J(J+1) + S(S+1) - L(L+1)}{2J(J+1)}\right)$$

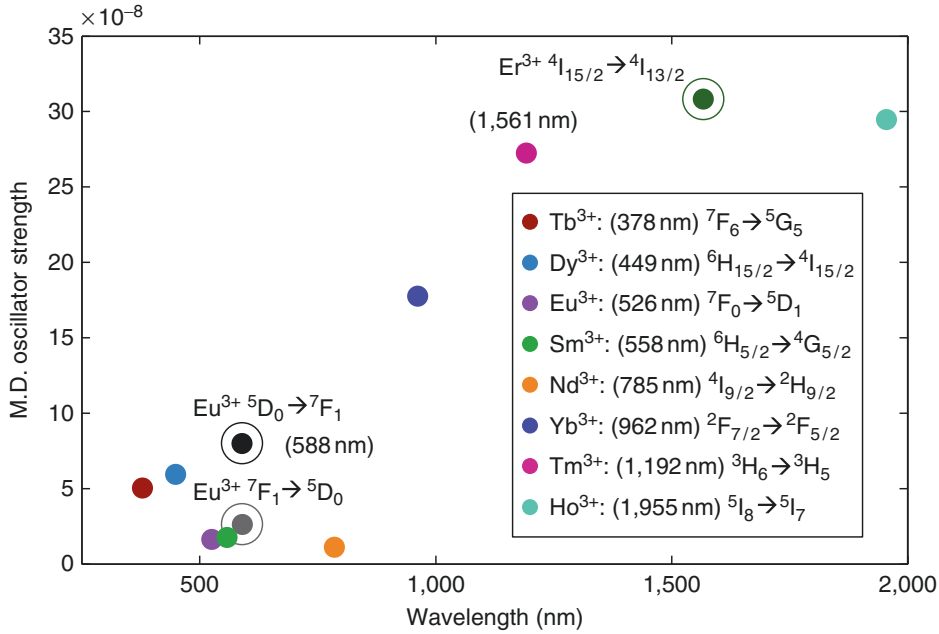
$$\left\langle {}^{2S+1}L_J \middle| \hat{H}_{MD} \middle| {}^{2S+1}L_{J+1} \right\rangle = (-\mu_B) \times \sqrt{\frac{(S+L+J+1)(S+L-J)(S-L+J+1)(L-S+J+1)}{4(J+1)}}$$

Using the above expressions, the magnetic dipole line strength for the $^7F_1 \leftrightarrow {}^5D_0$ transition in Eu^{3+} can be calculated as follows:

$$\left\langle {}^7F_1 \middle| \hat{H}_{MD} \middle| {}^7F_0 \right\rangle = -\mu_B 2\sqrt{3}$$

$$\left\langle {}^5D_1 \middle| \hat{H}_{MD} \middle| {}^5D_0 \right\rangle = -\mu_B \sqrt{6}$$

$$S_{MD}\left(Eu^{3+}:{}^7F_1 \leftrightarrow {}^5D_0\right) = 0.1159\mu_B^2$$



with which the spontaneous emission rate from $^5D_0 \rightarrow {}^7F_1$ and the oscillator strength for absorption from $^7F_1 \rightarrow {}^5D_0$ can be calculated based on the degeneracy $g = 2J + 1$ of the initial state:

$$A_{MD}\left(Eu^{3+}:{}^5D_0 \rightarrow {}^7F_1\right) = \frac{16\pi^3\mu_0}{3h}\left(\frac{n}{\lambda}\right)^3 \frac{0.1159\mu_B^2}{2(0)+1} = 15.4n^3 s^{-1}$$

$$f_{MD}\left(Eu^{3+}:{}^7F_1 \rightarrow {}^5D_0\right) = \frac{8\pi^3 m_e}{3he^2c}\left(\frac{n}{\lambda}\right)\frac{0.1159\mu_B^2}{2(1)+1} = 2.66 \times 10^{-8} n$$

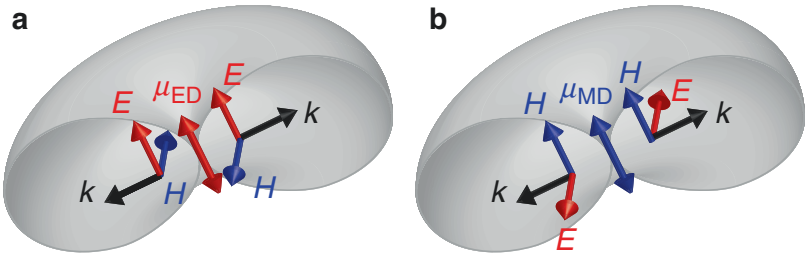
As a reference, Fig. 2 presents the calculated magnetic dipole oscillator strength for a number of Lanthanide ion transitions throughout the visible and near-infrared portion of the electromagnetic spectrum. Although these values may appear small, there are three important considerations that enhance the significance of these terms. First, most observable quantities scale with the product of the oscillator strength and oscillator density, and since these are single ion oscillator strengths, it is possible to pack many ions into a small volume. Second, these values are comparable to the electric dipole oscillator strengths in Lanthanide ions. For example, the electric dipole oscillator strength for the Er^{3+}: $^4I_{15/2} \rightarrow {}^4I_{13/2} \sim 1{,}550$ nm transition is on the order of 2×10^{-6} in vacuum [5]. Third, the magnetic dipole transition probability increases

O

Optical Frequency Magnetic Dipole Transitions, Fig. 2 Lanthanide Magnetic Dipole Transitions in the Visible and Near-Infrared Regime. Absorption line oscillator strength values labeled in the legend box are taken from Carnall et al. [10]. $^7F_1 \rightarrow {}^5D_0$ absorption and $^5D_0 \rightarrow {}^7F_1$ emission lines in Eu^{3+} calculated using eigenvectors from Ofelt [9]. $^4I_{15/2} \rightarrow {}^4I_{13/2}$ absorption line in Er^{3+} calculated using eigenvectors from Weber [5] (all values are based on free-ion calculations in vacuum; within a dielectric host, the oscillator strengths would increase by a factor of n)

significantly with host refractive index. This means that light emission from the 1,550 nm line ($^4I_{13/2} \rightarrow {}^4I_{15/2}$) in Er^{3+} doped LaF_3 is calculated to be 41 % magnetic dipole emission ($A_{MD} = 37.6/s$, $A_{ED} = 54/s$) [5].

Radiation from Electric and Magnetic Dipole Emission



Light emitted by an electric dipole transition can be modeled by the radiation from an oscillating classical electric dipole, i.e., a time-varying infinitesimal current source $\vec{j}\left(\vec{r}, t\right) = \mathrm{Re}\left\{-i\omega\mu_{ED}\exp(-i\omega t)\delta\left(\vec{r}\right)\hat{n}\right\}$. The direction of the oscillation defines the dipole moment orientation ($\hat{n}$), while its frequency defines the frequency of emitted electromagnetic radiation. For an electric dipole moment located at the origin and oriented along the z-axis $\vec{\mu}_{ED}(t) = \mathrm{Re}\{\mu_{ED}\exp(-i\omega t)\hat{z}\}$, the electromagnetic fields in the radiation zone ($kr \gg 1$) are given in spherical coordinates as [2]:

$$\vec{E}_{ED} = E_\theta\hat{\theta} = -\frac{|\mu_{ED}(t)|\sin\theta}{4\pi\varepsilon_r\varepsilon_0}\frac{k^2}{r}e^{ikr}\hat{\theta}$$

$$\vec{H}_{ED} = H_\phi\hat{\phi} = -\sqrt{\frac{\varepsilon_r\varepsilon_0}{\mu_r\mu_0}}\frac{|\mu_{ED}(t)|\sin\theta}{4\pi\varepsilon_r\varepsilon_0}\frac{k^2}{r}e^{ikr}\hat{\phi}$$

where θ is the polar angle measured from the z-axis, ϕ is the azimuthal angle, and $k = (\omega/c)n$ is the wave number in a homogenous dielectric medium with refractive index $n = \sqrt{\varepsilon_r\mu_r}$.

Light emitted from a magnetic dipole transition, on the other hand, resembles the radiation from an oscillating classical magnetic dipole, i.e., a time-varying infinitesimal current loop. The current loop creates a magnetic dipole moment in the direction normal to its surface. For a magnetic dipole moment located at the origin and oriented along the z-axis $\vec{\mu}_{MD}(t) = \mathrm{Re}\{\mu_{MD}\exp(-i\omega t)\hat{z}\}$,

Optical Frequency Magnetic Dipole Transitions, Fig. 3 Schematic representation of fields and radiation pattern emitted by an electric dipole (**a**) and a magnetic dipole (**b**)

the electromagnetic fields in the radiation zone ($kr \gg 1$) are [2]:

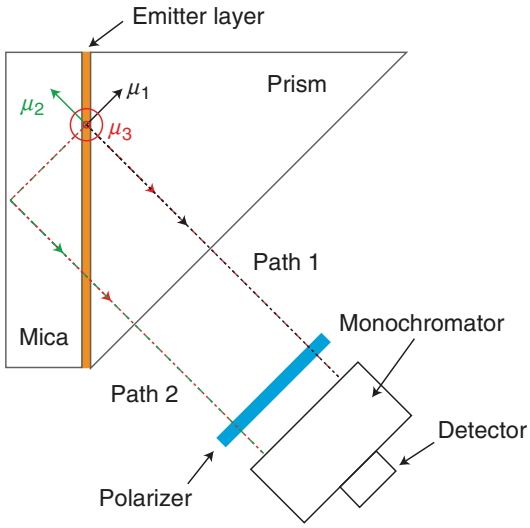
$$\vec{E}_{\mathrm{ED}} = E_\phi \hat{\phi} = -\sqrt{\frac{\mu_r \mu_0}{\varepsilon_r \varepsilon_0}} \frac{|\mu_{\mathrm{ED}}(t)| \sin\theta}{4\pi} \frac{k^2}{r} e^{ikr} \hat{\phi}$$

$$\vec{H}_{\mathrm{ED}} = H_\phi \hat{\phi} = -\frac{|\mu_{\mathrm{ED}}(t)| \sin\theta}{4\pi} \frac{k^2}{r} e^{ikr} \hat{\theta}$$

The radiation pattern for electric and magnetic dipoles in the far-field can be obtained by calculating the time-averaged Poynting vector, $\left\langle \vec{S} \right\rangle = \frac{1}{2}\mathrm{Re}\left\{ \vec{E} \times \vec{H}^* \right\}$:

$$\left\langle \vec{S}_{\mathrm{ED}} \right\rangle = \frac{c}{n} \frac{|\mu_{\mathrm{ED}}|^2 \sin^2\theta}{32\pi\varepsilon_r\varepsilon_0} \frac{k^4}{r^2} \hat{r}$$

$$\left\langle \vec{S}_{\mathrm{ED}} \right\rangle = \frac{n}{c} \frac{|\mu_{\mathrm{MD}}|^2 \sin^2\theta}{32\pi\varepsilon_r\varepsilon_0} \frac{k^4}{r^2} \hat{r}$$



The fields and radiation patterns of electric and magnetic dipole emitters are shown in Fig. 3. It can be seen that both the electric and magnetic dipoles have the same $\sin^2(\theta)$ radiation pattern (shown in gray), but differing field symmetries. While the electric field radiated by an electric dipole has even symmetry with respect to the dipole location, the electric field radiated by a magnetic dipole has odd symmetry. In fact, all the magnetic dipole relations can be obtained from the electric dipole relations by the following transformations [2]:

$$\vec{E}_{\mathrm{ED}} \rightarrow \vec{H}_{\mathrm{MD}} \sqrt{(\mu_r\mu_0)(\varepsilon_r\varepsilon_0)},$$
$$\vec{E}_{\mathrm{ED}} \sqrt{(\mu_r\mu_0)(\varepsilon_r\varepsilon_0)} \rightarrow$$
$$-\vec{E}_{\mathrm{MD}}, \text{and } \mu_{\mathrm{ED}} \rightarrow \mu_{\mathrm{ED}}(n/c).$$

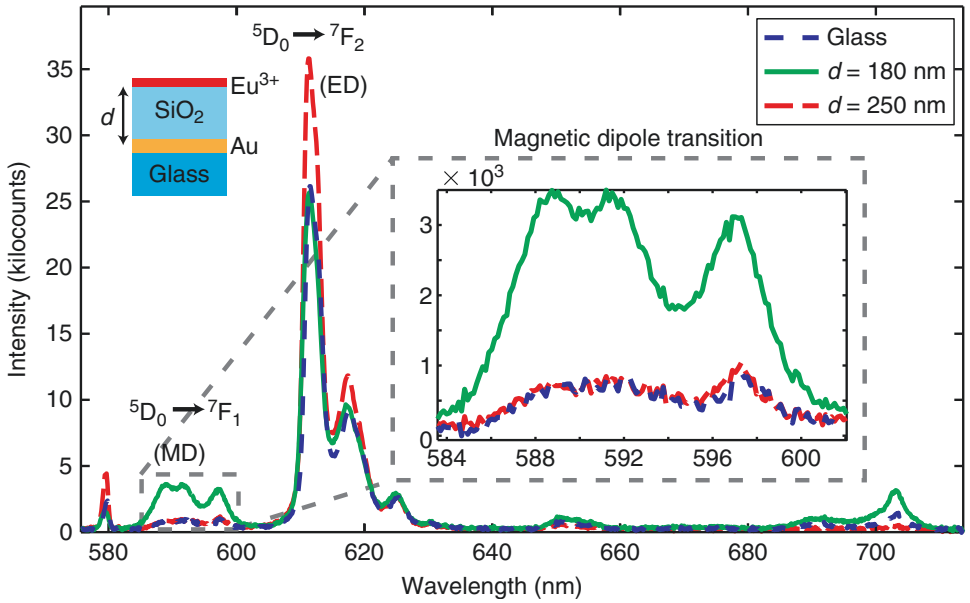
Identify Magnetic Transitions

Despite similar radiation patterns, magnetic and electric dipole emitters have different symmetries with respect to polarization as shown in Fig. 3. Measuring this polarization difference has been the prevalent method to experimentally distinguish electric and magnetic dipole radiation. In atomic gases, the Zeeman effect has been used to lift the degeneracy of the energy states and map the polarization of radiative transitions between different energy states with respect to the applied magnetic field direction [11]. In condensed matter systems, polarization differences combined with interference effects have been used to identify electric and magnetic dipole transitions [11–13].

Figure 4 shows the wide-angle interference experiment first used by Selenyi to confirm the dipole nature of light emission [12]. A very thin layer of emitters (thickness < wavelength of emission) is placed between a prism and thin (~10 μm think) sheet of mica. Assuming that light is emitted by either electric or magnetic dipole transitions, one can decompose all emission into the three orthogonal dipole orientations shown in Fig. 4 as μ_1, μ_2 and μ_3. Light emitted from these dipolar emitters can reach the detector (originally a photographic film) either directly (via path 1) or after reflection from the air–mica interface (via path 2). Since a dipole emitter does not emit in the direction of the dipole orientation, a dipole oriented as μ_1 (μ_2) will only emit via path 1 (path 2). However, a dipole oriented along μ_3 will emit via both paths and interfere at the detector. Thus, any observed interference is due solely to the μ_3 oriented dipole component of emission, and the introduction of a linear polarizer into the detection path allows one to identify whether the dipole is electric or magnetic in nature. For light emitted by an electric dipole oriented along μ_3, the electric field is polarized out-of-plane, whereas for a magnetic dipole oriented along μ_3, the electric

Optical Frequency Magnetic Dipole Transitions, Fig. 4 Wide-angle interference setup used to identify dipolar emission lines

field is polarized in-plane. Thus, when light is emitted by a pure electric dipole, one sees interference fringes for an out-of-plane oriented polarizer, and no fringes for an in-plane oriented polarizer. This was the original experiment performed by Seleyni [12]. On the other hand, when light is emitted by a pure magnetic dipole, one sees interference fringes for an in-plane-oriented polarizer and no fringes for an out-of-plane-oriented polarizer. This was the modified experiment used by Freed and Weissmann to demonstrate that the 588 nm emission in Eu^{3+} (from the $^5D_0 \rightarrow {}^7F_1$ line) is predominantly a magnetic dipole transition [13].



Applications

For decades, Lanthanide ions have served as important light emitters in a broad range of optical technologies from lighting and color displays to solid-state lasers and fiber-optic amplifiers. For example, Eu^{3+} and Tb^{3+} are common red and green phosphors in fluorescent light bulbs and phosphorescent white-light LEDs. Er^{3+} sensitized with Yb^{3+} is the gain media for 1,550 nm fiber amplifiers used in telecommunication networks.

Interestingly, the same shielded electronic structure that makes Lanthanide ions highly efficient (high quantum-yield) light sources also makes them ideal magnetic dipole emitters. Due to the filling rules for electron energy levels, the valence 4*f* electrons in Lanthanide ions are shielded by complete 5 *s* and 5*p* orbitals [6]. These closed shells protect excited electrons from non-radiative scattering events, thereby increasing the likelihood of radiative decay. This shielding also provides the time necessary to observe "forbidden" intra-4*f* magnetic dipole transitions. Although they are not always discussed in the literature, magnetic dipole transitions make significant contributions to the 543 nm line in Tb^{3+}, 980 nm line in Yb^{3+}, and 1,550 nm line in Er^{3+}.

Lanthanide emitters and their magnetic dipole transitions have also played a major role in the study of fundamental light-matter interactions. Drexhage used Eu^{3+} in his pioneering research on modified spontaneous emission near planar interfaces [14]. These studies were among the first detailed demonstrations of the Purcell effect at optical frequencies. Building on this work, Kunz and Lukosz observed clear distinctions in the modified emission rates and radiation patterns of the electric and magnetic dipole transitions in Eu^{3+} near interfaces [15]. These differences, based on self-interference effects, result from the different field symmetries of electric and magnetic dipole emitters. More recently, Eu^{3+} has been used to study local field effects and test the validity of different cavity models for electric and magnetic dipole transitions [16].

The electric and magnetic dipole transitions in Eu^{3+} have also been used extensively by physical chemists to investigate material properties. For example, the $^5D_0 \rightarrow {}^7F_1$ magnetic dipole transition has been used to probe crystal- and ligand-field effects in different host matrices [6]. In addition, the ratio between electric and magnetic dipole emission has been used to gauge the local symmetry. Unlike the $^5D_0 \rightarrow {}^7F_1$ magnetic dipole transition which is only weakly dependent on the host matrix, the $^5D_0 \rightarrow {}^7F_2$ is a hypersensitive electric dipole transition that requires a noncentrosymmetric ion site. Similarly, due to the relative

Optical Frequency Magnetic Dipole Transitions, Fig. 5 Modified emission spectra of Eu^{3+}chelate thin films at varying distances from a planar gold mirror. *Dashed blue line* shows reference spectra on a glass substrate without the gold mirror. Magnetic dipole emission is enhanced when Eu^{3+} ions are separated from the mirror by 180 nm spacer layer of SiO_2 (*green line*), whereas electric dipole emission is enhanced by a 250 nm spacer layer (*dashed red line*)

independence of the $^5D_0 \rightarrow {}^7F_1$ magnetic dipole transitions rate on the local chemical environment, it has been used as an internal reference to infer the quantum efficiency of Eu^{3+} in different materials [17].

Future Directions for Research

With the advent of metamaterials that support artificial magnetic resonances, there has been renewed interest in the natural magnetic resonances of Lanthanide ions. For example, Thommen and Mandel recently proposed that the electric and magnetic dipole transitions in Lanthanides could be used to realize homogeneous materials with simultaneously negative permittivity and permeability [18]. Their calculations suggest that an Er^{3+} doped crystal (i.e., a simple homogenous medium without the need for nanofabrication) could exhibit tunable, negative index response by using a weak magnetic field to split the degenerate electric and magnetic dipole transitions in the $\sim$ 1,550 nm $^4I_{15/2} \rightarrow {}^4I_{13/2}$ line. They also suggested other mixed transitions, including the 5 μm $^4I_{9/2} \rightarrow {}^2I_{11/2}$ transition in Nd^{3+} and the 470 nm $^5I_8 \rightarrow {}^3K_8$ transition in Ho^{3+}, that could support similar effects. Although their proposal has several practical limitations in terms of operating temperature, ion concentrations, and bandwidth, it nevertheless highlights one potential application of natural magnetic dipole transitions in the field of metamaterials. Another proposed application is the use of magnetic dipole transitions as local probes for optical frequency magnetic fields. Noginova and colleagues have suggested that the modified spontaneous emission from the $^5D_0 \rightarrow {}^7F_1$ magnetic dipole transition in Eu^{3+} could be used to study metamaterials and their optical frequency artificial magnetic resonances [19].

Modifying the spontaneous emission of magnetic dipole transitions also holds promise for new ways to tune and modulate Lanthanide-based light sources. By exploiting the coupled nature and differing field symmetries of electric and magnetic dipole transitions in Eu^{3+}, recent work has shown how self-interference effects in this

multilevel system can be used to selectively enhance electric and magnetic dipole emission [20]. By controlling the distance between a thin film of Eu^{3+} chelates and a planar gold mirror, these experiments demonstrated a greater than fourfold enhancement in the emission intensity of the $^5D_0 \rightarrow {}^7F_1$ magnetic dipole transition. This strong magnetic dipole enhancement, as shown in Fig. 5, results from self-interference effects that simultaneously inhibit the competing $^5D_0 \rightarrow {}^7F_2$ electric dipole transition while enhancing the magnetic dipole transition. Karaveli and Zia [20] show how simple optical structures can be used to tune emission spectra in multilevel ions with distinct electric and magnetic transitions, such as Eu^{3+}, and also suggest that similar structures could be used to tune emission polarization in multilevel ions with degenerate electric and magnetic transitions, such as the 1,550 nm line in Er^{3+}.

Definition

The optical properties of metal nanoparticles are governed by collective excitation of the conduction electrons. The electrons oscillate coherently under irradiation by light in the visible and near-IR regions of the electromagnetic spectrum. These coherent oscillations are known as local surface plasmon resonances. The wavelength of excitation of the plasmon resonances shows strong variation with the size, shape, and dielectric environment of the particles. Modeling this variation by solving Maxwell's equations for the interaction of light with the nanoparticles provides a useful tool for the design and interpretation of experiments. The entry describes traditional analytical and numerical methods used to solve Maxwell's equations, and it presents representative results of calculations using these methods. Firstly, electrostatic methodologies are discussed and applied to the modeling of spheres, shells, and ellipsoids with dimensions considered in the quasistatic (small particle limit) regime. Mie theory is then introduced and used to model the full electromagnetic optical solution for a sphere with dimensions considered outside of the quasistatic regime. Finally, the numerical methodology of the discrete dipole approximation technique is introduced and implemented to model the optical properties of gold rods and prisms with varying aspect ratios.

Overview

The field of plasmonics aims to exploit the unique optical properties of metallic nanostructures to control and manipulate light at the nanoscale. The optical response of these structures is unique because, unlike dielectrics, metals have a negative dielectric function, which upon irradiation with light, enables them to support collective electron excitations known as localized surface plasmon resonances (LSPR) [1, 2]. As the name suggests, these resonances exist between the metal surface and the surrounding dielectric, and not only produce extinction cross sections that exceed their geometric cross sections, but also produce extremely high local electric field intensities. One of the enormous advantages of plasmonic nanoparticles lies in the ability to tune the position of their LSPR from the visible (in the case of gold spheres) to the infrared (IR) part of the spectrum (in the case of anisotropic particles such as gold rods and prisms). Moreover, changing the geometry of the nanostructure allows unprecedented control over the location and magnitude of the concentrated electric fields on the surface of the nanoparticle itself. Further control can be achieved by varying the polarization of the incident light with respect to nanostructure geometry. This has motivated abundant interest in the synthesis of geometrically varying nanometallic structures such as spheres, rods, triangular prisms, and a plethora of other anisotropic particles where the aim is to produce monodisperse particles with precise control over the wavelength of their highly absorbing or scattering LSPR. This capability to control LSPR wavelength is important to a variety of technologies for chemical and biological sensing, where the change of wavelength in the presence of analytes provides the sensing modality. In addition, control of LSPR wavelength is also useful in surface-enhanced Raman scattering (SERS)

studies, where enhanced fields at the surfaces of the nanoparticles leads to enhanced Raman scattering that can be used to identify adsorbed molecules.

Electrodynamic modeling, i.e., solving Maxwell's equations [3] for the interaction of light with the nanoparticles, contributes significantly to the development of this research because the optical response of these particles is well described with classical (continuum) theory. This allows the calculation of the particle extinction cross sections, in other words how much light is absorbed and scattered by the particle, as well as the plasmonically enhanced electric field that is important in SERS.

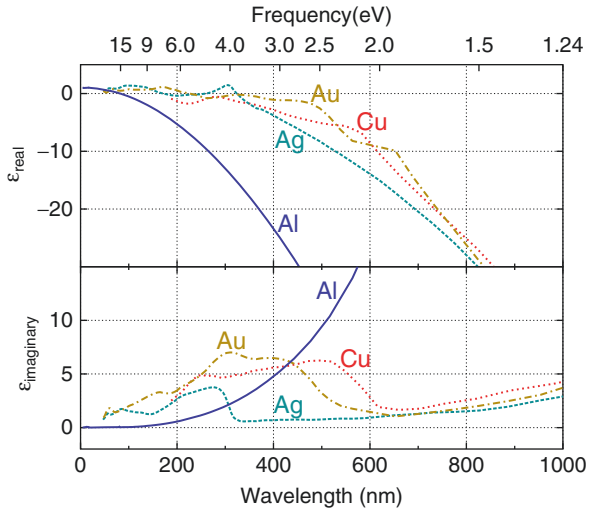
This entry will focus on both analytical and numerical methods that are used to model the electrodynamic properties of noble metal nanoparticles. Only isolated nanoparticles are considered in this discussion, but it should be noted that arrays of nanoparticles, as well as other nanostructures such as nanostructured metal films are also of great interest to the plasmonics field.

The choice of using either an analytical or a numerical method to solve Maxwell's equations depends on the geometry of the particle to be considered. Spherically symmetric particles such as spheres can be modeled using an analytical solution based on Mie [4] theory. On the other hand, anisotropic particles such as rods and prisms need to be modeled using numerical, grid-based methods such as the discrete dipole approximation (DDA) [5] or the finite-difference time-domain (FDTD) [6] method. This pedagogical entry will focus specifically on the standard Mie and DDA methods because they are both extremely versatile and very well known within the electrodynamics community. The Mie, DDA, and FDTD (and other) methods have advantages and disadvantages over one another, and for further details on these techniques as well as applications that extend beyond what one could describe as the "standard" use of the techniques, the authors refer the reader to the following citations [7, 8].

Section "The Dielectric Function" details the Drude model, which is used to describe the dielectric function of metals, particularly the dependence of the dielectric function on frequency, leading to a simple analytical description for the origin of plasmon resonances, and the dependence of resonance frequency on particle structure. Section "Analytical Methods to Solve Maxwell's Equations" describes the mathematical basis behind the electrostatic analytical techniques used to model the extinction spectra of spheres, shells (coated spheres), and ellipsoids. The full electromagnetic solution (Mie theory) for a sphere is also described in this section. Finally, in section "Numerical Methods to Solve Maxwell's Equations," the mathematical formalism of the numerical DDA method is detailed and applied to calculate the optical properties of gold rods and triangular prisms.

The Dielectric Function

The electromagnetic response of metal particles is governed by the dielectric function of the metal from which they are made. A commonly used model for the complex dielectric function, ($\varepsilon = \varepsilon_{\text{real}}^{\text{Drude}} + i\varepsilon_{\text{imaginary}}^{\text{Drude}}$) of a free-electron gas was described by Drude [1] using:



$$\varepsilon_{\text{real}}^{\text{Drude}}(\omega) = 1 - \frac{\omega_{\text{p}}^2}{\omega^2 + \gamma^2} \tag{1a}$$

$$\varepsilon_{\text{imaginary}}^{\text{Drude}}(\omega) = 1 - \frac{\omega_{\text{p}}^2 \gamma}{\omega(\omega^2 + \gamma^2)} \tag{1b}$$

Here the plasma frequency, ω_{p}, determines the dispersion characteristics of the metal and can be determined from the density of free electrons, N, using

$$\omega_{\text{p}} = \sqrt{\frac{Ne^2}{\varepsilon_0 m_{\text{e}}}} \tag{2}$$

where e is the charge on the electron, m_{e} is electron mass, and ε_0 the permittivity, or dielectric function, of free space. The damping constant, γ, describes the way electrons scatter off ions, other electrons, defects, grain boundaries, and interfaces in the system. The real part of the dielectric function describes the motion of the free and

Optical Properties of Metal Nanoparticles, Fig. 1 Experimentally measured dielectric functions of aluminum, copper, silver, and gold. Aluminum exhibits pure Drude behavior, albeit with a large electron–phonon scattering component (large γ). Copper and gold have interband transitions in the visible (which appear as deviation from Drude behavior in $\varepsilon_{imaginary}$) giving them their distinct bulk colors. Silver has interband transitions in the ultraviolet

bound charges in a material. The imaginary part describes the energy *loss* mechanisms in the sample. The loss mechanisms can be broadly cast into two categories: the first category is frequency independent terms, which include electron–phonon, electron–defect, and electron-surface scattering. The electron-surface scattering term can be included as an addition to the experimentally measured dielectric function to account for the finite size of the nanoparticle. This is important when the mean free path of the electrons is approximately greater than the size of the nanoparticle. These frequency independent terms can be included in the Drude phenomenological scattering rate [2]:

$$\gamma = \gamma_{\text{phonon}} + \gamma_{\text{defect}} + \gamma_{\text{surface}}(a) \qquad (3)$$

where a is the size of the particle. The frequency dependent mechanisms include electron–electron scattering (which for metals is quite small compared to the electron–phonon scattering term) and interband transitions. Interband transitions occur when the incident photon excites an electron from an occupied to unoccupied state in the metal. Since interband transitions are not well modeled using a Drude function, the total experimental dielectric function is usually decomposed into a Drude contribution and an interband contribution:

$$\varepsilon^{\text{experimental}}(\omega) = \varepsilon^{\text{Drude}}(\omega) + \varepsilon^{\text{interband}}(\omega) \qquad (4)$$

Figure 1 shows the experimental dielectric functions for aluminum, copper, silver, and gold. In the UV and visible, aluminum exhibits pure Drude character with no interband transitions. Gold and copper have a large interband contribution in the visible, giving them their distinct bulk colors. The interband transitions in silver occur in the UV, and hence bulk silver is highly reflective across the visible.

Properties of Resonances in Terms of the Dielectric Function

When a photon in vacuum impinges on a flat surface with a negative permittivity and low loss (imaginary permittivity), it is reflected unless certain boundary conditions are met. By introducing surface roughness, a grating, or a prism onto the surface, the boundary conditions are modified and allow for the excitation of surface plasmon polaritons (SPP). The SPP manifests as a free-electron charge oscillation that propagates along the surface of the metal.

For metal nanoparticles, the geometry of the particle defines boundary conditions for Maxwell's equations that allow for excitation of local surface plasmon resonances (LSPRs). In this case, the free charges in the particle are displaced from equilibrium by the incident photon. A restoring force arises from the attraction of the electrons to the now positively charged ions. The extent of the displacement, and hence the restoring force, depends on the geometry of the particle and the real part of the dielectric function of the metal. When the motion of the electrons in the particle and the applied field are out of phase by $\pi/2$, all of the energy contained in the applied field can be used to accelerate the electrons, creating a resonance. To maintain causality, the imaginary part of the dielectric function of the metal must always be positive (i.e., it takes finite time for the electrons to respond to the incident field). This positive value introduces a phase lag between the oscillating electrons and the applied field. This limits the rate at which energy can be coupled into the nanoparticle, determining the maximum field strength and the maximum extinction cross section.

It is common to describe the portion of light that interacts with a particle by calculating the extinction *efficiency*. This is the extinction cross section [1] ($C_{\text{ext}} = C_{\text{abs}} + C_{\text{sca}}$, with C_{abs} and C_{sca} the absorption and scattering cross sections, respectively) normalized to the cross-sectional area, A, of the nanoparticle ($C_{\text{ext}}/A = Q_{\text{ext}} = Q_{\text{abs}} + Q_{\text{sca}}$). The importance of scattering versus absorption depends heavily on the application of interest. For plasmonic heating applications, such as photothermal therapy [9], the absorption efficiency determines all of the important properties of the system, and scattering should be minimized to avoid wasting energy. However, for SERS and surface-enhanced fluorescence, the total extinction should be maximized. This is because the total field in the vicinity of the particle is comprised of the absorption limited evanescent field which decays exponentially with distance from the surface, and the radiating or scattered field, which couples energy out of the system.

Analytical Methods to Solve Maxwell's Equations

The Quasistatic Approximation

For particles very much smaller than the wavelength of light, the applied field is effectively constant over the surface of the particle. Because the field is assumed to be spatially uniform but oscillatory in time, this regime is called "quasi"-static. This neglect of retardation not only simplifies Maxwell's equations, but also simplifies the analysis of the general properties of LSPRs for a variety of particle shapes. In particular, for each shape and polarization direction, there is a value of the dielectric function that allows for the excitation of a LSPR. In the quasistatic approximation, this resonance condition only depends on the wavelength through the dielectric function.

Spheres in the Quasistatic Limit: A Derivation

As an example of the simplicity of the quasistatic approximation, a summary is provided of the derivation of the polarizability of a small sphere of radius a with a dielectric function of the form with a dielectric function of the form $\varepsilon = \varepsilon_1 + i\varepsilon_2$, embedded in a non-absorbing medium with dielectric constant ε_{m}. Such a derivation can be found in many electrodynamics text books; here the derivation follows Ohanian [10]. The fundamental equation of quasistatics is Laplace's equation, $\nabla^2\Phi = 0$, where Φ is the scalar potential. For the sphere in a medium, it is appropriate to introduce two scalar potentials, one inside the particle, $r < a$, and the other outside the particle, $r > a$. Omitting the azimuthal angle ϕ (for symmetry reasons), the fields associated with these potentials are:

$$\mathbf{E}_1 = -\nabla\Phi_1(r,\theta), \qquad \mathbf{E}_2 = -\nabla\Phi_2(r,\theta) \quad (5)$$

where the subscript 1 indicates inside and 2 indicates outside the sphere. These potentials obey Laplace's equation in the region in which they are defined:

$$\nabla^2\Phi_1(r, < a, \theta) = 0, \quad \nabla^2\Phi_2(r > a, \theta) = 0 \quad (6)$$

In order to extract useful information from these equations, the scalar potential is required

to satisfy several boundary conditions. The normal component of the electric displacement field ($\mathbf{D} = \varepsilon\mathbf{E}$) must be continuous across the boundary of the particle, and so the following boundary condition is introduced:

$$\varepsilon \frac{\partial \Phi_1}{\partial r}\bigg|_{r=a} = \varepsilon_{\mathrm{m}} \frac{\partial \Phi_2}{\partial r}\bigg|_{r=a} \tag{7}$$

Analogously, the parallel component of the electric field must be continuous at the boundary. This boundary condition is included in the more general expression:

$$\Phi_1(a,\theta) = \Phi_2(a,\theta) \tag{8}$$

The final boundary condition is that the potential outside the particle must reduce to the potential of the incident field at an infinite distance from the sphere (here assuming that the polarization is along the z axis):

$$\lim_{r\to\infty} \Phi_2(r,\theta) = -E_0 r\cos(\theta) \tag{9}$$

Solutions of Laplace's equation in spherical coordinates take the form of the Legendre Polynomials, P_n, of order n:

$$\begin{aligned}\Phi_1(r,\theta) &= \sum_{n=1}^{\infty} B_n r^n P_n(\cos(\theta)),\\ \Phi_2(r,\theta) &= -E_0 r\cos(\theta) + \sum_{n=1}^{\infty} A_n \frac{P_n(\cos(\theta))}{r^{n+1}}\end{aligned} \tag{10}$$

where the coefficients A and B are unknown. Substituting Eq. 10 into the boundary conditions (7) and (8) provides two sets of linear equations:

$$\begin{aligned}&\varepsilon_{\mathrm{m}}\left(-E_0\cos(\theta) + \sum_{n=1}^{\infty}(n+1)A_n\frac{P_n(\cos(\theta))}{a^{n+2}}\right)\\ &\quad = \varepsilon\sum_{n+1}^{\infty} nB_n a^{n-1}P_n(\cos(\theta))\end{aligned} \tag{11}$$

and

$$\begin{aligned}&-E_0 a\cos(\theta) + \sum_{n=1}^{\infty} A_n \frac{P_n(\cos(\theta))}{a^{n+1}}\\ &\quad = \sum_{n=1}^{\infty} B_n a^n P_n(\cos(\theta))\end{aligned} \tag{12}$$

Solving A_1 in terms of the incident field $(-E_o\cos(\theta))$ forces all the higher-order terms to be zero, and gives the following potentials:

$$\Phi_1(r<a,\theta) = -E_0 r\cos(\theta)\frac{3\varepsilon_{\mathrm{m}}}{\varepsilon + 2\varepsilon_{\mathrm{m}}} \tag{13a}$$

$$\Phi_2(r>a,\theta) = -E_0 r\cos(\theta)\left(1 - \frac{a^3}{r^3}\frac{\varepsilon - \varepsilon_{\mathrm{m}}}{\varepsilon + 2\varepsilon_{\mathrm{m}}}\right) \tag{13b}$$

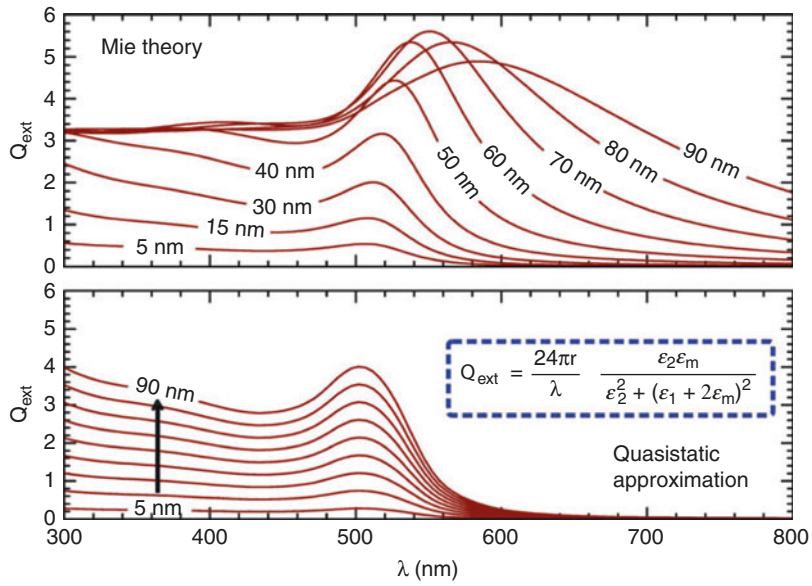
The second term in Eq. 13b is the potential associated with a point dipole. Combining this with Eq. 5, the field outside the particle can be written:

$$\mathbf{E}_2 = \mathbf{E}_{\mathrm{inc}} + \mathbf{p} = \mathbf{E}_{\mathrm{inc}} + \alpha\mathbf{E}_{\mathrm{inc}} \tag{14}$$

This gives the polarizability of the sphere in the background medium:

$$\alpha = 4\pi a^3 \frac{\varepsilon - \varepsilon_m}{\varepsilon + 2\varepsilon_m} \tag{15}$$

There are also higher-order solutions that arise when terms in the incident field higher than the constant term are included. By solving the A_2 term for the incident field, the so-called quadrupole mode is excited. These higher-order resonances are discussed in the following section.



To determine the extinction and scattering cross sections of the sphere described by Eq. 15, the following relations are introduced:

$$C_{\mathrm{ext}} = k\mathrm{Im}(\alpha) \tag{16a}$$

$$C_{\mathrm{sca}} = \frac{k^4}{6\pi}|\alpha|^2 \tag{16b}$$

where $k = 2\pi/\lambda$ is the wavenumber in the medium and λ is the wavelength. Equation 16a is only valid in the limit of small scattering, and so it is sometimes written $C_{\mathrm{abs}} = k\mathrm{Im}(\alpha)$ [1]. To

O

Optical Properties of Metal Nanoparticles, Fig. 2 A comparison of the extinction efficiency of gold nanospheres in vacuum using (*top panel*) Mie's fully retarded solution to Maxwell's equations and (*bottom panel*) the quasistatic approximation. The spectra are labeled with the particle radius

determine the extinction efficiency of the nanosphere, the real and imaginary parts of the dielectric function are substituted into Eq. 15, and then the imaginary part is selected:

$$\alpha = 4\pi a^3 i \frac{3\varepsilon_2 \varepsilon_m}{\varepsilon \frac{2}{2} + (\varepsilon_1 + 2\varepsilon_m)^2} \tag{17}$$

Substituting this into Eq. 16 and dividing by the cross section (πa^2) gives:

$$Q_{\text{ext}} = \frac{24\pi a}{\lambda} \frac{\varepsilon_2 \varepsilon_m}{\varepsilon_2^2 + (\varepsilon_1 + 2\varepsilon_m)^2} \tag{18}$$

This expression has several interesting properties. The extinction efficiency grows larger for increasing sphere radius and contains no information about the range of particle radii for which it is valid. On resonance, the real part of the dielectric function is just $\varepsilon_1 = -2\varepsilon_m$. At the resonance wavelength, λ_p, the strength of the resonance is limited by how small the imaginary part of the dielectric function is, and how large the medium index is. This can be seen by substituting $\varepsilon_1 = -2\varepsilon_m$ into Eq. 18, which, after simplifying, gives:

$$Q_{\text{ext}} = (24\pi a/\lambda)(\varepsilon_m/\varepsilon_2) \tag{19}$$

Figure 2 shows the extinction efficiency of gold nanospheres of increasing radius in vacuum ($\varepsilon_m = 1$). To assess the size regime where the quasistatic approximation is valid, the fully retarded Mie solution is also included (Mie theory is discussed in the next section). There is a strong resonance at around 500 nm and a tail that extends into the UV. The resonance at 500 nm is the dipolar LSPR, which occurs when $\varepsilon_1 = -2$. The UV tail is caused by interband transitions in this region of the spectrum (see Fig. 1). As predicted by Eq. 18, increasing the particle size in the quasistatic approximation proportionally increases the extinction efficiency.

Nanospheres: A Fully Retarded Solution to Maxwell's Equations

Figure 2 shows that the quasistatic approximation predicts the resonance position to within 20 nm for particles with radii up to about 40 nm. Beyond $a = 40$ nm, retardation of the field plays a role in the resonance position and causes a red-shift of the LSPR. To fix this, Mie theory is used: An analytical solution to Maxwell's equations for spheres that was developed by Gustav Mie in 1908 [4]. It fully describes the effects of retardation, including radiative damping and higher-order multipole resonances.

In a generalization of Mie's solution, the extinction and scattering efficiencies are described in terms of a size parameter $x = 2\pi a/\lambda$ and two coefficients a_n and b_n, which cover electric and magnetic partial waves of multipole order n: [1]

$$Q_{\text{ext}} = \frac{2}{x^2}\sum_{n=1}^{\infty}(2n+1)\text{Re}[a_n + b_n] \tag{20a}$$

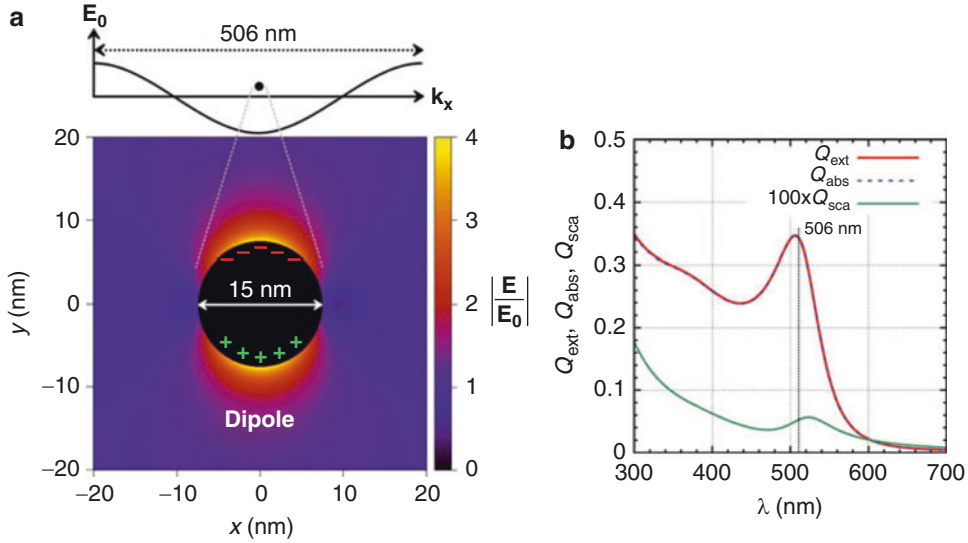
$$Q_{\text{sca}} = \frac{2}{x^2}\sum_{n=1}^{\infty}(2n+1)\left(|a_n|^2 + |b_n|^2\right) \tag{20b}$$

The coefficients are given by:

$$a_n = \frac{m\psi_n(mx)\psi_n'(x) - \psi_n(x)\psi_n'(mx)}{m\psi_n(mx)\xi_n'(x) - \xi_n(x)\psi_n'(mx)} \tag{21a}$$

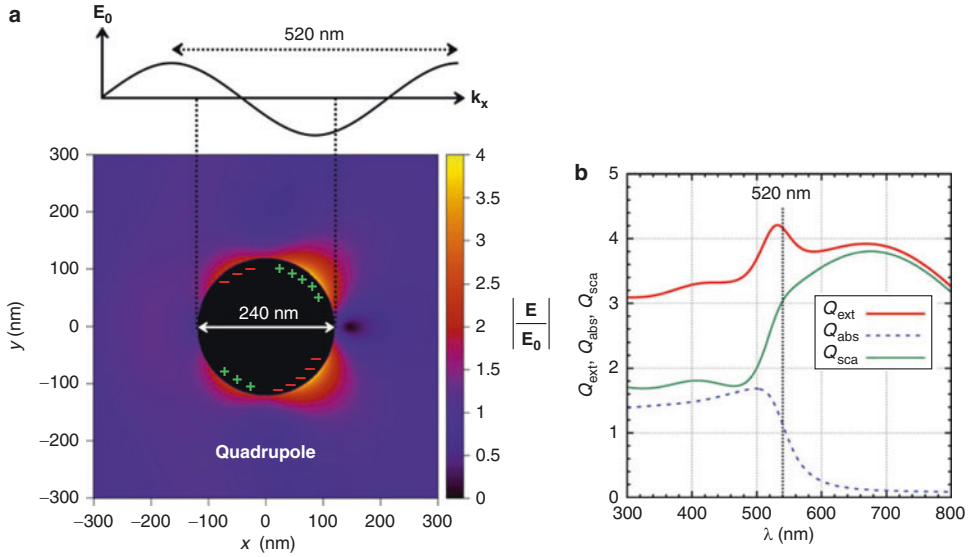
$$b_n = \frac{\psi_n(mx)\psi_n'(x) - m\psi_n(x)\psi_n'(mx)}{\psi_n(mx)\xi_n'(x) - m\xi_n(x)\psi_n'(mx)} \tag{21b}$$

where ψ_n and ξ_n are spherical Ricatti–Bessel functions and primes indicate taking a derivative with respect to the argument. The resonance condition is now much more complex in the sense that it is an explicitly size-dependent quantity, even for the dipole mode ($n = 1$). Bohren and Huffman [1] developed a "finite size correction" to adjust the position of the resonance given by the quasistatic approximation. The general principle is that when the denominator of Eq. 21a goes to zero, a surface plasmon is excited. So, by expanding the Ricatti–Bessel functions to order x^2, an additional term appears that can easily be added into Eq. 18. The result is:



$$Q_{\text{ext}} = \frac{24\pi a}{\lambda}\frac{\varepsilon_2\varepsilon_m}{\varepsilon_2^2 + (\varepsilon_1 + 2\varepsilon_m + 12x^2/5)^2} \tag{22}$$

It is clear that this additional term slowly red-shifts the resonance as the particle size is increased. Including a term proportional to x^3 in the denominator in Eq. 22 leads to a theory called the Modified Long Wavelength approximation [11] in which the plasmon is both shifted and broadened with increasing particle size. These are general features of all nanoparticle plasmonics: Larger particles have red-shifted and broadened resonances. This is evident in Fig. 2, and the broadening is usually ascribed as due to radiative effects where the energy incident on the particle is re-emitted (i.e., scattered) with a high enough rate that plasmon excitation is partially quenched.



So far the quadrupole ($n = 2$) and higher-order resonances that appear for larger particles have not been discussed. Figures 3 and 4 show the fields around a small (7.5-nm radius) and large (120-nm radius) gold sphere. For the small sphere, the only mode that appears is the dipole mode, as discussed in the quasistatic regime. In this case, the field on the surface of the sphere is almost 90° out of phase with the incident wave, and a large portion of the photon energy is used to accelerate the electrons (this can be seen in Fig. 3b, by comparing the absorption and scattering efficiencies). The large sphere exhibits two modes: a red-shifted, broadened dipole mode at a wavelength of 670 nm and a quadrupole mode at around 520 nm. The dipole mode is broadened due to radiative effects as noted above. For the quadrupole mode, half of the particle is polarized parallel to the incident photon, and half is polarized antiparallel. Both include a phase factor that is not quite 90°. It is easy to assume that this might only occur when the diameter of the particle is comparable to half the wavelength. However, this is not the case and multipole solutions exist even for small particles, they are just dwarfed by the strength of the dominant dipole mode and do not appear in spectra.

Shifting the Surface Plasmon Resonance Wavelength

In the previous section, it was noted that increasing the size of a nanoparticle red-shifts the surface plasmon resonance. As the radius of a sphere is increased, the extinction efficiency passes through a maximum for some finite radius (compare the extinction for 70 and 80 nm spheres in Fig. 2). Beyond this critical radius, radiative depolarization reduces the resonance strength. However, there are a number of other methods for shifting the surface plasmon resonance to the red that do

Optical Properties of Metal Nanoparticles, Fig. 3 (**a**) The strength of the electric field around a 7.5-nm-radius gold particle in vacuum. The relative size of the particle is given compared to the wavelength in the upper panel. At this size, the incident electric field is effectively constant across the particle. (**b**) The extinction, scattering, and absorption efficiencies of the sphere in (**a**). The extinction spectrum is dominated by absorption. The scattering efficiency has been scaled by a factor of 100 to aid visibility; it contributes very little to the total extinction

Optical Properties of Metal Nanoparticles, Fig. 4 (**a**) The electric field around a 120-nm-radius gold particle in vacuum. The particle size is compared to the incident wavelength in the upper panel. Because there is significant variation of the incident field across the surface of the sphere, it is possible to excite a quadrupole mode. (**b**) The extinction, scattering, and absorption efficiencies of the sphere in (**a**). The extinction is dominated by scattering in this size regime

not involve radiative effects. For spheres, the only alternative to increasing the radius is to embed the sphere in a background medium of high refractive index. Alternative, nonspherical particle geometries can be used to red-shift the plasmon wavelength, including nanoshells, nanorods, nanocubes, and nanotriangular prisms. In the following sections, the effects of increasing the refractive index of the medium into which a sphere is embedded are discussed, followed by an examination of quasistatic results for nanoshells and nano-ellipsoids. From there, more complicated structures are introduced; those where analytic solutions are not available. In some cases, the quasistatic limit is not applicable to the particle size regime of interest, and so numerical solutions to Maxwell's equations are investigated.

Firstly, returning to the polarizability of a sphere in the quasistatic limit. There are two equivalent resonance conditions for Eq. 17. The first is the usual way, the frequency is scanned across the spectrum and a resonance occurs when:

$$\varepsilon_1(\omega) = -2\varepsilon_m \tag{23}$$

Alternatively, the background medium index can be varied to coincide with the real part of the dielectric function at a given frequency:

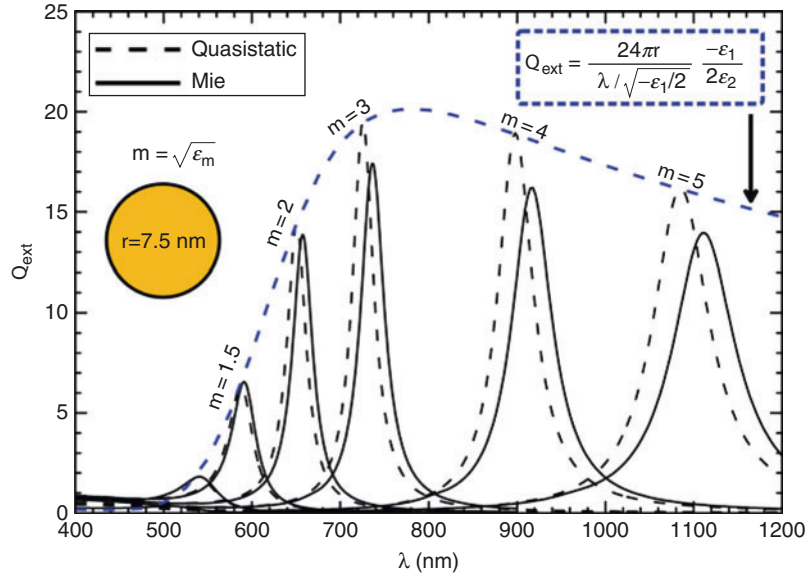
$$\varepsilon_m = -\frac{\varepsilon_1(\omega)}{2} \tag{24}$$

This second resonance condition allows one to determine the general properties of the resonance. By substituting Eq. 22 into Eq. 17, the polarizability reduces to:

$$\alpha = 4\pi a^3 i \frac{-3\varepsilon_1}{2\varepsilon_2} \tag{25}$$

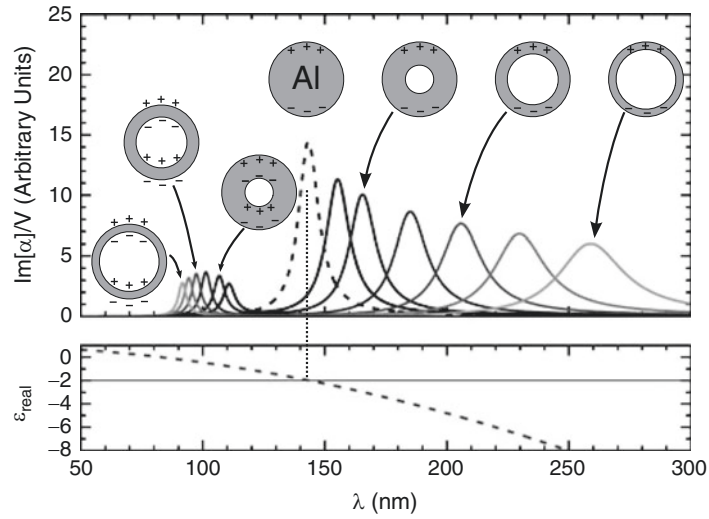
This expression determines the height of the resonance assuming that the medium index can be matched to the permittivity. To explain this further, Fig. 5 shows expression (25) as well as the traditional expression (18) and the full Mie solution for 7.5 nm gold spheres embedded in materials with increasing medium index. The trend shows that for gold, the extinction efficiency is maximized when the medium refractive index is $m = 3$ (materials such as mercury sulfide have a refractive index this high).

Shells in the Quasistatic Limit



Unlike spheres, nanoshells exhibit two fundamental resonances in analogy to the bonding and antibonding orbitals in molecules [12]. The symmetric dipole like mode shifts from the sphere resonance condition at $\varepsilon_1 = -2\varepsilon_m$ toward the red as the shell thickness decreases. The second mode is an antisymmetric mode that is blue shifted from the sphere resonance. The polarizability of a nanoshell with a core with a dielectric constant ε_c is given by:

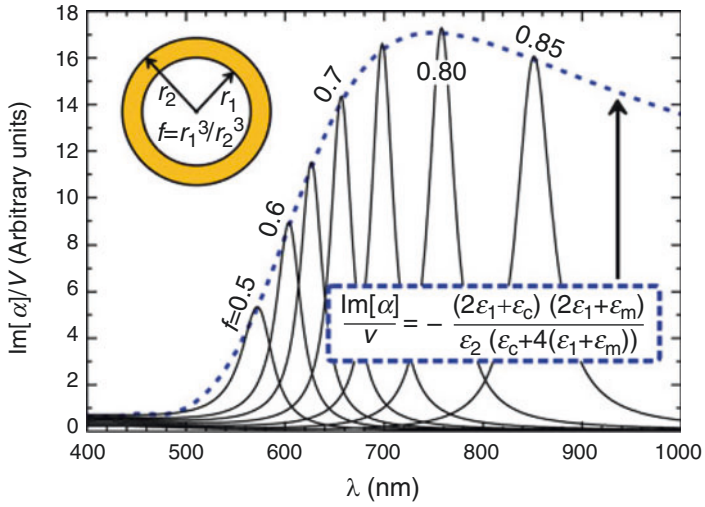
$$\alpha = V\frac{(\varepsilon_s - \varepsilon_m)(\varepsilon_c + 2\varepsilon_s) + f(\varepsilon_c - \varepsilon_s)(\varepsilon_m + 2\varepsilon_s)}{(\varepsilon_s + 2\varepsilon_m)(\varepsilon_c + 2\varepsilon_s) + 2f(\varepsilon_s - \varepsilon_m)(\varepsilon_c - 2\varepsilon_s)} \tag{26}$$



where $f = r_1^3/r_2^3$ is the fraction of the volume occupied by the core (r_1). A schematic of the charge distributions and spectra including both symmetric and antisymmetric resonances for aluminum nanoshells is displayed in Fig. 5. Aluminum was chosen in this case because metals such as gold do not exhibit the blue-shifted resonance due to interband transitions in the region of wavelengths for which $\varepsilon_1 > -2\varepsilon_m$. The red-shifted, symmetric resonance is of much more practical significance, as it allows the plasmon resonance of gold and silver nanoshells to be tuned across the visible spectrum. By changing the shell thickness only marginally, the resonance position can be shifted drastically over a large range of wavelengths. In Fig. 6, the plasmon resonance for gold nanoshells is tuned across the visible by increasing the radius of the core with respect to the shell. Following a similar method that was used for the spheres, an expression can be derived for the general scaling of the plasmon resonance. First, note that a resonance occurs when the denominator of Eq. 24 goes to 0. This can be done by changing the fill factor

$$f = -\frac{(2\varepsilon_m + \varepsilon_1)(\varepsilon_c + 2\varepsilon_1)}{2(\varepsilon_c - \varepsilon_1)(\varepsilon_1 - \varepsilon_m)} \tag{27}$$

O



Optical Properties of Metal Nanoparticles, Fig. 5 The extinction efficiency of gold spheres embedded in media with increasing refractive index. The radius of the particle is fixed at 7.5 nm. The quasistatic solutions (*dashed curves*) are given by Eq. 18, and the general trend (*bold dashed curve*) is given by substituting Eq. 25 into Eq. 16a.; in this expression, the wavelength is considered to be in the high refractive index medium, and hence must be divided by Eq. 24. The Mie solutions (*solid curves*) are red-shifted from the quasistatic solution. The shift is exacerbated in high refractive index media because the wavelength in these media is effectively shorter (increasing radiative effects)

Optical Properties of Metal Nanoparticles, Fig. 6 Hybridization of surface plasmon resonances on aluminum nanoshells. *Top panel*: The polarizability normalized to volume for nanoshells with increasing core radius. Data for a nanosphere is included (*dashed curve*). *Bottom panel*: the real part of the dielectric function of aluminum

until a resonance occurs for a given value of the dielectric function of the metal. The fill factor is a real quantity, and so it cannot contribute to the matching of any term in the resonance condition that is imaginary. As such, the imaginary parts of the dielectric function have been removed. Substituting this solution back into Eq. 24, selecting the imaginary part of the resulting

Optical Properties of Metal Nanoparticles, Fig. 7 The normalized polarizability of gold nanoshells with vacuum cores embedded in vacuum (calculated using Eq. 26). The curves are labeled with their respective fill factors. The dashed curve describes the general trend of the resonance on the nanoshell; however, it is only valid for small values of the core and medium permittivity

expression, and assuming that the background medium and the core have small dielectric constants compared to the real part of the dielectric function results in:

$$\frac{\mathrm{Im}[\alpha]}{V} = \frac{(2\varepsilon_1 + \varepsilon_c)(2\varepsilon_1 + \varepsilon_\mathrm{m})}{\varepsilon_2(\varepsilon_\mathrm{c} + 4[\varepsilon_1 + \varepsilon_\mathrm{m}])} \tag{28}$$

which provides a general trend of how the polarizability (and hence the extinction efficiency) varies as the resonance position shifts to the red. This is also shown in Fig. 7. It is interesting to point out that this expression scales with wavelength in the same way as the expression for a sphere (i.e., compare Figs. 5 and 7).

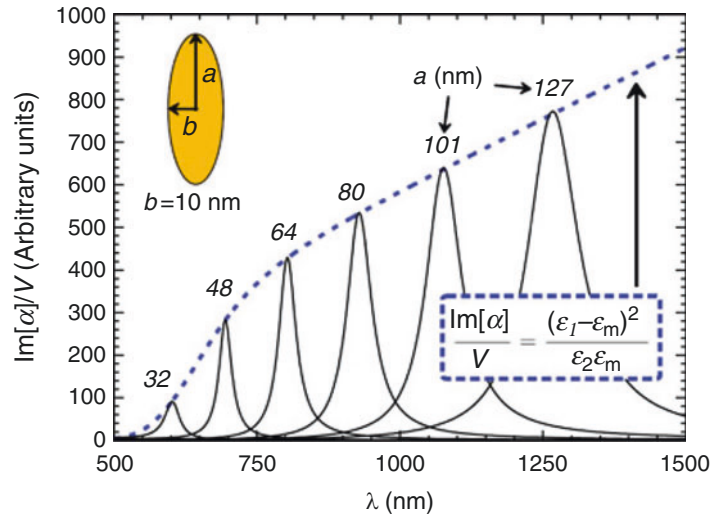
Ellipsoids in the Quasistatic Limit

When the geometry of a nanoparticle is distorted from that of a sphere, additional resonances appear for each axis of the particle which is asymmetric. To simplify the discussion, only prolate, rod-like, spheroids are discussed. A spheroid is an ellipsoid having two equal axes, and in the prolate case, the long axis is the unique axis. For spheroids in the quasistatic limit, two of the three possible plasmon modes are degenerate because the field is assumed constant over the particle. As such, there are two nondegenerate resonances: a red-shifted "longitudinal" mode that occurs along the long axis of the ellipsoid and a blue-shifted "transverse" mode that occurs along the short axis, as first described by Gans [13] in 1912. The polarizability for both axes of the ellipsoid is given by:

$$\alpha_\mathrm{ellipsoid} = V\frac{\varepsilon - \varepsilon_\mathrm{m}}{\varepsilon_\mathrm{m} + L(\varepsilon - \varepsilon_\mathrm{m})} \tag{29}$$

where V is the ellipsoid volume and L is a depolarization factor that depends on the aspect ratio of the ellipsoid (length/width) and the dimension of interest (i.e., $L = L_\mathrm{long}$ or $L = L_\mathrm{trans}$). The depolarization factor for the longitudinal mode is described by: [1]

$$L = \frac{1-e^2}{e^2}\left(-1 + \frac{1}{2e}\ln\frac{1+e}{1-e}\right) \tag{30}$$



where e is the eccentricity of the particle (a is the radius of the long axis, b is the radius of the short axis:

$$e = \sqrt{1 - \left(b^2/a^2\right)} \tag{31}$$

By noting that the sum of the depolarizations on each of the axes must equal 1, and recalling that two of the modes are degenerate, the transverse depolarization can be expressed as:

$$L_\mathrm{trans} = \frac{1 - L_\mathrm{long}}{2} \tag{32}$$

O

Optical Properties of Metal Nanoparticles, Fig. 8 The longitudinal resonance on a gold ellipsoid as a function of length. The short radius is fixed at 10 nm, and the background dielectric constant is fixed at 1. The strength of the resonance grows continuously as it is shifted into the infrared

For a purely ellipsoidal structure, the transverse resonance blue shifts away from the sphere resonance as the length of the rod is increased, or as the width is decreased. So it would seem that for metals such as gold, the transverse resonance would be heavily damped by interband transitions. In reality, the most common experimental structures are actually capped or flat-ended cylinders, and the transverse resonance appears at approximately the same wavelength as the resonance for a sphere. The longitudinal resonance wavelength depends not specifically on the length of the ellipsoid, but instead on the ratio of the length to the width (aspect ratio). This is evident from the relationship in Eq. 29. Figure 8 shows the effect of increasing the aspect ratio of a gold ellipsoid in vacuum, that is, by fixing the width of the ellipsoid and increasing the length. Just as in previous cases, the imaginary part of Eq. 28 has been selected:

$$\frac{\alpha_{\text{ellipsoid}}}{V} = i\frac{\varepsilon_2\varepsilon_{\text{m}}}{\varepsilon_2^2 L_{\text{long}}^2 + \left(\varepsilon_{\text{m}} + L_{\text{long}}(\varepsilon - \varepsilon_{\text{m}})\right)^2}, \tag{33}$$

which is proportional to the extinction efficiency. The longitudinal resonance on the ellipsoid scales in a fundamentally different way to that of a sphere or a nanoshell. The resonance strength does not peak around 750 nm, but instead continues to climb as the resonance is shifted into the infrared. To determine the general properties of the ellipsoid resonance, the denominator of Eq. 29 is set to zero, and solved for L_{long}:

$$L_{\text{long}} = -\frac{\varepsilon_{\text{m}}}{\varepsilon_1 + \varepsilon_{\text{m}}} \tag{34}$$

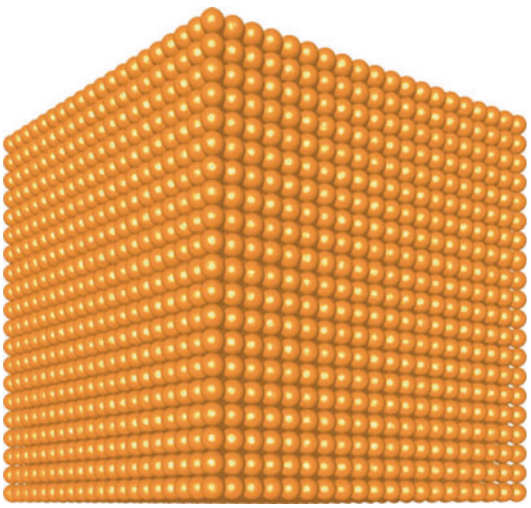
Substituting this back into Eq. 33 gives the general scaling of the resonance:

$$\frac{\alpha_{\text{ellipsoid}}}{V} = i\frac{(\varepsilon_1 - \varepsilon_m)^2}{\varepsilon_2\varepsilon_{\text{m}}} \tag{35}$$

In this case, the polarizability is proportional to the real part of the dielectric function *squared*. Because $|\varepsilon_1| > \varepsilon_2$ for wavelengths up to about 10 μm, the resonance strength will continue to grow rapidly.

Numerical Methods to Solve Maxwell's Equations

The first half of this entry described a variety of analytical expressions which can be used to solve Maxwell's equations and calculate the extinction efficiency and electric fields in the vicinity of spherically or axially symmetric particles. Here the discrete dipole approximation (DDA) is discussed. The DDA is one of the numerical techniques that can be used to model the extinction spectra and electric fields of arbitrarily shaped



particles which are difficult or impossible to determine analytically.

DDA: The Discrete Dipole Approximation Method

The discrete dipole approximation was first developed in 1973 by Purcell and Pennypacker [14] as a numerical technique to calculate the absorption and scattering of electromagnetic radiation by arbitrary-shaped targets. This technique is very popular in the electrodynamics community due to its implementation by Draine et al. into the freely available software package DDSCAT [5].

A benefit of the DDA is that it can be used to model targets that are not spherically symmetric. It does this by representing an arbitrary-shaped target by an array of N dipoles within a cubic grid, an example of which is shown in Fig. 9. Here the target is a 20-nm-edge-length cube with a dipole size of 1 nm and the edges of the cube lie along the x, y, z Cartesian axes.

The polarizability, α_i, of each dipole is then calculated based upon the dielectric function and position within the target r_i. After the dipole polarizabilities have been calculated the target absorption C_{abs} and scattering, C_{sca} cross sections can be calculated as described below [15].

Optical Properties of Metal Nanoparticles, Fig. 9 A 20-nm-edge-length cube target composed of individual 1-nm dipoles, generated by the DDSCAT target generation function

If the index $i = 1, 2, \ldots N$ represents each dipole within a cubic lattice, then upon application of a plane wave field, the induced dipole moment, P_i is given by [16]:

$$P_i = \alpha_i . E_{loc,i} \tag{36}$$

where α_i is the dipole polarizability tensor and the electric field $E_{loc,i}$ is the sum of the incident electric field $E_{inc(r_i,t)}$ and the radiated electric field $E_{dip,i}$ from the surrounding $N-1$ dipoles [16]

$$E_{loc,i} = E_{inc}(r_i, t) + E_{dip,i} \tag{37}$$

with

$$E_{inc}(r_i, t) = E_0 e^{i(kr_i - \omega t)} \tag{38}$$

where E_0 is the amplitude of the electric field, k is the wave vector, r_i is the position vector of the dipole, ω is the angular frequency, and t is time.

$E_{dip,i}$ is the electric field radiated from all dipoles which are not located at index r_i, as given by [16]

$$E_{dip,i} = -\sum_{j \neq i} A_{ij} . P_j \tag{39}$$

This implies

$$E_{loc,i} = E_0 e^{i(kr_i - \omega t)} - \sum_{j \neq i} A_{ij} . Pj \tag{40}$$

Each element A_{ij} is defined by the following equation for an electric field from a radiating or oscillating dipole [16]

$$A_{ij} . P_j = \frac{e^{ikr_{ij}}}{r_{ij}^3} \left\{ k^2 r_{ij} \times (r_{ij} \times P_j) + \frac{1 - ikr_{ij}}{r_{ij}^2} \left[r_{ij}^2 P_j - 3 r_{ij} (r_{ij} . P_j) \right] \right\} \tag{41}$$

where $i \neq j$, and r_{ij} is a vector that points from dipole j to dipole i (and the scalar magnitude of r_{ij} is used where appropriate in Eq. 41).

Substituting Eq. 41 into Eq. 38 and simplifying to find $E_{inc}(r_i, t)$ gives a set of $3N$ complex linear equations [16]

O

$$E_{inc}(r_i,t) = \frac{P_i}{\alpha_i} + \sum_{j\neq i} A_{ij}.P_j \qquad (42)$$

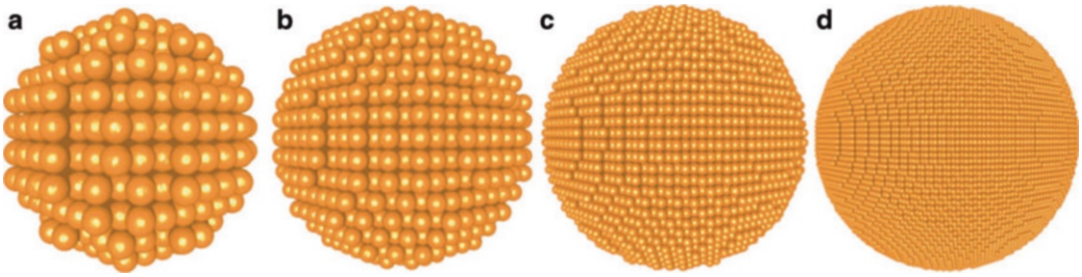
Iterative methods are used to solve this set of linear equations, and the DDSCAT authors provide a choice of three algorithms. For all of the calculations presented here the Biconjugate Gradient with stabilization algorithm has been implemented to solve Eq. 42 for P_i because it is one of the faster and better-behaved algorithms. Once P_i is known, the cross sections C_{abs} and C_{sca} can be calculated from Eqs. 43 and 44, respectively [16].

$$C_{abs} = \frac{4\pi k}{|E_{inc}|^2}.\sum_{i=1}^{N}\left\{\mathrm{Im}\left[P_i.\left(\alpha_i^{-1}\right)^* P_i^*\right] - \frac{2}{3}k^3|P_i|^2\right\} \qquad (43)$$

$$C_{ext} = \frac{4\pi k}{|E_{inc}|^2}.\sum_{i=1}^{N}\mathrm{Im}\left(E_{inc,i}^*.P_i\right) \qquad (44)$$

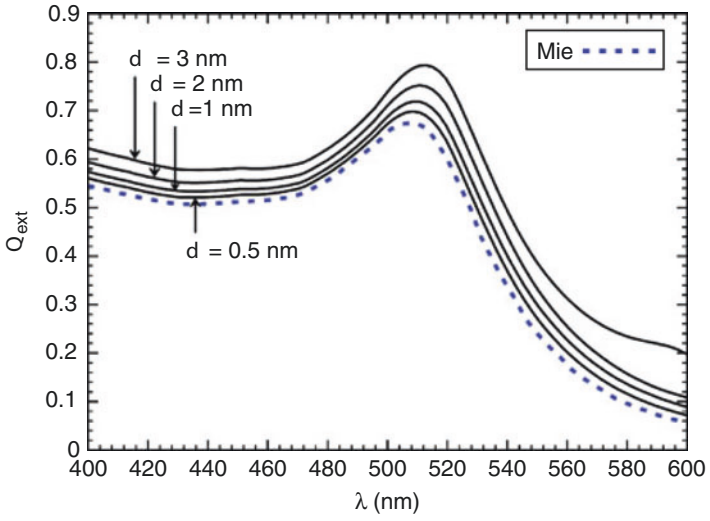
In the first implementation of DDA, the Clausius–Mossotti Relation (CMR) [15] was used to calculate the dipole polarizabilities a_i based upon the complex refractive index m (of the material associated with the ith dipole), such that

$$\alpha_{CMR} = \frac{3d^3}{4\pi}\left(\frac{m^2-1}{m^2+2}\right) \qquad (45)$$



where d is the inter-dipole spacing. This approach is exact in the quasistatic regime; however, it is not exact at finite wavelengths because radiative damping is not taken into consideration in Eq. 45. To overcome this problem, Draine [15] introduced the Lattice-Dispersion-Relation (LDR) which required that the polarizability of dipoles on an infinite lattice give the same dispersion relation as a bulk medium [15]. In the LDR approach, the radiative reaction correction occurs naturally and the polarizability is given by

$$\alpha_{LDR} = \frac{\alpha_{CMR}}{1+\left(\frac{\alpha_{CMR}}{d^3}\right)\left[(b_1+m^2b_2+m^2b_3S)^2(kd)^2 - \left(\frac{2}{3}\right)i(kd)^3\right]} \qquad (46)$$

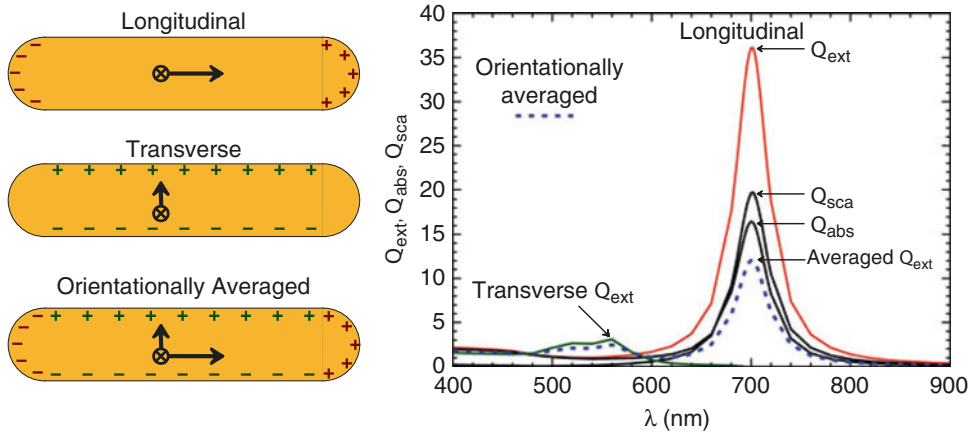


where $b_1 = -1.8915316$, $b_2 = -0.1648469$ and $b_3 = -1.7700004$. S depends on the wave-vector direction and incident polarization and given as $S = \sum_j \left(a_j e_j\right)^2$. a and e are the unit propagation and polarization vectors, respectively, and the directions $j = 1, 2, 3$ correspond to the dipole lattice axes.

The LDR guarantees convergence of the DDA for a homogeneous infinite material; however, its applicability to light interacting with nanoparticles is based on experience and testing of convergence. An example of convergence testing can be seen below, where both Mie theory (exact solution to Maxwell's equations) and DDA (with varying dipole spacings) are used to calculate the extinction spectrum of a 30-nm-diameter gold sphere. Dielectric data from Johnson and Christy [17] for gold in vacuum was used for both sets of calculations. For the DDA method, the 30-nm-diameter sphere was represented with four different dipole spacings, namely, 3 nm (sphere A, 552 dipoles), 2 nm (sphere B, 1,792 dipoles), 1 nm (sphere C, 14,328 dipoles), and 0.5 nm (sphere D, 113,104 dipoles). Schematic figures showing the increased dipole numbers within the sphere, as generated by the DDSCAT target generator, can be seen in Fig. 10.

Comparison of the extinction efficiencies calculated using both Mie theory and DDA are shown in Fig. 11. It can be seen that the spectrum for the sphere with a dipole spacing of 3 nm is not converged with the exact Mie spectrum as only 552 dipoles are used to represent this target structure. As the dipole spacing is reduced from 3 to 1 nm, providing a concomitant increase in the number of dipoles within the sphere target, the spectra start to show convergence with that calculated using Mie theory. Decreasing the dipole spacing to 0.5 nm increases the number of dipoles within the target sphere over 200 times (113, 104); however, convergence of the spectrum to the same peak position and magnitude to the exact Mie spectrum is never quite achieved. Indeed, DDA is not guaranteed to be exact as noted above, but, in practice, the quality of comparisons between

Optical Properties of Metal Nanoparticles, Fig. 10 DDSCAT target generated representation of a 30-nm-diameter gold sphere with decreasing dipole sizes of 3 nm (sphere A), 2 nm (sphere B), 1 nm (sphere C), and 0.5 nm (sphere D)

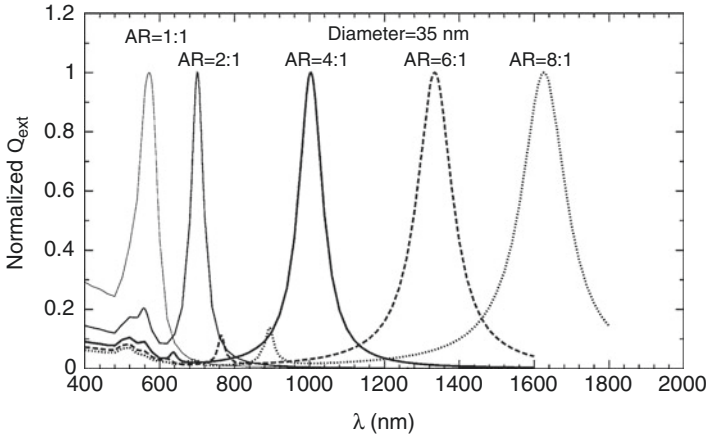


Optical Properties of Metal Nanoparticles, Fig. 11 Calculated extinction spectra of a 30-nm-diameter gold particle in vacuum. Results using both Mie theory and the DDA method with decreasing dipole spacings are shown here with the aim of showing convergence of the spectra with Mie theory as the dipole numbers are increased

DDA and exact results is comparable to that seen in Fig. 11.

Moreover, although not shown here, achieving convergence of near-field properties such as electric fields is more difficult when compared with far-field properties such as extinction efficiencies due to the rapidly changing nature of the contribution of nearby dipoles to the electric field at the particle surface. Decreasing the dipole spacing does help convergence; however, there is a limit to how small the dipoles can be made because as the number of dipoles within the target increases, so does the computational time (approximately as NlnN), and so a compromise must be met between calculation accuracy and computational expense.

One of the benefits of the DDA method is that the dipoles need only be used to represent the target structure and not the surrounding dielectric medium (no grid points are required to describe the empty space surrounding the target) as this is taken into account by dividing the target dielectric data and the incident wavelength by the medium dielectric data to produce a *relative dielectric function*. This reduces the overall number of dipoles required to describe the target/medium system and helps to reduce computational time. A further benefit is that the DDA method is capable of modeling particles with dimensions where the quasistatic regime does not apply, allowing the calculation of higher-order modes. Specific



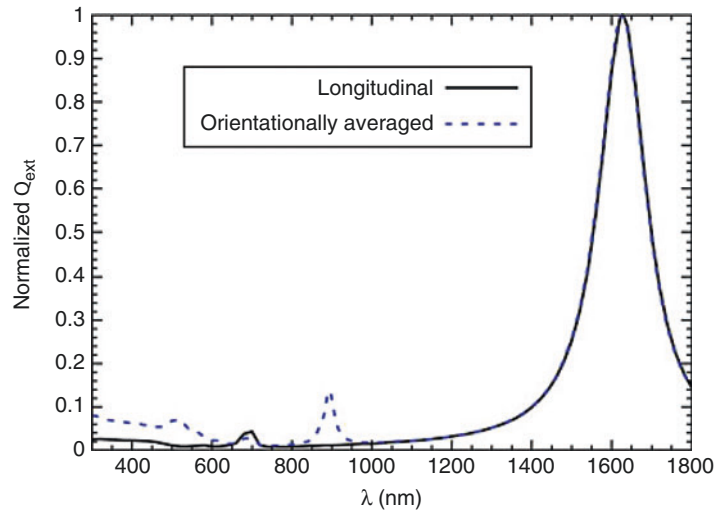
Optical Properties of Metal Nanoparticles, Fig. 12 (*Left*) Schematic depiction of the charge distributions produced when the incident wave vector is perpendicular to the long rod axis with longitudinal (*top rod*), transverse (*center rod*), and orientationally averaged (*bottom rod*) polarizations. (*Right*) The calculated extinction spectra for a 35-nm-diameter, 2:1 aspect ratio rod with different polarizations with the longitudinal mode showing the absorption and scattering contributions

examples will be discussed in the following sections where rods and prisms are modeled.

Implementation of DDA to Calculate the Optical Response of Nanorods

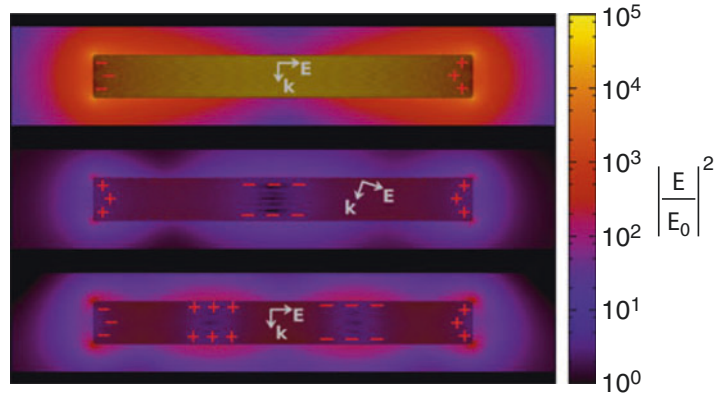
To illustrate the capabilities of the DDA method, here it is used to calculate the optical response of cylindrical gold rods with a constant diameter of 35 nm and increasing aspect ratio. The aspect ratio is defined as the ratio of the rod length to the rod diameter. A dipole spacing of 1 nm was used for all calculations shown here. These rods were modeled to be immersed in water by dividing the incident wavelength and the refractive index of gold, from Frederikse and Weaver [18], by the refractive index of water (1.331) in the DDA calculation. Orientationally averaged calculations were performed to enable all of the resonances (transverse, dipole, and higher order) to be shown. To perform these calculations, the cylindrical rod target was initially assumed to have its long axis along the *y*-axis and its short axis along the *x*-axis of a space-fixed coordinate system. The incident wave vector **k** propagates along the *x*-axis, and polarization was considered along both the *y*- and *z*-axes [19]. The rod was then rotated through 90° in several steps with respect to **k**, and the extinction spectra calculated at each step were combined to generate an orientationally averaged result. Figure 12 (left) shows a schematic depiction of the charge distributions produced within the rod for different polarizations, namely longitudinal; polarized along the long axis (top), transverse; polarized along the short axis (middle) and orientationally averaged; where a combination of polarizations are considered (bottom). The calculated extinction spectra of a 35-nm-diameter, 70-nm-length rod are shown in Fig. 12 (right) with the aim of depicting the variation in extinction spectra produced based on the polarization incident upon the target. The transverse mode is evident between the wavelengths of 500 and 580 nm, while the longitudinal mode is evident at 700 nm. Only the orientationally averaged extinction spectrum shows a combination of both the transverse and longitudinal modes. The scattering efficiency of the longitudinal mode is the dominant component of the extinction efficiency. As the length and diameter of the rod are increased, radiative effects will increase the amount of scattering, and the absorption efficiency will reduce.

Figure 13 shows the calculated orientationally averaged extinction spectra for 35-nm-diameter rods with increasing aspect ratio. The maximum dipole ($n = 1$) extinction value for each rod



Optical Properties of Metal Nanoparticles, Fig. 13 Orientationally averaged extinction spectra of 35-nm-diameter rods with increasing aspect ratios ranging from 1:1 through to 8:1

spectrum has been normalized to 1 purely for clarity purposes. This is necessary as the charge separation along the rod increases as the length of the rod increases allowing the magnitude of the dipole extinction to increase and dwarfing the quadrupole and higher-order resonances of the smaller aspect ratio rods [19]. For example, the 1:1 aspect ratio rod produces a maximum dipole extinction of ~14.5, while the 8:1 aspect ratio rod produces a maximum dipole extinction value of ~51.5.

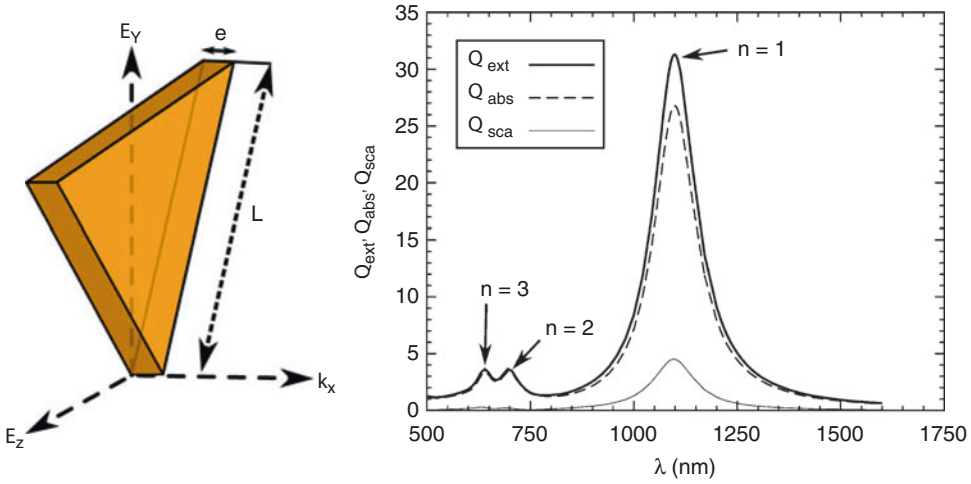


Transverse resonances are evident for the rods with aspect ratios greater than 1:1. These resonances lie in the region between the wavelengths of 500 and 600 nm and are not greatly affected as the aspect ratio of the rod increases as will be described in more detail below. Conversely, it can be seen that the longitudinal dipole resonance red-shifts as the aspect ratio of the rod increases, similar to that described by Gans theory when applied to ellipsoids (see previous section). For example, the rod with an aspect ratio of 2:1 produces a dipole resonance at 581 nm, and increasing the length of the rod to an aspect ratio of 4:1 shifts the dipole resonance to 1,034 nm. A further increase in aspect ratio to 6:1 shifts the resonance to 1,401 nm. These results demonstrate the attractive nature of rods in potential applications that require precise control over the position of the dipole resonance wavelength.

Also evident in Fig. 13 is the presence of higher-order resonances for rods with aspect ratios of 4:1, 6:1 and 8:1. A quadrupole ($n = 2$) resonance is evident at 636 nm for the 4:1 rod and 764 nm for the 6:1 rod. In the case of the 8:1 aspect ratio rod, the quadrupole resonance is evident at 894 nm as well as an octopole ($n = 3$) resonance at 692 nm (more evident in Fig. 14). One of the advantages of using orientationally averaged calculated spectra is that all of the even ($n = 2, 4, \ldots$) and odd ($n = 1, 3, \ldots$) higher-order modes are present because there are no selection rules governing plasmon excitation in this case [19]. In general, the longitudinal plasmons have induced polarizations that are either symmetric or antisymmetric with respect to a 180° rotation of the rod, and only the antisymmetrical resonances can couple if the electric vector of the light (i.e., the polarization vector) is along the rod axis. This leads to the even modes being forbidden for longitudinal polarization, as can be seen more clearly in Fig. 14, where both fixed (longitudinal) and orientationally averaged polarizations were used to model the extinction spectra for the 35-nm-diameter and 280-nm-length (8:1) rod. The quadrupole mode is not evident in the spectrum for fixed longitudinal polarization due to the symmetry of the rod, but the octopole is. Conversely, the orientationally averaged polarization spectrum shows both the quadrupole and octopole higher-order modes.

A more detailed interpretation of the induced charge distributions within the rod for the dipole, quadrupole, and octopole modes can be seen in Fig. 15. Here the $|E|^2$ fields have been calculated for the same 35-nm-diameter, 8:1 aspect ratio rod

Optical Properties of Metal Nanoparticles, Fig. 14 Calculated extinction spectra for a gold 35-nm-diameter, 280-nm-length rod (8:1) with both fixed and orientationally averaged polarizations



Optical Properties of Metal Nanoparticles, Fig. 15 Calculated $|E|^2$ fields for a 35-nm-diameter, 8:1 aspect ratio rod showing the dipole at 1,628 nm (*top*), quadrupole at 894 nm (*middle*), and octopole at 692 nm (*bottom*)

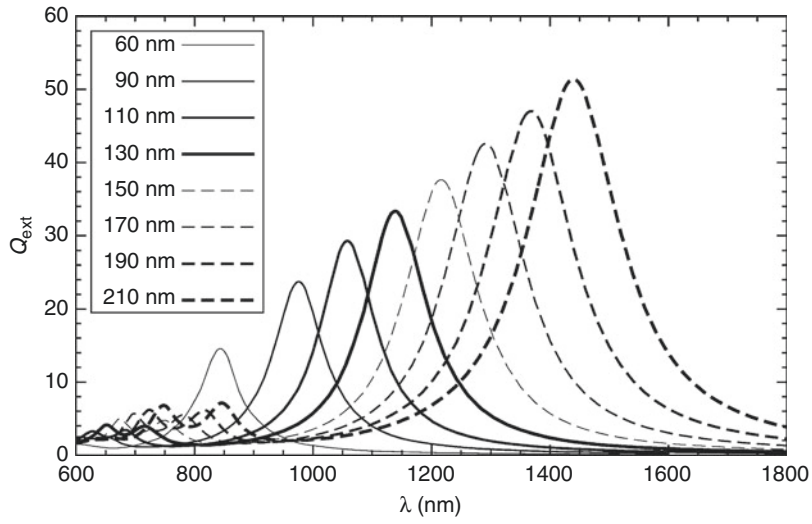
as described in Fig. 14 at the wavelength corresponding to each of the modes with the dipole at 1,628 nm (top), quadrupole at 894 nm (middle), and the octopole at 692 nm (bottom). Although $|E|^2$ does not show the direction of the induced polarization, the figure shows the expected signatures of odd and even symmetry modes, with a nodal surface in the middle of the rod for the 894 nm (even symmetry) mode.

From this it is clear that variation of the incident electric field across the length *and* the width of the particle is necessary to break the selection rules and excite the 894-nm mode. This also follows a similar vein to the production of the quadrupole resonance in a sphere in Fig. 3b.

Implementation of DDA to Calculate the Optical Response of Triangular Prisms

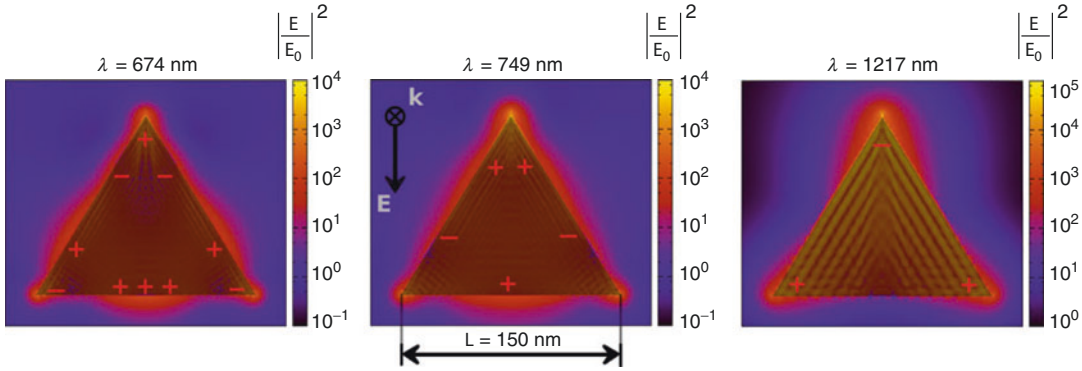
Triangular prisms have been modeled at great length by the electrodynamics research community because, like rods, they allow for the tunability of plasmon resonances as a function of their aspect ratio. Here gold triangular prisms with a thickness of 7 nm and edge lengths of 60, 90, 110, 120, 130, 150, 170, 190, and 210 nm were modeled by DDA (dipole spacing of 1 nm) with the aim of demonstrating how the resonance modes of these particles can be tuned from the visible to the IR by varying the aspect ratio as well as showing the criteria required to produce higher-order resonances. In this case, the aspect ratio of a

Optical Properties of Metal Nanoparticles, Fig. 16 Orientation of the prism with respect to the incident wave vector and polarization (*left*). Calculated spectra of a 120-nm-edge-length, 7-nm-thick (aspect ratio ~17) prism, showing dipole ($n = 1$) and higher-order modes ($n = 2, 3$)



prism is the ratio of the prism length to prism thickness.

All of the prisms were modeled as gold in water using the *relative* dielectric data of Johnson and Christy [17]. The face of the prism was fixed along the *yz*-plane, with the wave vector incident along the *x*-axis and polarization along the *y*-axis, as can be seen in Fig. 16 (left).



The calculated spectrum for a prism of 7-nm thickness and 120-nm edge length (aspect ratio of ~17) is shown in Fig. 15 (right). Absorption is the dominant contribution to the extinction efficiency due to the size of this particle. If the size of the prism were allowed to increase, scattering would become the dominant contribution to the extinction efficiency, as was also the case for spheres and rods. The dipole mode is excited at 1,099 nm, and higher-order modes are also excited at wavelengths of 696 and 640 nm. These higher-order resonances will be described in more detail below. The focus henceforth will center on the dipole resonance.

Figure 17 shows extinction spectra calculated with polarization along the y-axis for 7-nm-thick prisms with edge lengths of 60 nm (aspect ratio ~8.5) through to 210 nm (aspect ratio = 30). Increasing the aspect ratio of the prism causes the dipole plasmon resonance to red-shift due to shape effects. For example, the 60-nm-edge-length prism excites a dipole resonance at 843 nm. Increasing the edge length of this prism to 210 nm allows the production of a dipole resonance in the near-IR part of the spectrum at 1,082 nm. It is not necessary to normalize the maximum extinction values for each spectrum to 1, as was the case for the rod spectra, because the higher-order modes are not dwarfed by the magnitude of the dipole resonances of the larger aspect ratio prisms. This makes it easy to demonstrate nicely how the extinction cross section at the dipole plasmon resonance maximum exceeds the geometrical extinction cross section by approximately 50 times in the case of the 210-nm-edge-length prism. The magnitude of the dipole resonance wavelength increases because the charge separation along the face of the prism also increases as a function of prism edge length (as was the case for the rods).

It can also be seen from Fig. 17 that structures with edge lengths of 90 nm and larger produce higher-order resonances to the blue of the dipole resonance. Higher-order modes are generally produced because of the variation of the incident field within the particle geometry, as described above for the higher-order resonances in rods. Here, in particular, the higher-order modes are excited

Optical Properties of Metal Nanoparticles, Fig. 17 Extinction spectra for prisms oriented as per Fig. 14 (*left*) with a thickness of 7 nm and edge lengths ranging from 60 to 210 nm

Optical Properties of Metal Nanoparticles, Fig. 18 Calculated $|E|^2$ fields for the 150-nm-edge-length prism with a thickness of 7 nm, showing the dipole ($n = 1$) at 1,217 nm (*right*), quadrupole ($n = 2$) at 749 nm (*middle*), and octopole ($n = 3$) at 674 nm (*left*)

with relative ease. However, this is because the prisms have been modeled with sharp edges, as opposed to the slightly rounded edges of synthesized prisms. Sharp prism edges are more conducive to the excitation of higher-order resonances, and it has been shown that rounding of the prism tips lends itself to a reduction of the excitation of higher-order modes as well as a blue-shifting of the dipole resonance.

From the spectra in Fig. 17, the 150-nm-edge-length prism was selected to provide more detailed information on the higher-order modes. The dipole resonance is excited at 1,217 nm, the quadrupole at 749 nm, and the octopole at 674 nm. The calculated $|E|^2$ electric fields were calculated at the wavelength of each of these modes and can be seen in Fig. 18 for polarization along the *y*-axis.

The presence of the + and − symbols on the figures helps indicate the charge distribution excited for each resonance mode. The production of these resonance modes follows a similar vein to those produced in spheres and rods, as described previously. Essentially, the incident electric field could be considered constant across the thickness of the particle due to the prism dimensions, which

allows for excitation of the dipolar mode at 1,217 nm. At shorter wavelengths, the contribution of the electric field of the incident light varies along the edges of the prism. This allows for quadrupole and octopole modes at 749 and 674 nm, even though the incident field does not change sign across the depth of the particle (as is the case for a sphere). Interestingly, the tips of the prisms are associated with the greatest plasmonic electric field enhancement greatest plasmonic electric field enhancement. This has led to these regions on the prisms to be known as "hot-spots." Near these locations, the sensitivity to the dielectric environment, for example, the surrounding solvent, is greater than the "colder-spots" on the prism. These interactions are short-ranged, which means that only molecules within <10 nm of the hot-spot provide high index of refraction sensitivity. On the other hand, the colder regions of the prism, such as the edges and the faces, are less sensitive to the dielectric environment but are longer ranged (up to 30 nm) [20].

Conclusion

This entry focused on understanding plasmon resonance excitation for noble metal nanoparticles, and using analytical and numerical computational techniques to solve Maxwell's equations for the interaction of light with these nanoparticles so as to predict or interpret the properties of the plasmon resonances. The plasmon resonance properties of the nanoparticles were found to be very sensitive to the size, shape, and dielectric environment of the nanoparticles, but electrodynamic modeling is capable of describing these properties accurately. The choice of electromagnetic modeling technique depends strongly on particle geometry and particle size. Quasistatic analytical solutions were presented for particles that were considered small compared to the wavelength of the incident light, in particular spheres, shells and ellipsoids. Quasistatic theory provides a useful approach for relating plasmon resonance wavelength to nanoparticle structure; however, it is only applicable to small particles. For spheres, it is possible to obtain a full electromagnetic solution as described by Mie theory, and this shows that the LSPR wavelength is strongly dependent upon the diameter of the spherical particle, with a broadening of the plasmon resonance width and the production of higher-order modes evident as the particle diameter is increased. The position of the dipole plasmon resonance for both shells and ellipsoids in the quasistatic regime was dependent upon their aspect ratio, with larger aspect ratios pushing the LSPR further to the red.

Numerical solutions using the DDA were introduced to model the interaction of light with nanostructures which could not be solved by analytical means. At specific applications, the DDA was used to calculate the optical spectra and electric fields for gold rods and triangular prisms. It was shown that the dipolar resonance red-shifts as the aspect ratio of both of these structures is increased, much as is predicted by quasistatic theory for spheroidal particles. However, since the DDA method provides a full electromagnetic solution, the higher-order modes within these structures are also correctly calculated.

Definition

Optical techniques are that using light to inspect or characterize the materials. Nanostructures are a material or a combination of materials limited in size at least in one direction of the space. It is generally accepted that the size of a single nanostructure must be below 100 nm.

Overview

This entry is devoted to the description of the main optical techniques used in the characterization of nanostructures in general, and, in particular, of semiconductor nanostructures. Most of these techniques have been used in the characterization of bulk materials over the years and the basic principles are widely described in many textbooks. The main variation when they are applied to the characterization of nanostructures is the insertion of a confocal microscope or the combination of optical microscopy with atomic force microscopy (AFM). The wavelength of the light in the so-called optical region ranges from the near ultraviolet (UV), 180–400 nm (3.1–6.9 eV), to the near infrared (IR), 700–5 μm (0.25–1.8 eV). It includes, obviously, the visible region, from 400 to 700 nm (1.8–3.1 eV). The most important techniques in the optical region are optical imaging, absorption and emission spectroscopies, and Raman and infrared spectroscopies. The basic principle of the different techniques, the experimental setups, and the particularities when they are applied to the characterization of nanostructures will be described.

The prefix nano can be applied when one of the dimensions of the material is smaller than 100 nm. This includes two-dimensional structures like quantum wells or superlattices, or more recently graphene or a few layers of transition metal dichalcogenides (WS_2, $MoSe_2$, for instance), quasi-one-dimensional nanostructures called nanowires, and quasi-zero-dimensional nanostructures like self-assembled quantum dots, nanowire heterostructures, or metallic and semiconducting nanoparticles.

Microscopy

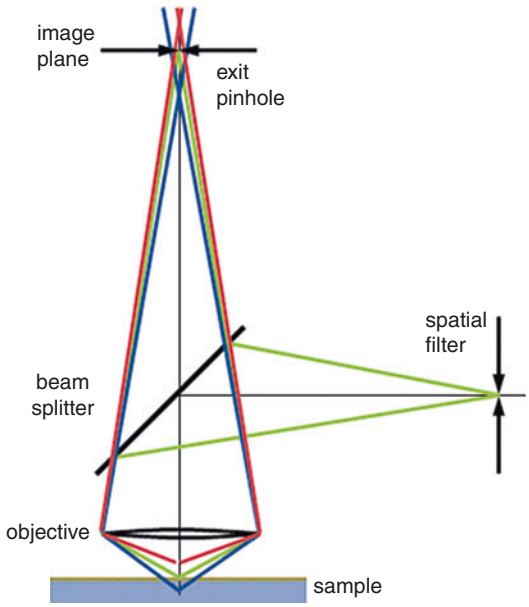
Optical microscopy is one of the first steps in the characterization of materials. It allows the visualization and selection of samples prior to manipulating or processing in order to perform more complicated analyses. The microscope was one of the main instruments used during many years in material science and biology. Actually, biology was one of the fields pushing the development of optical microscopy toward a significant improvement of the resolution in the last decade.

Following the Rayleigh criteria, the lateral or in-plane resolution of a microscope is given by the expression [1]:

$$d_{x,y} = \frac{0.61\lambda}{NA},$$

where λ is the wavelength of the light and NA the numerical aperture of the lens or objective, given by:

$$NA = n \sin \alpha,$$



n being the refractive index of the medium (usually air) over the focusing point and 2α the aperture angle. The axial resolution or depth focus is:

$$d_z = \frac{2\lambda}{NA^2}.$$

Even if an objective has a *NA* close to 1 (a very good 100× objective can have a $NA = 0.9$), the resolution limit is $\sim 300 - 500$ nm. Unfortunately, the resolution limit cannot be directly reached with a conventional microscope due to many factors like scattering in the sample surface, optical aberration in the components of the optical system, etc. Further image processing and deconvolution methods can help to improve the spatial resolution [2]. Some of the inherent problems of conventional microscopy have been solved with the help of confocal microscopy.

Confocal Microscopy

The difference between a conventional and a confocal microscope is the illumination (see Fig. 1). In a confocal microscope, two spatial filters are used, one at the entrance, where the light is filtered from the source through a pinhole, and an exit pinhole where the visualization region of the sample is selected (if it is a transparent sample or a living cell, it can be any point inside the field of view of the microscope). The scattered light or the light reflected from any other points in the field of view is rejected by the exit pinhole. With a 100× objective, using a 100 μm entrance pinhole, the image of the pinhole on the sample can be reduced to 1 μm. The field of view of a microscope with a 100× objective is ∼200 μm. In order to obtain an image of the surface of the sample, the exit pinhole must be scanned over the *xy* plane. With a CCD and the appropriate software, it is possible to obtain a 3D image scanning the exit pinhole in the *xy* plane for different depths.

Optical Techniques for Nanostructure Characterization, Fig. 1 Schematic diagram of a confocal microscope. The light is filtered through an entrance pinhole and focused onto the sample with an objective. The collected light is filtered by an exit pinhole. By moving *up* and *down* the exit pinhole, we can collect the light from a different plane in the sample. Usually, either the exit pinhole or the sample is scanned in the *xy* plane in order to obtain an image of the sample on a CCD

Near-Field Scanning Optical Microscopy

The resolution in conventional microscopy cannot be better than $\sim 300 - 500$ nm, since it is limited by the diffraction of the light. There is, however, an ever-increasing demand for optical imaging techniques in the length scale of 1–500 nm, beyond the diffraction limit of the light. On one hand, in materials science, the dimension of many semiconductor devices or structures has been reduced in the last decades to the range of 10–100 nm. There are a number of increasing applications based on semiconductor quantum dots or quantum wires and an increasing demand on optical characterization techniques able to supplying information at these scales. On the other hand, in biology, the interest is focused nowadays in the study of living cells or complex molecules, in the range of a few nanometers. During the last decades, an important amount of imaging techniques has been developed, like scanning electron microscopy (SEM), atomic force microscopy (AFM), or near-field scanning optical microscopy (NSOM or SNOM). The advantage of AFM or NSOM, as compared to SEM, is that the samples under study are not necessarily in vacuum. There are several entries in this book on AFM, SEM, and NSOM. We will give in this section a few basic concepts of NSOM, which will be useful in the next sections.

The basic idea is to perform the measurements with the optical source or detector much closer to the sample than the wavelength of the light. In this "near-field" regime, the resolution is given by the size of the source or detector instead of the wavelength of the light. The advantage of NSOM as compared to AFM is that the interaction of the sample with the light can be analyzed as a function of the wavelength (spectroscopy), or the dynamical behavior of this interaction by means of time-resolved measurements. In near field there are basically two modes of operation; the first one is called aperture NSOM and the second apertureless NSOM or ANSOM [3]. In the first technique, a metalized optical fiber with a very small aperture is utilized to shine light on the sample which is collected from below with a high *NA* objective. The sample is mounted on an *xy* plate in order to map over a finite region and produce an image. The optical resolution is given by the size of the aperture in the optical fiber, which is typically of the order of 50–100 nm. There is an alternative option, which uses the metal tip of an AFM resonating at high frequency. The optical image is collected also with a high *NA* objective, but the signal is filtered using a lock-in amplifier working at the modulation frequency of the tip. Since there is no aperture, the technique is called ANSOM. In ANSOM the signal collected depends on the interaction of the dipole produced by the tip with the sample and the spatial resolution is of the order of the size of the tip, which can be of a few nanometers.

There are other optical techniques allowing the increase of the resolution using far-field optics. A summary of these techniques can be found in Ref. [2]. Some of them (4Π confocal microscopy, image interference microscopy, or harmonic excitation light microscopy) are based on the interference of two or more laser beams and a further image treatment. There are also nonlinear methods and a combination of far-field and near-field optics. The resolution limit in most of the methods is of the order of 100 nm. However, most of these techniques do not supply a direct image of the sample, but a fluorescence image, and they are mainly applied in biology.

High-Resolution Interference Microscopy

The drawback of NSOM is its scanning character; it avoids the collection of information over the entire sample in parallel, and fluctuation on the image can appear. Also, the distance between the tip and the sample has to be kept as constant. Usually in an optical image, only the intensity is taken into account. There is a technique, called phase contrast microscopy, due to Fritz Zernike, where the phase is also considered. This technique is used in biology to increase the contrast in biological systems. It corresponds to the case where the scattered light is small compared to the directly transmitted light. In the case where the scattered light completely interferes with the direct light, there are spatial points in the wave field where the amplitude is zero. Associated to these points, there is a phase singularity. There are two cases of phase singularities, called screw and edge singularities (also called dislocations or optical vortices). In order to obtain singularities in the far field, the object must have a certain width compared to the Abbe resolution limit. Once the singularities appear, their position can be obtained theoretically with an unlimited resolution, high-resolution interference microscope (HRIM). In Ref. [4] a HRIM is described with a lateral spatial accuracy of 10 and 1 nm in depth.

Absorption and Reflectance Techniques

For many years, the standard procedure to characterize the fundamental electronic transition of a semiconductor was the measurement of the absorption coefficient via transmission experiments. In semiconductors, the first optical transition is actually called absorption edge. Transmission cannot be easily measured in the case of semiconductor nanostructures or nanoparticles and alternative techniques must be found out to analyze the absorption edge in that case. In addition, nanostructures present particularities in the absorption as compared to bulk

semiconductors due to the reduction of the dimensionality.

In this section the basic principles giving rise to the absorption in a solid will be given, and some of the techniques commonly used to obtain the optical constants of semiconductor nanostructures will be described.

Optical Constants and Dielectric Function

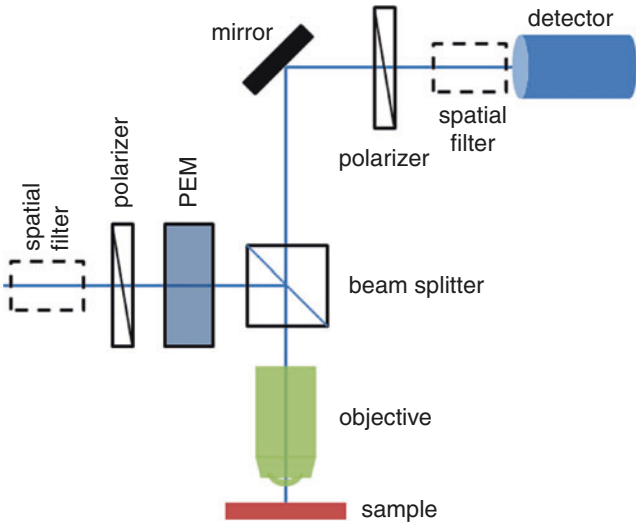
The response of a material to an electromagnetic wave, in particular in the range from ultraviolet (UV) to near infrared (NIR), satisfies the Maxwell equations. In the most general case, in the ω domain, the electric displacement field can be written in terms of the electric field by means of the dielectric permittivity, $\vec{D} = \tilde{\varepsilon}(\omega)\,\vec{E}$, where $\tilde{\varepsilon} = \varepsilon_1 + i\varepsilon_2$ is a complex quantity ($\vec{E}$ and $\vec{D}$, in general, are not in phase). Usually, $\tilde{\varepsilon}(\omega)$ is named dielectric function, since it is a function of the frequency ω. In an absorbing material, the refractive index is in general complex, $\tilde{n} = n_1 + in_2$, and it is related to the dielectric function through the expression $\tilde{\varepsilon} = \tilde{n}^2$. Both the real and imaginary parts of either $\tilde{\varepsilon}$ or $\tilde{n}$ are named "optical constants" and from its knowledge it is possible to identify the material and to provide useful information on the electronic transitions, impurities, phase transitions, etc. Instead of the electric displacement field, the current density $\vec{J} = \tilde{\sigma}(\omega)\,\vec{E}$, where $\tilde{\sigma} = \sigma_1 + i\sigma_2$ is the complex conductivity $\left(\frac{\tilde{\varepsilon}=\varepsilon_\infty+i\tilde{\sigma}}{\omega}\right)$, can be used in an equivalent formulation. The reflectivity at the surface of the material can be written in terms of the refractive index:

$$\Re = \left|\frac{\tilde{n}-1}{\tilde{n}+1}\right|^2.$$

In semiconductors, instead of the imaginary part of the refractive index (also called extinction coefficient), it is more common to use the absorption coefficient:

$$\alpha(\omega) = \frac{2\omega n_2(\omega)}{c}.$$

Using samples with appropriate thicknesses $d(\alpha d \approx 1)$, it is possible to obtain $\alpha(\omega)$ in a wide spectral range through the Fresnel equations [1], neglecting the dependence of $\Re$ on n_2, which is a very good approximation close to the fundamental electronic transition. Unfortunately, in most of the nanostructure materials, this method is not suitable to measure the absorption coefficient. For metal or semiconducting nanoparticles, an effective medium theory is needed; in the case of semiconductor quantum wells or superlattices, there is always a substrate which most of the times is nontransparent. In other kinds of nanostructures, it is even more difficult to obtain α from transmission experiments. The absorption coefficient α must be obtained from reflectivity or emission experiments in an indirect way.



Spectroscopic Ellipsometry

Ellipsometry is an optical technique that analyzes the polarization ellipsis of the light reflected in the sample surface. In the simplest scheme an ellipsometer consists of a light source, a polarizer, an analyzer, and a detector. In spectroscopic ellipsometry usually a Xe lamp and a monochromator is used to supply monochromatic light. In order to obtain elliptical polarization after reflection, the polarization of the source cannot be parallel or perpendicular to the incidence plane (usually, the polarization is rotated 45°). The angle of incidence on the other hand is typically 70° for semiconductors, but it must be chosen carefully, depending on the Brewster angle of the material [5].

The incident and reflected electric field components, parallel (p) and perpendicular (s, from the German *senkrecht*) to the incidence plane, are related through the Jones matrix [6]:

$$\begin{pmatrix} E_p^r \\ E_s^r \end{pmatrix} = \begin{pmatrix} \tilde{R}_{pp} & \tilde{R}_{sp} \\ \tilde{R}_{ps} & \tilde{R}_{ss} \end{pmatrix} \begin{pmatrix} E_p^i \\ E_s^i \end{pmatrix},$$

where $\tilde{R}_{pp}$ and $\tilde{R}_{ss}$ are the complex Fresnel reflection coefficients of the sample for parallel and perpendicularly polarized light. The crossed terms describe the coupling between parallel and perpendicular light and are zero for an isotropic material. From the analysis of the ellipsis of

Optical Techniques for Nanostructure Characterization, Fig. 2 Micro-RDS setup. The polarized light is modulated with a PEM and the collected light is analyzed with a polarizer before detection. The PEM can be located after the polarizer or before the analyzer

polarization, a modulus and a phase can be obtained. If we define:

$$\tilde{p} = \frac{\tilde{R}_{pp}}{\tilde{R}_{ss}} = \tan\psi e^{i\Delta},$$

Δ is the phase difference between the parallel and perpendicular reflection coefficients and the modulus $|\tilde{p}|$ is written as $\tan\psi$ for convenience. Ellipsometry, however, can be used only around or above the fundamental electronic transition, since the imaginary part of the refractive index cannot be negligible as compared to the real part. Furthermore, to interpret the ellipsometry measurements, a realistic model is needed for the dielectric function of the material. These models were developed for anisotropic materials (high- T_c superconductors or semiconductor superlattices) in the 1980s [7]. For nanostructures with two-dimensional or three-dimensional confinement, new models have to be developed based on the Stokes–Müller formalism [5].

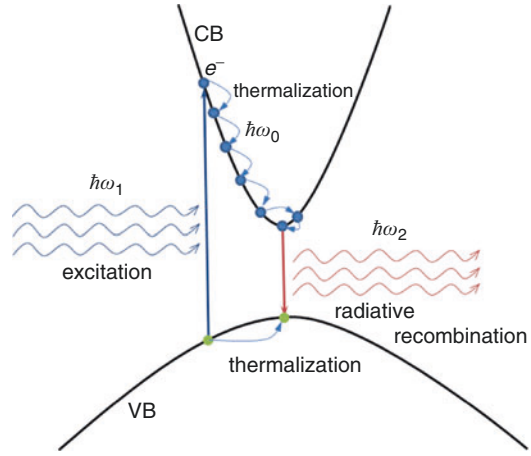
Although the measurement spot size can only be reduced to 25 μm, there are many characteristic properties of nanostructures that can be measured with larger spots, whenever the property we are interested in is given by the bundle (in the case of metal nanoparticles with similar sizes or uniform self-assembled quantum dots or quantum wires) or individual access to the nanostructure can be provided (for instance, by isolating a single quantum wire). Quantum confinement can drastically modify the optical properties of nanostructures, in particular, the fundamental electronic transition. Shape effects are also important, since the boundary conditions of the electric field can influence the optical response of nanostructured material. Structural changes in the nanostructure also affect the polarization properties of the reflected light. All these properties can be analyzed with a standard ellipsometer.

Ellipsometry on individual nanostructures has been recently performed by combining a NSOM (detecting through the optical fiber) or combining the ellipsometer with an AFM, enhancing the optical signal with a metallic tip [5]. Future developments go in this direction.

Reflectance Difference Spectroscopy

In reflectance difference spectroscopy (RDS), also termed reflectance anisotropy spectroscopy (RAS), the light incidences perpendicular to the sample surface. The technique measures the difference in the reflected signal between two perpendicular polarizations. A schematic of a RDS setup using a confocal microscope is shown in Fig. 2. The light, polarized at 45°, passes through a photoelastic modulator (PME) with its birefringence axis at 0°. The beam is reflected by a polarization-preserved 50/50 beam splitter down

to the objective lens, being focused on the sample surface. The reflected beam is directed to a second polarizer, set at 0°, and finally detected. The time-independent V_{dc} and the time-dependent V_{2f}, where f is the modulation frequency of the PEM, are simultaneously measured. If the sample is mounted in a xy plate, a RDS image of the sample surface can be obtained. If the light is varied in a spectral range, the spectral variation of the reflectance difference can be analyzed.



This technique is very sensitive in the analysis of surfaces and interfaces. The interpretation of the RDS data is not straightforward. The anisotropy can be due to spatial dispersion, surface reconstruction, chemical composition (oxidization) of the sample surface, stress, etc. [7].

Emission Techniques

When an electron is excited into the conduction band of a solid, the electron finally recombines with a hole in the valence band. Depending on the manner the electron is excited, the technique acquires a different denomination. If the electron is photoexcited, the recombination is called photoluminescence; if it is excited with an electron beam, it is called cathodoluminescence. In the case of excitation by an electric field, the corresponding process is electroluminescence. In principle, the luminescence decays are exponential or sometimes hyperbolic. But, it is well known that, for some materials, the luminescence glows for hours. This is the case of phosphorescence or thermoluminescence, processes dominated by traps. Only the most important emission processes observed in nanostructures will be discussed here: photoluminescence and cathodoluminescence and in particular their time evolution.

Photoluminescence

In an absorption process, an electron–hole pair is generated by means of a photon. The electron and the hole lose energy by emitting optical phonons, as sketched in Fig. 3, until the electron (hole) reaches the bottom (top) of the conduction (valence) band and finally a photon is radiated. This process is called photoluminescence (PL).

Optical Techniques for Nanostructure Characterization, Fig. 3 Scheme of a typical band-to-band emission process in a semiconductor: a photon of energy $\hbar\omega_1$ reaches a solid creating an electron–hole pair. The electron and hole thermalize emitting optical phonons, and finally the electron–hole pair recombines emitting a photon of energy $\hbar\omega_2$

The PL is, in some sense, the inverse of the absorption, but it is produced at a different energy due to the electron thermalization due to phonon emission. Many times, mostly in biological systems, the PL is called fluorescence, but the physical origin and properties of PL and fluorescence (emission after photon absorption in short decay times) is the same.

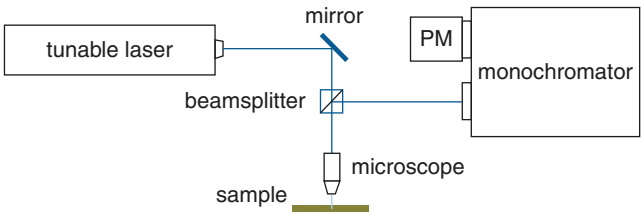
In the case of band-to-band transitions, the connection between the emission rate R_{cv} and the absorption coefficient α is given by the Roosbroeck–Shockley relation [7]:

$$R_{cv} = \frac{\alpha(\omega)2\omega^2 n(\omega)^2}{\pi c^2 [e^{\hbar\omega/kT} - 1]},$$

where $\hbar\omega$ is the photon energy, $n(\omega)$ the refractive index, and c the speed of light in vacuum.

There are several phenomena modifying the energy position of the emission or the profile in the particular case of nanostructures. Size effects or quantum confinement can produce a blueshift in the emission. This is a typical effect observed in semiconductor nanoparticles of different diameters, as soon as the diameter decreases. The effect of internal electric fields can shift down in energy

(redshift) the emission peak of the nanostructure. This is the case of the emission in nitride semiconductor quantum dots, for instance (quantum confined Stark effect). The existence of an accumulation or depletion layer in the surface of semiconductor nanowires can also modify the emission profile. Another important issue is the effect of alloying composition in ternary semiconductor nanostructures. Exciton localization due to alloy fluctuations produces an important Stokes shift in the PL.



The width of the emission peak of a bundle of nanostructures (like self-assembled quantum dots or nanowires) depends on the dissimilitude of the nanostructures composing the bundle. This width, due to electron–phonon interaction, is called homogeneous broadening. The increase of the broadening due to other factors like alloying fluctuations, defects, etc., is named inhomogeneous broadening. The homogeneous broadening has a Lorentzian line shape while the inhomogeneous broadening is Gaussian.

The emission properties of single nanowires can be measured using several techniques. The most typical method is to separate the nanowires from the substrate by sonicating them in a methanol solution, although they can also be separated mechanically. Large nanowires (from ZnO, Si, GaN, and InP) can be dispersed onto a metallic substrate and directly mapped using optical microscopy. The advantage of a metallic substrate is that the laser heat is dissipated through the substrate and the background does not contain sharp phonon lines that could mask the signal from the nanowires. If the nanowires are small, they can be dispersed on a silicon (or any other semiconductor) substrate marked with a grid by electron beam lithography (EBL). The nanowires can be positioned in relation to the marks by SEM, and from the SEM images, the marks can be located by means of optical microscopy. By studying the PL of a single nanowire, information on the strain distribution, composition, etc., along the nanowire can be obtained. The PL spectra will consist of narrow peaks corresponding to the homogeneous broadening of the emission of individual nanostructures.

EBL has also been used to make submicron holes in an optically opaque metal mask (Cr, for instance) on the surface of material containing self-assembled quantum dots. This enables spatially resolved photoluminescence spectroscopy to be selectively performed on only those dots that lie directly under the aperture. Provided the dot density is small, a single quantum dot can be studied even with a laser spot of 1 μm. Since the structure is just below the aperture, this is equivalent to using a NSOM, i.e., we are analyzing the near field.

Photoluminescence Excitation

The direct measurement of the absorption coefficient in semiconductor nanostructures is not possible in most of the cases. The reason is that the nanostructures are grown on a substrate or they are embedded in a different semiconductor, or simply it is not possible to perform a transmission measurement in order to extract the absorption coefficient. The alternative is to use a technique known as photoluminescence excitation (PLE), assuming that the obtained spectroscopic profile is equivalent, or proportional, to the absorption coefficient. The basic setup for a PLE experiment is shown in Fig. 4.

Optical Techniques for Nanostructure Characterization, Fig. 4 Photoluminescence excitation setup. The laser beam is focused on the sample using a confocal microscope and the emitted light is analyzed with a monochromator

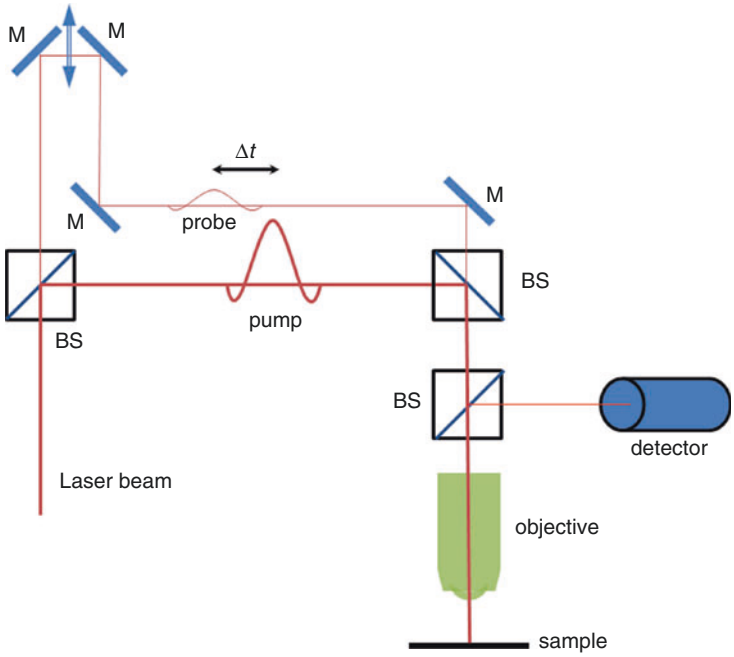
The detection wavelength is selected at the queue of the PL peak using a monochromator and a single channel detector. Then, the excitation wavelength is tuned covering the fundamental transition of the nanostructure. When the absorption coefficient $\alpha(\omega)$ increases, the absorption at the nanostructure increases and consequently the emission intensity also increases. The relation between the emission intensity I_{em} and the excitation intensity I_{exc} is [7]:

$$I_{em} = P_{abs} P_{relax} P_{rad} I_{exc},$$

where P_{abs}, P_{relax}, and P_{rad} are the probabilities of photon absorption, electron–hole relaxation, and radiative recombination, respectively. If electrons and holes relax via phonon scattering, they will lose energy as shown schematically in Fig. 3 until the radiative recombination is produced. In that case, I_{em} can be considered proportional to P_{abs}. If there are non-radiative channels of relaxation, PLE is not proportional to the absorption.

The excitation wavelength can be varied from the UV spectral range to approximately 1 μm in the IR using a dye or a Ti-Sapphire laser, but when an appropriate tunable laser to study the region of interest is not available, it is always possible to use an arc lamp or a halogen lamp in combination with a monochromator as excitation source.

Cathodoluminescence



The cathodoluminescence (CL) consists of the analysis of the emission signal in the optical range when excited with an electron beam. The generation of electron–hole pairs when irradiated with energetic electrons occurs through the mechanism of impact ionization. Scanning the electron beam through the sample provides mappings of the sample under study or spectral images point by point if a monochromator is coupled to the system. The spatial resolution in CL is not limited by the diffraction limit of the emitted light, but by the size of the spot of the e-beam. Actually, in bulk materials although the size of the beam can be small (it depends on the voltage applied and the beam current), the diffusion length of the carriers is the dominant limiting factor. In nanostructures, like semiconductor self-assembled quantum dots or nanowires laid on a metallic substrate, the luminescence of individual quantum dots or nanowires can be mapped at the nanometer scale, providing information on the composition, strain, etc. One disadvantage of the technique is that the sample must be under vacuum conditions, thus living cells cannot be studied.

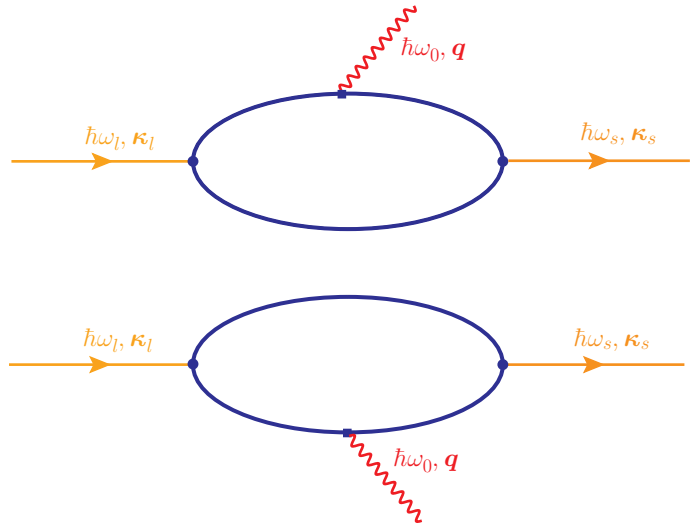
The standard equipment consists of a scanning electron microscope (SEM), either with the incorporation of an optical fiber assembly to extract the optical signal or an external optical microscope with a long working distance objective to collect the light. When the wavelength of the light is below 180 nm, a special setup in vacuum, as that shown in the review article of B. Dierre et al. [8], must be built.

Time-Resolved Photoluminescence

The development of new materials for electronics and optoelectronic applications requires a detailed knowledge of the electron dynamics on very short timescales. In a semiconductor nanostructure, an electron may move ballistically at a velocity of 10^7 cm/s, hence traveling 10 nm in 100 fs. These length and timescales have become of great importance in real devices.

Femtosecond spectroscopy is the most powerful technique to obtain information on electron dynamics on ultrashort timescales, since the electron–phonon interaction, the most important scattering mechanism of electrons in semiconductors, is in the range of femtoseconds. The dynamics of surface plasmon polariton (SPP) excitations in metallic and hybrid nanostructures, which is in the order of 1–100 fs, is also attracting increasing interest. Microscopic resolution can be achieved with confocal microscopy; if an improvement in the resolution is needed, we can use a NSOM or ANSOM. One of the most standard time-resolved techniques used in the study of semiconductor nanostructures and nanoparticles is the pump-probe experiment. A scheme of a pump-probe setup is shown in Fig. 5. A laser beam is divided with a beam splitter into the pump beam, with most of the power, and the probe beam, which arrives to the sample with a temporal delay Δt given by a translation stage. A second beam splitter is used to align the two beams. The response of

Optical Techniques for Nanostructure Characterization, Fig. 5 Pump-probe experiment setup. The laser pulse is divided into two by a beam splitter. The "pump" beam is focused into the sample using a microscope objective, while the "probe" beam is delayed appropriately using a translation stage. The "probe" signal is measured with a detector at the repetition rate of the pulsed laser (in the range of MHz) as indicated in the figure



the probe is synchronously detected. Changing the time delay snapshots of the electron dynamics on a femtosecond timescale can be obtained. A review of femtosecond spectroscopy in nanostructures can be found in Ref. [9].

Raman Spectroscopy

Micro-Raman scattering is a nondestructive characterization tool which allows to extract local and valuable information of semiconductor nanostructures. The technique can be applied to analyze first- and second-order phase transitions, phonon anharmonicities, strain states of the nanostructures, etc. Tuning the wavelength, resonance Raman scattering can provide information of single quantum objects. After a brief introduction of Raman scattering, the main techniques based on Raman scattering applied to nanostructures, giving some experimental examples, will be described.

Raman Scattering

Raman scattering (RS) is the inelastic scattering of the light by any kind of quasiparticles: phonons or lattice vibrations, magnon or magnetic oscillations, or electronic excitations (electronic Raman scattering). In semiconductor physics Raman scattering is commonly used for the study of the scattering of light by optical phonons. The direct interaction of light with phonons is produced in the infrared and it is measured by infrared reflectance (IR) spectroscopy. In the Raman effect, the conduction and valence band states participate as virtual intermediate states of the process. Thus, in a normal Raman process, as drawn in the Feynman diagram shown in Fig. 6, a photon produces an electron–hole pair or an exciton. In a second step, the electron or the hole emits or absorbs a phonon, and finally there is a recombination process and the electronic system is reestablished into its fundamental state. Since these are virtual processes, energy is not conserved; only the wave vector is conserved. The only conservation law is given by the Feynman golden rule: the energy of the outgoing photon, $\hbar\omega_s$, must coincide with the sum of the incoming photon energy, $\hbar\omega_l$, plus (absorption of a phonon) or minus (emission of a phonon) the phonon energy, i.e., $\hbar\omega_s = \hbar\omega_l \pm \hbar\omega_0$. In the case of phonon emission (absorption), the outgoing photon has a lower

Optical Techniques for Nanostructure Characterization, Fig. 6 Feynman diagram of a Raman process in a semiconductor. A photon with energy $\hbar\omega_l$ creates an electron–hole pair. In the first diagram, the electron emits or absorbs an optical phonon of energy $\hbar\omega_0$, and afterward the electron and hole recombine emitting a photon with energy $\hbar\omega_s$. In the second diagram, the hole emits or absorbs the phonon

(larger) energy than the incoming one and the process is labeled as Stokes (anti-Stokes) Raman scattering. At low temperature, the population of optical phonons is very low and the signal corresponding to anti-Stokes Raman scattering is very weak.

Since the electronic states are intermediate states of the process, the electronic band structure plays an important role in Raman scattering. In fact, when either the incoming or the outgoing photon is close to a critical point of the semiconductor, there is a tremendous enhancement of the Raman scattering efficiency, since the virtual states become real. This process is called resonant Raman scattering (RRS).

Since not all the sample volume scatters light, instead of the typical cross section used to describe scattering processes, the intensity of the Raman signal is given in terms of the scattering efficiency (scattering cross section per unit volume). For a Stokes process:

$$\frac{dS}{d\Omega} = \frac{\omega_s^3 n_s^3 n_l}{h^2 c^4 \omega_l} \times \sum_{F,I} \left| \sum_{\mu,v} \frac{\langle I|H_{eR}|\mu\rangle \, \langle \mu|H_{ep}|v\rangle \, (v|H_{eR}|F)}{(E_\mu - \hbar\omega_l)\,(E_v - \hbar\omega_s)} \right|^2 (N_0 + 1),$$

where I and F are the initial and final states of the system; μ and v the virtual intermediate states; H_{eR} and H_{ep} the electron–radiation and electron–phonon interaction Hamiltonians, respectively; E_μ and E_v the energy of the intermediate states; $\hbar\omega_l$ and $\hbar\omega_l$ the incoming and outgoing photon energy, respectively; and N_0 the phonon population, given by the Bose–Einstein distribution function $\left(N_0 = \frac{1}{e^{\hbar\omega_0/kT}-1}\right)$. The anti-Stokes process is proportional to N_0. This is the reason why at very low temperatures, the anti-Stokes scattering signal is negligible. Actually, from the rate of Stokes versus anti-Stokes Raman intensities, the lattice temperature of the sample can be obtained:

$$\frac{\dfrac{dS}{d\Omega(\text{Stokes})}}{\dfrac{dS}{d\Omega(\text{anti}-\text{Stokes})}} = e^{\hbar\omega_0/kT},$$

k being the Boltzmann constant and $\hbar\omega_0$ the energy of the corresponding phonon. When the energy of the incoming photon or the outgoing photon coincides with the gap of the material, the Raman efficiency can increase several orders of magnitude. The denominators are actually non-zero because of the broadening of the electronic states; an imaginary term corresponding to the linewidth must be added to the energy terms in the denominators of the scattering efficiency. By tuning the laser energy around an electronic

transition, RRS can be used to determine the corresponding electronic transition.

Raman Tensor and Selection Rules

The electron–phonon Hamiltonian has two contributions: a short-range and a long-range contribution. The short-range contribution, or deformation potential, is due to the local distortion produced by the optical phonon when it propagates through the lattice. The long-range or Fröhlich interaction is due to the change in the polarization vector $\vec{P}$ (actually on $\vec{\nabla} \cdot \vec{P} = \rho_p$, the polarization charges) carried by the polar optical phonons. The deformation potential Hamiltonian is a range 2 tensor and it depends on the specific phonon and the direction of propagation. The Fröhlich Hamiltonian is a scalar. Fröhlich electron–phonon interaction is inversely proportional to the wave vector of the phonon and it is very important under resonant conditions. It is responsible for the multi-phonon emission processes (multi-phonon RRS) and it competes in intensity with photoluminescence in polar semiconductors.

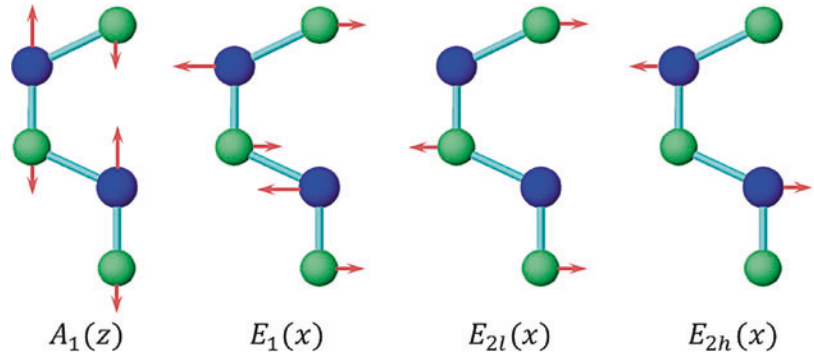
The electron–radiation interaction Hamiltonian contains, through the vector potential, the polarization of the incoming photon, $\vec{e}_l$, and the outgoing photon, $\vec{e}_s$. The Raman intensity is proportional to [7]:

$$I_{\text{Raman}} \propto \left| \vec{e}_l \cdot \Re \cdot \vec{e}_s \right|,$$

where $\Re$ is the Raman tensor of the corresponding optical phonon and it can be written as a 2×2 matrix. The observation of the phonon in a Raman experiment, or Raman selection rules, depends on the mode symmetry and the polarization of the light. Since most of the technological important semiconductors grow in the zincblende (ZB) or wurtzite (W) structure, the discussion on the selection rules will be particularized to these two special cases.

The zone-center optical phonons in the zincblende structure correspond to a triply degenerate three-dimensional representation, usually denoted by T_2 or F_2. The corresponding Raman tensor of the three modes can be written as:

$$\Re(T_2(x)) = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & d \\ 0 & d & 0 \end{pmatrix},$$



$$\Re(T_2(y)) = \begin{pmatrix} 0 & 0 & d \\ 0 & 0 & 0 \\ d & 0 & 0 \end{pmatrix},$$

$$\Re(T_2(z)) = \begin{pmatrix} 0 & d & 0 \\ d & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

The three axes x, y, and z are along the standard coordinate axes [100], [010], and [001], respectively. The triply degenerated zone-center phonons in the ZB structure split for $q \neq 0$ into a doubly degenerate transverse optical mode (TO) and a longitudinal optical phonon (LO). The reason is the coupling of the transverse electromagnetic field of light with the optical vibrations. In group theory, the zone-center phonons correspond to $q = 0$ and thus are triply degenerated.

The selection rules are written using the notation introduced by S. P. S. Porto [10], indicating the direction of the photon wave vectors and the corresponding polarizations as $\vec{\kappa}_l\left(\vec{e}_l, \vec{e}_s\right)\vec{\kappa}_s$. In the study of semiconductor nanostructures, due to the existence of a nontransparent substrate in most of the cases, the scattering geometries are limited to backscattering and 90° scattering. Forward scattering is only possible if the sample is transparent.

For ZB crystals, in backscattering geometry along the x axis, the Raman tensor $\Re(T_2(x))$ corresponding to the LO phonon can be observed in crossed polarizations, $x(y, z)\bar{x}$. For a TO phonon (the phonon polarization must be perpendicular to the propagation direction), the Raman tensor is a combination of $\Re(T_2(y))$ and $\Re(T_2(z))$. In that case either the laser or scattered polarization must have a component along x. By inspection of the corresponding matrices, it can be checked that the TO phonon mode is forbidden (not observable) on a (100) surface in backscattering configuration, since the light is a transversal wave and cannot have a projection of the polarization vector along the direction of propagation. The

Optical Techniques for Nanostructure Characterization, Fig. 7 Phonons in ZnS (Zn in *green* and S in *blue*) as given by the group theory analysis. Actually, the E_2 modes mix as explained in the text, giving rise to the E_{2l} and E_{2h} Raman modes

selection rules for other surfaces can be found in Ref. [6].

In the case of wurtzite crystals (four atoms in the primitive cell), there are nine optical modes, but two of them are silent modes (only observable with Hyper-Raman scattering). The allowed optical modes are:

$$\Re(E_1(x)) = \begin{pmatrix} 0 & 0 & c \\ 0 & 0 & 0 \\ c & 0 & 0 \end{pmatrix},$$

$$\Re(A_1(z)) = \begin{pmatrix} a & 0 & 0 \\ 0 & a & 0 \\ 0 & 0 & b \end{pmatrix}$$

$$\Re(E_1(y)) = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & c \\ 0 & c & 0 \end{pmatrix}$$

$$\Re(E_2) = \begin{pmatrix} d & d & 0 \\ d & -d & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

From these modes (see Fig. 7), the A_1 and E_1 modes are polar modes, since there is a change in the polarizability generated by the atomic movement, while the E_2 mode is nonpolar [11]. In the polar modes, the phonon polarization (direction of the atomic movement) has been indicated. The two E_2 optical modes correspond in principle to the movement of the anion and the cation, respectively, but they mix because they have the same symmetry. In the actual modes, both atoms vibrate; in the E_{2l}, the movement of the heaviest atom (Zn) dominates, while in the E_{2h}, the movement of the lightest atom (S) dominates. These modes can be interpreted as originated from the folder of the zincblende structure in the [111] direction. In the ZB structure, there are actually two modes in the L point where only one of the two atoms vibrates in opposite directions. In the A_1 mode, the atoms vibrate along the c-axis of the wurtzite structure. For a wave propagating along z, the mode is longitudinal ($A_1(LO)$), while for a mode propagating along a direction perpendicular to z, it is transversal ($A_1(TO)$), giving a discontinuity at the Γ point. The same occurs for the $E_1(x)$ vibrating along x; it is longitudinal if the phonon propagates along x, but it is transversal if the phonon propagates along y or z (in other words, the mode is degenerated for a phonon propagating along z, but splits into TO and LO if the phonon wave vector is along the x and y directions). The same applies for the $E_1(y)$ mode. The selection rules for the wurtzite structure can be summarized in Table 1 [11].

In Table 1, all unequal backscattering and 90° scattering geometries and the corresponding Raman allowed modes have been considered.

Confocal Raman Microscopy

In order to analyze thin films or nanostructures, it is essential to use a confocal microscope in order to improve the lateral and depth resolutions; otherwise, the Raman signal of the substrate can completely mask the signal from the thin film. In a micro-Raman setup, the laser beam enters in the system through a spatial filter in order to select the TEM mode. This spatial filter is equivalent to the entrance pinhole of a normal confocal microscope. The collected signal is filtered at the

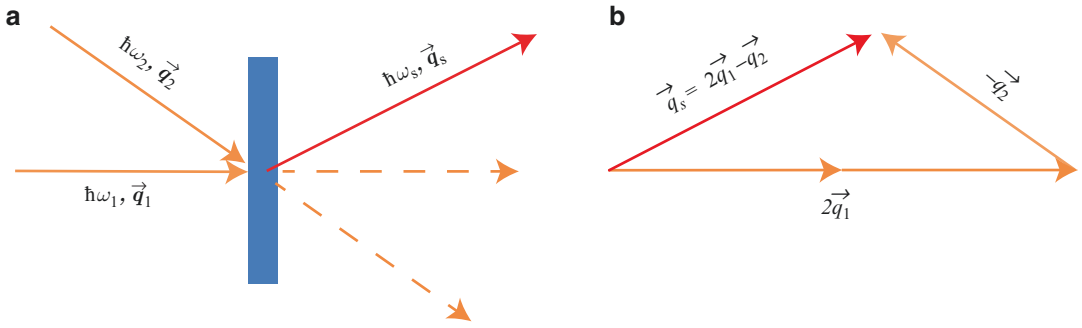
image plane with a confocal pinhole. The setup of a confocal Raman microscope is basically that shown in Fig. 1. The light at the exit pinhole is focused at the entrance slit of the Raman spectrometer. As in confocal microscopy, by using a motorized *xy* plate and a focusing system, it is possible to obtain three-dimensional Raman maps of the sample.

Direct Raman imaging of a nanostructure or a living cell is also possible if instead of a spectrometer, a band-pass filter is used to select the phonon emission. In order to suppress the stray light from the laser, we need a notch or edge filter.

Coherent Raman Spectroscopies

The Raman scattering technique described in the preceding sections refers to spontaneous Raman scattering, which corresponds to the term $N_0 + 1$ in the expression of the Raman efficiency. Actually, the Raman signal is proportional to this factor. We know that the anti-Stokes signal is proportional to N_0, but the population of phonons is very low even at room temperature. As a consequence, Raman signals are very low. It is possible to surpass this circumstance by stimulated emission. This alternative technique is named "coherent anti-Stokes Raman scattering" (CARS). With two laser beams, of energy $\hbar\omega_1$ and $\hbar\omega_2$, and wave numbers $\vec{\kappa}_1$ and $\vec{\kappa}_2$, we can tune $\hbar\omega_2$ in such a way that $\hbar\omega_1 - \hbar\omega_2 = \hbar\omega_0$. The anti-Stokes scattered signal is produced at (see Fig. 8):

$$\hbar\omega_s = \hbar\omega_1 + \hbar\omega_0 = 2\hbar\omega_1 - \hbar\omega_2$$



Similarly, we can show that:

$$\vec{\kappa}_s = 2\vec{\kappa}_1 - \vec{\kappa}_2$$

The wave vector of the scattered photon is twice the wave number of one of the incoming photons minus the wave vector of the photon corresponding to the second laser. The signal of a CARS experiment is usually nine or ten orders of magnitude stronger than that of a Raman experiment. The inconvenience of the technique is the existence of suitable tunable lasers in the range of interest. In the visible range, we can use a laser system consisting of a Q-switched Nd:YAG master oscillator, Nd:YAG amplifiers, frequency-doubling crystals, a dye laser, as well as a set of totally reflecting and dichroic mirrors and lenses adapted for purposes of

Optical Techniques for Nanostructure Characterization, Table 1 Possible backscattering and 90° scattering configurations where the Raman allowed optical modes of the wurtzite structure can be observed

Geometry configuration	Phonon mode
$z(y, y)\bar{z}$	$A_1(LO)$, E_2
$z(y, x)\bar{z}$	E_2
$x(y, y)\bar{x}$	$A_1(TO)$, E_2
$x(y, z)\bar{x}$	$E_1(TO)$
$x(y, x)y$	E_2
$x(y, z)y$	$E_1(TO)$, $E_1(LO)$
$x(z, z)y$	$A_1(TO)$
$x(z, x)z$	$E_1(TO)$, $E_1(LO)$
$x(z, y)z$	$E_1(TO)$
$x(y, y)z$	E_2

CARS experiments. The technique has acquired recent interest since the combination with a metallic tip, exciting the plasmons in the material, opens the field of CARS as a local probe [12].

Surface- and Tip-Enhanced Raman Spectroscopy

Surface-enhanced Raman scattering – or spectroscopy – (SERS) and surface-enhanced resonant Raman scattering (SERRS) are extremely sensitive and selective techniques that can be applied to study the Raman response of individual nanostructures or small molecules. These techniques have been used in biochemistry, materials science, or forensic. Although the exact mechanism of enhancement is not completely clear, it is known that the surface plasmon excitations of metallic nanoparticles are responsible for the enhancement. These excitations are produced in the UV or visible range in the case of small metallic nanoparticles. Substrates with ordered nanoparticles can be used, but it is also possible to produce the nanoparticles by chemical methods in a solution, put our sample on that solution, and evaporate the solvent. The diameter of the nanoparticles must be chosen in accordance to the wavelength of the laser used for the Raman experiment. An entry in this book that focuses on SERS is referred to the readers interested in the topic.

A related technique, tip-enhanced Raman spectroscopy (TERS), combines the use of an AFM and a confocal microscope. The Raman signal is enhanced by two mechanisms: (a) the surface plasmon generated at the metallic tip and (b) the lighting rod effect. In the first case, as in the case of SERS, the surface plasmons are excited by the laser, giving rise to an enhancement of the electric field at the tip covered with a noble metal film. In TERS it is essential to illuminate the contact of the tip with the sample and collect the scattered light efficiently. The lighting rod effect consists of the enhancement of the electric field at the apex of the tip when the polarization of the light is parallel to the tip shank. The easiest geometry is to illuminate and collect the light from the bottom using an inverted microscope, but this can only be done if the substrate is transparent or partially transparent, or the nanostructures can be dispersed on a cover slip of a microscope. In the most typical configuration, the illumination of the sample at the tip position is done from the side. TERS is applied nowadays to the study of IV and III-V quantum dots and nanowires, or in biology. A recent review on the topic and perspectives of the techniques can be found in Ref. [13].

Definition

The technique of optical tweezers and manipulation of small neutral particles by lasers is based on the forces of radiation pressure. These forces arise from the momentum of the light itself.

Overview

It has been first documented by Arthur Ashkin in 1970 that optical forces, or radiation pressure, could be used to trap and accelerate dielectric polarizable micron-sized particles [1]. For these experiments, a stable optical potential well was formed using two, slightly divergent, counter-propagating laser beams. This pioneering study established the groundwork for the well-known optical tweezers (OT) technique, where a single TEM_{00} laser beam is focused by a high numerical aperture (NA) objective lens to a diffraction limited spot.

In the ray optics regime, in which the dimensions of the trapped particle are larger than the wavelength of the laser light, known as the Mie regime, the origin of optical forces can be understood easily. Figure 1 shows the principle of optical trapping in the Mie regime. In Fig. 1a, a dielectric semitransparent sphere with a high index of refraction (n_b; e.g., polystyrene $n_b = 1.59$) is shown. This sphere is immersed in a fluid with index of refraction n_m (e.g., water n_m ~1.33). When exposed to a slightly focused laser beam with a Gaussian intensity profile, the sphere is drawn into the high-intensity region of the laser and then accelerated along the beam axis. Consider two rays "1" and "2" impinging on the surface of the sphere in a symmetrical manner about its center. At this moment, surface reflections are neglected. Most of the rays get refracted through the bead and give rise to forces F_1 and F_2 in the direction of momentum change. For theoretical consideration on the forces arising, the reader is referred to Grange et al. [2]. Due to the fact that the intensity of ray "1" is higher than that of ray "2," the force F_1 is higher than F_2. Adding all such symmetrical pairs of rays striking the sphere, it is imaginable that the force can be separated into two components, a gradient force, F_{grad}, and a scattering force, F_{scat}. The gradient component arises from the electric field gradient pointing toward the highest intensity region of the beam. The scattering force component, F_{scat}, which is pointing in the direction of the laser beam, is caused by the photons scattering on the surface of the sphere. In Fig. 1b, stable optical trapping in three dimensions is illustrated. If the laser beam is highly focused, a backward light force is generated. It can be shown that stable trapping occurs along the optical axis when the gradient force, which is composed of the sum of the two forces F_1 and F_2, overcomes the scattering force F_{scat}. This explains why (1) high NA

Optical Tweezers, Fig. 1 *Optical forces*. (**a**) Origin of scattering force, F_{scat}, and gradient force, F_{grad}, for a dielectric high index of refraction (n_b) sphere in a medium (n_m) in a mildly focused laser displaced from the TEM_{00} beam axis. The gradient component is oriented orthogonally to the axis of the laser beam, and the scattering is parallel. (**b**) The axial trapping requires highly convergent rays. A two-dimensional ray optics model illustrates the scattering and the gradient forces in the Mie regime. Since the axial trapping is weakest in the single beam configuration, counter-propagating laser traps have been developed [2, 16]

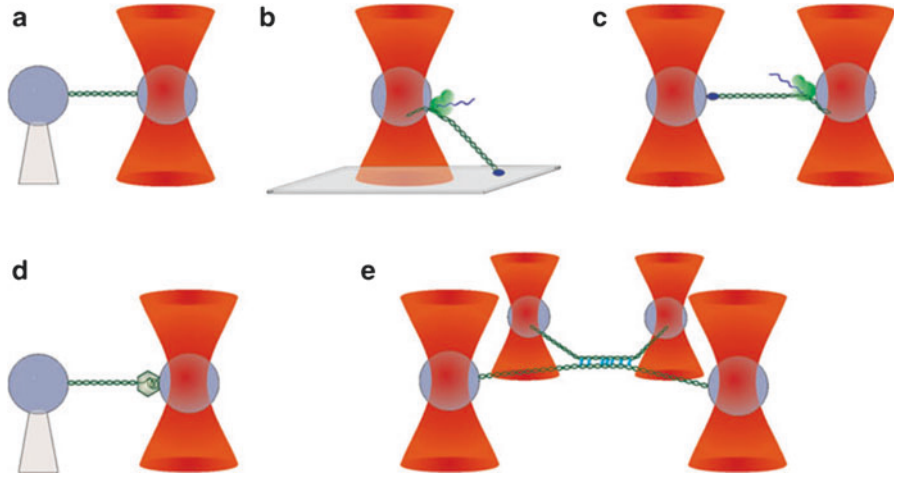
objective lenses have to be used and (2) the back aperture of the objective lens has to be overfilled to create the steepest possible gradient. When a particle is stably trapped, the sum of all forces acting on it is zero. If the particle is slightly displaced from the equilibrium point by applying an external force, the gradient force acts in the direction of the field gradient toward the center of the beam. This force depends linearly on the displacement similarly to a spring that follows Hooke's law. Optical forces are however very small, since 100 mW of laser power at the focus only produce forces of tens of piconewtons. At the focal point, not only dielectric spheres can be trapped, but also biological organisms such as cells, viruses, or bacteria as shown in 1987 by Ashkin and coworkers. The trapping of objects much smaller than the wavelength of the laser light, such as cooled atoms, has been demonstrated. This work resulted in the Nobel Prize in physics in 1997. Trapping cooled atoms cannot be understood by simple ray optics. For a more detailed insight into the principle of trapping atoms, the reader is referred to the entries of this encyclopedia where atomic clocks or Bose-Einstein condensates are discussed. For a good overview on the evolution of optical trapping, a review from Ashkin is recommended [3].

Choice of Light/Laser Source

The high-intensity radiation of the laser beam used in optical trapping experiments has the potential of effecting materials exposed to the radiation. In some experiments, laser power of more than a hundred milliwatts (mW) is used as a source. When focused to a micron-sized region, the light power in the trapping spot is equivalent to 10 MW/cm^2, which is over 600 million times greater than the flux of solar radiation on the Earth's surface on a sunny day. For chemical or other physical experiments, where the material manipulated is being modified, lasers with a wavelength in the visible regime are used. For biological research, laser light is in the near-infrared regime (NIR: $\lambda \sim 800$–1,100 nm) and the laser power is chosen depending on the system under investigation. In the high-power NIR, single biomolecules are less susceptible to optical damage than whole cells. The local heating of the surrounding liquid is in the range of only a few degrees Celsius. However, Steven Block's lab demonstrated in 1999 that live microorganism cells were affected by the radiation and showed physiological photodamage of live *Escherichia coli*.

Another technique, laser-tracking microrheology (LTM) was developed in the

mid-1990s to probe the mechanical properties of living cells by examining cellular viscoelastic properties [4]. Not only cells can be probed but also rheological properties of liquids in general. Micron-sized trapped objects such as beads or individual cells are moved with OT and can be used to generate fluid flow in two and three dimensions around the item and this can be combined with rheological measurements. Thereby, the bodies' displacements from the trap center are analyzed during the motion or when the optical trap is temporarily switched off. Such LTM measurements are highly reproducible, minimally invasive, and can be extended to in-depth studies of the rheological properties of liquids, cells, or internal cell compartments and microstructures in lab-on-a-chip devices [5].



Meanwhile, OTs are a focal point for interdisciplinary research ranging from condensed matter physics and physical chemistry to biology [6]. The fast emerging applications for OT have led to various technical innovations, thus improving the versatility of optical traps. The instrumental advances involve rapid position detection, sample positioning, trap stiffness determination, applying of controlled and calibrated forces. Multiple laser beams and computerized automation of laser beams have been used to study quasicrystals as well as polymer, metallic particles [7] and also aerosol droplets in air [8].

Most commonly TEM_{00} lasers with a Gaussian intensity beam profile are used to form a trap (see Fig. 1a). But physicists also started to use other beam profiles, such as Bessel beams, to enable the manipulation of micrometer-sized particles in multiple planes. Asymmetric beams for instance are used as tools to study the transfer of angular momentum from light to particles for their rotation. An overview on such developments is given in Ref. [9], where a series of experts in the field describe their optical experiments.

Setup of an Experiment

The interest for biologists in the OT technique comes from the fact that minute forces can also be measured with sub-pN accuracy and nanometer spatial resolution on the trapped object. Since such small forces are not accessible by conventional techniques, such as scanning-force-microscopy-based techniques (in aqueous/liquid environment, the natural "habitat" for many both in vitro and in vivo biological systems), OT has become a major investigating tool in biology (for recent reviews on instrumentation in optical trapping see [10–13]).

Biological molecules are often in the nanometer regime and are too small to be directly trapped by OT. The key to such experiments is the immobilization of the biological molecule of interest, such as deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and protein or molecular motor, on the surface of a micron-sized sphere. The sphere serves as a handle for optical manipulation. In the commonly used OT setups, interacting partner molecules or the other end of the manipulated molecule is attached either to a cover slide or to a second bead (which can also be trapped in three dimensions) see Fig. 2. The external control parameters, which can be manipulated in such experiments, are the end-to-end distance of the investigated biological system linked to the spheres/surfaces or the externally acting force in the range of 0.1–150 pN. In experiments one can vary the distance between the spheres, and then the optical force acting on the bead is recorded. The experimental plots of distance-versus-force give direct access to the mechanical properties of elongated molecules. Force-extension graphs are typically compared to worm-like chain or freely jointed chain models for polymers, and parameters that describe the polymer are extracted – most notably the persistence length, which describes the behavior of the polymer under thermal fluctuations. In the other experiments, where the position of one sphere is fixed and the force is kept constant, the molecular extension is the variable under observation. Such experiments allow direct examination of the kinetics of the involved molecules, may it be a biomolecular motor traveling along a defined path of another biomolecule (e.g., RNA polymerase along a DNA molecule [14]) or a change in molecular mechanics as observed in protein polymerization on DNA [15].

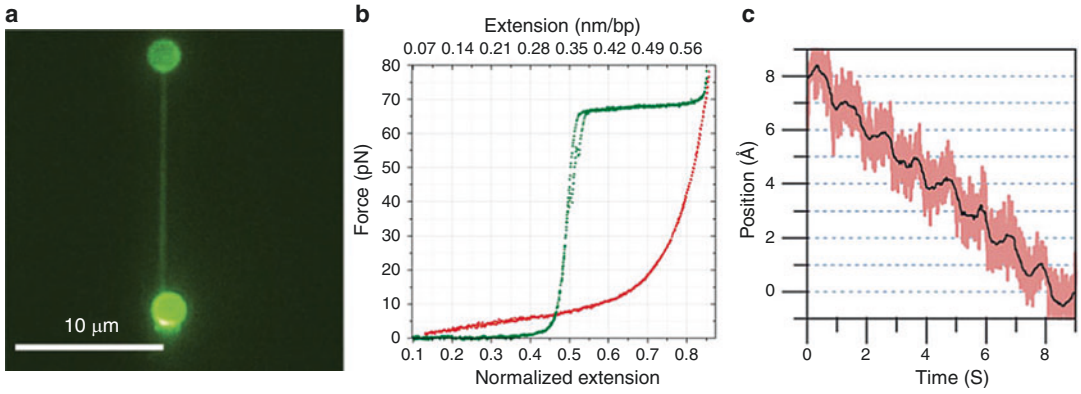
Optical Tweezers, Fig. 2 *Geometry of optical tweezers systems used in single molecule experiments*. (**a**) One end of the DNA molecule is attached to a microsphere held in the optical trap and the other end to a bead held by a glass micropipette by suction. Pulling force is generated by moving the micropipette, which is mounted on a piezoelectric stage [2, 15, 16, 24]. (**b**) RNA polymerase is attached to the trapped microsphere and to one end of the transcribed DNA. The other end of the DNA is attached to the glass slide of the flow cell mounted on the piezoelectric stage. Force is generated by moving the piezoelectric stage [12, 19]. (**c**) Dual optical traps are used to eliminate micromechanical noise coming from the glass slide or micropipette. Individual 0.34-nm base-pair steps of RNA polymerase translocation are observed in this setup (see Fig. 3c) [14]. (**d**) Geometry of the OT used for the investigation of bacteriophage φ29 DNA packing motor [20]. (**e**) Sequences of nonspecific protein-DNA interactions are investigated using four optical traps. The DNA-H-NS-DNA complex is formed by trapping two DNA molecules simultaneously in the presence of nucleotide-associated protein H-NS. Schematics are not drawn to scale

The single molecule approach to biology offers distinct advantages over the conventional approach of taking ensemble measurements. Parameters such as individual kinetics or motion can be investigated (e.g., observing a single molecular motor at work). One should keep in mind that the setup of these intricate experiments must be done in series, which is very time consuming. The required purity of the solutions and biological molecules is very important and different from "normal" molecular biological experiments where ensembles are investigated. The arrangement of an experiment in the OT starts with the production of modified molecules at a nano-molar concentration (~10^{11}/mL). The spheres thereby serve as handles for manipulation in the OT device. The strongest linkage of biomolecules to the interface of the spheres requires covalent binding and chemical activation steps. Each additional step reduces the amount of successfully anchored molecules on the interface. Therefore, a bigger quantity of modified biomolecules has to be produced at the start to end up with one molecular complex available for the OT experiment. Ligand-receptor pairs, such as biotin-streptavidin, histidine tags nitrilotriacetic acid (NTA), or antibody-antigen pairs (e.g., digoxigenin and anti-digoxigenin), are commonly used to provide specific, oriented, and tight binding to microspheres. Biomolecular interactions do not have to be activated like chemical reactions. This allows longer incubation periods to complete the interactions and often provides a successful coupling of the molecule to the surface of the spheres. Constant force experiments with forces exceeding 40 pN for long duration require either biotin-streptavidin or covalent linkage. The biomolecular "bonds" of single antibody-antigen pairs unbind after short periods while being pulled. The externally applied forces lower the activation barrier; therefore, the ligand unbinds faster from its receptor. To strengthen such interactions, some

researchers apply more than one of these bonds in series. This principle has already been used in DNA pulling experiments where multiple digoxigenins were introduced as tags on the DNA to anchor the molecule to the antibody-activated spheres [16].

Biological Applications of Optical Tweezers

In the following sections, experiments with OT, which are used for holding and manipulating a variety of nanometer- to micron-sized biological objects such as DNA, single molecules, membrane bilayers, intracellular structures, vesicles, and plant cells, are reported [12]. Trapping these distinct objects with laser tweezers enables measurements of their mechanical properties such as elasticity, stiffness, rigidity, torque, and dynamic behavior.



Single Molecular Systems in Optical Tweezers

To date several different homebuilt OT systems have been designed to manipulate single molecules of DNA and RNA, to investigate interactions between DNA and proteins and to measure the forces generated by single molecule motors. Thereby, the position of the trapped microspheres, which act as handles, can be tracked with sub-nanometer spatial resolution and sub-millisecond temporal resolution [17, 18].

Bustamante and coworkers performed one of the first single molecule experiments with OT in order to study DNA elasticity. In their assay, one end of the manipulated DNA molecule was attached to a bead held in the optical trap and the other end to a bead, which was held by a glass micropipette by suction (see Figs. 2a and 3a) [2, 16]. This assay gave detailed insight into the mechanical properties of double-stranded DNA (dsDNA) molecules for forces between 1 and 100 pN [16] (Fig. 3b).

Protein-DNA interactions are the most fundamental biomolecular interactions in the living cell. DNA elasticity plays an important role in the interactions with proteins and protein complexes. It was demonstrated that by cooperative protein binding to DNA, proteins act as a powerful molecular machine [15]. The seminal experiments, which focused on protein-DNA interactions involved in transcription, copying, and packaging of DNA, were performed around the turn of the century by the Block or Bustamante labs [19]. Most of these processes are performed by molecular motors, i.e., proteins with dynamic structures capable of converting energy stored in nucleoside triphosphates (NTPs) into mechanical work. For example, RNA polymerase is an enzyme that constructs RNA chains from DNA as templates in a process called transcription. Single molecule studies performed with OT gave comprehensive insight into the stall force, transcriptional pausing, and backtracking of RNA polymerase. Please refer to the review papers [18, 20] for a good overview. One of the OT geometries used for studying DNA transcription is shown in Fig. 2b. The transcribing RNA polymerase was attached to a microsphere held by the optical trap and the DNA is attached to the surface of a flow cell. The position of the flow cell could be precisely controlled by a piezoelectric stage. During transcription, the polymerase moved along the DNA and therefore shortened the distance from the sphere to the end of the DNA. To maintain a constant force on the RNA polymerase, respectively on the trapped bead, the piezoelectric stage moved along the direction of the polymerase to keep the bead in the laser trap at a constant position (i.e., at constant force). In both experiments, the DNA elasticity experiment (Fig. 2a) and the RNA polymerase experiment (Fig. 2b), the biomolecules were linked to a surface, which was "connected" to the external mechanical environment of the OT (micropipette or flow-cell wall). This connection introduces a positional noise of a few nanometers to the experiment due to the inherent thermal motion of the mechanical objects to which the biomolecules are attached.

A much more stable OT design was obtained by decoupling the spheres from mechanical objects introducing a second optical trap into the system. Instead of using a micropipette or a glass slide, a high-power laser beam was split optically to receive another attachment point with a second sphere, as illustrated in Fig. 2c [17, 18]. One of the beams was

Optical Tweezers, Fig. 3 *Single molecule experiments*. (**a**) Typical image of a combined fluorescence – OT experiment of DNA being stretched by externally applied forces. The DNA molecule in this experiment has a length of approximately 16 μm. The spheres are functionalized with streptavidin or are chemically activated to bind the ends of the modified DNA ends covalently. After successful tethering, the biomolecule is exposed to fluorescent dyes (i.e., *SYBR® green*) and extended. The individual laser power of each of the NIR ($\lambda = 830$ nm) counter-propagating trapping lasers is ~85 mW at the trap. The molecule can be stretched and relaxed numerous times without any change in its mechanics. To visualize the fluorophore-stained DNA, the molecule is illuminated for a couple of seconds by the built-in Argon laser ($\lambda = 488$ nm) and can be visualized with a confocal electron multiplying CCD. If the illumination time by the Argon laser (~4 mW) at the trap is increased to few tens of seconds, the molecule is optically damaged and ruptures due to breakage of covalent bonds. (**b**) Typical force-versus-extension curves of unlabelled double-stranded DNA (contour length = 0.5), and single-stranded DNA (contour length = 1) in buffer (10 mM HEPES pH 7.2, 1 mM EDTA, 150 mM NaCl). Curves are normalized to the contour length of single-stranded DNA (assuming a base-to-base distance of 0.7 nm). The DNA base-to-base distance (obtained by multiplying the normalized extension by 0.7 nm) projected onto the direction of the applied force is shown at the *top* [2, 15, 16]. (**c**) RNA polymerase moves in discrete steps along DNA molecule: Steps resolved for a stiffly trapped bead moved in 1-Å increments at 1 Hz. Data were median filtered with a 5-ms (*grey*) and 500-ms (*black*) window [14]

then moved by steering the beam with one precise optical mirror. This bead-DNA-bead dumbbell configuration allowed Block and coworkers to observe amazingly individual 0.34-nm base-pair steps of RNA polymerase translocation [14] (see Fig. 3c).

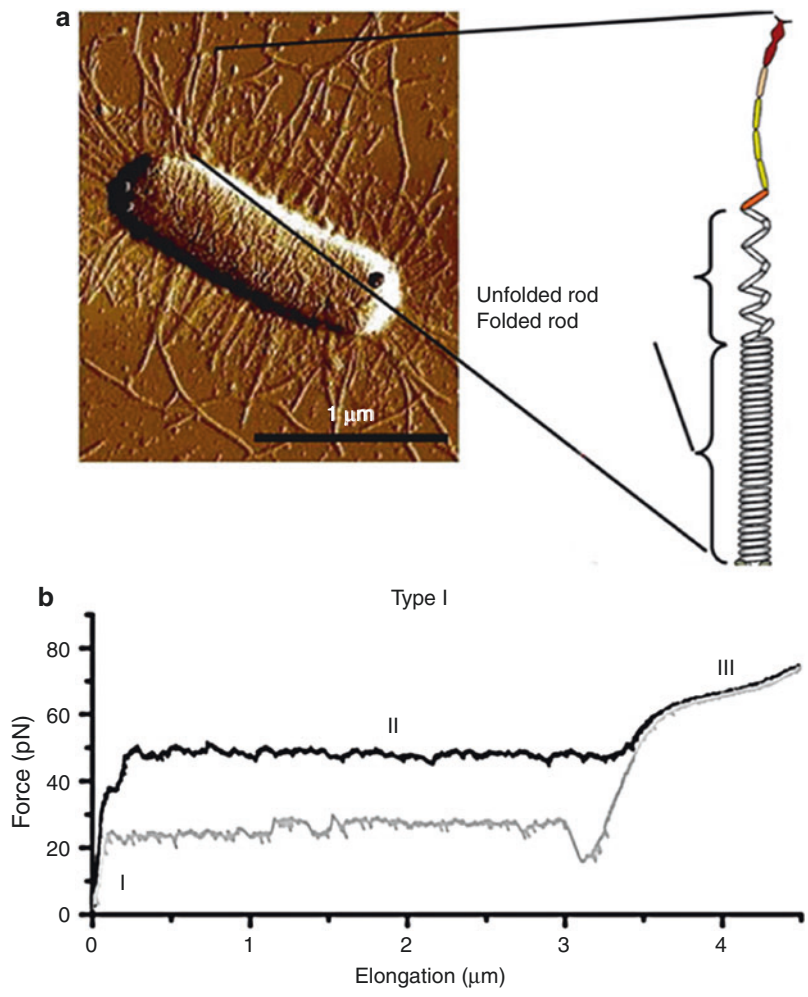
When viruses are reproduced by infected cells, they are reassembled from proteins which form a shell (i.e., a capsid) and from their genetic material, which they need to infect subsequent cells. The packaging of viral DNA by a rotary protein motor into the viral capsids was investigated with OT in 2001 by the Bustamante lab [20]. One of these studies (Fig. 2d) revealed that a bacteriophage φ29 motor can work against forces of up to 57 pN, making it one of the most powerful molecular motors known.

Optical traps have been used to probe the motion and mechanisms of various nucleic acid enzymes such as exonuclease, proteins that cut nucleic acids; helicases, proteins that unwind double-stranded DNA; and polymerases, proteins that synthesize RNA and DNA [18]. Today not only polymerase activity on DNA has been investigated on a single molecule level but also the translational activity of ribosomes acting on RNA or polypeptide chains [21, 22].

The genetic material of living cells is packed into condensed structures called chromosomes, the precise architecture of which is yet to be fully elucidated. The great complexity of chromosomal assembly is based on interactions between DNA and numerous proteins that bind DNA in sequence-independent manner. Optical tweezers proved to be an excellent tool for studying these interactions. In one study, researchers combined two optical traps to capture a pair of double-stranded DNA molecules and characterized protein-DNA complexes created in the presence of the DNA-bridging protein H-NS (Fig. 2e) [12].

Apart from protein-nucleic acid interactions, many biological interactions were investigated at

a single molecule level. Kinesin and dynein, molecular motors that transport cellular cargo by "walking" along microtubules, and myosin, a molecular motor that moves on actin filaments and generates the forces in muscles, have been investigated in depth for many years. The interaction forces of these motor proteins were among the first ones to be elucidated by OT [23].



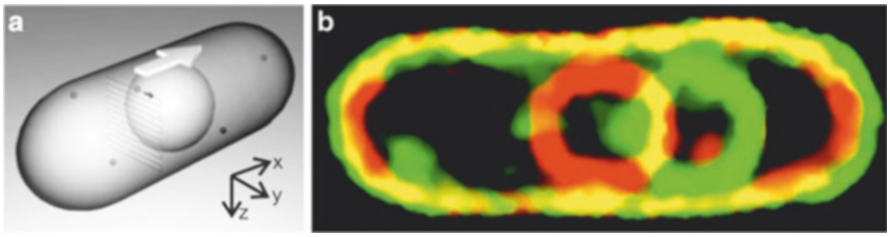
Since the size of biomolecules is in the order of nanometers, they are too small to be observed by classical diffraction limited optical microscopy. To overcome this limit, biomolecules can be fluorescently labeled and visualized using fluorescence microscopy. Fluorescently tagged molecules can be detected one by one. However, measuring single molecule forces and fluorescence at the same time is difficult due to the high level of background light from the optical traps, which is ten orders of magnitude greater than the light emitted by a single fluorophore. Over the last 5 years, instruments capable of simultaneous spatially coincident optical trapping and single molecule fluorescence were introduced to gain a more detailed insight into the nature of biomolecules. This combination was enabled by using improved optical designs, high-performance spectral filters, and automated rapid data acquisition [24, 25].

When applying a mechanical load on single molecules with OT, their response could be monitored using fluorescent probes. In Fig. 3a, an experiment on a single dsDNA molecule is shown [2]. A DNA molecule of 16-μm length was labeled with SYBR® green fluorophores and subsequently stretched with OT. The polystyrene bead in the upper part of the image (diameter 2.9 μm, coated with streptavidin) was trapped by two counter-propagating laser beams and acted as an anchoring point for the biotinylated end of the DNA. For such typical stretching experiments, the bead on the micropipette (with aperture <1 μm), to which the other end of the DNA was covalently coupled, was moved with nanometer precision by a piezoelectric stage until the DNA was extended to ~75 % of its contour length. Thereby, the force was raised above 1.5 pN and the DNA was then visualized in the confocal image plane of the microscope arrangement [2]. When extended further, the force on the molecule, which was measured by the change in light momentum flux, raised till the molecule reached a value of approximately 68 pN. At this force, the molecule undergoes a structural change and could be extended without much force to almost 1.7 times of its contour length [15, 16]. Further examples of combining optical traps with other analytical techniques will be presented later in this report.

Cells and Optical Tweezers

As mentioned before, one has to be careful with the choice of wavelength and the power of the laser used in optical trapping experiments. This is even more pronounced when whole cells are investigated. First experiments with whole cells, where cell membrane mechanics were investigated, were performed by the Sheetz group in the mid-1990s. A valuable application of OT could for instance be found in the study of bacterial motility and their adhesion to surfaces. Many types of bacteria express micrometer-long attachment organelles, the pili, which adhere to the host tissue and have an ability to uncoil and recoil. The pili facilitate bacterial conjugation, which is the exchange of genetic material from cell to cell. The folding mechanisms of piliated bacteria could be studied with force-measuring OT at single molecule level at a resolution in the low pN range [26]. For the first time, this method allowed the operator to assess forces mediated by individual pili on single living bacteria in real time. Recently, this technique was used to study how uropathogenic *E. coli* can withstand shear forces in a flow configuration [27]. Thus, force-measuring OT could help to understand these mechanisms enabling to fight infections caused by antibiotic-resistant bacteria. In Fig. 4, an image of a bacterium, which was manipulated with an OT, is shown.

Besides *E. coli*, also other mammalian cells such as red blood cells, nerve cells, and gametes were studied extensively by optical trapping [28]. Furthermore, OT could be used to spatially fix subcellular structures, which normally move inside a cell. Being optically trapped, these structures could be investigated with confocal microscopy. A recent example of such laser-based



Optical Tweezers, Fig. 4 (**a**) AFM image of a HB101/pPAP5 bacterium expressing pili. The schematic drawing shows the folded and unfolded parts of the pili. (**b**) Typical force-versus-elongation response of a single pili during unfolding (*upper curve*) and refolding (*lower curve*) at an elongation speed of 0.1 µm/s [27]. In region I, the pili are elongated up to a fraction of its relaxed length, and a linear force-elongation response is observed. In the following steady-state region II, a constant force is applied to the pili so that the unfolding process takes place. Region III originates from an overstretching of the pili

nano-surgery was the displacement of the cell nucleus to study the relevance of its intracellular position for the cell division and the resulting cell shape and size [29]. How internal cell structures like a nucleus can be manipulated by OT is shown in Fig. 5 [30]. Here cell internal particles, which diffract light (such as granules or organelles), can be trapped and then be displaced within the cell body. This mechanical motion induces effects onto surrounding structures such as the cell nucleus, which can be monitored.

Trapping outer cell components can also be realized using OT. These studies gave insight into essential cell functions such as cell motility, vesicle-mediated release or uptake of soluble and membrane components, or nanotube-mediated cell-cell communications [31]. Analyzing cell membranes with OT could even help to promote aging research, for instance by exposing endothelial cells to vertical forces using optical trapping. This experiment simulated the effects of high blood pressure to the blood vessels, and cell stiffening was observed indicating that the cells undergo complex morphological changes under the effect of external pressure [32].

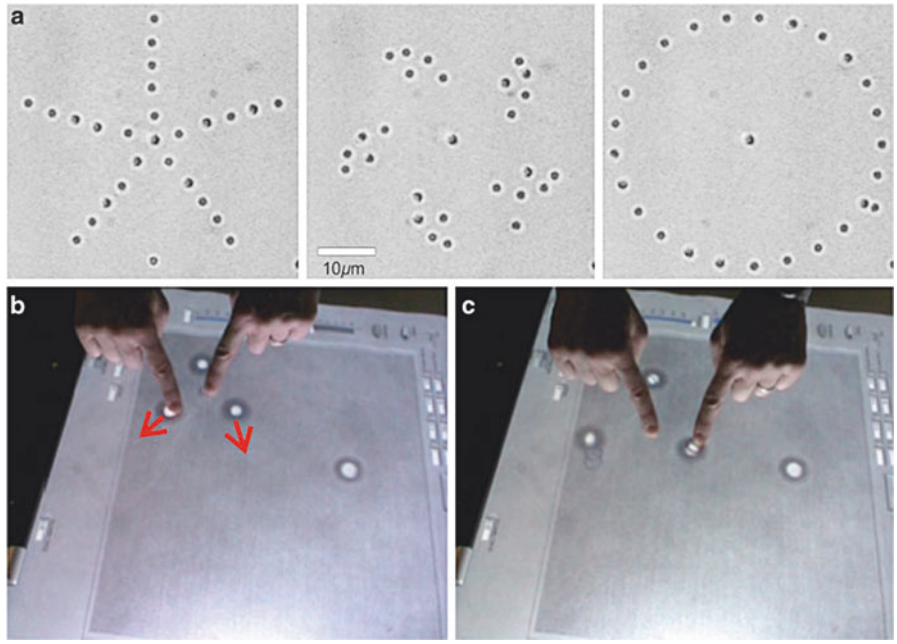
Optical Stretching of Cells

Normally, forces acting on a small scale like a single molecule or an organelle are investigated by optical tweezers, as reported above.

Optical Tweezers, Fig. 5 *Scheme of the cell nucleus being displaced due to optical tweezers*. (**a**) A lipid granule (*small sphere*) is trapped close to the nucleus (*large sphere*). The small granule is moved along the shown raster-scanning trajectory in the y-z plane (*small arrow*). At the same time, it is shifted in x direction (*big arrow*), thus pushing the adjacent nucleus forward in x direction [30]. (**b**) Superposition of two images of a single cell: before (nucleus in the *centre*) and after (nucleus moved to the *right*) the manipulation of the nucleus. The nuclear envelope and cell membrane were marked with GFP [29]

Nevertheless the forces acting on whole cells are also important, for instance during cell differentiation. To enable whole cell investigations, the optical stretcher, where two opposed laser beams are used to trap a cell, has been developed. In this experiment, no point force acts on the object. The photons generate surface forces at the opposite membranes and act on the whole structure, thus leading to a stretching of the cell along the beam axis [33]. When stretched, the elasticity of a whole cell can be measured and yield its Young's modulus. Thereby, the cell damage is reduced significantly since the optical stretcher only uses unfocused laser beams. This allows the application of higher laser powers to biological materials. Hence, the forces exhibited by an optical stretcher bridge the gap between OT and atomic force microscopy.

The optical stretcher has already been employed to stretch human erythrocytes, mouse fibroblasts, and PC12 cells [33]. In recent studies, the viscoelastic properties of cells have been correlated with their metastatic potential so that optical stretching has become a valuable technique for gaining new insights into the processes of cell migration and metastasis.



Combining Optical Trapping of Cells with Other Optical Techniques

As already mentioned before, nowadays, OT is often combined with other analytical methods to form powerful tools in single molecule studies. Besides fluorescence microscopy, Raman spectroscopy could be used simultaneously with OT. In a recent study, red blood cells were placed under stress with OT to simulate the stretching and compression the cells experience when passing through small capillaries. Simultaneously, the oxygenation state of the blood cells was monitored by Raman spectroscopy revealing a transition between the oxygenation and deoxygenation states of the cells when being stretched [34]. Raman spectroscopy combined with optical trapping could also be used to identify micrometer-sized particles, e.g., bacterial cells, in an aqueous environment. A single cell was immobilized in the laser trap and then the collection of its Raman signals could be maximized without any unwanted background signals from other particles or substrate surfaces. Thus, the OT analysis of the relative concentration of each type of organism in the aqueous solution was possible [35].

Holographic Applications of Optical Tweezers

With multiple laser beams, an array of several particles can be trapped at the same time. Such spatial arrangements of traps, also known as holographic tweezers (examples are shown in Fig. 6), can be achieved with two different methods:

(a) Scanning between trap positions: A single beam scans rapidly between several discrete

Optical Tweezers, Fig. 6 *Dynamic holographic tweezers in action*. (**a**) Polystyrene spheres with 990 nm in diameter are trapped simultaneously in dynamic tweezers and moved in the same plane from a star pattern into a circle [6, 37]: (*left*) the original configuration; (*middle*) after 16 steps; (*right*) the final configuration after 38 steps. (**b**) An arrangement of SiO_2 spheres is optically trapped, and the spheres can be seen in a multi-touch interface for holographic tweezers. (**c**) The arrangement was moved simultaneously in the direction of the *arrows* shown in **b** [39]

trap positions, which can be computer controlled. Thus, the single beam follows separate light paths, that are recombined before the beam enters the microscope. If the laser beam switches fast enough between the distinct positions, multiple objects can be trapped simultaneously because the viscous drag on them is high enough to keep them in the defined positions while the laser switches to the surrounding positions [36]. However, the number of objects which can be trapped with this technique is limited by the diffusion of the objects and the switching speed of the laser.

(b) Separate laser beams: A computer-addressed spatial light modulator (SLM) is employed to impose a predefined phase shift on the incoming laser beam. Thus, the coherent beam is split into many separate beams, each of which is focused into an optical trap by a strongly converging lens [6, 37, 38]. Computer-generated holograms thereby configure the resulting pattern of traps, and each trap can have individually specified characteristics, arranged in arbitrary three-dimensional configurations. Recently, a novel multi-touch interface for the interactive real-time control of holographic OT was presented to control numerous optical traps independently but simultaneously [39].

With permanent three-dimensional arrangements of OT, several new applications arose. Tweezer-organized structures can for instance be fixed in place by sintering or gelling, depending on the material surrounding the trapped objects. In this nanofabrication process, the intense illumination of the laser tweezers can even be used to drive spatially resolved photochemistry for fabricating small complex three-dimensional structures [6]. Moreover, three-dimensional configurations

of isolated cells such as *E. coli* have been obtained by trapping the cells within a gelatin matrix. When the trap was switched off and the gel was set, a permanent and vital cell architecture was maintained for several days, thus opening new perspectives in cell and tissue engineering using OT [40]. With such results, the development of holographic OT promises exciting new opportunities for research engineering and manufacturing at mesoscopic length scales.

Key Research Findings

The molecular actions of individual molecules or cells can be investigated in optical tweezer experiments in buffers that are very similar to their native environments. Experiments reach an accuracy of sub-nanometer resolution applying sub-piconewton forces. By scaling up to multiple traps using holographic techniques, new manufacturing of three-dimensional structures at mesoscopic length scales is possible.

Optimization of Nanoparticles

► Integrated Approach for the Rational Design of Nanoparticles

Optimization of Plasmonic Substrates for SERS Application

Marc Lamy de la Chapelle
Sorbonne Paris Cité, Laboratoire CSPBAT, CNRS, (UMR 7244), Université Paris 13, Bobigny, France

Introduction

Surface Enhanced Raman Scattering (SERS) is an analytical technique that provides a huge enhancement of the Raman signal. This technique is essentially based on the exploitation of the optical properties of metallic nanostructures. One of the main contributions of these properties is the excitation of the localized surface plasmon that can induce a huge enhancement of the electromagnetic near-field. By tuning the resonance of the localized surface plasmon, it is possible to optimize and control the SERS signal.

The Raman Spectroscopy

Raman spectroscopy is a vibrational spectroscopy that probes the vibrational modes of an excited molecule. These modes are directly related to the structure of the molecule and their frequencies depend on the mass of the molecule atoms, on the chemical bond nature and on the geometry of the molecules. Each vibration is specific of the molecular architecture as well as the molecule composition and can be used to identify and characterize the molecule, giving information on its chemical group and their spatial distribution. Thus, the Raman spectrum provides specific bands for each chemical or biological compound and is considered as an actual spectral signature for one individual compound.

The Raman spectroscopy is in fact based on an inelastic scattering process of a monochromatic light (a laser excitation for example) induced by an indirect transition between two different vibrational levels. Such transition can occur from the fundamental to the excited vibrational states or

from the excited to the fundamental vibrational states. In the first case, a decrease of the energy and of the frequency of the scattered light is observed (Stokes scattering process). In the other case, an increase of the energy and of the frequency is measured (anti-Stokes scattering process). In both cases, the measured spectral shift corresponds directly to the energy of the vibrational modes.

The intensity of these processes is directly related to the excitation electric field amplitude, E, and to the polarizability of the vibration mode, α, since the amplitude of the induced dipole moment of the vibrational mode, P, is defined as:

$$P = \alpha.E \quad (1)$$

The intensity of the Raman signal is then proportional to the square of the amplitude of P. However, the Raman cross section is very low (in the range of 10^{-30} to 10^{-26} cm^2) depending on the molecules and on its electronic structure. To reach high signal in Raman spectroscopy it is possible to either increase the number of molecules (increase of the concentration for example in solution) or increase the laser power. In the former case, it can be hard to get high amount of material especially in the case of biological molecules that are difficult to produce in large quantity. In the latter case, a high laser power can induce a degradation of the material by heating.

To avoid these two drawbacks, the increase of the Raman signal can also be reached by exploiting the local electromagnetic field enhancement obtained with metallic nanostructures. This method is called Surface Enhanced Raman Scattering (SERS).

The Surface Enhanced Raman Scattering (SERS)

The SERS is a very powerful method to increase the Raman signal of a specific molecule by several orders of magnitude, thanks to the use of metallic nanostructures of various shapes and sizes. Thus, any metallic surface that exhibits a roughness from the nanometric to mesoscopic scales can be considered as a SERS substrate and has the ability to enhance the Raman signal of any molecules in the close vicinity of the metallic surface. SERS can also be observed with metallic nanoparticles of different shapes (spheroids, ellipsoids, oblate, prolate, triangles, cubes…) and sizes (from few nanometers up to several hundreds of nanometers).

The enhancement of the Raman signal observed in SERS can be assigned to two different processes in the SERS: an electromagnetic process and the chemical process.

The chemical one is not completely understood but it is assigned to electronic interaction between the metallic surface and the electron cloud of the molecule. It can be modeled by a charge transfer or by the formation of a chemical bond between the surface and the molecule. In both cases, such interaction induces a modification of the electron distribution around the molecule and thus in favorable case, an increase of the molecule polarizability. This polarizability modification has an influence on the amplitude of the induced dipole moment, P, and thus induces an increase of the Raman signal. However, this enhancement is limited since it has been estimated to be around two orders of magnitude.

In fact the main effect that largely explains the SERS process is the electromagnetic one which contributes to the Raman signal enhancement up to eight orders of magnitude. The electromagnetic process is based on the enhancement of the electric field amplitude at the vicinity of the nanoparticle surface. This field enhancement is directly related to the optical properties of the nanostructure and more especially to the ability to excite the localized surface plasmon (LSP). The LSP is a collective oscillation of the free electron cloud inside the nanostructure. Hence, the LSP can be seen as an oscillation mode and thus its frequency depends strongly on the size, the shape and the metal nature of the nanostructure, and eventually on its coupling with other LSP from other closely packed nanostructures. As any oscillating system with a proper mode, the LSP is defined by a resonance frequency corresponding to the maximum of interaction with an excitation electromagnetic field. The LSP resonance (LSPR) position is

often determined as the maximum of the extinction (absorption and scattering) spectrum measured with the nanoparticles. The LSPR can be tuned in a wide spectral range just by changing the geometrical parameters or the metallic nature of the nanostructures. When excited with a monochromatic laser light close the LSPR, a huge enhancement of the electromagnetic field is created at the vicinity of the surface. This enhancement notably depends on the position of the excitation wavelength compared to the position of the resonance. In enhanced spectroscopies as SERS, it is actually important to optimize the position of the LSPR to reach the highest enhancement factor.

The enhancement factor can be determined taking into account the different light interaction processes between the excitation light, the nanostructure and the molecule. In fact, the nanostructure with the molecule at its vicinity has to be considered as a two bodies system and light interacts with both of them [1, 2]. First, the excitation light (excitation wavelength λ_0) interacts with the LSP and creates a first electric field enhancement. This enhanced electric field, E_{loc}, excites the molecule that scatters an enhanced Raman signal at a redshifted wavelength, λ_R, (Stokes process, decrease of the light frequency and increase of the light wavelength). The enhanced Raman signal can then interact with the nanostructure and the LSP. This process, called the reradiation process, induces a second enhancement of the Raman signal at the Raman wavelength, λ_R. The enhanced Raman dipole moment, P_{SERS}, and the enhanced intensity of the Raman signal, I_{SERS}, can be expressed as follows:

$$P_{SERS} = \alpha . f(\lambda_0) . f(\lambda_R) . E \tag{2}$$

$$\begin{aligned} I_{SERS} &= \alpha^2 . |f(\lambda_0) . f(\lambda_R)|^2 . E^2 \\ &= |f(\lambda_0) . f(\lambda_R)|^2 . I_{\mathrm{Raman}} \approx |f|^4 . I_{\mathrm{Raman}} \end{aligned} \tag{3}$$

with $f(\lambda_0)$, the enhancement factor at the excitation wavelength, λ_0, and $f(\lambda_R)$, the enhancement factor at the Raman wavelength, λ_R. If we assume that the excitation and Raman wavelengths are close (low Raman shift), the two enhancement factors will also be close ($f(\lambda_0) \approx f(\lambda_R) \approx f$) and the SERS signal will be enhanced at the power fourth of the field enhancement factor, f (as shown in Eq. 3). This explains why one can reach giant enhancement since even a low enhancement of the amplitude of the electric near-field can induce a large enhancement of the Raman signal. Both enhancement factors depend on the position of the LSPR comparing to the excitation and the Raman wavelengths.

Thus, the Raman signal of any molecules deposited at the nanostructure surface could be enhanced by several orders of magnitude depending on the LSPR and more generally on the optical properties of the nanostructures. Moreover, this enhancement occurs in the near field (approximately in the distance from the surface lower than the half of the wavelength) of the nanostructures. Indeed, the field created by the LSP is confined at the surface vicinity due to the evanescent nature of the LSP. Thus the amplitude of the enhanced field decreases exponentially from the nanostructure surface with a very short decay length close to a few tens of nanometer in the most favorable cases. Thus, only the first layers of molecules are in fact inside the enhanced field and only they contribute to the SERS signal. SERS is an extremely local spectroscopy to probe a few quantities of molecules and has enabled the single molecule sensitivity.

Optimization of the SERS Signal

To be able to control the enhancement factor obtained in SERS, it is of first importance to control the optical properties of the metallic nanostructures used as SERS substrate. Such approach is effectively necessary in order to reach reproducible SERS signal as well as to reach the best SERS signal. In this section, the discussion will be focused on the different parameters that have an influence on the SERS signal and how they have to be adjusted in order to optimize it. The main rules of optimization will be presented and clarified.

Control the Optical Properties to Tune the SERS Electromagnetic Contribution

First, as explained above, one has to control precisely the optical properties of the nanostructure and more specifically the position and the width of the plasmon resonance. In fact, the LSPR can be finely tuned by controlling the size and the shape of the nanostructures at the nanometer scale as well as their close environment including potential coupling. Thus, to reach such control of the optical properties and to follow precise requirements, the use of lithography methods as production techniques is required. The electron beam lithography (EBL) is the method that offers the highest flexibility since it allows the production of any kind of nanostructure shapes, sizes, and arrays with a precision below 10 nm. The principle of the EBL is the creation of a polymeric mask with the electron beam directly on the substrate. The mask precision is directly related to the beam size. As a consequence, this technique is a powerful tool to provide highly reproducible SERS substrate. However, it has several drawbacks since it is slow and the produced surface is small (width of only few hundreds of micrometer). This technique is expensive and is not suitable for the mass production of SERS substrates. To overcome such limitations, two other methods have been proposed: the nanosphere lithography (NSL) and the nanoimprint lithography (NIL). The NSL is based on the deposition of a monolayer of latex beads at the substrate surface that forms a mask to produce nanotriangles in hexagonal array. The principle of the NIL is the imprint of a nanostructured stamp that reproduces the nanostructures on a polymer to form the mask. Both techniques are cheaper and faster than EBL but they are limited in terms of shape for NSL (only nanotriangles can be produced) and of size for NIL (nanostructures should have size higher than 100 nm to be produced correctly) [2, 3].

SERS Versus LSPR

The main effect that is involved in the enhancement of the electromagnetic field around the nanostructures is the LSP. The close relation between the LSP and the SERS signal can be demonstrated by polarization experiments. Indeed, on elongated nanoparticles, several LSP modes can be observed along each axis of the nanoparticle. For example, with a nanorod with an aspect ratio around two (length around 100 nm and width around 50 nm), one can observe a LSPR along the length close to 700 nm and a LSPR along the width close to 520 nm. Thus, depending on the excitation polarization, it is possible to excite selectively each LSP. Since there is a large spectral shift (around 200 nm) between both LSPR, one can chose an excitation wavelength (633 nm for example) that is close to the LSPR (700 nm along the nanorod length) and out of resonance for the other one (520 nm along the width). When the excitation polarization is then rotated comparatively to the length of the nanorod, the efficiency of the LSP depends on the angle, θ, between the excitation polarization and the length of the nanorod ($\theta = 0°$, full excitation of the LSP; $\theta = 90°$, no excitation of the LSP). When the SERS signal is measured depending on θ, a clear correlation is observed between the LSPR and the SERS intensities [4]. It means that both intensities are maximum for the same angle ($\theta = 0°$ and 180°) whereas the SERS intensity is null when the LSPR is not excited ($\theta = 90°$ and 270°). Moreover, whereas the LSPR intensity follows a Malus law with an angular dependence in $(\cos(\theta))^2$, one can notice that the dependence of the SERS signal with the angle is closer to a $(\cos(\theta))^4$ law, which is a clear evidence of the dependence of the SERS signal is close to the 4th power of the near-field enhancement factor (Eq. 3).

As the LSP is assigned to the oscillation of the electron cloud, it is a resonant effect that induces a high interaction with the light for one specific wavelength (LSPR position) and on a specific wavelength range (width of the LSPR). Out of resonance, it is assumed that there is few or no interaction with light. It means that the field enhancement is directly related to the position of the excitation wavelength compared to position of the LSPR and as a consequence the SERS signal strongly depends on these relative positions. Moreover, as the enhancement factor (EF) in SERS includes one EF at the excitation wavelength as well as one EF at the Raman wavelength

due to the reradiation process, the SERS signal also depends on the position of the Raman wavelength compared to the position of the LSPR. Intuitively, one can easily assume that the best SERS signal is reached for a position of the LSPR between the excitation and the Raman wavelength in order to optimize both EF. Indeed, if the excitation (Raman) wavelength is close to the LSPR, the Raman (excitation) wavelength will be out of resonance that will induce a low global EF [2].

The position of the LSPR compared to the excitation and the Raman wavelengths is then the first parameter to be optimized to reach the highest SERS signal.

Several experiments have been done to determine the best LSPR position and it has been demonstrated that the above rule is respected for gold nanocylinders or nanotriangles produced by EBL or NSL respectively using an excitation wavelength between 514 and 633 nm [2, 4-6]. These experiments show a strong variation of the SERS signal depending on the position of the LSPR. A maximum is observed at the average between the excitation and the Raman wavelength whereas the SERS signal decreases rapidly outside this range. It is then possible to tune the SERS signal by changing the position of the LSPR.

