Definition

Manufactured nanoparticle. Manufactured nanoparticles are particles that have at least one dimension between 1 and 100 nm and are specifically engineered to have unique properties that do not exist in bulk materials with an identical composition.

Nanomaterial. A nanomaterial is a material that contains structured components with at least one dimension below 100 nm. These "nano-components" can be a solid (nanoparticle), liquid (nano-droplet), or gas (nanoporosity) phase, distributed in the material. A nanomaterial has no maximum size limit.

Nanoproduct. A nanoproduct is a commercial product that contains nanomaterial.

Colloid. A colloid is a material distributed in a dispersing medium, which is more submitted to Brownian random motion than to gravity attraction. Colloids typically have at least one dimension below 1 μm. They look homogeneous when observed by the naked eye.

Introduction

High-performance nanomaterials incorporating nanoparticles are making a massive intrusion into many industrial sectors from electronics to automotive, consumer goods, textiles, and pharmaceutics. More than 4,100 companies from 48 countries are involved in nanotechnology research, manufacturing, or applications [1]. In most of these applications, nanoparticles are surface coated with (in)organic compounds or doped with specific ions to obtain nanomaterials with specific characteristics. To date, more than 1,800 nanotechnology-based consumer products

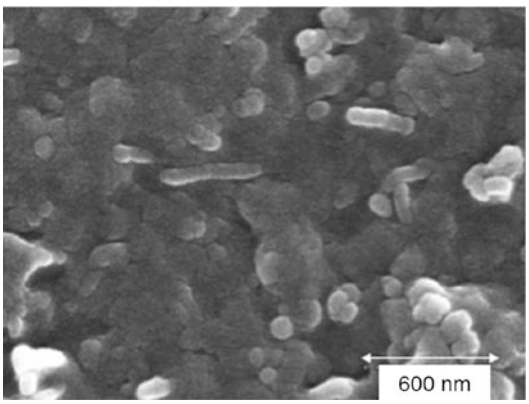
introduced to the market have been identified and listed in the non-exhaustive database proposed by the Woodrow Wilson Institute [2]. Current trends all indicate that human exposure to nanomaterials will continue to increase in the coming years as more products are developed and put on the market. This has resulted in elevated anxiety concerning the potential risks that are associated with nanotechnology [3–5]. Accidents, normal aging during regular use, or inappropriate storage of the related wastes are possible ways for the dissemination of nanomaterials, or their related by-products, into the environment.

Titanium dioxide (TiO_2) nanoparticles represent the highest mass production of nanoparticles in the world. Its commercial production for the years 2006–2010 has been estimated at 5,000 t/year and more than 10,000 t/year for the years 2011–2014 [6]. Robichaud et al. [7] estimated its worldwide production level at approximately 2.5 million metric tons by 2025. Nano-TiO_2 are indeed widely used in industrial applications taking advantage of their UV blocking (e.g., sunscreen formulation) or photocatalytic properties (e.g., self-cleaning surfaces). A major part of the production is used for "personal care" products (sunscreens, cosmetics), while the rest is used in industrial applications such as paints, plastics, catalysts, and ceramics. Such a large mass logically raises serious concerns about the fate and impact of these related nanoproducts when released into the environment [8–10].

For instance, there are evidences for the release of TiO_2 nanoparticles (up to 300 nm) used in self-cleaning exterior facade into runoff water [11]. Further in the water cycle, in wastewater treatment plants, the presence of submicronic Ti-based particles has been measured in raw sewage (100–3,000 μg/L) and even in the effluents after treatment (5–15 μg/L) [12]. Cosmetics, and especially sunscreens, are the commercialized nanotechnology-based products that underwent the largest growth from 2007 to 2010 in Europe [13]. In sunscreens, TiO_2 is the most used inorganic filter, because of its effective UV reflection and absorption capacities and its adequate tolerance by human skin. Moreover, for transparency and efficacy reasons, nano-sized TiO_2 particles are widely used. To inhibit their photoactivity, TiO_2 nanoparticles used in sunscreens are surface modified using aluminum oxide/hydroxide and/or silicon dioxide. Moreover, lipophilic coatings are also grafted at the surface to facilitate the dispersion of the nanoparticles in the oil phase of the cream. The resulting material is commonly named TiO_2-based nanomaterial.

These functionalizations typically used on nano-TiO_2 within sunscreen will undoubtedly alter not only the behavior but also the toxic impact of the nano-objects upon their release into the environment. The hydrophobic character of the outermost coating indeed prevents the dispersion in water, while the mineral surface layer prevents phototoxicity. However, one can wonder about the lifetime of these coatings when the sunscreen undergoes regular weathering expected with its use [14].

Consequently, it is necessary for rigorous human and environmental risk assessment to consider exposure scenarios, not only related to bare nanoparticles but also to commercialized nanomaterials throughout their life cycle [15], taking into account the different stages of their surface alteration.

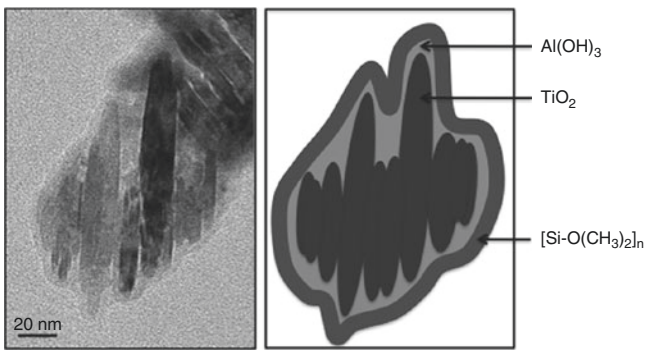


In this chapter, which focuses on the case of TiO_2 nanoparticles used in sunscreen as UV blockers, three related samples containing TiO_2 nanoparticles are compared in terms of behavior and fate in the aqueous environment, pure TiO_2 nanoparticles, TiO_2 nanomaterials used in sunscreen, and an actual sunscreen nanoproduct, so that gradual complexity in the chemical composition is explored from the bare mineral nanoparticles to the final commercialized cream. The effects of the corresponding surface properties can thus be evidenced as a function of their respective time evolution with aging.

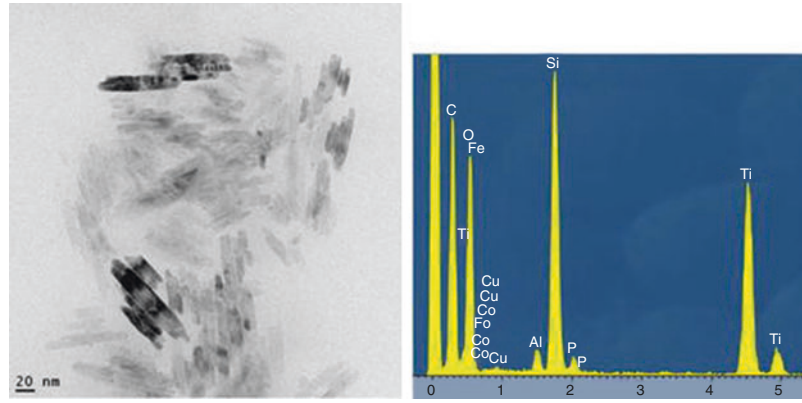
In addition to these parameters intrinsic to the nano-object's composition, different environmental factors also play a role on the fate of nanoparticles in aquatic systems. pH, salinity, naturally occurring particulate or dissolved materials from both organic or mineral origin, and porosity of the system are as many factors that significantly control the physicochemical behavior of nanoparticles in water, in close relation with

their surface properties [16, 17]. The main physicochemical reactions involved in these phenomena are presented here.

Nano-TiO_2, from Bare Nanoparticles to Sunscreen Formulation

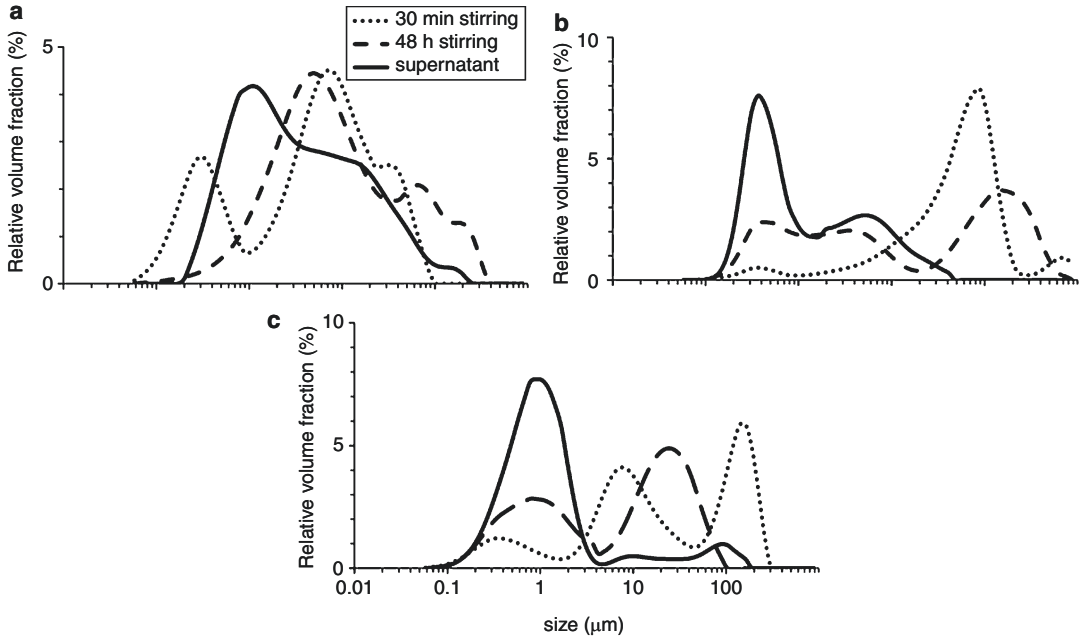


Pure TiO_2 nanoparticles used as bare nanoparticles were purchased by Alfa-Aesar Company under the trade name Titanium IV oxide, anatase, 32 nm, 39953. They consist of a powder of pure TiO_2 in the anatase form. As observed by scanning electron microscopy (Fig. 1), they are constituted of polydisperse agglomerates with sizes ranging from 100 to 600 nm. The fate of these pure TiO_2 nanoparticles in aqueous environment, and more particularly in a sandy porous medium saturated with water, was studied by Solovitch et al. [18].



Fate of Manufactured Nanoparticles in Aqueous Environment, Fig. 1 Scanning electron microscope picture of the bare TiO_2 nanoparticles

The TiO_2 nanomaterial T-Lite™ SF (BASF, Germany) is widely used in sunscreens as mineral UV blocker. Its nano-TiO_2 core is functionalized in the aim to be dispersed in the oil phase of the sunscreen formulation. Its coating consists in a first layer of photocatalysis scavenger aluminum hydroxide [$Al(OH)_3$] and of an outer layer, the hydrophobic dispersing agent polydimethylsiloxane (PDMS) consisting in $[Si\text{-}O(CH_3)_2]_n$ repeat units (Fig. 2). The behavior and aging of the T-Lite nanomaterial in aqueous system was studied by Labille et al. [19] and Auffan et al. [20].



A commercial sunscreen corresponding to high-volume product was selected for comparison with bare TiO_2 nanoparticles and coated TiO_2 nanomaterials in terms of behavior in aqueous systems. This product displays a very high Sun Protection Factor (SPF $\geq$ 50), which corresponds to one in six of the sunscreen market. Its component list includes titanium dioxide and aluminum oxide. No information was given by the manufacturer on the crystal form, size, or coating of the TiO_2 particles used in this sunscreen formulation. However, the presence of Ti, Al, Si, and C elements concentrated in or on the nanoparticles (Fig. 3) suggests a typical coating involving aluminum oxide and PDMS similar to the TiO_2 nanomaterial T-Lite SF considered in this entry. The aging and behavior in water of this sunscreen product and of three other similar formulations was studied by Botta et al. [21]. It revealed that the TiO_2 concentration in the studied sunscreen is about 4 w/w%, the rest of the formulation consisting mainly of organic components.

Dispersion in Pure Water

The effect of the nanoparticle coating or formulation on their potential dispersion in aqueous system is presented below in terms of dispersion kinetics measured for the three different materials considered. Laser diffraction was used to measure the size distribution of the dispersed particles versus time. On Fig. 4 are reported the size distributions measured on the three samples after 30 min and 48-h stirring in pure water. The three sample dispersions were carried under the same hydrodynamic conditions with a magnetic stirrer rotating at 690 rpm in a 1 L vessel. The mixtures consisted of 100 mg powder (bare TiO_2 or TiO_2 nanomaterial) or 1.5 g of cream stirred in 250 mL of Milli-Q water. After 48-h stirring, in order to better distinguish the potential presence of

nanometric or micrometric particles remaining stable in suspension, the samples were let to settle out during 48 h, and the size distribution was measured in the supernatants.

Pure TiO_2

The time-resolved size distribution of the pure TiO_2 nanoparticles is shown on Fig. 4a. Considering the 32 nm crystallite size announced by the manufacturer, an unexpected larger and polydisperse size distribution is measured. At 30 min stirring, the smallest particle size class appears above 60 nm and centered around 250 nm, but large aggregates up to 100 μm in size are also measured. With stirring time, these smallest units tend to disappear, while larger aggregates tend to grow, reaching a maximum size of 300 μm at 48-h stirring. After 48-h settling, even if the size distribution measured in the supernatant tends to overexpress the finest particles while the larger ones have been settled and removed, the disappearance of the nanometric units from the dispersion is confirmed to the benefit of micrometric aggregates centered around 1–10 μm. This apparent aggregation with stirring time was certainly due to the pH of the mixture which was let natural at 5.5. This pH corresponds exactly to the isoelectric point of the TiO_2 nanoparticles, which favors self-aggregation (see pH effect section). However, even at more acidic pH, the crystallite size of 32 nm could not be measured as distinct units dispersed in water. Solovitch et al. [18], who submitted the TiO_2 nanoparticle to an acidic treatment to protonate their surface and favor dispersion, measured by dynamic light scattering a size distribution centered around 150 nm.

This tendency for nanometric crystallites to associate together and build larger agglomerates can be explained by their exacerbated surface energy. According to the Young-Laplace's equation, the surface tension of a particle is inversely proportional to its radius of curvature, i.e., its size. With very small nanoparticles, this leads to a surface pressure so high that they are thermodynamically unstable. In order to minimize such a pressure jump across the solid surface, nanoparticles may aggregate together into larger and dense clusters [22].

TiO_2 Nanomaterial

As anticipated for the water-repellent PDMS coating, the initial behavior of the nanomaterial stirred in water is typical for a hydrophobic material in aqueous media, so that the powder is initially retained at the air-water interface. Nevertheless, under stirring, the behavior of the nanomaterial evolves rapidly like a more hydrophilic material. As soon as 30 min of stirring, the solid phase starts to disperse in the aqueous phase (Fig. 4b). Some large agglomerates of ca. 200 μm are measured; they are probably formed by hydrophobic interactions arranging agglomerates in lumps to minimize the solid/liquid surface contact. However, a second and minor class of sizes also arises around 300 nm, corresponding to colloidal residues. Its relative contribution tends to increase rapidly with time and reaches values up to 35 vol% after 48-h stirring. This submicron size allows the corresponding colloidal residues to remain stable in suspension when stirring is stopped, as confirmed by their major contribution in the size distributions measured after settling period.

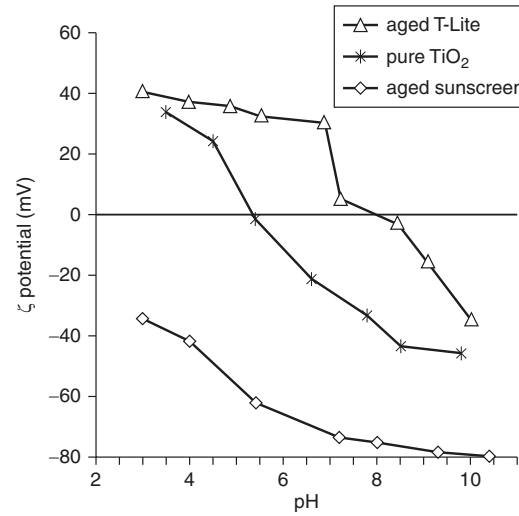
Such rapid dispersion in the aqueous phase of an originally hydrophobic material was explained by Auffan et al. and Labille et al. [19, 20] as being due to the desorption and alteration of the hydrophobic PDMS coating from the nanomaterial surface. Indeed, this was studied by measuring the release of Si from the nanomaterial to the solution during agitation in water by inductively-coupled plasma atomic emission spectroscopy (ICP-AES) [16] and by following the chemical structure of the PDMS by ^{29}Si CP-MAS NMR [20]. It revealed the desorption and alteration of most of the hydrophobic coating.

Concerning the $Al(OH)_3$ coating present in the initial nanomaterial, these works showed that it did not undergo significant alteration or dissolution in the alteration conditions used, thus remaining as a protective layer that prevents photocatalytic activity (see also section "Evaluation of the Nanoparticle Photoactivity").

F

Sunscreen Nanoproduct

Figure 4c shows the size distributions measured at the same stirring times for the sunscreen. Similar to the hydrophobic T-Lite nanomaterial, no size distribution could be measured at $t = 0$ due to the hydrophobic character which prevents immediate dispersion in water. Nevertheless, a relatively rapid dispersion in water was observed, with release of submicronic (<1 μm) particles as soon as 30 min of aging. Moreover, this seems to be a gradual process since the size distribution at 48-h stirring displays a higher amount of submicronic sizes.

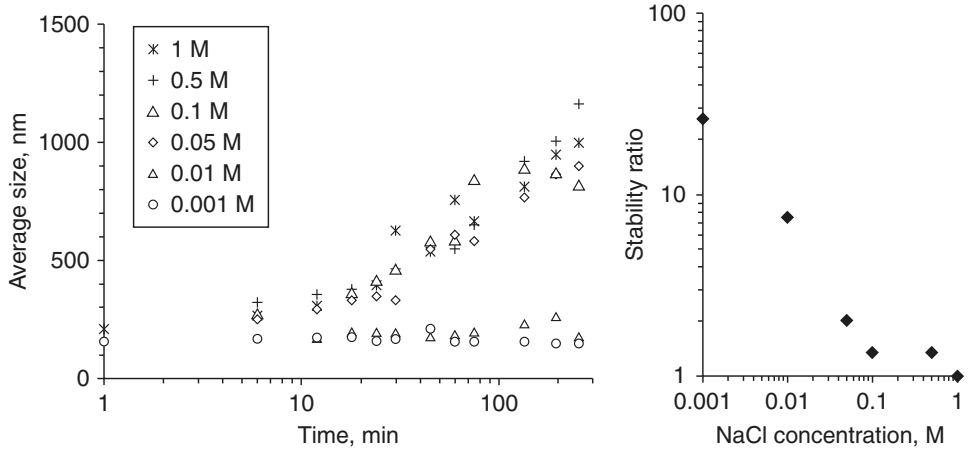


This tendency evidences the alteration of the initially hydrophobic material into residues displaying new hydrophilic surfaces, which enable their dispersion as submicronic entities. The size distributions of the residues constituting the stable suspension remaining after 48-h settling reveal a major fraction of this submicronic class. However, surprisingly, large agglomerates of several tens of micrometers are also measured in addition to the submicronic class. This larger class certainly corresponds to the agglomeration of organic matter into open structures with low density [21].

From the concentrations of the colloidal residues recovered after 48 h of stirring followed by 48 h of settling, a mass balance between the stable colloidal phase and the settled coarse phase can be estimated for the three nanoparticulate samples.

For the pure TiO_2 nanoparticles and TiO_2 nanomaterial, the ratio "dispersed/settled out" is about 50/50 and 25/75, respectively [19]. For the sunscreen, according to Botta et al. [21], the mass of the colloidal fraction dispersed in water represents between 20 % and 40 % of the initial sunscreen, while these colloids involve less than 30 w/w% of the total TiO_2 initially present.

Effect of pH on Nanoparticle Dispersion Stability



pH has a drastic effect on the dispersion stability. Adjusting the solution pH close to the isoelectric point of the dispersed particles will induce neutralization of the charged groups at their surface and thus the vanishing of the repulsive electrostatic interactions, at the benefit of the short-range and attractive van der Waals forces. This results in self-aggregation and sedimentation of the involved particles.

Fate of Manufactured Nanoparticles in Aqueous Environment, Fig. 5 Zeta potential evolution of nanoparticles versus pH

In order to better predict the dispersion stability of the nanoparticles as a function of pH, their electric surface potential can be estimated by electrophoretic mobility measurements. The values for the three samples of stable suspensions recovered after 48-h stirring +48-h settling were measured as a function of pH varying from 2 to 10. The zeta potential (ζ, mV) plots obtained are displayed in Fig. 5.

The titration curve obtained for the pure TiO_2 nanoparticles is typical for a metal oxide surface undergoing hydrolysis. The surface hydrolyzes in the presence of water to form hydroxide layers at the surface (≡M–OH). These polar hydroxyl groups confer to the oxide a hydrophilic and amphoteric character. They may become charged by reacting with H^+ or OH^- ions from the solution. At low pH, hydroxide surfaces adsorb protons and become positively charged (≡M–OH_2^+), whereas at high pH, proton desorption induces a negative surface charge (≡M–O^-). The overall surface charge of the oxide then results from the

Fate of Manufactured Nanoparticles in Aqueous Environment, Fig. 6 Aggregation kinetics of TiO_2 nanoparticles versus NaCl concentration (*left*); stability ratio of the TiO_2 suspension versus NaCl concentration (*right*)

respective expressions of all the hydroxyl sites according to the pH. The isoelectric point (IEP) of a surface is the pH of zero zeta potential. For TiO_2 surface, it is typically obtained in the range 4.8–6.9 depending mainly on synthesis specificities and relative development of the different lattice faces [17]. The TiO_2 nanoparticles considered in this entry have an isoelectric point at pH = 5.5 [18].

The zeta potential titration for the T-Lite nanomaterial revealed an isoelectric point for these colloidal residues at pH = 7.3. This IEP is characteristic for an aluminum hydroxide surface in agreement with the removal or alteration of the PDMS hydrophobic coating from the nanomaterial surface after 48-h stirring [19].

The stable suspension recovered from the commercial sunscreen displays a zeta potential remaining negative in all the pH range from 2 to 10. This does not fit with the surface charge expected from TiO_2 nor $Al(OH)_3$ used in the nanomaterials and identified respectively on the two other plots of Fig. 5. Nevertheless, Botta et al. [21] evidenced that some TiO_2 nanomaterials are well involved in the colloidal residues released from the sunscreen. In the panel of four sunscreens that they studied, TiO_2 constituted 0.6–9 wt% of the dry colloid mass. This is a relatively low proportion, which remains however in the same order as that in the initial sunscreen formulation (3–5 wt%). Thus, the organic components from the sunscreen formulation control the properties and behavior of the colloidal residues. Their negative surface charge is thus certainly due to some anionic organics such as disodium EDTA salt or oxidized siloxane polymers.

Effect of Salinity on Nanoparticles' Dispersion

Increasing salt concentration induces progressive screening of the repulsive electrostatic interactions between particles through compression of the electric double layer that surrounds each charged particle. The critical salt concentration above which attractive forces become predominant, termed the critical coagulation concentration (CCC), determines the limit for colloidal stability [17].

The aggregation kinetics of pure TiO_2 nanoparticles as a function of NaCl concentration are presented in Fig. 6 [18]. The stability ratio was calculated from the slope of the measured aggregation kinetics, as the ratio of the maximum aggregation rate obtained at the highest salt concentration to the aggregation rate measured at each salt concentration. The nanoparticles remained well dispersed at NaCl concentration below or equal to 10^{-3} mol/L, showing almost

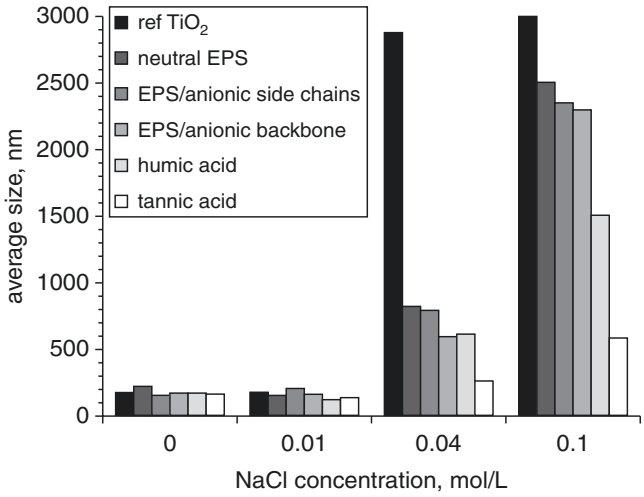
Fate of Manufactured Nanoparticles in Aqueous Environment, Table 1 Critical coagulation concentrations measured with NaCl for the three nanoparticulate suspensions tested

	CCC_{NaCl}
Pure TiO_2	10^{-1} M
T-Lite	$2\ 10^{-2}$ M
Sunscreen	10^{-3} to 10^{-1} M

constant size over a period of some 250 min. A slow aggregation regime occurred at $10^{-2} < [NaCl] < 10^{-1}$ mol/L (stability ratio > 1). The critical coagulation concentration is defined as that enabling fast aggregation regime, i.e., a stability ratio ≈ 1. In the pure TiO_2 sample, CCC_{NaCl} falls around $[NaCl] = 10^{-1}$ mol/L.

Another approach to determine the CCC for a colloidal dispersion consists in measuring the turbidity in the supernatant after a settling period. The CCC corresponds to the minimum salt concentration at which the turbidity drops. On one hand, this approach is less time consuming, requiring only one punctual measurement on a series of samples. However, on the other hand, measuring only one point for each salt concentration deprives of any kinetics information and implies a result depending on the measurement time. In other words, lower CCC value could be typically measured at longer settling time, due to the slow coagulation process.

This second approach was followed with stable aqueous suspensions obtained from TiO_2 nanomaterial and sunscreen nanoproduct [19, 21]. The respective CCC_{NaCl} values obtained in these works are reported in Table 1.



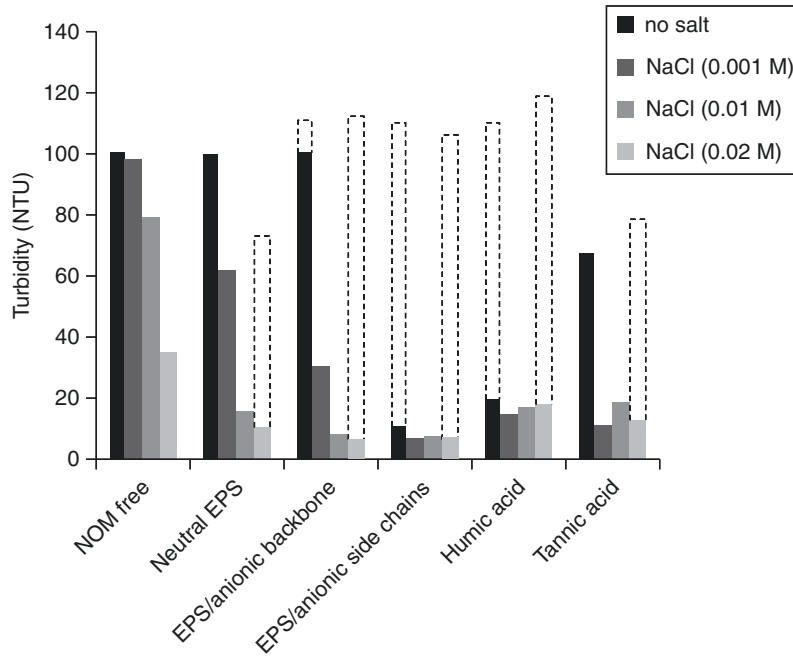
The typical salinity for seawater is around 5×10^{-1} mol/L. With the three nanoparticles' dispersions studied here having lower CCC_{NaCl} values, one could expect that they shall not remain stable in marine environment but rather undergo aggregation by coagulation mechanism. However, such simple consideration is mainly valid in synthetic system with very simple solution chemistry. In natural surface water, the presence of both suspended mineral particulate matter and natural organic matter must significantly alter the balance between dispersion and aggregation.

Effect of Natural Organic Matter on Nanoparticle Dispersion

In the two following examples of pure nano-TiO_2 and TiO_2 nanomaterial, different kinds of natural organic matter (NOM) were introduced into the nanoparticulate suspensions to evidence their effect on the nanoparticle dispersion stability. Three polysaccharides from rhizospheric bacterial origin (exopolymeric substances, EPS) and having high molecular weights (MW ≈ 2×10^6 Da): one neutral EPS and two branched anionic EPS with acidic residues located either in the backbone or in the side chains, a humic acid, and a tannic acid were tested. In all the presented experiment, the NOM concentration used were very diluted between 0.5 and 5 mg/L, so that no viscosity effect related to the high molecular weight was enabled.

Pure Nano-TiO_2

In Fig. 7 are reported the average sizes of the TiO_2 nanoparticles as a function of NaCl concentration and of the natural organic matter tested. In the absence of natural organic matter, the average size in the reference sample increases from 150 to 3,000 nm when NaCl concentration increases above 10^{-2} mol/L. This corresponds to the expected salt-induced aggregation observed in Fig. 6. The addition of natural organic matter contributed to favor nanoparticle dispersion despite the increasing salt concentration. This is typically due to the adsorption of the organic macromolecules onto the nanoparticle surface, inducing new repulsive interactions of steric and/or electrostatic nature. However, natural organic matters having different structural properties did not behave equally as a dispersing agent, depending strongly on the salt concentration. At $NaCl = 4 \times 10^{-2}$ mol/L, corresponding to the beginning of the fast aggregation regime (Fig. 6), the weak attraction forces occurring between the bare nanoparticles can be easily canceled by NOM addition, so that the average size obtained ranges six- to tenfold lower than the reference sample (250–800 nm). But at the highest salt



Fate of Manufactured Nanoparticles in Aqueous Environment, Fig. 7 Average size of TiO_2 nanoparticles as a function of NaCl concentration in the presence of different natural organic matters. pH = 8, TiO_2 = 50 mg/L, NOM = 1 mg/L

concentration 10^{-1} mol/L, the rapid aggregation measured with nanoparticles free of salt indicates the occurrence of stronger interparticle attraction forces. Such interactions could not be counterbalanced by all the NOM tested. EPS appeared as relatively inefficient dispersants. Humic acid enabled to decrease twofold the average aggregate size. Tannic acid appeared as the most efficient dispersant, limiting the average size at 500 nm despite the high salt concentration. The high charge density of humic and tannic acid molecules compared to EPS certainly favors nanoparticles' dispersion by creating new electrostatic repulsions between neighbor particles. However, when comparing neutral and anionic EPS, it appears that similar and weak dispersing effects were obtained with these three NOMs. The macromolecule anionicity is thus certainly not the driving parameter for dispersion. The molecular weight of the adsorbed macromolecules more likely appears determining in this example. Polysaccharides indeed display larger molecular weights, while tannic acid displays the lowest. With the experiment being conducted at a given NOM concentration, a lower molecular weight implies a higher number concentration, which favors surface saturation of the coated nanoparticles and thus their electrostatic stabilization. Zeta potential measurement of the nanoparticles coated with tannic acid molecules indeed reveals a significant negative surface charge thus supporting this mechanism.

TiO_2 Nanomaterial

The effect of NOM on the dispersion stability of the nanomaterial aqueous suspension is compared in Fig. 8 for two different concentration ratios: 2 and 20 wt% with respect to the mass of nanoparticles. Two opposite effects well known respectively as bridging flocculation and steric stabilization can be evidenced.

At 2 wt% of NOM, contrary to what was obtained with pure TiO_2 nanoparticles, the global effect observed was a destabilization of the dispersion. The supernatant turbidity was indeed significantly decreased in the presence of NOM, in varying extent depending on the type of NOM tested. This destabilizing mechanism is presumably bridging flocculation, in which organic macromolecules adsorb to more than one nanoparticle, creating bridges between neighboring units. The different NOM macromolecules evaluated were not all equal in terms of bridging ability. The EPS with anionic side chains and humic acid both demonstrated the highest ability to flocculate the nanoparticles, enabling an 80–90 % decrease in the turbidity in the absence of any salt. The other NOM sources required that salt be added to the solution to induce significant destabilization of the suspension. Salt addition indeed allows neighboring particles to come closer to each other, which may be a prerequisite condition for NOM-induced bridging

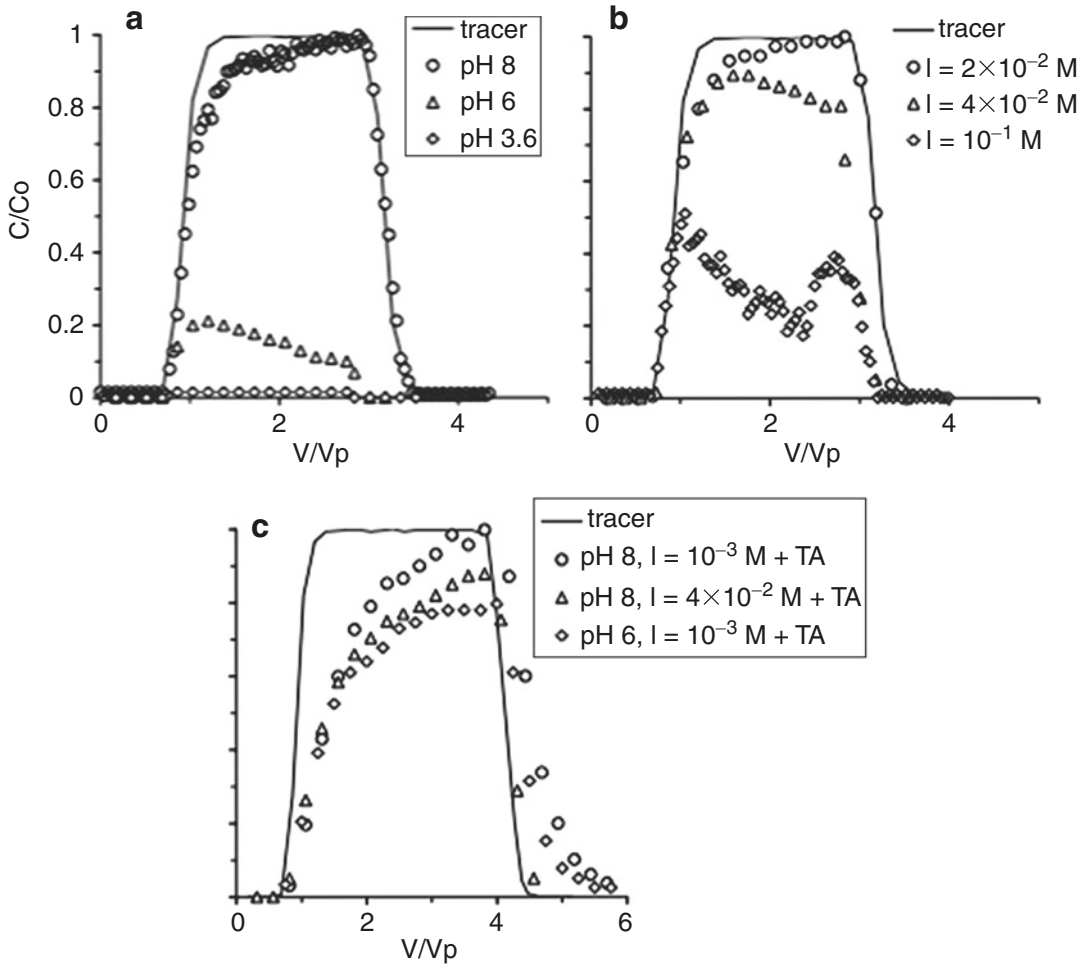
Fate of Manufactured Nanoparticles in Aqueous Environment, Fig. 8 Supernatant's turbidity of the T-Lite suspension after 48-h settling as a function of NaCl concentration and natural organic matter; NP = 25 mg/L; NOM/NP = 2 wt% (*solid histograms*) or 20 wt% (*dashed histograms*)

flocculation, depending on the macromolecule bridging efficiency. The less efficient macromolecule, the more salt addition required. Tannic acid and EPS with anionic backbone requiring salt concentration lower than the CCC_{NaCl} thus appear more efficient flocculent than neutral EPS which requires salt addition higher than the CCC_{NaCl}. The potential effects of molecular weight and spatial conformation cannot explain these discrepancies, since EPS with anionic side chains and humic acid are totally different in all these aspects, whereas both anionic EPS are more similar from this point of view. Nevertheless, the effects of the NOM anionicity and of the localization of this charge in the macromolecule likely appear as determining parameters. Indeed, the humic acid molecule is the most negatively charged, and the EPS with anionic side chains are likely to favor rapid attractive electrostatic interactions with the positively charged particles, which did not occur for the other types of NOM that were evaluated here. Indeed, the least-efficient flocculent has a neutral charge. The weak flocculent, EPS with anionic backbone, displayed acidic residues less exposed to the surrounding media. Finally, the tannic acid was a relatively good flocculent as soon as a minor salt addition was achieved. This condition is certainly due to its lower molecular weight compared to the humic acid, implying shorter interparticle bridges, which require prior approach of the neighboring particles via salt-induced partial screening of repulsive electrostatic interactions.

Conversely, at 20 wt% of NOM, further stabilization of the colloidal dispersion is observed, canceling salt-induced coagulation (Fig. 8). Similar to what was observed with pure TiO_2 nanoparticles, the mechanism involved here is again certainly steric or electrosteric stabilization. It is typically observed at high macromolecule concentration, when sorbed macromolecules saturate the surface of the particles, creating new repulsive interactions and thus dispersion stabilization.

Bridging flocculation mechanism is thus observed in the presence of a low amount of macromolecules sorbed to the colloid surface with regard to the total adsorption capacity of the colloid, while steric or electrostatic stabilization rather occurs at higher NOM concentration.

This has important consequences on the global fate of the nanoparticles in aqueous environments. Typically, in surface water where NOM concentrations range from 5 to 10 mg/L, the formation of stable nanoparticle dispersions may be favored. Conversely, in groundwaters where NOM concentration ranges from 0.1 to 2 mg/L, the flocculation of nanoparticles may be more likely. This effect has been observed elsewhere at the same weight proportions of NOM on clay colloids [23].



Since the ratio of nanoparticle to natural suspended matter plays an important role on the fate of both components, the nanoparticle concentration must be considered with caution in experimental fate studies. Predicted environmental concentration for Nano-TiO_2 in surface water ranges from 0.01 to 10 μg/L [24]. However, due to analytical detection limit, the aggregation kinetics presented here above and in most of the literature used nanoparticle concentrations higher than 10 mg/L. Such overestimation of the nanoparticle concentration completely alters the dispersion dynamic that may occur in real and complex environmental systems. In natural surface water, the probability that manufactured nanoparticles interact with each other is very low with regard to the likelihood of colliding with naturally occurring suspended matter present in significantly higher concentrations. It is thus reasonable to expect that the natural suspended matter will interact with the manufactured nanoparticles and potentially act as a carrier in the water column. This is the so-called heteroaggregation mechanism, which strongly affects the fate and transport potential of the manufactured nanoparticles. In the frame of ERA-NET SIINN Nanoheter Research Program [25], Labille and coworkers have studied this effect under realistic conditions, following both naturalist and mechanistic approaches. They showed that heteroaggregation of nano-TiO_2 indeed takes place in surface water with naturally occurring particulate or dissolved matter, depending on the sticking efficiency between the interacting components, i.e., on the chemical compositions of both these components and the dispersing solution [26].

Mobility Within Porous Media

The previous considerations of the main biophysicochemical reactions that may control the fate of particulate matter through the aqueous environment are most valid within the water column, which constitutes a relatively homogeneous dispersing phase. However, particulate matter undergoing, for instance, aggregation and sedimentation phenomena is expected to exit such monophasic and continuous system and to incorporate the more complex sediment medium. This latter consists of a solid, disordered, and porous phase saturated with water. The mobility or deposition of manufactured nanoparticles in this system is a real concern for bioaccessibility to benthic organisms. Similarly, bioaccessibility to terrestrial biota will follow the same issues as soil can be considered as another major porous receptacle for nanoparticles. *In fine*, via trophic chain or water transport through aquifers, this is exposure of humans to manufactured nanoparticles that may depend on their fate within porous media.

The diffusion column experiment is conventionally used to study the parameters determining the mobility or attachment of nanoparticles in a saturated porous medium. A mobile electrolyte circulates at a constant rate through a column filled with a stationary porous medium. At time 0, a volume of nanoparticles in suspension is injected into the circuit upstream of the column. The nanoparticle's concentration is measured in the mobile phase at the column outlet as a function of time and flux. The resulting evolution is called a breakthrough curve, typically box shaped. Many parameters can vary in the mobile phase (pH, ionic strength, hydrodynamic flow, water saturation) and in the stationary phase (porosity, mineralogy, grain size), and their effects on nanoparticle's attachment can be investigated.

The example presented in Fig. 9 deals with the pure TiO_2 nanoparticles injected within a sandy porous medium [18]. The breakthrough curves relative to different studied parameters (ionic strength, pH, presence of natural organic matter) are shown.

Fate of Manufactured Nanoparticles in Aqueous Environment, Fig. 9 Breakthrough curves of the TiO_2 nanoparticles within sand porous medium as a function of pH at I = 10^{-3} M (**a**), of salt concentration at pH = 8 (**b**), and in additional presence of tannic acid (**c**)

The influence of pH on the nanoparticle's retention in the column was studied at pH 3.6, 6, and 8 (Fig. 9a). The retention of nanoparticles in the column is nearly complete at pH = 3.6. This observation is consistent with the opposite surface charges of sand grains (−) and nanoparticles (+) at this pH, favoring electrostatic attractions between each surface. To the contrary, at pH = 8, particles and sand surfaces are both negatively charged, decreasing deposition down to 5 %. Finally, pH = 6 is very close to the pH of zero electric potential for the TiO_2 surface (IEP = 5.5; Fig. 5), which strongly favors self-aggregation of the nanoparticles, and alters their behavior in the porous medium. A high retention of TiO_2 is measured (78 %), certainly due to this aggregation effect. This is further confirmed when looking at the effect of salt concentration in the solution (Fig. 9b), since this parameter strongly controls the dispersion versus aggregation of the nanoparticle's suspension.

The ionic strength is expected to control the behavior of nanoparticles in the porous medium through electrostatic forces between sand grains and nanoparticles on one hand, but also between neighboring nanoparticles together on another hand. Both of these interactions are repulsive in nature at low ionic strength and may be screened

at high ionic strength, at the benefit of short-range attractive forces. A critical salt concentration can be defined beyond which deposition increases. This concentration is around 4×10^{-2} mol/L according to Fig. 9b. It is interesting to notice that this value coincides well with the critical coagulation concentration measured in a homogeneous and liquid medium (Fig. 6). The range 4×10^{-2} to 10^{-1} mol/L falls indeed exactly within the beginning of the fast aggregation regime. This strongly suggests a link between the aggregation of nanoparticles and their apparent deposition. Two reasonable mechanisms shall imply such a relation: (1) steric effects cause larger aggregates to deposit more likely than dispersed and smaller nanoparticles; and (2) drag forces through porous aggregates favor their deposition onto a collector, while individual nanoparticles rather follow streamline flow toward the column outlet [18].

Moreover, when the nanoparticle injection is stopped, their disappearance from the outlet solution is also much faster in conditions favoring their aggregation (pH 6 or NaCl $> 4 \times 10^{-2}$ M) than with well-dispersed nanoparticles which follow mainly the conservative tracer profile. This is due to size exclusion effect, which makes aggregates to visit a smaller portion of the available pore network within the column. Therefore, those aggregates that do not attach to the sand will pass the column more rapidly [18].

Furthermore, through its affinity for mobile or stationary inorganic surfaces, the presence of organic matter in the porous medium is likely to affect nanoparticle mobility. In a similar way to what is observed in dilute media, when organic molecules coat the nanoparticle or sand grain surface, the balance of the interactions between them will be modified by the new properties of each surface. Tannic acid was identified previously, among those tested (Fig. 7), as the natural organic matter displaying the highest dispersing effect on the TiO_2 nanoparticles even at high salt concentration. Adsorption isotherms of the tannic acid to sand or to TiO_2 nanoparticles revealed similar affinities for both surfaces.

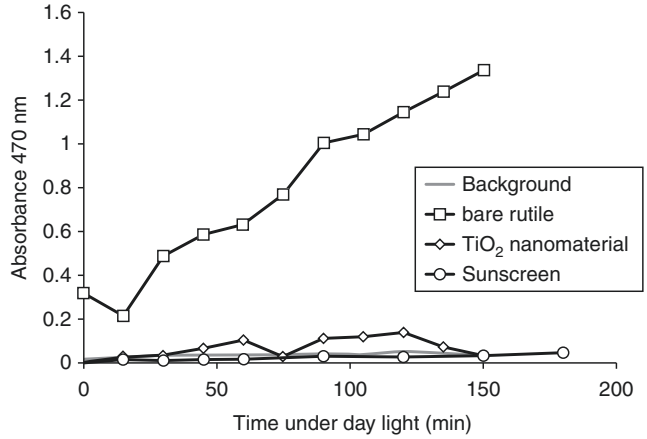


Figure 9c shows how tannic acid introduced into the nanoparticle suspension just before injection into the column strongly alters their breakthrough curve. At pH = 8, I = 10^{-3} M, where negligible deposition occurred in absence of NOM, due to both negatively charged surfaces, longer delay in the breakthrough curve and higher deposition rate are observed in the presence of the organic molecule. This is probably due to the affinity of the NOM molecule for both the sand and the nanoparticle surfaces, which may create bridges between both.