But this rule is no more applicable when the excitation wavelength is close to the near infrared. Indeed, for an excitation wavelength of 785 nm and for nanocylinders produced by EBL, the maximum of the SERS signal is reached for a LSPR close to 750 nm and thus largely outside the excitation and Raman wavelengths range [7]. Such effect has been assigned to a discrepancy between the near-field around the nanostructure and the far field. The SERS process is effectively a near-field effect since the enhanced Raman signal is produced by the enhanced field at the close vicinity of the nanostructure surface whereas the LSPR is measured by extinction spectroscopy in the far-field. It means that the highest field enhancement could not be reached at the wavelength corresponding to the LSPR. Such discrepancy has notably been explained by a spectral shift between the near-field enhancement and the LSPR [8, 9] due to the oscillation damping inside the nanostructures. This spectral shift should then increase with the LSPR width. It is important to take into account not only the position of the LSPR but also the excitation wavelength in order to optimize the SERS signal.

Another parameter that influences the SERS optimization is the shape of the nanostructure. Some experiments have been done on gold nanorods and nanowires produced by EBL at several excitation wavelengths (633 and 676 nm) [2, 10]. Such nanorods have some aspects ratio from 1 to 20 (length from 60 nm up to 1 μm, width 60 nm). For an excitation electric field parallel to the long axis of the nanorods, the SERS signal exhibits large variations depending on the length of the nanorods with several maxima for specific lengths (around 100, 350, 650 and 900 nm at 633 nm and 140, 400 and 700 nm at 676 nm). It has also been observed that for some specific lengths the SERS signal is null (length around 300 nm). The first maximum can be assigned to the first order of LSPR whereas the other ones are assigned to higher orders (3rd order for the second maximum, 5th order for the third one and 7th order for the last one). Indeed, in long nanorods, some higher orders of resonance can be excited since the length of the nanorods is no more negligible compared to the excitation wavelength. To respect the symmetry of the LSP mode along the nanorods, only odd modes can be excited. First, this observation demonstrates that the higher order of resonance can be SERS active in nanorods. This is not the case for nanocylinders since it has been shown that for nanocylinders larger than 200 nm exhibiting 3rd order of LSPR, no specific enhancement is observed. Second, the higher orders of LSPR can exhibit higher SERS signal than the dipolar one. This is notably observed at 633 nm for which the highest SERS signal is obtained for the 5th and 7th orders. Third, for any LSPR orders and any excitation wavelengths, the SERS signal is optimized for a LSPR position close to the Raman wavelength. The SERS behavior of the nanorods is then different from the one of the nanocylinders: different rule of optimization and no dependence on the

excitation wavelength. This specific behavior has been assigned to the elongated shape of the nanorods [4]. The use of electromagnetic model has shown that such shape favors the reradiation effect in SERS and thus the enhancement of the signal at the Raman wavelength. From such results, it is possible to determine that the nanorods acts as nanoantenna at the nanometric scale through the enhanced re-emission of the Raman scattering.

All these results demonstrate that the optimization of the SERS signal depends on the LSPR position and that some optimization rules can be extracted. However, these rules are strongly dependent on the shape and the excitation wavelength essentially due to the near-field interaction between the molecule and the nanostructure. In the aim of maximizing the SERS signal, it is of real importance to take into account such near-field effect and the geometry of the nanostructure is a key parameter for the SERS optimization.

Effect of the Environment

Another way to increase the SERS signal is to control the direct environment of the nanostructure.

As any resonator, the LSP can be damped by the local media that surrounds the nanostructure. The effect of this damping is directly related to the dielectric constant of the surrounding media and more specifically to its imaginary part that induces absorption of the excitation energy or of the LSP energy. As an example, one can consider the adhesion layer used to attach the gold nanostructures at the glass substrate surface. In most of the case, this adhesion layer is made of chromium, which has a large imaginary part of the dielectric constant in the visible range that is known to degrade the LSPR. It has been proposed to change this layer by a dielectric layer as the MPTMS that has no absorption in the visible range [11]. In this latter case, the LSPR has been improved since the use of the MPTMS layer induces an increase of the LSPR intensity and a decrease of the LSPR width and as a consequence an increase of the quality factor of the resonance. Such improvement of the LSPR has also a strong influence on the near-field enhancement. First, it has been demonstrated that the SERS signal is increased by one order of magnitude when the MPTMS is used compared to the Cr adhesion layer. A sharper LSPR induces a higher SERS signal. Second, a narrower LSPR width induces also a narrower SERS signal variation when the LSPR is tuned comparatively to the excitation and the Raman wavelengths. A higher quality factor of the LSPR induces a higher quality factor of the SERS efficiency.

One of the main effect used to increase the SERS signal is to approach several nanostructures together at distance lower than the half of the wavelength. The LSPs of these close nanostructures couple together to create a highly intense near-field in the gap between the nanostructures. The field enhancement is then largely higher than the one obtained with individual nanostructures due to the coupling. Since the amplitude of the LSP decreases exponentially with the distance from the nanostructure surface and since the decay length of the LSP amplitude is between 10 and 20 nm, the gap to get a coupling has to be lower than few tens of nanometers (typically lower than 20 nm). Moreover the field enhancement depends strongly on the gap and it increases exponentially when the gap decreases. Such geometry creates what is called in SERS "hot spots," thus providing huge enhancement factors. As a consequence, the SERS signal follows the same behavior than the one observed for the LSPR coupling, meaning highly intense Raman signal that increases exponentially when the gap decreases [12]. The ideal configuration is then to have the lowest gap between the nanostructures to reach the highest enhancement factor. However, keeping in mind that it is necessary to control the optical properties and the geometrical parameters of the nanostructures, it is difficult with the current lithography techniques to produce some coupled nanostructures with a gap lower than 10 nm with high reproducibility on a large surface. For controllable SERS substrate, such kind of signal optimization by the coupling approach is still not completely achievable.

Conclusion

The objective of this article was to give a large overview of the different parameters that influence the SERS signal and how the latter one can be optimized. First, we emphasized the relation between the LSPR position and the SERS intensity, demonstrating that some optimization rules can be extracted. Such rules depend essentially on the shape of the nanostructures as well as on the excitation wavelengths. It was also demonstrated that the higher orders of LSPR are SERS active and can provide higher SERS signal than the dipolar LSPR. Moreover, the relation between the LSPR position (measured in far field) and the SERS intensity (near-field interaction) is not totally obvious and has to be treated carefully. Second, it is clear that the direct environment of the nanostructures, either the surrounding media or the coupling between several nanostructures, has also a strong influence on the SERS signal. In all the cases, in order to control the optical properties of the nanostructures and as a consequence the SERS signal, it is of real importance to control precisely the geometrical parameters of the nanostructures and then to use lithography techniques that allow the production of nanostructures with high reproducibility. Thus, the control of the nanostructure geometry and architecture is a promising approach to produce some highly reproducible SERS substrates, which is the ideal achievement for any SERS applications.

Definition

Multi-scale manipulation refers to manipulation of objects with operational length scales ranging from several millimeters to nanometers. An optoelectric platform, which integrates multiple physical mechanisms, uses optically triggered electrokinetics to achieve multi-scale manipulation. These platforms are characterized by dynamic programmability and multitasking.

Overview

The growing demand for point-of-care analysis has motivated the rapid growth of the lab-on-a-chip (LoC) market. Considering the complexity, diversity, and multitasking nature of the technology, considerable efforts have been made to create a versatile platform capable of handling as many targets as possible. Multi-scale manipulation, or the ability to manipulate media and particles at multiple length scales, has been a significant and sought-out milestone in the LoC field for years. Despite a significant progress over the past decade in micro-/nanofluidics, overcoming the operational gaps of macroscale to microscale and microscale to nanoscale regimes remains a big challenge in the scientific community. Existing prior techniques, such as micropumps, microvalves, micropipettes, microgrippers, and so forth, heavily rely on continuous fluid flow and mechanical structures, thus increasing the difficulties in connections between different length domains. As a result, the multi-scale manipulation was not fully realized until digital microfluidics became practical. Recently, noninvasive manipulation techniques are rapidly emerging in many biomedical applications. Noninvasive manipulation typically utilizes optical, electrical, magnetic, or thermal measures to maneuver targets; therefore, no physical contact is involved. This free-of-contact capability is beneficial to biomedical applications due to the vulnerability and susceptibility of most biological materials to cross-contamination and mechanical stress. The potential of noninvasive techniques in multidimensionality and extensibility makes them the best candidates for carrying out multi-scale manipulation.

Two categories of length scale can be used to distinguish current noninvasive manipulation schemes: millimeters to sub-millimeters and micrometers to nanometers. For the first category, aqueous droplets are targeted due to ease of control, least cross-contamination, free from physical microfluidic components, and definitive geometry. Droplets act as carrying vessels for mediating various movements, such as mixing, splitting, translation, metering, and incubation. Without conventional structural connections, the gap between different length scales is no longer a hassle. Optoelectrowetting (OEW) [1], a technique based on electrowetting and photovoltaics, and its derivative, open optoelectrowetting (O-OEW) [2], are optoelectric techniques used in this regime. Both techniques enable dynamic

manipulation and simplify microfabrication. Unlike the first category, the second one usually deals with more diverse subjects, which include micro-/nanoparticles, quantum dots (QDs), cells, bacteria, nanowires, and nanorods. In this regime, the targets will go through a final processing step to achieve a designated task. Common manipulation scenarios may include separation, concentration, and sorting. Optoelectronic tweezers (OETs) [3] and rapid electrokinetic patterning (REP) [4] have shown more promise when compared to traditional techniques, such as dielectrophoresis (DEP) and electrophoresis (EP) in terms of programmability and maneuverability. The subtle combination of electric and optical domains broadens their applications. Since these techniques are compatible with either electric field, optical field, or both, an integration with other optoelectronic devices for a more powerful tool is viable.

Some attempts have been made to successfully achieve noninvasive multi-scale manipulation. Cho et al. [5] first demonstrated concentration and binary separation of latex particles in liquid vessels based on electrowetting on dielectric (EWOD) and electrophoresis. Later, Fan et al. [6] achieved live and dead cell sorting in droplets based on a platform composed of DEP and electrowetting. The length scales involved in both studies were several micrometers for particles/cells and millimeters for droplets. However, the operational flexibility remained very limited due to the permanent nature of the electrodes. After OEW, OETs, and REP were introduced, attention then shifted toward optoelectric tools to seek for more flexible manipulation techniques. Shah et al. [7] came up with a EWOD-driven device integrated with OETs for cellular isolation and analysis. Although the platform was not fully operated with the optoelectric means, OET performed its programmable potential in such kind of integrated system. Later, Kumar et al. [8] exhibited a fully optoelectric platform driven by O-OEW and REP. All electrode patterns were thus virtually and dynamically generated by incident light images. O-OEW, a modified OEW, was utilized for basic droplet handling. The hybrid system was built with added flexibility by replacing the stereotypical sandwiched structure with an open configuration. Similarly, Valley et al. [9] achieved similar results with OETs, although the underlying physics differ from REP mechanisms.

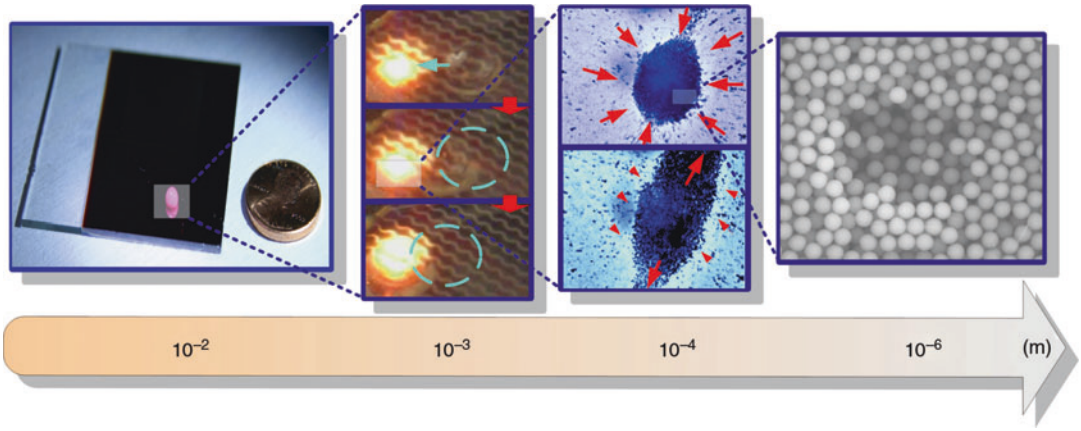

Figure 1 shows a chart of the hybrid optoelectrically enabled multi-scale manipulation and the corresponding length scales involved in different operational regimes. Due to the inherent compatibility between optoelectric techniques, the transitional gaps from one length domain to another become nearly seamless. Such hybrid techniques can engender new applications in lab-on-a-chip systems and may enable novel approaches to the investigation and application of fundamental electrokinetic phenomena.

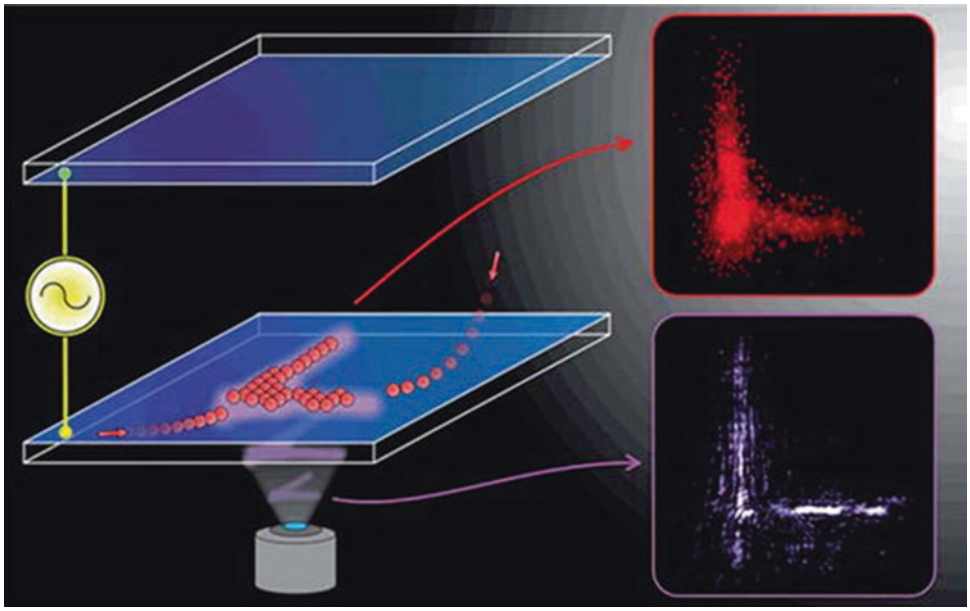
Methodology



In this section the mechanisms that have been employed as components of different multi-scale tools will be discussed. First REP and OETs – tools which target the micrometer to nanometer length scales – will be discussed. OEW will be discussed last that targets liquid droplets, objects typically within the millimeter length scale.

Rapid Electrokinetic Patterning (REP)

REP is an innovative new micro-/nanomanipulation tool that has been developed at Purdue University, USA. This technique is a noninvasive, real-time, dynamic, optoelectric manipulation tool that was first introduced in 2008 by Williams et al. [4]. The first reported chip configuration consisted of ITO-coated parallel electrodes biased with an AC signal (Fig. 2). It was demonstrated that in a low AC frequency regime (<200 kHz), micrometer-sized particles could be trapped and dynamically configured into various shapes on the electrode surface by using various optical landscapes produced from a laser operating at a wavelength of 1064 nm. Since this report, the technique has been extended to the use of nonuniform electric fields [10] and to particles as diverse as gold particles (200, 250 nm),

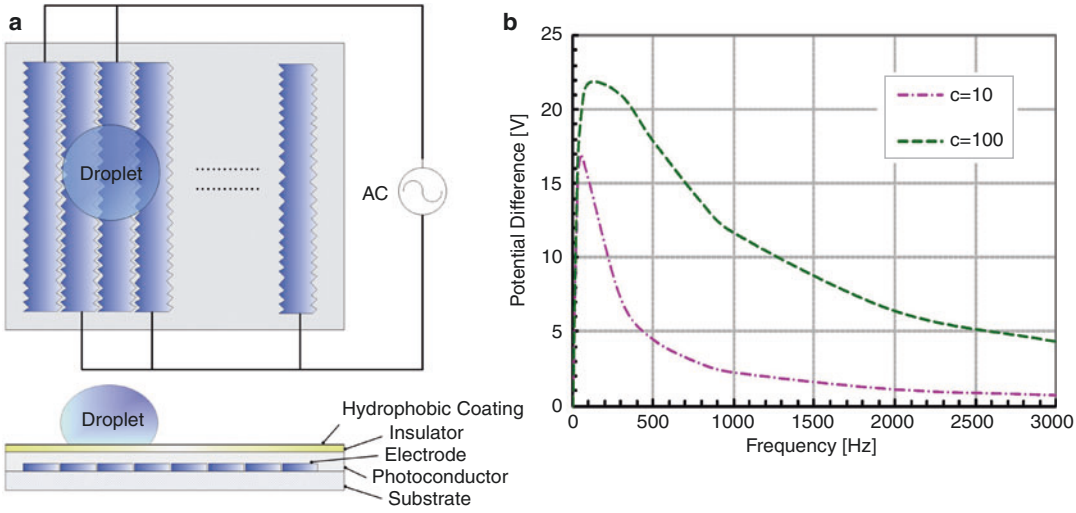
Optoelectrically Enabled Multiscale Manipulation, Fig. 1 Multi-scale capabilities of a hybrid optoelectric device. An aqueous droplet is manipulated by O-OEW. The illumination is provided through a microscope objective lens with focused broadband light. The applied AC biasing conditions were 50 V_{rms} at 300 Hz. Inside the droplet, 1 μm polystyrene particles are massively aggregated around an IR-illuminated site at the water-electrode interface. The applied AC biasing conditions were 28 V_{rms} at 25 kHz. The particle clump disperses when the IR illumination is off. Zooming the particle aggregation shows thousands of loosely packed particles stacked into several layers (Reprinted with permission from Kumar et al. [8]. Copyright 2010 American Chemical Society)

Optoelectrically Enabled Multiscale Manipulation, Fig. 2 In REP, laser illumination causes sharp temperature gradients in the medium through liquid and electrode heating, thus increasing mass transfer to the illuminated locations on the electrode surface. On the electrode surface, electrokinetic forces lead to the capture of the particles. In the figure, a laser hologram captures thousands of fluorescent (700 nm) beads into an "L" shape (Williams et al. [4]. Reproduced with permission from The Royal Society of Chemistry)

silica particles, and polystyrene particles (50 nm to 3 μm) [10, 11]. Lately, biological applications, such as bacterial manipulation [12] and fluorescent signal enhancement for bead-based bioassays [13], have also been demonstrated with the technique. The attempts provide an insight to implementing microsurgeries on microorganisms in the near future.

REP, in its classical rendition, relies on the creation of extremely localized temperature gradients to drive electrothermal microvortices in the chip. The temperature increase due to laser heating does not necessarily need to be significant (<5 K); however, tightly focused laser beams lead to an extremely high gradient of temperature ($>10^6$ K/m). Electrothermally driven microvortices increase mass transport to the laser-illuminated spot on an electrode, where low-frequency electrokinetics results in the capture of particles. A full discussion of the underlying mechanisms and chip configurations is not in the scope of current discussion, but interested readers can refer to a review article by Kumar et al. [11].

Optoelectronic Tweezers (OETs)



Distinct from REP, OET is an electrokinetic technique, which uses a strongly photoconductive substrate. In OETs, an illumination source locally increases the material's conductivity, creating reconfigurable "virtual" electrodes. Chiou et al. [14] first reported this device which consisted of two parallel ITO electrodes with a photoconductive material, hydrogenated amorphous silicon (a-Si:H), coating one of them. When illuminated a-Si:H increases its electrical conductivity several orders of magnitude, creating a localized increase in field strength, enabling dynamic virtual electrode configurations. Photoconductivity of a-Si:H is most efficient from red to near-infrared wavelengths, though a white light source can also be used.

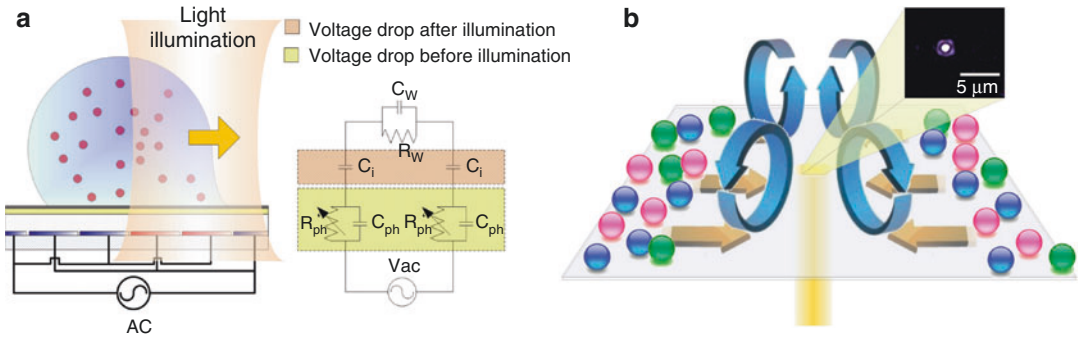
The reconfigurable illumination sources vary from a digital micromirror device (DMD), liquid crystal display (LCD), or a beam projector. Like REP, OET devices can also use a number of different electrokinetic mechanisms for its operation. They can use DEP, ACEO, or electrothermal flows for particle aggregation. Recent reviewed articles [11, 15] discuss in detail the underlying principles and operational regimes of OETs. OETs have trapped, sorted, and manipulated a variety of nonbiological and biological particles ranging from quantum dots to erythrocytes and leukocytes [16].

Optoelectrowetting (OEW)

Electrowetting (EW) alters the surface energy of the substrate under an aqueous droplet by modulating an external electric field. Charges induced by the electric potential are accumulated on both sides of the insulator. The droplet hence changes its geometric profile in response to the new energy state. Based on the core mechanism of EW, OEW [1] and O-OEW [2] delicately harvest the optical energy and convert it to the electrical energy through a photoconductor. In O-OEW, a photoconductor is arranged between the insulating and conductive layers serving as a binary gate in the presence of AC electric fields (Fig. 3a).

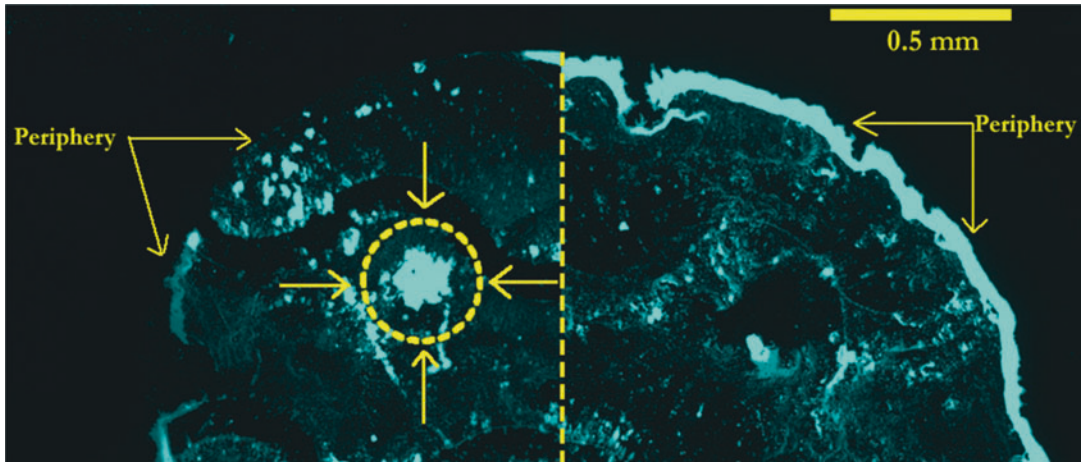
Light can lower the resistance in a photoconductor by activating a photovoltaic effect. It follows that the gate can therefore be opened by light but closed when the light is removed. The physics behind the on/off switching phenomenon is simply attributed to impedance shifting. In the absence of light, the photoconductor has high impedance. The majority of the potential drop hence is within the photoconductive layer in the dark. In the presence of light, however, the high impedance shifts to the insulator due to lowered resistance in the photoconductor. The potential drop across the insulator hence results in the conventional electrowetting effect. The overall switching phenomenon can be modeled with an equivalent circuit. The bright-to-dark potential difference across the insulator escalates as the frequency increases and then gradually declines when the frequency exceeds several hundred Hertz. The empirically operational range for an O-OEW device is estimated between 100 and 800 Hz [2] (Fig. 3b), but may vary with device geometry.

Optoelectrically Enabled Multiscale Manipulation, Fig. 3 (**a**) Schematic diagram of the chip layout. The interdigitated electrodes are connected to ground and electric potential alternately. The jigsaw edge is used to decrease the discontinuity between the gaps. The materials from the *bottom* to the *top* are glass substrate, titanium (Ti) (electrodes), *a*-Si (photoconductor), SiO_2 (insulator), and Teflon (hydrophobic coating). (**b**) Potential difference versus driving frequency. The potential difference is the difference between the dark and illuminated potentials in the insulator. Notation *c* denotes the photoconductivity ratio (light-to-dark conductivity ratio). The driving potential was 50 V_{rms}. The empirically operational frequency range was between 100 and 800 Hz. The frequency out of the range could result in limited or none O-OEW effect



Since the gate can be locally opened by a focused light spot, electrodes are virtually created. This feature enables programmability as well as dynamic manipulation without pixilated electrodes. Unlike EW, virtual electrodes not only simplify microfabrication but also impart O-OEW more maneuverability and flexibility. As compared to conventional OEW's sandwiched configuration, O-OEW had added freedom of sample introduction with coplanar arrangement of interdigitated electrodes. Detailed theories as well as applications of OEW are available [1, 2, 17].

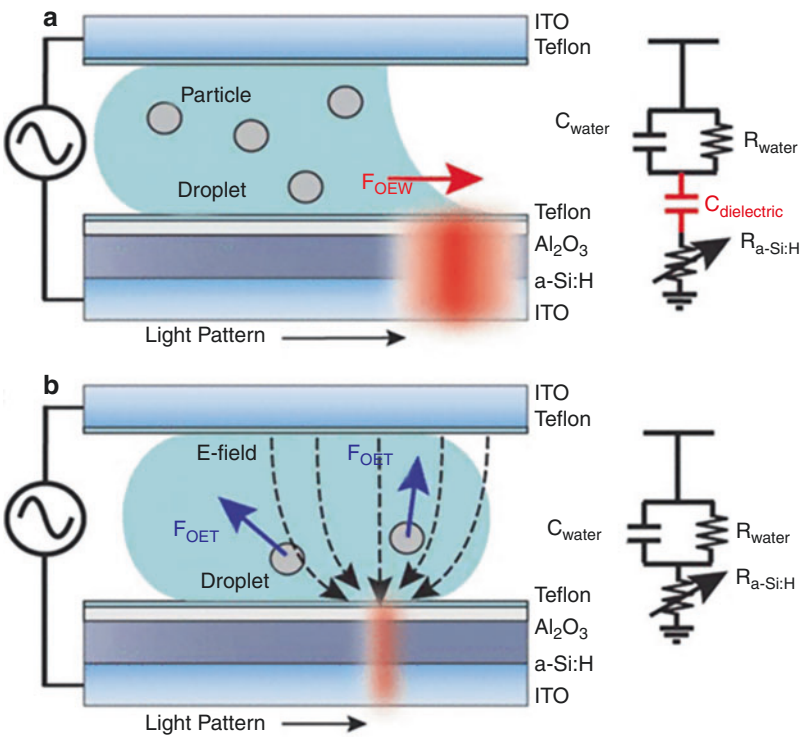
Key Research Findings



The first all optoelectric multi-scale manipulation was pioneered by Kumar et al. [8], where REP and O-OEW were combined to obtain multi-scale manipulation. This report was followed by Valley et al.'s work [9], where OETs and OEW were used simultaneously. In 2009, Shah et al. [7] had also demonstrated multi-scale manipulation in a device which integrated OETs and EW. Since only one of the techniques involved in Shah et al.'s device is optoelectric, this work will be discussed last.

REP+O-OEW

Kumar et al. [8] first demonstrated an all optoelectric device for multi-scale manipulation (Fig. 4). The multi-scale manipulation requirement was that a microliter aqueous droplet had to be moved to an appropriate work zone and subsequently concentration of suspended 1.0 μm fluorescent polystyrene beads close to the substrate surface had to be achieved. Thus, two distinct length scales, micron length scale for suspended particulates and millimeter length scale for droplet, were involved. To achieve this end, the researchers created an O-OEW device using ITO electrodes. Steering and mobilization of the liquid droplet was achieved using a red laser pointer in conjunction with the O-OEW device (Fig. 4a). Once, the liquid droplet was brought to the appropriate work zone, a focused infrared laser was used to create the REP effect, thus



Optoelectrically Enabled Multiscale Manipulation, Fig. 4 REP and O-OEW have been combined for achieving manipulation across length scales. (**a**) A droplet containing micron-sized particles is steered to an appropriate location using O-OEW. (**b**) REP is applied to aggregate micron-sized particles at a user-defined location. The particles aggregate under the influence of lateral ACEO and toroidal electrothermal flows (Reprinted with permission from Kumar et al. [8]. Copyright 2010 American Chemical Society)

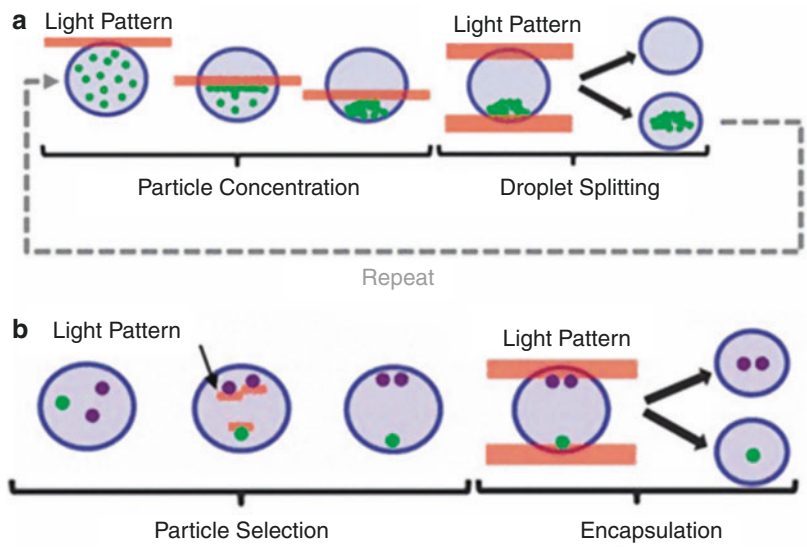
Optoelectrically Enabled Multiscale Manipulation, Fig. 5 The combined technique was used to aggregate particles at a known location, while the droplet dried (*left*). Typically, such a drying process leaves behind a ring of particles at the periphery (*right*) (Reprinted with permission from Kumar et al. [8]. Copyright 2010 American Chemical Society)

leading to rapid and massive particle accumulation at the illuminated site on the substrate surface. The REP mechanism in this device is slightly more involved than the one portrayed by Williams et al. [4] The REP effect here is caused by the combined effects of ACEO flows and electrothermal flows (Fig. 4b).

While displaying the ability to manipulate across length scales, the researchers also demonstrated a unique microfabrication technique. They used REP to concentrate particles in a region over many minutes, while the droplet dried. Evaporation of the droplet left behind an assembly of several thousands of particles (Fig. 5). Typically, a drying droplet leaves behind an assembly of particles in the shape of a ring – the effect being popularly known as the "coffee ring effect." The coffee ring effect, other than its popular appeal, has been vigorously studied for its varied applications such as in printing and sensing. The scientific community has long pursued techniques of altering the coffee ring effect by passive

Optoelectrically Enabled Multiscale Manipulation, Fig. 6 Illustration of operational principle. (**a**) Device operated by OEW (valid for frequencies, f < 100 kHz). This causes aqueous to move toward the light spot. Particles within the droplet are transported along with the droplet. (**b**) Device operated by OETs (f > 100 kHz). Particles within the droplet experience a DEP force when in the vicinity of incident optical pattern. In this regime, the device electrically looks identical to standard OETs (Valley et al. [9]. Reproduced with permission from The Royal Society of Chemistry)

techniques. Kumar et al.'s work [8] showed a novel way of actively altering the coffee ring effect.



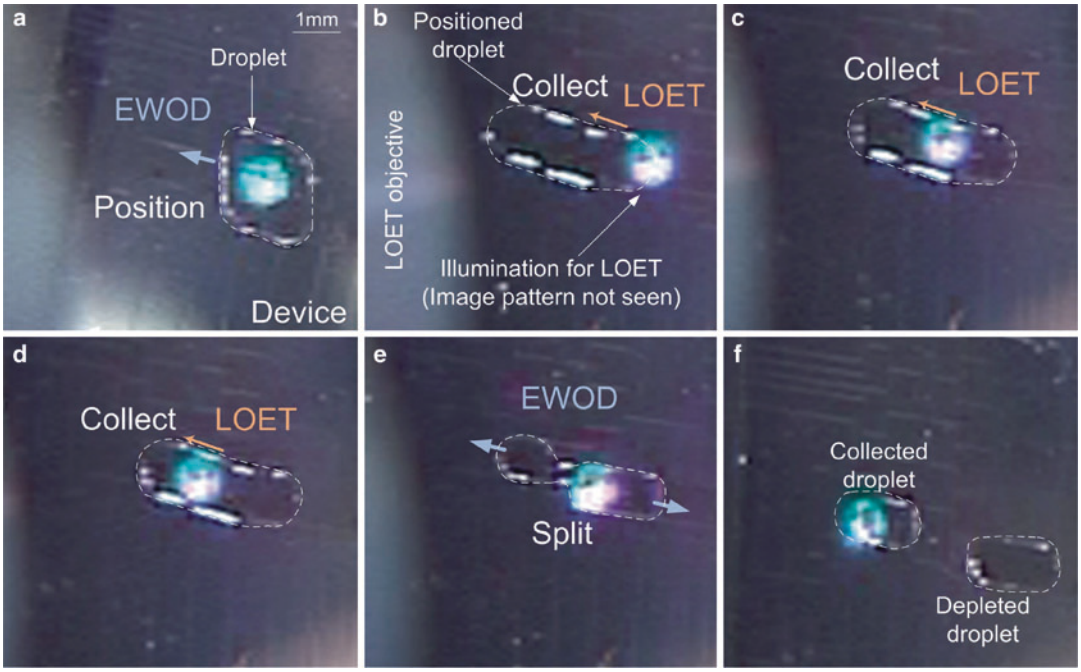
OET+OEW

A unique optoelectric platform integrating OEW and OET was first demonstrated by Valley et al. [9]. The platform is designed to manipulate droplets by OEW and suspended particles by OE-T. The maximum translational speeds of droplet and particle were reported to be 8 mm/s and 60 μm/s, respectively. The illustrative principles of the platform are depicted in Fig. 6. The platform is composed of indium tin oxide (ITO), a-Si:H, aluminum oxide (Al_2O_3), and Teflon for the bottom plate and Teflon and ITO for the top plate. An aqueous droplet containing particles is sandwiched between two plates. The distinct peak for the OEW operation is at 10–20 kHz, while the peak for OET is at 100–200 kHz.

Using this technique, polystyrene particles of 10 μm were concentrated by slowly sweeping a light bar across the droplet from one end to the other with a potential of 16 V_{pp} at 200 kHz (Fig. 7a) [9]. Subsequently, the platform was switched to the OEW mode with a potential of 32 V_{pp} at 10 kHz for droplet splitting. Compared to droplet splitting without OETs, the efficiency increased from 50 % to 93 %. Serially repeating the procedure of concentration and splitting increased the particle density (i.e., particles per volume) because the volume was divided in half each time. A second demonstration showed how a single cell can be selected and encapsulated using the hybrid technique (Fig. 7b). By changing the light image from one single bar to multiple bars, a specific cell was isolated from a group of HeLa cells. After splitting the droplet, the selected cell was solely encapsulated in an aqueous droplet.

OETs+EW

EWOD has been an effective means of manipulating droplets since it was first reported [18, 19]. OET is a recent tool that can handle



Optoelectrically Enabled Multiscale Manipulation, Fig. 7 (**a**) Procedure of concentration of a clump of particles. (**b**) Procedure of single cell selection and encapsulation (Valley et al. [9]. Reproduced with permission from The Royal Society of Chemistry)

microparticles in a dynamic way. The integration of OETs and EW leads to a brand new platform suitable for multi-scale biological applications. In this case, large discrete electrodes were physically fabricated on a substrate to address droplets. Interdigitated electrodes were fabricated on another substrate to steer particles. It was found that the current arrangement of EWOD and OETs on separate plates yields a better performance than the previous generation which has EWOD and OET devices interweaving together [7]. OETs use a photoconductor to gate the particle actuation, but EWOD uses an insulator, silicon nitride (Si_3N_4), to generate a major potential drop for electrowetting effect. Both plates are covered with a hydrophobic layer, Cytop, to provide high contact angle as well as insulating effect [7].

A driving potential of 3–5 V_{rms} at 200 kHz for OETs and a driving potential of about 120 V_{rms} at 20 kHz for EWOD were employed. The working medium of droplet was DI water, such that the live HeLa cells showed positive OETs at the frequency of the electric field used. The operational procedures are as follows (Fig. 8): (1) stretch the droplet in an elongated shape using EWOD, (2) sweep a light bar over the cells in one direction multiple times, (3) split the droplet, and (4) collect the live cells and dump the dead cells. Although only mammalian cells were demonstrated on this platform, the mechanism can be extended to all other biological species, such as bacteria, yeasts, etc. It should be noted that any targets smaller than sub-micrometers may not experience much OET forces due to the r^3 scaling law of DEP force.

Future Directions

The ability to manipulate fluids and process various biological species for sequential reactions constantly poses challenges to the current lab-on-a-chip applications. The typical challenges while dealing with cross-scale tasks include connections between different scale regimes, compatibility between techniques, sample collecting, cross-contamination, and disturbances from fluidic components or manipulation tools. As the technology advances, researchers are not just satisfied with the knowledge on the microscale but keen to explore the frontier on the nanoscale. However, except for some existing mechanical measures, such as AFM and STM, noninvasive techniques seem still far-fetched. Although, at present, scientists have been developing some tools to handle multi-scale targets, there remains a long journey before fully performing operations crossing more than five orders of length scale. Currently, the optoelectric devices coupled with

Optoelectrically Enabled Multiscale Manipulation, Fig. 8 Images showing the sequential operations of EWOD and OETs on the integrated device. The thick (*blue*) *arrows* represent EWOD actuation and the thin (*orange*) *arrows* represent OET actuation. (**a**) Droplet (350 nL) containing HeLa cells is positioned in the work site. (**b**–**c**) Droplet is stretched by EWOD, while the live cells are swept by OETs from one end to the other. (**e**) When all live cells are concentrated in the left side, EWOD forces then act on both ends of the stretched droplet to split it. (**f**) After the droplet breaks up, the left droplet contains the collected live HeLa cells, but the right droplet contains only dead cells (Shah et al. [7]. O

digital microfluidics (i.e., droplet manipulation) provide a niche in multi-scale manipulation. However, most operations are limited to the range from millimeters to mesoscale (sub-micrometers). Although both REP and OETs have manipulated micro- and nanoparticles under special conditions, considerable effort must be taken, and single-molecule manipulation remains difficult. It is highly anticipated that new breakthroughs in optoelectric devices can be made to resolve the aforementioned difficulties, such that the genuine multi-scale manipulation will be achieved to benefit future scientific research.

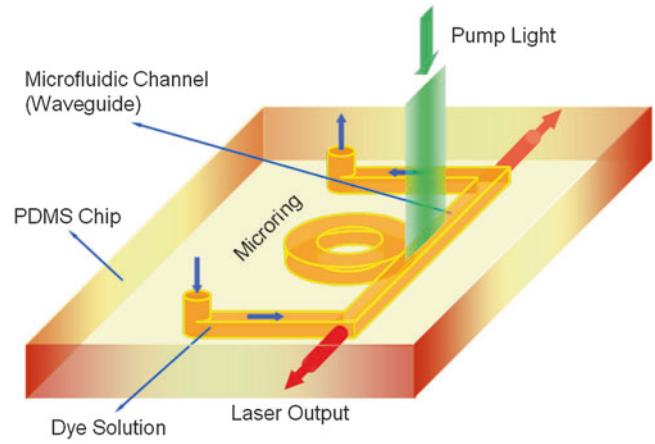
Definition

Optofluidic resonators are optical microcavities that are partially or completely made of liquids. Sensors based on optofluidic resonators use either passive cavity resonance shift or active lasing to detect small changes in refractive index, absorption, gain, or scattering in the vicinity of the resonator.

Overview

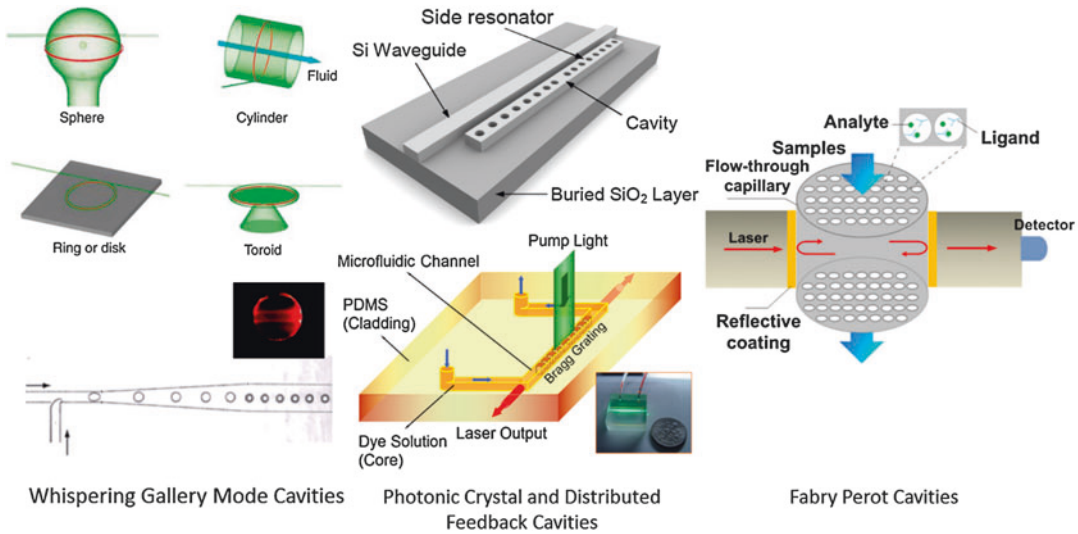
Optofluidics refers to the synergistic fusion of microfluidics and photonics [1, 2]. By integrating photonic and fluidic functions on a single chip, optofluidics not only gives rise to highly compact and integrated microsystems but also enables novel adaptive and reconfigurable photonic devices via microfluidic liquid manipulation. Although both photonics and fluidics have been independently miniaturized within the past three decades, it was not until very recently that the monolithic integration of the two became possible. Today, the channel dimensions in microfluidic devices have become comparable to or even smaller than the wavelength of light (i.e., <200 nm for visible light), and the materials

involved are often optically transparent. These two facts led to the realization that it is now feasible to build liquid-core or liquid cladding that are inherently compatible with microfluidic adaptation and integration. Optofluidic resonators are one of such structures.



In optofluidic resonators, part of the optical cavity is made of liquids. For example, a liquid droplet suspended in another immiscible liquid with lower refractive index forms a so-called whispering gallery mode (WGM) resonator, in which light is confined by continuous total internal reflections at the liquid/liquid interface [3]. Compared with their solid-state equivalents, optofluidic resonators offer some unique advantages, including

1. Liquid-core or liquid-cladding cavities enable tunable optical resonances with extremely large tuning range (refractive index change Δn can be as high as ~ 0.5 compared with <0.01 in most solid-state materials) by liquid filling, mixing, or replacement.
2. Flexibility of optofluidic resonator structures allows one to easily introduce functional optical materials such as dye molecules (optical gain or absorption), nonlinear optical liquids, liquid crystals, quantum dots, nanoparticles, and biomolecules into/onto the optical resonator. This can give rise to many functional photonic and sensing devices that are inherently tunable and reconfigurable.
3. Molecularly smooth optical surfaces induced by interfacial tensions enable ultrahigh quality factor (Q) resonators. For example, microdroplets, with their molecularly smooth surfaces and small sizes, represent an attractive optical resonator for making low-threshold lasers and ultrasensitive sensors [3]. The Q factors of microdroplet cavities can be as high as 108, and their mode volumes can be as small as a few picoliters [3], which makes them extremely sensitive to small changes in their environments.
4. Inherently compatibility with microfluidics allows for the seamless integration of liquid sample manipulation steps with optical sensing and characterization capabilities. Moreover, lithographically defined accurate optical alignment and no mechanically moving parts give rise to more reproducible, robust, and easy-to-use systems.
5. Simultaneous liquid and optical confinements at micron or submicron scale allow for highly efficient optical interrogation of target molecules or particles in subpicoliter volume liquids, which is ideally suited for single-molecule detection, single-cell analysis, and low-abundance biosensing applications.



An example of liquid-core microring resonator is described below to illustrate the general principle of operation. Then optofluidic resonators as sensors, in particular biosensors, are discussed.

Principle of Operation

Optical resonators (or cavities) confine light both spatially and temporally in some structurally defined resonance modes [3]. Traditional optical resonators are made of solid-state materials, whereas optofluidic resonators are partially or completely made of liquids. Figure 1 shows an example of a liquid-core guided-wave optofluidic microring resonator for dye lasing application [4]. In this device, the optofluidic resonator is made of a ring-shaped microfluidic channel (2 μm high and 2 μm wide) filled with a higher refractive index liquid (e.g., ethylene glycol, a common organic solvent, $n = 1.43$) than that of the cladding. The cladding of the waveguide and the microring resonator is made of poly(dimethylsiloxane) (PDMS) (RTV 615, $n = 1.406$ at 589 nm), a widely used polymer for microfluidic devices [5]. In such liquid-core optofluidic resonators, both the spatial modes and the resonance wavelengths can be controlled, to some degree, by the choice of the liquid. For example, by mixing two different solvents such as ethylene glycol and ethanol, the core refractive index can be tuned from 1.36 to 1.43. When the core/cladding index contrast is less than 0.003 (i.e., core refractive index is less than 1.409 when using a PDMS cladding), the waveguide supports only the two degenerate fundamental transverse modes. The

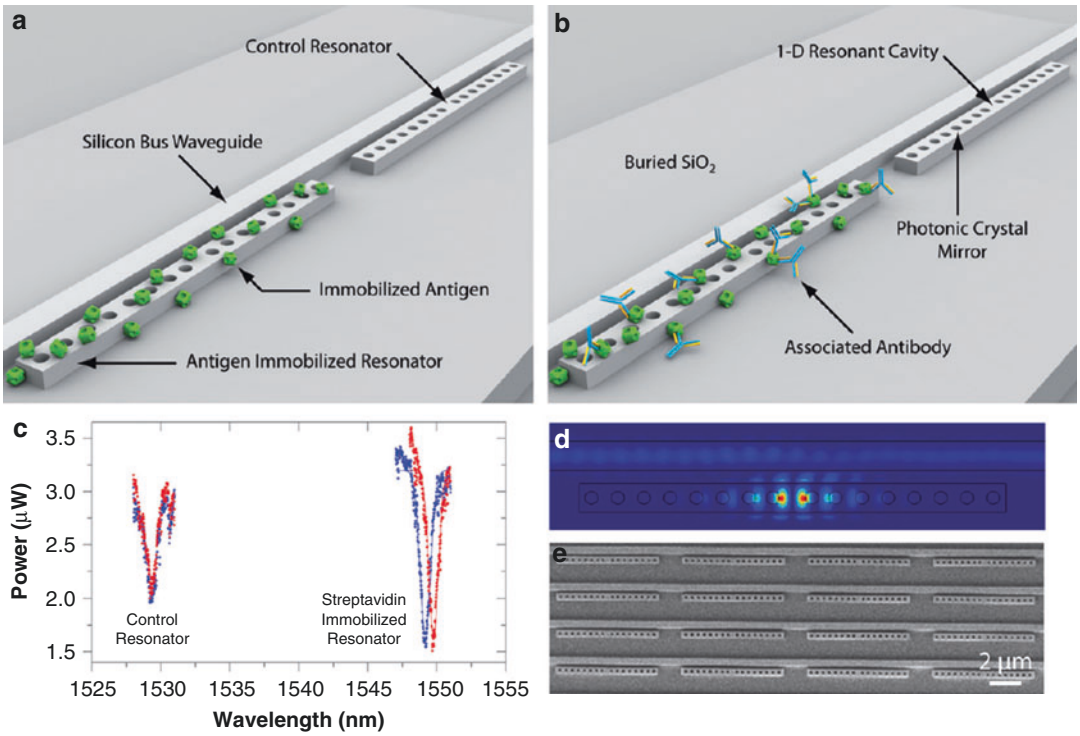
Either the resonator itself (core) or its surrounding (cladding) is liquid

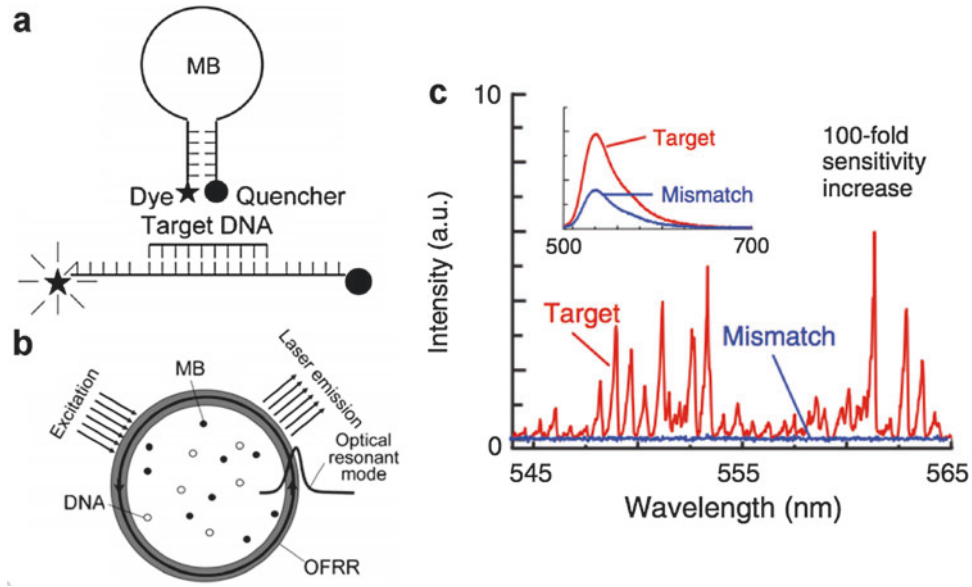


resonant wavelengths of a microring resonator are determined by the condition

$$m\lambda_m = 2\pi n_{eff} R \qquad (1)$$

where λ_m is the mth resonant wavelength, n_{eff} is the effective index of the guided mode, and R is the ring radius. It's clear from this expression that the optofluidic structure enables tunable resonances by changing n_{eff} or m, which provides a convenient tuning mechanism. Changing the refractive index of the liquid core changes the effective index, and switching dye molecules covering different spectral regions can change the resonance order m. This intrinsic optofluidic tunability can also be used for sensing applications because any change in refractive index in the liquid core will lead to a resonance shift.

Types of Optofluidic Resonators



Optofluidic resonators can be classified into liquid-core, liquid-cladding, and all-liquid resonators based on the liquid components. In addition, the type of the cavity can be used to classify optofluidic resonators. Figure 2 shows the three most common cavity types: whispering gallery mode (WGM) cavities [6, 7], photonic crystal or DFB type cavities [8, 9], and Fabry-Perot type cavities [10]. Each type of optofluidic resonator has its own unique advantages and suitable applications. For example, WGM cavities can have ultrahigh quality (Q) factors if the cavity surface is formed by some interfacial tension effect such as a melted glass microsphere or a liquid droplet. High Q factors can give rise to very narrow linewidth cavity resonances favorable for low-threshold lasing and ultrasensitive sensing applications. Photonic crystal or DFB cavities are more amenable to planar lithographic fabrication process, thus more suited for on-chip integration with microfluidics. Microfluidic channels can be cofabricated with the optofluidic cavity structure to allow for on-chip microfluidic tuning and sample introduction. Fabry-Perot cavity is well suited for intracavity sensing and spectroscopy applications because the ease of access to its introcavity space. Thus far, all types of cavities have been demonstrated in optofluidic formats for various applications. For comprehensive review on their implementations and applications, references [12] and [6] are recommended.

(**d**) Finite difference time domain (*FDTD*) simulation of the steady-state electric field distribution within the PC resonator at the resonant wavelength. (**e**) SEM image showing the multiplexing capability of the optofluidic PC resonator array [9]

Sensing Applications

The liquid-core or liquid-cladding structure combined with compatibility with microfluidic sample manipulation makes optofluidic resonators attractive for biosensing applications. In fact, most optofluidic resonator structures can function as sensors by simply replacing the liquid core or cladding with another liquid carrying the target analytes such as a buffer solution with some biomolecues of interest. Figure 3 shows a passive liquid cladding 1D photonic crystal (PC) resonator for protein detection [9]. In this sensor, a nanofabricated on-chip silicon 1D PC resonator is covered by a PDMS microfluidic chamber. The optofluidic PC resonators were evanescently coupled to act as a control. The liquid (or cladding) is 1× PBS buffer containing 0.1 % Tween-20 and 0.2 g/ml bovine albumin (PBST). When antistreptavidin containing PBST was introduced into the chamber, the resonance wavelength shifted (Fig. 3c). The highly localized optical mode greatly enhanced light-matter interaction and enabled target detection on the order of 63 ag bound mass. The planar structure of the device also enabled multiplexed detection of interleukins 4, 6, and 8 using a sandwich assay on an array of PC resonators. Figure 4 shows another unique biosensing application enabled by active optofluidic resonators, i.e., lasers [13]. Traditionally, single base-pair DNA mismatch is detected by fluorescence-based detections. However such detection methods have low discrimination ratios because the fluorescence different is caused by a single base mismatch. Fan et al. devised a unique signal amplification scheme by using an optofluidic laser as the sensor. An optofluidic ring resonator (OFRR) was used as the laser cavity. Target DNA and molecular beacon (MB) probes were incorporated as part of the laser gain medium. A perfectly matched (PM) DNA and a single-base mismatched (SM) DNA are used to test the system performance. Although a small binding affinity difference between PM DNA and SM DNA causes only a small change in the laser gain, this small difference is amplified by the laser action into two orders of magnitude differences in the

Optofluidic Resonators and Sensors, Fig. 4 *Active Optofluidic Ring Laser for Single Base Mismatch Detection in DNA*. (**a**) Molecular beacon (*MB*) fluorescence is quenched when it is in the closed state and restored upon hybridization with the target DNA. emission intensity because of the strong optical feedback in the laser cavity. Detection sensitivity was increased 100-fold by using the OFRR laser when compared to fluorescence-based detection. The potential of active optofluidic resonators and lasers has been reviewed in [14]. It is noted that Fan et al. has demonstrated an optofluidic laser with a single molecular layer of gain made of GFP or dye-labeled DNA [15].

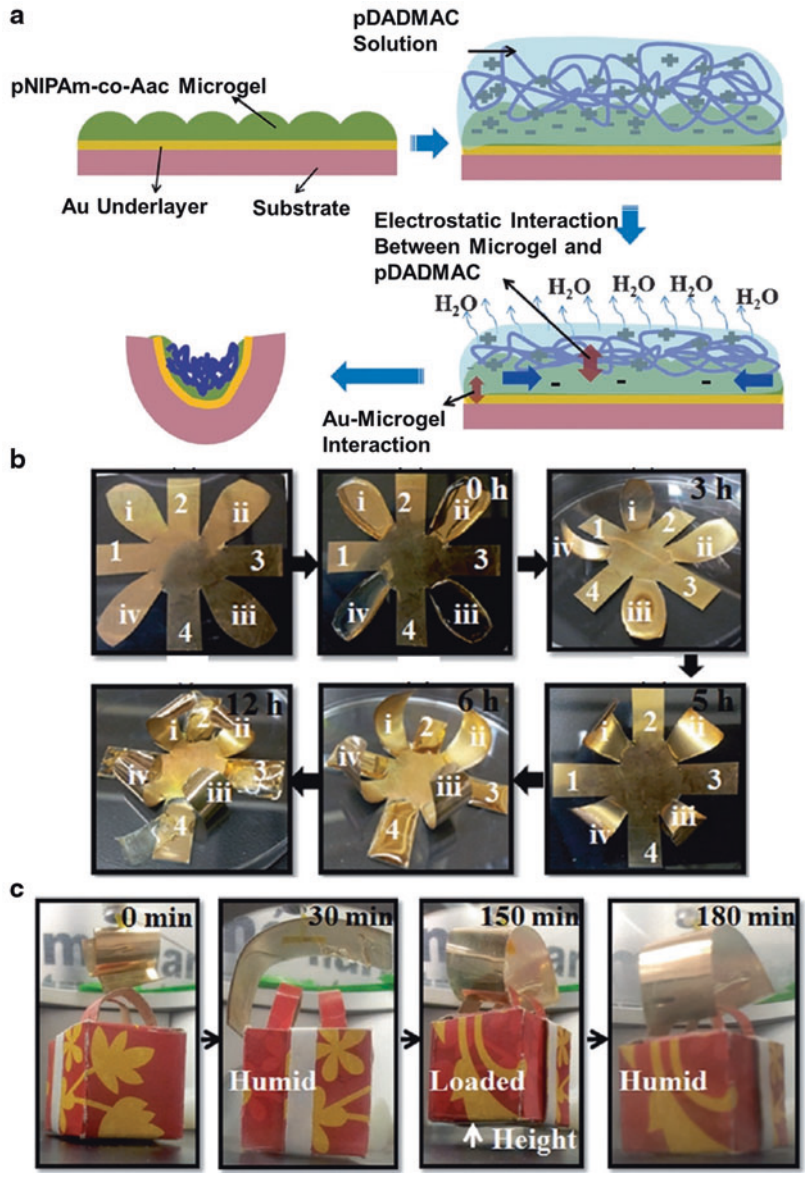
responsive gels or polymers and able to act upon their external environment by converting input energy into mechanical work.

Overview

Organic actuators have shown their considerable potential for the applications in medical devices, prostheses, robotics, toys, biomimetic devices, and micro/nanoelectromechanical systems. Compared to conventional metallic and ceramic actuators, the advantages of organic actuators are flexibility, light weight, low cost, and quiet operation compliance. Many actuators that respond to various external stimuli have been developed using polymers as base materials: polymer gels, cross-linked liquid crystal polymers, conducting polymers, and shape memory polymers. As Fig. 1 shows, the promise of developing organic

actuators has inspired scientists for decades and led to the design and operation of polymers that exhibit mechanically relevant movements, such as contraction/expansion, bending, twisting, swimming, and inchworm walking [1–5].



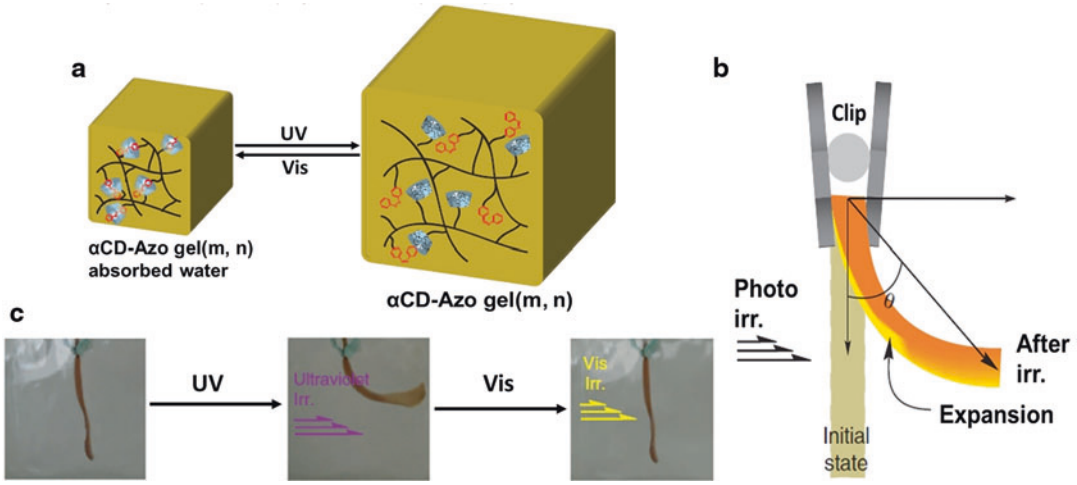
Gel Actuators

A polymer gel contains an elastic cross-linked network and fluid filling in their interstitial space of three-dimensional network, which provides softness as well as high biocompatibility. Gels have the ability to swell or shrink due to the large amount of liquid they can hold and undergo change in shape or volume in response to external stimuli, i.e., thermal, electric energy, light, and pH. Research in stimuli-responsive polymer gels, especially hydrogels, has persisted over several decades, and a great deal of work has been dedicated to develop useful actuators [6].

One of the most studied hydrogels to date is poly(N-isopropylacrylamide) (pNIPAm), which is often used as a matrix of hydrogels. A pNIPAm-microgel-based device is able to do work and lift masses many times the mass of the device, in response to simple changes in the humidity of its environment [7]. Acrylic acid (AAC), a weak acid having a pKa of approximately 4.25, is added to pNIPAm-based microgels. At pH $>$ 4.25, the AAc groups are deprotonated, thus making the microgels negatively charged (polyanionic), while they are neutral at pH $<$ 4.25 owing to AAc protonation. As Fig. 2a shows, the monolayer of pNIPAm-co-AAc microgels is deposited on an Au-coated substrate. Subsequently, a solution containing oppositely charged poly(diallyldimethylammonium chloride) (pDADMAC) is added to the microgel-coated substrate. The pDADMAC solution had a pH of 6.55, which rendered the microgel layer polyanionic; thus, the pNIPAm-co-AAc microgels swell by reason of the charge-charge repulsion in the polymer network of the microgels. Then, the pDADMAC layer contracts after the water evaporation due to the increase of hydrophobic interactions between the pDADMAC chains. Since the electrostatic interactions between pDADMAC and the microgels, and the interaction between microgels and the Au layer, are strong, three of them as an integration bend when the polymer dries. In other words, upon drying, the pDADMAC layer contracts bending the substrate.

As Fig. 2b shows, a flexible substrate with alternate arms was exposed to the same pDADMAC solution used above while keeping the other arms empty. The arms exposed to the pDADMAC solution curled up owing to the strong interactions between the pDADMAC and the microgels after solution drying. However, there was no response when the empty arms were exposed to polyanionic poly(sodium 4-styrenesulfonate) (PSS) solution (20 %) and dried in ambient condition. Figure 2c shows a device manipulated to lift a box by changing the humidity of a chamber. The curled substrate was hung from a string into a humidity chamber (0 min). As the humidity rose, the device uncurled and then loaded the box along with decrease of humidity to 10 %. While maintaining this humidity, the box was lifted off the chamber surface (150 min). A subsequent increase in the humidity allowed the device to reopen and drop the box (180 min). These arms are able to be actuated in response to humidity and act as muscles or arms to resist forces many times its own mass.

The development of remotely manipulating an actuator without any direct contact is of great importance. Yoshinori and coworkers designed a photoresponsive supramolecular actuator by integrating host-guest interactions and photoswitching ability in a hydrogel [8]. As Fig. 3 shows, a photoresponsive supramolecular hydrogel with α-cyclodextrin (αCD) as a host molecule and an azobenzene derivative as a photoresponsive guest molecule exhibit reversible macroscopic deformations in both size and shape when irradiated by UV light at 365 nm or visible light at 430 nm in water. After UV irradiation from the left side of the plate gel, the complex between αCD and cis-azo units decomposes to expand αCD-azo gels and bends to the right. Vis irradiation causes isomerization from the cis to the trans form, and complexation between αCD and the azo units regenerates, restoring the αCD-azo gel.



Organic Actuators, Fig. 2 Polymer-based muscle expansion and contraction. (**a**) PNIPAm-co-AAc microgels were deposited on the substrate obtaining a monolithic monolayer of microgels on the Au. PDADMAC solution renders the pNIPAm-co-AAc microgel negatively charged initiating the electrostatic interaction between the microgels and polyelectrolyte. Upon drying, the pDADMAC layer contracts bending the substrate. (**b**) Arms i-v exposed to the pDADMAC solution were bended while Arms 1–4 exposed to the PSS solution were no response after drying for 6 h. (**c**) The device lifted a box by changing the humidity of chamber [7] (Copyright 2013 Wiley-VCH)

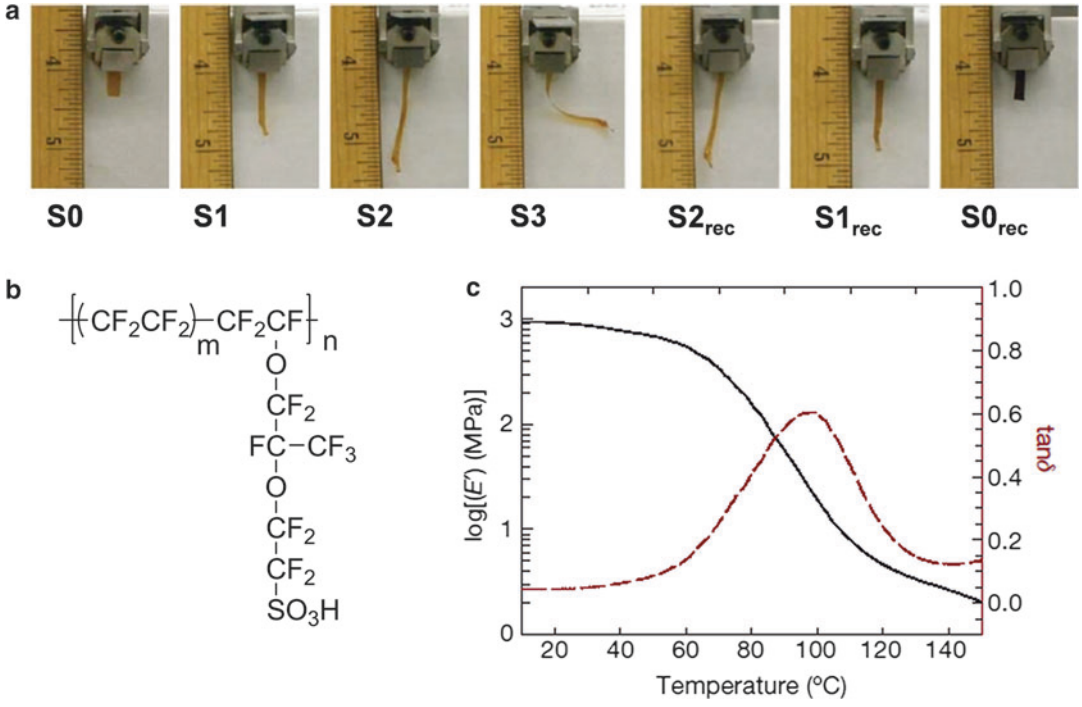
Supramolecular hydrogels are hopeful to realize "muscle fibrils" in biological systems.

Shape-Memory Polymer Actuators

Shape-memory effect (SME) is the capability of a material to recover the original shape in a predefined way in response to an appropriate stimulus, such as light, electric fields, alternating magnetic fields, or water. Shape-memory polymers (SMP) are physical- or chemical-nature polymer networks, in which net-points being connected by chain segments determine the permanent shape [9]. Upon applied external stress, these chain segments could make certain an orientation to obtain the required deformability. Until an appropriate stimulus is applied to the shaped body, this temporary shape is induced to recover to the original shape.

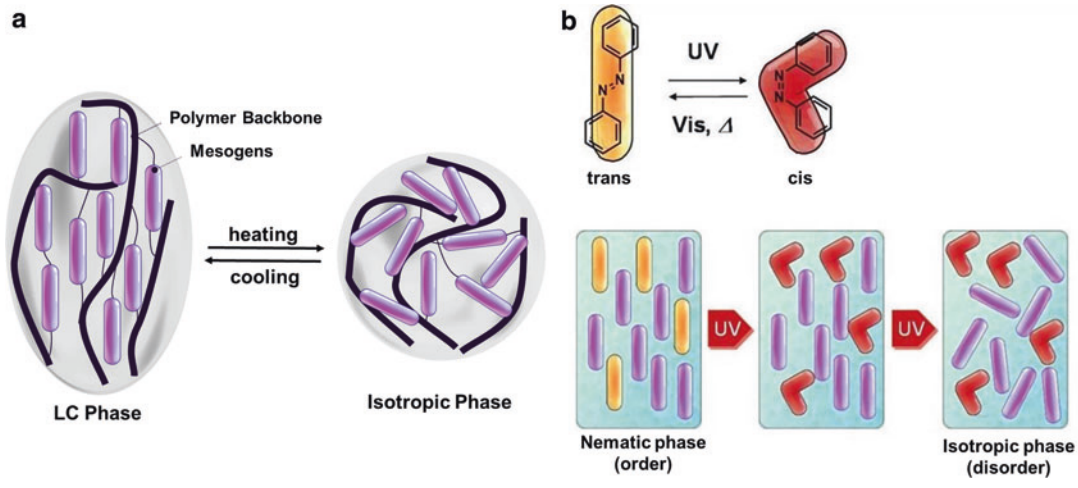
So far, the most extensively investigated group of SMPs were thermally induced SMPs. SMPs

Organic Actuators, Fig. 3 Expansion-contraction of photoresponsive artificial muscle regulated by host-guest interactions. (**a**) Schematic illustration of the expansion and contraction of αCD-azo gel irradiated by UV and Vis light. (**b**) Lateral view of αCD-azo plate gel hung with a clip. (**c**) Image of the plate gel bending behavior in response to UV and Vis light [8] (Copyright 2012 Nature Publishing Group)



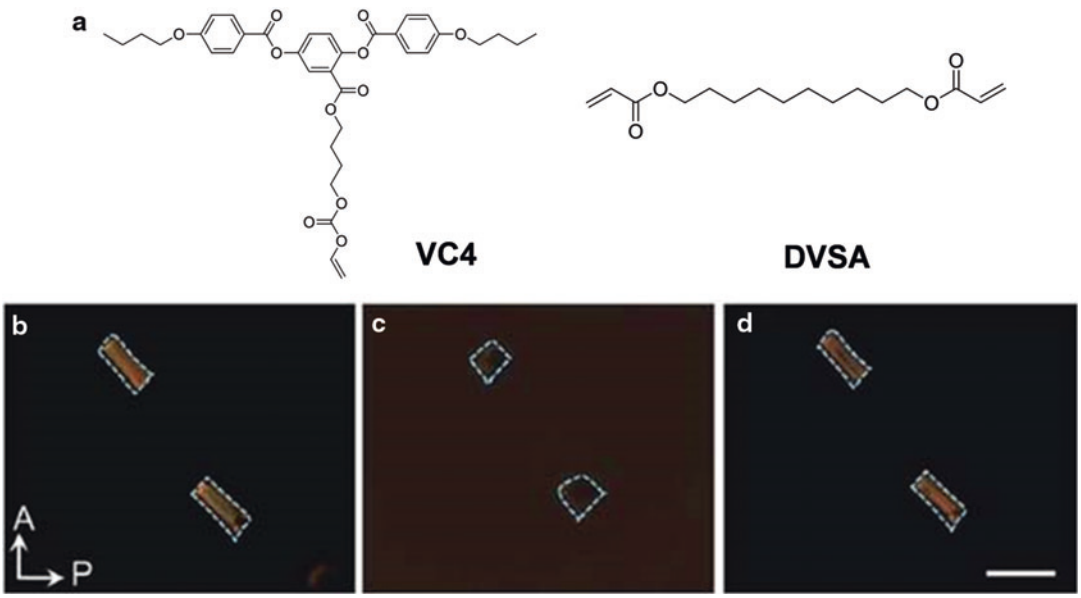
can be deformed by applying external stress upon transition temperature T_{trans} and fixed in a temporary shape. When cooled below T_{trans}, the temporary shape becomes stable. This process is called programming. Then, reheating induces the recovery of the stored permanent shape. Recently, Tao Xie et al. designed a multishape (triple or quadruple-shape) memory polymer and fulfilled sequential recovery to its original (permanent) shape from two, three, or four previously programmed temporary shapes [10, 11]. For example, perfluorosulphonic acid ionomer (PFSA) is a commercial thermoplastic polymer with a polytetrafluoroethylene backbone and perfluoroether sulphonic acid side chains (Fig. 4b). As Fig. 4a shows, starting as an original shape S0, PFSA can memorize three temporary shapes (S1, S2, and S3) in the same shape-memory cycle. Subsequent heating to the relevant temperatures led to the recovered shapes ($S2_{rec}$, $S1_{rec,}$ and $S0_{rec}$). The versatile shape-memory properties are stemmed from its broad glass transition of PFSA (55–130 °C, Fig. 4c). We can think of it as infinitely sharp transition temperatures continuously distributed across the broad transition.

However, SMPs may not be suitable when the material is expected to operate reversibly in response to repeated decreases and increases of temperature.



Cross-Linked Liquid Crystal Polymer Actuators

Liquid crystal (LC) is a thermodynamically stable fluid phase characterized by some anisotropy of properties. The LC molecules have a tendency to point along a common axis, called the director. They may be regularly arrayed in either one or two dimensions. Hence, LCs have many unique properties, such as a variety of different LC phases, differing in the positional or orientational order.



De Gennes proposed the possibility of using cross-linked LC polymers (CLCPs) as artificial muscles, by taking advantage of their substantial contraction in the direction of the director axis and cooperative motion [12]. For example, when the nematic CLCP films are heated above the nematic-isotropic phase transition temperature T_{trans}, the nematic order decreases, and the CLCPs exhibit a general contraction along the alignment direction of the mesogens; CLCP films will revert to their original size by expanding as the temperature drops below T_{trans} (Fig. 5a). Based on the above principle, it was reported that

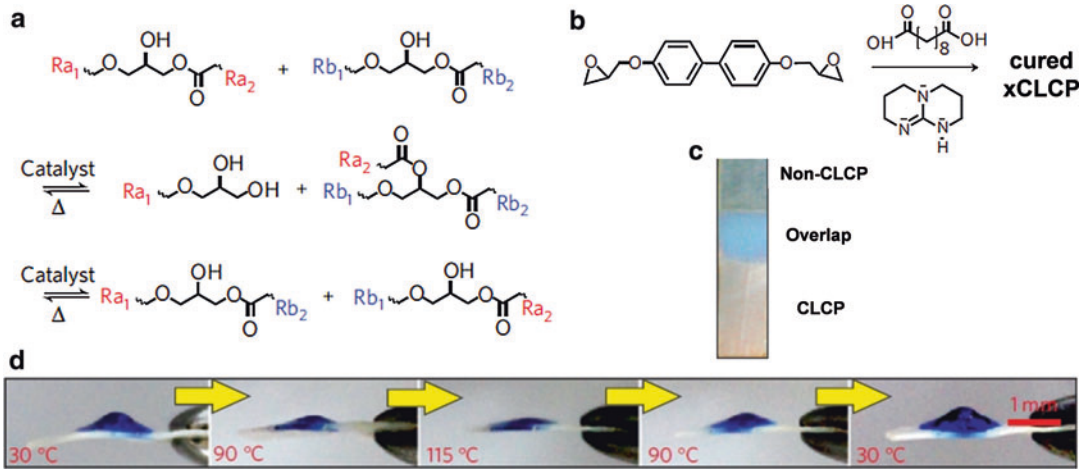
(**b-d**) The shape of an isolated pillar with the diameter of 20 mm changes with temperature under polarizing optical microscope (from left to right, T =30, 96, and 48 °C) [13] (Copyright 2013 Wiley-VCH)

microsized CLCP pillars prepared by a soft lithography technique underwent a contraction when heated to T_{trans} (Fig. 6) [13]. Besides, Zentel et al. fabricated micropumps from CLCP core-shell particles via a microfluidic double-emulsion process. A liquid core which is wrapped into the LC shell is reversibly pumped into and out of the particle by actuation of the LC shell responsive to the change of temperature (Fig. 7) [14].

Real-world applications of the CLCPs are lacking because the mechanical properties of the CLCPs become unreliable over many actuation cycles and difficult to reprocess. Yan Ji and Eugene Terentjev et al. showed that the processing bottleneck of the CLCPs can be overcome by introducing exchangeable links in place of permanent network cross-links [15]. As Fig. 8a demonstrates, they used a transesterification reaction to generate an exchangeable CLCP. With the added catalyst, the fast breaking and reforming of ester bonds are above the activation barrier at a temperature T_v, that is, the designed xCLCPs can be reshaped or reprocessed at $T > T_v$. At temperatures below T_v, exchange reactions become slow exponentially, and the network acts as a classical covalently bonded thermoset. Reversible transesterification also allows an xCLCP film to bond with a non-LC epoxy elastomer from the reaction of the diglycidyl ether of bisphenol A and diacid above T_v (Fig. 8c). As Fig. 8d shows, as the temperature goes up, the height of the dome-shaped CLCP actuator decreases because of the contraction induced by the thermal phase transiton; on cooling back to the LC phase, the dome reappears in its original shape.

In addition, light-induced large contraction-elongation effects were achieved in the pioneering work by Finkelmann using azobenzene as a sensitive chromophore in a CLCP film [16]. The rod-like trans form of the azobenzenes stabilizes the phase structure of LC phase, whereas the bent cis isomer tends to destabilize the phase structure of mixture (Fig. 5b).



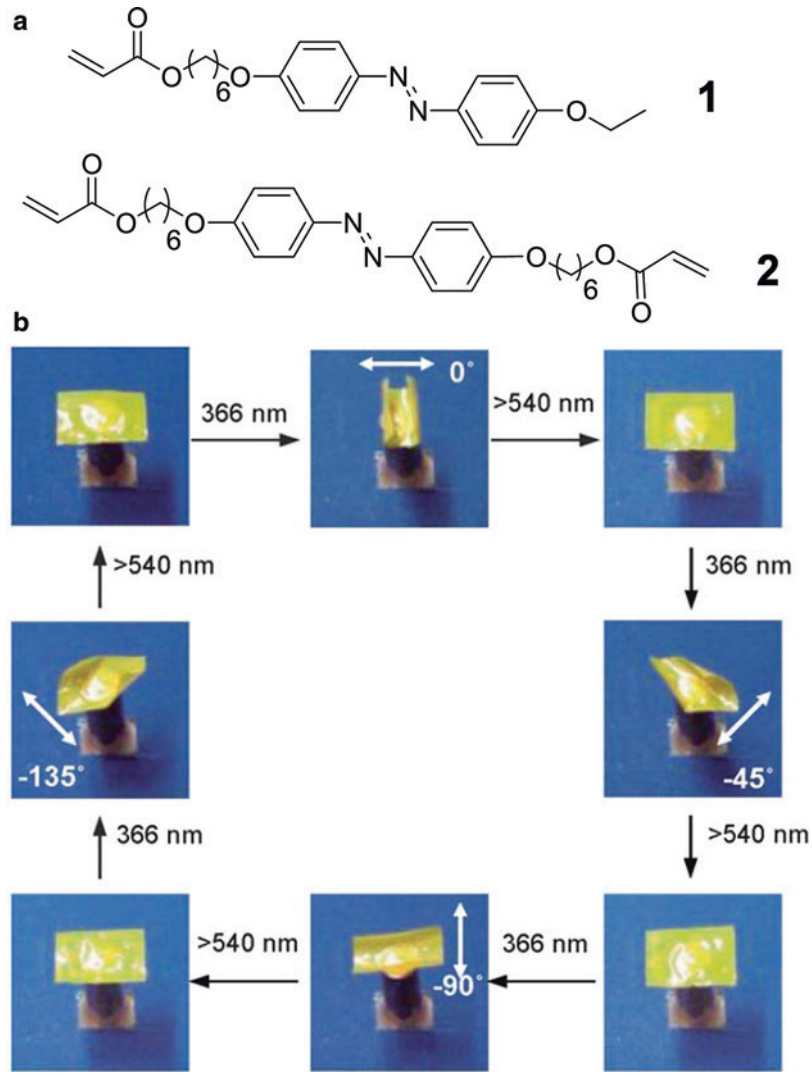
The most interesting property of an azobenzene-based CLCP film is the capability to perform three-dimensional movement, which could be advantageous for a variety of real manipulation applications. By means of the selective absorption of linearly polarized UV light in macroscopically randomly aligned CLCP films, Ikeda

Organic Actuators, Fig. 7 (**a**) The triple co-flowing geometry of the microfluidic set-up allows the fabrication of nematic shell particles filled with a glycerol core. Dispersed in the surrounding continuous-phase silicone oil, the monomer droplets are polymerized by ultraviolet light. (**b**) Chemical structures of the reactive mesogen (1) and crosslinker (2) in the monomer mixture. (**c**) Schematic drawing of the micromanipulator to penetrate the particle shell with a thin glass capillary. (**d**) When heated to the isotropic phase at 130 °C, the phase transition results in a deformation of the LCE shell. The force exerted by the actuating shell pushes the liquid glycerol core into the capillary. Once the particle resumes its former shape in the nematic phase at 90 °C, the glycerol sinks to its original level (scale bar, 100 mm) [14] (Copyright 2012 Nature Publishing Group)

et al. realized that the deformation direction of a polydomain CLCP film was chosen precisely along any direction, as Fig. 9 shows [17]. Because of the high concentration of the azobenzene moieties in the film and the high extinction coefficient of the azobenzene moieties at around 360 nm, most of the incident photons are absorbed by the film surface. Only the surface region facing the incident light undergoes the decrease in alignment order of LC and phase transition. As a result, the contraction is generated only in the surface layer, causing the films to bend toward the irradiation source.

Some interesting designs from the photoresponsive CLCPs present an opportunity to realize soft actuators in more applications. For example, Palffy-Muhoray and coworkers demonstrated that the CLCP sample doped with azobenzene dyes swam away from the laser beam, with an action resembling that of flatfish [5]; Ikeda et al. fabricated the first light-driven plastic motor with the use of CLCP/polyethylene laminated films [18]; Yu et al. utilized photoresponsive CLCPs as microvalves and micropumps [19, 20] and other relative applications, such as light-controlled quick switch of adhesion on a microarrayed CLCP superhydrophobic film and light-switchable behavior on the reflection spectra of a microarray of the azobenzene CLCP induced by the photodeformation [21, 22].

(**d**) Reversible cycle of a dome-shaped moulded CLCP actuator becoming completely flat on heating to the isotropic phase [15] (Copyright 2014 Nature Publishing Group)



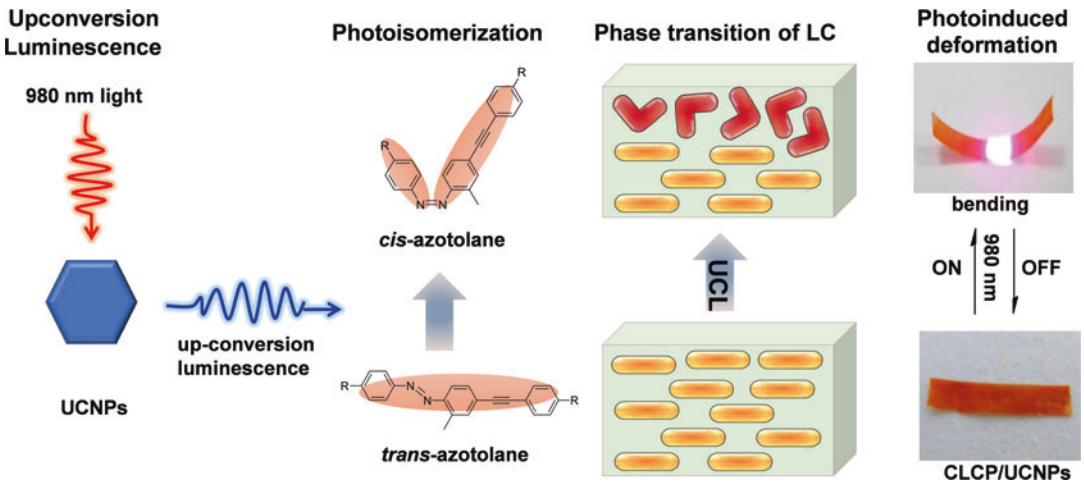
The photoinduced deformations mentioned above are interesting; however, UV light is harmful to our health. Yu et al. fist reported visible-light-induced bending and unbending of azotolane-containing CLCPs, whose deformation even occurred upon irradiation with sunlight [23]; then, they demonstrated a visible-light-driven microrobot, which can pick, lift, move, and place milligram-scale objects [24].

Furthermore, Yu et al. incorporated upconversion nanophosphors (UCNPs) into the azotolane-containing CLCP film and succeeded in generating fast bending of the resulting composite film exposed to continuous-wave (CW) NIR light at 980 nm. Under excitation with a CW 980 nm laser, the as-prepared UCNPs show blue emission, and the main upconversion lamination (UCL) emission peaks at 450 nm and 475 nm overlap the absorption band of the azotolane CLCP film (between 320 and 550 nm) perfectly; thus, the UCL light triggered molecular-scale motion (trans-cis photoisomerization of azotolane), which is converted into large macroscopic deformations (Fig. 10) [25].

Most recently, Yu et al. achieved red-light-controllable CLCP driven by low-power excited triplet-triplet annihilation-based upconversion luminescence (TTA-UCL) [26]. A red-to-blue TTA-based upconversion system was incorporated into rubbery polyurethane film and then assembled with an azotolane-containing CLCP film. The film bent toward the light source irradiated by 635 nm laser at low power of 200 mW cm^{-2} (Fig. 11). This work is a significant step forward to develop a novel red-light-controllable CLCP based on TTA-UCL.

Some other interesting movements of the CLCP films such as cilia-like motion and twisting have also been developed. As Fig. 12 shows, Oosten et al. used an azobenzene-containing film with a splay bent configuration which improved the bending strength of the material and utilized inkjet printing technology to create cilia-shaped structures [27]. The response of A3MA polymer cilia in water to light is shown in Fig. 12b. Two parts of the CLCPs incorporated with different azobenzene chromophores allow for a wavelength-selective control in the bending of the different segments. Thereby, the motion of natural cilia is mimicked.

Based on a combination of a nematic LC and a small amount of chiral dopant, Fletcher



Organic Actuators, Fig. 9 (**a**) Chemical structure of the LC monomer (1) and crosslinker (2) used for preparation of the film. (**b**) Images of the film bending in different directions in response to linearly polarized UV light with different polarization directions at $\lambda = 366$ nm. et al. succeeded in spring-like motion of the CLCP toward mimicking the mechanical behavior of plant tendrils [28]. As Fig. 13a shows, the orientation of the LC molecule changes smoothly by 90° from the bottom surface to the top surface. The helical shapes depend on the angle at which the ribbon is cut (Fig. 13b). With UV light irradiation, left-handed spiral ribbons B decreased in their macroscopic pitch, and the corresponding right-handed ribbon D is just the opposite (Fig. 13c). It is remarkable to observe inversion of the helical sense from right-handed to left-handed (ribbons E).

Electroactive Polymer Actuators

Electroactive polymers (EAPs) are polymers that exhibit a change in size or shape when stimulated with an electric field. Compared to their inorganic counterparts (e.g., shape-memory alloys, carbon nanotubes, and piezoelectric ceramics), the polymer-based EAP materials allow many attractive properties and unique characteristics including relatively inexpensive, lightweight, mechanically robust, easily processable, and commercially scalable. Further, they can be configured into almost any shape, and their properties

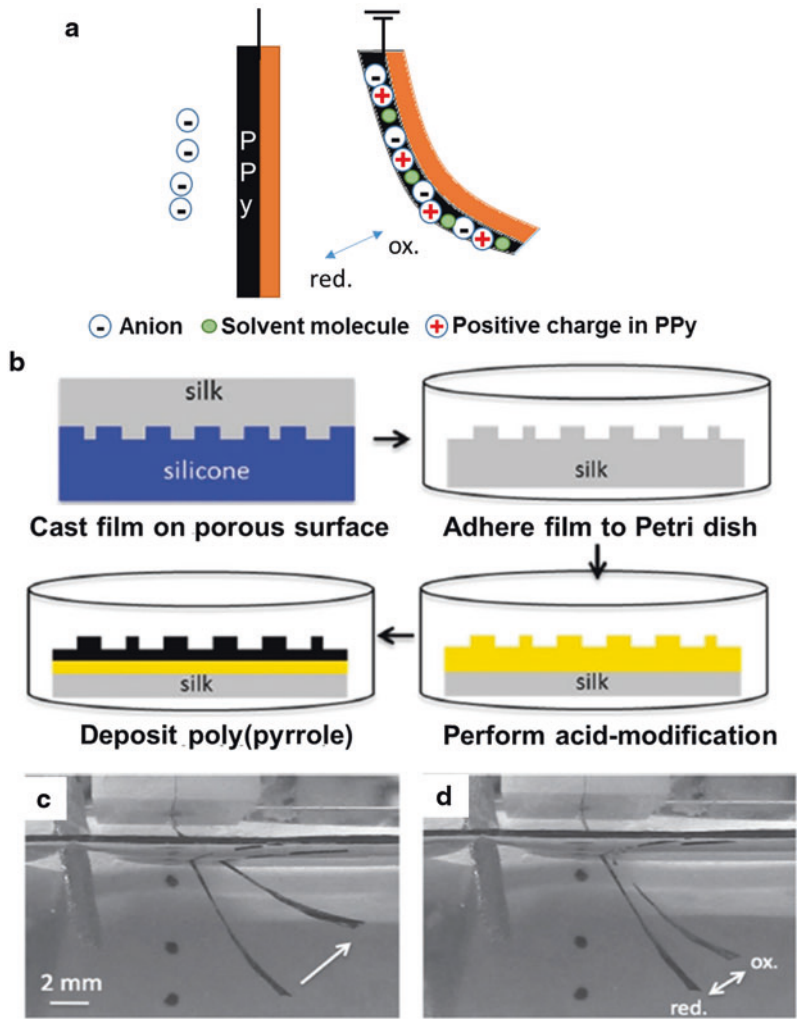
can be tailored to suit a broad range of requirements. Impressive advances in improving the actuation strain capability of EAPs are attracting the attention of engineers and scientists from many different disciplines. EAP types are divided into two major groups based on their primary activation mechanisms: electronic electroactive polymers (driven by electric fields and coulomb forces) and ionic electroactive polymers (driven by the drifting or diffusion of ions).

The leading electronic EAP types include ferroelectric polymers, dielectric EAPs, and electrostrictive graft elastomers, which respond quite fast because of no diffusion of charge species. This type of EAPs can be made to hold the induced displacement while activated under a DC voltage without consuming electrical energy, making these EAPs highly efficient for robotic applications. These materials have a high mechanical energy density. However, generating a large deformation requires a high activation field of 100 V/μm or more, which may be close to the electric breakdown level. It is a large challenge to make the field-activated EAP materials applicable for commercial devices, because they are needed to produce large strain using dramatically lower voltages than currently needed [29].

Examples of ionic EAP materials include ionic polymer-metal composites (IPMCs), conductive polymers (CPs), gels, and carbon nanotubes. They undergo volume changes due to a reversible counterion insertion and expulsion during redox cycling. Depending on whether anion or cation exchange predominates, the active layer will either (1) expand upon oxidation due to anion insertion and contract upon reduction due to anion expulsion or (2) contract on oxidation due to cation expulsion and expand on reduction due to cation insertion. Actuators based on CPs can be electrically controlled at low operating voltages (typically 1–3 V), continuously switched between expanded/contracted states.



Murphy et al. fabricated a single-component, metal-free, biocompatible, and electromechanical actuator device using a conductive interpenetrating network of silk fibroin and poly

Organic Actuators, Fig. 13 (**a**) An illustration shows the orientation of the LC molecule changing smoothly by 90° from the bottom surface to the top surface. The ribbons display a variety of shapes that depend on the direction in which they are cut, from left-handed or right-handed ribbons to ribbons for which chirality is not expressed macroscopically. (**b**) Spiral ribbons irradiated for two minutes with ultraviolet light ($\lambda = 365$ nm) display isochoric winding, unwinding and helix inversion as dictated by their initial shape and geometry [28] (Copyright 2014 Nature Publishing Group)

(pyrrole) (PPy) [30]. As Fig. 14 shows, aqueous silk solutions were cast onto a silicone baking mat resulting in only one porous face. After acid modification, PPy is covalently attached to the porous silk surface on which it is deposited. PPy is completely integrated with the silk film making no delamination. For maximal actuation, a ± 3.0 V square wave was applied for 50 cycles at 1 Hz firstly aiming to a more consistent macroscale actuation behavior, then the fast-sequence ± 3.0 V square wave was applied to the films at two-minute intervals. During the initial 50-cycle curing sequence, films typically exhibited a net expansion in addition to the observed oscillation. During the second actuator cycle, the silk-PPy composites contracted under reduction as well as expanded under oxidation in PBS. Obviously, the network operates primarily by anion exchange.

O

Organic Actuators, Fig. 14 (**a**) Schematic diagram of PPy bilayer actuator expansion and contraction. (**b**) Illustration of the bilayer actuator film fabrication process. The free-end actuation behavior of a 3 × 10 mm silk-PPy film. (**c**) A ±3.0 V square wave was applied for 50 cycles at 1 Hz. (**d**) by 16 cycles at 1/120 Hz in PBS [30] (Copyright 2014 Wiley-VCH)

In this mechanism, counteranions and accompanying solvent molecules are expelled when the cationic PPy is reduced to its neutral form, resulting in a contracting motion. Upon oxidation, the anions are reinserted, resulting in expansion or stiffening of the film. This is the first demonstrations of a fully biocompatible, metal-free actuator device operated in a biologically relevant environment.

Future Direction for Research

The market potential for organic actuators is quite remarkable, as they have such advantages as flexibility, light weight, low cost, and quiet operation compliance. Many types of organic actuators have already been developed as artificial actuators in response to external stimuli such as change in temperature, light, and electric field. Not only two-dimensional but also three-dimensional motions in any direction have been achieved which are useful for the application as actuators. In the rapidly developing world of advanced materials, the application is determined by the material's performance and production costs. Therefore, to make the organic actuators applicable for commercial devices, further effort is required in tailoring the different material systems to specific demands of selected applications.

Many challenges and opportunities remain for using these smart materials for "real-life" applications, such as realization of low-cycle fatigue, biocompatibility, resistance in harshness of the operating conditions (extreme temperatures, radiation effects, and very high reliability and durability requirements) and design of complex motions.

Organic bioelectronics (OBOE)

Definition

Active materials used for electrochemical devices are either organic or more commonly inorganic metal (−oxides). This entry only covers organic polymer materials and their application in life science research. Organic Bioelectronics [1] (OBOE) are carbon-based (therefore defined as organic) devices engineered from conductive polymers. The active parts of organic bioelectronic devices are usually composed of conjugated polymers, alone or in combination with other materials to form a primary or secondary interface with biological specimens (therefore defined as bio-). The conductivity of the polymer materials makes it possible to design devices that have the same functionality and capability as common electronics (therefore defined as -electronics). The devices can be manufactured to a multitude of different geometrical designs depending on applications targeted.

Overview and Background

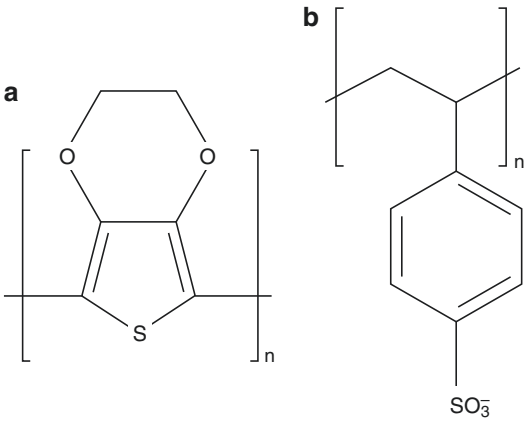
Synthetic polymers revolutionized the technology of materials in the beginning of the twentieth century, when the first commercial plastic, bakelite found its use as a lightweight alternative to outmatch iron and steel in many applications. In 1977, Heeger, MacDiarmid, and Shirikawa achieved conductivity in polymers, a major breakthrough, for which they were awarded the Nobel Prize year 2000. This finding opened for the use of polymers in completely new areas such as in electronic industry and today a wide array of conducting polymers are synthesized, whose different levels of conductivity vary from almost insulators to good conductors. Besides the electronic properties of conducting polymers, the materials have also attracted much attention because of their unique electrochemical properties which are utilized in organic electrochemical transistors (OECT), polymer batteries, electrochromic displays, sensors, and actuators. The novelty of organic electronics results in part from the fact that these materials offer new or improved electroactive and opto-chromic features with respect to its inorganic counterparts as they are flexible, can be manufactured using printing tools, and for life science applications generally show a high level of biocompatibility and other desired features such as flexibility, optically transparent at visible wavelengths, and more.

Basic Methodology

The key to electrical conductivity in polymers are the alternating double bonds that build up the conjugated backbone. These bonds offer free electrons or holes in non-hybridized orbitals of carbon of the polymer and are thus able to participate in transporting electrical current. The electrical conductivity can be modulated by doping the polymer, that is, addition of another compound that

forms an ionic complex with the polymer chain that either donates or accepts one valence electron to further enhance the conductivity. Positive doping (p-doping) is achieved by the removal of one electron from the valence band while donating one electron to the valence band is termed negative doping (n-doping).

Since many conductive polymers can be doped and undoped by electrochemical reactions and hence change their intrinsic properties like conductivity, color/transparency, and surface properties, they are very well suited for active electrochemical circuits for biointerfaces.



A useful property of many conductive polymers is the ability to conduct not only electrons but also ions, which is accompanied by a mass transport of matter in and out of the material. The one-dimensional characteristics of conjugated polymers provide coupled transport of both electronic and ionic charged species. Such co-existing charge transport can be exemplified by the conducting polymer poly (3,4-ethylenedioxythiophene) (PEDOT) doped with the charge-balanced counter-ion poly(styrene sulphonate) (PSS) which forms the polymer-polyectrolyte PEDOT:PSS (Fig. 1). The entire bulk of a PEDOT:PSS film can undergo electrochemical switching. This requires electronic transport along the conjugated backbone of PEDOT, while ionic transport occurs primarily in the PSS polyelectrolyte phase. PEDOT undergoes electrochemical switching according to the half reaction

$$\mathrm{PEDOT^{+}PSS^{-}} + \mathrm{M^{+}} + \mathrm{e^{-}} \Leftrightarrow \mathrm{PEDOT^{0}} + \mathrm{M^{+}} : \mathrm{PSS^{-}} \quad (1)$$

M^+ represents a monovalent cation and e^- an electron. As the reaction goes to the right, reduction of PEDOT to its neutral state occurs, while in the left direction oxidation of PEDOT takes place. Thus, switching of PEDOT between its neutral and oxidized state requires both cations and electrons to the reaction site, while the polymer chains themselves are effectively immobilized.

The possibility to electronically control the redox state of the conducting polymer material is a key feature in biointerfacing since it serves as a translator of biological signals (ions) and electronic signals. Examples of these applications are shown in the next section.

Mass transport of counter-ions in and out of the material during an electrochemical switch is often associated with a change in volume of the bulk material in part due to solvents (e.g., water) that follow the ions into the material. This can be utilized in actuators, and an example of a biomedical application is presented in the next section.

Key Research Findings and Biomedical Applications

Organic Bioelectronics for Modulation of Cell: Surface Interactions

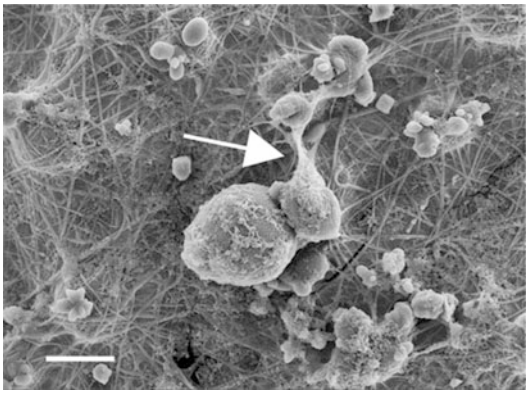
Previous research in the conducting polymer field has shown that these materials offer a possibility to reversibly alter the above-mentioned surface features through electronic control. Submerged in an electrolyte, conducting polymers undergo reduction or oxidation reactions, depending on the direction of the current applied. Using polypyrrole (PPy) as an electroactive cell culture substrate also revealed that electric addressing of the PPy surface promoted neurite outgrowth from cultured neuronal cells, and this effect was

Organic Bioelectronics, Fig. 2 Complex patterning of the extracellular matrix, cells, and tissues under in situ electronic control is the aim of the technique shown above. The distribution of MDCK epithelial cells along the channel of an organic electrochemical transistor is shown to be actively controlled by the gate and drain voltages, as electrochemical gradients are formed along the transistor channel when the device is biased; *top* = 0.0 V; *middle* = 0.5 V; *bottom* = 1.0 V; cells are visualized by F-actin staining (Reproduced with permission from Bolin [5])

correlated to an increase of fibronectin adsorbed to activated PPy surfaces [2].

The conducting polymer PEDOT has become increasingly popular in various bio-applications. In its doped oxidized state, it shows high conductivity and possesses great stability. The material shows high biocompatibility, and it performs very well in aqueous solutions over extended periods of time [3]. The electrochromism as well as other optical properties of the material, that is, optical transparency, lend itself very well to perform microscopy-based analysis, which is a popular tool in cell biology studies.

PEDOT doped with Tosylate (PEDOT:To) is one material that has been investigated to see whether its electronically regulated surface properties could be used to modulate adhesion and proliferation of the renal epithelial cells (Madin Darby canine kidney cell line, (MDCK)). Functionalized cell culture dishes, with conducting polymers coated onto the bottom, is one application, in which cells were subjected to two adjacent electrode areas. By applying low voltage to the electrodes, typically in the range of 0.5–1.5 V, the dish becomes an electrochemical cell with cell culture medium serving as the electrolyte. Electronic addressing of the dish causes redox reactions in the two electrodes: the negatively biased electrode becomes oxidized and the positively addressed electrode turns reduced. Svennersten et al. analyzed whether different redox states of PEDOT:To affected cell adhesion and subsequently cell proliferation. MDCK epithelial cells were shown to readily adhere to, spread, and proliferate on the reduced electrode, while the oxidized surface presented only few, unspecifically bound, apoptotic cells. The oxidized state of PEDOT:To induced a conformational change in surface-bound fibronectin, making the RGD domain, critical for integrin binding, inaccessible. As cells cannot form focal adhesion complexes, cell adhesion is abrogated. This study demonstrates how one physical entity, that is, the redox state of the conducting polymer, acts via several layers of complexity to indirectly regulate something as sophisticated as cell adhesion [4].



Cell density gradients and chemical gradients act in concert to direct a number of biological functions such as cell migration and morphogenesis. Modulation of the number of adhesion sites on biotic and abiotic surfaces is commonly used to produce cell gradients of different densities. Due to the inherent reversible surface characteristics of conducting polymers, this material has been explored as the basis of the establishment of dynamic gradients [5] (Fig. 2). Organic electrochemical transistors (OECT), a variant of the

organic thin film transistor (OTFT), comprise a channel which has an electrochemical potential gradient. Based on PEDOT:To, a lateral design of the OECT was generated, which had an exposed channel surface [6]. The electrochromic properties of PEDOT can be utilized to image the potential along the channel. The device properties and the functionality of the OECT can be even further optimized, by altering the ratio between the gate versus channel area, as demonstrated by Malliaras and coworkers [7].

While this transistor design establishes a close to exponential gradient of the redox potential and accordingly the cell density, linear redox gradients can also be produced. When PEDOT:To is coated on top of an indium tin oxide (ITO) film, the redox state of the polymer followed the linear potential gradient of the ITO film, and this was also reflected in the cell density. As it appears that linear as well as exponential gradients can be created using the same conducting polymer, it may suggest that these devices will become useful tools when deciphering the role of the vast array of linear and exponential gradients found in biological systems [8].

Organic Bioelectronics for Active 3D Matrix Environments for Cell Interaction

3D scaffold electrodes are considered to offer relatively lower impedance characteristics for electrical interfacing for cultured cells by mimicking the structure of natural extracellular matrix. The structural features of these scaffolds are in the nanometer scale, thus allowing nutrients and small molecules to freely diffuse through the matrix, while cells cannot move without an effort. Much effort is accordingly invested in engineering-suitable 3D matrices for cell cultures. Dependent on the nature of the material, scaffolds are produced by different methods. Nano-scaled fibrous scaffolds are commonly fabricated by self-assembly, phase separation, and electro-spinning. Several studies, mostly concerning neuronal cells and brain tissues, demonstrate the suitability of integrating conducting polymers in synthetic scaffolds. As the polymer's conducting property adds an active function to the nano-scaffolds, a potential can be delivered to depolarize excitable cells.

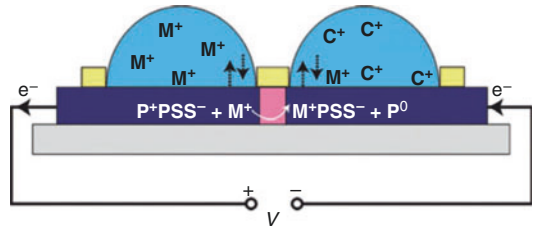
Organic Bioelectronics, Fig. 3 Scanning electron micrograph of a SH-SY5Y neuroblastoma cell on PEDOT:To coated PET nanofibers. Neurite indicated by *arrow*. Scale bar = 10 mm (Figure reproduced from Bolin [10])

The efficient charge transfer is due to the high surface-to-volume ratio of conducting polymer-coated nano-scaffolds [9].

By depositing the conducting polymer PPy onto nano-fibers made from PLGA (poly (lactic-co-glycolic acid)), these electrically active nano-fibers were found to promote the outgrowth of neurite extensions. Similarly, depolarization of neuroblastoma cells, cultivated on PEDOT:To deposited onto PET (poly-ethylene-traphtalate) nanofibers (Fig. 3), resulted in the activation of voltage-operated Ca^{2+} channels, leading to an increase of the intracellular $[Ca^{2+}]$ [10].

Biological material can also be used as a cast for conducting polymers. This opens for a possibility to build a conducting matrix in situ, within the tissue. Martin and co-workers demonstrated this concept by electropolymerizing PEDOT around neuronal cells to maximize the interaction with the cell [11].

This shows that electroactive nano-fibers as well as direct casting of conductive polymers can work as tight electronic interfaces and may thus be useful as a novel tool for cell biology studies in vitro as well as in vivo, that is, as an interfacing component in neural prosthetics.



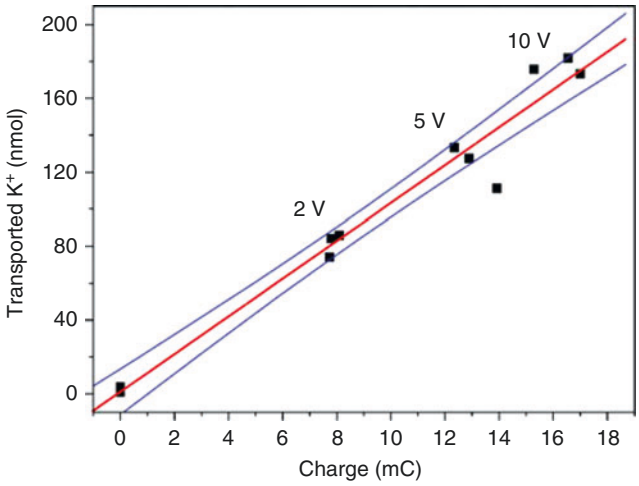
Organic bioelectronic actuators take advantage of the volume change and swelling of the polymer bulk caused by the electrochemical switch. By fixing the polymer to an electrochemically inert

material, the device will stretch, bend, or extend depending on its geometrical design. This feature can be used in biomedical applications and has been shown for micromanipulation of single cells, for example [12].

Organic Bioelectronics for Transport and Delivery of Bio-substances In Vitro and In Vivo

The use of conductive polymers in drug delivery devices has also been demonstrated. By applying a potential, substances such as neurotrophins can be released from delivery electrodes fabricated from conducting polymers [13]. Similarly, PEDOT and PPy-coated nanostructures fabricated on microelectrodes have been used to obtain spatially defined release of the anti-inflammatory drug dexamethasone [14]. Major challenges of electrochemically active drug release polymer electrodes is, however, the difficulty to achieve a proper concentration of the released compound, which preferentially should be in the same range as the physiologically relevant condition, as well as to achieve a device in which the delivery can be switched on and off.

Utilizing the ionic conductivity of conjugated polymers (explained in the previous section) true electronic control over the transport and release of charged molecules can be achieved. Recently, the "organic electronic ion pump" (OEIP) was developed to provide a device for lateral transport and electronically controlled delivery of ions and other positively charged ions and biomolecules [15]. The OEIP is produced from a single film of the conductive polymer PEDOT:PSS patterned into two or more electrodes joined by a "transport channel." Over-oxidation of the PEDOT:PSS renders the channel electronically insulating but ionically conducting. A hydrophobic resist covers the channel and provides openings to position the electrolytes on top of the electrode areas. By applying a voltage between the electrodes an electrochemical circuit is established. Oxidation of PEDOT occurs at the anode/source whereas reduction occurs at the cathode/target (Fig. 4). Migration of ions in the channel resembles the transport of charged molecules, such as DNA and proteins, in conventional gel electrophoresis

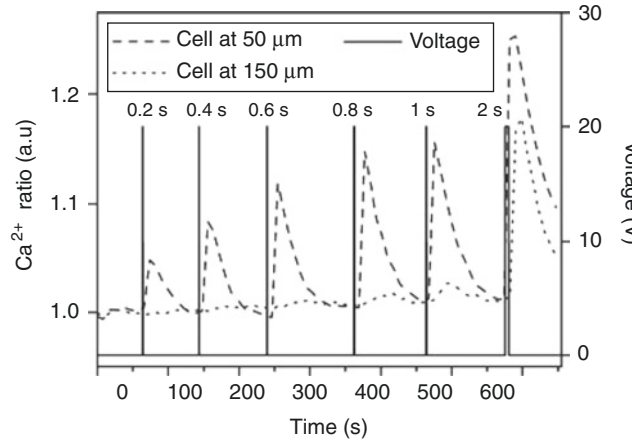


Organic Bioelectronics, Fig. 4 Schematic cross-section of the OEIP. The cation M^+ is present in a relatively high concentration in the source electrolyte (*left*) and binds to PSS in the polymer film. When *V* is applied, PEDOT (denoted P) in the source electrode (*left*) is oxidized. The positive charge on the polymer chain is neutralized with PSS, thereby releasing one M^+. Simultaneously, the target electrode (*right*) receives an electron, and PEDOT:PSS on this side is consequently reduced. There is a net flow of M^+ from the left to the right and every transported (monovalent) ion ideally corresponds to one charge measured between source and target. As the polymer film is very thin (200 nm), ion exchange will immediately occur between the target electrode and the target electrolyte, which also contains other cations (C^+). Hence, the concentration of M^+ increases in the target electrolyte as soon as voltage is applied and as long as source and target electrodes can be oxidized and reduced, respectively (Figure reproduced from Isaksson [15])

systems. In gel electrophoresis, the motion of charged species through an electrically charged field in the gel matrix separates molecules according to their charge and size. In analogy to this, the OEIP offers electrophoretic transport and delivery of positively charged ions and bio-molecules in the absence of a liquid flow and pressure.

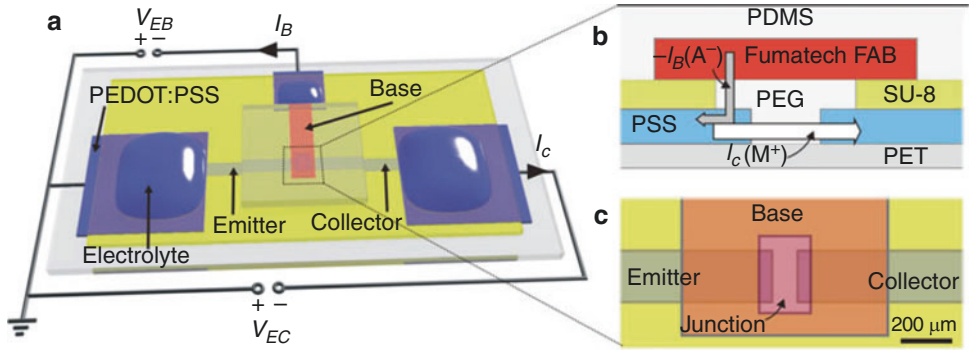
The powerful features of the OEIP can be utilized in many biological applications; the most natural is in cell signaling research, where researchers are challenged by the complexity of cellular signaling patterns, both to study them but also to try to mimic them.

The basic functions of the OEIP were first verified by transport of the metal ion K^+. When the device is switched "ON," using solutions of K^+ as source and Na^+ as target electrolyte, K^+ is transported through the channel and delivered into the target electrolyte. The OEIP is connected to a source meter monitoring the current in the electronic branch of the circuit throughout the experiment. By calculating the total charge transported



Organic Bioelectronics, Fig. 5 Relationship between K^+ delivered to the target system after 10 min and the total charge measured in the electronic circuit (i.e., integrated current) for driving voltages set to 2 V, 5 V, and 10 V. The middle line shows the linear fit and the two outer lines represent the 95 % confidence interval (Figure reproduced from Isaksson [15])

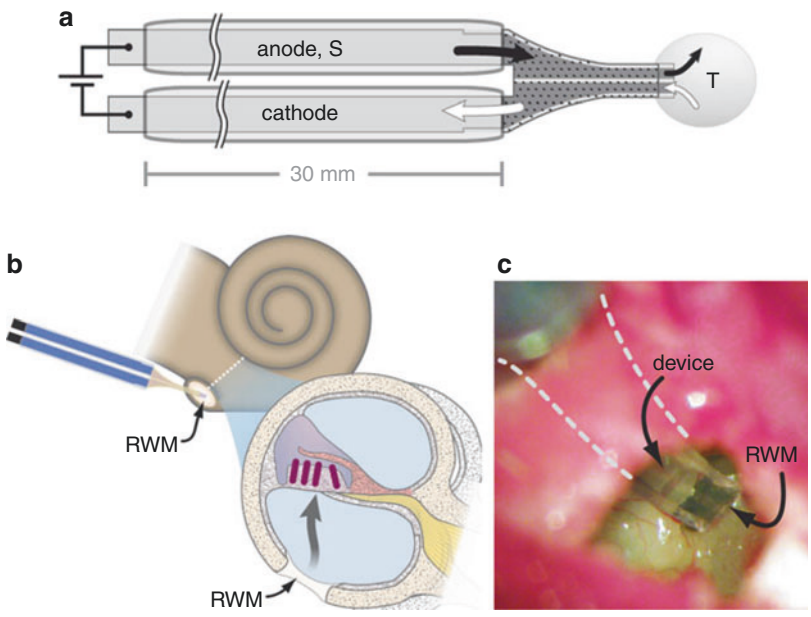
from the source to the target electrode, that is, the integrated current and comparing it to the amount of K^+ delivered to the target a linear relationship can be established between the amount of material delivered and the total charge. For K^+ the electron-to-ion ratio equals 1, that is, delivery efficiency is 100 %, indicating that for each electronic charge measured in the circuit one K^+ is delivered to the target (Fig. 5). Capacity and efficiency of the OEIP is in part dictated by the current bias but also its dimensions. These criteria allow fine-tuning of substance delivery. The OEIP polymer channel was miniaturized from 4 mm down to 10 μm for fine-tuning purposes but also to fit the dimensions of a single cell. The miniaturization of the channel to sizes compatible to that of individual cells has also the advantage that it allows high spatial and temporal precision of single cell stimulation. This precise delivery mechanism was shown by triggering single neuroblastoma cells with the quaternary ammonium cation acetylcholine (ACh), a small molecular neurotransmitter found in both the peripheral and central nervous system [16].



The Ca^{2+} ion is one of the most versatile signaling entities in the cell. Research over the last decades has revealed that cells use repetitive signals, known as Ca^{2+} oscillations, when information must be relayed over longer time periods. The switchable nature of ion delivery in the OEIP provides a novel tool to decipher the role of the frequency and amplitude components of the Ca^{2+} oscillations. Due to the electronic control of the OEIP, switching the device ON/OFF will result in a similar ON/OFF behavior of the electrophoretic delivery. This strategy can accordingly be used to establish temporally device-induced, controlled oscillations. Figure 6 shows a typical example of OEIP-induced Ca^{2+} oscillation in cells. By pulsing the delivery of ACh using the 10 μm-channel OEIP, a repetitive Ca^{2+} response was induced in single neuroblastoma cells (Fig. 6). The strength of the Ca^{2+} response can also be modulated by changing the pulse-length of the electronic induction of the transport. Control of dynamic parameters, such as frequency and amplitude, is not limited to ACh, but has also been demonstrated using H^+.

To further increase the fine-tuning and also ease the integration of multiple circuits for molecular transport an ion bipolar junction transistor (IBJT) has been developed [17] (Fig. 7). This is the ionic analog to conventional semiconductor bipolar junction transistors and shows that amplification, addressing, and processing also can be achieved in more complex bioelectronic bio-molecular circuits.

Abnormal protein aggregates, that is, amyloid fibrils is a common marker for many diseases. Utilizing the H^+ transport of the OEIP, the device has been shown to induce spatially controlled formation of amyloid fibrils, a unique way of producing these in vitro [18].



Organic Bioelectronics, Fig. 6 Ca^{2+} responses in SH-SY5Y cells after delivery of ACh from the outlet of the 10 µm-OEIP. Indicated times represent the duration of the pulse (Reproduced with permission from Tybrandt [16])

Organic Bioelectronics, Fig. 7 (**a**) The IBJT biased according to the common-emitter configuration. PEDOT:PSS electrodes with aqueous electrolytes generate the ionic currents within the device. Emitter and collector (cation selective) meet the base (anion selective) defining the junction. (**b**) Vertical cross-section along the emitter-collector configuration (not to scale). The emitter and collector (~250 nm thick PSS) are patterned on *top* of a PET substrate. A cross-linked PEG gel (referred to as the junction) is employed into the opening of the 10 µm thick SU-8 insulating layer. The base (~20 µm thick) contacts the gel and is covered by a PDMS seal layer. *IC* is the flow of cations (M^+) from the emitter to the collector, while *IB*, in steady state, primarily consists of anions (A−) migrating from the base to the emitter. (**c**) Top-down view of the IBJT. Emitter and collector are horizontally separated by 100 µm and the base covers the whole junction area (Figure reproduced from Tybrandt [17])

Stimulating neuronal activity in vivo is generally performed using neural probes that generate electrical signals. Compared to chemical messengers, electrical signals cannot discriminate among the target cells, as all excitable cells in the stimulated area will be affected. A technique allowing local stimulation using a specific chemical compound is highly desirable, and this need has sparked great activities in the area of drug delivery systems. Delivery systems are often classified as "active" or "passive."

A typical example of an active system is microfluidics. These systems are liquid phase–based, generally small, programmable, and self-contained devices for sustained, local release. Hydrogels, on the other hand, represents a passive system, made of cross-linked water-soluble polymers. These systems are commonly used in clinical practice for wound-healing and tissue regeneration. The above-mentioned techniques have been applied in inner ear diseases and disorders, where local delivery has been a

(**b**) Cartoon depicting the experimental setup in vivo. *Dotted line* indicates a slice through the cochlea, expanded below. *Gray arrow* = diffusion of ions through the RWM. (**c**) Device mounted on the RWM in a guinea pig. The two ion channels are visible as dark stripes on the transparent substrate (Figures reproduced from Simon [19])

long-standing challenge. The cochlea is a complex structure of the inner ear that converts sound into neural activity. The coiled liquid-filled tube includes a membrane stretched across the middle of the tube and covered with sensory hair cells detecting sound using their mechanotransduction apparatus. Because these elements are exceptionally force- and flow-sensitive, and since the cochlea contains only a limited volume of liquid (so-called perilymph), it makes local delivery to this site exceptionally challenging. As substances are transported in the OEIP via electrophoretic transport rather than liquid flow, this device is very attractive to use for local delivery in vivo in general and the cochlea in particular. The inner hair cells utilize glutamate as the primary neurotransmitter and were thus used in a proof-of-concept study where in vivo OEIP–transported Glu modulated the hearing in a guinea pig model [19] (Fig. 8). This study shows that OBOE can be used as an interface for translating electrical signals into chemical messengers that specifically target one type of neuron, thereby modulating mammalian brainstem responses.

The previous section covered the possibility of organic bioelectronic devices to create gradients of surface interfaces. To form controlled gradients of bio-substances within a liquid, that is cell culture medium or other biological liquid interfaces, there is yet another challenge. The non-convective molecular delivery of the OEIP is a unique advantage in this instance, as a bio-substance is transported to the outlet of the OEIP, it spreads by diffusion into the target electrolyte. The migration through the polymer channel occurs at a constant rate, and the applied voltage can then be used to balance the delivery rate to the diffusion characteristics for the specific bio-substance. Using computational analysis, a model of the local concentrations of ions evolving from the channel outlet can be predicted. This has been shown in vitro by creating neurotransmitter gradients of ACh that at different spatial positions of the neuronal cell results in a response or no response [16].

Future Directions for Research

Organic bioelectronics are shown to be powerful tools for both in vitro as well as in vivo applications within life science. At the same time, further development and several areas of improvements are being investigated to increase versatility and performance. On the technology side, development of more advanced components that makes

the electrochemical circuits of OBOEs as complex as their traditional electronic counterparts and allows for more integrated devices with multifunctionality can be foreseen. The recently developed IBJT is a distinct example that in the future will allow for matrix addressing of biological specimens, for example, cells. Adding complexity to the devices also include integration of already existing organic electronic innovations, for example, polymer batteries to make the organic bioelectronic circuit self-supporting or adding in sensors to allow for automation and feedback regulation. Improvements in materials and manufacturing will also yield further miniaturization of the OBOE devices and circuits to even better match the sizes and dimensions encountered in biology. This will allow for the expansion of both in vitro and in vivo applications, where OBOE devices will be able to target and modulate endogenous signal-transduction pathways rather than rely on chemical drugs in drug-delivery applications.

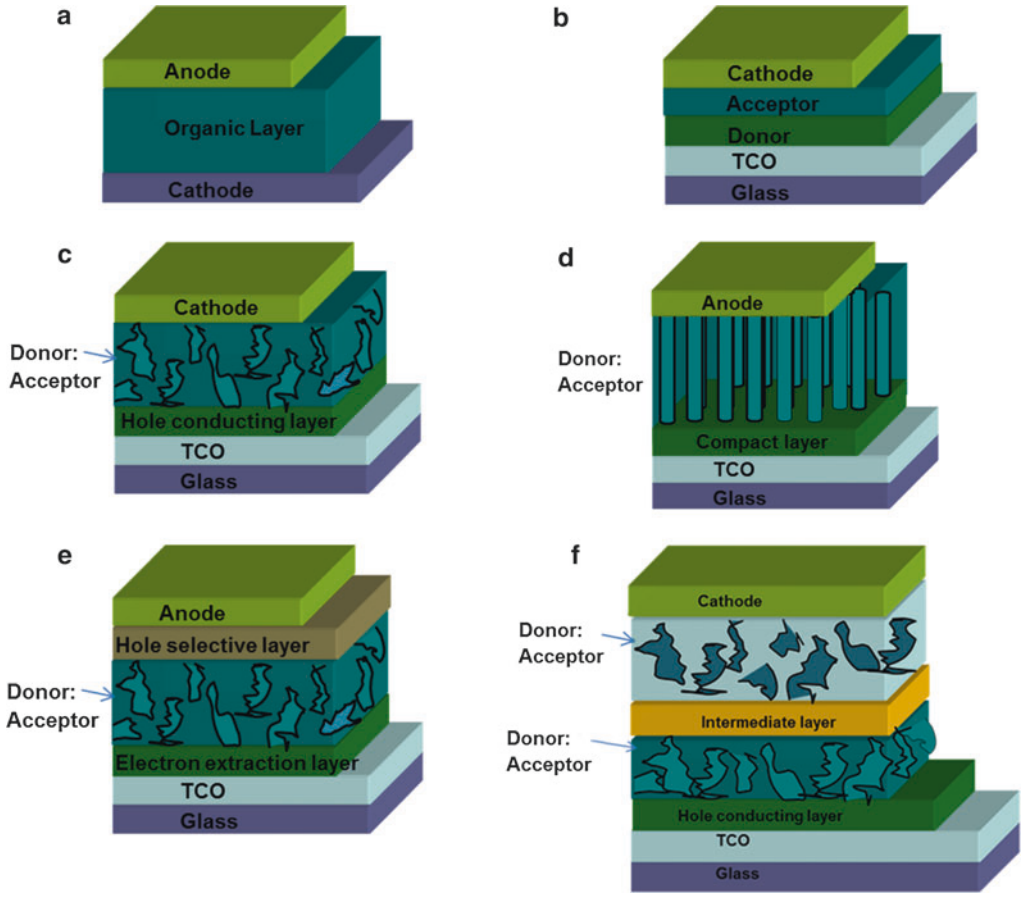
Organic solar cells

Definition



Organic solar cell (OSC) is a type of device made up of thin films of an organic semiconductor material such as conjugated polymer or small molecule as a donor blended with an acceptor material. The donor harvests sunlight. Upon light absorption, exciton (an electron–hole pair) is generated and dissociated at the donor–acceptor interface. The excited electron is transferred to the acceptor and then collected by the cathode, while the hole is transported to the anode. The acceptor materials can be either carbon based as fullerene derivatives (PCBM) or inorganic nanocrystals (e.g., CdSe, TiO_2, ZnO). An efficient organic solar cell requires not only a large interfacial area between the donor and acceptor but also a bicontinuous interpenetrating network that provides one continuous channel for electron transport and another consecutive pathway for hole transfer.

Overview

Organic solar cell (OSC) has gained extensive research interests attributing to its simple fabrication process, abundant raw materials as well as mechanical flexibility and being lightweight. Organic solar cell is a promising cost-effective alternative for the inorganic semiconductor counterparts. Herein, organic solar cell configurations, organic donor and acceptor materials, basic concepts in photovoltaic parameters, and device operation physics are introduced. Organic solar cell can be classified as single-layer, bilayer, bulk-heterojunction (BHJ), ordered-heterojunction, inverted, and tandem configurations. Conjugated polymers such as poly(3-hexylthiophene) (P3HT) and poly(p-phenylene vinylene) (PPV) derivatives are typically used as donor materials for harvesting sunlight; fullerene derivatives PCBM and inorganic semiconductor materials such as CdSe, TiO_2, and ZnO with various nanostructured morphologies are applied as acceptor materials. Short-circuit current density (J_{sc}), open-circuit voltage (V_{oc}), and fill factor (FF) are the key parameters to determine solar cell power conversion efficiency (PCE, η). Six main steps including (i) photon absorption (η_a), (ii) exciton generation (η_{ex}), (iii) exciton diffusion (η_{diff}), (iv) exciton and polaron dissociation (η_{ed}), (v) charge transport (η_{tr}), and (vi) charge collection (η_{cc}) govern solar cell performance. The maximized performance of each step would lead to the highest available efficiency. Further improvement in solar cell efficiency needs to explore novel donor and acceptor materials and new device architectures, as well as the fundamental understanding of the operation mechanism of organic solar cells.

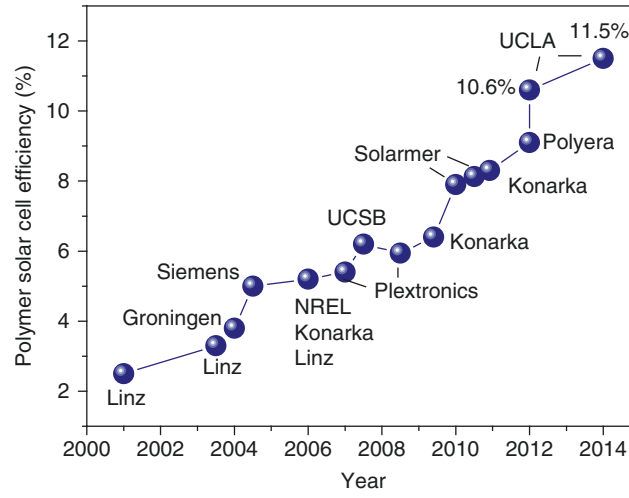
Background

Limited supply and adverse environmental effects from the combustion of fossil fuels have driven people to search for clean and sustainable energy. Solar is an abundant and renewable energy source. Sunlight harvesting and converting it directly into electricity are known as photovoltaics, which has been regarded as one of the

Organic Photovoltaics: Basic Concepts and Device Physics, Fig. 1 Configuration of polymer solar cells: (**a**) single-layer structure, (**b**) bilayer heterojunctions, (**c**) bulk heterojunctions (BHJ), (**d**) ordered heterojunctions, (**e**) inverted structure, and (**f**) tandem structure

most promising technologies that can be an alternative to fossil fuels. The commercial solar cell marketing currently is dominated by the inorganic semiconductor-based solar cells such as silicon solar cells, which typically require sophisticated high-temperature processing and complex engineering, rendering them cost prohibitive as an energy source for wide applications. These cells are also hampered by limited mechanical flexibility. Polymer solar cells show great potential as a low-cost alternative to Si solar cells because they can be fabricated using inexpensive painting or simple printing. In addition to their low cost, polymer solar cells offer additional advantages of being lightweight and having mechanical flexibility. Here the basic concepts and device physics of organic photovoltaics will be presented.

Organic Solar Device Configuration



The early stage of organic solar cells was made in a single-layer configuration as shown in Fig. 1a. The devices were fabricated by preparing an organic layer sandwiched between a low-workfunction metal layer (Al) and a high-workfunction metal layer (Au). The solar cells showed poor photovoltaic performance due to inefficient exciton dissociation [1]. Because of low dielectric constant in organic semiconductors,

exciton binding energy (E_b) is relatively large with a typical value of ~0.1–0.4 eV [1]. This is different from Si solar cells, in which the photoexcited electrons and holes have a quite weak binding energy that can be separated by the built-in electric field of a PN junction [2]. However, in organic solar cells, the built-in electric field is not high enough to dissociate the photogenerated excitons.

Then in 1986, Tang [3] reported a bilayer solar cell consisting two distinctive layers (one is donor layer and the other is acceptor layer). The cell was fabricated by thermally evaporated copper phthalocyanine (p-type) and perylene diimide (n-type) derivatives, respectively, between indium tin oxide and silver electrodes. This cell is also called as "Tang cell" and its configuration is shown in Fig. 1b. The cell power-conversion efficiency has reached ~1 % under simulated solar illumination. Cell performance improvement was attributed to the creation of planar interface between the donor and acceptor layer, which provided an energetically favorable interface for exciton dissociation. The acceptor is usually more electronegative and thus electrons have a tendency to transfer to the acceptor, and holes stay with the donor. In order to enhance exciton dissociation and prevent exciton recombination, a large interfacial area is preferred. However, the drawback of bilayer solar cells is that the interfacial area is limited by the fixed planar structure between the donor and acceptor layer. In addition, exciton diffusion lengths in organic semiconductors such as conjugated polymers are only about 5–15 nm, while the light-absorption depth in organic semiconductors is ~100 nm for sufficient light absorption [4]. Since the exciton dissociation area is fixed at the interface between two distinctive layers, only the excitons generated within exciton diffusion lengths can reach the interface for dissociation. Thus, a majority of excitons decay to the ground state rather than separate as free-charge carriers in bilayer devices.

To solve the limitations of bilayer solar cells and substantially increase both the light absorption and the interfacial area for exciton dissociation, the bulk-heterojunction concept (Fig. 1c) was introduced by Yu et al. [5]. Fullerene C_{60} and its derivatives PCBM have been applied as the electron acceptor since the ultrafast photoinduced electron transfer from a conjugated polymer (MEH-PPV) to fullerene (C_{60}) at a time scale of 50 fs was found by Heeger [6], and fullerene and its derivatives have been proved as the most efficient type of acceptors so far. Bulk-heterojunction solar cells are typically assembled by blending the donor and acceptor materials together and then sandwiching the mixture layer between two electrodes. The nanoscale morphology of the donor and acceptor is a crucial factor limiting the cell performance, and solvent selection affects the solubility of fullerene which thus leads to the different roughness of blend films. Besides solvent, thermal and solvent annealing methods are demonstrated as effective approaches to improve cell efficiency since the polymer chain ordering are reorganized through the treatment. The bulk-heterojunction solar cells have been extensively studied, and great progresses have been achieved in increasing organic solar cell efficiencies.

Ordered heterojunction solar cells (Fig. 1d) were also investigated, and they are considered as an ideal configuration for solar cell application, because they have direct charge transport pathway. Inorganic acceptor semiconductors can be made as nanotube-, nanorod-, and nanowire-shaped structures, and they can be vertically aligned onto conducting substrates. The polymer solution can be infiltrated into the nanoporous and nanospaces by spin coating or drop casting. The devices can also be assembled by in situ synthesis of polymer via UV-light irradiation, chemical oxidative method, or electrochemical polymerization methods. However, so far, cell efficiencies have been lower than those of randomly mixed bulk-heterojunction polymer solar cells. A possible reason is that the in situ synthesized polymers might not have the same high quality as the ex situ synthesized polymers because the latter can be purified and optimized before used for solar cell fabrication. Another possibility is that in situ synthesized polymers are generally combined with inorganic acceptors that usually have less photovoltaic performance than fullerene derivative-based solar cells.

Organic Photovoltaics: Basic Concepts and Device Physics, Fig. 2 Efficiency evolution of polymer solar cells from 2001 to 2014 [9–11]

Inverted solar cell (Fig. 1e) is made of n-type buffer layer on top of a transparent cathode (conducting glass), then the active layer, p-type buffer layer, and a metal anode layer were stacked subsequently. The inverted structure was first reported by Yang and Li et al. in 2006; they used a low-workfunction interfacial layer Cs_2CO_3 to lower the workfunction of ITO [7]. Transition metal oxides such as V_2O_5, MoO_3, and WO_3 were usually used as a hole-buffer layer placed on the anode side to form the inverted structure. ZnO has been demonstrated to be an efficient p-type buffer layer in the inverted device. The major advantage of inverted design compared with the conventional one is the better cell stability.

Tandem solar cell (Fig. 1f) was firstly invented by Boer and Janssen in 2006 [8]. Tandem solar cell consists of more than one sub-cell with the complementary light-absorption properties from donor materials, and an interconnecting layer such as MoO_3, TiO_2(n type)/PEDOT:PSS (p type), and ZnO(n type)/PEDOT:PSS(p type) was employed to connect the top and the bottom cell. The overall device shows higher performance than that of individual sub-cell.

Figure 2 shows the efficiency evolution of polymer solar cells in the last decade. So far, the highest cell efficiency of 11.5 % with a triple-junction polymer solar cell has been in reach by Yang's group at UCLA.

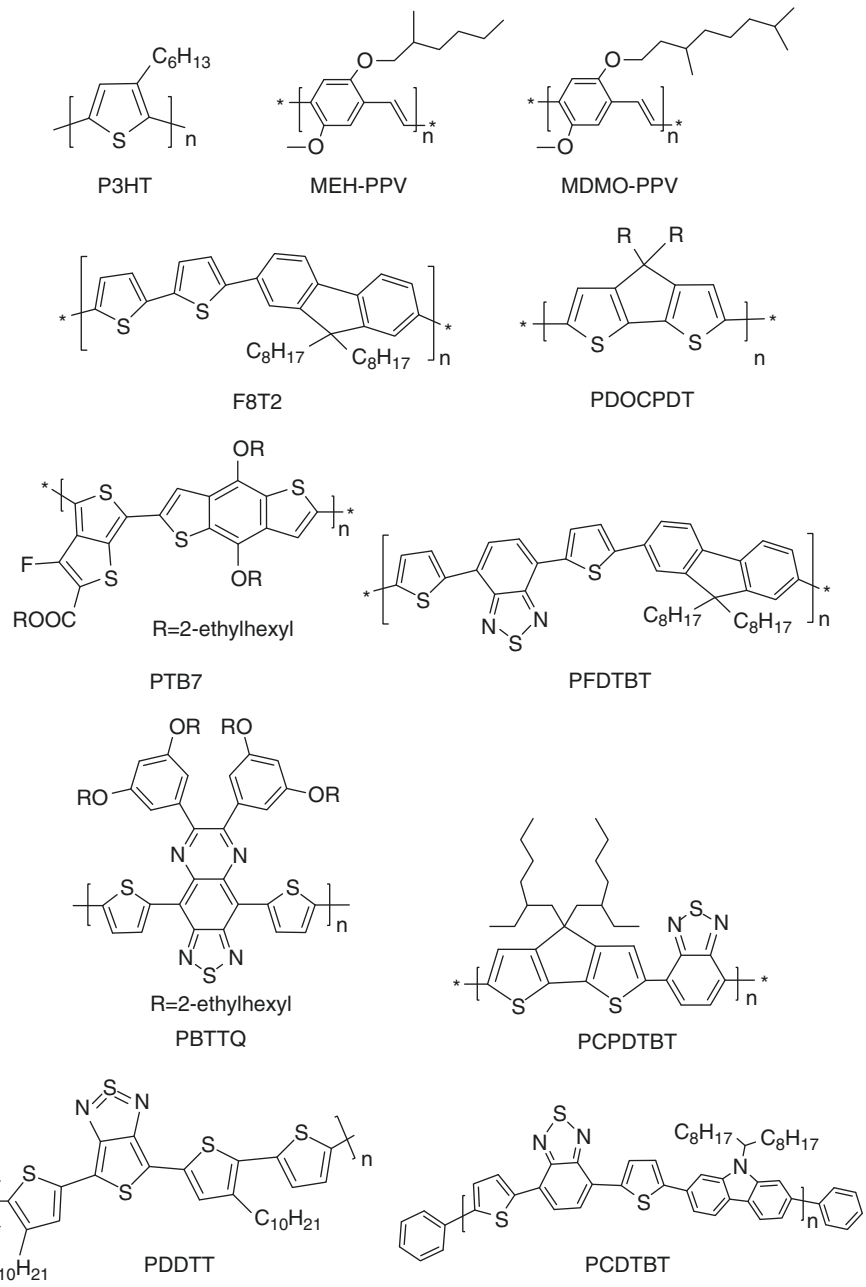
Organic Photovoltaic Materials

Donor Materials (p-Type Materials). The conductivity in organic semiconductors is attributed to the alternating single and double bonds or alternating single and triple bonds. In the system with alternating single and double bonds, the s orbital and two p orbitals form three hybridized sp^2 orbitals, which form σ bonds; while the fourth orbital (p_z) is perpendicular to the plane of the hybridized sp^2 orbitals, forming a π bond. The single bonds are σ bonds; the double bonds include a σ-bond and a π-bond. In the system of alternating single and triple bonds, the s orbital and one p orbital form two hybridized sp orbitals, while the other two form π orbitals. The single bonds are only σ bonds, while the triple bonds have one σ-bond and two π-bonds. The overlap of π orbitals causes delocalization that is the origin of carrier conductivity. Because of Peierls instability, the system is distorted and asymmetric; the single bonds become a little longer, while the double or triple bonds become a little shorter. Thus, the π electrons produce two delocalization energy bands: one is from lower-energy bonding π orbitals (π band) and the other is from higher-energy anti-bonding π orbitals (π^* band) [4]. The former is generally called the highest occupied molecular orbitals (HOMO) and the latter is the lowest unoccupied molecular orbitals (LUMO). The HOMO–LUMO gap usually determines the

optical properties such as photon absorption and emission. Most organic semiconductors have a bandgap within 1.5–4 eV and a high absorption coefficient up to $\sim 10^5$ cm^{-1}. Therefore, an incident visible-light photon has sufficient energy to excite an electron from the HOMO to the LUMO of conjugated polymers. This makes them well suited to absorb visible light for photovoltaic application.

A variety of conjugated polymers have been used as donor materials in organic solar cells. Polythiophene (PT) and its derivatives poly(3-hexylthiophene) (P3HT), poly(p-phenylene vinylene) (PPV) and its derivatives are two major types of polymers. These polymers typically only absorb light up to 650 nm, showing a limited light-harvesting capability. Further substantial increases in device efficiency will partly depend on significant broadening of absorption spectra to harness low energy photons beyond those of the current polymers. Low-bandgap polymers have been used for broader light harvesting of the solar spectrum. In addition, the polymers need to have a relatively high degree of planarity and high carrier mobility. The polymers should be able to self-assembled into a more organized structure with enhanced backbone packing and charge transport using treatments such as thermal and solvent annealing. The donor polymers should also properly phase separate and create a hole-transport network with efficient hole transport, and the donor–acceptor interfaces need to be finely managed within the exciton reach to increase exciton dissociation. The energy levels (LUMO and HOMO) also need to be optimized to achieve efficient charge transfer as well as a high effective bandgap ($E_{DA} = LUMO_A - HOMO_D$) for high open-circuit voltages (V_{oc}). Generally, the key optical and electronic properties of donor polymers are their bandgaps, LUMOs, and carrier mobilities. Their bandgaps should be close to the optimal $\sim$1.5 eV [1, 10, 12]. Figure 3 lists some conjugated polymers used in organic solar cells [1].

Acceptor materials (n-type materials). In organic solar cells, the acceptor materials need to have a higher electron affinity than the donor polymers. In other words, the LUMO of acceptor materials need to lie well below the related LUMO of various polymers, making them energetically favorable for exciton dissociation and charge transfer at the interfaces. In addition, a high-electron-accepting ability is also required for acceptors used in solar cells. For example, fullerene and its derivatives $PC_{61}BM$ and $PC_{71}BM$ (Fig. 4) are capable of taking multiple electrons. Another property is high electron mobility, which works as a "speed limit" for electron transport. In addition, inorganic nanoscale semiconductors such as CdSe, TiO_2, and ZnO with different kinds of nanostructures can be used as acceptors or electron-transport materials in polymer/inorganic hybrid solar cells. These inorganic nanostructures can be prepared into various morphologies through wet chemistry methods. Different shapes such as nanoparticles, nanorods, nanosheets, tetrapods, and hyperbranched nanostructures of various inorganic were investigated. Figure 5 shows the scanning electron microscopy (SEM) images of ZnO nanofilms with nanoridge (a), nanosheet (b), and nanorod (c) shape. The morphologies mainly affect the interface area between inorganic and polymers, thus influencing the exciton dissociation. See entry on "► Hybrid Solar Cells".

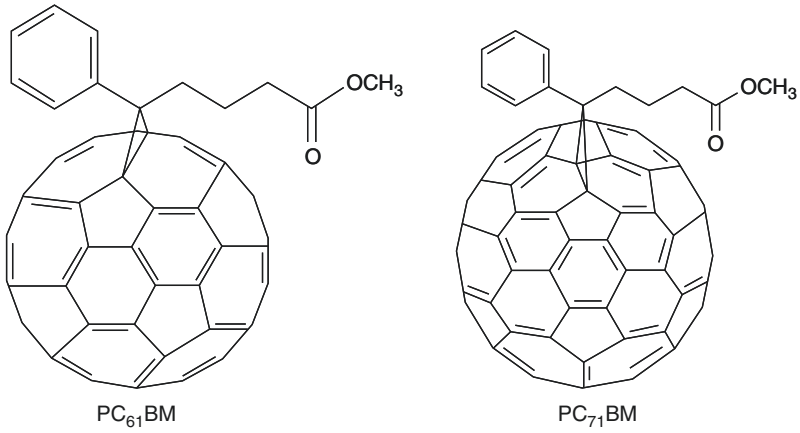


O

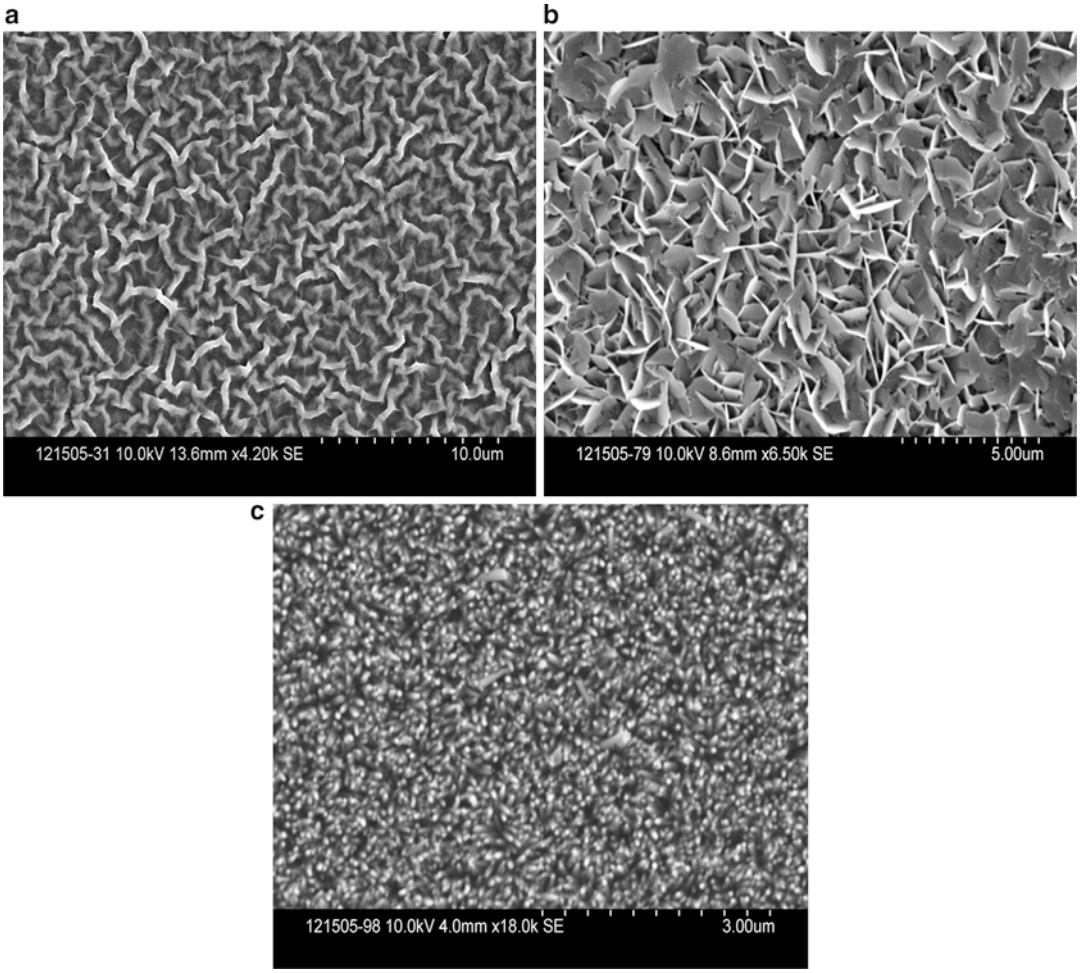
Basic Concepts in Organic Photovoltaics

Characterization of a solar cell. Solar cell performance can be illustrated by current density–voltage (J–V) curves, which are shown in Fig. 6a under dark (black curve) and illumination (red curve). The power density ($P = JV$) was plotted (blue curve). From the J–V curve, open-circuit voltage (V_{oc}), short-circuit current (J_{sc}), and energy-conversion efficiency (η) can be obtained.

$$\eta = \frac{J_m V_m}{P_s} = \frac{J_{sc} V_{oc} FF}{P_s} \tag{1}$$



where J_m and V_m are the current and voltage at the maximum power point, respectively, FF is the fill factor, and P_s is the incident light power density.



Organic Photovoltaics: Basic Concepts and Device Physics, Fig. 3 Chemical structures of some conjugated polymers used in solar cells

The equivalent circuit of a solar cell is shown in Fig. 6b. A series resistance (R_s) may originate from contact and bulk semiconductor, and a shunt resistance (R_{sh}) may come from poor diode contact [15]. The J–V characteristics can be described as

$$J = J_0\left\{\exp\left[\frac{q(V - JR_sA)}{nk_BT}\right] - 1\right\} + \frac{V - JR_sA}{R_{sh}A} - J_{ph} \quad (2)$$

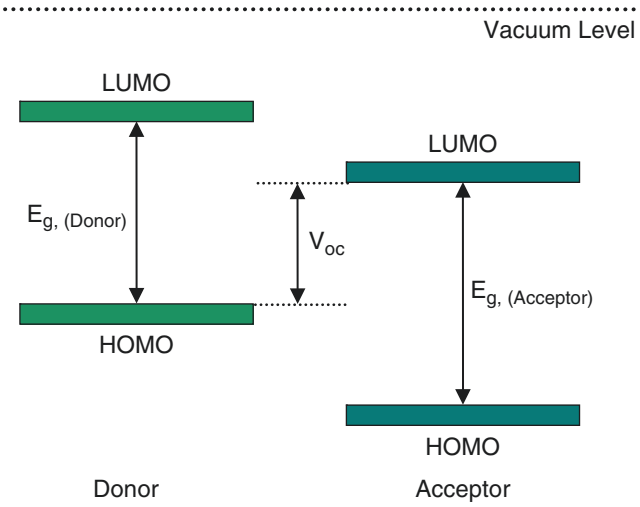
O

Organic Photovoltaics: Basic Concepts and Device Physics, Fig. 6 (**a**) The characteristic current density- and power-voltage curves under dark and illumination; (**b**) equivalent circuit for polymer photovoltaic cells

where k_B is Boltzmann constant, T is temperature, q is elementary charge, A is device area, n is ideality factor of the diode, J_0 is reverse saturation current density, J_{ph} is photocurrent, R_s is the series resistance, and R_{sh} is the shunt resistance. The J–V curves and photovoltaic parameters including J_{sc}, V_{oc}, and FF strongly depend on the n, J_0, R_s, and R_{sh}.

Short-Circuit Current Density. Short-circuit current density (J_{sc}) is the photocurrent generated by a photovoltaic device under illumination at short-circuit condition. It depends on the incident light intensity and absorption spectra of active materials, which can be described as [10]



$$J_{sc} = \int_{E_g}^{\infty} e \cdot N_{ph}(E) \cdot EQE(E) dE \qquad (3)$$

where N_{ph} is the spectral photon flux of incident light, E_g is the bandgap of active materials, E is the photon energy, and EQE is the external quantum efficiency.

Open-Circuit Voltage. Open-circuit voltage (V_{oc}) is defined as the voltage across the cell under illumination with a zero current at which the dark current and photocurrent are exactly canceled out [2]. V_{oc} is the largest voltage output from a solar cell [16]. By solving the current density verse voltage equation (Eq. 2) at $J = 0$ and $V = V_{oc}$, V_{oc} can be derived as [17]

$$V_{oc} = \frac{nk_BT}{q} \ln\left(\frac{J_{ph}}{J_0} + 1 - \frac{V_{oc}}{J_0 R_{sh}}\right) \qquad (4)$$

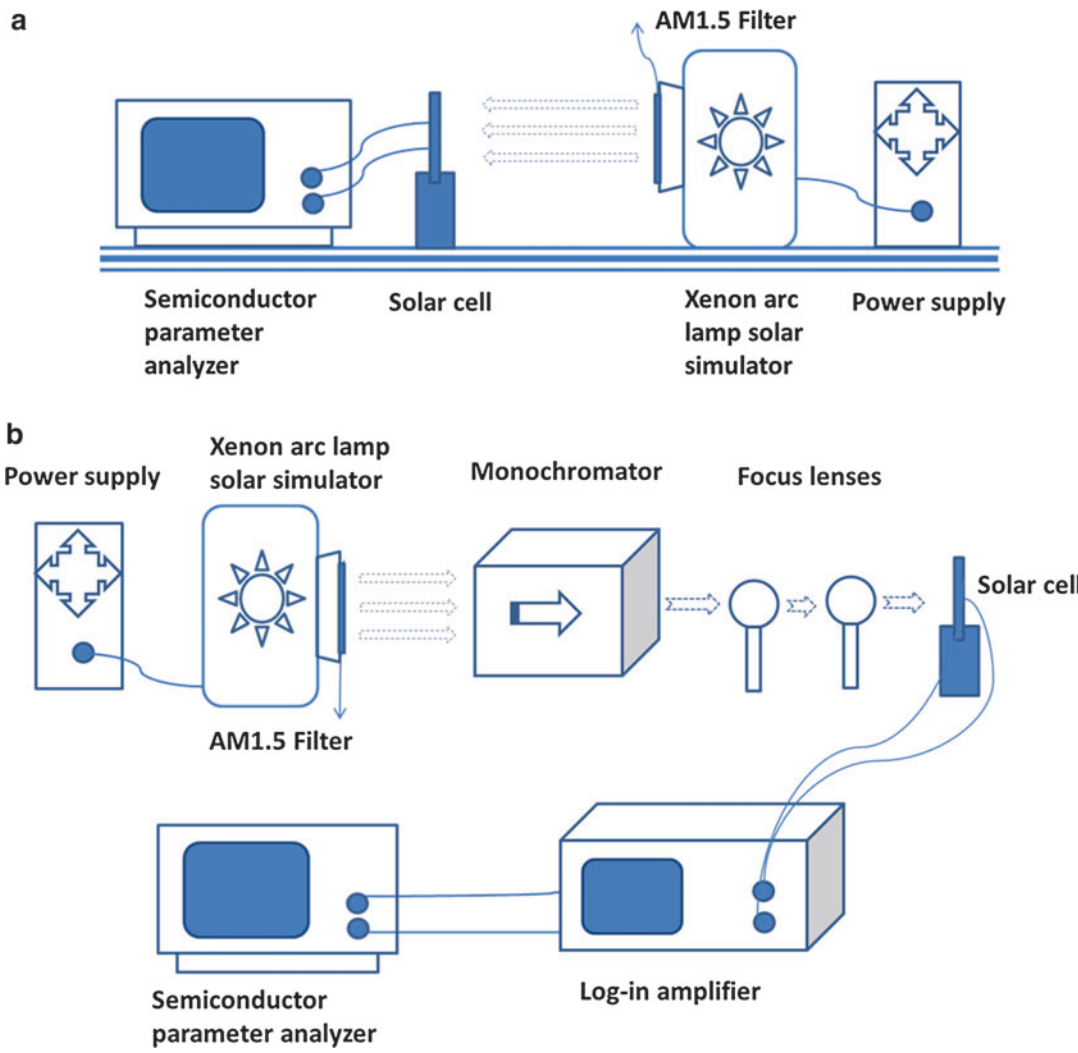
The V_{oc} of polymer–fullerene solar cells have been widely studied. In early days, the V_{oc} was considered to be determined by workfunction difference of the two electrodes originally based on metal–insulator–metal (MIM) devices. Further studies show that the V_{oc} linearly depends on the donor–acceptor effective bandgap ($E_{g,DA} = HOMO_D - LUMO_A$) [18]. Scharber et al. reported $V_{oc} = E_{g,DA}/e - 0.3\text{V}$ for various polymers with different HOMO energy levels and they found that 0.3 V is an empirical value that describes the difference between the V_{oc} and maximum built-in potential (V_{bi}) [12]. More recently, Vandewal et al. [19] studied the relationship between the V_{oc} and $E_{g,DA}$ and found that the $E_{g,DA}$ (a theoretical maximum of V_{oc}) is proportional to the experimental V_{oc} but several 100 meVs larger (e.g., $V_{oc} = E_{g,DA}/e - 0.43\text{V}$). The donor–acceptor properties, mass fraction of crystalline nanofiber polymer in the entire film, and film morphologies can affect $E_{g,DA}$ [4, 20]. The difference between the V_{oc} and $E_{g,DA}$ is possibly caused by energetic disorders, radiative and nonradiative recombination, and band bending due to carrier diffusion [4, 19]. To maximize V_{oc}, this difference between the V_{oc} and $E_{g,DA}$ needs to be minimized.

Organic Photovoltaics: Basic Concepts and Device Physics, Fig. 7 Energy-level diagram of a donor and acceptor system with the theoretical maximum ($E_{g,DA} = HOMO_D - LUMO_A$)

Low-bandgap polymers can be used to increase light absorption for a higher photocurrent by broadening the absorption spectrum; however, the decrease of conjugated polymer bandgaps will also affect the V_{oc}. In a bulk-heterojunction solar cell, the theoretical maximum V_{oc} can be described as

$$V_{oc,\max} = E_{g,DA} = E_g - (LUMO_D - LUMO_A) \quad (5)$$

If the E_b is comparable in both the low- and high-bandgap polymers, then the energy offset ($LUMO_D - LUMO_A$) needed to dissociate excitons is also comparable. Thus, according to Eq. 5, a lower bandgap (E_g) will lead to a reduced theoretical maximum of V_{oc}. In order to achieve significantly higher energy conversion efficiency, a balance between donor bandgap (mainly determining J_{sc}) and donor LUMO (mainly determining V_{oc}) needs to be achieved if a specific acceptor material is used with its LUMO or the conduction band is fixed. Figure 7 shows the energy-level diagram of a donor and acceptor system with the theoretical maximum ($E_{g,DA} = HOMO_D - LUMO_A$).



Fill Factor. Fill factor (*FF*) is a parameter, together with J_{sc} and V_{oc}, used to calculate the maximum power output from a solar cell. *FF* is defined as the ratio of the maximum power ($J_m V_m$) to the product of J_{sc} and V_{oc} [16].

$$FF = \frac{P_m}{J_{sc}V_{oc}} = \frac{J_m V_m}{J_{sc}V_{oc}} \quad (6)$$

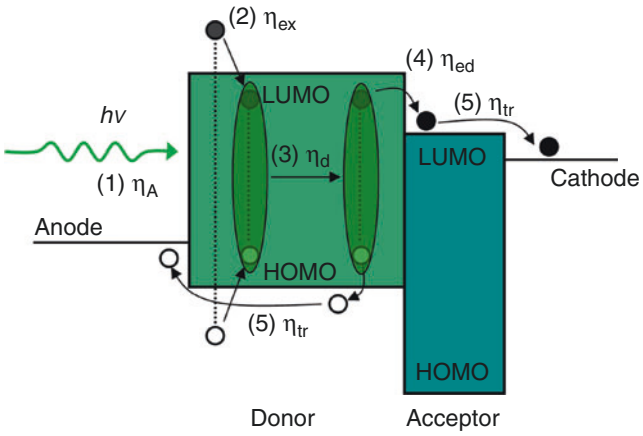
The *FF* is affected by the series resistance (R_s) and shunt resistance (R_{sh}). The relationship can be derived herein [17]. High *FF* can be achieved with a low R_s and a high R_{sh} (ideally $R_s = 0$, $R_{sh} = \infty$). Therefore, the R_s needs to be minimized and the R_{sh} should be maximized to ensure a high *FF*. The dependence of *FF* on R_s and R_{sh} can be approximated as [17]

$$FF(R_s, R_{sh}) \approx FF(0,\infty)\left[\left(1 - \frac{J_{sc}R_s}{V_{oc}}\right) - \left(\frac{V_{oc}}{J_{sc}R_{sh}}\right)\right] \quad (7)$$

External and Internal Quantum Efficiency. External quantum efficiency (*EQE*), called incident photon-to-electron conversion efficiency (*IPCE*), is defined as a percentage of the number of charge carriers collected at the electrode under short-circuit condition to the number of photons incident on the device. *EQE* can be calculated from Eq. 8. Internal quantum efficiency (*IQE*) is defined as the percentage of absorbed photons at a given wavelength which are converted to the

Organic Photovoltaics: Basic Concepts and Device Physics, Fig. 8 (**a**) Schematic of current density versus voltage (J–V) measurement setup; (**b**) schematic of incident photon-to-electron conversion efficiency (IPCE) measurement setup [13]

current. The relationship of *EQE* and *IQE* can be found as Eq. 9.



$$EQE = \frac{J_{sc}hc}{P_s\lambda e} = \frac{1240J_{sc}}{P_s\lambda} \tag{8}$$

$$IQE = \frac{EQE}{1-R-T} \tag{9}$$

where h is Planck's constant, c is velocity of light, R is reflectance, and T is transmittance.

Measurements of Solar Cells

Current Density versus Voltage (J–V) Measurements. Dark and illumination current density versus voltage (J–V) measurements can be tested using semiconductor parameter analyzer combined with a xenon lamp AM 1.5 solar simulator as shown in Fig. 8a [21]. The first step is to use a standard silicon photodetector to calibrate the light intensity at 100 mW/cm^2. Then a sample solar cell is located at the fixed position with a

Organic Photovoltaics: Basic Concepts and Device Physics, Fig. 9 Energy level diagram of a donor–acceptor organic solar cell with key processes. Note step 6 (charge collection) is integrated into step 5 (charge transport) and thus not shown in this figure (hγ: photon energy) [1]

sweeping voltage from −1 to 1 V under dark and light illumination. The current was then measured by a semiconductor parameter analyzer. Solar cell parameters such as open-circuit voltage (V_{oc}), short-circuit current (J_{sc}), and fill factor (*FF*) can be obtained from the measurement. Solar cell efficiency () is calculated using Eq. 1.

External Quantum Efficiency (EQE). External quantum efficiency (*EQE*) can be tested using the setup as shown in Fig. 8b. Since *EQE* is wavelength dependent, a monochromator is used to sweep the wavelength in a certain range. The voltage from the parameter analyzer through a log-in amplifier is measured. A standard silicon photodetector is first illuminated by the monochromator light via a set of focus lenses and the voltage is recorded. Then the sample solar cells are tested at the same position when light illuminated. Since the *IPCE* value of the standard device is known, the *IPCE* of the sample cell can be calculated comparing to the reference of the standard device cell using the equation below:

$$IPCE_{\text{cell}} = \frac{V_{\text{cell}}}{V_{\text{ref}}} IPCE_{\text{ref}} \qquad (10)$$

Device Physics

Solar cell is a device that produces electricity from sunlight. Upon illumination, photons are absorbed by an active layer, and then electron–hole pairs are generated as excitons. The excitons need to diffuse to a donor–acceptor interface to dissociate into free charges. After that, electrons and holes need to transport to electrodes through their corresponding percolation pathway. During these processes, six main steps affect device performance (Fig. 9): (i) photon absorption (η_a), (ii) exciton generation (η_{ex}), (iii) exciton diffusion (η_{diff}), (iv) exciton and polaron dissociation (η_{ed}), (v) charge transport (η_{tr}), and (vi) charge collection (η_{cc}). The η is the yield of each process.

These six processes determining solar cell performance can be better understood in a connection with *EQE*, which can be expressed as the product of the η in the above steps.

$$EQE = \eta_a \times \eta_{ex} \times \eta_{diff} \times \eta_{ed} \times \eta_{tr} \times \eta_{cc} \qquad (11)$$

Photon Absorption. The photon absorption yield η_a is determined by the absorption spectral band, optical absorption coefficient, and thickness of a photoactive layer, as well as internal reflection [22]. Most semiconducting polymers (e.g., P3HT, MDMO-PPV, etc.) have a bandgap larger than 2 eV, which limits light absorption range less than 650 nm. Therefore, only a small portion of sunlight can be absorbed in polymer solar cells. Usually, the thickness of an active layer is on the order of 100 nm to avoid exciton and charge transport loss. To well balance sufficient light absorption and efficient charge transport, both a wide absorption spectral band and a high absorption coefficient are important for absorbing enough sunlight. The absorption coefficients of conjugated polymers were reported to

be much higher than that of silicon so that a thin layer (e.g., 100 nm) of polymers is thick enough to absorb sufficient light.

Exciton Generation. Upon light absorption, the exciton is generated and a so-called charge transfer (CT) state is formed. Since the dielectric constant in the organic semiconductor is smaller compared with the inorganic semiconductor, the photoinduced electron–hole pairs cannot be dissociated into free electrons and holes by the thermal excitation; thus the tightly bound excitons with a binding energy of 0.3 ∼ 1.4 eV are formed.

Exciton Diffusion. The exciton moves in the organic semiconductor matrix within the limited diffusion length. The efficiency (η_{diff}) of exciton diffusion to a donor–acceptor interface is related to its exciton diffusion length (L_D) and distance (L_i) between the photoexcitation location and the donor–acceptor interface which serves as a dissociation center. The L_D is equal to $(D\tau)^{1/2}$, where D is diffusion coefficient and τ is exciton lifetimes [23]. Excitons can diffuse to a donor–acceptor interface with $L_i < L_D$; otherwise, they recombine with a reduced η_{diff} [24]. Typically, exciton diffusion length is in the range of 5 ∼ 15 nm for conjugated polymers [1].

Exciton Dissociation. The efficiency (η_{ed}) of exciton dissociation into free holes and electrons relies on the donor and acceptor LUMO energy offsets and internal electric field at a donor–acceptor heterojunction [24]. The minimum energy required to dissociate an exciton in a conjugated polymer is the same amount of energy that is needed to overcome the exciton binding energy. This energy can be provided by the offset between the LUMO energy levels of the donor and acceptor [24]. Once the exciton is dissociated, the hole and electron stay on the donor and acceptor material, respectively, but they are still bound as a polaron pair by Coulomb attraction [4]. To get free electrons and holes, such polaron pairs need to be separated. The polaron pair dissociation can be described by the commonly used Braun–Onsager model, in which the polaron pair dissociation probability is [4]

$$P(F) = \frac{k_d(F)}{k_d(F) + k_f} \tag{12}$$

where F is the electric field, k_f is the polaron pair decay rate to the ground state, and k_d is the polaron pair dissociation rate, which can be expressed as

$$k_d(F) = \frac{3\gamma}{4\pi r_{pp}^3} \exp\left(-\frac{E_b}{k_B T}\right) \frac{J_1\left(2\sqrt{-2b}\right)}{\sqrt{-2b}} \tag{13}$$

$$\gamma = \frac{q}{\varepsilon_0 \varepsilon_r} (\mu_e + \mu_h) \tag{14}$$

$$E_b = \frac{q^2}{4\pi\varepsilon_0 \varepsilon_r r_{pp}} \tag{15}$$

$$b = \frac{q^3 F}{8\pi\varepsilon_0 \varepsilon_r (k_B T)^2} \tag{16}$$

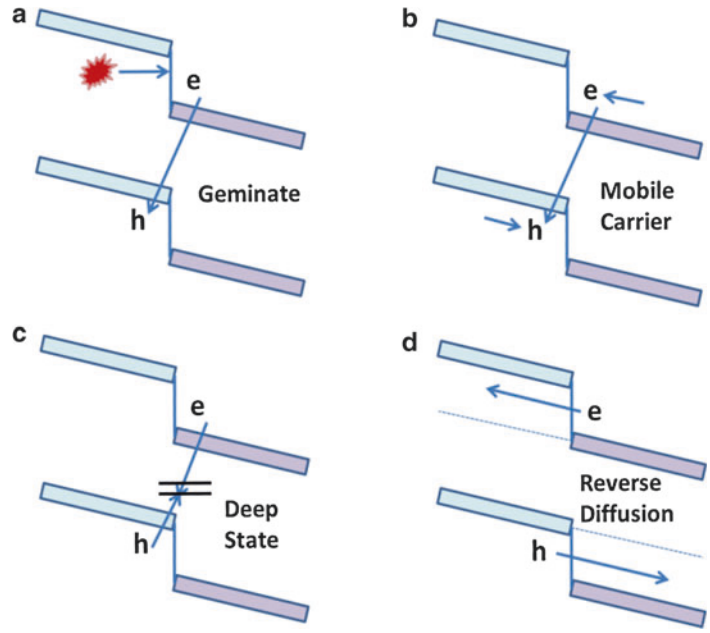
where γ is the Langevin recombination factor, r_{pp} is the radius of the initial polaron pair, E_b is the polaron pair Coulomb binding energy, k_B is the Boltzmann constant, T is the temperature, J_1 is the first-order Bessel function, μ_e is the electron mobility, μ_h is the hole mobility, ε_0 is the permittivity in vacuum, and ε_r is the relative permittivity.

Carrier Transport. The η_{tr} is carrier transport efficiency. The holes are transported in a donor material, while the electrons are transported in an acceptor material. Both the donor and acceptor materials are required to form highly efficient percolation networks spanning the entire active layer to provide efficient charge transport. Drift and diffusion current are the major driven forces for the transport of electrons and holes to their corresponding electrodes. The drift current relates to the potential gradient in the solar cell, which is decided by the workfunction difference of the electrodes, while the diffusion current is formed by the diffusion of the carriers through the carrier concentration gradient. In order to achieve efficient charge transport, a balanced hole and electron is needed to avoid the accumulation of carriers in the interface of the active layer and the electrode. The low mobility of the organic materials is a major factor that limited the carrier

transport; thus, the active layer has to be thin enough to allow the carrier to arrive at the electrode in their lifetime. The polymers also need to have a higher degree of planarity for efficient backbone stacking to achieve a high hole mobility. Through the treatments such as thermal and solvent annealing, the polymers should also be able to self-assemble into a more organized structure. In a typical organic solar cell made by the donor–acceptor blends, the overlap of wave functions between adjacent sites in both the donor and acceptor phase is not strong; the carrier transport states are also localized. Thus, the separated charges can only transport by hopping from one localized site to the next with a low carrier mobility. The hopping transport rate can be described by a Miller–Abrahams hopping rate [4, 25]

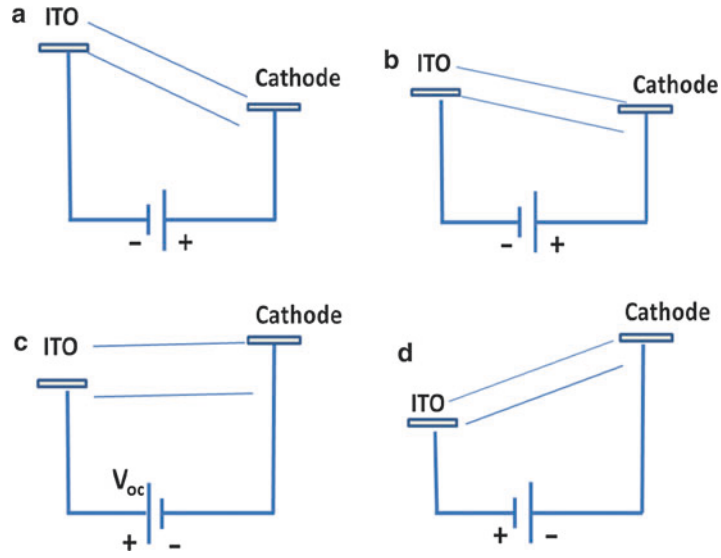
$$v_{ij} = v_0 \exp(-\gamma r_{ij}) \begin{cases} \exp\left(-\frac{E_j - E_i}{k_B T}\right) & E_j > E_i \\ 1 & E_j \le E_i \end{cases} \tag{17}$$

where v_0 is the maximum hopping rate or attempt-to-escape frequency, γ is the inverse of localization radius, r_{ij} is the distance between sites i and j, and $E_j - E_i$ is the height of energetic barrier (energy difference between sites i and j). The term $\exp(-\gamma r_{ij})$ is from tunneling, which is related to the wave-function overlap between sites i and j. If the hopping transport is upward, the term $\exp\left(-\frac{E_j - E_i}{k_B T}\right)$ is a thermally activated process. Using Miller–Abrahams transition rate and Monte Carlo simulations within Gaussian density of states (DOS) without considering site correlation, the carrier mobility in a donor polymer and its dependence on temperature and electric field can be predicted as [26, 27]



$$\mu = \mu_0 \exp\left\{-\left(\frac{2\sigma}{3k_B T}\right)^2 + C\left[\left(\frac{\sigma}{k_B T}\right)^2 - \sum^2\right]\sqrt{F}\right\} \tag{18}$$

where μ_0 is the mobility when $T \to \infty$, σ is the width of the Gaussian DOS, C is a constant related to site spacing, $\sum$ is the degree of spatial disorders, and F is the electrical field.



Charge Collection/Extraction. The η_{cc} is charge collection/extraction efficiency. It is the fraction of the charges transported from the active layer to the electrodes with respect to the total free charges that are supposed to transport to the electrodes. Once separated, the polarons (electrons and holes) must travel to their corresponding electrodes to be collected. When the carrier transports to the active layer/electrode interface, there needs to have an ohmic contact to ensure the efficient charge collection, i.e., the workfunction of anode matches with the HOMO of donor, and the workfunction of cathode matches with the LUMO of acceptor. The η_{cc} depends on the device architecture, energy levels of the active layer and the electrodes, and surface recombination at the organic–metal interface [4, 24].

Recombination Loss. Recombination loss is one of the major reasons for low solar cell performance. There are four main recombination mechanisms existing in organic solar cells, namely, geminate, mobile carrier, deep-state, and reverse diffusion recombinations [28] as shown in Fig. 10. Germinate recombination occurs when the electrons and holes recombine before they dissociate. Mobile free-carrier recombination is also called Langevin recombination, and it is the recombination of mobile electrons and holes. Localized deep-state recombination involves the recombination of trapped carriers and mobile carriers. It correlates to the deep-state density. Reverse diffusion to the contacts happens when an exciton dissociates close to one of the electrodes, and the carrier diffuses to the reverse electrode and recombines at the contact.

Operation of Solar Cells. Solar cells can be operated under various biases. Figure 11a shows that under large reverse bias, exciton dissociation and charge transport are enhanced due to the strength of built-in electric field by a large bias. Drift current is dominant at this case. In Fig. 11b, when the applied bias is close to zero, carriers are driven by the built-in field and then collected by respective electrodes. Figure 11c shows that the applied bias reaches to a point that is equal to the built-in field. In this case, diffusion current dominates since the electric field is quite small inside

Organic Photovoltaics: Basic Concepts and Device Physics, Fig. 10 Four main recombination mechanisms occurred in the bulk-heterojunction (BHJ) solar cells: (**a**) geminate recombination, (**b**) mobile carrier recombination, (**c**) deep-state recombination, and (**d**) reverse diffusion

Organic Photovoltaics: Basic Concepts and Device Physics, Fig. 11 Operation of the solar cell at different biases: (**a**) large reverse bias; (**b**) small reverse bias; (**c**) positive bias when the internal field is equal to zero, which is called as open-circuit condition; and (**d**) large positive bias

the device. When the applied bias switches to the positive condition, as in Figure 11d, the applied field is larger than the built-in field, and the potential gradient in the device is reversed, carrier injection occurs via tunneling mechanism resulting in the positive current.

Summary

In summary, organic solar cell device structures, materials, basic concepts, and device physics are introduced. To make organic solar cells available for commercial applications, additional basic

research in material synthesis, fundamental understanding of device physics, and device engineering are still needed. Organic photovoltaic technology becomes a potential cost-effective energy source, and further research also needs to improve device efficiency and stability.

Definition

The demand for small, low-cost sensors that can be built on flexible plastics has driven the rapid maturation of synthetic methodology in the field of organic material-based electronics. This is because organic materials can be processed at low temperatures even close to room temperature offering the potential for very-low-cost manufacturing. The flexibility and light weight that organic materials possess allows a variety of simple low-cost deposition techniques including solution casting, ink-jet printing, stamping, dip-coating, and spray-on and spin-on coating, which enable roll-to-roll manufacturing. Even though organic semiconductors are not desirable for use in applications needing very high switching speeds because of their poor carrier mobility, about three orders of magnitude lower than that of single crystalline silicon, they provide ease of fabrication, flexibility, and conformability able to accommodate the requirements to develop biochemical and physical microsensors that possess good portability, low-power dissipation, and compact device integration. Sensors based on organic electronics can be implemented for diverse applications in medical diagnostics and care, environmental monitoring, food monitoring, and military defense.

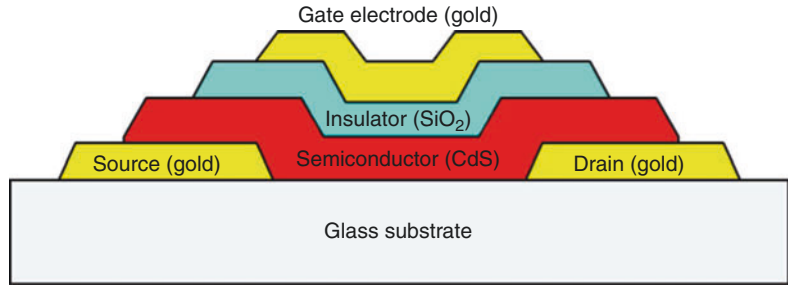
Charge Transport in Organic Semiconductors

Organic semiconductors have been studied since the late 1940s [1], especially concerning conjugated small molecules and polymers. However, their organic semiconducting characteristics were too poor for utilization in any real device development. The interest in organic semiconductors faded until the late 1970s because of their severe limitations, such as very high density of defects and traps and very low carrier mobility [2]. Discovery of the conducting properties of polymer polyacetylene in 1977 by Shirakawa, MacDiarmid, and Heeger (Noble Prize in Chemistry 2000) led to a large amount of research into the new field of organic electronics. Since this discovery, organic materials have received considerable attention as potential replacements for their inorganic counterparts in flat panel display driver circuitry, light-emitting elements, solar cells, as well as in thin-film transistor (TFT) and sensor applications since they exhibit the advantage of simple, cheap, low-temperature, thin-film processing.

Organic semiconductors can be classified into two groups: conjugated polymers and short conjugated oligomers (small molecules). The former includes, for instance, poly-3-hexylthiophene, poly-p-phenylene vinylene, polyacetylene, and its derivatives, while the latter contains pentacene, anthracene, and rubrene. Organic molecular crystals are known to be formed by rather weak Van der Waals attraction, resulting in pronounced

polaron formation due to the strong electron–lattice interaction, so the charge transport in organic semiconductors must be profoundly different from those of covalently/ionically bonded inorganic semiconductors. However, the charge transport in organic TFTs is still not well understood even though there have recently been several models reported to explain the mechanism, such as multiple trapping and release [3] and variable range hopping [4] models.

Organic molecules are commonly described as compounds containing carbon atoms combined with other atoms, which typically possess a wide energy bandgap (1–4 eV) and a small bandwidth (0.1–0.5 eV). Among them, such conjugated small molecules and polymers as pentacene, α-sexithiophene (α-6 T), and poly-3-hexylthiophene (P3HT) have been especially preferred as the active materials in organic devices owing to their relatively high mobility. For inorganic semiconductors, the structures are generally sustained by strong covalent or ionic bonds that keep atoms in the lattice, and their charge carrier transport in a material, typically explained by the single-electron approach, is described as the movement of highly delocalized plane waves in wide bands. However, this band transport model is not simply applicable to organic semiconductors with complicated structural organizations, requiring still further studies to understand the real nature of transport mechanisms in organic semiconductors.



The molecular structure of organic semiconductors is composed of regularly alternated single (σ) and double (π) chemical bonds. Their molecular structure can be mainly categorized into two different types: intramolecular structure of individual molecules composed of covalently bonded atoms, and intermolecular structure of molecules in the lattice consisting of discrete molecules held together by weak Van der Waals forces. In the intramolecular structure, the covalent bonds between atoms are formed by overlapping sp and p_z orbitals in which the former results in σ bonds with localized σ-electrons and the latter leads to π bonds with delocalized π-electrons spread out over the molecule, and across the conjugated backbone. The π-electrons are responsible for physical and chemical properties as well as intermolecular interaction related to the formation of crystal structures in organic semiconductors. In the intermolecular structure, the orientation of molecules is determined by the summation of interaction energies, the Van der Waals interaction, and the quadrupolar interaction. The van der Waals interaction stemming from a fluctuating dipole moment on a molecule is weak and prefers face-to-face orientation of the molecules. On the other hand, the quadrupolar interaction arising from the permanent quadrupole moments by π orbitals favors edge-to-face orientation of molecules. Hence, the crystal structure is determined by the interplay of the two interactions, and, as a consequence, the most common crystals, such as naphthalene, tetracene, and pentacene, exhibit a herringbone arrangement of the molecules [5].

Charge transport is significantly dependent on the intermolecular interaction which determines π overlapping between neighboring molecules. The π orbital overlap is affected by the orientation of molecules, which results from the interplay of van der Waals and the quadrupole interaction. Therefore, it is very important to understand the molecular structure in order to explicitly explain the charge transport in organic molecules.

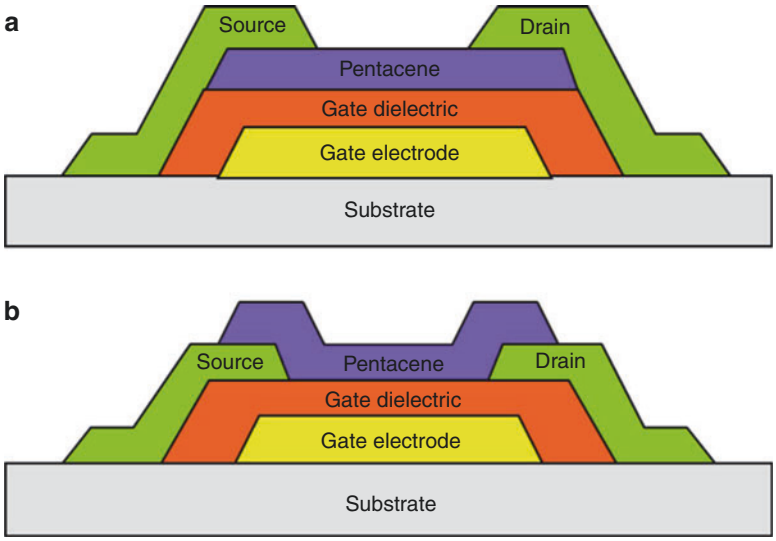
Organic Thin-Film Transistors (OTFTs)

After Lilienfeld's new idea on field effect devices was proposed in the 1930s [6], Weimer [7] first developed thin-film transistors based on a top-gate staggered structure using thin films of polycrystalline cadmium sulfide as the active semiconductor layer in 1962. Figure 1 shows the early TFT device structure that he employed. The device was fabricated onto a glass substrate by evaporating all the components of the TFTs through shadow masks. The current–voltage characteristics of this device were similar to those of a metal-oxide-semiconductor field effect transistor (MOSFET).

Since Weimer reported the first TFT based on cadmium sulfide, TFTs have been developed with different semiconductor materials as the active layer such as cadmium sulfide, cadmium selenide,

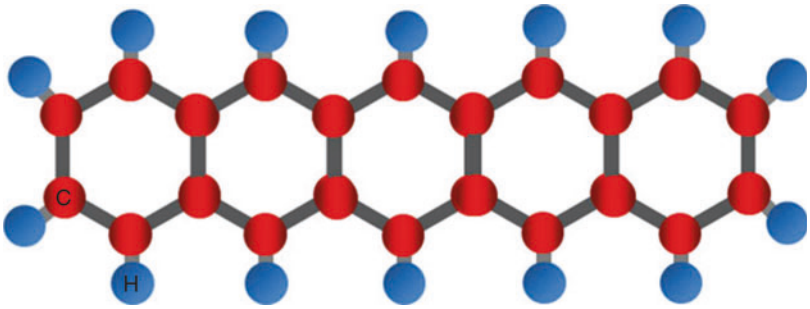
Organic Sensors, Fig. 1 Cross section of Weimer's top-gate staggered TFT structure [7]

tellurium, and lead sulfide. In the late 1970s, Spear and LeComber [8] reported that hydrogenated amorphous silicon (a-Si:H) could be doped, and shortly after the report, LeComber et al. [9] first proposed to use amorphous silicon in active matrix flat panel display applications. Since then, a-Si:H thin-film transistors have been intensively researched and developed in spite of their poor electronic properties compared to crystalline silicon films. The technology of TFTs based on a-Si:H is attractive in large-area applications such as portable computer displays, digital scanners, solar cells, medical imaging sensors, and active matrix liquid crystal displays (AMLCD).



One of the main advantages of using amorphous silicon is that a uniform thin film can be easily achieved over large areas, for instance, using plasma-enhanced chemical vapor deposition (PECVD). Furthermore, amorphous silicon can be deposited at relatively lower temperatures ($\sim$250 °C) than other materials, such as polysilicon ($\geq$600 °C) allowing low weight, and rugged polymeric substrate. Typically, a-Si:H TFTs exhibit about 1 $cm^2/V \cdot s$ field effect mobility, around 1 V threshold voltage, and high on/off ratio of $\sim 10^8$.

However, the processing temperature of a-Si:H TFTs is still not low enough to enable low-cost, flexible, and large-area applications. For instance, commercially available flexible polymeric films typically limit process temperature to less than 200 °C. However, electronics based on organic semiconductors capable of being processed at lower temperatures than a-Si can be aimed at such flexible applications where ease of fabrication, mechanical flexibility, low-cost, and large-area applicability are of particular importance.



Since the first demonstration of OTFTs in 1983 [10], their performance has been improved dramatically, greatly increasing the carrier mobility from $10-^4$ to 1 $cm^2/V \cdot s$ [11]. OTFT technology involves the use of organic semiconductor compounds in electronic components, flat panel displays, organic light-emitting diodes (OLED), and so forth. The interest in the study of OTFT, in particular, was derived from the fact that the device is easy to fabricate compared to traditional silicon-based transistors. More specifically, low-process temperatures may allow organic TFTs to be realized on inexpensive plastic substrates, rather than on rigid materials as traditionally necessary.

There are two common device configurations used in OTFTs, as shown in Fig. 2. The first one is a top-contact device with source and drain electrodes evaporated onto the organic semiconducting layer (Fig. 2a). The other is a bottom-contact device with the organic semiconductor deposited onto prefabricated source and drain electrodes (Fig. 2b). The current–voltage characteristics of OTFTs show behavior similar to a MOSFET, thus enabling the employment of the MOSFET model to analyze OTFT behavior. The major difference between OTFTs and MOSFETs is the mode in which the conducing channel is formed. Thus, OTFTs operate in the accumulation mode, while MOSFETs form the conducting channel in the inversion mode.

The current and voltage behavior in an OTFT, based on the gradual channel approximation, is as follows:

Organic Sensors, Fig. 2 OTFT device configuration. (**a**) Top-contact structure (**b**) bottom-contact structure

Organic Sensors, Fig. 3 A molecular structure of pentacene

For the non-saturation region: $V_{DS} < V_{GS} - V_T$

$$I_{DS} = \mu_{FE} C_o \frac{W}{L}\left[(V_{GS} - V_T)V_{DS} - \frac{V_{DS}^2}{2}\right] \quad (1)$$

For the saturation region: $V_{DS} > V_{GS} - V_T$

$$I_{DS} = \frac{\mu_{FE} C_o W}{2L}(V_{GS} - V_T)^2 \quad (2)$$

where W and L are the channel width and length, Co is the gate dielectric capacitance, VT is the threshold voltage, VDS is the drain-source voltage, VGS is the gate-source voltage, and μEF is the field effect mobility that can be extracted from:

$$\mu_{EF} = \frac{2L}{WC_o}\left(\frac{\sqrt{\partial I_{DS}}}{\sqrt{\partial V_{GS}}}\right)^2 \quad (3)$$

Figure 3 shows the molecular structure of pentacene, a well-known p-type organic material, which is currently under extensive investigation for use in TFTs as the active layer because of its highest field effect mobility among all organic semiconductors reported to date. Since the carrier mobility strongly depends on the π-orbital overlap of neighboring molecules, the ordering of the organic materials controlled by relatively weak Van der Waals interactions is the key to improvement in the mobility. It has been well known that the formation of highly ordered pentacene films resulting in large grains is significantly affected by both growth conditions and substrate surfaces such as deposition rate, substrate temperature, substrate morphology, and chemical properties of the substrate. Since the nucleation of the first monolayer is extremely sensitive to defects and/or impurities on the substrate, careful treatment of the substrate surface is strictly required to obtain

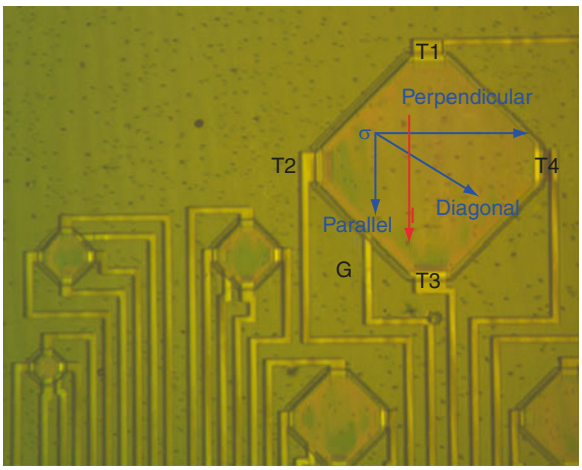
large as well as highly ordered grains. Grain boundaries associated with trap sites act as carrier barriers that dominate charge transport by trapping at the boundaries. This intergrain transport is mostly responsible for the low mobility of the devices. Thus, the investigation of close correlation between the morphology and the structural properties of organic semiconductors should be first required to obtain the most advantageous structures and morphological characteristics for improved performance of organic devices.

Organic Sensors

Over the last decade, micro-fabrication technologies have been extensively applied to yield a miniaturized biochemical and physical sensor in order to monitor various parameters such as ion diffusion, temperature, strain, and electrolyte conductivity leading to the successful development of multi-parameter measuring systems including electronic nose/tongue, micro total analysis system (μTAS), and lab-on-chip. It is obvious that microsensors based on the principle of the field effect and solid state transport in semiconductor structures offer a number of advantages over traditional physiobiological sensors with regard to real-time electronic readout, small size, and rapid response.

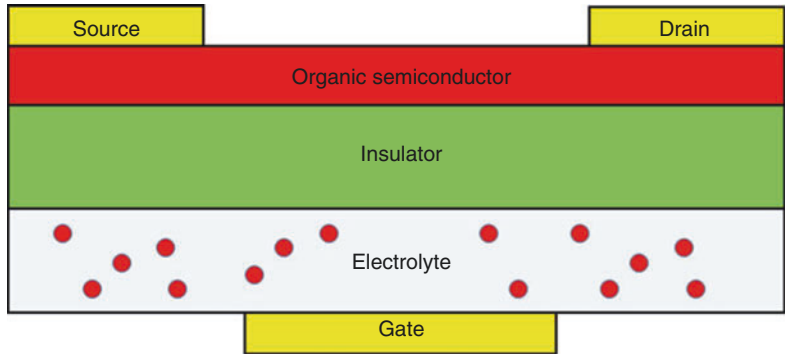
In the last several years, much research effort has been devoted to the use of OTFTs as multi-parameter sensors, pursuing good levels of selectivity, reliability, and reproducibility at low cost. This is due to the fact that OTFT sensors can provide a variety of information from changes in multiple properties on exposure to biochemical as well as physical quantities, such as the bulk conductivity of an organic thin film, the saturation current, the threshold voltage, and the field effect mobility. It is obvious that the multi-functionality in such a multi-parameter sensor operating in different modes enables both envisioning and realization of a simple "higher order" sensor network, which leads to low-cost manufacturing and easy commercialization. In addition, the inherent characteristics of field effect devices such as signal amplification are expected to provide transistor-based sensors with enhanced detection limits and sensitivity compared to usual chemiresistor, amperometric, or potentiometric sensors. Recently, the possibility of using OTFTs for sensing devices has been demonstrated by many research groups. In this case, the conductivity of the organic semiconductor is modulated due to the direct interaction with gas, pressure, humidity, and strain.

As one of the promising applications of organic electronics, large-area strain sensors integrated with transistor matrix capable of monitoring shape, strain, force, and/or pressure in a subject material have been envisioned for a broad spectrum ranging from microsurgery, point-of-care (POC) diagnostics, and monitoring of respiration rate to arrays such as flexible artificial skins of robots and structural health monitoring systems for aging aircrafts. Especially, the key to POC diagnostics is the development of small, light, portable, and implantable sensor devices that are capable of monitoring and controlling diseases in real time so that health-care professionals can make rapid and accurate diagnosis of diseases. This will ensure the effectiveness of therapy along with early detection. Thus, there has been high demand at the POC for development of biochemical and physical microsensors that possess good portability, high sensitivity, low-power dissipation, and compact device integration.



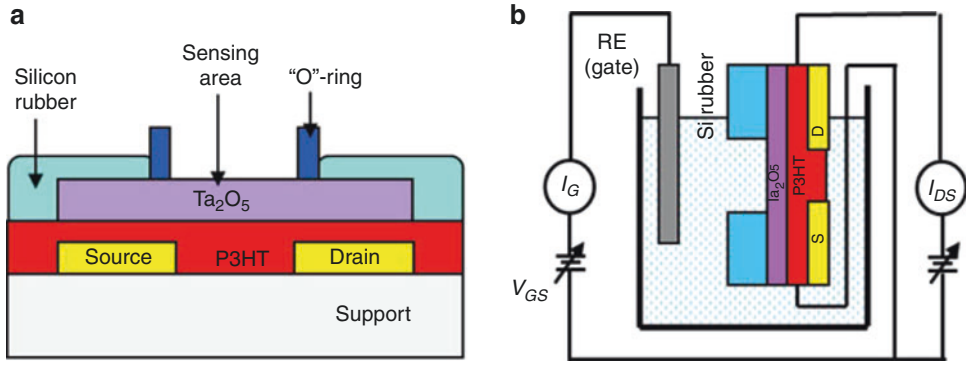
It is obvious that such flexible strain sensors will help construct a POC system for continuous health monitoring when integrated into clothing to provide patients with a safe and comfortable environment for home health care, illness prevention, and citizen medicine. The system monitors various physiological vital parameters measured from the skin including thermal, electrical, geometrical, and mechanical parameters to enable early detection, which help suppress the occurrence of acute events and complications leading to hospitalization and extended hospital treatment. From geometrical and mechanical parameters, it is expected that strain sensors constituting a wearable monitoring system are capable of collecting health data such as respiration rate and amplitude, heart rate, blood pressures, and detection of falls.

Strains sensors, usually bonded to the structures to be tested, measure the change in the resistance of conductors as directly proportional to mechanical motion (strain) experienced by the sensor. Inorganic semiconductors such as amorphous and microcrystalline silicon have recently been employed as the strain-sensing element and fabricated on a flexible film to overcome the limitation of conventional strain sensors based on metallic foils and rigid piezoresistive semiconductors [12, 13]. However, the high Young's modulus (∼200 GPa) of the inorganic materials limits the use for applications with large flexible polymeric substrates due to the large stiffness mismatch that is generated in the interface of the inorganic semiconductor elements and the flexible films. This may lead to irreversible plastic substrate deformations, degrading the sensor performance in terms of reliability and repeatability. Thus, the use of organic materials with low Young's modulus (∼5 GPa) as the sensing element is expected to minimize the induced stress concentration.



Ji et al. first developed organic flexible strain sensors that employed a thin-film transistor-like structure in conjunction with a Wheatstone bridge configuration, as shown in Fig. 4 [14]. The conductivity of the sensor is field controllable by the bias applied to the gate electrode, which tailors the sensor's sensitivity. This strain sensor consisted of five electrodes, one of which was the gate (G) electrode capable of controlling the field-induced conducting layer of pentacene to turn the sensor on and off, thereby tailoring the sensor sensitivity. This pseudo-TFT sensor operated in a depletion mode (normally on) in which it exhibited typical field effect transistor characteristics in a gate voltage range of 40 to −60 V, revealing a good saturation behavior at high drain current.

Pressure sensors, consisting of OTFTs and pressure-sensitive rubber developed by Someya et al. [15], provide the possibility of realizing a practical artificial skin thanks to the inherent flexibility and low-cost processing of organic circuits. A variation of drain current is measured under the application of different pressures from 0 to 30 kPa. Subramanian et al. recently developed printed RFID electronics including passive components (inductors and capacitors) and organic transistors for item-level tracking applications [16].



Zhu et al. [17] proposed a humidity sensor based on OTFTs that can be envisioned to monitor relative humidity in moisture-sensitive environments such as use in semiconductor manufacturing and packaging, medical, pharmaceutical, and food manufacturing. Humidity can affect the charge transport properties of organic active layers in many ways. When H_2O molecules diffuse into the crevices of polycrystalline organic materials and react with the trapped carriers in there while changing their morphology, they will alternate the electric field at the grain boundaries, which

Organic Sensors, Fig. 6 (**a**) Schematic of the device structure used for pH sensor, and (**b**) schematic of the measurement setup [18]. This pH sensor detects Ph variations occurring in the bulk of the solution through field-enhanced conductivity of the organic semiconductor using Ta_2O_5 material that possesses a number of proton-sensitive surface sites

decrease the rate of charge transport by increasing the amount of energetic disorder through charge–dipole interactions. All these factors will affect the carrier mobility, saturation current, on/off ratio, threshold voltage, and so on. They measured the sensor output with respect to time dependence of the saturation current (I_{DS}) when the OTFT was alternatively exposed to vacuum and N_2 gas with different levels of relative humidity (RH). It turned out that the saturation current of the OTFT drops dramatically by nearly one order of magnitude when exposed to 70 % RH.

Ion-sensitive field effect transistors (ISFET) using OTFTs, as shown in Fig. 5, have been used to detect ions where the gate insulator is exposed to an electrolyte containing the analyte. The source-drain current is modulated by the electric field across the insulating gate dielectric which is controlled by ions at the electrolyte–insulator interface. Bartic et al. presented OTFTs fabricated with poly (3 hexylthiphene) regioregular (P3HT) as the semiconductor layer to be used as a pH sensor that can detect both charged and uncharged chemical species in aqueous media, as shown in Fig. 6 [18]. This pH sensor

detects pH variations occurring in the bulk of the solution through field-enhanced conductivity of the organic semiconductor using Ta_2O_5 material that possesses a number of proton-sensitive surface sites. They also realized a glucose biosensor with the same structure by anchoring an enzymatic layer of glucose oxidase (GOx) on the dielectric of the organic transistor where the biocatalytic reaction between glucose and GOx modifies the local concentration of proton on the dielectric surface leading to the variation in drain current.

Crone et al. proved that a variety of organic semiconducting materials being used in OTFTs can offer advantages to develop sensor arrays for selective gas detections [19]. Eleven different organic sensor materials based TFTs were exposed to 16 various gaseous analytes including alcohol, ketones, thions, and ring compounds while measuring the source-drain current of the TFTs which gave rise to selective patterns associated with each analyte due to different semiconductor-analyte pair response mechanisms. Crone et al. have also pointed out the fact that the OTFT sensor can be readily integrated into a circuit system with superior performance to discrete chemiresistor sensors. For instance, the ring oscillator sensor they developed exhibited a higher sensitivity to octal vapor with a faster recovery time than discrete transistor sensor [20].

Future Directions for Research

The tremendous progress in the performance of organic electronics, including OTFTs, opens wide horizons for the use of organic devices as compact sensing systems. However, developments in sensors using organic semiconductors still remain at the laboratory stage. It can be predicted that the impact of organic electronics on sensing applications will be dependent on the stability of the sensors in a real environment, the ability to design a new structure of sensors that is suitable for the integration of sensor arrays, and the cost of the sensors themselves, which determines whether this technology will move from the research state to potentially commercial phases.

Definition

Perfluorocarbon (PFC) nanoparticles represent a multifunctional platform consisting of a PFC core

encapsulated within a phospholipid monolayer. The particles have been developed for magnetic resonance (MR) molecular imaging to noninvasively map the expression of important biomarkers of disease.

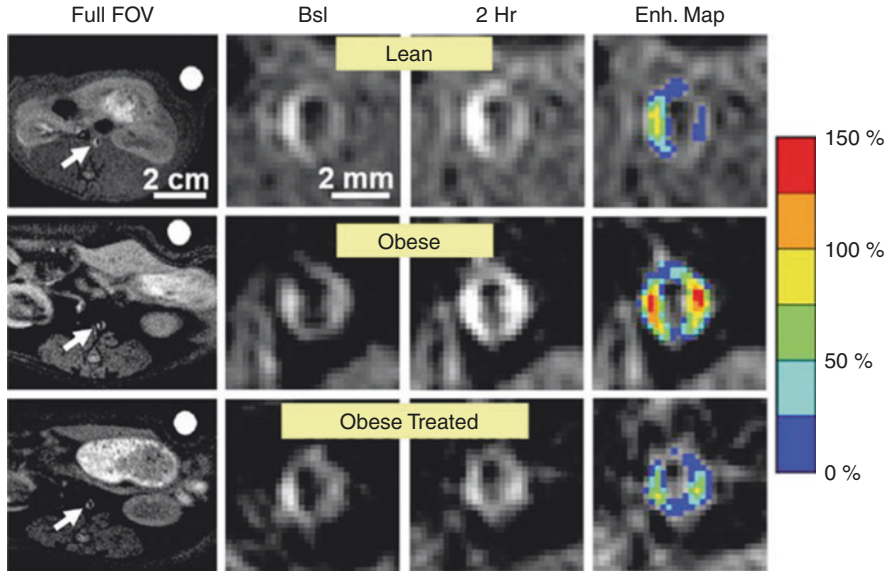
Introduction

Perfluorocarbon (PFC) nanoparticles consist of a liquid PFC core encapsulated by a phospholipid monolayer. PFCs represent a family of modified hydrocarbon molecules in which the hydrogens are replaced with fluorine atoms [1–3]. The carbon–fluorine bond is very stable and biologically inert due to the dense electron cloud, which prevents chemical reactions with other compounds [2]. PFCs with molecular weights between 460 and 520 are biocompatible, showing no toxicity, carcinogenicity, mutagenicity, or teratogenic effects. PFCs have tissue half-life residencies ranging from 4 to 65 days. They are not metabolized. Instead, they are reintroduced into the blood circulation from clearance organs, such as the liver, by lipid carriers and are exhaled via the lungs [2]. PFC nanoparticles have been formulated for a wide range of molecular imaging and targeted drug delivery applications. The particles are typically 250 nm in diameter, which is large enough to constrain them to the intravascular space. As a result, PFC particles are often targeted to intraluminal biomarkers expressed by endothelial cells, such as integrins, selectins, or adhesion molecules [2, 3].

Magnetic resonance (MR) molecular imaging aims to identify and map the expression of important biomarkers on a cellular scale. Typical MR imaging techniques lack sufficient resolution and sensitivity to directly detect these molecular signatures due to their very low concentrations in vivo. To overcome this limitation, nanoparticle agents are often employed to specifically bind to the biomarker of interest, accumulate at the site of pathology, and generate sufficient image contrast. Nanoparticles offer a large surface area for the incorporation of multiple binding ligands (to improve targeting efficacy) and multiple paramagnetic chelates (to amplify the signal enhancement). In some cases, the nanoparticle may also serve as a drug delivery agent, providing diagnostic and therapeutic information via noninvasive MR imaging.

A number of other medical imaging modalities are capable of molecular imaging, including positron emission tomography (PET), single photon emission computed tomography (SPECT), and optical imaging [4]. Like MR imaging, these modalities typically rely on specifically designed contrast agents that bind to the molecular biomarker of interest. For PET and SPECT imaging, the contrast agents consist of a radioactive element for detection. In optical imaging, the contrast agent will utilize fluorescence or bioluminescence for mapping expression of cellular receptors. MR imaging, however, has certain important advantages over these other modalities for molecular imaging applications. MR imaging offers higher spatial and temporal resolution than PET or SPECT and provides greater tissue penetration than optical imaging. This allows MR imaging to combine anatomical and/or functional information with molecular imaging, much like the multimodality benefits of PET/CT. In addition, MR imaging may be better suited for serially tracking disease progression or therapeutic response compared to nuclear imaging due to concerns of cumulative radiation dose.

Molecular imaging with PFC nanoparticles has been applied to a wide array of disease biomarkers, therapeutic drugs, and imaging modalities [2, 3]. PFC nanoparticle formulations have been developed for ultrasound imaging [5], computed tomography [6], nuclear imaging [7], optical imaging [8–10], MR [3], as well as multimodality applications. For example, combined ^{99m}Tc SPECT and MR imaging of $\alpha_v\beta_3$-integrin-targeted PFC nanoparticles has been used to map tumor angiogenesis with high sensitivity and high resolution [7]. The $\alpha_v\beta_3$-integrin is a heterodimeric transmembrane glycoprotein expressed by numerous cell types, including endothelial cells, macrophages, platelets, lymphocytes, smooth muscle cells, and tumor cells [2]. Endothelial expression of $\alpha_v\beta_3$-integrin is required for the migration and invasion of vascular endothelial cells, and therefore, serves as a

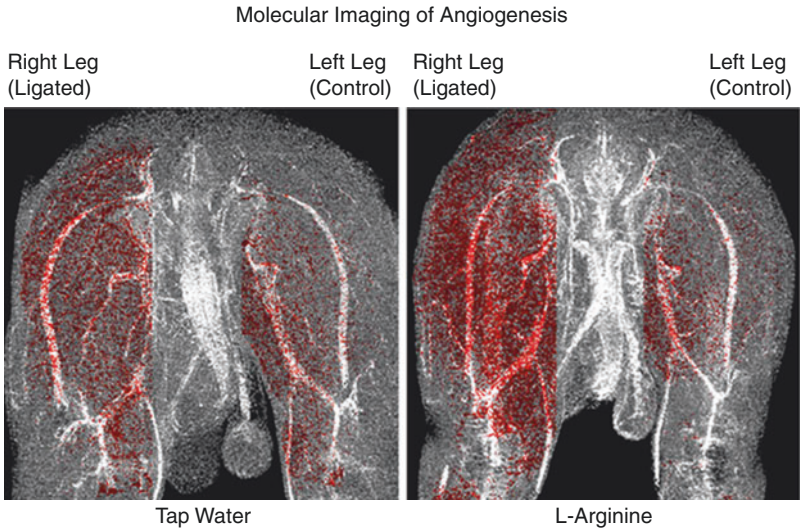


biomarker of angiogenesis [11]. Since PFC nanoparticles are constrained to the vasculature, they are not exposed to nonendothelial integrin-expressing cells, which improves binding specificity to the neovasculature [2]. Nuclear imaging offers very high sensitivity, which is preferred for the detection of occult tumors or metastases within large tissue regions. However, the limited spatial resolution of nuclear imaging precludes detailed characterization of the pathology. Incorporating a ^{99m}Tc nuclear imaging agent onto $\alpha_v\beta_3$-integrin-targeted gadolinium nanoparticles yielded a high-sensitivity nuclear signal that was used to guide further high-resolution MR imaging and characterization of tumor angiogenesis [7]. MR molecular imaging demonstrated a coherent, asymmetric, patchy pattern of angiogenesis along the outer aspects of the tumor mass, consistent with an angiogenic phenotype.

In the case of ultrasound imaging, PFC nanoparticles represent a significant departure from conventional contrast agent design. Most ultrasound contrast agents consist of gas bubbles to maximize the backscatter of ultrasound waves and thereby increase the image contrast. However, these bubbles are quite large (more than 1 μm in diameter) and are quickly entrapped within the lungs. This severely limits the practical application of bubbles in molecular imaging because they do not circulate long enough to bind to biomarkers of disease and accumulate at the sites of pathology. PFC nanoparticles, however, have a long circulatory half-life and are inherently echogenic due the differences in the speed of sound between water and the PFC core. This ultrasound backscatter is typically not sufficient to visualize particles in the blood stream. Instead, the particles must accumulate at the target site, forming an "acoustic mirror" to generate significant image contrast. Targeted PFC nanoparticles have been used for molecular imaging of fibrin in acute arterial thrombus, high-frequency intravascular imaging, and imaging with novel ultrasound receivers, called information theoretical detectors [5].

Along with MR molecular imaging, PFC nanoparticles have been employed to label cells and noninvasively track implantation and migration of cell therapies [1, 3]. While MR molecular imaging with PFC nanoparticles typically utilizes paramagnetic chelates for detection with ^{1}H MR, tracking of cells labeled with PFC nanoparticles often relies on ^{19}F MR. ^{19}F has a relatively high sensitivity, 83 % compared to ^{1}H, and there is virtually no native background signal. Thus, the PFC core can provide a definitive and quantitative MR signature [1]. PFC nanoparticles can be internalized by stem cells without the need of a transfection agent and ^{19}F MR imaging can quantitatively track the cells in vivo [1]. The high sensitivity of ^{19}F MR allows the in vivo detection of as few as 2,000 labeled cells. For some applications, modification of the surfactant surface of the particles improves cellular uptake. For example, PFC nanoparticles formulated with cationic phospholipids on the particle surface can be effectively internalized by neural stem cells [1].

Molecular Imaging of Therapeutic Response

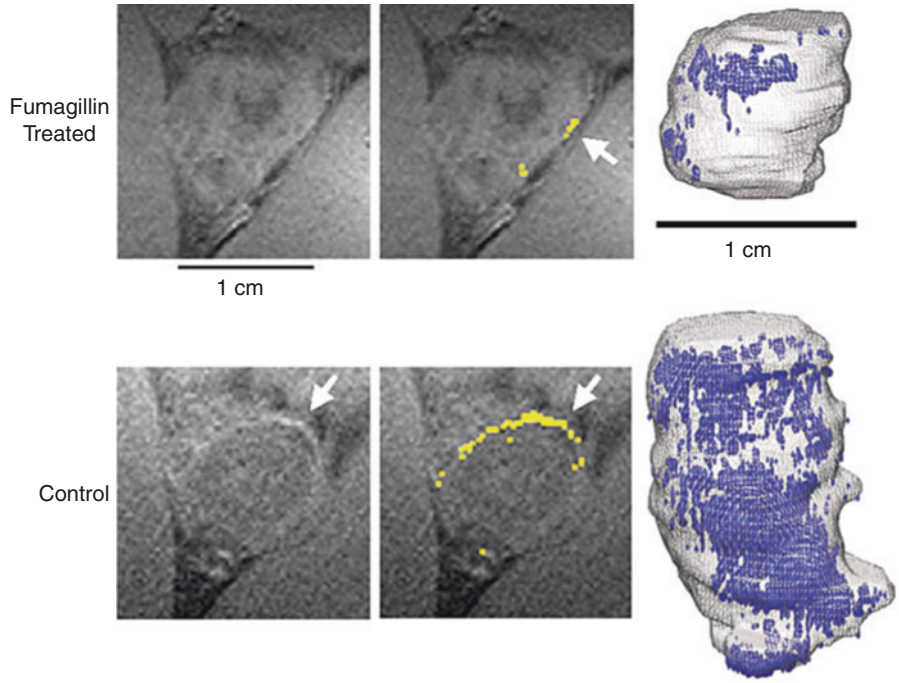


One potential clinical application of MR molecular imaging with PFC nanoparticles is to serially map biomarkers of disease progression and/or therapeutic response. Noninvasive imaging could be used to monitor the biochemical signatures of disease, providing earlier and more specific detection of pathology compared to tracking symptomology or the occurrence of clinical events. For example, molecular imaging of angiogenesis can serve as a biomarker of atherosclerosis and can be used to monitor the physiological effects of a range of therapeutic treatments [3]. Paramagnetic $\alpha_v\beta_3$-integrin-targeted PFC nanoparticles have been utilized to characterize angiogenesis in the aortic wall of an atherosclerotic rat model and to monitor the effects of benfluorex (an appetite suppressant) on aortic angiogenesis [12]. The JCR:LA-cp rat is a model of metabolic syndrome characterized by obesity, insulin resistance, hyperlipidemia, and vasculopathy. The obese rats displayed higher food consumption and body weight, as well as increased insulin, leptin, cholesterol, and triglyceride levels compared to the lean controls. In conjunction with this typical metabolic syndrome

Perfluorocarbon Nanoparticles, Fig. 1 Full field-of-view ("Full FOV") images of JCR rats showing large abdominal fat deposits in the obese (*middle*) and obese-treated (*bottom*) animals that were absent in the lean (*top*) rat (*arrows* denote aortas). Magnified views of the abdominal aorta in lean, obese, and obese-treated rats at baseline ("Bsl") and 2-h ("2 Hr") post injection of targeted nanoparticles displaying signal enhancement in the aorta wall. Percent signal enhancement maps ("Enh. Map," false-colored from *blue* to *red*) demonstrate higher MR signal enhancement in the untreated obese animal, indicating active angiogenesis supporting development of atherosclerotic lesions (Reprinted with permission from Cai et al. [12])

phenotype, MR molecular imaging revealed increased aortic angiogenesis in the obese animals, indicative of actively developing atherosclerotic plaques in the arterial wall (Fig. 1). Benfluorex reduced food consumption, body weight, insulin, and leptin in obese-treated rats, but had no effect on serum cholesterol or triglyceride levels. In a similar fashion, benfluorex reduced aortic angiogenesis in the obese-treated animals to the same level as the control lean rats. These molecular imaging results were corroborated by histological measurements of microvascular density. Therefore, MR molecular imaging with $\alpha_v\beta_3$-integrin-targeted PFC nanoparticles can noninvasively monitor atherosclerosis in a rat model of obesity and can monitor the neovascular effects of an appetite suppression therapy.

However, atherosclerosis does not always lead to an increase in angiogenesis. In a rabbit model of peripheral vascular disease, hypercholesterolemia causes a reduction in the angiogenic response to chronic muscle ischemia, which can be normalized with a pro-angiogenic therapy, such as L-arginine supplementation [13]. MR molecular imaging was performed 10 days after femoral artery ligation with paramagnetic $\alpha_v\beta_3$-integrin-targeted PFC nanoparticles. Molecular imaging revealed diffuse angiogenesis throughout the ischemic limb for both L-arginine-treated and untreated groups (Fig. 2). However, the angiogenic response was significantly increased in L-arginine-treated animals compared to the untreated controls. Furthermore, the integrin-targeted formulation produced two times higher MR enhancement compared to nontargeted particles, demonstrating improved identification of angiogenic vasculature with biomarker targeting. X-ray angiography was performed 40 days postligation to measure the development of collateral vessels feeding the ischemic muscle tissue. More collateral vessels were observed in L-arginine-treated rabbits compared to the untreated controls. Histologic staining of muscle capillaries revealed a denser pattern of microvasculature in L-arginine-treated animals, confirming



Perfluorocarbon Nanoparticles, Fig. 2 Molecular imaging of angiogenesis shows highly diffuse enhancement throughout the ligated (*right*) leg of cholesterol-fed rabbits with only slight enhancement of the control (*left*) leg. The L-arginine-treated rabbit (*right panel*) shows a more dense distribution of angiogenesis in the ligated limb compared with the control animal (*left panel*) (Reprinted with permission from Winter et al. [13])

the MR and X-ray imaging results. Noninvasive molecular imaging with PFC nanoparticles could be used for early detection of response to angiogenic therapies directed at ischemic diseases, such as peripheral vascular disease or myocardial infarction, to enable personalized optimization of treatment strategies.

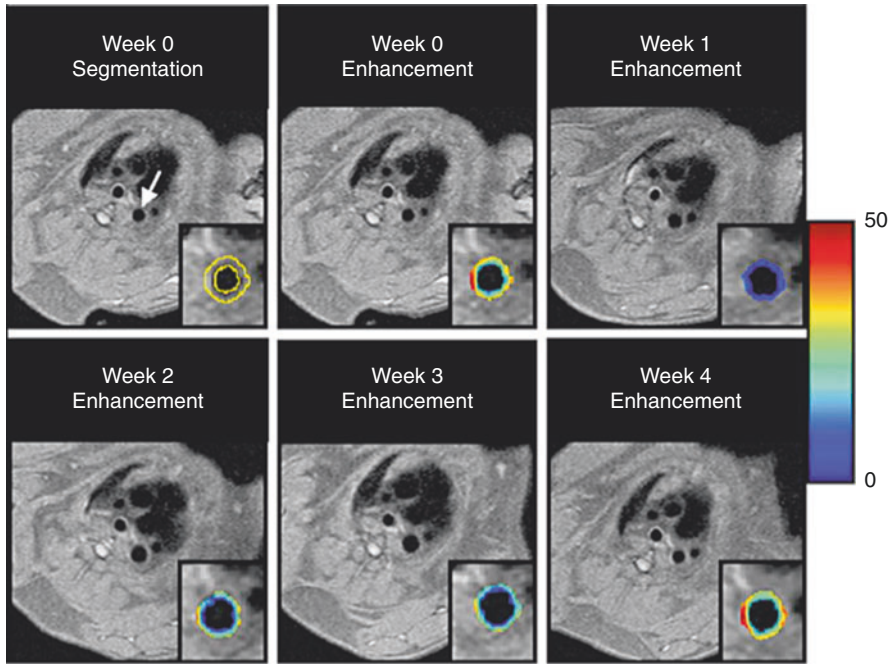
Targeted Antiangiogenic Therapy

In the realm of targeted drug delivery, PFC nanoparticles have been utilized to carry a number of antiangiogenic drugs. In particular, the potent antiangiogenic drug, fumagillin suppresses angiogenesis by inhibition of methionine aminopeptidase 2 (MetAP2) [9]. Targeting the particles to a biomarker of angiogenesis, such as the $\alpha_v\beta_3$-integrin, provides a means to specifically direct potent drugs to the sites of pathology, improving the therapeutic efficacy and decreasing the occurrence of unwanted side effects. Combining a specifically targeted molecular imaging agent with a therapeutic drug could benefit patients in a wide range of clinical scenarios. The imaging agent would allow confirmation and quantification of local drug delivery and enable personalization of treatment protocols based on the pharmacokinetics in the target tissue. In addition, specific targeting of the agent could improve uptake and retention of the drug at the sites of disease while lowering the exposure to other susceptible organs and reducing the occurrence of side effects.

Paramagnetic PFC nanoparticles targeted to the $\alpha_v\beta_3$-integrin have been used for sensitive detection of angiogenesis in Vx2 tumors implanted in New Zealand white rabbits [2]. In vivo competition studies demonstrated that the targeted particles specifically bind to the $\alpha_v\beta_3$-integrin. Furthermore, MR molecular imaging with the targeted nanoparticles was able to differentiate between growing tumors and inflammatory lesions resulting from rejected cancer cells. These tumor cell remnants appeared identical to the viable growing tumors on standard T2-weighted MR images, but molecular imaging of angiogenesis showed negligible neovasculature in these masses. Antiangiogenic therapy has also been demonstrated in this animal model using $\alpha_v\beta_3$-integrin-targeted fumagillin nanoparticles [14]. Treatment with $\alpha_v\beta_3$-integrin-targeted fumagillin nanoparticles reduced the tumor volume significantly compared with animals given nontargeted fumagillin nanoparticles, $\alpha_v\beta_3$-integrin-targeted nanoparticles without drug or saline (Fig. 3). The MR imaging data was used to generate a 3D map of tumor angiogenesis, which showed a coherent asymmetric peripheral distribution characterized by dense neovessel regions interspersed with a finer, reticular pattern.

Perfluorocarbon Nanoparticles, Fig. 3 *Left*: Molecular imaging of targeted antiangiogenic therapy (fumagillin) in rabbit Vx-2 tumors showing diminished MR contrast enhancement in the treated animal (*top*) versus the control animal (*bottom*). *Middle*: MR enhancement, color coded in *yellow* (*arrows*), demonstrating reduced tumor angiogenesis in the fumagillin-treated animal. *Right*: 3D maps of tumor angiogenesis showing an asymmetric distribution of neovasculature (*blue*) that is dramatically reduced in the fumagillin-treated rabbit (Reprinted with permission from Winter et al. [14])

Another possible biomarker of angiogenesis is Robo4, an endothelial specific guidance receptor that is expressed on tumor neovasculature but not mature vessels [15]. Paramagnetic PFC nanoparticles were coupled to a Robo4 antibody and evaluated in a mouse melanoma tumor model [15]. Both Robo4-targeted and $\alpha_v\beta_3$-integrin-targeted nanoparticle formulations generated greater MR image contrast than particles lacking a targeting ligand or coupled to scrambled targeting ligands. Microscopic analysis of particle binding was performed with Robo4-targeted rhodamine nanoparticles and $\alpha_v\beta_3$-integrin-targeted AlexaFluor 488 nanoparticles. Binding of $\alpha_v\beta_3$-integrin-targeted particles was generally more prevalent than the binding of Robo4-targeted nanoparticles, particularly in the tumor periphery. Thus, PFC nanoparticles can be used for both macroscopic MR molecular imaging as well as light microscopy to define cell binding of the particles and the coexpression of different cellular receptors.



MR molecular imaging of angiogenesis has also been demonstrated in human melanoma tumors (40 mm^3) implanted in immunocompromised mice using $\alpha_v\beta_3$-integrin-targeted PFC nanoparticles [2]. Again, in vivo competition studies demonstrated the high specificity of ligand-directed targeting, which was further corroborated microscopically using $\alpha_v\beta_3$-integrin-targeted fluorescent PFC nanoparticles. As an alternative to targeting the $\alpha_v\beta_3$-integrin for mapping angiogenesis, the $\alpha_5\beta_1$-integrin has been explored as a biomarker of tumor neovasculature [8]. The $\alpha_5\beta_1$-integrin is an important adhesion molecule, which regulates endothelial cell migration and survival during angiogenesis. The $\alpha_5\beta_1$-integrin is not expressed on normal quiescent blood vessels, but its expression is induced on tumor blood vessels and in response to angiogenic

factors, including basic fibroblast growth factor, interleukin-8, tumor necrosis factor-alpha, and the angiomatrix protein Del-1. The utility of a dual $\alpha_5\beta_1(\alpha_v\beta_3)$-integrin targeting ligand for molecular imaging and targeted delivery of fumagillin was compared with the use of a targeting ligand specific for only the $\alpha_v\beta_3$-integrin. MR signal enhancement maps revealed a sparse network of neovessels predominantly located in the tumor periphery. Treatment with $\alpha_5\beta_1(\alpha_v\beta_3)$-integrin-targeted nanoparticles containing fumagillin further decreased the already small amount of neovessel enhancement to an almost negligible level; however, the tumor volume was not decreased. Since this tumor model displayed a very sparse neovasculature and was relatively slow growing, it is not surprising that an antiangiogenic therapy did not significantly decrease the tumor size. Clinically, MR molecular imaging of angiogenesis could be used to characterize small tumors, such as breast, lung, or colon, and stratify patients into antiangiogenic therapies based on the abundance of neovascular biomarkers. Such a procedure for screening potential patients may yield improved therapeutic benefits with decreased risk of side effects.

Similar to the growth of tumors, the development of atherosclerotic plaques requires the recruitment of new blood vessels to meet the high metabolic demands of the abnormal tissue. In atherosclerosis, angiogenesis occurs in the vasa vasorum of large caliber arteries, such as the aorta, carotids, and coronaries. Since antiangiogenic therapies can slow the progression of cancer, it is reasonable to investigate if these treatments could be employed to normalize atherosclerotic vessels. The acute antiangiogenic response to $\alpha_v\beta_3$-integrin-targeted paramagnetic nanoparticles containing fumagillin has been studied in atherosclerotic rabbits [16]. MR imaging was used to estimate drug deposition in the aortic wall. One week later, the level of neovascular $\alpha_v\beta_3$-integrin expression was assessed using $\alpha_v\beta_3$-targeted paramagnetic nanoparticles without fumagillin. Aortic areas displaying high MR enhancement at the time of treatment had the largest subsequent reduction in $\alpha_v\beta_3$-integrin-targeted MR signal 1 week later, suggesting that combining imaging with therapy may not only confirm and quantify the local delivery of chemotherapeutics but may also provide early predictions of the subsequent treatment effects.

In addition to the acute response to therapy, MR molecular imaging could provide serial monitoring of the end organ effects with the ultimate goal of optimizing drug treatment regiments and customizing patient protocols. The antiangiogenic effect of atorvastatin with and without targeted delivery of fumagillin was serially monitored for 8 weeks by MR imaging in atherosclerotic rabbits [9]. Atorvastatin was dosed continuously via incorporation into the feed, while fumagillin treatment was provided once every 4 weeks. During 8 weeks of study, atorvastatin treatment did not reduce $\alpha_v\beta_3$-integrin expression in the aortic wall. Fumagillin treatment, on the other hand, resulted in a transient (2–3 weeks) reduction in image enhancement, indicating successful antiangiogenic treatment (Fig. 4). Combining the fumagillin and atorvastatin treatments yielded a persistent decrease in the MR signal, suggesting that chronic statin treatment could be used to prolong the effects of discrete doses of an antiangiogenic agent. Histology revealed that the MR image enhancement was strongly correlated to the microvascular density in the aortic wall in a logarithmic fashion. An effective and sustained antiangiogenic treatment may halt plaque progression and stabilize atheromas by decreasing intramural hemorrhage and inflammation.

One of the benefits of using a molecular imaging contrast agent for targeted drug delivery is that imaging can provide a noninvasive measurement of drug deposition at the site of pathology and elimination from the body. Paramagnetic $\alpha_v\beta_3$-integrin-targeted PFC nanoparticles have been utilized to quantify the pharmacokinetics of the particles in both the blood pool as well as the target tissue in an atherosclerotic rabbit model [3]. Noninvasive monitoring of the particle biodistribution and elimination could be used as a surrogate marker for the tissue levels of lipophilic drugs incorporated in the nanoparticle formulation. Typically, pharmacodynamic measurements rely on blood sampling without consideration of the drug accumulation in the target

Perfluorocarbon Nanoparticles, Fig. 4 Serial imaging of aortic wall angiogenesis for monitoring targeted antiangiogenic therapy with fumagillin nanoparticles. *Top*: Black blood image of the thoracic aorta (*arrow*) prior to antiangiogenic treatment (Week 0) demonstrating segmentation of the vessel wall (*outlined in yellow*) and patchy areas of high angiogenesis within the aortic wall (color-coded as percent enhancement of MR signal). At week 1, the MR enhancement is drastically reduced due to the antiangiogenic effect of fumagillin. *Bottom*: The level of signal enhancement gradually increases at Weeks 2 and 3 after fumagillin treatment. At Week 4, the level of enhancement is practically identical to the Week 0 image (Reprinted with permission from Winter et al. [9])

tissue. Noninvasive mapping of drug concentrations in the end organ could provide significant clinical advantages in monitoring targeted therapeutic agents and determining the local drug concentrations beyond the blood pool. Atherosclerotic rabbits were injected with either $\alpha_v\beta_3$-targeted or nontargeted paramagnetic nanoparticles at a dose of 1 mL/kg (0.0046 mmol Gd^{3+}/kg), which is 20-fold lower than the standard dose of conventional gadolinium agents (0.1 mmol Gd^{3+}/kg). Blood sampling was performed to determine the bulk pharmacokinetic behavior of the nanoparticles, and T1-weighted MR images of the descending aorta were collected over 24 h to ascertain binding to the angiogenic microvasculature in the vessel wall.

A three-compartment pharmacokinetic model was developed to describe the in vivo behavior of the nanoparticles in both the blood pool as well as the aortic wall. Compartments 1 and 2 represent the bulk distribution of nanoparticles throughout the blood stream. The third compartment consists of the vasa vasorum of the aortic wall where the nanoparticles can specifically bind to the $\alpha_v\beta_3$-integrin. The constants that describe the transfer into and out of this compartment, k_{13} and k_{31}, are lumped parameters that are used to describe both passive transfer and active binding.

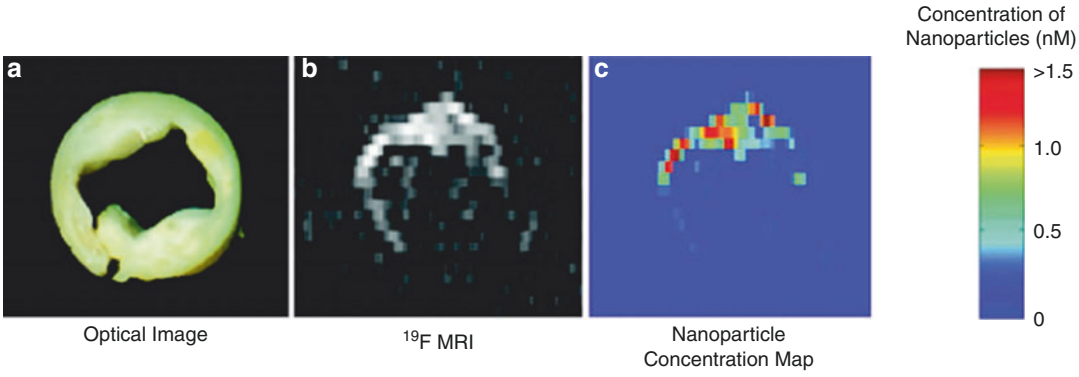
Blood sampling after IV injection of nanoparticles demonstrated the half-life for the distribution phase was 20.2 min, while the elimination half-life was 11.9 h. MR imaging of the aortic wall revealed that the targeted nanoparticle agent generated at least twofold higher signal enhancement at 0.5 and 1 h post injection than the nontargeted nanoparticles. Fitting both the blood clearance and tissue uptake data with a three-compartment model showed no significant differences in k_{12}, k_{21}, v_1, or k_{31} between the

targeted and nontargeted groups. However, k_{13} (representing transfer from the blood into the aortic wall) and k_e (elimination from the blood pool) were significantly higher for the targeted formulation. While k_{13} represents the passive transfer from the blood into the third compartment in a standard three-compartment model, the nanoparticles are not just passively transferred but also actively binding within the third compartment. These two effects cannot be differentiated with this model and combine together, resulting in an apparent increase in k_{13} for the targeted nanoparticles compared to the nontargeted formulation. The pharmacokinetic parameters were used to calculate the tissue exposure to the nanoparticles. The local tissue concentration of targeted nanoparticles was doubled compared to nontargeted particles (1.64 vs. 0.84 nmol Gd^{3+}/g tissue/h, respectively). The amount of gadolinium that reached the aortic vasa vasorum was 0.18 % of the total dose for nontargeted particles and 0.38 % for targeted nanoparticles. These results demonstrate that MR can be used to noninvasively track binding of a molecularly targeted contrast agent, which has previously only been accomplished with nuclear and optical imaging. The gadolinium chelate on the particle surface could provide a surrogate marker for tracking the biodistribution of a lipophilic drug payload [9, 16, 17]. Rather than relying on blood pool measurements of drug concentrations, noninvasive imaging could serially monitor the actual concentration of the drug in the end organ and lead to more accurate modeling of therapeutic response.

Targeted Antiproliferative Therapy

In addition to antiangiogenic drugs, PFC nanoparticles have been formulated to deliver drugs that inhibit the pathological proliferation of various cell types. The progression of both cancer and atherosclerosis typically involve uncontrolled cell division and a wide range of antiproliferative drugs have been developed to fight these diseases. For example, smooth muscle cells line the luminal aspect of arteries and are involved in the progression of atherosclerosis. Tissue factor, a transmembrane glycoprotein with a prominent role in angiogenesis, thrombosis, cell signaling, hemostasis, and mitogenesis, is expressed on smooth muscle cells in response to vascular injury. MR molecular imaging of tissue factor targeted PFC nanoparticles showed that the targeted particles bind to cultured smooth muscle cells at a concentration of 468 pM, while nontargeted particles only reach a concentration of 88 pM [3]. The MR measurements were validated by gas chromatography of the samples, revealing a particle concentration of 530 pM for the targeted nanoparticles and 111 pM for the nontargeted nanoparticles. Smooth muscle cell proliferation portends restenosis following coronary angioplasty. Therefore, the utility of PFC nanoparticles for delivery of antiproliferative drugs, including doxorubicin and paclitaxel, to smooth cells has been studied [2]. Exposure of the cells to targeted doxorubicin or paclitaxel nanoparticles significantly inhibited proliferation. Including the targeting ligand on the particle surface significantly increased the antiproliferative effect, particularly for paclitaxel. In vitro dissolution studies revealed that nanoparticle drug release persisted over 1 week. Targeted antiproliferative results were dependent on the hydrophobic nature of the drug and noncovalent interactions with other surfactant components. MR molecular imaging of the bound nanoparticles was demonstrated with both ^{1}H and ^{19}F MR imaging. A targeted paramagnetic nanoparticle carrying an antiproliferative payload to specific cell types could provide a novel, MR-visualizable, and quantifiable drug delivery system for the prevention of restenosis after angioplasty.

Clinically, drug-eluting stents are often used to locally release antiproliferative drugs for inhibiting restenosis following angioplasty. However, in-stent thrombosis can occur with these devices due to endothelial damage from the antiproliferative drugs. An alternative approach has been pursued with PFC nanoparticles loaded with antiproliferative agents and targeted to cellular biomarkers or the extracellular matrix [18]. Furthermore, these nanoparticle agents can be used to visualize ruptures in the artery wall



resulting from the angioplasty balloon. Paramagnetic $\alpha_v\beta_3$-integrin-targeted PFC nanoparticles containing rapamycin were used to locally deliver a drug payload through microfractures created by balloon overstretch injury. The local delivery of rapamycin inhibited arterial stenosis without impeding endothelial healing [18]. MR imaging demonstrated that the integrin-targeted nanoparticles remained bound to the injured arterial wall 30–40 min after balloon overstretch and reestablishment of blood flow. Two weeks after injury, MR imaging showed significant luminal stenosis in vessels treated with control formulations: $\alpha_v\beta_3$-integrin-targeted nanoparticles without drug, nontargeted nanoparticles with rapamycin or saline. In vessels treated with $\alpha_v\beta_3$-integrin-targeted rapamycin nanoparticles, no lumen irregularities were observed on MR angiograms. Histology showed $\alpha_v\beta_3$-integrin-targeted rapamycin nanoparticles decreased neointimal proliferation by 40 % compared to controls. Endothelial healing was evaluated 1, 7, 14, and 28 days after balloon injury and showed no differences between $\alpha_v\beta_3$-integrin-targeted rapamycin nanoparticles and the controls.

Another therapeutic approach to inhibit cellular proliferation uses host defense peptides that embed in the phospholipid cell membrane to create pores and disrupt normal cellular physiology. Melittin is a cytolytic peptide derived from honeybee venom that ruptures lipid membranes. PFC nanoparticles conjugated with melittin have been used as a therapeutic delivery vehicle in cancer models [19]. Melittin PFC nanoparticles were injected intravenously in mice bearing MDA-435 tumors [19]. Ultrasound imaging showed that treated tumors grew 25 % slower than controls. In a mouse melanoma model, four intravenous injections of melittin nanoparticles reduced the tumor size by 80 % compared to control injections of saline or nanoparticles lacking melittin. In a genetically engineered model of squamous carcinoma, treatment with integrin-targeted melittin nanoparticles resulted in an 80 % reduction in dermal papillae, the site of dysplasia in this model. In cultured cells, free melittin causes necrosis resulting in the release of lactate dehydrogenase (LDH) due to the disruption of cell membranes and cytochrome c indicating mitochondria damage. Cultured cells exposed to targeted melittin nanoparticles showed cytochrome c release, but only minimal LDH, suggesting a shift to apoptotic cell death rather than necrotic cell death. Thus, drug delivery with PFC nanoparticles could be utilized to modulate the therapeutic mechanism of action.

^{19}F MR Molecular Imaging

MR detection of paramagnetic PFC nanoparticles typically relies on the effect of gadolinium on the ^{1}H MR signal. The paramagnetic nature of gadolinium increases the water relaxation rate and generates signal enhancement on T1-weighted MR images. An alternative approach achieves direct detection of the PFC core of the nanoparticles via ^{19}F MR imaging [1, 3]. ^{19}F has a relatively high sensitivity, 83 % compared to ^{1}H, and there is virtually no native background signal. Thus, the PFC core can provide a definitive and quantitative MR signature [1]. For example, ^{19}F MR of fibrin-targeted PFC nanoparticles could be used to map the formation of thrombi on ruptured atherosclerotic plaques and quantify the extent of ruptures in the fibrous cap. Human carotid endarterectomy samples were treated with fibrin-targeted paramagnetic nanoparticles and imaged at 4.7 T [20]. ^{1}H MR imaging showed high levels of signal enhancement along the luminal surface due to nanoparticle binding to fibrin deposits (Fig. 5). A ^{19}F projection image of the artery showed an asymmetric distribution of nanoparticles around the vessel wall corroborating the ^{1}H signal enhancement. Co-registration of the quantitative nanoparticle map with the ^{1}H image permitted visualization of both anatomical and pathological information in a single image. Combining information from ^{1}H and ^{19}F MR imaging could allow prediction of subsequent occlusion or distal embolization from unstable or disrupted plaques, and aid clinical decision-making for acute invasive intervention versus pharmaceutical therapies.

PFC nanoparticles can be formulated with different perfluorochemicals to yield particles that

Perfluorocarbon Nanoparticles, Fig. 5 Direct detection of fibrin-targeted PFC nanoparticles utilizing ^{19}F MR imaging. (**a**) Optical image of a cross section of a human carotid endarterectomy sample showing moderate luminal narrowing as well as several atherosclerotic lesions. can be differentiated by ^{19}F MR. Fibrin-targeted nanoparticles consisting of perfluorooctylbromide (PFOB) or perfluoro-15-crown-5-ether (CE) have been distinguished based on the unique chemical shifts of each compound [1]. Both ^{19}F imaging and spectroscopy could identify PFOB and CE nanoparticles. The signal to noise for PFOB was lower than CE (10 vs. 25, respectively), presumably due to the single CE peak (20 equivalent fluorine atoms) compared to the multiple PFOB peaks (17 fluorine atoms distributed over 5 peaks). A clear linear relationship between the ^{19}F signal intensity and nanoparticle concentration was demonstrated for both PFOB and CE using both imaging and spectroscopy. Multiple PFC nanoparticle agents could be used to target different epitopes and achieve a noninvasive analogy to immunohistochemistry. For example, simultaneous quantification of angiogenesis in the vessel wall and fibrin deposition on the plaque cap could be used to evaluate the pathophysiological stage of an obstructive atherosclerotic lesion.

Tissue inflammation is another biological marker of unstable atherosclerotic plaques, inducing the release of cytokines and upregulating the production of proteins like vascular cell adhesion molecule-1 (VCAM-1). PFC nanoparticles targeted to VCAM-1 were injected into genetically engineered ApoE$^{-/-}$ mice, which mimic the clinical progression of atherosclerosis, to map inflammation [3]. These mice display focal inflammation and macrophage infiltration in the kidneys. To definitively identify nanoparticle binding in the kidneys, ^{19}F MR imaging was performed on a 11.7 T research scanner 2 h after injection of VCAM-1 targeted PFC nanoparticles. The ^{19}F signal arising from the PFC core provided an unambiguous marker of particle accumulation, without the innate signal variations that can confound typical ^{1}H signal enhancement with traditional paramagnetic or superparamagnetic MR contrast agents. VCAM-1-targeted nanoparticles accumulated in ApoE$^{-/-}$ kidneys to a greater extent than nontargeted nanoparticles (3.7 billion particles/g of tissue vs. 0.9 billion particles/g). The uptake of targeted nanoparticles was also higher in the kidneys of ApoE$^{-/-}$ mice compared to non-ApoE$^{-/-}$ controls (3.7 vs. 1.6 billion particles/g). Control animals displayed no significant difference in the uptake of targeted versus nontargeted nanoparticles (1.6 vs. 1.5 billion particles/g).

Typically, targeted MR contrast agents generate image enhancement as a result of both nonspecific blood pool signal as well as the specific binding of the agent to the biomarker of interest. Separating out these two contributions can be very difficult to achieve in vivo. One method to suppress the nonspecific signal utilizes diffusion-weighted ^{19}F spectroscopy to null the

signal arising from moving particles, representing the unbound fraction in the blood pool, while retaining the signal from stationary particles that are specifically bound to the target epitope [1]. A genetically engineered mouse model of squamous cell cancer, derived by incorporating human papilloma virus into the mouse genome, was studied with a 11.7 T research scanner. Transgenic and age-matched control mice were scanned 90 min after injection of $\alpha_v\beta_3$-integrin-targeted PFC nanoparticles to assess angiogenesis in these precancerous lesions. Both the transgenic and control mice displayed decreased ^{19}F signal with increasing b-values. However, 60–100 % of the ^{19}F signal remained at b-values near 60,000 s/mm^2 in the transgenic animals, while no detectable ^{19}F signal was observed in control mice at b-values of 1,500 s/mm^2. The calculated ADC of PFC nanoparticles was 33.1 m^2/s in the transgenic mice, significantly lower than the 19,563 m^2/s ADC in the controls.

Angiogenesis is a prominent feature in the progression of aortic valve stenosis. Cholesterol-fed rabbits develop aortic valve sclerosis, characterized by gross thickening, macrophage infiltration, calcification, and eventual bone formation that mimics the clinical presentation of the disease. Cholesterol-fed rabbits underwent ^{19}F MR imaging after injection of $\alpha_v\beta_3$-integrin-targeted nanoparticles to quantify angiogenesis in the aortic valve leaflets [1]. The cholesterol feeding caused gross thickening of the aortic valves accompanied by extensive foam cell infiltration, non-calcified bone deposition, activation of myofibroblasts, abnormal microvascular proliferation, and upregulation of $\alpha_v\beta_3$-integrin expression. None of these abnormalities were observed in the normal valve tissue from control animals.

The crown ether (CE) signal arising from the nanoparticle contrast agent was readily detected and distinguished from a perfluorooctylbromide (PFOB) quantification reference based on the chemical shifts of these perfluorocarbon species, allowing quantification of the total volume of bound nanoparticles. The volume of targeted nanoparticles bound to the valves was 19.5 nL, which was more than three times higher than the amount of nontargeted nanoparticles (5.6 nL). Competitive inhibition of $\alpha_v\beta_3$-integrin binding reduced the amount of nanoparticles in the valves by about half (10.3 nL). Valves from healthy rabbits treated with targeted nanoparticles contained almost nine times fewer nanoparticles (2.3 nL) than the valves from cholesterol-fed rabbits. These techniques may be useful for assessing atherosclerotic components of preclinical aortic valve disease in patients and could assist in defining efficacy of medical therapies. The sensitivity of this approach for molecular detection of sparse quantities of inflammatory epitopes in very thin structures at high field strengths establishes a basis for future efforts to develop localized spectroscopic methods at clinical field strengths that could be useful for detecting disease and monitoring therapies.

Conclusions

PFC nanoparticles have been utilized for a wide range of molecular imaging, cell tracking, and targeted drug delivery applications. The relatively large size of the particles constrains them to the intravascular space, allowing specific targeting to endothelial expression of integrins, selectins, and adhesion molecules. PFC nanoparticles have a large surface area, which provides a means to incorporate multiple binding ligands and multiple paramagnetic chelates to the particle surface. The particle surface can also serve as a drug reservoir that selectively delivers a therapeutic payload to the targeted cell population. The dual role of PFC nanoparticles as both a molecular imaging contrast agent and a drug delivery vehicle can be exploited to provide diagnostic and therapeutic information via noninvasive MR imaging, or most of the other common clinical imaging modalities, including ultrasound, nuclear imaging, and computed tomography. Although PFC nanoparticles not currently approved for clinical use, the future applications of these agents in the management of patients with chronic diseases could aid in diagnostics, therapeutics, and/or follow-up of treatment efficacy or disease

recurrence, by noninvasively mapping biomarkers associated with cancer or cardiovascular disease and specifically directing highly potent drugs directly to the sites of pathology.

Definition

Photolithography is a process used in microfabrication to selectively pattern a thin film substrate using light to transfer a geometric pattern from a photomask to a light-sensitive photoresist [1].

Introduction

Lithography is a technique used to transfer copies of a master pattern onto the surface of a solid material such as a silicon wafer. The word *lithography* (Greek for the words *stone* [*lithos*] and to *write* [*gráphein*]) refers to the process invented in 1796 by Aloys Senefelder, who inked Bavarian limestone and transferred a carved image from stone onto paper. The most widely used form of lithography is photolithography. In the IC industry, pattern transfer from masks onto thin films is accomplished almost exclusively via photolithography. Photomasking, followed by chemical processing, led to the photolithography now used in fabricating ICs (integrated circuits) and in miniaturization science. The first applications of the printed circuit board (PCB) (also printed wiring board or PWB) were invented in 1943 by the Austrian Paul Eisler. By 1961, Fairchild Semiconductor had introduced the first commercial integrated circuit in which photoetching processes produce large numbers of transistors on a thin slice of silicon (Si). Now, integrated circuits can be found in almost every electronic device, microprocessors, audio and video equipment, dishwashers, garage openers, security systems, automobiles, etc. With the first ICs, patterns had a resolution not better than 5 μm. Today, photolithography, x-ray lithography, and charged-particle lithography all achieve submicron printing accuracy. Intel introduced the Prescott Pentium IV chip in the fourth quarter of 2003, an IC chip incorporating 90 nm sized features, using UV photolithography. Chips based on a 65 nm technology became available in 2006, and the 32 nm node was achieved in 2009. Furthermore, first consumer-level CPU deliveries started in April 2012 using a 22 nm technology. In 2014, the 14 nm technology was also reached by semiconductor companies.

The combination of accurate registration and exposing a series of successive patterns leads to complex multilayered ICs. This essentially two-dimensional (2D) process has a limited tolerance for nonplanar topography, creating a major constraint for building non-IC miniaturized systems, which often exhibit extreme topographies. Photolithography has matured rapidly, and its ability to resolve ever-smaller features is constantly improving. For the IC industry, this continued improvement in photolithography resolution has impeded the adaptation of alternative, higher-resolution lithography techniques, such as x-ray lithography. Research in high-aspect-ratio resists features to satisfy the needs of both IC and non-IC miniaturization is also improving dramatically photolithography's capacity to cover wide ranges of topography. Performance of a photolithographic process is determined by its resolution, the minimum feature size that can be transferred with high fidelity, the registration, how accurately patterns on successive masks can be aligned, and throughput, the number of wafers that can be transferred per hour. Photolithography and pattern transfer involve a set of processes including photoresist coating, UV exposure, baking, developing, etc.

Wafer Cleaning and Clean Room

An important step, even before lithography proper, is wafer cleaning. Contaminants include solvent stains (methyl alcohol, acetone, trichloroethylene, isopropyl alcohol, xylene, etc.), dust from operators and equipment, smoke particles, etc. Stains or films may lead to adverse effects during oxidation and evaporation processes. Particulates, chunks of granular matter, may cause undesirable masking effects and scratches on the photomask during contact printing. All lithography processes take place inside a semiconductor clean room, which is a specially constructed enclosed area environmentally controlled with respect to airborne particulates, temperature (±0.1 °F), air pressure, humidity (from 0.5 % to 5 % RH), vibration, and lighting. In a Class 1 clean room, the particle count does not exceed 1 particle per cubic foot with particles of a size of 0.5 μm and larger, and in a Class 100 clean room, the particle count does not exceed 100 particles per cubic foot with particles of a size of 0.5 μm and larger. The allowable contamination particle size in IC manufacture has been decreasing hand in hand with the ever-decreasing minimum feature size.

Many different dry and wet methods for wafer cleaning currently in use, such as RCA1 and RCA2, developed by W. Kern, use mixtures of hydrogen peroxide and various acids or bases followed by deionized (DI) water rinses. Others include vapor cleaning; thermal treatment, for example, baking at 1,000 °C in vacuum or in oxygen; and plasma or glow discharge techniques, for example, in Freons with or without oxygen. Mechanical methods include ultrasonic agitation, polishing with abrasive compounds, and supercritical cleaning. Ultrasonic cleaning, which is excellent for removing particulate matter from the substrate, is unfortunately prone to contamination and mechanical failure of deposited films.

Masks

The stencil used to repeatedly generate a desired pattern on resist-coated wafers is called a *mask*. In typical use, a photomask – a nearly optically flat glass (transparent to near ultraviolet [UV]) or quartz plate (transparent to deep UV) with an absorber pattern metal (e.g., an 800 Å thick chromium layer) – is placed above the photoresist-coated surface, and the mask/wafer system is exposed to UV radiation. The absorber pattern on the mask can be generated by e-beam lithography which yields higher resolution than photolithography. A *positive* or *dark-field* mask is a mask on which the pattern is clear with the background dark. A *negative* or *clear-field* mask is a mask on which the pattern is dark with the background clear. A light-field or dark-field image, known as *mask polarity*, is then transferred to the semiconductor surface. This procedure results in a 1:1 image of the entire mask onto the silicon wafer.

Masks, making direct physical contact with the substrate, are called *contact masks*. Unfortunately, these masks degrade faster due to wear than noncontact, proximity masks (also referred to as *soft contact masks*), which are slightly raised, say 10–20 μm, above the wafer. Contact mask and proximity mask printing is collectively known as *shadow printing*. A more reliable method of masking is *projection printing* where, rather than placing a mask in direct contact with (or in proximity of) a wafer, the photomask is imaged by a high-resolution lens system onto the resist-coated wafer. The imaging lens can reduce the mask pattern by 1:5 or 1:10, making mask fabrication less challenging. Lithography is still mostly carried out using masks, but due to problems caused by masks, such as expense and time in fabricating them, contamination introduced by them, their disposal, and the difficulties in their alignment, research into maskless optical projection lithography (MOPL) is growing rapidly and broadly. One MOPL, an approach already on the market (http://www.intelligentmp.com), is based on the digital micromirror device (DMD) chip from Texas Instruments Inc. (TI) and relies on the same spatial light modulation technology used in DLP (digital light processing) projectors and HDTV (high-definition television) arrays in a DMD chip to project images on the photoresist. The resolution of DMD-based maskless photolithography (about 5 μm) is significantly less than with e-beam

lithography (0.25 μm) or laser writers (<1.0 μm), but it is a parallel technique, and for many applications, that is, in microfluidics, the lower resolution might not be an obstacle. Maskless zone plate array lithography (ZPAL) is another optical maskless technology which operates on the principle of diffraction rather than refraction.

Process

Photoresist Deposition

Lithography is the most expensive step in microelectronics technology, representing up to 35 % of the wafer manufacturing cost. Within lithography, photoresist coating is one of the more expensive steps. For silicon integrated circuits, the resist thickness after a prebake (see below for what a prebake does) typically ranges between 0.5 and 2 μm. For miniaturized three-dimensional (3D) structures, much greater resist thicknesses are often required, and complex topography might also call for a conformal resist coat over very high-aspect-ratio features. For thick resist coats, techniques such as casting and the use of thick sheets of dry photoresists replace the ineffective resist spinners.

As the first step in the lithography process itself, a thin layer of an organic polymer, a photoresist sensitive to ultraviolet radiation, is deposited on the oxide surface. The photoresist is dispensed onto the wafer which is held by a vacuum chuck. A speed of about 500 rpm is commonly used during the dispensing step enabling the spread of the fluid over the substrate. After the dispense step, it is common to accelerate to a relatively high speed to thin the fluid to near its final desired thickness. Typical spin speeds for this step range from 1,500 to 6,000 rpm, depending on the properties of the fluid (mostly its viscosity) as well as the substrate. This step can take from 10 s to several minutes. The combination of spin speed and time selected for this step will generally define the final film thickness. At these speeds, centrifugal force causes the solution to flow to the edges, where it builds up until expelled when surface tension is exceeded. The resulting polymer thickness, T, is a function of spin speed, solution concentration, and molecular weight (measured by intrinsic viscosity).

As alternatives to spin coating, several other methods can be used for photoresist application, including spray coating, electrostatic spraying or electrostatic deposition (ED), meniscus coating, silk screening, plasma deposition, electrophoretic photoresist deposition, dip coating, roller coating, curtain coating, extrusion coating, etc.

Soft Baking or Prebaking

After resist coating, the resist still contains up to 15 % solvent and may contain built-in stresses. The wafers are therefore soft baked (also preexposure baked or prebaked) at 90–100 °C for about 20 min in a convection oven, or at 75–85 °C for 1–3 min with a vacuum hot plate, to remove solvents and stress and to promote adhesion of the resist layer to the substrate. This is a critical step in that failure to sufficiently remove the solvent will affect the resist profile. Excessive baking destroys the photoactive compound and reduces sensitivity. Thick resists may benefit from a longer bake time. The resist thickness, for both negative and positive resists, is typically reduced by 10–25 % during soft baking. Hot plating the resist is faster, is more controllable, and does not trap solvent like convection oven baking. In convection ovens, the solvent at the surface of the resist is evaporated first, and this can cause an impermeable resist skin, trapping the remaining solvent inside. So heating in a convection oven must proceed slowly to avoid solvent bursts. Commercially, microwave heating or IR lamps are also used in production lines. The optimization of the prebaking step may substantially increase device yield.

Exposure and Postexposure Treatment

After soft baking, the resist-coated wafers are transferred to an illumination or exposure system where they are aligned with the features on the mask. For any lithographic technique to be of value, it must provide an alignment technique capable of a superposition precision of mask and wafer that is a small fraction of the minimum feature size of the devices under construction. In the simplest case, an exposure system consists of a

UV lamp illuminating the resist-coated wafer through a mask without any lenses between the two. The purpose of the illumination is to deliver light with the proper intensity, directionality, spectral characteristics, and uniformity across the wafer, allowing a nearly perfect transfer or printing of the mask image onto the resist in the form of a latent image.

In photolithography, wavelengths of the light source used for the exposure of the resist-coated wafer range from the very short wavelengths of extreme ultraviolet (EUV) (10–14 nm) to deep ultraviolet (DUV) (150–300 nm) to near ultraviolet (UV) (350–500 nm). In near UV, one typically uses the g-line (435 nm) or i-line (365 nm) of a mercury lamp. The brightness of shorter-wavelength sources is severely reduced compared to that of longer-wavelength sources, and the addition of lenses further reduces the efficiency of the exposure system. In general, the smallest feature that can be printed using projection lithography is roughly equal to the wavelength of the exposure source, in this example, 248 nm would be expected. The same laser, in combination with sophisticated resolution-enhancing techniques (RETs), may be used to produce more advanced circuits with transistor gate features of 160 nm and below. RET methods (see below) enable one to go quite a bit beyond the conventional Rayleigh diffraction limit. Other exposure systems now available include two DUV excimer lasers, the ArF at 193 nm and the F_2 at 157 nm, and extreme UV lithography (EUV) at 13.4 nm. The current generation of lithography is using 193 nm light from ArF lasers. In the case of EUV, a plasma or synchrotron source and all reflective reduction optics (4×) (at this wavelength, all materials absorb!) are used.

Postexposure Treatment

A postexposure treatment of the exposed photoresist is often desired, because the reactions initiated during exposure might not have run to completion. To halt the reactions or to induce new ones, several postexposure treatments are in use: postexposure baking (PEB), flood exposure with other types of radiation, treatment with a reactive gas, and vacuum treatment. Postexposure baking (sometimes in a vacuum) and treatment with reactive gas are used in image reversal and dry resist development. In the case of a chemically amplified resist, the postexposure bake is most critical. Although reactions induced by the catalyst that forms during exposure take place at room temperature, their rate is greatly increased by baking at 100 °C. The precise control of this type of postexposure bake critically determines the subsequent development itself.

Development

Development is the dissolution of unpolymerized resist that transforms the latent resist image, formed during exposure, into a relief image that will serve as a mask for further subtractive and additive steps. During the development of an exposed resist, selective dissolving takes place. Two main technologies are available for development: wet development, which is widely used in circuit and miniaturization manufacture in general, and dry development, which is starting to replace wet development for some of the ultimate line-width resolution applications.

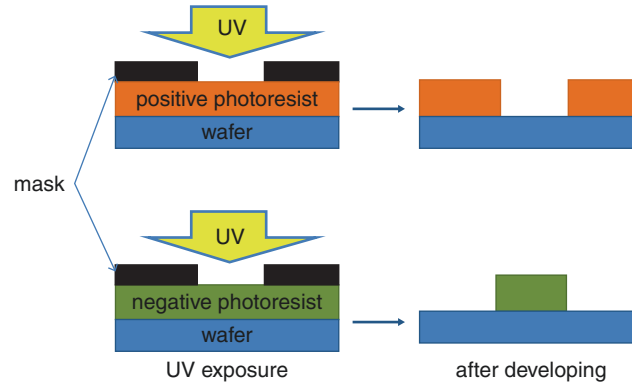
During batch spray development, fan-type sprayers direct fresh developing solution across wafer surfaces. Positive resists are typically developed in aqueous alkaline solutions and negative resists in organic ones. For alkaline developers, simple solutions of NaOH (Shipley 351) or KOH (AZ/Clariant 400 K) may be used, but because of the possibility of mobile ion contamination in Metal-oxide-semiconductor (MOS) devices, developers free of metal ions are preferred. The latter are usually tetramethylammonium hydroxide (TMAH) based (Shipley CD-26, MF-321, AZ/Clariant 300-MIF). Each developer has a different dilution, and some require longer development times than others. Developers are generally matched to a type of photoresist. Though they may be interchangeable to some extent, changing the type of developer used in a process will usually change the exposure time necessary to resolve the pattern. It should be noted that all of the abovementioned alkaline developers etch aluminum. If the micromachine or microchip, under construction, contains aluminum features, Shipley Microposit Developer Concentrate (MDC),

a mixture of proprietary alkaline salts (mostly phosphates) with the slowest aluminum etch rate, is a better developer choice.

The use of organic solvents leads to some swelling of the resist (especially for negative resists; see below) and loss of adhesion of the resist to the substrate. Dry development overcomes these problems, as it is based either on a vapor phase process or a plasma. In the latter, oxygen-reactive ion etching (O_2-RIE) is used to develop the latent image. The image formed during exposure exhibits a differential etch rate to O_2-RIE rather than differential solubility to a solvent.

De-scumming and Post-baking

A mild oxygen plasma treatment, the so-called de-scumming, removes unwanted resists left behind after development. Negative, and to a lesser degree positive, resists leave a thin polymer film at the resist/substrate interface. The problem is most severe in small (<1 μm) high-aspect-ratio structures where the mass transfer of a wet developer is poor. Patterned resist areas are also thinned in the de-scumming process, but this is usually of little consequence. Before etching the substrate or adding a material, the wafer must be post-baked. Post-baking or hard baking removes residual coating solvent and developer and anneals the film to promote interfacial adhesion of the resist that has been weakened either by developer penetration along the resist/substrate interface or by swelling of the resist (mainly for negative resists). Hard baking also improves the hardness of the film and avoids solvent bursts during vacuum processing. Improved hardness increases the resistance of the resist to subsequent etching steps. Post-baking frequently occurs at higher temperatures (120 °C) and for longer times (say 20 min) than soft or prebaking. The major limitation for heat application is excessive flow or melt, which degrades wall profile angles and makes it more difficult to remove the resist. Post-bake does induce some stress and resist shrinkage. Special care needs to be taken when the baking temperature is above the glass transition temperature, T_g, when impurities are easily incorporated into the resist due to the plastic flow of the resist.



Resists

The principal components of photoresists are a polymer (base resin), a sensitizer, and a casting solvent. The polymer changes structure when exposed to radiation; the solvent allows spin application and formation of thin layers on the wafer surface; sensitizers control the chemical reactions in the polymeric phase. Resists without sensitizers are single-component or one-component systems, whereas sensitizer-based resists are two-component systems. Solvent and other potential additives do not directly relate to the photoactivity of the resist.

If the photoresist is of the type called *positive* (also *positive tone*), the photochemical reaction during exposure of a resist weakens the polymer by rupture or scission of the main and side polymer chains, and the exposed resist becomes more soluble in developing solutions (say ten times more soluble). In other words, the development rate, R, for the exposed resist is about ten times faster than the development rate, R_0, for the unexposed resist. Two well-known families of positive photoresists are the single-component poly(methyl methacrylate) (PMMA) resists and the two-component DNQ resists comprised of a photoactive component (PAC) such as diazonaphthoquinone ester (DNQ) (20–50 wt%) and a phenolic novolac resin.

If the photoresist is of the type called *negative* (also *negative tone*), the reaction strengthens the polymer by random cross-linkage of main chains or pendant side chains, becoming less soluble (slower dissolving). Exposure, development, and pattern-transfer sequences for negative and positive resists are shown in Fig. 1.

The first negative photoresists were based on free radical-initiated photo-cross-linking processes of main or pendant polymer side chains, rendering the exposed parts insoluble. Commonly used negative-acting, two-component resists are bis(aryl)azide rubber resists, whose matrix resin is cyclized poly(cis-isoprene), a synthetic rubber. An example of a commercial, two-component negative photoresist is the Kodak KTFR [an azide-sensitized poly(isoprene) rubber] with a lithographic sensitivity (also photospeed) of

Photolithography, Fig. 1 Positive and negative resist: exposure, development, and pattern transfer

75–125 mJ/cm^2. Negative photoresists, in general, adhere very well to the substrate, and a vast amount of compositions are available (stemming from R&D work in paints, UV-curing inks, and adhesives all based on polymerization hardening). Negative resists are highly resistant to acid and alkaline aqueous solutions as well as to oxidizing agents. As a consequence, a given thickness of negative resist is more chemically resistant than a corresponding thickness of positive resist. A comparison of negative and positive photoresist features is presented in Table 1. This table is not exhaustive and is meant only as a practical guide for selection of a resist tone.

Resists typically are removed (stripped) once they have served their function as temporary stencils. Some negative resists, hardened through UV exposure, are used as permanent components of miniature devices. Two prominent examples in this category are polyimide and SU-8-based resists. Polyimides are a class of polymers synthesized from two monomers: a dianhydride and a diamine. Commercial products are supplied as soluble polyamic acid (PAA) intermediates, which undergo a thermal imidization with the evolution of water to form an insoluble polyimide. Polyimide is used as an interlayer dielectric because of its desirable characteristics such as a high thermal stability with a glass transition temperature, Tg $>$ 300 °C, a low dielectric constant, a good chemical stability, and an ease of processing.

Most resists in IC and Micro-Electro-Mechanical Systems (MEMS) fabrication are deposited as liquids, whereas resists used in printed wiring board (PWB) manufacture are usually dry film resists that come in rolls (ranging from 2 to 60 in. wide and 125 to 1,000 ft. long) and are laminated onto the substrate instead of being spin coated on it. Dry film resist formulations are sandwiched between a polyolefin release sheet and a polyester base, rolled up on a support core. Dry film resists offer advantages such as excellent adhesion on most substrates, no liquid handling since there is no solvent, high process speed, excellent thickness uniformity over a whole substrate, simple handling, no formation of edge beads, low exposure energy, low cost, short processing time, and near vertical sidewalls. There are a variety of dry film photoresists widely used and commercially available, examples include Riston®, Ordyl BF 410, Etertec® 5600, DF 4615, and DFR-15. All are used in the manufacture of circuit boards and can be made quite thick, and all are candidates for broad use in MEMS as well.

Photoresist stripping, in slightly oversimplified terms, is organic polymer etching. The primary consideration is the complete removal of the photoresist without damaging the device under construction. There are many commercial strippers available; some are specific for positive resists (e.g., ACT-690 C from Ashland), others for negative resists, and still others are universal strippers (e.g., ACT-140 from Ashland). Other popular commercial strippers are Piranha and RCA clean. Wet stripping solutions lose potency in use, causing stripping rates to change with time.

Photolithography, Table 1 Comparison of traditional negative and positive photoresists

	Resist type	
Characteristic	Positive resist	Negative resist
Adhesion to Si	Fair (priming required)	Excellent (priming not required)
Available compositions	Many	Vast
Baking	In air (+)	In nitrogen (−)
Contrast γ	Higher, e.g., 2.2	Lower, e.g., 1.5
Cost	More expensive	Less expensive
Developer	Temperature sensitive (−) and aqueous based (ecologically sound)	Temperature insensitive (+) and organic solvent (−)
Developer process window	Small	Very wide, insensitive to overdeveloping
Influence of oxygen	No (+)	Yes (−)
Lift-off	Yes	Yes
Mask type	Dark field: lower defects	Clear field: higher defects
Opaque dirt on clear portion of mask	Not very sensitive to it	Causes printing of pinholes
Photospeed	Slower	Faster
Pinhole count	Higher	Lower
Pinholes in mask	Prints mask pinholes	Not so sensitive to mask pinholes
Plasma etch resistance	Not very good	Very good
Proximity effect	Prints isolated holes or trenches better	Prints isolated lines better
Residue after development	Mostly at <1 μm and with high aspect ratio	Often a problem
Resolution	High	Low (>1 μm)
Sensitizer quantum yield Φ	0.2–0.3	0.5–1
Step coverage	Better	Lower
Strippers of resist over		
Oxide steps	Acid	Acid
Metal steps	Simple solvents	Chlorinated solvent compounds
Swelling in developer	No	Yes
Thermal stability	Good	Fair
Wet chemical resistance	Fair	Excellent

Accumulated contamination in solutions can be a source of particles, and liquid-phase surface tension and mass transport tend to make photoresist removal difficult and uneven. Dry stripping or oxygen plasma stripping, also known as ashing, has become more popular as it poses fewer disposal problems with toxic, flammable, and dangerous chemicals. Dry stripping is more controllable than liquid stripping, less corrosive with respect to metal features on the wafer, and, more importantly, it leaves a cleaner surface under the right conditions. Finally, it does not cause the undercutting and broadening of photoresist features that can be caused by wet strippers.

Critical Dimension and Overall Resolution

The absolute size of a minimum feature in an IC or a miniature device, whether it involves a line-width, spacing, or contact dimension, is called the *critical dimension* (CD). The overall resolution of a process describes the consistent ability to print a minimum size image, a critical dimension, under conditions of reasonable manufacturing variation. Many aspects of the process, including hardware, materials, and processing considerations, can limit the resolution of lithography. Hardware limitations include diffraction of light or scattering of charged particles (in the case of charged-particle lithography or hard x-rays), lens aberrations, mechanical stability of the system, etc. The resist material properties that impact resolution are contrast, swelling behavior, thermal flow, chemical etch resistance, etc. The most important process-related resist variables include swelling (during development) and stability (during etching and baking steps). Resolution frequently is measured by line-width measurements using either transmitted or reflected light or other metrology techniques. Optical techniques perform satisfactorily for features of 1 μm and larger, providing a precision of ± 0.1 μm. The successful performance of devices depends upon the control of the size of critical structures across the entire wafer and from one wafer to another, referred to as line-width control. A rule of thumb is that the

dimensions must be controlled to tolerances of at least ±1/5 of the minimum feature size.

Correct feature size must be maintained within a wafer and from wafer to wafer, as device performance depends on the absolute size of the patterned structures. In the shadow printing mode, including contact and proximity arrangements of mask and wafer, optical lithography has a resolution with limits set by a variety of factors. These include diffraction of light at the edge of an opaque feature in the mask as the light passes through an adjacent clear area, alignment of wafer to mask, nonuniformities in wafer flatness, and debris between mask and wafer. Diffraction causes the image of a perfectly delineated edge to become blurred or diffused. The theoretical resolution, R, that is, the minimum resolved dimension in a grating mask ($b_{\min}$ for a line or a space), is given by

$$\mathrm{R} = b_{\min} = k\sqrt{\lambda\left(\mathrm{s} + \frac{\mathrm{z}}{2}\right)} \qquad (1)$$

where

- $b_{\min}$ = half the grating period and the minimum feature size transferable
- s = the gap between the mask and the photoresist surface
- λ = wavelength of the exposing radiation
- z = the photoresist thickness
- k = a constant which theoretically is ~1.5

Depending on the relative magnitude of s and z, one distinguishes between contact and proximity printing. The square root relation in contact and proximity printing is a consequence of the near-field or Fresnel diffraction theory valid in the near-field region just below the mask openings; this contrasts with the far-field behavior (Fraunhofer diffraction) of projection lithography (see below). Self-aligned printing can be regarded as an extreme form of contact printing where there is no gap between the mask and the substrate. In contact printing, a photomask is pressed against the resist-covered wafer with pressures in the range of 0.05–0.3 atm., and the s, in Eq. 1, is zero. The theoretical maximum resolution is seldom achieved, however, as only diffraction effects were taken into account to derive Eq. 1. The other factors mentioned above (wafer flatness, mask alignment, etc.) and shadowing effect (penumbral blur) usually conspire to make the resolution worse.

In proximity printing, spacing of the mask removed from the substrate (by at least 10 μm) minimizes defects that result from contact. On the other hand, diffraction of the transmitted light reduces the resolution. The degree of reduction in resolution and image distortion depends on the wafer-to-substrate distance, which may vary across the wafer.

In projection printing, wafer contact is completely avoided; a high-resolution lens projects an image of the photomask onto the photoresist-covered wafer. Imaging in this case is far-field or Fraunhofer diffraction dominated, and the Rayleigh criterion for far-field resolution can be considered. A dimensionless constant k_1 can be used to define the practical limiting resolution R in projection printing as

$$\mathrm{R} = k_1 \frac{\lambda}{\mathrm{NA}} \qquad (2)$$

where k_1 = experimentally determined dimensionless parameter that depends on resist parameters, process conditions, mask aligner optics, etc.

To achieve higher resolutions, instrumentation designers want to work at shorter wavelengths λ, higher NA, and smaller k_1.

Since the mid-1980s, the demise of optical lithography has been predicted as being only a few years away, but each time a new resolution limit approaches, some new method extends the useful life of the technology. The three main technologies involved in printing ICs and other miniaturized devices are resist technology, mask technology, and the exposure tool, all of which need to be addressed to optimize lithography resolution. Strategies for improved resolution can be achieved through using chemically amplified resists, antireflection coatings, improved mask technology (such as optical proximity correction), improved exposure equipment (such as off-axis

illumination), etc. DUV photolithography is expected to continue until the 45 nm node through these resolution enhancing techniques. The 32 nm node is viewed as beyond the scope of DUV lithography.

Next-Generation Lithographies (NGLs) and Lithography Research

In the IC industry, continuous improvements to DUV photolithography have postponed the industrial adoption of alternative next-generation lithographies (NGLs), such as extreme ultraviolet lithography (EUVL), x-ray lithography, charged-particle beam lithography based on electrons and ions (such as electron and ion projection techniques), and imprint lithography (nanoimprint lithography [NIL] and step-and-flash imprint lithography [SFIL]), because of the huge financial investment in existing photolithography equipment. These NGLs are regarded today as important technologies for the beyond-the-DUV-lithography era, either for mask making or for actual IC production. In addition, many lithography approaches in the R&D stage, including lithography based on very thin resist layers and block copolymers, zone plate array lithography (ZPAL), quantum lithography (two-photon lithography), and proximal probe-based techniques such as atomic force microscopy (AFM), scanning tunneling microscopy (STM), dip-pen lithography (DPL), near-field scanning optical microscopy (NSOM), and apertureless near-field scanning optical microscopy (ANSOM), are attracting more and more research interest. It is quite possible that some of the alternative lithography tools in the R&D category will emerge as serious next-generation lithographies (NGLs) in the coming years.

Extreme Ultraviolet Lithography (EUVL)

Extreme ultraviolet lithography (EUVL), using wavelengths in the 10–14 nm range to carry out projection imaging, is perhaps the most natural extension of optical projection lithography as, in principle, it only differs in terms of the wavelength. This type of radiation is also referred to as *soft x-ray radiation* and *vacuum UV*. Sources for this type of radiation are laser-produced plasmas and synchrotrons. EUV is strongly absorbed in virtually all materials, and, consequently, imaging must be carried out in vacuum; also, all camera optics as well as masks used must be reflective rather than refractive. New resists and processing techniques must be developed as well.

Photolithography, Table 2 Light sources for various types of lithography

Wavelength [nm]	Source	Range
436	Hg arc lamp	G-line
405	Hg arc lamp	H-line
365	Hg arc lamp	I-line
248	Hg/Xe arc lamp, KrF excimer laser	Deep UV (DUV)
193	ArF excimer laser	DUV
157	F2 laser	Vacuum UV (VUV)
~10	Laser-produced plasma sources	Extreme UV (EUV)
~1	X-ray tube, synchrotron	X-ray

X-ray Lithography

X-ray lithography employs a shadow printing method similar to optical proximity printing. The x-ray wavelength (4–50 Å) is much shorter than that of UV light (Table 2). Hence, diffraction effects are reduced and higher resolution can be attained. For instance, for an x-ray wavelength of 5 Å and a gap of 40 μm, resolution can be around 0.2 μm. In contrast, with electron lithography and ion beam lithography, no charged particles are directly involved in x-ray exposures, which makes the need for vacuum less stringent.

X-ray lithography is superior to optical lithography due to its use of shorter wavelengths and its very large Depth of field (DOF) and because exposure time and development conditions are not as stringent. Reproducibility is high since results are independent of substrate type, surface reflections, and wafer topography. Another important benefit is that x-ray lithography is immune to low-atomic-number (Z) particle contamination

(dust). With an x-ray wavelength on the order of 10 Å or less, diffraction effects generally are negligible, and proximity masking can be used, increasing the lifetime of the mask. In x-ray lithography, there are essentially no optics involved, and, although this sounds like an advantage, it also presents one major disadvantage since one can only work with 1:1 shadow printing. No image reduction is possible, so the mask fabrication process is very complicated. In the United States, IBM remains the only major champion of x-ray lithography for next-generation lithography. At the end of 1999, IBM fabricated several PowerPC 604e microprocessor batches to demonstrate the viability of the method. In Japan, there are still many players involved such as NTT, Toshiba, Mitsubishi, and NEC.

LIGA

The LIGA technique (a German acronym for Lithographie, Galvanoformung, Abformung) was invented about 20 years ago. LIGA exploits all of the advantages of x-ray lithography listed above. The LIGA process involves a thick layer of resist (from micrometers to centimeters), high-energy x-ray radiation, and resist development to make a resist mold. By applying galvanizing techniques, the mold is filled with a metal. The resist structure is removed, and metal products result. Alternatively, the metal part can serve as a mold itself for precision plastic injection molding. Several types of plastic molding processes have been tested, including reaction injection molding, thermoplastic injection molding, and hot embossing. LIGA enables new building materials and a wider dynamic range of dimensions and possible shapes.

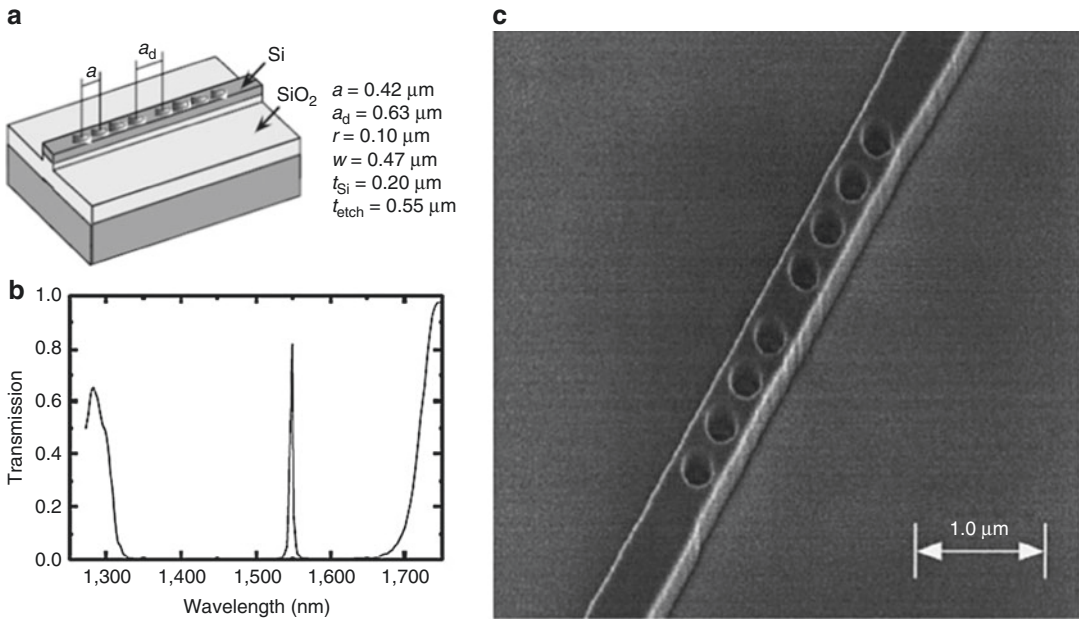
Photonic Crystal Nanobeam Cavities

Parag B. Deotare and Marko Loncar
Electrical Engineering, Harvard School of Engineering and Applied Sciences, Cambridge, MA, USA

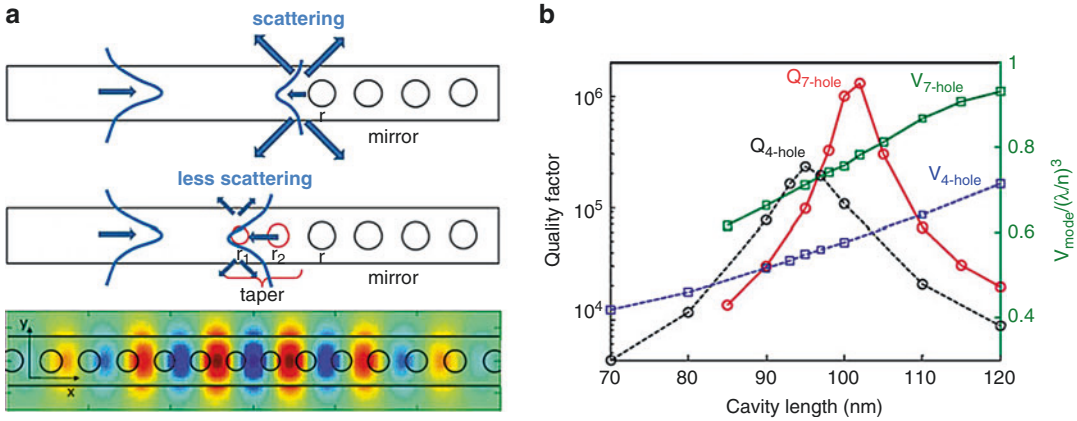
Definition

Photonic crystal nanobeam cavities are high quality factor, small mode volume optical resonators formed by using photonic crystal Bragg mirrors in the longitudinal direction and total internal reflection in the others.



Introduction

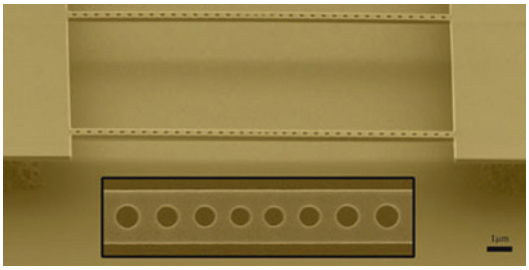
On-chip manipulation of light is of great importance for applications ranging from optoelectronics and nonlinear optics to biochemical sensing and cavity quantum electrodynamics. Ultra-high quality factor (Q) optical resonators are



indispensable for these applications since they enhance the probability of light-matter interaction due to their ability to store photons for many optical cycles [1]. Traveling-wave-based resonators, and micro-toroid resonators in particular, have been used to achieve some of the largest Q factors to date [1]. For many applications, however, the figure of merit is proportional to the ratio between resonator's Q and mode volume (V_{mode}), which can be quite large in traveling-wave geometries. Therefore, standing-wave optical resonators, capable of having very small mode volume, have been explored as an attractive alternative [1]. These structures, based on a Fabry-Perot geometry, typically consist of the region in which light can propagate (e.g., an optical waveguide), terminated at its both ends with optical mirrors. The mirrors are often in the form of a 1-D Bragg mirror, as in the case of vertical cavity surface emitting laser (VCSEL), for example. In 1987, the Bragg mirror idea was extended to 3-D by Yablonovitch [2] and John [3] who proposed 3-D photonic crystals as a platform suitable for realization of ultimate cavities with wavelength-scale mode volumes and ultra-high Qs. Unfortunately, fabrication of these 3-D periodic optical structures has proven to be challenging and in spite of great effort no ultra-high Q small mode volume cavity based on 3-D photonic crystals has been realized to date. This prompted researchers to consider alternative approaches, based on lower-dimensionality photonic crystals. In particular, planar photonics crystals, based on 2-D periodic lattices realized in thin semiconductor membranes [4] received considerable interest due to the ease of fabrication and compatibility with standard planar microfabrication technology. State-of-the-art fabrication techniques, combined with creative cavity designs, have resulted in wavelength-scale optical cavities with $Q > 10^6$ (experimental) and Q/V_{mode} values larger than traveling wave resonators. Recently, however, it has been demonstrated that photonic crystals with even lower dimensionality, resembling some of the early distributed feedback (DFB) cavity designs, can be used to realize cavities with performance rivaling and even outperforming those based on 2-D planar photonic crystals. These photonic crystal nanobeam cavities (PCNCs), based on chirped 1-D optical lattices, also have a physical footprint which is exactly the same as that of an optical waveguide and therefore, represent the smallest cavity geometry that can be made using dielectric materials only. Furthermore, nanobeams enable realization of high-Q small-V_{mode} cavities even in low-index materials (e.g., SiO_2, polymers) [5, 6], thus vastly increasing the library of photonic materials suitable for realization of ultra-high Q/V_{mode} cavities. The near-field of PCNCs is highly accessible, which allows for easy light-material interaction and which is useful for sensing [6], optical trapping [7], and optomechanics [8, 9]. PCNCs can be easily and naturally integrated with optical waveguides for efficient delivery of light [10, 11]. Cavities that support ultra-high Q modes with both TE and TM polarization [12] can be easily realized. All of these features, many of which are hard to achieve using 2-D photonic crystals, make photonic crystal nanobeam cavities an ideal platform for practical applications.

Design Evolution

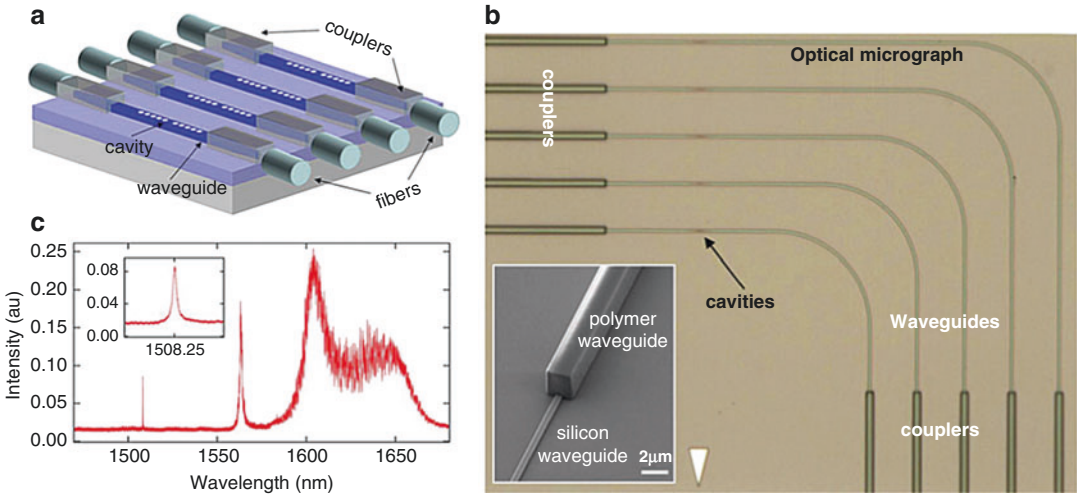
The idea of waveguide-based micro-cavities has been around for more than 15 years. It was first proposed at MIT [13] in 1995 and then experimentally realized 2 years later [14]. Figure 1a shows the schematic of the device which consisted of a waveguide segment surrounded with two lattices of holes that play the role of Bragg mirrors. Light trapping is achieved in this system via a combination of Bragg scattering (in longitudinal direction) and total internal reflection (in two transverse directions), resulting in an optical resonance as shown in Fig. 1b. The theoretical value of Q was calculated to be $Q = 280$ whereas the experimentally measured value was 265 (Fig. 1c). Such a low value of Q factor was due to the suboptimal design. In particular, light scattering at the interface between the Bragg mirror and the central cavity region was responsible for the low Q factor (Fig. 2a) due to the mismatch in the effective mode indices of the two regions.



Photonic Crystal Nanobeam Cavities, Fig. 1 (**a**) Schematic of photonic crystal nanobeam cavity (PCNC) (**b**) simulated transmission of the device showing the bandgap and the cavity resonance [13] (**c**) SEM image of the fabricated device. The measure Q of the device was 265 [14]

Photonic Crystal Nanobeam Cavities, Fig. 2 (**a**) Schematic showing the effect of taper on scattering loss due to mismatch of the waveguide mode and the Bloch mode. Cavity mode electric field (Ey) for a 7-hole taper (**b**) simulated results from [16] showing the variation in Q and mode volume for different taper and cavity lengths. Cavity length was defined as the distance between two innermost holes (indicated in Part **a**)

In order to increase the Q of the cavity it is necessary to *taper* propagating mode of the cavity region into the exponentially decaying mode of the Bragg mirror [15, 16]. This mode matching, analogous to impedance matching problem in electronics, can be achieved using a multi-hole taper toward the cavity [15]. By doing so, the waveguide mode index can slowly be reduced to match the Bragg index which significantly reduces the scattering and provides exponential increase in cavity Q, at an expense of slight, linear increase in the cavity mode volume. By increasing



the number of holes used in the taper, near adiabatic conversion between the two modes could be achieved. By putting two of such engineered tapered (chirped) mirrors back to back, ultra high-Q cavity could be realized. The electric field of a cavity mode formed by using a 7-hole taper is shown in Fig. 2a. The effect of tapered holes on the Q and mode volume was first studied in silicon nitride material system for operation in visible [16] and the results are shown in Fig. 2b. The figure shows Q as a function of cavity length, defined as distance between two central holes in the structure, for two different numbers of tapered holes used in the mirror. It can be seen that the drastic increase in Q can be achieved for an optimal value of the cavity length. Also, it is apparent that the Q values depend strongly on the precise cavity length which puts stringent requirement on the fabrication quality needed for the realization of ultra-high Q cavities.

Ultra-High Q Nanobeam Cavities

In order to validate the designs, devices were fabricated in silicon-on-insulator (SOI) material platform (Fig. 3) using state-of-the art nanofabrication technology. The highest Q measured in such cavities that operated in telecom wavelength range was 750,000 [17]. The cavities were probed using a free-space cross-polarization technique popularly known as resonance scattering. This technique is relatively straightforward to implement but suffers from poor in- and out-coupling of light, in particular in the case of high-Q cavity modes. Other characterization techniques that have been used to characterize nanobeam cavities include evanescent coupling using a tapered fiber [8] and butt coupling [10] (Fig. 4a). The latter technique, particularly suitable for realization of integrated on-chip

Photonic Crystal Nanobeam Cavities, Fig. 4 (**a**) Schematic showing butt coupling technique using spot-size converter couplers based on polymer waveguides and inverse-tapered silicon waveguides. (**b**) Optical micrograph showing the fabricated device with the in- and out-coupling pads, silicon waveguide, and PCNC. Inset shows an SEM image of the polymer coupling pads. networks, takes advantage of spot-size converters to couple light from tapered optical fiber into the on-chip optical waveguide. In this case, the converter is in the form of polymer (SU-8 photoresist) waveguides (ref. Fig. 4b) whose cross-section and resulting mode profile is comparable to the spot emerging from the tapered optical fiber. Light is then adiabatically coupled from polymer waveguide into the silicon waveguide using the inverse taper geometry, and then from the silicon waveguide into the nanobeam cavity using adiabatically tapered photonic crystal [10, 11].

Efficient coupling of light into the cavity is achieved by using hole taper similar to the one described earlier [11]. Light transmitted through the system is collected by a second spot-size converter and tapered fiber. Figure 4b shows an optical micrograph of such a fabricated structure with the input coupling pads, silicon waveguides, cavities, and output coupling pads. Inset shows the zoomed-in image of the polymer coupling pad. Coupling efficiencies as high as 80 % over more than 150 nm could be achieved using this technique. The transmission spectrum shown in Fig. 4c features the excellent quality of signal to noise achieved using the above technique. The inset shows the zoomed region around the cavity resonance.

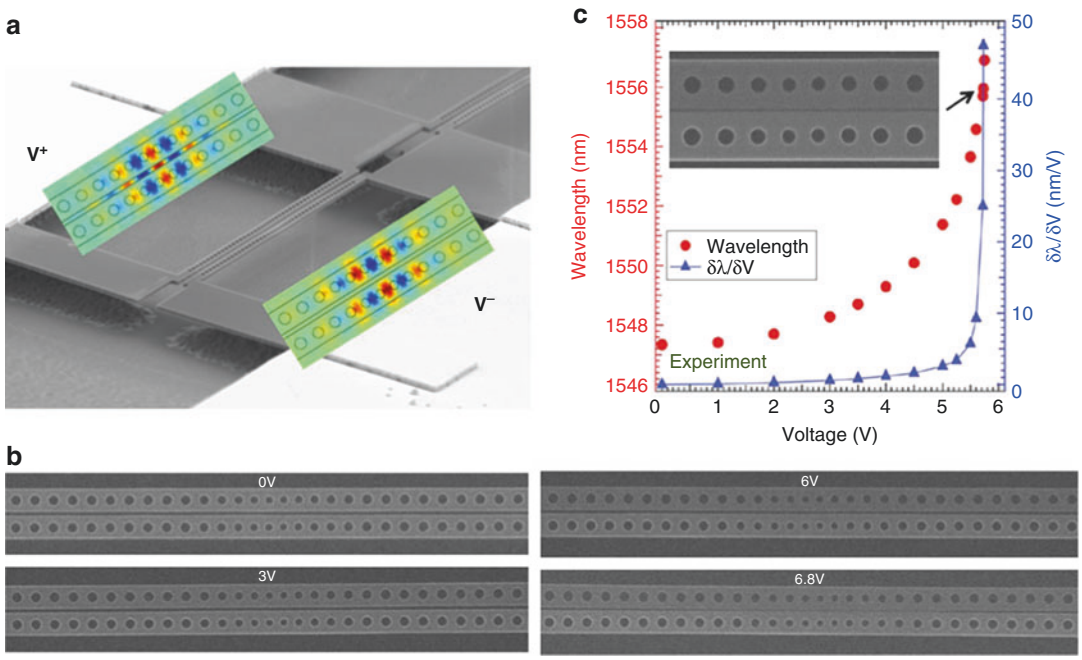
There have been quite a few variations in the design of the periodic structure of the ultra-high Q nanobeam cavity, including ladder cavities [18] with rectangular holes, bookshelf/domino structures [18], and parabolic width-taper cavity [19]. However, the working principle of all of these approaches is the same and is based on efficient effective index matching between cavity and mirror regions. Another common feature of all the different design strategies is that they are all intuition-based and involve extensive parameter search and trial-and-error-based optimization in order to find the optimal taper profile (the radius and spacing of the holes in the taper section). To overcome these limitations and streamline the design process, thus significantly reducing the time needed for the design of ultra-high Q structures, a deterministic method to design ultra-high Q cavities has recently been proposed and experimentally demonstrated [10]. This approach not only eliminates trial-and-error-based shifting and resizing of holes, but also results in cavities that feature high transmission at the cavity resonance: $Q > 10^7$ with transmission of 97 % (Fig. 5).

As mentioned in the introduction, nanobeam cavities enable realization of ultra-high Q cavities, with small mode volumes, even in materials with low refractive index. This is typically very hard to achieve using 2-D planar photonic crystals since the bandgap is typically closed due to low-index contrast. Nanobeam cavities do not suffer from this problem since 1-D bandgap is always open even for the smallest index modulation. Recently, high-Q all-polymer cavities with index contrast between core (cavity material) and cladding as low as 1.15 have been experimentally demonstrated [6].

Finally, it has been demonstrated that photonic crystal nanobeam cavities also play a role of *phononic crystals* and are capable of localizing phonons [9]. Furthermore, simultaneous confinement of photons and phonons allows for strong interaction between mechanical and optical excitations, thus enabling both exploration of exciting physics at nanoscale and realization of novel

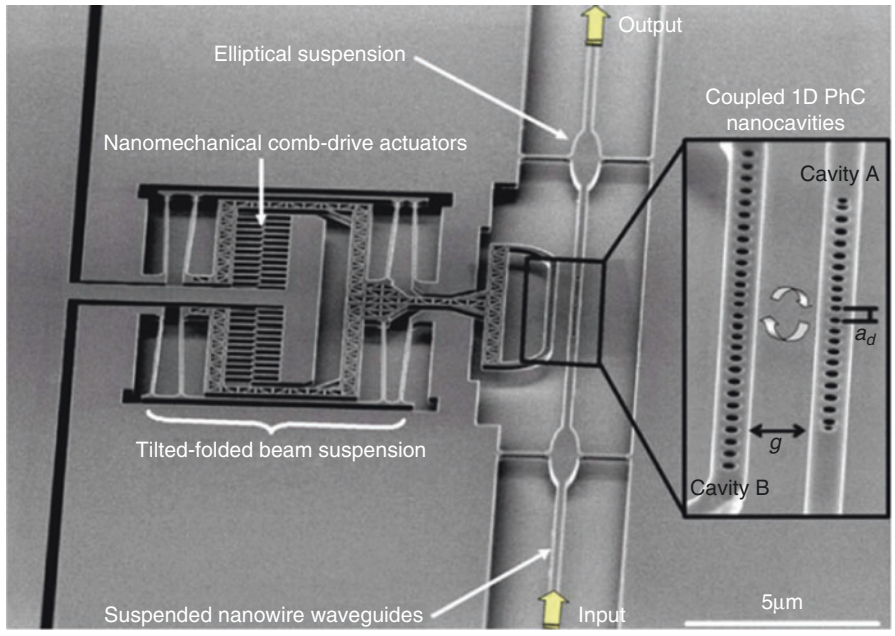
devices. For example, electromagnetically induced transparency (EIT) in photonic/phononic crystal nanobeam cavity was demonstrated and successfully used to alter the group velocity of light thus realizing optical delay lines of interest for optical buffering, filtering, and signal processing [20].

Applications



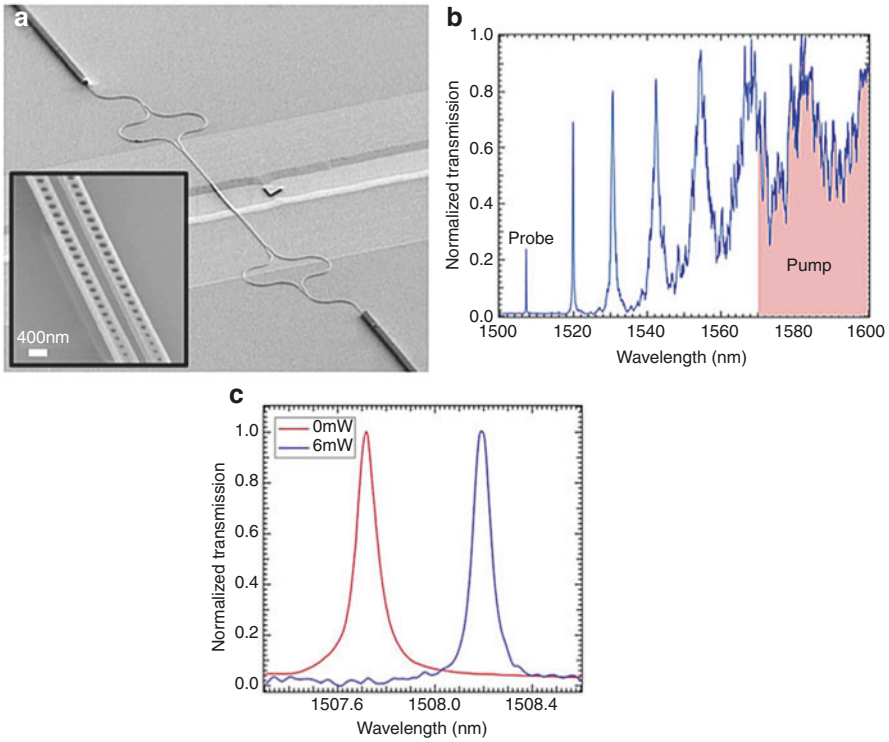
One promising application of nanobeam cavities is realization of compact optical filters and spectrometers. However, due to fabrication limitations, some degree of post-fabrication wavelength trimming is needed in order to bring the resonance of the filter (cavity) to the desired wavelength. Moreover, optical devices that could be dynamically and reversibly configured to operate at vastly different wavelengths (optical analog to FPGAs) would be of great interest for practical applications. Conventional techniques, based on thermal effects and free carrier injection, suffer from high steady-state power consumption and small tuning range, respectively. These limitations can be overcome by taking advantage of mechanical degrees of freedom of suspended photonic crystal nanobeam resonators.

Using coupled photonic crystal nanobeam cavities [21], a reconfigurable photonic crystal filter [22] that can be dynamically, continuously, and reversibly tuned over a wide wavelength range was proposed and demonstrated. These devices, which combine the fields of NEMS and nanophotonics, consist of two doubly clamped photonic crystal nanobeam cavities separated by a gap smaller than 100 nm. Coupling between cavity modes results in two super modes with even and odd symmetry [8, 21] – the situation analogous to coupled quantum wells.



The symmetric mode of such coupled system is extremely dispersive to the separation between the nanobeams which allows for the tuning of this mode by controlling the separation. On the other hand, the asymmetric mode of the system is virtually insensitive to the changes in the separation, which can be attributed to higher-order effects such as a coupling-induced frequency shift [21]. The separation between nanobeams can be controlled using capacitive force, for example: An external bias voltage can be applied to two gold electrodes (Fig. 6a) that are in contact with Si with which the cavities were made of. In this way, the two cavities form the plates of a parallel plate capacitor. The capacitive force is strong enough to bend the beams toward each other as shown in Fig. 6b, which in turn has a strong effect on the resonant wavelength of the structure. Using this approach, tunable filters with a tuning range of $\sim$10 nm for less than 6 V bias and negligible steady-state power consumption were demonstrated. The latter is a very important feature, because once reconfigured, *they do not dissipate any power*. In addition, due to their low mass and flexibility, the energy required to deflect nanobeams is extremely low, and is estimated to be well below the femtojoule level. Therefore, nanoscale optomechanical devices can be used to realize programmable optical systems that can be pre-configured (and reconfigured) using electrical signals, and will likely find applications in low-power optical circuit switching and programmable photonics. It should also be noted that when properly biased, only a few mV of additional electrical signal is enough to move the nanobeams and induce the shift in cavity resonance larger than one linewidth, thus completely detuning the cavity from the incoming optical signal (originally in resonance with the structure) [22].

Significant improvements in the tuning range can be obtained by using more sophisticated actuation methods. For example, Fig. 7 shows a tuning technique that uses a mechanical comb drive to move one of the cavities thus changing the gap between the cavities and resonance of the system [23]. This technique can achieve extremely small gaps as it does not suffer from the pull-in effects which can be detrimental for capacitive actuation approach discussed above.



In addition to electrical actuation, nanoscale optical devices can be actuated using light [8, 24]. Figure 8a shows a structure consisting of freestanding coupled nanobeam cavities interfaced with optical waveguides and fiber couplers (for efficient in- and out-coupling of light). Optical transmission through the system

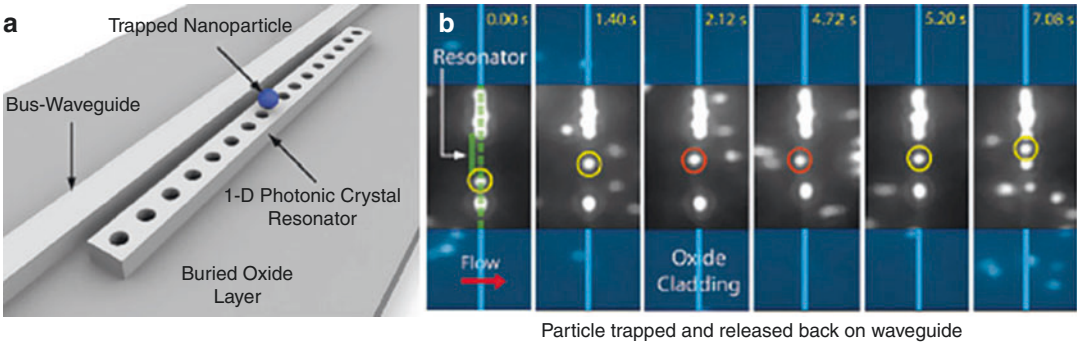
(**b**) A transmission spectrum of the fabricated cavity. The even cavity mode – *probe* – is at ~1,507 nm (Q ~15,000) and the *shaded* region can be used to pump outside the bandgap. (**c**) Cavity resonance was tuned from 1,507.72 to 1,508.19 nm when 6 mW of *pump* power at 1,583 nm was used. Cavity tuning was due to contribution from thermo-optical, nonlinear, optical, and optomechanical effects

(experimental) is shown in Fig. 8b, whereas the tuning of cavity resonance for 6 mW of pump power at 1,583 nm is shown in Fig. 8c. The cavity tuning was due to contributions from thermo-optical, nonlinear optical, and optomechanical effects [24].



Alternatively, optomechanical systems can be used to read out mechanical motion optically. Figure 9 shows the mechanical spectrum of the structure in air (mechanical modes excited by Brownian motion), detected by monitoring optical transmission through the device. However, it is important to note that this measurement also affects the mechanical properties of the devices, as seen in Fig. 9: Optical signal can stiffen or soften mechanical resonances (induce an additional effective spring constant) via optical gradient force [8].

Owing to their small mode volume and footprint, nanobeam cavities are also excellent candidates for the realization of low-threshold nanolasers with a large spontaneous emission (β) factor [19, 25]. Furthermore, it is possible to realize tunable/programmable nanolasers by taking advantage of mechanical degrees of freedom of coupled nanobeam cavities, as discussed above [26]. PCNCs can also be designed to support TE and TM modes simultaneously, which is of interest for nonlinear frequency conversions [12]. Scaling properties of photonic crystals can be used in PCNCs to design cavities in microwave regime allowing for integrating of RF with photonics. Finally, PCNCs are excellent candidates for applications in sensing [6, 7] and for manipulation of particles suspended in fluid (optical trapping). Figure 10a shows the schematic of the device

Outlook

Nanobeam photonic crystal cavities have developed significantly since they were first proposed more than a decade ago. Greater understanding and improvements in the design methods along with the advancement in nanofabrication processes has significantly helped research outgrow the challenges in making ultra-high Q wavelength-scale optical resonators. The last few years of research has seen nanobeam photonic crystal cavities mature as a photonic device and allowed researchers to not only solve current technological problems but also explore new research areas involving enhanced light-matter interaction. Their use in tunable filters, switches, delay lines, sensing, particle manipulation, etc., has already been demonstrated. Their wavelength-scale dimensions, flexible structure, and small footprint area along with the scalable nature make them ideal to be used for applications in the entire electromagnetic spectrum. Emerging areas of research include RF, Terahertz, and Mid-IR photonics.

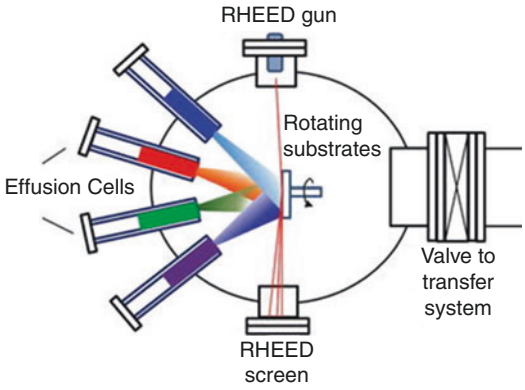
Definition

Physical vapor deposition (PVD) is referred to deposition processes of thin films and nanostructures through the evaporation of solid precursors into their vapor phase by physical approaches followed by the condensation of the vapor phase on substrates. The whole process consists of three stages: (1) evaporation of the solid source, (2) vapor phase transport from the source to the substrates, and (3) vapor condensation on the substrates. Since PVD technique can convert solid materials into vapor phase without chemical processes, they are very convenient and possible to deposit many types of materials into thin films and nanostructures.



Classification

PVD techniques can be classified based on the techniques used to evaporate the solid source materials into their vapor phase [1, 2]. These techniques include (1) thermal evaporation, (2) ion sputtering, and (3) arc discharge. In the following subsections, examples of PVD based on these evaporation techniques will be described.

PVD by Thermal Evaporation

Molecular Beam Epitaxy

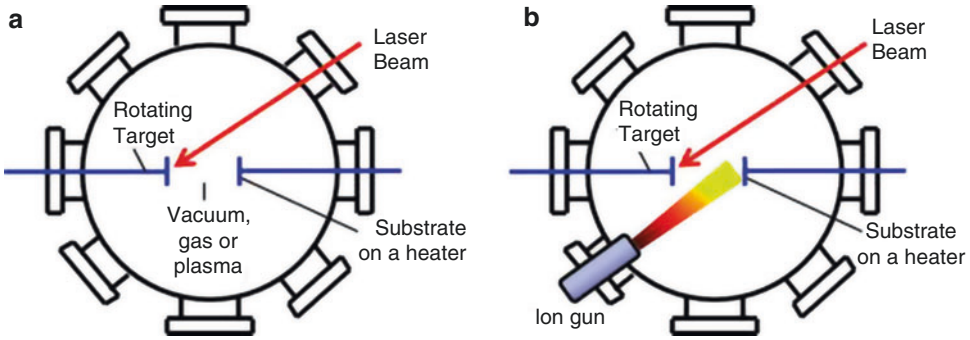
Molecular beam epitaxy (*MBE*) is a PVD technique conducted under ultrahigh vacuum (UHV, better than 10^{-9} mbar) where epitaxial deposition of thin film crystal on crystalline substrates can be obtained by using one or more vapor sources (*effusion cells* or sometimes called *Knudsen cells*). An effusion cell consists of a crucible (made of graphite, pyrolytic boron nitride, quartz, or tungsten) where the solid source can be heated and evaporated by hot filaments (Fig. 1). For example, powders of gallium (Ga) and arsenic (As) can be evaporated in separated cells until they are sublimate into vapors. When these separated beams of element vapors are condensed on a heated Si substrate, crystallized thin films of gallium arsenide (GaAs) will be formed. A typical MBE system has a reflection high-energy electron diffraction (RHEED) system to provide in situ monitoring of the crystal growth processes.

Physical Vapor Deposition, Fig. 1 Schematic drawing of a typical molecular beam epitaxy system

The major advantage of MBE comes from its controllable deposition rate at the atomic or molecular scale. This can be achieved due to the use of effusion cells that enable the generation of "molecular beam," where the generated vapors have low interparticle collisions before they reach to the substrate surface. This means the evaporated atoms escape from the orifice of the cells through effusion and have long mean free path. They neither interact with each other nor with the gases in the vacuum chamber. Due to this capability, MBE was recently used for the growth of graphene, but the outcome is debatable [3, 4]. Finally, gases were also used as the precursors instead of solid sources, and such configuration is called *gas-phase MBE* or more appropriately *chemical beam epitaxial* (*CBE*) [5].

In this case, the pyrolysis of either trimethylindium (TMIn) or triethylindium (TEIn) and trimethylgallium (TMGa) or triethylgallium (TEGa) at the heated substrates was used as the In and Ga source, while As_2 and P_2 were obtained by thermal decomposition of the trimethylarsine (TMAs) and triethylphosphine (TEP). Such approach is more like a combined MBE and *metal-organic chemical vapor deposition* (*MOCVD*) and is sometimes called *metal-organic molecular beam epitaxy* (*MOMBE*).

In fact, *MBE* is an advanced form of thermal evaporation technique with highly controllable deposition thickness (and thus with the drawback of slow deposition rate) due to the use of effusion cells and high vacuum. For the deposition of amorphous thin films, much simple setup can be employed with less demanding vacuum level ($\sim 10^{-2}$ mbar in a glass bell jar chamber). This approach is simply called *direct resistive evaporation* and can be achieved by passing a large current through a resistive wire or foil containing the solid material to be deposited. The heating element is often referred to as an "evaporation source." The evaporation source can appear in many forms including tungsten wires in the form of filaments or baskets and thin tungsten, tantalum, or molybdenum foils in the form of boats.



PVD by Electron Beam (E-Beam) Evaporation

In contrast to *MBE*, e*lectron beam physical vapor deposition* (*EBPVD*) provides very high deposition rate on large deposition areas. *EBPVD* is referring to thin film deposition initiated by electron beam evaporation. The deposition rate is typically ranging from tens of nanometer/minute to hundreds of micrometer/minute, although a rate as high as 50 μm/s was reported [6]. *EBPVD* is based on electron beam evaporation of anode materials (usually in ingot form) in high vacuum (10^{-4} mbar). A typical *EBPVD* system can have multiple electron guns and sources. The electron beams can be generated by either thermionic emission or field emission of filaments. These beams are then accelerated to a high kinetic energy and focused on the ingot. The energy of these electrons is converted into thermal energy as the beam bombards the surface of the ingot. The high deposition rate of *EBPVD* without corrosive products meets the needs of industrial applications. A potential drawback of *EBPVD* is that filament degradation in the electron gun results in a nonuniform evaporation rate. In addition, *EBPVD* may cost contamination of the deposition chamber as the vapors generated from the source materials are coated everywhere in the vacuum chamber, the so-called line-of-sight process.

Pulsed Laser Deposition

Pulsed laser deposition (*PLD*) is a *PVD* technique where a high-power pulsed laser is used to generate vapors (i.e., laser ablation) from a solid target followed by the condensation of the vapors on substrates. The experimental setup for *PLD* is relatively simpler than many PVD techniques, but the laser ablation mechanism is quite complex [7]. As shown in Fig. 2a, a *PLD* system consists of a pulsed laser, a vacuum chamber with a rotating target holder, and a substrate holder with a heater. *PLD* can be performed in vacuum at various substrate temperatures. During film deposition, laser pulses are focused on the surface of a solid target through a viewport of the chamber by using a thin lens. This will generate a laser spot with very high *irradiance* (*I*, power per unit area) and local electric field, where $I = \frac{1}{2}\varepsilon_o c E_o^2$ [8]. Here, E_o is the amplitude of electric field of the laser, c is the speed of light in vacuum, and ϵ_0 is the vacuum permittivity. The local electric field is sufficient to cause atomic bond breaking and dielectric breakdown of the target materials to initiate vaporization of the target materials. This vapor will absorb the remaining portion of the laser pulse, and the electric field of the pulse will accelerate electrons and ions inside the vapor to create rapid heating and to form laser plasma. Continued absorption of the laser pulse will cause a highly directional expansion of the laser plasma perpendicular to the target surface. This expanding vapor is called laser plume that propagates toward the substrate placed several centimeters opposite to the target.

PLD can be conducted in vacuum or in a low-pressured gas ambient. When *PLD* is conducted in reactive gas ambient (say oxygen or nitrogen), the technique is called *reactive PLD*. In this case, the expanding laser plume

Physical Vapor Deposition, Fig. 2 Schematic drawings of a typical pulsed laser deposition (*PLD*) system operated (**a**) in vacuum or with auxiliary plasma or (**b**) with auxiliary ion beam

will form shock waves and cause chemical reaction between the target vapor and the gas molecules. *PLD* can also be modified into various configurations. For example, plasma can be applied to enhance the interaction of the vapors with the gas ambient, and the technique is called *plasma-enhanced or plasma-assisted PLD*. For example, such an approach was shown to control the phases of nitride thin films [9, 10]. Sometimes, an auxiliary ion beam is irradiated on the surface of the substrates during thin film deposition as shown in Fig. 2b, and the technique is called *ion beam-assisted PLD*.

In fact, the mechanism of laser ablation and the quality of samples deposited by PLD depend strongly on the wavelength and energy of the pulsed laser. This can be understood by the absorption of the laser light by the laser plasma when the plasma index of refraction, $n(\omega)$, becomes complex. According to the relation $n^2(\omega) = 1 - [\omega_p/\omega]^2$, a complex $n(\omega)$ will occur when $\omega_p > \omega$ [8]. This means, shorter laser wavelength (larger ω) will reduce the chances of such plasma heating effect. However, one should also consider that the laser plasma frequency, $\omega_p = [N\ e^2\ m_e\ \varepsilon_0]^{1/2}$, where m_e is the mass of electron and N is the electron density. In this case, to avoid plasma heating, N must be minimized, which can be obtained by keeping the laser energy or irradiance low. Plasma heating will lead to the so-called photothermal ablation. For example, photothermal ablation of h-BN target will transfer h-BN target to the substrates and prevent the formation of cubic phase (c-BN) [8]. Photothermal ablation of graphite target at longer laser wavelength will also prevent the formation of diamond-like carbon film [11] as the sp^2 species from the graphite are transferred to the substrates.

PVD by Sputtering

Sputtering is a process where atoms are released from a solid target material due to bombardment of the target by energetic particles such as ions and atoms. The atoms released from the target can then be deposited as thin film on substrates and is commonly referred as PVD by sputtering. The physics behind the process is momentum transfer from the incident ions/atoms to the target materials through collisions. The average number of atoms ejected from the target per incident particle is called the sputter yield. The yield depends on the ion incident angle, the energy of the ion, the masses of the ion and target atoms, the surface binding energy of atoms in the target, and the crystalline orientation of the target when crystals are used as the target. There are many approaches to generate sputter including the use of DC, AC, and RF plasmas or external ion beams.

Sputtering offers several advantages over other PVD techniques including (1) large area deposition as compared to PLD, (2) convenience for thin film deposition of alloy/composite and materials with high melting points, and (3) avoidance of device damaging from X-rays generated by electron beam evaporation. However, sputtering also has the following disadvantages: (1) more

complicated setup than PLD, (2) contamination more likely to occur due to the use of plasma as well as relatively lesser vacuum level, and (3) the film morphology that may be rougher and even damaged due to bombardment of energetic growth species and clustering of the growth species in the relatively high deposition pressures.

PVD by DC, AC, RF, and Magnetron Sputtering

PVD can be obtained by applying plasma in various configurations. The simplest one is to apply a DC potential across the substrate (anode) and target (cathode). In this case, plasma can be generated when gases are introduced (10–100s of mTorr) at sufficient electric field strength ($\sim$ a few kV/cm). For example, argon gas is often used, as argon ion can lead to high sputter yield and uniform glow discharge. These Ar ions will bombard the target surface to generate vapors that will be deposited to the substrates. Despite the simplicity, the DC configuration will have the following issues: (1) positive charges will build up on the target surface and cause sparking within the plasma and (2) not suitable for insulating target. To avoid these issues, AC and RF configurations are often used. In these cases, the potential between the target and substrate is alternating so that the target will be negative in potential more often (to generate sputtering) than positive potential. These configurations will also allow lower operation pressure ($\sim$10–30 mTorr).

The use of magnetron can further enhance the deposition rate at even lower pressures by the use of DC, AC, or RF electric fields. RF potential is of advantage, since it can be used for insulating targets and is applicable in an antenna configuration, that is, without positive bias voltages on the substrates (less electron bombardments and less substrate heating). In this case, the target is placed on the magnetron surrounded by strong electric and magnetic fields. Electrons in the RF plasma will follow helical paths around the magnetic field lines and generate more ionizing collisions near the target surface with the surrounding gas. Thus, more ions will be created and will lead to a higher sputtering and deposition rates. Because of higher ionization rates, plasma can be sustained at a lower pressure.

PVD by Ion Beam Sputtering

Ion beam sputtering (*IBS*) is a PVD technique in which the target is evaporated by an external ion source (ion beam). In a typical ion source, ions are generated by collisions of neutral gas atoms/molecules with electrons. They are then accelerated by the electric field by a grid electrode toward the target. Before these ions leave the source, they are neutralized by electrons from a second external filament. The major advantage of PVD by *IBS* is that the energy and flux of ions can be controlled independently. In addition, the *IBS* approach is applicable to insulating and conducting targets since the flux of "ions" (which are neutralized as they are emitted from the ion beam) that strikes the target is composed of neutral atoms/molecules.

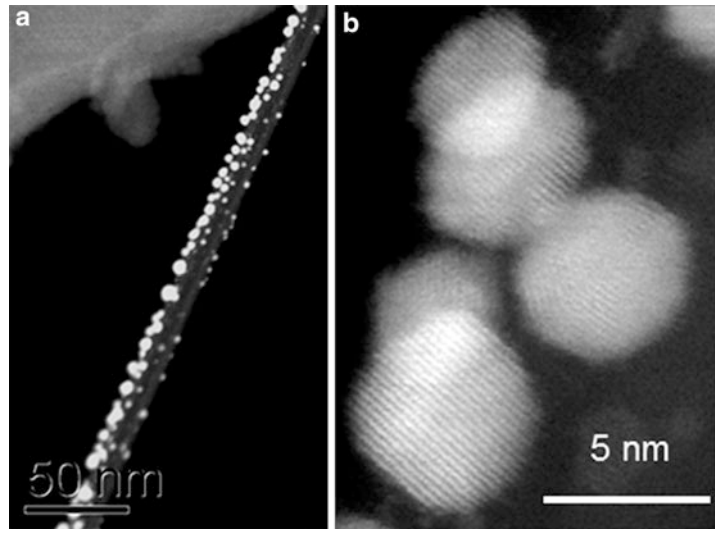
Reactive Sputtering

Like the PLD process, reactive sputtering can be achieved by mixing reactive gases (N_2, O_2, etc.) with the inert gas (Ar, Kr, etc.). While the inert gas is responsible for the sputtering of the target materials, the reactive gases are used to initiate chemical reactions with the target vapors to form oxide or nitride films. Like *PLD*, reactive sputtering can also be achieved by various configurations. For example, plasma can be applied to enhance the interaction between the target vapors and the reactive gas ambient, and the technique is called *plasma-enhanced or plasma-assisted deposition*. Sometimes, an auxiliary ion beam is irradiated on the surface of the substrates during thin film deposition, and the technique is called *ion beam-assisted deposition* (*IBAD*).

PVD by Arc Discharge

In addition to PVD by thermal evaporation and sputtering, the desired vapors for thin film deposition can be obtained by arc discharge of the target. This is sometimes called *arc vapor deposition* [1], where a high-current (10^4–10^6 A/cm^2), low-voltage (tens of voltages) discharge was applied on the target. For example, *cathodic arc deposition* refers to arc vapor deposition using the target as the cathode. In this case, a high-voltage "trigger arc" will be ignited between the cathode and a sharp auxiliary anode. This will form "seed"

electrons and ions to initiate a low-voltage, high-current discharge between the target cathode and the adjacent anode.



On the other hand, target materials can be evaporated by using the target as the anode of the arc discharge. This PVD process is referred as *anodic arc deposition*. In fact, this process is similar to e*lectron beam physical vapor deposition* (*EBPVD*) discussed earlier, where arc discharge is generated by irradiating an unfocused electron beam on the target anode. The electrons can be made to spiral in a magnetic field to further ionize the evaporated materials from the target prior to deposition. Like most other PVD processes, *reactive arc vapor deposition* can be performed by both *anodic arc deposition* and *cathodic arc deposition* using reactive gases like nitrogen and oxygen. This will lead to the formation of nitride and oxide films.

The deposition rates of *arc vapor deposition* are usually higher than that of PVD by sputtering. This is one of the advantages of *anodic arc deposition* and *cathodic arc deposition* in addition to the low operation voltage. On the other hand, contamination is the potential drawback of most plasma-based PVD processes. In addition, particulates or the so-called macros are undesired for thin films deposited by *anodic arc deposition* and *cathodic arc deposition*. Macros are formed by ablation of molten or solid particles by thermal shock during arc discharges.

Examples of PVD Approaches for Nanotechnology

Physical evaporation techniques like arc discharge [12] and laser ablation [13] are important on the discovery of carbon nanotubes (CNTs). However, PVD techniques discussed here are not popular for the growth of nanomaterials in comparison to chemical vapor deposition (CVD). The major reason is the tendency of forming thin films and amorphous by-products on the surfaces of catalysts which cause "poisoning" effect and prohibit the formation of nanotubes or nanowires [14]. However, there have been some pioneering works reported on the growth of nanotubes and nanowires by PVD techniques such as sputtering, PLD, and MBE. For example, vertically aligned carbon nanotubes (CNTs) were first successfully deposited by RF plasma-assisted pulsed laser deposition [15]. In this approach, two RF plasmas were employed. The first one was applied on the substrates to form a negative bias voltage during deposition. The second one was applied on a ring electrode located between the graphite target and the substrates. Hydrogen gas was used for the plasma generation, and Fe powders (20 nm in diameter) were employed as the catalysts. Although the density of these CNTs is low, these nanotubes have high structural order with internal nanotube diameter as small as 0.4 nm. The formation of these smallest possible CNTs was confirmed by transmission electron microscopy (TEM). Later, CNTs were deposited by magnetron sputtering with a dc bias voltage on substrates [16]. Prior to the growth of CNTs, Ni films (10 nm thick) were deposited by e-beam evaporation to form nanoparticles that later function as the catalyst for the vapor–liquid–solid (VLS) process. However, these CNTs are defective with bamboo-like structures. Later, RF plasma-assisted pulsed laser deposition was used to achieve low-temperature growth of boron nitride nanotubes (BNNTs) [14, 17]. In this case, pyrolytic boron nitride pallets were used as the targets, and a RF plasma was applied on the substrates to create bias voltages, which are important to eliminate the formation of boron nitride thin films. Again, these BNNTs have internal nanotubes of 1 nm in diameter with high structural order.

Various PVD approaches were also employed for the synthesis of nanowires/nanorods. For example, ZnO and Zn_{1-x} Mg_x O nanorods were grown by MBE on oxidized Si substrate coated with Ag catalyst [18]. In both cases, an ozone/oxygen mixture was used as the oxidizing source. The Zn and Mg cation fluxes were provided by a Knudsen effusion cell using high purity Zn and Mg metals as the sources. The growth of vertically aligned ZnO [19] and MgO [20] nanowires can also be obtained by PLD using ZnO or MgO targets, respectively. Gold particles were used as the catalysts for both cases.

More recently, PLD was shown to produce gold nanoparticles on the wide band gap (~6 eV) boron nitride nanotubes (BNNTs) [21]. These nanoparticles have functionalized the electrically insulating BNNTs to become the tunneling channel of tunneling field effect transistors (TFETs) without involving any semiconducting properties. Such transistors without the use of semiconductors are interesting as these TFETs by-pass many fundamental issues of semiconducting FETs such as leakage current, short channel effect, and high contact resistance when the devices are scaled down to the quantum limits. Because of the related tunneling effect, these gold nanoparticles' functionalized BNNTs are called quantum dots' (QDs) functionalized BNNTs (QDs-BNNTs). As shown in Fig. 3, gold QDs smaller than 10 nm are preferentially coated on one side of the BNNT.

Definition

Enhancement or modifications of properties in the nanometric range is the core of nanotechnologies. Nanoparticles exhibit size-related properties that differ significantly from those observed in fine particles or bulk materials. Properties can be intrinsic (e.g., electrical, magnetic, optical, etc.) or extrinsic (e.g., aggregation state, surface area, etc.). Then what makes nanoparticles so attractive also raises questions of "new" toxic "nano-effects." It is then worth trying to identify which specific properties can generate biological harmful effects.

More than these "new" nano-properties aspects, the second issue is to manufacture materials that incorporate those nanoparticles. Then exposure to nanoparticles will depend not only on intrinsic properties of nanoparticles, but also on extrinsic properties related to the stability and durability of their incorporation.

Overview

Introduction

The success story of nanoparticles in many scientific and technological fields is based on their unique physicochemical properties and reactivity. Indeed engineered nanoparticles are designed to exhibit specific optical, electronic, magnetic, or chemical properties that are strongly related to the exponential increase in the number of atoms localized at the surface as the size decreases [1]. However, the uniqueness of nanoparticles that makes them so attractive may also raise questions about the environmental and health risk they could generate. Indeed is there any relation between their new physicochemical properties and potential new biological hazards?

Moreover the tremendous development of nanotechnologies leads to a huge variety of manufactured nanoparticles with varying chemical composition, size, shape, crystal structure, surface area, surface chemistry and charge, solubility... etc., e.g., [1].

It is therefore challenging to determine which of those unique intrinsic or extrinsic properties can be at the origin of their biological danger. In the following, we will focus on the different properties, how to determine their evolution in biological media and how they can affect living organisms.

Physicochemical Properties of Nanoparticles

Even if there is no consensus concerning the definition of engineered nanoparticles, most of the definitions indicate that besides the size, "*Novel properties differentiate nanoparticles from the bulk material typically develop at a critical length scale of under 100 nm*" or "*phenomena not observed in larger structures start to become apparent . . .*". But what are these novel properties or phenomena not observed for larger structures? What is the size at which the latter properties occur? One of the most emblematic example concerns gold. Indeed gold has been a topic of fascination since its discovery in almost all ancient and modern civilizations. Gold preserve its brightness for years which made his high value for art. Everybody has in mind that the magnificent death mask of Egyptian pharaoh Tutankhamun is made of gold. Moreover, gold chemical inertness is related to its high monetary value [2]. But its chemical inertness is a matter of size since at the nanoscale it can be exceptionally active as a catalyst for instance but only for particles below 2–3 nm [3].

Among the vast diversity of engineered nanoparticles, many other properties can be tailored in different scientific and technological fields. Indeed optical properties can be modified to use nanoparticles as biological dyes for instance. QDots are of good examples to trace, label, or image biological organisms or cells. In the case of QDots, the band gap energy (related to the fluorescence wavelength that is to say the color) is constant for large particles whatever their size but only if larger than 6–8 nm. The bandgap energy strongly increases when size of particles decreases below 6–8 nm. Photocatalytic properties may also be tailored not only as function of size, but also as function as the crystal structure. TiO_2 anatase phase exhibits optimum photocatalytic degradation of organic contaminants at various sizes that are much below 100 nm (e.g., ~7 nm for trichloroethylene or around 11 nm for chloroform). But in any case, anatase is much more efficient than rutile, indicating that besides size, crystal structure also strongly affects physicochemical properties.

Thermal properties may also vary in relation with size decrease. For instance, tin and indium melting point can be strongly reduced by 80 °C and 120 °C, respectively (e.g., in [1]) when their diameters decrease from 100 to 10 nm. More surprisingly, their normalized heat of fusion that is supposed to remain constant in classical

thermodynamics exponentially decreases when size decreases below 20 nm in diameter. Solubility is also affected by size decrease. It is intuitive to predict that the dissolution kinetics of particles is function of the specific area and aggregation state, with of course faster dissolution kinetic for the smallest particles, but what about the thermodynamic crystal solubility K_b? K_b is supposed to be constant and generally similar to the solubility product K_{sp}.

$\ln K_b = \ln K_{sp} + f(\gamma/r)$ (with γ is the surface tension and r is the characteristic length of the crystal).

For particles larger than 25 nm, $f(\gamma/r)$ can be approximated as a constant function. But this simplification fails for smaller nanoparticles as the size dependence of the morphology and γ cannot be ignored.

Other examples of physicochemical properties modification with size could be given (magnetic, electrical, etc.). Besides these intrinsic properties, it is worth detailing nanoparticles when introduced in aquatic media. Indeed some confusion may exist between dissolution and dispersion. Due to their small size, when nanoparticles are homogeneously distributed in aquatic media, particles cannot be detected by eyes and appear as if particles may be totally dissolved to ionic species. However, (colloidal) dispersion is the term referred to suspended material in the 1–250 nm range. Colloidal dispersions are thermodynamically unstable even if the aggregation rate can be very slow.

Latter examples are good illustrations of the high variety of properties that can change or be enhanced as size of particles decreases in the nanometric size range. It is therefore challenging to prioritize which properties are of main concern in relation with toxicity.

Determination of Nanoparticle's Properties in Biological Media

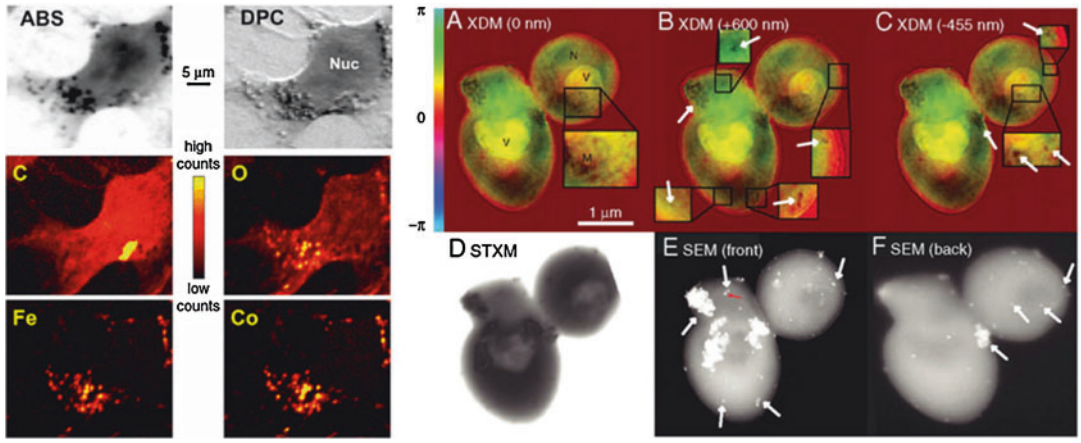
Generalities

Even if challenging, determining the evolution of physicochemical properties of nanoparticles in relation to human and environmental exposure requires to answer to, at least, two questions, in order to define the appropriate useful techniques.

First of all, which structural and characterization information are considered to be important? As detailed before their aggregation in the media, their (mean) size and shape, dissolution or solubility, their surface area, redox stability, surface charge, and surface chemistry are of prime interest.

Secondly, in which conditions the nanoparticles have to be characterized? A three-step procedure have been formalized in which the characterizations need ideally to be performed (1) *on as-synthesized nanoparticles* in their native state (dry or hydrated state, depending on the synthesis), (2) in situ *on nanoparticles dispersed in the media* used for the environment and toxicity tests (ultrapure water, phosphate-buffered saline solution cell culture media. . .), and (3) in vivo or in vitro *on particles interacting with the living systems* tested (bacteria, cells, animals, plants, etc.).

Numerous characterization and detection techniques exist to determine these physicochemical properties of nanoparticles in a toxicological or biological context. There is no best technique, each of them has their specificities, advantages, and disadvantages. However, in order to limit at the maximum the discrepancies between the results, the same technique has to be employed for each step of the characterization. Several recent review papers summarize different and complementary analytical techniques (e.g., [4]. . .). We will here focus on recent techniques using X-ray. Their large penetration depth, especially in the hard X-rays regime, is interesting in a large range of applications because of its compatibility with in situ or in vivo conditions, in most of the cases without any special sample preparation, directly on the nanoparticles in suspension, for example. Moreover, specific interactions of X-rays with matter provide elemental and chemical sensitivity that have made X-ray techniques a very attractive tool.



X-Ray Imaging

Advances in X-ray spectromicroscopy techniques based on new third-generation synchrotron

sources have opened unprecedented opportunities in terms of spatial resolution to analyze nano-sized compounds in biological systems [5]. Different possibilities exist to improve the contrast using X-ray microscopes with respect to optical or electron microscopes. They can be schematically described looking at the different interaction processes occurring between the incident photons (or the associated wave) and the sample. (1) The *photon absorption* which strongly depends on the chemical nature of the element (the higher the atomic number of an element, the stronger will be the absorption). (2) The *fluorescence emission* resulting from the decay process. (3) The *phase shift* of the incoming wave induced by the matter/sample interaction. (4) The *photon diffraction* by the sample. These processes give rise to different kinds of X-ray microscopy, among them Transmission X-ray Microscopy (TXM), Scanning Transmission X-ray Microscopy (STXM), X-ray fluorescence with microbeam (μXRF), and X-ray Diffraction Microscopy (XDM).

Examples of imaging performed with these techniques are shown on Fig. 1, on fibroblast cells exposed to nanoparticles using STXM in absorption (ABS) and differential phase contrast (DPC) modes combined with μXRF (Fig. 1, *left*) [5], and on yeast using XDM compared with Scanning Electron Microscopy (SEM) and STXM (Fig. 1, *right*) [6].

First example deals with the toxicity of $CoFe_2O_4$ nanoparticles, nano-sized magnets that can be potentially used in combined cancer therapy if their biocompatibility is demonstrated. μXRF maps indicate that, for the probed concentrations, these nanoparticles do not penetrate the nucleus. Precise localization of the elements with respect to the different constituting parts of the cell is possible by acquiring at the same time an image, the best contrast being obtained in DPC mode (Fig. 1, *left*, upper part). Spatial resolution in this soft-X-ray microscope is sub-50 nm. An improvement of the resolution can be achieved by shifting to DCM microscopy as shown by Nelson et al. [6] who obtained a "resolution between 11–13 nm, the highest resolution in X-ray imaging of a biological specimen." *Saccharomyces cerevisiae* yeasts were imaged after labeling using colloidal gold particles. These labels were positioned to correlate the images obtained by the three different ways, to have a probe to estimate the resolution and the probing depth. The 3D XDM image obtained after reconstruction allows to image the internal part of the cell (which can be compared to the image obtained in transmission using STXM) or the two opposite walls of the cell

Physicochemical Properties of Nanoparticles in Relation with Toxicity, Fig. 1 *Left*. Uptake and interaction of $CoFe_2O_4$ nanoparticles with fibroblast cells imaged using absorption (*ABS*) and differential phase contrast (*DPC*) combined with μXRF analysis of the C, O, Fe, and Co (From [5]). *Right. Saccharomyces cerevisiae* yeast imaged using XDM (three images corresponding to three different analyzing depth), STXM, and SEM (Ref. [6])

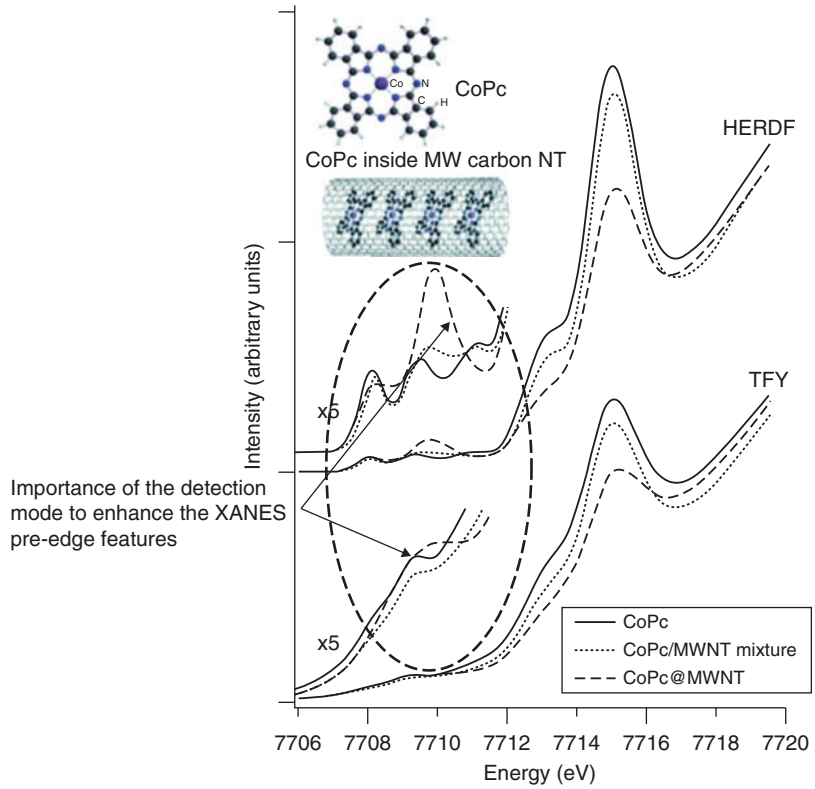
(which can be compared in this case to the two images obtained in SEM). This technique is really promising even if it still remains quite challenging, to image thick cells, too thick to be studied by transmission electron microscopy.

From Long-Range to Short-Range Orders in Nanomaterials

X-ray scattering and X-ray Absorption Spectroscopy techniques (XAS) techniques provide valuable information on long- and short-range orders existing inside (X-Ray Diffraction, XRD) and between (Small-Angle X-ray Scattering, SAXS) nanoparticles, with a great sensitivity to their shape.

SAXS experiments have been performed to follow the kinetics of aggregation or dissolution of ZnS nanoparticles as a function of the mean size of the particles and of the pH of the solution [7]. Levard et al. [8] have combined SAXS and XAS in situ experiments to study the growth mechanisms of imogolite-like aluminogermanate nanotubes at various stages of their formation, from the precursor (rooftile-shaped particles) to the nanotubular structure. 20 % of Ge vacancies have been also determined in the Ge layer from XAS analysis. Finally, structure of iron oxide nanoparticles in aqueous suspension was probed by high-energy powder XRD on a large angular range coupled to atomic pair distribution function (PDF) analysis, well suited for determining the internal atomic ordering and the geometry of nanoparticles [9]. This PDF technique provided detailed structural information for γ-Fe_2O_3 spherical and tetrapod-shaped nanoparticles.

These techniques are performed using synchrotron radiation in order to perform kinetics experiments and XAS spectroscopy, but SAXS and XRD experiments can also be performed using laboratory sources, preferably at high energy (Mo or Ag Kα anode).



Electronic Structure and Short-Range Order in Nanomaterials

XAS is now a well-established structural technique that allows to determine the electronic structure (valence) and the local order (geometry of the site, chemical nature of the neighbors, etc.) of a selected element in a sample. Being only sensitive to the local order, XAS is well suited to study either amorphous, ill-ordered, or well-crystallized samples, in the solid or liquid states, and has been then quite naturally used for the nanoparticles studies [10]. Numerous examples of the application of this technique for nanotoxicology studies can be found (e.g., [11, 12]). In this particular field, two conditions are required. Acquisitions need to be performed in the fluorescence mode, to be sensitive to a small amount of nanoparticles, using, for example, of conventional solid state detector, with a medium energy resolution (ca. 200–250 eV). Moreover, a high resolution is necessary to detect accurately the subtle variations upon interaction with a solution or a biological media. This second requirement is especially true in the pre-edge and edge part of the signal (X-ray Absorption Near Edge Structure, XANES).

High-Energy Resolution Fluorescence Detection (HERFD) allows to further enhance XANES sensitivity. Even if not extensively used at present, this technique has gained a lot of interests and under development on many synchrotron beamlines. Using a detector with an energy resolution better than the core hole lifetime broadening gives XANES spectra with sharper spectral features compared to conventional total fluorescence (TFY) spectra. Example of such sharpening is illustrated in Fig. 2. The structure of Cobalt phthalocyanine (CoPc), free or encapsulated inside multiwalled carbon nanotubes has been probed using either TFY or HERFD [13]. The differences in the pre-edge using conventional TFY spectra are really small, until those obtained by HERFD clearly put in evidence a modification of the Co conformation when CoP is free or encapsulated. Complete analysis shows that Co atoms move out of the molecular plane by a fraction of Angstrom.

Physicochemical Properties: Biological Effects Relationships

Some recent reviews inventoried NPs that are toxic to living organisms, e.g., [14–16]. There are now obvious examples of the toxic effects of

Physicochemical Properties of Nanoparticles in Relation with Toxicity, Fig. 2 TFY XANES pre-edge and edge region compared to HERFD spectra for three CoPc samples. The pre-edge is magnified by 5 for clarity (From Ref. [13])

C_{60} fullerenes to bacteria, to daphnia, etc., Nano-TiO_2, nano-CeO_2, nano-Ag, etc., can also be toxic to various organisms ([14, 15] etc.), or even colloidal silica to rat and mice [16]. But despite the growing body of literature, many conclusions remain contradictory. For instance, dose–response relationship are not always observed even for equivalent systems. Lovern et al. [17] clearly observed such relationship in the case of daphnia mortality exposed to 25 nm TiO_2, while Hund-Rinke et al. [18] were unable to determine a LC50 value for 30 nm TiO_2 in contact with Daphnia due to chaotic results. In many cases, the degree of physicochemical characterization of nanoparticles is not equivalent and one cannot identify why results are inconsistent. As previously discussed, nanoparticles can differ by many aspects due to variation in size, shape, redox properties, surface charge, crystal structure, chemical composition, adhesion to surfaces, etc., and beyond a list of results, it is worth addressing the effects of various physicochemical parameters of NPs on their toxic effects.

Effects of Aggregation State and Size

Most of pioneer published results dealing with NPs toxicity mainly focused on size effects. Can toxic effects only be due to the small size of particles? Size was mainly measured by TEM that implied dry state characterization. However, the size was not characterized in nutritive or aquatic test media. Indeed the dispersion state of NPs (aggregation vs. dispersion) in contact with living organisms can change from one study to another. At this stage, it is worth detailing that here aggregation is referred to an assembly of particles which are loosely attached to each other. It means that aggregation is a reversible phenomenon and that NPs can aggregate in aquatic media but can disaggregate in presence of stabilizing agents like proteins. Then one has to keep in mind that aggregation can be reversible. There is a generally accepted idea assuming that aggregation of NPs impedes the determination of specific properties of NPs. It is obvious that the transport and mobility are strongly affected. Nevertheless, intrinsic or specific "nano"

physicochemical properties of NPs are not necessarily (or even significantly) affected by aggregation processes. In the particular case of surface chemical reactivity, Auffan et al. [1, 19] have shown that surface normalized quantity of probe molecules sorbed to iron oxide particles is strongly enhanced for particles smaller than 12 nm. Using arsenite as surface reactivity molecular probe, the quantity of arsenite adsorbed to the maghemite (γFe_2O_3) surface per surface unit reached 3.6 As/nm^2 for 300 nm and 20 nm particle size while it increased up to 11 As As/nm^2 for 12 nm particles. This surface reactivity was not affected by aggregation [19]. The example of Nano-Fe_2O_3 in contact with E. coli can illustrate that the aggregation state as well as the size may not be the most important parameters in terms of toxicity [20]. Indeed, [20] have shown that 8 nm maghemite (Fe_2O_3) had no toxic effect toward E. coli regardless of the aggregation state of the NPs.

Effects of the Redox State Evolution and Instability

As function of their chemical composition redox states of NPs can change in biological redox/pH conditions. Indeed most elements exhibit various possible redox states that are or are not stable as function of Eh and pH values. It is obvious for all metals that they can exist under metallic or oxidized forms. But even when oxidized, some elements can exist under various redox states. Metals like Fe, Mn, Cr, or rare earth like Ce illustrate such variability (Fe^{2+}, Fe^{3+}; Mn^{2+}, Mn^{3+}, Mn^{4+}, Mn^{7+}; Cr^{3+}, Cr^{6+}; Ce^{3+}, Ce^{4+}, etc.). Living organisms and especially eukaryotic cells metabolism cannot support large pH variation. For most eukaryotic cells, pH is buffered in the 7–8 pH range. In the case of redox potential (noted Eh), oxidative phosphorylation in mitochondria is based on a series of redox reactions at near circumneutral pH for which potentials are from −0.32 (NAD^+/NADH) to 0.29 V (cytochromes). Besides oxidative phosphorylation (respiration), extracellular Eh is generally controlled by thiol/disulfide redox systems (mainly GSH/GSSH and Cys/CySS) for which Eh vary in the −0.140/−0.08 V range. In such conditions, many elements can be redox unstable leading to electron exchange between NP surface and surrounding media. This could then be the starting point of disequilibrium of the redox balance and then to oxidative stress (See Box 1). In the specific case of iron, Auffan et al. [21] have shown that nano-zero valent iron as well as nano-magnetite (Fe_3O_4) can be toxic to E. coli. The study reported that the oxidation of iron in contact to bacteria can be at the origin of the toxicity. The potential of the redox couple characteristic of Fe^0 nanoparticles at pH = 7 is in the $Eh_{Fe^{2+}/Fe(0)} = -0.40/-0.7$ V range as function of the Fe concentration [22] which is lower than the typical Eh in biological media. This allowed the oxidation of Fe^0(s) in contact with E. coli. This oxidation is directly responsible of toxic effects through the generation of an oxidative stress, as demonstrated by an enhanced toxicity of these Fe NPs toward a mutant strain of E. Coli deprived of defense mechanism against oxidative stress. Other examples in the literature confirm the importance of the redox "instability" of nanoparticles. Using XANES at Ce L3-edge, Thill et al. [12] and Auffan et al. [11] have shown that the cytotoxicity/genotoxicity of CeO_2 was due to the reduction of surface Ce (IV) ions to Ce(III).

Box 1

Oxidative stress is a major problem that concerns all the cells living in the presence of dioxygen. It originates from the production of highly toxic reactive oxygen species (ROS), including superoxide radical $O_2^{\bullet -}$, hydrogen peroxide H_2O_2 and hydroxyl radical $HO^{\bullet}$. Although cells have developed efficient antioxidant systems to detoxify ROS, any deficiency of these systems or overload by overproduction of ROS can result in severe cellular damages such as proteins, lipids, and DNA oxidations, which can ultimately lead to cell death. It is now well documented that oxidative stress is involved in the pathogenesis of a variety of diseases such as cancers, asthma,

(continued)

pulmonary diseases, Alzheimer, Parkinson, and in ageing [1].

$$\underset{oxygen}{O_2} \xrightarrow{e^-} \underset{\substack{speroxide\\ anion}}{O_2^{\bullet -}} \xrightarrow[2H^+]{e^-} \underset{\substack{Hydrogen\\ peroxide}}{H_2O_2} \xrightarrow[OH^-]{e^-} \underset{\substack{Hydroxyl\\ radical}}{OH^{\bullet}} \xrightarrow[H^+]{e^-} H_2O$$

: formation and elimination of ROS

Several studies have related the toxicity of some NPs to an oxidative stress toward biological models [2]. In order to better understand the cellular oxidative stress pathways induced by NPs, identification and quantification of the specific ROS produced directly or indirectly by NPs represent an important issue.

In vivo detection and quantification of ROS are far from being trivial and require the use of specific techniques [3, 4]. This is mainly due to the fact that ROS are unstable species and are present at very low steady-state concentration in the cells. Various methods using synthetic probes have been developed to detect ROS in vivo. Some of these probes lead to a fluorescence signal upon oxidation by ROS, which is very well adapted for in cellulo detection by fluorescence microscopy. However, some of them lack of specificity and may lead to false interpretations for the presence of ROS [3, 4]. For example, the use of dichlorofluorescein (DCF) as a fluorescent peroxide probe is complex and crucially lacks of selectivity in vivo [5]. Hydroethidine (HE, MitoSOX™), a cell permeable compound which is specifically oxidized by $O_2^{\bullet -}$ into the fluorescent 2-hydroxyethidium (2-OH-E+) compound, has been described as an interesting $O_2^{\bullet -}$ probe [6]. However, in the cell, HE also generates other fluorescent compounds that are not related to the reaction with $O_2^{\bullet -}$. Consequently, direct quantification of 2-OH-E+ production in whole cells by fluorescence microscopy is not possible, and chromatography analysis

(continued)

of extracts obtained after cell lysis must be carried out in order to quantify 2-OH-E+ production [7].

In vitro, ROS detection is much less challenging since control experiments can be usually carried out in order to make corrections for nonspecific reactions. Probes like cytochrome c and tetrazolium salts XTT have been widely used to detect $O_2^{\bullet -}$ in vitro [3, 4]. Spin trap nitrones, like DMPO or DEPMPO, associated with electron paramagnetic resonance spectroscopy (EPR) are well adapted to detect the unstable radical species $O_2^{\bullet -}$ and $HO^{\bullet}$ [3]. However, in vivo, their use is more difficult since the nitrone adducts resulting from the reaction of the spin trap with $O_2^{\bullet -}$ or $HO^{\bullet}$ are unstable and can be easily reduced by cellular reductants [3].

Effects of NPs Shape and Aspect Ratio

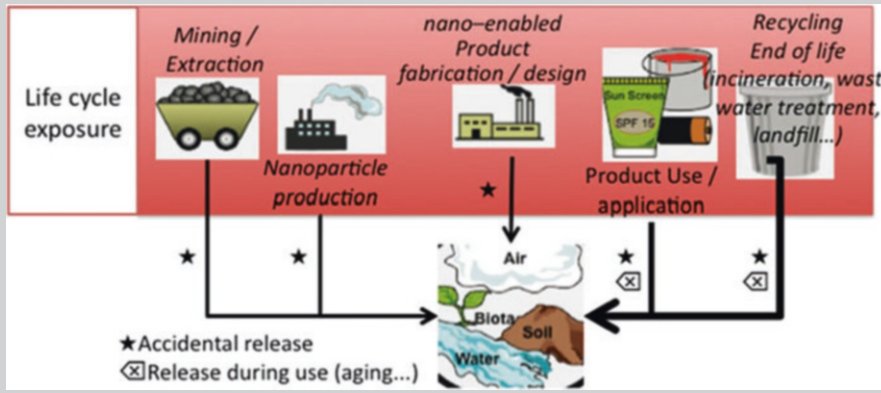
The toxicity of particles as function of their shape does not concern only nanoparticles. Indeed, many studies concerning asbestos toxicity have demonstrated that the toxicity can be partly related to the aspect ratio. Then comparison between asbestos and carbon nanotubes legitimated the worry concerning probable toxic effects of NPs. Poland and coworkers [23] have shown that "*long multiwalled carbon nanotubes result in asbestos-like, length dependent, pathogenic behavior*." However, the mechanisms at the origin of the toxicity of long (>15–20 μm) nanotubes still remain unclear. In the case of nano-silver, it is possible to produce spherical, truncated triangular, rods nanoparticles. Pal et al. [24] have shown that that the biocidal effects depend on silver NPs shape with the higher effect for truncated triangular NPs. It has been emphasized that the {111} lattice plane exhibit the highest reactivity to sulfur- or phosphorus-containing soft bases, such as R-S-R, R-SH, RS, or PR3. Then sulfur-containing proteins in the membrane interacting with Ag NPs (with high affinity {111} lattice plane) can lead to membrane disruption or strong damage.

Effects of NPs Solubility

As discussed in the "Physicochemical properties of Nanoparticles" part, NPs solubility may substantially vary from thermodynamic prediction deduced from larger particles. The small size and consequently large surface area is of high concern to address possible NPs dissolution. It has been mentioned that in the case of toxic metals the dissolution will increase the concentration of free metal ions in contact with living organism. This is particularly true for silver nanoparticles for which the dissolution is associated with a change of the redox state (oxidative dissolution). It has been reported that upon contact with a bacterial cell, biocide Ag^{+} is released from the surface of NPs, which then interacts with bacterial cell membranes and inhibits respiratory enzymes (e.g., [25]). In the case of ZnO NPs, dissolution and release of Zn^{2+} play an important role in the biological toxicity (e.g., [26]). Dissolution is also discussed in the case such as Quantum Dots, even if recent developments prevent or strongly decrease QDots solubility via specific surface coating.

Effects of NP Adhesion to Cells

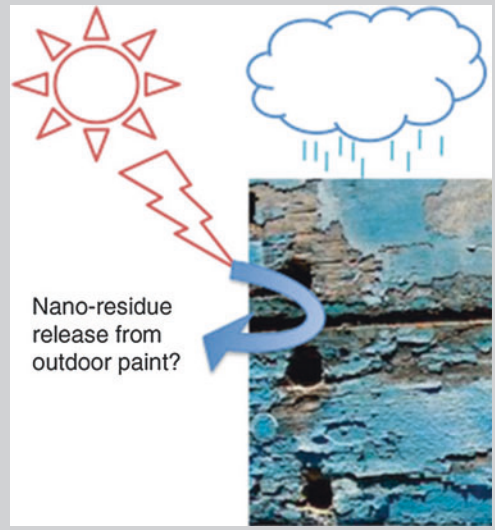
NPs can be chemically unstable (dissolution, oxidation, reduction, etc.), inducing biological effects. However, the toxicity level may be enhanced or alleviated by additional parameters. For instance, it has been shown that nano-CeO_2 can be reduced when both E. coli and Synechocystis are exposed [27]. But the reduction of Ce^{4+} to Ce^{3+} induced a much more intense effect on E. coli. Indeed, at the highest nano-CeO_2 concentration, the percentage of survival cells was still 35 % for Synechocystis while no cell was alive in the case of E. coli. This difference may be explained by the production of extracellular polymeric substances (EPS) preventing direct contact between cell membranes and nano-CeO_2 due to strong adsorption and adhesion of NPs. Thus, in the event of redox phenomena, the added distance between NPs and the membranes and the EPS shield itself may provide at least partial protection against the toxicity.



Effects of Chemical Composition, Crystal Structure. . .

Besides NPs properties discussed above, other parameters can induce biological effects. The chemical composition of NPs is of utmost importance. Many metals and metalloids are known to

be toxic like for instance Cd or Se. Their use by nanotechnology to elaborate nanoproducts or nanomaterials must be done with care. Any dissolution of NPs incorporating Cd (for instance) will lead to toxicity, and it is worth developing any specific design to enhance their chemical stability and prevent at best their direct contact with external media. Most importantly, one has to define whether or not other less toxic element can be used to reach the same level of performance.



Box 2: Exposure During Life Cycle of Nanoparticles and Nanomaterials

Most of the time, nanoparticles are surface modified prior to their incorporation in final products. Therefore, it is very likely that nanoparticles will not be directly released in the environment.

The degradation of products due to external conditions (sun, rain, etc.) may generate the release of by-products containing nanoparticles.

For instance:

From Nanoparticles to Nano-Residues of the Nanomaterials Life Cycle

Nanoparticles and nanomaterials may be released from point sources like factories or landfills that may be more related to accidental events or technical defects during the processes. But most of the release may be due to indirect exposure through the life cycle of the nanomaterials. Indeed, for most applications, nanoparticles are surface modified and generally are embedded in the final product. Therefore, they do not come into direct contact with consumers or the environment. Their surface modification can strongly affect their behavior and especially their toxicity. NPs in commercial sunscreens can illustrate the difference between bare nanoparticles and surface modified nanoproducts. Indeed, the nanoparticles of TiO_2 are coated with AlOOH and polydimethylsiloxane for their use as sunscreens. The release of nano-residues from commercial NPs-based sunscreens is no longer a hypothesis, but has become a fact [28–30]. The major effect of the remaining Al-based coating is a protection against the generation of superoxide ions from the photoactive/phototoxic TiO_2 core. This surface modification of the nano-TiO_2 results in a substantially lower toxic potential of the residue as long as the protective layer remains stable (See Box 2).

Conclusion

This section discussed the relationships between the physicochemical properties of nanoparticles and their biological effects. As described above, nanoparticles differ from each other by many aspects and not only size and shape. Aggregation state, chemical stability, solubility, etc. can change from one to another NP leading to difficult comparison when toxicity occurs. Then, even if many issues remain unsolved, it clearly appears that the toxicity strongly depends on an accurate physicochemical characterization of nanoparticles and nanomaterials. However, while characterizing several properties like chemical composition, size, shape, crystal structure, surface area, surface chemistry, charge, and solubility of the initial NPs is now well accepted (but not always performed!), information is still lacking as, more than initial product characterization, it is worth determining the evolution of important parameters during the interaction between NPs and biological organisms. However, such accurate determination of nanoparticles in biological media remains highly challenging as discussed in this section.

Definition of the Subject

Laser near-field nanomanufacturing is manufacturing nanoscaled materials and complex structures at the nanoscale by means of phase change/explosion with the near-field focused laser beam, whose spot size is usually smaller than its wavelength.

Introduction

Nanofabrication and nanomanufacturing involve manufacturing of materials, structures, devices, and systems down to the nanoscale. There are two basic categories of fabrication, top-down and bottom-up or self-assembly processes, containing a growing number of chemical and physical techniques, such as chemical methods, chemical vapor deposition, molecular beam epitaxy, atomic layer epitaxy, lithography, self-assembly, and countless newly developed techniques. Among those methods, laser-assisted nanomanufacturing plays an important role due to its highly coherent feature. To achieve a resolution below the diffraction limit, various near-field mechanisms of laser-assisted technologies have been developed in past decades, such as the laser-assisted nanopatterning and nanoimprinting lithography, near-field scanning optical microscopy (NSOM), superlens, nanoscale aperture, and scanning probe microscopes (SPM).

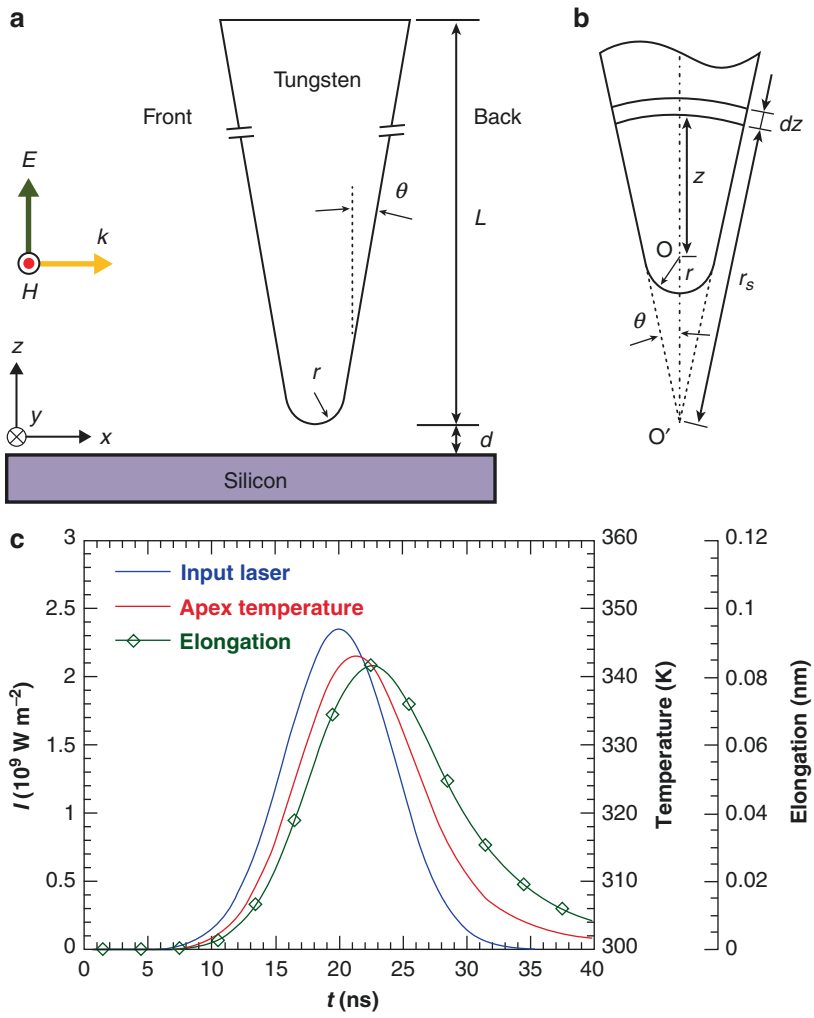
The laser-assisted tip-based fabrication is a large branch of laser-assisted manufacturing techniques by using SPM tips. The SPM tip is an ideal tool for apertureless NSOM due to its tiny but sharp geometry. When a laser irradiates the SPM tip, it can bend the propagation direction of the laser and focus and enhance the optical field in an extremely small area in proximity to the tip apex. The enhancement factor could be more than 100 by using a scanning tunneling microscope (STM) tip. This strongly enhanced optical field is then utilized to develop a new fabrication method by using laser-irradiated STM tip [1]. The absorption of this enhanced optical field could generate heat in the sample surface and induce phase change at the nanoscale, finally modifying the surface. Similar to STM, atomic force microscopes (AFM) can focus the laser beam to a nanoscale spot as well to achieve surface manufacturing at the nanoscale.

This entry focuses on experimental and computational works about laser-assisted SPM nanostructuring. Section Near-Field Focusing and Heating by the Micro/Nanoscale AFM Tip: Effect on the Tip introduces experiment and simulation of the temperature and optical field distribution in the AFM tip when it is heated by near-field focusing laser. Section Near-Field Focusing and Heating by the Micro/Nanoscale AFM tip: Effect on the Substrate discusses the study about

the temperature measurement and optical field distribution simulation in a silicon substrate next to the apex of the AFM tip. Sections Near-Field Focusing by Micron/Submicron Particles: Experimental Study and Near-Field Thermal, Optical, and Mechanical Phenomena: Modeling are for experiments and simulation study, respectively, for the near-field thermal, optical, and mechanical phenomena of a silicon plate under the micro/submicron particles. Section Material Structure Evolution Under Near-Field Laser Heating mainly focuses on the simulation work about material's structure change under near-field laser heating, including structure evolution and the effect of shock waves.

Near-Field Focusing and Heating by the Micro-/Nanoscale AFM Tip: Effect on the Tip

The enhanced optical distribution in and around the apex of a tip has been widely studied. The thermal evolution and thermal distribution, however, was studied little. Chen et al. [2] has conducted high fidelity and systematic simulation of near-field thermal transport in an AFM tungsten tip under laser irradiation. The electromagnetic field and temperature distribution is simulated in a domain housing a tungsten SPM tip and silicon substrate system.



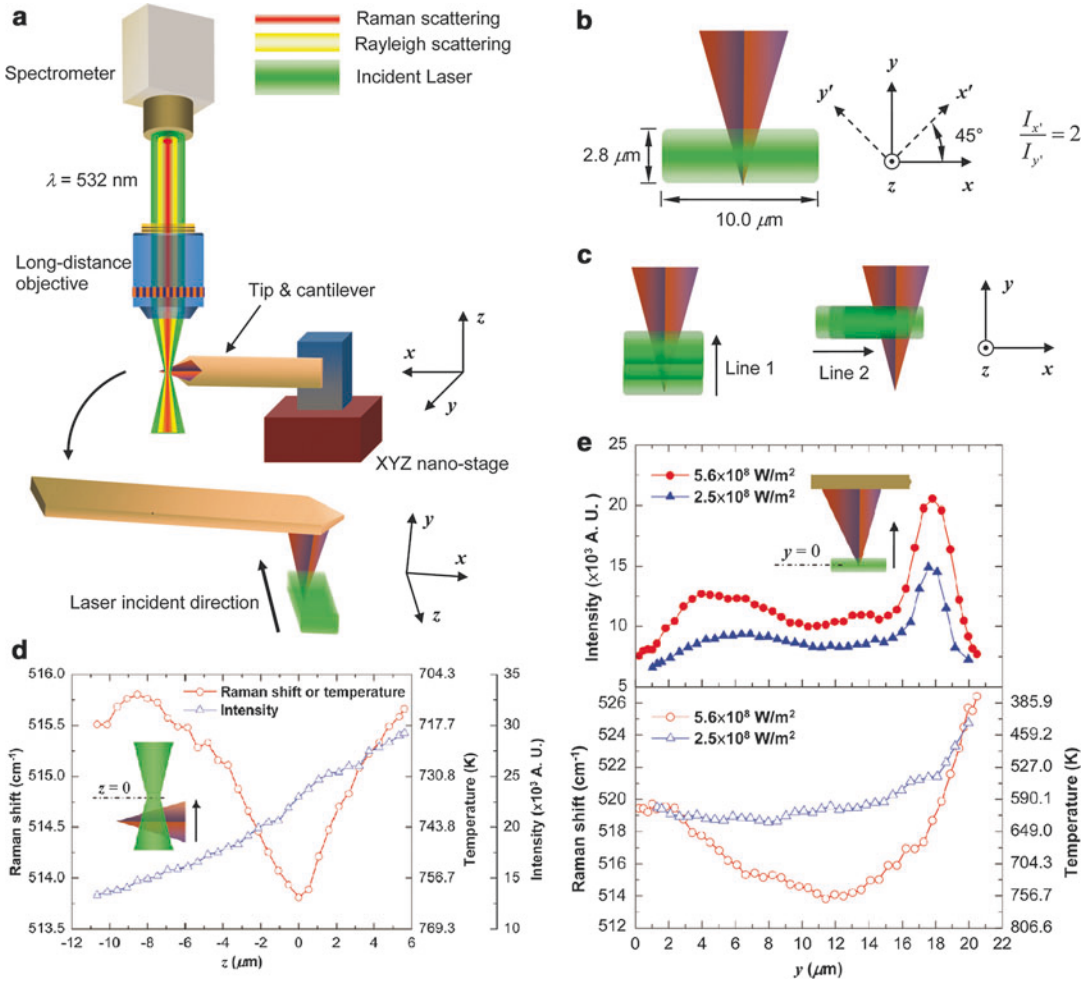
FEM Modeling for Both Optical and Thermal Physics in AFM Tip Under Irradiation

The model (Fig. 1a) employs a conical tungsten tip ended with a hemisphere on the silicon substrate. The modeling is performed by using a high-frequency structure simulator (HFSS V12.1 ANSYS, Inc.), a full-wave high-frequency 3-D finite element modeler of Maxwell's equations. Maxwell's equations are solved across the vacuum domain. Tetrahedral elements with a length shorter than one-fourth of the incident wavelength are set in the whole domain. They are further refined in areas where the high field gradient may occur. Absorbing boundaries are applied for the domain. The incident plane wave is along the x direction of the tip.

The geometry of the tip is shown in Fig. 1b. The length L of the tip model is carefully chosen as 600 nm which is a good approximation of 15 μm long commercial tips. The tip apex radius $r = 30$ nm and the half taper angle $\theta = 10°$ are used in the simulation. The distance d between the tip and substrate is set as 5 nm. The Poynting vector simulation illustrates the incident laser is bent around the tip and concentrated under the apex, and the extremely intensive electric field appears there. The largest enhancement factor around 15 under the apex in the model is given by the electric field simulation. In contrast, the electric field is much less enhanced inside the tip, since only a small fraction of laser penetrates into the tip. The electric field is not symmetrical inside the tip. Its gradient decreases along the laser's incident direction.

Three factors significantly affect the electric field enhancement: the laser polarization direction, the geometry of the tip, and the distance between the tip apex and the substrate. The intensity enhancement of the electric field depends on $\cos^2\varphi$, where φ is the polarization angle to the tip axis. Only the component along the tip axis of the incident laser makes a contribution to the electric field enhancement under the tip apex. For the geometry factor, the optimum r for electric field enhancement is about 9 nm when the half taper angle θ is 10°. For a tip with a fixed radius of 30 nm, the field enhancement first increases along with θ increasing when θ is less than 25°, and the field enhancement keeps pretty much constant in the range of 25–30° and then decreases as θ goes beyond 35°. Moreover, the peak field enhancement decreases exponentially as the tip–substrate distance increases, and a shift of field peak position is observed being away from the tip axis. This shift vanishes when the tip touches the substrate.

A single pulse is applied on the tip to study the temperature evolution and distribution in the tip at room temperature (300 K). The simulation of the temperature distribution in the tip is conducted with commercial computational software FLUENT (V12.0.1 ANSYS, Inc.). The intensity of the electric field is calculated according to the Poynting vector. The maximum temperature in the tip apex is delayed (Fig. 1c) due to the thermal conduction in the tip when compared with the



Physics in Laser Near-Field Nanomanufacturing: Fundamental Understanding and Novel Probing, Fig. 1 (**a**) Schematic of the tip–substrate system, (**b**) geometric structure of the tip model, and (**c**) the temperature evolution against the time (Reprinted from ref. [2], © IOP Publishing. Reproduced by permission of IOP Publishing. All rights reserved)

maximum energy in the laser pulse. The resulting temperature distribution is affected by two factors: the heat source due to laser absorption and the geometric shape of the tip. As the polarization angle or apex radius increases, the peak apex temperature decreases. The half taper angle strongly affects the thermal transport in the tip. The peak apex temperature declines with an increased taper angle, even though the laser intensity inside the tip is increasing in the meanwhile.

Experimental Details of Temperature Measurement in the AFM Tip

The corresponding experimental work is conducted with a freestanding AFM silicon tip [3] under the laser irradiation with a micrometer spatial resolution. A single crystal silicon (antimony doped) tip (CSG10, K-Tek nanotechnology) is mounted on a three-dimensional piezo-actuated nanostage with a positioning resolution of 20 nm. The stage with the sample is placed under the laser spot at the focal level of a confocal Raman microscope system (Voyage, B&W Tek, Inc.). The tip axis is horizontal and along the y direction of the nanostage. The cantilever is along the x direction, and the laser is incident vertically along the z direction. The whole system is placed in air. The laser beam is focused through a 20× microscope objective (NA = 0.40, WD = 12.0 mm) with a focal spot size of $2.8 \times 10.0\ \mu m^2$. The laser beam is partially polarized along the x' and y' directions as shown in

Physics in Laser Near-Field Nanomanufacturing: Fundamental Understanding and Novel Probing, Fig. 2 (**a**) Schematic of experimental setup (no to scale). (**b**) Configuration of the laser beam at the focal spot when the laser illuminates the side surface of tip. (**c**) Laser spot moving directions with respect to the tip during experiment. (**d**) Raman shift, temperature, and Raman intensity when the tip moves upward along the z direction in the vicinity of focal spot. (e) Raman intensity and Raman shift along line 1 [as shown in Fig. 2c, in the y direction] under energy fluxes of 5.6×10^8 and 2.5×10^8 W/m^2, respectively (Reprinted from ref. [3], © IOP Publishing. Reproduced by permission of IOP Publishing. All rights reserved)

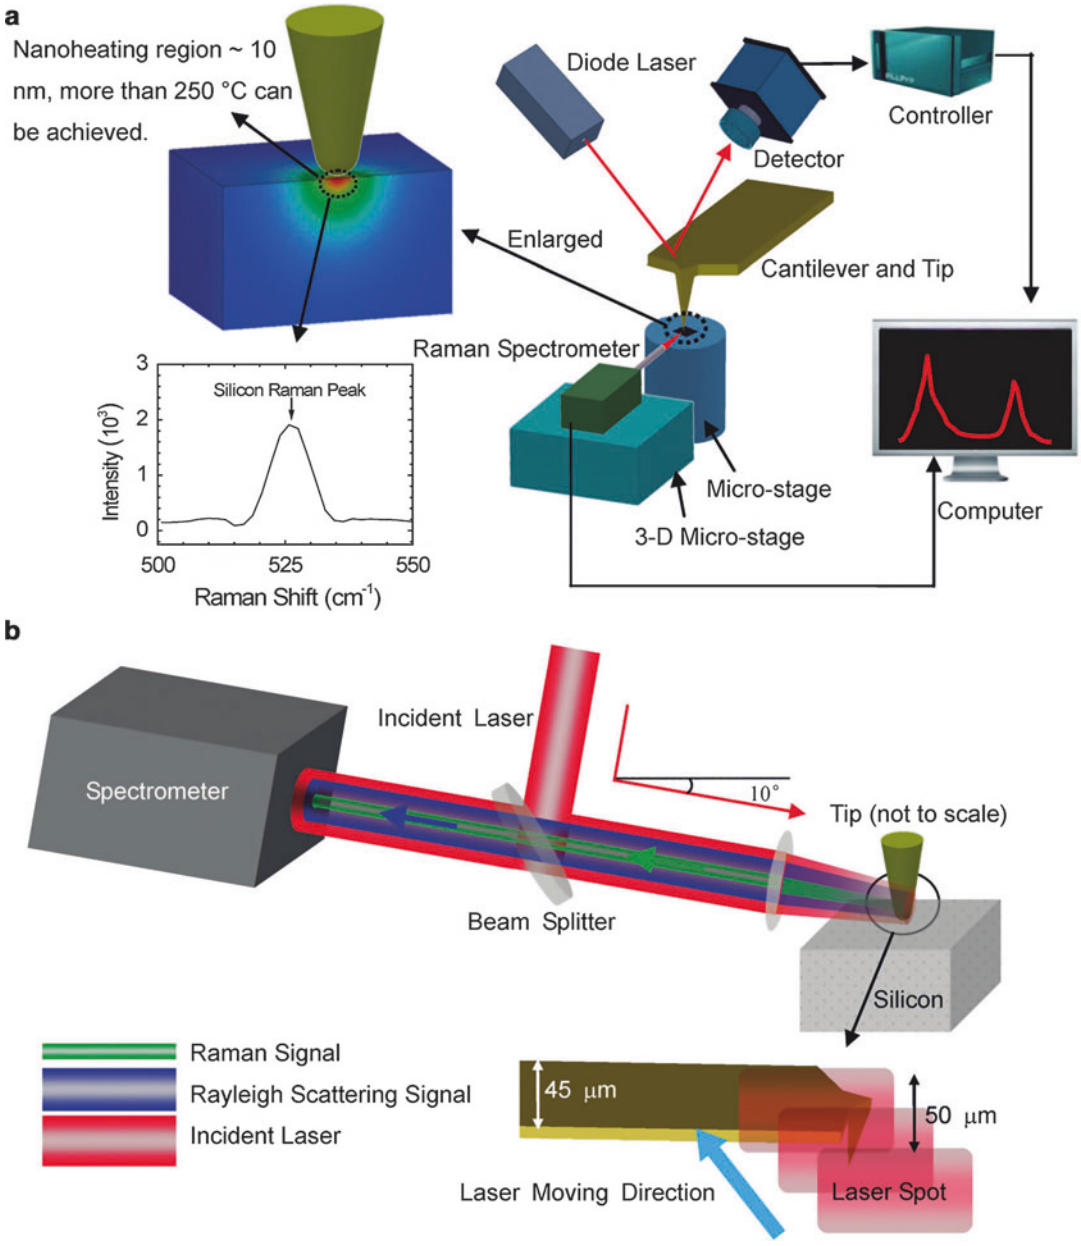
Fig. 2b. The nanostage is aligned to make sure that the laser is coming in along the z direction. The tip axis is perpendicular to the longer side of the laser spot. In this case, the tip axis has an angle of 45° with respect to the direction in which the polarized laser has the strongest intensity. The laser with a wavelength of 532 nm is used as both Raman probe and heat source. To investigate the heating effect caused by laser, the tip is illuminated with different laser powers of 4, 7, 12.7, and 15.9 mW.

The Raman shift method of Raman thermometry is used to determine the temperature rise of the Si AFM tip under laser irradiation. Raman shift will become smaller when the temperature of the probing area goes up. The exact temperature rise is then calculated based on the theoretical calculation introduced by McCarthy et al. [4]. To precisely extract the Raman shift, the silicon Raman peak in all measured spectra is fitted with the Gaussian function. In order to exclude the

focusing effect on the experimental result, the diffraction image of the tip under laser illumination is examined to precisely monitor the focusing level.

The temperature rise in the tip is first studied as the tip moves along the z direction, and the whole travel covers the focal spot (Fig. 2d). When the tip moves upward closer to the focal spot, the Raman shift decreases and the temperature increases; analogously, when the tip passes the focal spot and keeps moving upward, the Raman shift increases and the temperature goes down. Nevertheless, the Raman intensity increases during the whole process. When the laser spot is moved along the tip axis at the focal level from tip apex to cantilever, the temperature in the tip increases first and then decreases (Fig. 2e). The corresponding temperature increases from 603 to 754 K and then declines to 728 K. This is a trade-off between the increasing of laser absorbing area and the increasing heat conduction to the base of the tip even the cantilever. The incident laser intensity also strongly affects the heating condition.

To investigate the mechanism of the near-field heating in the experiment, the electric field distribution around the tip and inside the tip is calculated using the similar method as described in section FEM Modeling for Both Optical and Thermal Physics in AFM tip Under Irradiation. The highest field enhancement is 5.19 and 2.86 for under the tip apex and inside the tip, respectively. A one-dimensional heat transfer model is used to calculate the temperature distribution along the tip axis. Details of the calculation can be found in the reference [3]. The highest temperature of 448 K is obtained at the hemisphere apex from the calculation, while the measured temperature is approximately 600 K. The difference between them could be induced by further thermal conductivity reduction of the Si tip by its dopants and the underestimated laser scattering/absorption in the tip.

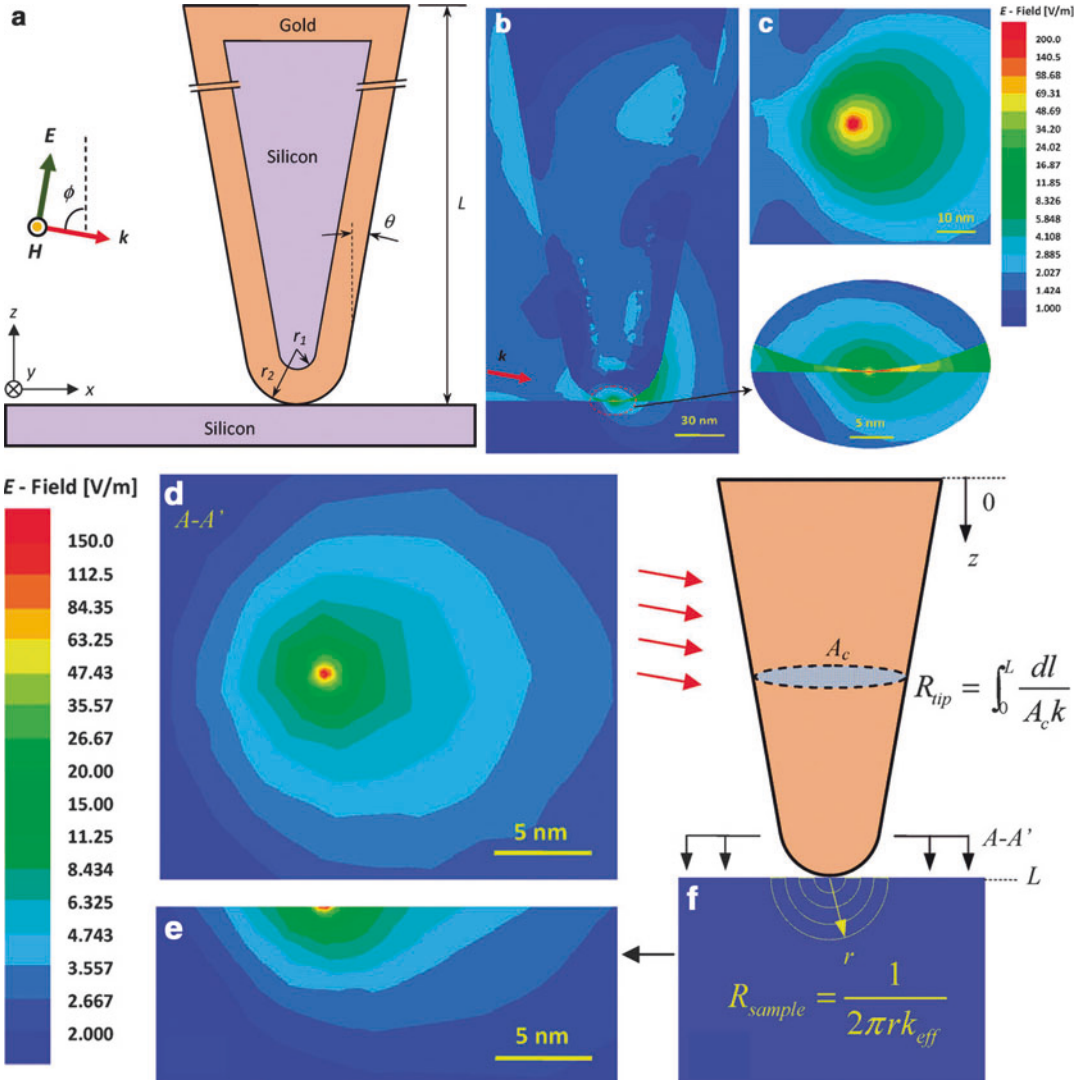


Near-Field Focusing and Heating by the Micro-/Nanoscale AFM Tip: Effect on the Substrate

According to Chen's study, an AFM tip can induce the near-field enhancement on electromagnetic field next to the tip apex when an external laser irradiates the tip. Besides, the local heating in the substrate beneath the tip can also induce a considerable temperature rise. The first experimental work for the direct temperature measurement was done by Yue et al. [5]. The Raman shift method is applied to measure the temperature variation in a sub-10 nm area of the silicon substrate beneath the apex of the AFM tip.

Experimental Details

Before the temperature measurement, thermal response calibration is conducted between Raman shift of Si peak and temperature from room temperature to 230 °C. A silicon sample is heated using a power-adjustable electrical heater and temperature is sensed by a T-type thermocouple. The Raman signals are excited by using the 785 nm probing laser from the Raman spectrometer (B&W Tek). The Raman spectra are then fitted with the Gaussian function to obtain precise Raman shift of the Si peak. The obtained linear relationship between Raman shift and temperature is used to determine the temperature in the substrate in the experiment.



The experimental setup is shown in Fig. 3. A silicon substrate is mounted on a 3-D nanostage in the AFM system, and the 20 nm gold-coated AFM silicon tip is fixed above the substrate. A Raman spectrometer (B&W Tek) is mounted on another 3-D microstage and placed in front of the fixed AFM tip–substrate system. A beam splitter and a lens are placed on the optical path between Raman probe and the tip. The incident Raman laser is focused on the tip by using the lens, and the reflected incident laser is then used to monitor the irradiating position. The incident angle with respect to the tip axis is kept to be around 80° in order to reduce the Raman signal directly from the unheated silicon. Three cases with three different polarized angles, 15°, 30°, and 75° (with respect to the tip axis), are studied. In 15° and 30° cases, the temperature rise is more than 200 °C in the sub-10 nm area in the silicon substrate due to the near-field focus effect next to the AFM tip apex.

Simulation Study of the Near-Field Optical Effect and Thermal Effect

The simulation of corresponding electric field enhancement is also conducted to well explain the mechanism behind the above experiment. The HFSS (V13 ANSYS, Inc.) is used for calculating the electric field distribution in a tip–substrate system. The simulated model is

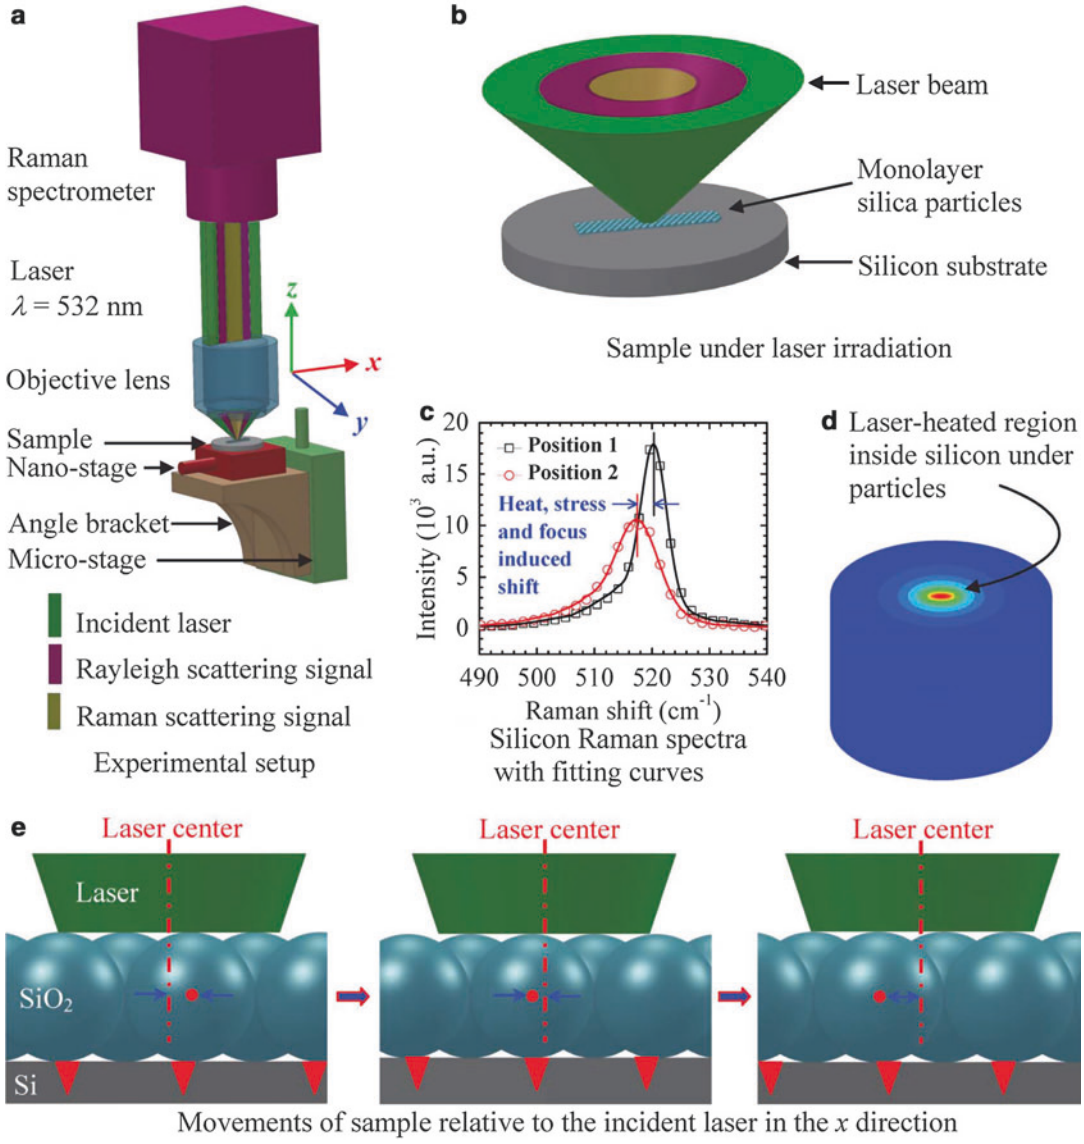
shown in Fig. 4a: a well-defined rectangular domain contains a 20 nm gold-coated silicon tip and a 200 nm thick silicon substrate. The length L of the tip in the model is 600 nm, the half taper angle θ is 10°, and the apex radius r_1 is 10 nm. The polarized laser illuminates the tip along the x direction with an incident angle ϕ of 80° to the z direction. The simulation result (Fig. 4b–f) shows a large enhancement of the electric field only in the vicinity of the contact point between the tip and substrate. This extremely strong electric field focuses into a hemisphere with a diameter of sub-10 nm in the silicon substrate.

P

Nonlinear Optical Absorption and Ballistic Heat Conduction in the Near-Field Focused Region in the Substrate

To calculate the temperature rise in the near-field heating region, a thermal model is established as $\int_{\Delta V} I\beta\, dv = (T - T_\infty)/R_{\text{th}}$ which means an equilibrium between heat generation from the enhanced electric field and heat transfer from the heating region to the outside. ΔV is the near-field heating domain ($\Delta V \approx 2\pi r_e^3/3$). r_e is the effective radius of this heating region. It can be derived from nonlinear photon absorption induced by the high intensity of the optical field in the silicon. The electric field under the tip is first enhanced due to the near-field effect on the incident laser. This enhanced electric field then excites the tip again which contributes to an additional radiated electric field enhancement. Both enhancements of the electric field by the incident laser and the excited tip are second order; meanwhile, they are symmetrical in the same wavelength. Therefore, the overall magnitude of the intensity would be $\sim M^4$ [6]. M is the magnitude of enhanced electric field. The optical field intensity under low polarization angles (15° and 30°) is as high as 10^{14} W/m^2 within a 1 nm radius hemispherical region in silicon. The avalanche ionization process then occurs due to the short absorption depth (75 nm) in this region [6], where the electrical field intensity exceeds the threshold. Thus, the effective radius r_e of the hemisphere region is calculated as 0.8 nm in the case of 15° polarization angle.



To calculate the theoretical temperature rise, the thermal resistance from the heating region to the outside is also needed. R_{th} is expressed as $1/(2\pi r_e k_{\text{eff}})$, where k_{eff} is the local effective thermal conductivity. k_{eff} is determined by considering the strong ballistic heat transfer effect due to the extremely small heating region. This heating domain (within 10 nm scale) is even smaller than the mean free path of silicon as 43 nm at room temperature. Thermal equilibrium cannot be achieved because of not enough scattering and collisions of phonons [7]. The thermal conductivity (k_{eff}) is then used for the heating region in silicon, which can be expressed as $3k/(3 + 4\tau)$, where k is the thermal conductivity of bulk silicon, and $\tau = r/\Lambda$, where Λ is the mean free path of the phonon in bulk silicon. The effective thermal conductivity is evaluated as 2.5 W/(m·K) in the calculation region. Thus, the temperature rise in this sub-10 nm domain is calculated as 235 °C and 105 °C for the 15° and 30° cases, respectively, which agree well with the experimental result. For the 75° case, a very weak optical field intensity enhancement occurs, and the temperature rise is negligible.

Near-Field Focusing by Micron/Submicron Particles: Experimental Study

Micro-/nanoparticle is another kind of useful geometry for inducing ultra-focusing and heating into sub-wavelength. This technique has been widely used in laser-assisted nanopatterning and nanolithography on a large-area substrate. Knowledge of the temperature and stress in the nanoscale beneath the particles is critical for process control and optimization. At present, the extremely small size of this heating area (~100 nm or less) remains a big challenge for nanoscale temperature, stress, and optical field probing because the heating area is very small and not immediately accessible for sensing. Tang et al. [8–10] did the pioneering and systematic experimental study of the effects of temperature, stress, and near-field focusing in the silicon plate under a single silica particle, a glass fiber, and a layer of particles, with Raman spectroscopy.

Experimental Details

The sample is prepared by spreading a single layer of glass nanoparticle mixture on a clean silicon wafer using a tilting technique. Different sizes of particles, 200, 400, 800, and 1,210 nm (diameters), are used. Details can be found in reference [8]. The experimental setup for temperature, stress, and optical field mapping is shown in Fig. 5. The sample is mounted on a combined stage under the confocal Raman system (VoyageTM, B&W Tek, and Olympus BX51): a

Physics in Laser Near-Field Nanomanufacturing: Fundamental Understanding and Novel Probing, Fig. 5 Schematic of experimental setup for far-field nanoscale imaging (not to scale). (**a**) A sample is located under an objective-focused laser beam from a Raman spectrometer. The movement of sample in the x direction is controlled by a piezo-actuated nanostage. The focal level of the laser on the sample in the z direction is controlled by a motorized microstage. (**b**) The sample consists of a silicon substrate and a monolayer of silica particles. The spot size of the incident laser is about 0.5 μm in the x–y plane on a silicon substrate. (**c**) The Raman spectrum shifts to left due to the near-field laser heating, the stress, and the out-of-focus effect. (**d**) The silicon substrate is heated in a sub-wavelength region ($r \sim 200$ nm) right beneath the particles. (**e**) During the experiment, the position of the laser beam is fixed, and the sample moves along the x direction controlled by the nanostage electrically without any touch of the sample and other equipment. P

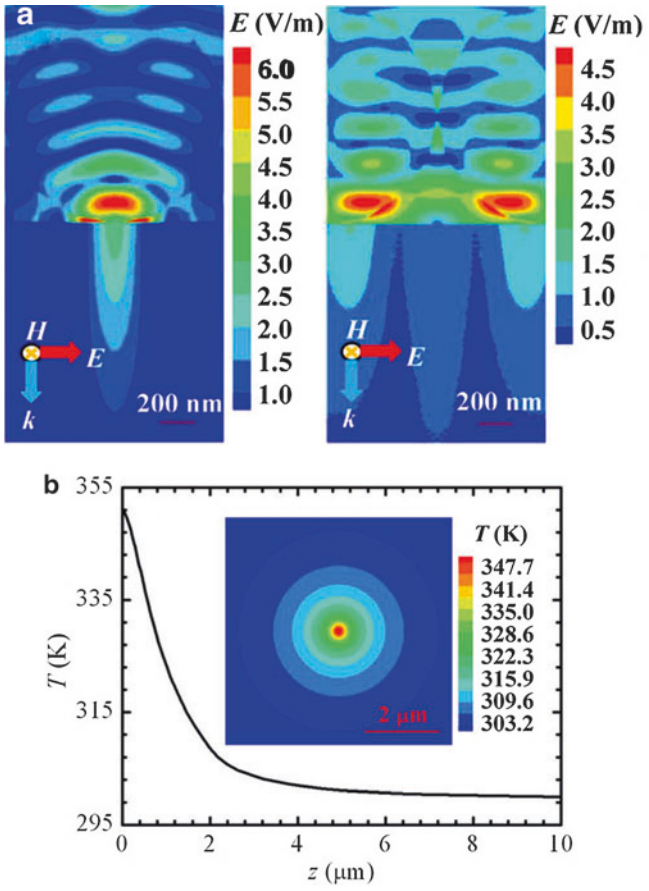
piezo-actuated nanostage with a resolution of 20 nm (ThorLabs NFL5DP20) in the x direction (imaging direction) and a motorized translation stage (ThorLabs MT1-Z8) in the z direction. The mapping process is conducted along the x direction. The motorized stage is fixed tightly to exclude the movement in the z direction. The Raman laser is the only laser source used for both near-field excitation and probing, which is focused on the top of glass nanoparticles by a 100× objective lens (NA = 0.8). When passing through the SiO_2 particle, the laser is further focused to an even smaller spot size. Temperature and stress mapping are carried out by measuring Raman spectra along the x direction. Four energy levels of incident laser are applied in the experiment.