At pH = 8, I = 4×10^{-2} M, nanoparticles free of NOM undergo aggregation and display a typical breakthrough curve as previously described. In the presence of tannic acid, the coated nanoparticles remain well dispersed, and the breakthrough curve rather follows a delayed breakthrough similar to that obtained at I = 10^{-3} M, but with a slightly higher deposition.

At pH = 6, I = 10^{-3} M, while TiO_2 nanoparticles free of NOM are weakly surface charged and undergo significant aggregation and deposition, nanoparticles coated with tannic acid acquire a negative surface charge that favors dispersion and facilitates transfer through the porous medium.

Evaluation of the Nanoparticle Photoactivity

The potential photoactivity of the nanoparticles would imply under UV exposition the production of reactive oxygen species (ROS) that alter the neighboring organic matter. ROS are indeed responsible for oxidative stress which is a major cause of mortality for the living organisms exposed, due to Fenton reaction. The potential superoxide anion production by TiO_2 nanoparticles is presented here as a function of their coating or embedding. Bare TiO_2 is known to be highly photocatalytic and is commonly used as a positive reference. However, the colloidal residues released from the alteration of pure nanomaterial or of global sunscreen have been shown previously to remain respectively coated with an aluminum oxide layer or embedded in a large amount of organic components. The persistence of these surface layers certainly plays a significant role on the potential photoactivity of

Fate of Manufactured Nanoparticles in Aqueous Environment, Fig. 10 Assessment of ROS generation by the three nanoparticules' suspensions studied (pure nano-TiO_2, altered TiO_2 nanomaterial, and altered sunscreen nanoproduct). XTT (2,3-bis(2-methoxy-4-nitro- 5-sulfophenyl)-2H-tetrazolium-5-carboxanilide) was used to target and measure the superoxide anions. Measurements were performed at 470 nm

the colloids. The potential superoxide anion production by these samples was assessed under light excitation by the reduction of a tetrazolium dye, the XTT (2,3-bis(2-methoxy-4-nitro- 5-sulfophenyl)-2H-tetrazolium-5-carboxanilide). XTT is reduced by superoxide anion to produce water-soluble formazan molecule that can be photometrically monitored at the absorbance at 470 nm. In this experiment, the bare TiO_2 nanoparticles used as positive control were nano-rutile, in suspension at 50 mg/L. With the anatase TiO_2 form being naturally more photocatalytic than the rutile form used in sunscreens, the pure anatase TiO_2 nanoparticles studied in this entry would not have been a relevant reference. The absorbance data for the three samples are compared in Fig. 10. As expected, the rutile sample has an obvious photoactivity.

However, after the aging condition used in these works, the colloidal residues formed from nanomaterial or sunscreen did not generate superoxide. At the nanomaterial's surface, the Al-based layer remaining after alteration prevented the chemical interactions between the Ti atoms of the surface of the nano-TiO_2 core and the O_2 and/or H_2O molecules from the solution. This inhibited the promotion of electron-/hole + of the nano-TiO_2 core and the ROS generation. In the case of the sunscreen residues, not only the TiO_2 core of the nanomaterials used in the formulation was certainly still coated with a similar mineral ROS blocker, but the nanomaterials were also embedded within large aggregates of organic components that might not let the light pass. These two components both acted like barriers that prevented photo excitation of the TiO_2 core and assumed the absence of ROS production.

Conclusion

Among the wide concern of the risk assessment of nanotechnologies, this entry focused on the particular case of TiO_2 nanoparticles used in sunscreen as UV blockers. Three nanoparticulate samples, corresponding respectively to gradual steps of complexity in the chemical composition from the bare mineral nanoparticle to the final commercialized cream, were compared. Both the effects of the respective surface properties and of the environmental conditions on the fate of nanoparticles in aqueous system and their photoactivity could be evaluated.

In terms of surface properties, the dispersibility of nanoparticles in water highly depends on their affinity for the dispersing medium, i.e., their hydrophilic/hydrophobic character. While bare TiO_2 nanoparticles display a hydrophilic surface ready for easy aqueous dispersion, TiO_2-based

nanomaterials used in sunscreen formulation are more often functionalized with a hydrophobic coating. Moreover, final sunscreen formulation is also typically constituted of a water in oil emulsion, with hydrophobic character. However, along aging, the nanomaterial's coating was mainly altered and desorbed, and the sunscreen underwent significant textural reorganization, both tending to release in water submicronic residues with hydrophilic surface. These colloidal by-products involving TiO_2 nanoparticles then remained stable in aqueous suspension and thus ready for further transfer or interaction. The TiO_2 nanomaterial residues had a $Al(OH)_3$ surface newly exposed originating from their underlying functionalization. The sunscreen residues were constituted for more than 90 w/w% of organic components from the formulation, embedding the TiO_2 nanoparticles and driving the colloid's surface properties. In both altered samples, the non-exposure of bare TiO_2 mineral to the external environment prevented its well-known photoactivation, giving rather inactive colloids in terms of UV excitation and ROS production.

By controlling the occurrence and intensity of electrostatic interactions, both pH and salinity in water mainly drive not only the dispersion stability of nanoparticles in water but also their potential interaction and heteroaggregation with the surrounding elements (e.g., naturally occurring colloids, porous media, etc.). The respective surface charges of the involved elements with regard to that of nanoparticles are indeed a major parameter that determines the fate of both.

However, such easily predictable interactions are often screened in natural systems by the presence of natural organic matter. These molecules indeed likely interact with dispersed nano- or not nanoparticulate matter, strongly altering its surface properties, i.e., its dispersion stability. Two opposite effects can be typically observed and were evidenced again for nano-TiO_2 in this entry. Bridging flocculation inducing nanoparticle aggregation occurred at low NOM/nanoparticle ratio when adsorbed macromolecules were able to build bridges between neighbor nanoparticles. Steric or electrostatic repulsions, favoring nanoparticle's dispersion, were rather obtained at high NOM/nanoparticle's ratio when the nanoparticles' surface got saturated with adsorbed macromolecules.

Despite its focus on only one kind of nanoproduct, this entry clearly raises the major role played by the surface properties of the studied nanoparticles on their fate and impact when released into the aqueous environment. Surface properties are moreover expected to evolve continuously along the product life cycle, depending on the alteration and interaction enabled. This points out the high complexity in evaluating the global risk assessment of nanotechnologies and, to manage this, raises the key question of the relevance of the studied nanoparticles with regard to those potentially occurring in the environment.

Cold field electron emission from nanostructured materials

Definition

Field electron emission is the quantum-mechanical tunneling of electrons from a material surface into vacuum, usually from electron states near the emitter Fermi level, under the influence of a high electric field typically of magnitude 1–10 V/nm.

Overview

Cold Field Electron Emission

In field electron emission (FE), applying a high negative electric field, of magnitude typically 1–10 V/nm, causes electron tunneling from a material surface into vacuum. If electrons are emitted mainly from states near the Fermi level, as usual in room-temperature emission, the process is called "cold field electron emission" (CFE). CFE from metals and, later, semiconductors and other materials has attracted experimental attention for more than 90 years. The first detailed account in English was given in 1922 by Lilienfeld [1], who wanted to build small X-ray devices for medical applications; the first satisfactory physical explanation was given by Fowler and Nordheim (FN) in 1928/1929 [2–4].

F

Note that the derivation in Ref. [2] lacks transparency and may not be mathematically valid; however, Eq. 18 in Ref. [2] is a correct asymptotic approximation for transmission coefficient, and the approximate formula Eq. 21 for emission current density is correctly derived (see Ref. [4]). However, Eq. 22 in Ref. [2] is not correct (see Ref. [3]). Reference [5] includes a brief overview of earlier history.

In the 1930s, Müller developed the clean, pointed-wire field electron emitter and with it the field (electron) emission microscope (FEM) [6]. By the 1960s, the surface-science technique of field emission microscopy was well developed [7]. Later, FE energy distributions were measured [8]. The theory of FE and FE energy distributions from metals and semiconductors, as it stood in the 1980s, is described in a textbook by Modinos [9].

The most useful surface-science application was the study of adsorbate behavior, notably surface diffusion on clean metal surfaces. Probe-hole techniques allow the current from a small surface area to be measured [10]. A field emitter exhibits faces of different crystallographic orientations; these can be accessed in a single experiment.

Field emitters have technological applications as electron sources. *Single-tip field emitter* (STFE) sources have high brightness and small optical size and are routinely used in electron microscopy and e-beam lithography [11, 12]. Two-dimensional emitter arrays can be fabricated by various techniques, giving *large-area field emitters* (LAFEs) suitable for flat panel displays and maybe electron tube devices [13, 14].

The original LAFE was the "Spindt cathode" [15], a lithographically created array of microfabricated metallic tips (commonly Mo). Until very recently, several factors limited its operating performance and lifetime. In particular, Joule heating at high emission currents, coupled with bombardment by ionized residual vacuum-system gases, caused tip erosion and blunting.

Spindt cathodes currently find use in ion sources and mass spectrometers. Huge efforts have been invested in developing displays based on Spindt cathodes, with some success [14]. There is an ongoing effort to find alternatives that are robust in industrial vacuum conditions and can deliver high uniform current density at low operating voltages. A key factor is to develop nanostructures with a high density (high number per unit area) of individual sharp emitters.

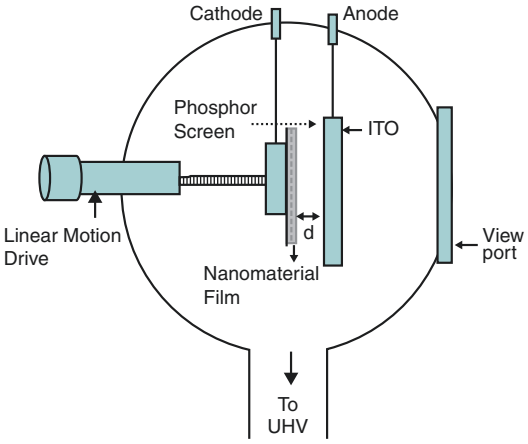
Emergence of Nanomaterials

As regards sharpness, the small size of nanomaterial emitters gives them inherent advantages. All metallic and semiconducting nanomaterials have the potential to deliver current at lower applied voltages than conventional field emitters. Recent years have seen sharp increases in studies of how to prepare nanomaterial films with high emission site density (ESD) and into the properties of the resulting LAFEs.

Many materials, including metals and ceramics, have been synthesized in nanometric forms. These are characterized by large surface-to-volume ratio, as compared with bulk materials. To be suitable for CFE, materials must have vacuum compatibility (low vapor pressure), mechanical robustness (ability to withstand the mechanical stress due to high electric fields), and resistance to ion bombardment. A desired target is an average or "macroscopic" current density J_M in the range 100–1000 A/m^2 (10–100 mA/cm^2), for applied macroscopic fields of around 1–20 V/μm. Also, it must be possible to deposit the nanomaterial onto a suitable flat substrate, with uniform ESD and relative ease.

The nanomaterials of interest to CFE can be broadly classified into: amorphous carbon, carbon nanotubes, and graphene; nanoforms of wide-bandgap semiconductors such as SiC, AlN, GaN, BN, Si, and ZnO; and nanoforms and nanostructures of established electron emitters such as LaB_6. Carbon nanotubes have small radii (up to ∼50 nm) and are attractive because of the high field enhancement offered. Wide-bandgap semiconductors have low work function and in some cases negative electron affinity. Silicon nanostructures can be easily integrated with microelectronic devices.

Reference [16] discusses early work on carbon-based LAFEs and other nanostructured heterogeneous materials and possible emission mechanisms. References [17] and [18] cover



(ultimately unsuccessful) attempts to develop LAFEs based on amorphous carbon films. Reference [19] provides an overview of material issues related to cold cathodes. Reference [20] comprehensively reviews inorganic semiconductor nanostructures and their FE properties. References [21–23] comprehensively review the FE properties of carbon nanotubes. References [24] and [14] provide good general introductions to CFE and its applications in nanoelectronics. Many nanomaterials in principle have suitable basic properties, but only those that can be reliably deposited with a high ESD of sharp nanoforms are suitable for device applications.

Basic Production and Testing Methodologies

Nanostructured materials are usually deposited/coated onto a flat substrate (typically of area 1 cm^2), to form a LAFE. The substrate is an electrical conductor or semiconductor. The deposition method depends on the material properties. Methods used include chemical vapor deposition, arc plasma deposition, pulsed laser deposition, electrodeposition, electrochemical deposition, and spin coating. Si is the most common substrate, because it can be integrated with electronic device technology.

In the diode configuration often used for testing emitter properties, this coated substrate forms the cathode. The anode is normally an ITO-coated, conducting glass plate, with or without phosphor coating. The anode-cathode separation is typically in the range 100 μm to 5 mm, with the separation maintained by a quartz or alumina spacer.

Figure 1 shows a typical system. A holder carrying the anode and cathode is mounted in an ultrahigh-vacuum chamber that is subsequently evacuated to a pressure of 10^{-8}–10^{-7} mbar. A high voltage (typically up to 10 kV) from a stable DC supply is applied between anode and cathode. The emission current (typically 10^{-9}–10^{-3} A) is measured by an electrometer amplifier. Current-voltage characteristics are usually measured over a wide voltage range. Current stability is studied by setting the current initially at some appropriate level and then recording its value at regular time intervals. An FE image

Field Electron Emission from Nanomaterials, Fig. 1 Schematic of planar diode assembly mounted in a vacuum chamber

(showing the distribution of emission current density across the emitter) can be observed on the anode screen and recorded as appropriate.

Elements of Emission Theory

Introduction

In describing CFE theory for nanomaterials, three particular problems confront the writers of an encyclopedia entry. First, there are unfortunate clashes in terminology, notation, and practice between older theory papers and the newer experimental papers on nanomaterials. This work uses a compromise convention defined in "Appendix." Second, for interpreting CFE results, experimental nanomaterial papers often employ an oversimplified "elementary" equation originally used for undergraduate teaching about CFE from metal STFEs of large apex radius and, when describing LAFE emission, often omit an important correction factor (α_f below).

This elementary equation is not strictly applicable to any real material, but is often used as part of an "elementary" method of analyzing the slope of a Fowler-Nordheim plot (FN plot) (see below). The method aims to characterize emitter sharpness by extracting a value for its field enhancement factor (FEF) (see below). Unfortunately, the

method is not valid in many cases, which causes the third problem. Past inability to identify invalid cases has meant that many spuriously large FEF values have been published. A small survey [25] suggested that perhaps 40 % of the many hundreds of relevant papers in the literature report spuriously large FEF values.

Detailed CFE theory for nanomaterials is material specific, often exceptionally complicated and usually far from fully worked out. We give here a high-level overview of CFE theory and current-voltage data analysis that can in principle accommodate the equations conventionally used and, hopefully, more-accurate theory yet to be developed. Table 1 above gives definitions and values of universal constants used. As usual in FE contexts, fields, current densities, and related quantities are treated as positive, even though they would be negative in classical electromagnetism.

Basic Equations of Cold Field Electron Emission

In CFE theory, a central quantity is the *local emission current density* (local ECD) J_L at any arbitrary position on the emitter surface. The local surface electric field E_L at this position defines the barrier experienced by electrons tunneling there and is called here the (local) *barrier field*. J_L depends on E_L, and both vary with position across the surface. The emission current i_{es} from a single emission site ("ES") is found by integrating J_L over the area of the site; thus $i_{es} = \int_{ES} J_L dA$. If a characteristic surface position "C" within the site is considered (say, where J_L has a local maximum), and J_L has the value J_C there, then the result of integration can be written $i_{es} \equiv J_C A_{ns}$. This form of area definition was introduced in Ref. [3] and defines a *notional emission site area* A_{ns}. Similarly, if i_e denotes the *total emission current* from a LAFE, then the formula

$$i_e = A_n J_C \tag{1}$$

defines a *notional emission area* A_n for the LAFE, where J_C is the LAFE maximum value of J_L (or, alternatively, some other LAFE characteristic value of J_L).

CFE theory can be formulated at various levels of complexity. In *orthodox CFE theory*, which is a complexity level used by theoreticians to discuss experimental results (on the grounds that this is the simplest theory that has any chance of being nearly realistic), the tunneling barrier is assumed to be a Schottky-Nordheim (SN) barrier (see below), and J_C can be written in terms of the characteristic barrier field E_C by the linked equations:

$$J_C = \lambda_C J_{kC}. \tag{2a}$$

$$J_{kC} = a\phi^{-1}E_C^2 \exp\left[-bv_F\phi^{3/2}/E_C\right]. \tag{2b}$$

In Eq. 2b, a and b are, respectively, the first and second Fowler-Nordheim (FN) constants (see Table 1), ϕ is the local work function at point "C," and v_F is a particular value of a mathematical function best called the *principal*

Field Electron Emission from Nanomaterials, Table 1 Basic universal emission constants. Values are given in the units often used in field emission. e denotes the elementary positive charge, m_e the electron mass in free space, and h_P Planck's constant. In these units, e has the value 1 eV V^{-1}. (Based on 2014 values of the fundamental constants)

Name	Symbol	Derivation	Expression	Numerical value	Units
JWKB constant for electron	g_e	–	$4\pi(2m_e)^{1/2}/h_P$	10.246 33	$eV^{-1/2}\ nm^{-1}$
First Fowler-Nordheim constant	a	$z_S(e/g_e)^2$	$e^3/8\pi h_P$	1.541 434	$\mu A\ eV\ V^{-2}$
Second Fowler-Nordheim constant	b	$2g_e/3e$	$(8\pi/3)(2m_e)^{1/2}/eh_P$	6.830 890	$eV^{-3/2}\ V\ nm^{-1}$
Schottky constant	c	–	$(e^3/4\pi\varepsilon_0)^{1/2}$	1.199 985	$eV\ (V/nm)^{-1/2}$
(Constant in Eq. 20)	–	c^2	–	1.439 964	$eV^2\ (V/nm)^{-1}$
(Constant in Eq. 39)	–	ab^2	–	$7.192\ 494 \times 10^{-5}$	$A\ eV^{-2}\ nm^{-2}$
(Constant in Eq. 27)	–	bc^2	–	9.836 239	$eV^{1/2}$

Schottky-Nordheim (SN) barrier function. The value of v_F depends on the values of ϕ and E_C and typically is around 0.7.

The parameter J_{kC} defined by Eq. 2b is called the *characteristic kernel current density* (for the SN barrier), and the parameter λ_C is the *characteristic local pre-exponential correction factor.* The reason for introducing J_{kC} and splitting Eq. 2 as above is that – for given choices of ϕ_C, E_C, and barrier form (here the SN barrier) – J_{kC} can be calculated *exactly.* All theoretical uncertainty in predicting the ECD J_C appears in λ_C. Exact realistic calculation of λ_C would be intensely difficult, is in some cases beyond the current capabilities of quantum mechanics, and is unlikely to happen in the foreseeable future. For metals, λ_C is thought (in 2015) to lie in the range $0.005 < \lambda_C < 11$.

Equation 2 is the $J_C(E_C)$ form of the *orthodox Fowler-Nordheim-type (FN-type) equation*.

Inserting Eq. 2a in Eq. 1 yields the $i_e(E_C)$ form of this equation, namely,

$$i_e = A_n J_C = A_n \lambda_C J_{kC} \equiv A_f J_{kC}, \tag{3}$$

where the *formal emission area* A_f [$\equiv A_n\lambda_C$] is defined by Eq. 3.

Many experimental nanomaterial papers, however, use elementary FN theory as found in undergraduate textbooks. In elementary theory, the tunneling barrier is taken as exactly triangular, and the parameters v_F and λ_C are replaced by unity, yielding the *elementary FN-type equations*:

$$J_C^{el} = J_{kC}^{el} \equiv a\phi^{-1}E_C^2 \exp\left[-b\phi^{3/2}/E_C\right]. \tag{4}$$

$$i_e^{el} = A_f J_{kC}^{el}. \tag{5}$$

Current density and current values predicted by orthodox FN-type equations can be significantly different from those predicted by elementary FN-type equations.

Auxiliary Parameters

Area efficiency parameters. The parameters A_n and A_f are always much less than the geometrical (or *macroscopic*) *area* A_M of the LAFE (sometimes called its *footprint*). The *notional area efficiency* α_n (formerly called the "area efficiency of emission" and denoted by α_M) and the *formal area efficiency* α_f are defined via the relationships:

$$\alpha_n \equiv A_n/A_M, \quad \alpha_f \equiv A_f/A_M, \quad \alpha_f = \alpha_n\lambda_C. \tag{6}$$

These parameters are measures of how much of the device area is actually emitting. Values of α_f are not well known, but are thought to usually lie in the range $10^{-11} < \alpha_f < 10^{-3}$.

For a LAFE, the average (or *macroscopic*) *current density* J_M (averaged over the whole LAFE footprint) is defined by

$$J_M \equiv i/A_M. \tag{7}$$

This macroscopic current density is given in orthodox theory by

$$J_M = (A_n/A_M)J_C = \alpha_n J_C = \alpha_f J_{kC}, \tag{8}$$

and in elementary theory by

$$J_M^{el} = \alpha_f J_{kC}^{el} = \alpha_f a\phi^{-1}E_C^2 \exp\left[-b\phi^{3/2}/E_C\right]. \tag{9}$$

The values of all the area-like parameters may need to depend on whether they are being used in the orthodox equation or the elementary equation. In LAFE literature, α_f is often wrongly omitted from elementary FN-type equations where it ought to be present. The resulting defective equation massively overpredicts values of emission current density and emission current (which may be misleading for nonexperts) and probably also makes it difficult for experimentalists to see how to extract α_f-values from experimental results. It needs to be emphasized that omission of α_f is not the result of using an elementary model; rather it is a serious and widespread conceptual error.

The basic reasons for using "formal" area parameters, in addition to the existing "notional" area parameters, are twofold. (1) It is better to have only one parameter subject to theoretical uncertainty in an equation for i or J_M. (2) The "formal" parameters correspond more closely to

what experimentalists would deduce from FN plots in orthodox emission situations (see below), in contrast to the "notional" parameters, which correspond more closely to what an exact theory would calculate or to the emitting area that might be seen in an FE image.