De-conjugation of Thermal, Stress, and Optical Effects

The obtained Raman spectra are first fitted using the Gaussian function to get the precise Raman intensity, Raman shift, and linewidth. Raman intensity, Raman shift, and linewidth of the Si peak will vary against temperature. The Raman intensity and shift decrease, while the linewidth broadens as the temperature rises. Among these three parameters of the Raman peak, the linewidth is closely relevant to the phonon lifetime. It is strongly affected by the temperature in collection area, but the stress has little effect on it. Therefore, the linewidth method is available for direct temperature analysis. Raman shift depends on both the local stress and temperature, and Raman intensity is mainly affected by the intensity of the incident laser and the temperature of the silicon substrate. The optical field intensity variation and the stress distribution can be obtained through analyzing Raman intensity and shift, respectively. Therefore, the periodic variation of the combined effect of the near-field optical heating, local stress, and the optical field in space can be separately detected by analyzing the variation of the Raman intensity, Raman shift, and linewidth along the mapping path.

The optical alignment in the system and laser energy will affect the Raman intensity, but they are independent of the sample. To quantitatively obtain the nanoscale local stress and temperature in the silicon substrate based on the intensity in this particle–substrate model, the Raman spectrum for bare silicon is referred at the same measurement condition. The effect induced by the incident laser can be eliminated when the Raman intensity ratio from silicon under particles to that from bare silicon, I_{SiO2}/I_{Si}, is applied. The difference between I_{SiO2} and I_{Si} is caused by the temperature rise under the irradiation. The silica particle-induced near-field focusing effect largely raises the temperature of the silicon substrate in the probed area. The intensity ratio I_{SiO2}/I_{Si} is then normalized by dividing the extrapolation value at 0 laser energy $[I_{SiO2}/I_{Si}]_{E=0}$. The normalized intensity ratio $[I_{SiO2}/I_{Si}]/[I_{SiO2}/I_{Si}]_{E=0}$ reduces when energy flux increases. With the calibration of I_{Si} against temperature, the temperature rise ΔT induced by 1,210 nm particles are obtained from 10.0 to 56.1 K with an uncertainty of ±7.0 K, when the laser energy percentage goes from 25 % to 100 %.

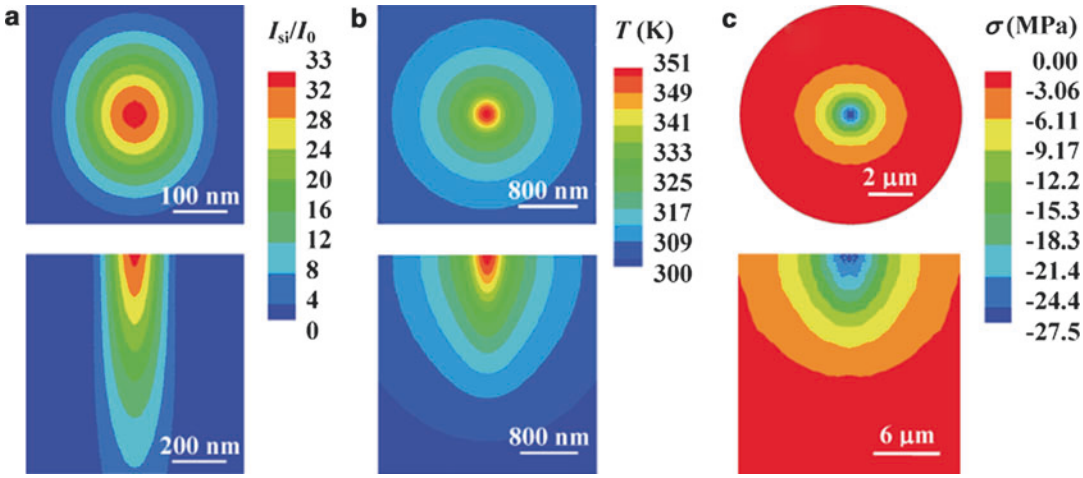
The thermal stress σ inside the silicon under particles is then determined by using both Raman shift ω and linewidth Γ. Due to the fact that Γ is less sensitive to stress than ω, the experimental linewidth and Raman shift can be expressed as $\Delta\Gamma_{exp} = \Delta\Gamma_{\Delta T} + \Delta\Gamma_{focus}$ and $\Delta\omega_{exp} = \Delta\omega_{\Delta T} + \Delta\omega_{focus} + \Delta\omega_{\sigma}$, respectively, when the temperature rise and out-of-focus effect induced by the particles are considered. With the slopes for linewidth and Raman shift against temperature increase in the calibration and the calculated ΔT from intensity, $\Delta\Gamma_{focus}$ can be easily obtained. Another calibration is conducted to obtain the relationship between $\Delta\Gamma_{focus}$ and $\Delta\omega_{focus}$ induced by the out-of-focus effect: $\Delta\omega_{focus} = -0.21–0.77\Delta\Gamma_{focus}$. Thus, $\Delta\omega_{\sigma}$ and even σ can be both obtained easily. A proportionality constant of $-3.6\ cm^{-1}$/GPa [11] is adopted for calculating the stress σ inside silicon based on the variation of Raman shift $\Delta\omega_{\sigma}$. According to the calculation, σ increases from 140 to 370 MPa with an uncertainty of 640 MPa as the energy percentage of laser goes up from 25 % to 100 %.



The cases of silicon under particles of smaller sizes, 800, 400, and 200 nm, are also studied. It is found that the maximum Raman intensity ratio (I_{max}/I_{min}) decreases as the particles decreases from 1,210 to 160 nm. 140 nm diameter particles

would be the minimum size which can be detected by using this confocal Raman system. The lateral resolution improves with the increase of the particle size. The best resolution of about 20 nm is achieved when the particle diameter is 1,210 nm.

Near-Field Thermal, Optical, and Mechanical Phenomena: Modeling



The 1,210 nm particle–substrate case is also studied with the finite element method by using HFSS (V14 ANSYS, Inc) [8–10]. A quarter of the silica particle and the substrate are used due to the consideration of the amount of mesh density and calculation in HFSS. A plane wave ($\lambda = 532$ nm) irradiates normally from the top of the particle. In the experiment, the laser spot size is smaller than the diameter of the 1,210 nm particle. To meet the experimental condition, only the parts of particles inside the laser spot area remain in the model. The rest parts are cut off to avoid receiving the plane wave. Perfect H and Perfect E symmetry boundaries are applied for symmetrical planes. Absorbing (radiation) boundaries are applied for other boundary planes in the domain. Two typical cases regarding different laser-particle positions in an imaging period are simulated, and the resulting electric field distribution is shown in Fig. 6a.

The temperature distribution inside the silicon substrate is calculated by using FLUENT (V12.0.1 ANSYS, Inc) based on the electric field distribution. Because of the symmetry of the temperature distribution inside the silicon, a quarter cylinder computational domain with a radius of 5 mm and a height of 10 mm is adopted in the simulation. Both vertical cross sections use symmetrical boundary conditions and the top surface is set as adiabatic. The temperature of peripheral and bottom surfaces of the domain and the initial

temperature of the substrate are set at 300 K. The calculated temperature profile in the silicon substrate beneath the silica particle is shown in Fig. 6b.

The stress distribution in the silicon substrate beneath a single silica particle is also studied [9]. The thermal stress distribution inside the silicon substrate (Fig. 7) is simulated with ANSYS V14. The model as well as the temperature distribution is imported from the FLUENT calculation. The peripheral and foot end surfaces of the model are fixed. The top boundary is not constrained. Both vertical cross sections are symmetrical. The calculated maximum thermal stress in the single particle case is around 30 MPa, which is much lower than the experimental value (160 Mpa) determined from Raman shift and linewidth. The difference between the experiment and the simulation is mainly induced by the setting of the incident laser and the out-of-focus effect in experiment.

Material Structure Evolution Under Near-Field Laser Heating

In laser-assisted STM nanostructuring, as a direct consequence of nanoscale heating, the nanodomain of a sample just below the STM tip experiences intense heating, phase change, phase explosion, stress development and propagation, and rapid structural evolution. The enhanced optical field, light confinement, and only the thermal evolution of the sample surface under the STM tip without phase change have been widely studied. Furthermore, in surface nanostructuring, the final surface nanostructure is strongly affected by solidification of the molten material. The solidification process is driven by the heat conduction in the material and is much slower than the heating and melting processes that are largely driven by the laser energy input. Previous works mainly focused on the simulation in a small scale and short time duration. In this section, studies for a longtime behavior of a large system consisting of more than one hundred million atoms are introduced for the material structure evolution: heating, melting, phase change, solidification, and defect formation in the laser-assisted STM nanostructuring. The model used in the simulation is designed with true dimensions though the simulated result is based on several artificial assumptions.

Methodologies of Large-Scale Parallel Molecular-Dynamics (MD) Simulation

At nanoscale, the thermal movements of molecules/atoms show strong statistical variations in space since thermal equilibrium cannot be well established. MD simulation, which directly tracks the movement of molecules/atoms, is capable of exploring the physical phenomena down to molecular/atomic levels. A designed thin free-standing argon film at 50 K is irradiated with a near-field focused laser beam. The distribution of the optical field in space and time for this laser beam is constructed as

$$I = I_0 \exp\left(\frac{-\left(\vec{r} - \vec{r}_0\right)^2}{r_g^2}\right) exp\left(\frac{-(r - r_0)^2}{r_g^2}\right), \tag{1}$$

where I_0 is a laser beam intensity constant, r is the location of the laser beam, r_0 is the center of the sample surface, r_g is a length constant determining the size of the laser beam, t is the time, t_0 is a time constant determining the peak location of the laser intensity in the time domain, and t_g is a time constant determining the pulse width of the laser beam.

To simulate the laser–argon film interaction, the movement of atoms is governed by the Newtonian equation,

$$m_i \frac{d^2 r_i}{dt^2} = \sum_{j \neq i} F_{ij}, \tag{2}$$

where m_i and r_i are the mass and position of atom i, respectively. F_{ij} is the interaction force between atoms i and j and is computed from the Lennard-Jones (LJ) potential as $F_{ij} = -\partial \phi_{ij} / \partial r_{ij}$. The Lennard-Jones potential ϕ_{ij} follows the form

$$\phi_{ij} = 4\varepsilon \left[\left(\frac{\sigma_e}{r_{ij}}\right)^{12} - \left(\frac{\sigma_e}{r_{ij}}\right)^{6} \right], \tag{3}$$

The half-step leapfrog scheme is used in the simulation. For argon, the cutoff distance r_c adopts the widely accepted value $2.5\sigma_e$. Computation of the force between an atom and its neighbors is arranged by the cell structure and the linked-list method.

When studying the longtime behavior of a large system, the physical domain is divided into N subdomains of the same size as shown in Fig. 8a, and these subdomains are distributed over a parallel computer consisting of

N computing nodes. Each node is responsible for the MD simulation of one subdomain. The parallel program is developed using MPICH. Periodical boundary conditions are applied to the boundaries in the x and y directions and free boundary conditions to the boundaries in the z direction. Details of the parallel treatment are discussed in reference [12]. Nowadays, various MD simulation packages are available for parallel computation. Still this subdomain scheme saves significant time for data exchange among computing nodes.

The numerical treatment of the laser absorption in the sample is shown in Fig. 8b. The MD domain is divided into cubic cells with a little larger size than cutoff distance. Take cells 1 and 2 as examples; cell 1 is the first cell to absorb the laser energy when the laser propagates from one layer to another along the z direction. The laser energy absorbed by cell 1 within each time step is

$$\delta E_1 = E_1\left(1 - exp\left(\frac{-\delta z}{\tau_1}\right)\right), \qquad (4)$$

where E_1 is the laser energy reaching cell 1 within one time step δt, $E_1 = \int_A I\delta t \cdot dA$. δz is the z dimension of cell 1. τ_1 is the modified artificial absorption depth due to heating, explosion, and other physical processes. The artificial absorption depth is designed to reflect the volumetric absorption of the laser beam in the sample rather than to represent the practical experimental condition. When laser arrives at cell 2, the energy is $E_2 = E_1$ - δE_1. The laser energy absorbed by cell 2 can be calculated with eqn. 4. The laser keeps propagating and the energy absorption process is continued in the following cells until the energy is totally absorbed. The kinetic energy of atoms in the material is excited by the energy transferred from the laser beam, while the momentum of atoms is conserved during laser energy absorption.

The Material Structure Evolution: Heating, Melting, Phase Change, Solidification, and Defect Formation

The solidification and crystallization of an argon film of 100,776,960 atoms is simulated over 2 ns [13] after the irradiation of a near-field enhanced pulse laser. The film is comprised of 648 fcc unit cells (350.83 nm) in the x and y directions and 60 fcc unit cells (32.48 nm) in the z direction. The length of the film is much larger than the beam spot of 25 nm, and the thickness is much thicker than the optical absorption depth 10 nm. The pulse energy is taken as 8×10^{-15} J, which corresponds to an energy density level of 50 MW/cm^2. Before applying laser heating, the simulation is run for 100 ps, during which the velocity of atoms is scaled to make the sample to reach 50 K gradually. After this velocity scaling, the sample is simulated for another 100 ps to eliminate the disturbance introduced by the velocity scaling. Free spaces are added below and above the sample to capture the movement of atoms escaping from the sample. The entire computational domain measures 350.83 nm in the x and y directions and 759.10 nm in the z direction with the back side of the sample located at 213.71 nm.

Epitaxial regrowth process is observed in this longtime simulation. The atomic dislocation is induced by thermal strain in the epitaxial regrowth. The normal compressive stress and negligible shear stress decline when the melting occurs. The distance between atoms is studied to reflect the crystallinity and distinguish solid and liquid. The solid–liquid interface moves at an average speed of 3–5 m/s which increases with time, and the spatial distribution of the moving speed at the solid–liquid interface in nonuniform. Two edges of the liquid region in the nanohole solidify first, and their solidification speed is faster than that at the bottom because the heat conduction area at the two edges is much stronger, which leads to the appearance of nonuniform epitaxial regrowth.

Irregular perturbations at the edge of the nanohole are observed in simulating the surface nanostructuring with a pulse-laser-assisted STM [14]. To explore the thermal and mechanical mechanisms, another system consisting of more than 200 million atoms is modeled by employing large-scale parallel MD simulations. The sample is designed as 648 fcc unit cells (350.83 nm) in the x and y directions and 60 fcc unit cells (32.48 nm) in the z direction. The pulse energy is taken as 1.6×10^{-14} J, which corresponds to an energy

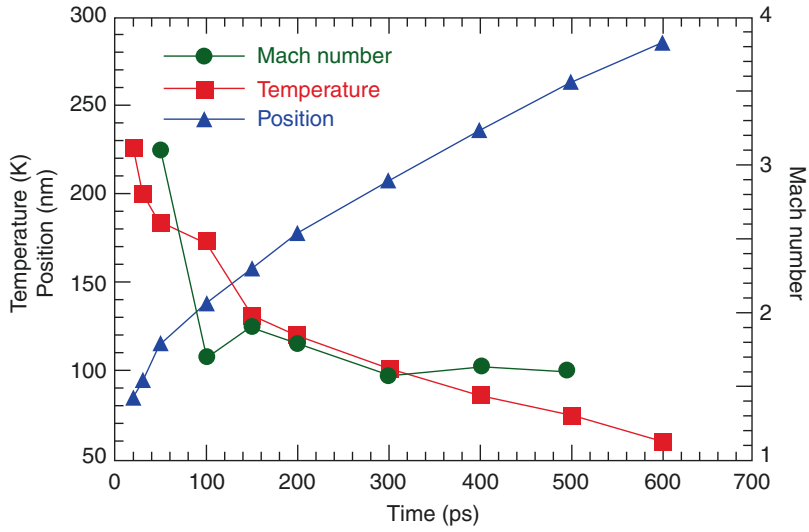
density level of 100 MW/cm^2. Strong compressive stress develops beneath the sample surface due to the absorption of the strong laser power. These compressive stresses then drive atoms' movement to induce phase explosion. In addition, the anisotropic propagation of the stress occurs in the material because of the direction-dependent stress wave speeds in the crystal. Visible subsurface structural damages are observed in the direction of 45° with respect to the z axis. The strong tensile stress resulting from the reflection of the compressive stress at the bottom plays the most significant role in inducing the structural damage.



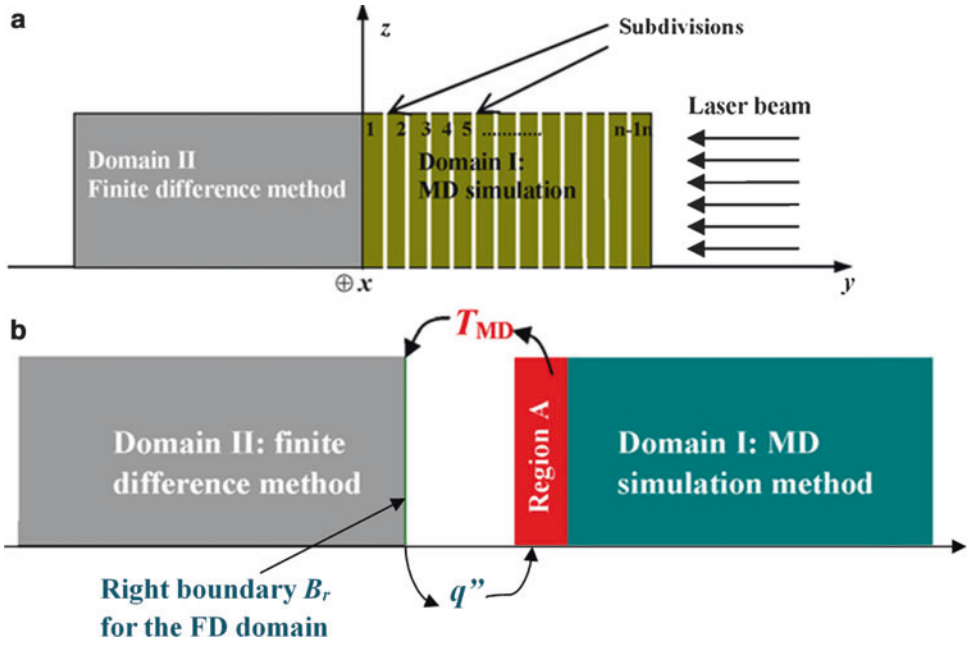
The solidification process of the nanohole after laser heating is also studied by varying the power of the pulse laser [15]. The MD simulation is performed on a very small surface area (tens of nanometers in diameter) in argon crystals, with eight different levels of laser beam energy input: 0.05, 0.1, 0.2, 0.35, 0.5, 0.75, 1, and 1.1 fJ. The corresponding maximal energy density levels are about 12, 24, 48, 84, 120, 180, 240, and 260 MW/cm^2, respectively. The detailed sizes of simulated domains are listed in Table 1. The effect of stress reflection from the bottom of the sample on the final nanostructure is reduced by using suitable large domain size. The diameter, depth, and edge protrusion of the nanohole increase when the laser fluence slows down. The largest melting thickness is reached after the laser heating stops because the melting procedure still continues due to the fact that heat conduction is continuing and its rate is much lower than the heating speed.

Shock Wave

During the process of laser-assisted SPM nanostructuring, intense laser heating will make the solid-state material transfer directly into gas phase to result in phase explosion. The ejected atoms have high kinetic energy and movement speed. When an ambient gas is present, this high-speed movement could compress ambient gas atoms in a very short time, leading to a strong shock wave. It is a very important phenomenon though it is little useful in nanomanufacturing. The first atomistic modeling work on shock wave was done by Zhang et al. [16] in picosecond laser–material interaction. The formation of the shock wave in the nanoscale domain could significantly affect the laser–material interacting zone and the nanostructuring process.

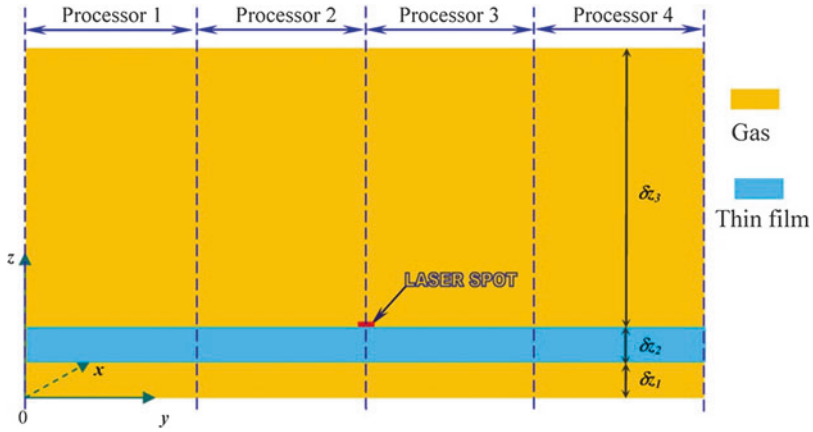
In the shock wave phenomena, the kinetic and physical properties of the disturbed gas compression are explored in a nanodomain in near-field laser–material interaction [17]. The gas compression is driven by the high-speed movement of the molten particulates ejected from the solid target in a nanodomain. The quick interaction between solid and gas atoms compresses the gas and forms a steep shock wave front, which moves at a supersonic speed. The fast compression of gas also induces a steep interface of density, temperature, and pressure distribution, which are viewed as typical characteristics of nanoscale shock waves. Evolutions of shock wave front position, velocity, and Mach number are shown in Fig. 9, illustrating quick decay during wave propagation. Because of energy dissipation, the temperature, pressure, and speed of the shock wave experience a fast decay, but the Mach number always remained higher than 1, meaning the shock wave always persisted in the simulation.

A one-dimensional model is established to simply describe the shock wave front in nanosecond laser–material interaction. The longtime



Physics in Laser Near-Field Nanomanufacturing: Fundamental Understanding and Novel Probing, Fig. 9 Evolution of the shock wave front temperature, position, and Mach number against time (Reprinted from ref. [17], Copyright (2007), with permission from Elsevier)

phase change, including solid–liquid interface speed, temperature, maximum melting depth, and ablation rate, is systematically studied [18]. The whole modeled domain is divided into two subdomains as shown in Fig. 10. Subdomain I is directly subjected to the nanosecond laser irradiation, and its length along the y direction is much longer than the laser melting depth. Subdomain II only experiences heat conduction, and its length is longer than the thermal diffusion length in the material. Subdomain I and II are simulated with finite difference method and MD method, respectively. The temperature and heat flux are continuous at the interface. Periodical boundary conditions are used along the x and z directions as shown in Fig. 10. Strong fluctuation is observed at the solid–liquid interface and surface of the molten pool. No visible superheating is observed at the solid–liquid interface. The melting stops later. A higher peak melting speed appears with higher laser fluence. An almost linear relationship is observed between the ablation yield and the laser fluence, indicating weak phase explosion.



The properties of background gas also have effects on the shock wave [19, 20]. The molecular weight and density of background gas are considered on the laser-induced shock wave. A quasi-three-dimensional model (Fig. 11) is constructed to study a free argon thin film in a gas environment. This simulated system consists of over 2 million atoms so the parallel computation is employed. Eight cases of different background gases are studied in two groups. Details are listed in Table 2. The lower ambient pressure or lighter background gas causes the larger area being affected and a weaker shock wave front. The molecular weight of background gas has little effect on the final kinetic energy of the ablated material and the energy of the background gas regardless of the ambient pressure and laser fluence. When the ambient pressure is reduced, more kinetic energy is carried out by the ablated material, while less energy is transferred to the ambient gas. By studying the ablation in the temporal domain, a heavier ambient gas is observed to bounce back the ablated material.

Concluding Remarks

The experimental and computational works mainly focus on the laser-assisted tip–substrate interaction. The near-field focus effect largely enhances the optical field in the substrate under the tip other than inside the tip. The large parallel MD simulations are carried out to study longtime surface evolution after an intensive pulse applied on it including material structure evolution: heating, melting, phase change, solidification, and defect formation. A shock wave is observed

and systematically studied. The effect of gas background is also considered.

There are some problems still faced in nanomanufacturing. The nanostructuring is a dynamic process, and the processing area is very small (low to the nanoscale). The phenomena occurring in this area are difficult to observe and measure. In the SPM tip-assisted nanomanufacturing, the near-field effect will be easily changed due to vulnerable tip. Either the bump damage or the contamination of the apex of the tip will broaden the tip and finally changes the near-field optical field distribution in and around the tip. Furthermore, in this tip–substrate system, the tip and the substrate are so close to be considered in contact with each other. Therefore, any thermal expansion from the tip and the substrate induced by the local laser heating will result in

measurement instability. Right now the measurement for laser-assisted tip-based nanomanufacturing takes a longer time compared to the time of the dynamic process in the manufacturing. The manufacturing is confined in the nanoscale as well. Future improvement of this technique is required to develop the quick response of the measurement and scale up the manufacturing and improve the scalability in industries.

Nano-piezoelectricity

Definition

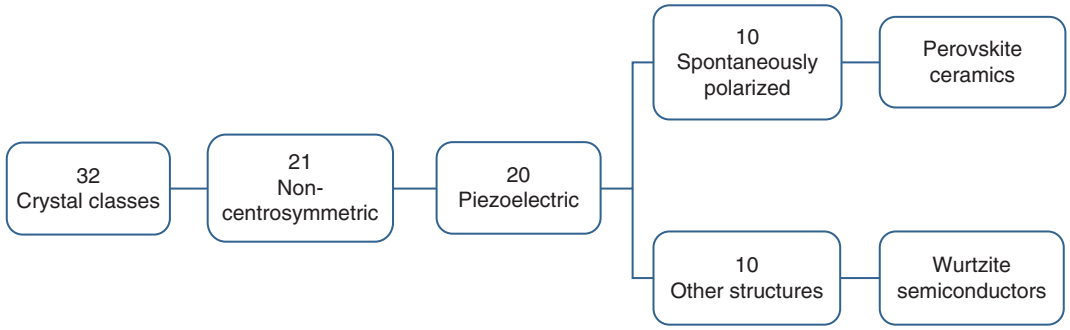
Piezoelectricity is a phenomenon of strain-induced electric polarization in certain crystals, which can be used to create a mechanical action by applying an external voltage for sensors and actuators or a mechanical straining that can produce a voltage for energy conversion.

Piezoelectricity

Piezoelectricity was discovered by Jacques and Pierre Curie during their systematic studies of the effect of pressure on the generation of electrical charge by crystals in 1880. It is a reversible physical phenomenon, as there is the direct piezoelectric effect and the reverse piezoelectric effect.

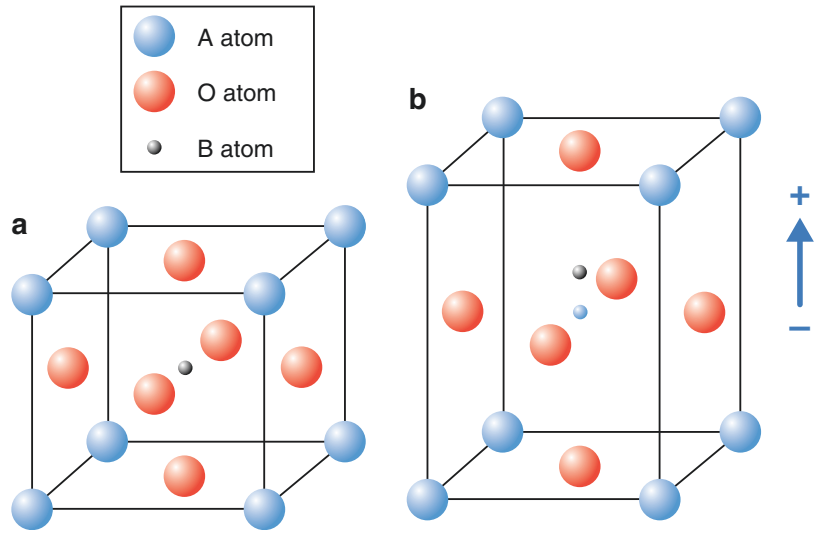
Direct piezoelectric effect is defined as: *electric polarization produced by mechanical strain in crystals belonging to certain classes, the polarization being proportional to the strain and changing sign with it* [1].

Reverse (or inverse) piezoelectric effect is defined as: *a piezoelectric crystal becomes strained, when electrically polarized by an amount proportional to the polarizing field*.



Structures of Piezoelectric Crystals

The nature of piezoelectricity comes from the lack of centrosymmetry/inversion symmetry in the crystal (Fig. 1). Twenty one out of all 32 crystal classes lack inversion symmetry, and 20 of them exhibit piezoelectric effect [2]. The two most important classes include perovskite structure, which occurs in ceramics such as lead zirconate titanate (PZT) and barium titanate ($BaTiO_3$), and wurtzite structure, which occurs in semiconducting materials such as zinc oxide (ZnO), gallium nitride (GaN), indium nitride (InN), and zinc sulfide (ZnS).

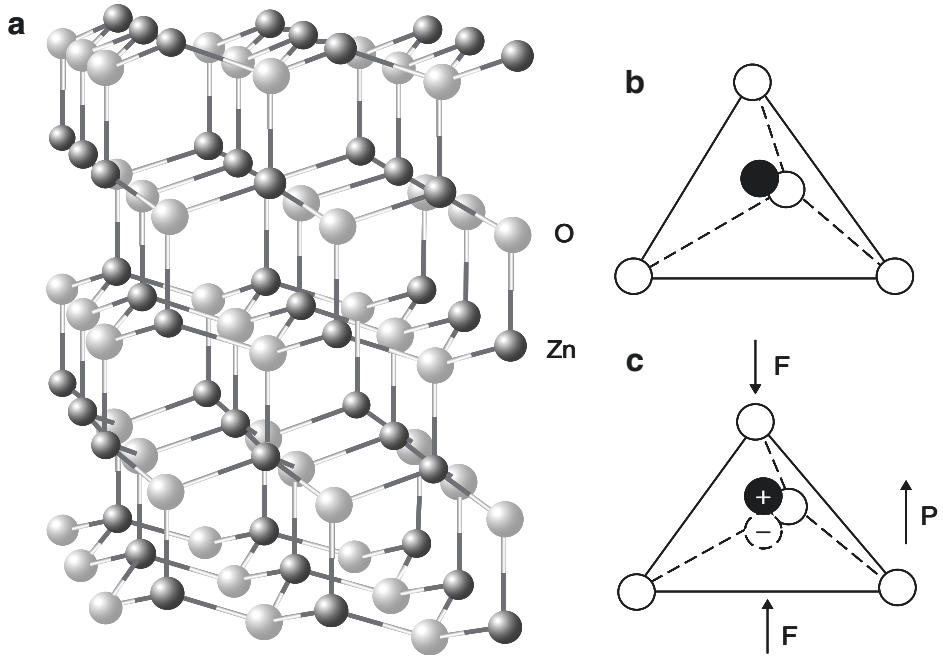


Perovskite Structure

The perovskite structure gets its name from the mineral $CaTiO_3$ and is adopted by many oxides that have the chemical formula of ABO_3 [3]. The most widely used piezoelectric ceramics, including barium titanate ($BaTiO_3$) and lead zirconate titanate (PZT), are formed in this structure.

As shown in Fig. 2a, in the unit cell of perovskite compound, type "A" atom is in the cube corner

Piezoelectric Effect at Nanoscale, Fig. 1 Scheme of piezoelectric crystal classes



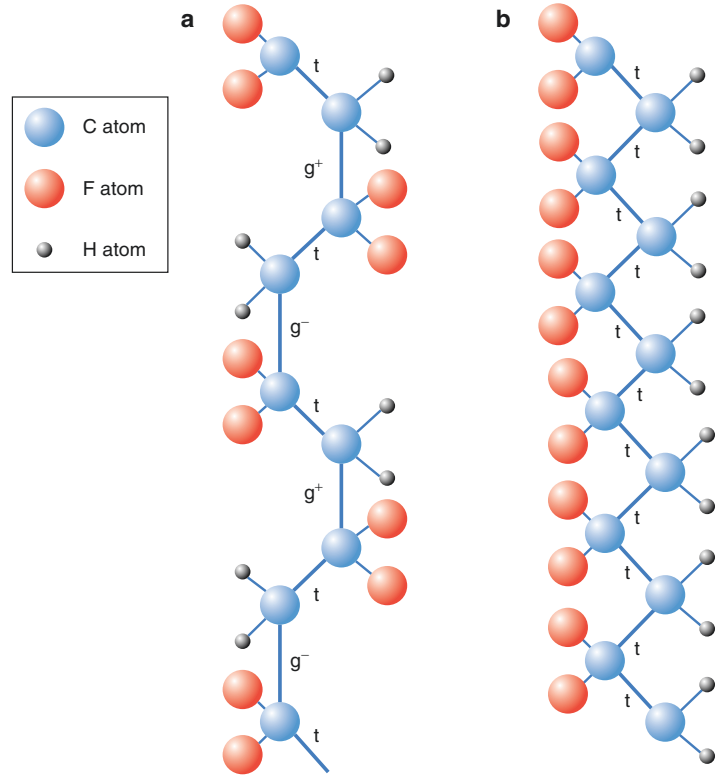
Piezoelectric Effect at Nanoscale, Fig. 2 (**a**) Ideal perovskite structure, (**b**) perovskite structure with distortion and polarization along *c*-axis

positions (0, 0, 0), type "B" atom is in the body center position (1/2, 1/2, 1/2), and oxygen atoms are in the face-centered positions (1/2, 1/2, 0). However, in real cases, since ion sizes hardly meet the stringent requirement for stability, most perovskite structures are distorted and lose their cubic symmetry and commonly shift into orthorhombic or tetragonal phases [4]. When "B" atoms are displaced in such distortion, as shown in Fig. 2b, the center for negative charge and positive charge in the crystal no longer coincides with each other and results in an electric dipole. This is where the piezoelectricity comes from.

Since the piezoelectricity originates from rather randomly oriented distortion, it is much more complicated and is correlated with the concept of ferroelectricity. In most cases, perovskite ceramics forms polycrystalline structures with multiple electric "domains." Each domain has a size in the order of 10–100 nm, and even though each individual domain is piezoelectric itself, the whole ceramic does not show macroscopic dipole without poling, as they have differently oriented electric dipoles. Electrical alignment of the dipoles, or electric poling as stated in most cases, is required to activate the piezoelectric effect in the ceramics. Similar to ferromagnetic materials, a characteristic temperature, the Curie temperature (T_C), exists in perovskite ceramics, above which they lose their electric polarization induced in the poling process.

There are multiple methods for fabricating perovskite ceramic nanostructures [5]. The top-down methods include electron-beam-

Piezoelectric Effect at Nanoscale, Fig. 3 ZnO with wurtzite structure and illustration for the formation of dipoles ([8], Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission)



assisted fabrication, nanoprinting, and self-assembling and they provide high-precision positioning and size control. However, top-down methods are limited in resolution and prone to processing damage. In comparison, the bottom-up approaches allow much smaller feature sizes but suffer from poor registration and thus require substrate patterning that in turn involves top-down processing. For one-dimensional nanostructure, solution-phase decomposition and hydrothermal chemical synthesis [6] can result in single crystalline nanorods and nanowires, sol–-gel method associated with nanochannel templates or electrospinning can produce polycrystalline nanowires, and wetting of the porous templates can produce nanotubes.

In all of the conventional piezoelectric materials, PZT has the best performance and the widest application. Its piezoelectric coefficient d_{33} can be as high as 400 pC/N and can be higher than 600 pC/N when doped with lanthanum [2, 7]. However, since it is a lead-containing chemical, it is not environmentally and biologically friendly without proper packaging, and its applications in the nanoscale region are thus restricted, as such applications are often related to biomedical or environmental issues.

Wurtzite Structure (ZnO, GaN)

The wurtzite crystal structure is named after the mineral wurtzite and is the crystal structure for various binary compounds. Wurtzite structure occurs in most piezoelectric semiconductors, including zinc oxide (ZnO), gallium nitride (GaN), cadmium sulfide (CdS), silicon carbide (SiC), and so on, and among them, ZnO is the most widely used in one-dimensional nanostructure and the key material for nanogenerators, piezotronics, and piezophototronics, as will be discussed later.

As shown in Fig. 3, in a Wurtzite structure, each of the two individual atom types forms a sublattice which is hexagonal close pack (HCP) type, and they form tetrahedral coordination with each other [8]. Distinct from Perovskite structure, Wurtzite structure crystals do not need distortion

Piezoelectric Effect at Nanoscale,
Fig. 4 Illustration of the two main conformations of PVDF. (**a**) α conformation, (**b**) β conformation

or external poling to break the centrosymmetry. In single crystal Wurtzite materials, there are strong and uniform dipoles along the *c*-axis, and the dipole direction is determined by the stacking order of the anions and cations and, more specifically, *+c* for cation to anion and *-c* for anion to cation. The orientation and polarity determine the direction of the piezoelectricity in the crystal. In ZnO, the interaction of the polar charges at the surface results in the growth of a wide range of unique nanostructures, such as nanobelts, nanosprings, nanorings, and nanohelices.

The synthesis of ZnO nanostructures is easy and convenient. To fabricate large-scale nanowire arrays, chemical hydrothermal at 80 °C can be carried out on any substrate, while physical vapor liquid solid (VLD) or physical or chemical vapor solid (PVD or CVD) growth can give results with higher aspect ratio and higher density on substrate with proper lattice match.

As will be discussed in latter sections, one-dimensional wurtzite nanostructures, especially ZnO nanowires and nanobelts, promote the new concept of "piezotronics," which is the coupling between piezoelectricity and semiconductor transport property and "piezophototronics," which is the result of three-way coupling of piezoelectricity, photonic excitation, and semiconductor transport property.

Piezoelectric Polymer

Piezoelectricity also occurs in semicrystalline polymer materials. The most famous and widely used of them are polyvinylidene fluoride (PVDF) and its copolymers [9].

In PVDF, hydrogen atoms are positively charged, and fluoride atoms are negatively charged with respect to the carbon atoms so that each monomer has an inherent dipole moment. As shown in Fig. 4, PVDF has several conformations: α (tg^+tg^-), β (all trans), and γ ($tttg^+ttg^-$). In α conformation, the dipoles along the chain cancel each other so that the overall piezoelectric effect is zero, and this conformation is the non-piezoelectric conformation. In the β conformation, the alignment of all its dipoles is in the

same direction normal to the chain axis. In this way, once strain is applied on the β-phased polymer and the chain is either stretched or compressed, the dipole strength will change, and extra net charge will be induced so that this conformation is piezoelectric. Since the nature of PVDF is ferroelectric, electric poling is also needed for the dipoles on the polymer chains to align so that the polymer will have piezoelectric response.

The crystallinity of pure PVDF is usually 50 ∼ 60 %. In its copolymer with TrFE and TFE, the crystallinity can be increased to nearly 100 % after annealing, and the portion of β conformation is also larger, and the piezoelectric response is thus greater. The piezoelectric coefficient in PVDF can be as high as a negative value of −33 pm/V, and that of PVDF-TrFE can be as high as −38 pm/V.

The synthesis of piezoelectric polymer nanofibers can be easily carried out through the process of electrospinning.

Theory of Piezoelectricity in One-Dimensional Nanostructures

In theoretical concern, piezoelectricity refers to the linear coupling of electricity and mechanics [10]. Considering electrical behavior, we have Maxwell's equation, $D = \varepsilon E$, where D is electric displacement, ε is permittivity, and E is electric field. Considering mechanical behavior, we have Hooke's law, $S = sT$, where S is strain, s is compliance, and T is stress. To describe piezoelectricity, the coupled equations are given as

$$\{S\} = [s^E]\{T\} + [d^t]\{E\}$$
$$\{D\} = [d]\{T\} + [\epsilon^T]\{E\}$$

where $[d]$ is the direct piezoelectric effect matrix and its transpose $[d^t]$ is the inverse piezoelectric effect matrix, and their specific form is related to the point group to which the crystal belongs. The most frequently used parameter is the piezoelectric coefficient d_{33}, with expression $d_{33} = (\partial D_3/\partial T_3)^E = (\partial S_3/\partial E_3)^T$, so the unit of d_{33} is either C/N or m/V, and generally in materials d_{33} is often in the order of 10^{-10}–10^{-12} C/N or m/V. When normal stress is applied along the polarization axis and on the surface charge is collected, d_{33} can be simplified as the volume change when subject to an electric field or the electric polarization when subject to stress. A similar parameter d_{31} is applied when stress is applied at right angle with the polarization axis.

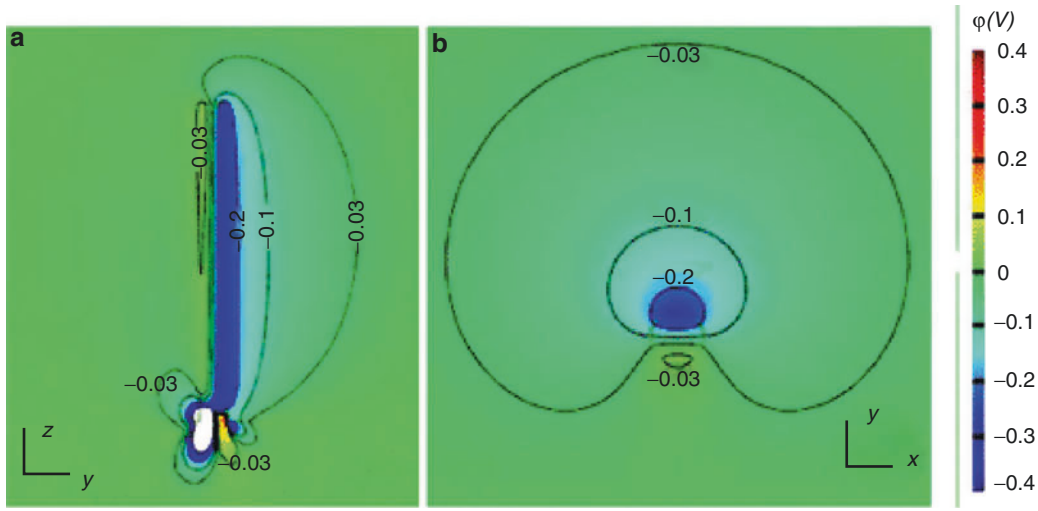
Theoretical approaches have been applied on calculating piezoelectric potential distribution in piezoelectric nanostructures. A continuum model was built for calculating the electrostatic potential in a laterally bent nanowire (NW) [11].

To derive the relationship between the potential distribution in a NW and the dimensionality of the NW and magnitude of the force applied, four sets of equations for static piezoelectric material are first listed:

1. Mechanical equilibrium equation, $\nabla \cdot \sigma = \vec{f}_e^{(b)} = 0$, where σ is the stress tensor.
2. Constitutive equations, $\begin{cases} \sigma_p = c_{pq}\epsilon_q - e_{kp}E_k \\ D_i = e_{iq}\epsilon_q + \kappa_{ik}E_k \end{cases}$, where c_{pq} is the linear elastic constant, e_{kp} is the linear piezoelectric coefficient, and k_{ik} is the dielectric constant.
3. Geometrical compatibility equation, $e_{ilm}e_{jpq}\left(\partial^2\epsilon_{mp}/\partial x_l \partial x_q\right) = 0$ where e_{ilm} and e_{jpq} are Levi-Civita antisymmetric tensors. Small deformation of the NW is also assumed for simplicity of the derivation.
4. Gaussian equation of electric field, $\nabla \cdot \vec{D} = \rho_e^{(b)} = 0$, under the assumption that the piezoelectric NW has no conductivity.

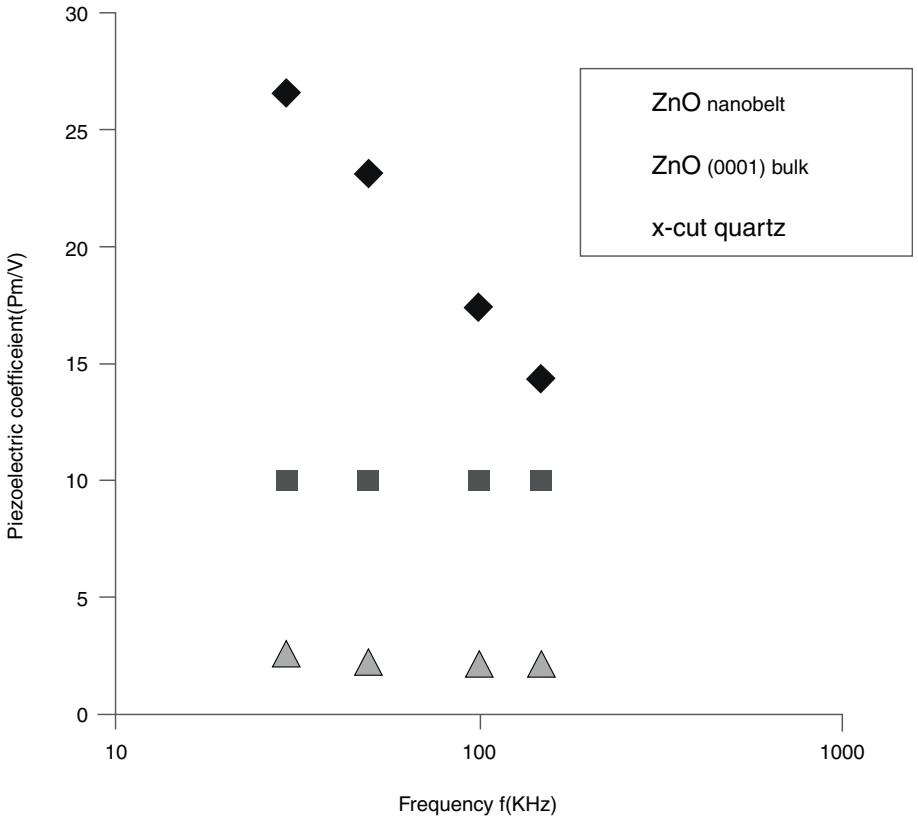
For analytical analysis, a perturbation theory has been developed based on these equations. Under different orders of approximation, the four equations correspond to different extends of decoupling and coupling between the electric field and mechanical deformation: the zeroth-order solution stands for purely mechanical deformation without piezoelectricity; the first order is the result of direct piezoelectric effect, where stress/strain generates an electric field in the

NW; and the second order shows the first coupling of the piezoelectric field to the strain in the material. For the calculation of piezoelectric potential in an insulating NW, the first-order approximation is sufficient, and it gives analytical results less than 5 % away from finite element method (FEM) numerical calculation for potential distribution in a typical NW with diameter $d = 50$ nm and length $l = 600$ nm at a lateral bending force of $f = 80$ nN.



For further investigation on the interaction of piezoelectric potential with semiconductor transportation properties, charge carrier concentration can be substituted into the Gaussian equation of electric field, and the equation is modified as $\nabla \cdot \vec{D} = (\partial/\partial x_i)\left(e_{iq}\epsilon_q + \kappa_{ik}E_k\right) = \rho_e^{(b)} = ep - en + eN_D^+ - eN_A^-$, where p is the hole concentration in the valance band, n is the electron concentration in the conduction band, N_D^+ is the ionized donor concentration, and N_A^- is the ionized acceptor concentration. For n-type nanowires, it can be assumed that $p = N_A^- = 0$ and vice versa for p-type. Considering band structure and charge carrier distribution equations, there can be numerical solution of the modified equations. As shown in Fig. 5, FEM solutions based on these equations are given for a typical ZnO NW with moderate doping (Ref. [36] of [12]).

Further investigation is also carried out considering the contact of semiconducting NW with metals [13]. When a ZnO NW is under nonuniform deformation, the local piezoelectric potential distribution at different positions shows significant effect on and distinct trend of variation in the charge carrier transport characteristic. This can help understanding the characteristics of piezotronic devices based on NW of wurtzite materials by controlling local contact position and contact size.

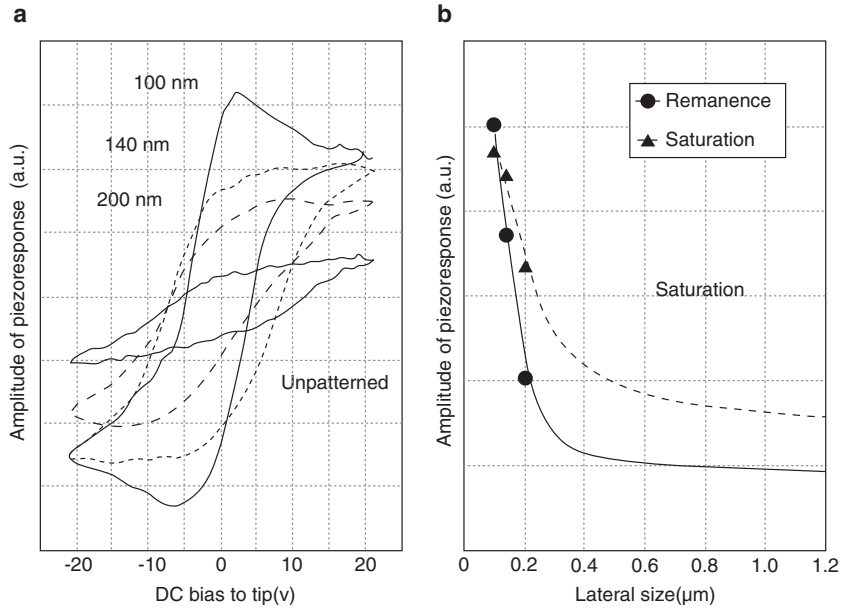


Effect of Size on Piezoelectricity

Size Effect in Wurtzite Nanocrystals

At nanoscale, many interesting effects occur, and this can affect physical properties of materials, including piezoelectric properties. In nanowires (NW) and nanobelts (NB), crystal defects such as dislocation and vacancies will concentrate and eliminate on the surface, and perfect single crystallinity is more easily achieved at this scale of dimension. As a result, during piezoelectric

Piezoelectric Effect at Nanoscale, Fig. 5 Plot of calculated piezoelectric potential φ. Regarding a ZnO NW with diameter $d = 50$ nm and length $l = 600$ nm at a lateral bending force of $f = 80$ nN for the NW is the same as in Fig. 4 except that it is n-type semiconducting with $N_D = 1 \times 10^{17}$ cm^{-3} (Adapted with permission from Ref. [36] of [12] "Gao, Y.F., Wang, Z.L.: Equilibrium potential of free charge carriers in a bent piezoelectric semiconductive nanowire. Nano Lett. **9**, 1103–1110 (2009)." Copyright 2009 American Chemical Society)



Piezoelectric Effect at Nanoscale, Fig. 6 Frequency dependence of piezoelectric coefficient of ZnO nanobelts, ZnO bulk material, and x-cut quartz (Adapted with permission from Ref. [41] of [12] "Zhao, M.H., Wang, Z.L., Mao, S. X.: Piezoelectric characterization of individual zinc oxide nanobelt probed by piezoresponse force microscope. Nano Lett. **4**, 587–590 (2004)." Copyright 2004 American Chemical Society)

measurement of individual zinc oxide NB with dimension of tens of nanometers in thickness, hundreds of nanometers in width and tens of micrometers in length, the effective piezoelectric coefficient d_{33} is revealed to be frequency dependent and varies from 14.3 to 26.7 pm/V, which is about onetime larger than that in bulk ZnO, around 10 pm/V, as shown in Fig. 6.

Size Effect in Perovskite Nanostructures

Since in perovskite materials, piezoelectric performance is tightly related to the concept of domain, the case of size effect is much more complicated, and there are multiple factors to take into consideration. Intrinsically, at nanoscale, competition exists between thermal vibrations and the correlation energy which aligns the dipoles, but greater surface area also helps eliminate defects. Extrinsically, grain boundaries and other microstructural factors can also have various influences.

Between 10 and 1,000 nm, which is bigger than or equal to the scale of a typical single domain and similar to the state of art piezoelectric nanodevices, controversial size effects can occur in differently processed materials regarding the sequence of patterning and crystallization of the nanostructure. This controversy is caused by extrinsic factors related with post annealing. In structures that were patterned with high-energy ion etching after crystallization, which leads to higher concentration of oxygen and lead vacancies, several reports reveal the inherent reduction in the piezoelectric coefficient in ultrathin PZT

Piezoelectric Effect at Nanoscale, Fig. 7 Ferroelectric loop showing increased piezoelectric response with shrinking size. (**a**) Loops on patterns with different lateral sizes and on the unpatterned film, and (**b**) remnant polarization and saturation as a function of lateral size [14]

films. With post annealing, nonswitching of pinned domains helps stabilize and enhance piezoelectric effect. In thin film studies, the observed increase of piezoelectric response amplitude can be as high as 300 % when decreasing the feature size of patterns on epitaxial PZT thin film from 200 to 100 nm, as shown in Fig. 7. The crystalline nature of patterns might also have contributed to this difference: single crystalline tends to have better piezo performance with smaller scale than polycrystalline. In template method, synthesized PZT NW enhanced piezoelectric response than the value in thin film was also discovered [5].

Under 10 nm, intrinsic factors have more influence on the piezoresponse. People have used phenomenological models and first principal/ab initial calculations to predict the behavior of such nanostructures, and their prediction is based on the competition and cancelation of thermal drift. In general, the results are shown as (1) depolarizing fields exist near the surfaces to reduce polarization and (2) piezoelectric state becomes unstable below certain sizes, which is estimated to be 7–10 nm along each of the three directions of well-known materials such as $BaTiO_3$. Microscopy study in this scale has been done and verified these predictions to some extent. This gives us important information that fabricating piezoelectric devices under the scale of 10 nm using perovskite structure materials will hardly result in better performance.

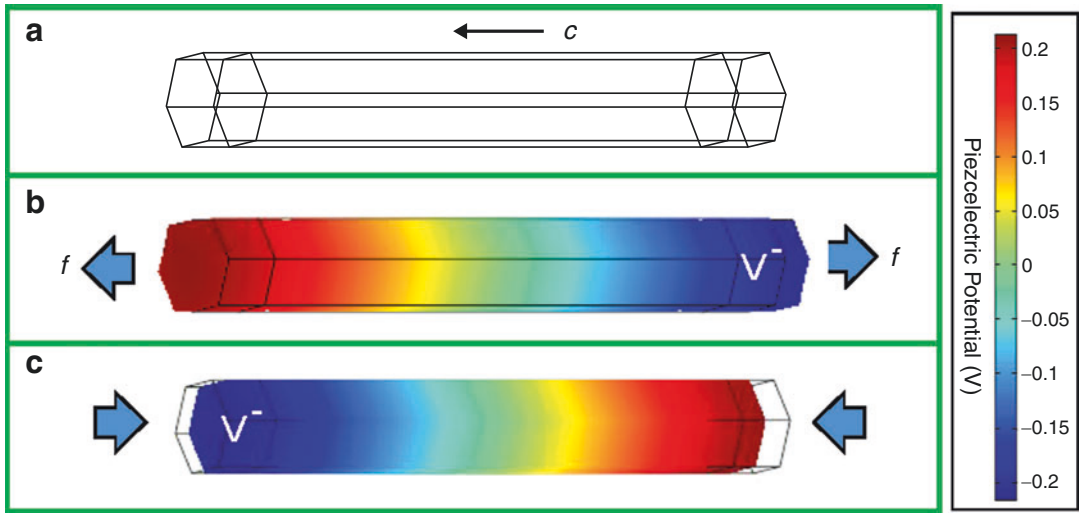
Applications of Nanoscale Piezoelectric Properties

As mentioned in previous sections, for materials with perovskite structure, the enhancement of performance at the nanoscale is not always significant, and related application is very limited. For materials with wurtzite structures however, especially for ZnO NW and NB, the interaction of piezoelectricity with semiconducting transportation process brings about new phenomena and draws great research interests, into the new concept of "piezotronics" and even "piezophototronics." These applications include piezoelectric field-effect transistor, piezoelectric diode, piezoelectricity-based nanosensors, piezoelectricity-enhanced photodetector, and,

most importantly, the piezoelectric nanogenerators.

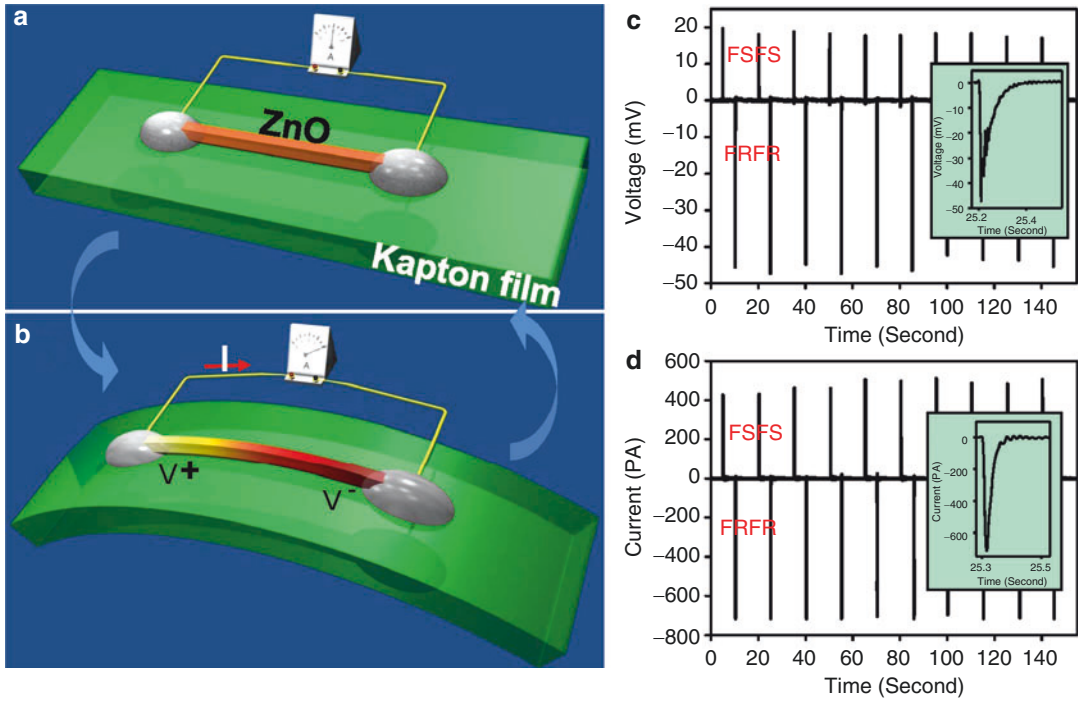
Piezoelectric Nanogenerator

The future of nanotechnology research is likely to focus on the areas of integrating individual nanodevices into a nanosystem that acts like living specie with sensing, communicating, controlling, and responding. A nanosystem requires a nanopower source to make the entire package extremely small yet with high performance. The goal is to make self-powered nanosystem that can operate wirelessly, independently, and sustainably. Harvesting energy from the environment is a choice for powering nanosystems especially for biomedical applications. Since mechanical energy is a conventional form of energy that exists in our living environment, it is essential to explore innovative nanotechnologies for converting mechanical energy (such as body movement and muscle stretching), vibration energy (such as acoustic/ultrasonic wave), and hydraulic energy (such as body fluid and blood flow) into electric energy that will be used to power nanodevices without using battery. This is a key step toward *self-powered nanosystems* [15].



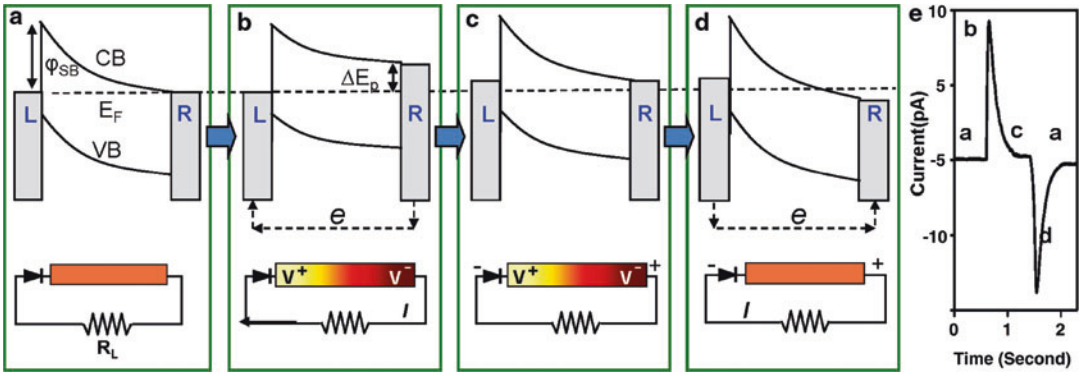
Dr. Z.L. Wang's group in Georgia Institute of Technology is the first to invent an innovative approach for converting mechanical energy into electric energy by piezoelectric zinc oxide nanowire arrays [16]. The operation mechanism of the nanogenerator (NG) relies on the piezoelectric potential created by an external strain; a dynamic straining of the nanowire results in a transient flow of the electrons in the external load due to the driving force of the piezopotential. The nanogenerator technology has been developed from fundamental science, to engineering integration and to technological scale-up. As today, a gentle straining can output 1–3 V at an instant output power of $\sim$2 μW from an integrated nanogenerator, using which a self-powered nanosensor has been demonstrated [6]. This technology has the potential applications for powering MEMS/NEMS that requires a power of the microwatt to milliwatt range.

The fundamental of nanogenerator relies on the presence of the piezoelectric potential (piezopotential) generated in a nanowire/nanobelt via dynamic straining. As demonstrated in previous sections, ZnO has the wurtzite structure, in which the tetrahedral coordinated O^{2-} and Zn^{2+} are stacked layer by layer along the *c*-axis. The lack of central symmetry results in the piezoelectric property of ZnO, which is vital for the mechanic-electric energy conversion with the ZnO-based nanogenerator.



The cations and anions are tetrahedral coordinated in the wurtzite-structured ZnO. At the strain-free status, the charge center of the cations and that of anions coincides with each other. When an external strain is applied, the structure is deformed so that the charge centers for cations and anions separate and result in an electric dipole. Because the ionic charges are not free to move and the intrinsic free-charge carriers can only partially screen them if the doping level is low, the piezoelectric field is preserved as long as the NW is strained. The potential created by the polar ions is called *piezoelectric potential or piezopotential*.

The presence of piezopotential is the fundamental physical basis of the nanogenerators and piezotronics (Fig. 8). When a strained crystal is connected to an external load, the electrons in the circuit are driven to flow in to partially screen the piezopotential, which is the energy conversion process. Therefore, *the principle of the nanogenerator is the transient flow of electrons in external load as driven by the piezopotential created by dynamic straining*.



Piezopotential-driven transient flow of electrons in an external load is the principle of the nanogenerator. Figure 9 presents a single wire generator (SWG) using a laterally packaged ZnO wire. In brief, a single ZnO wire was placed laterally on the flexible polyimide film. Silver paste can be used to fix two ends of the ZnO wire to the substrate and link the wire to the external measuring instrument through metallic wires. Electric measurement shows that a functioning SWG usually has rectifying *I-V* characteristic, indicating the existence of the Schottky contact at least at one end. Before the SWG is deformed, there is no measurable potential drop from the ZnO wire. When the substrate is bent, both the substrate

(**e**) Short-circuit current measurement in which the labels of *a*, *b*, *c*, and *d* indicate the corresponding process shown in subparts *a*–*d* (Adapted from Ref. [16] of [12] "Yang, R.S., Qin, Y., Dai, L.M., Wang, Z.L.: Power generation with laterally packaged piezoelectric fine wires. Nat. Nanotechnol. **4**, 34–39 (2009)")

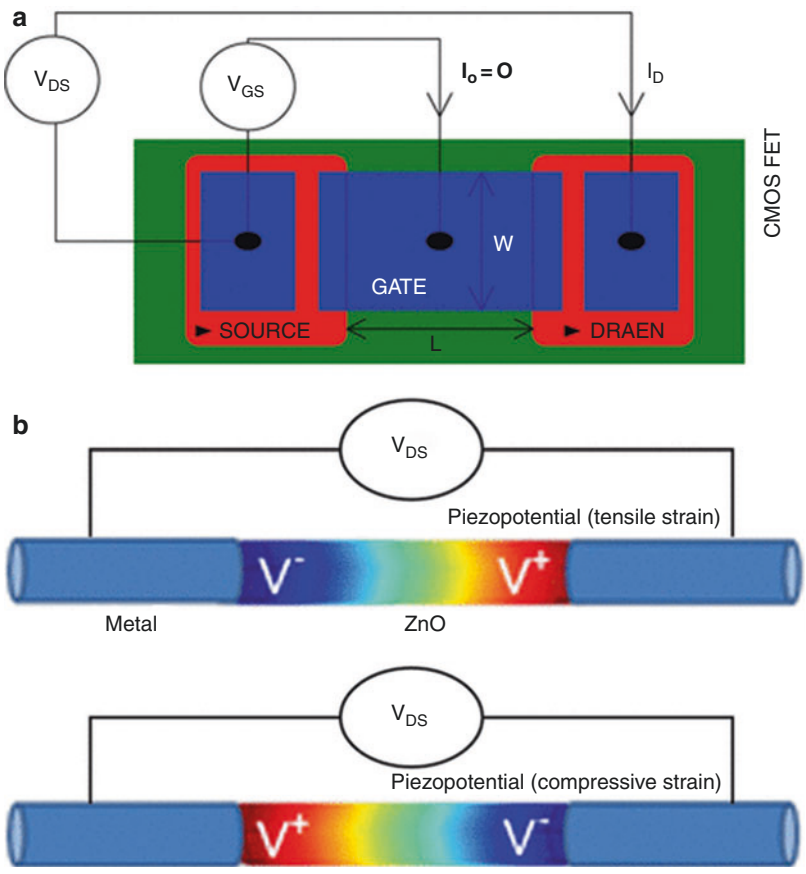
and the ZnO wire are under strain. Because the thickness of the substrate is much larger than the dimension of the ZnO wire, the ZnO wire is solely experiencing tensile strain when the bend is concave downward, as shown in Fig. 9b. As discussed earlier, tensile strain will result in piezopotential, such that the +*c*-axis side gains positive potential (light yellow) and −*c*-axis side gains negative potential (dark red). The potential difference between the two ends can then be measured either as open-circuit voltage (Fig. 9c) or short-circuit current (Fig. 9d).

The working mechanism of the SWG can be understood with the energy band diagram in Fig. 10. The Schottky contact at least at one end is necessary for the energy generation. It is assumed that the Schottky contact is at the +*c*-axis side (left side in Fig. 10a) and the energy generation follows in a similar way when the Schottky contact is on the other side or both sides. The entire wire is in equilibrium state without any strain and power output (Fig. 10a, e). When the wire is stretched, the tensile strain induces polarization of atoms, as well as piezoelectric field, in the crystal. Consequently, the +*c*-axis side holds positive potential and the −*c*-axis side holds negative potential. The potential difference is ΔE_p. The conduction band edge, as well as the Fermi level of the metal of the right-side electrode, rises up for the same amount of ΔE_p. The electrons in the external circuit should flow from the right-hand side to the left-hand side to compensate the energy difference, which will generate the first output signal if the flow rate is sufficiently large, as indicated in Fig. 10b, e. The electrons cannot flow across the interface due to the presence of a Schottky barrier ϕ_{SB}. The accumulation of the electrons at the interface will partially screen the piezopotential built in the wire. When the electrons and the piezoelectric field reach equilibrium, the Fermi energy on both sides is on the same level, and there is no more current flow (Fig. 10c, e). When the SWG is fast released, there is no strain inside the NW. As a result, the polarization and piezoelectric field vanish as well, and the equilibrium with the accumulated electrons is broken. The accumulated charge carriers flow back from the left-hand side to the right-hand side through the external circuit, producing the second output signal in the opposite direction, as shown in Fig. 10d, e.

Integration of SWGs is a major step toward the practical applications. Taking advantage of the small size of the NW, multiple SWGs can be built on a single substrate such that the hamster

can drive all SWGs simultaneously. Integration of up to four SWGs in serial has been demonstrated with the open-circuit voltage of ~0.1–0.15 V. The output current can also be improved with multiple SWGs in parallel. The work on the human finger and living hamster clearly demonstrated the capability of the SWG to scavenge mechanical energy from the biosystem. It also confirms the feasibility of using the SWG for harvesting the energy created by regular and irregular motions.



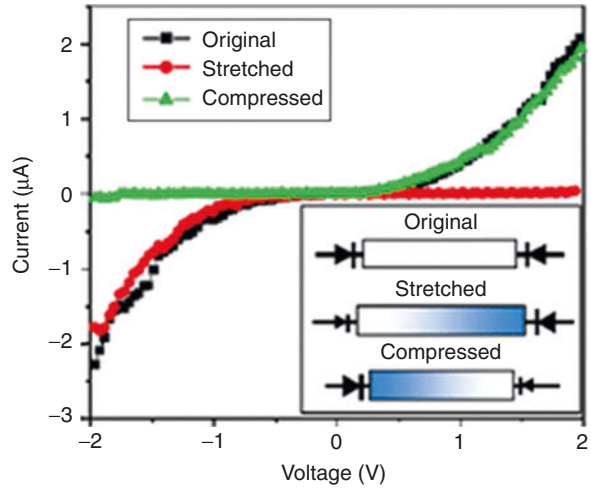
Piezotronics

A most simple FET is a two-end bonded semiconductor wire, in which the two electric contacts at the ends are the source and drain, and the gate voltage can be applied either at the top of the wire through a gate electrode or at its bottom on the substrate [8, 13]. When a ZnO NW is strained axially along its length, the piezoelectric potential continuously drops from one side of the NW to the other, which means that the electron energy continuously increases from the one side to the other. Meanwhile, the Fermi level will be flat all over the NW when equilibrium is achieved, since there is no external electrical field. As a result, the effective barrier height and/or width of the electron energy barrier between ZnO and metal electrode will be raised at one side and lowered at the other side; thus, it has a nonsymmetric effect on the source and drain. This is the *piezotronic effect* [11].

Once a strain is created in the semiconductor that also has piezoelectric property, a negative piezopotential at the semiconductor side effectively increases the local SB height, while a positive piezopotential reduces the barrier height. The polarity of the piezopotential is dictated by the direction of the *c*-axis for ZnO. The role played by the piezopotential is to effectively change the local contact characteristics through an internal field; thus, the charge carrier transport process is tuned/gated at the metal-semiconductor (M-S) contact. Figure 11 compares the piezopotential-gated FET and the traditional CMOS FET, which are different only by replacing the gate voltage by the inner-crystal piezopotential. With considering the change in piezopotential polarity by switching the strain from tensile to compressive, the local contact characteristics can be tuned and controlled by the magnitude of the strain and the sign of strain. This is the core of piezotronics.

The fundamental working principle of the p-n junction and the Schottky contact is that there is an effective barrier that prevents the charge carriers of both sides from crossing. The height and width of the barrier are the characteristic of the device. In piezotronics, the role played by the piezopotential is to effectively change the width of p-n junction or height of Schottky barrier (SB) by piezoelectricity, which has applications in maximizing the performance of the solar cell, photon detector, and LED by tuning the height of the local SB for achieving the optimum charge separation.

A simple piezotronic device is a polarity switchable diode that is made of a ZnO NW contacted with metal contacts at the two ends on an insulating polymer substrate. From the initial I-V curve measured from the device before applying a strain as shown in Fig. 12, the symmetric shape of the curve indicates that the SBs present at the two contacts are about equal heights. The equivalent circuit model of the device is a pair of back-to-back Schottky diodes, as illustrated in the inset in Fig. 12. Under tensile strain, the piezoelectric potential at the right-hand side of this NW was lower (denoted by blue color in the inset in Fig. 12), which raised the local barrier height (denoted by a large diode symbol in the inset). Since the positive piezoelectric potential was partially screened by free electrons, the SB height at the left-hand side remained almost unchanged. As a result, under positive bias voltage with the left-hand side positive, the current transport was determined by the reverse-biased SB at the right-hand side. While under the reverse-biased voltage with the right-hand side positive, the current transport depended on the reverse-biased SB at the left-hand side, which had a much lower barrier height than the right-hand one. Experimentally, the device thus exhibited a rectifying behavior in the positive voltage region, and the *I-V* curve in the negative voltage region overlapped with that of the original curve without straining. By the same token, under compressive strain, the device



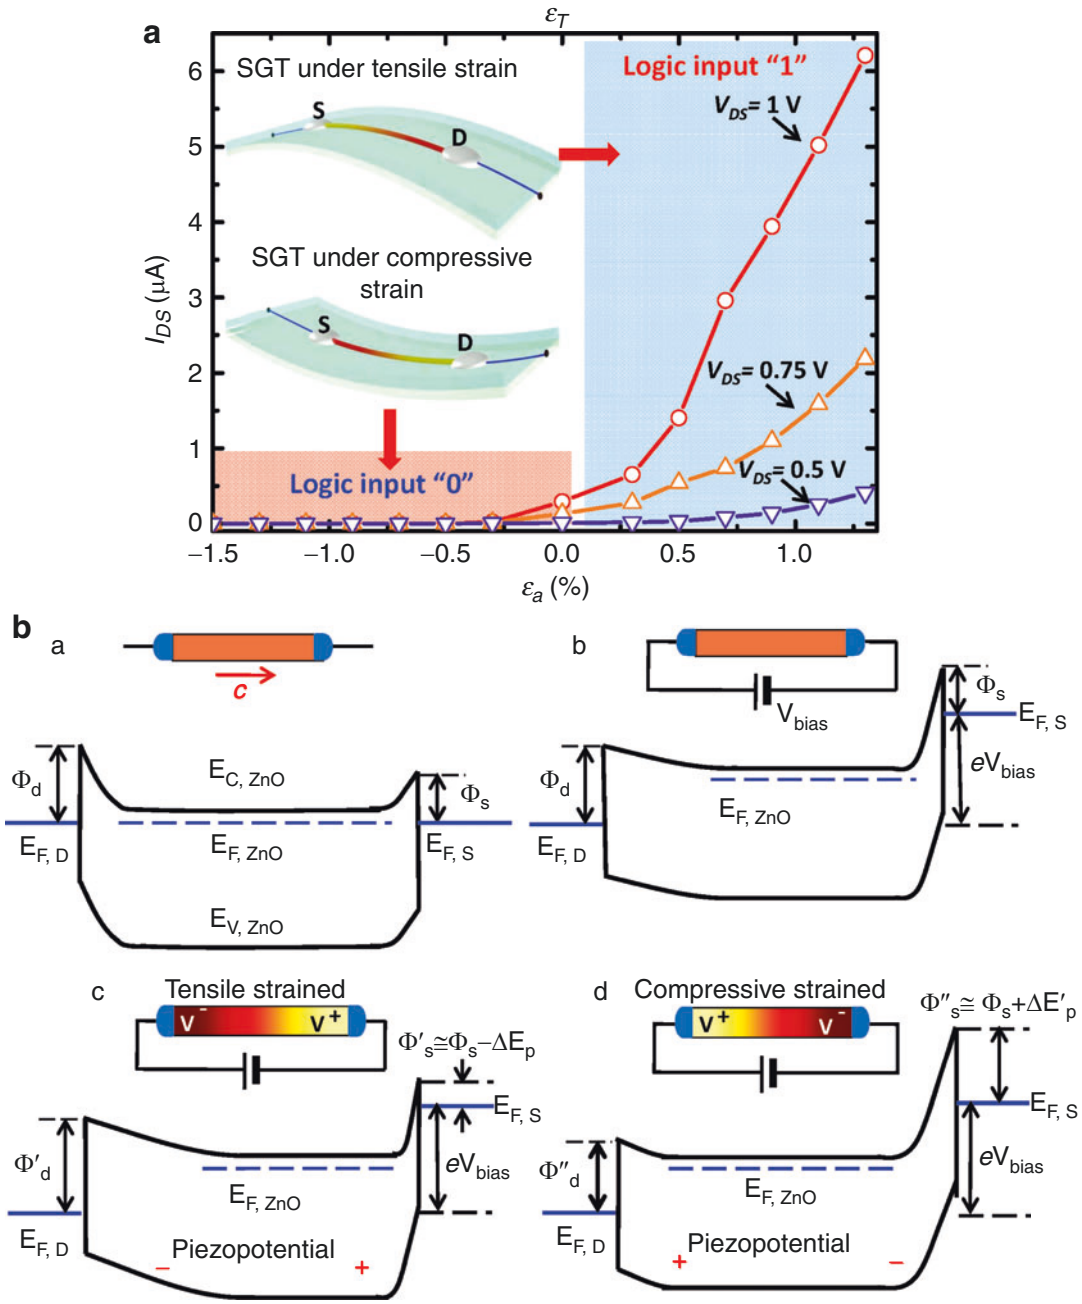
Piezoelectric Effect at Nanoscale, Fig. 11 A comparison of a CMOS FET and a piezotronic FET. The key difference is that the externally applied gate voltage V_{GS} is replaced by the stain-generated piezopotential, which tunes the charge transport insets are the enlarged view of the boxed area for one cycle of deformation. This is the core of piezotronics

exhibited a rectifying behavior in the negative voltage region, and the *I-V* curve in the positive voltage region overlapped with that of the original curve without straining, as shown by the green line in Fig. 12.

Piezotronic Logic Operations

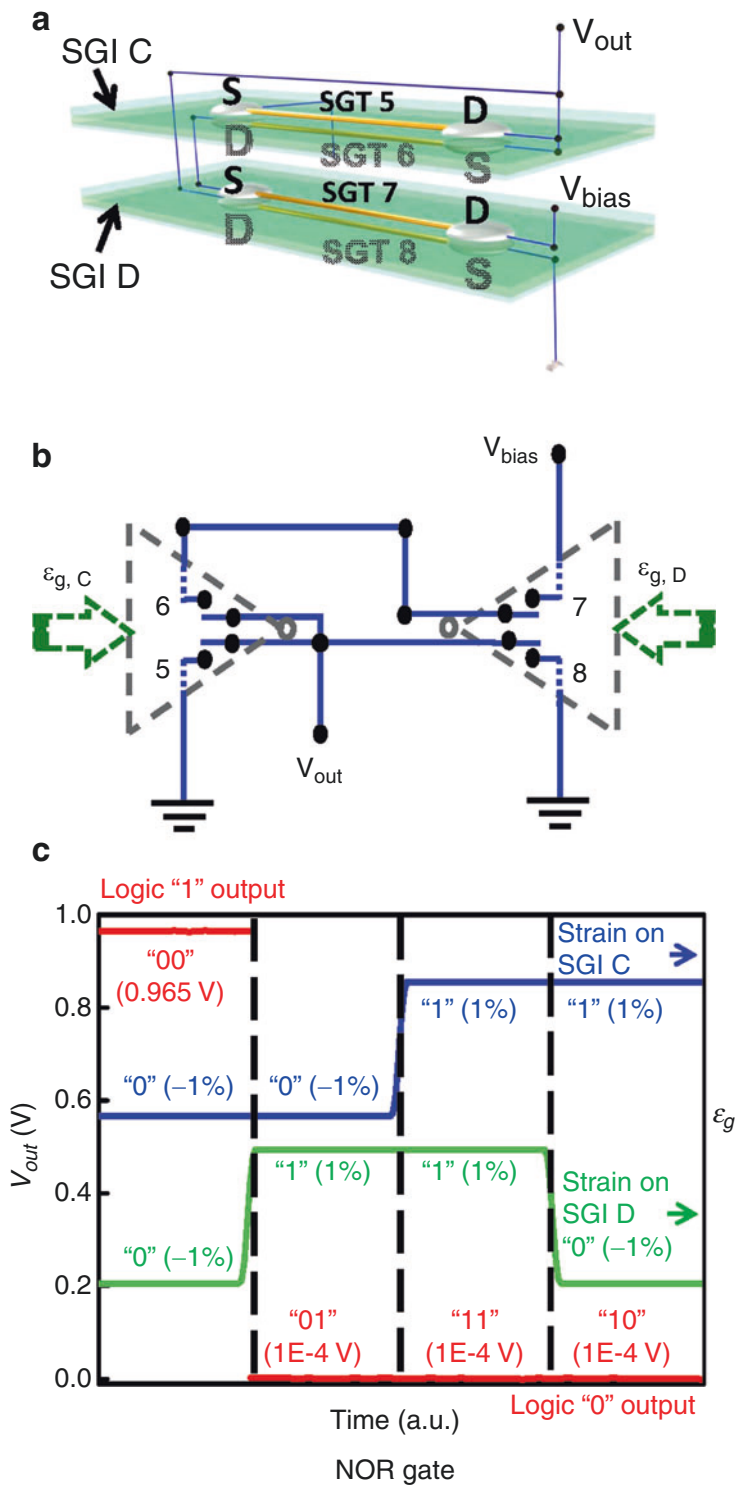
The existing semiconductor NW logic devices are based on electrically gated field-effect transistors (FETs), which function as both the drivers and the active loads of the logic units by adjusting the conducting channel width [17]. Moreover, the currently existing logic units are "static" and are almost completely triggered or agitated by electric signals, while the "dynamic" movable mechanical actuation is carried out by another unit possibly made of different materials. It is highly desirable to integrate the static logic operations with the dynamic mechanical action into one unit utilizing a single material. The first piezoelectric-triggered mechanical-electronic logic operation has been demonstrated using the piezotronic effect, through which the integrated mechanical actuation and electronic logic computation are achieved using only ZnO NWs.

A strain-gated transistor (SGT) is made of a single ZnO NW with its two ends, which are the source and drain electrodes, being fixed by silver paste on a polymer substrate (Fig. 13a). Once the substrate is bent, a tensile/compressive strain is created in the NW since the mechanical behavior of the entire structure is determined by the substrate. Utilizing the piezopotential created inside the NW, the gate input for a NW SGT is an externally applied strain rather than an electrical signal. I_{DS}-V_{DS} characteristic for each single ZnO NW SGT is obtained as a function of the strain created in the SGT (Fig. 13a) before further assembly into logic devices. A NW SGT is defined as forward biased, if the applied bias is



Piezoelectric Effect at Nanoscale, Fig. 12 Piezotronic strain sensor/switch. Changes of transport characteristics of an Ag/ZnO-nanowire/Ag device from symmetric *I-V* characteristic (*black*) to asymmetric rectifying behavior when stretching (*red*) and compressing (*green*) the wire. The inset is the equivalent circuit models of the device in corresponding to the observed *I-V* curves; different sizes of diode symbol are used to illustrate the asymmetric Schottky contacts at the two ends of the nanowire. The *blue* side is the negative potential side, and the other side is the positive side (Ref. [22] of [12], Adapted with permission from "Zhou, J., Gu, Y.D., Fei, P., Mai, W.J., Gao, Y.F., Yang, R.S., Bao, G., Wang, Z.L.: Flexible piezotronic strain sensor. Nano Lett. **8**, 3035–3040 (2008)." Copyright 2008 American Chemical Society)

connected to the drain electrode (Fig. 13a). For a SGT, the external mechanical perturbation-induced strain (ε_g) acts as the gate input for controlling the "on"/"off" state of the NW SGT. The positive/negative strain is created when the NW is stretched/compressed. The SGT behaves in a similar way to an *n*-channel enhancement-mode MOSFET, apparently indicating the working principle of the SGT.



The working principle of a SGT is illustrated by the band structure of the device. A strain-free ZnO NW may have Schottky contacts at the two ends with the source and drain electrodes but with different barrier heights of Φ_S and Φ_D, respectively (Fig. 13b-a). When the drain is forward biased, the quasi-Fermi levels at the source ($E_{F,S}$) and drain ($E_{F,D}$) are different by the value of eV_{bias}, where V_{bias} is the applied bias (Fig. 13b-b). An externally applied mechanical strain (ε_g) results in both band structure change and piezoelectric potential field in a ZnO NW. The former leads to the piezoresistance effect, which is a nonpolar and symmetric effect at the both source and drain contacts. Since ZnO is a polar structure along *c*-axis, straining in axial direction (*c*-axis) creates a polarization of cations and anions in the NW growth direction, resulting in a piezopotential drop from V^+ to V^- along the NW, which produces an asymmetric effect on the changes in the SB heights (SBHs) at the drain and source electrodes. Under tensile strain, the SBH at the source side reduces from Φ_S to $\Phi'_S \cong \Phi_S - \Delta E_P$ (Fig. 13b-c), where ΔE_P denotes the effect from the locally created piezopotential and it is a function of the strain, resulting in increased I_{DS}. For the compressively strained SGT, the sign of the piezopotential is reversed; thus, the SBH at the source side is raised from Φ_S to $\Phi''_S \cong \Phi_S + \Delta E'_P$ (Fig. 13b-d), where $\Delta E'_P$ denotes the piezopotential effect on the SBH at source side, resulting in a large decrease in I_{DS}. Therefore, as the strain ε_g is swept from compressive to tensile regions, the I_{DS} current can be effectively turned from "on" to "off," while V_{DS} remains constant. This is the fundamental principle of the SGT.

Logic operations of NW strain-gated NOR gate have been realized by integrating SGTs, which are gated individually by the applied strains, according to corresponding layout rules

(Figs. 14a, b). The output voltages of NOR gate versus the input gate strains are shown in Fig. 14c. It can also be seen that NW strain-gated NOR gate with active loads exhibit better overall performance, such as larger logic swing, compared to passive-load NOR gate. Using the SGTs as building blocks, other universal logic components such as inverters and NAND and XOR gates have been demonstrated for performing piezotronic logic calculations, which have the potential to be integrated with the current NEMS technology for achieving advanced and complex functional actions in nanorobotics, microfluidics, and micro/nanosystems.

Conclusion

With reduction in material size, its mechanical robustness, elastic modulus, and toughness improve dramatically. It can easily go way beyond the nonlinear but still elastic mechanical deformation without causing plastic damage. The piezoelectric effect at nanoscale is expected to be largely enhanced so that they can be effectively used for ultrasensitive sensors/actuators and energy converters.

The two most recent important advances in using the nanoscale piezoelectric effect have been introduced here. One is the nanogenerator that converts mechanical energy into electricity utilizing tiny physical motion. Besides its potential for large-scale applications such as harvesting ocean wave and wind energy, it finds application in driving wireless nanodevices and nanosystems for medical science, environmental/infrastructure monitoring, defense technology, and even personal electronics. It is a key step for building self-powered nanotechnology.

The second important concept in science is the piezotronics. Electronics fabricated by using inner-crystal piezopotential as a "gate" voltage to tune/control the charge transport behavior is named *piezotronics*. *Piezo-phototronic effect* is a result of three-way coupling among piezoelectricity, photonic excitation, and semiconductor transport, which allows tuning and controlling of electro-optical processes by strain-induced piezopotential. These designs are different from the CMOS field-effect transistor by replacing the externally applied gate voltage using a crystal generated inner potential (piezopotential) for controlling the charge transport. It is a transistor controlled by a force/strain. It will find applications in human-computer interfacing, mechanical-triggered electronics, nanomachine, electronic signature, medical diagnostics, and sensor.

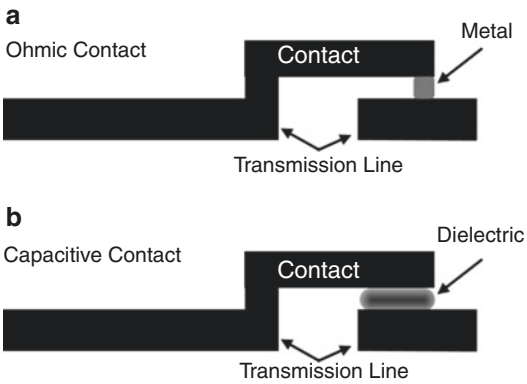
Piezoelectric Switches

Definition

A piezoelectric switch is an electromechanical relay or switch relying on piezoelectric actuation to provide the force necessary to close or produce a gap between electrical contacts. In practical use, these switches can be designed for systems operating with carrier frequencies from DC to tens or hundreds of GHz.

Overview

The routing of electrical signals is controlled by switches of various types. For mechanical switches, a number of transduction techniques have been utilized including electrostatic, electromagnetic, thermomechanical, and piezoelectric. Fundamental to most radio frequency (RF) circuits, a switch is used not only to control the path of electrical circuits but also the phase and timing of the circuits. The continuous miniaturization of military radar and communication systems requires development of smaller, more energy-efficient switches for continuous control of a wide variety of electronic signals [1]. Additionally, switches are required for ever-increasing frequencies, making existing solid-state technologies less attractive to the system designer because of larger power losses and decreases in linearity as the frequency increases [2]. In short, microelectromechanical systems (MEMS) switches provide a very low-loss, low-power, and highly linear, with respect to input power, alternative to existing solid-state switch technologies. Moreover, they are significantly smaller than macro-switch technologies. Unlike electronic switches, PIN diodes and field-effect transistors (FET), a well-designed MEMS switch is extremely linear with respect to input power and does not create distortion, such as harmonics or intermodulation products, in the electrical signal [2]. Next-generation missile seeker radar, smart cellular phone technologies, and communication-on-the-move systems require highly linear, low-power, broadband RF switches as a fundamental building block [1, 3].



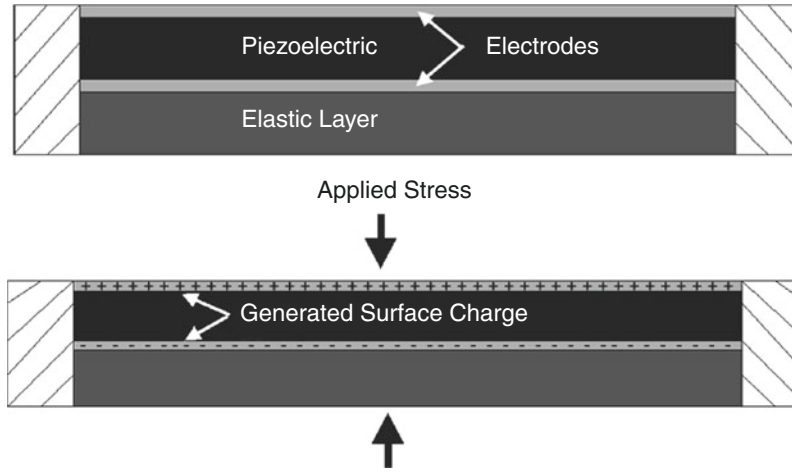
History and Brief Background of MEMS Switch Development

The development of MEMS switches began with the effort of Petersen at IMB in 1979 [4] and then continued with Hughes Research Laboratories on

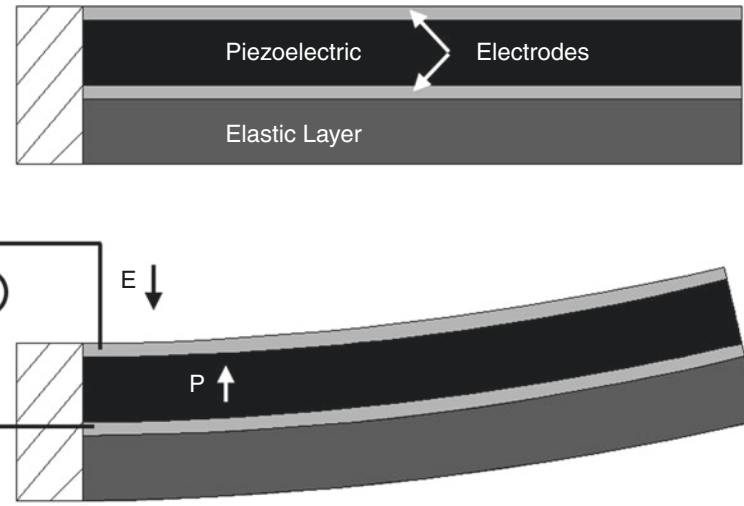
micromachined microwave actuators (MIMACs) that produced the first switch capable of operating up to 50 GHz [5]. Following this research, a concentrated effort began in developing switches in both series and shunt configurations for a wide variety of applications, including lower-frequency commercial cell phones and high-frequency military radar and communication systems [1–3].

All MEMS switches have a few basic components for their operation. This includes the signal line, switch contact(s), and actuator(s). The signal line can be designed for use with signals ranging from DC to sub-THz. For low-frequency operation, a simple electrical trace commonly comprised of gold or other conductive metal can be utilized. For higher-frequency operation, the signal line requires greater design consideration. For MEMS switches, the signal line is commonly configured using coplanar waveguide or microstrip transmission line geometries.

MEMS switches are defined by two different types of contacts: ohmic and capacitive (see Fig. 1). Capacitive contact switches utilize a thin dielectric film between two metals with adjustable gap. At elevated frequencies, the RF energy is capacitively coupled through the dielectric to the switch contact. As a result, capacitive switches are generally limited to higher-frequency operation (>6 GHz) where capacitive coupling is feasible with reasonably sized capacitive contacts. In contrast, ohmic contacts use two metals to create the switch contact. Ohmic switches provide the opportunity for very broadband operation using carrier frequencies from DC on upward. It should be noted that the type of contact material is crucial for high-performance switches with long lifetime. Although beyond the scope of this entry, dielectric materials with low charge-trapping densities are preferred for capacitive contacts (e.g., silicon nitride and alumina), and metals with high hardness and low probability of creating frictional polymers are preferred for ohmic contacts (e.g., ruthenium and ruthenium oxide).



Piezoelectric MEMS Switch, Fig. 1 Schematic illustration of (**a**) ohmic and (**b**) capacitive switch contacts



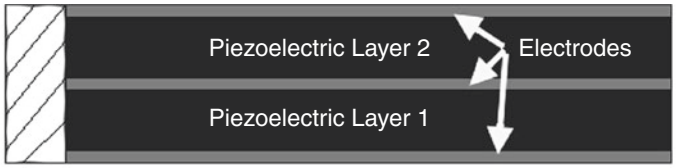
The final critical component is the actuator. Historically, most reported MEMS switches have utilized electrostatic actuators in which a metal beam is suspended over both a bias electrode and one of the switch contacts [2]. The remainder of this entry, however, will focus on an alternative actuation mechanism, piezoelectricity, and the piezoelectric actuators' role in MEMS switch technologies. When compared with switches actuated by electrostatic force, one critical advantage of piezoelectric switches is the full control of their displacement when the switch is making contact. In contrast to piezoelectric switches, electrostatic switches experience a "pull-down voltage" wherein there is an instability in the gap between the actuator and its bias electrode. Once the pull-down voltage is reached and the gap of the electrostatic capacitor is reduced to 2/3 of the gap at 0 V, a positive feedback is created in the device. A smaller gap creates larger closing force, which in turn moves the switch in the direction of even smaller gaps. This process of constant acceleration ends when the contact is closed against a typically immovable transmission line. In contrast, piezoelectric MEMS switches move only in response to the magnitude of the DC actuation voltage. They do not exhibit positive feedback and their dynamic behavior is well controlled. As a result, switches with piezoelectric actuation can be operated where the contacts close with only a modest acceleration resulting in minimal contact bounce, thus improving switch cycle reliability [6].

Piezoelectricity

Piezoelectricity is comprised of two electromechanical responses, a direct effect and a converse

Piezoelectric MEMS Switch, Fig. 2 Illustration of the direct piezoelectric effect applied to a piezoelectric unimorph membrane

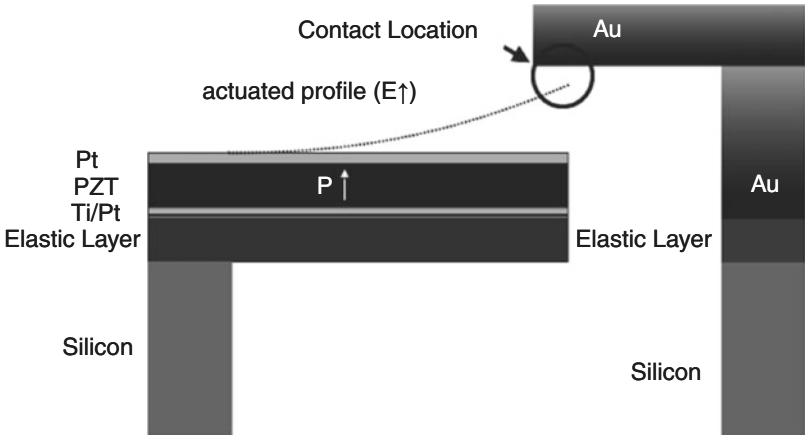
Piezoelectric MEMS Switch, Fig. 3 Illustration of the converse piezoelectric effect applied to a unimorph cantilever with the vertical scale exaggerated



effect. The direct effect refers to the generation of charge under the application of an applied stress and is governed by Eq. 1 where the induced electric displacement (D_i) is proportional to the piezoelectric coefficient (d_{ijk}) and the applied stress (T_{jk}). The converse effect refers to the generation of strain under an applied electric field and is governed by Eq. 2, where the induced strain (x_{jk}) is proportional to the piezoelectric coefficient and electric field (E_i).

$$D_i = d_{ijk} T_{jk} \tag{1}$$

$$x_{jk} = d_{ijk} E_i \tag{2}$$



In application, the direct effect can be used for sensing and energy harvesting in which the applied stresses are used to generate surface charges on the piezoelectric (see Fig. 2). For actuators, an applied electric field generates a strain in the piezoelectric layer producing flexure in unimorph actuators (see Fig. 3) and bimorph actuators (see Fig. 4). In switch applications, the piezoelectric unimorph can be combined with overhanging contact cantilevers to create a functioning switch (see Fig. 5).

The tensor notation for the aforementioned relationships can be simplified using matrix notation where the subscripts i, j, and k having

Piezoelectric MEMS Switch, Fig. 4 Illustration of the converse piezoelectric effect applied to a bimorph cantilever with the vertical scale exaggerated

Piezoelectric MEMS Switch, Fig. 5 Cross-section schematic of a PZT unimorph and electrical contacts configured for use as switch

values 1–3 are replaced with the subscripts p and q with values of 1–6 [7]. As a result, d_{ijk} is transformed to d_{ip}. The d_{ip} (strain) and e_{iq} (stress) piezoelectric coefficients are the most useful for thin-film sensor and actuator applications and are related by the elastic constant, c_{pq}^{E}, in Eq. 4.

$$e_{iq} = d_{ip} c_{pq} \tag{3}$$

For thin-film composites where the piezoelectric layer is rigidly attached to a supporting elastic layer (i.e., thin film or substrate), the out-of-plane stress, X_3, is generally set to zero while the longitudinal strain, x_3, varies from a combination of the piezoelectric effect and elastic coupling from the Poisson effect. As a result, an effective thin-film piezoelectric coefficient, $e_{31,\,f}$, can be related to the common piezoelectric coefficients, d_{31} and e_{31} (see Eq. 5), by compensating for the clamping effect experienced by piezoelectric thin films in composite structures [8, 9].

$$e_{31,f} = e_{31} - \frac{c_{31}^{E} e_{33}}{c_{33}^{E}} = \frac{d_{31}}{\left(s_{11}^{E} + s_{12}^{E}\right)} \tag{4}$$

Piezoelectric Materials: Ferroelectrics and Non-ferroelectrics

The important piezoelectric and dielectric material properties for the three most common thin-film piezoelectrics, ZnO, AlN, and lead zirconate titanate (PZT), are listed in Table 1. A few

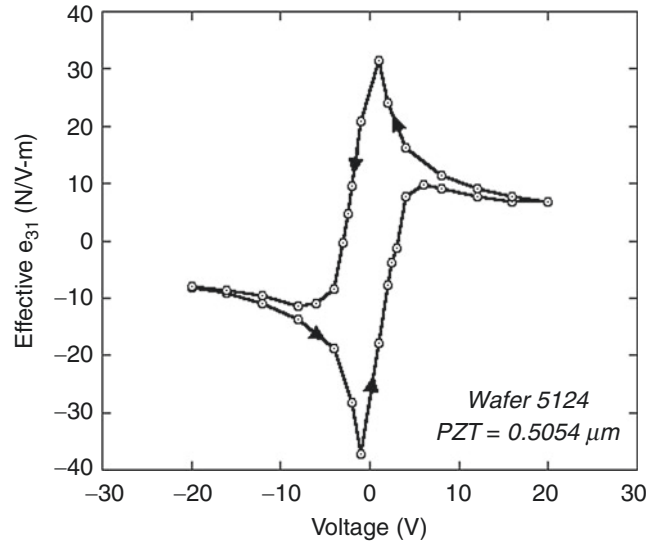
distinctive features to recognize are the differences in crystal structure and the effective thin-film piezoelectric coefficient, $e_{31,f}$, of these three compounds. The difference in crystal structures can be summarized as a distinction between purely polar materials and ferroelectric materials. Pure polar materials such as AlN and ZnO do not permit the polarization vector to change orientations relative to the crystal lattice. The polar direction is crystallographically defined along the c-axis of the wurtzite crystal structure. In contrast, ferroelectric materials, such as PZT, have a spontaneous electric dipole moment that can be reoriented between crystallographically defined stable states by a realizable electric field (i.e., before dielectric breakdown occurs) [10]. As a result, extremely large polarization values and subsequently large dielectric constants and piezoelectric coefficients can be achieved in ferroelectric materials.

Another important characteristic distinction between purely polar materials and ferroelectric materials is the use of the constitutive equations of piezoelectricity, Eqs. 1 and 2, which describe the linear response of piezoelectric materials. These, generally, can be applied successfully to polar piezoelectric thin films like AlN and ZnO in most circumstances. However, ferroelectrics, like PZT, can display pronounced stress and electric field induced nonlinear material responses. This is particularly true for thin films and actuators. Thin films permit the application of extremely large electric fields with modest operating voltages due to the film thicknesses involved. Piezoelectric MEMS actuator applications typically drive the material well beyond the coercive field. For a half-micron thin film of PZT (52/48), for example, the coercive field corresponds to an applied voltage of approximately 2.5 V. Ferroelectrics even show significant nonlinearity below the coercive field [17]. Despite this fact it is surprising that, for both bulk material and thin-film applications, the linear piezoelectric equations are often used to describe the device response in ferroelectric materials. To accurately model ferroelectric MEMS device response, under high operating field (actuators) and/or bias field (sensors) conditions, these significant nonlinearities must be taken into account.

At the high fields encountered in MEMS actuators, the total strain response is due to the combination of the linear response and nonlinear piezoelectricity including saturation effects, domain wall motion, and electrostriction. All dielectrics display the property of electrostriction, whereby externally applied electric fields induce a strain response that is proportional to the square of the field strength. Equation 5 describes the total strain response in ferroelectric materials where Q is the appropriate electrostrictive coefficient, P_s is the spontaneous polarization, E is the applied electric field, and κ is the appropriate dielectric constant. The first term defines the remnant strain. The second term is equal to the linear piezoelectric coefficient (d_{ij}) multiplied by the electric field. The last term is the strain due to electrostriction. As the applied field strength increases, the electrostrictive term contributes more to the overall strain response in the material.

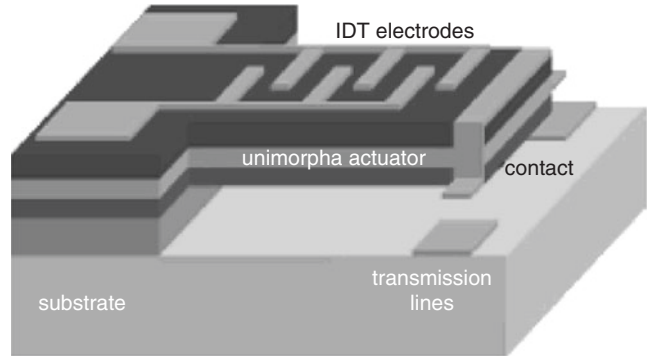
Piezoelectric MEMS Switch,
Fig. 6 Displacement versus voltage plot for a PZT thin-film cantilever comprised of a 0.5 μm elastic layer ($SiO_2/Si_3N_4/SiO_2$)/0.1 μm Ti/Pt bilayer, 0.505 μm PZT (52/48), and a 0.1 μm Pt top electrode. Key aspects of this diagram include the hysteretic displacement characteristics upon bipolar voltage swings. Additionally, all but a small fraction of the displacement occurs in one direction

$$x = QP_s^2 + 2\varepsilon_o \kappa QP_s E + Q(\varepsilon_o \kappa E)^2 \qquad (5)$$



At large applied stresses and electric fields, significant contributions to the total strain response (Eq. 5) are due to nonlinear piezoelectricity and the extrinsic response. These nonlinear material properties used for design purposes are best measured for specific materials and processing conditions. Due to these complex nonlinear effects, the ratio of total strain to applied electric field is referred to as the effective electroactive coefficients. These coefficients can be used with the models described above using field-dependant functions.

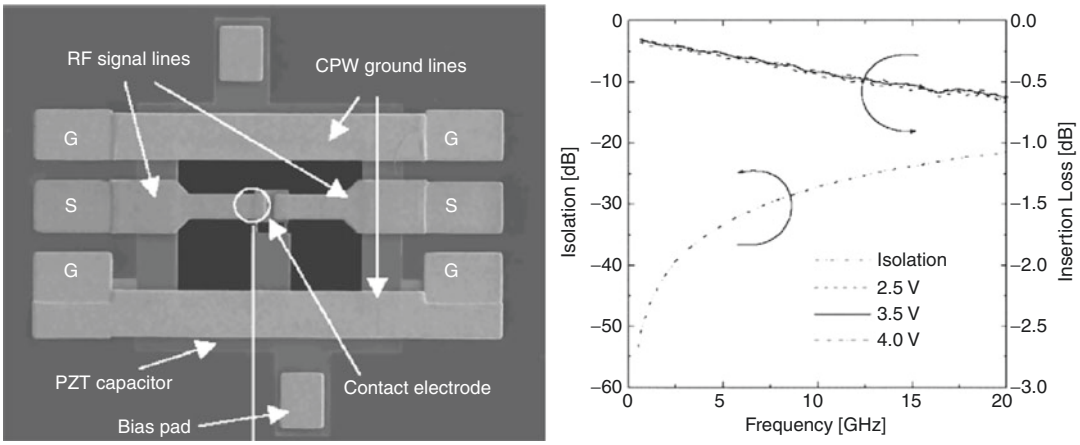
Perhaps the most important consequence of these nonlinear effects is the absence of a large bipolar strain response when operated above the coercive field. Figure 6 shows voltage-displacement data from a simple unimorph PZT MEMS-actuated cantilever, illustrating the so-called butterfly loop. The plot was obtained by sweeping the actuation voltage up to a positive voltage, then reducing to zero, then sweeping down to a negative voltage, and finally returning to zero field. The extracted effective electroactive piezoelectric stress constant, e_{31eff}, corresponds to the displacement data in Fig. 6 and is illustrated in Fig. 7. This effective piezoelectric constant includes the small signal piezoelectric effect, electrostriction, and strain induced by large polarization charges associated with overcoming a pinched ferroelectric hysteresis loop.



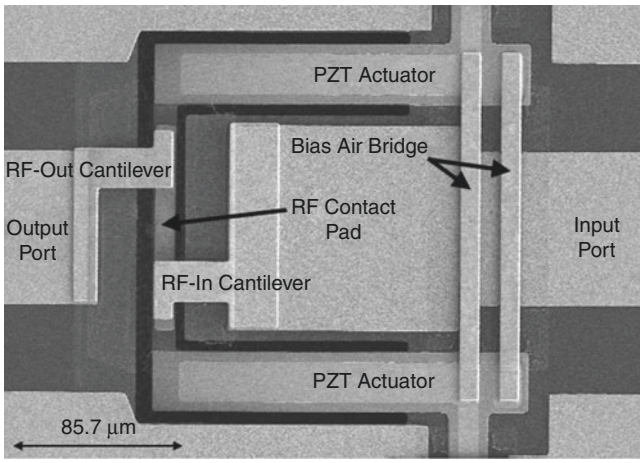
The response of the device is seen to be bipolar only in the regime between the positive and negative coercive voltages where the negative displacement reverts to a positive displacement (the "V" regions of the lower curves). Thus for large electric fields (i.e., in excess of the coercive field) applied to the piezoelectric material, the sense of the piezoelectric strain is independent on the applied field polarity, therefore only a single sense of the piezoelectric strain is possible. In terms of the device, the in-plane contraction of the piezoelectric material at large fields gives a negative sense to the piezoelectric actuation force. The standard configuration of the d_{31} mode MEMS unimorph, with the neutral axis below the midplane of the piezoelectric layer, gives a positive sense of the moment arm. Piezoelectric MEMS devices based on ferroelectric materials are most often operated under unipolar conditions and hence avoid much of the hysteresis observed in Fig. 6.

Piezoelectric Switch Actuator History

One of the key limitations of electrostatically actuated MEMS switches is the inability to



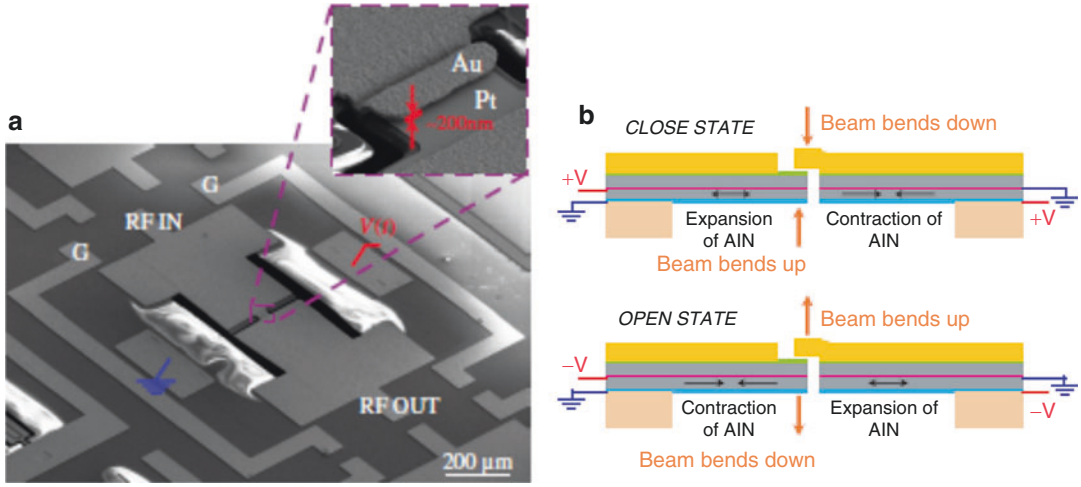
Piezoelectric MEMS Switch, Fig. 7 Effective piezoelectric stress constant, $e_{31,eff}$, versus voltage extracted from the displacement-voltage measurements for the PZT thin-film unimorph described in Fig. 6



Piezoelectric MEMS Switch, Fig. 8 Illustration of a thin-film PZT unimorph switch developed at Penn State University [20] (Reprinted with permission. Copyright 2003 American Institute of Physics)

combine a low actuation voltage with excellent DC and RF performance (i.e., contact force and insertion loss, respectively) and reliability. Attempts to lower the actuation voltage with electrostatic switches generally rely on reducing either the mechanical stiffness of the released structures or the gap between the mechanical bridge/cantilever and the corresponding biasing pad [18]. Reductions in the stiffness can limit the restoring force of the switch and can lead to stiction failures [19]. Decreasing the electrode gap limits the high-frequency RF performance (in particular, the isolation in the open state for series switches) [2].

The first functioning piezoelectric MEMS DC relay was demonstrated by Gross et al. using in-plane poled PZT film actuators [20]. These devices used a cantilever beam with a supporting elastic layer, a PZT thin film as the actuator, and patterned gold structures to act as the electrodes (see Fig. 8). This device operated as low as 20 V with a switching on time as low as 2 μs. The first reported working RF MEMS switch using PZT thin films used bulk micromachining to release a unimorph actuator and a suspended transmission line [21]. This design utilized a cantilever that is perpendicular to the wave propagation direction along the RF conductor of the coplanar waveguide (CPW). The switch operated as low as 2.5 V with an insertion loss better than 0.7 dB and isolation better than −21 dB up to 20 GHz (see Fig. 9). The first surface micromachined approach for creating a PZT-actuated RF MEMS switch was developed by Polcawich



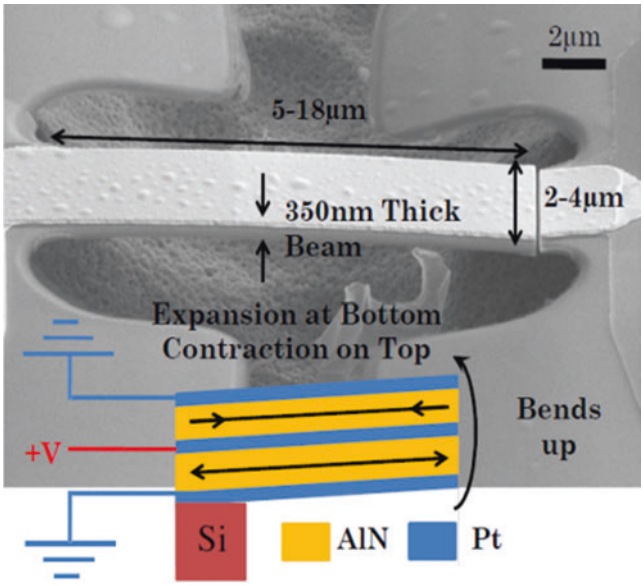
Piezoelectric MEMS Switch, Fig. 9 SEM image of a bulk micromachined RF MEMS series switch using a thin-film PZT actuator to complete the signal path [21] (Reprinted with permission. Copyright 2005 IEEE)

Piezoelectric MEMS Switch, Fig. 10 SEM image of a PZT-actuated RF MEMS switch [22] (Reprinted with permission. Copyright 2007 IEEE)

et al. [22]. These devices operated at less than 10 V and demonstrated temperature-stable performance from −25 °C to 100 °C for normally open series switches with isolation less than −20 dB and insertion loss of better than −1.0 dB up to 40 GHz [23] (Fig. 10).

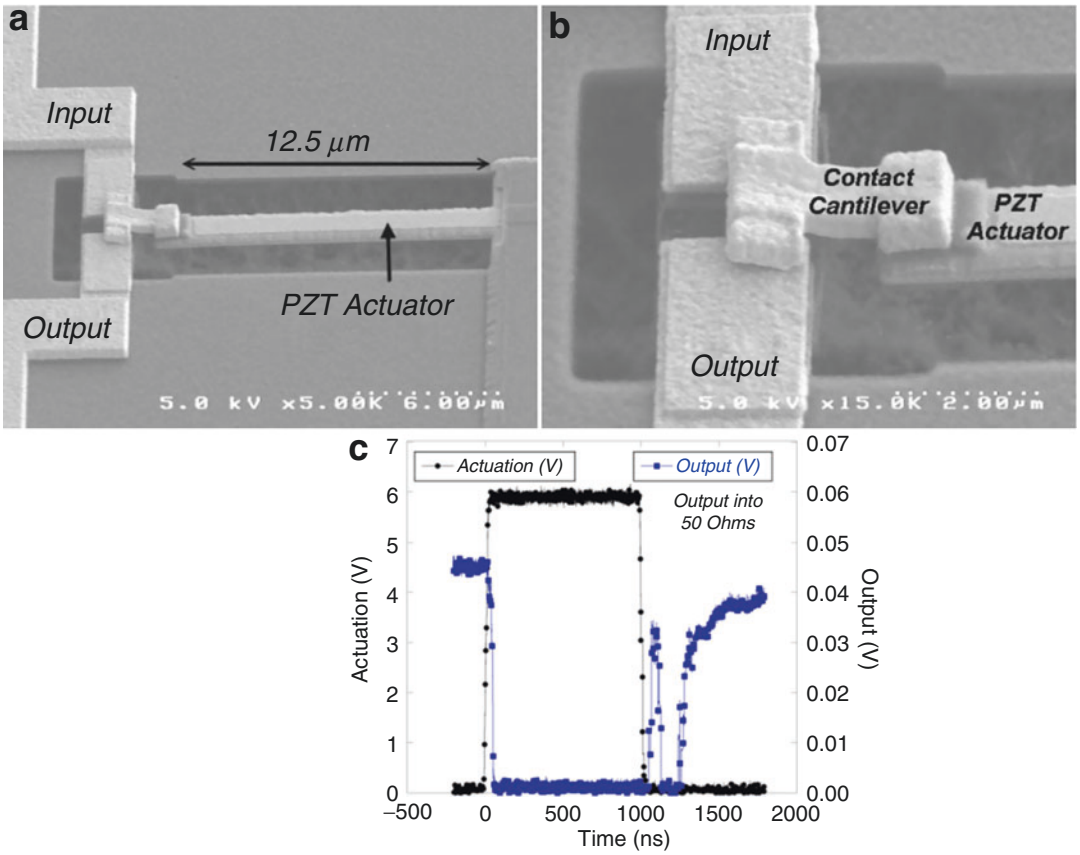
The interest in radio and cell-phone frequency-compatible AlN-based filters has motivated the development of integrated piezoelectric switches and contour-mode filters both operated with AlN thin films. Mahameed et al. created the first AlN-based MEMS switches demonstrating good RF performance up to the low GHz regime [24]. These devices feature an innovative approach to address residual stress deformation, temperature sensitivity, and the modest piezoelectric coefficients of AlN. A symmetric "dual-beam" design features pairs of actuators that experience similar residual stress- and temperature-induced deformations that minimize variations in the open-state contact gap despite the mechanical fluctuations (see Fig. 11). The device shows immunity to residual stresses, fast switching speeds (~2 µs), moderate actuation voltage (~20 V), and good low-frequency isolation (>26 dB) and insertion loss (<0.7 dB) at 2 GHz. These devices have also been successfully co-fabricated on the same wafer as contour-mode AlN RF MEMS resonators. The device fabrication leverages the process used for AlN

Piezoelectric MEMS Switch, Fig. 11 (**a**) SEM image of AlN RF MEMS switch with inset indicating the nano-gap contact location and (**b**) illustration of principle of operation of "dual-beam" architecture [24] (Reprinted with permission. Copyright 2008 Institute of Physics)



contour-mode resonators. Once these features are defined, including multiple AlN and Pt electrode deposition and patterning steps, an amorphous silicon sacrificial layer is deposited and patterned with liftoff. This is followed by the deposition and patterning of a thick-electroplated Au layer to provide RF transmission lines and unimorph actuator features. The switch is released using a xenon difluoride dry release to complete the process.

Switch Scaling



A number of groups are investigating mechanical logic technologies to address the limitations imposed in complementary metal-oxide-semiconductor (CMOS) transistors by gate oxide leakage. Static power consumption now rivals dynamic power consumption in CMOS and presents a significant challenge to the continued scaling of CMOS logic devices. Motivated by low-power nanomechanical logic applications, electromechanical relays based on either AlN or PZT have been investigated to provide practical solutions for low-power embedded microcontrollers. Switches have recently been demonstrated on both technologies using combinations of electron-beam lithography and focused ion beam milling [25–27].

The AlN-based devices consisted of a 100 nm AlN layer and were implemented in nanoscale bimorph cantilevered actuators similar to those described previously. The actuators were fabricated using a five-mask post-CMOS compatible process similar to the process outlined for the fabrication of the AlN RF MEMS switch discussed earlier. Displacements of 40 nm were achieved at 2 V in 18 µm long cantilever devices. A key difference in the process however is the use of a focused ion beam (FIB) tool. The nearly complete suspended clamped-clamped AlN beam is severed near one of the anchors with the FIB to create the cantilevered device seen in Fig. 12.

Similar to the scaled version of the AlN switch, a 3-D scaled version of the aforementioned PZT RF MEMS switch has been demonstrated. The switch shown in Fig. 13 was fabricated using an 11-step aligned electron-beam lithography process following the same process flow as its larger relative. The key differences were reductions in film thickness and gap along with reductions in lateral dimensions for the switch actuators and contact cantilever. In the normally closed configuration, the switch operated at 6 V demonstrated an opening response ranging from 17 to 33 ns with a corresponding closing response ranging from 33 to 43 ns.

Piezoelectric-Enabled Mechanical Logic

Piezoelectric RF switches have also become enabling in very low-power digital logic circuits. Leveraging the results highlighted in the switch-scaling section, one can extend the technology to enable a fully functional electromechanical-based logic. Both AlN and PZT thin films have successfully demonstrated mechanical logic functionality. To date, the AlN logic relays have been assembled to yield both NAND and inverter gates using a body bias on the actuator [28, 29]. The body bias is used to reduce the contact gap and enable dynamic operation at less than 1 V.

The low leakage current observed on a PZT-based actuator has led to the development of a digital, single-pole, double-throw (SPDT) mechanical relay with zero leakage current in one state and under 30 f. of leakage current in the other [30]. The device is shown schematically in Fig. 14 and with the two independent current paths highlighted in green via electron micrograph in Fig. 15. In addition to low leakage currents, the structure's material composition provides innate radiation hardening [31] and the SPDT configuration of this device, highlighted in Fig. 15, makes it optimally suited for complimentary logic circuits.

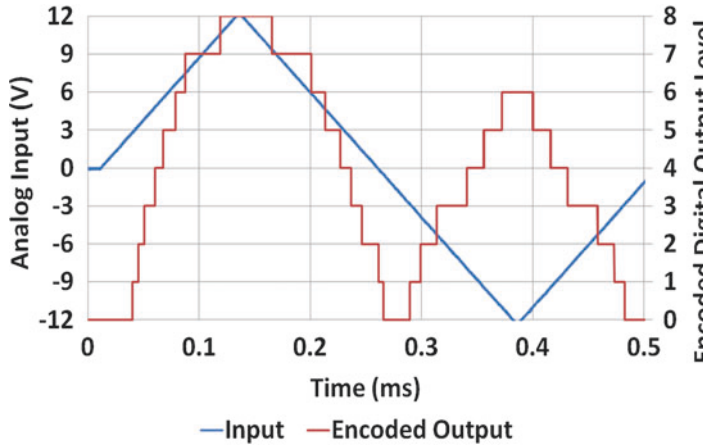
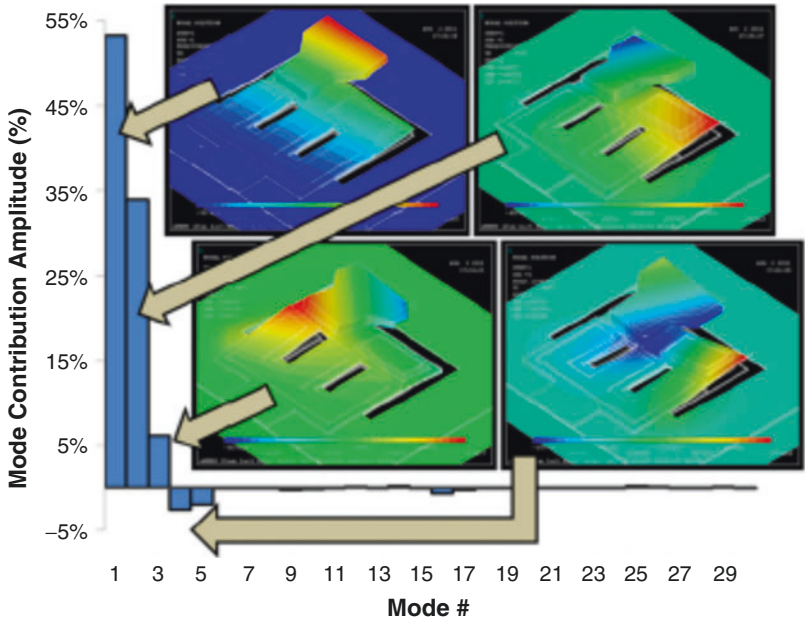
Always 1	–	–	VDD	OUTPUT		VDD



Piezoelectric MEMS Switch, Fig. 16 Measured results of Boolean AND function being performed via a PiezoMEMS relay

Due to PZT's large $e_{31,f}$ coefficient, large deflections, several hundred nanometers for nanomechanical logic, can be achieved at modest voltages. This enables the relay to have an open-state contact gap sufficient to support up to 40 V hot switched across its contacts while still allowing for fully functional Boolean logic operations at fewer than 2 V (see Table 2). Additionally, due to the ambipolar nature of metal-to-metal contacts, the device is well suited to functioning in a pass-gate logic configuration, allowing for a reduction in gate count without harming the signal integrity. Figure 16 demonstrates this behavior with a Boolean AND operation. Here, the top electrode of Fig. 15 is grounded, the bottom electrode is connected to "Input A," the normally closed (NC) input is grounded, the normally open (NO) input is connected to "Input B," and

Piezoelectric MEMS Switch, Fig. 17 SEM image of a piezoelectric thin-film mechanical relay-based analog-to-digital converter (ADC) [33]



Piezoelectric MEMS Switch, Fig. 18 Comparison between the analog input voltage (*blue*) to the encoded digital output level (*red*) for the 3-bit ADC illustrated in Fig. 17

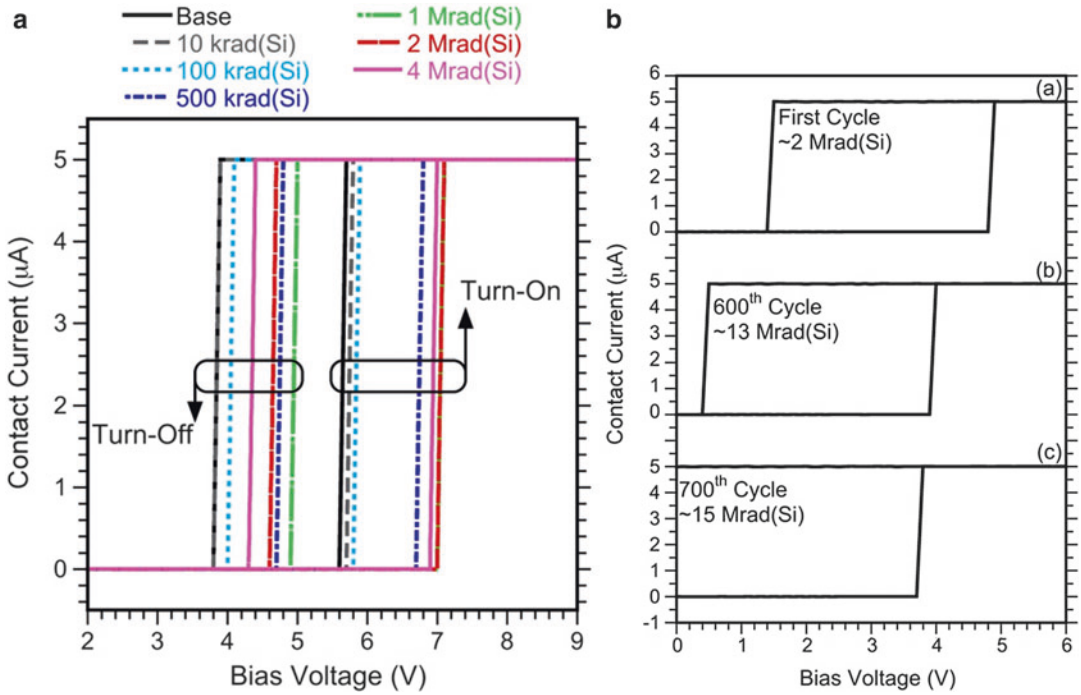
both the NC and NO outputs are connected together. In this configuration, when "Input A" is false, ground is shorted to the output, and when "Input A" is true, "Input B" is passed to the output. The additional Boolean functions and the related device configurations are listed in Table 2. The device can also operate as either of the two classes of digital memory: dynamic and static, and for additional information, see Refs. [32, 33].

In addition to basic Boolean operators, a slight modification to the relay can enable a multi-bit analog-to-digital converter. As shown in Fig. 17, an array of variable length piezoelectric actuators can be designed to realize a 3-bit ADC [33]. In this example, the length was varied from 11 to 29 µm with actuation voltages expected to range from 2 to 12 V. The resultant ADC encoded output along with the analog actuation voltage is shown in Fig. 18.

Switching Dynamics

A unique attribute of the design illustrated in Fig. 15 is the switching dynamics based on the electromechanical design. A reported dynamic model describes well the measured actuation voltage dependence on the propagation delay of PiezoMEMS relays [34]. The model explains the observed improvement in switching speed of

Piezoelectric MEMS Switch, Fig. 19 Plot of the peak modal displacements (in% of total) for the first 30 vibration modes. The modeled mode shapes for the first, second, third, and fourth modes are also included and the corresponding displacements are indicated. The peak displacements are the maximum values for each mode over a 4 μs period [34]



these devices relative to single degree of freedom switching speed models and suggests the strong potential for improved performance in RF MEMS and mechanical logic devices through the exploitation of higher-order vibrational modes (see Fig. 19). The model enables speed optimization of such devices via structural and electrode design to enhance the contribution of favorable vibrational modes and to suppress modes that reduce switching speed. For a detailed review of the model and the resulting improvements in switching speed, see [34].

Radiation Effects

To explore the radiation tolerance of the electromechanical relays, ^{60}Co exposure was used to examine the effects of total ionizing dose (TID) radiation on the piezoelectric properties and viability of PZT-based actuators to serve as devices within radiation-intensive environments [35]. The devices showed continued operation after 4 Mrad (Si) exposures in both the 0 V and 8 V fixed bias cases (see Fig. 20a). Moreover, under typical biasing conditions, the devices were able to operate correctly during exposure (855.6 rad(Si)/s) to a TID in excess of 13 Mrad(Si); see Fig. 20b. Data suggests that the changes detected are due to creation of defects in the PZT and subsequent pinning of domains and domain walls by the defects within the PZT material.

Conclusion

This entry provides a general overview of piezoelectric MEMS-based switch technologies and their application for RF circuits and mechanical digital relays. Both AlN and PZT thin films have demonstrated success operation of switches for both RF and digital applications. The fundamental material differences between the AlN and PZT result in the use of bimorph actuators for AlN and unimorph actuators for PZT. The key advantages of a piezoelectric switch can be summarized as low operating or drive voltage (typically sub-10 V) reducing the need for large area and power-consuming charge pumps for integrated drive applications and full control of actuator displacement when the switch is making contact to improve contact dynamics and improve reliability. Additionally, the piezoelectric N/MEMS switch has been shown to be capable of operation

under exposure to gamma radiation and able to survive to in excess of 13 Mrad(Si).

Piezoresistance; Piezoresistive effect; Semiconductor piezoresistance

Definition

Piezoresistivity is defined as change of resistance of semiconductors from the applied mechanical stress.

History

The discovery of piezoresistance dates back to the late nineteenth century (1856), when Lord Kelvin discovered the change of resistance in copper and iron wires. He compared the difference in the change of resistance of the two materials, while the elongation was the same [1]. The term "piezoresistance" was coined by Cookson in 1935, when he defined the term as the change in conductivity with stress [2]. The term "piezo" is rooted from the term "piezen" from the Greek meaning *to press*. "Piezoelectricity" sounds similar, but with a very different effect, where charge is generated from applied stress.

When Nobel laureates, Bardeen and Shockley invented the transistor, they also predicted relatively large conductivity change with deformation in single crystal semiconductors [3]. Later C.S. Smith, who was a visiting scientist at Bell labs, reported his pioneering results in the large piezoresistance in semiconductors [4]. Smith's work marked the start of semiconductor piezoresistive sensors (Table 1).

[d]Measured directly

In the 1960s, at least a couple of companies started manufacturing commercial silicon strain gauges, and in 1962, an "integrated" device using diffused piezoresistors was used to make pressure sensors at Honeywell [5].

From the early piezoresistive strain gauges to the present implanted piezoresistive pressure sensors and accelerometers, this technology required the three-dimensional micromachining of silicon. This requirement led to the development of bulk etching technology, and the development of MEMS technology.

Piezoresistance Essentials

Theory

Electrical resistance can be defined by a function of the resistivity of the material and the dimensions, as given in the following equation:

$$R = \rho \frac{l}{a}$$

where R = resistance, ρ = resistivity, l = length, and a = cross-sectional area.

So, the change of resistance is a function of the dimensional change and the resistivity change.

$$\frac{\Delta R}{R} = (1 + 2\upsilon)\,\varepsilon + \frac{\Delta \rho}{\rho}$$

where υ = Poisson's ratio and ε = strain.

The former term comes from the dimensional change, and the latter term is the resistivity change. The change of resistance to the applied stress is defined as the gauge factor.

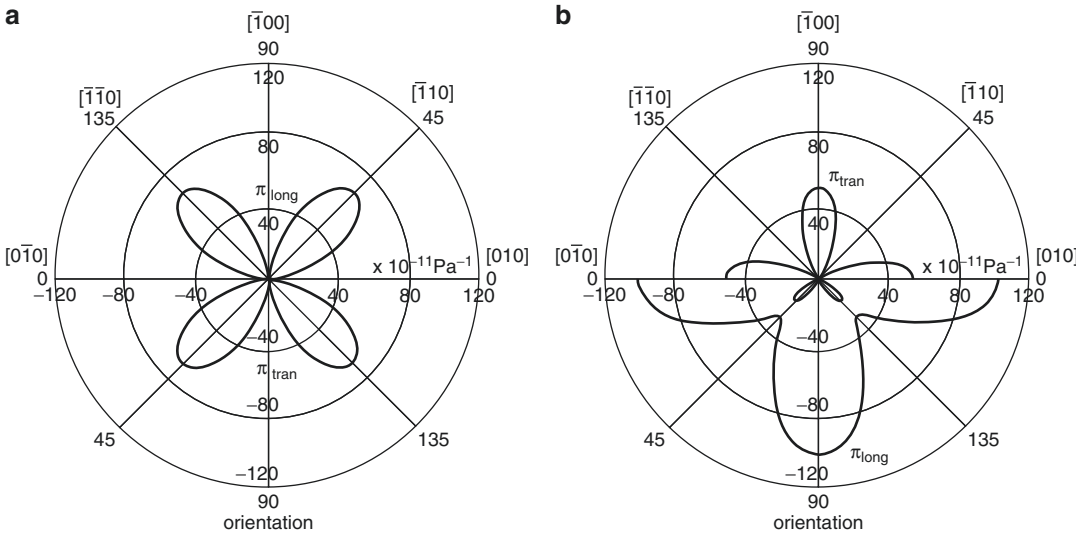
$$GF = \frac{\Delta R/R}{\varepsilon}$$

where GF = gauge factor.

For metals, geometric effect alone approximately accounts for 1.4–2.0 of gauge factor, and the change in resistivity is almost zero. However, for single crystal semiconductors, such as silicon and germanium, the change in resistivity can be 50–100 times larger than the geometric term. Because of this exceptional large resistivity change in semiconductors, a new term called "piezoresistive coefficient" denoted by "π" is defined as the following:

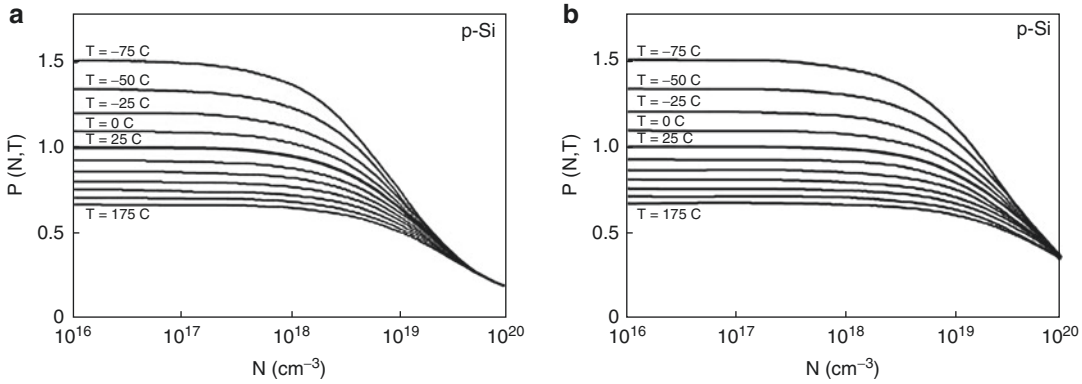
$$\frac{\Delta \rho}{\rho} = \pi_t \sigma_t + \pi_l \sigma_l$$

where π = piezoresistive coefficient, σ = stress, and the subscripts t = transverse, and l = longitudinal. Transverse stress and piezoresistive coefficient are defined as mechanical stress and electrical field being orthogonal, and longitudinal stress and piezoresistive coefficient are defined as mechanical stress and electrical field being parallel.



The theories to explain this large piezoresistive property of semiconductors are based on one-dimensional descriptions of electron and hole transport in crystalline structures under strain. The models are based on bandgap energy models, wave mechanics, and quantum effects; interested reader should refer to [6] for detailed explanation of the models.

N-type and p-type piezoresistors exhibit opposite trends in resistance change and different direction dependence under strain. The magnitude and sign of the piezoresistive coefficient depend on a number of factors including doping concentration, temperature, crystallographic direction, and relation between the current and stress direction. For n-type silicon, Herring explained piezoresistance in silicon or germanium using the Many-Valley model [7].



Fabrication

The most commonly used fabrication processes for doping piezoresistors are diffusion and ion implantation. Although both methods have its advantage for doping silicon, ion implantation is the dominant method used for doping piezoresistors.

1. Diffusion: Diffusion is the migration of dopant atoms from a high-concentration region to a low-concentration region. The fabrication steps for diffusion, most commonly involve pre-deposition and drive-in step. During pre-deposition, the wafers are placed in high temperature (900–1300 °C) with a gas-phase or a solid-phase dopant source. The dopant source (e.g., diborane, phosphine, or arsine) is carried in an inert gas (N_2 Ar). The resulting dopant profile is approximated by a complementary error function. After the pre-deposition step, the dopants are driven in deeper with high-temperature annealing. Diffusion method is still useful for high-dose doping (near solid solubility).
2. Ion implantation: Ion implantation provides better control of the dopant dose, which is why it is the preferred method to dope piezoresistors today. The process starts by accelerating the dopant ions at high energy (KeV to MeV) into the substrate. The implanted ions leave a cascade of damage in the crystal structure. Dopant distribution is approximated by a symmetric Gaussian distribution. During implantation, 7° tilt angle used

to avoid ion channeling effect. After implant, a short high-temperature annealing is used to restore the crystal lattice. Typical masking material is photoresist, silicon dioxide, or silicon nitride.

Design and Process Effects on Performance

Design and process conditions strongly affect the sensitivity and noise of the piezoresistor. Doping concentration and piezoresistor crystallographic orientation strongly affect the sensitivity. Choosing the device geometry, doping, and anneal conditions, the piezoresistive device designer must also consider the temperature coefficients of sensitivity and resistance, nonlinearity with strain and temperature, and noise limits.

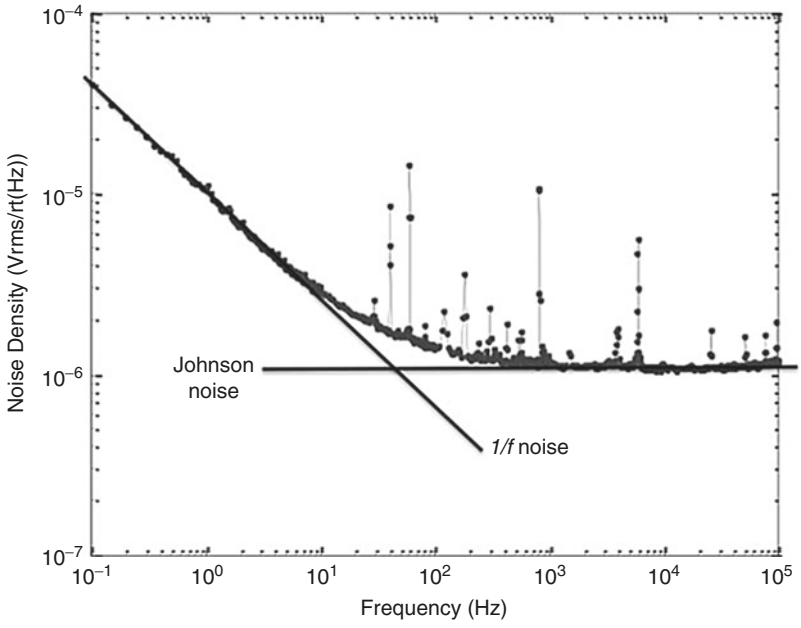
Kanda established the graphical representations of the piezoresistive coefficients in arbitrary orientations in the commonly used crystal substrates (Fig. 1) [8]. Kanda also showed theoretical calculations of the piezoresistive coefficients and dopant concentration (Fig. 2).

Resistors are generally sensitive to temperature. Silicon-doped resistors are also sensitive to

pressure. Temperature affects the absolute resistor values, but also affects the sensitivity. General trend is that the higher the sensitivity, the higher the temperature coefficient of the sensitivity. However, the rise in temperature sensitivity is faster than that of piezoresistive sensitivity. Sensor manufacturers use the Wheatstone configuration of sensors and conditioning circuits to compensate this temperature sensitivity.

Piezoresistive sensitivity also shows nonlinearity at high strain. So designers should avoid exerting strain higher than 0.1 %.

Noise



Noise in piezoresistors manifests as random fluctuations of the potential. Apart from other noise sources in the system, noise in the piezoresistor itself sets the fundamental limit in the resolution of the piezoresistor. Noise contributions come from two main components: Johnson noise (thermal noise) and 1/f noise (flicker noise). Figure 3 shows a representative example of piezoresistor noise.

The Johnson noise is determined by resistor value. So higher resistors have higher Johnson noise [9].

1/f noise is, as the name implies, inversely proportional to the frequency. So this noise component is the main culprit for low-frequency measurements. This is important since piezoresistors are used in mostly low-frequency static measurements. Although there are still debates on the source of this noise, there are two main popular theories. Hooge model views the fluctuation as carriers' mobility fluctuation by scattering centers [10]. Since the scattering centers depend on the quality of the crystal, annealing to repair internal damage reduces the noise. McWhorter model views the fluctuation as a surface effect scattering [11].

Alternative Piezoresistive Materials and Structures

Today, most commercially available piezoresistive sensors use silicon as the material. With the advances in material science, researchers studied new materials or scaling of the silicon to enhance the properties in sensitivity, and higher melting temperature.

Piezoresistivity, Fig. 3 Typical noise curve of a piezoresistor. The sloped *solid line* is the noise dominated by 1/f noise component plus the underlying Johnson noise. The *flat line* represents the inherent Johnson noise

Silicon Carbide (SiC)

Silicon carbide was attractive because of its superior mechanical properties over silicon such as higher modulus (424 GPa), higher sublimation temperature (1800 °C), and inertness to corrosive environments. Although the fabrication is not as straightforward as silicon, and growing oxide is a challenge due to the carbon in the film, SiC-based piezoresistive devices were able to achieve gauge factors as large as −35 [12] and withstand harsh operating environments, such as high temperatures (200–500 °C) [13] and high impact (40,000 g) [14].

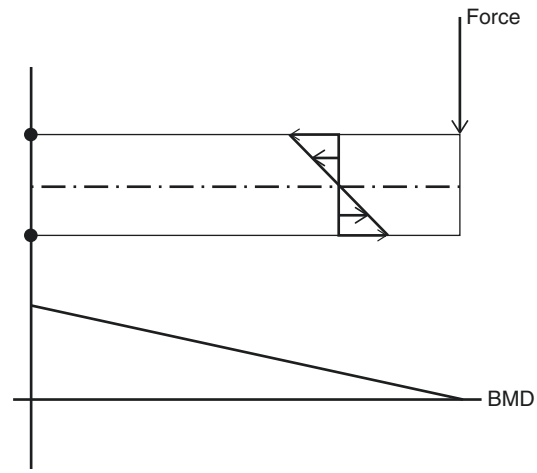
Diamond

Diamond has higher Young's modulus, yield strength, and thermal conductivity than silicon. The reported piezoresistive gauge factors of single crystal diamond range up to 3836. However, it is extremely difficult to grow single crystal diamond, and poly diamond has similar sensitivities as silicon carbide [15].

Carbon Nanotube (CNT)

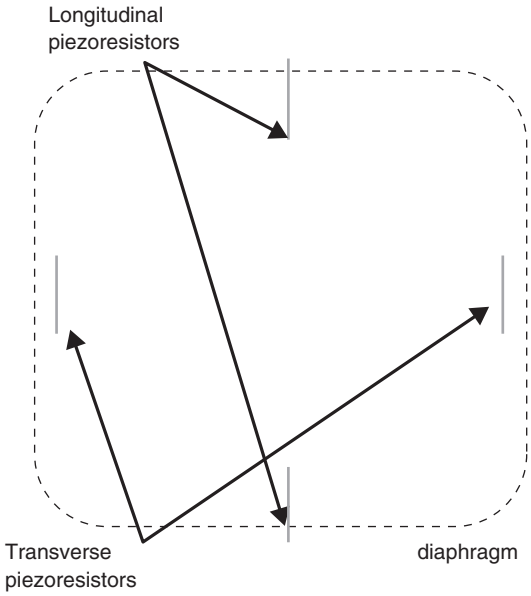
Carbon nanotubes are the strongest and most resilient materials known in nature. Electronically, based on the manner in which the graphene films are rolled, it can be metallic, semiconducting, or insulator. Gauge factors range from 400 to 850 [16] for CNT response adhered to pressurized membranes. However, the difficulty is in the ohmic connection to the CNT. A more manufacturable process was used mixing CNT to SU8, but the attained sensitivities were lower than what is possible with bare CNTs [17].

Silicon Nanowires



Silicon nanowires are simply reducing the dimension of conventional single crystal silicon components. Very high gauge factor, higher than 6000, was reported for silicon nanowires in dimensions under 100 nm [18]. Reducing the dimensions down to 100 nm is not a big challenge for modern lithography and further shrinking by self-limiting oxidation is possible. Neuzil reported that top-down manufactured (by standard clean room process) nanowires can reach up to 5000 of gauge factor [19]. However, recently Milne reported that his new measurement techniques revealed that the high change of signal is most likely due to long-term drift rather than high gauge factor [20].

Applications



Piezoresistors have the longest history of usage as MEMS devices since the 1950s [4]. Since they measure strain, piezoresistors have wide applications such as cantilevers, pressure sensors, and accelerometers.

Cantilevers

Cantilevers are used as force sensors, biosensors, or imaging (atomic force microscopy (AFM)). Figure 4 is showing where the piezoresistor should be placed, which is the maximum stress location of the cantilever. For force sensing applications, scaling is important to measure smaller cantilevers to measure smaller force. Piezoresistors do have advantage in this area, since they can more easily scale if compared to capacitive or optical detection methods. Tortonese et al. first used piezoresistive sensing for cantilevers and achieved 0.1 Å resolution [21] (Fig. 4).

Piezoresistivity, Fig. 4 A cantilever sensor representation. Upon applied normal force, the bending moment amplitude is shown by the bending moment diagram (*BMD*). The internal stress/strain due to the bending moment is shown by the *arrows*. Therefore, the maximum stress/strain points are at the root of the cantilever and at the *top* and *bottom* surfaces of the beam

Piezoresistivity, Fig. 5 Typical piezoresistive pressure sensor layout. The *dotted line* is representing the micromachined diaphragm. Upon applied pressure, the two longitudinal piezoresistors change resistance in opposite direction as the two transverse piezoresistors. Forming a complete Wheatstone bridge with these four resistors, this configuration allows the maximum output

Pressure Sensors

Pressure sensing is the most reported application for piezoresistive MEMS sensors. With four piezoresistors at the four edges forming a Wheatstone bridge configuration, the output is maximized in a differential sensing configuration. Upon applied pressure, the two longitudinal piezoresistors change in opposite direction as the two transverse piezoresistors (Fig. 5).

Wheatstone bridge also improves the temperature sensitivity by canceling the temperature coefficient in each neighboring resistor. Piezoresistive sensing is still the most dominant sensing type for all MEMS pressure sensors. The only downside of piezoresistive sensing for pressure sensors is the inability to adapt to polysilicon surface micromachining. However, recent work from Bosch using porous 0silicon showed a very low-profile manufacturing process without the need of backside etching [22].

Accelerometers

One of the very first MEMS accelerometers reported used piezoresistive transduction [23]. Numerous research articles reported the use of piezoresistive sensing in accelerometers. Recent products from Hitachi metals and Hokuriku use a novel three-axis sensing structure for piezoresistive accelerometers. However, the most dominant sensing method used for commercial accelerometers is capacitive. This is due to the fact that capacitive sensing can be more sensitive by employing very flexible springs without the need to have large strain concentration on the springs themselves. Capacitive sensing has proven to be more scalable for accelerometers.

Conclusions

Short after the discovery of transistors in 1947, piezoresistive property has been discovered in 1954 [4]. Through more than 50 years of steady development, piezoresistive sensors have transformed the way we live. It is used in numerous medical, automotive, aerospace, and consumer markets. While it is one of the easiest sensing techniques to construct, the fundamental physics is still not well understood. With the advances in material science, new materials are being proposed and studied. Yet, still the simplest implanted piezoresistors are the most common forms in use today. Piezoresistive sensing will always be in the MEMS designers' toolbox and employed in many devices in the years to come.

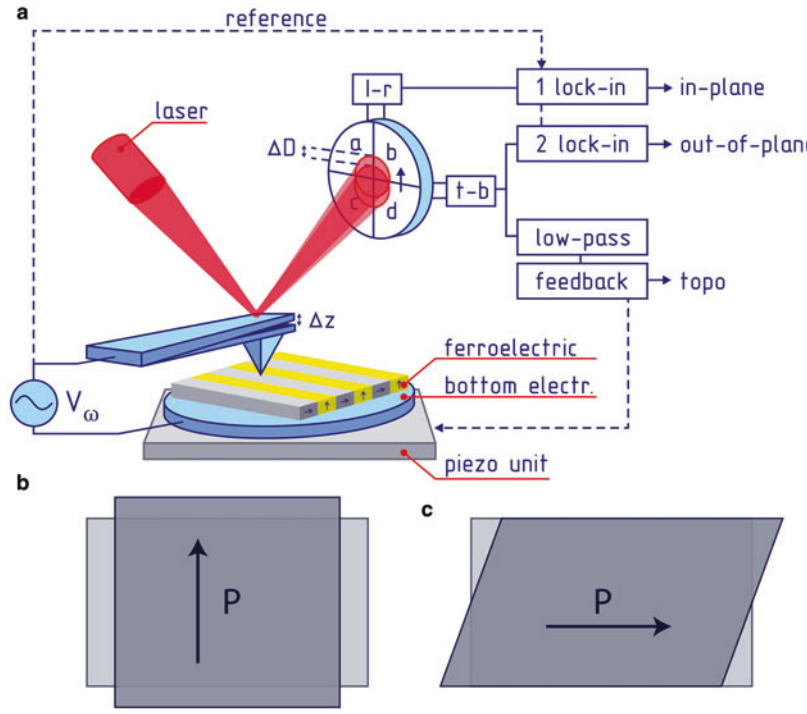
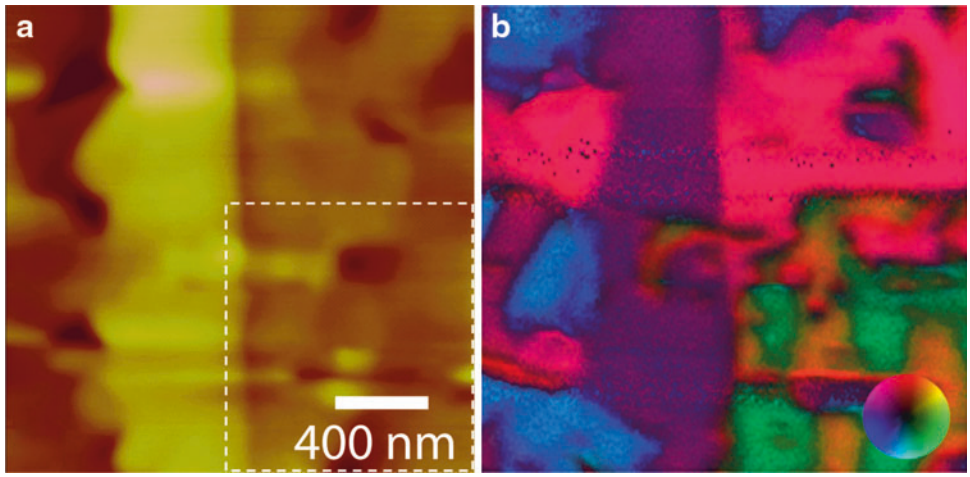
Definition

Piezoresponse force microscopy and spectroscopy (PFM and PFS, respectively) refer to a family of scanning probe microscopy (SPM) techniques based on the coupling between electrical bias and mechanical response (electromechanical detection). PFM and PFS are broadly used for the characterization of piezoelectric and ferroelectric properties (domain structure, switching dynamics, etc.) at the nanometer scale and are also applicable to polar biological and macromolecular systems. PFM is closely related to electrochemical strain microscopy (ESM), an SPM method used for the characterization of ionic transport and electrochemical reactivity on the nanoscale in ionic conductors.



Introduction

PFM and PFS were originally developed for the characterization of ferroelectric materials. The history of PFM can be traced to the first studies of local bias-induced sample deformations in piezoelectric materials using scanning acoustic microscopy [1] and scanning tunneling microscopy [2]. The seminal work by Kolosov and Gruverman [3] gave rise to the application of this method for imaging and manipulating domain structures in ferroelectric materials. Recent advances in PFM and PFS have allowed a wide variety of materials to be studied, including piezoelectric semiconductors, ferroelectric polymers, biological polymers, and energy materials. Many historical aspects of PFM development are discussed in recent books and reviews [4–10]. The unique aspect of PFM compared to other SPM techniques is the detection principle, which utilizes the coupling between bias and strain, often allowing for quantitative measurements.



Principles of PFM

PFM is implemented using an atomic force microscope (AFM) operated in contact mode. A nanometer-sized probe tip attached at the end of a microfabricated cantilever is brought into contact with a sample. The interaction force between the sample and the tip causes the cantilever to deflect, which can be detected using an optical beam method, i.e., through the displacement of a laser beam reflected off the backside of the cantilever and into a photodetector (Fig. 1). Typically, a feedback loop is employed which adjusts the tip-sample separation to keep the cantilever deflection and hence the (static) loading force constant. In PFM, a conducting probe is used, and an alternating current bias is applied to the conducting cantilever to create a highly localized time-dependent electric field at the probe tip apex. When the sample under investigation is piezoelectric, the material will deform, i.e., expand and contract, in response to the applied field. The tip can simultaneously be used as the sensor to detect this bias-induced deformation. The frequency of the ac-bias (typically 3 kHz–3 MHz) is chosen to be much higher than the scan rate of the AFM (~1 Hz), and thus, using a lock-in amplifier technique, the sample topography and piezoelectric response can be recorded simultaneously. The piezoelectric response is generally measured as an amplitude and phase signal. The PFM amplitude signal corresponds to the distance the tip is deflected and is thus directly related to the deformation of the sample. The latter is determined by piezoelectric tensor coefficients (in the laboratory coordinate system), which in turn depend on the crystal structure of the material under investigation and the crystal orientation. The PFM phase signal is related to the phase-lag of the piezoelectric response of the material compared to the sinusoidal ac-bias used to induce the deformation. When the direction of the applied electric field is parallel to the polarization direction of the ferroelectric domain under investigation, the domain will expand. Conversely, when the electric field and polarization are antiparallel, the domain will contract. Thus, the PFM phase provides information about the orientation of the ferroelectric polarization. The nanoelectromechanics (tip bias- and strain-induced phenomena) of PFM is reported in detail elsewhere [10]. A simple schematic of PFM is shown in Fig. 1. Note that similar to contact mode AFM, PFM can be operated in air, liquid, and vacuum environments.

For materials with general crystallographic orientation, the surface deformation is not necessarily purely out-of-plane (Fig. 1b), and the surface can shift laterally (shear deformation) depending on the polarization direction and the piezoelectric coefficients (Fig. 1c). This shear motion results in cantilever torsion for a tip in contact with the sample surface. Thus, in order to develop a full picture of the polarization orientation, it is important to measure both the tip deflection (vertical PFM) and torsion (lateral PFM) [11] (Fig. 1). In such a way, it is possible to reconstruct the three-dimensional real-space polarization direction in the material. An example of such vector PFM [12] imaging of an epitaxial bismuth ferrite film

Piezoresponse Force Microscopy and Spectroscopy, Fig. 1 (**a**) Schematics of the PFM experimental setup and (**b**) out-of-plane and (**c**) in-plane sample deformations which result in cantilever deflection (t-b signal output) and torsion (l-r output), respectively

The *dashed line* in (**a**) indicates a region subjected to a dc-bias prior to imaging. The *color wheel* in (**b**) indicates the ferroelectric polarization orientation and magnitude (Reproduced with permission from Ref. [13], copyright 2010, Wiley-VCH Verlag GmbH & Co. KGaA)

is shown in Fig. 2. Note that torsion can occur on domain walls, and, e.g., even 180° domain walls in tetragonal (001)-oriented material can be visible in LPFM amplitude images.

Domain Writing by PFM

In PFM imaging, an ac-bias is applied to the tip. This allows for local probing of the piezoelectric

properties and for ferroelectric domain orientation imaging. The application of a dc-bias via the tip to the sample can cause local polarization reversal if the highly localized electric field at the tip exceeds the local coercive field of the material. Thus, PFM can be used for local domain writing and for subsequent imaging of the polarization reversal. Dense arrays of written domains have been envisioned for polarization-based information storage. Information bits can be written as small domains with opposite polarization, and the read cycle can be achieved using the same tip by measuring the amplitude and the phase of the piezoelectric response. These memory devices are expected to achieve high densities, limited only by the size of the written ferroelectric domains and the presence of possible cross talk [14].

Polar surfaces of ferroelectrics are characterized by the presence of surface charges and electric potential and can be used in a broad set of applications, including local molecular self-assembly, physical adsorption/desorption, chemical reactions, and charge transfer reactions, and for the manipulation of individual organic molecules. Exploring the effect of ferroelectric polarization on chemical reactivity, an approach for assembling complex nanostructures consisting of oxide substrates, metal nanoparticles, and organic/biological molecules [15, 16] has been demonstrated (ferroelectric lithography). Controllable and selective deposition of molecular and metal species onto nanoscale domain-patterned ferroelectric templates may provide an alternative route to lithographic fabrication methods.

PFM Versus Other SPMs

The unique aspect of PFM is that for piezoelectric materials in the classical continuous mechanics regime, the electromechanical surface displacement is independent on the contact area. In other words, the displacement produced by the application of 1 V at the center of a 1 m, 1 mm, and 10 nm electrode will be the same. This behavior is fundamentally different compared to, e.g., contact mode mechanical AFMs, in which adhesion force, contact stiffness, and other parameters describing the properties of the tip-surface junction scale linearly with the tip-sample contact size. Correspondingly, on non-flat surfaces, the effects of material properties and topography variation cannot be unambiguously decoupled (direct topographic cross talk). In PFM, the response is intrinsically quantitative, albeit it can still be affected by the position-dependent transfer function of the cantilever (indirect cross talk), the tip sliding along the sample surface, etc.

Similarly to other force-based SPM techniques, the signal-to-noise ratio in PFM can be greatly improved if imaging is performed close to the contact resonance frequency of the cantilever. The quality factor of the resonances can be as high as ~100, allowing for a two-order increase in signal strength compared to the off-resonance case. Quantitative PFM measurements can be performed if the frequency of the electric signal driving the cantilever is adjusted to follow the contact resonance at each point on the surface. However, classical strategies based on phase-locked loop detection are inapplicable to PFM, since the phase of the local response depends on the local polarization direction. In the past several years, techniques have been developed to enhance the signal-to-noise ratio in PFM and to quantify the piezoresponse signal, including dual-amplitude resonance tracking (DART) PFM [17] and band excitation (BE) PFM [18]. In DART-PFM, two ac-biases are sent to the tip, with frequencies chosen such that one is on each side of the contact resonance. A feedback loop is employed to keep the difference in the amplitude measured at each frequency equal to zero, allowing the contact resonance to be tracked, i.e., remain in between the two frequencies during scanning. In BE-PFM, the cantilever is electrically excited across a band of frequencies, typically chosen to contain the contact resonance peak at all surface locations, allowing the resonant frequency and the quality factor of the system to be measured directly.

PFM Spectroscopies

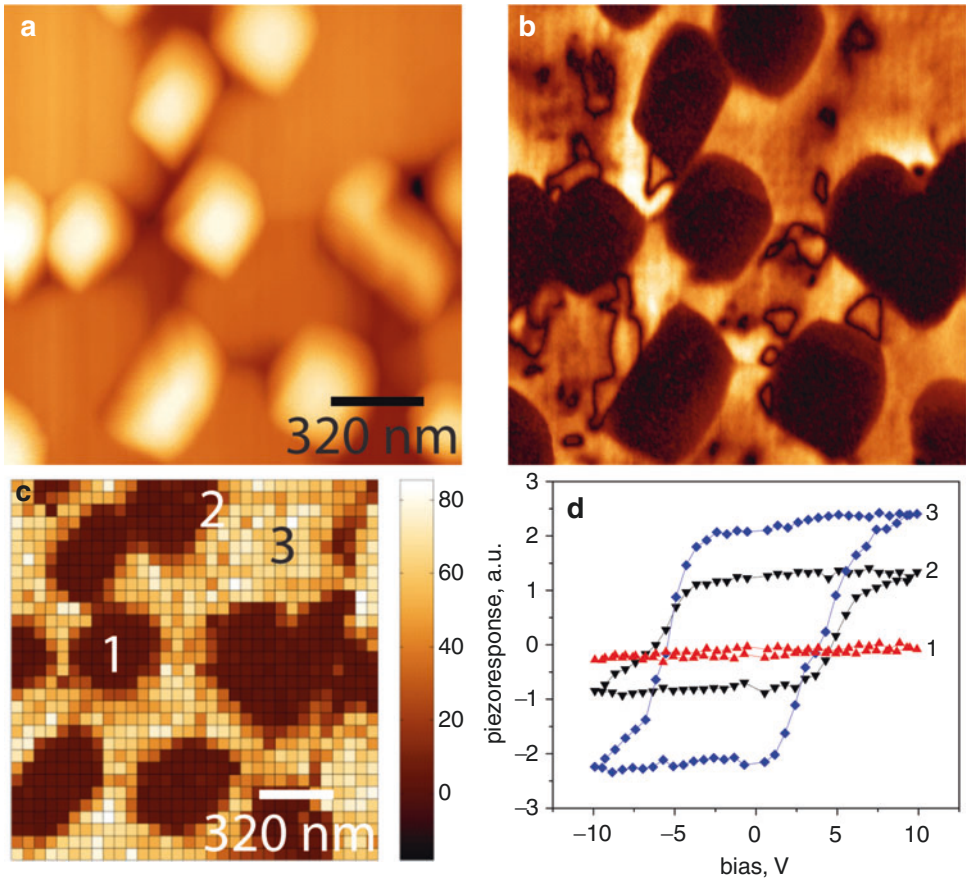
PFM can be extended to spectroscopic modes, in which the response is measured as a function of (i) time during or after the application of a

bias pulse (time spectroscopy), (ii) bias during a triangular sweep (voltage spectroscopy), and (iii) ac-bias amplitude. More complex measurement sequences (e.g., first-order reversal curve (FORC) measurements) have also been demonstrated. These spectroscopic modes can in turn be implemented as spectroscopic imaging modes (similar to, e.g., force volume mode imaging in AFM), in which the spectroscopic sweeps are performed at every point in an image.

Switching Spectroscopy Piezoresponse Force Microscopy

In switching spectroscopy PFM (SS-PFM), the ac-bias is superimposed onto a dc-bias waveform, which cycles between a maximum and minimum dc voltage value (i.e., a triangular voltage sweep). SS-PFM allows local piezoelectric hysteresis loops to be measured at each pixel in an image, providing a nanoscale analog to macroscopic ferroelectric polarization-voltage loops. Each loop can be analyzed to determine the width of the loop, the nucleation biases, the remanent polarization, etc. These extracted switching parameters can then be plotted as two-dimensional maps, allowing correlations between switching properties and local topography to be identified. Note that SS-PFM can be operated in single-frequency, DART, and BE-PFM modes.

As an example of the SS-PFM imaging mode, maps of piezoelectric response and switching properties for $BiFeO_3$-$CoFe_2O_4$ (BFO-CFO) heterostructures are shown in Fig. 3. The BFO film is ferroelectric, whereas the CFO nanopillars are non-ferroelectric (and ferromagnetic). The ferroelectric behavior is clearly seen in the PFM amplitude image in Fig. 3b, in which the BFO regions are bright (i.e., have high piezoresponse) and show clearly visible domain walls, whereas the response from the CFO pillars is negligible. In the SS-PFM mode, the hysteresis loops are acquired over the same region on a rectangular grid. Shown in Fig. 3c is the work of switching map (i.e., the area under the hysteresis loop). Note that the loops are open (Fig. 3d) when measured on the BFO matrix and are closed when measured on the CFO nanopillars. The SS-PFM image illustrates that the polarization switching within BFO is very uniform, indicative of a highly uniform material, which is not affected by proximity to the second-phase inclusions.



Time Spectroscopy in PFM

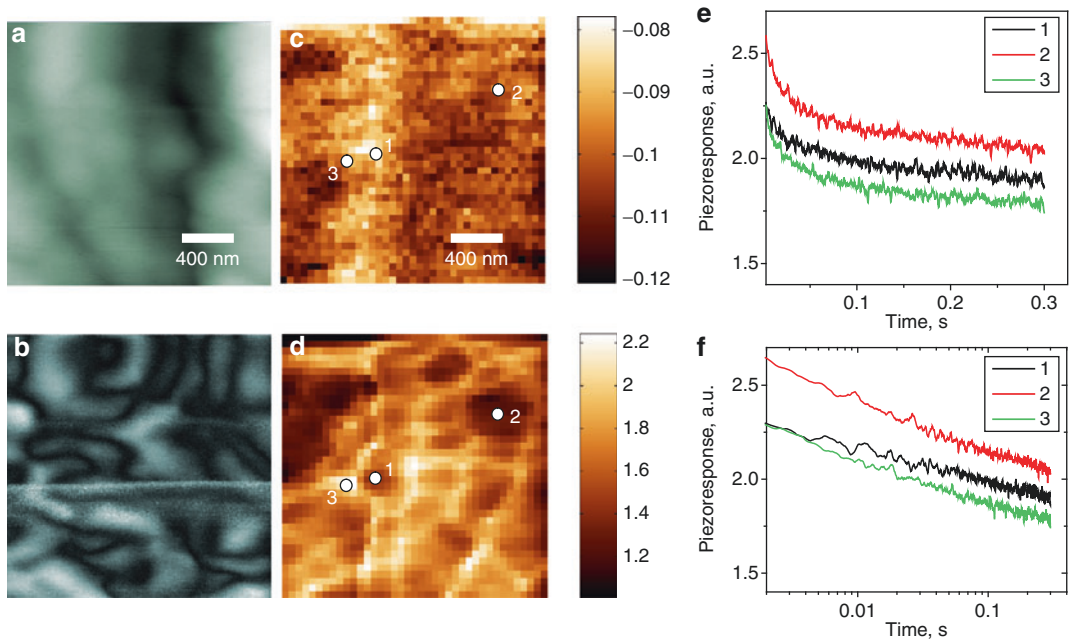
PFM can be extended to study time-dependent dynamic properties of materials. In time-resolved (TR) PFM, the local piezoelectric response is measured during the application of a dc-bias pulse and upon the completion of the pulse. As with SS-PFM, the response curves can be modeled to reveal information about local relaxation behavior of polymers and ferroelectric relaxors. Note that TR-PFM can also be operated in single-frequency, DART, and BE-PFM modes.

An example of TR-PFM is shown in Fig. 4 for the ferroelectric PMN-PT (solid solution of lead magnesium niobate (PMN) and lead titanate (PT)) relaxor. Here, polarization response at each point following the application of voltage pulse is collected. The response curves are fitted by the logarithmic function, $PR(t) = B_0 + B_1 \ln t$, and the spatial maps of offset, $B_0(x, y)$, and slope, $B_1(x, y)$, are shown in Fig. 4e, f, respectively. Note that both maps indicate the presence of mesoscopic structures and contain a number of uncorrelated features, indicative of the validity of the analysis and demonstrating the presence of intrinsic *dynamic* inhomogeneities within the material.

More Complex Spectroscopies

The characteristic aspect of hysteretic systems is the fact that the response is generally history dependent. For example, for a linear or nonlinear resistor, each value of current corresponds to only one value of applied external voltage. In a hysteretic system, the instantaneous value of current depends on the voltage history. However, the knowledge of the hysteresis loop for one type of field sweep does not allow for the prediction of a different one – e.g., knowledge of the hysteresis behavior in the (−10 V,10 V) bias window is insufficient to describe the (0,10) or (−5,10) bias windows. For certain classes of systems, this limitation can be bypassed using FORC measurements that allow one to reconstruct the response for an arbitrary field history. Another aspect of

Piezoresponse Force Microscopy and Spectroscopy, Fig. 3 (**a**) Topography of BFO-CFO and (**b**) corresponding PFM amplitude. (**c**) SS-PFM map of the work of switching and (**d**) representative loops from CFO (*1*), the CFO-BFO heterostructure interface (*2*), and BFO (*3*) (Reproduced with permission from Ref. [19], copyright 2007, Institute of Physics)



these materials is that the response can be time dependent, necessitating the study of the frequency or time dependence of the signal. To address these phenomena locally, more complicated time- and voltage-dependent spectroscopies in PFM are being developed.

PFM of Functional Materials

The materials that can be imaged by PFM are by definition functional materials in that they exhibit electromechanical coupling – they mechanically deform in an applied field. The classes of materials that have been investigated by PFM include ferroelectrics, biopolymers and polysaccharides, and piezoelectric polymers. Many recent advances in investigating functional materials using PFM have been published in Special Topics issues of the *Journal of Applied Physics* [21].

Ferroelectrics

Ferroelectric materials are a subset of pyroelectric materials, which in turn are a subset of piezoelectric materials. Piezoelectric materials exhibit linear electromechanical coupling, while pyroelectric materials have a permanent spontaneous polarization. In ferroelectric materials, the direction of this spontaneous polarization can be changed, i.e., switched between stable directions corresponding to different ferroelectric domains. These domains are readily imaged by PFM in

various ferroelectric families such as perovskites, Aurivillius layered structures, tungsten bronze ferroelectrics, hexagonal manganites, and organic materials and, recently, in a number of multiferroics (i.e., materials having both ferroelectricity and ferromagnetism simultaneously) and various composites [8, 22]. These measurements are indispensable for understanding the functionality of ferroelectrics at the nanoscale (e.g., within a single grain in polycrystalline ferroelectrics) and various size effects in as-grown and structured materials [23]. A ferroelectric relaxor is a special case of a ferroelectric material where long-range polarization is disrupted by defects and very small mesoscopic structures are observed on the surface on a length scale much smaller than the "normal" micron-sized ferroelectric domains in these materials. These properties have recently been accessed by time-, temperature-, and depth-dependent PFM measurements, demonstrating the power and capabilities of PFM to uncover the polarization mechanism in complex materials with coexisting order parameters and disorder [24].

Biosystems

The piezoelectric properties of biopolymers and polysaccharides have been studied on the macroscopic scale for some time, and several researchers have speculated on a relation between piezoelectricity in these materials and biological functionality such as bone remodeling. PFM is ideally suited for such studies and has been applied to a wide variety of biomaterials and in amino acid microcrystals [25]. These measurements are found to be especially important in macromolecules such as collagen fibers and, recently, in bioinspired peptide nanotubes [26]. The exceptional piezoelectric properties of the latter observed by PFM have renewed the interest in artificial biomaterials for biological sensor- and actuator-based applications. It has been also shown that PFM can be used as a high-resolution nanoscale tool for uncovering

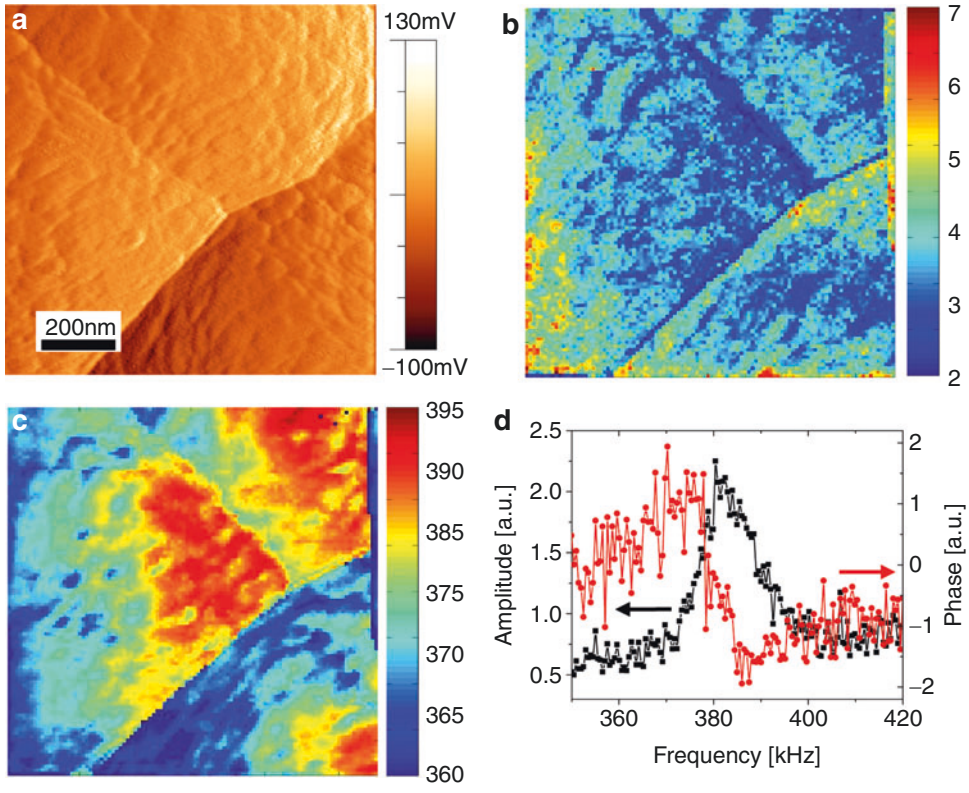
new features in complex biological materials, including cells and tissues, such as aortic walls [27].

Polymers

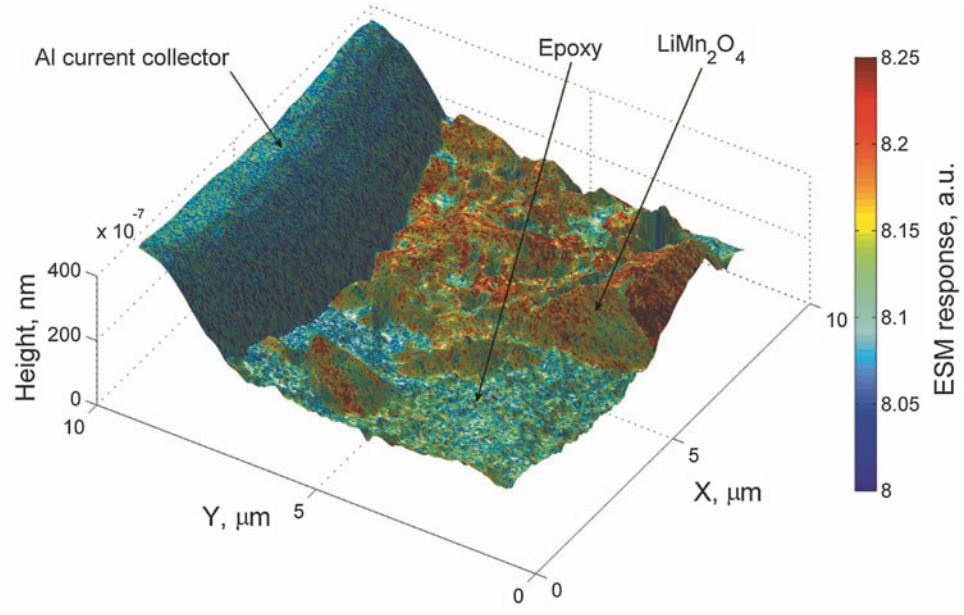
Many synthetic polymers, including polypropylene, polystyrene and poly(methyl methacrylate), semicrystalline polyamides, and amorphous polymers such as vinyl acetate, are piezoelectric. However, piezoelectric effects in these materials are relatively weak and often unstable and, therefore, are of limited practical significance. Strong and stable piezoelectric properties have primarily been found in the synthetic polymer polyvinylidene fluoride (PVDF) and PVDF copolymers. PFM has been found to be extremely useful for studying local piezoelectric properties in PVDF because it allows one to relate the surface topography to the local polarization response in these semicrystalline materials where a mixture of material phases is often observed. It has also been demonstrated that PFM can effectively probe nanostructured PVDF nanomesas (Fig. 5). Studying polarization switching in these soft ferroelectric materials is one of the challenges for PFM because of the possible coupling present between electrostatics, piezoelectricity, and elasticity.

PFM of Device Structures



PFM is essentially a nanoscale polarization probe and, as such, can be used to study ferroelectric devices based on polarization dynamics and switching, including nonvolatile ferroelectric random access memories (NV-FRAM), thin-film capacitors, piezoelectric elements for microelectromechanical systems (MEMS), and novel multiferroic devices with multiple memory states [29]. As for NV-FRAM, the bit value is represented by one of the two distinguishable remanent polarization states of a ferroelectric material in a capacitor configuration. The spatial variation of the ferroelectric properties, e.g., the static and dynamic domain configurations, becomes critical as the NV-FRAM capacitor size decreases. If the ferroelectric properties of a material vary on a micron scale, then micron-sized capacitors would exhibit a significant capacitor-to-capacitor variation in their electrical properties, often resulting in a failure of the device. These properties have been extensively studied by a number of groups [30–33], and it has been shown that the polarization dynamics differ significantly as the lateral size of the ferroelectric capacitors is scaled down. Analogously, ferroelectric-based MEMS have been found to

be sensitive to scaling in both lateral and vertical dimensions. This makes PFM a useful industrial tool, e.g., for quality control in the production of memory chips and micromechanical devices based on the piezoelectric effect.



Electrochemical Strain Microscopy

Bias-strain coupling can be driven by electrochemical mechanisms as a consequence of ionic motion in applied electric fields. PFM can be used to probe ac-bias-induced ionic motion in energy materials, giving rise to electrochemical strain microscopy (ESM) [34–37]. In ESM, a biased SPM tip concentrates an electric field in a nanometer-scale volume of the material, inducing interfacial electrochemical processes at the tip-surface junction and ionic currents through the solid. The intrinsic link between the concentration of ionic species and/or the oxidation states of the host cation and the molar volume of the material results in electrochemical strain and surface displacement.

The ESM imaging mode is based on detecting the strain response of a material to an applied electric field through a blocking or electrochemically active SPM tip. The high-resolution (<10 nm) data shown in Fig. 6 demonstrates ESM imaging on a Li-intercalated Si-anode surface [38]. A full suite of spectroscopic imaging modes can also be implemented in ESM. To date, ESM has been demonstrated for a variety of lithium-ion materials, including layered transition metal oxide cathodes, silicon anodes, and electrolytes such as LISICON; oxygen electrolytes,

including yttria-stabilized zirconia and samarium-doped ceria; mixed electronic-ionic conductors for fuel cell cathodes; and some proton conductors. Even cross sections of commercial Li batteries have been recently studied [39]. An example of ESM of a Li battery composite cathode is shown in Fig. 7, where active Li_2MnO_4 particles demonstrate much higher ESM signal as compared to the other parts of the composite. Inhomogeneous ESM signal distribution is directly related to the Li activity within the grains providing nanometer resolution. Such studies should shed light on the mechanisms of degradation related to the loss of battery charging capability.

The ability to probe electrochemical processes and ionic transport in solids is invaluable for a broad range of applications for energy generation and storage (e.g., batteries and fuel cells). The viability of electric vehicles and grid storage as key components of a renewable energy technology hinges on advances in battery energy densities and lifetimes. An example of ESM has the potential to aid in these advances with two major improvements over existing technologies: (a) the resolution to probe nanometer-scale volumes and (b) imaging capability extended to a broad range of spectroscopy techniques. In addition, because electrochemical strains are ubiquitous in virtually all solid-state ionics, ESM is applicable to all battery and fuel cell materials in energy technologies and electroresistive/memristive materials in information technologies.

Summary

Electromechanical coupling is ubiquitous in systems ranging from piezoelectrics and ferroelectrics to polar macromolecules and solid-state ionics. Piezoresponse force microscopy and spectroscopy are the techniques that have opened these phenomena to scientific inquiry, providing advances ranging from sub-10 nm domain imaging and lithography to probing intricate polarization structures in ferroelectric relaxors, polar polymers, and biosystems and to revealing details of electrochemical processes in battery materials. The future of this field clearly contains many more serendipitous discoveries.

Plasmon resonance energy transfer from metallic nanoparticles to biomolecules

Definition

Plasmon resonance energy transfer is the energy stored in the collective movement of free electrons in metallic nanoparticles being transferred to the adsorbed chemical and biomolecules with match electronic transition energy.

Overview

Nanoparticle Plasmon Resonance

A plasmon is defined as the collective and periodic free electron movement in metallic structures under electromagnetic excitation. Free electrons in the metal conduction band are not bounded to the nucleus, so they can move in the applied alternating electromagnetic field within the physical boundary of metal materials producing an alternating electron current. Like the resonance modes in mechanical movements, there exist plasmon resonance modes with minimal energy damping. If the plasmon resonance modes fall into the optical frequency range, especially the visible frequency range, the resonating free electrons in metallic nanostructures form an optical dipole to reemit light.

The plasmon resonance modes are dependent on the dielectric constants of the metallic nanoparticle and the surrounding material. Within the optical frequency range, the complex dielectric constants or the permittivity of the metallic materials such as gold and silver changes rapidly with the light wavelength while the dielectric constants of dielectric materials remain nearly unchanged. The plasmonic polarizability has to be modified when the metallic structure approaches sub-100 nm scale. At this scale, the dimension of the metallic nanostructure becomes comparable to the mean free path length of the conduction electrons in metal. The physical boundary of the metallic nanostructures poses a boundary condition for the plasmon resonance mode. Nanoplasmonic structures are thus referred to the metallic nanostructures such as nanoparticles with discrete plasmon resonance modes which are dependent on the nanostructure geometries and surrounding medium.

Plasmon Resonance Energy Transfer

Nanoparticle plasmon resonance [1, 2] is distinctive from the propagating surface plasmon resonance on metallic thin film [3]. It is spatially confined within the physical boundary of the nanoparticle; however it can be continuously transferred to adjacent metallic nanoparticles [4, 5] through plasmon coupling. It has also been conjectured for a long time that the plasmon resonance energy can be possibly transferred to chemical or biological molecules adsorbed on metallic nanostructures [6, 7]. This entry will review the highest-sensitivity-ever nanoscopic biomolecular absorption spectroscopy enabled

by plasmon resonance energy transfer (PRET) from a single metallic nanoparticle to a conjugated biomolecule and chemical molecule. Due to PRET, quantized plasmon quenching dips are observed in single nanoparticle scattering spectra which correspond to the absorption spectral peaks of conjugated biomolecules. The hybrid nanoparticle–biomolecule PRET system allows near single molecular sensitivity absorption spectroscopy with nanoscale spatial resolution for in vivo functional molecular imaging.

Although not directly observed before, PRET was accounted for one of possible explanations for surface-enhanced Raman scattering [8, 9] and fluorescence [10] on single nanoparticles. Experimentally the plasmon resonance of gold and silver nanoparticles conjugated with various biomolecules such as DNA [11], peptide [12], and biotin-streptavidin [13] has been studied by single particle Rayleigh scattering spectroscopy [14, 15]. All these previous studies demonstrated the shift of plasmon resonant wavelength by changing dielectric medium due to structural changes of biomolecule conjugated on the surface of single metallic nanoparticles. Since most of the previous cases have conjugated biomolecules with optical absorption or electronic resonance peaks in ultraviolet (UV) or far-infrared range on gold and silver nanoparticles with visible plasmon resonance peaks, only the shift of plasmon resonance peak was observed. However in this chapter, metalloprotein Cytochrome c (Cyt c) was conjugated on a single 30 nm gold nanoparticle in order to observe the direct quantized plasmon resonance energy transfer from the nanoplasmonic particle to Cyt c, as seen in Fig. 1.

Theory

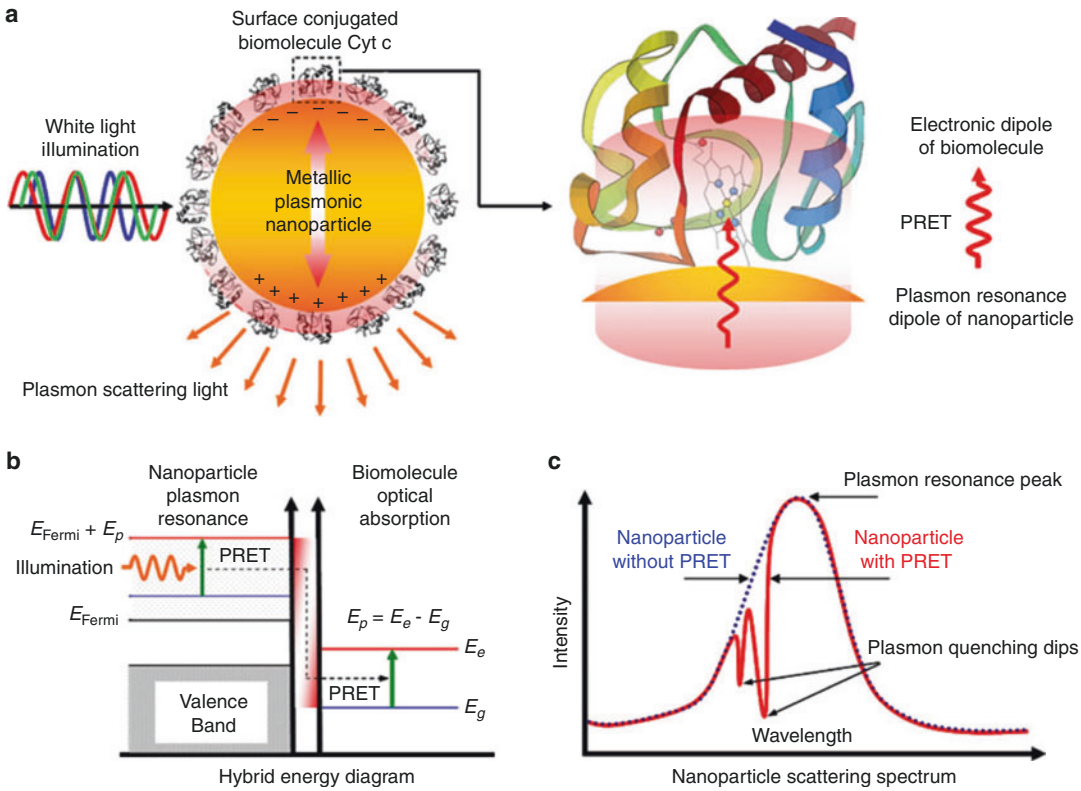
The strict modeling of plasmon resonance energy transfer between metallic nanoparticle and adsorbed resonance chemical and biological molecules requires quantum mechanical calculation of electron interaction Hamiltonian between nanoparticle and molecules.

$$H_I = \frac{1}{4\pi\varepsilon_0} \times \int dr_{\text{molecule}} \int d^3 r_{\text{metal}} \frac{\rho(r_{\text{molecule}})\rho(r_{\text{metal}})}{|R - r_{\text{metal}} + r_{\text{molecule}}|} \tag{1}$$

The above equation describes the interaction Hamiltonian where ρ is the electron density distribution in molecule or metallic nanoparticle and r is the radial distance of the electrons from the center of the molecule or nanoparticle and R is the distance between the molecule center and nanoparticle center. Apparently it is extremely difficult to precisely describe the three-dimensional spatial distribution of electron density; therefore some assumption and approximation have to be made to carry out the analytical calculation. Fortunately near the matched nanoparticle plasmon resonance and molecule electronic resonance the electron distribution may be approximated as dipolar distributions. Then the electron interaction becomes dipole–dipole interactions as described in Eq. 2.

$$H_I^{\text{dip}} = \frac{1}{4\pi\varepsilon_0} \times \left[\frac{\mu_{\text{molecule}} \cdot \mu_{\text{metal}} - 3(\mu_{\text{molecule}} \cdot \hat{d}(\mu_{\text{metal}} \cdot \hat{d})}{d^3} \right] \tag{2}$$

Here μ is the dipole moment operator and defined as



$$\mu_{\text{metal}} = \int r_{\text{metal}} \rho_{1,0}(r_{\text{metal}}) d^3 r_{\text{metal}}$$
$$\mu_{\text{molecule}} = \int r_{\text{molecule}} \rho(r_{\text{molecule}}) dr_{\text{molecule}} \tag{3}$$

Where ρ is simplified as the radial distribution of the electron density and especially for metallic nanoparticle $\rho_{1,0}$ becomes the dipolar plasmon charge density which is defined as

$$\nabla^2 \rho_{1,0}(r_{\text{metal}}) + \alpha^2 \rho_{1,0}(r_{\text{metal}}) = 0 \tag{4}$$

The constant α is the function of fundamental plasmon resonance mode frequency $\omega_{1,0}$ and bulk plasmon resonance frequency ωp as well as the electron velocity at Fermi energy vF. The expression is as the following:

P

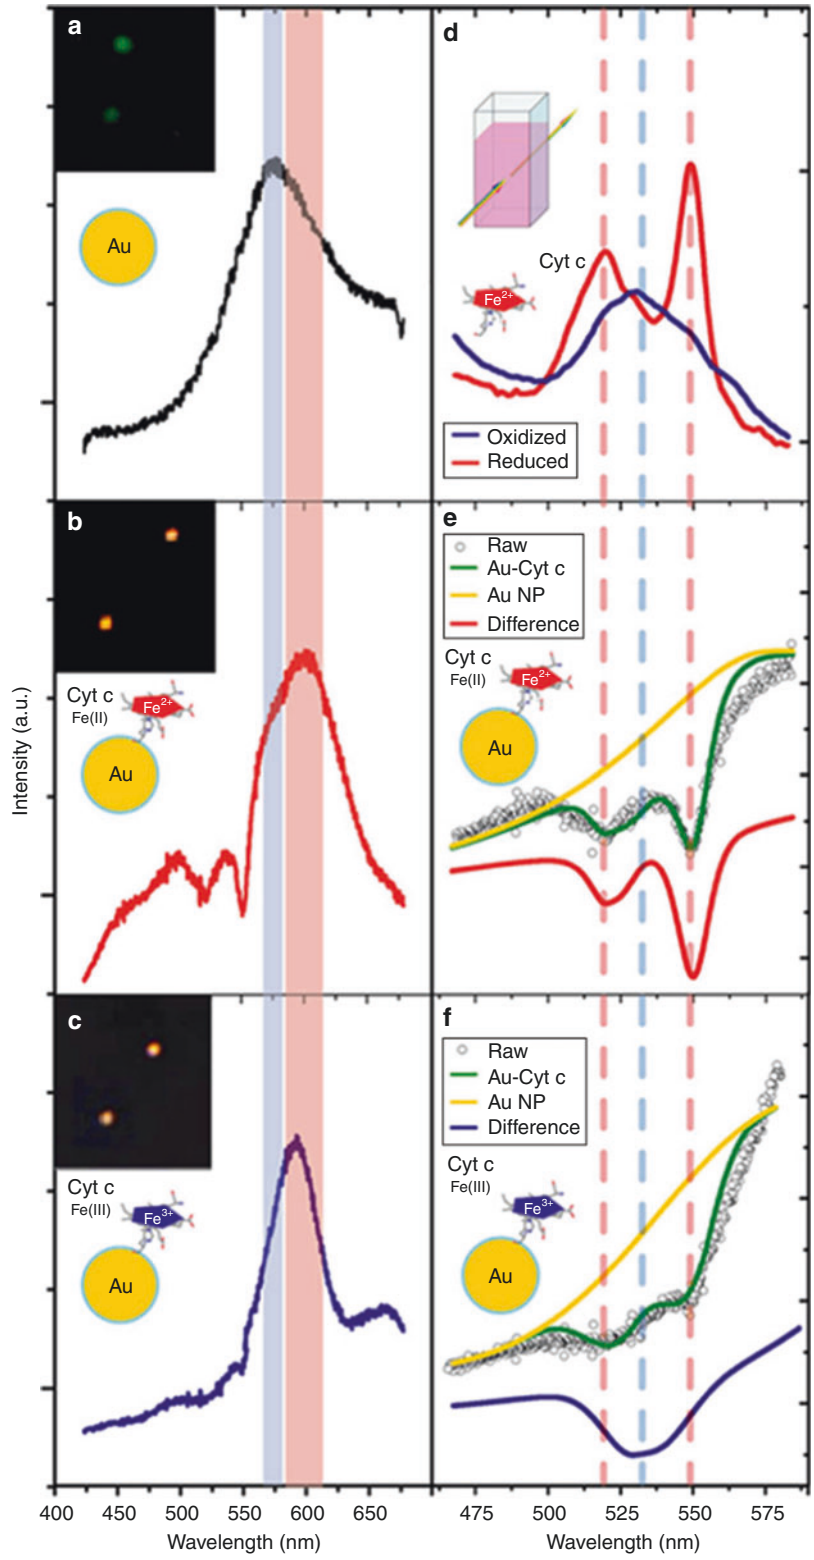
Plasmon Resonance Energy Transfer Nanospectroscopy, Fig. 1 Schematic diagram of PRET-enabled nanoscopic biomolecular absorption spectroscopy. (**a**) PRET from a single metallic nanoparticle to surface-conjugated biomolecules. The wavelength-specific plasmon resonance (collective free electron oscillation) in metallic nanoparticle is excited by white light illumination. The plasmon resonance dipole can interact with the biomolecular dipole and transfer energy to biomolecules. (**b**) Hybrid energy diagram showing quantized energy transfer process. With optical excitation, the free electrons in the conduction band of metallic nanoparticle are elevated from Fermi to higher energy level forming resonating plasmon. The plasmon resonance energy is transferred to the metalloprotein biomolecules (i.e., Cyt c) conjugated on the nanoparticle surface when matched with the electronic transition energy in biomolecule optical absorption. (**c**) Typical Rayleigh scattering spectrum of the single PRET probe. The energy transition in PRET is represented as quenching dips in nanoparticle scattering spectrum, and the dip positions correspond to the biomolecule optical absorption peaks

$$\alpha^2 = \frac{{\omega_{1,0}}^2 - {\omega_p}^2}{3{v_F}^2/5} \tag{5}$$

The dipole moment operator of the metallic nanoparticle at the fundamental plasmon resonance mode is then

$$\mu_{\text{metal}} \approx \left(\frac{4\pi^3 \varepsilon_0 \hbar \omega_p}{9\sqrt{3}}\right)^{1/2} a^{3/2} \tag{6}$$

Basic Methodology

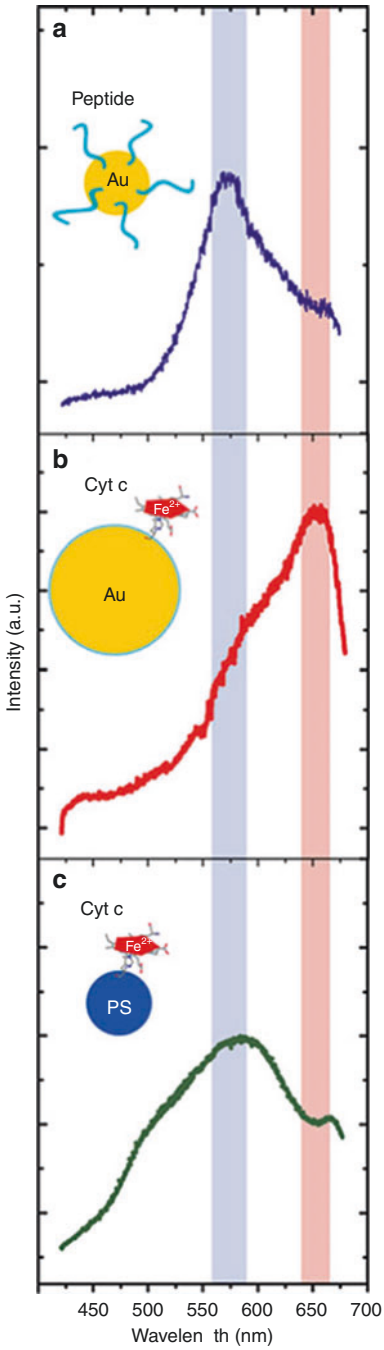


PRET-Enabled Biomolecular Absorption Spectroscopy

The intentional overlap of the absorption peak positions of desired biomolecules with the plasmon resonance peak of the metallic nanoparticle generates distinguishable spectral quenching dips on the Rayleigh scattering spectrum of single nanoparticle, which also allows near single

molecular level nanoscopic absorption spectroscopy (Figs. 1 and 2). Cyt c, a metalloprotein in cellular mitochondria membrane, acts as the charge transfer mediator [16] and plays a crucial role in bioenergy generation, metabolism, and cell apoptosis [17]. Unlike many other proteins, Cyt c has several optical absorption peaks in visible range around 550 nm coinciding with the 30 nm gold nanoparticle plasmon resonance, and more importantly it is a natural energy acceptor with electron tunneling channels [18]. Similar to the donor–acceptor energy matching in fluorescent (or Förster) resonance energy transfer (FRET) between two fluorophores, the critical matching of the localized resonating plasmon kinetic energy *Ep* in gold nanoparticles with the electron transition energy from ground to excited state *Ee*−*Eg* in Cyt c molecules permits the PRET process (Fig. 1b). The quantized energy is likely transferred through the dipole–dipole interaction between the artificial alternating dipole – resonating plasmon in nanoparticle and the biomolecular dipole. Previous work on surface plasmon–mediated FRET process [19, 20], superlens imaging [21], surface plasmon resonance shift of redox molecules [22], and very recent work on bulk optical extinction spectroscopy of nanoplasmonic particle clusters with conjugated resonant molecules [23] also indicate the possibility of such dipole–dipole interaction. Distinctively in this experiment, the plasmon energy quenching of nanoparticle due to PRET is represented as the "spectral dips" in the single nanoparticle scattering spectrum (Figs. 1c and 2) and the positions of dips match with the molecular absorption peak positions (Figs. 1c and 2). PRET is a direct energy transfer process and thus much more efficient and faster than optical energy absorption [10], so the absorption spectral peaks of conjugated Cyt c molecules on single gold nanoparticles can be detected with a simple optical system, which is otherwise impossible using conventional visible absorption spectroscopic methods.

The Cyt c conjugated 30 nm gold nanoparticles are dispersedly tethered on the surface of a transparent glass slide. The glass slide is mounted on a white light darkfield microscopy system with a true-color camera and a spectrometer to characterize the scattering image and spectrum of individual gold nanoparticles as well as the hybrid PRET probes (i.e., specific metallic nanoparticles with conjugated Cyt c molecules).



In comparison with the visible scattering spectrum of gold nanoparticles coated with only Cysteamine cross-linker molecules (Fig. 2a), the raw scattering spectra of gold nanoparticles conjugated with reduced (Fig. 2b) and oxidized Cyt c (Fig. 2c) show not only a scattering peak (plasmon resonance peak) but distinctive dips next to it. The spectral dips modulated on the nanoparticle scattering spectrum can be decoupled and converted to the visible absorption peaks of the reduced and oxidized Cyt c molecules (Fig. 2e and f). In accordance with the conventional visible absorption spectrum of bulk Cyt c solutions (Fig. 2d), the processed spectra have matched absorption peaks of reduced Cyt c around 525 and 550 nm, and oxidized Cyt c at 530 nm [24]. Although the near-field optical excitation efficiency from the nanoparticle scattering light is much higher than far field optical excitation (i.e., the photon scattered from the nanoparticle is more likely to transmit through and be absorbed by the surface conjugated biomolecules than those far away from the nanoparticle), the optical absorption at 550 nm by the ferrocytochrome c molecule monolayer only accounts for 0.03 % of the nanoparticle scattering light even for 100 % excitation efficiency (The absorption coefficient ε of horse heart Cyt c at 550 nm is 20.4 mM^{-1} cm^{-1}. For a completely packed monolayer of ~3 nm-in-diameter Cyt c molecules on 30 nm gold nanoparticle surface, the local concentration *C* of Cyt c on single nanoparticle is 47 mM. The optical path length *L* of a Cyt c monolayer is ~3 nm, so the optical absorbance is $A = \varepsilon CL \sim = 3 \times 10^{-4}$ assuming 100 % of scattering photon passing through the biomolecule monolayer.); therefore, the dramatic spectral dips are not a result of the direct optical absorption of Cyt c molecules.

The energy matching condition in PRET is further confirmed by three negative control experiments. For the first control experiment, synthesized peptides which have absorption peaks out of wavelength range of the plasmon resonance of a 30 nm gold nanoparticle are intentionally conjugated. As expected, the scattering spectrum of this hybrid system shows only the scattering peak because the absorption peaks of peptide do not coincide with the plasmon resonance spectrum of the nanoparticle (Fig. 3a). For the second control experiment, the importance of matching resonant frequency and molecular absorption peaks was tested by using a large gold nanoparticle cluster which has a plasmon resonance wavelength beyond 650 nm. As anticipated, the conjugated Cyt c absorption peaks can be hardly observed, including the 525 and 550 nm peaks for reduced Cyt c (Fig. 3b). For the third control experiment, dielectric polystyrene nanoparticles were conjugated with Cyt c and characterized. As expected, the plasmon quenching spectral dips cannot be found on the scattering spectrum of single dielectric polystyrene nanoparticle without plasmon resonance even though the dielectric nanoparticle also scatters light, which indicates the presence of excited free electrons is necessary for the PRET process (Fig. 3c).

The average surface density of Cyt c molecules on an individual gold nanoparticle is controlled by the molar concentration ratio used in the conjugation process. Considering the effective cross-sectional area of single Cyt c molecules and the surface area of single 30 nm gold nanoparticle, maximally around 400 Cyt c molecules can be tethered on a 30 nm gold nanoparticle. The scattering spectrum of many individual 30 nm nanoparticles was measured and extracted the reduced Cyt c visible absorption peaks. Due to the nonuniformity of the surface molecule numbers on each particle and nanoparticle plasmon resonance wavelength, the plasmon quenching or Cyt c absorption peak intensity shows variations from particle to particle (Fig. 4a), whereas the spectral measurement on each individual nanoparticle is repeatable and stable (Fig. 4b) and no photochemical changes are observed.

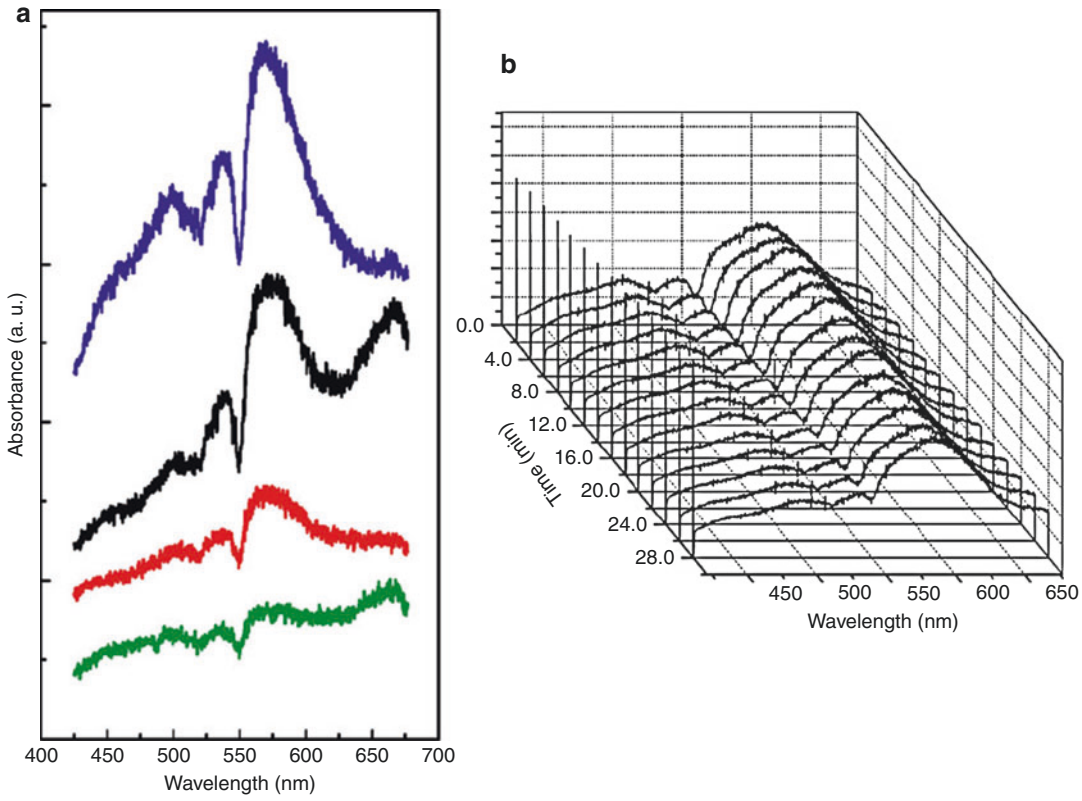
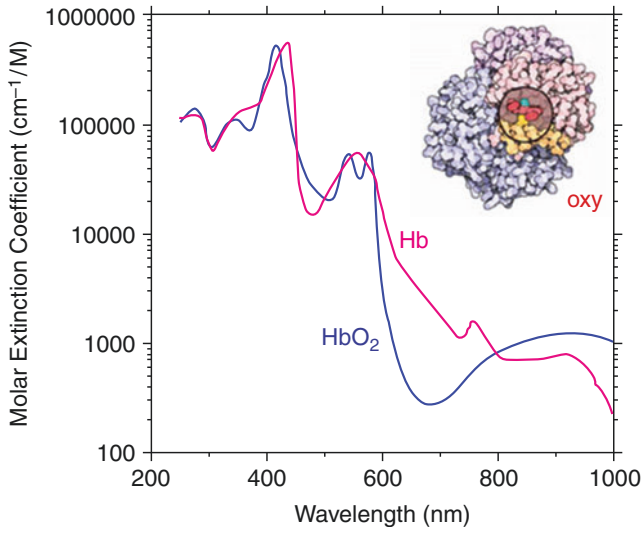
Plasmon Resonance Energy Transfer Nanospectroscopy, Fig. 4 Simulation of nanoparticle plasmon resonance coupling to a single Cyt c molecule. (**a**) Time-averaged total electromagnetic (EM) energy at 550 nm vertically polarized light excitation around the interface of single 30 nm gold nanoparticle and single 3 nm spherical molecules. The dielectric nanosphere is used to simulate single reduced Cyt c molecule with a wavelength-dependent complex refractive index (16). The EM energy is transferred to the single molecule and forms the dipolar energy distribution across the molecule. The inset image of the whole nanoparticle shows the energy coupling only occurs in the light polarization direction. (**b**) Time-averaged total energy profile at the cross-section line in (**a**) as the function of the excitation wavelength or energy. The energy distribution at each wavelength is normalized to the energy at the inner surface of the nanoparticle. The representative line plots of the energy profile at 370, 550, and 730 nm are superposed on the 2D color-coded energy distribution at corresponding wavelength positions. The dipolar energy of nanoparticle plasmon resonance is electromagnetically coupled to the single molecule around 550 nm, while at other wavelengths much less energy transfer is observed

Unpolarized white light source is used in all the above experiments.



Similar to the energy transfer process in FRET, the PRET efficiency is possibly dependent on the distance from the spectrally active moiety of biomolecules, e.g., Heme group for Cyt c, to the plasmonic nanoparticle surface as well as the relative orientations between the polarized plasmon resonance dipole and molecular dipoles (Fig. 5a). On the other hand, the simulated single nanoparticle PRET spectra (Fig. 5b) shows that the strongest plasmon resonance mode for a single Cyt c conjugated 30 nm gold nanoparticle occurs around 550 nm. This resonant frequency (i.e., energy) matching condition potentially explains why the plasmon quenching peak amplitude at 550 nm is relatively higher than at 525 nm (Fig. 2e) compared to the peak intensity ratio in Cyt c bulk solution absorption measurement (Fig. 2e). The scattering peak wavelength of the gold nanoparticle in experiments is higher than the simulated results due to larger numbers of Cyt c and Cysteamine molecules conjugated on surface.

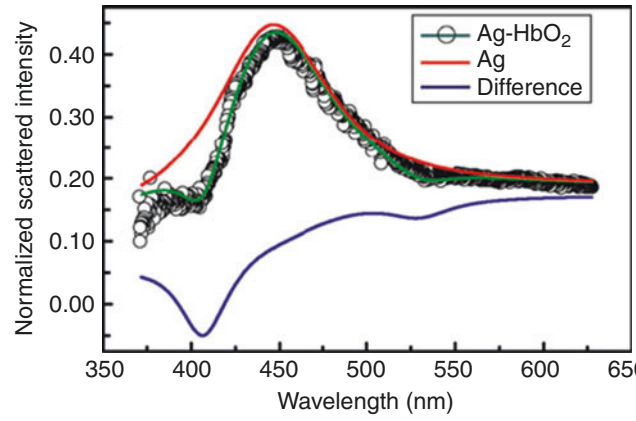
The PRET effect can be also observed for hemoglobin molecules conjugated with single silver nanoparticles. Hemoglobin molecule has a distinctive absorption peaks around 407 nm which is the sorbet band of the heme group. The absorption spectra of hemoglobin with and without binding to oxygen are shown in Fig. 6. Using PRET nanosensor, plasmon quenching dips were observed and corresponding to the Soret band (407 nm) of hemoglobin molecules on the surface of a single nanoparticle, as shown in Fig. 7.

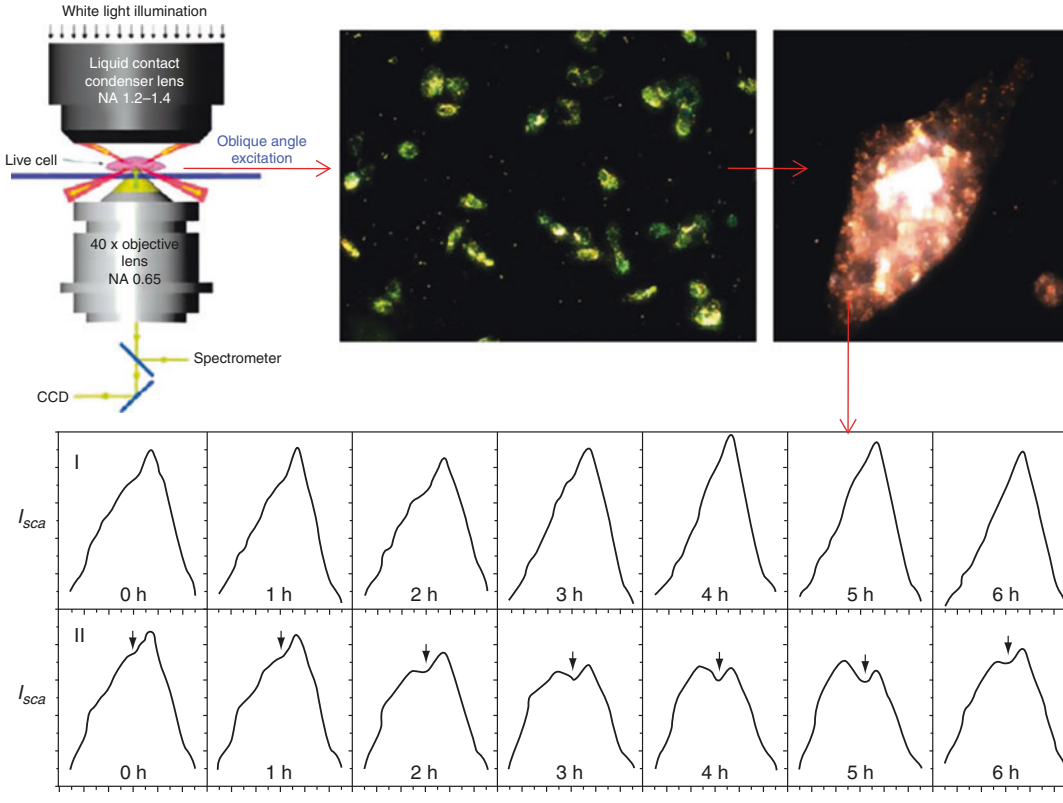


Key Research Findings

PRET Imaging of Nanoplasmonic Particles in Living Cells

The nanoplasmonic particles can be internalized into living cells via multiple ways, either by natural endocytosis of cells or assisted endocytosis such as lipo-transfection technique. The nanoplasmonic particles can be effectively internalized in living cancer cells using Fugene





Plasmon Resonance Energy Transfer Nanospectroscopy, Fig. 5 (**a**) Raw scattering spectra of four representative gold nanoparticles conjugated with reduced Cyt c molecules. The nanoparticle plasmon resonance peaks and PRET-induced plasmon quenching dips have variable intensities from particle to particle due to the nonuniformity of the conjugated molecule number and particle geometry; however the plasmon quenching peak positions are consistent. More than 50 individual nanoparticles were tested and PRET can be consistently observed. (**b**) Time-lapse measurement of scattering spectra of a single gold nanoparticle conjugated with reduced Cyt c molecules. The plasmon quenching spectral dips remain nearly constant during the whole time period of measurement. No photobleaching effect was observed

6 (Roche Diagnostics) transfection reagent [25]. The nanoplasmonic particles can be clearly imaged using our nanospectroscopy imaging system. Figure shows the dark field scattering image of individual liver cancer cells with many internalized nanoplasmonic particles. Recent study also shows that intracellular Cyt c molecules can be imaged using the PRET nanospectroscopy in a long-term continuous measurement [26] as shown Fig. 8.

(**b**) Relative transmittance spectrum of gold nanowire with (*black curve*) and without (*red curve*) molecule adsorption. (**c**) Spectral dips due to PRET in the infrared absorption spectra measured from gold nanowires in various lengths [27]

Near-Infrared PRET

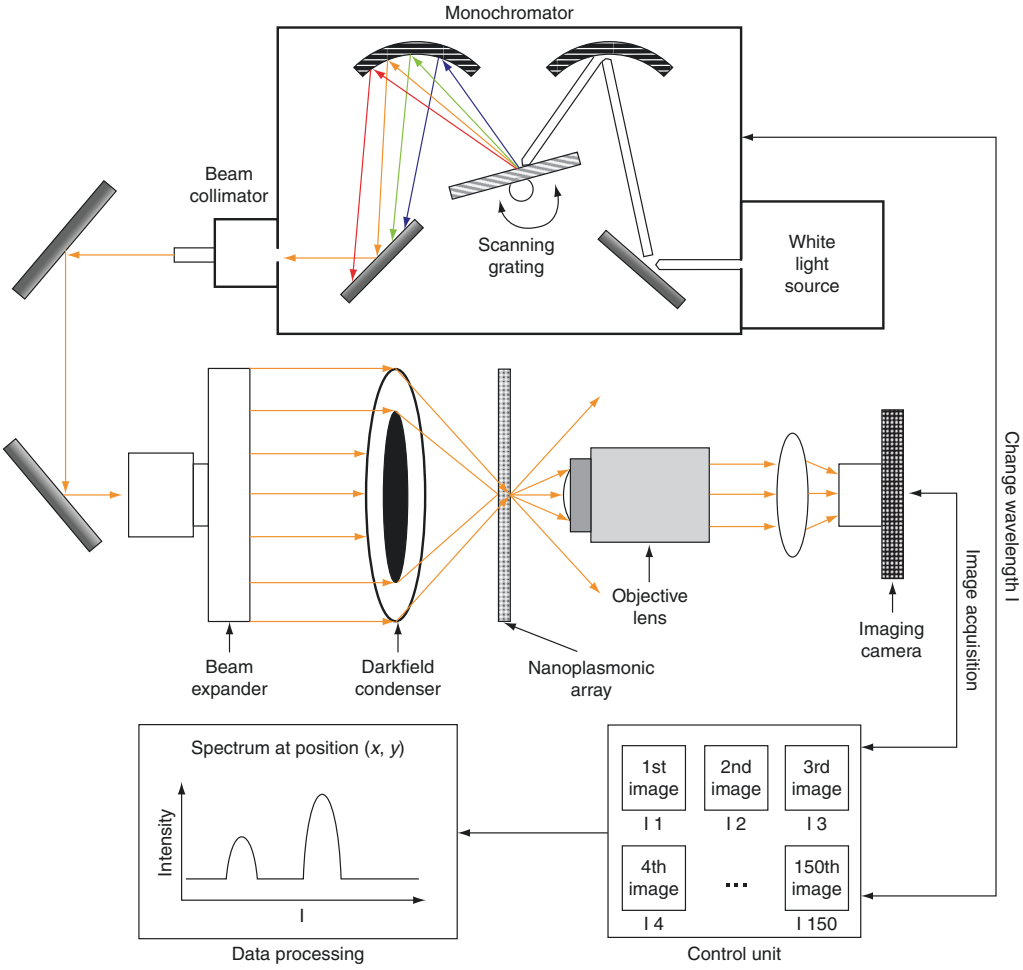
The aforementioned examples primarily occur in visible light regime due to the visible plasmon resonance wavelength of sub-100 nm gold or silver nanoparticles. As the matter of fact, the PRET effect is not limited to visible wavelength range. When using long gold nanowires with the microscale lengths, the PRET effect can be observed even in mid-infrared region [27]. As shown in Fig. 9a, the gold nanowire with 100 nm in diameter and 1.31 μm in length has the fundamental plasmon resonance mode along the long axis at about 3.41 μm. The gold nanowire will show very different absorption spectra when excited by perpendicularly and parallel polarized light (Fig. 9b). Only the excited light polarized along the long axis of the gold nanowire will be absorbed by the nanowire due to the fundamental plasmon resonance mode at 3.41 μm.

When certain chemical molecules are adsorbed on the surface of the gold nanowire, a few spectral dips can be clearly observed and they overlap on top of the nanowire absorption peak. The positions of the spectral dips exactly match with the infrared absorption peak wavelengths of the chemical molecule at 2855 and 2927 cm^{-1}. Even if the plasmon resonance wavelengths shift due to the nanowire length variation, the PRET spectral dip positions at infrared region remain identical and show high specificity to molecule species. However, the amplitude of the infrared PRET spectral dips is dependent on the extent how the infrared plasmon resonance peak of gold nanowire matches with the infrared absorption peaks of the adsorbed molecules. Since most of biological and chemical molecules have distinctive infrared absorption peaks, the PRET nanospectroscopy on gold and silver nanowires at infrared wavelength has even wider applications to detect small amount of adsorbed molecules without labeling process.

Applications

Whole-Field PRET Imaging

All previous PRET imaging works have been limited to the spectroscopy of several particles at



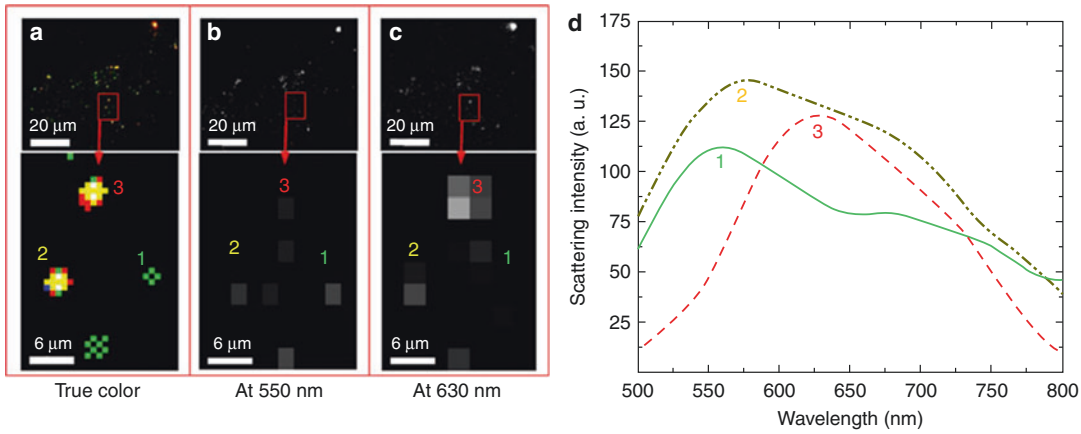
most, and whole-field intracellular PRET imaging has not been implemented to date due to the limitations imposed by current spectral imaging system. All existing imaging and spectroscopy systems for metallic nanostructures are based upon a microscopy system with a white light illumination source, a darkfield condenser, and a polychromator spectrograph, as shown before. In such a system, the field of view is limited to several microns by the width of the entrance slit to the polychromator even though the field of view of the objective lens is on the order of several hundred microns; therefore only a few nanoparticles or nanostructures that are aligned in a column can be imaged spectrally at once.

The polychromator entrance slit is required to limit data pollution for the high-resolution spectroscopy of each individual nanoparticle. Hence, in the case of spectrally imaging hundreds or even thousands of sparsely distributed nanostructures, the sample stage of the microscopy system must be translated either manually or automatically, which has two disadvantages. First, the spectra of separated nanostructures cannot be simultaneously captured and the acquired data will be from different instants in time, e.g., 20∼30 min for a 100 × 100 array, which voids their applicability in the real-time monitoring of multiple biomolecular interactions. Second, the focal plane will tend to drift due to the stage translation which may change the condition of the immersion liquid between the sample and darkfield condenser lens, and thus manual refocusing is often required.

A new multispectral imaging system was constructed to simultaneously monitor the individual scattering spectra and plasmon resonance wavelength of large numbers of nanoplasmonic particles distributed within the field of view of a microscopy objective lens without mechanically scanning the sample [28]. The multispectral imaging system currently supports frame rates as high as 2 s per frame (wavelength) that could potentially be increased by using a light source with a higher power or an image detector with greater sensitivity, by which the image signal-to-noise ratio can also be increased. In contrast with the configurations of previous imaging systems, our whole field plasmonic imaging system consists of a multispectral illumination source synchronized with an intensity imaging camera rather than a polychromatic spectrograph. As shown in Fig. 10, the white light from a halogen lamp is coupled into a scanning monochromator which is controlled by a computer program to output a monochromatic light beam with varying wavelength and specified spectral step size. The monochromatic light beam is then focused and illuminated on the sample by a darkfield condenser (N. A. = 1.2∼1.4). A 40× microscopy objective lens (N. A. = 0.8) is used to collect the scattered light, which is captured by a CCD camera. The monochromator and image acquisition control software are integrated and they are synchronized to capture a single image at each wavelength of interest. The image acquisition can be finished in a few minutes and the acquisition time is dependent on the chosen spectral range and resolution.

All images are stored as grayscale data files and are analyzed by an image processing program. The bright spot regions (typically 1∼10 pixels) in each image are recognized by the analysis program as individual nanoplasmonic structures of interest. The mean intensity value of these small regions is extracted from the image at each wavelength as the raw scattering spectra data. The mean intensity value in a large, empty (black) region is also measured at each wavelength as the background spectrum, which is subsequently subtracted from the raw scattering spectra. The difference spectra are then scaled according to the previously stored spectrum of the light output from the monochromator to yield the final scattering spectra. The process of the image analysis and the spectral data reconstruction is completely automated by the computer program.

As a demonstration, randomly dispersed Au colloidal nanoparticles were used on a glass slide as the imaging sample. The diameters of the Au nanoparticles vary from 20 to 80 nm, so their plasmon resonance wavelengths, and thus their scattering colors are different. Figure 11a shows the true-color scattering image of the nanoparticles within ∼1/10 of whole view field of the objective lens. The true-color image is taken



Plasmon Resonance Energy Transfer Nanospectroscopy, Fig. 10 Configuration of the multispectral imaging system for the scattering spectra measurement of nanoplasmonic particles in the whole field of view [28]

in the same darkfield microscopy system but with a white-light illumination source and color camera. Figures 11b and 2c show the scattering intensity images of the same nanoparticles within the same field of view taken by our system at 550 and 630 nm, respectively. Figure 11c shows the scattering spectra of three representative nanoparticles marked in Fig. 11a–c. The plasmon resonance wavelengths (spectral peaks) of these three nanoparticles are respectively 560, 580, and 630 nm, which agree well with their colors (green, yellow, and red) in Fig. 11a and their relative intensities in Figs. 11b and 10c. The Au "particle" with red scattering color could be a cluster of a few Au nanoparticles, because the plasmon resonance wavelength of individual Au nanoparticle is shorter than 600 nm according to Mie scattering theoretical predictions. Although only the scattering spectra of three typical particles are shown here, the spectral information for all the other nanoparticles in the field of view are also stored at once and can be reconstructed in the same fashion.

Future Directions for Research

Although only the PRET in the visible wavelength range is observed here due to the optical properties of gold nanoparticles and Cyt c molecules, the PRET process at UV and near infrared range could be envisioned by using different properties (i.e.,

Plasmon Resonance Energy Transfer Nanospectroscopy, Fig. 11 (**a**) True-color scattering image of thousands of dispersed Au nanoparticles. For the clarity of the image, a field of 100 × 100 μm is cropped from the whole view field of ~300 × 300 μm. The lower picture is the zoom-in image from the marked area (*square*) of the upper image. (**b**) and (**c**) show the scattering intensity image of the same Au nanoparticles as in (**a**) with 550 and 630 nm monochromatic illumination, respectively. (**d**) Scattering spectra of three representative particles marked as *1*, *2*, and *3*, respectively, in the images [28]

size, shape, free electron density, etc.) of metallic nanoparticles with UV or near infrared plasmon resonance wavelength. The PRET-based ultrasensitive biomolecular absorption spectroscopy on single metallic nanoparticle could be used for molecular imaging such as genetic analysis of small copies of latent nucleotides, activity measurements of small numbers of functional cancer biomarker proteins, and rapid detection of little biological toxin, pathogen, and virus molecules. Additionally PRET could be applied in intracellular biomolecule-conjugated nanoparticle sensors to detect localized in vivo electron transfer, oxygen concentration, and pH value changes in living cells with nanoscale spatial resolutions. Furthermore the optical energy in advanced plasmonic devices [29] could be potentially tuned by functional biomolecules taking advantage of the PRET process.

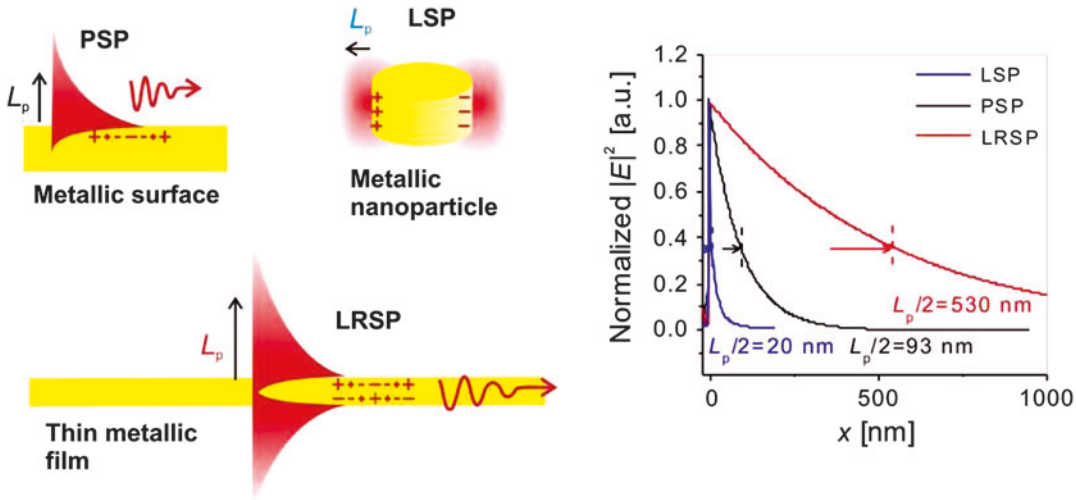
Definition

Plasmonics offers efficient means for enhancing sensitivity of fluorescence bioassays for detection of chemical and biological analytes. In this method, specific capture of target analyte from analyzed liquid sample at metallic sensor surface with attached recognition elements is observed by using fluorophore labels (e.g., organic dyes or quantum dots). These labels are probed by the confined field of surface plasmons that originate from collective oscillations of charge density at a surface of metallic films or metallic nanoparticles. The excitation of surface plasmons is accompanied with strongly increased intensity of electromagnetic field which couples with fluorophores. The combination of surface plasmon-enhanced excitation rate fluorophore absorption wavelength, improved quantum yield, and directional emission at the emission wavelength allows enhancing the detected fluorescence intensity per captured molecule by several orders of magnitude. When implemented to heterogeneous

assays, limit of detection can be improved by similar factor.



Overview

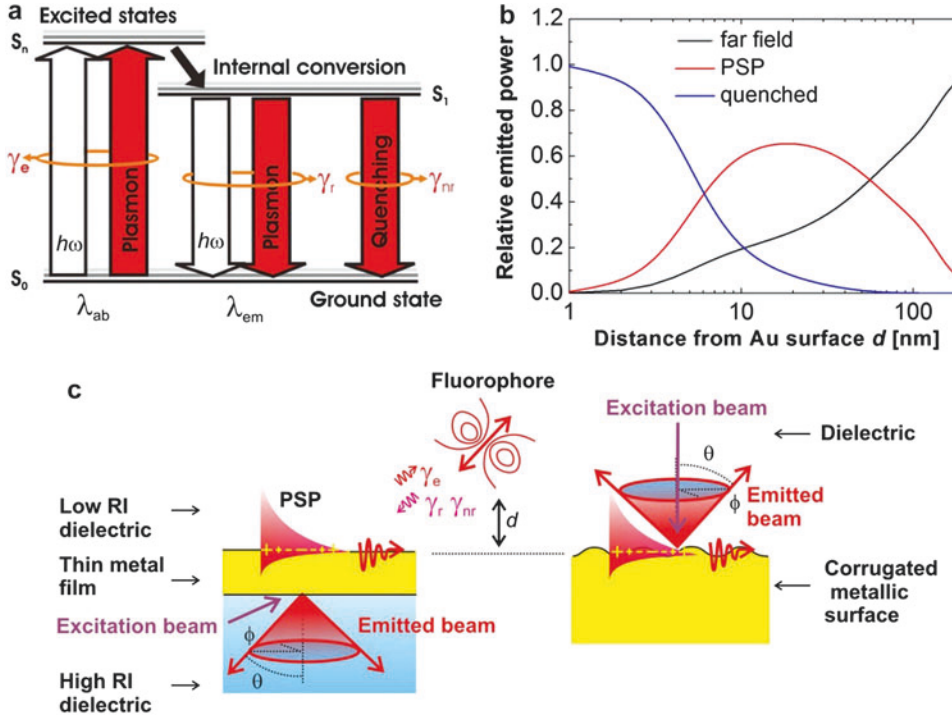
The emission of fluorophores placed above a metallic surface was investigated since the 1970s of the last century [1, 2]. These studies revealed that the lifetime of an excited fluorophore is dramatically reduced due to the coupling with so-called surface lossy waves (leading to quenching at distances below Förster radius of ~10 nm) and propagating surface plasmons (that is observed at longer distances up to ~100 nm). The emitted photons that are trapped by propagating surface plasmon (PSP) modes can be partially recovered by reverse Kretschmann configuration [3] or by periodic corrugation of the metal surface [4, 5]. These techniques for out-coupling of PSPs allow extracting the emitted fluorescence photons from the surface to a highly directional beam and deliver them to a detector.

The coupling of fluorophores with PSPs provides efficient means for increasing sensitivity of heterogeneous fluorescence bioassays. In this type of assays, fluorophore emitters are used as labels to report affinity binding of target molecules from analyzed liquid sample at the surface with attached recognition elements such as antibodies or oligonucleotides [6–9]. The interaction of fluorophore labels with PSPs at their absorption λ_{ab} and emission λ_{em} wavelengths can increase their "brightness" and thus offers means to detect smaller number of captured molecules on the surface. In analytical applications, this translates to the possibility of detecting smaller concentrations of analyte in a sample and improved limit of detection (LOD).

Surface Plasmons

As Fig. 1a illustrates, PSP modes travel along a continuous metallic film and probe the adjacent dielectric medium above the surface with enhanced electric field intensity $|E|^2$. This field exponentially decays as $\exp(-2x/L_p)$, where x states for a distance from the metal surface. The probing depth is typically quantified by a half of penetration depth $L_p/2$ that is equal to about 90 nm for PSPs on a gold surface in contact with aqueous medium at a red wavelength of $\lambda = 633$ nm. The probing depth can be changed

Plasmonic Amplification for Fluorescence Bioassays Utilizing Propagating Surface Plasmons, Fig. 1 Examples of surface plasmon modes on metallic films and metallic nanoparticles (*left*). Comparison of probing depth of regular propagating surface plasmons (PSPs) and long-range surface plasmons (LRSPs) on a gold surface in contact with water and of localized surface plasmons supported by a gold disk with diameter of 110 nm and height of 50 nm (*right*). Wavelength of $\lambda = 633$ nm was assumed



by a design of the surface plasmon-supporting metallic structure. For example, the coupling of PSP modes at opposite interfaces of a thin metallic film gives rise to new plasmonic modes with tunable characteristics. This coupling can occur when a thin metallic film is sandwiched between dielectrics with similar refractive index [10]. For probing of aqueous medium that exhibits refractive index close to $n = 1.33$, such geometry can be realized by depositing a thin metal film (with thickness of few tens of nanometers) on the top of a low refractive index fluoropolymer such as Cytop from Asahi Inc. ($n = 1.34$) or Teflon AF from DuPont Inc. ($n = 1.31$) [11, 12]. The near-field coupling of PSPs at opposite interfaces of a metal film gives rise to the occurrence of long-range surface plasmons (LRSP) that exhibit weaker confined field and thus probe deeper away from the metal. An example in Fig. 1 shows that for 20 nm thick gold film on the Teflon AF surface, the aqueous medium is probed by the extended LRSP field with the probing depth of $L_p/2 = 540$ nm at a wavelength of $\lambda = 633$ nm. Let us note that the probing depth can be tuned between that of regular PSPs and (virtually) infinity by changing the thickness metal and by introducing a small perturbation to the refractive index symmetry [13].

Plasmonic Coupling with Fluorescence Emitters

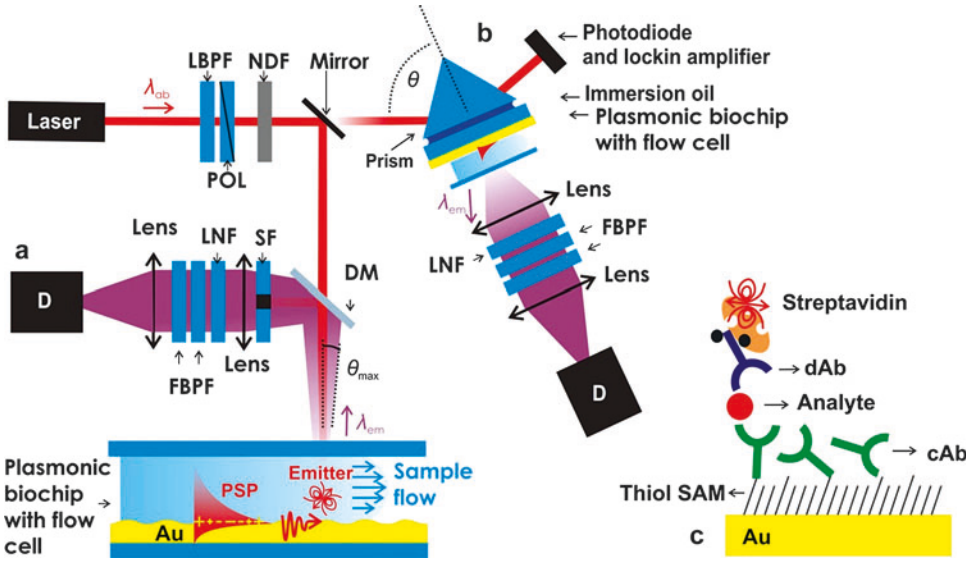
The resonant coupling of light with PSP modes confines its energy to a small volume in vicinity to a metal surface which leads to the strong enhancement of electromagnetic field intensity. The field intensity at metallic surface $|E|^2$ can be normalized with that of the excitation beam $|E_0|^2$ in order to quantify field intensity enhancement. Depending on the confinement and losses of excited PSP modes, the field enhancement $|E/E_0|^2$ can reach values up to $\sim 10^2$ (it should be noted that much stronger enhancement was observed upon the excitation of localized surface plasmons on sharp metallic nanoparticles that feature more confined field [14]). As Jablonski diagram in Fig. 2a illustrates, PSPs couple with a fluorophore at both emission and excitation wavelengths λ_{ab} and λ_{em}, respectively. This interaction strongly depends on the distance d between the fluorophore and metallic surface. Figure 2b shows the relative power emitted by a fluorophore at a red wavelength $\lambda_{em} = 670$ nm above a gold surface. At distances d below $\sim$10 nm, the fluorescence intensity is mostly quenched due to the Förster energy transfer. At the distance of about $\sim$20 nm, the majority of energy is emitted via PSPs. When moving farther away from the surface, the fluorophore emits preferably to the far field.

Figure 2c shows two common schemes that allow converting the fluorescence light that is trapped by PSPs into waves propagating into far field. PSPs that are generated by fluorescence at λ_{em} can leak through a thin metallic film when the reverse Kretschmann geometry of attenuated total reflection (ATR) method is used. For randomly oriented emitters (fluorophores), the fluorescence light is reemitted to a cone beam that propagates below the thin metal at a polar angle θ at which surface plasmon resonance occurs. Alternatively, diffraction on periodically corrugated metallic surface allows for out-coupling of PSPs into the far field.

For the plasmonic amplification of fluorescence, the emitter (which is typically a fluorophore label anchored to a biomolecule) is placed on a metallic surface and exposed to the intense surface plasmon field. The fluorescence intensity that is delivered to a detector can be increased by three effects. Firstly, the coupling of an excitation beam with PSPs increases the excitation rate of emitter that is (far from saturation) proportional to the field enhancement $|E/E_0|^2$ at the absorption wavelength λ_{ab}. Secondly, the emitter radiates fluorescence light at the emission wavelength λ_{em} via PSPs that can be afterward reemitted to a specific direction toward a detector. This feature improves the fraction of emitted photons that are delivered to the detector from above the plasmonic structure f_d compared to that without it f_{d0}. Thirdly, near-field coupling of the emitter with PSPs can improve its quantum yield η (particularly for emitters with low intrinsic quantum yield η_0). Let us note that these three effects can be combined and the total enhancement factor EF (defined as fluorescence intensity emitted by a

Plasmonic Amplification for Fluorescence Bioassays Utilizing Propagating Surface Plasmons, Fig. 2 (**a**) Jablonski diagram showing surface plasmon-mediated transitions between the fluorophore ground state and higher excited states. (**b**) Comparison of the emitted power from randomly oriented dipole that is quenched, emitted via PSPs, and radiated directly to the far field depending on the distance from a flat gold surface *d*. (**c**) Schematic out-coupling of PSP modes via reverse Kretschmann geometry of ATR method (*left*) and by using diffraction on periodically corrugated metallic surface (*right*)

fluorophore at a metallic structure F normalized with that without the structure F_0) can be expressed as



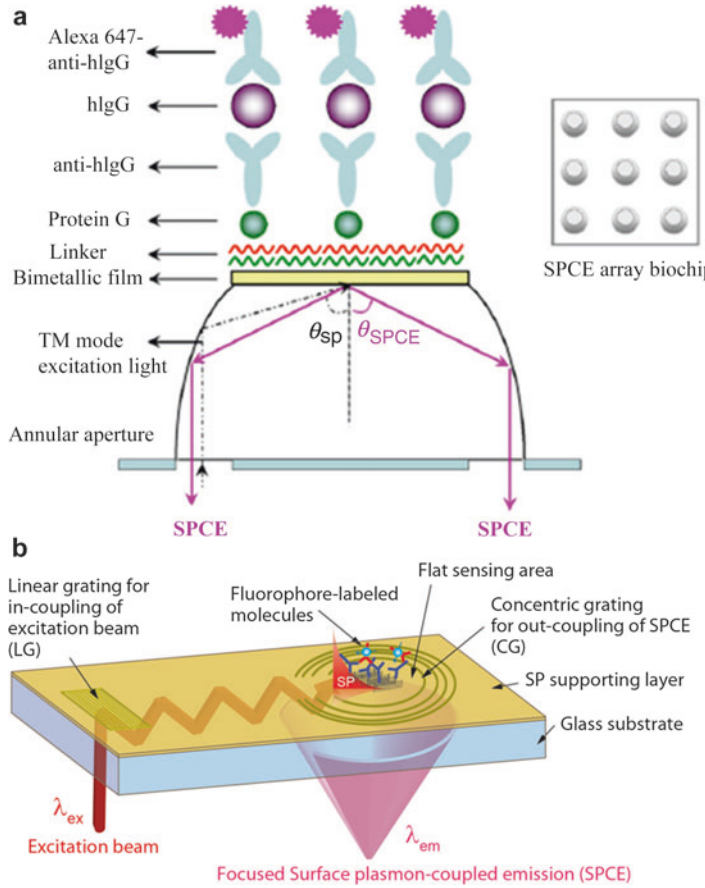
$$EF = F/F_0 \propto |E/E_0|^2 \times f_d/f_{d0} \times \eta/\eta_0. \quad (1)$$

It should be noted that the EF strongly depends on the emitter orientation which is in most experiments not controlled. For ensembles of fluorophores, Eq. 1 typically needs to be averaged over all possible orientations and locations of emitter on plasmonic structure (mode details on such models can be found in literature [15, 16]).

Implementations of Plasmon-Enhanced Fluorescence Biosensors

The employing of PSPs for the amplification of fluorescence signal mostly utilizes epifluorescence or total internal reflection fluorescence (TIRF) geometries that are depicted in Fig. 3a, b, respectively. In the epifluorescence-based sensors, an excitation beam at a wavelength that coincides with the absorption band of used fluorophore label at λ_{ab} is made incident on a sensor chip a with plasmonic structure. The surface plasmon-enhanced field intensity at this wavelength probes the assay on the surface (see Fig. 3c) and excites fluorophore labels that report the target analyte binding events. The fluorophore emits light at the emission wavelength λ_{em} directly to the far field or via PSPs that are subsequently out-coupled toward a detector.

The TIRF-like geometry allows for combined surface plasmon resonance (SPR) and fluorescence measurements based on ATR method with Kretschmann geometry (see Fig. 3b). In this implementation, the resonantly excited surface plasmon waves on a thin metal film can probe



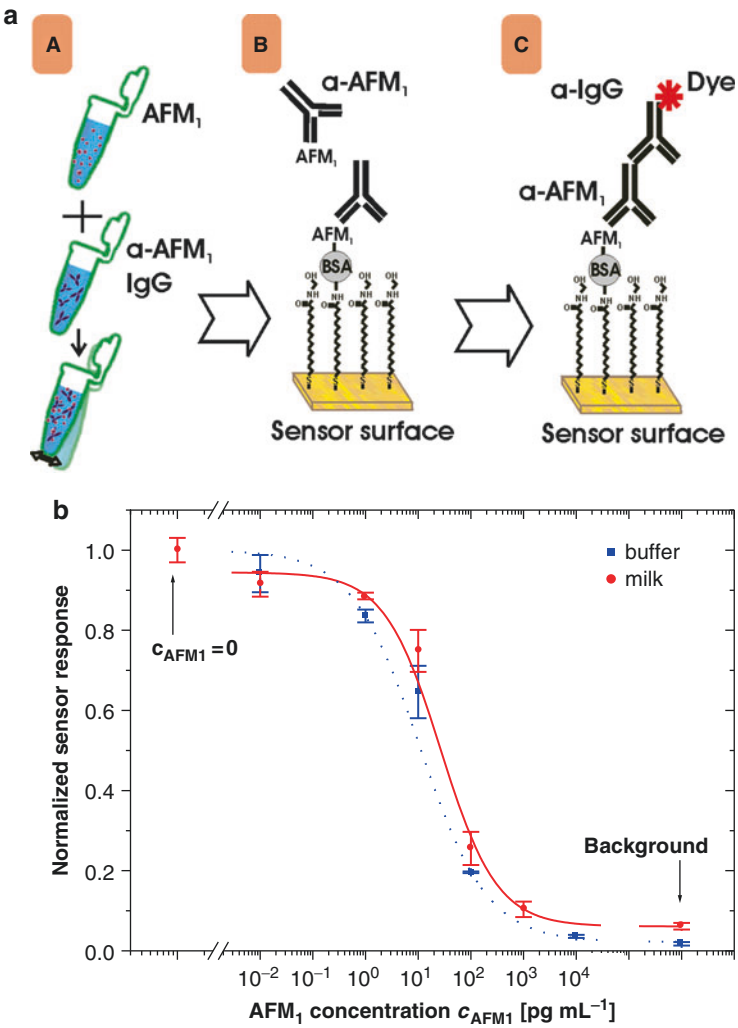
Plasmonic Amplification for Fluorescence Bioassays Utilizing Propagating Surface Plasmons, Fig. 3 Schematics of (**a**) total internal reflection fluorescence (TIRF) and (**b**) epifluorescence geometry with the surface plasmon-based amplification of fluorescence light intensity. (**c**) An example of sandwich immunoassay with the fluorescence detection that utilizes capture antibody (cAb) attached to a surface and biotinylated detection antibodies (dAb) that are decorated with fluorophore-labeled streptavidin

the binding events by (i) changes in refractive index due to the capture of target analyte leading to a shift of the SPR angle and (ii) fluorescence light that is excited by the enhanced surface plasmon field intensity when fluorophore labels are used [7]. The fluorescence light that is directly emitted perpendicular to the surface through the sample can be detected. Optical filters are used in order to decrease background signal (see Fig. 3). The laser band-pass filter (LBPF) blocks light propagation at wavelengths different from the excitation laser wavelength that is close to the absorption wavelength of used fluorophore λ_{ab}. Laser notch filter (LNF) is employed to block the laser light intensity that is typically much stronger than that of emitted fluorescence light at λ_{em}. In addition, fluorescence band-pass filters (FBPF) are used to select only the light at wavelengths around λ_{em}. In general, the fluorescence intensity is weak, and thus low light intensity detectors (D) such as photomultiplier, avalanche photodiode, or cooled CCD are used.

In the TIRF-like geometry depicted in Fig. 3b, the majority of fluorescence light intensity is leaking through the thin metallic film and propagates in the form of a characteristic surface plasmon-coupled emission (SPCE) cone. In order to retrieve this fluorescence light and deliver it to a detector, glass hemispherical prisms were used [17]. Later on, this approach was implemented by using miniaturized parabolic elements that can be embossed to polymer chips [18]. As Fig. 4a shows, such element allows directly imaging SPCE intensity to a detector and offers means for measurements with array detection format. Alternatively, concentric diffraction grating was proposed for out-coupling of SPCE signal and its imaging to a detector [19]; see Fig. 4b. This approach can be implemented by mass production-compatible technologies such as nanoimprint lithography and holds potential for simplification of the more traditionally used optical schemes.

Examples of Applications

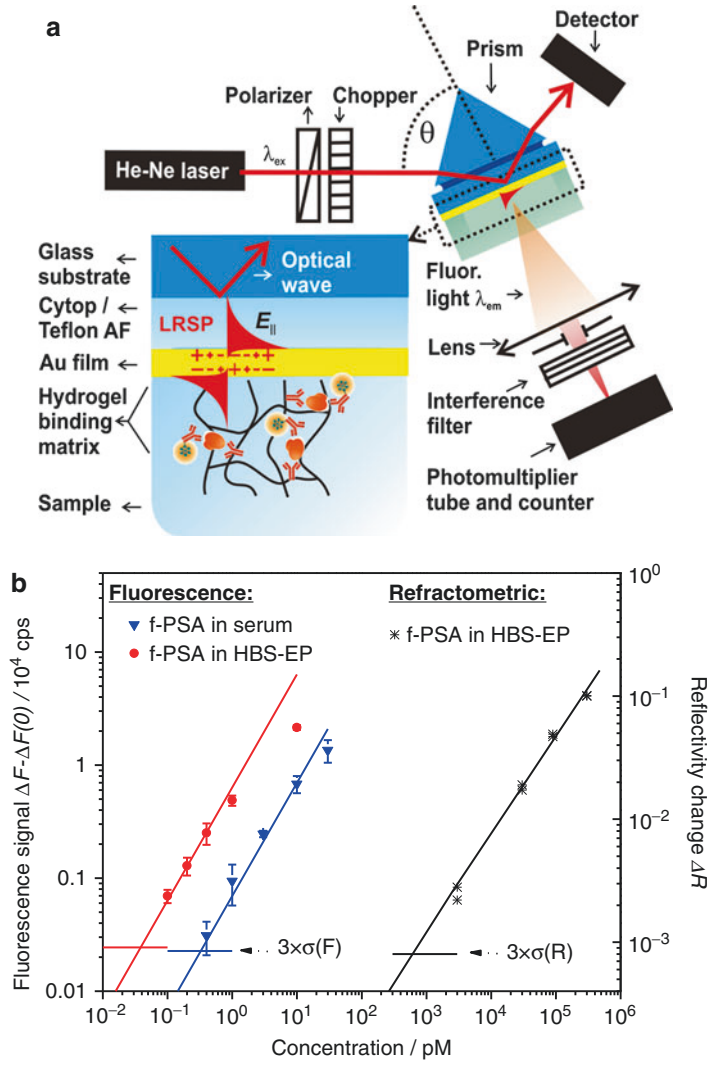
Since the end of the last century, numerous fluorescence biosensors that utilize plasmonic amplification of fluorescence signal were developed for detection of nucleic acids [20], proteins [6], as well as whole cells [21]. These efforts were



Plasmonic Amplification for Fluorescence Bioassays Utilizing Propagating Surface Plasmons, Fig. 4 Optical elements for the extraction of SPCE utilizing reverse Kretschmann configuration and (**a**) paraboloid elements and (**b**) concentric diffractive lens (Reproduced with permission from Yuk et al. 18 and Toma et al. 9)

mainly motivated by the increasing needs for assays with enhanced sensitivity in important areas of medical diagnostics (analysis of biomarkers), food control, and security (detection of harmful compounds such as toxins or pathogens). This section illustrates the plethora of sensor architectures and achieved performance characteristics by several examples. It should be noted that it does not cover the whole area and does not present a critical review in this field.

Plasmon-enhanced fluorescence biosensors were utilized for detection of low molecular weight analytes by using an inhibition competitive immunoassay. For instance, Wang et al. detected aflatoxin M_1 (AFM_1) with the molecular weight of 328 Da by using an optical arrangement similar to that depicted in Fig. 3b [22]. This harmful analyte is a metabolite of mycotoxin aflatoxin B_1 produced mainly by *Aspergillus flavus* and *Aspergillus parasiticus* pathogens. The gold sensor surface was functionalized by using a thiol self-assembled monolayer with a conjugate of AFM_1 and bovine serum albumin for the inhibition competitive immunoassay; see Fig. 5a. Monoclonal rat antibody against AFM_1 was incubated with a sample containing AFM_1, and the unreacted antibody was flowed over the sensor surface and detected by using a secondary anti-rat antibody that was labeled with a Cy5 dye. As the calibration curve in Fig. 5b shows, the limit of detection of AFM_1 present in milk was determined to be 0.6 pg/ml (1.8 pM) and the whole analysis required 53 min.

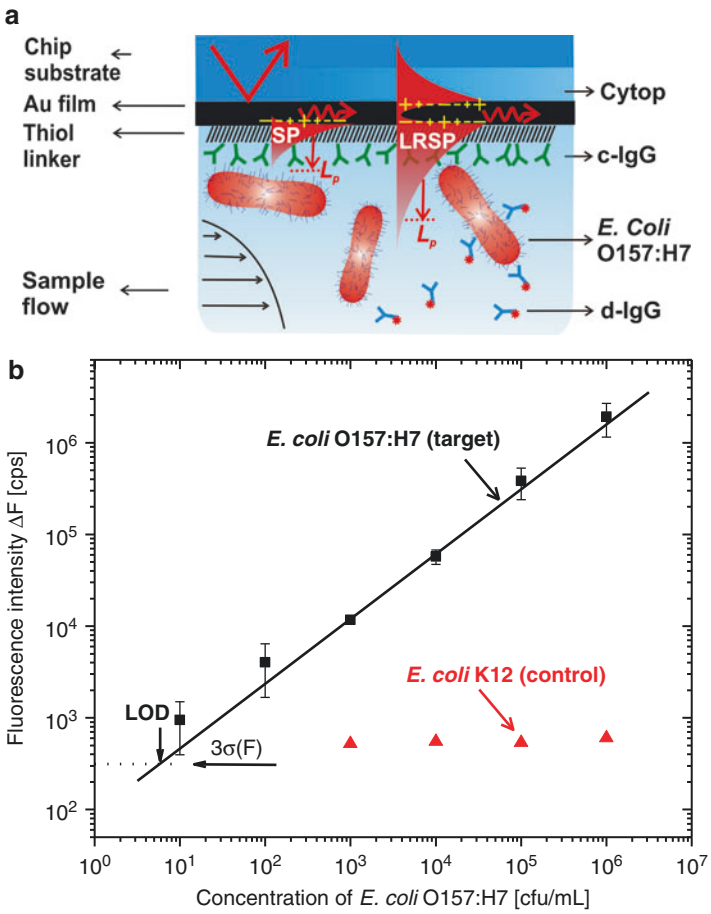


Prostate-specific antigen (PSA) is a biomarker with a molecular weight of 33–34 kDa that is present in the blood at around nM concentrations and used for a diagnosis of prostate cancer. Improving the sensitivity of PSA assays for the analysis at lower concentrations has been pursued for point-of-care diagnosis (POC) of female breast

Plasmonic Amplification for Fluorescence Bioassays Utilizing Propagating Surface Plasmons, Fig. 5 (**a**) Schematic of inhibition competitive immunoassay for detection of aflatoxin M1 and (**b**) a calibration curve for the aflatoxin M1 surface plasmon-enhanced fluorescence biosensor (Reproduced with permission from Wang et al. 22)

cancer [108], for early identification of prostate cancer relapse [109], and in forensic applications [110]. A biosensor for detection of free prostate-specific antigen (f-PSA) using long-range surface plasmon-enhanced fluorescence spectroscopy (LRSP-FS) and photo-cross-linked carboxymethylated dextran hydrogel matrix (depicted in Fig. 6a) was reported by Wang et al. [23]. In this approach, there was used a three-dimensional hydrogel binding matrix with a thickness of around 1 μm that offers the advantage of large binding capacity which can translate to higher efficiency in capturing of target analyte from a sample. In order to probe the whole volume of the binding matrix, long-range surface plasmons with increased probing depth were used. By using the sandwich immunoassays, the sensor allowed for detection of f-PSA in buffer and human serum with the limit of detection (LOD) of 34 f. and 0.33 pM, respectively, and the analysis time was of 35 min. This LOD was about four orders of magnitude better than that for SPR-based detection as can be seen from calibration curves presented in Fig. 6b.

Similar optics that allows probing to about micrometer distance from the metallic sensor surface was implemented for detection of large bacterial pathogens with around micrometer size by



Plasmonic Amplification for Fluorescence Bioassays Utilizing Propagating Surface Plasmons, Fig. 6 (**a**) Surface plasmon-enhanced fluorescence biosensor with a biointerface architecture based on three-dimensional hydrogel matrix that is probed by LRSPs. (**b**) Comparison of calibration curves of free prostate-specific antigen (f-PSA) assay with direct SPR readout (*black curve*) and with plasmonically amplified fluorescence readout for serum (*blue curve*) and buffer (*red curve*) samples (Reproduced with permission from Wang et al. 23)

Huang et al. [21]. As depicted in Fig. 7a, sandwich immunoassay was used, and labeled detection antibodies were bound to the analyte that was affinity captured on the sensor surface. By using the PSP modes with increased probing depth, fluorophore labels on the whole area of the analyte were excited and contributed to the sensor signal. This fluorescence readout principle was carried out for *E. coli* O157:H7 and provided the limit of detection of six colony-forming units in one milliliter (cfu/mL). As can be seen in the calibration curve presented in Fig. 7b, the assay was highly specific and required 20 min.

Conclusion and Perspectives

Plasmonics provides highly efficient amplification in important analytical tools based on surface-enhanced Raman spectroscopy (SERS), surface-enhanced infrared absorption spectroscopy (SEIRA), and plasmon-enhanced fluorescence spectroscopy (PEF). In the fluorescence spectroscopy, plasmonic structures supporting propagating surface plasmons can provide enhancement of fluorescence signal by a factor $EF > 10^2$, and in conjunction with immunoassays, it offers the limit of detection at low fM

concentrations and the analysis time of several ten minutes. By tuning the probing depth of intense field of surface plasmons, a range of analytes can be detected and various biointerface architectures can be used. In order to translate this method to viable commercial technology, plasmonic sensor chips that are compatible with established fluorescence scanners and microscopes are pursued [25, 26]. For these applications, plasmonic structures that can be prepared by using mass production – compatible methods such as nanoimprint lithography – are of high interest [27]. In parallel, dedicated devices for research applications where fluorescence detection is combined with surface plasmon resonance were described [7]. In addition, the plasmonic amplification of fluorescence signal is subject of implementation to miniaturized devices for sensitive analysis in field that does not rely on using specialized laboratory environment [28].

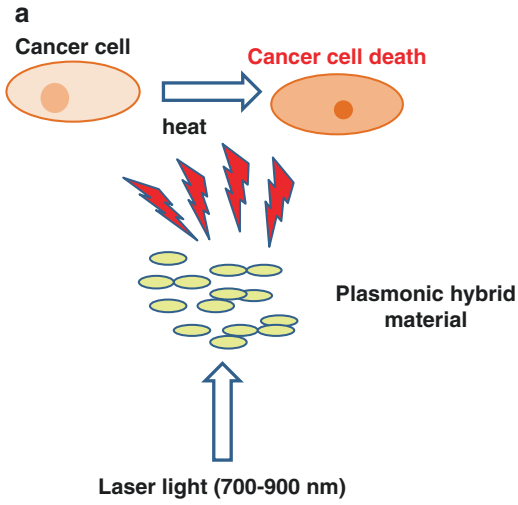
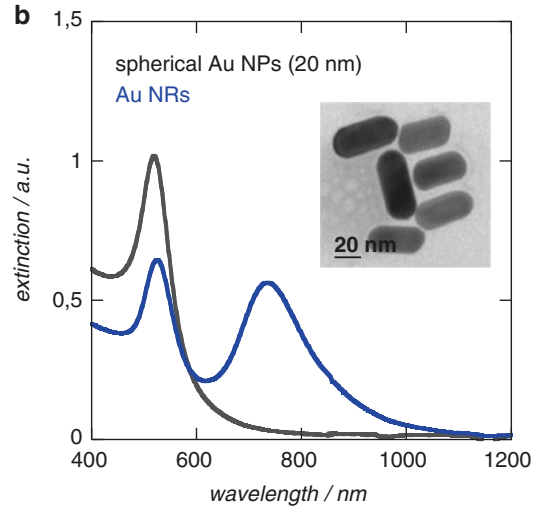
Definition

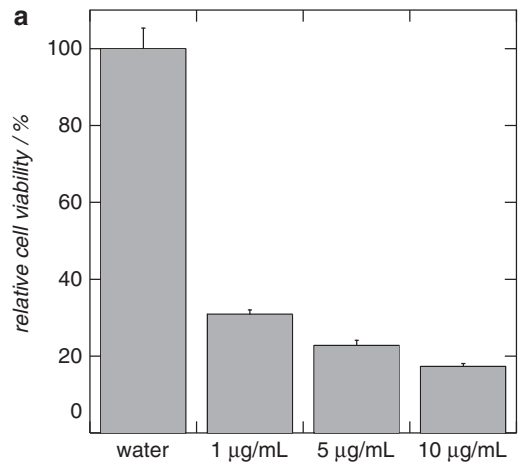


Plasmonic photothermal therapy is based on the use of metallic nanostructures such as gold nanorods as efficient photoabsorbing agent for achieving photothermal ablation of tumors.

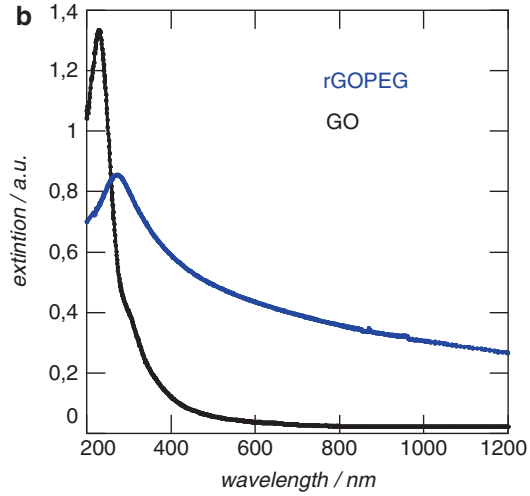


Background

According to the International Agency for Research on Cancer (IARC), the specialized cancer agency of the World Health Organization, an estimated 14.1 million new cancer cases and 8.2 million cancer-related deaths occurred in 2010, compared with 12.7 million and 7.6 million, respectively, in 2008 [1]. The major therapeutic approach for the treatment of a wide range of cancers remains chemotherapy. However, nonspecific delivery of chemotherapeutic agents leads to systematic side effects of normal tissues and limited efficacy in killing the tumor. Indeed, a disadvantage of many drug-based therapies particularly when administered orally or intravenously is that the compound does not localize to the target site. Recently, the use of nanoparticle-based therapy has been proposed for achieving a higher level of precision. The objective of nanoparticle-based therapy is to specifically accumulate the nanostructures in the tumor rather than the normal tissue by engineering the particle's shape, size, and/or chemical property (Fig. 1a). Larger nanoparticles have been shown to be retained in the liver and spleen while passing relatively freely through other organs. This type of passive targeting has been used in radiotherapeutic treatments of liver cancers [2]. Similarly, the fact that tumor vasculature is more permeable than that of healthy tissue can be exploited to concentrate nanoparticles in tumorous tissue due to enhanced permeability effect [3]. A more sophisticated approach is to modify the surface of the nanoparticles with ligands showing high affinity to receptors on tumor or tumor vasculature cell surfaces [4, 5].



Among the nanoparticles that are currently considered for therapy, gold nanostructures have shown to be particularly well suited for tumor treatments. Spherical gold nanostructures absorb light strongly in the visible region due to the coherent oscillations of the metal conducting electrons in strong resonance with visible light frequencies of light at ≈520 nm (Fig. 1b). Their synthesis is based on the reduction of $HAuCl_4$ in the presence of citric acid, which acts as both reducing and stabilizing agent (capping agent).



Unlike spherical nanoparticles, more complex shapes such as nanorod or nanoshell structures, the excitation wavelength can be shifted to the near infrared (NIR) with absorption maxima between 700 and 900 nm (Fig. 1b). We have

Plasmonic Photothermal Therapy with Gold Nanorods/Reduced Graphene Oxide Core/Shell Nanocomposites, Fig. 1 (**a**) Cancer therapy by plasmon photothermal therapy and (**b**) optical extinction spectra of citrate capped spherical gold nanoparticles (*black*) and gold nanorods (*blue*) (inset: TEM image of Au NRs) [6]

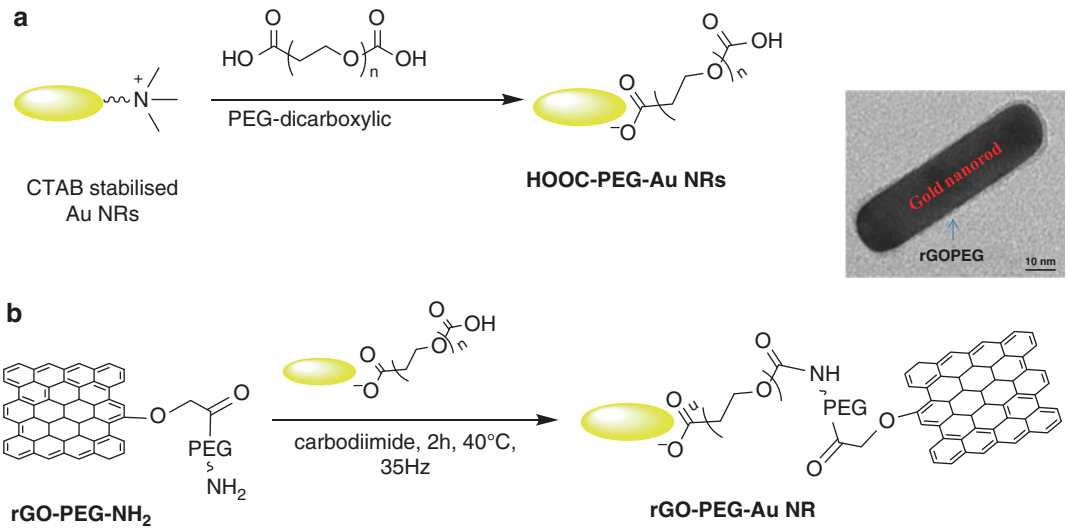
shown recently that cetyltrimethylammonium bromide (CTAB)-modified gold nanorods (Au NRs) can be obtained by a simple seed-mediated procedure [6]. The Au NRs are well dispersed in size and shape with an average length of 33 ± 1 nm and width of 13 ± 1.8 nm (TEM image in the inset of Fig. 2b). The UV–vis spectrum displays two extinction bands at 548 and 706 nm. The resonance band at 706 nm corresponds to the longitudinal plasmon oscillations, while the band at 548 nm is due to the transverse plasmon oscillation band, confirming the presence of elongated Au NRs. The NIR spectrum is particularly interesting as water, melanin, and hemoglobin have absorption minima, and light between 700 and 900 nm is most likely to pass directly

through tissues without significant absorption and heat generation [7]. Exposure of Au NR-marked tumors to infrared light will thus result in a strong local light absorption and generation of localized heat (Fig. 1a). The highly efficient production of heat from the absorbed light energy by Au NRs makes these structures of great promise in photothermal therapy (PTT) of cancers and other diseases [8]. Indeed, from the point of cancer therapy, the strong light absorption of Au NRs ensures affective laser therapy at relatively low energies, rendering the therapy method in addition minimally invasive.



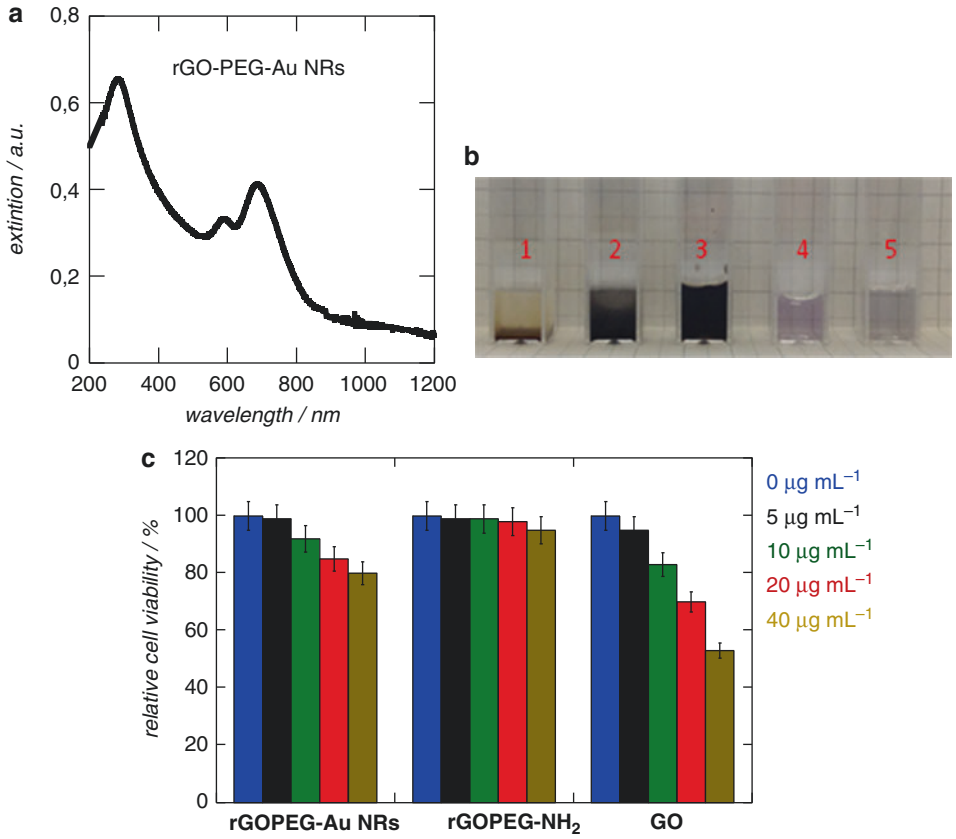
The first report on the use of gold particles as photothermal agent in photothermal therapy was by Halas and coworkers in 2003 [9]. NIR irradiation of gold-on-silica nanoshells led to rise in the temperature of the target region to 40–50 °C, which selectively destroyed the target breast carcinoma cells [10]. Au NRs have generated a significant interest for photothermal applications due to their relatively small size and high theoretical absorption coefficients [11]. However, one of the major concerns using Au NRs was the cytotoxicity of the surfactant, cetyltrimethylammonium bromide (CTAB), used in the manufacturing of the nanorods (Fig. 2a). CTAB molecules can induce cytotoxicity by disrupting cellular membranes [12]. CTAB is not only toxic to cells but also very difficult to remove completely [13, 14]. In addition, CTAB-coated Au NRs lack cancer-targeting capabilities, something of critical importance for active targeting cancer cells.

Graphene oxide (GO) and in particular reduced graphene oxide (rGO) have recently emerged as most promising nanomaterials for photothermal therapy [15–21]. The strong optical absorption across the visible for GO (Fig. 2b) and in the NIR spectrum for water-soluble polyethylene glycol modified rGO (rGOPEG) (Fig. 2b) coupled with high chemical and thermal stability allowed rapid temperature rise and efficient way of heating. GO possesses unique features such as facile synthesis, abundant functional groups, and good biocompatibility making it highly suitable as surface coating. Yang et al. reported one of the first NIR photothermal therapies of cancer cells by using graphene nanosheets functionalized with polyethylene glycol [21]. The effect of the chemistry and lateral size of GO on the photothermal efficiency was investigated by the same group [22].

However, there are some important limitations of graphene-based materials for photothermal therapy. Graphene exhibits some concentration-dependent cytotoxicity effects usually originating from (i) generation of reactive oxygen species [23], (ii) interaction with extremely sharp edges of graphene [24], or (iii) trapping within aggregating rGO sheets [25]. For clinical cancer treatments, graphene concentrations of $\approx$10 μg mL^{-1} or less are recommended [26]. In line with this recommendation, Robinson et al. reported an in vitro photothermal treatment of cancer cells by using 6.6 μg mL^{-1} of rGOPEG using a NIR laser power of 15.3 W cm^{-2} for 8 min [18]. Such high optical power causes efficient ablation of tumor located deeply inside the body but can substantially damage the surface of normal tissues. This limitation was recently overcome by using rGO nanomesh for photothermal treatment of cancer cells with 10 μg mL^{-1} rGO nanomesh at 0.1 W cm^{-1} for 7 min [27].

Coupling Graphene to Gold Nanorods

A different, but highly promising, design of an efficient photothermal agent would be the encapsulation of plasmonic nanostructures with rGO (Fig. 3). Indeed, some groups reported the synergetic effect that hybrid matrices composed of gold nanostructures and GO or rGO have on photothermal energy conversion efficiency [15, 16, 28, 29]. The hybrid materials were prepared by embedding gold particles within a graphene matrix or through electrostatic interactions between positively charged gold nanostructures and negatively charged GO. We have shown lately the interest of rGO covalently modified with gold nanostructures as a photothermal agent. Such a hybrid was synthesized via amide bond formation between amine-PEG-terminated rGO (rGO-PEG-NH_2) and HOOC-PEG-Au NRs (Fig. 3). The synthesis of



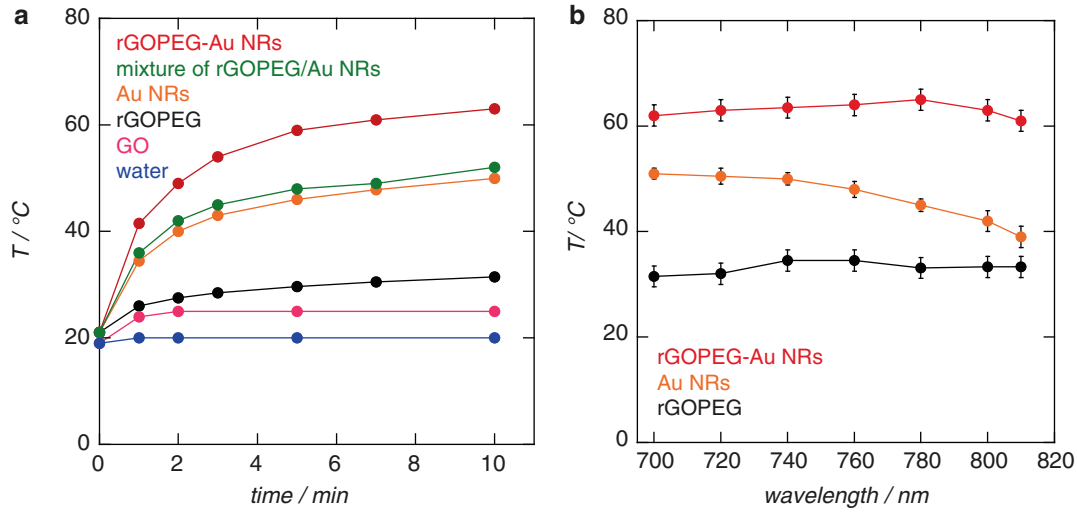
Plasmonic Photothermal Therapy with Gold Nanorods/Reduced Graphene Oxide Core/Shell Nanocomposites, Fig. 3 (**a**) Synthesis of HOOC-PEG-Au NRs. (**b**) Covalent linkage of rGO-PEG-NH_2 with HOOC-PEG-Au NRs; TEM image of a Au NR coated with rGO-PEG-NH_2

the water dispersible HOOC-PEG-Au NRs was performed following the well-established seed-mediated procedure in the presence of CTAB and dicarboxylic polyethylene glycol in the growth solution [30, 31]. Reaction of carboxylated GO sheets [32] with diamine-PEG (1.5 kDa) through amide bond formation yields highly soluble and stable amine-terminated PEG-rGO of 50–70 nm in size. Reaction of rGO-PEG-NH_2 with HOOC-PEG-Au NRs resulted in Au NRs wrapped with rGOPEG (Fig. 3). A representative TEM image of the rGO-PEG-Au NR hybrid shows the presence of a rGOPEG layer of ≈1.5 nm around the Au NRs.

The UV–vis spectrum of the rGO-PEG-Au NR hybrid displays two bands at 589 and 680 nm corresponding to the transverse and longitudinal plasmon oscillations of the Au NRs, respectively (Fig. 4a). The presence of rGO is furthermore evidenced by the absorption maximum at 270 nm and an overall increase in the absorption from the visible to the NIR. The rGO-PEG-Au NR hybrid (average size of 60 ± 15 nm) is in addition highly dispersible in aqueous media and stable for several months (Fig. 4b). In contrast to the HOOC-PEG-Au NRs, the in vitro toxicity of the hybrid to MDA-MB-231 cells was drastically improved (Fig. 4c). No obvious decrease of cell viability was noticed for MDA-MB-23 cells when incubated with rGO-PEG-Au NRs (10 μg mL^{-1}) for 78 h in strong contrast to Au NRs (Fig. 2a), where at the same concentration, cell viability was around 20 %. The hybrid also proved to be less toxic than GO, but somewhat more cytotoxic than rGO-PEG-NH_2.

Photothermal Efficiency

The photothermal efficiency in solution was studied under NIR illumination at 700 nm (close to plasmon band of Au NRs at 680 nm) in 96-well plates using a pulsed titanium/sapphire laser (chameleon model, coherent). Solutions (1 mL) of the different hybrids were illuminated for up to 10 min at a power of 10 W cm^{-2} and then imaged with an IR camera (ThermoVision A40, ThermaCAM Researcher Pro 2.9 software), allowing measurements of temperature changes (Fig. 5a). Irradiation of equal mass concentrations (10 μg mL^{-1}) of Au NRs and rGO-PEG-NH_2 for 10 min resulted in temperature increase for distilled water from 20 ± 1.5 °C to 32 ± 1.5 °C for rGO-PEG-NH_2 ($\Delta T = 12 \pm 1.5$ °C with $\Delta T =$

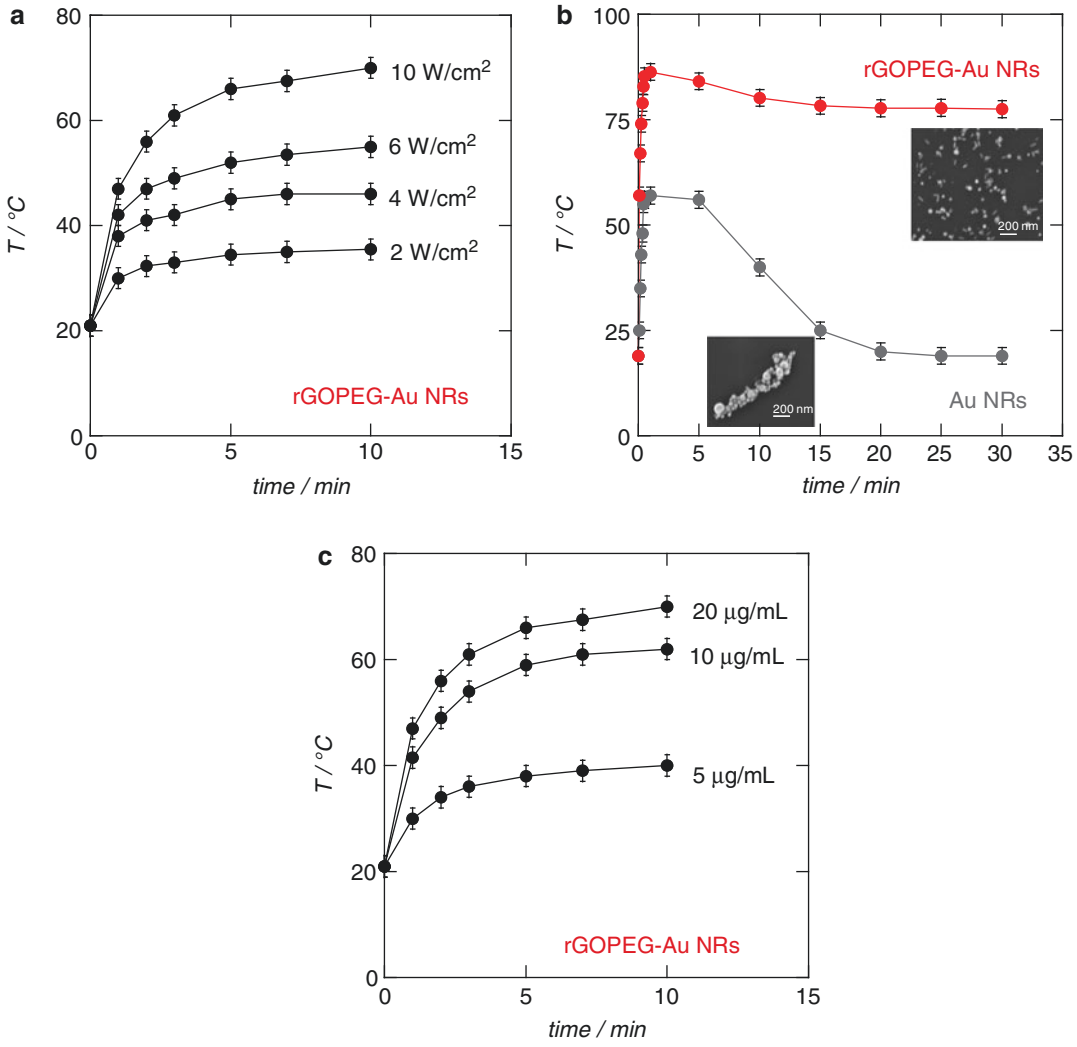


Plasmonic Photothermal Therapy with Gold Nanorods/Reduced Graphene Oxide Core/Shell Nanocomposites, Fig. 4 (**a**) UV–vis of rGO-PEG-Au NRs. (**b**) Stability of different matrices in DMEM buffer (100 μg mL^{-1}): (1) GO, (2) rGOCOOH, (3) rGO-PEG-NH_2, (4) Au NRs, and (5) rGO-PEG-Au NRs. (**c**) Relative cell viability of MDA-MB-231 cells to incubation with different concentrations (0–40 μg mL^{-1}) of rGO-PEG-Au NRs, rGO-PEG-NH_2, and GO for 78 h

T_{final}−20 °C) and 50 ± 2 °C for Au NRs (ΔT = 30 ± 2 °C). At equal mass concentration, Au NRs are much more efficient photothermal probes. The covalent coating of Au NRs with rGO-PEG-NH_2 induced significant temperature changes, reaching in the case of rGO-PEG-Au NRs 63 ± 2 °C (ΔT = 43 ± 2 °C) after 10 min irradiation. These independent measurements demonstrate the greater photothermal effect of Au NRs coated with rGO-PEG-NH_2 as recently highlighted by Kim et al. [28]. The enhancement of the photothermal effect of the hybrid is attributed to additional light absorption by rGO-PEG-NH_2 to that of Au NRs. Moreover, the covalent linkage of rGO-PEG-NH_2 onto Au NRs (Fig. 3) is crucial for the synergetic effect. Indeed, simple mixing of Au NRs with rGOPEG (same mass ratio 1:1) did not show any photothermal enhancement when compared to Au NRs alone (Fig. 5a, green line). We can, therefore, conclude that the close interaction between the gold plasmons and rGO-PEG-NH_2 is critical for enhanced photothermal effect seen with rGO-PEG-Au NRs.

Interestingly, while as expected the Au NRs show a clear dependence of the photothermal efficiency on the irradiation wavelength, the photothermal profile of the rGO-PEG-Au NR hybrid remains unchanged (Fig. 5b).

The effect of the irradiation intensity on the photothermal efficiency of the rGO-PEG-Au NR hybrid can be evaluated from Fig. 6a. While a maximum temperature of 63 ± 2 °C was achieved



Plasmonic Photothermal Therapy with Gold Nanorods/Reduced Graphene Oxide Core/Shell Nanocomposites, Fig. 5 (**a**) Photothermal heating curves of the different matrices dissolved in distilled water (10 μg mL^{-1}) under NIR illumination (700 nm) at 10 W cm^{-2} for 10 min using a pulsed titanium/sapphire laser for distilled water alone (*blue*), GO (*pink*), rGO-PEG-NH_2 (*black*), Au NRs (*orange*), mixed Au NRs and rGO-PEG-NH_2 (1/1) (*green*), and rGO-PEG-Au NRs (*red*). (**b**) Wavelength dependence of the photothermal response between 700 and 810 nm

using 10 W cm^{-2} for water, decreasing the laser power to 2 W cm^{-2} resulted in merely 35 ± 1 °C. An additional interesting observation with the hybrid is its high stability under laser irradiation. Indeed, increasing the power density up to 30 W cm^{-2} showed no effect on the hybrid morphology over time, while Au NRs are not stable under such irradiation conditions (Fig. 6b). As seen in the SEM images in the inset of Fig. 6b, gold nanoclusters are formed and the plasmonic heating effect is lost. These results suggest that the rGO-PEG-NH_2 coating not only enhanced the photothermal properties of Au NRs but also protected them from degradation over time. Figure 6c depicts the photothermal response as a function of rGO-PEG-Au NR hybrid concentration of an aqueous solution irradiated at 700 nm for 10 min at 10 W cm^{-2}. The result clearly indicates a concentration dependence response of the hybrid material. According to the data in Fig. 6, the optimal parameters for a photothermal therapy on cultured cells are a laser power of ≈5 W cm^{-2} and a concentration as low as 10–20 μg mL^{-1} of the hybrid.

Conclusion and Perspectives

The use of reduced graphene oxide coatings on metallic nanostructures has shown to have favorable effects on the photostability and photothermal properties. In addition, the presence of PEG units in the core/shell structure makes this multifunctional material well dispersed in aqueous media. The biocompatibility of the material is in addition largely increased and neglectable in vitro toxicity has been achieved. Such nanostructures could thus serve as powerful photothermal agents for in vitro and in vivo plasmonic photothermal therapeutic treatment of cancer cell killing but also for effective killing and deactivation of different pathogens. The emergence of antibiotic-resistance bacterial strains makes the development of alternative strategies for combating bacterial infection of high priority. The use of gold/graphene-based photothermal agents for in-line photothermal sterilization may become possible. Furthermore, the rGO-PEG-NH_2 shell provides anchor points for the conjugation of

Definitions

Plasmonic structures for solar energy harvesting describe the use of surface plasmons to increase the energy conversion efficiency of solar cells.

Introduction

The field of plasmonics describes the interaction of light with matter in or near nanostructured metals and owes its existence to so-called surface plasmons at the interface of metal nanostructures and dielectrics [1]. Plasmonics have found widespread use in analytical chemistry and are being researched for a variety of applications in photonics such as optical computers, nanoscale lasers, and more. Starting in the early 1990s, publications in the field of surface-plasmon (SP) research have seen geometric growth, with almost 4,000 papers

Plasmonic Structures for Solar Energy Harvesting, Fig. 1 Four different strategies proposed for plasmonically enhancing photovoltaics: (**a**) forward scattering and confinement illustrated by the *lighter shaded* areas, (**b**) direct field enhancement, (**c**) waveguiding, and (**d**) creation of surface plasmons inducing altered excited-state dynamics leading to more efficient exciton creation. published in 2010. In contrast, publications on the use of surface plasmons in photovoltaic (PV) applications have only recently taken off, with about 50 papers published per year currently.

Surface plasmons are collective oscillations of conduction electrons sustained on nanoscale metals. They are well known to enhance optical electromagnetic fields in their vicinity and show extraordinary light-scattering properties. This realization leads to the intriguing idea of using such metal nanostructures in PV applications. The energy of surface plasmons also depends strongly on the shape and size of the nanostructured metals. As a consequence, a solar cell designer can tune the spectral response of SP active systems in such a manner that the solar spectrum is harvested equally well at all wavelengths [2].

Numerous approaches are being pursued to use surface plasmons in PV applications. Figure 1 illustrates these approaches. Firstly, SPs are used to more efficiently couple light into solar cells by efficient forward scattering, as well as efficient internal reflection of light (Fig. 1a). Secondly, the well-known property of SPs where they strongly enhance the optical electrical field is used to enhance optical absorption in the absorber (Fig. 1b). Thirdly, a grating pattern is used that couples light waves into SP polariton waveguide modes in the absorber region of the solar cell (Fig. 1c). Approaches a to c differ mostly by the placement of the plasmonic structures. Lastly, the creation of hybrid exciton plasmon states leads to new light-absorbing states or to altered excited-state pathways that can lead to increased overall efficiency (Fig. 1d). A fifth method to employ surface plasmons in solar energy conversion will not be extensively discussed here. In this method, the surface plasmon absorbs the solar energy directly and a "rectenna" structure is used to tap the electrical energy. Although intriguing, it is currently of little practical relevance but could become so in the future.

Surface plasmons are caused by the interaction of surface charges with the electromagnetic field incident on the surface. They comprise collective oscillations of the conduction electrons in the surface. When one solves Maxwell's equation for the interface between a metal and a dielectric, the dispersion relation for surface plasmons is given by [1]:

$$k_{SP} = \frac{\omega}{c}\sqrt{\frac{\varepsilon_d \varepsilon_m}{\varepsilon_d + \varepsilon_m}}. \quad (1)$$

For SPs to be possible, the complex dielectric constant of the metal ε_m must be opposite in sign of that of the dielectric ε_d on top. With metals, this is possible because ε_m is negative over a large frequency range. Equation 1 also shows that the momentum of the SP mode $\hbar k_{SP}$ is always greater than the momentum of the free-space photon of the same frequency $\hbar k_{fs} = \frac{\omega}{c}$. This leads to the realization that if one wants to generate SPs using

Plasmonic Structures for Solar Energy Harvesting, Fig. 2 (**a**) Schematic representation of a surface-plasmon polariton (Reprinted by permission from Macmillan Publishers Ltd: Nature, Ref. [1], copyright 2003). (**b**) Interaction of light with a spherical nanoparticle. Figure 2b was inspired by Ref. [3]

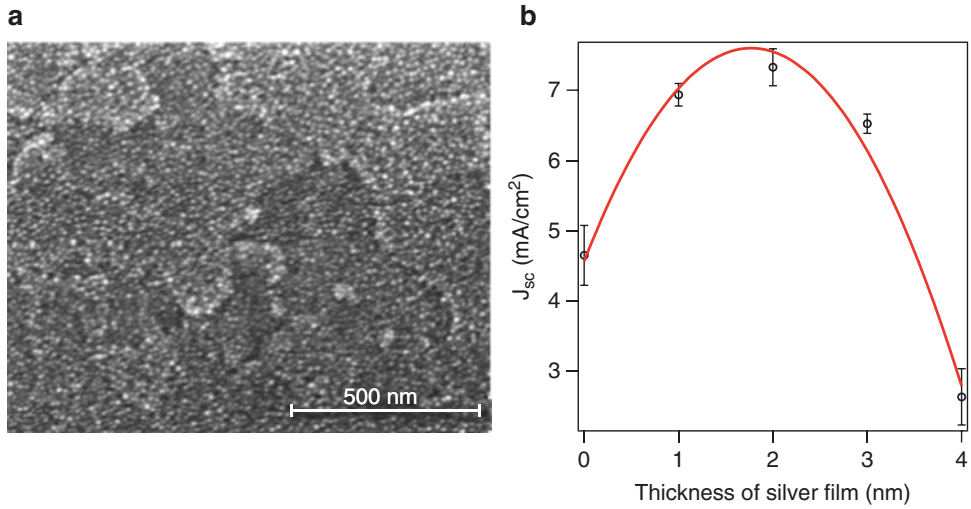
light, extra momentum must be supplied. Such extra momentum can be supplied by three different methods. The first is by using prism coupling and is of little practical relevance to solar energy conversion. Secondly, extra momentum can be supplied by scattering by a nanoscale feature such as an isolated metal nanoparticle, or a topological defect such as a nanohole. Lastly, periodic structuring of a metal surface (e.g., a grating) at wavelength scales of visible light allows the light to be momentum matched to the SPs on the metal surface. The last two methods discussed above are of great significance to solar energy conversion and are the basis of all strategies for including SP formation in solar cells.

The surface plasmon that arises on a periodically structured metal interface is called a surface-plasmon polariton (SPP). A SPP can be thought of as a photon caught at the interface between the metal and dielectric. These collective oscillations have a combined electromagnetic and surface charge character as shown in Fig. 2a [1]. The SPP waves are transverse magnetic (TM) in character and their electromagnetic field intensity is highest at the surface and decays exponentially away from the interface. The increased electrical field above the surface can be used to enhance optical absorption. They can also be used to guide light along the surface horizontally into the active layer of a device, causing increases of optical absorption because of the improved length of interaction of the light wave with the active layer of the solar cell.

The second type of surface plasmon is observed in isolated nanostructures and is visualized in Fig. 2b. It is easiest explained by visualizing a small metal nanoparticle in the electromagnetic field of an incoming light wave. The electromagnetic field moves the sea of conduction electrons up and down in unison at the frequency of the incoming light. The combination with the stationary positive ions of the metal causes a fluctuating dipole. The resonant oscillation frequency of such a nanoparticle where the movement of the conduction electrons is maximized is determined by several factors: the density of conduction electrons, their effective mass, and the shape and size of the distribution of charges (i.e., the particle size and shape). Metal nanoparticles can show multiple resonances such as the aforementioned dipole resonance, as well as higher modes such as a quadrupole mode. Not surprisingly, the oscillating dipole and multipole modes cause strong electromagnetic fields in the neighborhoods of such particles that can enhance optical absorption and strong light scattering (i.e., the particle reradiates the energy) that can direct light into light-absorbing structures. See Ref. [3] for a comprehensive discussion of nanoparticle resonances and their behavior.

Forward Light Scattering Using Metal Nanostructures

The strategy of using metal nanostructures on the front surface of solar cells is well established and is shown schematically in Fig. 1a. Metal particles



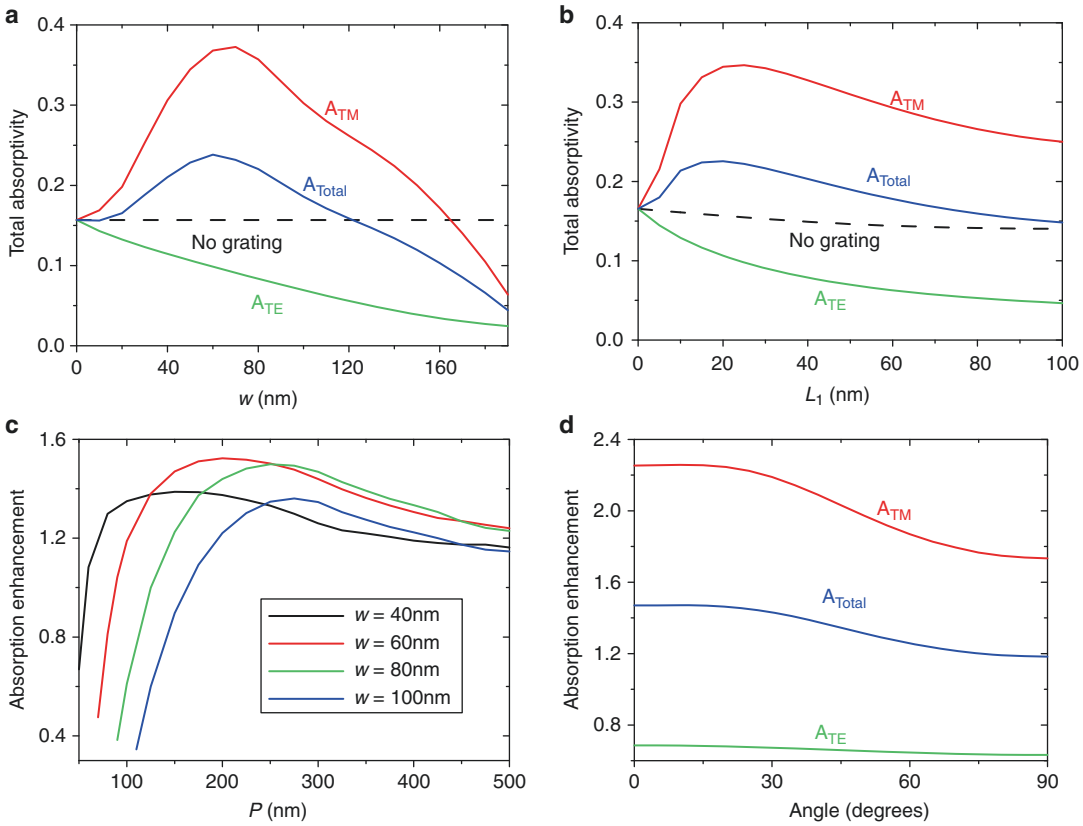
embedded in a homogenous medium scatter light evenly in all directions. However, when such a particle sits at or in the interface between two dielectrics, it will scatter preferentially into the medium with the highest dielectric constant [4]. Analogous to structuring the front surface of solar cells, which is common especially for silicon-based cells, these nanostructures will scatter the light sideways into the active region of the solar cell, allowing a substantial increase of optical path length. At the same time, because a major fraction of the light is now traveling at an angle inside the active layer, it is less likely to escape from the active layer (it is trapped) because it is incident on the top surface again at an angle more shallow than the critical angle. For these reasons, the inclusion of particles at the top surface can cause strong increases in optical absorbance probability by the active layer.

The front-scattering strategy has been extensively studied, especially in silicon photodiodes and solar cells and has been shown to be effective [5, 6]. One question that remains is whether metal particles in such a geometry are more effective than using simple light-scattering structures such as oxide nanoparticles, pyramids, and others. When designing an effective light-coupling strategy, one must weigh the benefit of improved forward scattering with the losses that occur inside the plasmonic nanoparticles due to simple ohmic heating upon absorption of light – something that does not occur in simple dielectric scattering structures. It is known that smaller particles, in principle, are more effective at scattering light into the active layer, but also that ohmic losses are considerable in the smallest particles. Since ohmic (absorption) losses scale more or less with the volume V of the particles, whereas light-scattering scales with V^2, larger particles improve this trade-off [4]. Therefore, one would expect an optimum particle size for scattering efficiency. Catchpole and Polman recently carried out a study of different particle geometries and found that cylindrical and hemispherical geometries are more effective than simple spherical particles, and that parallel dipole orientation of the surface plasmon to the surface can lead to more effective light scattering than the Lambertian value [4]. On the other hand, a direct comparison of the enhancement in the case of metal particles versus that when using silica nanosphere scatterers showed that silica nanospheres provide a similar enhancement to the photocurrent as plasmonic gold nanoparticles. Such silica particles are also good candidates for increasing the light in-coupling in silicon solar cells [7]. This result indicates that possibly there is no convincing case from the perspective of cost for using plasmonic structures for forward-scattering geometries because scattering oxide particles are more economically produced than metal nanoparticles and are also more stable to air exposure.

Direct Field Enhancement Using Embedded Nanostructures

Metal nanostructures can be used to enhance the optical field in their direct vicinity and can therefore be used to enhance optical absorption. The strategy to use this effect is shown schematically in Fig. 1b. The optical enhancement effect has been used widely to enhance the Raman cross section of analyte molecules by orders of magnitude, even enabling the detection of individual molecules. The enhancement of the optical fields around metal nanostructures is usually expressed as an enhancement of the square magnitude of this field because optical absorption processes to a first approximation scale linearly in this quantity. Enhancements of 4 orders of magnitude are attainable, but factors of more than 10 are more common [8].

The direct enhancement approach has been shown to work well in organic solar cell structures where silver particles or other silver nanostructures have commonly been sandwiched between layers or embedded in the active layer of the device [9–12], but also have been used in this manner in inorganic semiconductor-based devices [8, 13]. Figure 3 shows the enhancement of the photocurrent in a bulk heterojunction device fabricated by vapor depositing silver on top of an indium tin oxide conducting front electrode and subsequent deposition of PEDOT:PSS (a transparent conducting polymer), a P3HT/PCBM layer, and a

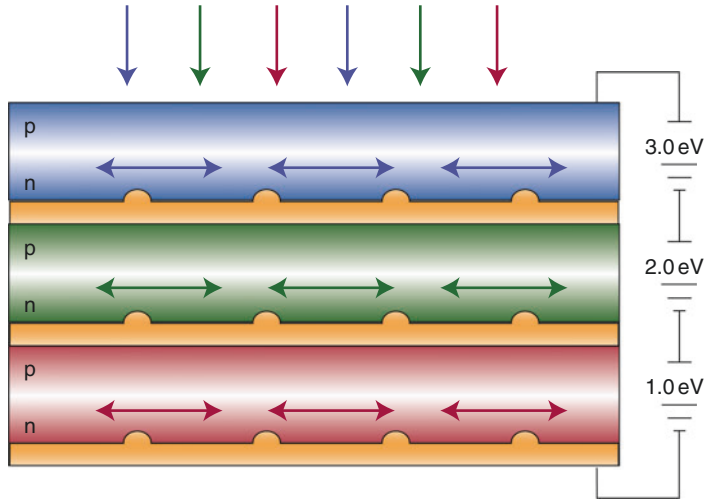


Plasmonic Structures for Solar Energy Harvesting, Fig. 3 (**a**) Silver nanoparticles created by vapor deposition on an ITO electrode. (**b**) Observed enhancement of the photocurrent of an organic photovoltaic device deposited on *top* of the structure shown in Fig. 3a. Data previously published by the author in Ref. [11]

Ca/Al top contact. In such devices, the conversion efficiency can be almost doubled by including silver nanoparticles [11]. In the structures discussed here, especially those where light is incident through the nanoparticle arrays, it is sometimes difficult to separate the effect of field enhancement and enhanced in-coupling of light due to enhanced forward scattering or decreased reflectance. It can be controversial whether any observed enhancement is actually due to field enhancement.

When there is direct contact between the metal nanostructures and the active layer, strong enhancements of the field are expected, but a major problem that can be encountered is that metal nanostructures can act like recombination centers or can quench excited states by energy transfer [10]. This can happen either by capturing both electrons and holes from the semiconductor or by energy transfer from an exciton in the semiconductor to the metal particle, followed by thermalization. Also, in certain PV technologies (such as organic solar cells, which rely on the semiconductor having a low dielectric constant to maintain a constant electrical field over the device to aid in charge separation), the presence of metal nanoparticles can collapse this field because of their very large negative dielectric constant. Direct contact is essential for the greatest absorption enhancements because field enhancement around a metal structure decays approximately exponentially with distance. Therefore, a maximum in the enhancement is expected somewhere in the neighborhood of 5–10 nm, where energy transfer is not efficient but where the evanescent field from the metal nanostructure has not yet fully decayed. This indicates that insulating spacers could be effective when the enhancing particles are in direct contact. Such spacers have typically been provided by buffer layers such as oxides and transparent polymers [11, 13, 14]. Because the spacer layer lowers the expected field enhancement, the benefit of the plasmonically active nanoparticles as direct field enhancers has been limited to small increases in efficiency.

An interesting use of silver nanoparticles that exploits both the optical field enhancement and the strong tendency to cause recombination is to use such particles in the interconnect between two subcells in a tandem device. In this region, charge carriers are supposed to recombine to allow the voltages of the subcell to add up and to mitigate the recombination problem. Such a use of silver nanoparticles has been demonstrated on small molecule organic solar cells [15].



Plasmonic Structures for Solar Energy Harvesting, Fig. 4 Absorption enhancement in a thin-film organic solar cell using CuPc and PTCBI as an active layer by including a metallic grating as a function of the width of the metal lines (w), their thickness (L_1), and period (P) for normally incident light-polarized transverse magnetic (*TM*) and transverse electrical (*TE*) with respect to the grating repeat direction (Reprinted with permission from Ref. [17], Copyright 2010, American Institute of Physics)

P

The aforementioned applications are only scratching the surface of the possible enhancement in solar conversion applications by using direct field enhancement by metal nanoparticles. The enhancement that has been demonstrated to date has mostly been in non-optimized designs, and there is much room for further engineering of this enhancement strategy in organic PV, as well as many other types of solar cells.

SPP Waveguide-Enhanced Photovoltaics

Metallic, plasmonically active grating structures can be used to direct light into waveguide modes in solar cell structures by generating SPPs (see Fig. 1c). This strategy basically rotates the travel direction of incoming light waves 90°, allowing it to travel as SPPs at the interface between a metal contact and the active layer of the device. This allows for extraordinary improvements in the optical path length of light inside the active area of a solar cell. When light is resonant with the plasmon resonance frequency, significant losses are expected from Joule heating of the metal. However for wavelengths to the red side of this frequency, there can be significant gains in absorption efficiency. An analysis of this trade-off can be found in [16]. To illustrate the potentially very large gains that can be made using the SPP waveguide approach, Fig. 4 shows the expected absorption enhancement in an organic solar cell structure that includes a grating structure, which enhances optical absorption of the active layer significantly [17] even if the effect of loss in

Plasmonic Structures for Solar Energy Harvesting, Fig. 5 Plasmonic tandem solar cell concept with layers tuned to different wavelengths of solar light. Semiconductors with different bandgaps are stacked on *top* of each other, separated by a metal contact layer with a plasmonic nanostructure that couples different spectral bands of the solar spectrum into the corresponding semiconductor layer (Reprinted by permission from Macmillan Publishers Ltd: Nature Materials, Ref. [4], Copyright 2010)

the metal structures is taken into account. Such waveguide approaches are expected to be especially useful in solar cell designs where thin layers have to be used either because of charge transport and recombination limitations in the active layer, or because of economical or material supply reasons.

An intriguing idea for SPP waveguide-like modes in a tandem solar cell concept was recently proposed by Atwater and Polman [4]. Figure 5 shows this concept schematically. In each layer, a metallic grating is employed that is tuned to enhance the absorption of only the wavelength of light that is desired in that layer. Such a structure could reduce the required thickness of the active layers of the device, which currently are often deposited using expensive vapor-phase methods and non-earth-abundant elements.

Contrary to the large amount of theoretical investigations into these structures, few have been demonstrated experimentally, and the potential gain in efficiency remains largely theoretical at the moment. Furthermore, a remaining question is whether such grating structures can be fabricated economically over large areas. SPP-active gratings are currently made using relatively expensive methods such as focused-ion-beam etching or e-beam lithography. More promising methods include conformal imprint lithography using rubber stamps that can generate large-area deposition mask patterns, as well as nanosphere lithography and laser interference lithography.

Enhancement of Third-Generation Approaches

A novel approach to employing plasmonics in solar cells is shown schematically in Fig. 1d. In this approach, the presence of surface plasmons fundamentally alters the excited-state dynamics of the photoactive system, driving a photosystem to a normally unlikely outcome. This approach can be especially significant in systems that employ third-generation photoconversion concepts. Such concepts potentially transcend the limits of single-bandgap photoconverters by converting energy that would normally be wasted as heat. Limiting theoretical efficiencies for such solar cells have been estimated to be around 50 % under solar illumination, which is much higher than the limit of about 30 % for a traditional, first-generation solar cell. Examples of such approaches where plasmonic nanostructures can be helpful are multiple-exciton generation (MEG) and singlet

fission (SF). Both of these processes are so-called quantum cutting processes, where a single incoming photon is converted into multiple excited states. In the case of MEG, a semiconductor nanoparticle (i.e., a quantum dot) is used that is so small that carriers in it behave like particles in a box, and the bandgap of the material widens. At the same time, the energy levels go from a continuum to a set of discrete levels. Under the right conditions, it becomes possible for a single highly excited state (i.e., an exciton) to break into multiple excitons at the bandgap energy. If one could design solar cell structures that separate these excitons faster than the recombination of the excitons, a commensurate increase in efficiency could be obtained. Although some promising structures have been demonstrated, it seems likely that new structures and concepts are needed. It has been theorized that surface plasmons can aid in the efficiency of long-range energy transfer between quantum dots and inorganic PV devices [18]. This could potentially lead to efficient energy funnel structures, aided by SP active nanostructures that lead the multiple excitations created by the MEG process away from the originating quantum dot before recombination occurs. At the moment, however, such structures are still purely theoretical.

Singlet fission is another process that can lead to much higher efficiency solar energy conversion. The process is observed in molecular systems and molecular crystals. In short, an excited molecule transfers about half of its energy to another similar molecule or another moiety on the same molecule. The molecule itself will go from the singlet excited state to a triplet state that is about halfway down in energy from the singlet excited state. At the same time and in a coherent fashion, the partner molecule undergoes a transition into the triplet state. The overall double-triplet state still has singlet spin character, making the transition spin allowed. Again, as in MEG, a single excitation is converted into multiple excited states, leading to a decrease in the loss of energy to thermalization of charge carriers. Singlet fission is observed in a large array of different molecular systems, as well as in molecular crystals such as rubrene. It has been postulated that modification of excited-state dynamics can be responsible for more efficient SF processes. Recently, it was observed that pentacene deposited on a silver nanohole array shows more efficient production of triplets and slower triplet–triplet recombination [19]. Possibly, this is due to the surface plasmons creating an efficient pathway to decohere the spin states of the two triplets that start out in coherence.

As mentioned before, SPs can also be used to enhance long-range energy transfer. This effect was recently demonstrated in an organic solar cell structure where light absorbed in a rubrene antenna that had no electrical connection to the cell was effectively transferred to the active device using SPPs resonant in a purposely designed cavity [20]. Such a configuration could be used to design solar cells where light absorption is uncoupled from charge generation and transport.

It is likely that future third-generation photoconversion systems will rely on surface plasmons to increase their likelihood of leading to charge carriers not just by increasing the absorbance probability of light, but also, by fundamentally altering the excited-state dynamics. Using surface plasmons as partner states in such processes is a promising avenue to strongly increased photoconversion efficiencies in the future.

Synonym

Bottom-up fabrication of plasmonic materials

Definition

Plasmonics in self-organized media addresses the characteristics of localized surface plasmon resonances in nanostructured/nanopatterned materials realized by bottom-up fabrication methods.

Fundamentals of Plasmonics

The localized surface plasmon resonance (LSPR) is a resonant oscillation of the free-electron gas confined within a metallic nanostructure driven by an incident electromagnetic (EM) wave. Physically, the charges displaced by the EM field experience a restoring force due to their mutual attraction; when the characteristic oscillation frequency ω_0 associated to the restoring force matches that of the EM field, the resonance condition is met for the plasma oscillation [1]. At the LSPR, the extinction of EM radiation is greatly enhanced as a result of an increase of both scattering and absorption cross sections.

The enhanced scattering arises from the reradiation of the EM field that is induced in the metallic medium, whereas the absorption is related to the non-radiative decay of the plasma oscillations that typically leads to the dissipation of the power associated with the EM wave within the metallic nanostructures. The accumulation of a large net charge in proximity of the nanostructures' surfaces at the LSPR frequency leads to large enhancement of the local EM field (near-field regime) in the immediate proximity of the structures' surface with respect to its free-space value. Such an enhancement is exploited for nonlinear optical spectroscopies, like surface-enhanced Raman scattering (SERS), whose yield scales nonlinearly with the local field, thereby promoting plasmonic systems as platforms for high-sensitivity molecular detection [2].

Since the LSPR frequency, amplitude, and linewidth depend upon a multitude of electronic and geometric effects, controlled modifications of the nanostructures' constituent materials (electron density, material's losses), dielectric environment (supporting substrates, host media, adsorbed molecules), and geometrical parameters (nanostructures' size and shape) allow to flexibly tune the plasmon's characteristics. Such a tunability probably ranks as the single most relevant aspect that contributed to establish plasmonics as an invaluable tool in fundamental and applied photonics research. In order to make the most of plasmonics' numerous applications, it is crucial to tailor the LSPR characteristics according to the desired requirements. For plasmon-enhanced spectroscopies or optical-signal waveguiding, matching the LSPR frequency against narrow-linewidth excitations is required; for plasmon-enhanced photovoltaics, broadband plasmon features are often more advantageous. In the following, we will briefly introduce the main concepts of plasmonics, the key factors that contribute to the LSPR tunability, and the configurations that are typically fabricated for maximizing the EM-field enhancement ratio for nonlinear spectroscopy applications.

Let us consider an ellipsoidal metallic particle with semiaxes a_γ ($\gamma = x, y, z$) oriented along the Cartesian axes, immersed in a transparent dielectric host and far from any other polarizable entity. Let the dielectric constants of the metal and the host be ϵ_m and ϵ_h, respectively. When the particle is much smaller than the wavelengths $a_\gamma \ll \lambda$ (quasi-static approximation, QSA), we can

neglect spatial retardation effects. If the host is homogeneous and isotropic, then $\boldsymbol{E}_{loc} = \epsilon_h \boldsymbol{E}_0$, and we can write:

$$\boldsymbol{p} = \epsilon_0 \epsilon_h \boldsymbol{\alpha} \otimes \boldsymbol{E}_0 \tag{1}$$

where $\boldsymbol{\alpha}$ is the polarizability tensor of the particle. For ellipsoidal particles, α is diagonal, with principal values α_γ given by [1]

$$\alpha_\gamma = v \frac{\epsilon_m - \epsilon_h}{\epsilon_h + L_\gamma(\epsilon_m - \epsilon_h)} \quad \gamma = x, y, z \tag{2}$$

where $v = (4/3)\pi a_x a_y a_z$ is the particle's volume and L_γ are the *depolarization factors* that can be written as

$$L_\gamma = \frac{a_x a_y a_z}{2} \int_0^\infty \frac{dq}{\left(q + a_\gamma^2\right) \sqrt{\prod_{\eta=x,y,z}\left(q + a_\eta^2\right)}} \tag{3}$$

and satisfy the sum rule $\sum_\gamma \mathrm{L}_\gamma = 1$.

For spherical particles, we have $a_x = a_y = a_z \equiv a$, and the geometrical factors reduce to $L_\gamma = 1/3$ in all directions: the polarizability is isotropic, and from Eq. 2 we find

$$\alpha_{\mathrm{sph}} = 3v \frac{\epsilon_m - \epsilon_h}{\epsilon_m + 2\epsilon_h} \tag{4}$$

If $\mathcal{I}m[\epsilon_m(\omega)]$ is small or slowly varying, the resonance condition for spherical particles simplifies to

$$\mathcal{R}e[\epsilon_m(\omega)] = -2\epsilon_h \tag{5}$$

which is called the *Fröhlich condition* for the LSP resonances.

Another interesting case is given by the cylindrical limit, i.e., when $a_z \gg a_x, a_y$. Now, the depolarization factor along the main axis (L_z) vanishes, implying that the cylinder can be polarized only by electric fields lying in the *xy* plane. For the case of a prolate ellipsoid, the LSPR in the longitudinal geometry (electric field polarized along the major axis) redshifts as the aspect ratio (defined as the ratio of the major to the minor axis) increases, while the LSPR in transverse excitation (electric field polarized along the minor axis) correspondingly blueshifts.

Beyond the quasi-static regime, retardation effects become relevant, and multipolar charge distributions set in due to the inhomogeneous EM-field distribution over the nanoparticle (NP). Under these conditions, the optical response of a metallic NP is determined by the superposition of LSPR corresponding to the different orders of the multipolar charge distribution, giving rise to broader resonances; for increasing NP size, the LSPR of all orders are monotonically redshifted.

The LSPR are heavily influenced by the dielectric characteristics of the surrounding medium, which can be simply composed of a homogeneous dielectric host, or include other particles within the near-field EM-coupling range (i.e., with a mutual spacing in the order of 1/10 of the LSPR wavelength or below). As apparent from Eq. 5, an increase in the NP-host dielectric constant translates into a LSPR redshift. More in detail, the LSPR redshift exhibits an exponential decay upon the thickness of the medium surrounding the particle, meaning that the LSPR is sensitive to the variation of dielectric function within few tens of nanometers from the NP surface [3]. This local sensitivity forms the basis of the exploitation of LSPR for sensing of adsorbed molecules, provided selective binding sites at the surface of the metal nanoparticles are created by functionalization [4].

Whenever NPs are brought closer and closer, the mutual influence of the NP local fields affects the collective LSPR characteristics and the EM-field distribution. The most striking and interesting example of this many-particle effects is provided by the so-called dimer configuration, where two identical plasmonic NPs are placed close to each other, few nanometers apart. In such a configuration, an enhanced field *hot spot* is generated within the interparticle gap at the collective LSPR frequency. Series of NPs aligned in linear chains can be built as infinite series of dimers, thus generating a multitude of hot spots, and analogously so for NP arrays, that thus become prototypical substrates for plasmon-enhanced nonlinear spectroscopy [5].

Fabrication Issues

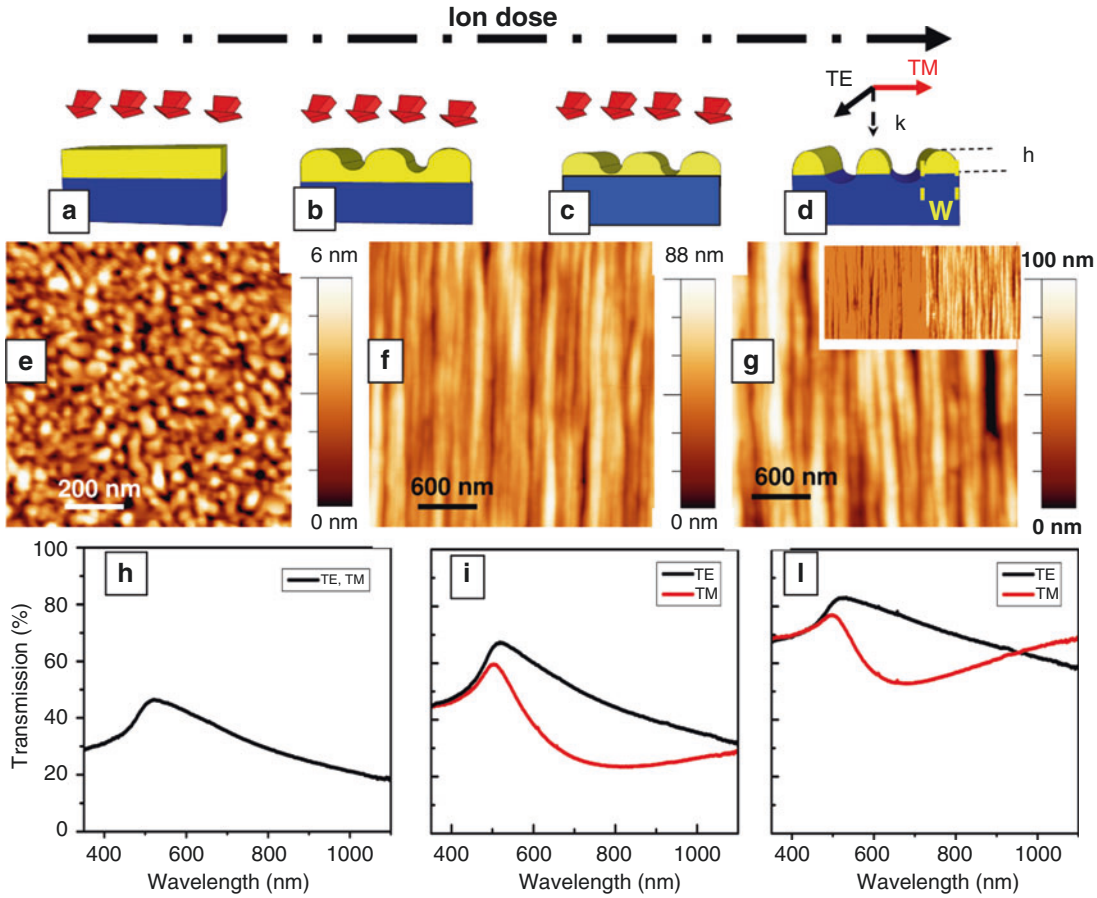
The fabrication schemes suited for realizing plasmonic nanostructures can be grouped for convenience into two broad categories, the so-called "top-down" and "bottom-up" approaches. Top-down methods include all the diverse forms of lithography that allow the fabrication of nanostructures with a high degree of morphological precision, albeit sometimes at the expense of a higher price and lower throughput. These methods are called for in those specific applications for which the precision and control in the NP shape and/or in the architecture of many-particle systems is of paramount importance. This includes cutting-edge research applications like ultrahigh-sensitivity plasmonic detectors and sub-wavelength optical waveguiding.

Bottom-up methods instead exploit spontaneous processes to produce nanostructured materials. They target the achievement of metastable configurations characterized by the tendency to develop regular patterns on specific, system-dependent length scales, harnessing the process' kinetics. Bottom-up strategies are typically employed in all those circumstances in which large-area plasmonic systems must be grown at low fabrication costs and in which the physical effect under investigation is not vulnerable to the unavoidable morphological disorder. Clearly, while bottom-up approaches cannot challenge lithography in terms of the variety and degree of precision of the achievable nano-architectures, specific niche applications exist in which spontaneously fabricated structures retain a significant advantage over lithography, even aside from fabrication-cost issues. Some significant examples are related to applications in which a broad size distribution and the consequent broadband plasmonic response provide an inherent advantage. In this respect we can, e.g., mention disposable plasmonic sensors, photon outcoupling in light-emitting devices, or broadband photon harvesting in thin-film solar cells induced by a self-organized arrays of plasmonic scatterers whose resonances match the solar spectral range [6]. In addition, bottom-up methods are typically more flexible material wise and in general lend themselves to be more easily applied under ultra-controlled conditions (e.g., ultrahigh vacuum), thereby allowing to target reactive metals as well.

Self-organized materials naturally exhibit a certain degree of morphological disorder (NP size, shape, geometrical arrangement), as a result of the spontaneous amplification of fluctuations in the systems' morphology which are the basis of the self-organization process itself. Such a dispersion in the morphological parameters of the constituent building block can be fully probed in ensemble measurements. As far as the plasmonic response is concerned, disorder impacts the system properties in two manners: ensembles of plasmonic nanostructures which are sufficiently sparse, i.e., located outside one another's near-field coupling range, exhibit a plasmonic response determined by the incoherent summation of the individual response (inhomogeneous broadening). If the nanostructures' size distribution is large enough that size-dependent redshift and broadening of the plasmonic response are present, the collective response will fully bear trace of these effects. Conversely, in ensembles of near-field-coupled nanostructures, superradiant dipolar modes become effectively delocalized over several NPs, smoothening the effects of morphological disorder and achieving an ensemble response that is spectrally narrower than the incoherent superposition of all the constituents' individual response [7]. Depending upon the application envisaged (broadband response over spectrally narrow features), one of the two approaches might be followed.

Plasmonics systems are composed of a metallic and an insulating counterpart. The insulator, supporting or even embedding the nanostructured metallic material, guarantees the required electron confinement. Different bottom-up fabrication approaches may involve the direct nanopatterning of the metal, regardless of the insulator morphology, or the preliminary patterning of the insulator that later acts as a template for realizing metallic nanostructures. We will in the following discuss examples from both classes.

Plasmonic Arrays by Direct Ion-Beam Sputtering



Among the approaches which have been exploited for the bottom-up fabrication of nanoscale patterns, the use of defocused ion-beam

sputtering (IBS) has gained a growing attention due to the ease of implementation, the flexibility, and the scalability over macroscopic substrate areas employing standard industrial equipment. Planar substrates of a wide class of materials, after irradiation with noble gas ions at energies in the range from few hundreds of eV to several tens of keV, develop periodic patterns when the ion fluency $\mathcal{F}$ exceeds 10^{16}–10^{17} ions/cm^2; depending on the sputtering conditions, and in particular on the incidence angle of the ions, a rich variety of patterns can be observed [8]. In an oversimplified classification, near normal incidence, a smoothing regime is predominant for single component systems, while, for some compound semiconductor substrates, close-packed arrays of dots or mounds can be formed [9]. At higher incidence angles, below a critical value θ_c (in the range of 60–70°), amorphous materials like glasses or materials which become amorphized following ion impact (semiconductors) develop a ripple pattern with ridges running perpendicular to the ion projection. For grazing incidence angles above θ_c, the ripple pattern is instead rotated by 90° with ridges running parallel to the ion projection. A classical model describing the early stages of pattern formation (small amplitude approximation) of an initially flat substrate under IBS conditions has been proposed by Bradley and Harper in the continuum limit [10]. The basic idea of the model is that a periodic ripple undulation arises as the result of the interplay between the destabilizing action of the ion beam, which tends to roughen the surface, and the stabilizing surface relaxation mechanisms which reduce the interface width. The erosion velocity at a given surface point turns out to depend on the local curvature of the topographic profile and is faster for the valleys (regions with positive curvature) than for the peaks (regions with negative curvature). The smoothing terms which counteract ion-induced roughening instead arise from thermally and/or ion-induced diffusion of the mobile defects which are determining surface relaxation. At higher ion fluencies, the simplified small amplitude approximation does not hold anymore, and nonlinear terms must be taken into account in order to describe the experimental observations within the continuum approximation [11]. The general lines of this description hold for a broad class of transparent dielectric materials employed as substrates in low-cost photonic and plasmonic applications such as soda lime and borosilicate glasses, silicon, silica, and alumina.

The case of metal surfaces and films, of interest in plasmonic applications, is more complex because the crystalline properties of the substrate are preserved even after prolonged sputtering at low ion fluxes and at sufficiently high temperature (*diffusive regime*). Thermally activated surface diffusion of mobile defects is in fact no more isotropic, but oriented along the high symmetry directions of the substrate unit cell. Additionally, the presence of an extra energy barrier for defect crossing at atomic step edges (the Ehrlich-Schwoebel barrier) biases mass transport in the uphill direction so that adatoms are preferentially attracted by the *ascending* step edges while vacancies by the *descending* step edges; as a consequence of the *kinetic* competition between the destabilizing uphill currents and the diffusive relaxation currents (Villain instability), a periodic mounded pattern develops in the direction of the dominant uphill current [12]. At high ion fluxes and/or low temperature, the anisotropic diffusive relaxation mechanisms are hindered, and, in analogy to amorphous substrates, the pattern formation process is dominated by the erosive action of the ion beam. Thus, under *erosive* IBS conditions (high ion fluxes and/or low substrate temperature at grazing incidence), both single-crystal [8] and polycrystalline metal surfaces can develop an undulated ripple pattern-oriented parallel to the ion-beam projection [13].

Nanowires by Direct IBS

The steps leading to the transformation of a rippled polycrystalline metal film into a self-ordered one-dimensional array of disconnected nanowires (NWs) by *direct* IBS patterning are outlined with the help of the sketches of Fig. 1a–d and of the atomic force microscopy images in Fig. 1e–g. The initial morphology of the pristine metal film is characterized by the size of the polycrystalline grains [14]; in the example shown in Fig. 1e, thermal evaporation of a 150 nm Au film leads

Plasmonics in Self-Organized Media, Fig. 1 (**a**–**d**) Sketches of the direct IBS at $\theta = 82°$ of a polycrystalline Au film as a function of the ion dose. Low doses: thick film (**a**) and rippled pattern (**b**). Higher doses: disconnection threshold (**c**) and arrays of laterally disconnected Au NWs (**d**). (**e**–**g**) AFM topographies corresponding to the sketches (**a**, **c**, **d**). (**h**–**l**) Optical transmission spectra corresponding to the topographies (**e**–**g**), for light polarization parallel (TE) and perpendicular (TM) to the ripple ridges

to the formation of grains with an average size in the 80 nm range.

Increasing $\mathcal{F}$ beyond 10^{16}–10^{17} ions/cm^2, elongated ridges are formed which can exceed several micrometers in length, with a lateral periodicity in the range of 100 nm and with an amplitude which can reach several tens of nm (Fig. 1b). Extinction (absorption) spectroscopy of polarized light in the VIS-NIR spectral range allows to follow the evolution of the optical properties of the patterned Au film and to correlate them in a straightforward way to the morphological modifications induced by the IBS process. The optical spectra of samples irradiated at increasing ion doses are shown in Fig. 1h–l. Two characteristic linear polarizations of the incident light, i.e., transverse magnetic (TM – electric field perpendicular to the ripple's ridges, red traces) and transverse electric (TE – electric field parallel to the ripple's ridges, black traces), are used. In Fig. 1h, one can see the optical spectra of a still connected rippled film corresponding to the sketch in Fig. 1b. The spectral signatures are similar to those of a flat Au metal film with no evidence of polarization dependence. For $\mathcal{F}$ in the range of 10^{18} ions/cm^2, film erosion increases up to the point that the ripple valleys reach the dielectric substrate, and the metal film decomposes into an array of laterally disconnected NWs separated by linear nanogaps as shown in Fig. 1c and f. The NW array is

characterized by a lateral periodicity in the range 100–120 nm, while the length of individual NWs can exceed several micrometers. The individual nanowires are composed by polycrystalline grains with predominant (111) in-plane texture and with densely packed domain boundaries [14]. The corresponding optical spectra shown in Fig. 1i reveal that at the onset of Au NW disconnection, a polarization dependent extinction minimum becomes evident in the TM transmittance spectra, a typical fingerprint of the LSPR [15]. The TE spectra still resemble the behavior of a connected Au film, since metal NWs are elongated for several micrometers in the long-axis direction. It is worth to notice that the plasmonic extinction band centered around 800 nm spans a broad range from about 550 to 1000 nm. This is a consequence of the intrinsic dispersion of the lateral size (w) of the Au NWs in the early stages of the disconnection process (inhomogeneous broadening) and of a redshift of the dipolar LSP resonances due to near-field coupling between adjacent NWs separated by small gaps. Further increasing $\mathcal{F}$ in the 10^{19} ions/cm^2 range, the average NW width w is reduced, and the interwire gap amplitude is increased from few nm up to several tens of nm as evidenced in Fig. 1d. The inset in Fig. 1g evidences on the left side a region in which the NW array has been removed by means of a micrometric tip thus exposing the underling glass substrate with deep trenches where local erosion has occurred in correspondence to the gaps. Looking at Fig. 1l, one observes a progressive increase of the transmittance due to the thinning of the metal film and a narrowing of the LSP resonance band essentially related to a reduction of the NW size distribution and to an increase of the gap width. Moreover, as the average w/h out-of-plane aspect ratio of the NWs reduces, a blueshift of the plasmonic band down to 650 nm occurs. This example highlights the potential of *direct* ion-beam sputtering as a self-organized nanopatterning approach capable of transforming a polycrystalline metal film supported on a low-cost dielectric substrate into an array of nanowires with broadband plasmonic response. Tailoring of the LSP resonance is possible by changing the ion dose and/or the metal (e.g., Au, Ag, Cu, or Al).

Near-Field Enhancement and SERS

IBS-fabricated NW arrays naturally lend themselves to be applied as substrates for plasmon-enhanced SERS, thanks to the high density of *hot spots* generated in the nanometric gaps between the NWs. Recurring to commercial software for EM solving, one can calculate the near-field intensity and distribution in the proximity of arbitrary shaped and spaced metal nanoparticles. As an example, one can consider two identical gold prolate nanoellipsoids placed in close proximity side by side; when the nanocavity width reads 2 nm, at the LSP resonant condition, the EM intensity in the gap region is enhanced almost 50-fold and rapidly drops to almost zero as the nanocavity width is increased to 60 nm. The tailored near-field coupling of the plasmonic nanostructures thus represents one of the most challenging issues for the development of high-sensitivity spectroscopy applications exploiting the fluorescence and/or Raman signal.

In this context, the local field enhancement in the vicinity of the NW arrays of Fig. 1 has been probed detecting the SERS signature of a monolayer of methylene blue molecules chemisorbed inside the nanocavities [16] and directly mapping the near-field distribution in the vicinity of the metal nanostructures acquired via scanning near-field optical microscopy (SNOM). An enhancement factor of the order of 10^4 is found for the Raman signature when the pump laser wavelength matches the plasmonic resonance of the nanowires and when light is polarized along the nanocavity axis (i.e., along the NW's short axis). The enhancement factor rapidly drops by almost 2 orders of magnitude when the polarization of the pump laser is rotated by 90°, i.e., parallel to the NW long axis, so that the LSP resonance is no more excited. The possibility to switch off the LSP resonance by simply rotating the laser pump polarization allows to separate the chemical and electromagnetic contribution to the Raman enhancement factor since the same sample location and molecular ensemble are probed. Furthermore, the SERS signal turns out to be polarized along the nanocavity axis independently from the polarization of the pump. This proves that only the component of the molecule's Raman dipole

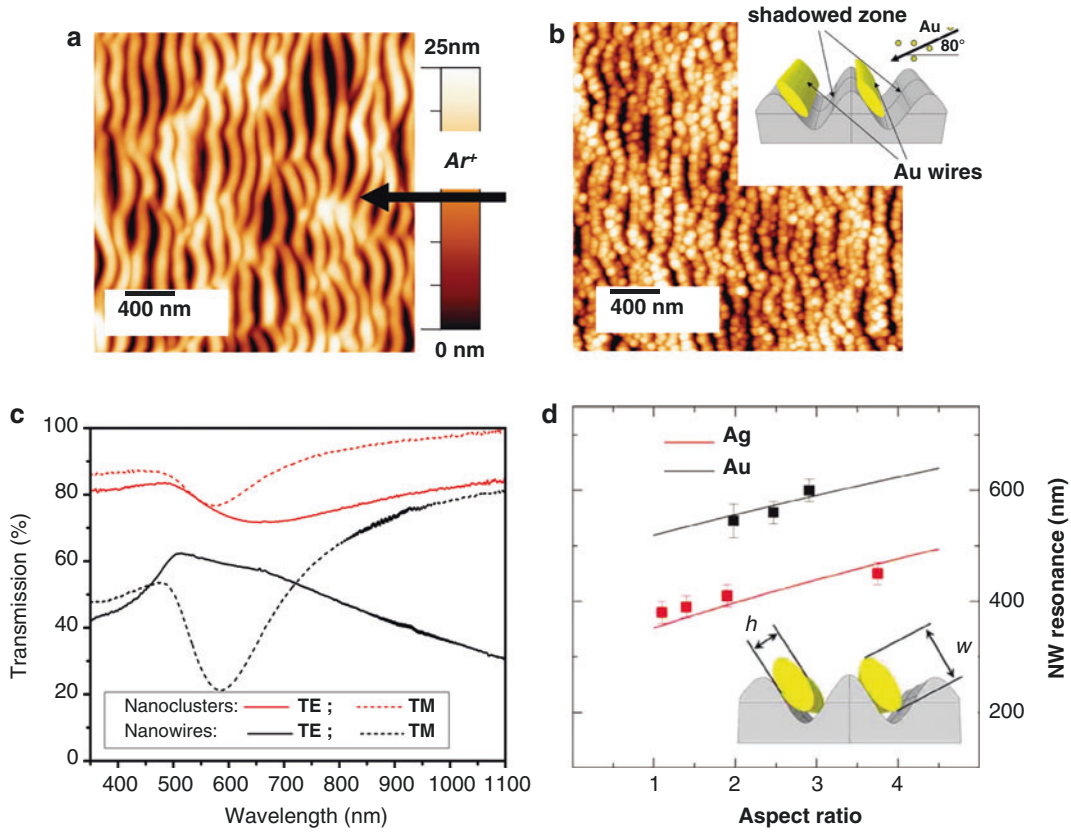
parallel to the nanocavity axis is selectively excited by the plasmonic resonance and that the measured SERS signal arises from those molecules which are located within the narrowest nanocavities, i.e., those hot spot regions in which the NWs are near-field coupled.

It is also worth to highlight that the broad and tunable plasmonic band of the gold NWs is interesting for promoting photon harvesting in photovoltaic devices through light trapping and scattering [6]. In fact, the LSP resonances of the self-organized arrays of plasmonic nanoparticles overlap a large part of the solar spectrum due to the intrinsic size dispersion of the NW array. Even more interestingly, the NW arrays form a percolated network which combines anisotropic electrical conduction with sheet resistance as low as few Ohm/square and a high optical transparency in the 70–80 % range [17]. NW arrays can thus be considered as an alternative to ITO-based transparent conductive oxides with the additional benefit of supporting LSP resonances tunable over the VIS-NIR solar spectral range.

Template-Driven Fabrication of Plasmonic Nanostructures

The template-driven fabrication of plasmonic nanostructures exploits an existing morphological nanopattern on the insulator's surface to steer the formation of metallic nanostructures. Thus, when metal atoms are deposited on the insulator nanopattern, the template morphology acts as a partitioner for the deposited material, forcing the fractioning of an otherwise continuous metal film into disconnected plasmonic units, with size and periodicity dictated by the regular spatial patterns of the template. The shape of the metal nanostructures, now all roughly similar in volume, might then be dictated by the kinetics and geometry of the deposition process or further modified by bringing the system to a thermodynamically stable state.

Methods to fabricate the insulating template include, among others, the patterning by ion-beam sputtering of an initially flat insulator (crystalline or amorphous), the miscut or faceting of insulating single-crystalline materials that exploits in various ways the strong dependence of the surface energy upon the crystallographic orientation in single-crystal materials, or the self-assembly of arrays of close-packed nanospheres. Fabricating the metallic (plasmonic) nanostructures on top of a nanopatterned insulator typically relies on the deposition of a nominally uniform metal layer, sometimes in peculiar geometric configuration (e.g., glancing angle deposition) to boost the conformality to the template. The deposition might be sometimes followed by post-deposition treatments such as annealing.

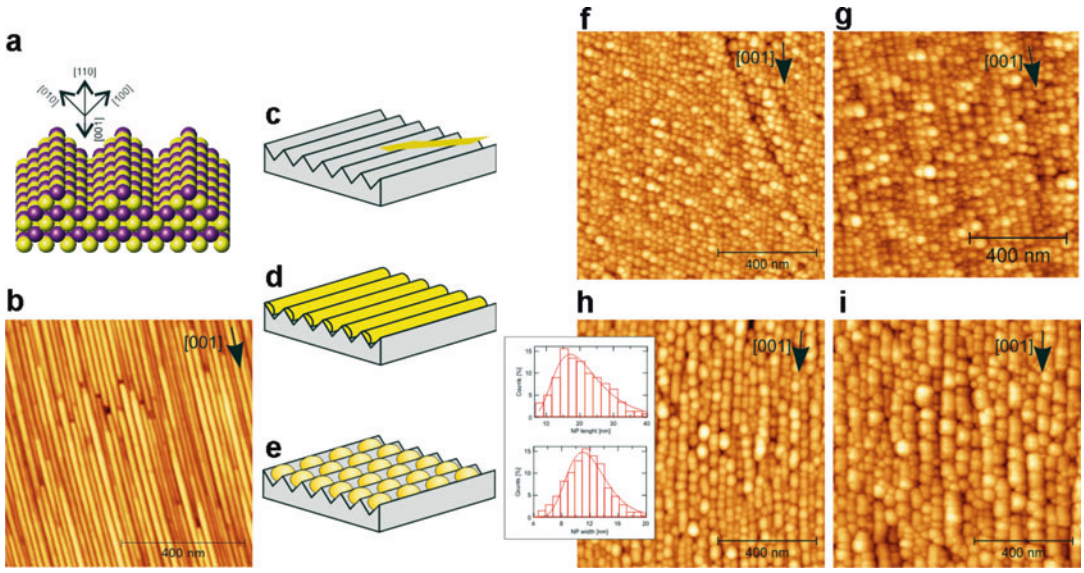


The use of prestructured dielectric templates allows to circumvent some of the inconvenients that arise when performing the *direct* patterning of a metal. For example, the synthesis of ordered metal NW arrays by *direct* IBS nanopatterning depends crucially from the self-organization properties of the metal film, while the flat supporting substrate plays a negligible role. This means that adopting the same direct IBS patterning conditions (ion energy, ion flux, ion incidence angle), the morphological parameters of the NW distribution will be different when different materials like Ag, Cu, or Al are employed [14, 13].

In the following, we describe an alternative approach for the synthesis of arrays of plasmonic nanoparticles which does not depend on the specific properties of the metal employed. The morphological parameters of the array can in fact be constrained geometrically if nucleation of the metal nanoclusters is achieved by glancing angle deposition on a faceted template, according to the sketch in the inset of Fig. 2b or Fig. 3c.

In particular, in view of plasmonic applications, the method allows a great flexibility in the choice of noble metal clusters such as Au, Ag, and Cu which are characterized by a plasmon resonance in the visible-NIR spectral and Al in the UV spectral range.

Arrays of One-Dimensional Structures on Templates Prepared by Ion-Beam Sputtering



Ion-beam sputtering at non-grazing incidence angles $\theta < \theta_c$ has been reported to produce periodic patterns on a broad class of amorphous

Plasmonics in Self-Organized Media, Fig. 2 (**a**) AFM topography of a typical ripple pattern obtained by IBS on a soda lime glass substrate at $\theta = 35°$. (**b**) AFM topography acquired after deposition of 16 nm of Au at grazing angle (80°) on the rippled templates showing 1D chains of connected nanoclusters localized on the illuminated facets. (**c**) Optical extinction spectra of 1D arrays of disconnected Au nanoclusters (*red traces*) after deposition of 8 nm at 70° and connected NWs (*black traces*) after deposition of 16 nm at 80°. (**d**) Graph of the spectral position of LSP for Au and Ag NWs as a function of the out-of-plane aspect ratio *w/h*

substrates. In view of low-cost plasmonic applications, the possibility to employ as templates transparent dielectric substrates like soda lime glass is particularly attractive. IBS irradiation of glass substrates at $\theta = 35°$ leads to the formation of regular faceted ripples with tunable periodicity in the range 100÷350 nm, peak-to-valley height in the range 5÷60 nm, and length of the ridges in the range 1÷3 μm [18].

As an example, the topography of Fig. 2a reveals the typical rippled morphology of a glass template nanostructured by IBS after $\mathcal{F} = 6 \cdot 10^{18}$ ions/cm^2, with a periodicity around 150 nm and a height of about 20 nm. The typical slope of the tilted ripple facets is in the range 10°–20°. If Au evaporation is performed at a perpendicular azimuthal angle with respect to the ripple ridges, and at a polar glancing angle around 80°, the spatial distribution of the metal atom flux becomes modulated by the local facet angle which determines an alternating sequence of shadowed regions with no Au flux and illuminated regions with high flux. Preferential homogeneous nucleation of the clusters is thus forced near the top of the illuminated ridges, where the Au flux is the highest (Fig. 2b) [19]. For the lowest metal equivalent thickness (defined as the thickness of the homogeneous film that the same quantity of deposited material forms on a flat surface), nucleation of 1D chains of disconnected nanoclusters takes place on the illuminated facet, in registry with the underlying

Plasmonics in Self-Organized Media, Fig. 3 (**a**) Schematic atomic arrangement of nano-faceted rock salt (110) surfaces. (**b**) Atomic force microscopy image of a nano-faceted LiF(110) surface. (**c**–**e**) Elementary steps involved in fabricating metallic nanoparticles on a nano-faceted LiF(110) surface: grazing angle deposition, formation of nanowires, and temperature-induced dewetting. (**f**–**i**) AFM images recorded for Au/LiF(110) systems obtained depositing an equivalent thickness of Au t_{Au} on nanopatterns with periodicity Λ: (**f**.) $t_{Au} = 4.5$ nm, $\Lambda = 30$ nm; (**g**) $t_{Au} = 4.8$ nm, $\Lambda = 40$ nm; (**h**) $t_{Au} = 5.4$ nm, $\Lambda = 45$ nm; and (**i**) $t_{Au} = 7.2$ nm, $\Lambda = 55$ nm. The deposition was followed by annealing at 400 °C. Inset of panel (**h**): size distribution of the NP semiaxis in the direction parallel and perpendicular to the LiF ridges

glass pattern, while for higher Au doses, the 1D chains coalesce from a percolated nanowire as shown in Fig. 2b.

The morphological anisotropy of the Au clusters is reflected in their dichroic response as shown by the optical transmission spectra of Fig. 2c. The red traces refer to 1D chains of disconnected Au nanoclusters grown at a reduced Au equivalent thickness of 8 nm. For light polarized perpendicularly to the ripple ridges, the TM spectrum (red dashed line) is characterized by a localized extinction minimum around 570 nm due to the excitation of the localized surface plasmon resonances along the short axis of the clusters. For longitudinal polarization (TE spectrum, red continuous line), a broader extinction minimum is observed which is redshifted around 670 nm. The anisotropic excitation of the broadband LSP resonances confirms that for low metal doses, the growth of disconnected and anisotropic clusters with a broad size distribution is favored parallel to the ripple ridges. By further increasing the metal coverage to 16 nm, laterally ordered arrays of connected polycrystalline NWs are formed, due to agglomeration, coalescence, and coarsening of the primitive 1D chains of clusters, as shown in the AFM image of Fig. 2b. The change in the optical response is evidenced in Fig. 2c: for longitudinal polarization (TE, black continuous line), the extinction spectrum resembles those of a continuous connected Au film, while for TM polarization, a deep extinction minimum around 580 nm can be attributed to the excitation of LSP dipolar resonances polarized transversely to the NW axis.

In this nanopatterning approach, for a given template pattern, the spectral position of the LSP resonance can be simply tailored by changing the evaporation conditions, i.e., metal dose and incidence angle (which affect the nanocluster out-of-plane aspect ratio w/h) or alternatively the metal itself since the LSP resonance depends on the free-electron density n_e through the bulk plasmon frequency:

$$\omega_p = \sqrt{\frac{n_e e^2}{m^* \epsilon_0}}.$$

As an example in Fig. 2d, the characteristic spectral range of TM-polarized LSP resonances of Au and Ag nanoclusters is plotted as a function of the out-of-plane aspect ratio w/h of the NWs. A change of this aspect ratio from 1 to 4, obtained by varying the thickness h of the metallic wire, allows to spectrally shift the plasmon band by about 100 nm both for Au and Ag NWs. A stronger spectral shift of about 200 nm is instead observed when comparing Au and Ag NWs with the same out-of-plane aspect ratio, due to the modified dielectric constant of the material. The tunability of the LSP resonance and the strong field localization effects of the nanoparticle arrays supported on the templates can also be exploited in order to enhance weak nonlinear optical effects such as in second harmonic generation (SHG). As an example, when the tilted arrays of Au nanowires such as those of Fig. 2b are illuminated by a pump beam resonant with the LSP, a strong amplification of the SHG signal is observed in comparison to a reference flat Au film [20].

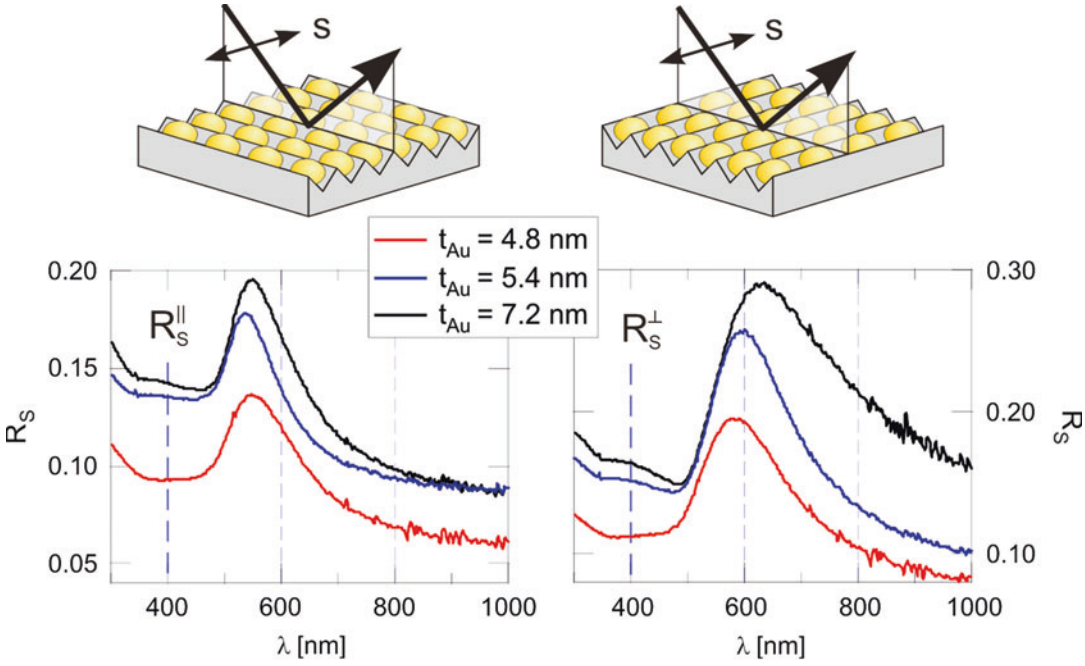
2D Plasmonic Arrays

The plasmonic nanoparticle arrays prepared by glancing angle deposition on self-organized rippled templates show a good degree of morphological control in the direction perpendicular to the ripple ridges, since nucleation takes place in registry with the undulated glass facets, but do not allow to control size selection and lateral ordering of the nanoclusters in the direction parallel to the elongated facets. The self-organized nanopatterning approaches based on ion-beam sputtering so far have succeeded in preparing 2D arrays of nanodots only at surfaces of some selected compound semiconductor [9] but not on the low-cost transparent dielectric substrates of interest in photonic applications. This can be obviated in several ways, thus serving the double purpose of selecting the lateral size of the nanoparticles and their periodicity along both symmetry directions. The simplest strategy is the adoption of self-assembled templates endowed with a two-dimensional periodicity, while a further scheme exploits the thermal dewetting of regular NW arrays to effectively split them along their translationally invariant axis. As the dewetting occurs in a constrained manner, the NWs tend to split in a regular fashion, creating a quasi-periodic arrangement of clusters. In the following, we will discuss the fabrication of 2D arrays by constrained dewetting of nanowires and employing self-assembled monolayers of polymeric microspheres as a deposition template [21].

Ionic Crystal Faceting

As long as the constrained dewetting is concerned, we will address the plasmonic media fabricated exploiting the self-organized faceting of ionic crystals. Ionic crystals like NaCl, LiF, and MgO exhibit the characteristic rock salt crystallographic structure, where (100) surfaces are the most energetically favorable. Starting from a suitably oriented ionic crystal surface, typically with (110) or (111) orientation, either thermodynamic processes (annealing) or out-of-equilibrium procedures (molecular beam homoepitaxy) lead to a surface rearrangement that leaves the lowest-energy crystal face exposed, as schematically shown in Fig. 3a [22, 23]. In the first stages of the process, surface instabilities, in the form of (100)-oriented facets, are generated in random positions on the surface. Going on, these facets typically grow larger in size evolving toward well-defined nanostructures in the form of triangular waves or three-sided pyramids for (110)-cut surfaces and for (111) surfaces, respectively. The nanostructures typically exhibit a remarkably narrow size distribution, thanks to the strong size selection occurring during their development.

The mean nanostructure periodicity Λ in these systems can be tuned in a certain window (typically 20 nm to 70 nm) as a function of the process temperature T, due to the temperature dependence of parameters involved in the faceting process, such as the adatom mobility, providing a simple method to tune the typical nanostructures' size. Characteristic periodicities down to $\Lambda \approx 20$ nm are thus achievable over areas as large as the available crystals' size, typically larger than the cm^2.



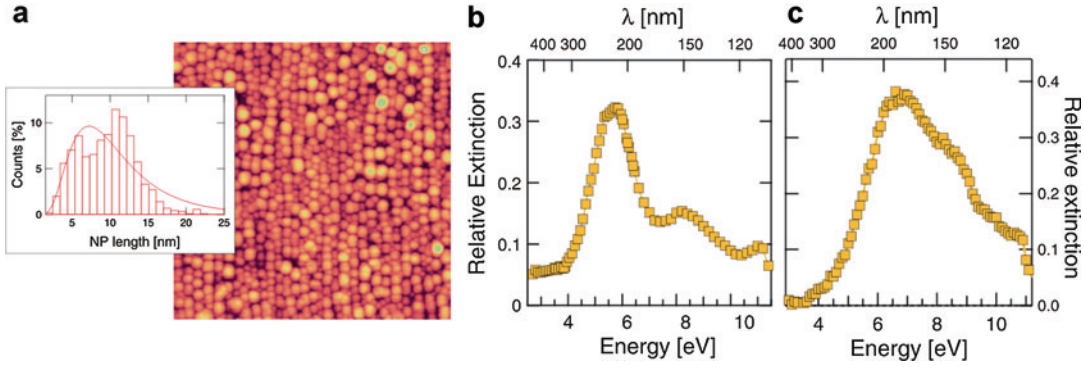
We notice that this periodicity nicely complements, at the lowest size limit, the ones achievable by IBS, so that a broad periodicity range becomes accessible by a suitable combination of both techniques.

An example of coherently oriented triangular wave nanostructures obtained on a LiF (110) surface is shown in the atomic force microscopy image of Fig. 3b. The insulating crystals do not undergo amorphization during the faceting process, thus maintaining their pristine bandgap, a factor particularly appealing for plasmonic application in the UV and DUV, where the formation of defective states in the insulator can negatively affect the LSPR detection. We will discuss in more depth two examples of metal/insulator plasmonic structures based on LiF self-organized substrates, in which the plasmonic counterpart is respectively represented by Au and Al. The general scheme for the realization of the plasmonic systems is represented in Fig. 3c–e. Starting from the bare nanopatterned LiF (110) surface (c), a metal film is deposited at grazing incidence to form NWs (d) that dewet to form regular NP arrays upon annealing (e). We will discuss two cases. The first, featuring Au as the plasmonic metal, will be representative of the plasmonic response tuning achieved by acting upon macroscopic variables. The second, featuring Al, is an example of the way in which the smallest-NP-size limit in self-organized materials can be exploited for pushing the high-energy limit of plasmonics.

In Fig. 3f–i, we report a few atomic force microscopy images representative of Au NPs formed onto a nanopatterned LiF (110) surface. The images (f) to (i) were obtained depositing an equivalent thickness t_{Au} of Au on nanopatterns with periodicity of Λ, respectively: (f) $t_{Au} = 4.5$ nm, $\Lambda = 30$ nm; (g) $t_{Au} = 4.8$ nm, $\Lambda = 40$ nm; (h) $t_{Au} = 5.4$ nm, $\Lambda = 45$ nm; and (i) $t_{Au} = 7.2$ nm, $\Lambda = 55$ nm. The deposition was followed by annealing at 400 °C. The images clearly show the formation of regular arrays of Au agglomerates, aligned along the LiF nanoridges. While the array pitch in the direction transverse to the LiF ridges is dictated by the template periodicity, the regular NP periodicity along the ridges stems from the constrained dewetting of the Au deposited within each individual nanogroove. The morphological bounds given by the LiF ridges restrict the mass transport, resulting in structures that are much more regular with respect to those obtained by unconstrained dewetting. Increasing the Au equivalent thickness from 4.5 to 7.2 nm allows indeed to change the in-plane aspect ratio of the NPs from circular to ellipsoidal. This demonstrates the tunability of a nanoscale property by means of a macroscopic parameter, one of the major advantages of bottom-up methods [24]. The tunable substrate can be then fruitfully employed as support for near-field-coupled optically active materials whose optical response can be tuned via the influence of the LSPR [25].

In the inset of Fig. 3h, we report the size distribution of the NP semiaxis extracted from the corresponding image. The mean semiaxis of the particles is 17 ± 7 nm in the direction along the ripples and 11 ± 3 nm in the transverse direction, well within the quasi-static approximation limit for Au. It must be noted that all the images clearly show a limited degree of disorder, in the NP size, shape, and array arrangement. The mean NP-array pitch is around 40 nm, implying that each NP finds itself within the EM near-field interaction range of the neighboring particle.

The plasmonic response of the arrays of Fig. 3g–i is reported in Fig. 4. There, reflectivity data measured with s-polarized radiation with the incidence plane oriented either parallel (right panel, TE geometry) or perpendicular (left panel, TM geometry) to the LiF ridge orientation are reported, as schematically represented in the top panels. The LSPR gives rise to the prominent peak in the spectra. The arrays of Fig. 3g, having the in-plane aspect ratio closer to 1, exhibit isotropic optical response (red line), meaning the LSPR wavelength does not change between the TE and TM excitation geometries. A macroscopic birefringence of the samples is induced in correspondence of an increased in-plane aspect ratio of the NPs (blue and black lines, corresponding to Fig. 3h and 3i). There, the TE configuration excites the longitudinal plasmon in the particles that redshifts due to the NP elongation.



Plasmonics in Self-Organized Media, Fig. 4 *Top left* (*right*), optical geometry for the reflectivity measurements with the light polarization oriented across (along) the LiF nanoridges. *Bottom*, s-polarized reflectivity spectra for the Au/LiF NP arrays reported in the AFM images of Fig. 3 (**g–i**) (*black*, *blue*, and *red line*, respectively). On the *left* (*right*) are reported spectra obtained with light polarization across (parallel) the LiF ridges

The close proximity of the NPs also implies that the dipolar plasmon mode, the only one clearly observable in this case, is effectively delocalized over neighboring NPs, due to the near-field coupling. Thus, despite the large size dispersion and the remarkable positional disorder of the NPs, the plasmon peaks stay narrow and well defined, and the LSPR becomes largely insensitive to the *single particle* size/shape dispersion. Incidentally, the extremely high achievable areal density of NPs (of the order of 10^{11} NP/cm^2) also makes these substrates ideal for SERS, due to the large number of plasmonic *hot spots*. At variance with the NW case, SERS enhancement is achieved for both TE and TM excitation geometries, being particularly intense in TE configuration, where hot spots are created in between the NPs lying within the same LiF groove.

The capability of bottom-up techniques to fabricate NPs with remarkably small size finds a particularly interesting application in the plasmonics of aluminum. Historically, indeed, the most widely employed plasmonic material is the noble metal Au, due to its low dielectric losses in its LSPR spectral window and, above all, its extremely high resistance to corrosion and to plasma-etching procedures. Ag outperforms all metals in terms of plasmonic performances (field enhancement, LSPR intensity), but its reactivity limits its applicability. For both metals, the achievable LSPR spectral range is however upward limited in energy by the presence of strong interband absorption at 2.5 eV (Au) and just below 4 eV (Ag). Other metals, like the free-electron metal aluminum, do not suffer from such drawbacks, allowing to stretch the achievable LSPR range to the deep ultraviolet (DUV) spectral range.

For Al nanospheres in vacuum, the theoretical LSPR in the quasi-static approximation is found at a wavelength $\lambda \approx 140$ nm. The NP-size constraints for the quasi-static approximation are therefore more stringent than for Au or Ag, implying that LSPR from aluminum particles can quickly redshift and broaden even for relatively small NP size. For Al, the dipolar limit, for which

Plasmonics in Self-Organized Media, Fig. 5 (**a**) AFM image of an Al NP array obtained depositing 2.5 nm equivalent thickness of Al on a nano-faceted LiF (110) surface. (**b**) Extinction spectra of arrays of core/shell Al NPs. (**c**) Extinction spectra of arrays of purely metallic Al NPs

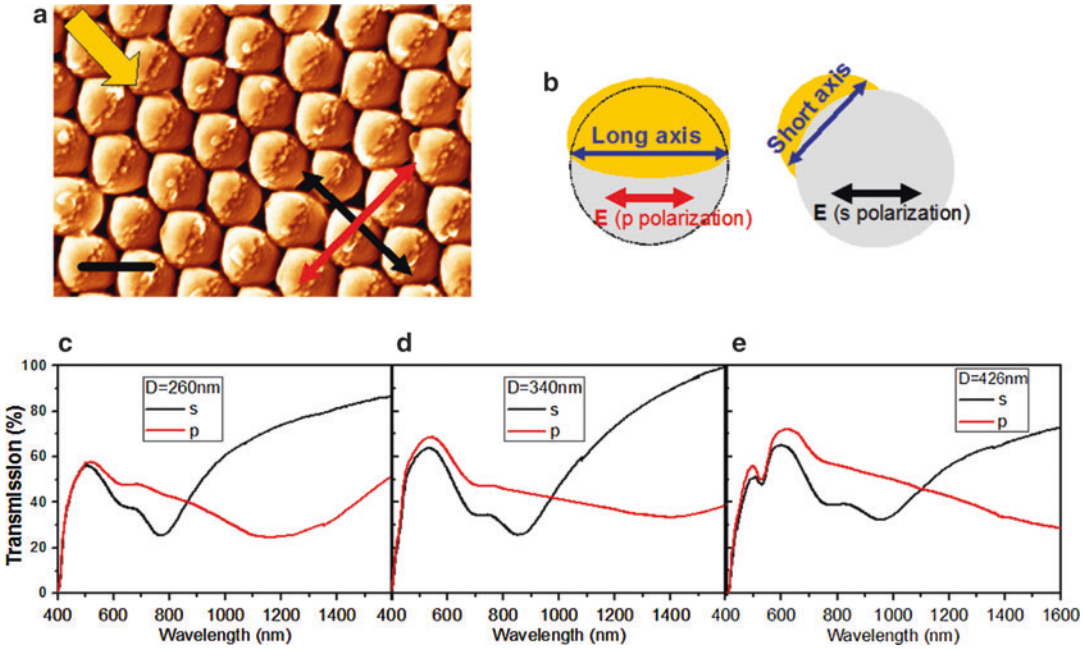
the LSPR has the highest energy and spectral purity, requires a particle diameter below 10 nm. Bottom-up methods can here fruitfully compare with lithography, whose lower size limit for Al is around 40 nm of diameter.

A further issue, as far as Al is concerned, is the quick formation of a few-nm-thick oxide layer on the surface of the NPs upon exposure to the atmosphere. From the plasmonic point of view, the formation of the oxide shell has the effect of locally increasing the environmental dielectric function, hence, redshifting the LSPR. This effect can be fruitfully exploited to achieve Al LSPR in the visible range, yet it is a drawback for DUV plasmonics, and as such might be circumvented only by fabrication and storage under controlled environments, such as UHV.

At its lowest limit, the self-organized faceting of LiF produces nanostructures with characteristic periodicity down to 20 nm. On this template, Al NPs with typical diameter within the dipolar-limit constraints can be thus fabricated. In Fig. 5a, we report an AFM image of an array of Al NPs fabricated on a nanopatterned LiF (110) surface, in a vacuum vessel with a base pressure $p < 1 \times 10^{-8}$ mbar. The Al NPs were realized depositing a 2.5 nm equivalent thickness film on a LiF (110) template with $\Lambda \approx 25$ nm, followed by annealing at 670 K. The exposure of the chip to the atmosphere leads to the formation of a 2 nm thick oxide around their metallic core. In full analogy with Au, the AFM image shows that Al forms ordered arrangements of clusters aligned along the LiF nanoridges. In the case under scrutiny, the mean size of the metallic Al core of the NPs is around 13 ± 5 nm, with an oxide shell thickness of 2 nm, well within the QSA size limit.

In Fig. 5b, polarized light absorption measurements of the Al NP ensemble are reported. Due to the high photon energies involved and in order to avoid spurious absorption by water vapor, the transmission measurements were performed making use of a synchrotron radiation light source and under high-vacuum conditions. The transmission spectra were measured at normal incidence and room temperature, with the electric field polarization oriented transverse to the direction of the LiF ridges (TM configuration). The absorption spectra show a marked extinction peak at energies as high as 5.8 eV. This peak represents the dipolar plasmonic mode of the array, and its high energy clearly demonstrates the successful achievement of a plasmonic response in the DUV spectral range for Al NPs [26].

A further blueshift of the LSPR was achieved by fabricating the NP arrays within the same high-vacuum environment under which their optical characterization is performed, as shown in Fig. 5c. At variance with the previous case, the arrays were not exposed to the atmosphere between the fabrication and the measurements, thus preventing the formation of an oxide shell. Under these conditions, the dipolar LSPR is pushed to 6.8 eV of photon energy ($\approx$ 180 nm),



so far the highest value reported for optical excitation of metallic nanoparticles [27].

Interestingly, the dipolar peak of Al NP arrays stays remarkably sharp, despite the much stronger influence of the NP size on the LSPR energy. This is again a positive consequence of the above-described strong near-field coupling of the NPs, in absence of which significantly broader peaks are to be expected. Unlike the previous case of Au, the dipolar LSPR peak is accompanied by sizable sub-peaks on its high-energy side that originate, as shown by calculations, from higher-order plasmon resonances. Comparing Au and Al, no significant differences in mean NP size or in the degree of disorder of the arrays can be noticed. The high-order resonances are much more pronounced in the Al case simply due to the different dielectric characteristics of the two materials. In Au, the QSA plasmon resonance occurs around 550 nm in the arrays, and the NPs fully satisfy the condition $d \gg \lambda_P$ This leads to negligible high-order plasmonic resonances that are further damped by excitation of interband transitions. In Al, much stronger multipolar modes are expected due to the more stringent QSA limit, and those experience a very weak damping due to the absence of dissipation channels in Al at those energies.

Nanosphere Lithography

A simple alternative for the formation of ordered templates which cover large areas of a glass substrate is to employ self-assembled monolayers of polymeric microspheres [21]. In most approaches, the nanosphere monolayers have been employed as a sacrificial stencil mask for depositing ordered arrays of metal clusters on the underlying substrate by evaporating metal at normal incidence through the gaps of the close-packed hexagonal layer [28]. Here instead we describe an approach in which the nanosphere monolayer is directly employed as the supporting template for the array of plasmonic nanoparticles formed by glancing angle evaporation. In Fig. 6a, a scanning electron microscopy (SEM) micrograph shows a close-packed monolayer of 260 nm polystyrene microspheres self-assembled from a colloidal solution on a glass substrate. Au evaporation at glancing angles above 70° forces nucleation of the metal atoms only on the illuminated portions of the spheres which are shaped as half-moon crescents (brighter regions), while the shadowed portions of the sphere remain uncovered by gold (darker regions). In this way, by changing the diameter of the nanospheres, it is possible to tune both the periodicity of the array and the lateral size of the individual Au nanocrescents. As highlighted in the sketch of Fig. 6b, the nanocrescents are strongly anisotropic with a characteristic short axis, parallel to the evaporation direction, and a long axis running perpendicular to it.

The morphological anisotropy of the nanocrescents is reflected in their optical extinction spectra as highlighted in Fig. 6c. Transmission of polarized light through the Au nanocrescents acquired for light polarization parallel (s) and perpendicular (p) to their short axis (sketch in Fig. 6b) evidences a strongly dichroic behavior. For s polarization (black traces), a sharp extinction minimum is observed around 800 nm due to the excitation of the dipolar LSP resonance along the short crescent axis. On the other hand, for p polarization (red traces), the spectrum is characterized by an extinction minimum which is redshifted toward the IR spectral range, due to the dipolar LSP excitation parallel to the long axis of the structures. Furthermore, an additional feature, ascribed to a higher-energy quadrupolar mode, is observed for both light polarizations around 650 nm. The dipolar LSP resonances of the nanocrescents can be tailored in a simple way by changing the geometrical parameters of the template (nanosphere diameter) or the aspect ratio of the nanocrescents (evaporated metal thickness and deposition angle). In Fig. 6c–e, we compare the optical extinction spectra of the Au nanocrescent arrays when increasing the diameter of the polystyrene spheres from 260 to 340 and 426 nm, at a fixed grazing incidence angle $\theta = 70°$ and for the same Au thickness 10 nm. The general trend, analogously to the data observed for grazing incidence evaporation on the rippled glass template, is that by increasing the width to thickness aspect ratio of the nanocrescents, the dipolar plasmon resonance is

Plasmonics in Self-Organized Media, Fig. 6 (**a**) SEM topograph of a monolayer of 260 nm polystyrene microspheres decorated with Au nanocrescents. Metal deposition of 10 nm is performed at $\theta = 70°$ with the Au beam parallel to the *yellow arrow*. The black scale bar corresponds to 300 nm. (**b**) Sketch of the morphology of the crescents, characterized by a short axis (parallel to the evaporation direction) and by a long axis (perpendicular). (**c**–**e**) The optical transmission spectra are measured for light polarization parallel (p, *red trace*) and perpendicular (s, *black trace*) to the long axis of the crescents for increasing the sphere diameter from 260 to 340 and 426 nm.

redshifted. By increasing the sphere diameter, the short-axis plasmon mode observed in the s-polarized spectra thus shifts from 780 to 880 and 950 nm, respectively; the broad resonance corresponding to the long-axis dipolar plasmon mode observed in the p-polarized spectra instead shifts deep into the NIR spectral range, starting from 1150 to 1400 nm and finally extending beyond 1600 nm. We can thus conclude that the combination of low-cost self-ordered transparent templates with grazing incidence deposition of noble metals is a viable alternative for the controlled production of two-dimensional metal nanocluster arrays with tunable plasmonic response in the VIS-NIR spectral range [29]. The strong field localization effects induced in the presence of the dipolar LSP resonances supported by the nanocrescents are also at the basis of the nonlinear enhancement of the SHG signal which has been recently observed also for such kind of nanostructures [30].

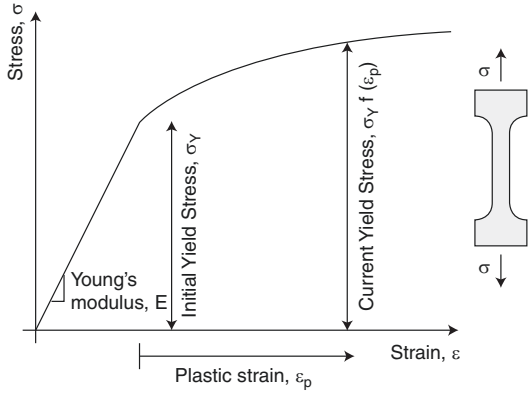
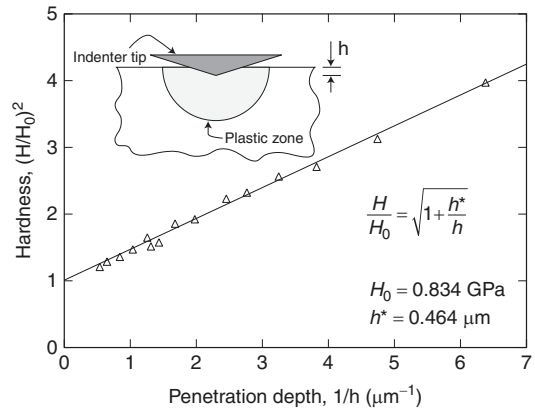
Higher-order plasticity theory; Strain gradient plasticity theory



Definition

Plasticity theory is the mathematical formalism that describes the constitutive model of a material undergoing permanent deformation upon loading. For polycrystalline metals at low temperature and strain rate, the J_2 theory is the simplest adequate model. Classic plasticity theory does not include any explicit length scale, and as a result, the constitutive behavior is independent of the sample dimensions. As the characteristic length of a sample is reduced to the micro (and nano) scale, careful experimental observations clearly reveal the presence of a size effect that is not accounted for by the classical theory. Strain gradient plasticity is a formalism devised to extend plasticity theory to these smaller scales. For most metals, strain gradient plasticity is intended to apply to objects in the range from roughly 100 nm to 100 μm. Above 100 μm, the theory converges with the classical theory and below 100 nm surface and grain boundary effects not accounted for in the theory begin to dominate the behavior. By assuming that the plastic work (or in some theories, the yield strength) depends not only on strain but also on strain gradients (a hypothesis physically grounded in dislocation theory and, in particular, in the notion of geometrically necessary dislocations (GND) associated with incompatibility due to strain gradients), an intrinsic length scale is naturally introduced, allowing the theory to capture size effects. According to most theories, the intrinsic length scale is of the order of the distance between dislocation-clipping obstacles or cellular dislocation structures (typically, submicron to tens of microns). This continuum theory is appropriate for length scales that remain large relative to the distance between dislocations. As the sample length scale is dropped below this level, dislocations must be modeled individually, and discrete dislocations simulations (DSS) are the preferred approach. At even smaller scales, molecular dynamics (MD) becomes the applicable tool. This article presents a brief overview of one of the simplest continuum strain gradient plasticity theories that reduces to the classical J_2 theory when the scale of the deformation becomes large compared to the material length scale. This simple theory captures the essence of the experimental trends observed to date regarding size effects in submicron to micron scale plasticity.



Plastic Flow of Materials and the Emergence of Size Effects at Small Scales

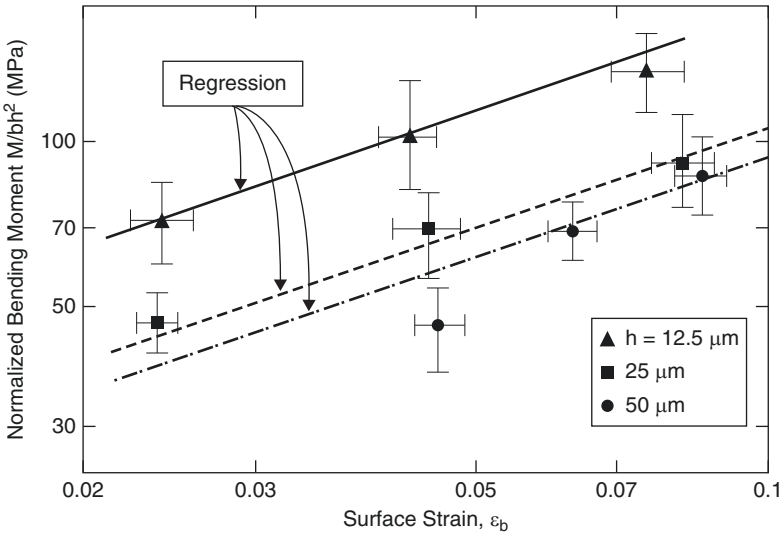
When ductile materials are loaded beyond their elastic limit, permanent deformation will result, involving long-range displacement of atoms (i.e., displacements much larger than the atomic spacing). In metals, this deformation occurs through the motion of dislocations. A typical stress–strain curve for uniaxial tensile loading is depicted in Fig. 1. In polycrystalline samples at low temperatures ($T < 0.5\ T_m$, with T_m the melting point of the material on the absolute scale) and relatively low strain rates ($\dot{\varepsilon} < 10/s$), a simple constitutive equation relating uniaxial stress to uniaxial strain is typically adequate. The flow stress can be defined as:

$$\sigma = \sigma_Y f\left(\varepsilon_p\right) \tag{1}$$

Plasticity Theory at Small Scales, Fig. 1 Typical stress–strain curve for an elastoplastic material in uniaxial tension. Young modulus, initial yield strength, and hardening behavior are illustrated

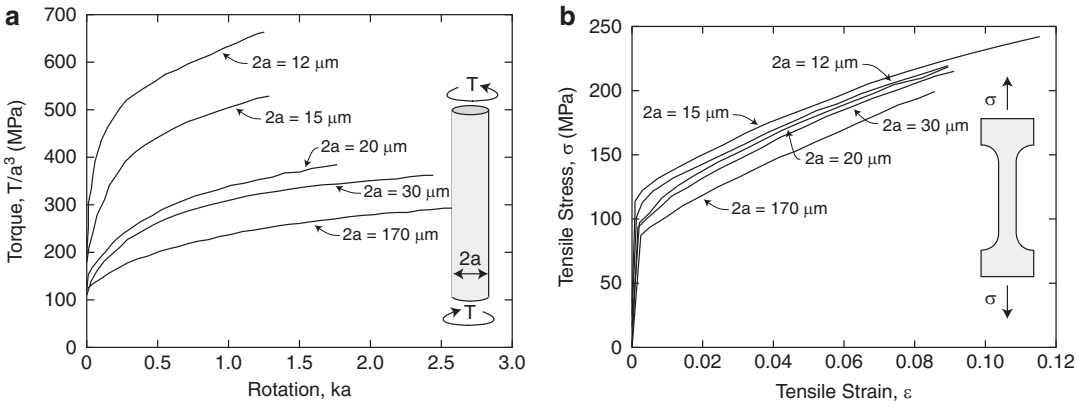
Plasticity Theory at Small Scales, Fig. 2 Dependence of hardness of cold worked polycrystalline copper on the indentation depth. The data fit a linear model almost perfectly (Modified from Ref. [2])

with σ_Y the initial yield strength, ε_p as the uniaxial plastic strain, and $f(\varepsilon_p)$ the hardening function. A power-law expression for f is often adequate. The plastic work per unit volume can be expressed as:



$$U_P(\varepsilon_p) = \int_0^{\varepsilon_p} \sigma d\varepsilon_p = \sigma_Y \int_0^{\varepsilon_p} f(\varepsilon_p) d\varepsilon_p \qquad (2)$$

Generalization of this behavior to general three-dimensional states of stress and strain is the objective of plasticity theories and is reviewed in the next section.



For samples with characteristic dimensions larger than 10–100 μm (depending on the material), yield strength and hardening are independent of sample dimension, rendering (Eq. 1) scale independent. Traditional plasticity theories embody this critical concept. Over the past two decades, though, as technological advances allowed measurements of mechanical properties in smaller and smaller systems, unexpected size effects became evident, typically suggesting that smaller samples are stronger. A large body of experimental literature supports this finding. Here, for the sake of conciseness, three key observations are reviewed. For a more exhaustive list, see [1].

(a) *Materials are harder when indented at smaller depths* [2]. A number of careful nanoindentation experiments were conducted and compiled by Nix and Gao [2], revealing a linear dependence of hardness on indentation depth: $(H/H_0)^2 = 1 + (h^*/h)$, where H is the hardness for a given depth of indentation, H_0 the hardness in the limit of infinite depth, and h^* a characteristic length of order 1 μ that depends on the shape of the indenter, the shear modulus of the material, and H_0 (Fig. 2). The effect becomes negligible as the indentation depth is increased to a depth well beyond h^*.

(b) *Thinner foils are stronger in bending than thicker ones* [3]. Experiments conducted by bending thin nickel foils around a mandrel revealed that thinner samples are stronger and strain harden more than thicker samples. Scaling arguments based on classic plasticity theory predict that the normalized moment, M/bh^2 (with b and h the foil width and thickness, respectively), should depend uniquely on the plastic strain at the foil surface, $\varepsilon_b = h/2R_0$, with R_0 the mandrel radius. For foils of different thickness but identical material, the results should superimpose in the absence of an intrinsic length scale, a conclusion clearly negated by experimental evidence for foil thicknesses between 12.5 and 50 μm (Fig. 3). Importantly, an opposite (albeit less significant) trend is observed in tension, i.e., thinner samples are weaker. Although this conclusion has not been fully rationalized,

Plasticity Theory at Small Scales, Fig. 3 Size effect in bending on thin nickel foils. Substantial strengthening is observed for thinner films, consistently with predictions from SGP theories. Importantly, the same effect is not observed in tension (Reprinted from Ref. [3])

Plasticity Theory at Small Scales, Fig. 4 Experimentally measured size effect in torsion of thin copper wires. (**a**) A significant size effect is reported for pure torsion. (**b**) Nearly no size effect is observed in uniaxial tension, confirming that the strengthening entails the presence of strain gradients (Modified from Ref. [4])

it clearly demonstrates that strengthening at small length scales entails the presence of strain gradients.

(c) *Thinner wires are stronger in torsion than thicker ones* [4]. In this classic experiment by Fleck et al. spearheading intense activity in the development of strain gradient plasticity theories, thin copper wires in diameters ranging from 15 to 170 μ were tested in tension and torsion. Dimensional analysis based on conventional plasticity theory predicts a dependence of the normalized torque, T/a^3 (with a the wire radius), on the plastic shear strain at the surface of the wire, $\gamma_s = \kappa a$, with κ the angle of twist per unit length. Again, data from samples of different radius should superimpose, when plotted in these coordinates. Experimental results clearly contrast with this prediction (Fig. 4a). Once again, tensile tests do not show the same trend (Fig. 4b), confirming that the strengthening is associated with the presence of strain gradients.

A constitutive theory incorporating an explicit dependence of the stress on strain gradients

P

(in addition to strain) could in principle explain all the size effects described above. An elementary theory encompassing this principle is discussed below. As explained above, observations (b) and (c) clearly indicate that the strengthening effect disappears as the gradients are removed. It is important to mention that this conclusion changes as the sample size is reduced to sub-micrometric dimensions: in these regimes, substantial size-dependent strengthening is observed under uniform stresses in single crystals (see entry on "▶ Size-Dependent Plasticity of Single Crystalline Metallic Nanostructures" in this volume).

Conventional Plasticity Theory (J_2 Deformation Theory)

The goal of plasticity theories is the generalization of the one-dimensional model to general, three-dimensional states of stress and strain. For the sake of simplicity, in this article the attention is limited to plastically isotropic materials (i.e., materials for which the flow stress and hardening behavior are independent of the orientation of the coordinate system). It is also assumed that the loading is monotonic and proportional ($\sigma_{ij} = \lambda\sigma^0_{ij}$, with σ^0_{ij} a constant stress state and λ a loading parameter; throughout this article, indicial notation is adopted: when two indices appear in one term of an equation, summation over those indices is implicitly assumed; see [5] for details) at least approximately. This condition justifies the use of deformation theory, a constitutive model relating plastic strain to stress independently of the loading path. For more general loading scenarios (including all cyclic loadings), a more elaborate theory relating increments of stress and plastic strain (flow theory) is required [5, 6].

The yield point in a uniaxial tensile test (Fig. 1) generalizes to a yield surface, defined in a six-dimensional stress space as the envelope of all stress states resulting in elastic deformation: $f(\sigma_{ij}) = 0$. If $f < 0$, the behavior is completely elastic, whereas if $f = 0$ plastic deformation occurs.

Under the common assumption that a hydrostatic state of stress ($\sigma_{ij} = -p\delta_{ij}$) can be neglected in characterizing plastic behavior, f is taken as a function of the deviatoric stress tensor ($s_{ij} = -\sigma_{ij} - (1/3)\sigma_{kk}\delta_{ij}$). For isotropic materials, the most general dependence can be expressed as $f(J_2, J_3) = 0$, where $J_2 = (1/2)s_{ij}s_{ij}$ and $J_3 = (1/3)s_{ij}s_{jk}s_{ki}$ are the second and third invariants of the deviatoric stress tensor. In the J_2 theory of plasticity, the dependence of f on J_3 is ignored, and thus the yield surface can be simply represented as $f(J_2) = 0$. From Eq. 1, we have $J_2 = \sigma_Y^2/3$, with σ_Y the yield strength in uniaxial tension. This is the well-known Von Mises criterion [7]. Similarly, the hardening function f can be chosen as an isotropic function of the plastic strain tensor, ε^p_{ij} (isotropic hardening). In the simplest theories, it is also common to assume that hardening depends only on the second invariant of ε^p_{ij}, with $\varepsilon^p_{kk} = 0$ (plastic incompressibility). Thus, the yielding condition for an isotropic material in a general state of stress can be still written in scalar form as:

$$\sigma_e = \sigma_Y f(\varepsilon_p) \tag{3}$$

with:

$$\sigma_e = \sqrt{\frac{3}{2}s_{ij}s_{ij}} \text{ and } \varepsilon_p = \sqrt{\frac{2}{3}\varepsilon^p_{ij}\varepsilon^p_{ij}} \tag{4}$$

The numerical factors 2/3 and 3/2 are introduced so that the equivalent stress, σ_e, and the plastic strain magnitude, ε_p, coincide with stress and plastic strain for uniaxial tensile loading.

The plastic work per unit volume can then be expressed as:

$$U_p(\varepsilon_p) = \int_0^{\varepsilon_p} \sigma_e d\varepsilon_p = \sigma_Y \int_0^{\varepsilon_p} f(\varepsilon_p) d\varepsilon_p \tag{5}$$

which is identical to Eq. 2, as long as stress and plastic strain are defined as in Eq. 4.

As the Cauchy stress tensor σ_{ij} and the strain tensor ε_{ij} are work-conjugate, the plastic strain tensor can be expressed as:

$$\varepsilon_{ij}^{p} = \frac{\partial U_p}{\partial \sigma_{ij}} = \frac{\partial U_p}{\partial J_2}\frac{\partial J_2}{\partial \sigma_{ij}} = \frac{\partial U_p}{\partial J_2} s_{ij} = \frac{3}{2}\frac{\varepsilon_p}{\sigma_e} s_{ij} \quad (6)$$

where the relation $J_2 = \sigma_e^2/3$ was adopted. The implication is that according to J_2 deformation theory, the plastic strain tensor is codirectional with the stress deviator.

Strain Gradient Plasticity Theories

As mentioned earlier, the theory presented in the previous section does not contain any intrinsic length scale, and is thus incapable of predicting the size effects depicted in Figs. 2, 3, and 4. The most natural way of introducing a length scale in the constitutive model is to assume that the plastic work is a function of an enhanced strain measure that incorporates both the plastic strain, ε_{ij}^{p}, and the plastic strain gradients, $\varepsilon_{ij,k}^{p}$. The deformation version intended for application to proportional or near-proportional loading was introduced by Fleck and Hutchinson [4] and represents the application to plasticity theory of higher-order elasticity theories first introduced by Toupin [8] and Mindlin [9]. The simplest implementation defines the plastic work per unit volume as:

$$U_p(E_p) = \int_0^{E_p} \sigma_e d\varepsilon_p \quad (7)$$

where:

$$E_p = \left((\varepsilon_p)^{\mu} + \left(\ell \varepsilon_p^{*}\right)^{\mu} \right)^{1/\mu} \quad (8)$$

The measure of the plastic strain gradient, ε_p^{*}, can be defined in many different ways [10, 11]. Here the representation $\varepsilon_p^{*} = \sqrt{\varepsilon_{p,i}\,\varepsilon_{p,i}}$, based on the choice made by Zibb and Aifantis [12], is adopted for mathematical convenience. Based on dimensional considerations, the dependence of E_p on ε_p^{*} requires the introduction of an intrinsic length scale ℓ. This definition generates a family of theories, as a function of the parameter μ. The choice $\mu = 1$ appears to give the best agreement with experimental observations (e.g., it predicts the linear dependence of hardness on indentation depth, Fig. 2 [1]), but most formulations have used $\mu = 2$ for mathematical reasons. This section surveys the basic predictions and general trends of such theories. A physical interpretation of the intrinsic length scale ℓ is provided in the following section.

The general trends predicted by this theory are easily elucidated. Imagine a perfectly plastic object ($f(\varepsilon_p) = 1$) of characteristic dimension h, subject to an average plastic strain, ε_p. Dimensionally, the plastic strain gradient is given by $\varepsilon_p^{*} = c\,\varepsilon_p/h$, with $c \approx 1$. According to Eq. 7 and Eq. 8, the plastic work per unit volume can be expressed as:

$$U_p = \sigma_Y(1 + c\ell/h)\varepsilon_p \quad (9)$$

Comparing Eq. 9 to the classic J_2 theory prediction, $U_p = \sigma_Y \varepsilon_p$, one concludes that this strain gradient plasticity theory predicts a yield strength elevation of $1 + c\ell/h$. As the length scale of the object, h, approaches the characteristic materials length scale, ℓ, the yield strength elevation becomes significant.

In general, the potential energy functional can be written as:

$$\Phi = \int_V \left(\frac{1}{2} C_{ijkl} \varepsilon_{ij}^{e} \varepsilon_{kl}^{e} + U_p(E_p) \right) dV - \int_{S_T} \left(T_i u_i + t \varepsilon_p \right) dS \quad (10)$$

with $\varepsilon_{ij}^{e} = \varepsilon_{ij} - \varepsilon_{ij}^{p} = \varepsilon_{ij} - \frac{3}{2}\frac{\varepsilon_p}{\sigma_e} S_{ij}$. Here, C_{ijkl} are the elastic moduli (isotropic here) with $\sigma_{ij} = C_{ijkl}\varepsilon_{kl}^{e}$ and where T_i and $t = \tau_i n_i$ are prescribed on S_T. This class of theories, referred to as higher-order theories, inevitably introduces a new stress measure, τ_i, that is work-conjugate to the plastic strain gradient, i.e., $\tau_i = \partial U_p/\partial \varepsilon_{p,i}$. Specification of an additional boundary condition is required, involving t, ε_p or a combination of both, thus allowing solution to a wider variety of problems, intractable with conventional plasticity theory. For example, passivation layers can be

applied on the surface of a solid, forcing the plastic strain to vanish at the surface. (For more details, see [11].)

The solution to Eq. 10 represents a minimum with respect to u_i and ε_p, assuming a monotonic uniaxial stress–strain curve (Eq. 1). The material length scale, ℓ, must be obtained by fitting one set of experimental data that brings in strain gradient effects.

Application to the torsion problem presented in Fig. 4 illustrates the predictive capability of the theory. Full details of the analysis are presented in Ref. [1]. Elastic strains constitute a very small contribution to the tensile and torsion data in Fig. 4, justifying the adoption of a power-law tensile stress–strain curve of the form $\sigma_e = \sigma_0 \varepsilon_p^N$. The strain measure ε_p must be replaced by E_p for all loading cases involving strain gradients, as explained above. The ensuing plastic work can then be expressed as:

$$U_p\left(E_p = \frac{1}{N+1}\right)\sigma_0 {E_p}^{N+1} \tag{11}$$

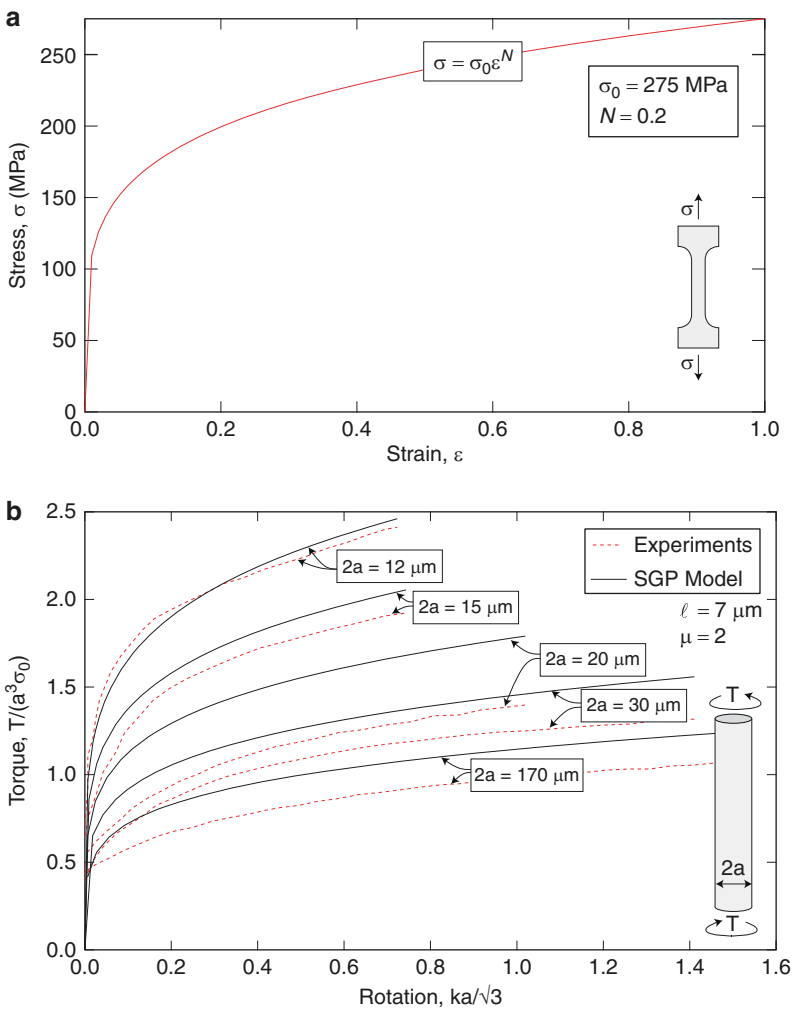
In torsion, with κ as the twist/length, the shear strain varies with distance, r, from the center of the wire according to $\gamma = \kappa r$, such that $\varepsilon_p = \kappa r/\sqrt{3}$ (with $\kappa > 0$), $\varepsilon_p^* = \kappa/\sqrt{3}$, and $E_p = \frac{\kappa}{\sqrt{3}}\left[r^\mu + \ell^\mu\right]^{1/\mu}$. The torque, T, under monotonically increasing κ is:

$$\frac{T}{\sigma_0 a^3} = \left(\frac{\kappa a}{\sqrt{3}}\right)^N \frac{2\pi}{\sqrt{3}} \int_0^{\mathrm{I}} \left[\zeta^\mu + (\ell/a)^\mu\right]^{\frac{N+1}{\mu}} \zeta d\zeta \tag{12}$$

where a is the radius of the wire.

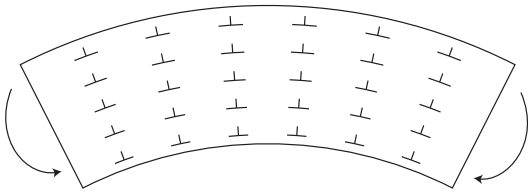
The tensile stress–strain curve in Fig. 5a is plotted with $\sigma_0 = 275MPa$ and $N = 0.2$, giving an approximate fit to the experimental curves in Fig. 4a. With these same values and with the choice $\ell = 7\mu m$, the trends of the experimental torsion data in Fig. 4a are approximately captured by the theoretical curves from Eq. 12 in Fig. 5b. $\mu = 2$ was chosen for all calculations.

Although in this brief survey the attention was limited to the deformation theory version of strain gradient plasticity (both for mathematical convenience and transparency of scaling effects), more general flow theory versions (relating plastic strain increments to the increments of stress in a manner which has intrinsic strain-path dependence) have been developed [13–16]. The constitutive behavior based on flow theory is applicable to any loading history (including cyclic loading, in principle, although none of the existing versions have been vetted for such loadings) and almost always requires a finite element formulation to analyze problems of interest.



In the next section, the intrinsic length scale ℓ will be qualitatively related to basic notions from dislocation theory.

Physical Interpretation of the Intrinsic Material Length Scale



Conventional strain hardening and yield stress elevation are attributed to the interaction of mobile dislocations with relative immobile *statistically stored dislocations* (SSD). The density of SSD, ρ_{SSD}, increases proportionally to the accumulated plastic strain, according to $\varepsilon_p \approx \rho_{\mathrm{SSD}} bd$, with b the burger's vector and d the average distance traveled by a dislocation (defined by the spacing of obstacles). As emphasized by Ashby [17], accumulation of plastic strain gradients requires the introduction of additional dislocations to ensure geometric compatibility (Fig. 6): unlike SSDs, these *geometrically necessary dislocations* (GND) must be arranged in space to accommodate the incompatibility associated with the plastic strain gradient and scale as $\varepsilon_p^* \approx \rho_{\mathrm{GND}} b$. The motion of both families of dislocations contributes to the plastic work. If one assumes that SSD and GND do not strongly interact, a simple additive contribution is appropriate. According to this model, the plastic work can be expressed as:

$$\begin{aligned} U_p &\approx \sigma_Y(\rho_{\mathrm{SSD}} bd + \rho_{\mathrm{GND}} bd) \\ &\approx \sigma_Y\left(\varepsilon_p + d\varepsilon_p^*\right) \end{aligned} \tag{13}$$

Comparison with Eq. 9 immediately reveals $\ell \approx d$. As the average distance traveled by a dislocation is

Plasticity Theory at Small Scales, Fig. 5 (**a**) Power-law stress–strain curve in pure tension (extrapolated at large strains), giving an approximate fit to the data in Fig. 4a. (**b**) Strain gradient plasticity prediction (Eq. 12, with $\ell = 7\mu$m, $\mu = 2$) for the torsion data of Fig. 4b, based on the stress–strain law in (**a**)

Plasticity Theory at Small Scales, Fig. 6 Cartoon illustrating the formation of geometrically necessary dislocations (GND) in pure bending

comparable to the average spacing between obstacles, this simple analysis suggests that usually $\ell \approx 1 - 20\mu$m, consistent with experimental results and modeling prediction (Fig. 5).