Barrier field and related parameters. The *emission voltage* V_e (also called the "device voltage") is the voltage between the emitting region at an emitter tip (or emission site) and the counter-electrode. For simplicity, it is assumed here that V_e is the same for all emitter surface points, although this may not be true for some real emitters. The relation between E_L and V_e can be written in two equivalent ways:

$$E_L = \beta_V \; V_e \tag{10a}$$

$$E_L = V_e/\zeta_L \tag{10b}$$

where β_V is the *local voltage-to-barrier-field conversion factor* (VCF) and ζ_L [$\equiv 1/\beta_V$] is the *local conversion length* (LCL). Where measurement circumstances allow, a *characteristic VCF* $\beta_{V,C}$ and/or a *characteristic LCL* ζ_C can be found from experimental current-voltage data (see below). Experimental values of ζ_C typically lie in the range 20–1000 nm, with sharper emitters tending to have smaller ζ_C-values. Gomer's classic formula $E_a = V_e/k_a r_a \approx V_e/5r_a$ [7] (where "a" labels apex values) makes the LCL five times the emitter apex radius r_a, but this is not a good approximation for many LAFEs, because the value of ζ_C is determined by the whole system geometry.

Equation 10a has been the more commonly used (usually with the symbol β rather β_V). However, because the symbol β is widely used in modern CFE literature to denote field enhancement factors (FEFs) (see below), rather than VCFs, it is recommended that (in the interests of avoiding confusion Eq. 10b rather than Eq. 10a should be used in the future.

LAFEs are normally produced/tested in parallel-plane geometry, using a plate separation d_{sep} that is very much greater than the height h of any nanostructure on the cathode plate. In these conditions, a *(true electrostatic) macroscopic field* E_M can be defined by

$$E_M = V_e/d_{sep}, \tag{11}$$

and a (*true electrostatic) field enhancement factor* (FEF) β_F by

$$E_L = \beta_F E_M. \tag{12}$$

It follows that (in parallel-plane geometry) β_F, β_V, and ζ_L are related by

$$\beta_F = \beta_V d_{sep} = d_{sep}/\zeta_L. \tag{13}$$

Thus, for a LAFE, the characteristic FEF $\beta_{F,C}$ can be obtained from the characteristic VCF $\beta_{V,C}$ or (better) the characteristic LCL ζ_C.

Note that some authors call β_V a "field enhancement factor," despite the fact that it has different units and dimensions from β_F. This confusing convention adds to the case for replacing use of β_V by use of the local conversion length ζ_L.

For nonparallel-plate configurations or if h is comparable with d_{sep}, the term "macroscopic field" is sometimes given meanings or a definition different from that given above. These alternatives are not discussed here.

If the system geometry, including the detailed geometry of individual emitter/emission sites, is known, then FEF values and/or LCL values can be estimated by treating the objects involved as classical conductors and solving Laplace's equation numerically. However, this is not always valid; in particular, it will not be valid if field penetration and band bending occur [9, 26].

A situation often discussed is a classical conductor with the shape of a hemisphere on a cylindrical post of radius r_c, standing alone on one of two parallel planes, with the second plane (the counter-electrode) well separated from the first. There are no known exact analytical solutions to this electrostatic problem; the best approximate formulae are fits to numerical solutions of Laplace's equation. Various formulae for the FEF $\beta_{F,a}$ at the hemisphere apex have been given (see, e.g., [27–30]). The best simple formula,

good in the range $100 < (h/r_c) < 500$ and accurate to within 12 % [27], seems to be

$$\beta_{F,a} \approx 0.72\ h/r_c, \tag{14}$$

where h is the height of the post + hemisphere. An older version, with the factor 0.72 omitted, is often used, but is significantly less accurate.

For these formulae to be adequately valid, the counter-electrode must be separated from the post apex by a distance d_{gap} very large in comparison with h (ideally, $d_{gap} > 10h$). With an array of identical posts, the posts must be separated laterally by a distance at least h to $2h$; otherwise, the value of $\beta_{F,a}$ is significantly reduced; this effect is best called *mutual screening*.

Parameters of Merit for Large-Area Field Emitters

With a LAFE, the technological objective is to generate a macroscopic current density J_M that is both sufficiently uniform and as high as is needed, using an extraction voltage V_e that is as low as possible. Important engineering parameters are: (a) the characteristic field enhancement factor, $\beta_{F,C}$; (b) the characteristic local conversion length ζ_C; (c) the *onset voltage* $V_{e,on}$ at which J_M has some specified value $J_{M,on}$ (usually chosen as between 10^{-3} and 100 A/m^2); and (d) the *emission site density* (ESD). The formal area efficiency α_f would also be an important parameter if experimental practice were to measure this (where possible), but currently it is not.

The characteristic FEF $\beta_{F,C}$ assesses how "sharp" the most strongly emitting LAFE nanofeatures are; a primary requirement for a good emitter is sufficiently high $\beta_{F,C}$. The characteristic LCL ζ_C assesses the geometry of the whole engineered LAFE (which, in the finished product, would often have both an extracting electrode and an anode); ζ_C depends both on emitter sharpness and on how close the extracting electrode can be put to the emitter. The onset voltage $V_{e,on}$ also assesses these things, but additionally takes into account the emitter work function ϕ, since low ϕ leads to low $V_{e,on}$.

ESD values are best determined by measurements with an appropriate scanning machine (e.g., Ref. [31]), given some criterion for identifying emission sites. The formal area efficiency α_f would probably be linked in a qualitative or semi-quantitative way to the ESD, but few values are available (how to determine α_f reliably is a current research topic).

Another parameter often used is the *apparent macroscopic onset field* $E_{A,on}$ defined (in parallel-plane geometry), via measured onset voltage, as

$$E_{A,on} = V_{m,on}/d_{sep}. \tag{15}$$

$E_{A,on}$ is somewhat easier to determine than $\beta_{F,C}$ and ostensibly assesses the combined effect of emitter sharpness and low work function. It is related to $\beta_{F,C}$ by

$$E_{A,on} = (E_{C,on}/\beta_{F,C})(V_{m,on}/V_{e,on}) \tag{16}$$

where $E_{C,on}$ is the *characteristic local onset field*. The value of $E_{C,on}$ that corresponds to a given onset macroscopic current density $J_{M,on}$ varies somewhat, depending on LAFE details, but as an order-of-magnitude estimate, one can take $E_{C,on} \sim 1$ V/nm.

In practice, for non-lithographically produced emitters, the preparation of good emitters may involve compromise between adequate uniformity and high characteristic FEF. The advantage of lithographic techniques is that LAFEs can be made with high uniform ESD; the main disadvantages are the higher infrastructure and production costs involved.

Experimental CFE current-voltage characteristics are normally interpreted by using Fowler-Nordheim plots, as discussed below. To understand the associated theory, it is helpful to be aware of further aspects of basic CFE theory.

Conceptual-Level Theory of Local Emission Current Density (ECD)

For notational simplicity in the theory below, a modified notation is now used. The symbols E and J are used below to refer to *characteristic local values* of these parameters (and not to

macroscopic parameters); β and ζ refer to *characteristic* local values of FEF and LCL. The voltage conversion factor (VCF) represented above by β_V is not used (but its characteristic value would be given by $1/\zeta$). Note that this notation convention is different from that used in many experimental papers, which use E and J to denote macroscopic quantities.

The details of local ECD theory involve the electronic band structure of the emitting material. If emission comes mainly from a single electronic band or sub-band, the following approach is used.

An electron in a specific emitter state, approaching the surface from the inside, has an escape probability given by the *tunneling probability D* for the barrier it encounters. A reference state "R" is selected (usually the state with the highest D-value from among those that would be occupied at 0 K), and the corresponding tunneling probability D_R is evaluated. The contributions to the local ECD J_L from all occupied emitter states are then summed, and the result is written

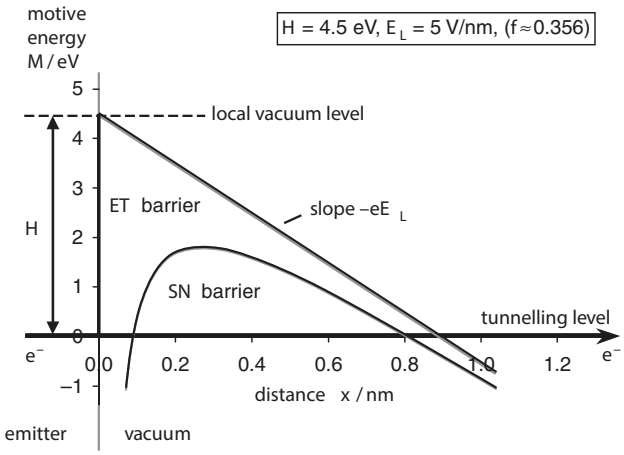
$$J_L \equiv Z_R D_R. \tag{17}$$

The parameter Z_R is defined by Eq. 17 and is termed the *effective supply for state* R.

The mathematical form of Z_R can differ widely for different materials, but the form of D_R usually depends only on the nature of the barrier. This is much the same for all materials and is examined below. In more-general situations, emission may come from more than one band or sub-band and/or from well-defined individual electron states (including surface states); J_L may then need to be expressed as a sum of terms of the form of Eq. 17.

In practice, CFE theory is nearly always presented for the case of single-band emission where the reference state is that of a Fermi-level electron moving *forward* (i.e., at right angles to and toward the emitting surface). This electron sees a barrier equal to the local work function ϕ. Other parameters relevant to this reference state are subscripted "F." This theory, set out below and usually called *Fowler-Nordheim (FN) theory*, was originally derived for free-electron metals, but also applies (to some extent) to semiconductors if most of the emission comes out of surface states (which is thought to often be the case [9]) and if band-structure pinning occurs. FN theory is widely used as if it were an approximation applicable to all materials, although this is not in valid in all contexts.

Tunneling Probability Formulae for the CFE Regime



Deep tunneling is tunneling that occurs at energy levels well below the barrier maximum. In the CFE regime, by definition, nearly all escaping electrons (including any electron in state F) escape by deep tunneling. Consequently, a good approximation for D_F is the *Landau and Lifshitz tunneling probability formula* (see Ref. [32]):

$$D_F \approx P_F \exp[-G_F] \equiv P_F \exp\left[-v_F b \phi^{3/2}/E\right]. \tag{18}$$

For the electron in state F, v_F ("nu$_F$") is a correction factor related to the barrier's mathematical form; P_F is the tunneling pre-factor; and G_F is the barrier strength (see below) (also called the "Gamow exponent" and the "JWKB exponent"). As a rough rule, Eq. 12 is valid to better than 5 % if G_F and P_F are well known and $G_F > 3$; the accuracy of Eq. 12 improves significantly as G_F increases.

The *barrier form* (or "shape") is determined by what terms appear in the mathematical expression for the *electron motive energy* $M(x)$, where x is distance measured from the emitter's electrical surface. When the electron wave function separates in Cartesian coordinates (which is an underlying assumption usually made), $M(x)$ is identified by writing the Schrödinger-equation component for motion normal to the emitter surface in the form $\hat{K}\psi = -M\psi$, where $\hat{K}$ is the kinetic-energy operator. Applying this to state F gives $M_F(x)$. G_F is then defined by $G_F \equiv g_e \int \{M_F(x)\}^{1/2} dx$, where g_e is a universal constant defined in Table 1 and the integral is taken across the region where $M_F(x) \geq 0$; the barrier-form correction factor v_F is then defined via Eq. 18.

In principle, Eq. 18 and related definitions apply to a barrier of any well-behaved form.

Field Electron Emission from Nanomaterials, Fig. 2 Electron motive energy as a function of distance x from the emitter's electrical surface, for the exactly triangular (ET) barrier and for the Schottky-Nordheim (SN) barrier defined by Eq. 19. For both barriers depicted here, the zero-field height $H = 4.5$ eV and the barrier field $E_L = 5$ V/nm

In practice, CFE theory often uses the *Schottky-Nordheim (SN) barrier* $M^{SN}(x)$, which is the simplest realistic barrier (but is not physically correct for very sharp emitters). This barrier is illustrated in Fig. 2 and defined by

$$M^{SN}(x) = H - eEx - e^2/16\pi\varepsilon_0 x, \qquad (19)$$

where e is the elementary positive charge and ε_0 the electric constant. For the SN barrier, v_F is given by $v(f)$ ["vee(f)"], where $v(f)$ is a particular value of a mathematical function $v(l')$ called the *principal SN barrier function* [33, 34]. The parameter l' is a mathematical variable [34]. In the derivation of a formula for CFE current density through a SN barrier of zero-field height ϕ, l' is put equal to the *scaled barrier field* f for this barrier, where f is a dimensionless physical modeling parameter defined by

$$f \equiv E/E^* = c^2\phi^{-2}E. \qquad (20)$$

Here, E^* is the field necessary to reduce an SN barrier of zero-field height ϕ to zero, and c is the *Schottky constant* shown in Table 1. For notational simplicity, the parameter value $v(f)$ is sometimes denoted by the alternative symbol v_F, as earlier.

In older literature (e.g., [35, 36]), the function v is expressed in terms of a different mathematical variable y [$= +\sqrt{l'}$]. The change from y to l' is a mathematical simplification [34] that also helps physical understanding [33]. A good simple approximate formula for $v(l')$, and hence $v(f)$, now exists [37, 38]:

$$v_F \equiv v(f) \approx 1 - f + (1/6)f\ln f. \qquad (21)$$

This formula is valid to better than 0.35 % over the whole range $0 \le f \le 1$ and is adequate for nearly all technological purposes.

For the SN barrier, values of the tunneling pre-factor P_F have been calculated as a function of barrier field and zero-field barrier height by Mayer [39]. In practice, the pre-factor nearly always lies in the range 0.2–1.5 and can usually be neglected.

As already noted, many nanomaterial papers do not use the SN barrier but employ the elementary approximation that puts $P_F = 1$ and models tunneling as taking place through the exactly triangular (ET) barrier $M^{ET}(x) = H–eEx$. For this elementary model, $v_F = 1$.

Emission-Value-Based Fowler-Nordheim-Type Current-Voltage Equations

A feature of CFE literature is that FN-type equations (and related analyses) are formulated using several different pairs of independent and dependent variables, in particular $J_L(E_L)$, $J_M(E_M)$, $J_M(E_A)$, $i_e(V_e)$, and $i_m(V_m)$, where i_m and V_m are the measured current and voltage (which may be different from i_e and V_e) and E_A is the "apparent macroscopic field" discussed further below. Although $J_M(E_M)$- and $J_M(E_A)$-type formulations

are common in nanomaterial papers, $i_e(V_e)$- and $i_m(V_m)$-type formulations are theoretically more satisfactory and are used here. (It is shown later how to derive $J_M(E_M)$-type results from a current-voltage formulation, when circumstances permit.)

Equations above imply that the $i_e(V_e)$ form of the new standard FN-type equation can be written as the linked equations:

$$i_e = C_{iVe} V_e^2 \exp\left[-v_F b \phi^{3/2} \zeta_C / V_e\right] \tag{22a}$$

$$C_{iVe} \equiv A_f a \phi^{-1} \zeta_C^{-2} \tag{22b}$$

where C_{iVe} is defined by Eq. 22b. In so-called FN coordinates, Eqs. (22a) and (22b) together become

$$\begin{aligned} L_e\left(V_e^{-1}\right) &\equiv \ln\left\{i_e / V_e^2\right\} \\ &= \ln\{C_{iVe}\} - v_F b \phi^{3/2} \zeta_C / V_e, \end{aligned} \tag{23}$$

where $L_e\left(V_e^{-1}\right)$ is defined by Eq. 23. If any voltage dependence in C_{iVe}, ϕ, or ζ_C can be disregarded as "small," the tangent to this equation can be written [40] in the form

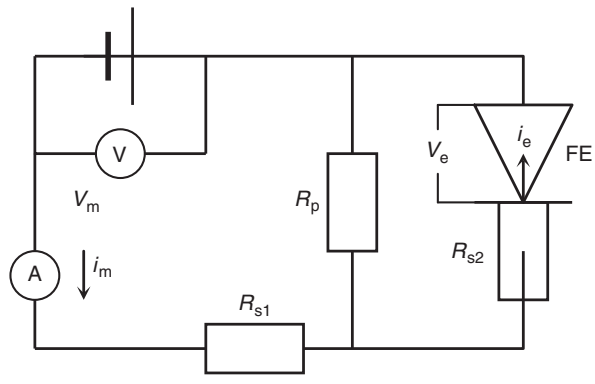
$$L_e = \ln\{r_{2012} C_{iVe}\} - s b \phi^{3/2} \zeta_C / V_e, \tag{24}$$

where s [33] and r_{2012} [40] are two of the SN barrier functions.

The *slope correction function* $s(f)$ and *2012 intercept correction function* $r_{2012}(f,\phi)$ are defined and (using Eq. 21) adequately approximated by

$$s(f) \equiv v_F - f \mathrm{d}v_F/\mathrm{d}f \approx 1 - f/6 \tag{25}$$

$$r_{2012}(f,\phi) \equiv \exp[-\eta \mathrm{d}v_F/\mathrm{d}f] \approx f^{-\eta/6} \mathrm{e}^{5\eta/6} \tag{26}$$



where the dimensionless work-function-related parameter η is given by ([33], see Eq. 6.1)

$$\eta \equiv b c^2 \phi^{-1/2}. \tag{27}$$

For illustration, $\eta = 4.64$ when $\phi = 4.50$ eV. Values of $s(f)$ are tabulated in [37] and [41], and values of $r_{2012}(f,\phi)$ in [40]; however, applying a calculator or a spreadsheet to Eqs. 25 and 26 provides values of s and r_{2012} that are adequate for most technological purposes. Illustrative values, for $\phi = 4.50$ eV and $f = 0.30$, are $s \approx 0.95$ and $r_{2012} \approx 120$. The suffix "2012" is being used to distinguish r_{2012} from an earlier function, now superceded, that was also called the intercept correction function, was denoted by r or r_N, and was defined differently.

Measured-Value-Based Fowler-Nordheim-Type Current-Voltage Equations

Figure 3 shows a schematic diagram of the circuits used to measure CFE current-voltage characteristics. A field electron emitter is a nonlinear device,

Field Electron Emission from Nanomaterials, Fig. 3 Illustrative measurement circuit for the current-voltage (i-V) characteristics of a field electron emitter, showing resistance in series and parallel with the emitting device FE. The emission parameters are denoted by $\{i_e, V_e\}$ and the measured parameters by $\{i_m, V_m\}$. Arrows denote the direction of *electron* flow

analogous to a pn-junction diode, and has an effective resistance R_e given by

$$R_e = V_e/i_e = \left(\phi\zeta_C^2/A_f a V_e\right)\cdot\exp\left[v_F b\phi^{3/2}\zeta_C/V_e\right]. \quad (28)$$

R_e is very large at low emission voltages, but becomes much smaller as V_e increases.

Careful system design can usually make the parallel resistance R_p very large (effectively infinite), but it is often impossible to eliminate the series resistances. When $R_p \approx \infty$, these combine to give a *total series resistance* R_s. Hence, conceptual distinction is needed between the *emission quantities* $\{i_e, V_e\}$ and the *measured quantities* $\{i_m, V_m\}$.

Usually one can take $i_e = i_m$, but V_e and V_m are related by

$$V_e = V_m - i_m R_s. \quad (29)$$

Defining a parameter Θ (the *voltage ratio*) by $V_e = \Theta V_m$ gives

$$\Theta \equiv V_e/V_m = R_e/(R_e + R_s). \quad (30)$$

Inserting this into Eq. 22a, and putting $i_m = i_e$, yields the $i_m(V_m)$ form of the new standard FN-type equation, which (as before) can be written as linked equations, namely,

$$i_m = C_{iVm} V_m^2 \exp\left[-v_F b\phi^{3/2}\zeta_C/\Theta V_m\right] \quad (31a)$$

$$C_{iVm} = A_f a \phi^{-1}\zeta_C^{-2}\Theta^2, \quad (31b)$$

where C_{iVm} is defined by Eq. 31b. In FN coordinates, Eq. 31 becomes:

$$L_m(V_{m^{-1}}) \equiv \ln\{i_m/V_{m^2}\} = \ln\{C_{iVm}] - v_F b\phi^{3/2}\zeta_C/\Theta V_m, \quad (32)$$

where $L_m(V_{m^{-1}})$ is defined by Eq. 32. The tangent to this curve can in principle be written in the mathematical form

$$L_m = \ln\{\rho C_{iVm}\} - \sigma b\phi^{3/2}\zeta_C/V_m, \quad (33)$$

where σ and ρ are generalized slope and intercept correction functions, but at the time of writing (in early 2015), it is – in most cases – impossible to reliably calculate (or even reliably estimate) values for σ and ρ. In most cases, this makes the usual methods of extracting reliable information from FN plots unworkable when $\Theta \neq 1$.

F

Interpretation of Experimental Current-Voltage Characteristics

Introduction

Existing data-analysis methods for measured current-voltage data are based either on the emission-value-based $[i_e(V_e)]$ form of the new standard FN-type equation given above (call these *orthodox methods*) or on the elementary equation derived from it (call this the *elementary method*). These methods were originally developed for firmly mounted metal emitters, of moderate to large apex radius, that were in good electrical contact with the high-voltage supply. Over the last few years, it has become increasingly clear that these traditional data-analysis methods do not work satisfactorily for many nanomaterial emitters, and that in principle it is important to use the measured-value-based $[i_m(V_m)]$ form of the relevant equation.

In practice, at present, this is usually only possible when we can approximate $i_m = i_e$ and $V_m = V_e$. However, for orthodox data-analysis methods to work adequately, *additional* theoretical constraints are necessary, and these give rise to the concept of the *orthodox emission situation* (specified below) – which is the situation in which orthodox methods do work adequately. If the actual emission situation is nonorthodox, then neither orthodox nor elementary data-analysis methods will work satisfactorily.

Thus, from the data-analysis point of view, what we need are a specification of what constitutes an orthodox emission situation, a reliable data-analysis method for orthodox situations, an experimental test of whether a given emission

situation is orthodox or not, and methodologies for carrying out data analysis in nonorthodox situations. The first three of these things are now in place; the fourth is the subject of active research, which is complicated because there are many possible physical causes for non-orthodoxy.

The Orthodox Emission Situation

The (theoretically perfect) orthodox emission situation complies with the following requirements [25]:

1. The emission voltage V_e is the same at all points on the emitter surface (i.e., there are no Fermi-level variations across the surface) and is equal to the measured voltage V_m (i.e., there is no voltage drop across a series resistance).
2. The measured current i_m is equal to the emission current i_e (i.e., there are no leakage currents).
3. The emission mechanism is deep tunneling through an SN barrier, and consequently the measured current is given by a version of the FN-type equation (Eq. 31).
4. In addition, in this equation (Eq. 31), (a) $\Theta = 1$; and (b) the only quantities that vary with V_m are V_m itself and the barrier-form correction factor v_F.
5. In particular, the local work function value ϕ is independent of both measured current and voltage and has the value assumed by the data analyst.