Modeling Plasticity of Very Small Samples

The strain gradient plasticity theory described in this entry is still a continuum theory (i.e., it does not model individual dislocations). As the size of the sample is reduced to the point that only a handful of dislocations exist across the characteristic length scale, this fundamental assumption breaks down. In this case, numerical approaches which explicitly model dislocation interactions are required. Molecular dynamics (MD) is a natural modeling strategy, but its application is limited to relatively small samples and extremely high strain rates. Discrete dislocations simulations (DDS) present an approach that bridges the two

theories [18–20]. These models generally utilize a FE continuum framework to solve for stresses, strains, and displacements, and treat dislocations as singularities, which both affect and are affected by the global strain and stress fields. Dislocations motion is governed by the Peach–Koehler equation and standard dislocation–dislocation interaction laws. Dislocation sources like Frank–Read and single-arm sources are introduced at statistically random locations. These models (both in two-dimensional and three-dimensional) are computationally more efficient than full-scale MD simulations, but have not yet fully succeeded in duplicating key aspects of the experimentally measured size effects in plasticity [21].

Open Issues, Future Developments, and Final Considerations

One reason why strain gradient plasticity theories have not been widely embraced is the ambiguity surrounding the definition of the intrinsic length scale. Although the scaling arguments presented in this article ascribe its physical basis and define its order of magnitude, a quantitative physical model allowing expression of ℓ as a function of measurable materials parameters is still lacking. Attempts to define such a model based on dislocation theory are still ongoing. At the same time, efforts are still underway in developing a fully consistent flow theory version of strain gradient plasticity and in implementing such theories in finite element codes.

Metal plating

Definition

Plating is a film coating process on a substrate through either chemical or electrochemical reactions in the solution. In chemical plating, several chemical reactions occur in the plating solution to deposit metal on a substrate. In electrochemical plating, known as electroplating, metal ionic species in the plating solution react with electrons supplied by an external electrical power supply to deposit metal onto a substrate.

Overview

Plating is used to change the surface properties of a substrate, for example, hardness, wear resistance, friction, adhesion, corrosion, and electrical or thermal conductivity, and also to decorate objects. Films are deposited by either chemical or electrochemical reactions which are distinguished by whether an outside source of electric current is involved in the reaction. Chemical plating is a non-galvanic plating method where crystallization occurs on the substrate, providing films with no upper limit in thickness. The electroless plating deposits a metal film on nonconductor such as synthetic plastics, which already makes this process important in the printed circuit industry. The list of synthetic plastics to be plated is growing because of the importance of the process for a variety of industrial applications. Electrochemical plating or electroplating is referred to as electrodeposition and is a fairly simple process. A negative charge is placed on the object that is electroplated, which is called cathode and a positive charge is placed on the anode. Both the cathode and the anode are immersed in an electrolyte solution containing the charged particles of dissolved metal that deposit metal on the substrate by passing current through an external circuit between the cathode and the anode. The surface of substrate must be cleaned thoroughly. Recessed areas plate less than other external surface due to the difference of proximity to plating source, often resulting in making a scratch more prominent, rather than being smoothened by the plating process. The thickness of the electroplated films is generally controlled by adjusting time and current in the electroplating process, enabling to control film thickness with nanometer scale accuracy. Three-dimensional nanostructures are produced by the electroforming process in the nanoscale templates such as a metal nanowire array grown through nanopores formed in a polymer matrix. The electroplating process is called anodizing when the object is anodic and an oxide film is formed on the surface.

Basic Methodology

Chemical Plating

Chemical plating is classified into (1) deposition by homogeneous reaction of a metal ion with a reducing agent in solution and (2) deposition by heterogeneous reaction on the substrate specified for the autocatalytic reaction [1].

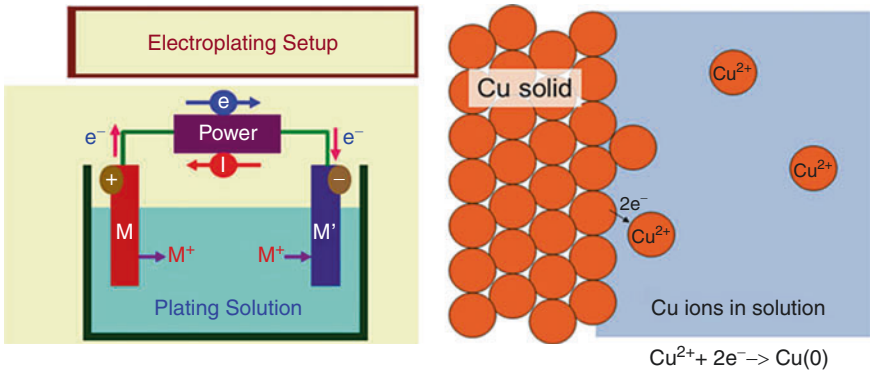
1. Homogeneous reduction reaction takes place in a solution containing a metal ion to be

deposited and a reducing agent that reacts with the metal ion and crystallizes to grow a metal film on the substrate. One old art is silver mirrors that are deposited on glass or synthetic plastics. This process involves a solution of silver salt (e.g., $AgNO_3$) as one solution and a reducing agent (e.g., sucrose) dissolved in a second solution. The two solutions are mixed before using, or sprayed from a two-nozzle gun on the substrate to be silvered. This method is also used to deposit Cu, Ni, Au, and PbS.

2. Autocatalytic chemical reaction takes place only on catalytic surfaces immersed in the solution where a chemical reducing agent provides electrons for the reaction $M^{n+} + ne = M_0$ with no use of external electric power source. This inhomogeneous process requires that the deposited metal layer itself must be catalytic to continue plating on the growing layer and enables continuous deposition of a metal or alloy simply by immersion in the plating solution. In that regard, at least theoretically there is no upper limit to the film thickness to grow. Compared to electroplating, the deposition process has advantages of simplicity and essentially less porous films than electroplating. There are two critical steps before plating. In the first step a reducing agent (e.g., $SnCl_2$) is adsorbed on the plastic surface (sensitization step), which in the following step reduces $PdCl_2$ in a dilute solution to Pd deposited on the surface at discrete sites [nucleation step]. This method deposits Ni, Co, Pd, Pt, Cu, Au, Ag, and some alloys containing P or B in the metals. Among them, Ni is the most important film that is deposited from hypophosphite baths, formulated as

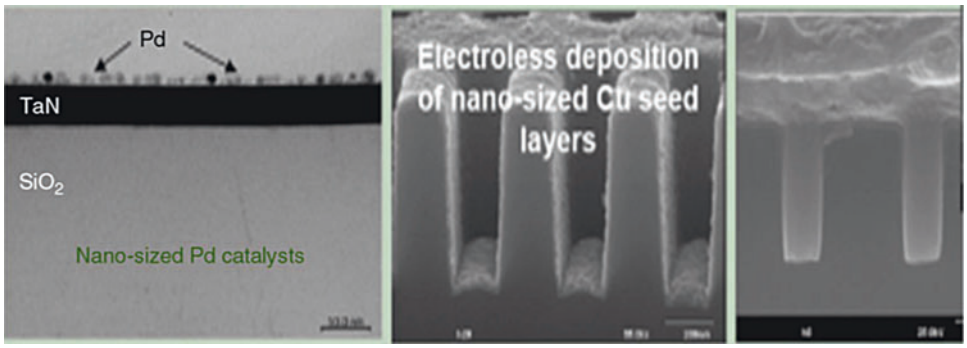
$$2H_2PO_2^- + 2H_2O + Ni^{2+} = Ni + H_2 + 4H^+ + 2HPO_3^{-2} \quad (1)$$

Electroplating



Electroplating involves passing an electric current between two electrodes immersed in an electrolyte. When current enters or leaves an electrode, a chemical change takes place at the interface between electrode and electrolyte. For example, a metal cation in the electrolyte receives electron at the interface to deposit as a metal layer. An electrolyte is an ionic solution – solution of acids, bases, salts, fused salts, or some gases – where ions are moved by the electrical potential gradient applied between two electrodes. Ions in the solution are usually hydrated or complexed. Metals in the solution are either in the cationic or in the anionic form. In the latter, the metal is complexed with a ligand or coordinating agent [e.g., $Zn(CN)_2{}^{-4}$]. The conductivity of electrolyte is far lower than metal electrode, for example, the conductivity of 1 % solution of NaCl is about 5×10^7 times lower than that of copper. The electrode where reduction takes place is the cathode and the electrode where oxidation takes place is the anode. In the electrolyte cell where electroplating takes place, the cathode is the negative electrode and the anode is the positive electrode (Fig. 1).

In electroplating, the quantity of electricity that passes through the electrolyte cell measures the amount of chemical change. Theoretically if the chemical change is solely the deposition of metal and no current leakage occurs, the mass of metal deposit can be exactly calculated as follows:



$$G = Iet = 96,500 \quad (2)$$

where G is grams of metal, I the current (A), e is the electrochemical equivalent weight (gram) which is atomic weight divided by the valance charge, and t is the time (second). In most cases, the electroplated metal weight is less than predicted by Eq. 2 because of additional reactions involved, such as the co-deposition of hydrogen with metal at the cathode and the evolution of oxygen at the anode which is dissolving in electrolyte. Current efficiency in electroplating varies widely and depends on such factors as electrolyte bath composition, temperature, agitation, pH, and current density.

Anodization is the electroplating process that takes place at anode where the surface metal is converted to a form of its oxide while hydrogen evolves at the cathode. The principal application is to Al for corrosion resistance, coloring, and electrical insulation. Other metals to be anodized

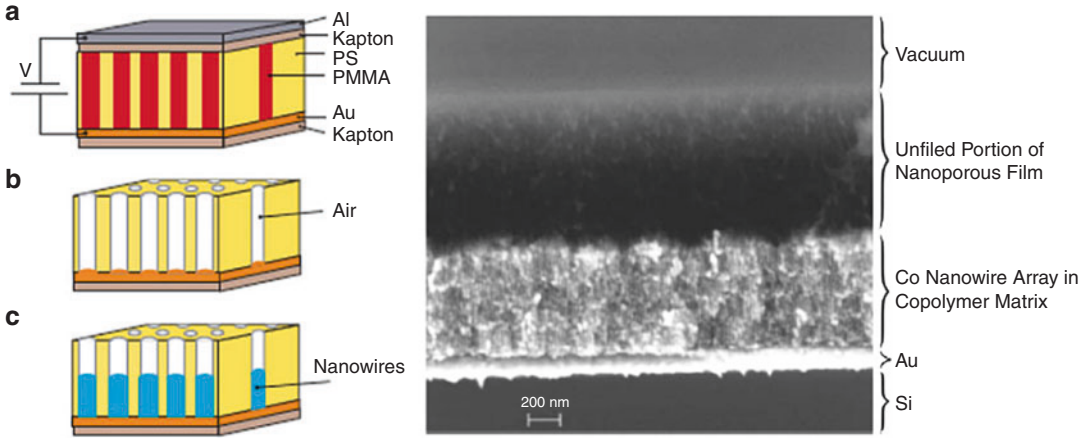
Key Research Findings in Nanotechnology



Copper metallization in damascene process. In the modern microprocessors, the wiring material changes from aluminum to copper to accommodate a large number of transistors interconnected in the restricted space. Copper electroplating takes place to fill the trenches and holes in the dielectric layers with copper in the damascene process for wiring (Fig. 2).

Porous anodic alumina [3]. Porous alumina layers are produced by the anodization of aluminum in an acidic electrolyte. The pores are circular or arranged in a close-packed array of square, triangle, and hexagonal opening. This process starts with an artificial laying-out of the initiating indentation sites in the arrays patterned by photolithography and from which corresponding shapes are produced as anodization proceeds in an acidic electrolyte. The pore size, pore spacing, and film thickness are all controllable (Fig. 3).

Electroforming through lithographic masks. Combining electroplating with novel lithography techniques becomes a powerful electroforming technique in the fabrication of microstructures or nanostructures. A representative example is the LIGA process where X-ray lithography creates high aspect ratio structures of photoresist mask, which allows for the fabrication of three-dimensional MEMS devices of a few hundred microns in height [4]. Using nanolithography

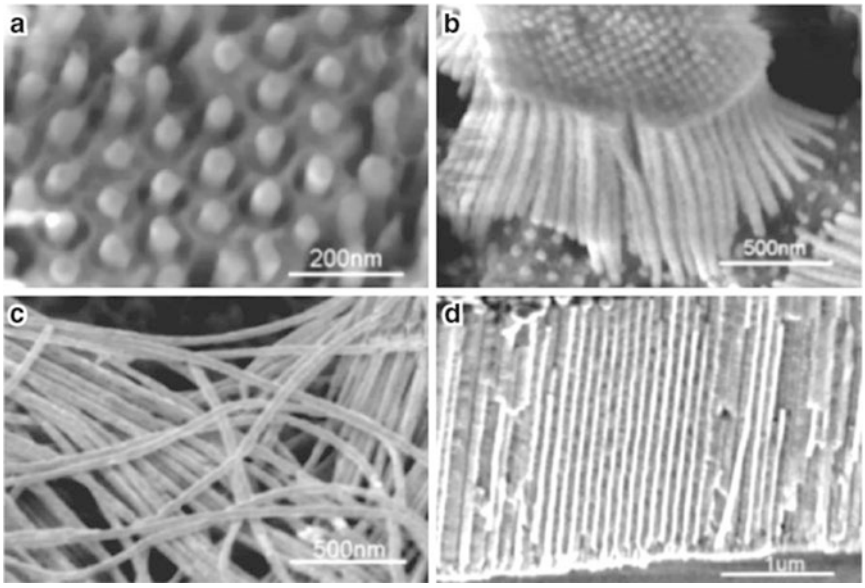
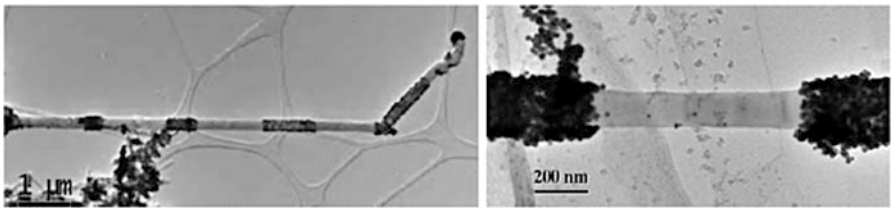
The growth of the nanowires is terminated before the template is completely filled



techniques produces templates including nanoscale features that can produce high-fidelity replicas.

Electrodeposited nanowires. Nanowire arrays are produced by electroplating in diblock copolymer template [5] or porous anodic alumina template [6] (Figs. 4, 5, and 6).



Selective plating on silicon nanowire. P-n junctions are grown in situ in semiconductor nanowires for various electronic or optical applications. Au is selectively coated onto the n-type segments of silicon nanowire p-n junction which allows to measure the position of p-n junction and segment length [7].

Future Directions for Research

Plating is less expensive than any other thin and thick film deposition methods. Because of the economical advantage continuous effort will be made to produce plated films with desirable

Plating, Fig. 5 Nanowires grown in porous anodic alumina template [6]. mechanical, physical, chemical, and optical properties that meet particular application requirements. Electroplating is simple to control the deposition rate by controlling the current. In that regard, electroplating is a superior technique for the production of nanoscaled structures made of crystalline pure metals, alloys as well as nanocomposites. Electroplating of metal in templates enables the fabrication of miniaturized structures from submillimeter to nanometer-scaled dimensions with extremely high precision replicas. Research will be continued to provide various three-dimensional nanostructures (e.g., nanowires and nanofilm) in conjunction with the progress of innovative nanotemplate fabrication techniques.

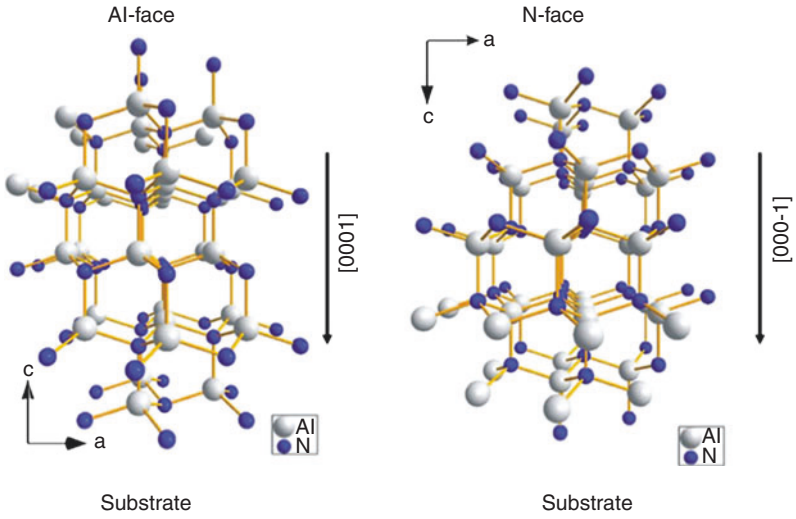
Pyroelectricity; Spontaneous polarization

Definition of Crystal Polarization

According to the number of rotational axes and reflection planes, crystals can be divided into 32 classes (point groups). Twenty of these classes exhibit a non-centrosymmetric structure leading to a direct piezoelectric behavior, i.e., an electric field is generated when the crystal is submitted to mechanical force and vice versa. Of these 20 piezoelectric classes, 10 are additionally polar, which implies that they possess a spontaneous polarization, having a dipole in their unit cell. These crystals are called pyroelectric. If this dipole can be reversed by an external electric field, the material is also called ferroelectric. Any dielectric material develops a dielectric polarization (electrostatics) when an electric field is applied, but only substances exhibiting a natural charge separation in the absence of external electric fields are polar. This material property is determined solely by its crystal structure.

- Piezoelectric crystal classes: 1, 2, m, 222, mm^2, 4, −4, 422, 4 mm, −42 m, 3, 32, 3 m, 6, −6, 622, 6 mm, −62 m, 23, −43 m
- Pyroelectric crystal classes: 1, 2, m, mm^2, 3, 3 m, 4, 4 mm, 6, 6 mm



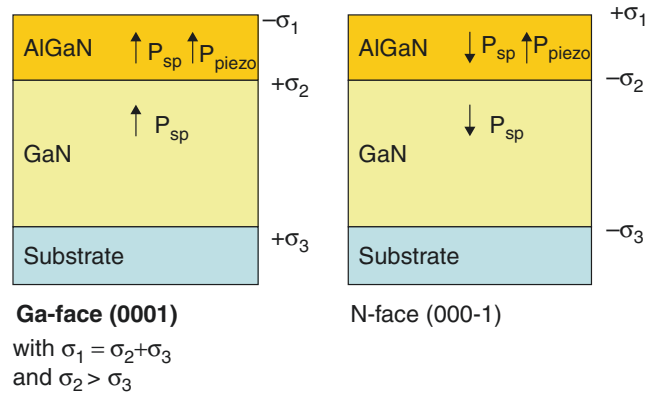
Examples for materials exhibiting both, a spontaneous and a piezoelectric polarization, are given in Table 1. In most cases, two or more polytypes exist, meaning that the same composition can occur in different crystal structures. Here, only the polar crystal structure (i.e., wurtzite or hexagonal) is given, the corresponding polytype is indicated in case of SiC. The polar properties of ternary and quaternary alloys such as AlGaN, AlInN, and AlInGaN can be interpolated from the involved binary composites. However, this interpolation is not strictly linear but exhibits a parabolic component.

Origin of the Spontaneous Polarization

Crystallographic polarity along certain crystal axes can occur, when two different sequences of the atomic layering in the two opposing directions can be observed. For binary A–B compounds with wurtzite structure, the sequence of the atomic layers of the constituents A and B is reversed along the (0001) and (000–1) directions.

Polarization-Induced Effects in Heterostructures, Table 1 Overview of III-V nitride, silicon carbide, and II-IV oxide materials with wurtzite structure exhibiting both spontaneous and piezoelectric polarization. Values are given in (C/m^2) for the main polar axis

Material	Crystal class	Spontaneous polarization P_{SP} (C/m^2)	Piezoelectric polarization P_{PE} (C/m^2)		
			e_{15}	e_{31}	e_{33}
AlN [1, 2]	$P6_3mc$	−0.081	−0.48	−0.60	1.46
GaN [1, 2]	$P6_3mc$	−0.029	−0.3	−0.49	0.73
InN [1, 2]	$P6_3mc$	−0.032		−0.57	0.97
2H-SiC [3]	$P6_3mc$	−0.007	0.08	−0.10	0.20
ZnO [4]	$P6_3mc$	−0.0503	−0.489	−0.664	1.243
BeO [4]	$P6_3mc$	−0.0363	−0.275	−0.436	0.804
MgO [4]	$P6_3mc$	−0.134	−0.428	−0.763	2.004
CdO [4]	$P6_3mc$	−0.107	−0.831	−0.790	1.584



Polarization-Induced Effects in Heterostructures, Fig. 1 Crystal structure of AlN illustrating the polarity along the main crystal axis in wurtzite binary A-B compounds [5]

The corresponding <0001> and <000–1> faces are the A-face and B-face, respectively (Fig. 1). Please note that they also differ in their chemical behavior.

Each A-B (cation-anion) bond has a dipole character; its strength depends on bond length and charge distribution of the binding electron due to the different electron negativities of cation and anion. In case of wurtzite crystals, the tetrahedral binding structure consists of one vertical and three in-plane cation-anion bonds between an atom and its nearest neighbors. In case of an ideal crystal, the dipoles which correspond to these four bonds compensate each other. However, in an ideal wurtzite crystal, the distance to the second nearest neighbor is by 13 % shorter along the polar axis than the distance to the second nearest neighbors within the (basal) plane. This is not the case in cubic crystals. This in fact finally leads to an electric field (i.e., electric polarization) in the direction of the polar axis of the crystal [6]. Real crystals can still deviate from the ideal structure in bond lengths and angles, leading to an additional lattice distortion which in return changes the values of the spontaneous polarization.

Charge Carrier Accumulation at Heterostructure Interfaces

Typical applications of polar semiconductors require the epitaxial growth of heterostructures,

Polarization-Induced Effects in Heterostructures, Fig. 2 Scheme of a simple AlGaN/GaN heterostructure with its spontaneous and piezoelectric polarization; the GaN layer is assumed to be unstrained

i.e., a layer stacking with multiple layers of polar materials exhibiting a similar crystal structure is grown on a (hetero-) substrate. A multitude of possibilities exist to stack various layers of binary, ternary, or even quaternary compounds within one material class (e.g., combinations of AlN, InN, GaN, AlInN, InGaN, AlGaN, and AlGaInN layers) or even in combining different classes (ZnO/GaN, GaAs/GaN, AlN/SiC). Each single layer then possesses an individual internal electrical field which is the result of its polarization. Since pseudomorphically grown layers are strained in most cases, the total polarization of each layer is the sum of its spontaneous polarization due to the pure material property and of its piezoelectric-induced polarization due to strain. Such layer stackings can be achieved in both polarization directions (i.e., A- or B-face), which defines the direction of the internal electric field. In all cases, the polarization exhibits an abrupt change in its value or even a change in its sign (positive or negative) at the layer interfaces, resulting in a net sheet charge. This effect is commonly used intentionally in devices based on polar materials. To simplify matters, a detailed explanation will be given for one material combination only.

A commonly used structure (compare section Application) is based on thin $Al_xGa_{1-x}N$ layers grown on thick GaN buffer layers (Fig. 2). Without external electric fields, the total polarization of a GaN or AlGaN layer is the sum of the spontaneous polarization $\mathbf{P}_{SP}$ of the ideal crystal lattice, and of the strain-induced or piezoelectric polarization $\mathbf{P}_{PE}$. The piezoelectric polarization can be calculated from the deviation of the real crystal from its ideal structure. In case of epitaxial grown layers, a biaxial strain occurs due to the alignment of the lateral lattice constant of one layer to the layer beneath. Then, the lateral strain $\varepsilon_x, \varepsilon_y$ is calculated from the difference between the as-grown lattice constant a_{real} and a_0 (depending on the composition ratio x):

$$\varepsilon_x = \varepsilon_y = \frac{a_{real} - a_0(x)}{a_0(x)} \tag{1}$$

The corresponding vertical strain ε_z represents the deviation of the vertical lattice constant c and can be calculated using the elastic constants C_{11} and C_{33}:

$$\varepsilon_z = \frac{c_{real} - c_0(x)}{c_0(x)} = -2\frac{C_{13}}{C_{33}}\left(\frac{a_{real} - a_0(x)}{a_0(x)}\right) \tag{2}$$

The piezoelectric polarization is then given by:

$$P_{PE} = e_{33}(x) \cdot \varepsilon_z + e_{31}(x) \cdot (\varepsilon_x + \varepsilon_y) \tag{3}$$

$$P_{PE} = 2 \cdot \frac{a_{real} - a_0}{a_0} \cdot \left(e_{31} - e_{33} \cdot \frac{C_{13}}{C_{33}}\right) \tag{4}$$

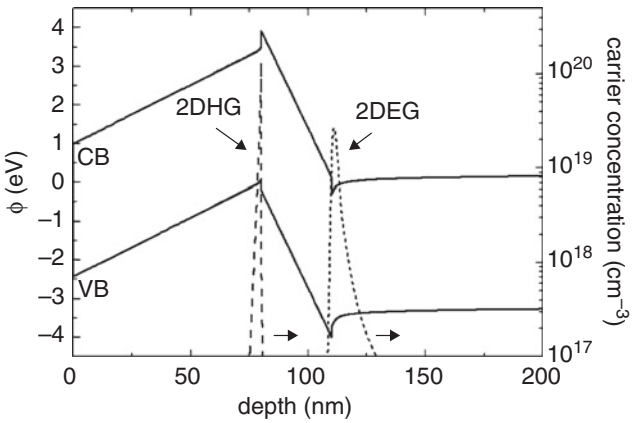
The piezoelectric polarization is negative for tensile and positive for compressive strained AlGaN barriers over the whole range of

compositions. Since the spontaneous polarization for group III-nitrides is negative, it always points toward the substrate in case of metal-face heterostructures. As a consequence, the alignment of the piezoelectric and spontaneous polarization is parallel in the case of tensile strain, and antiparallel in the case of compressively strained top layers. The piezoelectric, as well as the spontaneous polarization, changes its sign, when N-face structures are considered instead. The polarization field abruptly changes at all heterostructure interfaces resulting in a net sheet charge density σ, which is defined by the polarization difference ΔP of the adjacent layers:

$$\begin{aligned}\sigma(P_{SP}+P_{PE}) &= \Delta P \\ &= P_{SP}(A1GaN) - P_{SP}(GaN) \\ &\quad + P_{PE}(A1GaN)\end{aligned} \quad (5)$$

If this sheet charge density is positive as it is the case of the above-considered heterostructure, it will be compensated by free electrons. This results in a two-dimensional accumulation of electrons at the interface, which is also called two-dimensional electron gas (2DEG). Its sheet charge density can be calculated according to [5]:

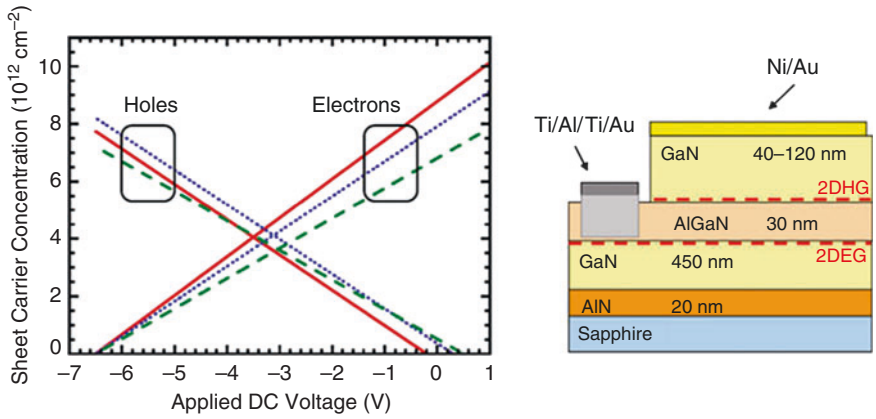
$$\begin{aligned}n_s(x) = &\frac{\sigma(x)}{e} - \frac{\varepsilon_0 E_F}{e^2}\left(\frac{\varepsilon_{AlGaN}(x)+\varepsilon_{GaN}}{d_{AlGaN}}\frac{\varepsilon_{GaN}}{d_{GaN}}\right) \\ &- \frac{\varepsilon_0\varepsilon_{AlGaN}(x)}{e^2\cdot d_{AlGaN}}\left(e\phi_{AlGaN}(x) + E_F(x) - \Delta E^C_{AlGaN}(x)\right)\end{aligned} \quad (6)$$



with the Fermi energy E_F of GaN, the relative dielectric constants ε_{GaN} and ε_{AlGaN}, the Schottky barrier height eϕ at the surface and the conduction band offset ΔE_c at the interface. Vice versa, a negative sheet charge density will cause an accumulation of holes at the interface. As the Schottky barrier height at the surface directly influences the sheet carrier density, the choice of the contact material as well as applied external voltages at the surface leads to an increase or depletion of the sheet carrier density. This phenomenon is the typically used effect in applications based on the field transistor configuration (see section "Application").

In case of heterostructures containing more than one interface, electron and hole accumulations can occur at the respective interface, resulting in a coexistence of 2D electron and hole gases within the same structure. In Fig. 3, the simulation results of a triple heterostructure GaN/AlGaN/GaN is displayed, showing the course of the conduction band and a slightly asymmetric charge distribution at the interfaces.

This coexistence recently has been proven by electro-reflectance measurements [7]. Shifting the net internal electric field by applying an external voltage leads to a corresponding decrease or increase of the electron and hole density (Fig. 4).



Application

The electron transport properties at heterostructure interfaces in polar semiconductors provide a new field of pyroelectronics and pyrosensors. Thus, the pyroelectric character of

Polarization-Induced Effects in Heterostructures, Fig. 3 Simulation results for a GaN/AlGaN/GaN heterostructure. Displayed are valence band (*VB*), conduction band (*CB*), and the resulting 2D hole gas (2DHG) and 2D electron gas (2DEG) at the interfaces

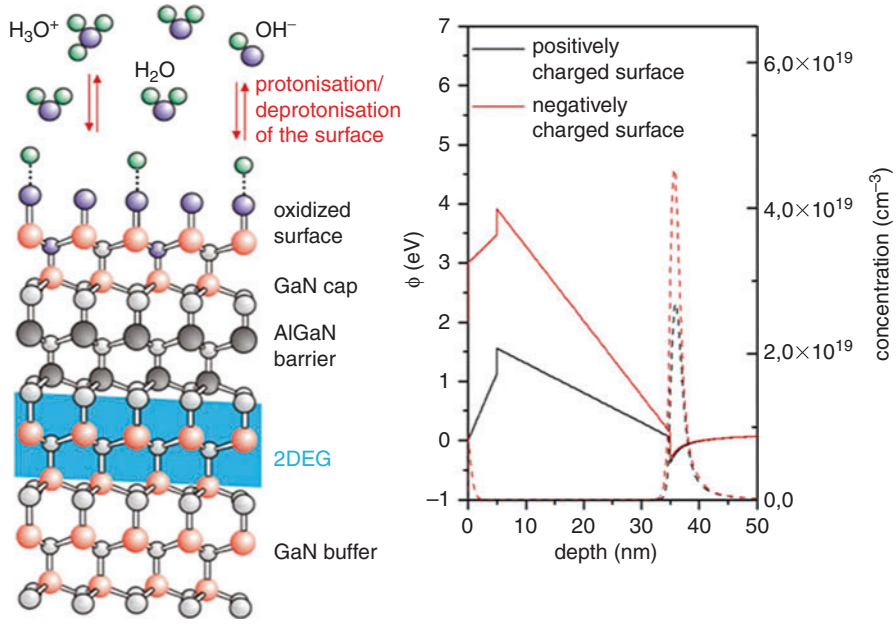
such semiconductors yields a novel degree of freedom in designing and tailoring devices for modern micro- and nanoelectronic as well as for micro- and nanomechanical applications. The interface charges, which are induced by the above-described spontaneous and piezoelectric polarization, respond very sensitively to changes of the overall electric field caused by mechanical strain, the adsorption of ions, wetting by polar liquids, or exposure to gases.

High Electron Mobility Transistors (HEMTs)

Generally, devices for high currents and high frequencies require a material with high charge carrier mobilities and high saturation velocities in the electron channel. The v-E characteristic defines the electron mobility μ_n, as the slope of the v-E characteristic at low-electric field, and the saturated velocity v_{sat} as the constant, field independent value of the electron velocity at high electric field. Compared to Ga(In)As as a classic semiconductor for rf applications, electron and hole low field mobilities in GaN are three times smaller, which results in lower maximum operation frequencies. GaN, however, has a larger saturation electron velocity. The fairly good electron mobility and the outstanding high saturation velocity in connection with the high thermal stability and the large band gap of GaN makes AlGaN/GaN-based transistors promising candidates for microwave power amplification (frequencies $>$ 1 GHz, power $>$ 1 W/mm). For this application, high electron mobility transistors (HEMTs) are the most attractive kind of transistors. Originally, HEMTs were developed based on AlGaInAs/(In)GaAs heterostructures on GaAs or InP substrates [8]. These devices are also known as MODFETs (Modulation-doped FETs), HFETs (Heterojunction FETs), TEGFETs (Two-dimensional electron gas FETs), or SDHT (Selectively doped heterostructure transistors). While in GaAs-based HEMTs, the 2DEG is formed at the heterostructure interface as a consequence of strong asymmetrically doping, in GaN-based HEMTs, the interface accumulation is due to polarization charges as described before (Figs. 2 and 3) without intentionally doping. Electron confined in those channels might have a substantially higher mobility due to their separation from their heavily doped source region, and their accumulation in a low-doped region, where impurity scattering has no dominant influence. The mobility in heterostructures increases with Al content [9]. Due to the increased polarization gradient (caused by higher spontaneous polarization as well as higher strain-induced piezoelectric polarization), the 2DEG sheet charge density increases. The mobility peaks for an Al-mole fraction, which is dependent on the barrier thickness and decreases for both lower and higher mole fractions.

Polarization-Induced Effects in Heterostructures, Table 2 Comparison of electron mobilities and velocities in AlGaAs/GaAs and AlGaN/GaN heterostructures and bulk material

	μ_{bulk} (cm^2/Vs)	μ_{bulk} (cm^2/Vs)	v_{peak} (cm/s)	v_{sat} (cm/s)	Ref.
AlGaAs/GaAs	10,000 (10 K)	10,00,000 (10 K)	5×10^7 (77 K)		[11]
AlGaN/GaN	2070 (115 K)	75,000 (77 K)	3×10^7 (300 K)	2.5×10^7 (300 K)	[12, 14]



Polarization-Induced Effects in Heterostructures, Fig. 5 Basic structure of an AlGaN/GaN HEMT

Typically, room temperature mobility in the range of $\mu_n \sim 1000–1500$ cm^2/Vs is obtained for device applications. This mobility is affected by several scattering mechanisms. Limiting mechanisms in the AlGaN/GaN heterostructures are scattering at (1) threading dislocations, (2) due to the interface roughness between AlGaN and GaN, and (3) due to the random distribution of Al and Ga atoms within the alloy. The electron enhancement in AlGaN/GaN heterostructures was first reported in 1991 [10]. It was attributed to the two-dimensional character of the electrons, which has been demonstrated by mobility enhancement at lower temperatures as well as Shubnikov-de-Haas oscillations. Now, sheet concentrations of 10^{13} cm^{-2} or higher are achievable close to the interface, well in excess of those achievable in other III–V material systems [5]. In addition, the piezoelectric polarization of the strained top layer is more than five times larger as compared to AlGaAs/GaAs structures, leading to a significant increase of the sheet carrier concentration at the interface (Table 2).

The application of AlGaN/GaN HEMTs for microwave applications was proposed in 1994 [15]. Such HEMTs can be used in power as well as small-signal applications. In the first case, the device has to withstand high drain source voltages and drain currents. Here, the large breakdown voltage, the achievable high channel conductivity, and the good thermal properties of GaN are advantageous for the devices. A schematic cross section is given in Fig. 5. Typically, AlGaN/GaN HEMT devices are established on sapphire or SiC substrates, seldom also on silicon substrates [16]. First, thick GaN films are grown for reduction of growth defects and device isolation. The 2DEG channel is formed between this GaN buffer and an AlGaN top layer with a thickness of 15–30 nm. Occasionally, thin GaN (~3 nm) are grown on top of the heterostructure in order to improve the stability. Drain and Source contacts are usually Ti/Al based and are alloyed in a high temperature annealing step. The gate contact is crucial for operation at high frequency and has typically T- or Y-shaped cross sections. Additional field plates are employed to reduce the local field enhancement at the gate contact edges, thus enhancing the breakdown voltage. Finally, the device has to be passivated for stable operation, which is commonly achieved by deposition of SiN_x, SiO_2, Sc_2O_3, or related materials.

The achievable frequency roughly scales with the transconductance of the device. Thus, thin barriers (thickness d) as well as small gate lengths L_g are preferable for high-frequency operation. Small-signal amplifier transistors usually have small gate lengths (<200 nm); the breakdown voltage, however, is low (~ < 10 V). Power HEMTs, on the other hand, have rather uncritical

Polarization-Induced Effects in Heterostructures, Fig. 6 The hydroxyl groups on the GaN cap layer of an AlGaN/GaN heterostructure reacting with (**a**) water, (**b**) acidic, and (**c**) alkaline solutions and the resulting impact on the 2DEG sheet carrier density [17]

gate lengths. Especially for blocking voltages exceeding 100 V, gate lengths >1 μm are sufficient.

The strong polarization in AlGaN/GaN heterostructures is considered to be one source of some of the experienced reliability problems. To minimize such effects, alternate barrier materials such as InAlN have been employed, which are less polar. In addition, InGaN layers have been used instead of a pure GaN buffer as well as AlN interlayers at the AlGaN/GaN interface to improve the confinement of the 2DEG electrons.

Electrolyte-Gated Field Effect Transistors

The development of biosensors based on group III-nitrides received an increasing interest in the last years. In analogy to the development of biologically applied FETs (BioFETs) based on silicon enzymes, DNA, antibodies, and whole cells have already been successfully been used as transducing element. Especially the strong bond strength and the resulting high band gap are responsible for the excellent chemical stability and biocompatibility of the nitride materials. Therefore, no functionalization is required for the adhesion and proliferation of cells on the surface. In order to attach different biomolecules, the modification methods, which have been developed for Si-based BioFETs, can easily be adopted. Sensitivity and limit of detection for the first reported AlGaN/GaN-BioFETs were shown to be at least similar and often exceeding silicon-based devices and their background noise is significantly lower.

The strong responses of AlGaN/GaN field effect structures have been explained by the site-binding model, which has previously been applied to Si-ISFETs. According to this model, the metal oxide forms amphoteric hydroxyl groups (M-OH) at the surface when the surface is exposed to aqueous solutions. Depending on the pH value of the solution, these sites can either be protonated ($M\text{-}OH_{2+}$), neutral (M-OH), or deprotonated (M-O-) (Fig. 6). At a low pH value, i.e., a high concentration of H_3O_+, they act as a proton acceptor, and at high pH values, i.e., a high concentration of OH^-, they act as proton donators. This results in a change of the surface charge which in turn enhances/depletes the sheet charge density n_s in the 2DEG at low and high pH, respectively.

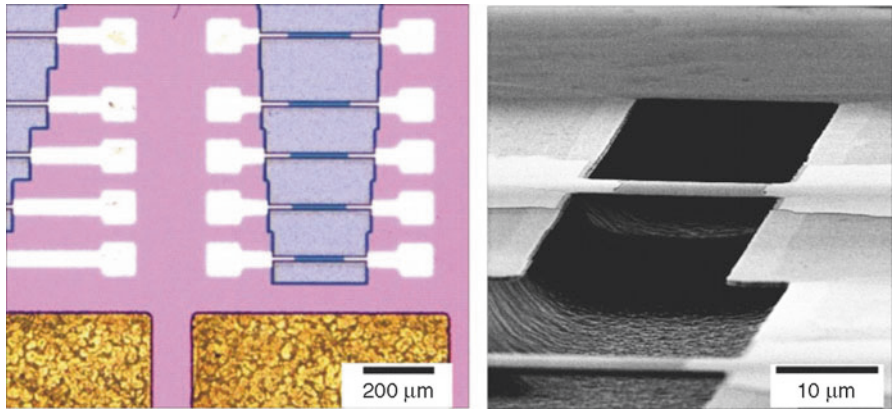
The pH response of the AlGaN/GaN heterostructure can also be used to record a pH change induced by a biochemical reaction in the solution, e.g., of an enzyme assay.

For the functionalization of group III-nitrides with biomolecules, different methods of covalent immobilization were applied which can be categorized as follows:

- Direct chemisorption of biomolecules on GaN via amine chemistry
- Deposition on organosilanes, e.g., aminopropyltriethoxysilane (APTES) followed by immobilization of biomolecules via amine chemistry
- Using the high affinity of thiols to a Au-coated gate directly via thiol-modified DNA or indirectly binding biomolecules through ester groups

One of the main advantages of group III-nitrides based ISFETs is their chemical stability under physiological conditions. Silicon is known to be attacked by many biological important agents; thus, an appropriate surface modification by native oxidization or by deposition of other metal oxides such as TaO_5 is required. Also, other semiconductors require a thorough passivation (e.g., GaAs in order to achieve a biocompatible surface). In contrast to that, (Al)GaN-based surfaces are naturally chemically inert, which greatly simplifies the device technology.

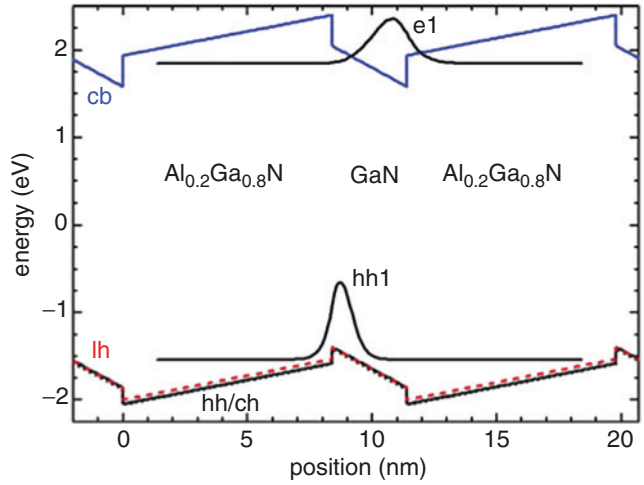
Microelectromechanical Systems



With the increasing requirements for microelectromechanical systems (MEMS) regarding stability, miniaturization, and integration, novel materials such as wide band gap semiconductors receive more and more attention. However, only few applications in MEMS have been reported yet, since the commonly used sapphire and silicon carbide heterosubstrates exhibit an extraordinary chemical stability and hinder the realization of freestanding functional layers by selective undercutting.

Nevertheless, wide band gap semiconductor materials, namely SiC, AlN, GaN, and AlGaN/GaN heterostructures, offer superior properties concerning mechanical, thermal, chemical, and biochemical stability. They show no or very low reaction with molecules from the air. For MEMS and NEMS, this is particularly advantageous as surface influences increasingly compromise their performance with decreasing device dimensions. Wide band gap materials exhibit outstanding ratios of the Young's modulus to the mass density, which, for a given resonator geometry and size, effects in significant higher mechanical operation frequencies than other materials, e.g., silicon, would allow [18].

The piezo- and pyroelectric properties of the group III-nitrides provide an elegant way for an integrated electromechanical coupling mechanism (Fig. 7). Thereby, the 2DEG serves as back electrode for the piezoelectric coupling of both, actuation and read-out [19]. Although other materials, e.g., functional ceramics such as Pb(Zr,Ti)O_3 (PZT), offer higher piezoelectric constants, the group III-nitrides convince by their structural quality and the dimensional control down to the monolayer level. The above-described 2DEG at the interface of AlGaN/GaN heterostructures can also be used for designing sophisticated MEMS-based sensor concepts. Due to its dependence on the spontaneous polarization of the interfacing materials, the 2DEG is sensitive to mechanical stress and other environmental influences such as temperature or chemical surface modifications. Additionally, this material allows the combination of MEMS and HEMT structures, thus opening the way to sensing concepts with integrated signal amplification.



Unintentional Polarization Effects

The quantum-confined Stark effect (QCSE) describes the effect of an external electric field upon the light absorption spectrum of a quantum well (QW). Without electric fields, electrons and holes within the quantum well only occupy states within a discrete set of energy subbands. Consequently, only a discrete set of frequencies of light may be absorbed by the system. Under the influence of an external electric field, the electron states shift to lower energies, while the hole states shift to higher energies, thus reducing the permitted light absorption frequencies. Additionally, the

Polarization-Induced Effects in Heterostructures, Fig. 7 Double clamped beam structures of AlGaN/GaN on silicon. *Left*: optical micrograph, the size varies from 275 to 350 µm, *right*: scanning electron micrograph of a 20-µm beam [20]

Polarization-Induced Effects in Heterostructures, Fig. 8 Quantum-confined Stark Effect illustrated at an AlGaN/GaN/AlGaN quantum well structure, as simulated by nextnano^3 [20]

external electric field shifts electrons and holes to opposite sides of the well, decreasing the overlap integral, which in turn reduces the recombination efficiency (i.e., fluorescence quantum yield) of the system due to a spatial separation. In case of polar materials, the above-described shifts in the energy subband levels and in the localization of charge carriers are not caused by external fields, but inherently caused by the polarization-induced internal electric field. Figure 8 shows the conduction (cb) and valence (heavy hole (hh), light hole (lh), and crystal-field split-off hole (ch)) band edges of an AlGaN/GaN heterostructure, including the effects of strain, piezo- and pyroelectricity. The ground state electron (e1) and the ground state heavy hole wave functions (hh1) are shown. Due to the built-in piezo- and pyroelectric fields, the electron wave functions are shifted to the right and the hole wave function to the left.

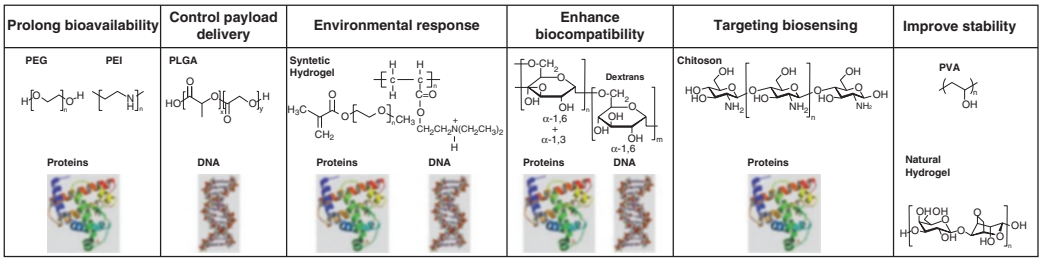
Definition

A polymer coating is defined as the chemical or physical binding of polymeric molecules on the surface of a substrate material.

Introduction

In the last two decades, the physical, chemical, and functional properties of polymers have been exploited to enhance the properties of nanomaterials. Polymer coatings are capable of shielding nanoparticles from adverse physiological environments, retarding their degradation or erosion, or protecting the body from the direct exposure to their toxic components. Recent advancements in polymer technology have also produced polymers able to change properties over time or according to environmental conditions (temperature, pH, etc.). Polymer-coated nanoparticles incorporated in nanocomposites have improved filler dispersion and developed materials with novel and sensational properties. Both natural and synthetic polymers can be used to modify nanomaterials through wet and dry surface-surface coupling techniques. Polymer coatings are currently considered as a valuable tool for the improvement of nanomaterials due to the fine control and tuning of their properties and due to the ability to add multiple functionalities to the engrafted surfaces. They have been employed in different settings, from medicine to oil industries, opening new promising application possibilities.

Natural and synthetic polymers have been used in medical applications for decades, thanks to their biocompatibility, biodegradability, and tunable properties. They have been injected, implanted, and used to host cells, to release drugs, to replace tissues, or to drive tissue regeneration. Historically, polymer coatings have been used in the surgical setting to improve prosthesis biocompatibility, facilitate bone implant fixation, and reduce fibrosis and contracture of mammary implants. Since the introduction of polymer coating in the field of medicine and surgery, their use has applied to the treatment, diagnosis, and monitoring of more complex pathologies such as cancer, cardiovascular disorders, and degenerative or metabolic diseases. The ability to obtain thin polymeric coatings and to control their self-assembly makes their use advantageous and versatile, especially in combination with nanomaterials and, in particular, with nanoparticles. This integration has served to not only protect nanoparticles from sequestration or degradation but also to lend them multiple functionalities. In essence, polymers can be considered the true enabler of the use of nanoparticles in the biomedical field, and today, multifunctional nanostructures combine the biomimetic and targeting properties enabled by the presence of complex coatings with their unique properties like remote control and photothermal activation.



For these reasons, also in the oil industry, the use of polymer-coated nanoparticles has been investigated for enhanced oil recovery (EOR) processes. EOR aims to recover trapped oil left in reservoirs after primary and secondary recovery. Nanoparticles, being interfacially active and able to modify surface properties, have been explored for use in a remarkable range of applications [1]. Even if they have already been able to change the wettability of rock or stabilize emulsions and foams, in order to be used for EOR processes, they must be able to migrate through porous media and be dispersible in water/brine, inexpensive, and injectable into a reservoir [2]. Nanoparticles with polymer chains grafted to the surface, showing improved stability and solubility, greater stabilization of foams and emulsions, and more facile transport through porous media, may represent an emerging, superior class of materials for EOR.

For similar reasons, the use of nanoparticles as filler for polymeric matrices has generated materials with exceptional properties. Crucial for the proper integration of these particles is the interface between the nanoparticles and the polymeric matrix; recently, grafting to the nanoparticles, the homopolymer brush with the same chemistry of the matrix has shown less agglomeration and better mechanical properties [3].

Polymer Coating of Nanoparticles

The crucial aspect of any therapeutic treatment is the identification of the cellular and molecular targets and the localization of the therapeutic molecules in the right place at the right time and dose. Nanotechnology offers solutions to address the biodistribution and bioavailability of the drug of

Polymer Coatings, Table 1 Scheme of polymeric coating applications and relative coating materials

choice and to achieve higher therapeutic efficacy and reduce systemic toxicity [4]. Some nano-based delivery systems lack the ability to control their trafficking inside the cell where biological barriers such as the lysosomal sequestration limit the advantage of using nanoparticles. To overcome these limitations, physical or chemical coatings of nanomaterials with biocompatible and biofunctional polymers have been the focus of many laboratories in the past two decades [5] (Table 1). By chemically conjugating the appropriate ligands, antibodies, or targeting moieties to the reactive functional groups on the polymer coating, nanoparticles have been targeted to specific body districts as needed [6]. Coating nanoparticles with hydrophilic polymers such as poly(ethylene glycol) (PEG) reduces the interfacial energy in an aqueous environment, preventing unwanted aggregation. Nanoparticles coated with hydrophilic polymers are less recognized by macrophages and opsonins in the body. This allows the nanoparticles to stealthily circulate in the blood for a longer period of time, thus increasing their possibility to reach their target site. Some of the substrate materials used to synthesize nanoparticles (iron oxide nanocrystals, gold nanoshells, quantum dots, and nanofibers) and nanodevices (nanosensors, micro and nanofluidic devices) [7] include metal and metal oxide particles (gold, silver, iron, zinc, and silicon) [8]. These compounds are ideally suited for many biomedical applications given their ability to be tracked in vivo, to be triggered by external fields or forces, and to react with the tissue microenvironment. The drawback of some of these nanoparticles (such as quantum dots made of an inorganic mixture of cadmium selenide and zinc sulfide) is their inherent toxicity [9]. Natural and synthetic polymers can be used to increase the biocompatibility of this class of nanoparticles and made possible their use in the clinical and preclinical settings.

Natural Biomaterials and Polymers

A variety of natural biomaterials and polymers can be adapted for biomedical applications. Because of their intrinsic biocompatibility, they represent an excellent solution for in vitro and in vivo applications. They include: polysaccharides, proteins, peptides, and DNA.

Polysaccharides such as starch, chitosan, dextran, agarose, alginate, and cellulose are a class of long-chain sugars and carbohydrates consisting of repeated monosaccharide units. Coating using these materials not only improves biocompatibility and the colloidal stability of nanoparticles in a physiological environment but also provides binding sites for the further functionalization of nanoparticles with various biological molecules such as peptides, antibodies, enzymes, DNA, and RNA. Dextran coating was initially introduced to reduce particles' toxicity. Glycochitosans, hydrophobically modified polysaccharides able to self-assemble in a core-shell structure, were used to reduce tumor growth through the delivery of RGB peptides and paclitaxel [10]. Heparin nanoparticles have prolonged the half-life and ID50 of the encapsulated drug and resulted in increased therapeutic efficiency [11]. DNA layer-by-layer capsules, able to shrink

in response to environmental stimuli, have been proposed for the controlled release of drugs [12].

Proteins, peptides, and poly(amino acids) may provide hydrophobic, hydrophilic, or amphiphilic coatings to nanoparticles due to the secondary and tertiary arrangement of their moieties. Bovine serum albumin (BSA), collagen, gelatin, and silk are widely used as protein-based coatings for tissue-engineering scaffolds and biomimetic approaches [13]. Proteins such as β-galactosidase were used to enhance immune response [14], while proteins that undergo solution pH-dependent association and dissociation could be used to induce reversible association-dissociation transitions by varying pH [15]. These coatings can be used to target the nanoparticles to a specific tissue or organ in the body and to respond to the local microenvironment to activate the release of the drug. The main drawback of these applications is the long-term retention of the biological activity of the protein coating in circulation which still remains a major challenge of the field.

DNA, or deoxyribonucleic acid, is a complex polymer based upon nucleic acid units bound by ionic and hydrogen bonds. Multilayered DNA coatings have been proven to be cyto- and histocompatible and to increase fibroblast proliferation without altering cell morphology [16]. It was reported that DNA coatings on magnetic Fe_2O_3 nanoparticles could decrease the magnetic interparticle interaction while retaining individual magnetism of Fe_2O_3 nanoparticles. DNA coatings affected the osteoblast-like cell differentiation through an increase in osteocalcin deposition indicative of enhanced differentiation.

Synthetic Polymers

Numerous synthetic polymers have been developed to replace or mimic naturally occurring molecules for various bioapplications, most of which derive from hydrocarbon-based monomers. They have been used in the coating of nanoparticles for therapeutic delivery, evasion of cellular sequestration, and environmental interaction. Although varied in chemical formulation, the principles of biocompatibility and biodegradability inherent to these compounds are paramount to their success and to the success of other novel formulations.

Poly(ethylene glycol) (PEG) is a hydrophilic polymer that can be chemically/physically cross-linked via acrylate modification to form a hydrogel. Based on the method of cross-linking, layer thickness and physical and chemical properties of PEG-based hydrogels may be precisely tuned. Its chemical structure allows for limited protein adhesion or immune response. PEG coatings can therefore improve the biocompatibility of nanoparticles while simultaneously preventing their aggregation, thereby enhancing their colloidal stability in body fluid [17]. PEG modification also provides protection for nanoparticles from being taken up by macrophages and monocytes, allowing them to temporarily avoid the mononuclear phagocyte system and have a prolonged circulation time in vivo. Such polymers prevent the particle surface from adsorbing plasma components due to the steric barrier and therefore, accumulation of blood proteins and recognition by macrophages is greatly reduced. In vivo studies observed that PEG coating allowed formation of stealth particles that globally distributed much better through the animal, while the PEG molecular weight did not affect probe biodistribution [18]. A successful example of PEG-lipid conjugation now advanced into clinical testing phases is DOXIL, a liposomal formulation of the chemotherapeutic agent, Doxorubicin (DOX). The in vivo data showed 90 % suppression of 4T1 murine mammary carcinomas and reduced toxicity compared to DOX [19]. DOXIL is now FDA approved for ovarian and breast cancer treatment. However, recent studies also assessed that repeated intravenous injections of PEGylated liposomes are characterized by reduced circulation time. This finding suggests that prolonged treatment with PEGylated liposomes can generate antibodies to PEG and lead to unexpected pharmacokinetic behavior.

Another synthetic polymer is *polyvinyl alcohol (PVA)* prepared by hydrolysis of polyvinyl acetate. It is biocompatible, biodegradable, and readily functionalized. PVA is water soluble, but

Polymer Coatings, Table 2 Summary of nanomaterial substrates, coating materials, methods, and applications

Nanomaterial	Coating material	Coating method	Function/application
Nanoparticles	Synthetic	Emulsion/solution	Controlled drug delivery
Nanoporous microparticles	PEG	CVD	Prolonged bioavailability
Nanowires	PVA	PVD	Improved stability/stabilized suspension
Implant	PEI	Chemical, physical binding	Enhanced loading efficiency
Microfluidic device	PLGA/PLLA	Electro-nanospray	Modified biointeraction
	PCL	Plasma	
	Natural	LBL	
	Polysaccharide	RAFT	
	Protein/peptide		
	DNA/RNA		

PEG poly(ethylene glycol), *PVA* polyvinyl alcohol, *PEI* Polyethylenimine, *PLGA* poly(lactic-co-glycolic acid), *PLLA* poly-L-lactide, *PCL* polycaprolactone, *DNA* deoxyribonucleic acid, *RNA* ribonucleic acid, *CVD* chemical vapor deposition, *PVD* physical vapor deposition, *LBL* layer-by-layer assembly, *RAFT* reversible addition-fragmentation chain transfer

resistant to oils and organic solvents, thus it can protect nanoparticles from agglomeration and allow them to form a uniform colloid in an aqueous biological environment [20].

Polyethylenimine (PEI), another synthetic polymer, has been widely used for gene delivery. PEI can form complexes with DNA and condense them into compact nanoparticles [21]. It is also capable of destabilizing the endosomal membrane by triggering osmotic swelling in the endosomes to increase DNA release [22]. PEI has become one of the most efficient nonviral transfection agents. The PEI-coated nanoparticles have been used as a successful vector for gene delivery. In the last decades, different PEI modifications, including thiol cross-linking, polymer size, covalent attachment, and branching degrees, achieved high transfection efficiency of plasmid DNA and siRNA into cells and live animals. It is important to consider that high molecular weight PEI can cause toxicity. Recent studies have shown that it is possible to reduce toxicity-maintaining effective nucleic acid delivery by using intermediate-length polymers, and coating with low molecular weight PEI polymers, while inefficient for gene delivery, is nonetheless efficient to increase delivery of antitumor agents into cancer cells [23].

Methods of Surface Coating

The surface properties of nano- and microparticles can be tuned by coating a thin film of polymeric materials to achieve the desired physical, chemical, optical, electrical, mechanical, and biomedical properties. There are two conventional approaches for nano- and microparticle coating, categorized as dry or wet methods depending on the environment of polymerization reaction [24] (Table 2). Dry methods include physical vapor deposition, chemical vapor deposition, plasma treatment, and pyrolysis of polymeric or nonpolymeric polyethylene glycol organic materials for in situ precipitation of nanoparticles. Wet methods include sol-gel processes, emulsification and solvent evaporation techniques, and layer-by-layer assembly methods. Combination and repetition of one or more coating methods recently have also been investigated to better control molecular variables of the attached chain and improve properties such as filler dispersion.

Dry Surface Coating

The two principal methods for dry coating of nanomaterials are *physical vapor deposition (PVD)* and *chemical vapor deposition (CVD)*. PVD is a technique that condenses vaporized

materials in vacuum and at high temperature to form a thin-film coating onto the substrate surface. The vaporized materials are usually carried by H_2, N_2, or inert gasses, and there is no chemical reaction involved in this process [25]. CVD is a chemical method to deposit gaseous reactants to the surface of substrate materials to form a thin solid film through chemical reaction or decomposition of the precursor in an activated (heat, light, plasma) environment. CVD method has been used as a coating method for various materials including nano/microparticles, nanocrystals, nanowires, etc. [26].

Another option for dry coating is *plasma treatment* which can be used to directly attach polymers to a desired surface, generating highly branched or cross-linked polymers. The principle of this technique is that the ionized and excited molecules and radicals activated by the electrical field collide and react with the substrate surface. The plasma technique is environmentally friendly and usually performed at room temperature, which provides this technique with flexibility for surface modification or coating of almost all substrates. However, there are challenges to the deposition of thin films on nanoparticles due to their severe aggregation and high surface-to-mass ratio. In order to achieve uniform coating by this technique, it is necessary to homogeneously expose the surface to the plasma as any unexposed area will be minimally coated. To solve this problem, a fluidized bed reactor has been used to serve as an ideal tool for gas-particle reactions. The combination of these two technologies provides an innovative way for nanoparticle surface modification [27].

Wet Surface Coating

Wet surface coating refers to the coating of nanoparticles in a liquid (usually aqueous) solution. It can be achieved by *sol-gel processes*, emulsification/evaporation, or layered assembly. Sol-gel is a chemical technique where a chemical or colloid solution (sol) acts as a precursor for integrated network nano/microparticles (gel). This method is characterized by a gel-like diphasic system containing both a liquid and a solid phase. It can be applied to the synthesis of solid materials (such as glass or ceramics) at lower temperatures than the conventional approaches or in nano/microparticle coating. A thin film is deposited onto the surface of the nano/microparticles and the composition of the film can be tuned by controlling the reaction parameters (temperature, composition, etc.) [28]. *Emulsification* involves two or more immiscible liquids: a liquid phase (dispersed phase), composed of the desired coating materials dispersed into small droplets in a second phase (continuous phase) by constant stirring. Surfactants can be added to the second phase to stabilize the newly formed droplets of the dispersed phase against the coalescence. By resuspending metal, inorganic, or organic nanoparticles into the dispersed phase, their surface is coated with thin polymer layers [29]. *Layer-by-layer (LbL) assembly*, a versatile and easy-to-use technique, has become a nanofabrication method for a broad range of applications. Basically, when LbL assembly is applied to nanoparticle coating, it is used to sequentially absorb positively or negatively charged species onto the nanoparticles by alternatively submerging the different materials into solutions. The multilayered coatings can alter the intrinsic surface characteristics of nanoparticles for desired physical, chemical, mechanical, thermal, and optical properties pertaining to diverse biomedical applications [30] as in the following examples. The electrostatic and covalent LbL assembly strategy of Dhuram et al. has been used to engineer nanoparticles with multilayer shells, small size distribution, high stability in physiological media, low toxicity, protection against macrophage uptake, triggered release and activation only after endocytosis, and enzymatic cleavage. Another successful modification of the LbL method has been developed by Caruso and coworkers using colloidal particles to coat the surfaces of nanomaterials. LbL assembly of a lipid bilayer and polyelectrolyte structures can be used in drug and gene delivery, thanks to the lipid bilayer's ability of accommodating biomaterials. Katsuhiko Ariga's group has developed mesoporous nanocompartment films through LbL assembly of mesoporous silica capsules.

These films were able to modulate the release of the payload by means of a nonequilibrium evaporation process. Mohwald's emulsion encapsulation combines the advantages of direct encapsulation of a liquid colloidal core with the accuracy and multifunctionality of LbL polyelectrolyte deposition. Their capsules show two different destruction mechanisms upon interaction with solid surfaces and hence may find interesting application in the pharmacy and medicine industry. Synthesis through LbL is a very flexible and easy coating method that may provide multiple functions and enhance particle functionality.

Reversible addition-fragmentation chain transfer (RAFT) polymerization is currently used to synthesize polymer brushes on nanoparticles. Recently, also bidisperse/bimodal polymer brush-anchored nanoparticles have been synthesized through a double RAFT polymerization that enables to independently control molecular weight, composition, and graft density. Indeed, bimodal brush-grafted colloidal nanoparticles improve interaction and dispersion within the matrix [31].

Future Perspectives

Polymer coating is a versatile powerful tool in nanomedicine and other fields, such as the oil industry and material sector, and all evidence suggests that its use will continue to grow. Tuning nanoparticle surface properties and stability, polymer coatings are a promising instrument for nanomaterial composites synthesis and in EOR processes. The different polymer coatings developed so far are able to overcome several limitations particular to drug delivery and nanotechnology, such as biocompatibility, bioavailability, and gene delivery efficiency. Furthermore, advances in polymer chemistry and nanotechnology will continue to provide additional compounds to develop more effective nanostructures able to target the desired tissue and to release the entire payload in a successful fashion. Through the exploration of polymer combinations and through the advent of new coating techniques, it has been possible to pave a new avenue in the biomedical and commercial application of polymers. RAFT polymerization, for example, was used to synthesize binary polymer brush-anchored nanoparticles and produce composite materials with improved mechanical and thermal properties. By improving stability and tuning surface interactions such as adsorption, aggregation, viscosity, and emulsion generation, under different environmental conditions, polymer-coated nanoparticles may more easily propagate through a reservoir and lead to more efficient EOR processes. As polymer coating continues to add more functionalities to nanodevices and nanoparticles, the innovation in their synthesis and modification will continue to bring a fresh breath of life into the field and contribute to the use of nanomaterials to the growing biomedical field. In particular, environmental responsiveness offers a unique opportunity to add functionality to the already versatile nanosystems. By being able to interact with the surrounding environment, polymer coatings can generate a new paradigm of smart therapeutics that only act in the presence of a specific stimulus. Finally, the versatility and variety of polymer coatings could offer a solution to the issue of patient-to-patient variability encountered in any approach of personalized medicine. By providing an optimal therapeutic regimen for each individual patient in response to their specific condition and background, they might facilitate the introduction of the concept of individualized therapy in the clinical arena.

Definition

In laser direct writing, two- and/or three-dimensional patterns are fabricated by the interaction of a focused laser beam with a target. Complex geometries are easily attainable by free-form writing with feature sizes as small as hundreds of nanometers. Two-photon polymerization is a specific case of direct laser writing where a photosensitive material is polymerized using a laser by means of multiphoton absorption.

Overview of Laser Direct Writing

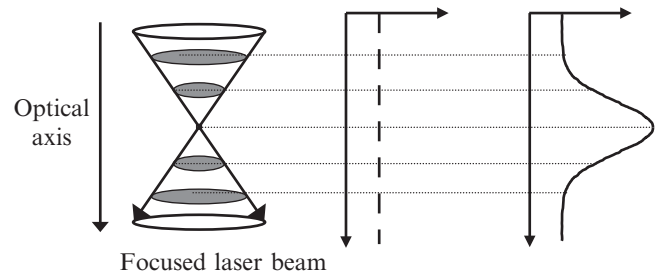
Lasers exhibit a number of features that make them unique sources of energy for several material processing methods. For example, they are indispensable tools for drilling, welding, and cutting in industrial manufacturing where high average and peak powers are required. Furthermore, by virtue of their high spatial coherence, lasers can produce patterns with resolutions that extend over four orders of magnitude from millimeters to hundreds of nanometers. And lastly, materials can be removed, added, or modified without physical contact between a tool and the target substrate allowing rapid and inexpensive turnover.

Many manufacturing techniques that use lasers to create patterns on the surface or in the volume of a material can be described as laser direct-write (LDW) processes [1]. In LDW, the interaction between the laser and the material can create different effects: voids by means of ablation, material state modifications by means of thermal cycles, and addition of diverse materials by means of chemical reactions or induced forward transfer procedures.

LDW creates patterns in a "spot-by-spot" fashion where the target substrate is moved around a fixed laser beam and/or the laser beam is scanned following predetermined outlines. Although this serial approach to create parts is slow compared to more traditional parallel approaches, two characteristics of LDW methods render it attractive and competitive in many applications. First, there are almost no topological constraints for creating structures. Second, by choosing the appropriate laser and experimental conditions virtually, any material can be processed. Examples of materials processed by LDW can be found among

conductors, semiconductors, dielectrics, and ceramics [2].

Both continuous wave and pulsed lasers have been successfully employed in LDW. In particular, the ones that have found the most uses thus far are infrared CO_2 gas lasers, ultraviolet excimer gas lasers, and visible solid-state lasers. When interacting with these kinds of lasers, materials absorb light in a linear fashion, and heating effects play an important role on the quality of the created patterns. If ultrashort (less than a picosecond) pulsed lasers are used for LDW, then energy is deposited in the material in a time range shorter than the electron–phonon coupling time (a few picoseconds) rendering thermal effects negligible [3]. Moreover, the likelihood to induce multiphoton absorption when using ultrashort pulsed laser is such that the matter/light interaction can be spatially confined to femtoliter volumes enabling high-precision and high-resolution patterning. Consequently, LDW processes that use ultrashort pulsed lasers have found a large number of applications in diverse fields as microfluidics, photonics, MEMS, cell development, tissue engineering, and medicine [4].



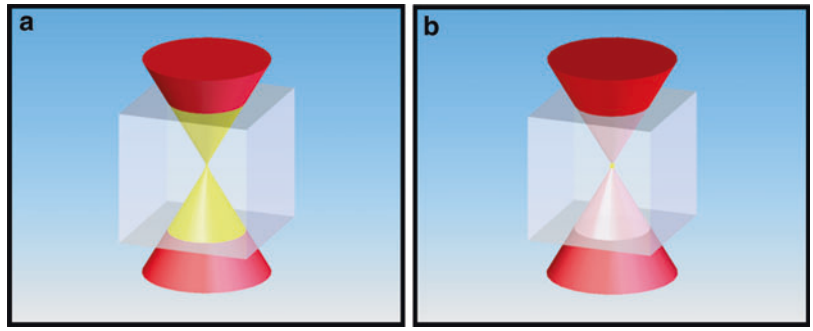
For many technologies, smaller is synonymous with better. Shrinking the size of devices brings many advantages: more components per unit area, lower power consumption, lower cost, faster response, and higher performance. An area of research that has affected almost every aspect of society because of device downsizing is microelectronics. Staggering examples of these changes can be found across diverse fields including automotive, computers, communications, and medicine. The successful story of microelectronics is based on the development of a set of tools that goes under the name of integrated chip (IC) technology and comprises processes such as photolithography and electron beam lithography [5]. By means of IC technology, microprocessors with millions of transistors can be routinely fabricated and launched in enormous numbers of calculations per second.

With the increasing complexity of micro-/nano-devices needed in most modern applications though, IC technology presents some limitations [6]. In particular these techniques are incompatible with many chemical and biological environments, creating features smaller than 100 nm is difficult, and they are not capable of fabricating structures with complex three-dimensional shapes. Furthermore, they cannot fabricate features on a curved or uneven substrate, and generally require expensive facilities. For these reasons, there has been a tremendous effort from the research community to develop unconventional micro-/nanofabrication techniques. Nano-imprint lithography, proximity probe lithography, and soft lithography were born from the desire to break free from the constraints of conventional lithography [7].

Two-photon polymerization (TPP) is a laser direct writing process for the fabrication of polymeric three-dimensional microstructures [8]. Because of its ability to produce geometries with no topological constraints with features smaller than 100 nm, TPP is a unique tool in the arsenal of unconventional microfabrication methods now available to scientists. Although the first report in the scientific literature of photopolymerization induced by a multiphoton absorption process appeared more than 40 years ago, it was a paper of Kawata and coworkers published in 1997 that established TPP as a technique for the fabrication of three-dimensional microstructures [9, 10]. Since then the number of works based on TPP has grown rapidly, allowing researchers in diverse fields such as nanophotonics, microelectronics, and bioengineering to create and use devices previously impossible to manufacture with conventional microfabrication procedures.

Three-Dimensional Micro-/Nanofabrication by Two-Photon Polymerization

The excited state of a molecule can be reached by the absorption of one photon of an appropriate wavelength or by the simultaneous absorption of two photons, each having half the energy required for the transition. In this case, two-photon



Polymer-Based 3D Micro-/Nanofabrication by Laser Direct Writing, Fig. 1 Integration of the intensity (—) and the intensity square (—) in each transverse section of the focused laser beam along the optical axis. While the probability of one-photon absorption is always the same, the probability of two-photon absorption is highest at the focal point

absorption is said to be degenerate. When the photons promoting the transition are of different energies (wavelengths), the process is said to be nondegenerate. Because of the simplicity of the experimental setup for degenerate two-photon absorption, most of the applications have used this technique. Two-photon cross sections of most molecules are very small, usually on the order of 1 GM or less, where 1 GM corresponds to 10^{-50} cm^4 s $photon^{-1}$ (GM stands for Göppert-Mayer in honor to the scientist who theoretically predicted multiphoton absorption). As a result, high local photon fluxes are needed to promote two-photon absorption. Commercially available Ti:sapphire lasers emitting at wavelengths in the near-infrared region of the spectrum and producing pulses shorter than 100 fs can meet this requirement. Each pulse has a peak power on the order of a kilowatt, while at a typical repetition rate of 80 MHz, the average power is on the order of milliwatts. When focused into tight spots, these lasers allow reaching the photon densities needed for two-photon absorption to occur.

Since the probability of a two-photon absorption event is proportional to the second power of the light intensity, excitation can be spatially localized. Figure 1 illustrates the total one-photon (dashed line) and two-photon (continuous line) absorption per transverse section of a focused laser beam. While the absorption probability is the same along the optical axis for a one-photon process, a maximum coinciding with the focal point is present for the two-photon process. Researchers have used the ability to confine excitation in a volume as small as a femtoliter by two-photon absorption in several applications, including photolysis, optical data storage, photochromism, and photodynamic therapy. Among these areas of research, the one that has experienced the most explosive growth is two-photon fluorescence microscopy [11].

In polymerization induced by a one-photon process, the excitation beam is usually greatly attenuated by linear absorption before reaching the focal point. Consequently, only the first layer of the photoresist (photosensitive material) is polymerized. If the intensity of the laser is increased, all the material along the optical axis may polymerize (Fig. 2a), or worse the energy dumped into the system is high enough to boil the material away. In either case the lack of polymerization control forbids the use of one-photon absorption for the fabrication of three-dimensional microstructures. Conversely, polymerization is confined to the focal point when excitation occurs via two-photon absorption (Fig. 2b).

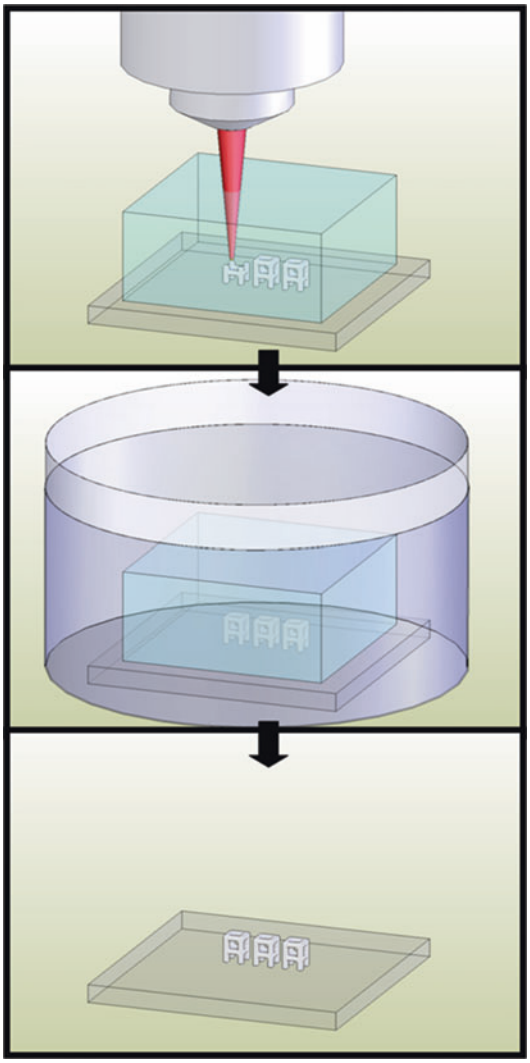
In TPP the selective excitation of molecules within the focal volume of a tightly focused beam allows for a spatial confinement of matter transformation. If the photoresist can be solidified by two-photon absorption, then three-dimensional microstructures with submicron resolution can be fabricated by means of accurate positioning of the laser focal point. As long as the solubility properties of the solidified and unsolidified photoresist

Polymer-Based 3D Micro-/Nanofabrication by Laser Direct Writing, Fig. 2 One-photon (**a**) and two-photon (**b**) polymerization. Only when nonlinear excitation occurs (2b), spatial confinement of the chemical reaction is observed

are different, the unpolymerized material can be washed away to leave the freestanding structures. A diagram representing the three main steps of TPP are shown in Fig. 3 where the proportions of the objects depicted have been exaggerated for viewing clarity.

Since the index of refraction of the photoresist changes upon polymerization, TPP can be monitored in real time by the aid of white light microscopy. Although in this way large failures of the procedure can be detected and corrected in time, the fine details of the microstructures cannot be observed. Furthermore, a three-dimensional view is impossible. Hence, prior to being employed in experiments, microstructures fabricated by TPP are carefully investigated by scanning electron microscopy (SEM) in order to check if the desired geometry and surface roughness were obtained. Figure 4 is an SEM image of a microstructure fabricated by TPP. The sample was positioned at a 45° tilt in order to reveal the complex topology.

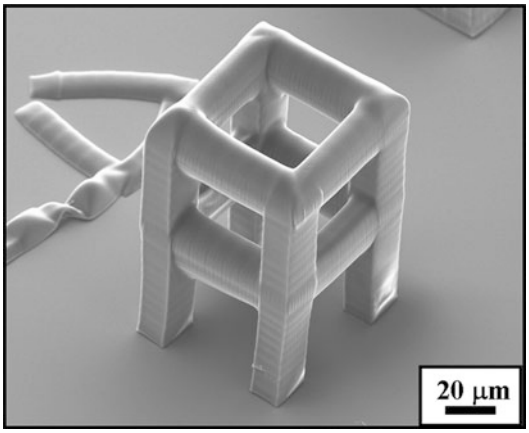
This fabrication process offers a unique combination of advantages. First, no topological constraints are present in the fabrication of three-dimensional structures. Second, sub-diffraction-limited feature sizes can be attained by employing laser intensities just above the intensity threshold at which polymerization will occur. Third, the optical penetration depth is greatly increased with the use of near-IR light. Fourth, movable components can easily be created without the use of sacrificial layers. Finally, the carbon-based nature of the materials can be used as a chemical handle to fabricate structures with tunable physical and chemical properties such as hardness, shrinkage, index of refraction, and chemical specificity, depending upon their application.



Size Characterization of Features Fabricated by Two-Photon Polymerization

The ultimate resolution and complexity of three-dimensional microstructures fabricated by TPP depends upon factors influencing the shape and size of the smallest polymerized volume element or voxel. It is the accurate overlapping of these voxels that produces the desired surface topology of the final structure.

The modification of the photoresist state from liquid to solid occurs in the region with the highest concentration of radicals. In TPP this corresponds to the central part of the square light intensity distribution at the focal plane. As a consequence, the shape of the polymerized voxels resemble an ellipsoid with the two minor axes equal to each other and lying in the geometric focal plane.

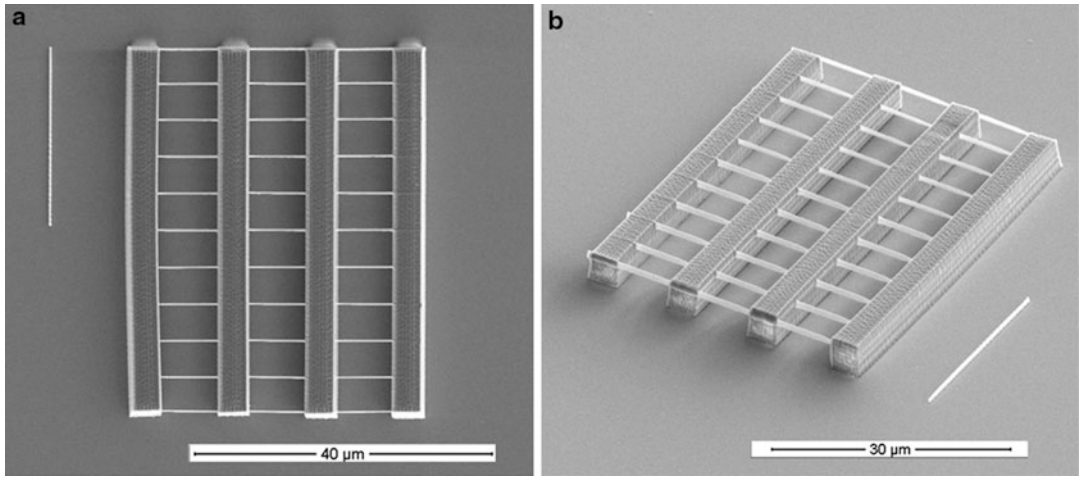


The volume of the polymerized voxel is proportional to λ^3, where λ is the wavelength of the laser beam used to induce two-photon absorption. Although shorter wavelengths will form smaller voxels, the choice of the excitation energy is dictated mainly by the photoinitiator efficiency. In general, the working wavelength of choice optimizes the product of the photoinitiator two-photon cross-section area and quantum yield for radical generation.

By assuming a Gaussian distribution of light intensity at the focal volume and a constant photon flux during a laser pulse, an equation predicting the voxel dimensions as a function of experimental parameters can be found. As expected, both voxel diameter and length increase with increasing values of exposure times and average powers.

Polymer-Based 3D Micro-/Nanofabrication by Laser Direct Writing, Fig. 3 Free-standing three-dimensional microstructures can be fabricated by TPP. First the desired pattern is "written" by precise positioning of the laser focal point in the photoresist. Then, the unsolidified remainder of the photoresist is washed away by means of an organic solvent, leaving only the newly fabricated microstructures on the substrate

When the conditions for TPP are optimized to achieve the best resolution, the ratio between the axial and lateral dimensions of the polymerized voxel (μ) varies from three to five. By increasing either exposure time or laser average power, this ratio becomes larger implying that the length of the voxel grows more rapidly than its diameter.



Polymer-Based 3D Micro-/Nanofabrication by Laser Direct Writing, Fig. 4 SEM image of a three-dimensional microstructure fabricated by TPP

Furthermore, μ is affected in larger degree by the laser average power than by the exposure time, and it saturates at long exposure times.

To obtain the highest fidelity of fabrication when writing a complex three-dimensional microstructure by two-photon polymerization, it is of uttermost importance the characterization of the voxel lateral and axial dimensions. One experimental technique employed to retrieve this information is the so-called ascending method. Separate voxels are fabricated on the substrate's surface keeping all writing conditions the same, but the laser focal volume positions in reference to the substrate/resin interface. Because a polymerized voxel will have a defined length, some of the voxels will be fully anchored to the substrate, while other will be lying sideway due their weak adhesion to the substrate. By imaging these latter voxels by SEM, it is possible to measure both their length and diameter.

Although this method has the advantage of reveling in one image both dimensions of a voxel, it has the drawback of not giving a direct measure of the voxel size when performing TPP. In almost all cases, TPP occurs by moving either the sample around a fixed laser beam or the laser beam within a fixed resin. In both cases, the microstructure is fabricated with a continuous overlap of voxels. Hence, a more direct way to get information on the feature size used in TPP is

Polymer-Based 3D Micro-/Nanofabrication by Laser Direct Writing, Fig. 5 SEM images of a test microstructure used to measure the width and the length of suspended lines fabricated by TPP. When the specimen is not tilted (**a**), a clear visualization of the line width is possible. When the specimen is tilted 45° (**b**), the axial dimension of the line is revealed

to fabricate lines suspended from the substrate by means of tall supports. These lines, generated by a single laser passes, can then reveal both the width and length of the polymerized feature size when imaged by SEM at different angles. An example of such a study is shown in Fig. 5.

Linear Versus Nonlinear Optical Absorption in Laser-Induced Photopolymerization

In two-photon polymerization, an intensity laser threshold exists below which no polymerization occurs. In the specific case of resins that polymerize through a radical mechanism, the presence of this threshold is a direct consequence of the chemical nature of the resins' components. The growth of macromolecular chains within the resin depends greatly on delicate ratios of the rate constants among several processes that occur at the same time. These are initiation, propagation, recombination, and termination. If radicals are not continuously generated during the initial stages of the polymerization reaction, no chains will be formed. In polymerization induced by light absorption, this mechanism results in the presence of an intensity threshold.

In first approximation, the accumulated exposure dose D of a single voxel induced for a N-photon absorption process can be described as:

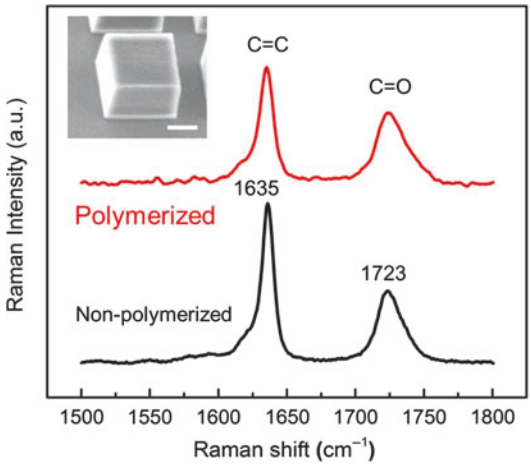
$$D \propto (P - P_{th})^N t, \tag{1}$$

where P is the laser average power, P_{th} is the laser threshold power, and t is the exposure time [12].

According to this model, in one-photon polymerization ($N = 1$), the exposure dose is linearly proportional to the laser average power. In two-photon polymerization ($N = 2$), the exposure dose becomes proportional to the squared of the laser average power. To take advantage of this model from an experimental point of view, a series of voxels are fabricated using different values of both laser average powers and exposure times. Among these voxels, there will be some with identical width that are created with different combinations of laser average powers and exposure times. Assuming that identical voxels are fabricated when the same exposure dose is employed, a log–log plot of exposure times and laser average powers used to create identical feature sizes can reveal the value of N in Eq. 1. Hence, careful dosimetry experiments, such as the ones described in the previous section, not only produce useful information regarding

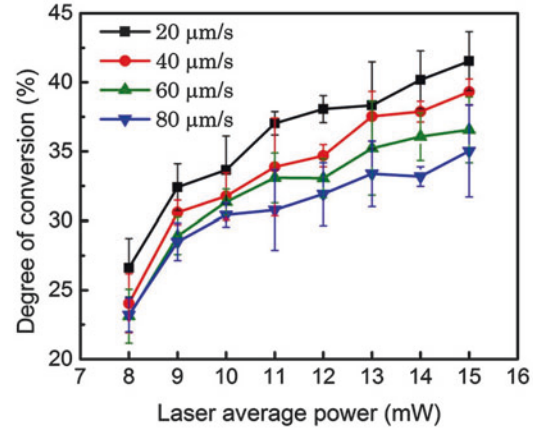
writing conditions to use when performing high-resolution TPP, but they can also offer insightful evidence on the nature of the light absorption process that starts polymerization.

Characterization of Microstructures Fabricated Using Two-Photon Polymerization Using Raman Microspectroscopy



Although TPP has become an enabling technology for several applications, there are still some fundamental aspects that have not yet been fully characterized. One of these aspects is the influence of the scanning pattern on the mechanical properties of the microstructures. Even if the same object can be realized utilizing different writing strategies, some approaches are better than others in producing accurate and dimensionally robust microstructures. Another aspect of TPP that requires a better understanding is the influence of the developing process on polymer swelling and solvent inclusion which might have a large impact on the structural integrity of the microstructures. To answer these and other questions, it is required to use an analytical technique capable of investigating the materials used in TPP at the molecular lever before and after laser processing. Raman microspectroscopy is a formidable tool for the characterization of microstructures fabricated by TPP. It allows for in situ and nondestructive monitoring of specific molecular bond vibrations with high spectral resolution and minimal sample preparation [13].

Raman provides comprehensive information about the vibrational modes of molecules by using light scattering. The Raman-scattered light from the molecules in the probed sample is shifted in the frequency domain relative from the excitation light center frequency, and it contains information about the vibrational frequencies and anisotropy of molecular vibrations. Vibrational modes are like fingerprints of molecules. Therefore, Raman scattering is endowed with the sensitivity to discern different molecular species. Raman spectroscopy has broad applications, ranging from fundamental physical chemistry, inorganic chemistry, biochemistry, art, and archaeology to highly practical forensic examinations.



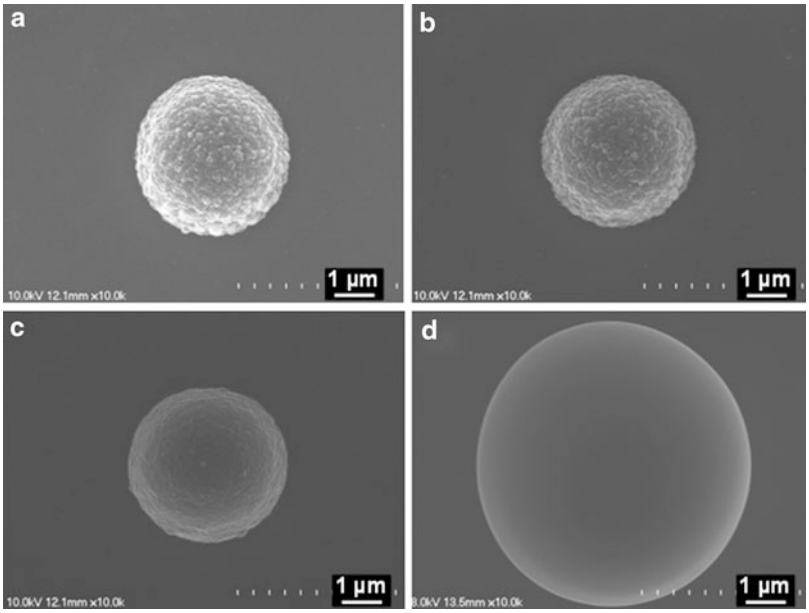
Most of the work in LDW by TPP has been performed using acrylic-based resins. To illustrate the utility of Raman microspectroscopy in characterizing TPP is thus useful to briefly describe the polymerization process involved. Acrylic-based resins are composed mainly of two molecular components, a photoinitiator and a mixture of monomers/oligomers [14]. The first one is the molecule capable of undergoing excitation by two-photon absorption and of generating active species (radicals) that start the polymerization process. In the presence of excited photoinitiators, the monomer/oligomer mixture forms a complex linked network, a polymer. Monomers and oligomers are present in the resin in much larger numbers than photoinitiators.

Radicals generated during laser irradiation react with the monomer/oligomer mixture to form high molecular weight materials through a chain growth mechanism. Several reactions with different rates for initiation, propagation, chain transfer, and termination occur at the same time. In chain polymerization, monomers and oligomers react only with the propagating reactive center, not with other monomers and oligomers, and chain addition ceases when the active species are depleted by a number of termination reactions. The molecular weight of chain polymers increases rapidly during polymerization, and monomer/oligomer to polymer conversion (degree of conversion) can widely range between 20 % and 90 % depending on the chemical nature of the monomers and oligomers. In acrylic monomers and oligomers, chain addition takes place in the carbon–carbon double bonds (C=C) present in the molecules ester moiety. Thus, during TPP the number of C=C bonds diminishes in favor to the formation of new intermolecular carbon–carbon single bonds (C–C).

The Raman spectra of a typical resin employed in TPP before and after polymerization are shown in Fig. 6. Two distinctive peaks are observed at 1,635 cm^{-1} and 1,723 cm^{-1} 1,635 which are ascribed to the vibrational modes of C=C and the carbonyl (C=O) groups of the monomer,

Polymer-Based 3D Micro-/Nanofabrication by Laser Direct Writing, Fig. 6 Raman spectra of a typical acrylic-based resin used in TPP before and after polymerization. The inset shows a scanning electron micrograph of a solid cube created by TPP and used to perform Raman microspectroscopy (5 μm scale bar)

Polymer-Based 3D Micro-/Nanofabrication by Laser Direct Writing, Fig. 7 Polymeric degree of conversion of microstructures fabricated by TPP using Raman microspectrometry



respectively. As a consequence of the diminished concentration of the C=C bonds following polymerization, the intensity of the peak at 1,635 cm^{-1} in the polymerized resin is smaller than in the unpolymerized resin. On the other hand, the intensity of peak at 1,723 cm^{-1} remains the same before and after polymerization because the carbonyl group does not participate in the chain reaction.

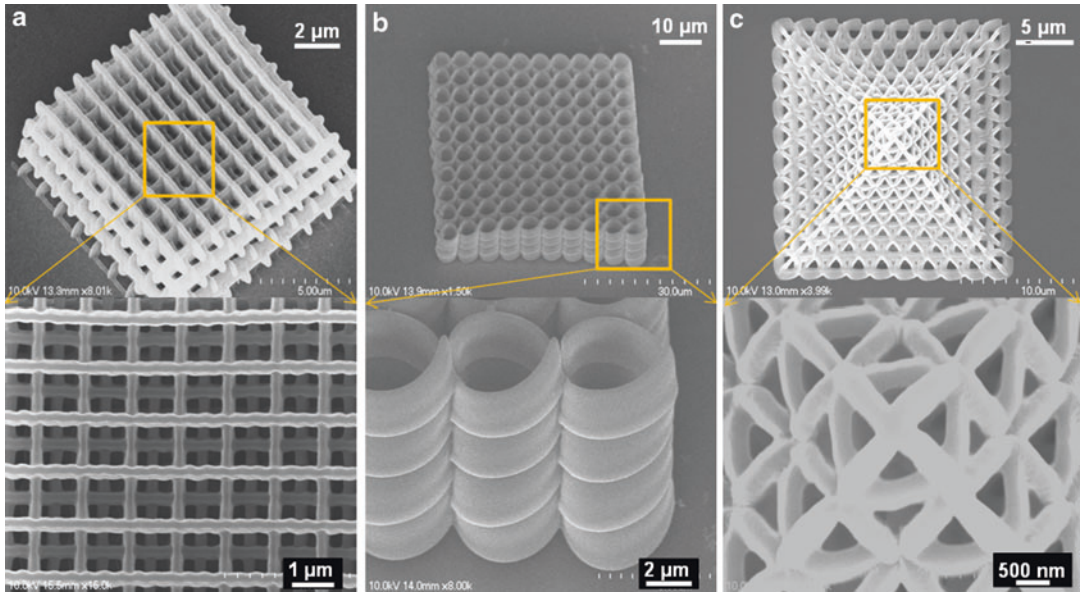
The area of a peak in a Raman spectrum is proportional to the concentration of the oscillators responsible for that particular Raman active mode. Thus, spectra such as the ones in Fig. 3 can be used to measure the degree of conversion (DC) in resins following TPP. DC represents the number of C=C bonds consumed during polymerization and is a major factor influencing the mechanical properties of the ultimate microstructure; the higher the DC, the stronger the polymer. Since the number of carbonyl groups in the resin remains the same before and after polymerization, the peak at 1,723 cm^{-1} can be used as internal reference for DC estimation. The percentage of DC is obtained using the following equation:

$$\mathrm{DC} = \left[1 - \frac{A_{C=C}/A_{C=O}}{A'_{C=C}/A'_{C=O}}\right], \qquad (2)$$

where $A_{C=C}$ and $A_{C=O}$ are the integrated intensities of the 1,635 cm^{-1} and 1,720 cm^{-1} peaks in the polymerized resin, respectively, while $A'_{C=C}$ and $A'_{C=O}$ are the integrated intensities of the same peaks in the unpolymerized resin.

To evaluate the usefulness of Raman microspectroscopy in TPP, a series of microcubes were fabricated first and then characterized using a confocal Raman micro-spectrometer. An SEM image of a microstructure used in the study is shown in the inset of Fig. 6. The micro-cubes were fabricated using several laser average powers and writing speeds. For each microstructure, Raman spectra like the ones in Fig. 6 were recorded and then used to measure DCs with Eq. 2. The results are shown in Fig. 7. At constant writing speeds, DC values monotonically increase with increasing laser average power. The highest DC value is around 43 %; larger DCs were not attainable because the resin will start to boil if higher laser average powers were used. During TPP, highly cross-linked macromolecules are formed that can severely limit molecular mobility. The probability that an unreacted C=C bond will encounter a radical is dramatically reduced with

Polymer-Based 3D Micro-/Nanofabrication by Laser Direct Writing, Fig. 8 Surface quality of 3D microstructures fabricated by TPP using different laser scanning methodologies: (**a**) raster scanning mode, 200-nm step; (**b**) raster scanning mode, 100-nm step; (**c**) raster scanning mode, 20-nm step, 1-h processing time; (**d**) annular scanning mode, 10-nm step, 20-min processing time



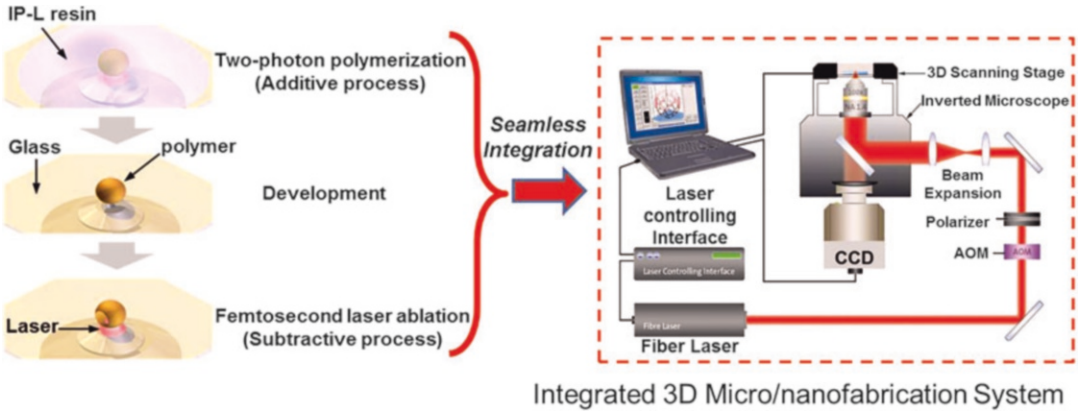
the evolving polymerization, and a complete conversion (DC = 100 %) is never achieved.

Array of Complex 3D Microstructures Fabricated by Two-Photon Polymerization

TPP is an additive femtosecond laser direct writing technique that uses photosensitive resins in 3D micro-/nanofabrication. Compared with other micro-/nanofabrication approaches, TPP offers both high resolution and relatively high throughput. TPP is intrinsically a three-dimensional microfabrication technique. Because of the nonlinear optical nature of light absorption, polymerization is confined in the focused laser beam. By moving the sample relative to the fixed focal position, arbitrary paths can be written into the resin. It can be simply described as using a laser beam to inscribe micro-/nanostructures in three dimensions. Compared to conventional stereolithography, TPP provides much smaller feature sizes allowing the reproduction of three-dimensional objects at the micron scale with unprecedented fidelity.

Microstructures targeted for optical application, such as micro-lens arrays, require high-quality surface profiles. When using TPP to fabricate these microstructures, the writing process needs to be optimized accordingly in order to obtain the desired surface smoothness. For example, it was found that raster scanning mode can hardly get high-quality surface as shown in Fig. 8a–c. In order to obtain a smoother micro-lens, an annular scanning mode cooperated with continuous variable scanning steps was adopted. By using this new scanning method, spherical micro-lens with high surface quality was readily produced (Fig. 8d).

Besides manufacturing micro-lens with excellent surface quality, TPP can easily produce another type of passive optical elements that otherwise will be difficult or impossible to make, and this is a three-dimensional photonics crystal. Photonic crystals are structures that present periodic alternation of materials with different indices of refractions. The most common photonic crystal is the one with a log–pile geometry that consists of layers of parallel rods in which the rod orientation in each layer is perpendicular to that of the adjoining layers. Photonic crystals have the interesting property of forbidding the propagation of certain modes of the electromagnetic spectrum. It turns out that this photonic band gap phenomenon occurs at wavelengths corresponding



Polymer-Based 3D Micro-/Nanofabrication by Laser Direct Writing, Fig. 9 SEM images of three-dimensional photonic crystals with different geometries. Woodpile (**a**), spiral (**b**), and pyramid (**c**) arrangements can be directly written by TPP with high spatial control

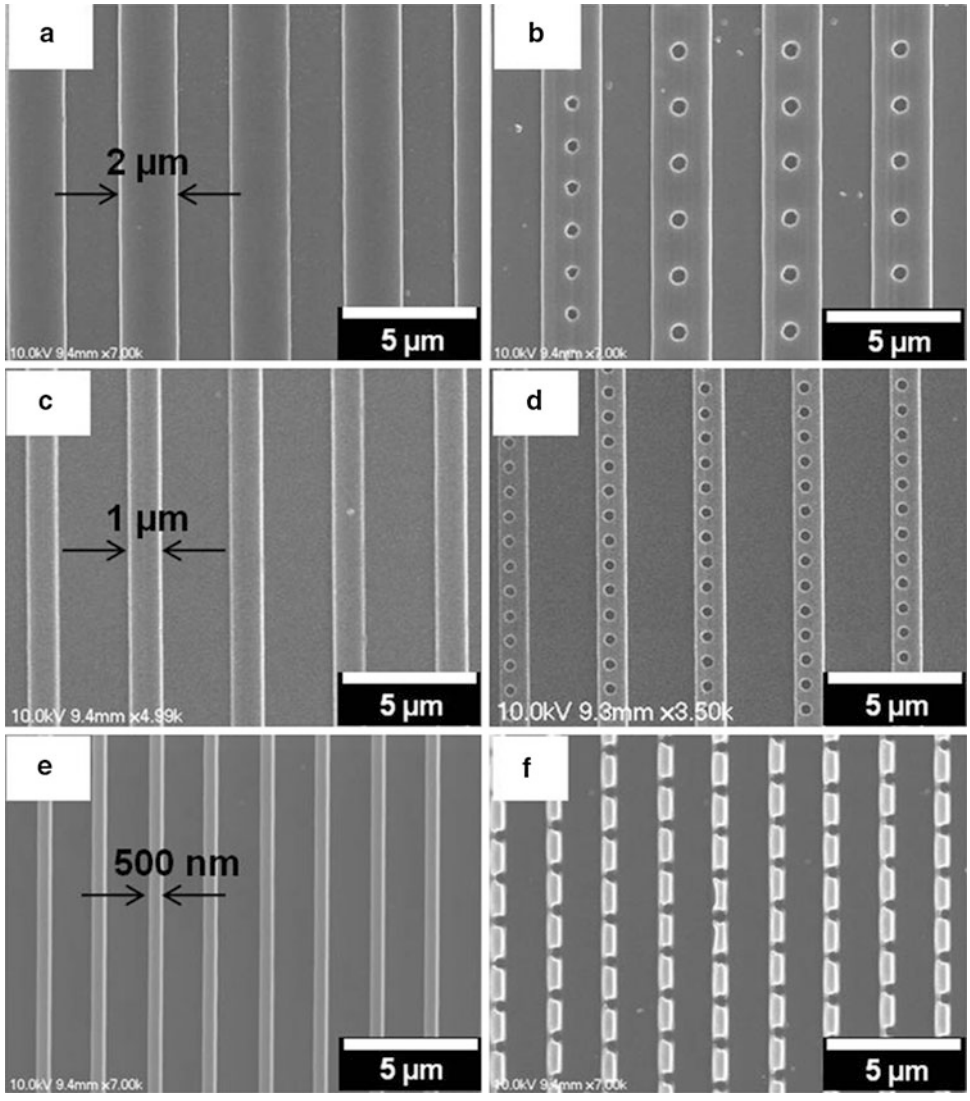
approximately to the distance between the rods. Thus, TPP is the preferred technique for the fabrication of photonic crystals that operate in the visible and near-IR regions of the spectrum. Furthermore, TPP permits to investigate the effect of different geometries than the log–pile stacks have on the performance of photonic crystals. A variety of three-dimensional photonic crystal structures fabricated using by TPP are shown in Fig. 9.

Comprehensive Micro-/Nanofabrication Combining Two-Photon Polymerization and Multiphoton Ablation

Fabricating advanced devices with complex 3D geometries calls for the use of both additive and subtractive processes. For example, a seamless spherical shell is difficult to be fabricated by either additive or subtractive process. In additive processes, the solid shell of the sphere prevents the dissolving of unexposed photoresist inside the sphere to produce a void. While in subtractive processes, a solid sphere has to be created before subtracting the inner part to make a hollow shell. Therefore, a comprehensive 3D micro-/nanofabrication method possessing both additive and subtractive functionalities is not only desirable but also in demand for advanced device fabrication. By combining TPP with multiphoton-induced laser ablation (MPA) in one experimental setup, a comprehensive 3D micro-/nanofabrication method integrating additive and subtractive processes can be achieved. The integrated fabrication method not only inherits the merits of both TPP and MPA such as writing feature sizes smaller than the diffraction limit and objects with sharp and clean edges, but it also offers the possibility to produce novel device structures which are difficult to be fabricated by either TPP or MPA alone [15].

A schematic design of the integrated 3D micro-/nanofabrication system combining both additive TPP and subtractive MPA processes is shown in Fig. 10. The whole fabrication process consists of three steps. First, TPP is employed to fabricate 3D solid microstructures inside a negative resin. Second, unsolidified resin is washed away by rinsing the sample in a developing solution. Third, a subtractive process based on MPA is

Polymer-Based 3D Micro-/Nanofabrication by Laser Direct Writing, Fig. 10 Schematic diagram of the comprehensive 3D micro-/nanofabrication combining additive TPP and subtractive MPA processes



carried out in air to tailor the cured resin to a desired 3D geometry. Depending on the size of the ultimate microstructure, TPP is performed by using laser average powers that vary between 3.5 mW and 8 mW. MPA, instead, requires laser average powers which are two to seven times higher than that used for TPP. To maintain a high degree of spatial confinement when performing both TPP and MPA, a high numerical aperture objective (1.4) is used.

An example of the capabilities of the "TPP + MPA" method in micro-/nanofabrication is shown in Fig. 11. It consists of arrays of polymer fibers with different diameters created by TPP. These dimensions were achieved by controlling the number of laser passes used for the realization of the fibers. The refractive index of polymerized resin is around 1.5. Therefore, these microstructures could be employed as light waveguides for integrated optics. Following TPP, a subtractive MPA process was performed. By removing selectively part of the polymerized resin, periodic patterns of holes with diameters of 500 nm were fabricated along the polymer fibers. The diameter and the periodicity of the holes can be adjusted by using different laser average powers and/or exposure times. The final result of the TPP/MPA process is a complex optical element that can function as a fiber Bragg gratings and that would be difficult to be fabricated by either TPP or MPA alone.

Future Directions for Research

All of the grand goals for nanoscience are dependent upon reliable ways to fabricate nanostructures. Methods that use laser direct writing process to achieve these goals show promising results in the fabrication of various nanomaterials and micro-/nanostructures of various dimensions which are challenging to be fabricated via conventional fabrication methods. An example of laser direct writing process that has achieved remarkable results in the production of complex three-dimensional microstructure is TPP. This technique is truly unique in that it can create three-dimensional microstructures with arbitrary geometries and feature sizes smaller than 100 nm.

Although TPP is almost ready to be implemented in a complimentary fashion to other more conventional microfabrication methods for industrial production, there are still two obstacles to its widespread use that need to be addressed. The first obstacle is speed. Being a serial process, TPP can produce only one object at a time slowing manufacturing progress and increasing its cost. The second obstacle is the limited array of materials available. It is then imperative to focus future research activities to solve these two shortcomings of TPP in order for this novel microfabrication method to be used in the development of advanced devices such as integrated optical circuits and lab-on-a-chip systems.

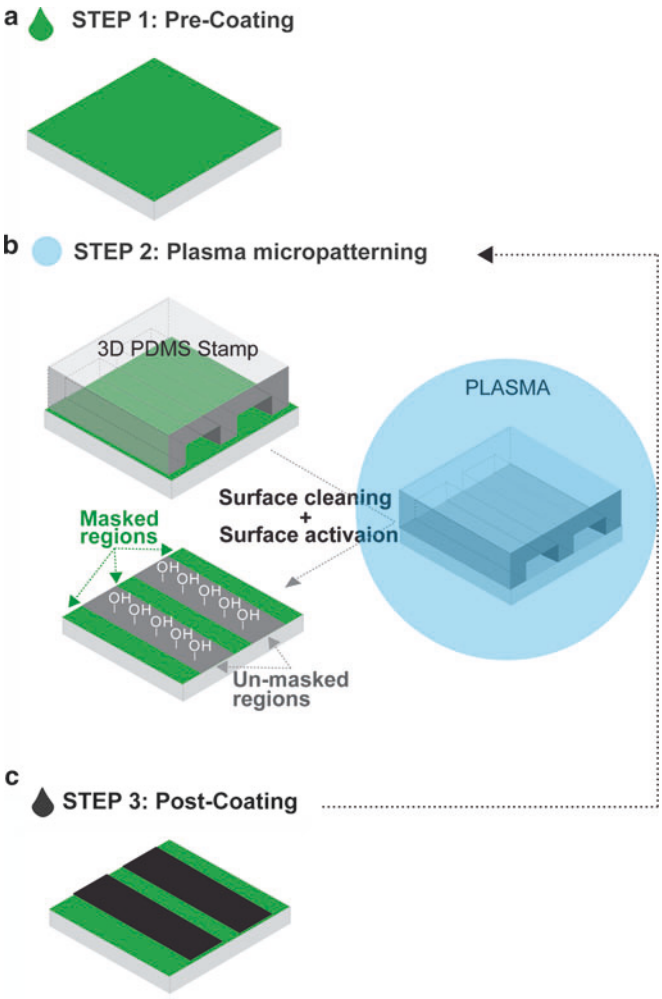
Definition

Plasma micro-contact patterning (PμCP) is a simple, efficient, and cost-effective method for the precise patterning of molecules on surfaces. It combines the use of low-pressure plasma with an elastomeric 3D mask to spatially control the removal of molecules, such as proteins, from a surface. The entire PμCP process is subdivided into three main steps: surface pre-coating, plasma micro-patterning, and surface post-coating. Surfaces are first pre-coated with a molecular species and then placed in close contact with the 3D mask. This allows the formation of two distinct regions: an unmasked open region which is accessible to

the plasma, from which the surface layer is removed, and a contact region which is physically protected from exposure to the plasma. In the final step, a second molecule is added to backfill the pattern generated through plasma treatment.

The PμCP technique allows the patterning of virtually any organic molecules on different surface materials and geometries (e.g., flat and curved surfaces and 3D microstructures). Moreover, it is a simple and robust procedure. The main advantages of this approach over traditional micro-contact printing are twofold: the stability of molecule binding to plasma-treated surfaces and the separation of the surface functionalization step from the actual micro-patterning step, which enables the precise control of concentration and uniformity of patterned molecules. In conclusion, PμCP is a simple way to generate surface patterns that are highly reproducible, stable, and uniform, making it a useful method for many applications.

Introduction



Micro-patterning techniques allow surfaces to be patterned with molecules at small-length scales. The need to fabricate surface patterns emerged with the miniaturization of electrical components in the first integrated circuits. Since then, micropatterning has been applied using a variety of methods [1, 2]. In general, a surface pattern is formed from a foreground pattern that is coated with a specific molecule of interest and a background pattern, generated by backfilling the areas in between foreground features (Fig. 1). The molecules used vary according to the specific patterning application, and the technique can be extended to generate more complex patterns made using >2 types of molecule.

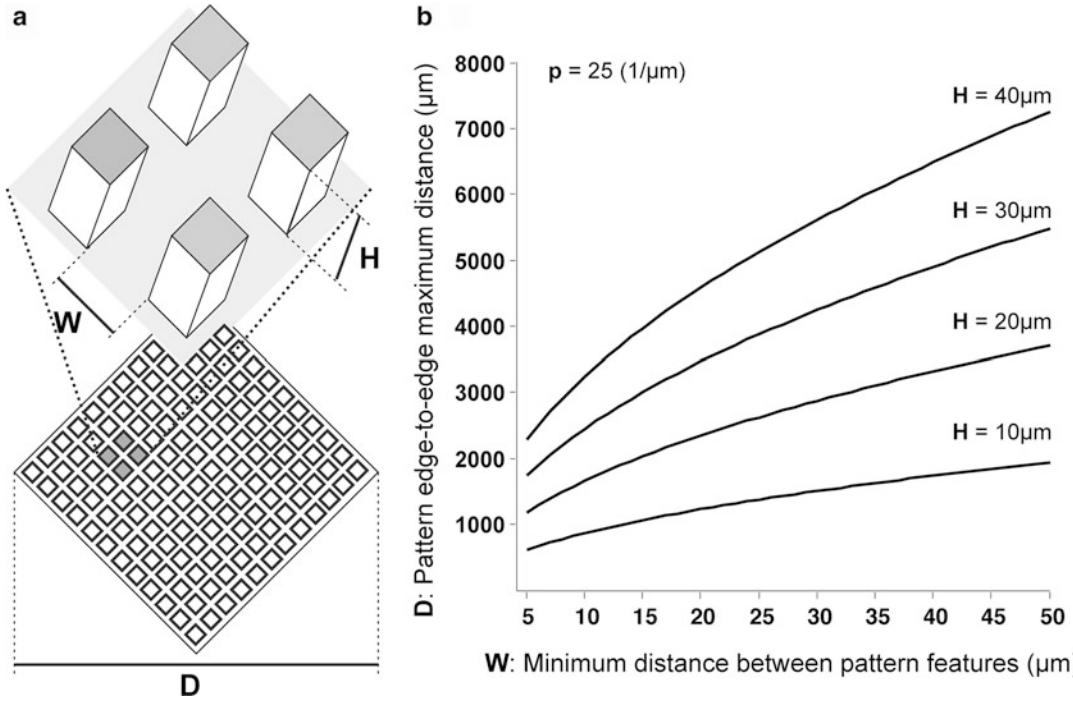
Many biological studies have demonstrated the importance of surface-patterning techniques for the study of fundamental biological processes [3–10]. An established application is to use micro-patterns to confine living cells to specific regions to study the effects of cell shape and spread area on cell behavior, e.g., as tracks for cell movement, and/or to impose a polar form on cells or to generate populations of cells with identical forms that can be used as an aid to quantification by enabling the simple averaging of behavior over large numbers of identically shaped cells [6, 10, 7, 3–5].

To confine the cells to regions with defined geometries, ligands known to bind native cell adhesion molecules are patterned to form foreground regions, while a cell-repellent molecule is used to backfill the background (Fig. 1). When plated onto this type of surface, cells specifically adhere to and spread onto the patterned regions, while retracting extensions that reach onto cell-repellent regions. As a result, this technique can be used to ensure that cells assume and maintain defined geometries imposed by the surface pattern.

The PμCP technique is based on plasma surface cleaning and is a simple, efficient, and cost-effective method for the precise patterning of molecules on surfaces. The PμCP combines the use of a 3D mask with plasma to produce highly reproducible, stable, and uniform molecular patterns. In particular, here is described a simple protocol for biopatterning using this technique, which can be easily adapted to other applications.

The PμCP is a simple procedure. In the first step, surfaces are coated with the molecule of interest (Fig. 1a). This can be done using virtually any surface materials or functionalization technique. Below, a simple protocol based on adsorption of fibronectin (a cell adhesive extracellular matrix protein) onto glass is described. A 3D mask patterned with geometrical features in relief is placed into conformal contact with the pre-coated surface to mask inked surfaces while leaving a 3D free-volume region accessible to plasma. The 3D mask with the glass attached is then plasma treated to remove the molecules from exposed surface regions (Fig. 1b), leaving the patterned region intact underneath the mask. Importantly, the plasma treatment leaves the cleaned surface with a hydrophilic and oxidized monolayer, which facilitates the binding affinity of subsequent coated molecules. In the final step, the mask is removed from the surface and a second molecule added to backfill the pattern generated through plasma cleaning (Fig. 1c). Steps 2 and 3 can then be repeated to form complex

Precise Biopatterning with Plasma: The Plasma Micro-contact Patterning (PμCP) Technique, Fig. 1 PμCP process. (**a**) Step 1: the surface is coated with the molecule of interest. (**b**) Step 2: the 3D mask is put in contact with pre-coated surface to form a free plasma accessible volume. A plasma treatment is then applied to remove the molecules bound to exposed surface regions. Pattern surface regions in contact with 3D mask remain intact. (**c**) Step 3: the second molecule of interest is added to backfill the surface regions previously cleaned by the plasma treatment. Importantly, Steps 2 and 3 can be repeated to make multi-patterns of different shapes and molecules (*black arrow*)



patterns using different molecules on the same surface (Fig. 1b, c).

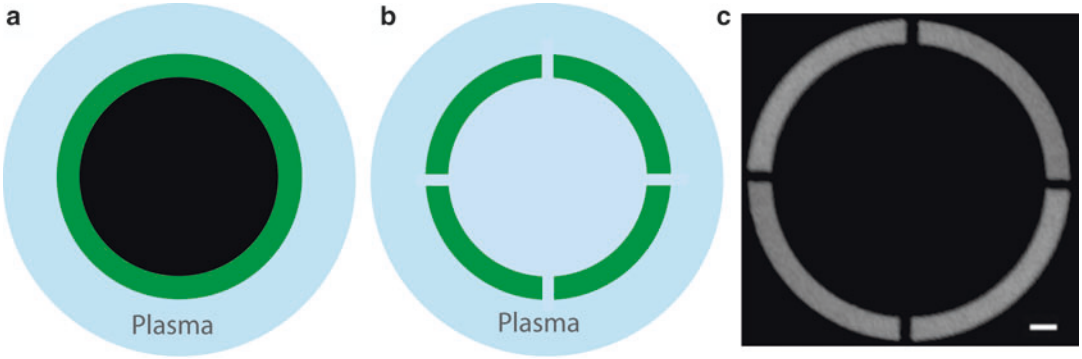
In subsequent paragraphs the single PμCP steps will be explained in detail, and a simple PμCP protocol for cell patterning will be described.

Methods

3D Mask Design and Fabrication

To produce the 3D mask, polydimethylsiloxane (PDMS, Sylgard 184, Dow Corning) was used. PDMS molds with very high fidelity to the master template (refer to the next paragraph for master fabrication) and its elastic properties allow the mask to make intimate contact with the surface. To fabricate the 3D PDMS mask with geometrical relief features, the prepolymer is mixed with a curing agent, poured onto the master, and cured at 70 °C for 3 h to cross-link the polymer. The standard PDMS to curing agent ratio is of 10:1. A 7:1 ratio for the PμCP technique was preferred. This produces stiffer masks improving feature stability when placed in contact with a surface. This is particularly important for masks with low-aspect-ratio features. Using a higher PDMS to curing agent ratio will make the 3D mask more elastic, a property that can be useful in producing patterns on curved surfaces or 3D microstructures (e.g., plastic tubes for implants, microfluidic channels).

Precise Biopatterning with Plasma: The Plasma Micro-contact Patterning (PμCP) Technique, Fig. 2 (**a**) Diagram showing the critical dimensions for the fabrication of the 3D mask. W: minimum pattern intra-features distance; H: pattern sidewall height; D: maximum pattern width distance. (**b**) A plot showing the relationship between *D*, *H*, and *W* according to the PμCP plasma penetration model described above given a specified range of values



To avoid problems associated with removing the 3D mask from the coated surface, the mask is first passivated using a silanizing agent. To do so, the wafer is put into a vacuum desiccator with 100ul of trimethylchlorosilane (silanizing agent) for 15 min. This work should be performed under a fume hood (refer to the material safety data sheet).

The 3D mask and photomask design for the PμCP should follow two main requirements. First, the free volume formed by the 3D mask in contact with the surface has to be externally accessible from the plasma. Therefore, when the pattern and photomask are designed, it has to be ensured that the geometrical features are not isolated inside a closed perimeter. Second, the plasma penetration is directly proportional to the 3D mask sidewall height (*H* in Fig. 2a) and to the minimum pattern intra-feature distance (*W* in Fig. 2a) and inversely proportional to the maximum mask width (*D* in Fig. 2a) (Fig. 2a). Numerical relationships between *W* and *H* and *D* were calculated by the following simple formula inferred empirically:

$$\frac{D}{H * \sqrt{W}} \leq p$$

where *p* is the "PμCP plasma penetration constant," calculated empirically to give optimal penetration value between 20 and 30 (1/μm).

The plot in Figure 2b shows the relationship between *D*, *H* and *W* according to the PμCP plasma penetration formula shown above for p=25(1/m) and a given range of values for *H*. Low *p* values give high plasma penetration efficiency into the 3D mask. Notably, high *H* value can give rise to feature buckling, and small *H* values and/or high *W* values can make the 3D mask roof collapse onto the surface [11]. Note that this does not take into account the flow of plasma through the device, which may be affected by the geometry of features and their connectedness.

Precise Biopatterning with Plasma: The Plasma Micro-contact Patterning (PμCP) Technique, Fig. 3 (**a**) An example of circular-shaped pattern with an internal hollow circle (*black region*) which cannot be accessed by the plasma. (**b**) Design of a 3D mask with small channels connecting the internal hollow shape with the 3D mask free volume, which can be accessed by the plasma. (**c**) Fibronectin pattern produced by using the PμCP with the 3D mask design shown in B. 3D mask dimensions: $W = 50$ μm, $H = 20$ μm, and $D = 3$ mm. Scale bar 5 μm

Mask stability can be improved by increasing the stiffness of the 3D mask and/or by gluing the top of a thin mask to a flat rigid surface (e.g., glass coverslip). To pattern large surface areas with a single PμCP application, multiple 3D masks on the same surface were placed.

A limitation of the PμCP technique is the difficulty of patterning hollow shapes (Fig. 3a). A solution to this problem can be obtained by designing the 3D mask in such a way that the internal hollow shapes are connected, by a small channel of a few microns, to the external free volume of the 3D mask (Fig. 3b).

Master Fabrication

A master, or template, is used to produce the 3D PDMS mask. A common way to produce a master is by exposing, through a photolithographic mask (photomask), a silicon wafer previously spin coated by a photoresist.

The PμCP technique does not require a special type of photolithographic mask (i.e., photomask). The minimum size of the pattern features determines the least expensive photomask that can be used without problems. The photomask can be designed by using commercial software (e.g., L-Edit, CleWin, AutoCAD, LayoutEditor) that produces GDSII, CIF, or DXF file formats. Once the photomask has been designed, it can be ordered from one of several photomask producers (e.g., JD Photo-Tools, Advance Reproductions). For the design requirements of the pattern shapes, sizes, and arrangement, refer to the above 3D mask fabrication paragraph. To make the process dust-free, all procedural steps are performed in a clean room.

Photoresist producers supply (e.g., MicroChem) clear processing guidelines for master fabrication. To enhance the release of the PDMS mold from the fabricated master, the wafer was passivated by a silanizing agent by putting the wafer into a vacuum desiccator with 100ul of trimethylchlorosilane (silanizing agent) for 15 min (work under a fume hood and refer to the material safety data sheet).

Surface Pre-coating

One of the main advantages of the plasma micropatterning over the standard micro-contact printing techniques is the possibility of separating the surface characterization from the actual surface-patterning step. In particular, by using PμCP, the molecules of interest can be applied to the surface before or after plasma treatment. This allows the concentration and uniformity of the molecules used to form the pattern to be precisely controlled (refer to the section "Precise Control of the Surface Patterning" for a detailed discussion on the precise control of the surface micro-patterning by using the PμCP). Here, a simple surface-coating

protocol based on adsorption of fibronectin onto a glass surface is described. Fibronectin adsorbs strongly and uniformly onto glass surfaces without compromising its ability to bind cells through integrin-mediated adhesion.

Materials
- Glass coverslips (Fisher Scientific) or glass bottom dishes/plates (MatTek)
- Ethanol 96 % (Sigma)
- Deionized H_2O
- Fibronectin (Sigma) or Fibronectin Alexa Fluor 488 nm (Invitrogen)

Equipment
- Laminar flow hood (NuAire)
- Nitrogen gas cylinder
- Sonicator (facultative, Branson, 2510)
- Vacuum storage system (facultative, custom produced)

Procedure
1. Glass surfaces are cleaned by bathing in 75 % ethanol, rinsed in deionized H_2O, and blow-dried with nitrogen.
   Optionally, glass cleaning can be improved by sonicating in 75 % EtOH for 15 min and rinsing with deionized H_2O. To keep the surfaces sterile, work under a laminar flow hood. If necessary, surfaces can also be cleaned using plasma or acid/alkali treatments.
2. Dried glass surfaces are immersed completely in 10–20 μg/ml fibronectin in deionized H_20 for 20 min. To generate a homogeneous surface coating, the entire glass surface must be immersed in the fibronectin solution. The fibronectin concentration used depends on the specific application.
3. Coated glass surfaces are then washed by deionized H2O and gently blow-dried with nitrogen.

Plasma Micro-patterning (Step 2)

Once surfaces are coated with the molecule of interest (in this protocol fibronectin), they are then treated with plasma to create the surface pattern. To do so, a 3D mask with the pattern features in relief is placed onto the pre-coated surface to create a free volume within the channels of the mask in which the plasma can penetrate to remove surface molecules. The 3D mask contact regions protected from the plasma will be left intact to form surface patterns. For this purpose, polydimethylsiloxane (PDMS) is an ideal material for the 3D mask because its elastic properties allow good contact and simple removal from the surface (see section "3D Mask Design and Fabrication" for details about 3D mask design requirements and fabrication).

For the plasma micro-patterning, oxygen plasma generated in a commercial plasma cleaner machine by electrically exciting an oxygen gas at low pressure (0.1–2 Torr) in a vacuum chamber was used. The plasma so generated has low temperature, positively and negatively charged molecules along with photons in the shortwave ultraviolet (i.e., vacuum UV or VUV) range and other reactive molecules. The surface removal is carried out by two main actions: (i) the breaking of organic bonds (i.e., C–H, C–C, C = C, C–O, and C–N) by the UV and (ii) the reaction of the plasma oxygen species (O_2^+, O_2^-, O_3, O, O^+, O^-, ionized ozone, metastable excited oxygen, and free electrons) with organic molecules on the surface to form H_2O, CO, CO_2, and lower molecular weight hydrocarbons, which are subsequently evacuated from the chamber. Thus, the plasma surface treatment removes the exposed surface molecules and leaves the bare surface with a hydrophilic oxidized monolayer, which facilitates the binding of subsequent molecules (Fig. 1b).

Materials
- Coated glass surfaces obtained from "surface pre-coating" step (see section "3D Mask Design and Fabrication")
- Deionized H_2O
- 75 % ethanol (in deionized H_2O)
- 3D PDMS mask (see section "3D Mask Design and Fabrication" for the 3D mask fabrication)

Equipment
- Plasma cleaner. It used the Femto plasma cleaner from Diener Electronic, Germany. This model of plasma cleaner allows the

manual control of the gas pressure, plasma time, power, and number of cycles.
– Sonicator (optional, Branson, 2510).

Procedure

1. The 3D mask is washed by sonicating in 75 % ethanol for 15 min and then rinsed with deionized water and blow-dried by nitrogen. It is important to ensure that the 3D mask and glass surfaces are dry for the next step. No washing is needed when using a newly fabricated 3D mask.
2. The clean, dry 3D mask is gently placed on top of the coated glass surface. A gentle pressure is applied with tweezers to allow even adhesion of the 3D mask to the surface. Adhesion can be monitored by close inspection.
3. The 3D mask with the glass surface attached is then placed into the plasma cleaner. The vacuum is switched on and three cycles of plasma treatments of 10 s each at 50 W power are performed. The parameters for plasma surface removal can vary between devices. Before PμCP routine use, a series of tests on the plasma cleaner are needed to find the optimal parameters (i.e., plasma time, power, and cycles). As a rule of thumb, the plasma time, power, and number of cycles need to be minimized. High plasma exposure could microblast the surface and modify the bulk material of the surface and the 3D mask.
4. The 3D mask is then gently removed from the glass surface and made ready for the post-coating step (see section "Surface Post-coating (Step 3)"). The 3D mask can be used straightaway for a new PμCP cycle (Fig. 1b, c). If needed, another cycle of PμCP can be carried out on the same patterned surfaces to make complex patterns with additional surface molecules. After lifting off the mask, inspect the patterned surface under a microscope to ensure that no PDMS residue remains on the surface. If PDMS residue is observed, then reduce plasma processing time, power, and/or number of cycles. If the problem persists, then use a new 3D mask.

Surface Post-coating (Step 3)

After the plasma micro-patterning step, a second molecule is added to coat the surface region removed by the plasma (pattern background). PLL-g-PEG was used as pattern background molecule as it is a cell-repellent molecule, which has been successfully used for cell micropatterning [12].

Materials

– Plasma micro-patterned glass surfaces obtained with the above protocols.
– PLL-g-PEG (0.1 mg/ml in HEPES). For the stock solution preparation, refer to the instructions from the producer (SuSoS, Switzerland, PLL(20)-g[3.5]-PEG(2)).
– Nitrogen cylinder with filtered spray gun (Innotech).

Protocol

1. Glass plasma micro-patterned surfaces are incubated in 0.1 mg/ml PLL-g-PEG solution at room temperature for 1 h.
2. Glass surfaces are rinsed in deionized H_2O and gently dried using nitrogen gas.

The patterned surfaces are now ready to be used. For best results, the patterned surfaces should be used the same day of the preparation. Optionally, patterned surfaces can be stored for months under vacuum and nitrogen or argon gasses at 4C. A low-cost and very simple design for a storage nitrogen/argon vacuum system can be requested from the authors.

Cell Patterning

Here a protocol for patterning adherent cells on PμCP-patterned surfaces is described. The PμCP protocol has been successfully used to pattern both adherent (e.g., RPE1, HeLa, MFC7A MFC10A, MDCK, HTC-116, A431, S2R+ cells) and nonadherent cells (e.g., *Drosophila* S2 cells and human T cells). In the case of nonadherent cells, patterning is achieved using 20 μg/ml concanavalin A (Sigma, C2272) on glass by the same protocol described above. Concanavalin A is a tetravalent lectin protein that binds a variety of glycosylated cell surface proteins and lipids.

Materials

- Cell dish/flask
- Trypsin (Gibco, the concentration depends on the cell type)
- 1× PBS (Gibco)
- Cell culture medium (the type and recipe of the culture medium depend on the cell type being used)

Equipment

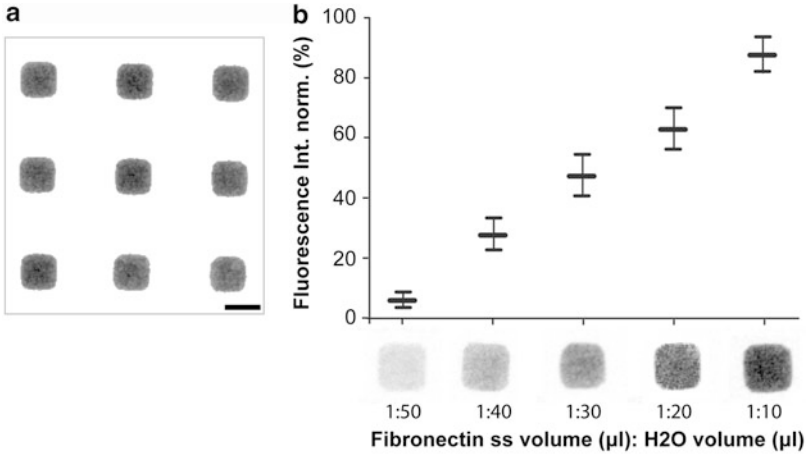
- Laminar flow hood (NuAire, TYPF A/B)
- Cell incubator (Fisher Scientific)
- Microscope (Nikon Diaphot inverted)
- Cell counter (Beckman) or hemacytometer
- Centrifuge (Thermo Scientific)

Protocol

1. Cell are washed with PBS, then detached from their culture surface using trypsin and resuspended in fresh culture medium.
2. Cells in suspension are centrifuged for 4 min at 1,200 rpm and resuspended in fresh culture medium. To detach cell clumps, gently pipette up and down the resuspended cells.
3. Cell numbers are determined and fresh medium is added to reach the desired density. Cell density for patterning needs to be determined empirically as it depends on the number and dimension of pattern features, overall surface area, and specific application.
4. Cells are plated onto the patterned surfaces and incubated to allow cell attachment and spreading.
5. After about 10 min, cells are examined under the microscope to confirm adhesion and confinement to the pattern. Attachment time can vary between cell types and cellular adhesive patterned molecule. In general cells attach and confine onto the pattern in 30–50 min after plating.
6. Nonattached cells are removed by gently exchanging the culture medium. Medium exchanges can be repeated to obtain the desired number of cells on the pattern. Ensure that the surface is left always wet to avoid cells dying during the culture medium change
7. Cells are incubated for at least 1 h to allow for complete cell spreading. Significantly, cells stably bind to plasma-patterned substrates for several days, without their destroying the pattern. This is not the case for micro-patterns generated by simple PDMS stamping (Fig. 7).

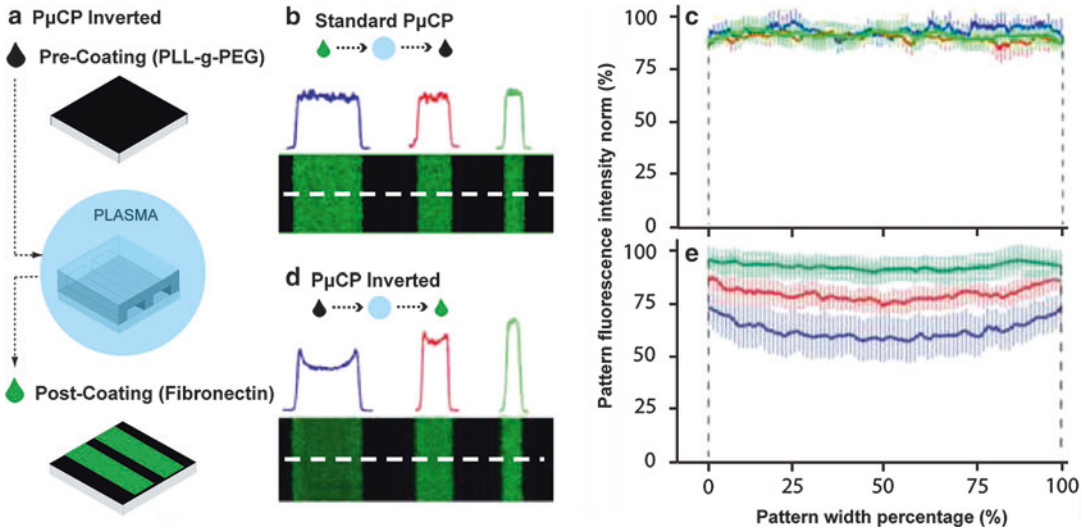
Results

Precise Control of the Surface Patterning



An important advantage of PμCP is the ease of controlling the concentration and uniformity of the patterned surfaces. To show that this is the case, the method described above was used to coat glass with five different concentrations of fluorescently conjugated fibronectin protein (Fig. 4) prior to PμCP. The results of this test showed that the patterns generated using PμCP are reproducible, having a maximum average variation of about 10 % across a small area of patterned substrate, and that concentration titration of the pre-coated fibronectin on glass results in a reproducible linear increase in surface fibronectin density as measured by fluorescence intensity (Fig. 4).

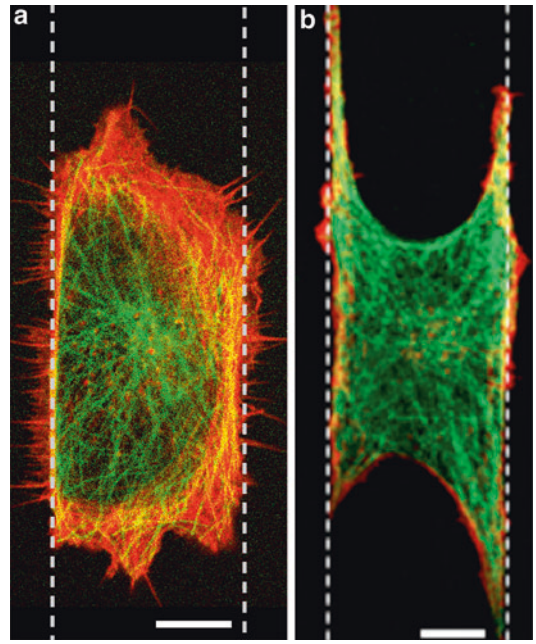
PμCP-Inverted Techniques: Comparison with the Standard PμCP



A variation to the PμCP procedure can be implemented by inverting the standard PμCP protocol above described to first coat the background layer (e.g., with PLL-g-PEG) before plasma treatment (micro-patterning step) and then application of the foreground (e.g., fibronectin) (Fig. 5a). This inverted PμCP technique (PμCP-inv) can only be applied to pattern features that form 3D mask with a 3D open space accessible to the plasma.

Interestingly, when fibronectin lines micropatterned by the standard PμCP were compared with the ones obtained by using the PμCP-inv technique, an increased concentration of molecules at the edges of the pattern produced by using the PμCP-inv technique (Fig. 5d, e) was observed. Furthermore, this pattern "edge effect" was dependent on the pattern size (i.e., line width) (Fig. 5d, e).

This edge effect was reproducible and seems likely to be due to differences in the diffusion of fibronectin over the micro-patterned PLL-g-PEG



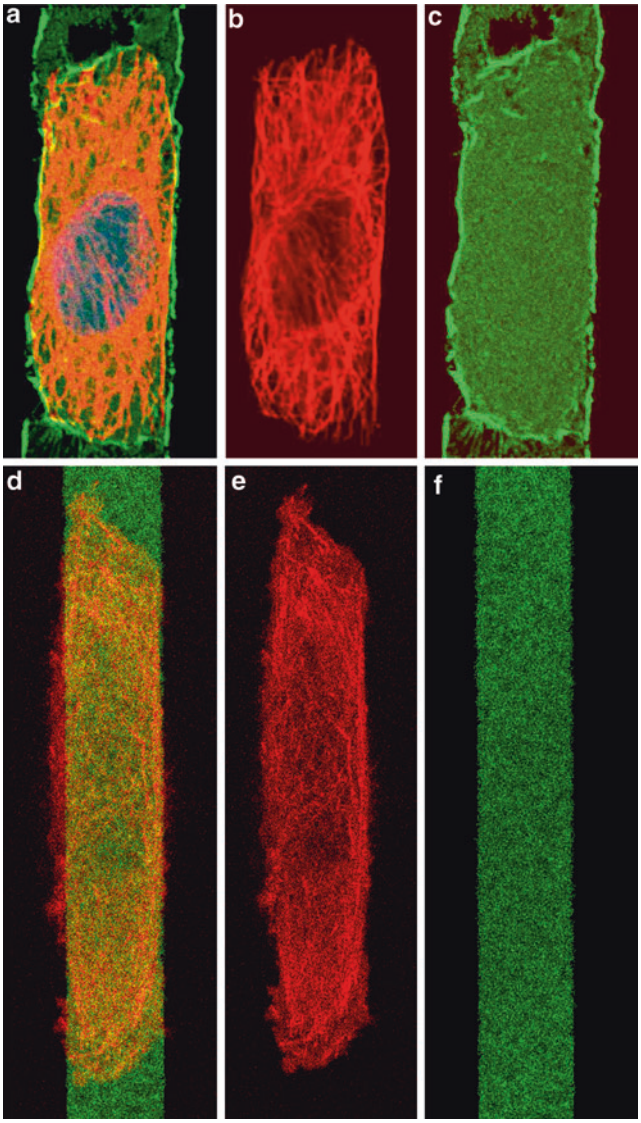
Precise Biopatterning with Plasma: The Plasma Micro-contact Patterning (PμCP) Technique, Fig. 4 Precise control of pattern concentration and uniformity using PμCP. (**a**) 10 × 10 μm fluorescently labeled fibronectin square-shaped patterns on glass produced by the PμCP technique. (**b**) A plot to show the fluorescence intensities of square-shaped fibronectin patterns generated using five different concentrations of fibronectin (ss = stock solution of 1 mg/ml) via the protocol described above. To compare images across acquisitions, fibronectin fluorescence images were corrected and the fluorescence intensity values expressed as percentage of the minimum and maximum intensity values. 3D mask dimensions: $W =$ 17.5 μm, $H = 20$ μm, and $D = 2$ mm. Scale bar 10 μm

Precise Biopatterning with Plasma: The Plasma Micro-contact Patterning (PμCP) Technique, Fig. 5 (**a**) PμCP-inverted (PμCP-inv) protocol. Images show fibronectin lines (*green*) of different widths (*thick*, *middle, and thin*) micro-patterned using the standard PμCP (**b**) or PμCP-inv (**d**), together with the corresponding normalized fluorescence intensity diagrams (direction indicated by the *dotted white line*). The images were acquired by confocal microscopy. PLL-g-PEG was used as background molecule (*black* areas in **b** and **d**). Graphs (**b** and **e**) show comparison between fluorescence intensities of the three fibronectin line width classes: thick (23–32 μm, in *blue*, $N = 13$), middle (13–22 μm, in *red*, $N = 11$), and thin (3–12 μm, in *green*, $N = 12$) micro-patterned using PμCP (**b**) or PμCP-inv (**c**) techniques. To compare fluorescence intensities of the different pattern line widths, the intensities were plotted against normalized line width. Graph bars indicate standard deviations. 3D mask dimensions: $W =$ 50 μm, $H = 20$ μm, and $D = 3$ mm

surface. Notably, this edge effect is not visible in the patterns generated by using the standard PμCP technique because the fibronectin coating is applied uniformly prior to plasma treatment (Fig. 5b, c). Nevertheless, the standard PμCP technique could in principle produce increased PLL-g-PEG concentration at the pattern edges. This does not represent a physical barrier as cells growing on thin fibronectin lines visibly extend and retract lamellipodium outside of the pattern onto the PEG. However, a more concentrated PLL-g-PEG rim all around the patterns could enhance the micro-patterning cell confinement.

Notably, when cells on the patterns were plated with increased concentration at the edges, it was found that cells show a nonuniform spreading. Cells preferentially spread along pattern edges forming a characteristic concave border (Fig. 6b). Importantly, this suggests that the correct control of the molecule pattern concentration and uniformity is crucial to avoid misinterpretation of the phenomena under observation.

Precise Biopatterning with Plasma: The Plasma Micro-contact Patterning (PμCP) Technique, Fig. 6 HeLa cells on fibronectin lines micro-patterned by using PμCP (**a**) or PμCP-inv (**b**) technique (f-actin in *red* and microtubules in *green*). In A the fibronectin pattern was produced by the standard PμCP protocol described above. In B to produce the edge effect, the fibronectins were coated at low concentrations (5 μg/ml) and short seeding time (15 min). 3D mask dimensions: $W = 50$ μm, $H = 20$ μm, and $D = 3$ mm. Scale bar 10 μm



Discussion

The PμCP technique is simple to implement and allows the precise control of surface characterization and micro-patterning steps. Furthermore, it allows the patterning of organic molecules on different surface materials and at different conformations (e.g., flat and curved surfaces and 3D microstructures). This makes the PμCP particularly suitable for biomedical applications but can be also easily adapted to other types of applications and different fields.

In the last 10 years, there has been a proliferation of new methods for micro-patterning, but two methods are mostly used in biology laboratories: the soft-lithography-based [1], in particular μCP, and UV-based techniques [13].

In comparison to the μCP, the PμCP has the advantage of having a better control over individual patterning steps. It aids the generation of reproducible and uniform patterns, which can be difficult to achieve using simple μCP [14]. Moreover, in our hands, μCP-patterned surfaces are not as resistant to contractile forces exerted by cells over long periods as those generated using PμCP (Fig. 7) [14]. The use of gold self-assembly on classical substrate for cell biology (e.g., plastic or glass) can be used to overcome in part to this problem [15], but with the drawback of adding complexity to the overall micro-patterning process. Nevertheless, the difficulty of controlling the loading and successive unloading and transfer of the molecules from the stamp to the surface still remains [16].

Using PμCP, it is possible to overcome these limitations by using the elastomeric stamp as a mask (3D mask) for the plasma micro-patterning and by separating the surface functionalization steps from the micro-patterning step. Furthermore, the use of the elastomeric stamp as 3D mask allows the micro-patterning of molecules on flat and non-flat substrates (e.g., 3D

Precise Biopatterning with Plasma: The Plasma Micro-contact Patterning (PμCP) Technique, Fig. 7 After 12h, HeLa cells tend to remove the line-shaped fibronectin pattern (A and C, in green) generated using the standard CP technique. This was not the case for the line-shaped fibronectin pattern generated with the PCP (D and F, in green), which remained stable. Cell microtubules are shown (B and E, in red)

microstructures, microfluidic channels, or tubing for biomedical applications). In addition, the elastomeric 3D mask can be cut and resized to allow the micro-patterning of surfaces inside chambers, dishes, and multi-well plates.

Potential problems associated with PμCP are the need of photolithography tools and skills for the master fabrication and plasma cleaner. Although these are not traditionally skills and tools available in a biological laboratory, the procedure for the master fabrication is simple, well established, and requires only about 2 h to be accomplished; and only a single master needs to be fabricated as many can be replicated from it by a simple epoxy replica molding process [17]. Alternatively, the fabrication of the 3D mask can be inexpensively purchased (e.g., BioTray). A plasma cleaner machine can be also purchased at a reasonable cost from different producers (e.g., Harrick Plasma, Plasma Etch, Glow Research, Diener Electronic). Alternatively, low-cost oxygen plasma cleaner machines can be built or purchased unassembled (e.g., Epsilon Micro Devices).

Another micro-patterning technique which is procedurally similar to the PμCP (in particular to

the PμCP-inv) which also offers good control on the micro-patterning process is the UV-based techniques [13]. In this case, deep UV light and photomask with transparent micrometer pattern features is used to locally irradiate a pre-coated PEG-based cell-repellent molecule monolayer. The pattern is then obtained by backfilling with a molecule of interest (e.g., fibronectin) the UV-irradiated areas. Unlike PμCP and μCP, the UV-based micro-patterning technique has the advantage of not requiring the master or stamp/3D mask fabrication. However, it requires the use of specialized equipment (i.e., UV ozone oven) and of an expensive photomask allowing the penetration of the deep UV light.

The PμCP- and UV-based techniques have in common the separation of the surface functionalization from the micro-patterning step [13]. However, the UV-based technique employs the inverse PμCP process (PμCP-inv is described in section "PμCP-Inverted Techniques: Comparison with the Standard PμCP"). The cell-repellent molecule is coated before the micro-patterning step (UV illumination), and the cell adhesive protein (e.g., fibronectin) is coated after it.

UV-based techniques give good control on the surface passivation but have the potential drawback of generating "edge effects" described above when low concentration or/and short incubation times of the post-coating molecule are applied. Consequently, good molecule uniformity can be only obtained by saturating patterned regions with a specific molecule at high concentration and/or long incubation times, compromising the control of pattern molecule concentration and uniformity. The PμCP it is not subject to this problem as the coating of the patterning molecule is applied to the non-confined surface before the plasma treatment.

A secondary advantage of the plasma treatment is the formation of an oxidized surface layer aiding subsequent surface chemistries and the binding of the plasma-cleaned micro-patterned surface to microfluidic devices. The PμCP also induces very efficient removal of the unmasked surface molecules by using a low-temperature plasma oxygen, which forms a "cloud" of reactive oxygen species that breaks organic bonds, cleans the surface, and evacuates residues, something that UV alone does not mimic. Note that short plasma exposure times and low power must be applied to prevent the surface bulk material being damaged. Moreover, a specific 3D mask design must be implemented to allow the efficient plasma penetration into the mask channels (see section "3D Mask Design and Fabrication").

One of the major limitations of micro-patterning technique is the difficulty of patterning at the nanometer scale. This limitation is mainly due to the use of light for the micro-patterning process. The plasma micro-patterning removal is mainly dependent on the penetration of atomic reactive species into the confined 3D mask open volume. Thus, PμCP has the potential to be used for nano-patterning, but further studies are needed to investigate the plasma penetration and efficiency in nano-compartments.

In conclusion, the PμCP technique is highly reproducible, is easy and fast to apply, allows the precise control of the patterned molecule concentration and uniformity, and has the potential to be applied to patterning molecules at nanometer scale.

Prenucleation Clusters

Denis Gebauer
Department of Chemistry, Physical Chemistry, University of Konstanz, Konstanz, Germany

Synonyms

DOLLOP (Dynamically Ordered Liquid-Like Oxyanion Polymer); Stable clusters; Stable pre-critical clusters

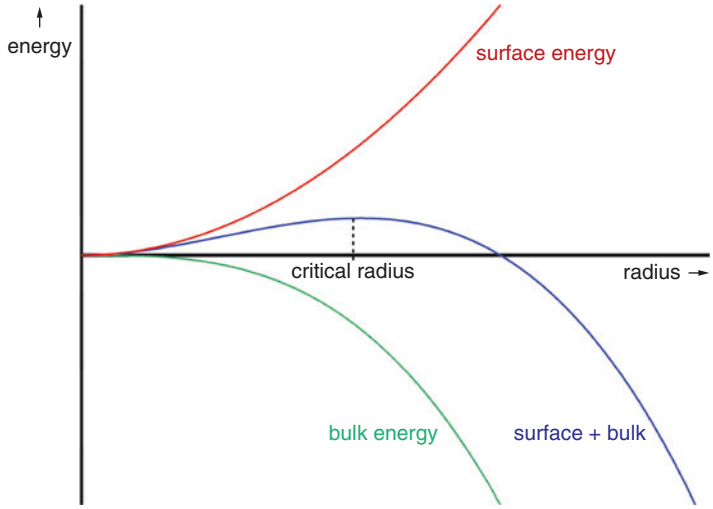
Definition

Prenucleation clusters are thermodynamically stable associates of atoms, ions, or molecules forming in solution, approximately 1–3 nm in size on average. They are solutes themselves and form based upon dynamic chemical equilibrium in undersaturated as well as supersaturated (metastable) solution states, playing a key role during nucleation of a second phase from the latter.

Overview

Relevance

How crystallization may be controlled is an important question, since many processes and applications depend on the control of



crystal polymorphism, morphology, size, and other crystal characteristics. However, today, the design of bottom-up approaches to tailor-made crystalline materials is still widely settled in the realm of trial and error. In order to improve these empirical approaches, (nano)technology depends on a molecular understanding of the underlying processes [1]. A look at living nature shows that organisms are able to control crystallization in sophisticated ways, and form mineralized structures – biominerals like bone, teeth, or nacre – that show outstanding material properties that are tailor made with respect to function through advanced micro- and nanostructures [2]. Many studies have indicated that biomineralization processes can proceed via so-called nonclassical, that is, particle-mediated pathways, which may also involve liquid and/or amorphous intermediates [3]. In contrast, classical theories presented in most crystallization textbooks only consider ion-by-ion, atom-by-atom, or molecule-by-molecule reaction channels for nucleation and growth [4].

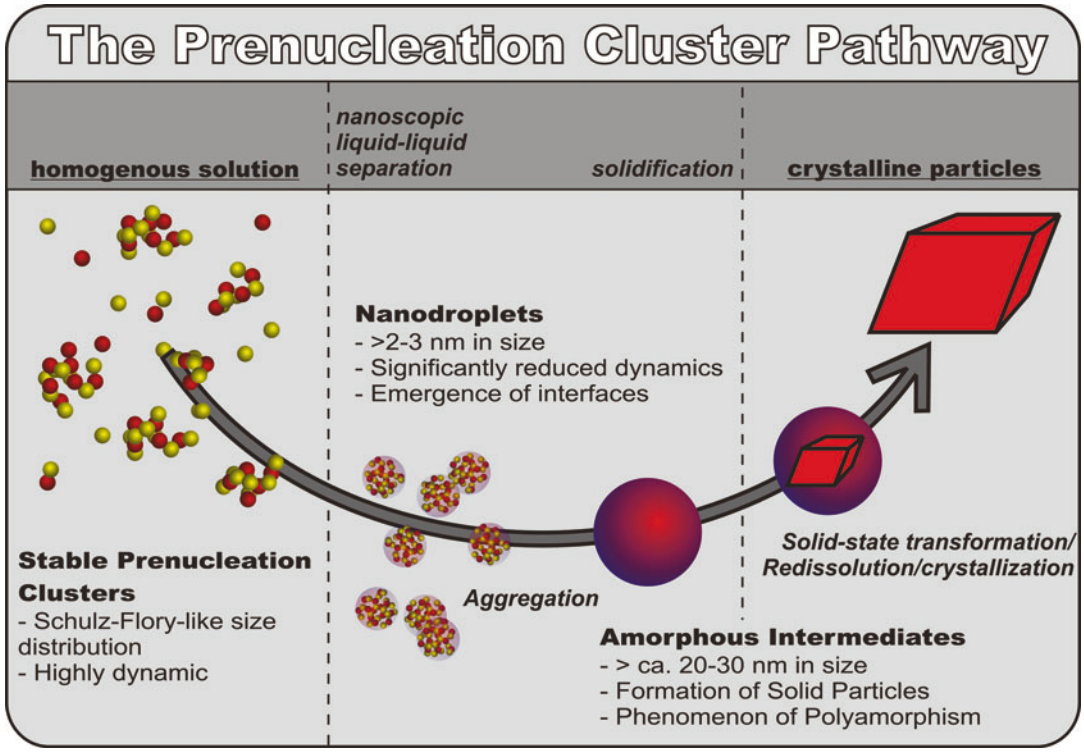
The notion of stable prenucleation clusters can be regarded as an important expansion of nonclassical concepts toward the most fundamental step in crystallization: nucleation [5]. The term "nucleation" refers to the onset of phase separation in a system that has become supersaturated. The existence of stable clusters is not taken into account within classical nucleation theory, which is the framework that is used to access nucleation phenomena in the majority of cases. Hence, an alternative reaction channel referred to as the "prenucleation cluster pathway" has been proposed [5], which includes a nanoscopic liquid-liquid separation as central event. In the proposed mechanism, stable prenucleation clusters play a key role as direct molecular solute precursors of phase-separated nanodroplets. There are strong indications that this pathway is relevant for many materials forming from aqueous solution, including the most important biominerals calcium carbonate and phosphate, as well as silica, iron oxides, calcium oxalate, but also small organic molecules like amino acids, urea, or citrate [5, 6].

Background: Classical Nucleation Theory

Nucleation means the onset of a phase transition, that is, the irreversible formation of the first nuclei of a nascent phase in a system that has become supersaturated. The work of Becker and Döring is commonly known as classical nucleation theory (CNT), which was originally derived for the formation of nuclei from supersaturated water vapors [7, 8]. The fundamental assumption of CNT is that the bulk energy of a forming nucleus drives nucleation, while the generation of a phase interface, and with it of interfacial surface, is the antagonist and impedes nucleus growth. The bulk energy (favorable, negative sign) scales with the cube of the radius of the nuclei, and their surface energy (unfavorable, positive sign) increases with the square of the radius. Hence, the bulk energy begins to balance the energetic costs due to the generation of a phase interface at a certain point (Fig. 1). A nucleus of this size is the critical nucleus. The critical size corresponds to a metastable state of equilibrium, and even infinitesimal changes toward smaller or larger sizes will lead to nucleus dissolution or growth without limit, respectively. The change in free enthalpy for the formation of (pre) critical nuclei is positive, hence formation of these species is thermodynamically improbable and can only occur through fluctuations on microscopic scales.

CNT makes several assumptions, among which the so-called capillary assumption is the most debatable. The oversimplification was realized already by Gibbs when he first formulated it: Nanoscopic nuclei of a nascent phase are assumed to behave as if they were macroscopic. There have been several empirical and semiempirical treatments of CNT that aim at the improvement of quantitative predictions of nucleation rates, which can deviate from measurements by many orders of magnitude [9]. Under purely qualitative considerations, though, CNT is successful in describing nucleation phenomena in principle. The hallmark of nucleation is the presence of a barrier, which scales with supersaturation (and temperature) and prevents nucleation from proceeding spontaneously, at least close to the saturation limit. CNT assumes that a nucleus of critical size is fundamental to the existence of this thermodynamic barrier.

Prenucleation Clusters, Fig. 1 Classical representation of the energy of a nucleus (*blue line*) in dependence of its radius in a supersaturated system. The surface energy gives a positive (unfavorable, *red line*) and the bulk energy a negative energetic contribution (*green line*), which are proportional to the square and the cube of the radius, respectively. Hence, at the critical size, the bulk term begins to balance the surface term



Prenucleation Clusters: An Alternative Concept

Prenucleation clusters, as opposed to classical nuclei, are considered to be solutes. Their formation is thus not linked to the problem of phase separation, at least during the initial stages. Mechanistically, prenucleation cluster formation can be conceived of being analogous with polycondensation reactions, yielding mostly chain-like assemblies of monomers. Hence, solute association leads to Schulz-Flory-like size distributions of a population of clusters [10]. Since a broad distribution of many clusters is entropically favorable, thermodynamically stable clusters will not grow without limit to macroscopic sizes. Also, the solute clusters will not aggregate, because there is no driving force for this due to the absence of interfacial surfaces.

Accordingly, five key characteristics have been suggested to define chemical species as prenucleation clusters [5]:

1. They are composed of chemical entities that also constitute the final solid but may include additional molecules like water.
2. Prenucleation clusters are thermodynamically stable solutes, around 1–3 nm in size on average, and there is formally no phase boundary with the surrounding solution.
3. They are direct molecular precursors to phase-separated species.
4. Stable solute clusters are highly dynamic and change configuration on timescales of hundreds of picoseconds, typical for rearrangements in solution.
5. They can exhibit distinct structural motifs and thereby give rise to the phenomenon of polyamorphism as observed in transient solid intermediates [11].

Computer simulations evidence that upon reaching a certain size, prenucleation clusters can internally develop higher coordination numbers than in the initial chain-like forms. This slows down their dynamics distinctly; thus, the clusters become different from the solution and should then be regarded as nanodroplets of a second phase. The resulting phase interface is subsequently reduced via aggregation, yielding larger, eventually solid amorphous nanoparticles most likely through solidification. However, the direct formation of (nano)crystalline species from prenucleation clusters should not be categorically excluded [5]. Returning to the hallmark of nucleation, the barrier of phase separation close to the solubility limit in the prenucleation cluster pathway is considered to arise from considerable energetic costs for condensing small dynamic solute clusters toward bulk-like states with distinctly higher coordination. Only fluctuations toward larger cluster sizes can lead to the development of somewhat higher coordination numbers,

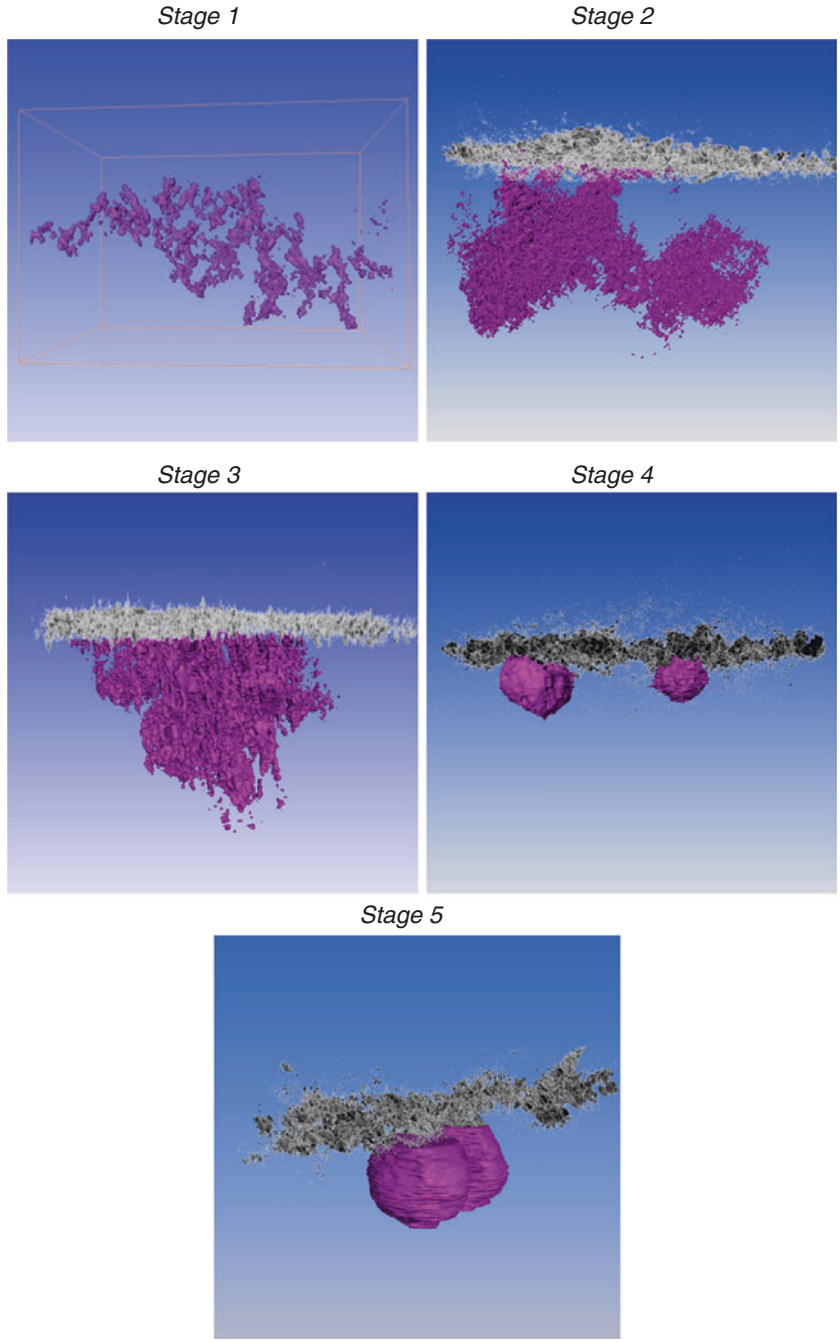
Prenucleation Clusters, Fig. 2 Schematic illustration of the prenucleation cluster pathway. Stable prenucleation clusters form in solution based on chemical equilibrium. They are direct molecular precursors to phase-separated nanodroplets, forming upon a nanoscopic liquid-liquid separation event. The key difference between prenucleation clusters and nanodroplets is the distinctly reduced dynamics of the latter. This corresponds to the emergence of interfacial surfaces, which are reduced via aggregation, yielding amorphous intermediates. These may solidify and eventually crystallize. For explanation see text

slowing down the dynamics, and phase separation yielding at first liquid nanodroplets can be initiated as described above. Physically, this event can be conceived of as entering a nanoscopic liquid-liquid miscibility gap [5]. A schematic overview of the prenucleation cluster pathway is illustrated in Fig. 2.

Key Research Findings

In case of electrolyte solutions, the prenucleation cluster concept essentially represents an expansion of classical ion-pairing models [5]. In older literature, it is postulated that ion association must be limited to ion pairs when corresponding experimental ion-binding profiles are linear. The basic argument in this case is that the formation of defined larger species would lead to curved ion-binding behavior, as can be shown easily utilizing the law of mass action [5]. The most prominent example for this observation is arguably calcium carbonate. The first central key research finding here is the realization that linear ion-binding profiles are in fact ambiguous and that the formation of higher associated states cannot be unequivocally ruled out based upon ion-binding profiles alone. This ambiguity arises when successive binding events that lead to the generation of larger associates (e.g., in case of calcium carbonate, binding of a calcium ion to a carbonate ion, binding of a calcium ion to a calcium carbonate ion pair, binding of an ion pair to an ion pair, and so forth) are assumed to be all equal and independent, that is, bound by equivalent energetics. Then, all association events are

macroscopically indistinguishable in the first place and may appear like simple ion pairing from the point of view of the law of mass action, despite the presence of large clusters. While this basic assumption may seem like an oversimplification, extensive computer simulations do show that it is indeed sustainable [5]. Thus, in any case, the unambiguous identification, or exclusion, of higher associated states crucially depends upon additional techniques like analytical ultracentrifugation, which can also show that the bound ions quantitatively reside in entities that are much larger than ion pairs on average [5].



Second, the thermodynamic stability of prenucleation clusters (equilibrium constant of formation $K >> 1$ and a corresponding change in free enthalpy of $\Delta G < 0$) is essential to explain the occurrence of a significant population of larger clusters, which can be analytically detected in the first place. In contrast, metastable species are in fact very rare (owing to an equilibrium constant of formation $0 < K < 1$, and thus $\Delta G > 0$) and usually cannot be detected analytically. Because a metastable state is regarded to be central to the nucleation event within the notions of CNT, stable species have to be regarded as inactive during phase separation processes according to this theoretical framework, because they cannot participate in metastable fluctuations that would lead to the random formation of a critical nucleus. Stable clusters would sit in a free energy trap and hamper formation of a critical nucleus, at least from a classical point of view [5, 12].

However, in the prenucleation cluster pathway, the stable clusters do not yield a solid metastable nucleus of critical size but form amorphous nanodroplets via a structurally more direct transformation, and these nanophases subsequently aggregate to form a new macroscopic phase. At this point, it is important to note that the existence of a nucleation barrier shows that phase separation is a generic consequence of metastable fluctuations, which do not necessarily require the existence of a classical critical nucleus. Thus, the third major key research finding is that metastable fluctuations can also occur in a stable cluster population. They lead to the random occurrence of large clusters through microscopic fluctuations, which correspond to metastable deviations from the equilibrium cluster size distribution. In turn, the random occurrence of a significant population of rather large clusters, which can condense internally as opposed to smaller ones, would be at first reversible and physically correspond to a binodal nanoscopic liquid-liquid separation event [5].

Future Directions for Research

Despite significant progress when it comes to the understanding of the prenucleation cluster pathway in the recent years, many open questions remain that need to be addressed. The following list does not demand to be complete and is supposed to give a rather generic overview:

- *Nucleation theory*: It is most important to include the notion of stable prenucleation clusters into a revised quantitative theory of nucleation. In this context, modeling and simulation approaches appear to be crucial. The implementation concerns homogeneous nucleation theory, but cluster-based pathways do play a role in heterogeneous phase separation processes as well (Fig. 3). The latter are of immediate importance for various industrial and technological problems but also in biomineralization and medical issues.
- *Biomineralization and additive-controlled crystallization*: It is now evident that prenucleation clusters play important roles during surface-induced crystallization in biomimetic approaches (Fig. 3), but their role in biological systems has not been shown directly. Importantly, the prenucleation cluster pathway can mechanistically explain the occurrence of liquid intermediate forms of minerals, which are considered to play a central role in biomineralization [13]. The latter phenomenon provides a direct link to additive-controlled mineralization, since such liquid intermediates can be stabilized by certain polymers. This immediately raises the question whether this phenomenon can be exploited more generally than previously assumed and

Prenucleation Clusters, Fig. 3 Computer-aided 3D visualization of tomograms from cryo-TEM of different stages of the surface-induced mineralization of calcium phosphate from simulated body fluid. Prenucleation clusters (*Stage 1*) that are approximately 0.9 nm in size aggregate upon tranformation into nanodroplets on an extrinsic surface (*Stages 2 & 3*) to form initially amorphous nanoparticles (*Stage 4*), which subsequently crystallize (*Stage 5*; data kindly provided by A. Dey and N. A. J. M. Sommerdijk)

how the prenucleation cluster pathway may improve the understanding of additive-controlled mineralization, as suggested for biomineralization [14].

- *Generality*: Prenucleation clusters have been shown to exist for a series of compounds, including most biominerals but also small organic molecules. The prenucleation cluster pathway may be a more general phenomenon that may apply to the formation mechanism of many solids, perhaps not only in aqueous solution. The generality of the prenucleation cluster concept has to be tested, including the identification of conditions under which cluster-based mechanisms of phase separation may or may not dominate.

Definition

Pulsed high-intensity ultrasound (pHIFU) is a technique used to physically modify the permeability and hydraulic conductivity characteristics of living tissue in order to increase penetration and accumulation of large molecular drugs or nanoparticles in the interstitial space. Pulsed HIFU is a form of *ultrasound-enhanced drug delivery*; however, while the latter may be assisted by the use of exogenous agents such as *ultrasound contrast agents* or *microbubbles*, those who use pHIFU generally rely on the physical interaction of the ultrasound with the tissue alone. The use of pulsed energy deposition is specifically designed to enhance the mechanical over the thermal effects of the focused ultrasound by allowing for deposited heat to dissipate even at high powers.

Microbubble contrast agents are avoided to prevent *cavitation* in the tissue.

Ultrasound and the Nanoparticle Delivery Problem

The transport of agents to tissues can be divided into steps based on the different physiological barriers presented, from administration to final interaction with individual cells. The relative importance of each step is dependent on the type of agent (size, surface chemistry), the type of tissue, and the type of administration (intravenous, direct injection). Assuming systemic injection, the amount of agent that ultimately reaches an individual cell depends, in some part, on eight factors: (1) agent-specific blood pool pharmacokinetics, (2) tissue perfusion, (3) local vascular topography, (4) agent-specific local vascular permeability, (5) agent-specific interstitial conductivity, (6) interstitial topography, (7) cellular affinity, and, finally, (8) vascular/lymphatic drainage efficiency. In the case of a direct (intratissue) injection, the first four factors are much less important but probably still play a role in the distribution of agents whose transport is convection dominated.

Nanoparticles pose a specific challenge to the natural transport scheme because of their sizes and surface chemistry. Certain issues, such as blood pool pharmacokinetics, have been largely addressed with various surface coatings and proper particle size; however, the issue of getting nanoparticles across vascular, endothelial, and cell membrane barriers and into the tumor parenchyma and cell is still a challenge. First, within the vasculature of tumors there are pockets of stasis and poor perfusion, due in large part to the improperly constituted and chaotic network of blood vessels in these environments [1]. This situation might be improved by increases in perfusion due to ultrasound hyperthermia or other vascular effects of ultrasound. Huge increases in perfusion are known to accompany hyperthermia in temperature-sensitive tissue such as muscle. Increases in tumor are much more modest and limited [2] but still important. Second, most of the currently successful nanoparticles targeted to solid tumors rely heavily on the atypically high fenestration of the endothelial barrier in tumors compared to most other tissues. This means that particles in the size range of ~50–200 nm in diameter have a tendency to accumulate preferentially in tumor tissue even without further considerations (known as the enhanced permeability and retention or EPR effect). Unfortunately, the exact size cutoff is highly dependent on tumor type and can be highly variable across tumors and even within the same tumor [3]. In tissues with poor fenestration, there is evidence that ultrasound treatment can enhance the movement of nanoparticles across the endothelium. Third, nanoparticles generally move most efficiently by convection; however, in the tumor microenvironment, convective flow beyond the vasculature is virtually nonexistent. The interstitial conductivity and topography that determine how an agent penetrates and distributes in the interstitial space by either convection or diffusion is not favorable to the movement of nanoparticles through tumors. Cellular crowding due to rapid growth and the production of a collagenous extracellular matrix can both result in barriers to large particle movement. As well, the lack of lymphatics in tumors contributes to poor drainage, causing high interstitial fluid pressures and sluggish flow. A number of preliminary experiments involving pHIFU and direct intratumoral injection of agents have suggested improved distribution in the interstitial space. A final issue is the difficulty of getting nanoparticles into the cell through the cell membrane. Although many potential techniques exist to address this problem, many of them leave the nanoparticle sequestered inside the cell only to be ejected later, or are not practical for clinical work. The effects of ultrasound cavitation can transiently increase membrane permeability (sonoporation), and may be able to provide a physical means of achieving intracellular accumulation of nanoparticles. All these considerations suggest strongly that there is a need to remodel or re-engineer the transportation dynamics to be more favorable to nanoparticle traffic, and that ultrasound treatment provides some opportunity to do so.

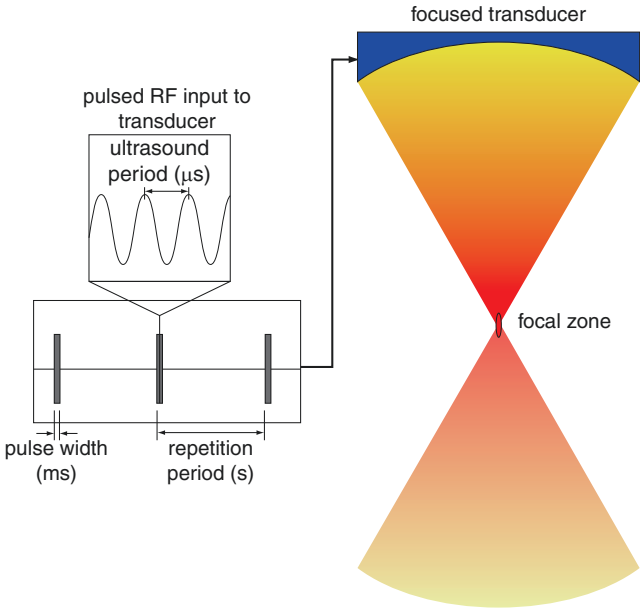
Basic pHIFU Physics

Ultrasound is a coherent traveling pressure disturbance that easily transports mechanical and thermal energy through biological soft tissues [4]. As ultrasound travels, the coherent wave is attenuated by absorption and scattering processes. A traveling ultrasonic pressure plane wave might generally be written as

$$p(x,t) = p_0 \sin\left(\omega\left(\frac{x}{c} - t\right)\right)\exp(-\mu_a x),$$

where p_0 is the pressure amplitude, ω is the frequency, c is the speed of sound, and μ_0 is the attenuation of the wave. The intensity of the wave is given by $I = \frac{p_0^2}{2\rho c}$ with ρ the density of the medium. At frequencies around 1 MHz, traveling at a speed of 1,500–1,600 m/s in water or tissue, the ultrasonic wavelength is on the order of 1.5–1.6 mm, much too long to directly couple to objects on the cellular scale. The low compressibility of water means that ultrasonic strains remain quite low even when pressures reach tens of atmospheres. Thus, the pressure disturbance itself, even at powers as high as 10^4 W/cm^2, is generally regarded as having no direct biological effects, unless cavitation is involved (see below). In the absence of cavitation, part of the wave energy is still continuously being reflected or absorbed as heat, a fact modeled with an attenuation coefficient. The attenuation coefficient, μ_a, determines how the wave transmits energy and momentum to the media through which it passes. Attenuation in general incorporates both scattering and absorption phenomena; however, often absorption is thought to be dominant. The absorption of the energy creates heat, and this heat per unit volume is given by

$$\dot{Q} = \mu_a I$$



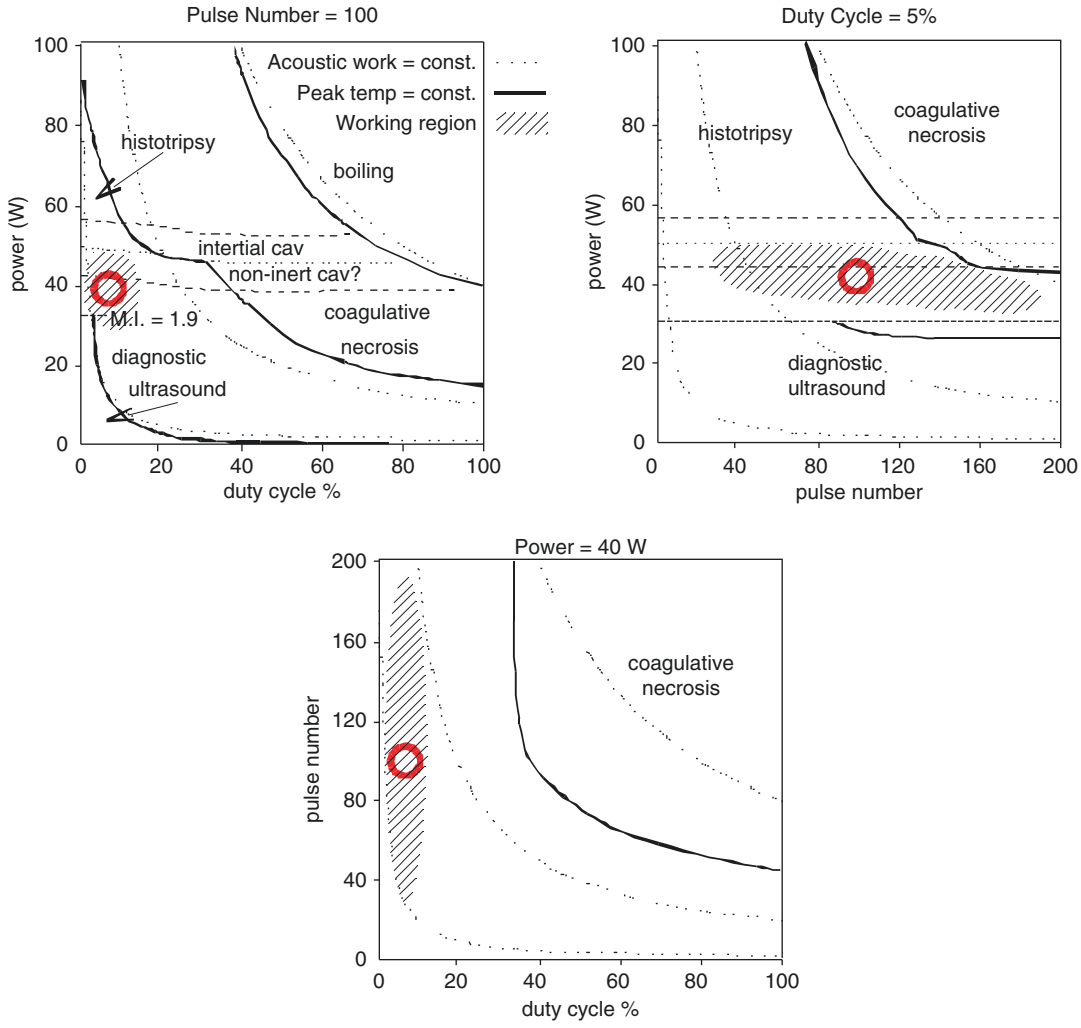
As well, both absorption and scattering result in a transfer of momentum from the wave to the medium. The resulting body force is known as the radiation pressure and is often written (ignoring scattering) as

$$F = \frac{\mu_a I}{c}$$

Generally, in the low megahertz frequency range, attenuation is not very large; however, at very high intensity the effect is still biologically significant. Such high intensity may be achieved by concentrating the ultrasound from a large source into a small volume. Focused ultrasound may be achieved by means of a curved transducer or an acoustic lens. Either way, the result is a concentration of much of the acoustic energy produced by the transducer into a diffraction-and-aperture-limited ellipsoidal focal spot (Fig. 1). In typical pulsed HIFU experiments, using a 1.0 MHz transducer with equal aperture and focal depth ($f = 1$), the spot size full-width half-maximum is about 1.5 mm in diameter and 7 mm in length. With this design, local peak intensities can range up to 10^4 W/cm^2. Pulsed HIFU powers are typically maintained in the range of 10^2–10^3 W/cm^2.

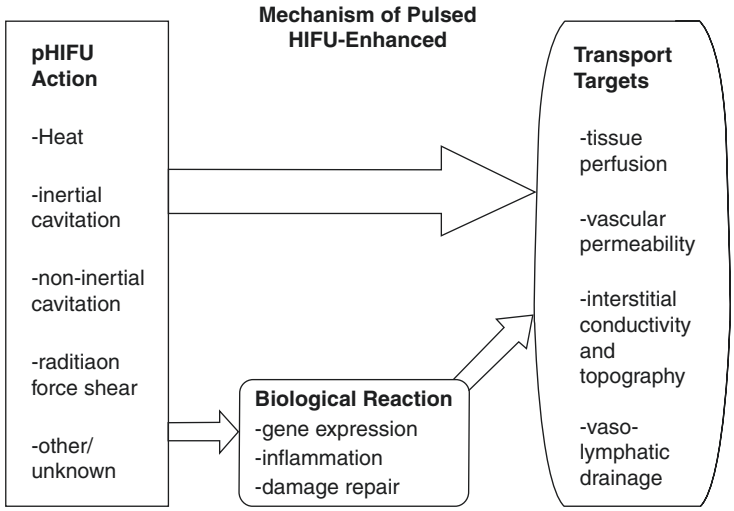
Ultrasonic heating is the basis of HIFU ablation and ultrasound hyperthermia treatment. The principal goal of using pulsed rather than continuous HIFU is to avoid overheating the tissue by allowing the heat deposited in the focal zone to diffuse, while still maintaining high peak powers to induce the mechanical effects. In fact, there will always be some unavoidable heating, but because the thermal response is relatively slow (order of seconds), it is governed by the average power. In contrast, the mechanical response is rapid (order of tens of milliseconds), and thus is related more to the peak power.

If sufficient levels of gas exist, either dissolved or in suspension, then acoustic cavitation becomes a possibility. In that case, rapid and large expansion of the gaseous phase can happen during the negative-pressure portion of the cycle, a phenomenon known as acoustic cavitation [5]. Because of the huge acoustic impedance mismatch between gas and liquid and because of the resonant expansion and contraction of gas microbubbles in an acoustic wave, cavitation produces an enormous concentration of energy in and around the microbubbles that can have a number of biological effects. Acoustic cavitation phenomena are divided into two types: the first, known as



Pulsed High-Intensity Focused Ultrasound, Fig. 1 Schematic of pulsed high-intensity focused ultrasound. Pulsed input to focused ultrasonic transducer results in high peak intensity, low average intensity beams, with highest energy density in and around the focal zone. The focal zone is scanned across the tissue to enable treatment of large volumes

noninertial or stable cavitation, involves gas bubbles resonating around an equilibrium size, while the second, known as inertial or unstable, involves the rapid expansion and subsequent violent collapse of gas bubbles. Generally, the existence of cavitation in tissue is inferred from its effect on the spectral content of the wave; in particular, the noninertial cavitation will create an unambiguous increase in half harmonic content, while inertial cavitation also causes an increase in broadband noise level. Both processes involve the concentration of acoustic, mechanical, and thermal energy in the neighborhood of the bubble, except that in the second instance, this energy is focused even more into a tiny volume during collapse, with resulting extremes in temperature and pressure. These in turn can have profound effects on tissue, including enhanced heating, membrane poration, and cell lysis.



Biological Impact of pHIFU

The set of acoustic parameters most often used for pHIFU applications are 100 pulses at 1 MHz center frequency, 5 % duty cycle, and 1 Hz repetition rate (50 ms on, 950 ms off), 40 W peak acoustic power, using an f = 1 transducer (approximately 2,200 W/cm^2 in water). Another common set of parameters employed roughly half the power and double the duty cycle. (The earliest studies described below used much higher total energy and peak powers; however, because the efficiency of the transducer was not measured, it is not clear precisely what these were.) Under these study conditions, mostly carried out in mouse models, researchers have demonstrated changes in normal and tumor tissues that effectively increase the rates of nanoparticle uptake by two to three folds over untreated tissues. The effects appear to be accompanied by edema and often inflammation. While the precise mechanism remains uncertain, some possibilities exist. It is widely accepted that inertial and possibly noninertial cavitation could cause such effects. Indeed, introducing cavitating microbubbles in the form of ultrasound contrast agents is a technique that has been employed for blood–brain barrier disruption [6]. However, under the conditions given, there is no evidence that the cavitation threshold is being reached during pHIFU in the absence of exogenous agents. Cavitation is very difficult to achieve in tissues, first, because the levels of available gas are small, and second, because the threshold for cavitation is increased

with increasing viscosity. Heating is a more likely factor, although preliminary studies have generally concluded that the heating and thermal dose produced is rather low when compared to standard hyperthermia treatments. However, many of the effects seen do appear to mimic those of hyperthermia. Finally, tissue shear is created by the radiation forces and also when the ultrasonic wave reflects from a boundary at some angle and undergoes mode conversion. The resulting highly attenuating shear waves propagate at a much lower velocity, approximately 30–100 m/s, therefore having a more biologically relevant wavelength of 30–100 μm. It is generally accepted that shear forces can mediate biological effects, particularly in the vasculature [7], where normal blood flow shear is known to be a factor in the proper maintenance of the endothelial layer. Such processes might be disrupted or mimicked by radiation force-induced streaming in the blood vessels. It is

Pulsed High-Intensity Focused Ultrasound, Fig. 2 Pulsed HIFU neighborhood in tissue "phase space," in relation to cavitation, thermal ablation, and diagnostic ultrasound. The effect on tissue of ultrasound in this region is incompletely understood. Axes are the principal treatment parameters in common units (reflecting the choice of f = 1, 1 MHz focused transducer, and 1 Hz pulse repetition rate): acoustic power (50 W acoustic power implies ~2,800 W/cm^2 in the focal zone), duty cycle (5 % implies pulse length of 50 ms), and total number of applied pulses

Pulsed High-Intensity Focused Ultrasound, Fig. 3 Pulsed HIFU acts to alter tissue transport either directly, by altering the physical properties of transport targets, or indirectly, by inducing biological changes that then influence transport properties

less clear how the relatively small shear strains of radiation forces, or the high frequency, rapidly attenuating shear waves, might affect the cells of bulk tissue.

As well as the direct physical effects of pHIFU on tissues, there is always the possibility of triggering secondary biological processes, such as inflammation. Indeed, pHIFU often appears to trigger a clear inflammatory response, at least in muscle. It is not so clear whether this is also true in tumor or other tissue, nor whether the observed vascular and parenchymal permeability is the cause or the effect of inflammation.

If tissue changes are considered as comparable to material phase changes, then pHIFU effects lie in volatile and unexplored regions of this phase space. This paradigm is illustrated in Fig. 2, which shows where treatment might be relative to a tissue phase map using the three fundamental treatment parameters as axes. Figure 3 lists the candidates for pulsed HIFU action and possible tissue targets.

Examples of Application

Pulsed HIFU has been explored in combination with a diverse set of agents, including small-molecule chemotherapeutics, thrombolytics, large-molecule therapeutics, antibodies, plasmid DNA, viral vectors, and nanoparticle drug carriers. The main goal of the technology since it was first conceived in the mid-1990s was to allow the uniform penetration of nanoparticle drug carriers throughout the tumor parenchyma. In that early study [8], the nanoparticle was a polymerized liposome containing gadolinium contrast agent of mean diameter around 100 nm. MRI was used to monitor the delivery of the particle to rabbit muscle. The delivery of plasmid DNA (fluorescent reporter gene) was successfully demonstrated in a mouse squamous cell carcinoma more than 5 years later [9]. Later, the same technique was used to enhance delivery of TNF alpha plasmid and the liposomal nanoparticle Doxil and for tumor therapy [10, 11]. In 2006–2007, pHIFU was used to deliver radioactive antibodies [12] as well as genes via viral vector to mouse tumor models [13]. It was also combined with small molecular weight chemotherapeutics [14] and thrombolytic agents [15]. During various mechanistic studies, the delivery of nanoparticle-sized fluorescent dextrans and microspheres were used as tracking agents. Most of the mechanistic studies were done in mouse tumor models or mouse muscle. Comprehensive reviews of these and other related studies are available [16, 17].

Future Directions

Pulsed HIFU produced by ultrasound and magnetic resonance image-guided systems will be

used for assisted delivery of a variety of tissue targeted and untargeted nanoparticles. Virtually any large molecule or nanoscale therapeutic agent can take advantage of this technology for improved, targeted delivery. In fact, to be truly efficacious, it is anticipated that many nanoparticle systems will require the assistance of this or similar technology. Finally, it is possible to combine image-guided pulsed HIFU with various ultrasound and energy-sensitive nanoconstructs for further control local and systemic therapeutic concentrations.

Definition

Quantum dot nanophotonic integrated circuits are photonic integrated circuits composed of nanoscale optoelectronic components made with semiconductor quantum dots.

The modern electronics industry was revolutionized by the invention of the transistor. Since then, the transistor has been the fundamental building block of all modern electronic devices widely deployed in various places including communication and computer systems. The number of transistors on an integrated circuit has roughly doubled every 2 years, following Moore's Law. Moore himself, however, has stated that this law cannot be sustained indefinitely due to the fundamental limits to miniaturization.

Although the demand for higher processor chip speeds in a computer system continues to drive the bandwidth and density requirements and performance for on-chip and chip-to-chip interconnects, using electrons as the information carrier is now facing the challenges of speed, power consumption, and crosstalk due to electromagnetic interference between channels. The limits of Moore's law call for fundamentally new ways to transmit, process, and compute information, not electronically, but perhaps optically. In general, smaller and faster photonic integrated circuit systems with versatile functionalities are desirable for applications not only in computation, but also in other areas such as optical communication and sensing. The need has fueled the development of new photonic devices, new fabrication methods like self-assembly, and the synthesis of new optoelectronic materials like nanocrystals and nanowires. With these advances, it is now possible to realize lasing, waveguiding, optical modulation, and detection in submicron scale devices. Furthermore, it is possible to pick and place nanoparticles on silicon substrates by merely exposing the substrate surface to a liquid droplet of suspended particles. With these new capabilities and tools, building nanoscale photonic

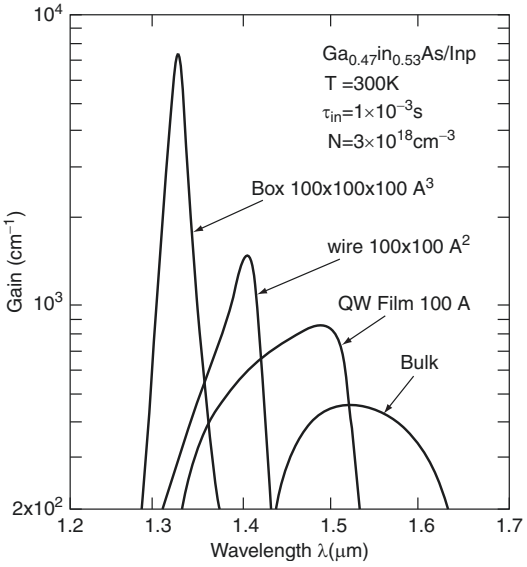
integrated circuits has begun to be widely investigated, in an effort to achieve an optical analogy of VLSI with higher speed, lower power consumption, and higher integration density.



The development of photonic integrated circuits has nonetheless been hindered by the diffraction limit, which restricts the extent of optical wave confinement to $\sim\lambda/2$ for guiding and transmitting optical energy in conventional optical waveguides, and constrains the integration density one can achieve using photons as information carriers. While electronic integrated circuit technologies are advancing fast in the sub-100 nm lithographic resolution regime, the diffraction limit must be overcome for photonics to successfully complement and perhaps replace some of the electrical components. The advances in nanofabrication technologies have facilitated the miniaturization and integration density of device technologies, with semiconductor quantum dots (QD), also referred to as nanocrystals (NC), as materials with high promise.

Since the early 1980s, the quantum dot has gained increasing notice and visibility. Combined with modern material science techniques, the focus has shifted from modeling behavior to implementing and taking advantage of the QD's unique properties for various applications. Originally, the quantum dot was conceived as the next logical step in lasing devices after quantum well and quantum film structures. Progressing from one- to two- and then to three-dimensional confinement of electron and hole wave functions narrows the gain spectrum and increases maximum gain, which reduces the threshold current to begin laser operation. Furthermore, the quantization of the electron and hole energy states and the material and size-specific absorption characteristics are responsible for enabling the high extinction ratios of QD optical labels in biomedical research, and provide a basis for several photonic devices, including transistors, switches, and, naturally, lasers.

Characteristics of QDs

In general terms, the quantum dot is a form of nanocrystals, or a monodisperse crystalline metal or semiconductor particle whose diameter is adjustable on the nanoscale. QDs are of particular interest from a device standpoint as the electron and photon behavior in the materials differ greatly from that of bulk materials. When deposited in an ordered manner and formed into a solid, collective traits may arise that are also distinctive. As an individual particle, the performance of a QD may be tuned through variations in size and shape, leading to changes in electron–hole generation and recombination dynamics, tunneling behavior, and energy transfer. As in bulk semiconductors, population inversion can be achieved with a sufficient excitation rate and energy, which results in an emission coefficient greater than the absorption coefficient leading to net optical gain. Furthermore, the three-dimensional confinement of electron–hole pairs (exciton wave function) leads to discretized energy levels and delta-function-like distribution of the density of states. Under excitation, the emission of QDs is spectrally much sharper than their bulk material counterparts, which results in a sharp gain spectrum and therefore high gain, low loss, and high quantum efficiency (Fig. 1) [1]. The spectral response of QDs can be easily tuned by particle size and composition. These unique properties make QDs ideal materials for optoelectronic applications.

Conventional QD photonic devices utilize self-organization at the interface of strained epitaxially grown III–V or II–VI semiconductor layers to create pyramidal QD nanostructures due to lattice mismatch. The fabrication is often done through metal-organic chemical vapor deposition (MOCVD). The Stranski–Krastanov process is the basis for manufacture of the first QD lasers, which have been theoretically and experimentally demonstrated with improved gain characteristics and reduced lasing current thresholds compared to quantum well and quantum film structures. Although high-quality optoelectronic devices have been obtained using the self-organization method, the process itself is often not compatible with silicon CMOS fabrication. Another process to fabricate QDs is through chemical synthesis, or solution-based processes. The resulting QDs are in colloidal form and have been widely used as fluorescent tags in biomedicine. The colloidal

Quantum Dot Nanophotonic Integrated Circuits, Fig. 1 Gain spectra for $Ga_{0.47}In_{0.53}As/InP$ 100 Å × 100 Å × 100 Å cubic QD, 100 Å × 100 Å quantum wire, 100 Å-thick quantum well film, and bulk crystal. The calculation was done assuming $T = 300$ K, intraband relaxation time $\tau_{in} = 1 \times 10^{-13}$ s, and electron–hole density $N = 3 \times 10^{18}$ cm^{-3} [1]

QDs can then be subsequently deposited on a variety of substrates including silicon and mixed with different materials using various methods to be described later, resulting in rapid expansion in applications such as whispering gallery lasers, sensors, organic LEDs, and solar cells.

In the colloidal case, where individual nanoparticles are fabricated in a solution suspension, the composition materials often fall in the semiconductor category such as II–VI and III–V. The process often involves controlled injection of reagents into the solvent to nucleate and grow the compound of interest. Recently, synthesis of group IV semiconductor QDs has also been investigated. In the case of CdSe nanocrystals, dimethylcadmium, and organophosphine selenide combine to form a core QD structure. A shell layer, such as ZnS, may be subsequently added by solution growth to suppress surface oxidation and improve the fluorescence behavior. The diameters of the core and shell thicknesses determine the energy levels in the QD, which affect the absorption spectrum and correspond to the emission wavelength of the photon generated after the excitation and recombination of an electron–hole pair [2]. The shell layer also allows further surface chemical treatment to enable specific reactions with surrounding media. By design, a shell material with a larger bandgap is commonly selected to enable better electron–hole pair confinement, whereas the surface is treated with stabilizers and can be conjugated with molecules for specialized binding activity, which is dependent on the application.

Colloidal QDs offer high fabrication and integration flexibility. This article focuses on the fabrication, deposition, and photonic devices made of colloidal QDs.

QD Fabrication

Solution-based fabrication of QDs involves techniques to achieve colloids in a controlled manner [3]. To begin, a solvent containing stabilizing and reacting chemicals is poured into a vessel and typically heated to a temperature ideal for stimulating NC formation. Then, a rapid injection of metal-organic material supersaturates the solution and breaks above the nucleation threshold. Subsequently, small particles form, or nucleate, to reduce the energy within the system. Over time, if the rate of injection is below the consumption rate of reagents, then no new nuclei are created and the existing NCs incorporate more metal-organic precursors to become larger.

With regards to specific compounds, long alkane chains attached to phosphorous or phosphorous oxide provide the active ingredients in the solvent mixture. For II–VI semiconductor NC fabrication, the precursors include metal alkyls consisting of the group II metal element and organophosphine chalcogenides or bistrimethylsilylchalcogenides incorporating the group VI chalcogenide element. Taking the CdSe QD as an example, dimethylcadmium and organophosphine selenide are commonly used.

As for ensuring monodisperse nanocrystals, the size distribution will tend toward homogeneity

given that the initial nucleation event produced particles whose eventual dimensions eclipse the original volume. Moreover, a secondary growth phase known as Ostwald ripening may aid the process by dissolving smaller NCs with high surface energy in favor of material deposition on the larger ones. Overall, the procedure may be calibrated and timed to synthesize particles of a desired size. Additionally, reactants and NCs are removed from the solution as appropriate.