This set of theoretical assumptions (a) reduces Eq. 31 to Eq. 22, but with "e" everywhere replaced by "m," and (b) ensures that Eqs. 23, 24, 25, 26, and 27 are applicable. Theoretically, this is what existing orthodox analysis assumes (though in some cases further approximations are made). No real emitter or emission situation is "exactly orthodox," but many situations are "nearly orthodox," with orthodox data analysis adequately applicable.

However, with nanomaterial emitters, there are many real emission situations that are excluded by the orthodoxy requirements, particularly by requirement (4). These include situations where there is significant series resistance in the measurement circuit, situations where field-dependent changes in emitter geometry occur, and situations where the typical emission site apex radius is less than about 10–20 nm, to name but a few.

Orthodox Data Analysis Using Fowler-Nordheim Plots

A theoretical or experimental data plot made in FN coordinates is called a *Fowler-Nordheim plot (FN plot)*. Clearly, for an orthodox emission situation, the slope S_{iV}^{oes} and intercept $\ln\{I_{iV}^{oes}\}$ of the theoretical tangent described by Eq. 23 (but with "e" replaced by "m") are given via:

$$\begin{aligned} S_{iV}^{oes} &= -sb\phi^{3/2}/\zeta_C; \\ I_{iV}^{oes} &= r_{2012}\ \ C_{iVm} = r_{2012}A_f a\phi^{-1}\zeta_C{}^{-2}. \end{aligned} \tag{34}$$

The correction factors s and r_{2012} are both slowly varying functions of the measured voltage, because (in the orthodox emission situation) there is a well-defined linear relationship between V_m and the scaled barrier field f used above, namely,

$$V_m = (\zeta_C E^*)f. \tag{35}$$

Raw experimental data may also be plotted in this way, and the plot is often nearly linear. An exact straight line can be fitted to the experimental data, either manually or by linear regression, and its equation can be written

$$L_m = \ln\{I_{iV}^{fit}\} + S_{iV}^{fit}V_m{}^{-1}. \tag{36}$$

There are several slightly different ways of analyzing FN plots, but the most flexible is the *tangent method.* In this, one assumes that the experimental plot is equivalent to the theoretical tangent at some particular value $V_m = V_t$ that corresponds (via Eq. 35) to the value $f = f_t$. For this value the correction factors have the values s_t and r_t. One then takes the fitted slope and intercept in Eq. 36 to be good estimates of the theoretical slope and intercept in Eq. 34, which yields the formulae

$$\zeta_C = -S_{iV}^{fit}/s_t b\phi^{3/2} \tag{37}$$

$$A_f = I_{iV}^{fit} \times \left(\phi\zeta_C^2/r_t a\right) = \left(I_{iV}^{fit}\right)\left(S_{iV}^{fit}\right)^2/r_t s_t^2 ab^2\phi^2 \equiv \Lambda_t \left(I_{iV}^{fit}\right) \left(S_{iV}^{fit}\right)^2, \quad (38)$$

where Λ_t is the particular value $\Lambda(f_t,\phi)$ of the *area-data extraction parameter* $\Lambda(f,\phi)$ defined by

$$\Lambda(f,\phi) = 1/\left(r_{2012} s^2 ab^2\phi^2\right). \quad (39)$$

$\Lambda(f,\phi)$ is a new SN barrier function. Λ is broadly similar in purpose to the function Γ found in older literature (e.g., [42]); however, Λ is defined in a significantly different way and supercedes Γ.

The value chosen for f_t needs to correspond to a point near (or slightly to the left of) the middle of the range of $(1/V_m)$ values used to make the FN plot (or the part of it being analyzed). For an emitter with $\phi = 4.50$ eV, the value of f_t might typically be around 0.30 [43]. Corresponding values of other parameters in Eq. 38 are $s_t \approx 0.95$, $r_t \approx 120$, and $\Lambda_t \approx 6$ nm^2/A. This value of s_t can be used in a first application of Eq. 37.

Values derived as above for ζ_C are not particularly sensitive to the value chosen for f_t, but values of A_f can be. Better estimates of ζ_C and A_f can be obtained by using the extracted value of ζ_C and the observed midrange value of V_m^{-1} to obtain a revised estimate of f_t, via Eq. 35. Revised estimates of r_t, s_t, and Λ_t can then be obtained from relevant formulae given above, and revised estimates of ζ_C and A_f made by reapplying Eqs. 37 and 38.

If needed, the value of the characteristic FEF $\beta_{F,C}$ can be obtained from ζ_C via Eq. 13, and the value of the formal area efficiency α_f can be obtained from A_f via Eq. 6. Arguably, this is the best method of obtaining values of $\beta_{F,C}$ and α_f, since it is based on FN plots made using raw experimental data. Nevertheless, many experimental papers show FN plots ostensibly of the type $[\ln\{J_M/E_M{}^2\}$ vs $1/E_M]$ (often actually of the type $[\ln\{J_M/E_A{}^2\}$ vs $1/E_A]$). Obviously, this alternative approach requires pre-conversion of the raw experimental data. In orthodox emission situations (but not in nonorthodox situations), valid values of $\beta_{F,C}$ and α_F can be obtained from

$$\beta_{F,C} = -S_A^{fit}/s_t b\phi^{3/2} \quad (40)$$

$$\alpha_f = \Lambda_t \left(I_A^{fit}\right) \left(S_A^{fit}\right)^2, \quad (41)$$

where $S_A{}^{fit}$ and $I_A{}^{fit}$ are the slope and intercept of the straight line fitted to such a plot.

In the elementary data-analysis method, as applied to orthodox emission situations, the parameters s_t and r_r are replaced by unity. This gives rises to error of about 5 % in the estimation of ζ_C or $\beta_{F,C}$, but would give rise to error by a factor of order 100 in the estimation of A_f or α_f. In practice, due in part to the widespread habit in nanomaterial literature of writing down a defective elementary FN-type formula [for $J_M(E_M)$] that erroneously omits the factor α_f, estimates of emission area and formal area efficiency are not normally made in nanomaterial work. It would be useful and entirely possible to do so in orthodox emission situations, but – to avoid unnecessary error – it would be desirable to use the orthodox data-analysis formulae described above, rather than elementary data-analysis formulae.

A Quantitative Test for Lack of Orthodoxy

The formulae in the preceding Section give valid results only in emission situations that are "nearly orthodox." In nonorthodox situations the formulae generate spurious results. In particular, they generate spuriously large values of the characteristic FEF $\beta_{V,C}$ [25]. In [25], Forbes has recently described an experimental test for detecting lack of orthodoxy. This test can be applied to any type of FN plot (even when numerical values, but no units, are shown on the axes). The test involves extracting values of scaled barrier field f from an experimental FN plot, using the formula

$$f^{extr} = -s_t\eta/\left[S_X^{fit} \cdot \left(X^{-1}\right)^{expt}\right], \quad (42)$$

where X is the independent variable used in the plot, $(X^{-1})^{expt}$ is the experimental horizontal-axis value of interest, and S_X^{fit} is the fitted (negative) slope. One can take $s_t \approx 0.95$, as above. From this

formula, f-values can be found that correspond to the ends of the range of X-values measured (or to the ends of the range over which plot linearity is observed). This provides an apparent experimental range of f-values. The test assesses whether this extracted range is reasonable.

For any given value of the local work function, four indicative boundary f-values $\{f_{lb} < f_{low} < f_{up} < f_{ub}\}$ can be specified as described in [25]. All these values depend on the assumed value of local work function. For illustration, for $\phi = 4.50$ eV, the set of values is {0.10, 0.15, 0.45, 0.75}; f-value sets for other work function values are given in [25]. The test is an engineering triage test. (1) If the whole extracted range lies between f_{low} and f_{up}, then this range is "apparently reasonable." (2) If any part of the extracted range is below f_{lb} or above f_{ub}, then this range is "clearly unreasonable." (3) If part of the extracted range is outside the "apparently reasonable" range, but not in either of the "clearly unreasonable" ranges, then further investigation is required.

If the extracted range is "apparently reasonable," then the emission situation is orthodox or "nearly orthodox," and use of the formulae above is valid. If the extracted range is "clearly unreasonable," then it is almost certain that the formulae above will generate spurious results. If "further investigation is required," then there is a significant possibility the formulae above will generate unreliable results.

In work reported in [25], a small sample of 19 published FN plots, taken from nontraditional emitters of various kinds, were tested in this way. Approximately 40 % of these FN plots yielded "clearly unreasonable" f-value ranges, indicating that the related published FEF values are spuriously high. This suggests that there are a large number of unreliable FEF values in the literature and that often we do not know which are reliable and which are not.

If an FN plot exhibits two emission regimes with a break of slope between them, then this is a clear indication that the higher-current regime is nonorthodox. The lower-current regime may or may not be orthodox. Reference [25] also identified instances where a nearly linear (slightly curved) single-regime plot turned out to be nonorthodox.

It is arguable that the orthodoxy test should be applied to all published nanomaterial FN plots before any LAFE characterization parameter derived from such a plot is used for any other purpose, and that the orthodoxy test should be applied as part of all new FE investigations of nontraditional materials.

Clearly, a need exists to develop alternative methods of analyzing current-voltage data taken in nonorthodox FE situations. Methods currently being explored [44] include (a) development of an engineering ansatz that would enable a spurious FEF value to be modified toward the true FEF value; (b) attempts to derive V_e values from V_m values, by simulations that involve modeling the series resistance and comparing simulated $i_m(V_m)$-type FN plots with experimental plots; and (c) attempts to derive slope and intercept correction factors for nonplanar geometries where the emitter has small apex radius and to explore quantum-confinement effects in greater detail. There are many possible causes of non-orthodoxy and many conceivable methods of dealing with them. Investigation of how (where practicable) to deal with these problems is still in its early stages, and detailed comment here would be premature. For further information about FN-plot analysis, see Ref. [44].

Field Electron Emission from Planar Emitters

As indicated in the introduction, anisotropic one-dimensional (1D) and two-dimensional (2D) nanostructures have been recognized as potential field emitters for practical applications in various vacuum microelectronic devices, such as flat panel field emission displays (FEDs), X-ray tubes, and microwave tubes. Generally, for field emission research and development (R&D) studies, nanostructures are deposited onto a conducting substrate in a thin-film form. Such an assembly of nanostructures, called earlier a "large-area field emitter" (LAFE), is also known as a "multi-tip emitter." LAFEs are effective

emitters primarily because the high aspect ratios of the individual emitting structures lead to high field enhancement factors.

In principle, LAFEs can be deposited onto rounded surfaces, but it is more common to deposit them onto planar substrates, in which form they are also known as *planar emitters*. FE R&D studies of the 1D and 2D nanostructures are usually performed in a planar diode configuration (also known as close-proximity geometry). In this configuration, the emitter (cathode) and the anode are held parallel in close proximity, with the interelectrode separation ranging from a few tens of micrometers to a few millimeters. The anode can be a semitransparent cathodoluminescent phosphor screen or a metal disk, typically about 20 mm in diameter. As indicated earlier, use of a phosphor screen facilitates observation and recording of the FE image.

Differences in practical aspects of FE studies of a planar emitter and a traditional single-tip field emitter (STFE), i.e., a single microtip of well-defined shape and size, may be summarized as follows:

1. In the conventional configuration employed for STFE studies, the interelectrode separation is a few centimeters or more, whereas in the planar diode configuration, it ranges from a few tens of micrometers to a few millimeters.
2. In STFE-type geometry, the anode is often a partly hemispherical semitransparent cathodoluminescent phosphor screen (radius about 5–6 cm), whereas in the planar diode configuration, the anode is planar and can be a semitransparent cathodoluminescent screen or a metal disk 5–20 cm in diameter.
3. In STFE-type geometry, the electrostatic field E_a at the STFE apex is usually estimated via Gomer's formula, which (as noted earlier) can be written in the various forms

$$E_a = V_e/k_a r_a = V_e/\zeta_a = \beta_{V,a} V_e, \qquad (43)$$

where V_e is the emission voltage, r_a is the STFE apex radius, k_a is usually called a *shape factor* or a "field factor," ζ_a is the apex LCL, and $\beta_{V,a}$ is the apex VCF. In the planar diode configuration, as discussed earlier, two types of electrostatic field are needed, namely, the macroscopic field E_M as defined by Eq. 11 and a characteristic local barrier field E_C. If the characteristic point is chosen to be at the apex of one of the individual emitters, this local field can alternatively be denoted by E_a and is related to E_M by the apex version of Eq. 12, namely,

$$E_a = \beta_{F,a} E_M. \qquad (44)$$

A habit in LAFE literature in general, and in nanomaterial literature in particular, is to denote both β_F and β_V by the unadorned symbol β, which is potentially confusing. Further, though most authors call our β_F a "field enhancement factor" (FEF), some authors apply this name to our β_V. To resolve the confusion, statements have been made such as "the field enhancement factor, β, has the units of cm^{-1} (or nm^{-1}) in the conventional geometry, whereas it is dimensionless in the planar diode configuration." However, it is unsatisfactory to have two different physical quantities, with different physical dimensions, called by the same name and allocated the same symbol, and alternative approaches have been suggested.

One possibility is to distinguish the two symbols by a suffix and give a different name to β_V, which is the approach adopted in this entry, but this is not entirely satisfactory. Another approach was the attempt (e.g., [29]) to have β_F-type FEFs denoted by the symbol γ. This has had some limited success, but use of the symbol β to denote FEFs remains deeply entrenched. Yet another approach is the proposal made earlier that the use of VCFs (i.e., β_V-type parameters) be abandoned and be replaced by the use of local conversion lengths (LCLs) given by $\zeta_L = 1/\beta_V$.

4. In STFE-type geometry, one can easily achieve magnifications of around 10^5–10^6 and resolutions of around 3–4 nm (or sometimes better), whereas the planar configuration offers poor magnification and

F

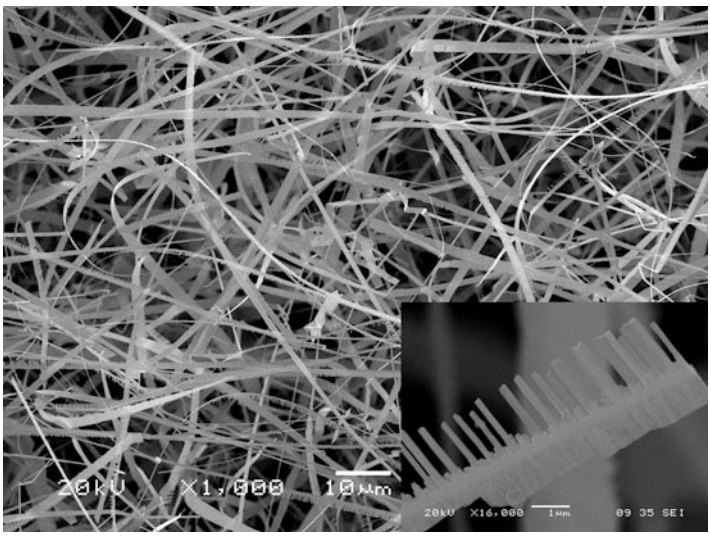
resolution. In fact, for the simple planar configuration, precise magnification and resolution cannot be obtained.

5. In STFE-type geometry, the STFE apex field can easily be (approximately) estimated from Gomer's formula (Eq. 42 above). With a planar emitter (i.e., a LAFE), it is difficult to make reliable theoretical estimates of electrostatic field at the apex of any individual emitter, because the geometry is much more complicated.
6. With a planar emitter, a large number of individual emission sites contribute to the total emission current. When an emitter has a high surface density of emission sites, it may be particularly suitable as a high-current-density electron source for practical applications in vacuum microelectronic devices such as flat panel displays and X-ray tubes.
7. Furthermore, for planar nanostructured emitters fabricated from semiconductors with a narrow bandgap, noticeable enhancement in the emission current density has been observed as a result of illumination by visible light. Such effects may contribute toward the development of a new generation of nano-optoelectronic devices.
8. As regards emission current stability, planar cathodes are somewhat inferior to STFE-type cathodes, for three reasons. (i) The surface area available for capture of residual vacuum gases is much larger, and adsorbed molecules may migrate to become adsorbed at emission sites, subsequently becoming desorbed. Hence, there is more fluctuation in the emission current, resulting from more-frequent time-dependent changes in local work function induced by the adsorbed molecules. (ii) Extinction and generation of emission sites may result from bombardment by ions created by electron-impact ionization of residual gas molecules in space above the array, particularly under "industrial vacuum conditions." (iii) Provision for thorough "degasing" or "in situ cleaning" of the planar cathodes involves instrumental complexity, in contrast to the situation for STFE cathodes, which can easily be heated in situ by mounting them on a heating loop.
9. For STFEs, basic theory uses the well-defined concepts of emission current i_e and local emission current density J_L, and no confusion arises. With planar emitters, the concept of macroscopic current density J_M is also used. As noted earlier, J_M can be less than the LAFE characteristic local ECD J_C by many orders of magnitude. However, some nanomaterial papers fail to distinguish properly between the two types of current density and/or fail to identify which type of current density their symbol "J" represents. J_M is related in some way to the surface density of emission sites, but exact estimation of the number of emission sites (which involves identifying which nanostructures are emitting the electrons) is a difficult task.
10. For STFEs, experimental FN plots are always based directly on the raw experimental data and hence are of the type $[\ln\{i_m/V_m^2\}\ vs\ 1/V_m^2]$. With planar emitters, it has become conventional to pre-convert the raw experimental data and make plots *ostensibly* of the type $[\ln\{J_M/E_M^2\}\ vs\ 1/E_M]$ (though it is argued above that in this case too it would be better to use plots of type $[\ln\{i_m/V_m^2\}\ vs\ 1/V_m]$), based on the raw experimental data.

The term "ostensibly" is used above because the pre-conversion process of dividing the measured voltage V_m by the plate separation d_{sep} does not necessarily generate a value of true macroscopic field E_M (which is defined as V_e/d_{sep}). Rather it generates the mathematical parameter E_A that can be called an *apparent macroscopic field.* If voltage drop occurs in the measuring circuit, then E_A is not equal to the true macroscopic field E_M present in the LAFE. Further, in this case, the quantity extracted from the slope of an FN plot of type $[\ln\{J_M/E_A^2\}\ vs\ 1/E_A]$ is not a true FEF, but a *pseudo-FEF* that may differ significantly in value from the true macroscopic (electrostatic) FEF associated with the LAFE under analysis.

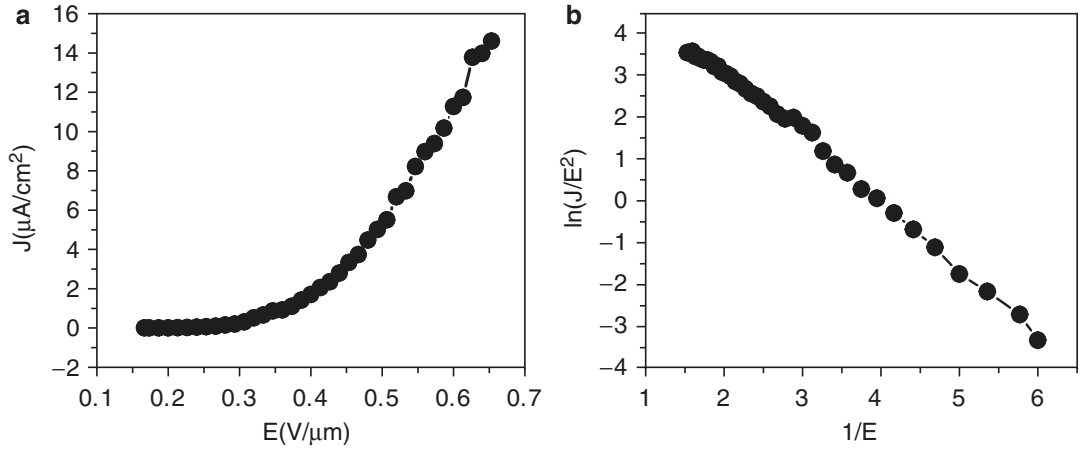
The mathematical analysis of FN plots of type $[\ln\{J_M/E_A^2\}\ \text{vs}\ 1/E_A]$ is complicated, confusing

and incompletely understood, and involves unsolved problems. Both conceptually and mathematically, it is easier to deal with plots of the type $[\ln\{i_m/V_m^2\}$ vs $1/V_m]$. Hence, if it is discovered (by applying the orthodoxy test to a plot of type $[\ln\{J_M/E_A^2\}$ vs $1/E_A]$) that an emission situation is nonorthodox, subsequent analysis (if possible at all) may be easier if the original raw data is replotted in the form $[\ln\{i_m/V_m^2\}$ vs $1/V_m]$.



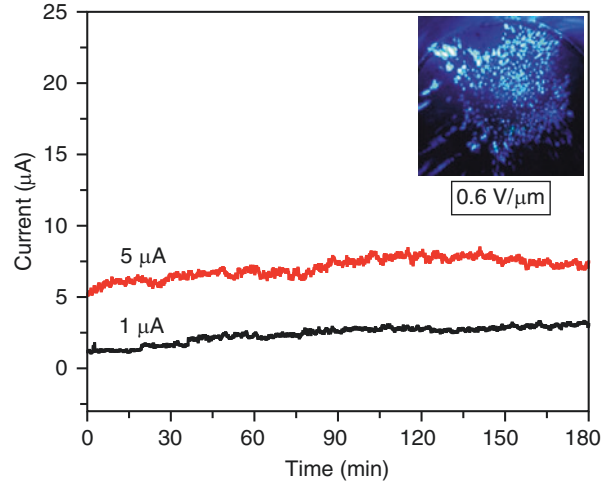
It is arguable that community use of (what are in reality) plots of type $[\ln\{J_M/E_A^2\}$ vs $1/E_A]$ has made it significantly more difficult for graduate students to recognize that arguments based on series resistance and Ohm's law may be the true explanation of puzzling experimental effects. This said, there is a good case for presenting LAFE results in the form of a direct plot of $J_M(E_A)$ since this makes it easier to compare the behavior of different nanostructures; similarly, there is a case for using plots of $J_M(V_m)$ to compare the performance of different engineered LAFEs. The best approach may be to use different forms of plot for different purposes.

Field Electron Emission from Cadmium Sulfide: A Case Study



Recently, MAM and DSJ have investigated the field emission properties of various nanoforms of cadmium sulfide (CdS), a II–VI semiconductor that is also a photoconducting material with controllable morphology. Here we discuss the case of CdS nanocombs grown on a silicon substrate. The substrate is chosen so that the application could be integrated with silicon technology. Details of the synthesis of nanocombs, based on thermal evaporation of the CdS, are described elsewhere [45].

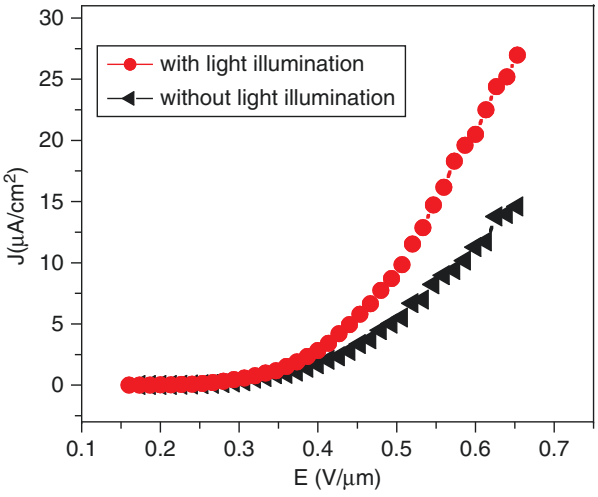
Figure 4 shows the SEM images of the as-synthesized CdS nanocombs grown on a silicon substrate. The structure of the nanocombs was analyzed using X-ray diffraction and was found to be the pure wurtzite CdS phase. The cathode as described above was mounted in a planar diode arrangement with a spacing of 1 mm between the anode and cathode. The whole assembly was placed in a vacuum chamber attaining a pressure near 10^{-8} mbar, and measurements were carried out at this pressure.



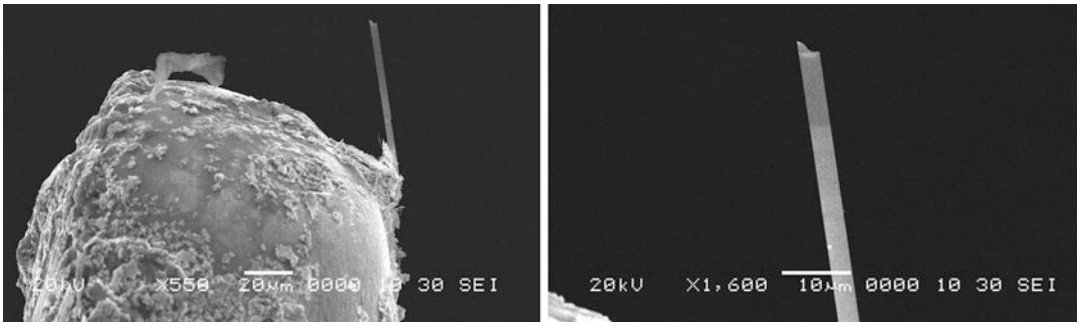
Current-voltage (i_m-V_m) and current-time (i_m-t) characteristics were measured, and the i_m-V_m data were converted to data relating macroscopic current density J_M to apparent macroscopic field E_A, using the parameter values $A_M = 1$ cm^2 and $d_{sep} = 1$ mm. Figure 5a depicts the $J_M(E_A)$ characteristics, and Fig. 5b the corresponding FN plot. (For simplicity, the symbols E and J are used in these figures to denote macroscopic quantities.) The FN plot is linear in the low-field region and

Field Electron Emission from Nanomaterials, Fig. 4 SEM image of as-synthesized CdS nanocombs grown on a Si substrate. The inset shows a closeup view of a nanocomb (Reproduced from Ref. [45]; copyright ©2011, Royal Society of Chemistry)

Field Electron Emission from Nanomaterials, Fig. 5 (**a**) Plot of macroscopic current density (here, J) against applied macroscopic field (here E) for the CdS nanocombs and (**b**) the corresponding Fowler-Nordheim (FN) plot (Reproduced from Ref. [45], copyright ©2011, Royal Society of Chemistry). In this plot, E (rather than E_M or E_A) denotes macroscopic field and J (rather than J_M) denotes macroscopic current density. In the FN plot, the units of E and J are, respectively, V/μm and μA/cm^2



Field Electron Emission from Nanomaterials, Fig. 6 Plot of emission current versus time for the CdS nanocombs. The inset shows a FE image recorded at an apparent macroscopic field of 0.6 V/μm (Reproduced from Ref. [45]; copyright ©2011, Royal Society of Chemistry)

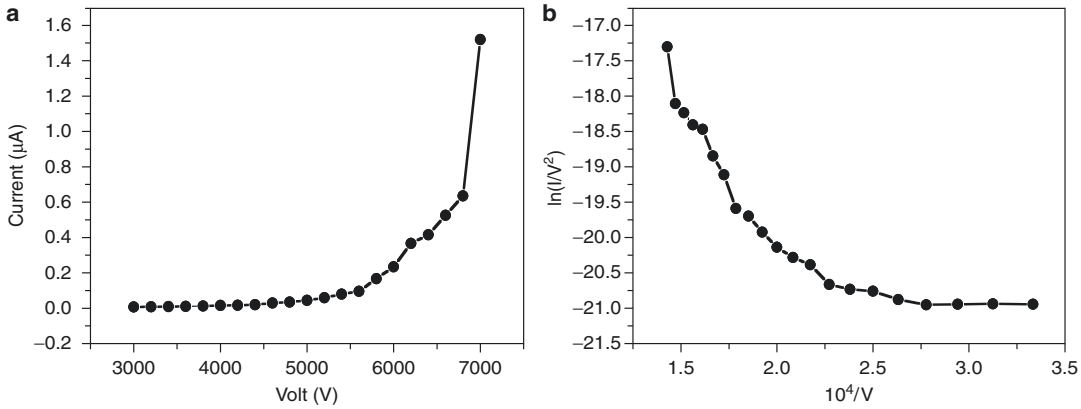


shows a slight saturation tendency in the high-field region. The apparent macroscopic onset field, defined as the field required to generate an emission current density of $\sim 10^{-3}$ A/m^2, is ~0.26 V/μm.

Figure 6 shows the i_m-t plots recorded to investigate the current stability at the base pressure of around 10^{-8} mbar. The average current at the preset levels of 1 μA and 5 μA is found to remain nearly constant. The inset of Fig. 6 shows the FEM image recorded at $E_A = 0.6$ V/μm. The FEM pattern helps when studying the emission uniformity over the emitting area, including emission spot flickering.

As noted above, CdS is a photoconducting semiconductor. Photosensitive FE studies were carried out by exposing the cathode to a constant-intensity visible light source. The cathode was illuminated with a 1300 W/m^2 halogen lamp, having intensity at the cathode measured as 80 W/m^2. Figure 7 shows the $J_M(E_A)$ plots with and without illumination. It can be seen clearly

Field Electron Emission from Nanomaterials, Fig. 7 Plot of macroscopic current density (here, J) against apparent macroscopic field (here, E) for the CdS nanocombs, with and without light illumination (Reproduced from Ref. [45]; copyright ©2011, Royal Society of Chemistry)



Field Electron Emission from Nanomaterials, Fig. 8 SEM images of the single nanowire attached to the tungsten needle

that the illumination enhances the CFE current density. The enhanced and unenhanced values (with and without illumination, respectively) of the apparent macroscopic onset fields (fields for drawing the current density 10^{-3} A/m^2) are 0.24 V/μm and 0.26 V/μm, respectively. The observed photosensitivity can be attributed to the creation, by photoexcitation, of electrons in excited states; in such states, electrons find it easier to propagate within the material and tunnel out of it.

An approximate value of the apparent characteristic field enhancement factor $\beta_{F,C}^{app}$ for the CdS LAFE can be calculated directly from the slope S_A^{fit} of the experimental FN plot (Fig. 5b), using Eq. 40, with $s_t = 1$ and the effective work function ϕ for field-emitting CdS taken here as 4.2 eV. This yields the value $\beta_{F,C}^{app} \approx 10^4$. This value looks implausibly large. Application of the orthodoxy test described above shows that Fig. 4b corresponds to the f-value range 0.49–1.4: this range is "clearly unreasonable," and we may conclude that the emission situation is nonorthodox and that the FEF value 10^4 is spuriously large. The exact reason for the non-orthodoxy of the CdS nanocomb is not currently known, but series resistance in the measuring circuit seems the most plausible explanation. Among the FN plots tested in Ref. [25] was one from a "CdS nanotip" [46]; this plot also was nonorthodox.

We, too, have studied the FE behavior of a single CdS emitter tip. A single pod from a CdS nanocomb was isolated and carefully attached it to a tungsten needle, using silver paste. Figure 8 shows the SEM image of a pod mounted on a tungsten tip. Figure 9a shows the $i_m(V_m)$

Field Electron Emission from Nanomaterials, Fig. 9 (**a**) Measured current-voltage characteristic for the single CdS nanowire shown in Fig. 8; (**b**) corresponding FN plot (Note the anomalous behavior of this FN plot)

characteristics for the emitter and Fig. 9b the corresponding FN plot. It is of interest that this single-emitter FN plot is markedly nonlinear, as compared with the LAFE behavior recorded in Fig. 4b. If the high-voltage and low-voltage parts of the FN plot are approximated by straight lines, then both these parts are found (via the test) to be nonorthodox. Detailed reasons for this anomalous behavior are not understood, but could, for example, relate to current-dependent resistance in the electron flow through the silver paint. The result illustrates the complications that can arise in nanomaterial studies.

Overall, the study of CFE from nanomaterials provides both exciting technological opportunities and interesting scientific challenges.

Appendix

Technical Conventions

Equation systems. The majority of nanomaterial papers now use the "modern" International System of Quantities and equations introduced in the 1970s [47]. This underlies the SI system of units and has recently been named the "International System of Quantities" (ISQ) [48]. However, some nanomaterial papers still use the old, hybrid, pre-SI system of equations and quantities used to describe field emission in the 1960s and earlier. In the old system the factor $4\pi\varepsilon_0$ does not appear, and the symbol e has context-dependent definitions and values. For clarity and in conformity with modern practice, this entry adheres strictly to the ISQ as regards quantities and equations.

Units and emission constants. However, where relevant, we use the ISQ-compatible system of atomic-level units that is customary in field emission. This system makes calculations simple when energies such as work functions are expressed in electron volts (eV) and local fields are in V/nm. Table 1 shows definitions and values of special universal constants used in this article, expressed in these units.

Nomenclature conventions. Newer nanomaterial literature often uses nomenclature conventions different from the older "mainstream" literature, but many theoretical papers use the older conventions. In particular, different meanings are often attached to the term "field" (and the symbol E or F) and to the term "current density" (and the symbol J). An indirect consequence, as noted in the main text, is that nanomaterial papers sometimes contain defective ECD equations in which the factor α_f (the "formal area efficiency") is missing. This difficulty can be avoided, as here, by careful definition or examination of what "current density" and "field" (and associated symbols) mean in a given paper and by the use of more specific terms and symbols where appropriate.

Although practice is not consistent in the literature, the symbols E and β, and the term β-value, tend to be used differently in mainstream and

Field Electron Emission from Nanomaterials, Table 2 Nomenclature conventions. In all cases the fields concerned are the negatives/magnitudes of the corresponding fields as defined in classical electrostatics. V_e denotes the emission voltage and V_m the measured voltage. "nwu" means "no well-defined usage"; "n/a" means "not applicable"

Quantity	Mainstream usage	Nanomaterial usage	Convention here
Electron energy	E	nwu	n/a
Local barrier field	F or F_L	nwu	E_L
Characteristic local barrier field	F or F_C	nwu	E_C
True macroscopic field ($\equiv V_e/d_{sep}$)	F_M	E	E_M
Apparent macroscopic field ($\equiv V_m/d_{sep}$)	nwu	E	E_A
Local conversion length ($\equiv V_e/E_L = 1/\beta_V$) short name:	n/a	n/a	ζ_L LCL
Voltage-to-barrier-field conversion factor ($\equiv E_L/V_e$) short name:	β β-value	nwu	β_V VCF
Field enhancement factor ($\equiv E_L/E_M$) short name:	γ nwu	β β-value	β_F FEF

nanomaterial papers. These usages, and the compromise convention adopted here, are shown in Table 2.

In principle, the symbol F is probably the better choice for the negative or magnitude of classical electrostatic field, as it allows E to be used for energy (or for classical electrostatic field); E is used here because this is the current nanomaterial community practice. The term "β value" is widely used in the literature, but is not used here because it is ambiguous. Rather, the acronym-based short name "FEF" or "VCF" is used, according to context. As indicated in the text, in order to avoid continuing confusion over the meaning of the symbol β, we suggest that in future the parameter "local conversion length" (ζ_L, $=1/\beta_V$) should be used instead of the parameter "voltage-to-barrier-field conversion factor" (β_V).

Finite-element analysis (FEA); Rigorous Maxwell solver

Definition

The finite-element method (FEM) is a numerical method for solving partial differential equations (PDEs). In the field of nano-optical devices, finite-element methods are mainly used for simulations of optical effects and optical device properties. The relevant models in this case are Maxwell's equations in various formulations. Main advantages of finite-element methods in this field are the exact representation of complex geometrical features present in real-world applications, the superior convergence properties which allow for very accurate results in relatively short computation times, and the stability and general applicability of the method to different simulation settings.

Mathematical Background

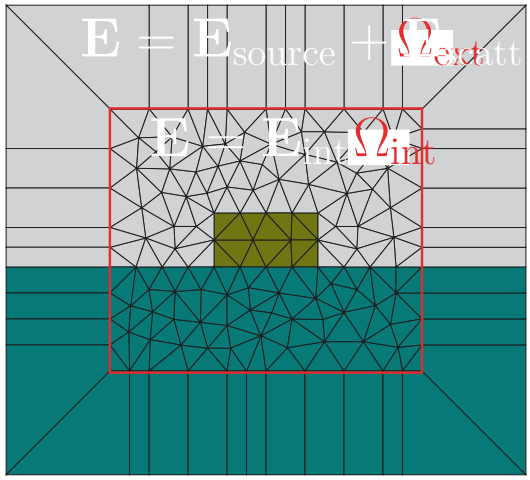
General

The finite element method offers a mathematically rigorous and elegant formalism for discretization of partial differential equations [6]. Instead of approximating the PDE itself, the key idea of FEM is the construction of an accurate finite-dimensional subspace of the original, infinite-dimensional solution space. The problem is then solved on this subspace, the finite-element space. A key concept for FEM is the so-called weak formulation of a PDE.

Weak Formulation of Maxwell's Equations

Physical laws are usually stated in a so-called strong form. For example Maxwell's equations in frequency domain read:

$$\begin{aligned} \mathbf{div}\,\mathbf{D} &= \rho, \\ \mathbf{curl}\,\mathbf{H} + i\omega\mathbf{D} &= \mathbf{J}, \\ \mathbf{curl}\,\mathbf{E} - i\omega\mathbf{B} &= 0, \\ \mathrm{div}\,\mathbf{B} &= 0. \end{aligned}$$



This set of equations is not closed. The electric and magnetic field $\mathbf{E}$ and $\mathbf{H}$ are connected to the electric displacement $\mathbf{D}$ and magnetic flux density $\mathbf{B}$ via constitutive relationships:

$$\begin{aligned} \mathbf{D} &= \varepsilon\mathbf{E} \\ \mathbf{B} &= \mu\mathbf{H}, \end{aligned}$$

where in the linear case ε and μ are the permittivity and permeability tensor. From above relationships a single equation for the electric field can be derived:

$$\mathbf{curl}\,\mu^{-1}\mathbf{curl}\,\mathbf{E} - \omega^2\varepsilon\mathbf{E} = i\omega\mathbf{J}. \qquad (1)$$

The electric current $\mathbf{J}$ is source of an electromagnetic field. In applications other types of sources

Finite Element Methods for Computational Nano-optics, Fig. 1 Triangulated geometry of a cross section of an optical waveguide (*green*) on an unbounded substrate (*blue*), surrounded by air (*gray*). The domain of interest is separated into an interior domain Ω_{int} and an unbounded exterior domain Ω_{ext}. In the interior the total field $\mathbf{E}_{\text{int}}$ is computed. In the exterior an incoming source field $\mathbf{E}_{\text{source}}$ can be predescribed and only the scattered field $\mathbf{E}_{\text{scatt}}$ is unknown. For waveguide mode and resonance problems $\mathbf{E}_{\text{source}}$ is zero, whereas for scattering problems $\mathbf{E}_{\text{source}}$ has to be a solution to Maxwell's equations in the exterior. For FEM, the unknown electric field is expanded into localized polynomial ansatz functions defined on the patches of the triangulation

like incident electromagnetic waves are also of great interest. In such a setup the nano-optical system is embedded into an infinite exterior. Numerically this problem is usually modeled by a total-field/scattered-field approach [9]. The domain of interest is separated into an infinite exterior Ω_{ext} which hosts the given incident field and the scattered field, and an interior Ω_{int} where the total field is computed. Figure 1 visualizes such a decomposition. A similar setup with zero incident field is used, when computing resonance or propagating mode problems on unbounded domains. For numerical simulations, the infinite exterior is treated using absorbing or transparent boundary conditions such as the perfectly matched layer (PML) method [1, 12] or the pole condition [8].

For application of FEM, the governing equation for the electric field (1) has to be transformed into weak formulation. First, it is tested with a vectorial function ϕ and integrated over $\mathbb{R}^3$:

$$\int_{\mathbb{R}^3} \phi\, \mathbf{curl}\, \mu^{-1} \mathbf{curl}\, \mathbf{E} - \omega^2 \phi \varepsilon \mathbf{E} = i\omega \int_{\mathbb{R}^3} \phi \mathbf{J}.$$

Integration by parts and the assumption that the electric field vanishes at infinity gives

$$\int_{\mathbb{R}^3} \mathbf{curl}\, \phi \mu^{-1} \mathbf{curl}\, \mathbf{E} - \omega^2 \phi \varepsilon \mathbf{E} = i\omega \int_{\mathbb{R}^3} \phi \mathbf{J}.$$

For a compact notation of the weak form of Maxwell's equations, the following bilinear and linear forms are introduced:

$$a(\phi, \mathbf{E}) = \int_{\mathbb{R}^3} \mathbf{curl}\, \phi\, \mu^{-1} \mathbf{curl}\, \mathbf{E} - \omega^2 \phi \varepsilon \mathbf{E},$$
$$f(\phi) = i\omega \int_{\mathbb{R}^3} \phi \mathbf{J}.$$

Furthermore, the function space H (**curl**) [6] is defined as the domain of a(ċ,ċ). The weak form of Maxwell's equations then reads as follows:

Find $\mathbf{E} \in \mathbf{H}(\text{curl})$ such that

$$a(\phi, \mathbf{E}) = f(\phi), \quad \forall \phi \in \mathbf{H}\,(\mathbf{curl}). \tag{2}$$

If a field $\mathbf{E}$ is solution to the strong form of Maxwell's equations (1) then it is also a solution to above infinite-dimensional variational formulation.

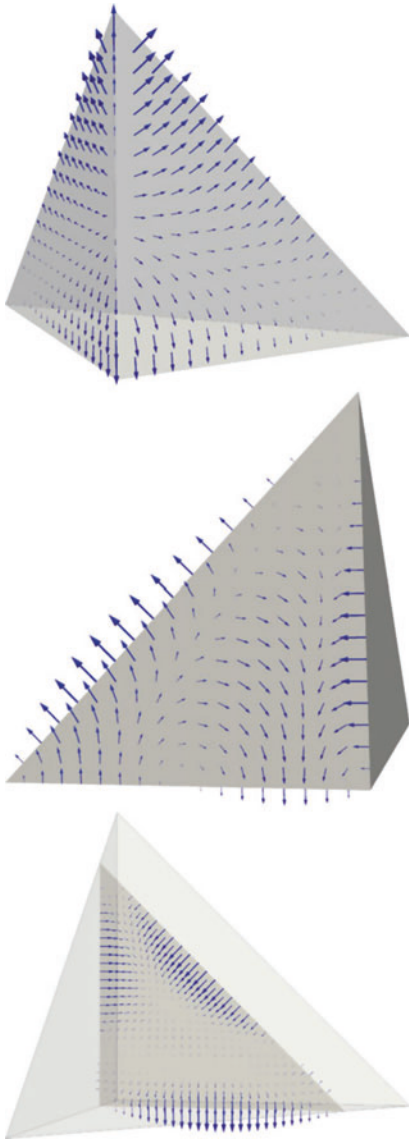
Finite-Element Discretization

A (conforming) finite element discretization of Maxwell's equations restricts the variational formulation (Eq. 2) to a finite-dimensional subspace V_h with $\dim V_h = N < \infty$.

Find $\mathbf{E}_h \in V_h$ such that

$$a(\phi_h, \mathbf{E}_h) = f(\phi_h), \quad \forall \phi_h \in V_h. \tag{3}$$

In order to derive an algebraic equation, a basis $\{\varphi_1, \ldots, \varphi N\}$ of V_h is constructed and the electric field is expanded according to $E_h = \sum_{i=1}^{N} e_i \varphi_i$.



The variational problem is then tested with all elements of the basis which gives a linear system of equations:

$$\sum_{i=1}^{N} a\left(\varphi_j, \varphi_i\right) e_i = f\left(\varphi_j\right), \quad \forall j = 1, \ldots, N.$$

The matrix $A_{ji} = a(\varphi_j, \varphi_i)$ is sparse and can be decomposed with efficient sparse LU solvers to obtain the unknown expansion coefficients e_i of the electric field.

An important aspect of FEM is the construction of the basis functions φ_i. For their definition, the domain of interest is subdivided by a triangulator into a number of small patches. A major advantage of FEM is the possibility to decompose basically arbitrary geometries with unstructured meshes, using different patches like triangles and quadrilaterals in 2D and tetrahedrons, prisms, pyramids, and bricks in 3D. Even curved so-called isoparametric elements are allowed. Figures 1 and 3 show finite-element triangulations of a 2D waveguide cross section and of a 3D photonic crystal microresonator. On each of the patches a number of polynomial ansatz functions up to degree p are defined, which gives the order of the finite-element approximation. For Maxwell's equations their construction is a nontrivial task. To arrive at well-posed problems without artificial spurious solutions, the properties of the appearing differential operators **div** and **curl** in Maxwell's equations have to be respected [6, 7]. The degrees of freedom of such **H(curl)**-conforming finite elements are the tangential field components on the boundaries of the patches. This mathematical property respects the physical feature of the electric field being only tangentially continuous across interfaces, while the normal component can be discontinuous. Figure 2 shows a number of finite element ansatz functions on a tetrahedron. The possibility to use higher-order ansatz functions for the electric field is a great advantage of FEM in nano-optical simulations.