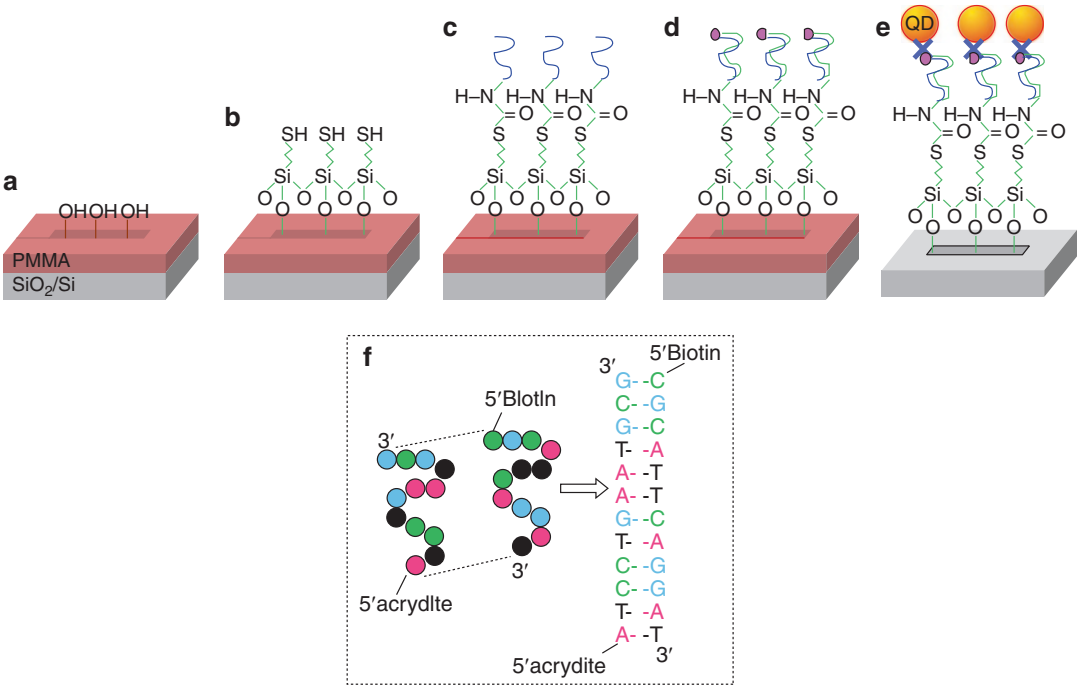
For creating core/shell QDs, the materials must have compatible deposition conditions and surface energies at the interface. Another requirement is that the nucleation threshold of the shell material be lower than the core, and interdiffusion between the core and shell elements must not occur. The production method of bilayer QDs generally appends to the core synthesis procedure by selecting out NCs of the desired size and adding them to a new reaction solution. Upon reaching the optimal temperature, precursors with the shell material are added at a rate which allows for gradual deposition onto the original particles but avoids a secondary nucleation [3]. To add the final capping layer, an exchange process is used whereby the stabilizing molecules attached to the NCs are interchanged through competition with an excess of another molecule, molecule group, or ion. Furthermore, clumping of particles is avoided if the repulsion strength of outermost layer is greater than the van der Waals attraction force.

On the whole, production of core and core/shell structures results in a size distribution of 5–10 % standard deviation from the mean. Further filtration and separation steps may be carried out to identify and collect nanocrystals of better uniformity. Some standard structural characterization methods for NCs include high resolution transmission electron microscopy (TEM) and both small- and wide-angle X-ray scattering (SAXS, WAXS) while analysis of the chemical constitution may be accomplished through nuclear magnetic resonance (NMR), X-ray fluorescence, and photoelectron spectroscopy.

Due to its nontoxicity and lower material cost, silicon (Si) QD is an actively pursued research topic and much effort in developing-related technologies that lead to future commercialization is being invested. Development in colloidal Si QD synthesis thus far lags behind the progress of II–VI QDs; nevertheless, processes that lead to Si QDs with good material characteristics have been demonstrated. Hydrogen-terminated colloidal Si QDs can be synthesized using a low temperature solution-based process [4]. The Si QDs can be prepared by a solution reaction using sodium silicide and ammonium bromide in dimethoxyethane (DME, 80 °C) and dioctyl ether (DOE, 260 °C). The chemical reaction of the process follows $NaSi + NH_4Br \rightarrow NaBr + NH_3 + Si/H + H_2$, where the desired product, the hydrogen-terminated Si NCs, is noted as Si/H. Once the surface of the Si QDs is hydrogen passivated, further functionalization via photoinitiated hydrosilation can be performed.

Si QDs can also be obtained using electrochemical etching [5]. The process starts with placing p-type boron-doped Si wafers with (100) orientation and 5–20 Ω-cm resistivity in a mixture of hydrofluidic acid (HF), methanol, hydrogen peroxide (H_2O_2), and polyoxometalates (POMs), with the latter two functions as catalysts. At high current density (>10 mA/cm^2) and an etching time of several hours, typical etched surface structures are micropores of diameter around 2 μm, while at low current density (<10 mA/cm^2) and short etching time, nanoscale porous surface is formed. Ultrasonication is used to disintegrate the etched wafer into colloidal Si QDs. Prior to this step, hydrosilylation reaction with chloroplatinic acid as catalyst can result in an octane-modified Si surface, which prevents aggregation of the QDs.

QD Deposition Process



Once the QDs are synthesized, they need to be positioned onto a substrate for further processing into nanophotonic devices. This can be achieved by various methods. In this section, a few examples are listed: Deoxyribonucleic acid (DNA)-directed self-assembly, APTES-mediated molecular self-assembly, solution-based drop-casting, and electrostatic layer-by-layer deposition.

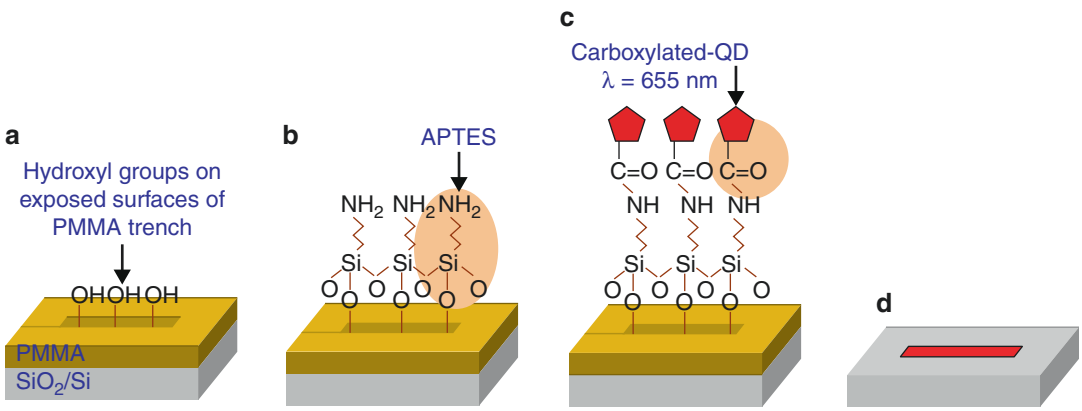
DNA-Directed Self-assembly

The process flow to assemble QDs through the DNA-mediated method is illustrated in Fig. 2 [6]. The area for QD deposition is defined in a layer of polymethylmethacrylate (PMMA) on an oxidized Si substrate using electron-beam lithography (EBL). The sample is then treated with oxygen plasma to generate hydroxyl (−OH) groups, which covalently bind to the dangling ends of silicon oxide and act as hooks for the next chemical reaction. Next, the first self-assembled monolayer (SAM) is formed by gas phase deposition of an organo-silane molecule, 3′mercaptotri-methoxysilane (MPTMS). The silane terminal anchors to the oxygen element of the hydroxyl groups, thus freeing the hydrogen as an energy minimization step while the mercapto, or thiol (SH), group becomes oriented to the outer surface.

The next step is to deposit the second monolayer, composed of a 12 base pair (5′acrydite-ATCCTGAATGCG-3′) chain of DNA terminated by acrylamide on the sample in solution form. This often involves diluting the base DNA with phosphate buffer solution (PBS) and $MgCl_2$. Immersing the sample in buffered acrylic acid followed by PBS rinse leads to passivation of inactivated MPTMS molecules and readies the sample for addition of the complementary DNA (cDNA). Biotin-linked cDNA is used to establish the third SAM. Now, the sample is ready for QD deposition. Streptavidin-bound QDs are combined in PBS and dropped on the surface. The QD assembly step utilizes the well-known biological recognition avidin-biotin binding pair where streptavidin, which is a protein, has four sites that preferentially attract and bind to biotin molecules. The last step is to remove the PMMA layer using toluene submersion.

One chief advantage of DNA-directed self-assembly approach is simultaneous deposition of different types of QDs to form a diverse range of

Quantum Dot Nanophotonic Integrated Circuits, Fig. 2 DNA-directed QD deposition process: (**a**) EBL pattern PMMA-coated substrate; (**b**) deposit MPTMS monolayer; (**c**) covalently bind with 5′acrydite-DNA; (**d**) hybridize with biotin-modified cDNA; (**e**) bind streptavidin-QDs to biotin-cDNA sites, remove PMMA; (**f**) detail of DNA chains as hybridized



QD structures through specific DNA-cDNA binding recognition. As streptavidin-conjugated structures will preferentially bind to biotin, the critical step is to prepare the QDs with the corresponding biotin-cDNA molecules before reacting them en masse to the base DNA on the substrate. The details of the procedure are much like before, but a few additional steps are required. In particular, use of EBL is needed to open up each of the sections upon which different QDs will be bound. Consequently, after the initial EBL round, the substrate would be treated with MPTMS followed by the passivation buffer and the first acrydite-terminated DNA. With adequate concentration and exposure time, the packing of the base layer with quench molecules will be dense and prevent assembly of subsequent DNA strands. The next EBL writing creates new patterns that are developed and the second round of MPTMS and acrydite-DNA sequence SAMs are added. The process is repeated for as many QD types, and hence DNA-cDNA pairings, that are desired. After the final set of base DNA is added and prior to assembly with the complementary strands, the biotin-cDNA chains are mixed with the matching QD solutions specific to the device design. Subsequently, the QD-cDNA solutions are deposited on the sample as a mass self-assembly step.

APTES-Mediated Molecular Self-assembly

Similar to the DNA-directed technique, the APTES-mediated molecular self-assembly method (Fig. 3) starts with oxygen plasma treatment of an oxidized Si substrate following EBL. Then, the process diverges with sample immersion into 3′aminopropyltriethoxysilane (APTES) thoroughly mixed in an isopropyl alcohol (IPA) and deionized water solvent. In contrast to MPTMS, the chemisorption of APTES leads to an amine ($-NH_3$) rather than a mercapto ($-SH$) group presented at the terminal. Following this, a droplet of carboxylated QDs mixed in deionized water with 1-ethyl-3-(3′dimethylaminopropyl)-carbodiimide (EDC), a coupling reagent that aids in binding amine and carboxyl groups, is deposited directly on the patterned region.

Solution-Based Drop-Casting

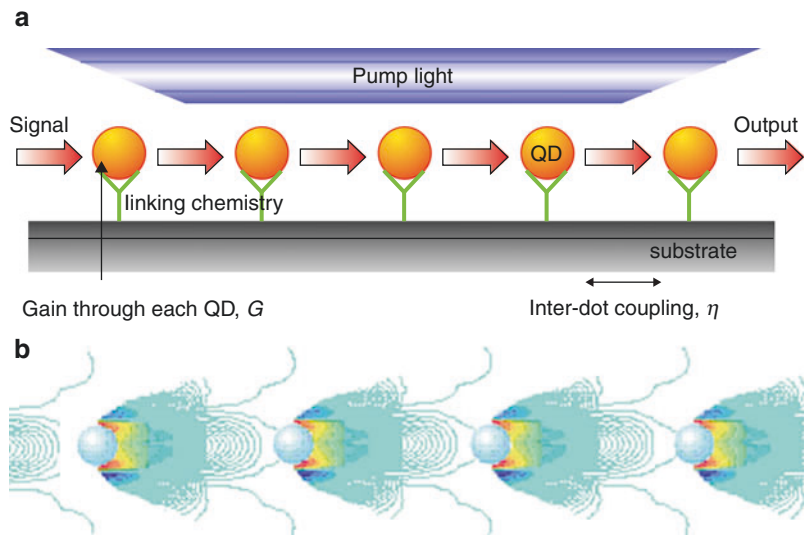
Drop-casting is a method previously used in large-area thin-film devices as a convenient and cost-effective means of making a QD thin film [7]. The method involves dispersing a concentration of QDs in a solvent and then micropipetting a liquid droplet onto a substrate. As the solvent evaporates, the QDs pack together to form a thin membrane on the surface of the substrate. The resultant thin film forms a nanocrystal solid while retaining some of the unique optoelectronic properties of

Quantum Dot Nanophotonic Integrated Circuits, Fig. 3 APTES-mediated molecular self-assembly of QDs: (**a**) EBL pattern a SiO_2/Si sample coated with PMMA; develop PMMA; treat with oxygen plasma to create hydroxyl groups on surface; (**b**) solution phase deposition of APTES; (**c**) carboxylated QDs covalently bind to the amine groups of APTES; (**d**) strip PMMA to leave the patterned QDs region

the individual QDs. The quality and thickness of the QD thin film is determined by several factors, including the type of solvent used, the concentration of QDs, the liquid volume of the droplet, the hydrophobicity of the substrate, the type of atmosphere, and the drying temperature. To achieve high-quality nanoscale thickness, using a mixture of hexane/octane as the solvent often achieves a better result. For larger scale thin-film photodetectors, the most common solvent is toluene. Typically, commercial QDs are also suspended in toluene. The hexane/octane mixture prevents ring formations on the resultant film, in part due to the higher rate of evaporation. A high concentration of surface ligands, which prevent the QDs from clumping together, can also result in an opaque or "dirty" thin film. To prevent this, the QDs can be washed by precipitating out of the host solvent with a reagent-like ethanol or methanol. The ethanol acts to strip the organic capping ligands from the shell of the QDs. Once the solution is centrifuged, the supernatant liquid is poured off and the QDs are allowed to dry in a desiccator. The dried QDs can then be redispersed in a solvent of choice. For example, commercially available QDs originally suspended in toluene can be washed and then resuspended in the hexane/octane mixture.

Electrostatic Layer-by-Layer Deposition

The deposition methods described previously achieves either a single layer of QDs or a QD film with unspecified thickness. To achieve controllable film thickness, electrostatic layer-by-layer deposition of QDs has been developed [8]. The patterned areas are pre-covered with a monolayer of charged molecules which serve as traps to capture the QDs by electrostatic bonding. Utilizing a similar electrostatic process, the QDs carrying opposite charges are deposited alternately, forming a multilayer film. By virtue of the layer-by-layer self-assembly, the film thickness can be controlled by the number of layers. Such fabrication process can be performed on a variety of substrates once their surfaces are modified with dangling hydroxyl groups, including silicon oxide and flexible substrates.

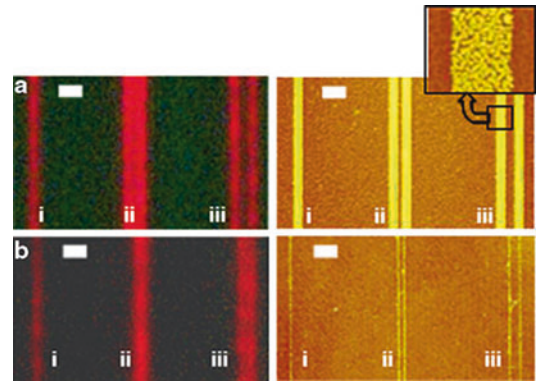


The length of ligands on the QD surface is critical to achieving short tunneling barrier and therefore high carrier mobility in the QD thin film. Extremely short ligands can be achieved using 2-mercaptoethylamine (MA) for positive capping and thioglycolic acid (TGA) for negative capping. The lengths of MA (∼0.4 nm) and TGA (∼0.3 nm) are short enough such that adjacent QDs' surfaces almost contact each other. TGA and MA also work as negative and positive thiol-stabilizers during CdTe QD synthesis. The precursors are formed in the ratio of Cd^{2+}: Te^{2-}: thiol stabilizer = 1: 0.5: 2.4 under appropriate pH conditions (11.5 for TGA and 5.75 for MA). The nanocrystals are grown by refluxing the reaction mixture at 100 °C and the particle size is controlled by refluxing time.

To prepare the substrate for electrostatic layer-by-layer deposition, an oxide-covered substrate is treated with oxygen plasma and dipped into NaOH to increase the density of hydroxide on the surface. Subsequently, the sample is immersed in (3-Aminopropyl)triethoxysilane (APTES) solution, followed by protonating the amines in diluted HCl solution for a few seconds. Upon this step, a high area density of positively charged amines on the surface of the substrate can be achieved. The layer-by-layer deposition of QDs is performed by immersing the chip first into TGA (negative)-CdTe QDs solution, then MA (positive)-CdTe QDs solutions. After washing away excess QDs with deionized water, each time of self-assembly will result in deposition of a monolayer of CdTe QDs. Repeating this process leads to a thin film of QDs with a controlled number of layers.

QD Nanophotonic Waveguide

The quantum dot waveguide consists of an array of densely packed QDs anchored to a substrate (Fig. 4a) [6]. A pump light illuminates the sample from above to create excited electron–hole pairs within the QD, which are then triggered by a signal light placed at the waveguide edge to recombine and emit a photon. The stimulated emission of photons occurs in a cascade fashion



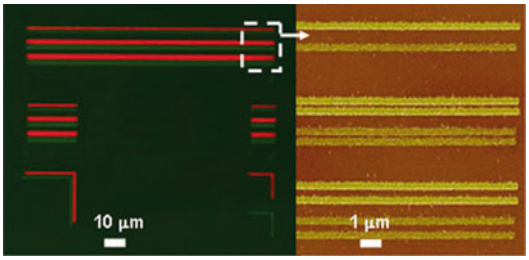
Q

Quantum Dot Nanophotonic Integrated Circuits, Fig. 4 (**a**) Schematic drawing of the QD nanophotonic waveguide. (**b**) Poynting vector distribution within the QD waveguide

downstream to generate a response at the output edge. The stimulated emitted photons are identical to the input signal photons in terms of wavelength, polarization, phase, and propagation direction. The overall transmission efficiency at the end of the waveguide depends on the inter-QD coupling efficiency and the gain available in each QD. To avoid wavelength mixing, the pump light energy is set at a higher level than the signal light energy. The finite-difference time-domain (FDTD) simulation of the Poynting vector distribution, representing the power flow and indicating photon transmission behavior in a QD waveguide, is shown in Fig. 4b. Upon absorption of the pump light and triggering of the signal light, the accepting QD produces energy as photons via stimulated emission, with the majority of energy aimed in the propagation direction to interact with the neighboring QD, causing a cascade of energy transmission.

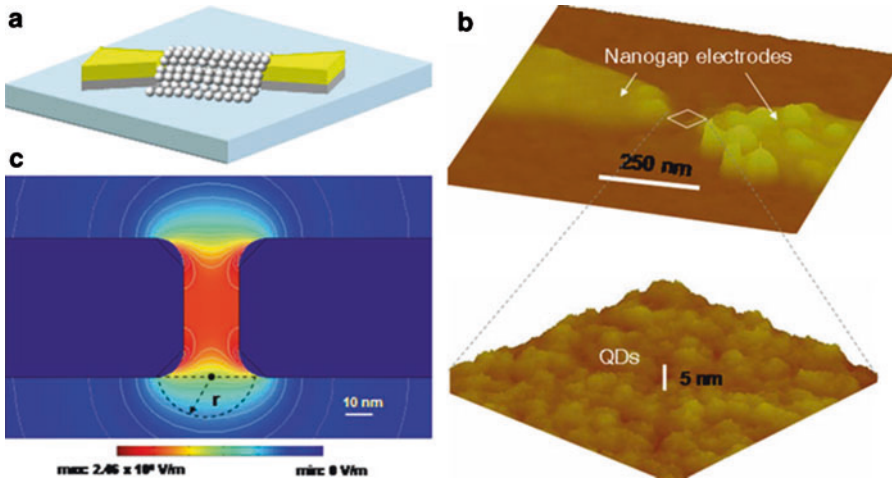
Fabrication of the QD nanophotonic waveguides has been accomplished through either the DNA-directed or the APTES-mediated molecular self-assembly fabrication described earlier. Fluorescence micrographs and atomic force microscope (AFM) images, in Fig. 5a, b, show attachment of 655 nm emission QDs aligned in the 100 and 500 nm width lines. An additional AFM image is shown as an inset in Fig. 5a to provide more details on the QD shape and

Quantum Dot Nanophotonic Integrated Circuits, Fig. 5 Fluorescence and corresponding AFM images of (**a**) QD waveguide with 500 nm width; the *inset* shows granular QD shape; and (**b**) 100 nm-wide QD waveguides in (*i*) single and pair formations spaced, (*ii*) 200 nm, and (*iii*) 500 nm apart. Scale bar is 1 μm in length



distribution within the waveguide. Measurement results on straight waveguides and waveguides with 90° bend demonstrated low-loss light transmission in sub-diffraction limit scale [6].

By repeating the fabrication process of the APTES-mediated self-assembly process, it is possible to create waveguides using QDs of different emission wavelengths to operate at targeted transmission wavelengths. Figure 6 shows the fluorescence microscope and AFM images of multiple QD waveguides with red (655 nm) and green (565 nm) emission wavelengths. The AFM

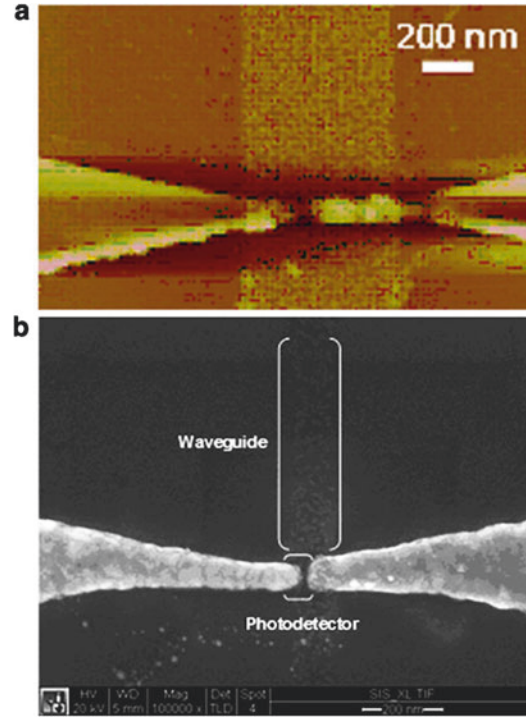


images represent the topological profile of the sample, showing well-packed monolayer coverage of QDs. The height is taller for the red patterns, corresponding to larger nanoparticles, as demonstrated by the brighter coloring consistent within the confines of the line.

Nanoscale QD Photodetector

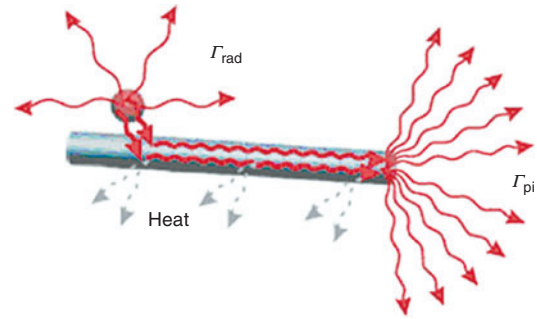
As the integration density of photonic integrated circuits progresses toward the submicron regime, it becomes imperative to detect the optical signal with nanometer resolution as well in order to preserve the on-chip integration density. The requisite photodetection devices are critical for integration of nanophotonics with electronics. The devices should also have high fabrication and integration flexibility with other nanophotonic devices. This can be achieved by a nanoscale QD photodetector with a simple configuration schematically depicted in Fig. 7a [9]. Colloidal QDs are placed between two electrodes spaced with a nanogap, so that electrons can tunnel between the electrodes through the QDs. Electron transport in colloidal QDs embedded in a metal-QD-metal structure typically involves significant potential barriers at the QD–QD interface as well as the QD–electrode interface. Transport between QDs can, therefore, be considered as a problem of hopping between localized states. Carriers with higher energies have a higher probability of tunneling through the QDs and contributing to the tunneling current. The effect of optical excitation on the electrical transport of such structures is to reduce the effective potential barrier from the QD to the electrode by exciting photo-generated carriers into higher energy states. The tunneling current increases when the QDs are photo-excited, thus achieving photodetection.

Quantum Dot Nanophotonic Integrated Circuits, Fig. 6 Fluorescence micrograph (*left*) and AFM image of zoomed-in region (*right*) of multiple QD-type waveguides. The emission wavelengths are 655 and 565 nm, corresponding to larger and smaller QDs. The different colors in the AFM image demonstrate the height difference between the two types of QDs



Quantum Dot Nanophotonic Integrated Circuits, Fig. 7 (**a**) Illustration of the nanoscale QD photodetector device structure. (**b**) AFM image with three-dimensional rendering of the device. (**c**) Finite element simulation of the electric field intensity in and around a 20 nm nanogap

The metal electrodes, spaced at nanometers apart, can be fabricated using electron-beam lithography (EBL). The QDs can be attached to the substrate through the various deposition methods described earlier. The fabrication process of the QD photodetectors consists of two simple steps: patterning of the metal electrodes and attachment of QDs. Both steps, either in sequence or separated, can be readily integrated with the fabrication of a wide range of nanophotonic components and devices. Figure 7b shows an AFM image in three-dimensional view of a device, and zoom-in of the QD film in the nanogap region.



Electron transport through the device is limited by the field-induced ionization rate of the photogenerated excitons, which in this case is proportional to the electron-tunneling rate between neighboring nanocrystals. Thus, for high responsivity, it is necessary to have high field intensities across the junction, which can be obtained most easily in a nanoscale gap. Figure 7c shows finite element simulation of the DC electric field distribution in the gap that is highly concentrated in and around the nanogap. The short distance between electrodes limits the number of tunneling steps required for electrons to traverse the gap, which also increases responsivity and enhances the speed of the device.

QD photodetectors are expected to achieve high sensitivity due to the high quantum efficiency of the nanocrystals. To achieve high-speed operation of the devices remains challenging, due to the tunneling barriers between QDs. Less than 500 f. light detection sensitivity and >125 kHz modulation bandwidth have been reported for the nanoscale QD photodetectors [9].

Integrated fabrication of the nanoscale QD photodetector with the QD waveguides is straightforward due to the nature of self-assembly deposition of QDs. The fabrication result in Fig. 8a shows the AFM topology of a 500 nm-wide QD waveguide aligned to the center of metal electrodes created by a break-junction process spaced approximately 22 nm apart. Figure 8b shows a SEM image of a 50 nm-wide QD waveguide aligned to the center of metal electrodes created using EBL spaced about 12 nm apart.

Quantum Dot Nanophotonic Integrated Circuits, Fig. 9 The emission from a single QD can be coupled to a plasmonic nanowire, creating a single plasmon source [10]

Quantum Dot – Plasmonic Waveguide Integration

Plasmonic structures are nanoscale metallic structures that can concentrate light into deep-subwavelength volumes. Therefore, they provide

a promising approach to interface diffraction-limited optical components with nanophotonic structures. Integration of a single QD with a plasmonic waveguide has been explored [10]. A CdSe QD is placed in close proximity to a silver nanowire (Fig. 9). When optically excited, the emission from the QD couples directly to guided surface plasmons in the nanowire, causing the end of the wire to light up and acting as a source of single, quantized plasmons. This approach can realize strong nonlinear interactions at the single-photon level, making a single-photon transistor possible [11].

Semiconductor nanocrystals

Definition

Semiconductor quantum dots (QD) are 1–10 nm nanocrystals consisting mainly of a semiconductor core with or without an inorganic passivation shell

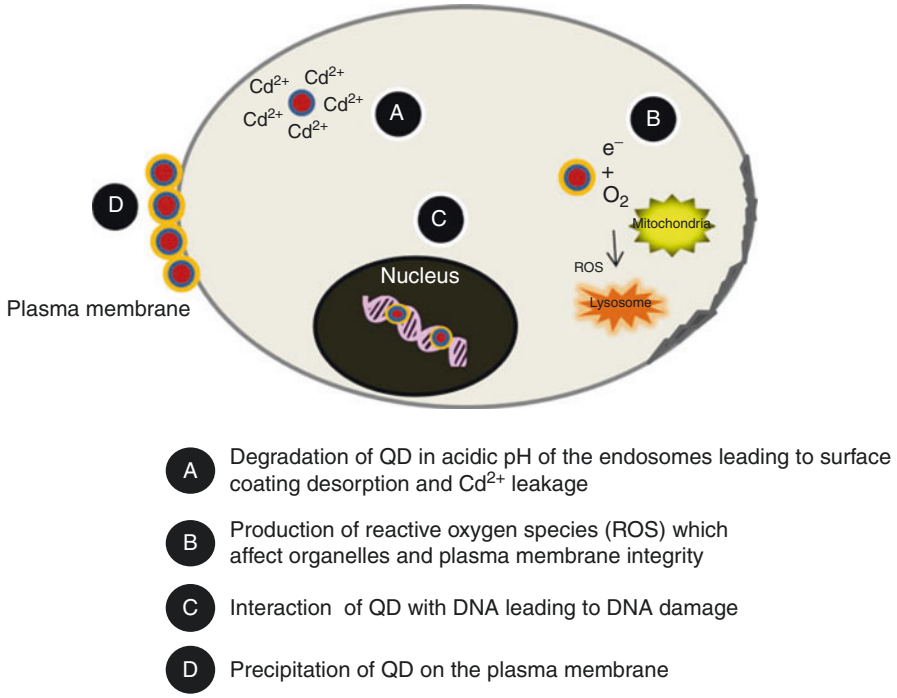
usually made of zinc sulfide (ZnS) [1]. The shell is generally used to protect the QD core from oxidation and photolysis and to minimize the associated toxicity related to the release of Cd^{2+} ions.

Currently QD are not only composed of CdS or CdSe but of many different semiconducting materials. These are derived from the II–VI elemental groups (e.g., zinc sulfide [ZnS], zinc selenide [ZnSe], and cadmium telluride [CdTe]), or the III–V elemental groups (e.g., indium phosphide [InP], indium arsenate [InAs]), or the IV–VI elemental groups (e.g., lead selenide [PbSe], lead sulfide [PbS]). In addition to the huge advances in semiconductor synthesis, novel QD such as CdTe/CdSe (core/shell), CdSe/ZnTe (core/shell), cadmium-free QD, and Mn-doped ZnSe have also been developed [2].

In biological sciences QD exhibit great potential as fluorescent probes for optical imaging and diagnostic applications in vitro and in vivo. Due to their bright fluorescence, pronounced photostability and broad excitation spectra, simultaneous detection of QD in different colors has enabled multiplexed imaging for tracking cancer cell metastasis and identification of tumor nodules in vivo [3–6].

QD Solubility and Ligation

QD can be prepared in either water-based or organic solvent environments. The latter approach produces uniformly dispersed QD with a range of emission colors ranging from ultraviolet to infrared. However, QD synthesized in apolar solvents contain organic shells that compromise their water solubility and consequently their compatibility with the biological milieu. Many strategies have been developed to overcome this limitation based on the surface ligation of QD with hydrophilic groups. Several hydrophilic ligands have been utilized to exchange the hydrophobic trioctylphosphine oxide (TOPO) coat on the QD surface with hydrophilic moieties, including: (1) thiol-containing molecules, such as mercaptoacetic acid (MAA), dihydrolipoic acid (DHLA) and mercaptopropyltris (methoxy) silane (MPS); (2) peptides; (3) dendrons; and (4) oligomeric phosphine. In spite of maintaining small mean diameters, surface modification methods generally tend to cause QD aggregation and decrease the efficiency of their optical properties (e.g., fluorescence intensity). Moreover, when labile ligands detach from the QD surface, QD-induced toxicity will increase correspondingly due to exposure to the QD core.



An alternative approach to make QD water dispersible and therefore more biocompatible is based on the hydrophobic interactions between the organic QD surface and the self-assembly of various amphiphilic molecules. Embedding or encapsulating organic QD into phospholipid micelles, lipid bilayers, and amphiphilic diblock or triblock copolymers was found to significantly increase QD diameter, but more importantly to preserve QD photostability, colloidal stability and enable QD application to physiological conditions without the release of the toxic Cd^{2+} ions.

QD Toxicity In Vitro

The toxicity of QD is mainly derived from their intrinsic core composition such as CdSe and CdTe [7, 8]. Cd^{2+} ions have been shown to be toxic upon their release from the QD core due to photolysis and/or oxidation (Fig. 1A). Other mechanisms contributing to QD-induced cytotoxicity have also been identified including: the formation of reactive oxygen species (ROS) that induce cell damage [9] (Fig. 1B) and the interaction of QD nanoparticles with the individual cell components (e.g., DNA or proteins) (Fig. 1C) or with the cell membrane (Fig. 1D).

QD-induced cell dysfunction is accompanied by apoptotic and necrotic biochemical changes including: morphological alteration in the plasma membrane; mitochondria and nucleus damage; lysosome enlargement; reduction in cytochrome C concentration; loss of mitochondrial membrane potential; and upregulation of peroxidized lipids [10].

The correlation between cytotoxicity and free Cd^{2+} ions has been established with the occurrence of significant cell death in the range of 100–400 μM Cd^{2+} ions. The blue shift in QD

Quantum Dot Toxicity, Fig. 1 Mechanism of QD toxicity

fluorescence spectrum has been proposed as an indication of QD size reduction and Cd^{2+} release. In addition, QD-induced cytotoxicity dramatically increased in the case of QD exposure to oxygen or ultraviolet (UV) light. In fact the principle of QD phototoxicity has been exploited for the development of photodynamic therapeutics [6].

Several attempts to reduce the inherent QD toxicity have been described. For instance, ZnS coating protects the QD core from oxidation, which minimizes Cd^{2+} leakage and reduces the QD-induced cytotoxicity. In addition, the use of antioxidants, such as *N*-acetylcysteine (NAC) has been shown to be effective in reducing QD cytotoxicity. To date, most cytotoxicity studies have used QD solubilized by direct exchange of the organic coat (TOPO) with hydrophilic ligands, such as mercaptopropionic acid (MPA-QD), mercaptoacetic acid (MAA-QD), mercaptoundecanoic acid (MUA-QD), cysteamine (QD-NH_2), and thioglycerol (QD-OH). In such cases, ligand detachment from the QD surface may also occur due to the weak interaction between the QD surface and the ligands, especially under unfavorable conditions like those in the endosomal compartment. Several studies have indicated that cell incubation with QD solubilized by ligand surface exchange has mostly been associated with severe cell death with increasing QD concentrations, similar to that induced by Cd^{2+} ions, which indicates the need for more stable QD. In contrast, lower cytotoxicity has been observed with polymer-coated QD.

Overall, the in vitro toxicity studies carried out so far have shown that the key determinants of QD toxicity are the nanocrystal composition and the type of surface functionalization. However, other factors including: cell type, QD size, concentration, and QD exposure to oxygen and UV light have also been found to influence QD cytotoxicity.

QD Toxicity In Vivo

The concern about the potential toxicity of QD in vivo is mainly due to the well-established toxicological profile of cadmium, the physicochemical

characteristics of certain QD surface coatings, and the size of QD. In general, the small diameter of nanoparticles provides a large available surface for interaction with different biological molecules. Moreover, nanocrystals of a few nanometers in size, such as QD, can enter vital organs such as the heart, lung, liver, and brain after intravenous administration. Therefore, studies that will help determine the toxicological risk and tolerated exposure levels of QD in vivo will be needed for any type of QD developed for biomedical use.

It has been previously described that QD nanocrystals and other nanoparticles could be inhaled and deposited in the respiratory tract, mainly depending on their size [11, 12]. It has also been shown that QD are capable of penetrating intact skin [13]. These preliminary studies suggest that extra care should be taken during QD handling especially during their manufacturing, since systemic toxicity can occur via QD inhalation and direct skin contact.

Preclinical research has shown that QD can be used to visualize lymph nodes and solid tumors in vivo following local or systemic administration. Many studies have also shown that intravenously administered QD mainly reside in the reticuloendothelial system tissues (liver, spleen, and lymph nodes) with no degradation or excretion for up to 2 years; however, no clinical signs of toxicity have been reported. More recent studies have shown that only QD of 5–6 nm in diameter, which is below the renal filtration threshold, were found to be excreted via the urine 4 h post-injection, while QD of larger diameters undesirably remained in the liver up to a few months, which may increase the potential toxicological risks from these nanoparticles in the long term. Interestingly, a recent study has reported that the QD dose in combination with the surface coating and charge play an important role in QD toxicity in vivo. For instance, carboxylated QD injected at a high dose in mice can activate blood coagulation and induce thrombus formation in the lung that can be lethal. Such studies further emphasize the need to investigate the effect of surface coatings on QD toxicity.

In conclusion, QD offer tremendous potential based on their optical properties. Even though a lot of interest and improvements have been achieved in terms of aqueous dispersion and compatibility in physiological environments, there is an inherent risk associated with exposure to QD nanocrystals, in particular those consisting of cadmium. Since the most meaningful clinical translation of QD technology is as probes for biomedical imaging, the acceptable toxicological risks should be minimal or nonexistent. This seems the most formidable challenge that QD technology has to overcome, because as can be seen from the available pharmacological studies, QD can reside in different organs when injected in living animals depending on various QD characteristics (size, dose, surface charge, and coating) and the route of administration. Furthermore, such studies have indicated that QD can accumulate in some tissues for extensive periods of time which requires further investigation to identify the long-term toxicological risks of QD before embarking on any clinical use of QD. In addition, even if QD are excreted from the body the toxicity profile of these nanocrystals on the environment (water and soil) should also be investigated.

Definition

The optical properties of quantum system including atoms, molecules, and quantum dots can be drastically modified by a metallic particle through surface plasmon resonance effect.

The presence of plasmonic metallic particle (MP) can affect the optical properties of a quantum system (QS) in a remarkable way. The mechanism here is the mutual effect of polarizations similar to the induced dipole moment through dipole-dipole interactions. This mechanism should be contrasted from the quantum electrodynamic effect due to the presence of boundaries such as cavity mirrors or microstructures that alter the electromagnetic density of states of the quantum vacuum. We develop a general quantum nonlinear formalism with exact vectorial description for the scattered photons by the QS. The formalism enables us to study the variations of the dielectric function and photon spectrum of the QS with the particle distance between QS and MP, exciting laser direction, polarization, and phase in the presence of surface plasmon resonance (SPR) in the MP. The quantum formalism also serves as a powerful tool for studying the effects of these parameters on the nonclassical properties of the scattered photons. The plasmonic effect of nanoparticles has promising possibilities as it provides a new way for manipulating quantum optical properties of light in nanophotonic systems.

Recent research interest is in the study of quantum dot-metallic nanoparticle system. Metallic

Quantum System Near Metallic Particle, Fig. 1 (Color online) Configuration of a quantum system (QS) and a metallic particle (MP) probed by a laser with field **E**. The internal states of the QS are described by a three-level system with *a*–*c* transition driven by a strong external control laser

nanoparticle can act as a nanoamplifier and pulse controller for quantum dot [1], as well as enhancement and suppression of emission between nanoparticles in the semiconductor-metal nanoparticle assemblies [2]. The presence of metallic surface can enhance the fluorescence emission rate of nanocrystal [3] and field localization through nanofocusing [4] and plasmonic nanoantenna in laser diode [5].

Interesting current research focuses on quantum plasmonics where surface plasmon resonance (SPR) can affect the strength of light-matter interactions. In return quantum coherence can affect the optical properties of the QS-MP hybrid system not only at near field but also at larger interparticle separation R or far field. To illustrate this remarkable effect, we consider the interaction between a quantum system (QS) and plasmonic metallic nanoparticle (MP) coupled through their own polarizations as shown in Fig. 1. QS is modeled by three-level atoms which exhibit electromagnetically induced transparency (EIT) of probe field in the presence of control laser. We analyze how the optical properties of the QS are affected by factors such as the distance R, laser parameters (frequency, direction, and polarization), and quantum coherence effects.

Plasmonic effect or surface plasmon resonance can be found in historical artifacts such as the famous Lycurgus cup and buildings such as colorful glass ceilings. Gold nanoparticles with various shapes and sizes give rise to different colors observed. Potential applications as chemical sensors and optical chip have attracted many researchers into this topic.

It is well known that metallic nanoparticles or microparticles generate quantized plasmon in the presence of electromagnetic radiation leading to nanoplasmonic effects with large intensity outside the metallic surface and surface mode with large and discrete wavevector. However, there are also important quantum effects in plasmonic system composed of atoms, molecules, or quantum dots, such as the Fano dip that has been explored [6]. Thus, the study will involve quantum theoretical formalism, particularly the density matrix $\hat{\rho}$ and the Liouville-von Neumann equation $\frac{d}{dt}\hat{\rho} = \left[\hat{H},\hat{\rho}\right]/i\hbar$.

The Hamiltonian of the QS with three-level system is

$$\hat{H} = \hat{H}_0 + \hbar\left(\Omega_b e^{-ivt}|a\rangle\langle b| + \Omega_c e^{-iv_c t}|a\rangle\langle c| + \text{adj}\right) \quad (1)$$

leading to a set of 3^2 coupled density matrix equations. The Rabi frequencies of the *effective* probe field $\mathbf{E}_{QS}$ and control field $\mathbf{E}_c$ are $\Omega_b = \frac{1}{\hbar}\wp_{ab}\cdot\mathbf{E}_{QS}$ and $\Omega_c = \frac{1}{\hbar}\wp_{ac}\cdot\mathbf{E}_c$, respectively. The *incident* probe laser field which depends on polarization angle ϕ and direction θ is given by

$$\mathbf{E}_p = E\left(\alpha\sin\theta, \alpha\cos\theta, \beta e^{i\phi}\right) \quad (2)$$

where θ gives the laser direction and $\alpha, \beta = \sqrt{1-\alpha^2}, \phi$ determines the ellipticity of polarization.

The three-level system is coupled by two fields: probe field and control field. The probability amplitude for the system to excite from level b to level a can interfere destructively in the presence of the control field, creating optical transparency window and preventing absorption. This is electromagnetically induced transparency which leads to transparency at resonant frequency ω_{ab} with two absorption peaks around $\omega_{ab} \pm \Omega_c$.

Exact expression of the electric field $\mathbf{E}_{dip}$ created by a dipole emitter with dipole moment $\mathbf{p}$, at any distance R, can be obtained from

$$\mathbf{E}_{dip} = \frac{K}{\varepsilon_{eff}} \left[A \begin{pmatrix} p_x \\ p_y \\ p_z \end{pmatrix} + B \begin{pmatrix} n_x \\ n_y \\ n_z \end{pmatrix} \mathbf{p} \cdot \hat{n} \right] \tag{3}$$

$$A(k,R) = \frac{k^2}{R} - \frac{1}{R^3} + \frac{ik}{R^2} \tag{4}$$

$$B(k,R) = \frac{3}{R^3} - \frac{3ik}{R^2} - \frac{k^2}{R} \tag{5}$$

$$\mathbf{p} \cdot \hat{n} = p_x n_x + p_y n_y + p_z n_z \tag{6}$$

where $\hat{n}$ is along the line from the dipole to the observation point, $K = \frac{1}{4\pi\varepsilon_0}$, k is the wavevector, and $\varepsilon_{eff} = \frac{2\varepsilon_b + \varepsilon_{MP}}{3\varepsilon_b}$ is the effective dielectric function that depends on that of the MP, ε_{MP}. The coefficients A and B are exact such that the theory is valid for arbitrary R.

The fields of both the QS and MP $\begin{pmatrix} E_{MPx} \\ E_{MPy} \\ E_{MPz} \end{pmatrix}$ affect each other leading to two coupled equations. The electric field at MP due to dipole in QS is

$$\begin{pmatrix} E_{MPx} \\ E_{MPy} \\ E_{MPz} \end{pmatrix} = \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix} + \frac{K}{\varepsilon'_{eff}} \widetilde{\rho}_{ab} \left\{ A \begin{pmatrix} \wp_x^* \\ \wp_y^* \\ \wp_z^* \end{pmatrix} + B \begin{pmatrix} n'_x \\ n'_y \\ n'_z \end{pmatrix} \wp * \cdot \hat{n}' \right\} \tag{7}$$

$$= \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix} + \frac{KM'}{\varepsilon'_{eff}} \widetilde{\rho}_{ab} \begin{pmatrix} \wp_x^* \\ \wp_y^* \\ \wp_z^* \end{pmatrix} \tag{8}$$

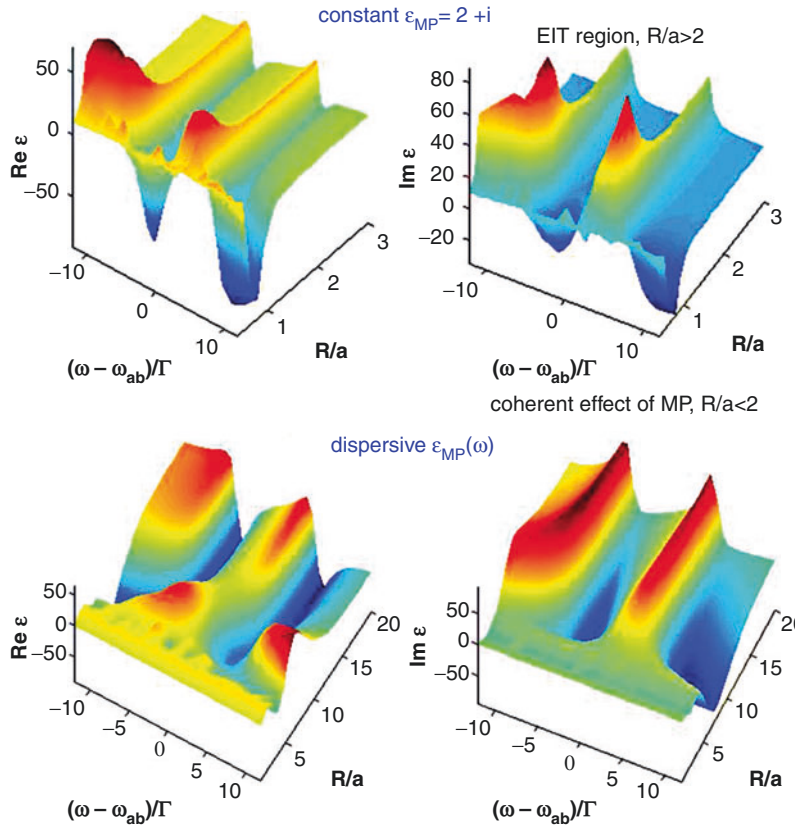
$$M' = \begin{pmatrix} A + Bn'_x 2 & Bn'_x n'_y & Bn'_x n'_z \\ Bn'_x n'_y & A + Bn'_y 2 & Bn'_y n'_z \\ Bn'_x n'_z & Bn'_y n'_z & A + Bn'_z 2 \end{pmatrix} \tag{9}$$

where $\varepsilon'_{eff} = \frac{2\varepsilon_b + \varepsilon_{QS}}{3\varepsilon_b}$. The effects of MP on a QS where the vectorial nature of the fields is included provide additional possibilities for manipulating the optical properties and mechanism of the QS by changing the direction, polarization, and phase of the probe laser. On the other hand, the electric field at QS due to polarizability of the MP is

$$\begin{pmatrix} E_{QSx} \\ E_{QSy} \\ E_{QSz} \end{pmatrix} = \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix} + \frac{K}{\varepsilon_{\text{eff}}} \left\{ A \begin{pmatrix} p_{MPx} \\ p_{MPy} \\ p_{MPz} \end{pmatrix} + B \begin{pmatrix} n_x \\ n_y \\ n_z \end{pmatrix} \mathrm{p}_{MP} \cdot \hat{n} \right\}$$

$$= \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix} + \frac{KM\alpha_{MP}}{\varepsilon_{\text{eff}}} \begin{pmatrix} E_{MPx} \\ E_{MPy} \\ E_{MPz} \end{pmatrix} \tag{10}$$

$$M = \begin{pmatrix} A + Bn_x^2 & Bn_x n_z & Bn_x n_z \\ Bn_x n_y & A + Bn_y^2 & Bn_y n_z \\ Bn_x n_z & Bn_y n_z & A + Bn_z^2 \end{pmatrix} \tag{11}$$



where we use $p_{MPj} = \alpha_{MP} E_{MPj}$ with polarizability α_{MP} and $j = x, y$. Solving the coupled equations gives the exact and general and vectorial local field description of the QS:

$$\begin{pmatrix} E_{QSx} \\ E_{QSy} \\ E_{QSz} \end{pmatrix} = \Lambda \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix} + G\widetilde{\rho}_{ab} \begin{pmatrix} \wp_x^* \\ \wp_y^* \\ \wp_z^* \end{pmatrix} \tag{12}$$

$$\Lambda = I + \frac{\alpha_{MP} KM}{\varepsilon_{eff}}, G = \alpha_{MP} \frac{KM}{\varepsilon_{eff}} \frac{KM'}{\varepsilon'_{eff}} \tag{13}$$

The vector field $\begin{pmatrix} E_{QSx} \\ E_{QSy} \\ E_{QSz} \end{pmatrix}$ is coupled to the

Q

Quantum System Near Metallic Particle, Fig. 2 (Color online) The spectra for the real and imaginary parts of the dielectric function versus R, the spacing between the QS and MP for different dielectric function of the metallic particle. (**a**) Constant $\varepsilon_{MP} = 2 + i$ and (**b**) dispersive $\varepsilon_{MP}(\omega) = \varepsilon_\infty - \frac{\omega_p^2}{\omega(\omega+i\Gamma_m)}$ with SPR

density matrix equations through the Rabi frequency $\Omega_b = \frac{1}{\hbar}\wp_{ab} \cdot \mathbf{E}_{QS}$.

Solving for the density matrix element ρ_{ab} numerically gives the dielectric function $\varepsilon(\omega) = 1 + \chi$ with $\frac{\chi = \frac{N|\wp_{ab}|^2}{\varepsilon_0}\rho_{ab}}{\wp_{ab}\cdot\mathbf{E}_p}$ for the linear optical properties of the QS. It is important to note that Im $\varepsilon(\omega) > 0$ (< 0) corresponds to absorption (gain). Results for the near-field $kR \sim 1$ can be found in [7].

We can learn about the coherent quantum and plasmonic effects by considering the following cases shown in Fig. 2. In the case of constant or nondispersive MP, $\varepsilon_{MP} = 2 + i$ (with no SPR), we only have a small enhancement and the EIT effect diminishes at $R \tilde{} 2a$. When dispersion is introduced (such as in the case of Ag) and with the surface plasmon resonance (SPR) condition $\varepsilon_{MP}(\omega_{SP}) + 2\varepsilon_b \simeq 0$, the effective dielectric function $\varepsilon_{eff} = \frac{2\varepsilon_b + \varepsilon_{MP}}{3\varepsilon_b}$ is close to zero. Here, we have a large plasmonic enhancement to the field $\mathbf{E}_{QS}$, where $\varepsilon_{MP}(\omega)$ is the dielectric function of metal at SPR frequency ω_{SP}. Typically, for gold or silver nanoparticles, we have negative value in the real part of ε_{MP} at the frequency ω_{SP}. To see the plasmonic effects on the EIT profile, we set $\omega_{ab} = \omega_{SP}$. With the coexistence of the SPR and the EIT effect, we can see how the SPR affects the double-resonant peaks of the EIT. Figure 2 shows that the EIT peaks are affected at a much larger distance $R \sim 20a$, which is about one order of magnitude larger than the case without SPR. This is due to the plasmonic effect which gives rise to long-range Foerster interaction. At small R, the EIT effect is quenched and the optical properties of QS are drastically changed.

The presence of the MP gives rise to the coherent interactions between the QS and MP, producing gain when the imaginary part of the dielectric function takes an opposite sign.

This effect provides laser switching of quantum optical properties between the regimes of EIT, absorptive and gain. With SPR effect of the MP, the local field of the QS is significantly enhanced by many orders of magnitude. This effect has profound implications on the atom-field coupling which can reach nonlinear regime even with a few photons. It opens up the practicality of quantum nonlinear optics, whereby quantum effects can coexist with nonlinear effects at microscopic level. The model shown can be extended to many particle system or mesoscopic particles composed of the quantum particles. This enables the quantum plasmonics to be extended to mesoscopic objects such as nanoparticles and microparticles.

Definition

Rapid electrokinetic patterning (REP) is a hybrid optoelectric technique that concentrates and manipulates particles via the combination of a uniform alternating current (AC) electric field and laser light. Alone, the AC electric field induces electric double layer (EDL) polarization of the dielectric particles. Coupling the AC electric field with the laser light produces a toroidal electrothermal flow. This flow sweeps colloids suspended in the solution and brings them close to the electrode surface where particles are trapped by particle-electrode interactions.

Overview

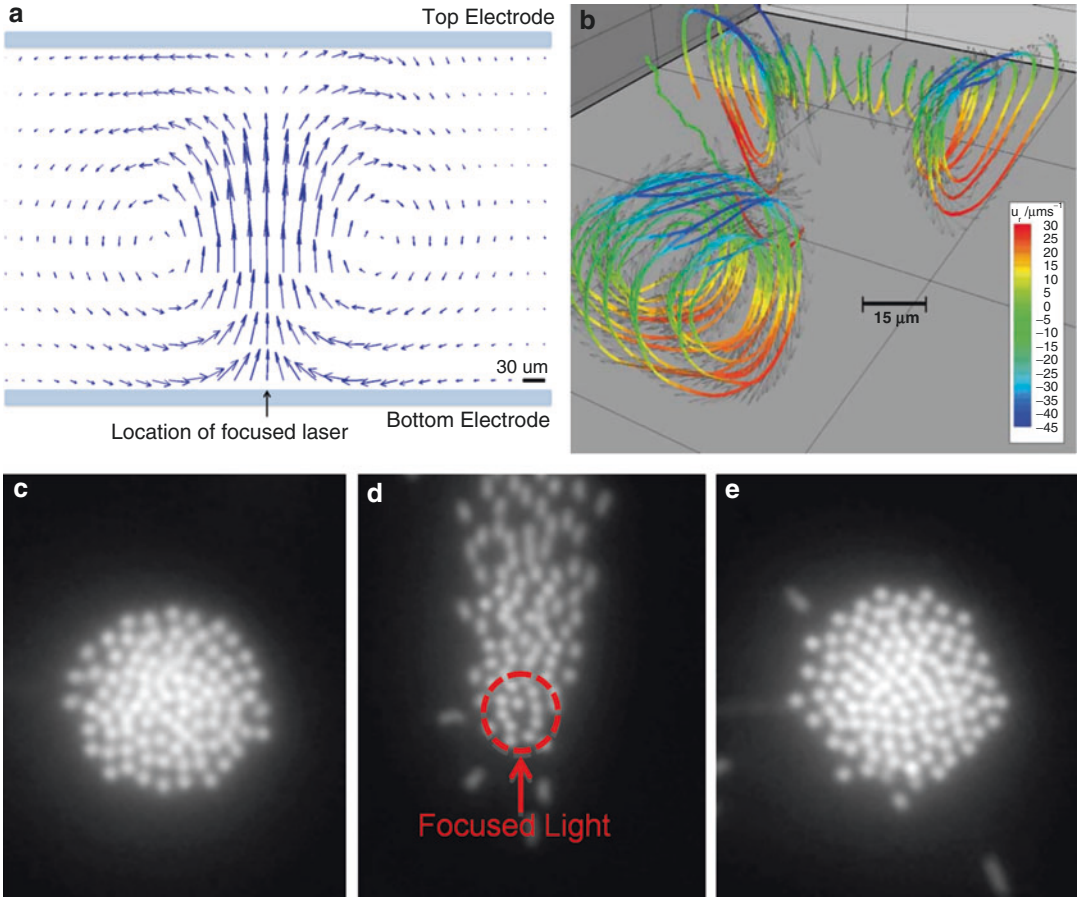
The ability to concentrate and manipulate colloids on chip provides potential solutions in fields of micromanufacturing, disease diagnostics, biology, and plasmonics [1–3]. The ability to dynamically configure clusters of particles decreases time-to-assemble and manufacture structures, which is a continuing issue in many lab-on-a-chip (LOC)-based systems [4]. Many optical and

electrokinetic techniques have attempted to alleviate these issues however certain limitations still exist. Purely optical techniques, such as optical tweezers, allow for only small numbers of particles to be captured within the beam waist of a laser beam [5]. On the other hand, purely electric techniques, such as dielectrophoresis, require complex fabrication of microelectrode that cannot be changed dynamically [6].

Rapid electrokinetic patterning is a dynamic, high-throughput technique that allows for micro- and nano-based patterning of colloids. REP requires the application of a uniform AC electric field and optical illumination in order to concentrate particles within solution. Optical illumination induces an axisymmetric temperature gradient within the chip, with the highest temperature at the beam focus. This temperature variation causes physical property variation, most importantly the electrical conductivity and permittivity. The applied electric field interacts with these material property variations to create a body force within the fluid and consequently an electrothermal vortex. The vortex transports colloids to the center of the torus where particles are trapped by particle-electrode interactions. This flow is produced whether the laser is focused at the top electrode or bottom electrode. Figure 1a provides an example of a laser focused on the bottom electrode. When focusing the laser at the top electrode, it would look like Fig. 1a but vertically reflected in the horizontal midplane.

REP enables particle manipulation, translation, sorting, and patterning. This wide variety of processes that the technique enables make it useful in fields like micromanufacturing, plasmonics, biological detection and cell sorting, as well as chemical analysis. Using light patterning, particles can be concentrated into different patterns and structures on the electrode surface [8]. For example, detection of pathogenic bacteria requires cell sorting and concentration. The ability to sort such entities with ease could be potentially resolved with REP [9, 10]. These tasks are highly desirable in the biomedical community, potentially allowing full-scale laboratory analysis with small sample volumes and on platforms the size of a credit card [4].

REP can simultaneously collect particles of a specific size and manipulate the colloidal cluster. This technique requires a heat source, such as a laser or microheaters, to provide a temperature gradient along with an AC electric field. REP provides several benefits. First, it is a noncontact high-speed manipulation method, accumulating a cluster of particles in a matter of seconds. Second, REP is highly repeatable, as under the same settings, the same particle clusters will form each time. Third, REP chips require simple fabrication and manufacturing.



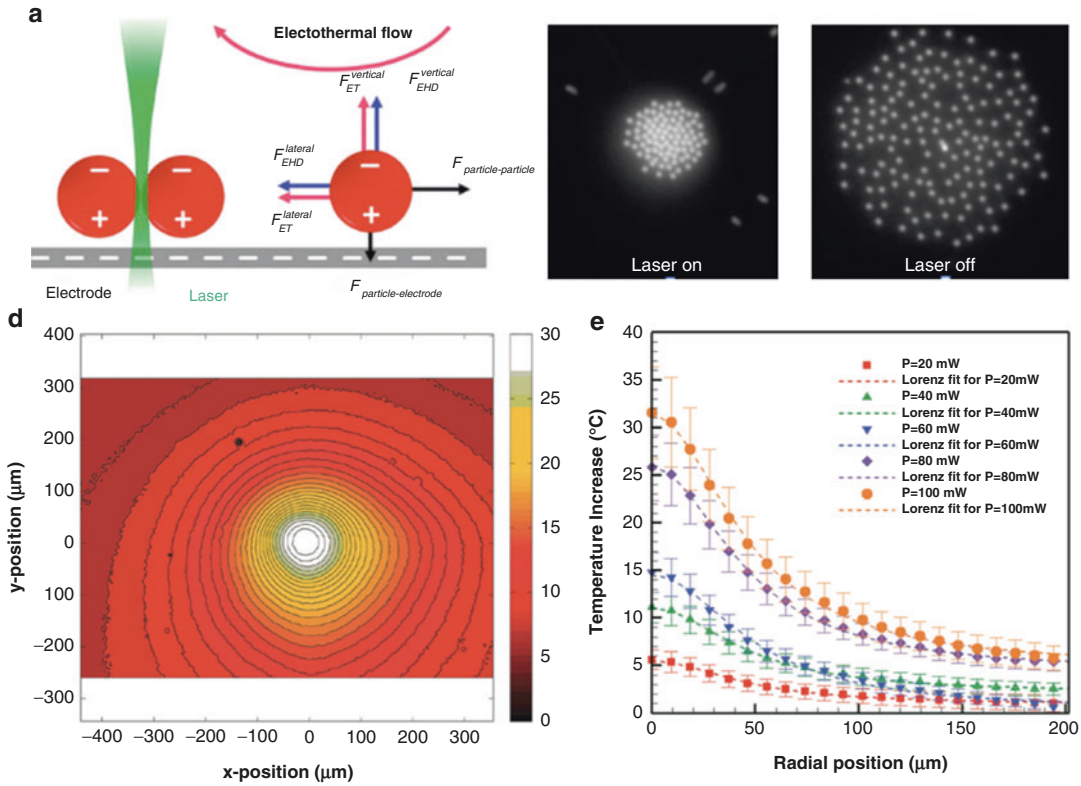
REP is a promising technique in its potential to contribute to a wide variety of fields in nano- and micro-technologies.

Physics

REP combines optics (using laser light) with electrokinetics (using an AC electric field). When coupled with one another, an electrothermal flow is produced in a toroidal fashion. This flow pattern "sweeps" particles toward the center of the torus' minor radius, where the temperature gradient generated by the nonuniform light source is maximum. The cluster of particles can be trapped onto the top or bottom electrode surface (depending on where the laser light is focused). An example of this is provided in Fig. 2b.

When the light source is removed from the apparatus, particles are no longer collected into the trap. Smaller-sized particles (i.e., <3 μm), post-light deactivation, are repelled from one another due to dipole-dipole repulsion (Fig. 2c). However, this repulsive effect is largely due to the AC electric field being maintained in chip. If the alternating current is removed, but the laser light is maintained, natural convection is seen within the apparatus [11] but usually at a speed an order of magnitude slower than that created by the electrical field. The coupling of the light source and AC electric field is vital for maintaining the concentration of particles.

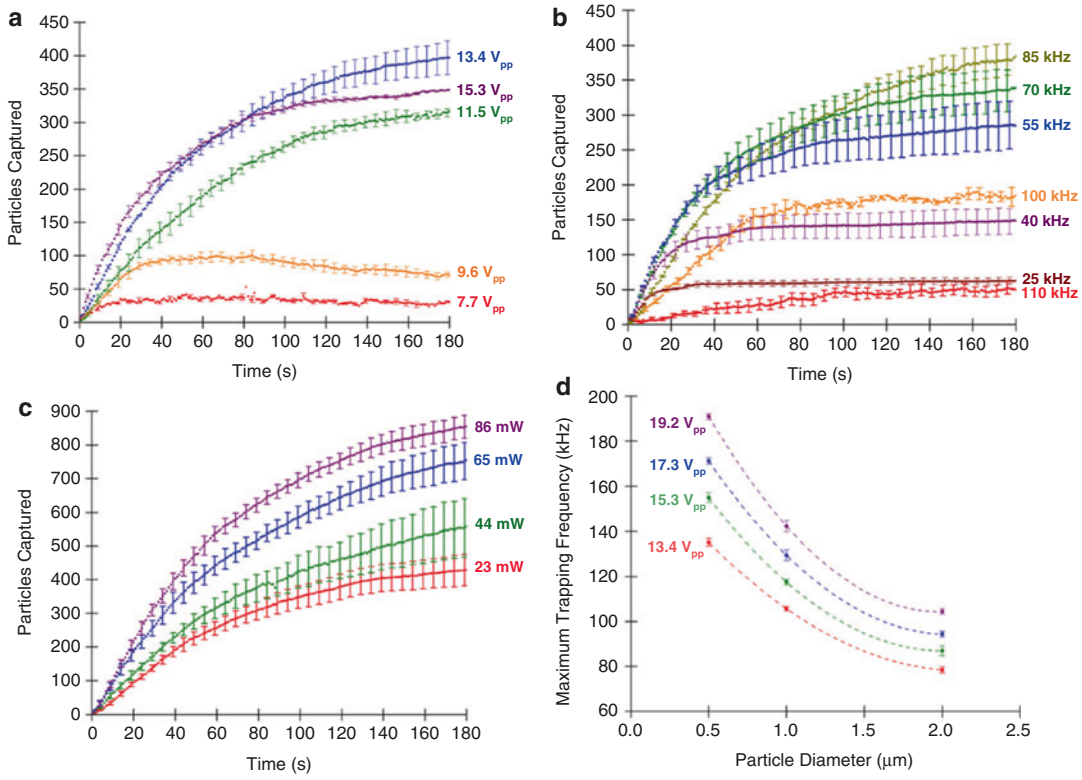
In more detail, dielectric particles are polarized due to the introduction of the electric field. There is a dipole force that acts between two neighboring particles. Due to their repulsion and self-organization on the electrode surface when



Rapid Electrokinetic Patterning and Its Applications, Fig. 1 **a** A 2D projection of electrothermal flow in REP. In this circumstance, a laser is focused on the bottom electrode of an REP chip, producing an upward flow on the inner radius of the toroidal fluid motion. **b** A 3D trajectory of the electrothermal flow at a frequency of 200 kHz. In this case the laser is focused at the top electrode surface (**b** Printed with permission from Kumar et al. Copyright 2010 Springer) [7]. **c** 1 µm particles are trapped in a monolayer using REP. These particles can be manipulated with ease, such as with **d** where the laser light is suddenly moved to an area below its original spot, and the particles are swept to the new location, until they are again in equilibrium in the trap, as seen in (**e**)

solely affected by the electric field, their lines of centers remain perpendicular to the electric field lines. As the laser light is combined with these electric field effects, the temperature gradient provided by the light induces a gradient for the conductivity and permittivity of the solution. This combination produces a toroidal electrothermal vortex, which is characterized by the time-averaged electrothermal body force equation:

$$\langle f_e \rangle = \frac{1}{2}\mathrm{Re}\left[\left(\frac{(\sigma\nabla\varepsilon - \varepsilon\nabla\sigma)\bullet E}{\sigma + i\omega\varepsilon}\right)E^* - \frac{1}{2}|E|^2\nabla\varepsilon\right] \quad (1)$$



In the time-averaged fluid body force equation, Re represents taking the real valued portion of the expression. The electric field is represented by E and its complex conjugate is E^*. The equation encompasses the gradient of conductivity, σ, and permittivity, ε, of the solution, which is created due to the temperature gradient produced by the optical source, and then finally the ω term represents the angular frequency. On the right-hand side of the equation, the left-hand term represents the Coulomb force, while the right-hand term is the dielectric force component [12].

Rapid Electrokinetic Patterning and Its Applications, Fig. 2 **a** The force relationships on a particle undergoing REP – the bottom electrode is negatively charged, where the particle with an induced dipole interacts with its surface. Both lateral and vertical induced drag force, and electrohydrodynamic forces act on the particle as well. Additionally, the particle-particle interaction force is shown (Reprinted with permission from Kwon et al. The laser is focused at the origin. **e** The effect of different laser powers (in mW) and its corresponding temperature increase, starting at the origin of the laser spot and propagating out radially (**d** and **e** Reprinted with permission from Kumar et al. Copyright 2010 American Chemical Society) [15]

From current understanding, four main electrokinetic relationships can be analyzed. The first relationship is the force between particles. Denoted $F_{particle}$, this force is what particles experience between one another (i.e., $F_{particle}$- $F_{particle}$). Under the AC electric field, the dipole-induced particles experience repulsion from one another. The second is the force between the electrode and particle ($F_{electrode}$- $F_{particle}$). As the electrothermal flow sweeps the particle into a monolayer formation, the particles undergo a physical interaction with the electrode. This electrothermal flow aids in a drag force that can be broken into vertical and lateral component ($F^{lateral}_{ET}$, $F^{vertical}_{ET}$). The fourth is an attractive particle-particle force ($F^{lateral}_{EHD}$, $F^{vertical}_{EHD}$). Polarized particles produce a local electrohydrodynamic flow due to the interaction between the electric field and an ionic double layer on the particle and electrode [13]. This force balance is demonstrated in Fig. 2a.

At a specific frequency, (1) the drag force due to electrohydrodynamic flow, (2) the force between the electrode and particle, (3) the force between particles, and (4) the drag force due to the electrothermal vortex balance one another at the trapping point. If the frequency is increased, the flow becomes so strong that particles are

rapidly swept and unable to be maintained within their respective cluster. However, this relationship is still under investigation.

Although these relationships do remain under investigation, Fig. 3 represents trends seen experimentally in REP. In Fig. 3a the number of particles captured increases linearly and then plateaus as the particle cluster reaches steady state. Furthermore, it is observed that higher applied voltages cause larger numbers of particles trapped (except for the 15.3 V_{pp} case). This 15.3 V_{pp} outlier case may be due to an increased electrothermal body force. This increase may overcome particle-particle and particle-electrode forces, ripping particles out of their original trap space. In Fig. 3b it is observed that the particles captured for various frequencies increase linearly and then plateau as the cluster reaches steady state. Figure 3c shows that the number of particles within the cluster increases linearly and then begins to reach steady state. The increase in laser power increases the number of particles captured. This may be due to the fact that as the laser power increases, the electrothermal flow velocity increases. This is due to a steeper temperature gradient, leading to faster particle circulation. This circulation brings particles closer to the colloid cluster, increasing the probability of particles to be pulled into the REP trap. Figure 3d shows the maximum trapping frequency for particles of different diameters before it fails to form a cluster. A particle of smaller diameter will remain trapped at a higher frequency when compared to a larger particle. Furthermore, the maximum trapping

frequency of the same particle increases as the applied AC peak-to-peak voltage increases [14].

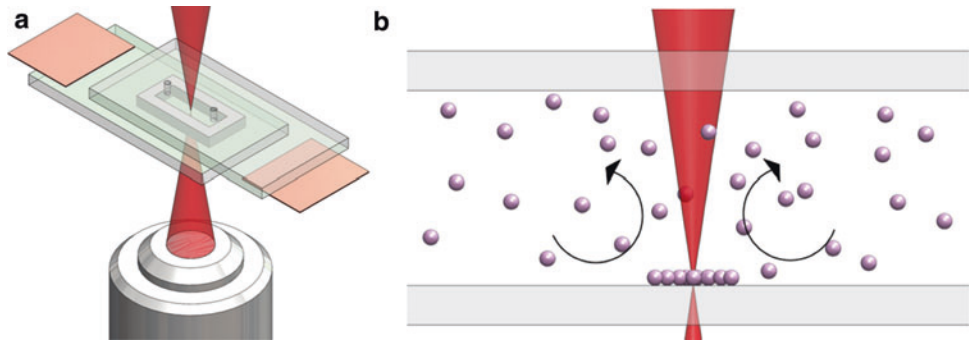
Methodology

Fabrication of REP chips is relatively simple. The chip is made of a thin-film electrode coated onto a glass substrate. Indium tin oxide (ITO)-coated glass substrates are typically used to conduct REP. This coating is highly transparent allowing for observation within the REP chip under a microscope.

Two of these substrates are placed with the electrodes facing one another with a spacer in between. This spacer is designed to define microchannels and wells. The spacer material is adhered to both electrodes and is nonreactive with the sample. In some cases, a commercial double-sided tape can be used to conduct short-term REP studies. The typical setup for conducting REP requires a laser source and an AC function generator. The laser is applied to a desired spatial location on chip. A representation of this setup is presented in Fig. 4.

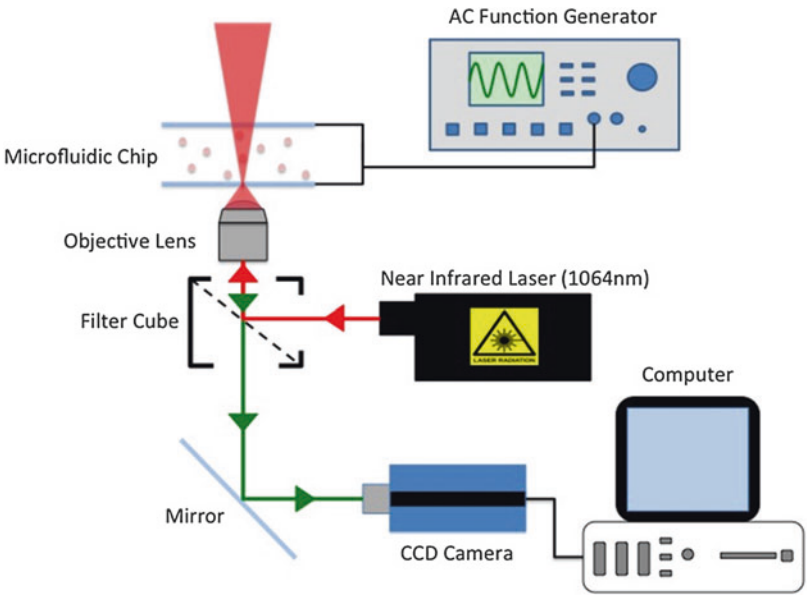
The channel is often illuminated using a near-infrared (NIR) laser of 1064 nm wavelength. However, alternative wavelengths may be used. Traditionally, the laser power used in REP is less than 200 mW. Furthermore, the laser frequency has to be considered so that the heat absorption of the laser onto the sample is minimal. Objective lenses are typically chosen to be at a magnification of 20× or larger. This ensures that the laser spot size is focused enough to create a steep temperature gradient. A schematic of the REP setup can be found in Fig. 5.

For electrical effects, an AC electric field with a frequency less than 200 kHz must be used. This induces polarization of the dielectric material. In higher frequency regimes, the particles relax, hindering the collection of the particles under REP. Very low-frequency regimes often result in self-organization of particles on the electrode surface, but in turn induce strong particle-electrode interactions.



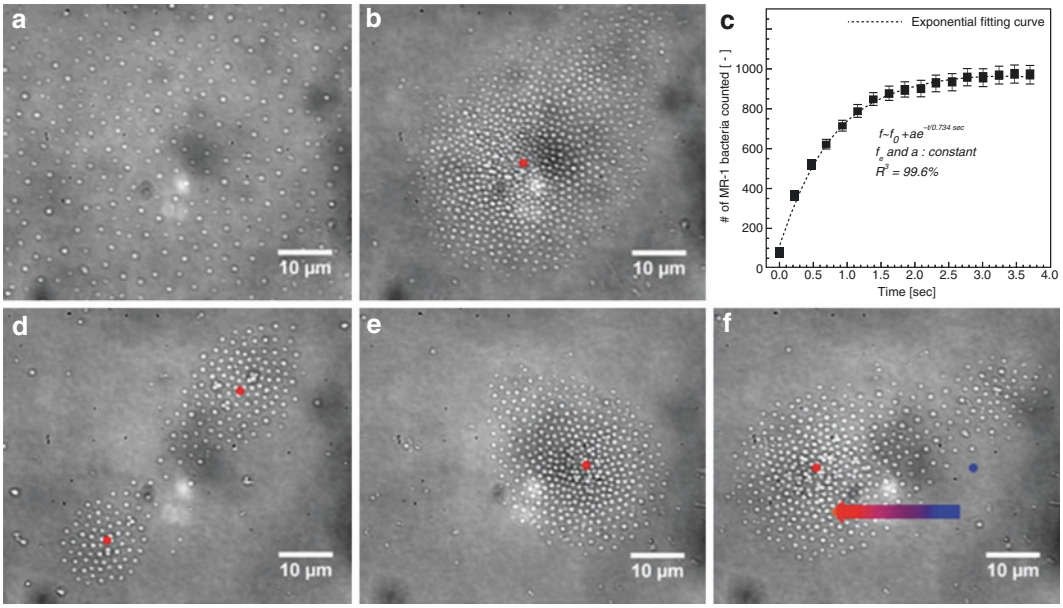
Particles must be suspended in low conductivity solutions (i.e., $\sigma \leq 10$ mS/m) [14, 15]. When particles are submerged in higher conductivity solutions, the electric double layer becomes thinner, increasing the particle-electrode adhesion.

Applications



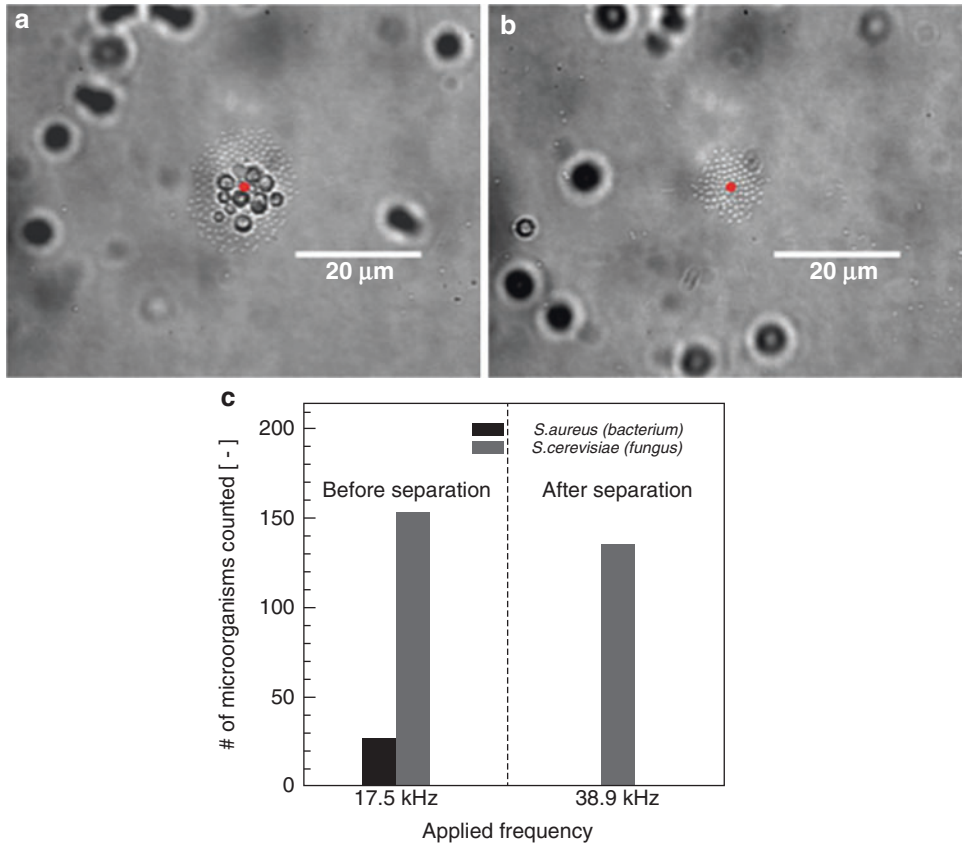
In recent years, researchers have investigated potential applications of rapid electrokinetic patterning. This spawned a wide spectrum of uses for this opto-electrokinetic technique, from biology to plasmonics.

In Biology



Biology wet labs are looking for alternative systems that allow for appropriate sampling of

Rapid Electrokinetic Patterning and Its Applications, Fig. 4 In image **a**, a demonstration of an REP chip with laser light focused on a particular plane, where **b** shows how at the beam waist of the laser particles are trapped on the electrode surface; note the *black arrows* correspond with the flow direction of the electrothermal vortex



Rapid Electrokinetic Patterning and Its Applications, Fig. 5 A schematic of a standard REP setup. A fabricated REP chip undergoes an AC electric field from a function generator as well as heating from laser light. The 1064 nm laser is often directed to the substrate via an objective lens from the microscope. The CCD camera records images from the objective

solutions. Current techniques often require large amounts of consumables (both from reagents and materials), which are both costly and environmentally unfriendly. Many optical and electrokinetic-based methods wish to alleviate these issues. However, biological applications are difficult to implement in optoelectric systems due to issues with their charge properties, uniformity in sample,

Rapid Electrokinetic Patterning and Its Applications, Fig. 7 **a** Showing how multiple species – *S. aureus* and *S. cerevisiae* – are collected with REP. **b** After changing frequency, the larger *S. cerevisiae* are swept out of the trap, and only the *S. aureus* remains. **c** Providing how in image (**a**) there are 150 bacteria and 8 fungi trapped and how after in (**b**) there are 125 bacteria and no fungi within the trap (Reprinted with permission from Kwon et al. Copyright 2012 Royal Society of Chemistry) [3]

and viability/compatibility with the system. Therefore, like with many optical and electrokinetic techniques, biological use with REP is currently being investigated. Kwon et al. published the first work, using REP as a bioassay platform. *Shewanella oneidensis*, a 1 µm rod-shaped bacteria, was examined with rapid electrokinetic patterning. This gram-positive MR-1 mutant was placed under an AC electric field, where the bacterium's major axis aligned with the electric field. After introducing the laser, the bacteria collected onto the electrode surface in their vertical orientation. Within 0.73 s, 700 organisms were maintained in the trap, saturating out at ~1,000. Figure 6a, b shows the *S. oneidensis* before and during trapping. This demonstrates the ability to quickly and dynamically collect the species under REP. Likewise, multiple laser spots allowed for the collection of multiple *S. oneidensis* clusters, and through movement of the laser, these traps could translate about the chip, as seen in Fig. 6d [3].

Kwon et al. also demonstrated collecting multiple organisms within an REP trap, depending on its critical frequency effects (Fig. 7). *Saccharomyces cerevisiae* (a 5 µm spherical-shaped fungus) and *Staphylococcus aureus* (a ~1 µm spherical-shaped bacteria) were investigated. These two geometrically similar species were chosen due to their shape and similar zeta potentials. Under a 17.5 kHz frequency, 10.07 V_{pp}, and 20 mW laser power, both species clustered together within the

Initially when the heaters are off, particles are freely dispersed in solution. After the heaters are turned on with the electric field, particles begin to accumulate on the surface of the electrode, in the location of the thin-film heaters (Reprinted with permission from Velasco et al. Copyright 2012 Elsevier) [17]

REP trap. However, by increasing the frequency to almost twice as much, the *S. cerevisiae* were swept away from the trap, whereas the *S. aureus* sample was maintained. This proved the capability of using REP as a method for separating small microbial samples on the basis of size [3].

Alternative Platforms

Producing a cost-effective, easily accessible, and minimally power-consuming REP system is a key requirement for developing REP-based portable devices. Currently, a 1,064 nm laser is used to illuminate the REP chip. This is easily controllable within the laboratory space but provides little-to-no mobility of the system. Williams et al. investigated thin-film heaters as an alternative for laser-induced electrothermal flow [16]. Velasco et al. took this theory further by experimentally fabricated resistors onto a glass surface and tested 1–2 µm polystyrene spheres in the system [17]. A 10 µm wide wire trace was used which produced a 0.5 K temperature gradient. The system allowed for trapping, patterning, and sorting of colloidal particles. The electrothermal vortex was slower as compared to traditional REP [17]. Examples of this work are provided in Fig. 8a–c. This successful work showed the potential capabilities of microfabricating REP systems that can be used in the field. This opens up a potential opportunity for future use as a portable electrokinetic system.

Park et al. investigated twin opposing microvortices (TOMV). Fabricating two coplanar ITO electrodes onto glass surface (partly covered with SU-8), an AC electric field was applied between them while introducing laser light through the chip. Depending on where the

Rapid Electrokinetic Patterning and Its Applications, Fig. 9 In **a** is a schematic of microfabricated ITO electrodes, partially blocked by a layer of SU-8 on a glass substrate. These coplanar electrodes are alternative to the traditional parallel ITO coverslips used. This design creates twin opposing microvortices, collecting particles at the electrode surface. In **b**, where the laser light is focused (demonstrated by the point drawn on the *bold colored line*), changes the orientation of the opposing microvortices (Reprinted with permission from Park et al. Copyright 2012 Royal Society of Chemistry) [1]

light was focused, the TOMV changed their orientation within the chip (Fig. 9). These tunable microvortices are of interest due to the specific control of location and mixing of particles. Asymmetric flows and interesting mixing effects are possible with this technique [1].

Ndukaife et al. fabricated plasmonic nanostructures to increase heating effects in a traditional REP chip [2]. This nanostructure array absorbed light optimally at 1,064 nm. By exciting the structure at resonance, a rapid heat gradient was produced. Due to the increased heating effect, the velocity of the electrothermal vortex increased. This showed the potential of plasmonic structures as an REP platform. This could be used further in biosensors as well for surface-enhanced Raman spectroscopy (SERS) [2]. However, it is important to note that the fabrication of plasmonic structures is cost and labor intensive due to the use of e-beam lithography. A carefully selected ITO electrode can produce a sufficiently strong flow without the need of nanostructures.

Conclusions

Rapid electrokinetic patterning poses an array of current and future applications in a variety of fields. Now that the technique has been developed, work is being done to apply it. As this space is being pursued, REP will be used for novel applications within a large spectrum of nano- and microscale phenomena.

Definition

Reactive empirical bond-order potentials are interatomic energy functions used in molecular dynamics simulation and modeling of nanosystems where an accurate but efficient description of chemical reactivity is required.

Genesis of Reactive Bond-Order Potentials

Atomistic simulation of a large number of atoms using molecular dynamics (MD) is a powerful tool for understanding the fundamental mechanisms present in nanomaterials systems. The ability to accurately model chemistry including reactivity, bonding, charge transfer, polarizability, mixing, etc., is central to this understanding. Underpinning these calculations is the atomic interaction potential. Ideally, the atomic interactions would be obtained directly from first-principles, i.e., through solution of Schrodinger's equation. However, such calculations are orders of magnitude too slow for the large number of energy evaluations required to study nanosystems

of reasonable size and practical interest. To obtain useful information in a reasonable amount of time, empirical, and semiempirical approximations to the atomic potentials have been developed. In this entry, a survey of reactive empirical bond-order and related interatomic potentials is presented.

An effective analytic potential should have a relatively simple functional form, which captures the essential essence of the underlying quantum mechanical bonding, and will be able to mimic experimental quantities by utilizing empirically derived functions and parameters. Empirical potentials are likely to include a wide range of fitting parameters, which are selected to reproduce cohesive energies, elastic constants, lattice constants, and surface energies. Ideally, the potential will also have some degree of transferability, having the ability to describe structures not included in the fitting database, at least in a qualitative sense. Finally, the resulting function should be relatively efficient computationally. The process of developing a potential, sometimes referred to as an art as well as a science, requires a combination of chemical insight, trial and error, and tenacity on the part of its developer.

Covalent materials, such as silicon and carbon, form strong directional bonds. This poses a challenge for potential development for this important class of materials. Many standard potential functions, such as the Lennard-Jones (LJ) potential or the embedded atom method (EAM), do not include any bond directionality. The Stillinger–Weber (SW) potential for solid and liquid phases of silicon was one of the first attempts to use a classic potential to overcome this challenge [1]. Stillinger and Weber based their potential model on a many-body approach. In this approach, the total energy is given as a linear superposition of terms representing different types of interatomic interactions, e.g., stretching, bending, rotation, and torsion. For the SW potential, the total energy includes only two of these terms, a pair- and triplet-term based on the geometric factors of bond length and bond angle, respectively. The total potential energy, *Etot*, is given by

$$E_{tot} = \frac{1}{2}\sum_{\substack{ij \\ (i\neq j)}} \phi_{ij}(R_{ij}) + \sum_{ijk} g(R_{ij})\, g(R_{ik}) \left(\cos\theta_{ijk} + \tfrac{1}{3}\right)^2. \quad (1)$$

Here ϕ_{ij} is the pair-term (bond stretching) representing electrostatic interactions between atoms i and j. The second summation is a three-body term, which represents bond bending between atoms i, j, and k. The term $g(r_{ij})$ is a decaying function with a cutoff between the first- and second-neighbor shell, and θ_{ijk} is the bond angle described by two neighbors j and k of atom i. The inclusion of the three-body term allows the potential to achieve an acceptable description of short-range order and of atom-exchanging diffusive motion in the liquid phase. While this potential is reasonably accurate when used for modeling solid silicon in the diamond cubic phase, it is biased toward the tetrahedral bond angle through the explicit inclusion of the factor $\left(\cos\theta_{ijk} + 1/3\right)$ in the three-body term. The inclusion of this trigonometric factor discriminates in favor of pairs of bonds with the tetrahedral geometry, i.e., $\left(\cos\theta_{ijk} = -1/3\right)$, and limits the transferability of the potential. For instance, it cannot accurately predict the energies for various non-tetrahedrally bonded, high-pressure phases of silicon, it does not correctly predict relative energies of surface structures, and the coordination of liquid-phase silicon is too low.

The family of potentials, CHARMM, AMBER, OPLS, etc., derived from the many-body approach described above for the Stillinger–Weber potential is often used in simulation of organic systems. These so-called force-field models are able to model structural and dynamical properties of very large molecules with a high degree of accuracy. However, it is important to note that the force-field methods generally do not allow for bond-forming or breaking to occur during simulation. Connectivity must be determined a priori. For a review of these potentials see for example Mackerell [2].

Abell presented a very general description of bonding based on the observation of a universal relationship between binding energy and bond

length in 1985 [3]. This relationship placed the bonding in crystalline solids and molecules on the same footing. The only criterion for bonding preference was the optimization of the binding energy with respect to the local coordination. The local coordination is, in turn, the dominant topological variable in the determination of binding energy. Soon after the publication of Abell, Tersoff developed a potential constructed to guarantee that this universal behavior was obtained [4]. The Tersoff potential was the first to attempt to incorporate the structural chemistry of covalently bonded systems into empirical potential energy function. The general form of the potential is

$$\begin{aligned} E &= \sum_i E_i = \frac{1}{2}\sum_{i\neq j} V_{ij}, \\ V_{ij} &= f_c\left[V_R\left(R_{ij}\right) - B_{ij}V_A\left(R_{ij}\right)\right], \end{aligned} \tag{2}$$

where E is the total energy of the system, E_i is the site energy for site i, V_{ij} is the interaction energy between atoms i and j, and R_{ij} is the distance between these atoms. The sum is over the j nearest neighbors of i; $V_R(R)$ and $V_A(R)$ are pair-additive repulsive and attractive interactions, respectively; f_c is a cutoff function to limit the range of the potential. For the Tersoff potential, the repulsive and attractive terms are represented by the Morse-type functions

$$\begin{aligned} V_R &= A\exp\left(-\lambda_1 R_{ij}\right) \\ V_A &= B\exp\left(-\lambda_2 R_{ij}\right), \end{aligned} \tag{3}$$

where A, B, λ_1, and λ_2 are all positive constants with $\lambda_1 > \lambda_2$. All deviations from the simple-pair potential are ascribed to the dependence of the bond-order B_{ij} on the local bonding environment or coordination. More specifically, the bonding strength for a bonded pair should be a monotonically decreasing function of the number of competing bonds, the strength of the competing bonds, and the cosines of the angles of the competing bonds. The innovative feature of the Tersoff potential is that it does not assume different forms for the angular functions for different hybridizations. In his work, B_{ij} has the form

$$\begin{aligned} B_{ij} &= \left(1+\beta^n \zeta_{ij}^n\right)^{-1/2n}, \\ \zeta_{ij}^n &= \sum_{k\neq i,j} f_c\left(r_{ijk}\right) g\left(\theta_{jik}\right) \exp\left[\lambda_3^3\left(r_{ij}-r_{ik}\right)^3\right], \\ g(\theta) &= 1 + c^2/d^2 - c^2/\left[d^2 + (h - \cos\theta)^2\right], \end{aligned} \tag{4}$$

where θ_{jik} is the bond angle between bonds ij and ik. The angular function $g(\theta)$ is determined globally by a fit to solid structures with different coordination. This gives the function a high degree of transferability. Tersoff extended his original silicon potential to include germanium, carbon, and combinations thereof. This potential form has also been extended to a variety of III-V semiconductors.

An empirical bond-order expression that described both hydrocarbon molecules and solid-state carbon was developed by Brenner [5] to model chemical vapor deposition of diamond films. Taking inspiration from the Tersoff potential, the form of the reactive empirical bond-order potential (REBO) potential allows for bonds to form and break with changes in hybridization. This first-generation Brenner potential is very similar to the Tersoff potential. Pair repulsive and attractive terms are again represented by Morse-type potentials. The primary difference is the way in which the bond order is handled for hydrocarbon molecules. The expression for the total bond order is

$$\overline{B}_{ij} = \frac{B_{ij} + B_{ji}}{2} + F_{ij}\left(N_i^t, N_j^t, N_{ij}^{\text{conj}}\right) \tag{5}$$

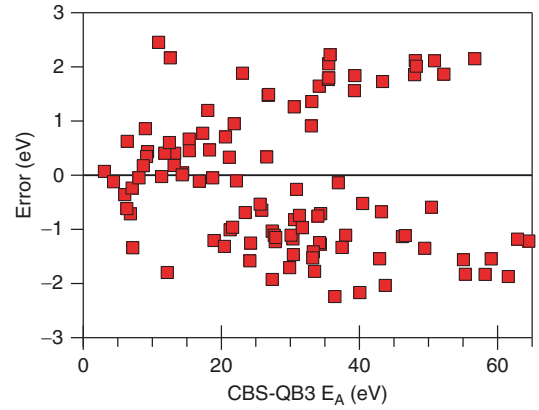
where

$$\begin{aligned} B_{ij} = &\left[1 + \sum G_i\left(\theta_{jik}\right) f_c\left(r_{ik}\right) e^{\alpha\left[\left(r_{ij}-R_{ij}^E\right)-\left(r_{ik}-R_{ik}^E\right)\right]}\right. \\ &\left. + H_{ij}\left(N_i^H, N_i^C\right)\right]^{-\delta}, \end{aligned} \tag{6}$$

The quantities Ni^C and Nj^H are the number of carbon and hydrogen atoms bonded to atom i. The total number of neighbors, Ni^{t} of atom i is $(Ni^{\text{C}} + Nj^{\text{H}})$, Nij^{conj} depends on whether a bond between carbon atoms i and j is part of a conjugated system, $G(\theta)$ is a function of the angle between bonds i-j and i-k and has the same form

as the Tersoff potential. The two- and three-dimensional cubic splines, H_{ij} and F_{ij}, have discrete nodal values that are modified so that the potential reproduces the energies of various hydrocarbon molecules. The resulting potential successfully describes the different bonding characteristics of hydrogen and carbon radicals and nonconjugated double and triple carbon-carbon bonds.

Extensions of the First-Generation REBO Potential



Because the Tersoff-Brenner formalism has been used successfully to simulate a wide range of processes such as chemical vapor deposition, diamond growth, carbon nanotubes, graphene, diamond-like carbon, etc., it was extended to other systems by various groups. In what follows, some examples of ways in which the first-generation REBO potential has been extended are provided. This analysis is not meant to include all such examples, however.

Parameterization of Additional Atom Types

Because bond-order potentials were designed to model chemical reactivity in covalent systems, it was logical to adopt the first-generation REBO formalism to model Si-H systems [6]. Parameterizations also exist for Si-F and Si-Cl. The first attempts to construct bond-order potentials capable of modeling three different atom types were two independently developed C-Si-H potentials. The C-Si-H potential of Beardmore and Smith is a hybrid potential which makes use of the C-H, Si-H, and Si-C parameters developed by Brenner [5], Murty and Atwater [6], and Tersoff, respectively. Because it is a hybrid potential, it inherits the strengths and weaknesses of the potentials on which it is based. The C-Si-H potential of Dyson and Smith, known as the extended Brenner (XB) potential, adopts the C-H parameters of Brenner and develops three new sets of parameters for Si-Si, Si-C, and Si-H [7] while maintaining the same functional form.

When chemical reactions occur during a simulation, the bond order of atoms must change in a continuous manner from reactant to product values. This is accomplished in the first-generation REBO hydrocarbon potential through the use of a bicubic spline $H_{ij}(N_i^H, N_i^C)$ (Eq. 6), which is a function of the number of neighbors surrounding atom i. To extend a bond-order potential to three atom types, such as Si-C-H, the spline function can be extended into ways. First, the cubic-spline function can be extended to three dimensions, such that it has the form $H_{ij}(N_i^H, N_i^C, N_i^{Si})$. This method provides the most flexibility in adjusting the bond order but can be difficult to code. Alternatively, because C and Si have similar electronegativities and possess similar bonding characteristics, a two-dimensional cubic spline that considers the number of neighbors of C and Si together, i.e., $H_{ij}\left(N_i^H, \left(N_i^C + N_i^{\mathrm{Si}}\right)\right)$, could also be used. This approach was adopted in both the Si-C-H potentials discussed above. This simplification has the advantage of simplifying the MD code. However, it is at the expense of a considerable loss in flexibility in fitting and, therefore, accuracy in reproducing a wide range of properties. For example, the errors in the energies of organosilane molecules calculated with the XB potential systematically increase with increasing molecule size (Fig. 1).

The performance of the XB potential was evaluated by Sbraccia et al. in 2002 [8]. Several

Reactive Empirical Bond-Order Potentials, Fig. 1 Error in atomization energies of $Si_xC_yH_z$ molecules predicted using the mXB potential relative to the atomization energy calculated using the CBS-QB3 method in the ab initio code Gaussian03 illustrating increasing error with atomization energy E_A (increasing molecule size)

problems, such as spurious minima in some potential energy curves, the incorrect energetic ordering for chemisorption of hydrocarbon molecules on Si surfaces, and over-coordinated carbon and silicon atoms were identified. These problems were corrected by altering a minimal set of parameters and the C–C interaction cutoff values. This parameterization is known as the modified extended Brenner (mXB) potential. It should be noted, however, that these changes do not improve the elastic properties of the solid phases of carbon or silicon [9] or the energies of organosilane molecules shown in Fig. 1.

Extension to Metals

Recently, a classical many-body potential for transition metal (Fe, Co, Ni) carbide clusters based on the bond-order type potential was developed [10]. The covalent interactions are based on the first-generation REBO potential. Deviations from the REBO potential formalism occur in the bond-order terms for carbon–metal interactions. The bond order for carbon–metal interactions has the form where b and δ are fitting parameters. For metal–metal interactions, instead of $B^* = \left(1 + b\left(N^C - 1\right)\right)^{\delta}$, multiplying V^A by B^*, the binding energy D_e and equilibrium bond length R_e are expressed as functions of the metal coordination number N^M and are given by

$$D_e = D_{e1} + D_{e2} exp\left\{-C_D\left(N^M - 1\right)\right\} \quad (7)$$

$$R_e = R_{e1} + R_{e2} exp\left\{-C_R\left(N^M - 1\right)\right\}. \quad (8)$$

The reader is referred to Shibuta and Maruyama [10] for all parameter values appearing in Eqs. 7 and 8.

Limitations

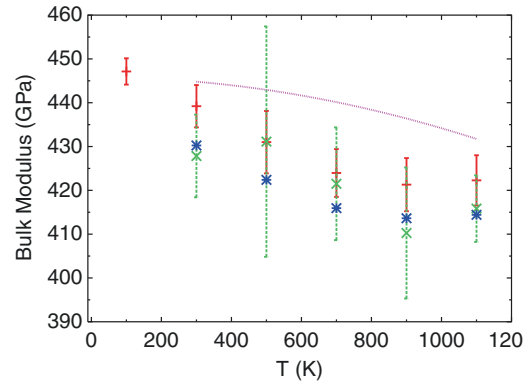
Before undertaking MD simulations with empirical potentials, careful thought should be given to the selected potential's inherent strengths and weaknesses and how these may impact the phenomena to be simulated. For example, multiple potential energy functions exist for modeling Si, including three versions of Tersoff's bond-order potential [4,11], SW [1], and the environment-dependent interatomic potential (EDIP) [12]. The majority of empirical potentials for Si do not accurately describe the three elastic constants for diamond cubic silicon [13]. In contrast, the EDIP and the 2B-Si [9] potentials do a good job describing elastic constants. However, the bond lengths for many of the crystalline silicon structures are overestimated when using the EDIP potential. For a more complete comparison of the strengths and weaknesses of Si potentials the reader is referred to Balamane et al. [13] and Schall et al. [9].

In general, four limitations have been identified with the first-generation REBO potential. First, the functional form of the pair potentials was not flexible enough to allow a parameter set that could simultaneously reproduce structural energies and force constants. In his original work, Brenner provided two parameter sets, one that provided an excellent fit to bond energies and a second that provided a to fit force constants [5]. Second, because the zero-Kelvin elastic constants C_{11}, C_{12}, and C_{44} for diamond were not included in the fitting database, they are not accurately reproduced by the potential [14]. Third, both the attractive and repulsive pair terms have finite values at zero separation. Thus, in highly energetic atomic collisions, it may be possible for an atom pass through another atom without being repulsed. Finally, the derivatives of the cutoff function $f_{ij}(r)$ are nonrealistic and may lead to spurious minima in energies for certain structures, particularly amorphous carbon [5].

Second-Generation REBO Potentials

To correct the shortcomings of the original potential, Brenner and coworkers developed a second generation of the REBO potential [15]. The repulsive and attractive pair terms have the forms

$$V^R(r) = f^c(r)(1 + Q/r)Ae^{-\alpha r} \quad (9)$$



and

$$V^A(r) = f^c(r)\sum_{n=1,3} B_n e^{-\beta_n r} \quad (10)$$

where A, Q, α, B_n and β_n are fitting parameters. The screened Coulomb function used for the repulsive pair interaction goes to infinity as interatomic distances approach zero, and the attractive term has sufficient flexibility to simultaneously fit the bond properties that could not be fit with Morse-type terms. The bond-order B_{ij} term is also significantly different from either the Tersoff or first-generation REBO potential. Separate terms are included that depend on local coordination and bond angles, radical character and conjugation, and dihedral angle for C–C double bonds.

By altering the functional form and expanding the fitting database, the second-generation REBO potential is able to provide significantly better descriptions of bond energies, lengths, and force constants for hydrocarbon molecules relative to the first-generation REBO potential. In addition, the zero-Kelvin elastic properties, interstitial defect energies, and surface energies for diamond are well reproduced. This potential also qualitatively reproduces the correct behavior of the elastic constants C_{11} and C_{44} of diamond with temperature. Coincidentally, the relatively poor agreement of the calculated C_{12} with the experimentally determined data combined with a fast softening of C_{11} with temperature results in bulk moduli that agree fairly well with the experimental values (Fig. 2) [14].

As a first step toward developing a Si–C–H bond-order potential, Schall et al. recently published parameters for silicon potential (2B-Si) based on the second-generation REBO formalism [9]. This potential does a reasonable job producing a broad range of properties of diamond cubic and amorphous silicon. In principle, the second-generation REBO formalism could be extended to a wide range of interatomic interactions to model chemical reactivity in nanoscale systems that contain multiple atom types. For example, Sinnott and coworkers used density functional theory to develop parameters within the second-generation REBO formalism for C–O, O–O, and O–H [16]. Because this potential is based on the second-energy REBO potential, it possesses all of its inherent strengths and weaknesses, such as a lack of intermolecular forces.

Reactive Empirical Bond-Order Potentials, Fig. 2 Bulk modulus of diamond as a function of temperature. Bulk values were calculated from the elastic constants using the relationship $B = \frac{1}{3}(C_{11} + 2C_{12})$. (+ signs), (*crosses*), and (*asterisks*) symbols represent values calculated with the direct, strain fluctuation, and stress fluctuation methods, respectively

The addition of a third atom type complicates the functional form of the bond order as discussed above. This potential suffers from the limitation discussed above by making use of a two-dimensional cubic spline instead of a three-dimensional cubic spline in the bond-order function. In addition, O is treated in a similar manner as C, despite the inherent differences in electronegativities of the two atoms. Additional parameter sets have also been developed recently by this group for Mo–S and C–F.

Covalent + Intermolecular Forces

To model chemical reactions in condensed phases, such as liquids, graphite, and self-assembled monolayers (SAMs), intermolecular forces must be added to the REBO potential. Goddard and coworkers added intermolecular forces to the first-generation REBO potential for hydrocarbons. Distance-based switching functions were used to turn the intermolecular forces "on" and "off." Intermolecular forces and torsional interactions have also been added to the second-generation REBO potential [17]. This potential, known as the adaptive intermolecular reactive empirical bond-order (AIREBO) potential, uses a unique algorithm to determine the conditions under which the intermolecular forces should be "on" and "off."

The AIREBO potential includes intermolecular interactions between nonbonded atoms and torsional interactions associated with a connected sequence of three bonds. This extension makes the AIREBO potential a particularly attractive tool for studying interfacial/tribological systems and liquids. The discussion below focuses on how intermolecular interactions are introduced without compromising the reactivity of the potential. For a discussion of how torsional interactions are modeled, the reader is referred to the original publication [17].

Intermolecular interactions are modeled through a Lennard-Jones (LJ) potential,

$$V^{LJ} = 4\varepsilon\left(\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right). \tag{11}$$

Only four parameters are taken as independent: σ_{CC}, σ_{HH}, ε_{CC} and ε_{HH}. The heterogeneous parameters are fixed by Lorentz-Berthelot combining rules,

$$\sigma_{CH} = \frac{1}{2}(\sigma_{CC} + \sigma_{HH}) \tag{12}$$

and

$$\varepsilon_{\mathrm{CH}} = \sqrt{\varepsilon_{CC}\varepsilon_{HH}}. \tag{13}$$

To merge this with a reactive potential, the LJ potential may be either completely or partially "turned off" in response to the chemical environment of the interacting pair. The key feature of the AIREBO potential is that it provides a means of smoothly interpolating between purely bonded and nonbonded interactions through a set of three switching functions S_{distance}, S_{bond}, and $S_{\mathrm{connectivity}}$. Each one of these switching functions may turn off the LJ interaction partially or entirely,

$$E^{\mathrm{LJ}} = (1 - S_{\mathrm{distance}}S_{\mathrm{bond}})\left(1 - S_{\mathrm{connectivity}}\right)V^{\mathrm{LJ}}. \tag{14}$$

For each switching function, a value of 1 is associated with turning off the LJ interaction completely, 0 is associated with a full LJ interaction, and values in between are associated with partial LJ interactions.

The distance-based switch, S_{distance}, is 1 for distances below r^{LJmin} and 0 for distances above r^{LJmax}. A cubic-spline function is used to interpolate at distances falling between the setpoints r^{LJmin} and r^{LJmax} to give a value for the switch between 0 and 1. The setpoints are fixed by requiring that the LJ potential minimum remain unchanged and that no artificial repulsive barrier is present as the LJ potential is switched off. These constraints require that $r^{\mathrm{LJmin}} = \sigma_{ij}$ and $r^{\mathrm{LJmax}} = 2^{1/6}\sigma_{ij}$.

The hypothetical bond-order-based switch S_{bond} interpolates to give values between 0 and 1 in the region $b^{\mathrm{min}} < b^{*} < b^{\mathrm{max}}$ using a cubic spline, 0 for a bond-order below this range and 1 for a bond-order above this range. The bond-order b^{*} is evaluated at r^{LJmin} for pairs separated by intermolecular distances (distances larger than r^{LJmin}), and thus at these distances b^{*} is a *hypothetical* bond-order that assesses the potential for these atoms to bond they approach one another. In the calculation of b^{*}, the distances of each atom in the pair to its neighbors remain unchanged.

The distance-based switch $S_{\mathrm{connectivity}}$ takes into account the set of all one-, two-, and three-bond sequences that connect the pair of atoms under consideration. For each atom pair in each sequence of bonds, a weight is calculated that is 1 for distances below r^{LJmin} and 0 for distances above r^{LJmax}. These setpoints are the same as in S_{distance}; however, for compatibility with the original REBO potential, a shifted half-period cosine function is used to interpolate between r^{LJmin} and r^{LJmax}. A weight for a sequence of bonds is calculated as the product of the sequence's individual bond weights. The $S_{\mathrm{connectivity}}$ switch is taken to be the largest sequence-weight found in the total set of sequences. In the adopted form for E^{LJ}, the switches S_{distance} and S_{bond} appear together as a product while $S_{\mathrm{connectivity}}$ appears on its own. Consequently, a full LJ interaction will be included for atom pairs that are not (1,2), (1,3), or (1,4) neighbors and are *either* beyond the cutoff distance r^{LJmax} *or* have a bond-order below b^{min}.

The treatment of the van der Waals interactions can be improved in the AIREBO potential by

treating the long-range forces so that the chemical environment is taken into account [18]. In the spirit of the REBO potential, the LJ parameters for carbon are functions of the number of N^C and N, or $\sigma_C(N^C, N^H)$ and $\varepsilon_C(N^C, N^H)$. Two-dimensional cubic-spline functions are used to interpolate between values with integer numbers of neighbors.

Modeling Reactivity in Systems Containing Charge

The electronic properties and nature of bonding in molecules and solids stems from the distribution of charges within the system of interest. The simplest way to add charges to MD simulations is to assign a fixed charge to each atom in the simulation. Fixed-charge schemes have several limitations; however, the most important of which is their inability to redistribute charges in a physically realistic manner. Charge clouds can be distorted when molecules are brought into close proximity, without reacting. When chemical reactions occur, charge needs to be transferred. For instance, the charge states of hydrogen and chlorine change dramatically when they approach each other to form an HCl molecule.

The first atomic-level, charge transfer model was developed by Rappé and Goddard [19] and is known as the electronegativity equalization (QEq) method. In this method, the charges in the system distribute themselves so that the electronegativity at each atomic site is equalized for a given nuclear configuration. This is equivalent to saying that the driving force to shift charge from one atom to another is zero, or the derivatives of the potential with respect to charge are zero. The self-energy $E_i^s(qi)$ on particle i is a function of the charge of the ion and is expressed in terms of the charge, electronegativity χ, and atomic hardness (a term related to the change in energy as a function of charge). Obtaining the charge on each atom for each nuclear configuration of N atoms requires taking the inverse of an N by N matrix. This method was utilized by Streitz and Mintmire in their examination of the aluminum/alumina interface using their ES + EAM potential [20]. Inversion of an N by N matrix at each MD time step usually scales as $O(N^2)$ and becomes computationally intractable as the size of the system increases. Several alternative numerical methods have been developed to solve the N linear equations in charge associated with the N by N matrix. To date, these methods have not found widespread application.

To avoid the matrix inversion, Rick et al. developed an approximate method to equalize the electronegativity based on an extended Lagrangian approach. In this method, charges are treated as dynamic variables that evolve explicitly with time [21]. Equations of motion for the positions and charges of the atoms can be shown to be:

$$m_i \ddot{r}_i = \frac{\partial}{\partial r_i} E_T(\{r_i\}\{q_i\}) \tag{15}$$

and

$$s_i \ddot{q}_i = \frac{\partial}{\partial q_{r_i}} E_T(\{r_i\}\{q_i\}) \tag{16}$$

where m_i, r_i, and q_{r_i} are the mass, position, and charge of the ith atom. The term s_i is a fictitious mass of the charge, which is chosen to provide numerical stability. The individual charges respond to deviations of the electronegativity equilibration by moving to a new charge which more closely satisfies the equilibrium condition. One advantage of this approach is that both equations of motion Eqs. 15 and 16 can be integrated using standard numerical integration algorithms. In addition, because the matrix-based solution for determining charge is not used, the code remains $O(N)$, a crucial requirement for large-scale simulations.

The Lagrangian-based dynamic-charge method, which amounts to an approximate implementation of the electronegativity equalization condition, suffers from one significant drawback, however. The dynamic-charge method is closely related to a single iteration, steepest-descent search for the electrostatic energy minimum. The magnitude of the charge transfer is controlled by a

constant factor for all atoms and simulation steps. Thus, the charge "lags" behind the atomic positions used in minimizing the energy and, as a result, the electronegativity equalization condition is not satisfied. To remedy this situation, Ma and Garofalini have introduced the iterative fluctuation charge (IFC) model [22]. The IFC model is able to satisfy the electronegativity equalization condition by performing multiple iterations for electrons (charge) while keeping the atomic positions fixed. The exact numerical criterion, or convergence factor Δ, for electronegativity equalization is $\Delta\left(\frac{eV}{atom}\right)=\frac{\sqrt{\left(\chi_i-\chi_{eq}\right)^2}}{N}=0$, where χ_i and χ_{eq} are the electronegativities on the ith atom and the equilibrium electronegativity. In practice, a small convergence factor, such as $\Delta=1.0\times10^{-8}$ is used in MD simulations. In addition, charges will oscillate about their fully converged, equilibrium values unless a damping factor is used. The selection of the damping factor and the fictitious charge-mass values can be optimized to achieve optimal damping while not preventing thermal coupling between atomic and electronic degrees of freedom.

Recently, the extended Lagrangian approach with the damping factor discussed by Ma and Garofalini [22] was used to examine the interface between Si and SiO_2 surfaces using a charge optimized many-body (COMB) potential [23]. The potential has the form:

$$E_T=\sum_i\left[E_i^S+\frac{1}{2}\sum_{j\neq1}V_{ij}\left(r_{ij},q_i,q_j\right)+E_i^{BB}\right], \tag{17}$$

where E_T is the total potential energy of the system, E_i^S is the self-energy term of atom i, V_{ij} is the interatomic potential between the ith and jth atoms, r_{ij} is the distance of the atoms i and j, and q_i and q_j are charges of the atoms, and E_i^{BB} is the bond-bending term of atom i. The interatomic potential energy V_{ij} consists of four components: short-range repulsion, U_{ij}^R, short-range attraction, U_{ij}^A, long-range Coulombic interaction, U_{ij}^I, and long-range van der Waals energy, U_{ij}^V, which are defined as

$$V_{ij}\left(r_{ij},q_i,q_j\right)=U_{ij}^R\left(r_{ij}\right)+U_{ij}^A\left(r_{ij},q_i,q_j\right)+U_{ij}^I\left(r_{ij},q_i,q_j\right)+U_{ij}^V\left(r_{ij}\right), \tag{18}$$

The repulsive and attractive terms in Eq. 18 are of the Tersoff form:

$$U_{ij}^R=f(r)Ae^{-\lambda r}\text{ and }U_{ij}^A=f(r)b_{ij}Be^{-\alpha r} \tag{19}$$

In Tersoff's original work, A, B, λ, and α are constants and $f(r)$ is a distance-based cutoff function, which limits the range of the potential. In shorthand notation, the energy contribution due the repulsive and attractive terms (i.e., the short-range pair potential) can be written as

$$E_{pair}=\sum_{j\neq i}f(r)Ae^{-\lambda r}+\sum_{j\neq i}f(r)b_{ij}Be^{-\alpha r}=V^R+bV^A \tag{20}$$

where b_{ij} is the bond-order function.

Modeling Charge Transfer During Chemical Reactions

Model fluctuating charges using the extended Lagrangian approach seems ideally suited to examine chemical reactions using MD. However, the use of this approach requires the definition of a charge-neutral entity, such as a molecule or the simulation cell. For example, Yu et al. recognized the problem with defining a charge-neutral simulation cell when simulating Si/SiO_2 interfaces. To circumvent this problem, the self-energy terms of the COMB potential were modified [23]. Rick et al. defined each water molecule as a charge-neutral entity in their examination of the structural properties of water [21]. Charge equilibration (QE) methods have been applied successfully to relatively homogeneous small-molecule systems near equilibrium. However, application of these methods to large molecules yields atomic charges and molecular dipole moments that are too large. This problem has been traditionally addressed by constraining sub-entities of large molecules to be charge neutral. This is problematic in a reactive environment where it would not be possible to

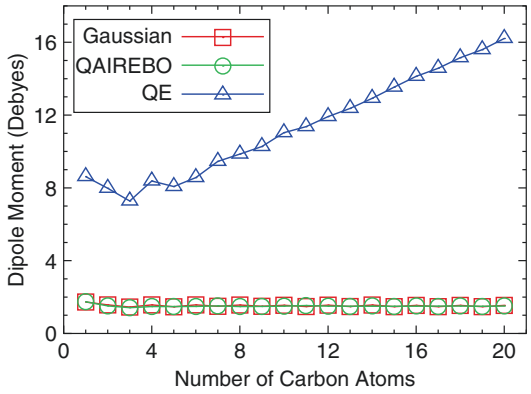
meaningfully adhere to a fixed set of molecule-based charge-neutral entities.

Recently, Mikulski et al. developed a method to integrate charge equilibration with bond-order potentials that does not require the assignment of charge neutrality to molecules [24]. The bond-order potential/charge equilibration (BOP/SQE) method is a bond-centered approach, where the charge of atom i is the sum of all charges transferred to it across each of its bonds. This has been referred to as a split-charge equilibration (SQE). The problem of the overestimation of dipole moments of large molecules is not solved by merely adopting the bond-centered (SQE) approach. A novel method is needed whereby each bond partly decouples from its bond network and settles into its own equilibrium. The BOP/SQE method connects the bond order of each bond to an amount of shared charge in each bond and interprets the split charge as an imbalance in where the shared charge is concentrated. Split charges cannot grow in size beyond this shared-charge limit, and if the nature of the bond is covalent, the size of the split charges should not get close to this limit. Thus, a fractional split charge is defined as the ratio of the split charge $\overline{f}_{ij}$ on atom i transferred from atom j to its shared charge $\overline{q_{ij}^{\max}}$, charge on atom i is expressed as

$$Q_i = \sum\nolimits_j \overline{f}_{ij}\, \overline{q_{ij}^{\max}}. \tag{21}$$

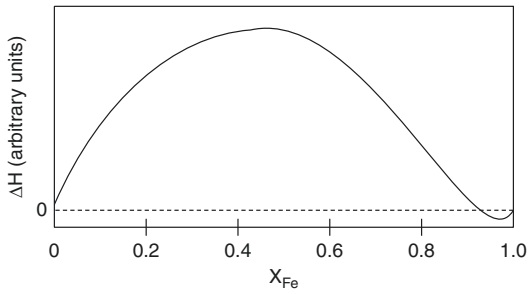
The shared-charge limit $\overline{q_{ij}^{\max}}$ is calculated directly from the bond order bij assigned to the bond from the BOP, $\overline{q_{ij}^{\max}} = \overline{q_{ij}^{\max}}\left(b_{ij}\right)$. Focus is now shifted from equilibrating split charges to equilibrating fractional split charges.

The equilibration process for bond ij is controlled by three factors: (1) The constant pull to increase charge separation associated with the traditional constant electronegativity difference $\left|\chi_i - \chi_j\right|$; (2) Coulomb interactions within the bond and with the surrounding environment; (3) A restoring force that approaches and infinite wall as the shared-charge limit is approached. The first two factors are analogous to the SQE condition but are applied to $\overline{f}_{ij}$ rather than $\overline{q}_{ij}$. The third, unique, element is implemented through inverse hyperbolic tangent function added to the charge-dependent electronegativity of each fractional split charge,



$$\overline{\chi}_{ij} = \left[\chi_i + J_{it}^{o} Q_i + \sum\nolimits_{k \neq i} J_{ij} Q_k\right] + \overline{\epsilon}_{ij} \tan h^{-1}\left(\overline{f}_{ij}\right). \tag{22}$$

The scale parameter $\overline{\epsilon}_{ij}$ can be tailored to each pair of atom types. Large values of $\overline{\epsilon}_{ij}$ cause the wall to gradually rise as soon as the split charges grow. The last term in this equation, or the charge-asymmetry penalty, serves to physically constrain the growth of the split charges and partially decouples each bond from its bond network. Therefore, the BOP/SQE formalism becomes a locally driven process that does not map back to the global equilibration of an entire molecule. With the selection of the scale parameter $\overline{\epsilon}_{ij}$ to reproduce the dipole moment of water, this method was shown recently to reproduce the correct trends in molecular dipole moments of long-chain alcohols (Fig. 3).



It should be noted, that other methods for handling chemical reactions where charge is included are being developed [25]. Because these methods are not bond-order potentials, they are not included in this overview.

Improved Description of Alloys

In a recent study of the thermodynamics an empirical potential description of Fe–Cu alloys, Caro et al. concluded that to study alloys in an empirical framework, heteronuclear interactions require additional modifications to the empirical formalism to incorporate concentration dependent interactions that reproduce the magnitude of excess enthalpy of mixing and asymmetry around the equi-atomic composition [26]. To illustrate this point, data for the heat of mixing in the Fe-Cr system as determined in an ab initio study conducted by Olsson has been replotted in Fig. 4. This figure clearly illustrates the deviation from ideality with both positive and negative heat of mixing in evidence.

Reactive Empirical Bond-Order Potentials, Fig. 3 Molecular dipole moments of straight chain alcohols calculated using Gaussian, charge equilibration (QE), and a fluctuating-charge MD code that uses the BOP/QE method of charge equilibration and qAIREBO potential

Reactive Empirical Bond-Order Potentials, Fig. 4 The enthalpy of mixing ΔH for the Fe–Cr system as a function of Fe fraction. (replotted from the work of Olsson) The solid line was calculated via first-principles. The dashed line indicates a linear interpolation corresponding to an ideal solution

Traditionally, empirical models for alloys use the Lorentz-Berthelot mixing rules (Eqs. 12 and 13). These rules reproduce the ideal heat of mixing, which is, strictly speaking, only accurate for dilute solutions of solute atoms in the host matrix. Caro et al. has proposed a method for reproducing the thermodynamic properties of concentrated alloys through a modification of the embedded atom method (EAM) formalism. The basic EAM description gives the total energy as a the sum of a pair potential, V, and an embedding function, F, which in turn depends on the electron density, ρ

$$E_{EAM} = \frac{1}{2}\sum V(r) + \sum F\left(\sum \rho(r)\right) \quad (23)$$

Consideration of first-principles calculations gives important information about the behavior of these functions. First, the embedding energy relative to the free atom energy goes to zero for zero electron density and should have a negative slope and positive curvature for the background electron density in metals. Second, the pair interaction term $V(r)$ is purely repulsive.

Caro et al. eschewed the commonly used Lorentz-Berthelot mixing rules and developed a new functional form for the cross potential for random alloy mixtures:

$$E_{RAND} = x_A^2 V_{AA} + x_B^2 V_{BB} + 2x_A x_B V_{AB} + x_A F_A(\widetilde{\rho}) + x_B F_B(\widetilde{\rho}). \quad (24)$$

Here x_A and x_B are the atomic fractions of alloy element A and B, respectively. The pair potential for each element denoted as V_{AA} or V_{BB}. The model adopts the assumption that atoms are embedded in the same average environment, through $F(\widetilde{\rho})$ where $\widetilde{\rho}$ is the average electron density seen by either atom type A or B in the host material. Caro et al. found that the contributions to the formation energy from the embedding term were negligible, leaving only the pair potential as the sole contributor to the formation energy for alloys. By assuming V_{AB} is a function of both composition x and distance r and can be separated into a product $h(x)$ $u_{AB}(r)$, an appropriate choice of the cross term is

$$V_{AB}(x,r) = h(x)\frac{1}{2}[V_A(r) + V_B(r)] \quad (25)$$

Where $h(x)$ is a fourth-order polynomial. This selection of the cross term allows for the description of any type of formation energy curves, with an ideal solution of $h(x) = 1$, for a regular solution. Through appropriate fitting of the polynomial coefficients, a positive or negative heat of mixing can be achieved. Stukowski et al. recently published a version of this potential function.

The methodology described above can also be extended to Tersoff-type potentials. The foundation of this approach was laid out by Brenner who

recognized that the EAM potential and Tersoff many-body potential are formally identical in the appropriate limits. The essential result is that it is reasonable to assume that embedding function $F(\rho(r))$ in the EAM formalism is equal to the attractive part of the Tersoff pair potential, bV^A. Similarly, it is a logical to assume that the repulsive terms in both EAM and Tersoff are equivalent. With these points in mind, a combination of the Tersoff potential with Caro's compositional dependence method can be expressed in shorthand notation as

$$E_{RAND} = x_A^2 V_{AA}^R + x_B^2 V_{BB}^R + 2x_A x_B V_{AB}^R + x_A \tilde{b} V_{AA}^A + x_B \tilde{b} V_{BB}^A. \quad (26)$$

where V_{AA} and V_{BB} are the repulsive and attractive pair terms, denoted by superscripts ^{R} or ^{A}, respectively, for the pure elements A or B as given in Eq. 3. The repulsive cross term V_{AB} is given in Eq. 26. Schall et al. have fit a multicomponent bond-order potential for Si–C–H systems, and it was found that the average bond-order $\tilde{b}$ must be normalized using a scaling factor to ensure compatibility between bond orders for derived for different pure element systems. The average bond order is then given as

$$\tilde{b} = \chi_{ij} \frac{b_{ij} + b_{ji}}{2}. \quad (27)$$

The normalizing factor χ_{ij} is equal to one for homonuclear atom pairs. For heteronuclear atom pairs, χ_{ij} is determined by fixing the average bond order to a value of one for a specified crystal structure. For example, in the Si–C system, χ_{ij} was determined by setting the average bond order for the β-Zn phase of SiC solving Eq. 27 for χ_{ij}. A similar scheme was utilized by Tersoff for multicomponent systems.

Summary and Future Directions

In the foregoing sections, a discussion of reactive empirical bond-order potentials was given. Such potentials were developed to describe the universal relationship between binding energy and bond length and have been extended from simple descriptions of single elements to multicomponent systems and then to a combination of solids and molecules. The motivation for the development of these potentials was to provide a computationally efficient means to model chemical reactivity, including an accurate description of bond-breaking and forming processes, while still using sound quantum mechanical principles. The original formalism has since been expanded to include descriptions of long-range interactions, torsion, charge transfer, and descriptions of alloys. This family of potentials has since been used to describe a wide variety of processes in nanomaterials systems. One serious limitation of the family of reactive empirical bond-order potentials is that only a relative few materials systems have been parameterized. As mentioned previously, parameterization of a potential involves quite a bit of art as well as science. In the future, semi-automated methods such as force matching that combine ab initio force calculations systematically with parameter fitting could help overcome this hurtle. In addition, the incorporation of more than three elements presents a significant challenge due to the complexity of the spline functions used to interpolate the bond order correction terms. To overcome this barrier, either compromises in the accuracy of the potential or new developments in multidimensional interpolation functions must be made.

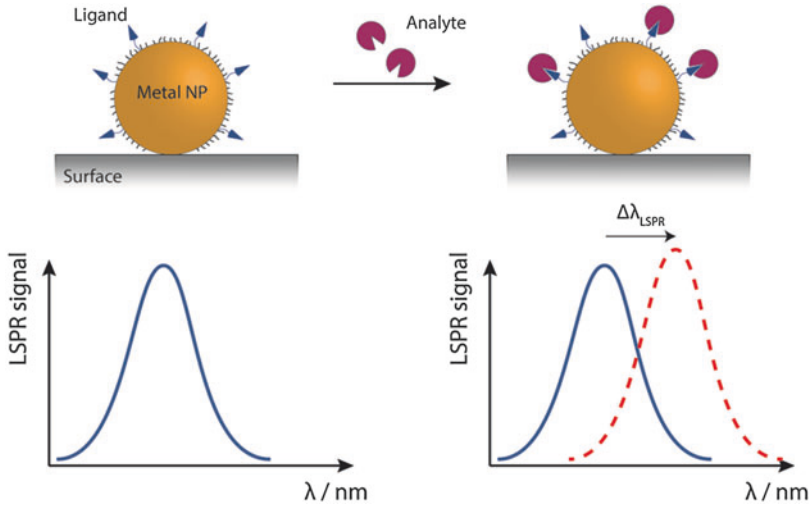
LSPR-based sensing; Nanoplasmonic sensing

Definition

Refractometric sensing using plasmonic nanoparticles exploits the excitation of localized surface plasmons in metal nanostructures to monitor changes in the dielectric properties in the close vicinity of the nanoparticle surface, caused by, for instance, the binding of a biomolecule to immobilized receptors. The sensitivity to small changes in refractive index enables real-time and label-free detection of molecular interactions at the metal nanoparticle surface.



Overview

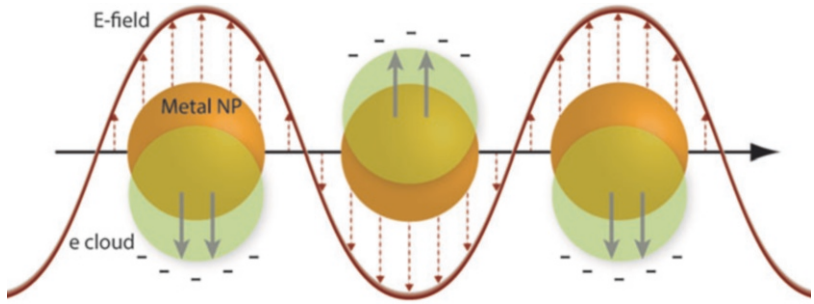
Surface plasmons are collective oscillations of the free electron gas at the surface of metals that can be induced by an external electric field, including electromagnetic radiation. When the size of the metal structures is reduced to nanoscale dimensions, the electron oscillations are confined in the nanostructures creating a phenomenon known as localized surface plasmon resonance (LSPR). The excitation of LSPR gives rise to a strong enhancement of electromagnetic fields in the near-field region, and the ability to concentrate electromagnetic radiation into particles of nanoscale dimensions has made plasmonic materials attractive for a large variety of applications, including molecular sensing. For most types of silver and gold nanostructures, the resonance frequency is in the visible region of the electromagnetic spectrum, which gives rise to distinct colors for nanoparticle ensembles. The colors emanate from the extensive absorption and scattering (extinction) of light by the nanoparticles at the LSPR frequency. The resonance conditions are highly dependent on a number of parameters, including (i) the nature of the nanostructures, i.e., their size, shape, and composition; (ii) their interaction with other, closely spaced metal nanostructures; and (iii) the dielectric properties of the surrounding medium. The latter enables metal nanostructures to be used as sensitive probes for detecting changes in the refractive index (RI) in their close proximity caused by for instance the adsorption of biomolecules to the metal surface. The RI dependency of the LSPR is the basis of nanoplasmonic refractometric sensing (Fig. 1). The highly localized sensing volume around metal nanostructures makes these materials attractive signal transducers in miniaturized sensors with high sensitivity to local RI changes.

Metal nanoparticles of different sizes and geometries, such as spherical, rod shaped, and triangular, can be prepared by wet-chemical synthesis and display plasmon resonance frequencies over the entire visible and near-infrared region of the electromagnetic spectrum. Moreover, metal nanoparticles can be immobilized on solid substrates by self-assembly for cost-efficient production of large nanoplasmonic arrays (>1 cm^2), which facilitates development of inexpensive LSPR-based biosensing devices.

Historical Background

The vibrant colors of metal nanoparticles have fascinated mankind for centuries and have been extensively used to decorate glass and ceramics. However, an explanation of the origin of these colors was not presented until the mid-nineteenth century by the pioneering work of Michael Faraday. Faraday synthesized gold nanoparticles by reducing gold salt with phosphorus, and after conducting a series of experiments, he concluded that the colors were caused by the presence of small particles of metallic gold that were suspended in the aqueous media [1]. Some decades

Refractometric Sensing Using Plasmonic Nanoparticles, Fig. 1 Schematic illustration of the basic concept behind refractometric sensing using plasmonic nanoparticles. Molecular interactions that take place at the surface of a metal nanoparticle change the conditions for the LSPR excitation that result in measurable changes in the extinction spectra, which enables real-time and label-free detection of the binding event



later, Richard Zsigmondy could verify the nanoscale dimensions of these particles by investigating them using an ultramicroscope. The techniques for fabrication and characterization of nanomaterials have advanced considerably since then, and it is now possible to produce well-defined nanostructures with respect to physical and chemical properties and to investigate their properties in great detail.

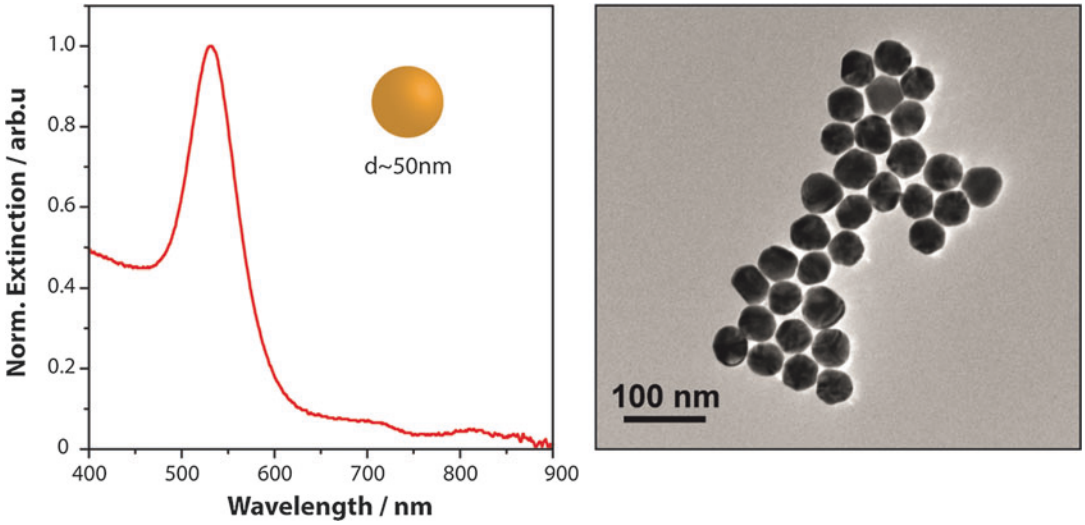
Refractometric sensing using surface plasmons was first described by Liedberg et al. in 1983 [2]. In this seminal work, propagating surface plasmons at the interface between a planar silver film and a dielectric were exploited to monitor antigen-antibody interactions. It took an additional 15 years before Englebienne showed that the same sensing principle also could be applied to localized surface plasmons in metal nanoparticles [3]. Both sensing schemes offer label-free and real-time detection of molecular interactions taking place at (or close to) the metal surface. Biosensing based on surface plasmon resonance (SPR) is today a commercially established technique that is frequently used to characterize a wide variety of biomolecular interactions. LSPR-based techniques are just about to find their way into the commercial market. In contrast to SPR, LSPR enables cheap, miniaturized, and multiplexed sensing using very simple optical setups.

Theory

Metals have partially filled conduction bands, which give rise to "free" electrons that can move within the material. When metal nanostructures are exposed to an external electric field, these electrons are displaced relative to the positive core of the atoms. The resulting induced dipole will oscillate with the same frequency as the external electric field (e.g., electromagnetic radiation). For small nanostructures the electrons will oscillate coherently at a specific frequency (Fig. 2). This creates a distinct peak in the extinction spectrum at the resonance frequency, known as the LSPR peak.

In 1908, Gustav Mie described the interaction between light and small metal nanoparticles in a homogenous medium by analytically solving Maxwell's equations [4]. He derived an expression for the optical extinction (sum of absorption and scattering) cross section (σ_{ext}) for metal nanoparticles much smaller than the wavelength of light ($2r << \lambda$):

Refractometric Sensing Using Plasmonic Nanoparticles, Fig. 2 Schematic illustration of localized surface plasmon resonance in spherical gold nanoparticles induced by an external electric field



$$\sigma_{ext}(\lambda) = \frac{24\pi^2 r^3 \varepsilon_d^{3/2} N}{\lambda \ln(10)} \frac{\varepsilon_i(\lambda)}{(\varepsilon_r(\lambda) + 2\varepsilon_d)^2 + \varepsilon_i(\lambda)^2} \quad (1)$$

where r is the radius of the nanoparticle, ε_d is the dielectric constant of the surrounding medium, N is the electron density, and ε_r and ε_i are the real and imaginary part of the complex dielectric function of the bulk metal, respectively. The plasmon resonance condition is fulfilled when $\varepsilon_r(\lambda) = -2\varepsilon_d(\lambda)$ if the imaginary part of the dielectric function is small (low losses). For small gold and silver nanoparticles, this resonance frequency falls in the visible region of the electromagnetic spectrum (gold ~ 520 nm and silver ~380 nm) which explains their distinct colors. However, the resonance frequency can be changed by varying the size and shape of the nanoparticles; thus, the plasmon resonance peak can be tuned over the entire visible region. For larger nanoparticles, the dipolar approximation is no longer valid since the electrons will not experience a homogeneous electric field (phase differences) which means that the expression in Eq. 1 cannot be used to accurately determine their optical properties. Instead, complex numerical methods like discrete dipolar approximation (DDA) and finite-difference time-domain (FDTD) simulations are frequently employed to describe the optical response for larger, spherical, or anisotropic nanoparticles.

Equation 1 shows that the extinction depends on the size and the optical properties of the metal nanoparticles as well as the dielectric properties of the surrounding medium. Consequently, the LSPR excitation will change when the refractive index of the surrounding medium changes. Biomolecules have a higher refractive index (~1.46) than water (1.33). A binding event of a molecular analyte to a ligand immobilized on the nanoparticle surface displaces water molecules and replaces them with the biomolecule, resulting in an effective increase in the refractive index of the medium surrounding the nanoparticle and a concomitant change in the extinction cross section.

Synthesis of Metal Nanoparticles

Procedures for metal nanoparticle synthesis have improved significantly during the last decades, and it is now possible to produce metal nanoparticles with a range of different structures and morphologies and that are composed of either a single or several different materials, resulting in nanostructures with unique optical properties. One of the most commonly used wet chemistry techniques to produce metal nanoparticles is based on metal ion nucleation using citrate reduction. This method was developed by Turkevich et al. in 1951, where gold chloride ($HAuCl_4$) was reduced by sodium citrate to generate fairly monodisperse gold nanoparticles in the size range of approximately 10–50 nm in diameter (Fig. 3) [5]. The sodium citrate acts both as a reducing agent and electrostatic stabilizer of the resulting nanoparticles. The size of the nanoparticles can be tuned by varying the ratio between the concentrations of gold salt and sodium citrate in water. A common synthesis method to obtain anisotropic gold nanoparticles is the seed-mediated growth method, which

Refractometric Sensing Using Plasmonic Nanoparticles, Fig. 3 Extinction spectra (*left*) and transmission electron microscopy (*TEM*) image (*right*) of spherical gold particles with an average diameter of 50 nm synthesized by citrate reduction of gold salt

utilizes reagents, typically surfactants in order to restrict the growth at certain crystal facets. This method has been used to realize a wide variety of nanostructures including nanorods, nanocubes, stare-shaped nanoparticles, and nanoprisms, which all show different LSPR frequencies.

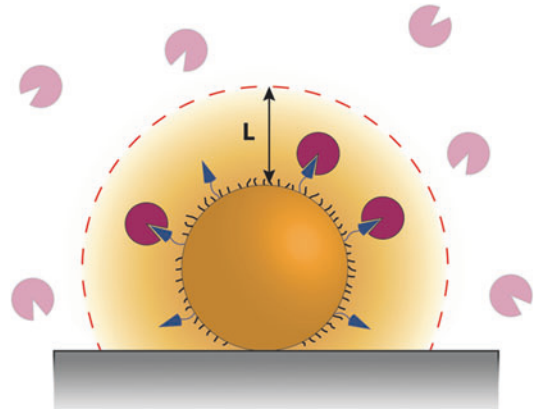
Refractive Index Sensitivity

Plasmonic metal nanoparticles can be utilized as transducer elements in refractometric sensors because of the sensitivity of LSPR to small changes in refractive index in the immediate vicinity of their surface. The sensitivity (η_B) is defined as the magnitude of the spectral response caused by a change in refractive index (Δn):

$$R = \eta_B \Delta n \quad (2)$$

where the spectral response (R) can be measured as a change in the plasmon peak wavelength position (nm) or in the signal intensity (extinction). This linear relationship refers to RI changes in the entire sensing volume around the nanoparticles, and η_B is therefore normally referred to as the bulk RI sensitivity, usually expressed in nm/RIU or ext/RIU. In order to achieve a large response for a specific RI change, the bulk RI sensitivity should obviously be as high as possible. Consequently, there are numerous reports on the synthesis of metal nanoparticles exhibiting different RI sensitivities, ranging from ~50 nm/RIU for small, spherical gold nanoparticles to >1000 nm/RIU for more complex, anisotropic nanoparticles [6]. However, Miller et al. have shown that the bulk RI sensitivity for metal nanoparticles is strongly related to their plasmon resonance frequency, and a linear relationship between the two parameters was obtained for particles with a plasmon resonance below 800 nm [7]. Accordingly, nanoparticles that exhibit a plasmon resonance at longer wavelength will display higher bulk RI sensitivity, which means that the aim of creating nanoparticles with high bulk RI sensitivity has merely been quests for synthesizing nanoparticles with longer plasmon resonance wavelength, i.e., lower energy. Silver nanoparticles generally exhibit higher sensitivity as compared to gold nanoparticles because of the different dielectric properties of the two metals. Silver nanoparticles can, however, easily undergo oxidation, which makes them less suitable for most sensing applications.

Metal nanoparticles that exhibit a high bulk RI will not necessarily exhibit a high sensing



performance since also the resolution must be taken into account. Large nanoparticles that display a plasmon resonance at longer wavelengths (in the near-infrared region) usually have a broad plasmon band due to dephasing and increased radiative damping. This makes it harder to accurately determine the plasmon peak maxima, which has a negative effect on the resolution. The figure of merit (FOM) is a measure that takes both the sensitivity and the resolution into account and is expressed as:

$$\mathrm{FOM} = \frac{\eta_B}{\mathrm{fwhm}} \tag{3}$$

where η_B is the bulk RI sensitivity and fwhm is the full width at half maximum, i.e., the plasmon peak width (in nm) at half its maximum value. Otte et al. have shown that the FOM value for gold nanorods is maximized for a plasmon resonance close to 700 nm, i.e., where an optimum relationship between sensitivity and resolution can be observed [8]. Also, it is advantageous to stay in this region since cheaper optical components can be used for plasmon resonance excitation and detection.

Sensing Volume

The sensing volume around a metal nanoparticle depends on the spatial distribution of the electromagnetic near field created as a result of the excitation of localized surface plasmons. The intensity of the near field decays exponentially from the metal surface, and the decay length is defined as the distance where the magnitude has decreased by 1/e (~37 %). Both the decay length (~10–20 nm) and the intensity of the near field depend on the physical properties of the metal nanoparticle and the dielectric properties of the surrounding medium. The sensing distance, i.e., the average distance from the metal surface where a change in RI can be detected, is strongly correlated to the decay length of the electric field. Numerous studies have been carried out in order to determine the sensing distance for various metal nanoparticle structures using different layer-by-layer techniques. In general, the reported

Refractometric Sensing Using Plasmonic Nanoparticles, Fig. 4 Schematic illustration of the highly localized sensing volume around a gold nanoparticle. The sensing volume depends strongly on the decay length (L) of the electromagnetic near field

sensing distances range between 20 and 30 nm. Hence, the ability of metal nanoparticles to detect changes in their surroundings is strictly limited to a small volume around the nanoparticles, which makes them suitable to probe highly localized RI changes, caused by for instance a molecular binding event to an immobilized receptor (Fig. 4). As the sensing response obtained as a result of adsorption of molecules on the nanoparticle surface is more relevant than the bulk RI sensitivity, an expression for the plasmon shift that can be expected when a molecular layer is formed around a metal nanostructure has been derived [9]:

$$\Delta\lambda_{\max} = \eta_B\left(n_{\mathrm{layer}} - n_{\mathrm{medium}}\right)\left(1 - e^{-\frac{2d}{L}}\right) \tag{4}$$

where n_{layer} and n_{medium} are the refractive indices of the adsorbed layer and the surrounding medium, respectively, d is the thickness of the adsorbed molecular layer, and L is the decay length of the electric field. Although, this expression is based on empirical findings, it gives a rather good prediction of the sensing response that can be obtained when a thin film of molecules are adsorbed at the surface of a metal nanoparticle.

Conventional SPR, based on propagating surface plasmons, exhibits a bulk RI sensitivity that is roughly one order of magnitude higher than LSPR. Despite this fact, the two sensing schemes

show a similar sensing performance when considering molecular adsorption close to the metal interface [10]. As the sensing volume of metal nanoparticles is small, the background signal, also known as the bulk signal, can be significantly lower than in conventional SPR-based sensors, which is advantageous in the analysis of low molecular compounds that will only induce small RI changes.

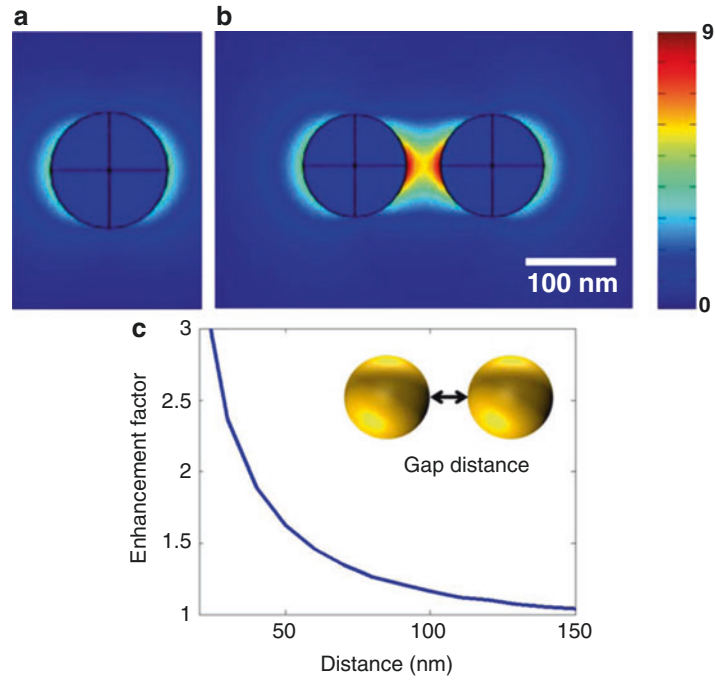
However, the strictly limited sensing volume associated with LSPR-based sensing limits the usage of bulkier surface chemistries and large recognition molecules (e.g., antibodies), since the molecular interactions of interest then will be located outside the actual sensing volume. Thin surface coatings and small recognition elements are thus appropriate to employ in LSPR-based sensing, ideally keeping the molecular interactions in the direct vicinity of the nanoparticle surface. However, it is a great challenge to realize a thin, functional surface coating that exhibits a high resistance against unspecific molecular adsorption.

Single Nanoparticle Detection

The highly localized sensing volume around metal nanoparticles makes them suitable transducer elements for miniaturized sensing. Single nanoparticle detection has been an area of intense research since this technique enables a significant reduction in the absolute detection limit, i.e., fewer analytes per nanoparticle, which is important both for miniaturization and multiplexed sensing. Single nanoparticles also show narrower plasmon bands as compared to an ensemble of particles, which improve the spectral resolution since smaller LSPR shifts can be detected. Dark-field microscopy techniques enable simultaneous single particle spectral plasmon mapping of multiple nanoparticles for single nanoparticle analysis. Although metal nanoparticles have a large extinction cross section, the scattered light intensity from a single nanoparticle is still rather weak, and the signal-to-noise ratio in the obtained extinction spectra is generally relatively low. The overall sensing performance is thus usually better when an ensemble of nanoparticles is used for detection since this gives a higher signal intensity and an improved signal-to-noise ratio.

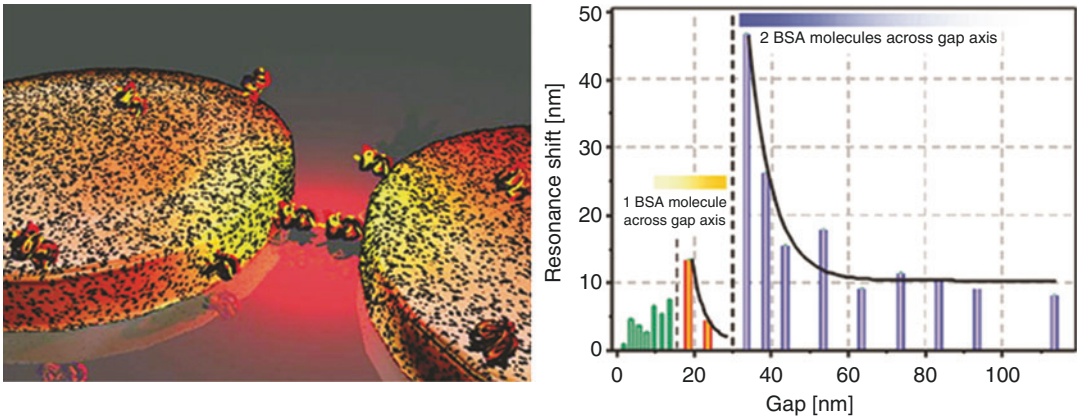
Substrate Effect

Nanoplasmonic sensing devices where the metal nanoparticles are immobilized on a solid support have several practical advantages as compared to using dispersed nanoparticles since immobilization facilitates handling, washing, storage, and regeneration of the sensor surface. Immobilization of nanoparticles can be achieved by self-assembly, using, for instance, thiol chemistry, or by physisorption using, e.g., electrostatic interactions between charged species adsorbed on the nanoparticle surface and the substrate. The self-assembly process can be controlled by an appropriate and defined surface chemistry at both the substrate and the metal nanoparticles and tuned by changing, e.g., the pH, ionic strength, nanoparticle concentration, or incubation time. However, tethering nanoparticles to a solid support will influence their RI sensitivity since the substrate will occupy a certain fraction of the sensing volume around the nanoparticles. This is known as the substrate effect and results in a reduction in the RI sensitivity. The magnitude of this reduction depends strongly on the fractional surface area of the nanoparticle that is in direct contact with the underlying substrate [11]. Thus, a flat structure like a nanodisk or nanoprism will be affected to a larger extent by the substrate effect than, for example, a nanosphere. Consequently, in order to reduce the influence of a substrate immobilization on the RI sensitivity, the contact area between the nanoparticle and the substrate should be minimized.



In addition, if the substrate has a higher RI value than the surrounding medium, the electric field created around the nanoparticles upon excitation can get redistributed, shifting a large part of the field toward the substrate. This will increase the substrate effect additionally since the RI detection is associated with the electric field. The redistribution of the electric field can, however, be reduced when using substrates with a low RI value, like Teflon ($n \approx 1.32$).

Plasmonic Coupling



Another way to tune the plasmonic response of metal nanoparticles is to utilize dipolar interactions between closely spaced nanoparticles. This is known as plasmonic coupling and results in appearance of hybridized plasmon modes where the plasmon frequency is highly dependent on the separation between the nanoparticles. Plasmonic coupling between closely spaced nanoparticles gives rise to regions where the electromagnetic field is strongly enhanced as compared to the incident electric field that is used for the excitation (Fig. 5) [12, 13]. These so-called hot spots are of large interest for sensing applications and have been extensively utilized in surface-enhanced Raman spectroscopy (SERS) where the signals from Raman-active molecules can be significantly enhanced. In addition, these regions have also been shown to exhibit a higher RI sensitivity, and an improved sensing performance can be achieved if the molecular interactions can be guided into these areas [14]. Plasmonic coupling is also utilized in colorimetric sensing schemes based on analyte recognition-induced changes in colloidal stability. This method was pioneered by Mirkin et al. who used DNA to facilitate an aggregation of gold nanoparticles [15].

Nanoplasmonic Biosensing

Numerous examples of LSPR-based biosensing schemes have been proposed for detection of a wide variety of analytes including DNA, proteins, and small organic molecules using different recognition elements. Due to the limited sensing volume around metal nanoparticles, LSPR-based biosensing is a suitable method for detection of small analytes. The smaller the analytes are, the smaller the RI change will be upon binding to the ligand, which consequently requires a high sensitivity in order to obtain an acceptable limit of detection. For example, Kabashin et al. showed that small molecular weight compounds can be detected by localized surface plasmons created in gold nanopillars, and they were able to detect biotin (244 Da) instead of streptavidin (52.8 kDa), which is normally detected [16]. In addition, Hall et al. showed that LSPR can be used to monitor

Refractometric Sensing Using Plasmonic Nanoparticles, Fig. 5 Electric field distribution plots for (**a**) a single gold nanoparticle and (**b**) a nanoparticle dimer. Refractometric Sensing Using Plasmonic Nanoparticles, Fig. 6 Binding of BSA in the gap of a gold nanodimer. By varying the gap distance, the binding of one or two BSA molecules could be identified and discriminated (Reprinted with permission from Ref. [18]. Copyright 2009 American Chemical Society)

protein conformational changes using an array of silver nanoprisms fabricated by nanosphere lithography [17]. Aćimović et al. were able to discriminate between the bindings of one or two BSA (bovine serum albumin) molecules by varying the gap distance between gold nanodisks (Fig. 6) [18]. Recently, a LSPR biochip based on gold nanorods was realized that enabled a multiplexed detection of cancer biomarkers (human alpha-fetoprotein and prostate-specific antigen) down to concentrations of 500 pg/mL [19]. These examples demonstrate the great potential of LSPR in the development of high-performance sensing platforms that can be produced at a low cost.

Future Perspective

Refractometric sensing using plasmonic nanoparticles is a promising strategy for detecting small, local changes in the surrounding dielectric environment. This real-time, label-free sensing technique enables miniaturization and multiplexed analysis, which is difficult to achieve using conventional SPR-based sensing. However, many challenges remain before cost-effective refractometric sensing platforms based on LSPR that exhibit high sensitivity, specificity, and robustness can be practically implemented and can compete with existing sensing technologies. Some of these challenges are discussed below:

Biofunctionalization: The highly localized sensing volume around metal nanoparticles is advantageous in many aspects but also put constraints on the surface chemistry that can be used since the distance between the recognition moiety and the nanoparticle surface must be kept to a minimum. A reliable and biofunctional surface chemistry, which both exhibit selectivity and low unspecific binding, is critical in the development of high-performing sensing devices. In order to fully exploit the advantages of LSPR-based sensing devices, the surface coating must hence be very thin while still displaying low nonspecific adsorption and selective recognition of target analytes.

Reproducibility: Although the techniques for synthesis of metal nanoparticles has advanced significantly during the last decade, there is still room for improvements with respect to batch-to-batch reproducibility and minimizing size and shape polydispersity that give rise to broad plasmon bands and lower the overall sensing performance. Lithographic techniques can be used to make nanostructures and patterns with high reproducibility, but generally at a higher production cost and facing problems with up-scaling as compared to colloidal self-assembly. Self-assembly of metal nanoparticles thus offers a simple and cost-effective way to produce nanoplasmonic substrates, but the assembly conditions needs to

be tightly controlled in order to produce nanopatterns with high reproducibility and to facilitate multiplexed sensing.

Localization: Plasmonic coupling between adjacent nanoparticles gives rise to areas with enhanced electromagnetic fields. If the molecular sensing can be guided into these regions, a significantly higher sensitivity can be obtained. Thus, it would likely be more beneficial to be able to control the orientation and interparticle coupling between closely spaced nanoparticles rather than optimizing the structure of individual nanoparticles. However, it is a great challenge to both obtain well-defined plasmon coupling and to guide the immobilization of recognition elements into these hot-spot regions to exploit the enhanced sensitivity.

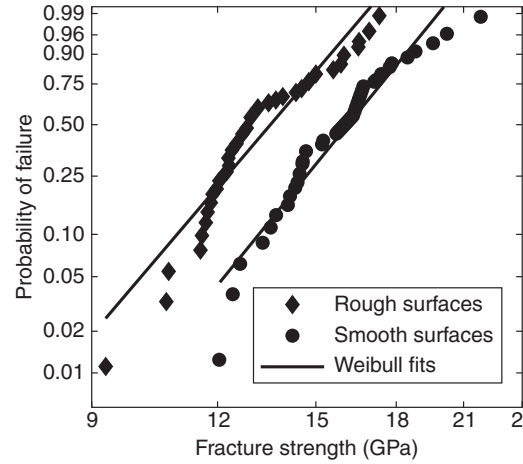
Definition

The continuous reduction in the size of structural device components promises improved efficiency and, often, new functionalities, which would otherwise be impossible with conventional macroscale devices. As a result, in the past decades numerous microsystem devices with nanoscale mechanical parts have been demonstrated and used in a variety of engineering applications, ranging from electrical circuit components to sensors, actuators, and biomedical applications [1]. This ongoing drive to create smaller new devices to perform critical functions requires significant attention to the mechanical reliability of materials used at nanoscales. To make use of the full mechanical potential of materials at decreasing sizes, fundamental properties, such as the elastic modulus, yield, fracture and fatigue properties, adhesion and intrinsic stresses, should be determined by testing relevant sized samples that have been fabricated or processed using the same procedures as the structure of interest and subjected to the same environmental conditions.

Overview

Even though bulk elastic properties are generally expected to remain constant down to a length scale of several nanometers, the mechanical reliability of materials depends significantly on the specimen size [2]. Despite their high theoretical strengths, most materials used in practical applications cannot sustain very high stresses due to intrinsic defects. An estimate for the minimum defect size that will cause failure can be obtained by an order of magnitude calculation considering Griffith fracture criterion (which suggests that an infinitesimal crack will propagate when the available strain energy is larger than that needed to create new surfaces) [3]. Accordingly, the plane-stress fracture strength of the material is given by



$$\sigma_f = \frac{1}{1.12}\sqrt{\frac{2E\gamma}{\pi l_c}}, \qquad (1)$$

where lc is the characteristic size of an ideal defect, γ is the surface energy per unit area, and E is the elastic modulus. Considering the theoretical strength of Si (calculated by atomistic simulations), $\sigma f = 23$ GPa [4], $\gamma = 1{:}25$ J/m^2 [5] and E = 130 GPa, Eq. 1 suggests that *a single 1-nm-long edge crack will reduce the strength of an otherwise defect-free Si component by 60 % to 9 GPa!*

Key Research Findings

As the dimensions of a material decrease down to nanometers, approaching the typical size of critical defects, the strength is expected to increase significantly with a potential to reach the theoretical limit. Recent experiments demonstrated that near-theoretical strength values that are more than 25 times higher than typical macroscale strengths could indeed be achieved for 190-nm-thick single crystal silicon structures [6, 7] and 15-nm-thick

low-pressure chemical vapor deposited low-stress SiN [8]. These ultrahigh strengths are very promising as they enable novel MEMS devices, which can reliably operate under very high stresses [8]. Yet, at decreasing size scales, the number of intrinsic volume defects decreases and surface-to-volume ratio increases. Hence, surfaces and process parameters gain importance. The above experiments on silicon [6] as well as stochastic simulations [7] show that atomic scale surface features, which would otherwise be negligible in larger structures start acting as defects (Eq. 1) and that they may significantly compromise the reliability of the nano-material. For instance, a slight increase in process induced root-mean-square (rms) surface roughness (from 0.4 to 1.5 nm) decreases the strength of Si nanobeams by approximately 20 % (Fig. 1). A similar effect is observed when the samples are exposed to air for an extended period. When surfaces are not effectively protected against oxidation, 1-nm-thick native oxide islands that form randomly on the surface have been shown to reduce the strength of structures by 30 % [9].

Reliability of Nanostructures, Fig. 1 Fracture strength statistics of nanobeams with different surface roughnesses. The estimated strength of the beams increases from 14.2 to 16.8 GPa as the surface roughness decreases from 1.5 to 0.4 nm

The above examples emphasize that at decreasing size scales, mechanical performance of structures is often dominated by a competition between size, grain structure, surface defects, and environmental conditions. How would failure statistics change as the average defect size approaches the size of the device? At what size scales would the environmental factors start dominating failure? Could the mechanical service life of structures be improved by modifying process parameters? Answering these three questions is crucial to effectively characterize mechanical reliability of any material used at the nanoscale.

Methodology

So far, various nanomechanical test procedures have been proposed, and a few commercial devices have appeared in the market as ultimate nanoscale test platforms. Initial studies have focused on commonly used MEMS materials, and more recently, nanomechanical experiments were also adapted to characterize biological nanostructures such as cells and proteins. Due to differences in experimental techniques, geometric properties of the samples used and fabrication procedures, there is a significant variation in the failure statistics reported by different groups.

Because of the number of parameters affecting mechanical response, there are still no standard techniques and it is difficult to come up with a universal method. The available experiments generally involve variations to well-established macroscale tensile, bulge, and bending tests. The choice of procedure depends on several factors among which, the most important are: size (a micron and nano-sized sample cannot always be tested by the same instrument), required statistical accuracy (due to their complexity some methods do not allow easy repetition), tested material (not all materials are compatible with the fabrication procedures necessary for the preparation of the samples).

Tensile Tests

The main advantage of a tensile test is its analytical simplicity. Since the gauge length of the specimen is under uniform stress and strain fields, load–displacement curves can easily be used to determine elastic modulus and failure properties

directly. Required displacement and load resolutions can generally be accommodated by commercially available piezoelectric or capacitive actuators and high-precision load cells [2]. Yet, handling tensile test specimens remains a major challenge: It is very difficult to grip an individual micron-sized sample from both ends to apply a uniform load. Sharpe and collaborators got around this problem by electrostatic gripping. They used an external probe that was temporarily attached to hundreds of micrometer long test samples by electrostatic attraction forces. The probe, which was connected to a load cell was then manipulated to load the samples to failure, while displacements were monitored via image processing. There have been many variations of this procedure as reviewed in detail elsewhere [2]. Using a different approach, Gaspar and coworkers [10] developed a homebuilt setup which uses a commercial load sensor and an automated stage to test micron-scale tensile samples that were supported by MEMS springs. The biggest advantage of the method, despite the relatively large length scales, is that it enables a very large number of tests to be performed at a short time.

The experiments that focused on smaller devices have generally employed specifically designed MEMS-based test setups, where the sample is integrated with the test device. For instance, Haque and coworkers [11] developed a tensile tester that allows in situ analysis of deformation inside an electron microscope while the sample is being loaded by MEMS beams. Similarly, some recent commercial devices by Hysitron [12] and others have promised similar functionalities. A comprehensive review of the test methods can be found in [2, 13, 14].

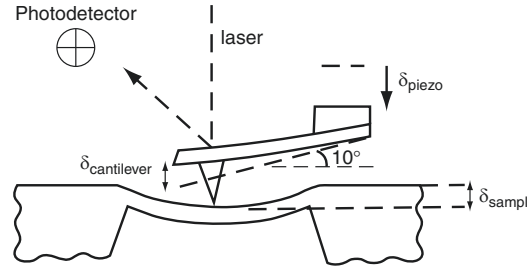
Bulge Tests

As another approach, bulge tests can effectively be used to test membranes with thicknesses approaching several nanometers while keeping the lateral dimensions in the order of hundreds of micrometers. This well-established method consists of measuring the out-of-plane deflection of a thin membrane under the influence of increasing pressure, applied from its backside [14]. The central deflection of the membrane is monitored continuously and the maximum stress at failure can be inferred from the corresponding pressure–deflection curves. Shrinking only the thickness (while keeping the other dimensions at μm/mm scales relaxes the experimental constraints on detection considerably. Recently, a homebuilt bulge test setup was successfully used to statistically characterize membranes that are as thin as 10 nm [8], while displacements were measured optically. Bulge tests also provide a very good alternative to study 2D materials such as graphene. However, the major disadvantage of the technique is the complicated analysis that is required to interpret the experimental data accurately.

Nanoscale Bending Tests with AFM

The third approach, which is reviewed in more detail here, is the nanoscale bending test. Bending tests offer many benefits over the above methods. Most importantly, gripping of the test samples is no longer a problem and the experimental procedures are generally simpler than in tensile tests. Since the test samples and test setup are independent from each other, there are fewer process restrictions and the effects of different parameters on reliability can be more easily studied. Finally, in a bending test, the area of fracture initiation can be effectively controlled without needing external notches. For an un-notched tensile test sample, fracture load can be reached anywhere along the beam: Sidewall surfaces and beam top or undersides have equal stresses and hence the defect distribution on all sides should be carefully considered. On the other hand, bending samples can be designed so that maximum stresses occur on the critical sites, hence, simplifying the corresponding statistical analysis. This point proves to be very useful when studying the effects of specific defects on mechanical performance [7]. Yet, the major drawback of the method is that the stress–strain distributions within the sample and its failure characteristics must be acquired indirectly, by processing the experimental load–displacement measurements.

Overview of the Method



Among all of the available methods, atomic force microscopy (AFM) is arguably the most popular

one for nanoscale bending tests, being extensively employed to characterize both mechanical device components and biological samples. AFM is a powerful analytical tool used mainly to determine the surface topography of structures with the help of a (usually) compliant cantilever, which is attached to a piezo scanner. For instance, in contact mode operation, the cantilever scans the surface of the material while it is in contact with the sample. A feedback control loop moves the piezo scanner vertically at each scan point to maintain a fixed force between the tip and the sample. This vertical piezo displacement can then be transformed into a topographic image of the surface. A nanomechanical AFM-based test consists of using an AFM cantilever, with known stiffness, to deflect a test sample until it fails. The applied force, F, and the sample deflection, δ_{sample}, are simultaneously measured during loading and the fracture strength of the tested structure is obtained from either a simple theoretical calculation or finite element analysis (FEA).

The first step in the experiment is to determine the position of the AFM cantilever tip relative to the test sample accurately. For this purpose, the sample of interest is imaged by a contact mode scan and the load application point is picked from the AFM image. Using the piezoelectric controls of the instruments, the cantilever tip is offset to the loading point with an accuracy of a few nanometers. Next, the sample is loaded. The schematic in Fig. 2 shows a cantilever loading a micron-sized test beam. When the piezo scanner is extended by δ_{piezo}, the AFM cantilever pushes against the sample, which is deflected by δ_{sample}, while the cantilever undergoes an upward displacement of $\delta_{\text{cantilever}}$. Since the total piezo extension, δ_{piezo} equals the sum of the cantilever and sample displacements, deflection of the test structure can be expressed as

$$\delta_{\text{sample}} = \delta_{\text{piezo}} - \delta_{\text{cantilever}} \tag{2}$$

Deflection Measurement To obtain load–deflection curves for individual samples, $\delta_{\text{cantilever}}$ is continuously recorded throughout the experiment by monitoring the position of the laser light, which is reflected off the back of the AFM cantilever and collected by a position-sensitive photodetector. The upward cantilever deflection results in a change in the photodetector output signal (S_{p}). Hence, every time a cantilever is attached to the piezo scanner, the relation between $\delta_{\text{cantilever}}$ and the S_{p} (in Volts) must be carefully calibrated. To relate S_{p} (V) to $\delta_{\text{cantilever}}$ (m), the cantilever is brought into contact with a noncompliant surface, such as a rigid Si piece. The piezo is extended by a known distance, δ_{piezo}, pushing the cantilever against the surface and the corresponding change in S_{p} is monitored. Throughout the calibration, since the surface remains rigid (neglecting elastic contact deformations), $\delta_{\text{cantilever}} = \delta_{\text{piezo}}$. Considering the nonlinearity often observed at higher deflections, this relation is best characterized by a third-order polynomial ($\delta_{\text{cantilever}} = c_1 S_{\text{p}}^{\,3} + c_2 S_{\text{p}}^{\,2} + c_3 S_{\text{p}}$), the constants of which are determined by a least-squares fit.

Reliability of Nanostructures, Fig. 2 Schematic of a nanoscale bending test with an AFM cantilever loading a double clamped test beam

Force Measurement The force, F, applied by the cantilever on the test structure is equal in magnitude and opposite in direction to the load that causes the cantilever to deflect by $\delta_{\text{cantilever}}$. As seen in Fig. 2, the AFM cantilever makes a 10° angle with the horizontal. Hence, any load, F, applied on the test structure will have a vertical component, $Fv = F\cos(10^\circ)$ and a much smaller, negligible, horizontal component, $Fh = F\sin(10^\circ)$. The vertical force applied on the beam is given by

$$F_v = k_{\text{cantilever}}\delta_{\text{cantilever}}, \tag{3}$$

where $k_{\text{cantilever}}$ is the stiffness of the AFM cantilever.

Accuracy of the force measurements strongly depends on $k_{\text{cantilever}}$. Using commercially available cantilevers may save lengthy fabrication steps; however, since the specifications are not precisely known, a careful calibration process is needed to accurately determine $k_{\text{cantilever}}$.

AFM cantilever stiffness calibration. When uncoated single-crystal Si cantilevers are used, the stiffness can be obtained from the cantilever dimensions and known elastic properties of Si. An SEM can be used to measure the lateral dimensions and the offset of the tip, which defines the effective length of the cantilever. Similarly, the tip height can be obtained using an optical surface profilometer. Measuring the cantilever thickness accurately is often the most important, yet, most difficult step, due to the inclined sidewalls resulting from the fabrication process.

An iterative method based on resonant measurements was recently proposed to accurately determine h and calculate $k_{\text{cantilever}}$ [6]. The resonant frequency of the cantilever in air, f_{air}, is measured with the AFM and the vacuum frequency, f_{vac}, is estimated by correcting for the effects of the air damping.

$$f_{\text{vac}} = \left[1 + \frac{\pi b \rho_{\text{air}}}{4h\rho_{\text{cantilever}}}\right]^{0.5} f_{\text{air}}, \qquad (4)$$

where ρ_{air} and $\rho_{\text{cantilever}}$ are the densities of air and the cantilever material respectively, b is the average width, and h is the thickness of the cantilever. (For typical cantilevers used in the experiments in [6], $f_{\text{vac}} \sim 1.002\, f_{\text{air}}$.) The vibration of the cantilever is then simulated by FEA while the thickness, h, is iterated until simulated and measured frequencies match. The stiffness, $k_{\text{cantilever}}$, is then calculated from a static FEA, which incorporates known elastic properties and the exact cantilever geometry.

Determining the Fracture Strength Finally, the experimental load–deflection curves are processed to obtain the Young's modulus, E, of the samples and the deformation of each sample is modeled with a nonlinear FEA simulation. The FEA model takes into account the maximum load at fracture, load application point, geometric properties, and calculated E values to determine the fracture stress, *maximum tensile stress along the length of the sample*, for each sample. Results from repeat tests can then be analyzed statistically.

Accuracy of the Measurements

The precision of the strength measurements strongly depends on the accuracy of the force measurement, since the fracture load is used to extract fracture strength from FEA. An approximate expression for the error in strength measurements is given by:

$$\frac{\Delta\sigma}{\sigma}; \frac{\Delta F_v}{F_v}; \frac{\Delta k_{\text{cantilever}}}{k_{\text{cantilever}}} + \frac{\Delta_{\text{cantilever}}}{\delta_{\text{cantilever}}} \qquad (5)$$

For this analysis, the cantilever stiffness can be expressed as $k \approx 3EI/L^3$, where $I = bh^3/12$, with a cantilever width, b, thickness, h, and length, L. Similarly, the thickness $h \approx cf_{\text{vac}}L^2$, where c is a constant and f_{vac} is the resonant frequency in vacuum. Hence, Eq. 5 becomes:

$$\frac{\Delta\sigma}{\sigma} = \frac{\Delta b}{b} + \frac{3\Delta f_{\text{vac}}}{f_{\text{vac}}} + \frac{6\Delta L}{L} - \frac{3\Delta L}{L} + \frac{\Delta\delta_{\text{cantilever}}}{\delta_{\text{cantilever}}} \qquad (6)$$

The relative errors in the width and length measurements are related to the resolution of the SEM images, while $\frac{\Delta f_{\text{vac}}}{f_{\text{vac}}}$ depends on the sensitivity of the frequency measurement. All of these are much smaller than 1 %. On the other hand, the precision of the AFM cantilever displacement is directly related to the precision of the AFM piezo scanner and the photodetector readout and will dominate the measurement error, depending on the setup being used.

Future Directions in Research

AFM has great potential to become the standard testing method for a large class of materials. No doubt, the biggest advantage of the method is the use of commonly available standard instruments,

hence allowing similar structures to be tested at different locations without needing specialized test apparatus. Being highly flexible, it can effectively characterize the effects of process defects and environmental degradation on mechanical reliability, hence addressing the questions postulated in the "Key Research Findings" section. Moreover, there are no material restrictions, and, upon correct choice of cantilevers, samples ranging from hundreds of nanometers to a few micrometers can repetitively be tested with very good-to-excellent accuracy. However, further studies are still needed to better understand the interaction between the tip and the sample during loading, determine the optimum tip and cantilever geometry to test different samples, and decide upon standard calibration procedures. One of the current challenges is also to develop new generation of AFM cantilevers in order to adapt the existing methodology to perform tensile tests at the same resolutions.

Wireless propulsion of helical nanobelt swimmers

Definition

Remotely powered propulsion of helical nanobelts is the swimming propulsion of nanoswimmers created by helical nanobelts.

Overview

Since swimming mobile micro-agents at low Reynolds number experience severe viscous drag, their swimming performances are much limited. Considering the most of in vivo environments are dynamic system, highly dynamic microswimmers would have a big technological impact in many fields. Engineering artificial flagella is inspired from nature's bacteria having their excellent motility. They are created from self-scrolled helical nanobelts. These swimmers are designed with a head and a tail, similar to nature's micro-organisms such as bacteria and their flagella. In this entry, the highly dynamic propulsion of biologically inspired artificial flagella which are remotely powered by electroosmotic force is introduced. They can swim as fast as 24 times of their body lengths per second and apply pressure higher than 300 Pa from their high energy conversion efficiency. Their swimming performance outran the other inorganic microscale swimmers and even nature's bacteria like *Escherichia coli*. These electroosmotic propelled helical nanobelt swimmers could be the potential biomedical carriers, wireless manipulators, and as local probes for rheological measurements.

Introduction

Rapid advancement in semiconductor electronics and microelectromechanical systems (MEMS) has accelerated the size reduction of functional systems like sensors or actuators. Considering much increased needs in less invasive biomedical or clinical tools to prolong human life, micro- or nanoscale systems have many promising features. One of the most important features is to reduce their size and disconnect them from wires. In this context, recent interest toward developing untethered biomedical micro- and nanorobots could be an alternative way to achieve less invasive and targeted medical therapy. Although they seem to increase the complexity of conventional medications, they are still promising due to their controllability, local therapy, and repeatability. Recent developments of in vivo biomedical nanorobots draw much interest in discovering new and efficient wireless power transfer methods and in controlled locomotion mechanisms. This kind of novel tools would have many potential applications, such as targeting, diagnosing, and treating blood clots or cancer cells, for neural cell probing and so on.

Although they are promising to such applications, they are still remained in laboratory experiments due to several reasons. The micro- or nanoscale mobile agents experience much more viscous drag due to the decreased Reynolds number which results in severely limited swimming performance. Considering the capillary of human's circulatory system has the average flow speed which can go up to 1 mm/s, mobile microagents should swim faster than this flow speed for their survival and task continuity. It should be noted that nature's bacteria have well adapted in such a harsh environment.

Many approaches aim to mimic natural bacteria for the locomotion of artificial nanostructures because of their excellent motility, around 5–10 times of body sizes per second [1]. The Nature has adopted several different propulsion techniques. The swimming of real bacteria is mainly divided into corkscrew-type rotating propulsion and the oscillation of flagella tail [2]. Several studies exploring similar propulsion techniques exist in the literature, with different efficiencies. Purcell uses a definition of swimming efficiency which compares the power used to propel a body at a given velocity to the power required to simply pull the body through the fluid at the same velocity (ε = power required to simply pull body/power consumed during propulsion) [2]. Under this definition, direct pulling with field gradient is 100 % efficient (i.e., $\varepsilon = 1$), and other methods would always perform less. Recently, direct pulling of nanowires, nanotubes and microtubes with excellent swimming performances (2 mm/s^{-1} which is

approximately 50–100 times per body size) was demonstrated by catalytic decomposition of hydrogen peroxide (H_2O_2). However, this technique only works in a solution like H_2O_2, allowing a catalytic reaction with Pt or Ag [3].

Among different propulsion methods, the use of magnetic effect is the most widely encountered. A rotating magnetic field was used to drive the macroscale flagella-like structure [4]. Microbeads were attached to natural bacteria and moved by flagella propulsion [5], 30-μm-scale bacterial flagella–like propulsion was demonstrated by an attached ferromagnetic metal pad under an external rotating magnetic field [6]. A linear chain of colloidal magnetic particles linked by DNA and attached to a red blood cell can act as a flexible artificial flagellum [7]. Further size reduction and applying same principle to drive artificial bacteria was achieved [8]. Lately, helical propellers are shown as an efficient solution at low Reynolds numbers [9].

Concerning the driving power source, there are several limitations of using an external field. The magnetic field gradient rapidly decreases with the distance from the source. Therefore, although the helical morphology is advantageous at low Reynolds numbers by reducing the viscous drag, the swimming performance of artificial structures is still much lower than the natural bacteria. To improve the swimming performance, increasing field intensity would be necessary.

However, the major challenge toward potential in vivo biomedical applications is the lack of closed loop motion control either by teleoperation or autonomous navigation. This lack is related to position-tracking issues. Widely used noninvasive biomedical sensors or imaging devices include radiography, computed tomography (CT), ultrasound echography, and magnetic resonance imaging (MRI). Considering the real-time navigation and high spatial resolution requirements, MRI is one of the most promising solutions. Ferromagnetic objects, or even magnetotactic bacteria, were tracked and navigated under real-time MRI [10]. In case of smaller objects at low Reynolds numbers, an additional propulsion-dedicated field gradient generator would probably be required. However, magnetic field gradient–based propulsion would be largely limited when it has to be used with an observation device such as MRI because of the conflict between the imaging and propelling magnetic fields. This problem can be avoided by using nonmagnetic propulsion.

As nonmagnetic approaches, the flapping or undulating motion of flagella was achieved in mesoscale using a commercial piezoelectric bimorph [11]. Microrobots that harness natural bacteria have also been demonstrated [5]. There are very few works on electric field–based wireless micro/nanorobots. For example, diodes were actuated using electroosmotic pumping [12]. It showed that electroosmotic field can be a good candidate for actuating micro/nano robots. However, the work was only demonstrated in macro scale and not scaled down to micro or nano.

In this entry, remote propulsion of artificial micro swimmers with high dynamic mobility (5–30 body lengths per second) at low Reynolds numbers by electroosmotic effect is described. These swimmers are based on helical nanobelt (HNB) structures. As different types of HNBs showed different swimming performances, choices of surface material and geometry is discussed along with the fabrication processes. The electroosmotic propulsion principle and experimental setups are presented. Finally, the experimental results on electroosmotic propulsion of HNBs in comparison with different locomotion techniques are described.

Self-Scrolled Helical Nanobelts as Artificial Flagella

Advantages of HNBs as Artificial Flagella

There are several different types of bacterial locomotion, such as rotating and undulating motions. Their major features, especially in terms of surface condition, geometry, and motility have evolved to swim efficiently at low Reynolds numbers. For example, *E. coli* bacteria consist of a highly elastic body formed of protein. Therefore, they can self-transform their morphology to increase their swimming velocity in a viscous liquid environment. It is considered that such

ability of natural bacteria is mainly attributed to the nonlinear mechanics of their flagella. To mimic similar performances of natural bacteria, the ultraflexible nanostructures with large nonconstant mechanics are considered to be necessary. The mechanical durability is also an important issue especially in harsh environments.

HNBs are one of the most flexible nanostructures that can be fabricated using standard microfabrication techniques with controlled geometry. Helical morphology appears as an adapted solution for electroosmotic propulsion because of the large surface-to-volume ratio to maximize the external energy reception. Another advantage is their elasticity to passively self-adapt their morphology in thick liquid environments by reducing viscous drag. Different types of nanobelts were synthesized and mechanically characterized [13]. Recently, HNBs revealed very large nonlinear mechanical properties along with giant piezoelectricity [14]. In case of electroosmotic propulsion, different surface coatings with thin films can also be achieved by standard microfabrication techniques to improve electrokinetic energy. The high surface-to-volume ratio of HNBs can disadvantageously increase friction at the liquid/solid interface. HNBs with hydrophobic surface coatings can reduce this friction to improve the swimming performance.

Additionally, harvesting energy from the environment would be an important advantage for mobile micro/nanoagents. Piezoelectric nanogenerators based on zinc oxide nanowire arrays were firstly proposed [15]. Nanowire-based, self-powered nanosensor has also been demonstrated [16]. Passive motions of HNBs during their swimming at low Reynolds number can self-harvest electrokinetic energy due to their giant piezoelectricity [14].

Therefore, considering the limitations of conventional propulsion mechanisms, remotely powered gradient pulling of HNBs should be efficient to swim in low Reynolds number liquid [9].

Fabrication Process

Four different types of HNB-based nanoswimmers, varying the materials and geometries, summarized in Table 1 are produced for testing purposes. Their propulsion efficiency is then compared in electroosmotic propulsion experiments.

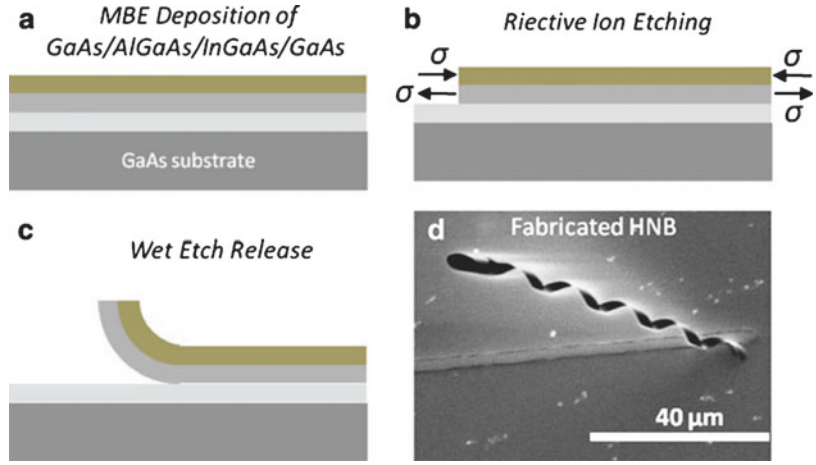

Figure 1 illustrates the fabrication process. The initial layers were grown on semiinsulating GaAs (AXT wafers) using a molecular beam epitaxy system (VEECO, Gen II MBE) equipped with a valved cracker for As and solid sources for Ga and In (Fig. 1a). For n-type doping, a Si source was used. Substrate temperature was measured by a pyrometer. After a thin GaAs buffer layer, the 500-nm thick sacrificial AlGaAs layer is deposited. The layer contains 20 % Ga in order to prevent oxidation. The sacrificial layer in previous designs was made of AlAs. The oxidation of these layers after exposure damaged the InGaAs/GaAs bilayer. On top of the sacrificial layer the InGaAs/GaAs layer is deposited which later self-forms into a nanospring. An In content of 15 % in the InGaAs layer was determined by X-ray diffraction (XRD) measurements. The thickness of this layer must be smaller than the critical thickness to maintain elastic strain. The layer properties along with other specifications of the structures are summarized in Table 1.

During the deposition of the InGaAs/GaAs bilayer on this wafer for HNB 1, it was attempted to get a slightly lower doping concentration than on the wafer that was used for HNB 2, 3, and 4. From the results, it seems that the doping concentration was too high which resulted in a partial self-compensation and, therefore, in a decrease in the effective doping concentration. The doping concentrations of the structures are 4.4×10^{18} and 8.5×10^{18} cm^{-3}. The initial pattern can be created through photolithography. Reversible photoresist AZ5214 was used as a resist. After the development of the resist, reactive ion etching (RIE) with a $SiCl_4$ gas was used to transfer the pattern to the InGaAs/GaAs bilayers. For HNB4, the thickness of photoresist was reduced around 50 nm with O_2 plasmas. For metallic HNB3, the Cr/Ni layers on the surface and on the heads to which the structures are fixed at the end were created before RIE through a lift-off process with negative photoresist AZ5214.

The Cr layer is 10 nm thick and serves as an adhesion layer. The 10-nm thick Ni layer is used for metal HNB3. Finally, a 2 % HF aqueous

(**d**) Produced HNB with a tail and a head (SEM photo)

solution at 4 °C was used to selectively etch the AlGaAs sacrificial layer under the InGaAs/GaAs heterostructures for the self-forming of the nanostructures (Fig. 1a). During this wet etch, the patterned bilayer curled up along a <100> direction, releasing the internal strain and forming 3-D structures. The direction of the scrolling is determined by the anisotropy in stiffness of the InGaAs/GaAs bilayer. After the wet etch release, the chips were rinsed in deionized water and subsequently in isopropyl alcohol [14]. Samples are also conserved in isopropyl alcohol in order to prevent oxidation by water of heads to which the structures are fixed.

Electromechanical Property

To understand the electrokinetic function of the applied strain by liquid environment, the piezoresistivity of HNBs is characterized. For the intrinsic property characterizations, the HNBs with metal pads attached on both sides were fabricated using microfabrication techniques [14]. With the metal connectors, good electrical contact can be achieved. Besides the electromechanical characterization, such connectors also allow for the integration of these structures into more complex assemblies. Nanomanipulation inside an SEM was used for their electromechanical property characterization. The experimental results showed that the structures showed unusually high piezoresistive response. Moreover, electrostatic actuation was used to excite the structures at their resonance frequency and investigate their resistance to fatigue. With their low stiffness, high strain capability, and good fatigue resistance, the HNBs can be used as high-resolution and large-range force sensors. By variation of design parameters, such as the number of turns, thickness, diameter, or pitch, an HNB with the required stiffness can be designed through simulation.

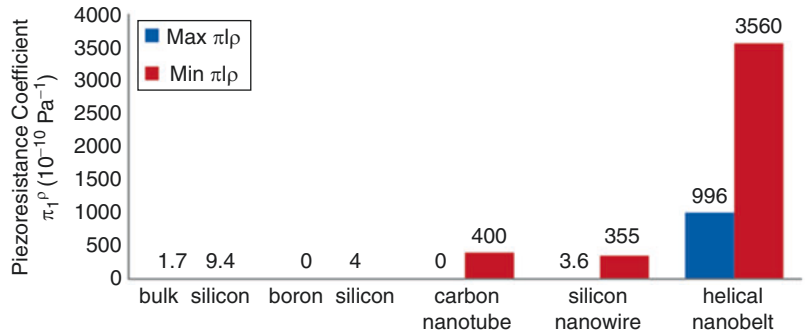
For the quantitative comparison with other piezoresistors, the piezoresistance coefficient can be obtained as,

$$\pi_l^{\sigma} = \frac{1}{X}\frac{\Delta\sigma}{\sigma_0} \quad (1)$$

where σ_0 is the conductivity under zero stress and X is the stress. The piezoresistance coefficient was defined with resistivity as $\pi_l^{\sigma}=\Delta\rho/\rho_0$. The conversion is $\pi_l^{\sigma} = -\pi_l^{\rho}$ for small σ. Uniaxial stresses were applied on HNB along their lengths. Since the linearity of each cycle from the measured data is almost constant, the widest measured region of the cycles was chosen to calculate the piezoresistance coefficient. Geometry information from Table 1 was used as the parameters.

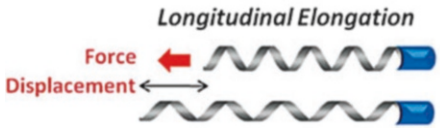
These obtained piezoresistance coefficients of HNBs based on Eq. 1 are compared with other elements of the piezoresistors. Each reported piezoresistance coefficients of Bulk Si, boron-doped Si, and Si-NW, and CNT were summarized in Fig. 2 in comparison with HNB [14]. Especially, Si-NW was recently reported as showing giant piezoresistive effect. The revealed piezoresistance coefficients of the HNBs are even much higher than the one of Si-NW. These results are straightforward from the benefit of HNB's flexibility considering the Eq. 1 since the tiny input stress (X) can cause the resistance change ($\Delta\sigma/\sigma_0$). At least the torsional effect seems to affect much to the high piezoresistive response of the HNBs. As was discussed on the difficulty in exact modeling of the piezoresistive HNBs, mechanism behind such a high piezoresistive response was not understood yet. However, there is the fact that the HNBs are the promising nanostructures to be used as the elements of ultraflexible electromechanical devices such as force sensors and bioinspired systems.

Mechanical Property



In addition to piezoresistivity of HNBs, they can perform like a spring to save energy from large-range mechanical force based on their nonconstant mechanics. Tuning fork force calibration tool was utilized to characterize the mechanics of HNBs in full-range tensile elongations. The tuning fork as force interaction tools have been proposed mainly to replace the AFM optical cantilevers for imaging [17]. The mechanical property (spring constant) of HNBs was measured by attaching them to the tuning fork tip. The force is obtained from the stiffness of HNBs measured by tuning fork gradient force sensor and by the displacement measurement of HNBs with SEM imaging. Figure 3 summarizes the measured mechanical property while HNBs are under tensile elongation. The nonconstant stiffness behavior of HNBs during their controlled tensile elongation was clearly revealed in their full-range elongation. The obtained stiffness ranges from 0.009 to 0.297 N/m with a resolution of 0.0031 N/m during full elongation and 0.011 to 0.378 N/m with a resolution of 0.0006 N/m for the nondestructive method. It was transformed into full elongation tensile forces as high as 2.95 μN for the first experiment and 1.56 μN for the second.

Wireless Propulsion of Helical Nanobelts



Principle of HNB Electroosmotic Propulsion

The propulsion of HNBs involves two conversions: transforming energy from an external source to a force and transforming this force into a motion. The proposed method to supply power remotely to HNBs is an electrokinetic process. Its main advantages for in vivo applications are the good tolerance of living organisms to electric fields and its compatibility with medical MRI imaging.

In general, the surface charge that develops at the solid–liquid interfaces plays an important role in a number of electrokinetic processes. Due to the presence of a thin interfacial layer named the Stern layer, it results in a nonzero electric potential at the liquid interface, also known as the zeta potential ζ. This potential is screened by mobile counterions diffusing in the liquid in a layer generally named Electrical Diffuse Layer (EDL), which has a typical thickness of a few tens of nanometers depending on the solution ionic strength. Under an electric potential difference, the resulting electric field puts in motion the excess counterions in the EDL. This moving layer drags the whole

liquid inside the fluidic medium, resulting in "pluglike" flows also referred to as electroosmotic flows (EOF). In addition, one should also consider the surface charge developing at the HNB surface. In the case of a HNB floating in liquid, its own Stern layer generates a flow which applies a hydrodynamic pressure on the surface of the robot, propelling it in the opposite direction.

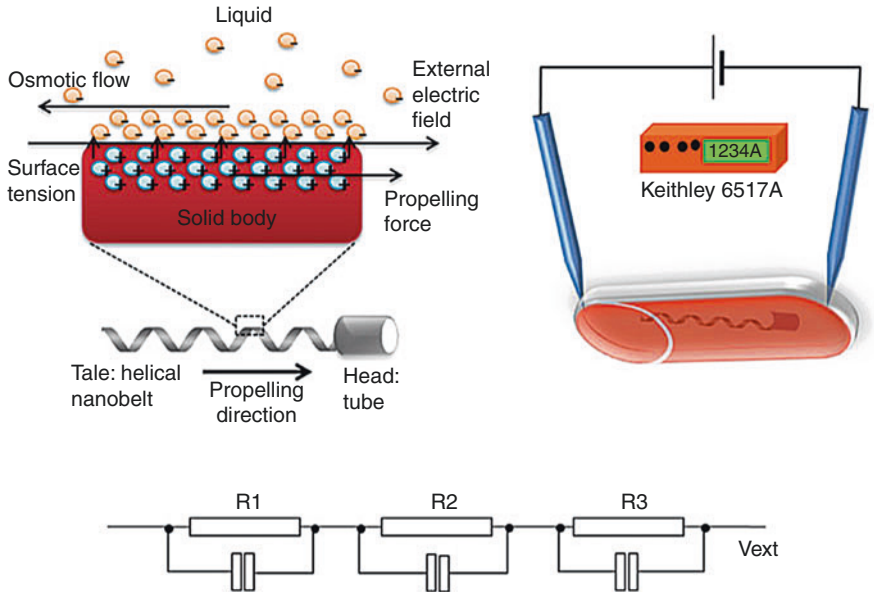

Figure 4 depicts the electroosmotic propulsion mechanism through the interface between HNB's thin membrane surface and liquid medium solution. Since the propulsion force occurs through the whole surface, the large surface-to-volume ratio of HNBs is very advantageous.

HNBs' motility results from a local electroosmotic flux powered by an external field. The specific direction of HNB's propulsion along the cathode and anode probes indicates that a DC field gradient along the HNB is responsible for this propulsion. The equivalent circuit can predict that the electroosmotic propulsion force is affected by the difference of electrical resistivity between medium solution and the HNB (Fig. 4). The electric voltage applied to the HNB by the external field can be estimated from a serially connected resistors model describing the ionic conductance through the liquid medium and the capacitors for the ionic layers. In a DC electric field, the resistance is the leading contribution. The resulting DC voltage of magnitude V_d induced in the HNB is modeled as

$$V_d = \frac{R_2}{R_1 + R_2 + R_3} V_{ext} \tag{2}$$

where V_{ext} is the DC input voltage applied to the probes in the petri dish, and R_1 (resistance between left electrode and HNB), R_2 (resistance of HNB), and R_3 (resistance between HNB and right electrode) are depicted in Fig. 4. Assuming that the resistance of the liquid is linearly proportional to the distance between the probes, Eq. 2 can be simplified as $V_d = E_{ext}\, l_d$, where l_d is the length of the HNB body and E_{ext} is the external DC field. The external DC field between the electrodes makes electroosmotic fluid flow along the HNB body.

Considering a liquid electrolyte, consisting of positive and negative particles in liquid solution, the interface between the electrolyte and the container wall generally forms a double layer in equilibrium, where a nonzero surface charge is screened by a very thin diffuse layer of excess ionic charge of width λ the Debye screening

Remotely Powered Propulsion of Helical Nanobelts, Fig. 4 Schematic diagrams of the experiments for HNB swimming. A DC bias was applied between two electrodes located through axial direction of HNB body. Thus, the propulsion direction can be controlled and predicted by the configuration of electrodes. For controlling the direction of electric field, micromanipulators with tungsten probes were utilized to form electrodes

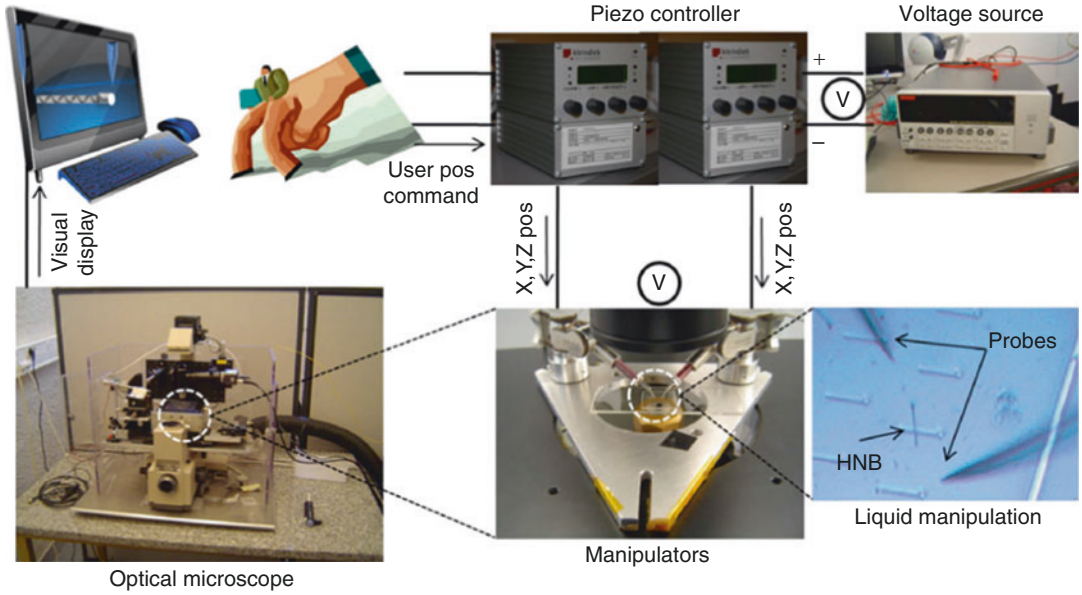
length (typically 1–100 nm). The double layer is effectively a capacitor skin at the interface, which has a small voltage ζ across called the zeta potential. The effect on the HNB and also the environment under electric field is further detailed in the following model which decomposes the part of intrinsic electrophoretic force directly generated to HNB and the electroosmotic flow from the surface interaction. Considering a tangential electric field E_{ii} applied in parallel to a flat surface, the electric field acts on ions in the diffuse part of the double layer, which drags the fluid to produce an effective slip velocity outside the double layer by the Helmholtz-Smoluchowski formula (Eq. 3) [18],

$$u_{11} = \left(\frac{2\varepsilon_0 \varepsilon_r \zeta_{HNB} H}{3\eta} - \frac{\varepsilon_0 \varepsilon_r \zeta}{\eta} \right) \vec{E} \qquad (3)$$

where $\varepsilon_0 \varepsilon_r$ and η are the electrolyte permittivity and fluid viscosity, which are constants (environment parameters). Increasing the speed of the HNB requires increasing ζ_{HNB} and H which are the zeta potential around the surface of the HNB and the Henri function, which depends on the geometry and hydrodynamic properties and the external field (E). On the negative term of the equation, the Zeta potential ζ on the borders of the surface is inversely proportional to the resulting speed, thus it should be minimized and controlled by applying experiments under closed microfluidic channel.

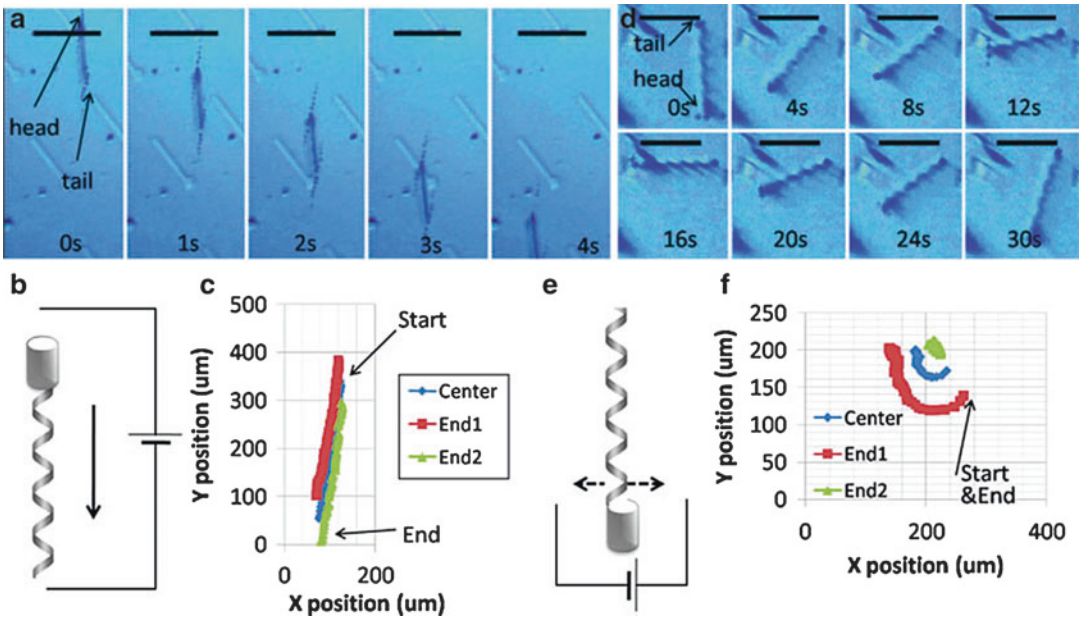
An important application of electroosmotic flow is capillary electroosmosis, where an electric field is applied down a capillary tube to generate a uniform plug flow (Eq. 3), driven by the slip at the surface. Typical flow speeds of 100 μm/s are produced by a field of 10 V/mm. This value will be used to compare the swimming performance of HNBs. It should be noted here that the electroosmotic propulsion does not depend on the size of the microagents. Thus, microscopic HNB could move theoretically about as fast as a macrosized one.

Electroosmotic Propulsion Experimental Setup



HNBs are detached from the substrate by micromanipulation. At the start of the experiments, the fixed end of produced HNBs are cut and released

from chips using a setup with two probes with high positioning accuracy under an optical microscope. Same probes are also used to generate the electric field through the liquid medium and HNBs. Total experimental setup is shown in Fig. 5. Two nanorobotic manipulators (Kleindiek, MM3A) are installed under optical microscope; each has three degrees of freedom and, respectively, 5, 3.5, and 0.25 nm resolutions in X, Y, and Z directions. For the application of the electrical field and high resistance measurement, an electrometer with a DC power supply (Keithley 6517A) is used. Two probes attached to each side of manipulators are positioned in less than 1 mm distance. To avoid the optical reflection from the meniscus between probes and liquid medium interface, longer probes (~5 mm) with sharp tips (diameter around 100 nm) are used.



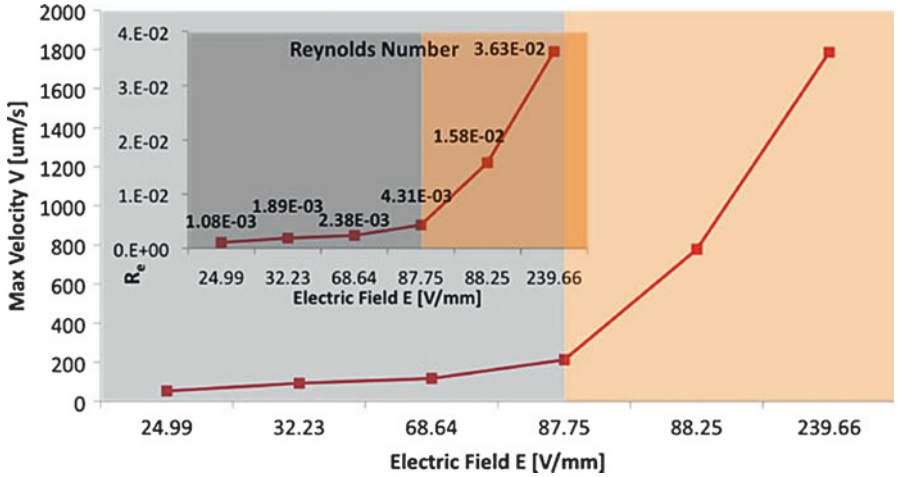
Controlled Swimming Experiments

Figure 6 demonstrates the forward and rotating propulsion of HNBs. Experiments are depicted in Fig. 6b, e. The swimming propulsions of HNBs are achieved by modifying the electrodes' configuration. A series of snap shots during forward (Fig. 6a) and rotating (Fig. 6d) propulsions were taken during the propulsion experiments. The trajectories of each swimming experiment are displayed in Fig. 6c, f. For trajectories, video analysis software and a custom-made C++ program are utilized. Rotation of HNBs was achieved by their aligning to the applied field direction. The probes attached to manipulators can change the configuration to generate the desired electric field gradient. Note that in this case the rotation was achieved using an HNB fixed in one extremity, while the other is free. The electrode configuration was fixed to make the HNB rotate. Furthermore, the forward and backward swimming direction can be converted without the complicated tumbling motion of *E. coli* bacteria.

It is confirmed that the swimming directions of HNBs could be easily controlled by differentiating the field gradient. For the steering control, the field gradient needs to be aligned to the rotational axes of the HNBs. In case of an untethered HNB, the rotation is achieved by controlling the field gradient. The high surface-to-volume ratio of

Remotely Powered Propulsion of Helical Nanobelts, Fig. 5 System setup for electroosmotic propulsion experiments: optical microscope with a camera is used to give user visual feedback and thus proper manipulation in liquid. User operates the piezo controller to manipulate tungsten probes, which are used to manipulate HNBs and to apply the electric field generated by an external voltage source

Series of snap shots during backward (**a**) and rotating, (**d**) propulsions are taken during the experiments (**b** and **e**). The trajectories of each swimming experiment are displayed in (**c**) and (**f**). The scale bars in (**a**) and (**d**) are, respectively, 80 and 60 μm



HNBs increases the swimming efficiency by increasing the charged area in a given volume and mass.

The maneuverability of the currently demonstrated electroosmotic HNBs is still limited to the basic motions compared to the magnetic field based approaches. However, this issue can be addressed using an array of embedded electrodes.

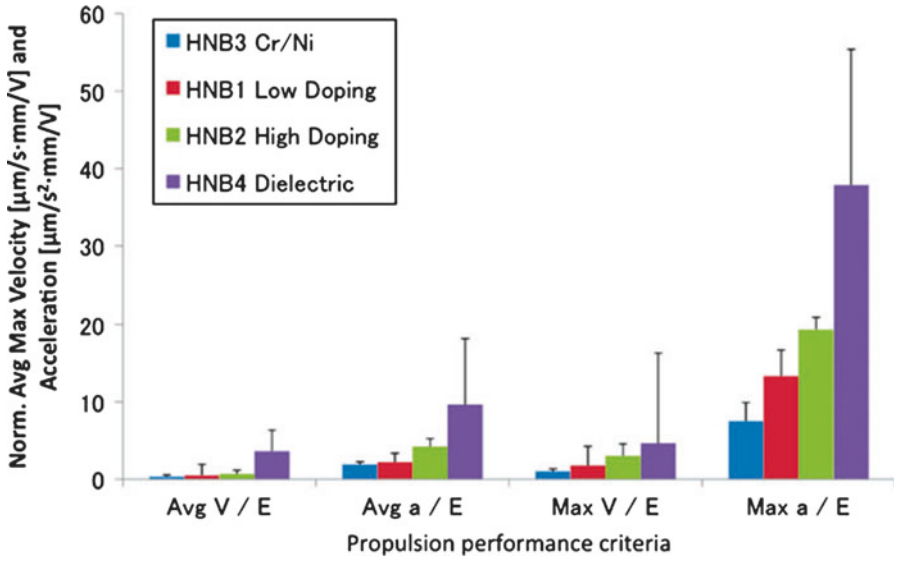
Comparison of Swimming Performance

Electrokinetic Effect

To further understand the repeatable swimming behaviors due to an electroosmotic force and to find the optimized design parameters, especially the surface profile, the swimming performances of four different types of HNB were characterized. High- and low-doping HNB, a metallic (Cr/Ni) one and a dielectric counterpart were analyzed. Figure 7 shows the average and maximum propulsion velocity and acceleration normalized by the applied electric field. HNB performance was investigated in several steps (6–11 steps) ranging from 24 to 401 V/m. It was difficult to compare four HNBs in identical single field intensity because the experimental configuration of probes and HNB is difficult to maintain between each experiment. Therefore, a statistical average velocity was chosen to describe the general behavior of different HNB. It should also be noted that experiments on different types of HNBs were conducted in different days which might slightly change electrical resistivity of the liquid medium. Even though the exact resistance values of the utilized HNBs were not verified because of the difficulty in collecting them after experiments, the intrinsic resistance of HNB can be predicted as $R_{HNB4} > R_{HNB1} > R_{HNB2} > R_{HNB3}$. Hence, the average and maximum velocities and accelerations depend on the resistance of HNB as was expected from the Eq. 3. Highly doped HNB2 showed better swimming performance than low-doped HNB1. This can be explained by the fact that the InGaAs layer thickness (estimated as 8–10 nm) of HNB2 is slightly thinner than the one of HNB1 (11 nm). It results in better performance in HNB2 than HNB1 from the reduced gravity

Remotely Powered Propulsion of Helical Nanobelts, Fig. 7 Dependence of HNB velocity on applied electric field intensity. The plot was obtained during the swimming experiments of a 74-μm-long HNB in isopropyl alcohol medium. The nonlinearity of the swimming performance is demonstrated at the region with higher electric field intensity than 87.75 V/mm. The *inset* figure shows the Reynolds numbers in different velocities versus applied electric field

effect and hydrodynamic friction, regardless of the higher conductivity. It reveals that the doping concentration does not play much role in the swimming performance compared to the geometry or volume effect. It should also be noted that the HNB3 and HNB4 are slightly thicker than HNB1 and HNB2 because of additional metallic or dielectric layers (Cr/Ni 10/10 nm, AZ5214 photoresist around 50 nm Table 1).

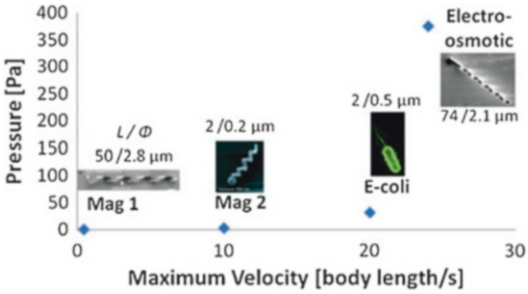


However, the HNB3 had lower performance, while HNB4 was better than the others. In the case of HNB3, this can be explained by the increase in hydrodynamic friction during swimming which slow down HNB. Furthermore, in case of metallic HNB3, the gravitational force can also increase the surface interaction force by dragging it down to the substrate. The detailed calculation and comparison of buoyancy force and gravitational force are not described here; however, the resulting nonfluidic forces (as the difference between the gravitational force and the buoyancy force) on HNB3 is 0.94 pN, which is two times higher than on HNB1 (0.43 pN). These negative effects on HNB3 reduce its swimming performance compared to the others (Fig. 8). The result of HNB4 is contrary to the HNB3 while additional layer was deposited onto the surface. It can be explained by the fact that the nonfluidic force of HNB4 was decreased by the increased buoyancy force from the photoresist, which has much lower density than both gold and nickel. The result clearly shows the high dependency on the surface charge and thus zeta potential in dielectric surface coating to HNB compared to conductive or semiconductor materials (Fig. 8).

Swimming Performance Comparison with Other Swimmers

The force generated by the HNB's swimming is estimated from the drag it overcomes, considering its shape approximately as an ellipsoid [8].

$$F = \frac{4\eta\pi a v}{\left[\ln\left(\frac{2a}{b}\right) - \frac{1}{2}\right]} \tag{4}$$



where a and b are the dimensions along the longitudinal and lateral axes respectively, η is the viscosity of the liquid medium; and v is speed of the HNB. For a 74-μm-long HNB with a diameter of 2.1 μm moving at 1.8 mm/s in isopropyl alcohol medium, the generated force of 1.3 nN (Eq. 4) is an order of magnitude higher than the conventional optical trap force which is less than 200 pN. Furthermore, HNBs can apply a large pressure

Remotely Powered Propulsion of Helical Nanobelts, Fig. 8 Dependence of normalized velocity and acceleration of propulsion on four types of HNBs. High- and low-doped semiconductor HNB showed higher swimming performance than metal (Cr/Ni)-coated HNB, and best performances are achieved with type 4 (dielectric)

up to 375.5 Pa, which can be advantageous for local manipulation, such as on biological membranes.

Compared to two rotating magnetic propulsions of helical nanostructures, the demonstrated electroosmotic propulsion of HNBs showed much higher swimming performance in terms of maximum swimming velocity and manipulation force. The demonstrated velocity (1,785 μm/s) can reach 90 times faster and the manipulation force and pressure reaching at around 1.3 nN and 375.5 Pa which are much higher than others respectively (Fig. 9).

Remotely Powered Propulsion of Helical Nanobelts, Fig. 9 Comparison of swimming performances of swimmers: Magnetic 1 [6], Magnetic 2 [8], *E. coli* [1, 19] and Electroosmotic HNB

Conclusion

This entry introduced biologically inspired microswimmers based on helical nanobelts. Helical nanobelts microswimmers have excellent electromechanical and mechanical properties which can mimic their original model in nature. The demonstrated direct pulling of HNBs by electro-osmotic pumping was proven to be an efficient energy conversion mechanism for microscopic artificial swimming objects and overcomes easily the viscous drag and gravitational forces in an aqueous environment at low Reynolds numbers. Swimming velocities as fast as 1.8 mm/s (24 times the body length per second) and pressure as high as 375.5 Pa are achieved by HNBs propelled by an electro-osmotic force under an external electric field. These performances are higher than other state-of-the-art microscale artificial swimmers with physical energy conversion. Note that the velocity of 24 body lengths per second is even faster than natural bacterial propulsion which is

their original model. Although helical morphology with a thin film is beneficial to such a fast swimming at low Reynolds numbers, the swimming performance appears to depend highly on the surface electrokinetic effects. Among the tested four different types, dielectric polymer coated HNB showed the best swimming performance compared to others with metallic or semiconductor surfaces. These HNBs can be used as wireless liquid manipulators, assemblers and nanorobots for biomedical or MEMS/NEMS applications or remote physical or chemical detection by functionalizing with proper readouts.

Synonyms

RNA interference (RNAi); Short-interfering RNA (siRNA); siRNA delivery

Definitions

RNA interference (RNAi) is the targeted down regulation of gene expression, most commonly

on the translational level by introducing synthetic double-stranded or short interference RNA (dsRNA, siRNA) into the cell. Gene expression is then reduced by employing an existing cellular mechanism for processing the dsRNA into the active, single-stranded form incorporated in a complex called RISC, which targets and leads to cleavage of the specific messenger RNA (mRNA) substrate.

Biomedicine is the field of medicine that develops concepts or mechanisms discovered or used in basic research into clinical applications. This process is called *From Bench to Bedside*. In the context of RNAi or drugs that are delivered to the organism or target tissue by using nanoparticles, biomedicine is sometimes referred to as nanomedicine. The size of the particles ranges between 1 and 300 nm.

Overview

The recent advances in the understanding of the molecular mechanisms of RNA interference (RNAi) have led to the concept that dsRNA can be delivered into cells to modulate pathogenic functions of genes. This mechanism opens new possibilities to cure diseases since the underlying cause of nearly every pathological process is the dysregulation of one or several genes at different steps in a physiological process. This therapeutic application of RNAi as a new type of drug has been quickly embraced by many researchers as a promising strategy for diseases which were hitherto considered to be difficult or nigh impossible to treat. However, the delivery of dsRNA into cells is not a trivial task due to their large size of approximately 14 kDa and negative surface charge. Additionally, RNA has a rather short lifespan under physiological conditions due to the efficient removal by nucleases.

In order to successfully employ RNAi to target pathological processes, the stability of siRNA has to be addressed. This is generally achieved by introducing chemical modifications to the nucleotides without inducing toxicity or through the selected drug vesicle. Since RNAi is highly sequence-specific, an appropriate sequence in the gene of interest has to be found and preferentially tested using different siRNAs against the same target. Further important factors which should be controlled for are off-target effects (OTEs), for example, cleavage of other mRNA than the sequence-defined target, which can arise despite the precision of the mechanism, and activation of the immune response which can be induced both sequence dependently and independently. The major challenge is still the delivery of the siRNA to the target organ for the treatment. This then expands the list of considerations to the choice of delivery vehicles and routes of administrations. For an excellent and comprehensive introduction into the field please see [11, 17].

Some of these issues, in particular the delivery of the siRNA, are solved by combining the expertise of material, chemical, and physical science to devise efficient vectors for delivery of the dsRNA into the target tissue. The development of carrier molecules in the nano-range, such as polymers, liposomes, peptides, and aptamers, goes hand in hand with the design of new therapeutics for various pathologies, such as cancer, genetic, and viral diseases. Notably, in less than 10 years since the discovery of RNAi, several drugs have been successfully developed and are currently tested in Phase I–III clinical trials in the United States (www.clinicaltrials.gov).

It is worth mentioning that RNAi can originate from either synthetic siRNA, which has to reach the cytosol for final processing and activation, or as plasmid-borne short hairpin RNA (shRNA). These plasmids must be delivered to the nucleus where the RNA is transcribed and undergoes a first step of processing before it is transported to the cytosol. This type of RNAi is generally carried by viral vectors and has been subject of extensive investigation. However, the focus of this review is nonviral delivery of siRNA; hence, the reader is referred to elsewhere for a further discussion of this area. Finally, bacteria have recently been employed as delivery vehicles for shRNA or siRNA in a process termed transkingdom RNAi (tkRNAi) or bacteria-mediated RNAi (bmRNAi).

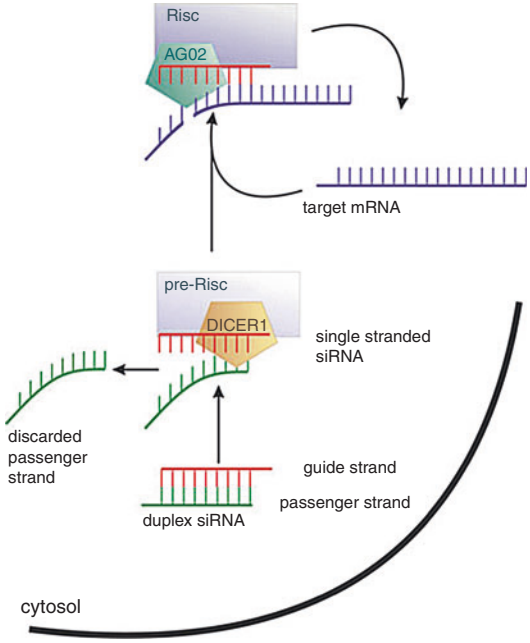
In this entry, the basic cellular mechanism of RNAi will be introduced. Important criteria for the design of siRNA such as sequence design and

chemical modifications will be discussed together with observed off-target effects (OTEs). This will be followed by an overview over physiological barriers and approaches chosen to deal with these challenges. Further, different types of delivery strategies will be presented which are currently employed in clinical applications according. Finally, how nanotechnology is integrated with RNAi will be discussed with an overview and discussion of a selection of particles presently utilized for in vitro, in vivo, and clinical trials.

Basic Mechanisms

RNA Interference: A Shared to Defend the Genome

In 2006, Andrew Fire and Craig Mello were awarded the Nobel Prize in Medicine or Physiology for their discovery of gene silencing through double-stranded RNA (dsRNA) in *Caenorhabditis elegans (C. elegans)*. Notably, their work describing this phenomenon had only been published for 8 years before they received the honors [5]. The observation that gene silencing could be achieved by the introduction of plasmid DNA into plants was first described some 20 years ago, but the importance of this curious finding was not recognized until it was reported by Andrew Fire and colleagues in one of the most widely used model organisms, the nematode worm *C. elegans*.



Although the exact mechanisms of RNA interference (RNAi) were unknown when it was first reported, not much time passed before it became clear that the strategies and functions of RNAi are conserved in plants, invertebrates and vertebrates, as well as many of the components of the pathway. Once long dsRNA has entered the cell, it is trimmed into small duplexes of approximately 20–25 nucleotides in the cytosol by an RNase III enzyme called DICER1. This step is followed by integration into a complex called pre-RNA induced silencing complex (pre-RISC), also thought to be mediated by DICER1, where further processing into single-stranded RNA (ssRNA) takes place. RISC contains DICER1 and several proteins from the Argonaute family, AGO1–4. The passenger (sense) strand is then degraded and the mature RISC is formed with the guide (antisense) strand integrated into RISC. The guide strand is complementary to mRNA and determines the specificity of RISC. When RISC encounters its target mRNA and perfect Watson–Crick base-pairing occurs, the mRNA is cleaved by the RISC-member AGO2. If the base-pairing is imperfect, the protein translation is disabled, but the mRNA is not cleaved by AGO2. This complex can be assembled stably over an extended period of time and catalytically regulate gene expression on the translational level (Fig. 1).

Since the discovery of RNAi, the knowledge of the field has progressed tremendously. Species possess a vast arsenal of their own small RNAs, for example, microRNAs (miRNA) or PIWI-interacting RNAs (piRNAs). The different classes of RNAs fulfill different functions such as regulating gene expression at the translational level, or they are expressed in specific tissues, for example, the germ line or neurons. Furthermore, RNA was found in the nucleus where it was found to regulate gene silencing at the transcriptional level by modulating histone modifications or DNA methylation levels. Further evidence proposes RNAi as some kind of nuclear pest control to defend the genome against insertion of mobile elements such as L1 transposons and viral DNA. Despite the rapid succession of discoveries of RNAi-governed processes, the detailed mechanisms by which these regulations are executed remain yet to be elucidated. Nevertheless, the impact the study of RNAi has had on the understanding of gene regulatory processes over the past decade must not be diminished. For comprehensive and recent reviews over the different pathways, processes, and the components of RNAi please refer to [12, 19].

Design of Synthetic Short RNA for Clinical Applications

Sequence Design

Intensive research into sequence design resulted in a set of criteria that greatly facilitates the development of suitable RNA duplexes for any given gene. There are a number of web tools available from either commercial or academic sources in order to identify appropriate RNAi target

RNAi in Biomedicine and Drug Delivery, Fig. 1 siRNA-induced silencing. Double-stranded siRNA is delivered to the cytosol, where it is recognized by DICER1, and incorporated into a pre-RISC complex upon which the duplex is separated and the passenger strand discarded. This processing step is also mediated by DICER1. The mature RISC complex is then formed and guided to target mRNA. Perfect match interactions between the guide (antisense) strand and mRNA lead to cleavage of the substrate mRNA by AGO2. A fully assembled RISC complex is stable and can catalytically inactivate a large number of mRNA. The model is a simplified depiction of the siRNA pathway only and omits transport of siRNA into the cell as well as other small RNA processing pathways. The nomenclature refers to human proteins

sequences [15]. The basic structure of the siRNA generally contains a central domain of 19 basepairs with an overhang of two bases at the 3′-end and a 5′-phosphate group. The reason for this type of synthetic siRNA to be common is because it is identical with the end product of the cellular RNAi pathway and DICER1. However, other siRNA varying in length between 19 and 27 basepairs and with either blunt or asymmetric ends have been shown to be efficient in vitro and to be processed by DICER1. Secondary structures of the siRNA as well as the target sequence should be considered together with the overall thermodynamic properties (T_m), which influence loading into RISC. As a rule, siRNA is more efficient when the 5′-end of the guide strand has a lower melting temperature than the 5′-end of the passenger strand by adjusting the A/U and G/C content, respectively. The positioning of individual bases has also been found to have an effect on efficiency of siRNA [2, 15].

Chemical Modifications to the Sugar or Phosphodiester Backbone

Chemical modifications of the dsRNA in order to increase the stability (T_m) under physiological conditions or reduce the susceptibility to RNase attacks include the introduction or replacement of various reactive groups on the base, sugar or phosphodiester backbone of the RNA. In general, the sugar backbone is modified at the 2′*O*- position, for example, to 2′-Fluoro. This modification does not interfere with loading into RISC or cleavage by DICER1. Another commonly used modification is 2′-*O*-Methyl. This nucleotide is occurring naturally in tRNA or ribosomal components and insertion of these modified nucleotides has been shown to abolish the induction of the innate immune system in mice. Locked nucleic acids (LNA), where the sugar ring is locked in the 3′-*endo* conformation due to the presence of a methylene bridge between the 2′-*O* and the 4′-C of the ribose, have been reported to increase stability successfully.

Modifications to the phosphodiester backbone include, for example, phosphorothioate, which has been shown to increase T_m and resistance to nuclease-mediated degradation. This modification can be easily integrated at defined positions, but it has been related to toxicity, loss of function, and nonspecific protein binding if large numbers of nucleotides in the siRNA are replaced with this modification. The replacement of the phosphodiester bond with a boranophosphate greatly increases stability of the dsRNA, but synthesis of this type of backbone requires in vitro transcription and the position of the insertion of boranophosphate can therefore not be defined. For excellent and detailed reviews of the design of siRNA and modifications, please refer to [1, 2, 8].

Off-Target Effects

A serious concern when developing siRNA as therapeutics are OTEs. They arise most commonly for the following reasons: activation of the innate immune system, sequence homology with other mRNAs additionally to the specific target, and when siRNA enters the cellular miRNA pathway. Initially, it was assumed that the short RNA duplexes could not induce an immune response. However, with the increasing number of work employing siRNA in vitro and in vivo, siRNAs were reported to stimulate the innate immune system and induce a strong interferon response. This activation has been shown to be both sequence dependent and independent, as well as cell-type specific. Intracellular receptors from the Toll-like family, in particular TLR3, 7, and 8 recognize RNA, either dsRNA (TLR3) or ssRNA (TLR7 and 8), and mediate the induction of IFN-α or IFN-β. These receptors are found either on intracellular organelles such as the endosome or lysosomes, as well as cells that constitute the innate immune system such as B cells or monocytes. Under given circumstances, siRNA can therefore induce the innate immune system [22].

In order to avoid OTEs based on sequence homology, it is recommended to carefully screen the transcriptome for similarities with the required siRNA. It is important to note that although single mismatches have been reported to abolish the efficiency of siRNA, short similarities of five to eight bases can direct RISC to unintentional targets. If siRNA engage in the miRNA pathway, the specific effect of siRNA on one gene is replaced by effects on many genes due to the nature of miRNA-mediated gene regulation. Generally, OTEs are dose-dependent and can therefore be circumvented by establishing dose–response curves and choosing the lowest efficient dose. Since it has been shown that downregulations of the targeted gene transcripts were in fact due to OTEs and not to the direct mediation of the administered siRNA, it is strongly recommended to test at least two or three different siRNAs against the same gene. This should result in reproducible effects and confirm that the expected and observed downregulation of the transcripts is due to the direct effect of siRNA [8, 15].

Delivery of Synthetic Short Interference RNA for Clinical Applications

Physiological Barriers

After the successful design, synthesis, and in vitro tests of a suitable siRNA compound, the next and likely more challenging obstacle to be overcome is the delivery of siRNA to its site of action. There is a consensus in the field that the vast potential of RNAi cannot be fully exploited yet because of the lack of efficient delivery vehicles to the target tissue. The body has various highly efficient strategies for clearance of foreign particles from the system, which are briefly described below in order to understand the difficulties in delivery and how they are addressed by the choice of appropriate vesicles or siRNA modification or both combined. Tremendous efforts are directed toward the development of a range of particles with different physicochemical properties which are equipped to reach the target organ and pass the physiological barriers [7].

If siRNAs are not immediately degraded by free nucleases then the next barrier is renal clearance, which is thought to determine the half-life of modified or naked siRNA in vivo. The small size of around 14 kDa, which is far below the cutoff of 40 kDa for glomerular filtration, and the hydrophilic nature of siRNA target these molecules for removal by the kidneys. The next trial is the clearance via the reticuloendothelial system (RES). The RES consists of mobile, circulating phagocytic cells, such as monocytes, or resident tissue macrophages that remove pathogens and cellular debris which remains from apoptosis, wound healing, or tissue remodeling. Large numbers of RES-associated cells reside in the liver, the Kupffer cells, and in the spleen or generally in other tissues with high blood flow and fenestrated vasculature.

Should carriers have successfully dodged clearance by any of the above-described pathways, they will then encounter the endothelial barrier lining the vascular lumen. Endothelial cells are tightly connected with the underlying extracellular matrix through integrins and they are joined together via a number of strictly regulated junctions. Endothelial cells are also

perforated with a large number of small pores of about 45 Å and rare large pores of 250 Å. Most of the transport of vesicles or siRNA is thought to be mediated via leaks in junctions rather than the pores themselves; however, there is some controversy regarding this matter. In many tissues, particles larger than 5 nm will not be able to extravasate through the endothelial lining, whereas organs such as the liver or spleen are easily accessible because of the extensive vasculature of these organs.

One specific type of endothelial barrier is the blood brain barrier (BBB) at the boundary to the astrocytes and pericytes where the endothelium forms an exceptionally tight lining to protect the brain. As progress in research into neurodegenerative diseases such as Alzheimer's reveals an ever-increasing number of genes which are potentially "drugable," the brain becomes an attractive target for siRNA. Under normal physiological conditions, this barrier is intact. However, the integrity of the BBB can be compromised during disease or through administration of certain drugs. Also, specific endothelial reporters have been described which could be employed to aid passage of particles across the BBB to the brain. Therefore, development of carriers that can deliver drugs across the BBB will become increasingly important to treat this kind of diseases.

The final step for successful delivery is the cellular uptake and, importantly, endosomal release into the cytosol. In general, particles enter a cell via receptor-mediated endocytosis. Recognition and binding to the receptor induces the formation of a vesicle which leaves the cell membrane on the cytosolic site. From there, the vesicles undergo a series of intracellular trafficking steps and maturation until, finally, late endosomes or lysosomes have been formed. The last challenge the particles face is the release from the endosome into the cell. The *proton sponge effect* has been described as a mechanism by which the trapped drug can exit the endosome. Briefly, acidification of the endosome leads to protonation of amine groups on the vesicle. This leads to an influx of protons and chloride ions, followed by water to equilibrate the changes in osmolarity, eventually causing rupture of the vesicle and release of its contents into the cytosol. For further reading, please see [7, 20].

Types of Delivery

In vivo application of siRNA can be classified, for example, into active or passive systemic and local/cellular delivery. Passive systemic delivery does not require any specific targeting sequences or molecules. It is based on the property of nanoparticles to accumulate in certain tissues under certain conditions. For example, nanoparticles or naked siRNA have been shown to accumulate in liver or spleen because of the specific structure of the endothelium, with large fenestrations of the microvasculature of these organs. Delivery of vesicles to inflamed tissue is thought to be mediated by the RES. Accumulation of particles in tumors has been attributed to the *enhanced permeability and retention effect* (EPR) in tumors. This is thought to be caused by reduced lymphatic drainage, leaky microvasculature, and enhanced angiogenesis of cancerous tissue.

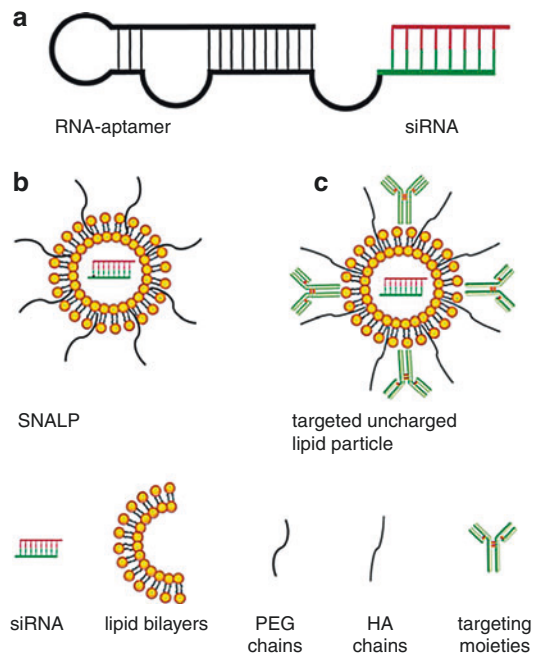
Active or targeted systemic delivery is more complex because it requires the carrier to be equipped with components such as antibodies, ligands against cell-surface receptors, or peptides from viral proteins targeting the nanoparticle to the desired cell type or tissue. Antibodies are used as whole entities, or fragments thereof, and they are generally directed against receptors which are increasingly expressed on tumor cells. Receptors that have been targeted include, for example, the epidermal growth factor receptors (EGFR) or human epidermal growth factor receptor-2 (HER-2), the iron-binding protein transferrin (Tf), which targets the transferrin receptor (TfR) responsible for iron uptake, as well as Toll-like receptors (e.g., TLR3). Successfully employed peptides are the rabies virus glycoprotein (RVG) or arginine-glycine-asparagine (RGD). Sugars, i.e., glucose or mannose, are recognized by a number of cell-type specific receptors and have also been successfully employed in delivery to specific cell types or across the BBB.

Naked siRNA has been injected using the hydrodynamic delivery method into mouse tail veins and was subsequently found to accumulate

in the liver and to a lesser extent in other organs such as the lungs. This method requires large volumes to be rapidly injected, and although successfully employed in mice and pigs, it is doubtful whether this way of administering systemic siRNA would be of therapeutic use in humans. The volume for injection needed is around 10 % of the body weight, and this would most likely lead to heart failure and death. Direct injection of siRNA is feasible if the target is easily accessible, such as is used, for example, for treatment of wet age-related macular disease or other diseases of the eyes where siRNA is injected directly into the eye. Several Phase I–III clinical trials have been approved by the US FDA. Other means of delivery that have been tested include topical administration which is useful for exposed sites, such as the skin. Inhalation is the means of choice for treatment of respiratory tract diseases. Electroporation has been used for delivery into muscle tissue. For more detailed information, please see [14, 18, 21, 22].

Delivery Vesicles and Nanoparticles

Considerations for the Design of an siRNA Carrier Investigation into suitable carriers over the past decade has resulted in a vast amount of materials and combinations of several components which all have advantages and disadvantages for delivery of specific cargo, the route of administration, and the target tissues. Criteria to be considered are the size and size distribution of particles, which is, for example, inversely related to cellular uptake and delivery to tumor tissue. Since the smallest microvessels have a diameter of 5–6 μm, particles must be considerably below this diameter in order to avoid accumulation and clogging which could lead to embolism. The surface properties of nanoparticles dictate whether they will be recognized and removed by the host immune system; non-modified hydrophobic particles are generally swiftly removed, whereas vesicles decorated with biodegradable materials which are hydrophilic such as polyethylene glycol (PEG) or polysorbate 80 (Tween 80) are better tolerated.



Drug loading capacities and the release characteristics are further important points. Loading can be achieved by two methods. The drug can be incorporated at the time of nanoparticle assembly or it can be absorbed after the formation of the carrier by incubation in a concentrated drug-solution. Highly efficient loading has been shown for siRNA due to the negative charge of the oligonucleotide and positively charged vesicles, such as cationic lipids or polymers. Drug release depends, for example, on the degradation of the carrier or how fast the drug can diffuse across the polymer membrane, as well as the solubility of the drug. A concise selection of the most frequently and successfully employed carriers is briefly described below. For a detailed description of these design considerations, please see [4, 18]. The reader is also referred to cross-referenced entries which elaborate in more detail the properties and design of nanoparticles specifically for drug delivery.

Aptamers Among biological macromolecules RNA has a unique place because of the ease of manipulation and synthesis similar to DNA, which is combined with a structural versatility found in proteins. These useful properties predestine RNA to be used itself as a building block for the assembly of nanoparticles called RNA-aptamers (Fig. 2a). Generally, aptamers are highly structured oligonucleotides that are obtained by SELEX (systematic evolution of ligands by exponential enrichment) for the required purpose. This is a protocol whereby a library of RNA-aptamers is subjected to iterative rounds of counter-selection and selection to yield aptamers which recognize, for example, specific receptors on target cells, proteins, as well as organic compounds. The prime features which make aptamers attractive carriers are their small size of a few nanometers compared to cationic polymers or liposomal carriers (upto 300 nm), that modified nucleotides can easily be integrated to increase stability in physiological conditions, they have low toxicity and are biodegradable. Instances where aptamers have been employed as carriers for siRNA include murine xenografts of prostate cancer where tumor growth and regression was mediated by aptamer-mediated siRNA delivery, or treatment against viral infection by

either targeting HIV gp120, a glycoprotein which recognizes and utilizes the CD4 receptors on T lymphocytes for entry, or the CD4 receptor itself [6, 10].

Cationic Polymers and Dendrimers The cationic polymer cyclodextrin (CDP) has been widely and successfully used as a carrier directed in particular against solid tumors. Advantages of this material are the low toxicity; it is not metabolized in humans and does not induce an immune response. CDPs are commonly of a tri-composite structure, where CDP is employed as the carrier for siRNA due to strong ionic interactions between the cationic polymer and the anionic nucleic acids. The particle is stabilized with the hydrophilic cycloalkane adamantane conjugated to PEG (AD-PEG). Targeting of the vesicle to tumors is achieved by adding an AD-PEG-Transferrin (AD-PEG-Tf) moiety because Tf is expressed abundantly in a number of tumors. This formulation carrying siRNA against the ribonucleotide reductase subunit 2 (RRM2), called CALAA-01 by Calanda Pharmaceuticals, was approved for Phase I clinical trials by the FDA in 2008. The reader is referred to [3, 9] for a comprehensive review on the development of CALAA-01.

Another cationic species that is frequently used for similar properties is polyethylene-imine (PEI), which can be synthesized to be of linear or branched structure and is then classified as a dendrimer. PEI efficiently forms stable nanoparticles with oligonucleotides and promotes endosomal release via the *proton sponge effect*. Because of its branched structure, it can carry a large payload. Despite the supreme quality of PEI as a siRNA delivery vesicle, its identified toxicity toward most cells is not a desirable side effect. Three approaches have been taken to address the toxicity issue of PEI. First, the dendrimer is equipped with targeting moieties such as RGD to reduce the toxicity to nontarget tissue. Second, maintaining the particle size below 10 kDa substantially reduced toxicity compared to larger particles of 25 kDa. Finally, ketalized carriers have been synthesized with the added advantage that these linkages are sensitive to acidic pH, and hence readily dissolve in endosome to release the cargo [13].

RNAi in Biomedicine and Drug Delivery, Fig. 2 Delivery vehicles for siRNA administration. Three types of vesicles are shown for delivery of siRNA. (**a**) RNA-aptamer with siRNA ligated. (**b**) Stable nucleic acid particle decorated with PEG (SNALP). (**c**) Uncharged lipid particle decorated with targeting moieties, i.e., single chain antibody fragment directed against Tf and HA chains

Liposomal Carriers Lipids as gene delivery vehicles have been used since the early 1980s. Cationic lipids are often used as vesicle due to the facile handling and preparation since they readily associate with the anionic nucleic acids. Moreover, routinely used reagents for in vitro transfection of cell culture are based on cationic liposomes, such as *Lipofectamine 2000* by Invitrogen or other equivalent products. The most commonly used cationic lipid is 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP) because it efficiently associates with nucleic acids. However, DOTAP was again shown to be cytotoxic; hence, this carrier was equipped with modifications which reduce this side effect, such as lactosylation. Another strategy to inhibit the growth of pancreatic xenografts on a murine model involved DOTAP decorated with histidine-lysine peptides. This facilitated endosomal escape and single-chain antibody

fragment directed against Tf, and this vesicle did not induce an IFN-response and could be administered at low doses due to the target specificity.

Another promising type of vesicle based on cationic lipids is the stable nucleic acid-lipid particle (SNALP) (Fig. 2b). The siRNA is embedded within the lipid envelope and the composition of SNALPs contains reduced cationic lipid content and is PEG-ylated. SNALPs have been subjected to extensive study as siRNA carrier against in vivo viral models with considerable success of full protection against infection of guinea pigs with the deadly Zaire strain of the Ebola virus. Another trial employed SNALPs with siRNA against apolipoprotein B levels in nonhuman primates, which was well tolerated and showed reduction of Apolipoprotein B (ApoB) and serum cholesterol among other physiological improvements. Following on from these promising results, several therapeutic siRNA-SNALP formulations against tumors or metabolic diseases are now in preclinical or have been admitted to Phase I clinical trials, and targets include VEGF and ApoB among others [8]. Further information on these trials can be found on www.clinicaltrials.gov or the web sites listed.

Since cationic liposomes have been associated with significant toxicities, development of vesicles composed of uncharged lipids has been resumed with considerable success. One lipid in particular has emerged as a promising carrier: 1,2-dioleoyl-sn-glycero-3-phosphatidylcholine (DOPC). These vesicles successfully reduced tumor xenografts of different origins. Targeted vesicles against the thrombin receptor (TR) expressed on some tumors greatly reduced not only TR but also angiogenic and invasive tumor markers, such as vascular enodothelial growth factor (VEGF) and matrix metalloproteinase 2 (MMP2). Techniques developed in order to maximize the payload of these nanoparticles utilize lyophilization followed by rehydration with siRNA. The half-life in circulation under physiological conditions of these particles was increased by surface coating with hyaluronic acid (HA), a naturally occurring glucosaminoglycan with properties equivalent to PEG (Fig. 2c). Further information can be found in [17].

Other Types of Carriers: Atellocollagen, Cationic Cell Penetrating Peptides (CPPs), Polylysine There are a number of other options for building siRNA-nanocarriers. Atellocollagen is a preparation of digested cationic calf dermal collagen successfully employed and well tolerated in animal models of inflammatory disease or tumor xenografts. Despite the fact that the studied atellogen-siRNA nanoparticles were not decorated with a specific targeting moiety, they were found to accumulate in tumors and inflamed areas presumably due to the EPR effect in these tissues. CPPs are short peptides with a high content of positively charged amino acids, in particular arginine, which can be synthesized or are derived from naturally occurring peptides, e.g., TAT from HIV-1 to facilitate cellular uptake. Initially thought to be fully soluble, it appears that their efficiency is due to aggregation into nanoparticles. Successful trials in vivo used polyarginine fused to cholesterol and siRNA against VEGF in a tumor xenograft. Another polyarginine-based CPP coupled with RVG was found to cross the BBB and reduce green fluorescent protein expression in a mouse model. Another type of carrier is based on polylysine (K) stretches. Initial problems with toxicity such as complement activation were overcome by PEG-modifications and the addition of histidine (H), which facilitates endosomal escape. Further, it was found that the efficiency as siRNA carriers was improved by increasing the histidine ratio compared to lysine [9].

Further Reading

Currently, 20 studies are listed on www.clinicaltrials.gov when searched for the keyword siRNA. This clearly shows that the challenges of delivery posed by the physiological barriers or physicochemical properties of the particles can be overcome. The marriage between advances in material sciences and the developing understanding of the physiological and pathophysiological processes culminates in the development of novel RNAi-based therapeutics for the treatment of diseases ranging from viral to inherited and age-related pathologies.

Due to space restraints, a number of additional excellent reviews could not be referenced in this entry; however, they can be found when searching Pubmed or Web of Science with keywords such as "siRNA AND nanotechnology." Further information on research and development of siRNA-based therapeutics can be found on the web sites of the leading companies.

Definition

The handling of micro- and nanoscale objects is an important application field of robotic technology. Nanohandling includes the finding, grasping, tracking, cutting, etc., of objects as well as different characterization methods such as indenting or scratching on the nanoscale. Measurement of different features of the object, probe positioning with nanometer accuracy, structuring or shaping of nanostructures, and generally all kinds of changes to matter at the nanolevel could also be defined as nanohandling in the broadest sense. This entry addresses several approaches that can be automated with the help of nanohandling robots. The development of nanohandling robot systems working in constricted work spaces (in a vacuum chamber of an SEM or under an optical microscope) and with a nanometer resolution and accuracy is a big technological challenge for the robotics research community. Advanced actuator and sensor technologies suitable for nanohandling have to be investigated and implemented as well as vision-based feedback methods for tracking and data acquisition. Another crucial issue is the development of real-time robot control methods that meet the demands of automated nanomanipulation. This entry presents several promising solutions and applications of robot-based nanohandling.

Robot-Based Automation on the Nanoscale

Introduction to the Topic

The handling of micro- and nanoscale objects is an important application field of robotic technology. It is often referred to as nanohandling, having in mind the range of aspired positioning accuracy for the manipulation of micro- and nanoscale objects of different nature. The nanohandling of objects may include their finding, grasping, moving, tracking, releasing, positioning, pushing, pulling, cutting, bending, twisting, etc. Additionally, different characterization methods like indenting or scratching on the nanoscale, measurement of different features of the object, probe positioning with nanometer accuracy, structuring or shaping of nanostructures, and generally all kinds of changes to matter at the nanolevel could also be defined as nanohandling in the broadest sense. As in the field of industrial robotics, where humans leave hard, unacceptable work to robots, robots with nanohandling capabilities can help humans to handle extremely small objects with very high accuracy. The size of these robots also plays an important role in many applications [1, 2]. Highly miniaturized robots, often referred to as microrobots, are able to operate in constricted work spaces, for example, under a light microscope or in the vacuum chamber of a scanning electron microscope (SEM). Microsystem technology (MST) and nanotechnology require this kind of robot, since humans lack sensing capabilities, precision, and direct manipulation at those scales. Automated nanohandling by microrobots will have a great impact on both these technologies [3]. This entry will address several aspects of nanohandling automation.

The development of nanohandling robot systems is a big technological challenge for the

robotics research community. Advanced actuator and sensor technologies suitable for nanohandling have to be investigated and implemented. Another crucial task is the development of real-time robot control methods that meet the demands of automated nanomanipulation. The latter is challenging, especially due to the difficulty of getting real-time visual feedback and the lack of advanced control strategies able to deal with changing and uncertain physical parameters and disturbances.

Trends in Nanohandling

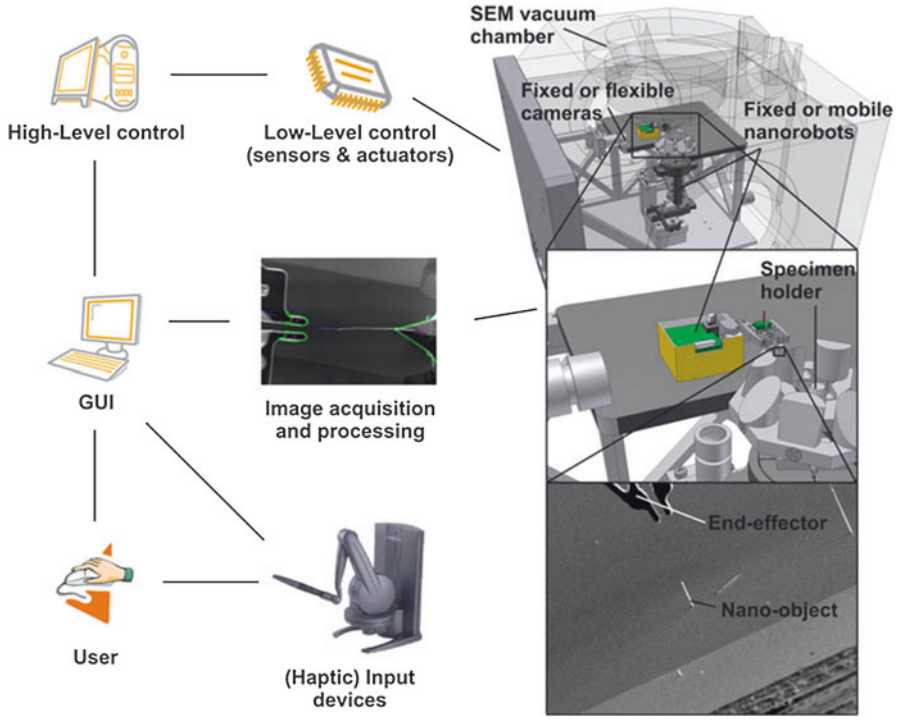
The following three approaches are being pursued in the nanohandling research community:

- Top-down approach utilizing serial nanohandling by microrobotic systems. The main goal is the miniaturization of robots, manipulators, and their tools as well as the adaptation of robotic technology (sensing, actuation, control, automation) to the demands of MST and nanotechnology. This approach is the major topic of this entry.
- Bottom-up approach or self-assembly, utilizing parallel nanohandling by autonomous organization of micro- and nanoobjects into patterns or structures.
- The use of a scanning probe microscope (SPM) as a nanohandling robot. In this approach, the (functionalized) tip of an atomic force microscope (AFM) probe or of a scanning tunneling microscope (STM) probe acts as a robot end-effector that is applied to a nanoscale part. This approach has been actively investigated in recent years [1, 2] and is discussed in section "AFM as a Nanohandling Robot."

Several other approaches like the use of optical tweezers or electrophoresis might also be adapted for automated nanohandling.

Automated Microrobot-Based Nanohandling

Microrobotics for handling micro- and nanoscale parts has been established as a self-contained research field for nearly 15 years and, in recent years, a trend toward the microrobot-based automation of nanohandling processes has emerged [4, 5]. Process feedback is the most crucial aspect of nanohandling automation. It is difficult to obtain reliable information when handling microscale and especially nanoscale parts. Vision feedback often is the only way to control a nanohandling process. For this reason, the vacuum chamber of a scanning electron microscope is, for many applications, the best place for a nanohandling robot. It provides an ample work space, very high resolution up to 1 nm, and a large depth of field. However, real-time visual feedback from changing work scenes in the SEM containing moving nanorobots is a challenging problem.



Automated Microrobot-Based Nanohandling Station (AMNS)

Figure 1 presents a generic concept of an automated microrobot-based nanohandling station (AMNS).

The microrobots are usually driven by piezoactuators that enable positioning resolutions down to sub-nanometer ranges. The microrobots of the station have a nanomanipulator integrated in their mobile platform, which makes them capable both of moving over longer distances and of manipulating with nanometer accuracy. This leads to more flexibility as the robots can be deployed anywhere inside the SEM vacuum chamber. Stationary robots can also be used in an AMNS. They are easier to control compared to mobile robots, which makes them more suitable for high-throughput automation. Depending on the application, different combinations of both robot types can be implemented.

The sensor system of the AMNS includes SEM, video cameras, force sensors, as well as position sensors integrated into the robots axes. The sensor data is sent to the station's control system for real-time signal processing. The control systems task is to calculate the positions of the robots and their tools as well as the positions of the parts to be handled or other objects of interest. The calculated positions serve as input data for the closed-loop robot control.

Teleoperation often is the first step on the way to automation. For this reason, a user interface is an important component of the AMNS.

Robot-Based Automation on the Nanoscale, Fig. 1 Generic concept of the AMNS [2]

The user can influence the handling process by a haptic interface and/or by a graphical user interface (GUI). A good overview of state of the art teleoperation techniques and applications is given in [6].

The positioning accuracy of the microrobots during automated nanohandling is affected by several factors, so that a powerful robot control system is required. On the low level of the control system, driving voltages for the robot actuators are calculated in real time, which keep the robot and its end-effector on the desired path. The high-level control system is responsible among others for path planning, error handling, and the time-saving parallel execution of tasks. GUI and haptic interface are supported by the high-level control system as well.

The AMNS concept has been implemented in different application fields for (semi-) automated nanomanipulation [2, 3]. Relevant aspects of this work will be introduced in the following sections.

Structure of the Essay

The following is a brief summary of the topics covered in the following sections.

Section "Real-Time Vision Feedback" covers the vision feedback in nanohandling robot stations. The focus is on the use of SEM in combination with real-time image processing algorithms, which is proposed as the near-field sensor for the automation of nanohandling tasks.

Section "Position Control Inside SEM" introduces fundamental considerations for automated positioning inside the SEM. The section encompasses actuation types, motion principles, closed-loop control mechanisms for nanorobots, SEM-based visual servoing, as well as the difference between macro- and microscale control engineering.

Section "AFM as a Nanohandling Robot" introduces the atomic force microscope as a robotic system for manipulation at the nanoscale. The AFM tip acts as a nanohandling tool to

change the position or orientation of a nanoobject or to modify the surface of a substrate with nanometric precision. Different application fields are introduced and current challenges in this field of research are discussed.

Section "Application Example: Handling of CNT" describes nanorobotic strategies for the microgripper-based pick-and-place handling of individual carbon nanotubes. For a reliable alignment in z-direction, a shadow-based depth detection technique is presented. Furthermore, special handling strategies are introduced for placing and releasing the CNT on the target structure. As an example, the automated assembly of so-called CNT-enhanced AFM probes is demonstrated.

Section "Application Example: Handling of Biological Materials" deals with the characterization and manipulation of biological objects by an atomic force microscope. An overview of relevant parameters for AFM measurements of samples in liquids and of soft samples is given. After a short introduction of the biological background, the current state of the art in automated AFM-based handling of biomaterials is given, ranging from the design of DNA-based nanoelectric circuits to the structuring of biosensor chips for medical and forensic use.

Real-Time Vision Feedback

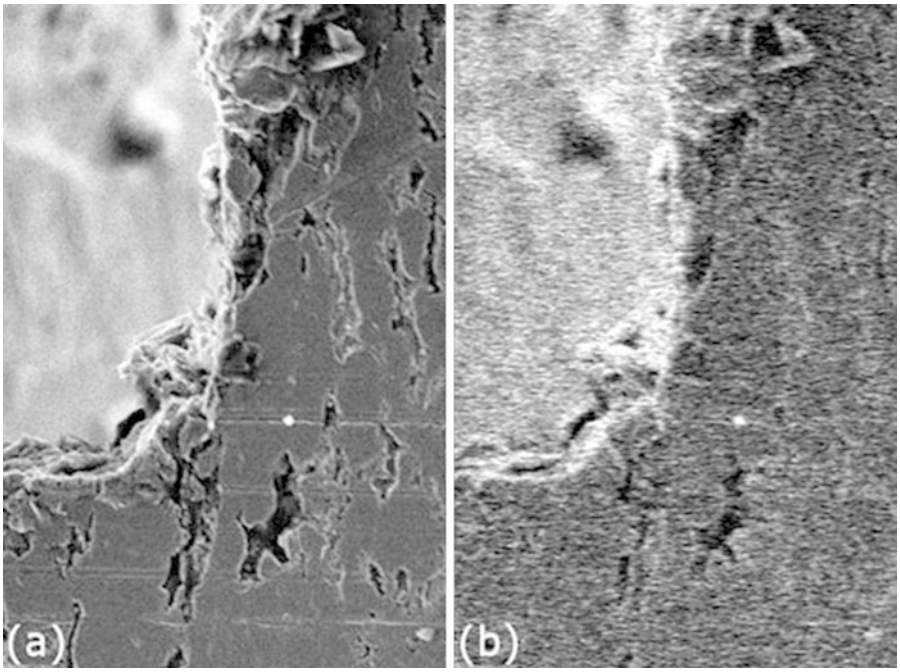
Manipulation and handling of objects on the nanoscale is subject to strong uncertainty on position and status of objects. This is due to the low mass of the objects of interest and the relatively high parasitic and interacting forces. Additionally, the choice of imaging modalities available at this scale is limited. Optical microscopes cannot deliver resolutions sufficient for imaging nanosized objects. Scanning probe microscopes like the AFM, though having the advantageous possibility to be used as a manipulator, do not exhibit the necessary speed for closed-loop feedback. The most flexible solution for imaging in this context is the SEM. It allows for observing processes at the nanometer range and still is fast enough to enable closed-loop control feedback. Drawbacks of the SEM are the sensitivity to noise and movement artifacts during fast scans, the possibility of distortions due to magnetic or electric influences generated by the AMNS, and the lack of three-dimensional information. Various approaches have been developed to deal with these conditions. The important properties of the SEM imaging and the tasks and approaches to solve the problems associated with it will be described in the following sections.

Imaging Source Properties

Certain properties of the SEM and its imaging process are important for the applied computer vision approaches. The most important negative property is the high level of noise. Noise can be reduced by frame averaging or pixel averaging which, however, also reduces the frame rate. Figure 2 shows the SEM images with low speed and high speed and the corresponding noise level.

The noise in the SEM can be modeled as additive noise:

$$g_{\mathrm{SEM}} = \mathrm{g} + \mathrm{g}_{\mathrm{noise}}$$



With g the true gray level value, $\mathrm{g}_{\mathrm{noise}}$ the noise component, and g_{SEM} the acquired gray level value.

Because the generation of secondary electrons is a statistic process and the number of electrons generated and detected can be assumed as Poisson distributed, the gray level fluctuation also has a Poisson characteristic.

Due to the scanning principle of the SEM, fast moving objects appear distorted in the images. This is due to the fact that the object has moved during the time needed to finish each line of the scan. This can significantly reduce the performance of computer vision algorithms. Therefore, the speed of robots has to be restricted if computer vision algorithms are required.

Typical Visual Feedback Tasks

For a successful nanohandling automation, visual feedback is needed for specific tasks. These can be described as object recognition, classification, and position determination. The latter can be executed in two dimensions and in three dimensions, respectively. Important especially for the position determination is speed in order to allow for closed-loop control. Still, even with fast imaging,

Robot-Based Automation on the Nanoscale, Fig. 2 SEM images at different scan speeds, acquired with a LEO 1,450 tungsten emitter SEM, (**a**) slow scanning, (**b**) fast scanning

control is often restricted to a look-then-move strategy, because the actuation is orders of magnitude faster than the imaging and subsequent visual feedback. When using SEM image acquisition with computer vision approaches as an image-based sensor, this is a limitation which cannot be overcome easily.

Object Recognition

Object recognition has the task of determining if an object of interest is in the view field or not. Many different approaches are known in traditional macro- or microscale imaging and computer vision. The approaches used at the nanoscale include template matching, statistical pattern recognition, and recognition based on local features. Object recognition algorithms used for nanohandling automation in many cases do not have special and elevated needs for noise robustness, because the recognition task is not time critical and low frame rates with high averaging can be used. Approaches used in nanohandling applications use support vector machines and various feature extraction algorithms. Applications include CNT-detection and detection of TEM lamellae [7].

Two-Dimensional Position Determination and Tracking

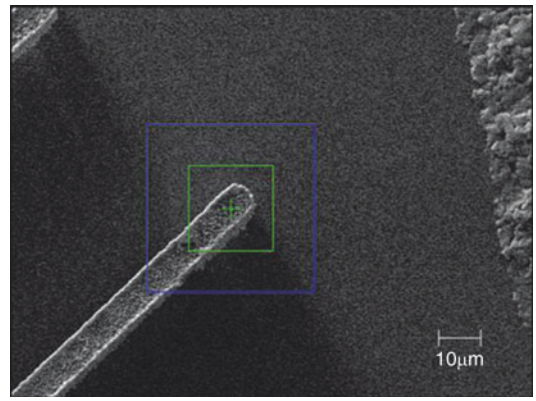
The positions of objects and tools are not known precisely through any sensor except for the SEM. Object position determination and tracking allows image-based visual servoing approaches to work. Example methods which have been developed to work on SEM images rely on template matching [8], active contours [3], and rigid body models [9]. What is common in all these methods is that some measures have been included to diminish the effect of noise on the algorithm performance, either by use of inherent noise robustness like in the case of correlation-based template matching, the use of regions to cancel noise influence, or the usage of multiple or even manifold features and the selection and weighting of these features according to their expected significance and robustness.

Different algorithms may be suitable for different needs, depending on the degrees of freedom

and the boundary conditions imposed by the system setup and the object properties. If the objects of interest are rigid, their appearance constant and known, their expected movement restricted to translations, and no magnification changes are required, template matching using cross correlation has turned out to be a robust and powerful yet simple approach. The idea is to calculate the cross correlation of a template image calculate the cross correlation of a template image and an input image I:

$$C(x, y) = T(x, y) * I(x, y)$$

In the resulting matrix, each value corresponds to the similarity of the image part to the template. Assuming that the object of interest is in the image, the position is with very high probability at the position of the maximal value in this matrix:



$$C(x_0, y_0) = \max(C(x, y))$$

The algorithm delivers a single position. It may well determine the position with subpixel accuracy, using weighting or interpolating techniques. The speed can be improved by using the frequency domain for calculation. In Fig. 3, the result of the algorithm can be seen. The template is marked at the place the best match is found.

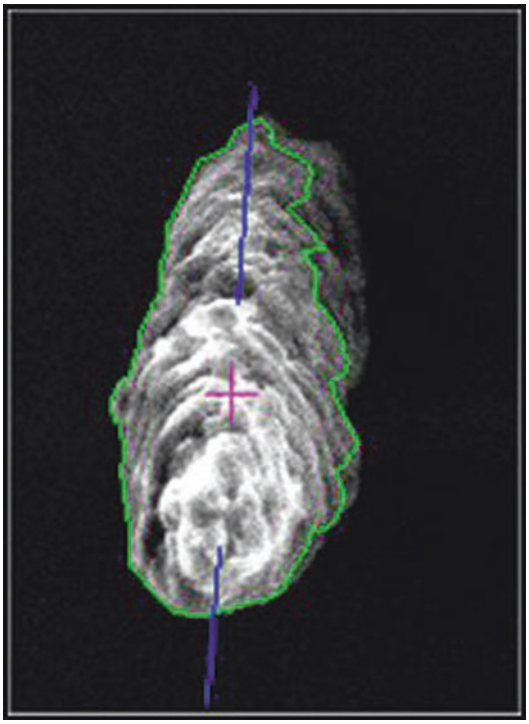
If the objects may rotate or change in size, active contours or rigid body models are more suitable, depending on whether an a priori model of the object is available or not. Also, the occurrence of occlusions is less problematic with these algorithms. The principle behind active contours is that a contour represented by a polygon or spline is combined with an energy function which will determine its shape and position. The energy function consists of two parts:

$$J = J_{\text{int}} + J_{\text{ext}}$$

J_{int} is the internal energy which purely depends on contour properties like length, compactness, or smoothness. For compactness, the internal energy J_{int} can be formulated as:

Robot-Based Automation on the Nanoscale, Fig. 3 Tip of a microgripper tracked with correlation tracking

$$J_{\text{int}} = \frac{L^2}{A}$$



The second part is the external energy, which depends on the image content or image features. Possible implementations of this evaluate the distance to edges or the region statistics. The energy function is minimized for each frame by applying transformations to the contour. These transformations can be either single point translations or Euclidean transformations of the whole contour.

Figure 4 shows an active contour tracking an object in SEM images.

Using single point translations, deformable and nonrigid objects can be tracked, but occlusion is problematic. Using Euclidean transformations of the entire contour, the algorithm is robust against occlusion at the expense of trackability of deformable objects. Using these kinds of algorithms, full automation of nanohandling applications has been performed.

Three-Dimensional Position Determination

A difficult issue with image-based position determination using SEM images is the extraction of the third dimension. Any setup used for nanohandling and nanomanipulation is essentially a three-dimensional one, which means that in many cases, a two-dimensional position extracted from an image is insufficient for reliable and flexible automation. Several approaches exist to solve this problem:

Robot-Based Automation on the Nanoscale, Fig. 4 Object tracked with active contours in SEM images

- Restrict the setup or degrees of freedom to a plane, which is an unpractical solution.
- Use different image sources to enable depth estimation from multiple views. This includes the usage of additional microscope cameras to roughly estimate the information missing in the SEM image, as well as the use of beam deflection mechanisms to acquire SEM images from different angles [3].
- Use models of the SEM image generation and the lens distortions to extract the third dimension. This has been successfully done with smaller magnifications by [9].
- Use additional information from the images, such as defocus [20] or shadow to estimate the missing information or at least determine if the object or tool is at the desired location in space.

All these approaches have different advantages and disadvantages. Restricting the setup or degrees of freedom as mentioned has the advantage that no additional measures are needed to deal with the three-dimensional problem. This restricts the possibilities for handling and manipulation to an unacceptable extent. The use of different sources may deliver everything from rough estimates in case of microscope cameras to very precise (nm resolution) measurements in case of well-designed stereo imaging SEMs or SEM/FIB combinations. Drawbacks here are the reduction in speed when using stereo SEM and the complex correspondence problem in very dissimilar images when using a camera or the SEM/FIB combination. The use of models for the SEM imaging has produced quite good results, but depends strongly on the accuracy of the imaging model and on the accuracy of the rigid body model of the object which is tracked. This restricts the application to some extent to objects for which a model can be assumed, and to a certain parameter range of the SEM imaging. The use of additional information from the image mainly concentrates on defocus and shadow. Using defocus of objects can deliver an accuracy up to 5 μm using time-consuming focus sweeps, and it can also be used to estimate the out-of-focus displacement and therefore the position of any object for a given frame, but with reduced accuracy and reliability. This is partly due to the complex nature of the electron beam optics and the high number of factors influencing the image, especially image and object sharpness.

Position Control Inside SEM

A common challenge for the automation of handling and assembly tasks in the SEM is the precise alignment of two or more objects carried by different robots. Such objects can be wafers with micro- or nanostructured components as well as different tools including grippers, probes, and cantilevers. Dependent on the size of the involved objects, the accuracy of this alignment has to be in the micrometer or even nanometer range. Accuracy in this sense stands for the precision of the relative alignment, that is, a nanoobject needs to be brought precisely into the opening of a gripper. For automated positioning, a closed-loop controller is necessary.

Actuation Types and Motion Principles

To facilitate closed-loop motion control inside SEMs, actuators capable of generating the required resolution need to be designed. Although there are efforts to scale conventional actuators such as electromotors to enable such a resolution, for example, employing backlash-free gears, novel actuation principles are better suited. In general, an actuator capitalizes on a *physical effect* in order to create motion. Most of the currently employed actuators for nanohandling are based on the inverse piezoelectric effect, that is, the controlled deformation of a piezoelectric element using an electric field. Piezoelectric actuators are popular owing to their large forces, high precision, and fast response time. Such actuators can create forces in the kN-range and respond to an input signal within microseconds. Major downsides are the limited deformation of about 0.1 % as well as a strongly nonlinear behavior affected by hysteresis and creep. Other physical effects that are used include electrostatic, thermal, and magnetostrictive actuators as well as shape memory alloys [4].

Piezoelectric actuators can be further categorized into scanning and step-wise actuators. *Scanning actuators* use a backlash-free cinematic structure based on flexure hinges to amplify the relatively small displacements of the piezoelectric elements. Although commercial actuators can reach working ranges of up to 500 μm, the working range is a severe limitation and usually a second actuator is required for coarse positioning. Furthermore, the electric field used for actuation cannot be generated with arbitrary precision and without noise. Thus, there is a trade-off between working range and resolution. *Step-wise actuators* are a solution to overcome these downsides. Instead of amplifying the piezoelectric element's motion using a mechanical structure, the stroke is used to perform small steps. Step-wise actuators have a virtually unlimited working range. Most step-wise actuators are hybrid actuators, so that the piezoelectric element can also be used in a scanning mode to create movements smaller than single steps.

Scanning actuators have the advantage of generating a smooth motion over the entire working range. Furthermore, due to the high force that can be generated by a piezoelectric actuator, very high accelerations and speeds are possible. Another advantage is that a rough knowledge of the actuator's position can be directly derived from the applied voltage. Homing is not required for scanning actuators and even open-loop movements are reliable to a certain extent. A downside is that a scanning actuator always returns to its initial position on power loss. Thus, microrobotic systems have to be designed in a way that this movement cannot result in a severe damage to the employed robots, tools, or objects. Furthermore, the nonlinear characteristics including hysteresis and creep are scaled with respect to the full working range. Thus, these effects have a significant influence and make sensor feedback necessary.

In contrast, step-wise actuators have opposed properties. Their working range is only restricted by the mechanical guides, usually in the centimeter range. They require a sensor because the executed steps are not sufficiently repeatable. Furthermore, dependent on the sensor, homing is required to find the initial location of the actuators. In addition to the large working ranges, major advantages of step-wise actuators are that they do not perform a significant movement if the power is lost and that hysteresis and creep are scaled with the step length.

The most commonly applied step-wise motion principle based on piezoelectric actuators is the stick–slip actuation principle [4]. This principle makes use of the high movement speed and acceleration of a piezoelectric actuator. A mobile part is connected to a piezoelectric actuator mechanically using a contact with a specific friction. If the piezoelectric actuator is deformed slowly, the friction forces the mobile part to perform the same motion. If the actuator is deformed rapidly, however, the inertia of the mobile part keeps it in place and the friction force is overcome generating a net displacement between actuator and mobile part. Alternating slow and rapid deformations into opposite directions generate a step-wise motion over long travel ranges.

Vision-Based Closed-Loop Control

On the macroscale, the location of the manipulated objects in a world coordinate system is either

known from the process design or can be measured by a variety of available sensors. To perform closed-loop positioning, a robot can move to this location with sufficient accuracy using its internal sensors. On the nanoscale, the position of objects has to be derived by processing images of the employed SEM (see section "Real-Time Vision Feedback"). SEMs, however, are designed to create highly magnified images and not to create highly accurate measurements. Thus, the resulting position is often time variant and nonlinear, so that the object's location in a world coordinate system cannot be accurately derived. In addition, the positioning itself has limited accuracy due to the size ratio between the robotic system and the handled objects. Commonly, a robot with a size of a few centimeters is used to manipulate an object with a precision of a few nanometers, that is, the robot is about six orders of magnitude larger than the required accuracy. Effects such as thermally- induced drift and limited mechanical stiffness lead to a nonlinear and time-variant relation between the position measured by a robot's internal sensors and the real position of the robot's tool. Thus, internal sensors are insufficient for reliable nanopositioning.

As known from the macroworld, the limitations of positioning based on internal sensors can be overcome by using the information generated by a visual sensor. Using vision feedback as a sensor for robotic manipulation is promising as it is a noncontact measurement and mimics human behavior. The initial technique, which is still used for most SEM-based positioning, extracts a position deviation from an image and then moves the robot either open loop or based on internal sensors to decrease this deviation. When the robot stops, another image is taken, again extracting and compensating for the deviation. This is called the *look-then-move* approach [10]. Two advantages of the approach are that low throughput rates of image processing are acceptable and that the entire setup can be handled in a quasi-static fashion neglecting dynamic aspects. The effectiveness, however, entirely depends of the accuracy of the visual sensor and the robot's open-loop control.

An alternative is to use the visual feedback as a low-level element in the motion control loop of a robot. This is called *visual servoing* [10]. Two challenges need to be solved to achieve effective visual servoing. First, the image processing needs to be fast. As the available processing power has significantly increased over the recent years, several image processing algorithms can be used for visual servoing. More complex algorithms, however, still require computation times on the order of seconds and do not allow for effective servoing. Second, the dynamic aspects of visual servoing need to be considered. The robot's movement as well as resulting vibrations leads to movement during image acquisition. This movement creates image distortions rendering most of the current image processing algorithms useless. Enabling an effective visual servoing, however, is a necessary step on the way of high-speed micro- and nanohandling viable for industrial application.

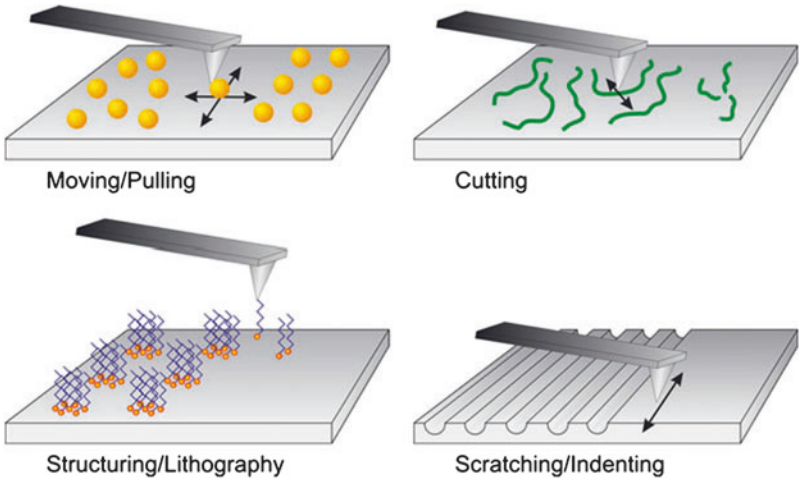
Closed-Loop Control

Based either on an internal sensor or on vision feedback, a closed-loop controller can be implemented. Closed-loop control on the micro- and nanoscale is significantly different from macroscale control [1]. Macroscale control mostly solves challenges arising from the dynamic behavior of systems, for example, inertia. On the micro- and nanoscale, these effects become negligible. As an example, a microrobot might carry a mass m of 30 g and can create a force F of approximately 0.02 N. Thus, its maximum acceleration a is:

$$a = F/m = 2/3\left[\mathrm{m/s^2}\right]$$

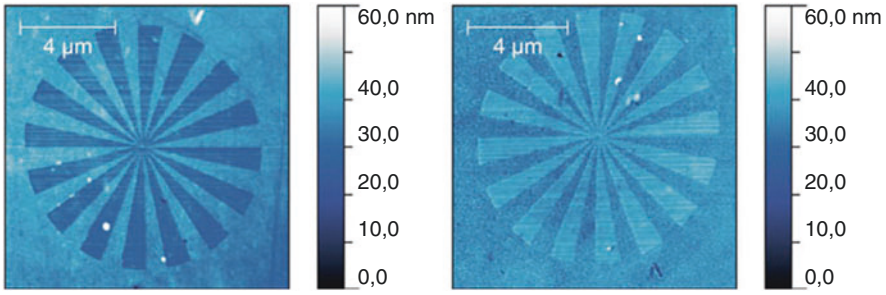
If it needs to accelerate to a velocity v of 500 μm/s, which is high for a micro- or nanooperation, it requires:

$$t = v/a \ = 0.375\ [\mathrm{ms}]$$



This is significantly faster than the update rate of any visual sensor. Thus, acceleration effects can be neglected. Therefore, for many applications and actuator types, a simple proportional controller is sufficient to perform an effective alignment.

AFM as a Nanohandling Robot



Since its development by Binnig, Quate, and Gerber [11], AFM has been increasingly recognized not only as a tool for imaging purposes, but also for manipulating at the micro-, nano-, and atomic scale. The main advantages of the AFM are its high resolution in the sub-nanometer range as well as its flexibility for operating under physiological conditions and in vacuum or liquid environments, depending on the specific application. In addition to its visualization capabilities, the AFM can be used for force spectroscopy and, with functionalized tips, for measuring electric, magnetic, or chemical properties. Moreover, the AFM tip can be used to manipulate objects or materials with nanometric precision and thus the AFM can also be seen as a nanohandling robot. AFM-based manipulation benefits from the fact that the AFM directly measures forces that are exerted during the manipulation and thus gives important feedback on the progress of the manipulation. Potential applications of AFM-based manipulations are manifold, ranging from the fabrication of nanoscale devices, reparation or modification of nanostructures to the characterization and handling of biological samples. Different types of manipulation can be conducted with the AFM including pushing, pulling, cutting, indenting, and structuring of a wide range of materials (Fig. 5).

Starting with unintended manipulations of Au-Clusters, reported 1987 by Baró et al. in [12], the AFM as a tool for manipulating single nanoentities became subject of increasing interest in the research community. A controlled manipulation of nanoscale objects by an AFM has been actively investigated over the last decade. Many publications exist describing the utilization of the AFM as an instrument for manipulating spherical nanoobjects such as gold nanoparticles as well as longish nanoobjects such as carbon nanotubes (CNTs), nanorods, or also biological objects such as DNA [2]. Figure 6 illustrates a successful manipulation of multiwalled CNTs that was conducted by the AFM tip. A commercially available dynamic-mode cantilever was used for both – the image acquisition as well as the manipulation. For imaging, conventional intermittent mode was used, whereas for manipulation the tip was brought into proximity with the surface and then moved laterally to mobilize the CNTs.

To perform a controlled movement of a nanoscopic object, it has to be localized and identified on the substrate first. A major drawback of AFM-based manipulation is the lack of an additional, visual sensor. Therefore, before any manipulation is conducted, the AFM usually has to be utilized to obtain a detailed image of the scenery in order to plan the execution of the manipulation. This imaging scan is most often performed in dynamic mode (intermittent or noncontact) in order to avoid any damage or unintended manipulation of the sample. For the manipulation, the AFM tip is brought into proximity with the object and moved – either in dynamic or contact mode, but without any feedback to control the z-direction – toward a predefined position. As a result, the object is then pushed forward by the repulsive forces. After a manipulation step, reimaging of the area of interest often becomes necessary to reveal the result of the manipulation. The disadvantage of this "look and manipulate" scheme is that the image acquisition process usually needs several minutes depending on the required quality. Moreover, the manipulation itself cannot be monitored by means other than the measured forces exerted by the cantilever and thus have to be performed in a "blind" way. Unfortunately, due to a variety of uncertainties, the results of the manipulation are often not satisfying and require frequent trial and error experiments. Real-time imaging would greatly help to make the manipulation process faster, more robust, and accurate. However, optical microscopy cannot be used as an additional real-time capable imaging method because its resolution does not fit the requirements for the manipulation of objects with nanometric dimensions. An alternative is given by the integration of the AFM into the vacuum chamber of an SEM to allow for real-time observation of the manipulated object and the AFM probe. However, this entails the disadvantage of restriction to vacuum and to some extent conductive sample materials, which is not feasible for many applications.

Robot-Based Automation on the Nanoscale, Fig. 5 Schematic view of manipulation tasks that can be performed by AFM-based robotic systems [1, 2]

Robot-Based Automation on the Nanoscale, Fig. 6 AFM topography star with diameter of 10 µm, fabricated on a gold layer (*left*) using mechanical AFM-lithography and the replica of this structure fabricated on polypropylene (*PP*) using the microinjection molding technique (*right*)

Besides its ability to manipulate nanoscale objects, the AFM tip can also be used to modify surfaces with nanometric precision or to change an object's shape, for example, by scratching, indenting, cutting, and dissecting. For nanomachining purposes, the AFM tip can be exploited as a nanohandling tool in order to act as, for example, a milling cutter, nanoscalpel, or nanoindenter. However, the type of interaction between AFM tip and substrate is not only mechanical, but may also involve chemical, thermal, or electrical impact. Over the last two decades, a large number of promising nanolithographic technologies have evolved and are still emerging that are based on such AFM-based nanomanipulation of surfaces. These techniques can be used among others for mask-free lithography on the nanoscale and provide a promising alternative to conventional technologies. Using AFM-based surface modification, material can either be removed (e.g., through direct mechanical scratching), chemically changed (e.g., resist exposure techniques or oxidation), or deposited (e.g., dip-pen lithography). A detailed review of such SPM-based lithography can be found [13]. An example for a novel process chain for small series production of nanostructures that is based on AFM-based mechanical lithography, which is the most basic type of AFM lithography, was introduced [14]. Figure 7 depicts how the mechanical AFM-lithography is utilized to fabricate a nanostructure that was subsequently replicated several times by means of the microinjection molding technique.

Up to now, the AFM as a robot for the nanomanipulation can only be found in

Robot-Based Automation on the Nanoscale, Fig. 7 Multiwalled carbon nanotubes on HOPG substrate manipulated by the AFM. When moving the AFM tip laterally, the height control loop was turned off in order to avoid slipping of the AFM tip over the CNT. It could be observed that, depending on the parameters chosen for manipulation (tip velocity, damping amplitude), cutting as well as pushing and pulling of the CNTs can be accomplished

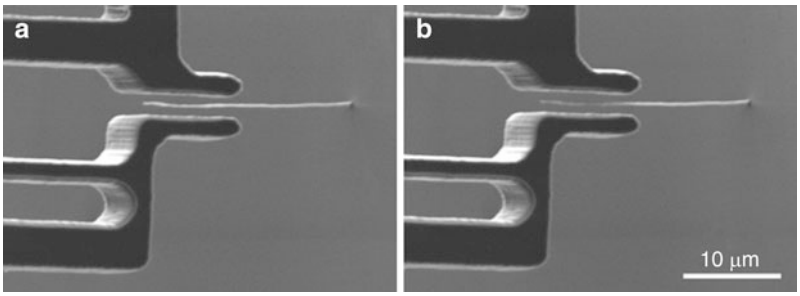
laboratories for prototypical issues. For industry, the serial AFM-based approach is still not reliable and fast enough to be successfully applied for productive use. To increase throughput and reliability of this sequential process, automation can be considered as a desirable goal. To reach this goal, however, a large number of challenging prerequisites have to be fulfilled.

Besides the lack of real-time imaging of the manipulation process discussed above, spatial uncertainties constitute an import error source. Although positioning inaccuracies caused by creep and hysteresis of piezoactuated scanning stages can nowadays most often be compensated by closed-loop operation, thermal drift of the AFM components lead to spatial positioning errors that are challenging to counteract. Solutions to overcome this problem have been addressed [1, 2, 15]. Moreover, sticking effects also play a crucial role in AFM-based nanohandling and therefore, substrate, cantilever, and tip material have to be carefully chosen in order to minimize these effects. A promising strategy that is pursued by several research groups aims at the precise modeling of the nanohandling task. To compensate for the uncertainty introduced by the inevitable "blind" manipulation, a model of the manipulation process is utilized enabling a manipulation in open-loop mode. Having a valid model of the nanomanipulation, including all relevant interactions between nanoobject, tip, and substrate, it is possible to calculate the expected position of the nanoobject during manipulation in real time. Using such a model for an augmented reality system, where a virtual reality is augmented by the calculated nanoworld situation, enables an additional visual feedback. However, this approach requires exact knowledge of the nanomanipulation phenomena, which is not yet available in the current state of nanosciences.

Application Example: Handling of CNT

Nanomaterials such as different kinds of nanowires and especially carbon nanotubes (CNTs) [16] have unique physical properties and can thus improve and enhance existing microsystems in a multitude of applications. Two main application areas have been identified where in particular the integration of CNTs into known microsystems is of high impact: CNT-enhanced AFM probes [17] for the analysis of high-aspect ratio structures and CNT-interconnects in microchip technology [18]. Even though parallel fabrication techniques will be required for a future bulk production of such devices, enabling technologies for the reliable manipulation of individual nanostructures and their prototypic integration into microsystems have to be developed. Automated robot-based assembly techniques are very promising to implement a fast

and systematic prototyping of CNT-based devices. In the following section, a microgripper-based strategy for the automated assembly of CNT-enhanced AFM probes is presented.



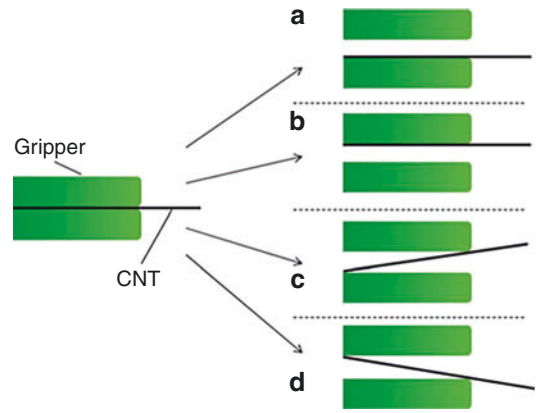
Nanorobotic Strategies for Microgripper-Based Handling of CNTs

In prior experiments, electrothermally actuated microgrippers have already been used for teleoperated pick-and-place handling of individual CNTs [19]. The CNTs used for the experiments have a typical diameter of 200 nm and are grown vertically aligned on a substrate with a spacing of 50 μm between nanotubes. In order to automate the microgripper-based handling of CNTs, special nanorobotic strategies have been developed. Most important are methods for the z-approach of gripper and CNT and for the reliable gripping and placing of CNTs that lead to a well-defined system state.

Methods for z-Approach of Microgripper and CNT An AMNS has been developed that can be integrated into the SEM [2], so that visual feedback from the microscope is available during the nanohandling tasks in addition to the integrated sensors of the positioning systems. Image processing algorithms for object recognition and tracking have been developed (compare section "Real-Time Vision Feedback") providing the x, y-position of gripper and nanotube. This two-dimensional position information can be used to automate the approach in x,y-direction. However, to receive information on the gripper's and CNT's relative z-position, additional contact sensors or three-dimensional systems are required. Such systems cause additional costs and reduce the available space within the SEM's vacuum chamber [20].

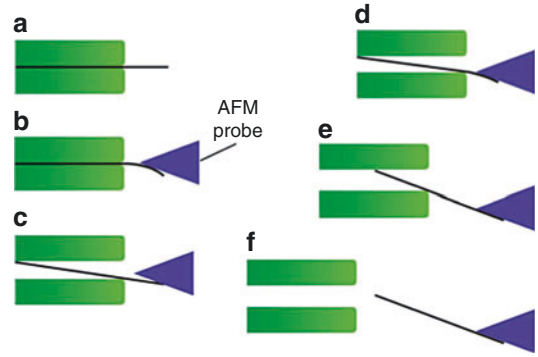
A novel so-called shadow-based depth detection method has been developed that, together with the focus information of the SEM, facilitates the automated z-approach of microgripper and CNT in any available SEM. First of all, the "depth-from-focus" technique [20] is used to coarsely align both objects in z-direction down to 50 μm. Then, for the fine approach of gripper and CNT, a shadow can be detected as soon as the CNT is located exactly between the gripper jaws. The gripper jaws block the secondary electrons from the detector. Figure 8 shows SEM images illustrating the shadow-based depth detection method. The clearly detectable shadow on the CNT in Fig. 8b is used as a stop criterion for the z-approach.

Gripping and Removing CNTs from the Growth Substrate Different gripping techniques for the reliable picking and removing of individual CNTs that are grown on a silicon substrate by chemical vapor deposition (CVD) have been discussed in [21]. The so-called shear gripping technique has been identified as the most reliable approach, requiring smaller gripping forces compared to tensile gripping. The microgripper is closed around the nanotube and



Robot-Based Automation on the Nanoscale, Fig. 8 Shadow-based depth detection for the alignment of microgripper and CNT in z-direction. (**a**) CNT is located below the gripper jaws, no shadow is detectable. (**b**) CNT is between the gripper jaws, a shadow is clearly visible

moved sideways to break the CNT off the substrate. After that, the gripped CNT can be transferred to the target structure.



Placing and Releasing CNTs on the Target Structure A novel handling strategy for placing and releasing CNTs onto the target structure has been developed. This strategy relies on the adhesion forces between CNT and microgripper jaws and thus avoids the need of additional joining techniques. After reopening the microgripper, the nanotube can be oriented in four different configurations. Either the CNT is connected by a line contact to one gripper jaw (see Fig. 9a, b) or the CNT is connected by two-point contacts to the gripper jaws (see Fig. 9c, d).

In case of the two-point contacts, the adhesion forces are smaller compared to the line contacts. For this reason, the two-point contact is preferred in order to easily place and release the CNT on the target structure. In addition, obtaining a well-defined system state after reopening the gripper is required to allow full automation of the placing and releasing process. For the automated microgripper-based mounting of an individual CNT onto the tip of an AFM probe, the strategy shown in Fig. 10 has been developed.

The closed microgripper holding the CNT (Fig. 10a) is approached to the tip of an AFM probe until a bending of the nanotube can be detected (Fig. 10b). This bending is detected automatically and used as the stop criterion of the z-approach. At the same time, the exerted force assures that CNT and gripper jaws are forming a two-point contact with defined orientation after reopening the microgripper (Fig. 10c). After this, the CNT is moved toward the AFM tip until a line contact is achieved (Fig. 10d). Because the adhesion forces of the line contact between CNT and AFM tip are much higher than the forces of the two-point contacts between CNT and gripper jaws, the nanotube can be easily released from the gripper jaws by retracting the microgripper (Fig. 10e–f).

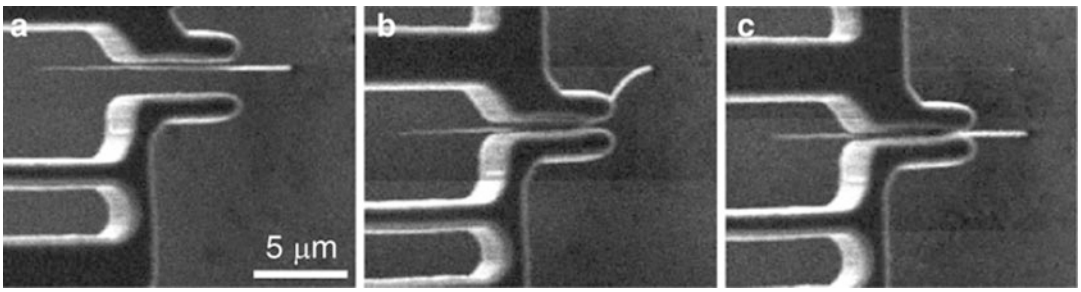
Automated Assembly of CNT-Enhanced AFM Probes

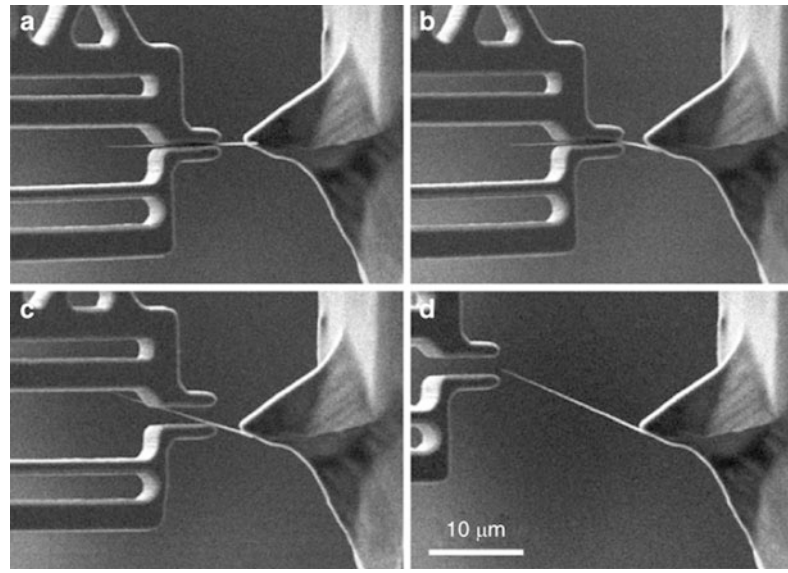
The position control techniques described in section "Position Control Inside SEM" have been used to fully automate the nanohandling task of mounting a CNT onto the tip of an AFM probe. For this purpose, the whole automation sequence has been divided into three subsequences: The initialization process, the gripping and removing process, and the process of placing and releasing the CNT. In the following, these three subsequences are described in detail with respect to automation purposes.

Initialization Sequence The first step of an automated robotic micro-nano-integration is the



initialization. For this purpose, all actuators are moved to a well-known starting position and the coordinate system of the internal position sensors are mapped to the coordinates of the SEM image. Then, the electrothermal microgripper mounted to the mobile microrobots is calibrated. A pattern of the microgripper is recorded that allows for tracking the position of the gripper by applying cross-correlation algorithms to the SEM images (compare section "Real-Time Vision Feedback"). After this, the CNT substrate is scanned automatically to index all CNTs. For each CNT, length and orientation are checked as a quality criterion and only the positions of suitable CNTs are stored to the database. Finally, the AFM probes are indexed by saving the exact position of the probes' tips to the database.

Picking Sequence As described in section "Gripping and Removing CNTs from the Growth Substrate", the shear gripping technique is used to grip and remove an individual CNT from the sample substrate. Figure 11 shows SEM images of the gripping sequence illustrating the process of breaking the CNT off the substrate. First, so-called coarse and fine positioning steps are performed placing the CNT between the gripper jaws (see Fig. 11a). Second, the microgripper is actuated and the CNT is detached by moving the gripper sideways (see Fig. 11b). Third, the gripped CNT can be transferred to the target structure.



Placing Sequence For the automated placing of the CNT onto the tip of an AFM probe, the nanorobotic strategy described in section "Placing and Releasing CNTs on the Target Structure" is used. Figure 12 shows SEM images of the automated placing sequence. After the coarse and fine approach between CNT and AFM probe has been realized in x,y-direction (see Fig. 12a), the final z-approach is performed until a bending of the CNT is detected (see Fig. 12b). Then, the gripper is reopened and a two-point contact between CNT and gripper jaws as well as a line contact between CNT and AFM probe tip is established (see Fig. 12c). Finally, the CNT can be easily released from the gripper jaws and placed onto the tip of the AFM probe by retracting the microgripper (see Fig. 12d).

Application Example: Handling of Biological Materials

Current research areas in molecular and cell biology, medicine, and process sensor technology (sensor systems monitoring various processes in industry and science) often require advances in the nanoengineering technologies to look for molecular phenomena with the highest possible resolution in order to enlighten the "black-box" which still shades most metabolic reactions. The aim of present work, starting from current medical problems, is to propose novel studies especially in molecular and cellular microbiology as well as virology with direct applications in medicine and industry, closing the bottom-up cycle. Thanks to advances in micro- and nanofabrication and micro- and nanorobotics, robotic systems which offer the possibility of characterizing and

manipulating biological objects can be developed today. The use of such systems enable new studies of single cell phenomena with nanometer resolution (e.g., studying the local mechanical and electrical properties of single bacteria for characterization and evaluation of the resistance to antibiotics or to the spread of infections) up to complete cell compounds (e.g., studying the mechanical properties of bacterial biofilms) and deepen the appreciation of the processes at the nanoscale. The following section will give a brief overview of the handling of biological objects using automated AFM-based approaches.

Manipulation and Handling of Biomaterials Using Atomic Force Microscopy

Section "AFM as a Nanohandling Robot" has already shown the basics of the AFM for the automated handling of nanoscale materials. In this subsection, a brief overview of the differences for biomaterials is given.

For characterization or manipulation, samples have to be immobilized on an adequate substrate. A common method is the immobilization on freshly cleaved mica. Mica has a hydrophilic, charged surface that binds proteins and other biomolecules easily. Occasionally, mica is treated with buffer systems, which change the charging of the surface. Gold substrates can also be used if coated with protein reactive monolayers.

The characteristics of the used cantilevers are determined by material, tip shape, and mechanical parameters such as spring constant, resonant frequency, and Q factor. For biological applications, cantilevers are usually made of silicon or silicon nitride. These materials are chemically inert and can be doped to induce electrical charges. Soft cantilevers ($C < 1$ N/m) are used for the contact mode and hard cantilevers ($C \approx 42$ N/m) are used for the tapping mode. If operated in liquids, the pH value and the presence of electrolytes influence the forces between tip and sample. Although a smaller tip radius results in more accurate images, it may be advantageous for soft biological samples, to use a duller tip reducing the risk of accidentally damaging the sample.

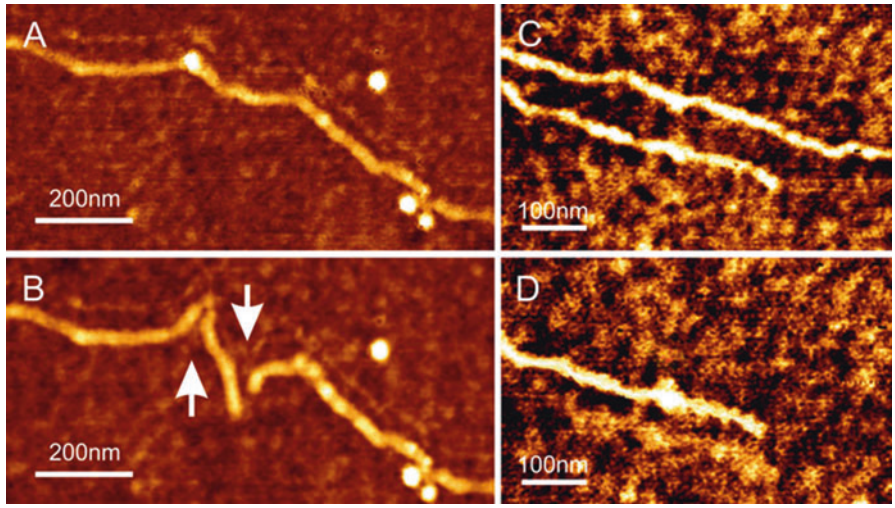
Compared to other methods (e.g., optical tweezers, dielectrophoresis) the AFM has some major advantages for the handling of biomaterials. The most important points are [1, 2, 22]:

- The AFM can be used in liquids, in vacuum, and at ambient conditions meaning that biological samples can be characterized and manipulated at their necessary physiological conditions. Furthermore, living samples and

their reaction to mechanical stimulation can be studied.
- The AFM can be used for imaging as well as for manipulation nearly at the same time.
- The possible resolution lies in the sub-nanometer range.
- Three-dimensional topological information can be obtained.
- No special preparation methods are necessary.

However, compared to the other methods AFM-based manipulation entails major drawbacks and limitations. Knowing these limitations is important to choose the right method or tool to handle or characterize a specific sample. The most important limitations are:

- A three-dimensional force measurement is not yet possible.
- The scanning speed is generally too low for real-time mapping.
- The scanning range for high-speed AFMs is still very low (about 3×3 µm).



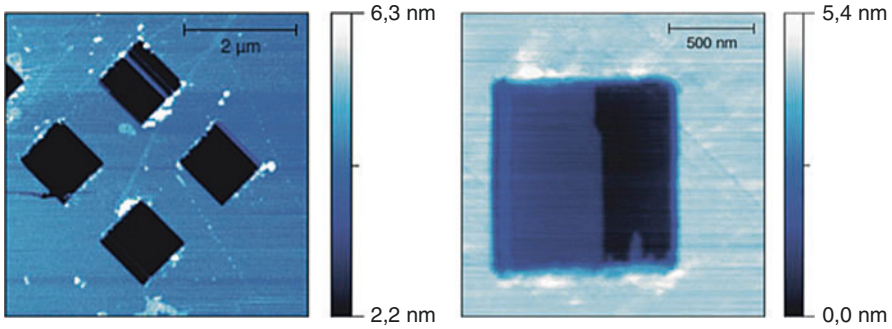
Examples of Automated Handling of Biomaterials with an AFM

In the following sections, current work on the field of handling, characterization, and manipulation of biomaterials is described. Current research mainly deals with the development of fully automated solutions for handling and manipulation of DNA, for solving of packaging problems in the future of nanoelectronics, and for structuring of biosensors for medical and forensic use.

Handling and Manipulation of DNA In accordance with the progressing miniaturization of electric circuits, new ways to realize smaller channel widths are needed. To overcome the limitations of silicon-based processing, the use of objects like CNTs or biomolecules like DNA is a promising solution. Nanowires produced via the metallization of DNA are promising candidates for nanoelectronic devices of future generations. DNA can be considered a basic building block for nanostructure fabrication because it provides unique self-recognition properties. DNA constitutes an ideal template for the organization of metallic and semiconductor particles into wire-like assemblies. Nanoscopic (thickness below 10 nm) and regular wire-like metallic structures can be efficiently produced because DNA molecules have a diameter of only two nanometers and a length in the micrometer range. Moreover, both the ends of DNA molecules and the surface of solid substrates can be functionalized through a variety of methods to create specific links between DNA and substrate, allowing for the integration of DNA molecules into specific, predefined sites of microstructured electronic circuits. By exploiting the specific recognition of complementary nucleotide sequences, complex structures made of DNA can be fabricated and metalized at a later stage. Packaging problems of next-generation nanoelectronics technologies, (e.g., single-electron transistors, quantum automata, molecular electronics, etc.) might also be addressed by using DNA strands.

Recently, many researchers have proven the feasibility of DNA manipulation by an AFM tip, primarily in liquid conditions. The next step toward high-throughput fabrication is automation of DNA handling. Figure 13 show two alternative immobilization procedures of DNA, which offer the potential of automated DNA manipulation in dry ambient conditions. Figure 13a shows a topographic scan of a DNA strand. The height of the DNA strand is about 1.5 nm. Figure 13b shows the same DNA strand after several manipulations by the AFM cantilever tip. The DNA was manipulated and successfully moved about 25–100 nm. Figure 13c, d shows an experiment to demonstrate the transport of DNA. Two separate DNA strands are shown. The upper DNA strand (Fig. 13c) was moved by several AFM strokes up to 300 nm. As a result, this DNA strand was removed from its location (Fig. 13d), without affecting the position of the lower DNA.

The presented methods for the handling of biomaterials show the potential for different usage scenarios in industry and scientific research. In case of the handling of DNA, the experiments demonstrate that a DNA manipulation and handling can be performed in dry ambient conditions.



Robot-Based Automation on the Nanoscale, Fig. 13 (**a**, **b**) DNA immobilized on silicon without surface modifications (**a**) and the same DNA after the manipulation process (**b**). On the *left* side of the strand, two short distance movements from *bottom* to *top* were implemented. As a result, the corresponding DNA parts have been pushed about 25 nm. On the *right* side, two long distance movements were implemented, resulting in DNA displacement by 100 nm. (**c**, **d**) DNAs immobilized on silicon without surface modifications (**a**) and the same substrate with *upper* DNA strand pushed away on the surface by the AFM tip, without affecting the *lower* strand (**b**)

Automated Structuring of Biological Materials for Biosensors Biosensors consist of a sensitive biological component, a transducer, or detector element, and associated electronics or signal processors. An accurate and well-defined preparation of the sensitive components made, for example, of microorganisms, cell receptors, proteins, enzymes, anti-bodies, or nucleic acids is crucial part of the sensor design. Commonly used methods are microstamping and microprinting, both of which are unable to decrease the structures of the biological component down to the nanometer range. However, higher density is necessary to increase the measurement accuracy and the number of different, simultaneously useable biocomponents. In this section, current work on automated design of high-density sensitive components using AFM-based lithography is introduced.

The compensation of spatial uncertainties plays an important role in automation of AFM-based handling. Although the effects of hysteresis and creep of the PZT-based scanner can be reduced by closed-loop control, spatial uncertainties caused by thermal drift are crucial and less straightforward to deal with. Especially in life science applications, where the AFM is often operated in humid environments, the effect becomes strong and often prevents successful nanohandling, let alone automation of the handling task. To achieve reliable results, the recently developed method for real-time drift compensation described in section "AFM as a Nanohandling Robot" and in [1, 15] was applied, both for the presented manipulation of DNA as well as for the AFM-based nanotooling described below.

As a first step toward the automated fabrication of biosensor components, rectangular areas were successfully structured into an APTES monolayer on mica (Fig. 14). To further investigate the correlation between the forces applied during manipulation and the resulting machining depths, a series of experiments was performed to scratch multiple areas.

By using the AFM, an automated structuring of biological materials for biosensors can be done.

Robot-Based Automation on the Nanoscale, Fig. 14 Height image of 1 × 1 µm area scratched into APTES monolayer by AFM machining. The two visible machining depths arise from different force set points used during the processing (*left*) and AFM height image of a series of 1 × 1 µm sized scratched areas (*right*)

The automation of the necessary processes will also lead to a feasible industrial use, as well as for clinical and research laboratories. The size of the resulting structures correlates with the resolution of the commonly used read-out techniques such as fluorescence microscopy or surface plasmon resonance spectroscopy.

Future Trends

In the future, closed-loop motion control in SEMs needs to be changed from the quasi-static look-then-move-approach to an effective visual servoing in order to implement high-speed micro- and nanohandling viable for industrial application. Furthermore, to allow for a more effective avoidance of both collisions and vibrations, the commonly implemented position control needs to be extended to trajectory control so that the robot moves with a predetermined velocity, acceleration and jerk at all times. Considering visual feedback, an important future task is to enable more reliable and faster feedback especially in case of fast moving objects, because of the artifacts and distortions generated by the object movement. Also speed, accuracy, and resolution of the z-position estimation still is a topic where significant improvements can be made.

The AFM has emerged as an important tool for the fabrication of nanoscale structures, as well as the handling and manipulation of biological objects and for the manipulation of nanoscale objects. To broaden the applicability of those techniques for productive use, it will become necessary to increase throughput significantly. For the lithographic techniques used to structure surfaces, the usage of multiple AFM tips in parallel will greatly enhance throughput. To speed up the assembly of individual nanoentities, achieving a high level of automation is an important research goal for the future. Further miniaturization of gripping tools can facilitate the nanorobotic pick-and-place handling of CNTs with smaller diameters. The optimization of the presented automated assembly sequence of CNT-enhanced AFM probes will lead to a high-throughput prototyping of CNT-based devices, which is an important pre-stage toward a direct integration of CNTs into microstructures by CMOS-compatible CVD-based fabrication techniques.

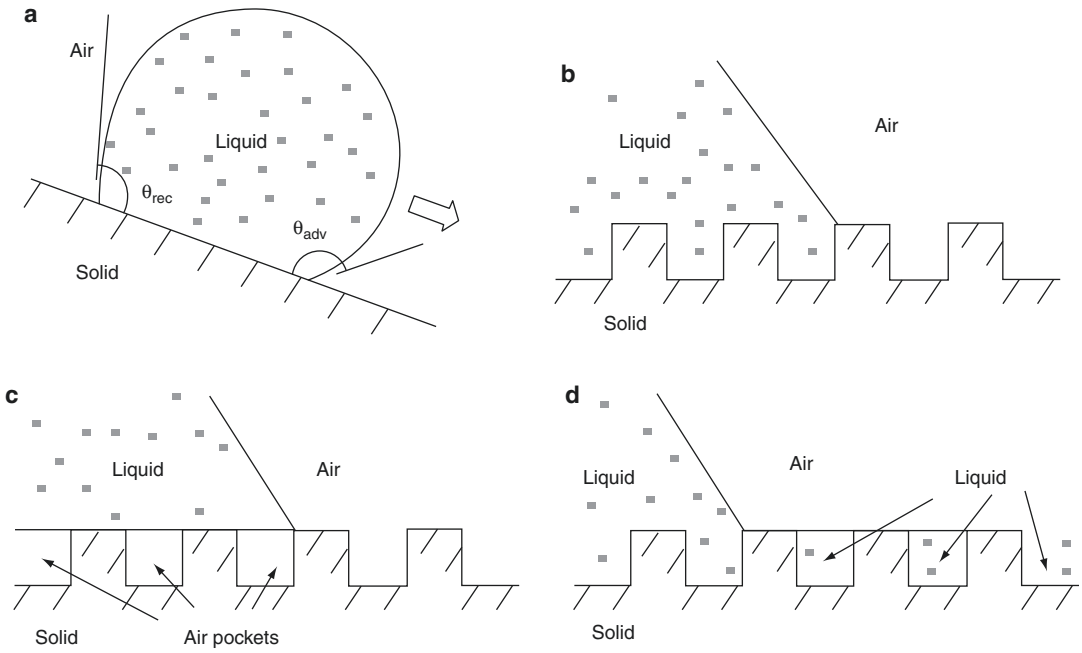
Petal effect



Definition

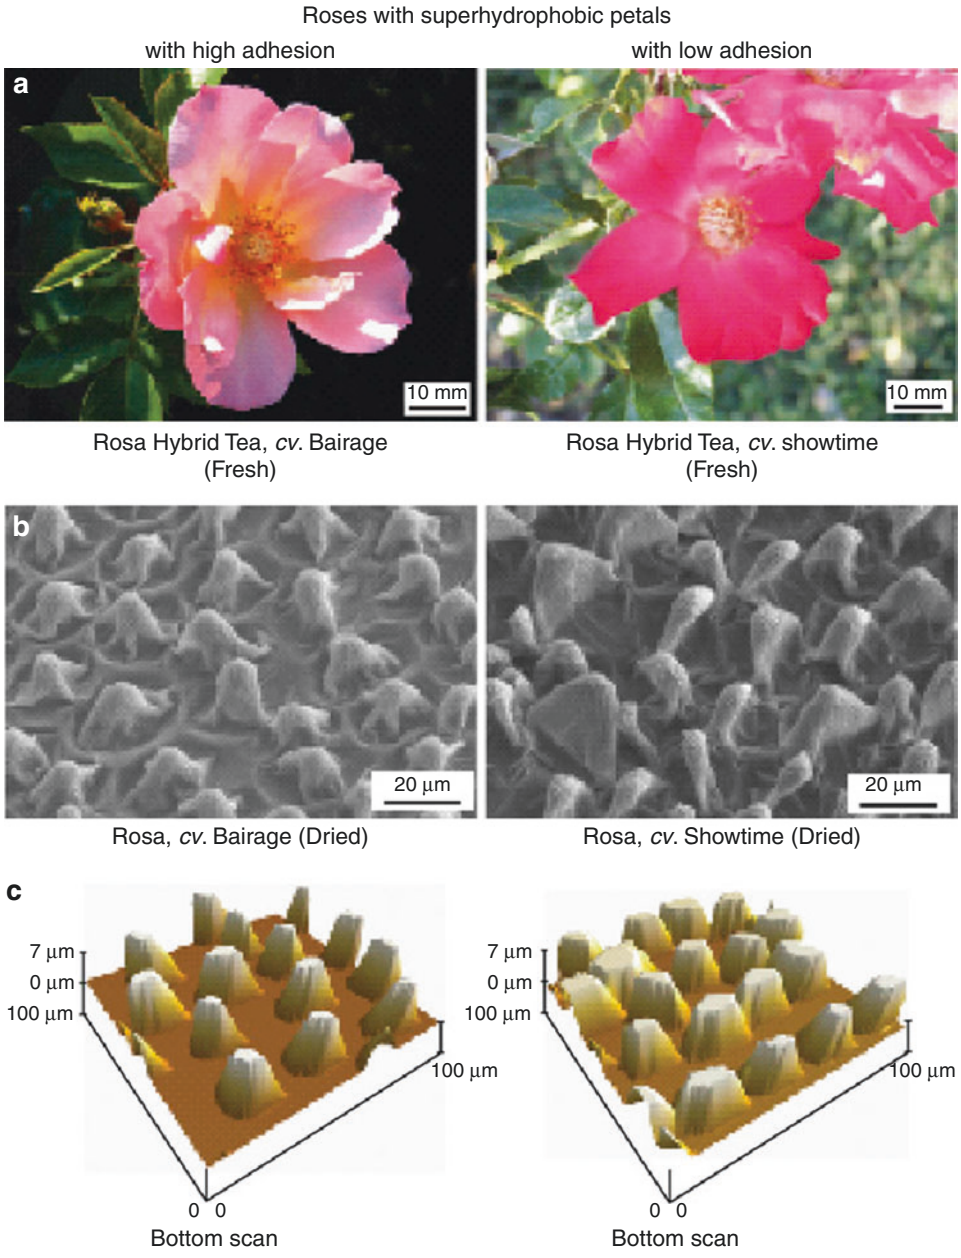
Rose petal effect is the ability of certain rough surfaces to have a high contact angle with water simultaneously with high adhesion (large contact angle hysteresis) with water.

Theoretical

Recent experimental findings and theoretical analyses made it clear that the early Wenzel [1] and Cassie and Baxter [2] models do not explain the complexity of interactions during wetting of a rough surface which can follow several different scenarios. As a result, there are several modes of wetting of a rough surface, and therefore, wetting cannot be characterized by a single number such as the contact angle (CA). Contact angle hysteresis (the difference between the advancing and receding CA) is another important parameter which characterizes wetting (Fig. 1).

Wetting of a solid is dependent upon the adhesion of water molecules to the solid. On the one

Rose Petal Effect, Fig. 1 (**a**) Schematics of a droplet on a tilted substrate showing advancing (θ_{adv}) and receding (θ_{rec}) contact angles. The difference between these angles constitutes the contact angle hysteresis. Configurations described by (**b**) the Wenzel equation for the homogeneous interface, (**c**) Cassie–Baxter equation for the composite interface with air pockets, and (**d**) the Cassie equation for the homogeneous interface

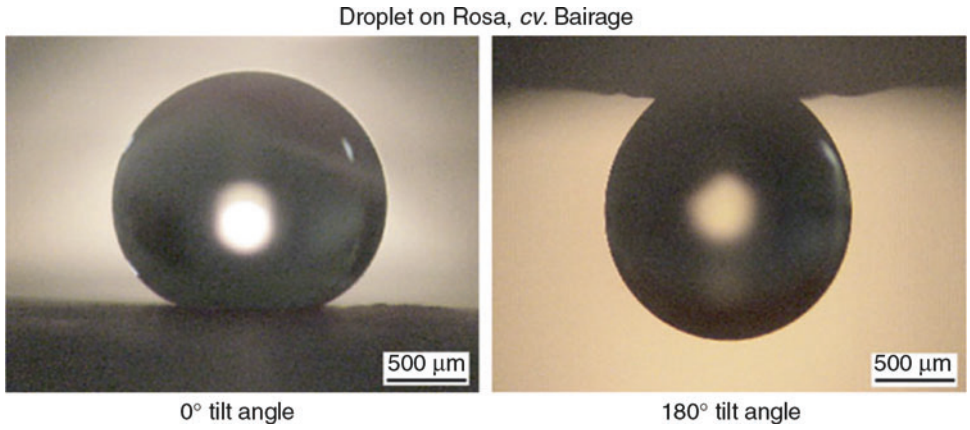


hand, a high CA is a sign of low liquid–solid adhesion. On the other hand, low CA hysteresis is a sign of low liquid–solid adhesion as well. It is now widely believed that a surface can be superhydrophobic and at the same time strongly adhesive to water [3–9]. The so-called petal effect is exhibited by a surface that has a high CA, but also a large CA hysteresis and strong adhesion to water.

Main Findings

Plant leaves and petals provide an example of surfaces with high CA, and high and low CA hysteresis. Bhushan and Her [3] studied two kinds of superhydrophobic rose petals: (1) Rosa Hybrid Tea, cv. Bairage and (2) Rosa Hybrid Tea, cv. Showtime, referred to as Rosa, cv. Bairage and Rosa, cv. Showtime, respectively. Figure 2 shows optical micrographs, scanning electron microscopy (SEM) images, and atomic force microscope (AFM) surface height maps of two rose petals. Figure 3 shows a sessile and a suspending water droplet on Rosa, cv. Bairage, demonstrating that it can simultaneously have high CA, high adhesion, and high CA hysteresis.

The surface roughness of the two rose petals was measured with the AFM, and the results for the peak-to-base height of bumps, the mid-width, peak radius, and bump density are summarized in Table 1. The data indicates that the low adhesion specimen (Rosa, cv. Showtime) has higher density and height of the bumps, indicating that the penetration of water between the microbumps is less likely. Wetting of a rough surface with a single level of hierarchy of roughness details can follow several scenarios (Table 2).



For a hierarchical structure with small bumps on top of larger bumps, a larger number of scenarios is available, and they are summarized in Table 3 and Fig. 4. Water can penetrate either into the micro- or nanostructure, or into both. In addition, the micro- or nanostructure can be

impregnated by water or air. The regimes with water penetrating into the microstructure can have high solid–water adhesion and therefore, high CA hysteresis.

Bhushan and Her [3] conducted a series of carefully designed experiments to decouple the effects of the micro- and nanostructures. They synthesized microstructured surfaces with pillars out of epoxy resin. The epoxy surfaces were reproduced from model Si templates and were created by a two-step molding process producing a dual replica (first a negative replica and then a

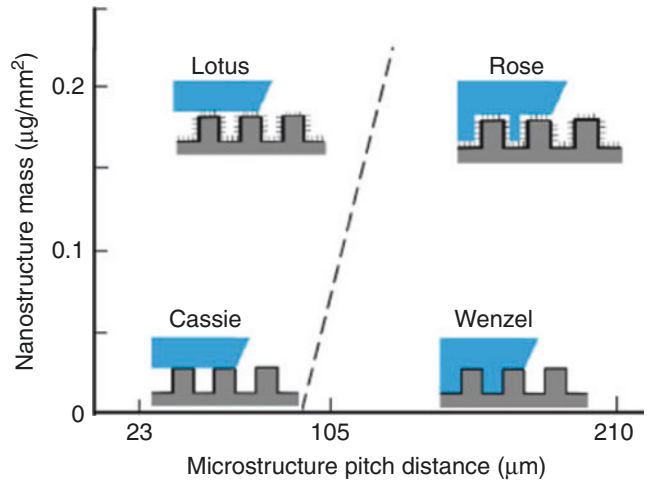
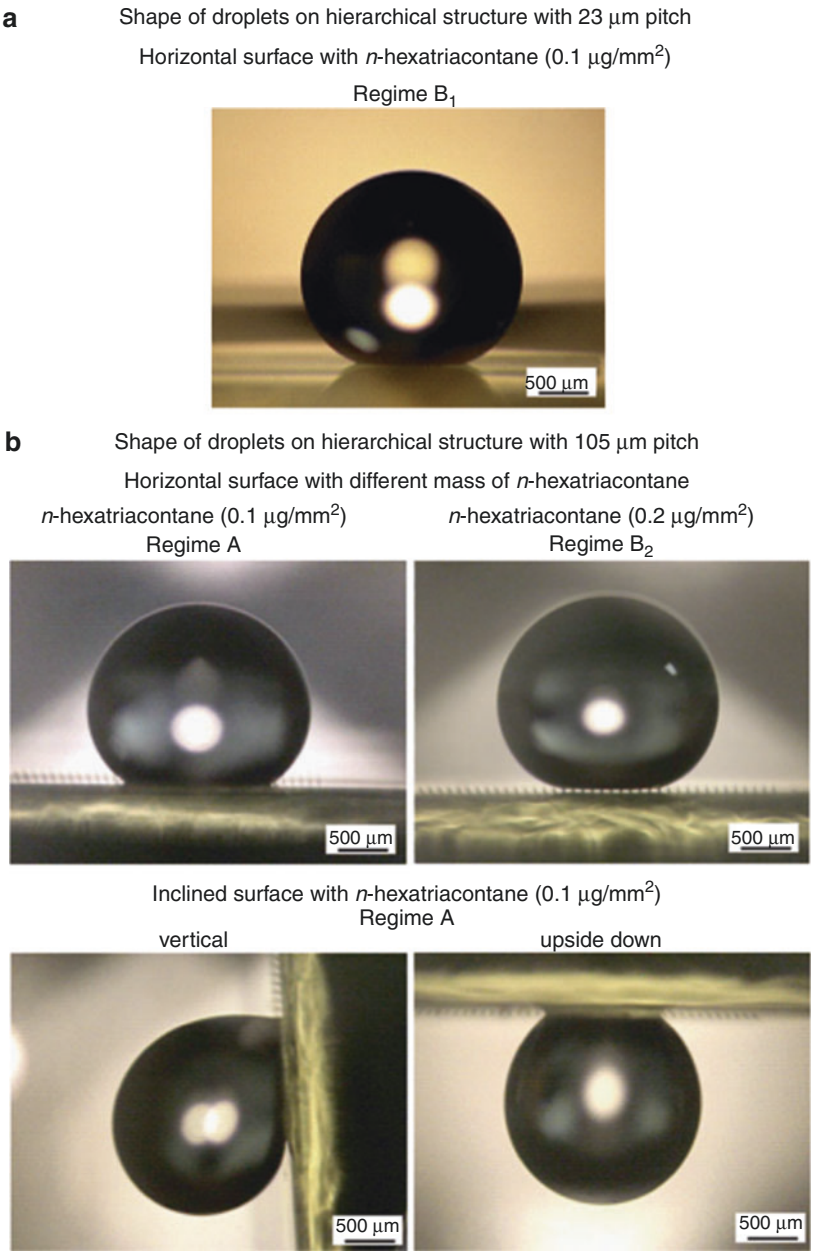
Rose Petal Effect, Fig. 4 Schematics of nine wetting scenarios for a surface with hierarchical roughness

Rose Petal Effect, Fig. 5 SEM micrographs of the microstructures and nanostructures fabricated with two different masses of n-hexatriacontane for hierarchical structure. All images were taken at 45° tilt angle. All samples are positive replicas, obtained from negative replica with dental wax and Si micropatterned master template (14 μm diameter and 30 μm height) fabricated with epoxy resin coated with n-hexatriacontane [3]



R

positive replica of the original Si template). Surfaces with a pitch (the periodicity of the structure of the pillars) of 23, 105, and 210 μm and with the same diameter (14 μm) and height (30 μm) of the pillars were produced. After that, nanostructures were created on the microstructured sample by self-assembly of the alkane n-hexatriacontane ($CH_3(CH_2)_{34}CH_3$) deposited by a thermal evaporation method. Alkanes of varying chain lengths are common hydrophobic compounds of plant waxes. On smooth surfaces, alkanes can cause a large contact angle and a small contact angle hysteresis for water droplets. To fabricate the nanostructure, various masses of n-hexatriacontane were coated on a microstructure. The nanostructure is formed by three-dimensional platelets of n-hexatriacontane. Platelets are flat crystals, grown perpendicular to the surface. They are randomly distributed on the surface, and their shapes and sizes show some variation. Figure 5 shows selected images. When different masses of wax are applied, the density of the nanostructure is changed.



For surfaces with a small pitch of 23 μm, while the mass of n-hexatriacontane is changed, there are only small changes in the static contact angle and contact angle hysteresis values, which means that they are always in the "Lotus" wetting regime. On the surface with a 210 μm pitch value, as the mass of n-hexatriacontane is increased, the static contact angle is increased, and the reverse trend was found for the contact angle hysteresis. This was interpreted as evidence that the nanostructure is responsible for the CA hysteresis and low adhesion between water and the solid surface. The results are summarized in Table 4. The wetting regimes are shown schematically in Fig. 6 as a function of the pitch of the microstructure and the mass of n-hexatriacontane. Small mass of the nanostructure material

Rose Petal Effect, Fig. 6 Schematic of a wetting regime map as a function of microstructure pitch and the mass of nanostructure material. The mass of nanostructure material equal to zero corresponds to microstructure only (with the Wenzel and Cassie regimes). Higher mass of the nanostructure material corresponds to higher values of pitch, at which the transition occurs

Rose Petal Effect, Fig. 7 (**a**) Droplet on a horizontal surface of hierarchical structure with 23 μm pitch and n-hexatriacontane (0.1 μg/mm^2) showing air pocket formation and (**b**) droplet on a hierarchical structure with 105 μm pitch and n-hexatriacontane (0.1 μg/mm^2) and 0.2 μg/mm^2 showing no air pocket and air pocket formation, respectively. Also shown is the image taken on the inclined surface with hierarchical structure with 0.1 μg/mm^2 showing that droplet is still suspended [3]

correspond to the Cassie and Wenzel regimes, whereas high mass of the nanostructure corresponds to the Lotus and Rose regimes. The Lotus regime is more likely for larger masses of the nanostructure material. Figure 7 shows a droplet on a horizontal surface of a hierarchical structure with 23 and 105 μm pitches and n-hexatriacontane (0.1 μg/mm^2). Air pockets are observed in the first case and not observed in the second case, indicating the difference between the two regimes [3].

To further verify the effect of wetting states on the surfaces, evaporation experiments with a droplet on a hierarchical structure coated with two different amounts of n-hexatriacontane were performed. Figure 8 shows the optical

Rose Petal Effect, Fig. 8 Optical micrographs of droplet evaporation on the hierarchical structured surfaces with 105 μm pitch value. n-Hexatriacontane (0.1 μg/mm^2)-coated sample has no air pocket formed between the pillars in the entire contact area until evaporation was completed. Hierarchical structure with n-hexatriacontane (0.2 μg/mm^2) has air pocket, and then the transition from the "Lotus" regime to the "Rose petal" regime occurred [3]

micrographs of a droplet evaporating on two different hierarchical structured surfaces. On the n-hexatriacontane (0.1 μg/mm^2)-coated surface, an air pocket was not visible at the bottom area of the droplet. However, the droplet on the surface has a high static contact angle (152°) since the droplet still cannot completely impregnate the nanostructure. The footprint size of the droplet on the surface has only small changes from 1820 to 1791 μm. During evaporation, the initial contact area between the droplet and hierarchical structured surface does not decrease until the droplet evaporates completely, which means complete wetting between droplet and microstructures. For the n-hexatriacontane (0.2 μg/mm^2)-coated surface, the light passes below the droplet, and air pockets can be seen, so to start with the droplet is in the Cassie-Baxter regime. When the radius of the droplet decreased to 381 μm, the air pockets are not visible anymore. The footprint size of the droplet on the surface is changed from 1177 to 641 μm, since droplet remained on only a few pillars until the end of the evaporation process [9].

The experimental observations of the two types of rose petals show that hierarchically structured plant surfaces can have both adhesive and non-adhesive properties at the same time with high CA. This is due to the existence of various modes of wetting of a hierarchical surface, so that water can penetrate either into macro- or nanoroughness, or into both. Water penetration into the microroughness tends to result in high adhesion with the solid surface, whereas the presence of the nanoroughness still provides high CA. As a result, two distinct modes of wetting are observed. One can be called the "Lotus" mode (with low adhesion) and another is the "rose" mode with high adhesion.

Definition

A scanning electron microscope (SEM) is an instrument that uses high-energy electrons in a raster scan pattern to form images, or collect other signals, from the three-dimensional surface of a sample.

Introduction

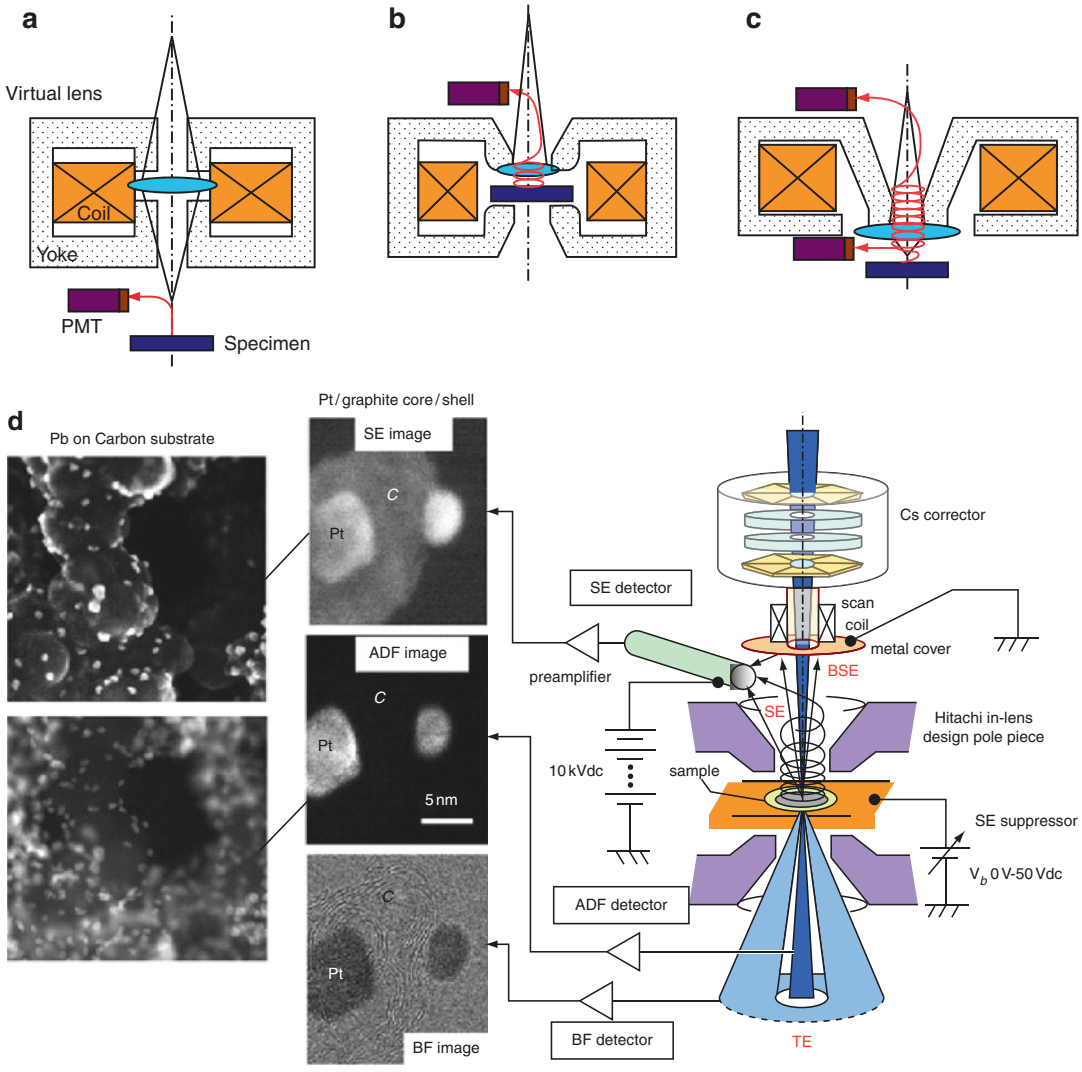
The scanning electron microscope (SEM) is one of the most popular and user-friendly imaging tools that reveal the surface topography of a sample. It is also widely used for structural characterization of materials and devices, especially in the field of nanotechnology. Today there are in excess of 50,000 SEMs worldwide, and it is often seen as a "must-have" apparatus for research institutes and industry laboratories. In the SEM, incident electrons interact with the atoms that make up the sample producing signals that contain information about the sample's surface morphology, composition, and other physical and chemical properties. The most common imaging mode in SEM lies in using secondary electrons. Since secondary electrons have very low energies, they are generated in and escape from regions near the sample surface. Combined with various detection systems, a SEM also can be used to determine the sample's chemical composition through energy-dispersive x-ray spectroscopy and Auger electron spectroscopy and identify its phases through

Scanning Electron Microscopy, Fig. 1 Schematics of configurations of the scanning electron microscopes proposed and developed by some notable pioneers in the SEM history. (**a**) Knoll in 1935, (**b**) Zworykin in 1945, and (**c**) Cambridge Instruments in 1965

analyzing electron diffraction patterns, mostly via high-energy backscattered electrons. Besides backscattered electrons, Auger electrons, characteristic x-rays, and other signals are generated from the interactions of the incident beam, and the sample under a SEM includes plasmons, bremsstrahlung radiation (noncharacteristic x-rays), cathodoluminescence, and electron-beam-induced current. This entry is focused on secondary-electron imaging related instrumentation, signal generation processes, and state-of-the-art imaging capabilities in SEM.

A Brief History

SEM was invented by Max Knoll in 1935 in Germany [1, 2] to study the targets of television tubes. The instrument consisted of electron-beam deflection coils that scan the beam on a plate as the sample in a cathode ray tube (CRT) and an amplifier that boosts the plate current to display the signal on another CRT (Fig. 1a). Two years later, Manfred von Ardenne built an electron microscope with a highly demagnified probe using two condenser lenses for scanning transmission electron microscopy and also tried it as a SEM. Zworykin and his coworkers of the RCA Laboratories in the USA designed and built a dedicated SEM in 1942. Its electron optics includes three electrostatic lenses with scan coils placed between the second and third ones. A photomultiplier was first used to detect secondary electrons (Fig. 1b). The essential components of this apparatus are similar to those used in modern SEMs. The probe size of the incident, or primary, electron beam had a diameter of about 10 nm. However, compared with transmission



electron microscopes (TEMs), at that period, it could not image secondary electrons satisfactorily due to the poor signal-to-noise ratios of the images [3]. Sir Charles Oatley and Dennis McMullan built their first SEM at Cambridge University in 1948. The SEM technology was further pioneered by many postgraduate students at Cambridge including Gary Stewart. The first commercial instrument, named as "Stereoscan," was launched in 1965 by the Cambridge Scientific Instrument Company for DuPont [4]. The instrument consists of electron multiplier detector with beryllium-copper dynodes to detect scattered electrons from the specimen surface. Images were displayed on a CRT, while another synchronized CRT recorded them on camera film. An Everhart-Thornley-type secondary-electron detector [5] significantly improved the detection efficiency of the low-energy secondary-electron signals (Fig. 1c). JEOL produced first commercial Japanese SEM, JSM-1, in 1966, while Hitachi commercialized its SEM, HSM-2, in 1969.

Instrumentation

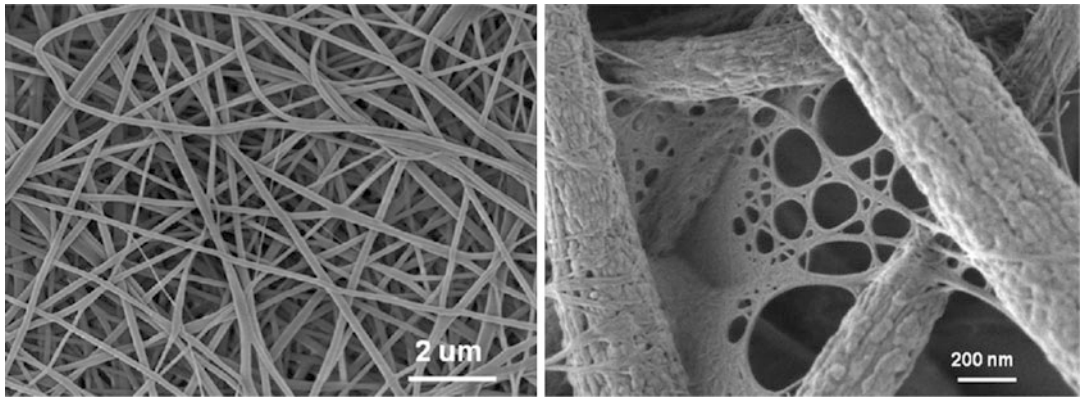
A typical SEM consists of an electron gun, an electron lens system, various electron-beam deflection coils, electron detectors, and display and recording devices [6]. In a SEM, an electron beam is emitted from an electron gun sitting on a thermionic filament cathode, or from a field-emission needle tip. Tungsten is often used for thermionic electron guns due to its low cost, high melting point, and low vapor pressure so that it tolerates heating to about 2,800 K for electron emission. Other types of electron emitters include lanthanum hexaboride (LaB6) cathodes, which offer higher brightness but require a better vacuum to avoid oxidizing the gun. Field-emission guns (FEGs) often used in modern SEMs can be the thermally assisted Schottky type, using emitters of zirconium oxide (ZrO), or the cold cathode type using tungsten <310> single crystal emitters and operated at room temperature. A cold field-emission gun has a much smaller source size (5–10 nm) than a tungsten filament (1–10 μm) with three to four orders of magnitude larger current density and brightness [7].

The typical energy range of the electron beam used in SEM is from 0.5 to 40 keV. The electron-condenser lens system usually demagnifies the electron source more than hundreds of times to form a small probe on the sample. The beam passes through pairs of deflection coils, or scanning coils, in the electron column, typically in the final lens, which deflect the beam in the x and y axes by applying an incremental current into the scan coils, so that it scans in a raster fashion over a rectangular area of the sample surface.

Historically, SEM incorporates an objective lens. Unlike the objective lens in optical microscopes or transmission electron microscopes (TEMs), its purpose in SEM is not to image the sample but to focus the small probe on the sample. There are three types of objective lenses: out-lens (Fig. 2a), in-lens (Fig. 2b), and semi-in-lens (Fig. 2c). Most early SEMs had the simplest out-lens design, in which the sample sits beneath the lens leaving a large area available in the sample chamber. However, the yoke gap across the optical axis acts as a lens with leakage field, thus yielding significant imaging aberration. The in-lens pole piece, originally designed for TEMs, was adopted for SEM to reduce spherical aberration. Hitachi developed the first commercial SEM with such a design in 1985 [8]. Their microscope operating at 30 kV reaches a probe size of 0.5 nm with spherical aberration coefficient C_s of 1.6 mm. The drawback of the design is that a conventional thin sample, similar to that used in TEM, is required because the sample sits inside the pole-piece gap. A design resulting from a compromise between the out-lens and in-lens is the semi-in-lens pole piece (Fig. 2c), offering reasonable spatial resolution but with larger open space for the sample chamber so that a thick sample can be used. Such a design allows the sample to be placed a few mm from the pole piece and a large magnetic field to be applied to produce a smaller focal length and less spherical aberration. SEMs with the semi-in-lens design played a significant role in characterizing devices for the semiconductor industry in early 1990s.

Scanning Electron Microscopy, Fig. 2 (**a**–**c**) Three different objective lens designs. (**a**) Out-lens, (**b**) in-lens, and (**c**) semi-in-lens. (**d**) Schematic of the lens detector configuration of the aberration-corrected scanning electron microscope, Hitachi HD2700C, that routinely achieves an atomic resolution in imaging using secondary electrons and transmitted electrons. Two examples are shown on the *left*; one is Pb particles on a carbon support, and the other is Pt particles with carbon-graphite shells. *BF* bright-field, *ADF* annular dark-field, *SE* secondary electrons, *TE* transmitted electrons, and *BES* backscattered electrons. The SE images clearly give a topographic view of the area and higher brightness of the light element C, compared with the corresponding ADF images

It is noteworthy that the in-lens design shown in Fig. 2b is very similar to that used in conventional TEM and/or STEM (scanning transmission electron microscope). Thus, with an efficient secondary-electron detector, a TEM or a STEM also can image a sample surface [9, 10]. Figure 2d shows a schematic of the objective lens (in-lens design), the sample, and the arrangement of detectors in the Hitachi HD2700C aberration-corrected SEM/STEM [11]. The instrument operates at 80–200 kV, allowing simultaneous acquisition of bright-field (BF), annular dark-field (ADF), and secondary-electron (SE) images. In the BF and ADF modes, the transmitted electrons are used



to form the images, thus providing structural information from the sample's interior. In contrast, in the SE mode, electrons emerging from the surface with low energies, or short escape length, are used, and thus, the signals are surface sensitive. Different imaging modes have their own advantages and limitations. Since the BF signals are close to the phase contrast seen in TEM, they offer high spatial resolution, but are difficult to interpret. ADF images, on the other hand, are based on Rutherford scattering, and thus, their image intensity is directly related to the sample's atomic number Z (the so-called Z-contrast imaging). Since BF and ADF images are projected images, they give little structural information in the direction of the beam's trajectory. In contrast, SE imaging offers depth information on the surface topography and is more sensitive to the light elements than is ADF imaging (see Fig. 2d). Combining these different imaging modes in an electron microscope with an in-lens design, it has been demonstrated that simultaneously imaging both surface (SE) and bulk (ADF) at atomic resolution is possible in thin samples for a wide range of elements, from uranium and gold to silicon and carbon [11, 12].

The electron detector is another important part of the SEM instrumentation. Although detector itself does not determine the image resolution in SEMs, it is essential to improve the SEM resolving power in terms of the signal-to-noise ratio. The commonest detector used in SEMs today still is that developed by Everhart and Thornley in 1957 [5], the so-called E-T detector. The detector consists of a photomultiplier, a light guide, and a positively biased scintillator. To attract low-energy electrons effectively, the scintillator is applied in a 10 kV dc bias to accelerate the electrons. The energized electrons cause the scintillator to emit flashes of light (cathodoluminescence) that then are transmitted to the photomultiplier. The amplified output of the electrical signals by the photomultiplier is displayed as a two-dimensional intensity distribution that can be viewed and photographed on an analogue video display. The Everhart-Thornley detector, which normally is positioned to one side above the specimen, exhibits low efficiency in detecting backscattered electrons because few such electrons are emitted in the solid angle subtended by the detector. Furthermore, its positive bias cannot readily attract the high-energy backscattered electrons (close to the energy of the incident electrons). Backscattered electrons are usually collected above the sample in a "doughnut-type" arrangement, concentric with the electron beam, to maximize the solid angle of collection.

Secondary-Electron Signal Generation

Secondary-electron (SE) imaging is the most frequently used mode of imaging in SEM. Secondary electrons, defined as the electrons with energy below 50 eV, are generated along the primary electrons' trajectories within the sample, but are subject to elastic and inelastic scattering during their passage through the sample. These electrons can be valence electrons or are ejected from the orbits of the inner shells (most likely the k-shells) of the sample. The consequence of their low kinetic energy is their shallow escape depth, which is about 1 nm for metals and up to 10 nm for insulators. The probability of escape decreases continuously with the increase of the depth below the surface. However, there is a nonzero probability of secondary-electron emission arising from inelastic scattering below the escape depth, as, for example, when a primary electron creates a fast secondary electron (energy > 50 eV) that travels toward the surface and generates a lower-energy secondary electron within the escape depth. The production of the secondary electron signals involves the generation, propagation, escape from the surface, and arrival at the detector. These four processes are detailed in the atomic imaging section.

The secondary electrons discussed here are often referred to as SE_I, i.e., the secondary electrons generated by the incident beam upon entering the sample. Secondary electrons generated by backscattered electrons when leaving the sample are termed SE_{II}. Secondary electrons generated when the backscattered electrons strike a lens pole piece or the sample chamber's wall and by primary electrons hitting the aperture are, respectively, called SE_{III} and SE_{IV}. Although SE_{III}

Scanning Electron Microscopy, Fig. 3 SEM micrographs of a polymer membrane that consists of electrospun fibrous scaffold for water filtration. The fibrous scaffold has an average diameter of 200 nm. The high-resolution SEM image on the *right* shows that cellulose nanofibers (5–10 nm in diameter) infused into the scaffold form a cellulose network to enhance the membrane's ability to remove bacteria and viruses. The images were taken with JEOL7600 SEM at operation voltage of 0.5 eV. A thin layer of carbon was coated on the sample to avoid charging. Note the bright contrast at the edge of the fibers generates a topological view of the fibrous structure

contain the information on the sample, SE_{IV} do not. Furthermore, there are fast secondary electrons, with energy higher than 50 eV. Bias experiments, wherein a positive dc voltage is applied to the sample to suppress the emission of the secondary electrons, were mainly designed to separate the SE_I from backscattered electrons; they cannot distinguish SE_I from SE_{II}, which for a very thin specimen should be negligible. Measuring other types of secondary electrons, including those with high energy, would require a different bias experiment. Heavy elements (high atomic number) that backscatter electrons more strongly than do light elements (low atomic number), and thus appear brighter in the image, can be used to yield contrast that contains information of a sample's chemical composition.

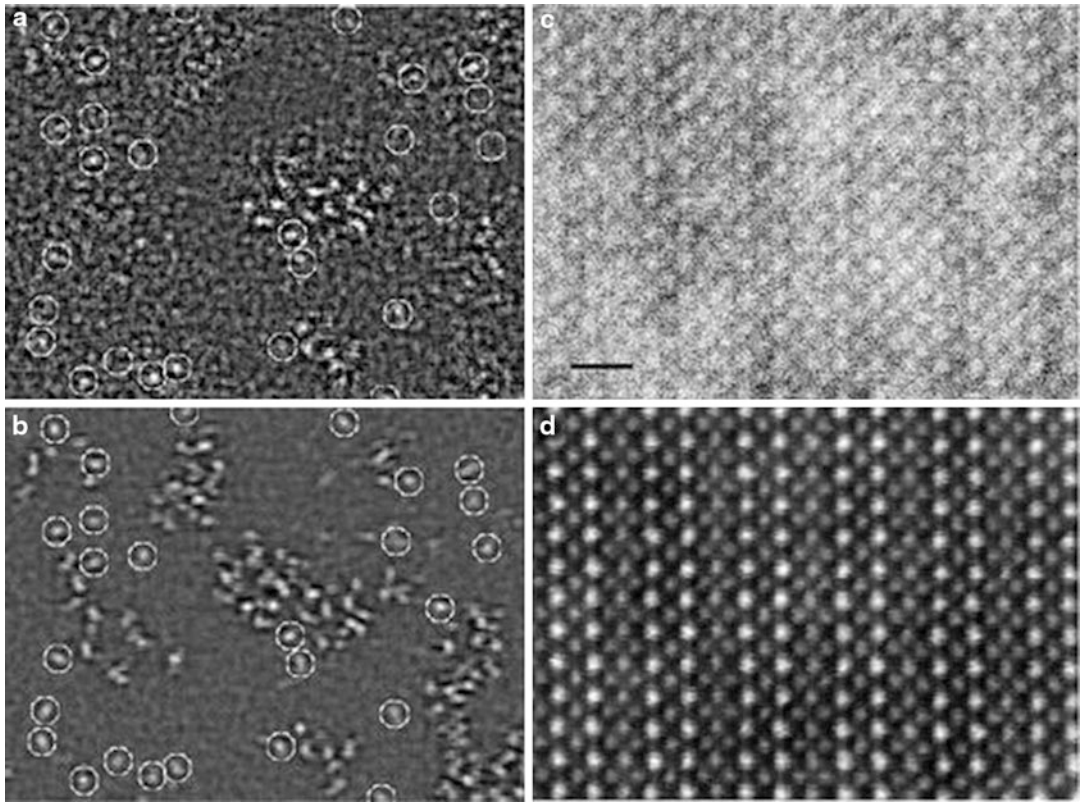
Figure 3 shows SEM images of a nanofiber containing polymer membrane developed for water filtration with enhanced ability to remove bacteria and viruses. The image on the right shows the structural network formed by the 5–10 nm diameter cellulose nanofibers. It reveals astonishing topographic details on how the cellulose nanofibers are interwoven with scaffold. In SEM images, flat surfaces give even contrast, while curved surfaces and sharp edges often appear brighter (high image intensity). This is due to the increased escape of secondary electrons from the top and side surfaces when the interaction volume intercepts them. Since the secondary-electron detector is biased with a high acceleration voltage, a surface facing away from the detector still can be imaged. Surfaces tilted away from the normal to the beam allow more secondary electrons to escape [13].

Atomic Imaging Using Secondary Electrons

In the last decade or so, high-resolution SEM has proven an indispensable critical dimension metrology tool for the semiconductor industry. The road map for semiconductor nanotechnology identifies the need for ultrahigh-resolution SEM in the quest for ever-decreasing device sizes. In a SEM, the size of the imaging probe often determines the instrument's resolution power. The probe size d (measured in full width and half maximum) is a function of the beam convergence; half-angle α is an incoherent sum of contributions from source size, diffraction limit, spherical aberration, and chromatic aberration and is given by

$$d^2 = \left(\frac{4i_p}{\beta\pi^2\alpha^2}\right)^2 + \left(\frac{0.6\lambda}{\alpha}\right)^2 + (0.5C_s\alpha^3)^2 + \left(C_c\alpha\frac{\Delta E}{E}\right)^2$$

where i_p is the probe current, α is the convergence half-angle, β is the source brightness, λ is the electron wavelength at beam energy E, ΔE is the energy spread, and C_s and C_c are, respectively, the spherical and chromatic aberration coefficients of the probe-forming lens. The first term on the right side of the equation is the probe size defined by the source size, the second term is due to the diffraction limit, and the third and the fourth terms are due, respectively, to the spherical and chromatic aberrations. Recent advancement on correcting spherical aberration in SEM and STEM diminishes C_s to zero, thus eliminating the third term and produces a small probe. It is important to note that the probe size also depends on the energy spread in the fourth term that includes the energy distribution of the primary electron beam and the fluctuation of the instruments' acceleration voltage.



In SEM, the image resolution depends not only on the instrument but also on the sample, or, more accurately, on the sampling volume of the sample from which the signal is generated. When the incident electrons impinge on a point of the sample's surface, they interact with atoms in the sample via elastic (change trajectory) and inelastic (lose energy) interactions. The size of the interaction volume depends on the electron's landing energy, the atomic number of the sample, and its density. The simultaneous energy loss and change in trajectory spread beam into the bulk of the sample and produce an interaction volume therein that, for a thick sample, can extend from less than 100 nm to around 5 μm into the surface, i.e., more than an order of magnitude larger than the original probe size. For a very thin sample (a few nm thick), the interaction volume, as the first approximation, might be defined as the probe size.

Figure 4 illustrates the atomic resolution images using secondary electrons on single uranium atoms (a) and the (010) surface of a $YBa_2Cu_3O_7$ crystal (c) recorded on the Hitachi HD2700C SEM/STEM (Fig. 2d). For comparison, the corresponding annular dark-field images using transmitted electrons, (b) and (d), respectively, are included. The equally sharp images in SE and ADF suggest negligible imaging delocalization. Such an attainable resolution was attributed to the combination of several factors: better design of the electro-optics of the instrument (including ultrahigh electric and mechanical stabilities) and the detector, aberration correction that reduces the probe size and increases the probe current, and the higher operation voltage that beneficially assures a very small volume of beam interaction for a thin sample.

The physical mechanism of producing the low-energy secondary electrons traditionally is ascribed to inelastic scattering and decay of collective electron excitation with the incident electron giving up, say, 20 eV, to produce a secondary electron with energy 20 eV energy minus the work function of the surface. Since the momentum transfer (scattering angle) of the scattering with 20 eV energy loss is small, the transfer should be delocalized to an area >1 nm; thus, atomic imaging using secondary electrons was not considered possible. Recent studies suggest that this is not the primary mechanism for secondary-electron imaging at least on a thin sample [11]. The secondary electrons responsible for atomic-scale resolution are generated by inelastic scattering events with large momentum transfer, including those from inner shell orbitals, which give rise to a sharp central peak in the point spread function for signal generation.

In general, four steps are involved in producing the signal that is used to form a secondary-electron (SE_I) image [12]: (1) the generation of secondary electrons through the inelastic scattering of primary electrons in the sample, at a generation rate, G; (2) random motion of these secondary electrons, which are scattered by atoms of the specimen both elastically and inelastically (potentially creating other secondary electrons of lower energies), such that, on average, T electrons reach the sample surface for each secondary electron generated; (3) the escape of secondary electrons over the potential barrier at the sample surface of the specimen, with an average probability P; and (4) the acceleration of the emitted electrons in vacuum, such that a fraction D reaches the electron detector.

The secondary-electron signal S is a product of these four factors: $S = G{\cdot}T{\cdot}P{\cdot}D$. To generate contrast in a scanned probe image, one or more of the

Scanning Electron Microscopy, Fig. 4 (**a**–**b**) Simultaneous atomic imaging using secondary electrons (secondary-electron mode, **a**) and transmitted electrons (annual dark-field mode, **b**) of uranium individual atoms on a carbon support (raw data). The *circles mark* the single uranium atoms. The atoms shown in (**b**) but not in (**a**) are presumably those on the back side of the support. (**c**–**d**) Simultaneous atomic imaging using secondary electrons (**c**) and transmitted electrons (**d**) of $YBa_2Cu_3O_7$ superconductor viewing along the [010] direction (raw data). The scale bar in (**c**) is 0.7 nm

above steps must depend on the x-coordinate of the electron probe in the scan direction, i.e.,

$$\frac{dS}{dx} = I_0 TPD\frac{dG}{dx} + I_0 GPD\frac{dT}{dx} + I_0 GTD\frac{dP}{dx} + I_0 GTP\frac{dD}{dx}$$

For most non-atomically resolved SE images obtained in a SEM, $\frac{dT}{dx}$ provides the main contrast mechanism: Secondary electrons created at an inclined surface or close to a surface step have an increased probability of escape, resulting in surface-topography contrast [14]. Less commonly, variations in surface work function contribute additional contrast by providing a nonzero $\frac{dP}{dx}$. In voltage-contrast applications, changes in surface voltage provide a nonzero $\frac{dD}{dx}$. Atomic number contrast is possible if the specimen is chemically inhomogeneous and G varies with atomic number, yielding a nonzero $\frac{dG}{dx}$. However, for atomic imaging in a thin sample (Fig. 4), the dominant mechanism can be quite different. $\frac{dG}{dx}$ is likely to play an important role in the atomic-scale contrast as a consequence of Z-dependence inelastic scattering cross section and channeling effect for crystals (for thickness in the order of extinction distance, it should be minor). Because secondary electrons are generated through inelastic scattering of the incident electrons, $\frac{dG}{dx}$ is limited by the delocalization of the scattering process, which may be described by the point

spread function for inelastic scattering. The term $\frac{dT}{dx}$ should be small, for adatoms or surface atoms that lie on the detector side of the sample. $\frac{dP}{dx}$ would not become important unless the effective work function varies on an atomic scale, and $\frac{dD}{dx}$ must be also negligible at atomic scale. These assumptions are reasonable because the scattering process disperses secondary electrons over a range of x that is comparable to the escape depth, typically 1–2 nm. Consequently, T, P, and D are x-averages that vary little with x on an atomic scale. For uranium atoms on a carbon substrate, the argument is even simpler; these atoms lie outside the solid, so the terms T and P are not applicable.

Future Remarks

Secondary-electron imaging is the most popular mode of operation of the scanning electron microscope (SEM) and traditionally is used to reveal surface topography. Nevertheless, this imaging method never was regarded as being on the cutting edge of performance, due to its perceived limited spatial resolution in comparison with its TEM or STEM counterparts using transmitted electrons. Recent work using aberration-corrected electron microscopes demonstrated that secondary-electron signals in the SEM can resolve both crystal lattices and individual atoms, showing SEM's unprecedented and previously unrealized imaging capabilities. Furthermore, the work demonstrates the incompleteness of present understanding of the formation of secondary-electron images. Secondary-electron imaging using high acceleration voltage with thin samples can now compete with TEM on spatial resolution and provide new capabilities, such as depth-resolved profiles, at the atomic level. There seems to be no fundamental reason why atomic resolution in secondary-electron imaging could not be achieved at the accelerating voltages of 0.5–40 keV that are currently used in conventional SEMs. It remains to be seen whether the integrated spherical and chromatic aberration of a probe-forming objective lens can be corrected to a sufficient degree at low operation voltages. One clear outcome thus far is the importance of preparing samples with clean surfaces in order to obtain interpretable and reproducible results.

Near-field scanning optical microscopy (NSOM)

Definition

Scanning near-field optical microscopy (SNOM) is a microscopic technique for nanostructure investigation that achieves sub-wavelength spatial resolution by exploiting short-ranged interactions between a sharply pointed probe and the sample mediated by evanescent waves. In general, the resolution of SNOM is determined by the lateral probe dimensions and the probe-sample distance. Images are obtained by raster-scanning the probe with respect to the sample surface corresponding to other scanning-probe techniques. As in conventional optical microscopy, the contrast mechanism can be combined with a broad range of spectroscopic techniques to study different sample properties, such as chemical structure and composition, local stress, electromagnetic field distributions, and the dynamics of excited states.

Introduction

Optical microscopy forms the basis of most of the natural sciences. In particular, life sciences have benefited from the fascinating possibility to study smallest structures and processes in living cells and tissue. Optical techniques feature extremely high detection sensitivity reaching single molecule sensitivity in fluorescence, Raman scattering and absorption spectroscopy. Besides the direct visualization, chemically specific information is obtained through Raman spectroscopy.

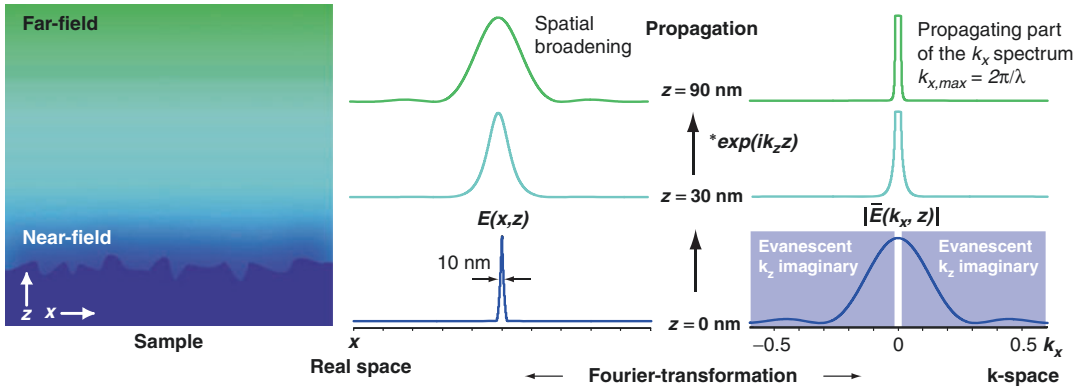
The resolution of conventional optical microscopes, however, is limited by diffraction, a consequence of the wave nature of light, to about half the wavelength. Concepts extending optical microscopy down to nanometer length scales below the diffraction-limit are distinguished into far-field and near-field techniques. Far-field techniques rely on the detection of propagating waves at distances from the source larger than the wavelength, while near-field techniques exploit short ranged evanescent waves.

Scanning near-field optical microscopy, initiated by pioneering work of Pohl, Lewis and others in the late 1980s and the beginning of 1990s gave access to nanoscale resolution for the first time. The history of near-field optics is reviewed in [1]. In addition numerous review articles and books exist describing fundamentals and applications (see e.g., [2–4]).

This entry introduces first the key physical principles beginning with the role of evanescent and propagating waves, and the loss of spatial information upon light propagation. Concepts of near-field detection are shown using different pointed probes. The next sections describe the experimental realization and present several

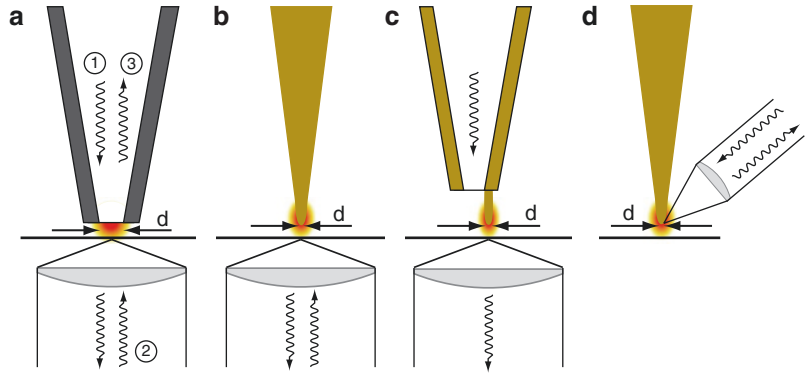
applications of SNOM. The outlook addresses future prospects of SNOM and remaining challenges.

Key Principles and Concepts



Near-field optics has its origin in the effort of overcoming the diffraction limit of optical imaging. The physical origin of this limit is sketched in the following starting with the distinction between propagating waves that form the optical far-field of a radiation source and their evanescent counterpart that dominate the optical near-field. A powerful tool to describe wave propagation is the so-called angular spectrum representation of fields expressing the electromagnetic field E in the detector plane at z as the superposition of harmonic plane waves of the form $exp\left(i\vec{k}\,\vec{r} - i\omega t\right)$ with amplitudes $\overline{E}\left(k_x, k_y, z = 0\right)$ emanating from the source plane at $z = 0$ [2].

$$E(x,y,z) = \int_{-\infty}^{+\infty}\int \overline{E}\left(k_x, k_y, z = 0\right) \times e^{i\left(k_x x + k_y y\right)} e^{\pm i k_z z} dk_x dk_y \quad (1)$$

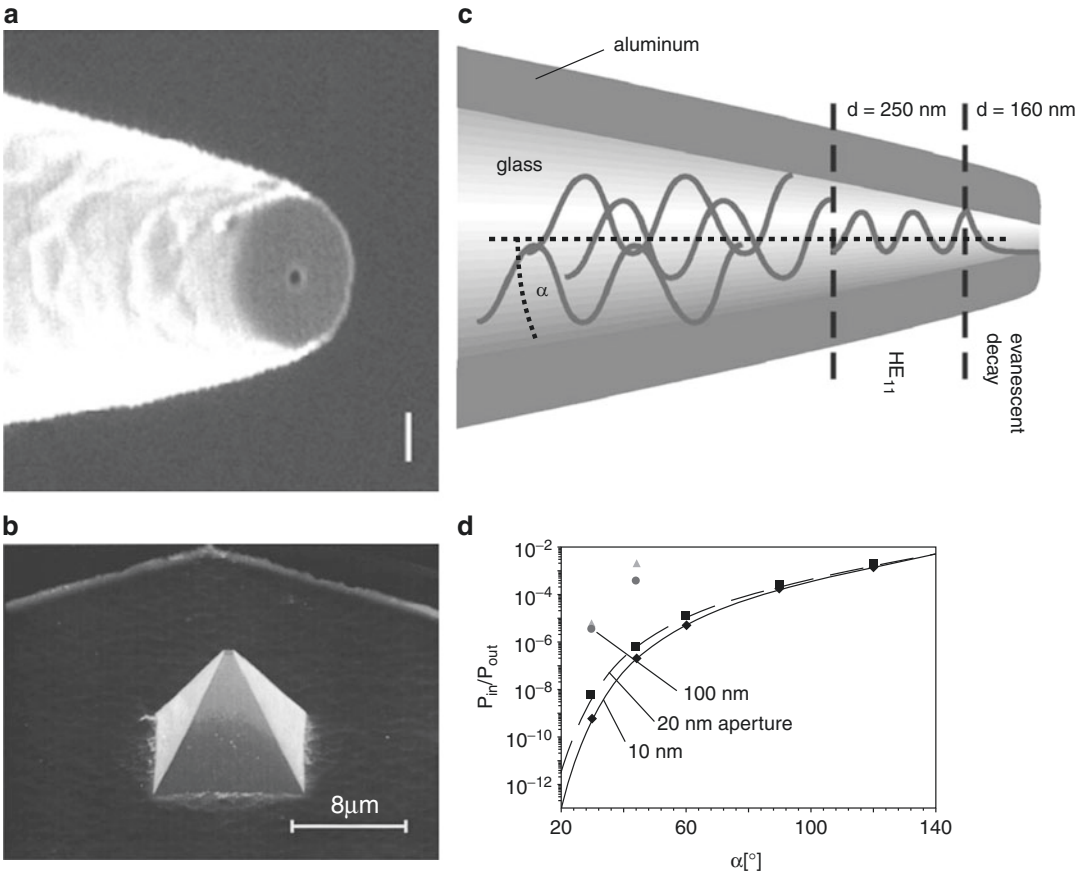


The wave vector $\vec{k}$ describing the propagation direction of the wave is represented by its components $\vec{k} = \left(k_x, k_y, k_z\right)$ while its length is fixed by the wavelength of light λ and the refractive index of the medium n through $\left|\vec{k}\right| = \sqrt{k_x^2 + k_y^2 + k_z^2} = 2\pi n/\lambda$. In Eq. 1, the time dependence of the fields has been omitted for clarity. For simplicity the following discussion is limited to the x-z-plane and $n = 1$ such that $k_z = \sqrt{4\pi^2/\lambda^2 - k_x^2}$. In Eq. 1 the term $e^{\pm i k_z z}$ controls the propagation of the associated wave: For $k_x \leq 2\pi/\lambda$ the component k_z is real and the corresponding wave with amplitude $\overline{E}(k_x, z = 0)$ propagates along the z-axis oscillating with $e^{-ik_z z}$. If $k_x > 2\pi/\lambda$ the component kz becomes complex and $e^{-|k_z z|}$ describes an exponential decay of the associated wave that is therefore evanescent. As a result, only waves with $k_x \leq 2\pi/\lambda$ can propagate and contribute to the field far from the source forming the far-field. Figure 1 schematically illustrates this behavior: In the center, the electric field $E(x, z)$ emanating from a narrow sub-wavelength source at $z = 0$ is shown together with its angular spectrum $\overline{E}(k_x, z = 0)$ calculated by the inverse of Eq. 1. The wave amplitudes $\overline{E}$ result from the Fourier-transformation of E with respect to the spatial coordinate x. As for the correlation between time and frequency domain, where a short optical pulse requires a broad frequency spectrum, a sharp field distribution requires a broad spectrum of spatial frequencies k_x.

Since only waves with limited spatial frequencies can propagate, the spectral width rapidly decreases with increasing distance from the source z leading to fast broadening of the electric field distribution in real space. In other words, propagation corresponds to low-pass filtering with frequency limit $k_{x,\max} = 2\pi/\lambda$. The far-field thus contains limited spatial frequencies equivalent to limited spatial information. To overcome this limitation different near-field concepts have been developed that are outlined in the following.

The key concept of SNOM is the probing of the sample near-field that contains the evanescent waves using a sharply pointed probe. Since evanescent waves decay rapidly for increasing distance to the source, the probe needs to be in close proximity to the sample. Waves with large kx components that carry high spatial information decay most rapidly following $e^{-|k_z|z}$ as can be seen from Fig. 1. Hence the spatial resolution obtained in an SNOM experiment drops fast with increasing tip-sample distance z. As for other scanning probe techniques that exploit short-ranged interactions, such as atomic force and scanning tunneling microscopy, AFM and STM, respectively, the lateral resolution is also determined by the lateral dimension of the probe. Two conceptually different types of probes can be distinguished: The first confines and samples electromagnetic fields using an aperture with sub-wavelength diameter (Fig. 2a). The second exploits the antenna concept that couples locally enhanced near-fields to propagating waves and vice versa (Fig. 2b–d). The two types, termed aperture and antenna probe, respectively, are illustrated in the following.

Scanning Near-Field Optical Microscopy, Fig. 1 Scheme illustrating the propagation of waves and the loss of spatial information. Initial field distribution $E(x, z = 0)$ at a 10-nm wide source in the x-z-plane (*center*) and corresponding angular spectrum $\tilde{E}(k_x, z = 0)$ (*right*). Near the source the spectrum contains both evanescent and propagating waves. Upper panels illustrate the evolution of the fields at $z = 30$ nm and $z = 90$ nm distance for a source wavelength of $\lambda = 500$ nm in vacuum. Only waves with $k_x \leq 2\pi/\lambda$ propagate. Evanescent waves decay exponentially following $e^{-|k_z|z}$. The decay of high spatial frequencies leads to spatial broadening and loss of spatial information in the far-field

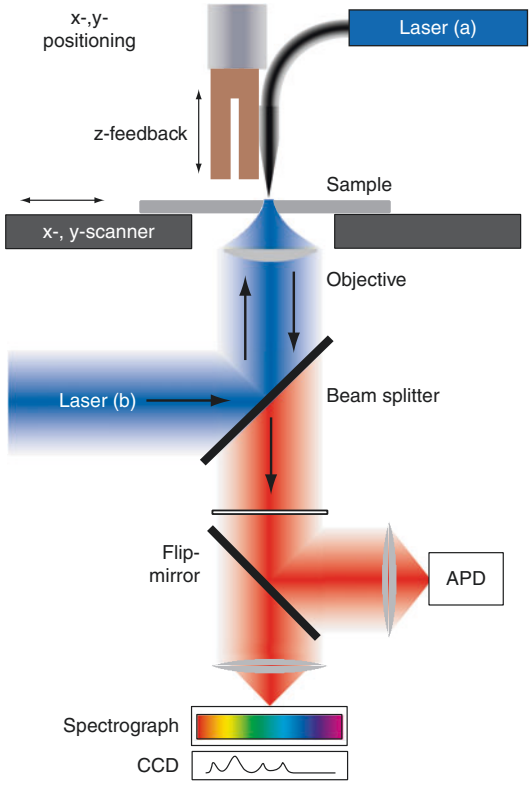


Scanning Near-Field Optical Microscopy, Fig. 2 Schematics of the most common SNOM probes and configurations: (**a**) Aperture probes are utilized in different modes: Near-field excitation – far-field collection ①, far-field excitation – near-field collection ② and near-field excitation – collection mode ③. (**b**) Tip-enhanced near-field optical microscopy (*TENOM*) using local field enhancement at a sharp metal antenna probe upon far-field excitation. (**c**) Tip-on-aperture (*TOA*) probe using local field enhancement at an antenna probe that is excited in the near-field of an aperture probe. (**d**) Scattering-SNOM (*s-SNOM*) based on far-field illumination and detection of local scattering at a sharp antenna probe. The label *d* indicates the structural parameter that determines the achievable spatial resolution

Aperture Probes

Aperture probes confine light by squeezing it through a sub-wavelength hole (Fig. 2a). This approach, termed aperture-SNOM, provides an enormous flexibility regarding signal formation. Different operation modes can be used that are capable of local sample excitation and/or local light collection. Depending on which step of the experiment exploits near-field interactions to obtain sub-wavelength resolution, aperture-SNOM can be implemented in excitation ①, collection ② and excitation-collection ③ mode (Fig. 2a).

The original scheme was proposed by Synge in 1928. He suggested to use a strong light source behind a thin, opaque metal film with a 100-nm



Scanning Near-Field Optical Microscopy, Fig. 3 (**a**) Scanning-electron microscopy (*SEM*) image of an aperture probe formed by a metal-coated tapered fiber with an aperture diameter of 70 nm (scale bar 200 nm) (Reprinted with permission from Veerman et al. [5]. Copyright 1999, John Wiley and Sons) (**b**) SEM image of a metallic hollow aperture probe microfabricated on a Si cantilever. S

diameter hole in it as a very small light source. In 1984, two groups adopted this scheme and presented the first experimental realizations in the optical regime [1]. The aperture was formed at the apex of a sharply pointed transparent probe tip coated with metal. Raster-scanning the probe was made possible by the scanning technology developed in the context of scanning tunneling microscopy (STM). In Fig. 3a, a scanning electron microscopy (SEM) image of an aperture probe consisting of a metal-coated tapered glass fiber is shown. At the front surface a well-defined aperture with diameter of 70 nm is seen.

Analytical expressions for the electric field distribution in a sub-wavelength aperture in a metallic screen were already presented in 1944 and 1950 by Bethe and Bouwkamp. Numerical simulations for metal-coated tapered fiber probes show that strong fields pointing in axial direction occur at the rim due to local field-enhancement by the metal coating (see Fig. 4). The center of the aperture is dominated by a weaker horizontal

Scanning Near-Field Optical Microscopy, Fig. 4 Schematic of an experimental setup applicable to aperture-probe SNOM (laser (**a**), excitation mode) and TENOM (laser (**b**)) in case of transparent samples. In the case of TENOM the fiber probe would be replaced by an optical antenna, for example, an etched metal wire. The probe tip is positioned in the focus of the microscope objective by piezo-electric actuators. The sample is raster-scanned using a closed-loop *x*-*y*-scanner while both laser and probe position remain fixed. The tip-sample distance is controlled using a tuning-fork shear-force feedback scheme. The optical signal is collected by the objective and detected either by a highly sensitive avalanche photodiode (*APD*) or energetically resolved using a spectrograph and a CCD

component [2]. The optical field distribution can be determined experimentally by raster-scanning single fluorescent molecules that act as point-like dipoles across the aperture while recording the fluorescence intensity [5] (see section "Fluorescence Microscopy" and Fig. 3).

Tapered aperture probes suffer from low light transmission due to the cut-off of propagating wave-guide modes. For probe diameters below the cut-off diameter only evanescent waves remain and the intensity decays exponentially toward the aperture (Fig. 2c, d). Probe designs, therefore, aim at maximizing the cone angle that determines the distance between aperture and cut-off diameter. Hollow-cantilever probes feature relatively large cone-angles as compared to fiber-based probes (Fig. 2b). On the other hand, the input power needs to be limited because of the damage threshold of the metal coating in case of fiber-based probes. Due to the limited transmission and the skin-depth of the optical fields on the order of several tens of nanometers, most aperture-SNOM measurements are carried out with apertures of 50–100 nm.

Antenna Probes

Antenna probes act as transmitter and receiver coupling locally enhanced near-fields to propagating waves and vice versa (Fig. 2b–d) [8]. To distinguish this approach from the earlier implementations based on apertures, it is also termed apertureless-SNOM or a-SNOM. Antenna probes can be used in two different techniques: (1) Scattering type microscopy [9, 10], also termed scattering-SNOM or s-SNOM, in which the tip locally perturbs the fields near a sample surface. The response to this perturbation is detected in the far-field at the frequency of the incident light corresponding to elastic scattering (Fig. 2d). (2) Tip-enhanced near-field optical microscopy (TENOM) in which locally enhanced fields at laser-illuminated metal structures are used to increase the spectroscopic response of the system at frequencies different from that of the incident light [8, 11] (Fig. 2b, c). The flexibility of this technique allows the study of a variety of spectroscopic signals including Raman scattering (tip-enhanced Raman spectroscopy (TERS)), and fluorescence as well as time-resolved measurements. In the following, the signal formation in the case of optical antennas is sketched.

Elastic scattering signal. The near-field interaction can be treated within a simplified model in which the tip is replaced by a polarizable sphere. Due to the antenna properties of the tip, laser excitation with incident fiel E_i creates a dominating dipole oriented along the tip axis in z-direction normal to the sample surface. This dipole induces

a mirror dipole in the sample depending on its dielectric properties. The mirror dipole's field, decreasing with the third power of distance, interacts with the tip dipole. Solving the system of electrostatic equations that describes the multiple interaction between tip and mirror dipoles neglecting retardation yields an effective polarizability of the coupled tip-sample system which fully expresses the influence of the sample.

$$\alpha_{\text{eff}} = \left(\frac{(\alpha(1+\beta)/1-(\alpha\beta))}{\left(16\pi(\alpha+z)^3\right)} \right) \qquad (2)$$

The scattered field can then be calculated from $E_s \propto \alpha_{\text{eff}} E_i$ reflecting the short-ranged interaction required for sub-diffraction resolution. Since the laser illuminates a greater part of the tip and the sample, elimination of background-scattering contributions is crucial. Efficient background suppression can be achieved by demodulating the detected intensity signal at higher harmonics of the tapping mode frequency (see section "Instrumentation"). Besides the amplitude of the scattered field, its phase can be retrieved using interferometric heterodyne detection [9].

Raman scattering signal. In the case of Raman scattering, the total signal depends on the product of the excitation and emission rates $k^{\text{ex}}(\lambda^{\text{ex}})\, k^{\text{rad}}(\lambda^{\text{rad}})$. As a consequence, the total signal enhancement scales with the fourth power of the field enhancement for small differences between the excitation λ^{ex} and emission wavelength λ^{rad} and assuming that the field enhancement at the tip does not depend sensitively on the wavelength.

$$M_{\text{Raman}} = \frac{k^{\text{ex}}_{\text{tip}}}{k^{\text{ex}}_{0}} \cdot \frac{k^{\text{rad}}_{\text{tip}}}{k^{\text{rad}}_{0}} \approx f^4 \qquad (3)$$

The factor f measures the ratio between tip-enhanced E_{tip} and non-enhanced electric field E_0 in the absence of the tip. For the general case of surface-enhanced Raman scattering (SERS), Raman enhancement factors are reported reaching up to 12 orders of magnitude for particular multiple particle configurations involving interstitial sites between particles or outside sharp surface protrusions. Since the signal scales with the fourth power, already moderate field enhancement, predicted for a single spherical particle to be in the range of $f = 10$–100 is sufficient for substantial signal enhancement.

Fluorescence signal. The fluorescence intensity depends on the excitation rate k^{ex} and the quantum yield η denoting the fraction of transitions from excited state to ground state that give rise to an emitted photon. The quantum yield is expressed in terms of the radiative rate k^{rad} and the non-radiative rate k^{nonrad} through $\eta = k^{\text{rad}}/(k^{\text{rad}} + k^{\text{nonrad}})$. Accordingly, the fluorescence enhancement due to the presence of the metal tip can be written as

$$M_{\text{Flu}} = \left(\frac{E_{\text{tip}}}{E_0}\right)^2 \left(\frac{\eta_{\text{tip}}}{\eta_0}\right) = f^2 \left(\frac{\eta_{\text{tip}}}{\eta_0}\right). \qquad (4)$$

Here, it is assumed that the system is excited far from saturation. From Eq. 4 it is clear that TENOM works most efficiently for samples with small fluorescence quantum yield η_0 such as semiconducting single-walled carbon nanotubes [11]. For highly fluorescent samples such as dye molecules, the quantum yield η_0 is already close to unity and cannot be enhanced further.

Because of the small separation between emitter and metal tip required for high spatial resolution, non-radiative transfer of energy from the electronically excited state to the metal followed by non-radiative dissipation in the metal has to be taken into account. This process represents an additional competing non-radiative relaxation channel and reduces the number of detected fluorescence photons. Metal-induced fluorescence quenching can also be exploited for image contrast formation (see e.g., [12]). In this case M_{Flu} in Eq. 4 becomes smaller than unity.

While the theory of energy transfer between molecules and flat metal interfaces is well understood in the framework of phenomenological classical theory, nanometer-sized objects are more difficult to quantify [2]. Tip- and particle-induced radiative rate enhancement and quenching has been studied in literature both experimentally and theoretically. Experiments on model systems formed by single dipole emitters such as molecules and semiconductor nanocrystals and

spherical metal particles revealed a distance-dependent interplay between competing enhancement and quenching processes. While semiconducting tips cause less efficient quenching, they also provided weaker enhancement because of their lower conductivity at optical frequencies.

Polarization and angular-resolved detection of the fluorescence signal of single emitters demonstrated that the fluorescence rate enhancement provided by the optical antenna also results in a spatial redistribution of the emission [13]. The same redistribution can be expected to occur for tip-enhanced Raman scattering. The spatial distribution of the enhanced electric field follows approximately the outer dimensions of the tip apex. Since the signal enhancement scales with higher orders of field enhancement, the optical resolution can surpass the size of the tip [11]. Stronger fields and field confinement are observed for so-called gap modes formed by metal tips on top of metal substrates.

The scheme depicted in Fig. 2b shows that in addition to the signal resulting from the near-field tip–sample interaction the confocal far-field signal contribution is detected, representing a background. This background originates from a diffraction-limited sample volume that is far larger than the volume probed in the near-field. The near-field signal has to compete with this background, and strong enhancement is required to obtain clear image contrast. This requirement is relaxed in case of low-dimensional sample structures such as spatially isolated molecules or one-dimensional nanostructures [11]. The near-field signal to background ratio can be improved by exploiting the non-linear optical response of sample and tip. Examples include two-photon excitation of fluorescence using a metal tip antenna and the application of the four-wave mixing signal of a metal particle dimer as local excitation source.

Instrumentation

Near-field optical microscopy exploits short-ranged near-field interactions between sample and probe. SNOM instruments thus require a mechanism for tip-sample distance control working on the scale of nanometers. Typical implementations utilize other non-optical short-ranged probe–sample interactions such as force or tunneling current used for topography measurements in AFM and STM, respectively. During image acquisition by raster-scanning the sample with respect to the tip, optical and topographic data are thus obtained simultaneously. Due to the strong tip-sample distance dependence of the near-field signal, cross-talk from topographic variations is possible that can lead to artifacts in the optical contrast. Tip-sample distance curves need to be measured to prove unequivocally the near-field origin of the observed image contrast. Since the optical signal results from a single sample spot only, SNOM instruments are often based on a confocal laser scanning optical microscope equipped with sensitive photodetectors.

Scattering-SNOM is often implemented with intermittent-contact-mode AFM in which the tip-sample distance is modulated sinusoidally at frequencies typically in the range of 10–500 kHz. The elastically scattered laser light intensity is demodulated by the tapping-mode frequency using lock-in detection for background suppression.

Since Raman and fluorescence signals are typically weak requiring longer acquisition times, signal demodulation is more challenging. In the case of single-photon counting time-tagging can be used to retrieve the signal phase with respect to the tapping oscillation. While this can be applied to single-color experiments, spectrum acquisition using CCD cameras in combination with spectrometers is not feasible at typical tapping frequencies.

In most aperture-SNOM and TENOM experiments, the tip-sample distance is kept constant by either using STM, contact/non-contact AFM, or shear-force feedback. Sensitive piezoelectric tuning-fork detection schemes operating at small interaction forces have been developed and are used for fragile fiber and antenna probes [2].

Probe Fabrication

The near-field probe forms the crucial part of an SNOM setup since both optical and topographic

signals are determined by its short-ranged interactions with the sample. Instrument development, therefore, focuses mainly on the design of optimized tip concepts and tip geometries as well as on fabrication procedures for sharp and well-defined probes with high reproducibility. These continuing efforts benefit substantially from improving capabilities regarding nanostructuring and nanocharacterization, using, for example, focused ion beam milling (FIB) or electron beam lithography (EBL).

Aperture Probes

Optical fiber probes. Sharply pointed optical fiber probes were the first to provide sub-diffraction spatial resolution and are widely used as nanoscale light sources, light collectors or scatterers (Figs. 2a and 3a). Probe fabrication requires a number of steps starting with the formation of a tapered optical fiber. Typically two different methods are used. Chemical etching of a bare glass fiber dipped into hydro-fluoric (HF) acid yields sharp tips [4, 7]. The surface tension of the liquid forms a meniscus at the interface between air, glass, and acid. A taper is formed due to the variation of the contact angle at the meniscus, while the fiber is etched and its diameter decreased. Chemical etching allows reproducible production of larger quantities of probes in a single step. A specific advantage is that the taper angle can be tuned and optical probes with correspondingly large transmission coefficient can be produced.

The second method combines local heating using a CO_2 laser or a filament and subsequent pulling until the fiber is split apart. The resulting tip shapes depend heavily on the temperature and the timing of the heating and pulling, as well as on the dimensions of the heated area. The pulling method has the advantage of producing tapers with very smooth surfaces, which positively influences the quality of the evaporated metal layer. Etched probes, on the other hand, typically feature rough surfaces. Pulled fibers, however, have small cone angles and thus reduced optical transmission as well as flat end-faces limiting the minimum aperture size.

The aperture is formed during the evaporation of aluminum. Since the evaporation takes place under an angle slightly from behind, the deposition rate of metal at the apex is much smaller than on the sides. This geometrical shadowing effect leads to the self-aligned formation of an aperture at the apex.

The ideal aperture probe should have a perfectly flat end face to position a sample as close as possible into the near-field of the aperture. Conventional probes generally have a roughness determined by the grain size of the aluminum coating, which is around 20 nm at best. Due to the corrugated end face the distance between aperture and sample increases, which lowers the optical resolution and decreases the light intensity on the sample. Furthermore, these grains often obscure the aperture, which makes the probe ill-defined and not suited for quantitative measurements [4, 5, 7]. Subsequent focused ion beam (FIB) milling can be used to form high definition SNOM probes with well-defined end face (Fig. 3).

Microfabricated cantilevered probes. Hollow-pyramid cantilevered probes can be batch-fabricated with large taper angles. Lithographic patterning of an oxidized silicon wafer first defines the position of the aperture and the dimensions of the cantilever beam by structuring the oxide layer [6]. Anisotropic etching of the exposed silicon with buffered HF forms a pyramidal groove for the tip and trenches for the cantilever beam. After removing the oxide layer on the opposite side anisotropic etching is used to open a small aperture in the pyramidal groove. A 120-nm chromium layer is deposited on the back side forming the hollow pyramidal tip that is finally freed by isotropic reactive ion etching.

Si_3N_4 tips can be fabricated by dry etching in a CF_4 plasma and covering with thin aluminum films. Microfabricated probes based on quartz tips attached to silicon cantilevers have also been reported [2, 7]. First sharp quartz tips were produced in hydrofluoric acid followed by coating with thin films of aluminum and silicon nitride. Reactive ion etching was then used to selectively remove the silicon nitride from the tip apex, while the remaining film served as a mask for

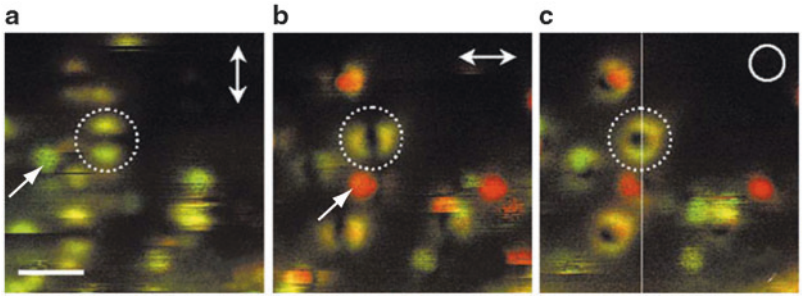
wet-etching of the protruding aluminum in a standard Al-etching solution, leaving a small aperture on the apex of the tip. For light coupling, windows are etched into the backside of the levers at the position of the tip.

Microfabricated tips provide several advantages over fiber-based probes. The mechanical stability is typically increased and often sufficient to measure also in contact AFM mode without destroying the tip. A reproducible fabrication of the tips leads to a well-defined aperture shape. Large taper angles of around 70° shift the position of the mode cut-off closer to the aperture, resulting in higher transmission.

Antenna Probes

Sharp metal tip are fabricated in a single step by simple electrochemical etching. In the case of gold, pulsed or continuous etching in hydrochloric acid (HCL) or a mixture of HCL and ethanol routinely yields tips with diameters in the range of 30–50 nm. These tips can either be used in shear-force mode after gluing to the prong of a tuning-fork or in STM-mode. Silicon or silicon nitride cantilevered probes can be coated by a thin metal film through evaporation. Subsequent nanostructuring by FIB-milling can be used to optimize tip parameters.

Tip-on-aperture probes need to be fabricated in a series of sequential steps [14] (Fig. 2c). First, a fiber-based aperture probe is produced on which a well-defined end face is formed by FIB-milling. In the second step, a nanoscale tip is grown by electron beam–induced deposition of carbon. Next, the carbon tip is coated by a thin layer of chromium to improve adhesion of an aluminum layer evaporated during the final preparation step. Since the length of the tip can be controlled during electron beam deposition, TOA probes can be tailored to provide optimum antenna enhancement for a chosen wavelength [8].



Applications in Nanoscience

The energy of light quanta – photons – is in the range of electronic and vibrational excitations of materials. These excitations are directly determined by the chemical and structural composition of matter. Optical spectroscopy, the energy-resolved probing of the material response to light exposure, thus provides a wealth of information on the static and dynamical properties of materials. Combining spectroscopy with near-field microscopy is particularly interesting since spectral information is obtained spatially resolved at the nanoscale. In the following several representative examples covering different material responses including fluorescence, Raman scattering and elastic scattering are briefly illustrated to highlight the capabilities of SNOM techniques.

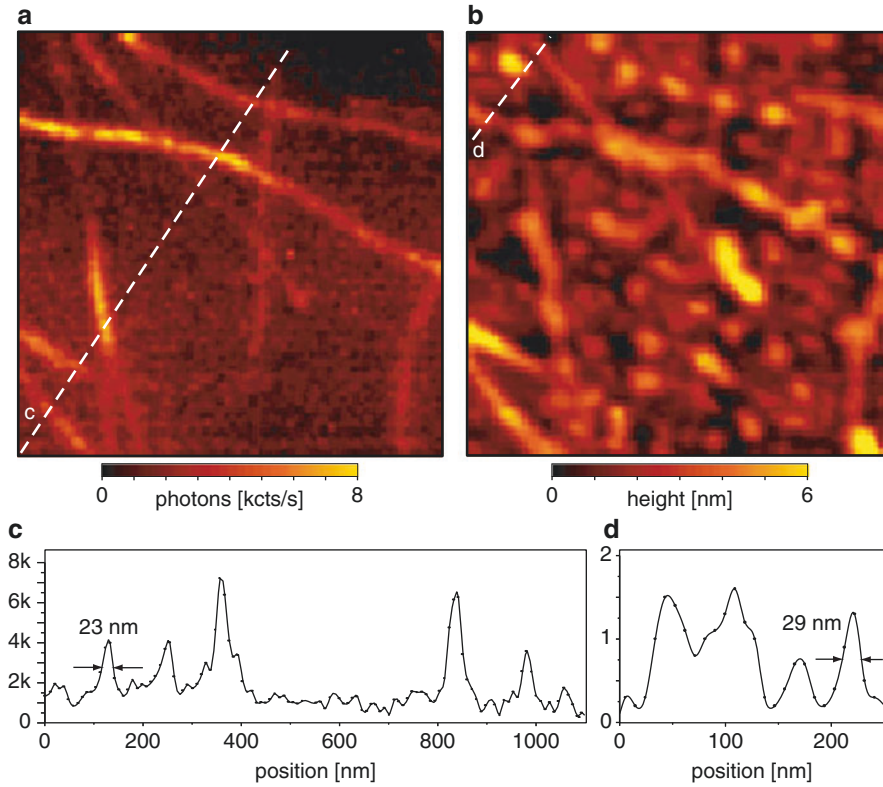
Fluorescence Microscopy

Fluorescence measurements were among the first applications of SNOM. In these experiments, aperture-based probes were used to probe highly fluorescent dye-molecules on substrates. Aluminum-coated fiber tips were used for excitation while the fluorescence was collected in the far-field by a high-numerical aperture objective. A molecule is excited only if the optical electric field is polarized parallel to its transition dipole moment. The resulting fluorescence patterns rendered by a single molecule with known orientation can thus be used to visualize the local electric field distribution at the probe. Conversely, the molecular orientation can be determined for known field distributions. These experiments showed that the strongest electrical fields do not occur in the center of the aperture, but at the rims of the metal coating. This is the result of local field enhancement at the thin metal rim (see section "Antenna Probes"). Two lobes with strong fields oriented in axial direction occur located on opposite sides of the aperture in the direction of the polarization of the incident linearly polarized light. Molecules with a transition dipole moment oriented parallel to the tip axis are excited efficiently by these field components as can be seen in Fig. 5 [5]. Rotating the polarization of the incident linearly polarized light is seen to rotate the resulting double lobe pattern that indicates the area with strongest fields.

Fluorescence measurements typically do not require high excitation densities and in many cases, the small light transmission of aperture

Scanning Near-Field Optical Microscopy, Fig. 5 Series of three successive aperture-SNOM fluorescence images of the same area (1.2 × 1.2 μm) of a sample of dye molecules embedded in a thin transparent polymer film. The excitation polarization, measured in the far-field, was rotated from linear vertical (**a**) to linear horizontal (**b**) and then changed to circular polarization (**c**). Circular features marked by arrows result from molecules with transition dipole moments oriented parallel to the sample plane. The double lobe structure marked by the dashed circle results from a molecule with perpendicularly oriented transition dipole moment. This molecule senses the strong electrical fields that occur at the rim of the metal aperture at positions determined by the far-field polarization. Scale bar 300 nm (Reprinted with permission from Veerman et al. [5]. Copyright 1999, John Wiley and Sons)

probes represents no major drawback. In fact, fluorescence imaging of single dye molecules with 32 nm spatial resolution has been demonstrated using a microfabricated cantilevered glass tip covered with a 60-nm-thick aluminum film. Due to the thickness of the virtually opaque film, possible contributions from surface plasmons propagating on the outside of the film have been discussed [4]. Examples of fluorescence microscopy measurements based on aperture probes also include, for example, studies of single nuclear pore complexes and the kinetics of protein transport under physiological conditions.



Optical antennas have been used for a variety of samples and materials including photosynthetic proteins, polymers, semiconductor quantum dots, and carbon nano-tubes [11]. The image contrast was based on local field enhancement provided by the tip. The spatial resolution achieved in these experiments was essentially determined by the diameter of the tip and ranged between 10 and 20 nm. Imaging can be combined with local spectroscopy to visualize emission energies on the nanoscale. Single-molecule experiments revealed the field distribution at the tip-antenna in analogy to the discussion made above for aperture probes [14].

While most of the reported studies were exploiting local signal enhancement, distance-dependent metal-induced quenching of fluorescence can also be used for high-resolution imaging. This approach provides sub 10 nm spatial resolution and has been applied to single fluorescent organic molecules and inorganic semiconductor nanorods (see e.g., [12]). In these experiments, the spectrally integrated fluorescence signal was demodulated by the tapping-mode frequency of the AFM cantilever after recording photon-arrival times.

Raman Microscopy

Raman scattering probes the unique vibrational spectrum of a sample and directly reflects its chemical composition and molecular structure. A main drawback of Raman scattering is the extremely low scattering cross-section which is typically 10–14 orders of magnitude smaller than the cross-section of fluorescence in the case of organic molecules. Raman measurements thus require higher laser intensities and in many cases the low transmission of aperture probes prohibits their application. The signal enhancement provided by the antenna tip in TENOM is substantial for the detection of nanoscale sample volumina. In the following, a review of selected examples is given to illustrate the possibilities of tip-enhanced Raman scattering (TERS) (see e.g., [11, 15]).

In Fig. 6, simultaneous near-field Raman and topographic imaging of individual single-walled

Scanning Near-Field Optical Microscopy, Fig. 6 Tip-enhanced Raman spectroscopy (*TERS*) of single-walled carbon nanotubes on glass. Simultaneous near-field Raman image (**a**) and topographic image (**b**). Scan area $1 \times 1\ \mu m^2$. The Raman image is acquired by detecting the intensity of the G′ band upon laser excitation at 633 nm. No Raman scattering signal is detected from humidity-related circular features present in the topographic image. carbon nanotubes is shown. The optical image in (a) reflects the intensity of the G′ band, a particular Raman-active vibrational mode of carbon nanotubes. The optical resolution obtained in this experiment was about 25 nm as can be seen from the width of the peaks in the cross-section in Fig. 6c.

The strong fields required for sufficient enhancement of the Raman scattering signal can cause laser-induced decomposition and photochemical reactions in the presence of oxygen. TERS of single electronically resonant molecules has been demonstrated for ultra-high vacuum conditions. A review focusing on single-molecule surface- and tip-enhanced Raman scattering can be found in [15].

Elastic Scattering Microscopy

Elastic scattering SNOM probes the dielectric properties of the sample and has been used from the visible to the microwave regime of the electromagnetic spectrum. Reviews of the fundamentals of the technique and representative applications can be found in [9, 10]. The majority of s-SNOM experiments have been reported for the IR to THz spectral range. Applications include detection of the Mott-transition in nanodomains, mapping of the doping concentration in semiconductors, surface characterization with a sensitivity of a single monolayer, strain-field mapping, and infrared spectroscopy of a single virus.

As an example nanoscale infrared spectroscopic near-field mapping of single nano-

transistors is shown in Fig. 7. A cantilevered metallized Si-tip operating in tapping-mode with an oscillation frequency of 300 kHz and an amplitude of about 60 nm was used [17]. The data clearly demonstrates the potential of s-SNOM for infrared spectroscopic recognition of materials within individual semiconductor nanodevices.

Based on the antenna approach, s-SNOM typically provides 10–20 nm spatial resolution determined by the diameter of the tip-apex. In most of the s-SNOM experiments to date, monochromatic laser sources were used. Since only the optical response at this frequency is determined, the acquisition of scattering spectra or spectrally resolved images can only be obtained sequentially with a series of image scans at different laser frequencies. New developments exploiting broadband NIR laser sources aim at overcoming this limitation, and recently obtained a spectral bandwidth exceeding 400 cm^{-1}.

Plasmonics and Photonic Nanostructures

SNOM plays a vital role in the field of plasmonics which deals with the study of optical phenomena related to the electromagnetic response of metals [18]. Near-field optical probes are particularly important for two reasons. First, they provide a means to locally excite propagating surface plasmon polaritons (SPPs) in metal films, a process that is not possible in case of propagating light waves because of momentum (k-vector) mismatch. The broad k-spectrum associated with the near-field of the probe contains sufficient bandwidth for efficient SPP-excitation (see Fig. 1). Second, near-field probes can be used simultaneously to convert SPPs back into propagating waves, thereby probing the local distribution of electromagnetic fields in the vicinity of metallic nanostructures. As an example, the near-field associated with SPPs has been visualized along gold nanowires using an aperture probe in collection mode (see Fig. 2a, [4]). This approach is also termed photon scanning tunneling microscopy (PSTM) to illustrate the analogy between evanescent electromagnetic waves and the corresponding exponentially decaying electron wavefunctions within the tunnel barrier of an STM. PSTM has been widely used to spatially resolve light wave propagation also in dielectric photonic nanostructures [4].

Besides the visualization of static field distributions, optical spectroscopy also allows for the

Scanning Near-Field Optical Microscopy, Fig. 8 Phase-sensitive and ultrafast near-field microscopy of a surface plasmon polariton (*SPP*) waveguide. The local electric field is collected by an aperture-probe and detected interferometrically in a Mach-Zehnder–type configuration. (**a**–**e**) Normalized amplitude information of the SPP wavepacket E-field. Succeeding frames are new scans of the probe. In between the frames the delay line is lengthened to 14.4 μm. Therefore, the time between two frames is 48 fs. The scan frame is 15 × 110 μm^2, scan lines run from *top* to *bottom*.