The accuracy of a finite-element solution depends on the choice of the finite-element space V_h in the variational formulation n. The better V_h approximates the continuous space **H** (**curl**), the more accurate the FEM solution gets. One possibility to increase accuracy is the subdivision of the mesh into smaller patches, which is referred to as h-refinement. Thereby, the quantity h denotes a

Finite Element Methods for Computational Nano-optics, Fig. 2 Higher-order H (**curl**)-conforming finite-element functions on a tetrahedron. The degrees of freedom of the ansatz functions are given by the tangential field components on a single edge (*top*), face (*middle*), and volume (*bottom*) of the patch. For the edge- and face-associated ansatz functions the tangential field component vanishes on all but one edge and face respectively. For the volume-associated ansatz function, the tangential component vanishes on all faces and edges

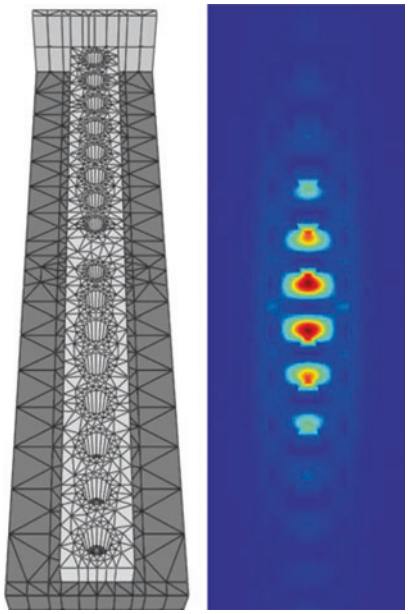
measure for the maximum size of the geometrical patches in the mesh. Self-adaptive mesh refinement can easily be implemented and leads to improved performance, especially in the case of multi-scale geometries. In contrast to other simulation techniques like finite-difference time-domain (FDTD), FEM furthermore allows for a high polynomial degree of the ansatz functions p to increase accuracy. Since often a dependence of the error proportional to h^p can be observed, this results in superior convergence properties and short computational times for FEM [6].

Application Example

Applications of FEM in the field of nano-optical devices include plasmonics, metamaterials, microstructured photonic fibers, microlithography, photonic crystal (PhC) materials and devices, optical semiconductor devices, micro-structured solar cells, microlithographic devices, optical metrology of nano-structures, and others. As a typical application example FEM simulations of high-Q resonances in PhC microcavities are reviewed [3].

Background: Photonic Microcavities

Photonic microcavities have been fabricated for various purposes [10]. One of the applications with potential high impact to technology is integrated optics: Integration of optical components with electronic circuits will provide increased functionality. Building blocks of integrated optical devices are optical waveguides, optical modulators, optical switches, and others. With their high quality factor (Q-factor) and small modal volume, one-dimensional (1D) PhC silicon-on-insulator microcavities are candidates for compact, integrated all-optical switching devices. High Q-factors have been reported for such devices, e.g., by Zain et al. [11]. Further designs of optical microcavities include 2D PhC resonators, micropillar cavities, microdisc, and microsphere resonators [10].



Numerical simulations of optical properties of microcavities are extremely helpful for an efficient design. Here, simulations of high-Q resonances in 1D PhC microcavities are reviewed. Numerical simulations of transmission spectra are performed using a time-harmonic FEM light scattering solver in combination with a propagating mode solver. Further an eigenmode solver is used for direct computation of resonance wavelengths and Q-factors. The used FEM solvers are parts of the program package *JCMsuite* [4].

Investigated Setup

The investigated microcavities consist of a silicon waveguide with square shape which is perforated with a finite number of cylindrical air pores and is supported by a silica substrate. The periodically arranged pores form a finite 1D PhC with a band gap in the relevant wavelength range. The cavity is realized by omitting one (central) pore. A specific setup with individual pore diameters and placements has been proposed and investigated experimentally by Zain et al. [11]. The tapered arrangement of the pore positions and diameters leads to high Q-factor and high transmission values. For FEM simulations, the geometry is discretized by prismatoidal elements [3]. Figure 3 (left) shows a part of a typical spatial mesh. A mirror symmetry allows to reduce the computational domain to one half of the cavity geometry. A typical computational domain has a size of some tens to some hundreds of cubic wavelengths. While these are moderate 3D computational domain sizes, the challenge of the simulation consists mainly in modeling the irregular geometry and in a precise resolution of the electromagnetic field. The very anisotropic intensity distribution on resonance can span many orders of magnitude. The model extends waveguide, substrate, and surrounding air to infinity by applying transparent boundary conditions to the corresponding faces.

Numerical Approach

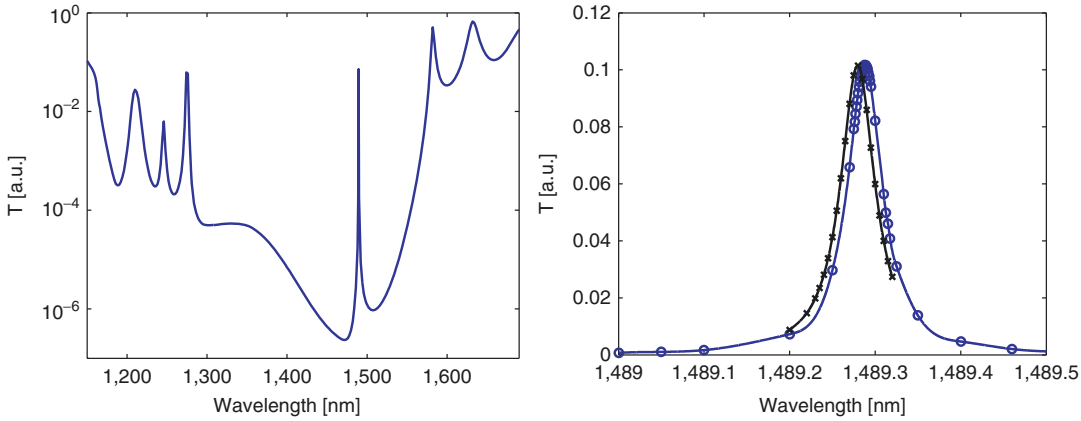
For simulating transmission through the cavity at specific wavelength λ_0, first the fundamental propagation mode of the waveguide at λ_0 is computed. The obtained mode field is used as an incident field on the boundaries of the 3D computational domain, such that the mode propagates in direction of the center of the waveguide. Then the

Finite Element Methods for Computational Nano-optics, Fig. 3 *Left*: Geometry of a PhC microcavity (with less pores than the actual setup of Zain et al.), discretized with a prismatoidal mesh (*dark gray*: silica substrate, *light gray*: silicon waveguide, perforated by conical air pores). The structure is surrounded by air; substrate and waveguides extend to infinity. *Right*: Intensity distribution at a wavelength close to resonance, in an *xy* cross section at the center of the waveguide (*blue*/*dark*: low intensity, *red*/*bright*: high intensity)

scattered light field is computed using higher-order finite elements. In post-processes, energy fluxes through interfaces and field distributions in several cross sections of the 3D light field distribution are extracted from the near field solution. Transmission spectra are obtained by performing a series of simulations with (adaptively) varied wavelengths λ_0.

Alternatively to simulating the light scattering response of the device, an eigenmode solver can be used for directly simulating the resonance properties (resonance wavelength and Q-factor) [3].

Validation of Numerical Results



Typically, for a given simulation task each actual simulation will give a different quantitative result unless exactly the same method, the same implementation, the same hardware, and the same numerical discretization parameters are used. This is due to numerical discretization errors (which are present in any numerical method), approximations of the model, implementation errors, and other causes. Hence, it is essential to check numerical results using one or several validation strategies:

- Convergence of the results when numerical accuracy is increased: For FEM simulation this means that it has to be checked that the numerical results converge at the expected rate under mesh refinement and under increasing polynomial order of the finite-element ansatz functions [6].
- Convergence to analytical solutions for simple setups.
- Agreement with results obtained using different numerical methods, like in this case, e.g., FDTD [2] within the numerical error bounds of the respective methods. Agreement with results obtained with the same numerical method, but with different implementations [5].
- Comparison with experimental results: agreement with experimental results within experimental and numerical error bounds when experimental data is accessible.

For the reviewed example, simulation results have been validated by comparisons to independent numerical and experimental results. Also a convergence analysis has been performed, which shows that solutions with high numerical accuracy are reached. Further, it has been checked that resonance wavelength and cavity Q-factor computed from the complex eigenvalue of eigenmode simulations agree perfectly with results from light scattering simulations. Also, in a parameter study it has been shown that slight geometrical variations of the air pores sidewall angle and of feature placement on a nanometer scale can lead to significant changes of transmission wavelength and Q-factor [3].

Numerical Results

Figure 4 (left) shows the simulated transmission spectrum corresponding to the experiment of Zain

Finite Element Methods for Computational Nano-optics, Fig. 4 *Left*: Simulated transmission spectrum of a 1D PhC microcavity composed by an arrangement of 24 air pores with diameters between 131 and 182 nm in a rectangular silicon waveguide with a cross section of 500 × 260 nm (setup of Zain et al.). *Right*: Detail of the transmission spectrum: resonance transmission peak at ∼1,489 nm. *Blue circles*: time-harmonic simulation results for polynomial finite-element degree $p = 3$; *black crosses*: results for finer mesh; *lines*: spline interpolation. With increased numerical accuracy, resonance peak position shifts by about 5×10^{-6} (8×10^{-12} m), FWHM of the interpolation shifts by about 1 % (0.5×10^{-12} m)

et al. The 1D PhC arrangement leads to a bandgap between 1,200 and 1,600 nm in the transmission spectrum. At the cavity resonance wavelength of about 1,489.2 nm, a distinct transmission peak appears within the bandgap. Zooming into the wavelength range of 1,489–1,489.5 nm (Fig. 4, right) shows that the full width at half maximum of the resonance is only about 50 pm (picometer), corresponding to a resonance Q-factor of about 30,000. Figure 3 visualizes the computed electric field intensity at an incident wavelength close to the cavity's resonance wavelength. Clearly, the photonic intensity distribution is stored in a small modal volume of few cubic wavelengths. Figure 4 (right) also shows transmission peaks resulting from simulations with different numerical resolution. Increasing the resolution (i.e., in this case refining the mesh) shifts the resonance wavelength by 8 pm for the shown data and changes the full width by ∼0.5 pm. Together with convergence checks performed for similar setups [3], this indicates that a high accuracy of the numerical results has been reached. While the agreement with the experimentally observed resonance wavelength of 1,479 nm is very good, the experimentally observed Q-factor of about 147,000 is significantly higher than the simulation result. This can be explained by both, experimental error budgets, and differences between the experimentally realized device and the model geometry on a nanometer scale.

Conclusion

The reviewed example highlights several advantages of the use of finite-element methods for the simulation of nano-optical devices:

- Complex real-life geometries can be described accurately, with exact spatial resolution.
- Unstructured meshes allow for spatial adaptivity.
- Higher-order finite elements have very good convergence properties, ensuring results of very high accuracy.
- Isolated problems can be treated rigorously, even in the presence of structured exterior domains.
- The general finite-element setting allows to solve different partial differential equations, e.g., in this case equations modeling light scattering, mode propagation in waveguides, and resonance modes in cavities.

- The usage of direct, sparse matrix-solvers allows to obtain steady-state results at relatively low computational costs and typically several orders of magnitude faster compared to time-domain methods.

Finite-Difference Frequency-Domain Technique

Georgios Veronis
Department of Electrical and Computer Engineering and Center for Computation and Technology, Louisiana State University, Baton Rouge, LA, USA

F

Definition

The finite-difference frequency-domain technique is a numerical technique for the solution of Maxwell's equations of electromagnetism in the frequency domain. It is based on approximating the derivatives in Maxwell's equations by finite differences, and results in a system of algebraic equations, which is solved using numerical linear algebra techniques.

Introduction to the Simulation of Plasmonic Devices

The finite-difference frequency-domain (FDFD) technique is a general-purpose numerical technique for the solution of Maxwell's equations of electromagnetism in the frequency domain. It can be applied to structures of any length scale and for sources of electromagnetic radiation of any frequency. Here, however, the focus is on the use of this technique in nano-optics, and in particular *plasmonics*.

Plasmonics is a rapidly evolving field of science and technology based on *surface plasmons*, which are electromagnetic waves that propagate along the interface of a metal and a dielectric. In surface plasmons, light interacts with the free electrons of the metal, which oscillate collectively in response to the applied field. Recently, nanometer scale metallic devices have shown the potential to manipulate light at the subwavelength scale using surface plasmons [1]. This could lead to photonic circuits of nanoscale dimensions.

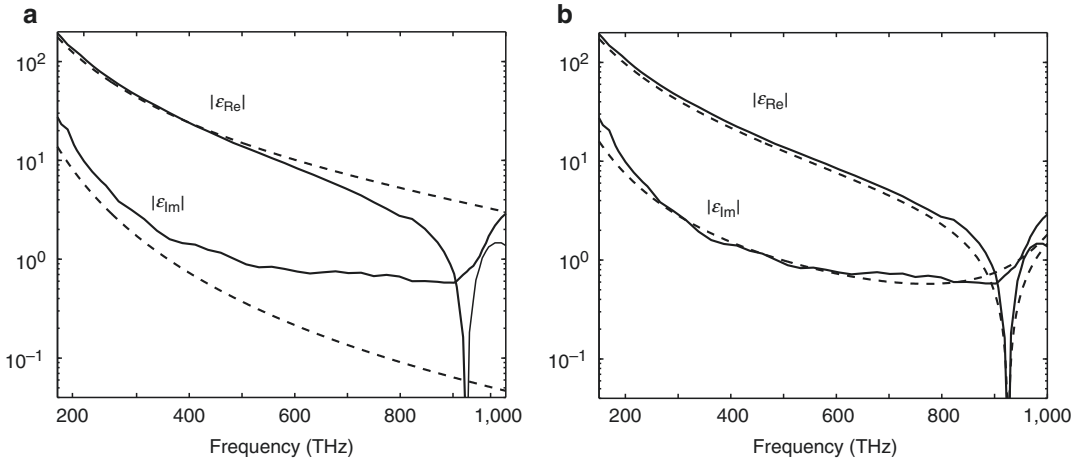
Surface plasmons can be described by macroscopic electromagnetic theory, i.e., Maxwell's

equations, if the electron mean free path in the metal is much shorter than the plasmon wavelength [2]. This condition is usually fulfilled at optical frequencies [2]. In macroscopic electromagnetic theory, bulk material properties, such as dielectric constant, are used to describe objects irrespective of their size. Here, all materials are assumed to be nonmagnetic $(\mu = \mu_0)$ and are characterized by their bulk dielectric constant $\epsilon(\mathbf{r}, \omega)$, where $\mathbf{r} = (x, y, z) = x\hat{x} + y\hat{y} + z\hat{z}$, and ω is the angular frequency. However, for particles of nanometer dimensions a more fundamental description of their optical and electronic properties may be required [3].

Analytical methods, such as Mie theory [4], can only be applied to planar geometries or to objects of specific shapes (spheres, cylinders) and have therefore limited importance in the analysis of plasmonic devices and structures. Numerical simulation techniques are therefore very important for the analysis and design of plasmonic devices. Numerical modeling of plasmonic devices involves several challenges which need to be addressed. First, as mentioned above, plasmonic devices can have arbitrary geometries. Several techniques are specific for one type of geometrical configuration and are therefore not appropriate for modeling of arbitrary plasmonic devices.

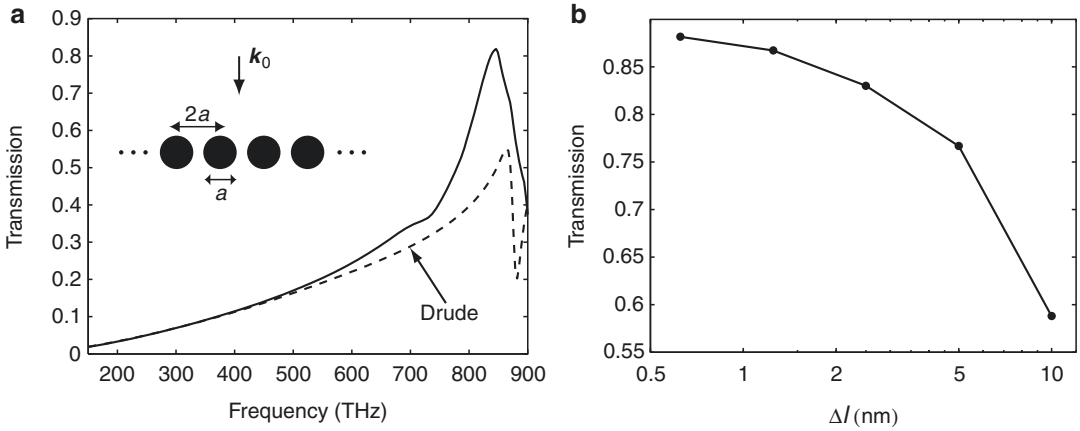
Second, the dielectric constant of metals at optical wavelengths is complex, i.e., $\epsilon_r(\omega) = \epsilon_{\mathrm{Re}}(\omega) + i\epsilon_{\mathrm{Im}}(\omega)$ and is a complicated function of frequency [5]. Thus, several simulation techniques which are limited to lossless, nondispersive materials are not applicable to plasmonic devices. In addition, in time-domain methods the dispersion properties of metals have to be approximated by suitable analytical expressions [6]. In most cases, the *Drude model* is invoked to characterize the frequency dependence of the metallic dielectric function [7]

$$\epsilon_{\mathrm{r,\ Drude}}(\omega) = 1 - \frac{\omega_p^2}{\omega(\omega + i\gamma)}, \qquad (1)$$



where ω_p and γ are frequency-independent parameters. However, the Drude model approximation is valid over a limited wavelength range [7]. The range of validity of the Drude model can be extended by adding Lorentzian terms to Eq. 1 to obtain the *Lorentz-Drude model* [7]

$$\epsilon_{r,\mathrm{LD}}(\omega) = \epsilon_{r,\mathrm{Drude}}(\omega) + \sum_{j=1}^{k} \frac{f_j \omega_j^2}{\left(\omega_j^2 - \omega^2\right) - i\omega\gamma_j}, \qquad (2)$$



where ω_j and γ_j stand for the oscillator resonant frequencies and bandwidths, respectively, and f_j are weighting factors. Physically, the Drude and Lorentzian terms are related to intraband (free electron) and interband (bound electron) transitions, respectively [7]. Even though the Lorentz-Drude model extends the range of validity of analytical approximations to metallic dielectric constants, it is not suitable for description of sharp absorption edges observed in some metals, unless a very large number of terms are used [7]. In particular, the Lorenz-Drude model cannot approximate well the onset of interband absorption in noble metals (Ag, Au, and Cu), even if five Lorentzian terms are used [7]. In Fig. 1, the Drude and Lorentz-Drude models are compared with experimental data for silver. It is observed that even a five-term Lorentz-Drude model with optimal parameters results in a factor of two error at certain frequencies.

Third, in surface plasmons propagating along the interface of a metal and a dielectric, the field is concentrated at the interface and decays exponentially away from the interface in both the metal and dielectric regions [8]. Thus, for numerical methods based on discretization of the fields on a numerical grid, a very fine grid resolution is required at the metal-dielectric interface to adequately resolve the local fields. In addition, several plasmonic devices are based on components of subwavelength dimensions [8]. In fact, most of the potential applications of surface plasmons are related to subwavelength optics. The nanoscale feature sizes of plasmonic devices pose an extra challenge to numerical simulation techniques.

The challenges involved in modeling plasmonic devices will be illustrated here using a simple example: an infinite periodic array of silver

Finite-Difference Frequency-Domain Technique, Fig. 1 Real and imaginary part of the dielectric constant of silver at optical frequencies. The *solid lines* show experimental data [5]. The *dashed lines* show values calculated using (**a**) the Drude model and (**b**) the Lorentz-Drude model with five Lorentzian terms. The parameters of the models are optimal and obtained through an optimization procedure [7]

Finite-Difference Frequency-Domain Technique, Fig. 2 (**a**) Calculated transmission spectrum of an infinite array of silver cylinders (shown in the *inset*) for normal incidence and transverse magnetic (*TM*) polarization (involving only the E_x, E_y, and H_z vector field components). Results are shown for a diameter $a = 100$ nm. The *dashed line* shows the transmission spectrum calculated using the Drude model (Eq. 1) with parameters $\omega_p = 1.37 \times 10^{16} s^{-1}$ and $\gamma = 7.29 \times 10^{13} s^{-1}$. (**b**) Calculated transmission at 855 THz as a function of the spatial grid size Δl

cylinders illuminated by a plane wave at normal incidence (inset of Fig. 2a). The FDFD method, which is described in detail below, is used to calculate the transmission of the periodic array. This method allows one to directly use experimental data for the frequency-dependent dielectric constant of metals, including both the real and imaginary parts, with no approximation. The fields are discretized on a uniform two-dimensional (2-D) grid with grid size $\Delta x = \Delta y = \Delta l$. The calculated transmission as a function of frequency is shown in Fig. 2a. Also shown is the transmission of the structure calculated with the Drude model of Eq. 1. It is observed that the use of the Drude model results in substantial error. In general, the Drude model parameters

are chosen to minimize the error in the dielectric function in a given frequency range [9]. However, this approach gives accurate results in a limited wavelength range, as illustrated in this example. In general, the complicated dispersion properties of metals at optical frequencies pose a challenge in modeling of plasmonic devices not encountered in modeling of low- or high-index-contrast dielectric devices.

The calculated transmission at a specific wavelength as a function of the spatial grid size Δl is shown in Fig. 2b. It is observed that a grid size of $\Delta l \cong 1$ nm is required in this case to yield reasonably accurate results. The required grid size is directly related to the decay length of the fields at the metal-dielectric interface. In general, modeling of plasmonic devices requires much finer gird resolution than modeling of low- or high-index-contrast dielectric devices, due to the high localization of the field at metal-dielectric interfaces of plasmonic devices. The required grid size depends on the shape and feature size of the modeled plasmonic device, the metallic material used, and the operating frequency.

In the following sections, the FDFD technique is introduced, and it is also examined how FDFD addresses the challenges mentioned above.

Introduction to Finite-Difference Methods

FDFD is based on approximating the derivatives in Maxwell's equations by finite differences. A brief overview of the main features of finite-difference methods is therefore first provided here. In finite-difference methods, derivatives in differential equations are approximated by finite differences. To approximate the derivative $df/dx|_{x_0}$ Taylor series expansions $f(x)$ about the point x_0 at the point $x_0+\Delta x$ and $x_0-\Delta x$ are used to obtain [6]

$$\left.\frac{df}{dx}\right|_{x_0} = \frac{f(x_0+\Delta x)-f(x_0-\Delta x)}{2\Delta x} + O\left[(\Delta x)^2\right]. \tag{3}$$

Here, the notation $O[(\Delta x)^2]$ (to be read as " order $(\Delta x)^2$ ") denotes the remainder term and indicates its dependence on Δx, i.e., that it approaches zero as the second power of Δx. Thus, Eq. 3 shows that a *central-difference* approximation of the first derivative is *second-order accurate*, meaning that the remainder term in Eq. 3 approaches zero as the square of Δx.

In finite-difference methods, a continuous problem is approximated by a discrete one. Field quantities are defined on a discrete grid of nodes. The rectangular grid with node coordinates $\mathbf{r}_{ijk} = \left(x_i, y_j, z_k\right)$ is the simplest and most commonly used. A field quantity at nodal location $\mathbf{r}_{ijk}$ is denoted for convenience as $f|_{ijk} \equiv f\left(\mathbf{r}_{ijk}\right)$. Based on Eq. 3, the first derivative can be approximated by the following central-difference formula

$$\left.\frac{df}{dx}\right|_i \cong \frac{f|_{i+1} - f|_{i-1}}{2\Delta x}, \tag{4}$$

which is second-order accurate, based on the discussion above, if the rectangular grid is uniform, i.e., $x_i = i\Delta x$. For example, if the numerical resolution in the x direction is increased by a factor of 10 ($\Delta x' = \Delta x/10$), then the error introduced by the finite-difference formula in Eq. 4 reduces roughly by a factor of $10^2 = 100$. Similarly, the second derivative can be approximated by the formula

$$\left.\frac{d^2f}{dx^2}\right|_i \cong \frac{f|_{i+1} - 2f|_i + f|_{i-1}}{(\Delta x)^2}, \tag{5}$$

which is also second-order accurate on a uniform grid [6].

By replacing derivatives in differential equations with their finite-difference approximations, algebraic equations are obtained, which relate the value of the field at a specific node to the values at neighboring nodes. By applying the finite-difference approximation to all nodes of the grid, a system of linear equations of the form $\mathbf{Ax} = \mathbf{b}$ is obtained. Since the equation for the field at each point involves only the fields at a few (typically two, four, and six in one, two, and three dimensions, respectively) adjacent points, the resulting system matrix is extremely sparse. Such problems

can be solved efficiently if direct or iterative sparse matrix techniques are used.

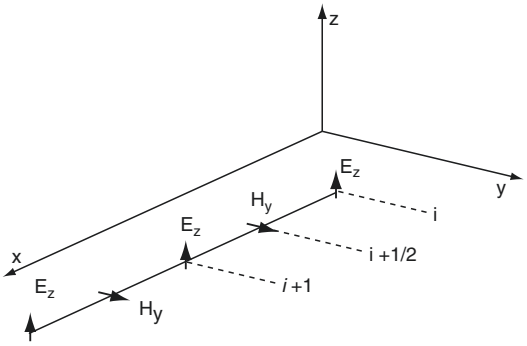
The FDFD Method in One Dimension

The FDFD equations will now be derived by approximating the spatial derivatives in Maxwell's equations with finite differences. Assuming an exp($i\omega t$) harmonic time dependence for all field quantities, Maxwell's curl equations in the frequency domain take the form

$$\nabla \times \mathbf{E}(\mathbf{r}) = -i\omega\mu_0 \mathbf{H}(\mathbf{r}), \tag{6}$$

$$\nabla \times \mathbf{H}(\mathbf{r}) = \mathbf{J}(\mathbf{r}) + i\omega\epsilon(\mathbf{r})\mathbf{E}(\mathbf{r}). \tag{7}$$

It should be noted that the field vectors $\mathbf{E}(\mathbf{r}, t)$, $\mathbf{H}(\mathbf{r}, t)$ are real (measurable) quantities that can vary with time, whereas the vectors $\mathbf{E}(\mathbf{r}, \omega)$, $\mathbf{H}(\mathbf{r}, \omega)$ are complex phasors that do not vary with time. The former can be obtained from the latter by multiplying by exp($i\omega t$) and taking the real part. For example,



$$\mathbf{E}(\mathbf{r}, t) = \mathrm{Re}\{\mathbf{E}(\mathbf{r}, \omega)\exp(i\omega t)\}. \tag{8}$$

It should also be noted that in most cases for simplicity the frequency dependence of the complex phasors is not explicitly shown, e.g., $\mathbf{E}(\mathbf{r})$ is used instead of $\mathbf{E}(\mathbf{r}, \omega)$. Maxwell's equations can be simplified by considering electromagnetic fields and systems with no variations in two dimensions, namely, both y and z. By dropping all the y and z derivatives in Eqs. 6 and 7, and assuming a current source polarized in the z direction ($\mathbf{J} = J_z\hat{z}$), Maxwell's equations simplify to

$$\frac{\partial E_z}{\partial x} = i\omega\mu_0 H_y, \tag{9}$$

$$\frac{\partial H_y}{\partial x} = J_z + i\omega\epsilon E_z. \tag{10}$$

In the *Finite-Difference Time-Domain* (FDTD) technique a staggered spatial grid, known as the *Yee grid* [6], is used for interleaved placement of the electric and magnetic fields. The Yee grid enables the approximation of the continuous derivatives in space by second-order-accurate two-point centered finite differences. Since the spatial derivatives involved in Maxwell's equations in the frequency domain are exactly the same as those in the time domain, the Yee grid can also be used in FDFD. The placement of the electric and magnetic fields on a one-dimensional (1-D) Yee grid for FDFD is identical to the one for FDTD and is shown in Fig. 3.

Finite-Difference Frequency-Domain Technique, Fig. 3 The placement of electric and magnetic field vectors in FDFD for Maxwell's equations in one dimension

For simplicity a uniform rectangular grid with $x_i = i\Delta x$ is considered, and the derivatives in Eqs. 9 and 10 are replaced with their finite-difference approximations to obtain

$$\frac{E_z|_{i+1} - E_z|_i}{\Delta x} = i\omega\mu_0 H_y\big|_{i+1/2}, \tag{11}$$

$$\frac{H_y\big|_{i+1/2} - H_y\big|_{i-1/2}}{\Delta x} = J_z|_i + i\omega\epsilon|_i E_z|_i. \tag{12}$$

As mentioned above, by applying Eqs. 11 and 12 at all points in the Yee grid, a system of linear equations is obtained, which can be solved to find the electromagnetic fields. If the system obtained from Eqs. 11 and 12 was directly solved, all electric fields $\left(E_z|_1, E_z|_2, \ldots, E_z|_{N_x+1}\right)$ and all magnetic fields $\left(H_y\big|_{1+1/2}, H_y\big|_{2+1/2}, \ldots, H_y\big|_{N_x+1/2}\right)$ would have to be included in the vector of unknown fields. (A 1-D Yee grid terminated at

electric field positions was assumed here.) Thus, the system of linear equations would have a total of $2N_x + 1$ unknowns. However, in the system of equations obtained from the FDFD algorithm, it is straightforward to eliminate either all the electric or all the magnetic fields. To see this, Eq. 11 is applied at two adjacent grid points:

$$\frac{1}{i\omega\mu_0}\frac{E_z|_i - E_z|_{i-1}}{\Delta x} = H_y\big|_{i-1/2}, \tag{13}$$

$$\frac{1}{i\omega\mu_0}\frac{E_z|_{i+1} - E_z|_i}{\Delta x} = H_y\big|_{i+1/2}. \tag{14}$$

Equations 13 and 14 are now substituted into Eq. 12 to obtain

$$\frac{1}{\Delta x}\frac{1}{i\omega\mu_0}\left(\frac{E_z|_{i+1} - E_z|_i}{\Delta x} - \frac{E_z|_i - E_z|_{i-1}}{\Delta x}\right) = J_z|_i + i\omega\epsilon|_i E_z|_i, \tag{15}$$

which can also be written as

$$\frac{1}{(\Delta x)^2}E_z|_{i-1} + \left[-\frac{2}{(\Delta x)^2} + \omega^2\epsilon|_i\mu_0\right]E_z|_i + \frac{1}{(\Delta x)^2}E_z|_{i+1} = i\omega\mu_0 J_z|_i. \tag{16}$$

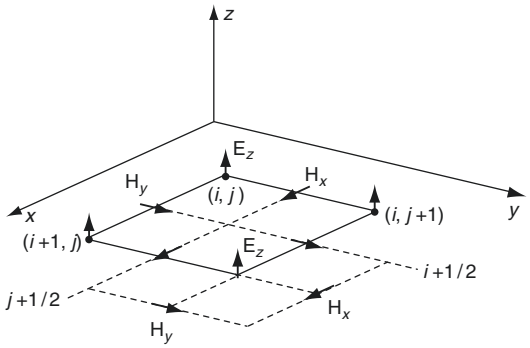
Thus, application of finite-difference approximations at the node location x_i results in a linear algebraic equation which relates the field $E_z|_i$ to the fields at the two adjacent nodes $E_z|_{i-1}$ and $E_z|_{i+1}$. By applying the finite-difference approximation to all internal nodes of the grid, a system of linear equations of the form $\mathbf{Ax} = \mathbf{b}$ is obtained, where $\mathbf{b}$ is determined by the source current $\mathbf{J}$:

$$\begin{aligned} a_{ii-1} &= a_{ii+1} = \frac{1}{(\Delta x)^2}, \\ a_{ii} &= -\frac{2}{(\Delta x)^2} + \omega^2\,\epsilon|_i\mu_0, \\ b_i &= i\omega\mu_0\, J_z|_i,\ x_i = E_z|_i. \end{aligned} \tag{17}$$

The FDFD equations for the boundary nodes depend on the boundary conditions at the boundary of the simulation domain. Typically, they involve only the two outermost nodes, e.g., $a_{11}x_1 + a_{12}x_2 = 0$. Thus, in the 1-D case the linear system matrix $\mathbf{A}$ is tridiagonal, and it is straightforward to eliminate the magnetic fields and obtain a system of equations which only involves the electric fields $\left(E_z|_1, E_z|_2, \ldots, E_z|_{N_x+1}\right)$ and has a total of $N_x + 1$ unknowns.

Finally, if Eqs. 9 and 10 are combined, the Helmholtz equation in 1-D is obtained:

$$\frac{\partial^2 E_z}{\partial x^2} + \omega^2\epsilon\mu_0 E_z = i\omega\mu_0 J_z. \tag{18}$$



When the spatial derivatives in this equation are approximated by centered finite differences, Eq. 16 above is obtained. In other words, the FDFD equations can be directly obtained by discretizing the Helmholtz equation for the electric field.

The FDFD Method in Two and Three Dimensions

For the 2-D case, it is assumed that there are no variations of either the fields or the excitation in one of the directions, say the z direction. Thus, all derivatives with respect to z drop out from the two curl Eqs. 6 and 7. A current source polarized in the z direction ($\mathbf{J} = J_z\hat{z}$) is also assumed, so that only the transverse electric (TE) polarization (involving only the H_x, H_y, and E_z vector field components) is excited [6] and Maxwell's equations simplify to

$$\begin{aligned} \frac{\partial E_z}{\partial y} &= -i\omega\mu_0 H_x, \\ \frac{\partial E_z}{\partial x} &= i\omega\mu_0 H_y, \\ \frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} &= J_z + i\omega\epsilon E_z. \end{aligned} \tag{19}$$

If Eq. 19 are combined, the 2-D Helmholtz equation is obtained

Finite-Difference Frequency-Domain Technique, Fig. 4 An FDFD unit cell for transverse electric (TE) waves. The small vectors with *thick arrows* are placed at the point in the grid at which they are defined. For example, E_z is defined at grid points (i, j), while H_y is defined at grid points $(i + 1/2, j)$

$$\frac{\partial^2 E_z}{\partial x^2} + \frac{\partial^2 E_z}{\partial y^2} + \omega^2 \epsilon \mu_0 E_z = i\omega\mu_0 J_z. \tag{20}$$

As mentioned in the previous section, the exact same FDTD Yee grid can be used in FDFD. A portion of the Yee grid for the TE case is depicted in Fig. 4.

The FDFD equations can be obtained by discretizing (Eq. 19). It is then straightforward to eliminate H_x and H_y to obtain the FDFD equations which only involve the E_z field. Here, however, the 2-D Helmholtz equation (20) is discretized to directly obtain the FDFD equations which only involve the E_z field. Once E_z is calculated by solving the FDFD equations, the H_x and H_y fields can be calculated by using the discretized versions of Eq. 19.

For simplicity a uniform rectangular grid with $x_i = i\Delta x$ and $y_j = j\Delta y$ is considered, and the derivatives in Eq. 20 are replaced with their finite-difference approximations to obtain

$$\begin{aligned} &\frac{E_z|_{i+1,j} - 2E_z|_{i,j} + E_z|_{i-1,j}}{(\Delta x)^2} \\ &+ \frac{E_z|_{i,j+1} - 2E_z|_{i,j} + E_z|_{i,j-1}}{(\Delta y)^2} \\ &+ \omega^2 \epsilon|_{i,j}\, \mu_0 E_z|_{i,j} = i\omega\mu_0 J_z|_{i,j}. \end{aligned} \tag{21}$$

Thus, application of finite-difference approximations at the node location $\mathbf{r}_{ij} = \left(x_i, y_j\right)$ results in a linear algebraic equation which relates the field $E_z|_{i,j}$ to the fields at the four adjacent nodes $E_z|_{i-1,j}, E_z|_{i+1,j}, E_z|_{i,j-1}, E_z|_{i,j+1}$. In the end, the finite-difference approximation is applied to all nodes of the grid to obtain one FDFD equation at each grid point (i, j). These equations form a system of linear equations $\mathbf{Ax} = \mathbf{b}$ with $(N_x + 1) \times \left(N_y + 1\right)$ equations and unknowns. The vector of unknown fields $\mathbf{x}$ will include the electric fields at all grid points (i, j), where $i = 1, 2, \ldots, N_x + 1$ and $j = 1, 2, \ldots, N_y + 1$. It should be noted that $\mathbf{x}$ is a 1-D vector. A one-to-one mapping between the 2-D electric field $E_z|_{i,j}, \quad i = 1, 2, \ldots, N_x + 1, \quad j = 1, 2, \ldots, N_y + 1$ and the 1-D vector of unknown fields $x_m, \quad m = 1, 2, \ldots, (N_x + 1) \times \left(N_y + 1\right)$ should therefore be constructed. Choosing the right mapping is in general important and can affect the convergence of the system of linear equations. One simple mapping function in the 2-D case is

$$m(i, j) = (i - 1)\left(N_y + 1\right) + j. \tag{22}$$

Using this one-to-one mapping function, the following system of linear equations is obtained:

$$\begin{aligned} a_{m(i,j)m(i-1,j)} &= a_{m(i,j)m(i+1,j)} = \frac{1}{(\Delta x)^2}, \\ a_{m(i,j)m(i,j-1)} &= a_{m(i,j)m(i,j+1)} = \frac{1}{(\Delta y)^2}, \\ a_{m(i,j)m(i,j)} &= -\frac{2}{(\Delta x)^2} - \frac{2}{(\Delta y)^2} + \omega^2 \epsilon|_{i,j}\, \mu_0, \\ b_{m(i,j)} &= i\omega\mu_0\, J_z|_{i,j}, \\ x_{m(i,j)} &= E_z|_{i,j}. \end{aligned} \tag{23}$$

The same approach can be applied to obtain the FDFD equations for the 2-D TM polarization case, as well as for the three-dimensional (3-D) case.

Numerical Dispersion of the FDFD Algorithm

A single plane wave propagating in a uniform medium has a simple *dispersion relation*

connecting the angular frequency ω and the wave number $k : \omega = ck$ [10], where c is the speed of light in the medium. Numerical techniques such as the FDFD technique introduce *numerical dispersion*. To derive the dispersion properties of the FDFD algorithm, a single wave or Fourier mode in space is considered. The dispersive properties of FDFD are assessed by obtaining the dispersion relation of the scheme, relating the frequency of a Fourier mode on the grid to a particular wavelength λ (or wave number k):

$$\omega = f_{\text{FDFD}}(k, \Delta x). \tag{24}$$

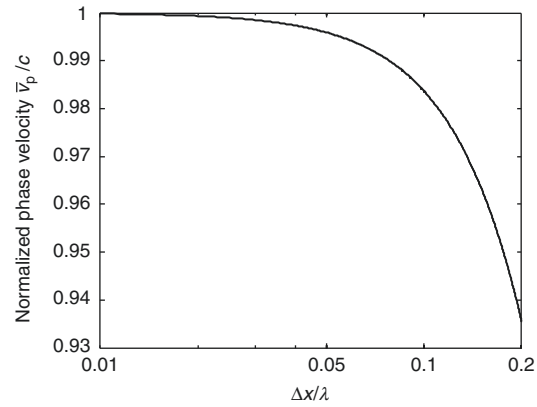
In the 1-D case, a plane wave propagating in a uniform medium is considered

$$E(x) = e^{\sqrt{-1}kx}, \tag{25}$$

and its discretized version is

$$E|_i = e^{\sqrt{-1}ki\Delta x}. \tag{26}$$

In the above equations, $\sqrt{-1}$ was used to avoid confusing it with the grid index i. In a uniform medium with no sources the FDFD equation (16) becomes



$$\frac{E_z|_{i+1} - 2E_z|_i + E_z|_{i-1}}{(\Delta x)^2} + \omega^2 \epsilon\mu_0 \, E_z|_i = 0. \tag{27}$$

Equation 26 is substituted into Eq. 27 to find

$$\frac{e^{\sqrt{-1}ki\Delta x}\left(e^{\sqrt{-1}k\Delta x} - 2 + e^{-\sqrt{-1}k\Delta x}\right)}{(\Delta x)^2} + \omega^2\epsilon\mu_0 e^{\sqrt{-1}ki\Delta x} = 0, \tag{28}$$

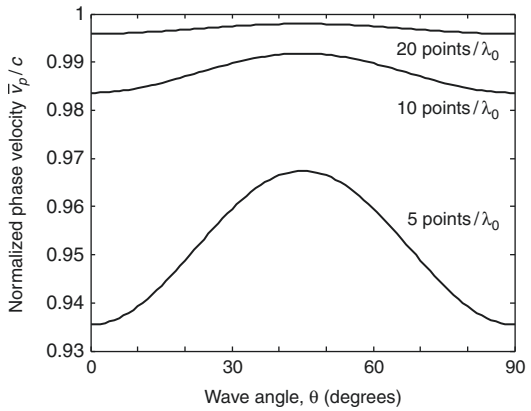
from which one obtains

$$\omega = ck\left(\frac{\sin\left(\frac{k\Delta x}{2}\right)}{\frac{k\Delta x}{2}}\right). \tag{29}$$

Finite-Difference Frequency-Domain Technique, Fig. 5 Dispersion of 1-D FDFD. Variation of numerical phase velocity with numerical resolution $\Delta x/\lambda$ in 1-D FDFD

Equation 29 is the dispersion relation of 1-D FDFD. It is observed that, in the limit $\Delta x \to 0$, Eq. 29 reduces to the exact dispersion relation $\omega = ck$. Using Eq. 29, the numerical phase velocity $\bar{v}_p \equiv \frac{\omega}{k}$ and group velocity $\bar{v}_g \equiv \frac{\partial\omega}{\partial k}$ of the FDFD scheme can be derived. The numerical phase velocity of 1-D FDFD as a function of the numerical resolution $\Delta x/\lambda$ is shown in Fig. 5. It is observed, for example, that for a spatial resolution of 20 grid points per wavelength $(\Delta x/\lambda = 0.05)$ the numerical error in the phase velocity is less than 1 %.

In the 2-D case, wave-like modes propagating in both x and y directions are considered



$$E(x, y) = e^{\sqrt{-1}\left(k_x x + k_y y\right)}, \tag{30}$$

and their discretized version is

$$E|_{i,j} = e^{\sqrt{-1}\left(k_x i\Delta x + k_y j\Delta y\right)}, \tag{31}$$

where k_x and k_y are the wave numbers in the x and y directions, respectively.

In a uniform medium with no sources, the 2-D FDFD equation (21) becomes

Finite-Difference Frequency-Domain Technique, Fig. 6 Dispersion of 2-D FDFD. Variation of numerical phase velocity with wave-propagation angle in a 2-D FDFD grid for three different cases of numerical resolution

$$\frac{E_z|_{i+1,j} - 2E_z|_{i,j}}{(\Delta x)^2} + \frac{E_z|_{i,j+1} - 2E_z|_{i,j} + E_z|_{i,j-1}}{(\Delta y)^2} + \omega^2 \epsilon \mu_0 \, E_z|_{i,j} = 0. \tag{32}$$

Equation 31 is substituted into Eq. 32 to find after some manipulation:

$$\omega^2 = c^2 \left[k_x^2 \left(\frac{\sin\left(\frac{k_x \Delta x}{2}\right)}{\frac{k_x \Delta x}{2}} \right)^2 + k_y^2 \left(\frac{\sin\left(\frac{k_y \Delta y}{2}\right)}{\frac{k_y \Delta y}{2}} \right)^2 \right]. \tag{33}$$

It is observed again that, in the limit $\Delta x \to 0$ and $\Delta y \to 0$, Eq. 33 reduces to the exact dispersion relation $\omega^2 = c^2\left(k_x^2 + k_y^2\right)$.

It can be seen from Eq. 33 that the numerical phase velocity $\bar{v}_p$ for the 2-D case is a function of angle of propagation through the FDFD grid. To see this, wave propagation at an angle θ with respect to the positive x axis is assumed, in which case $k_x = k\cos\theta$ and $k_y = k\sin\theta$, where $k = \sqrt{k_x^2 + k_y^2}$ is the wave number. Figure 6 shows a plot of normalized numerical phase velocity as a function of propagation angle θ. The dependence is, in general, relatively small (compared to dispersion errors due to the discretized grid), with $\bar{v}_p/c$ varying by only a few percent between $\theta = 45°$ and $\theta = 0°$, even for very coarse (e.g., $\Delta x = \Delta y = \lambda_0/5$) spatial grids. The dependence of $\bar{v}_p$ on propagation angle θ is known as *grid anisotropy* and is a source of additional numerical dispersion effects.

Finally, it is noted that, unlike FDTD, in FDFD only the spatial derivatives are approximated by finite differences. In fact, for time-harmonic sources and fields the FDTD equations reduce to the FDFD equations in the limit of $\Delta t \to 0$.

F

Waveguiding Structures

In the previous sections, it was described how Maxwell's equations are solved with the FDFD method when the fields are excited by a current source **J**. A slightly different approach is required if one is interested in determining the modes and the dispersion characteristics of waveguiding structures which are uniform in the z direction. If all field components have an $\exp(-\gamma z)$ dependence, it can be shown that Maxwell's equations reduce to [11]

$$-\epsilon_r k_0^2 h_x + \epsilon_r \frac{\partial}{\partial y}\left[\epsilon_r^{-1}\left(\frac{\partial h_y}{\partial x} - \frac{\partial h_x}{\partial y}\right)\right] - \frac{\partial}{\partial x}\left(\frac{\partial h_x}{\partial x} + \frac{\partial h_y}{\partial y}\right) = \gamma^2 h_x, \tag{34}$$

$$-\epsilon_r k_0^2 h_y - \epsilon_r \frac{\partial}{\partial x}\left[\epsilon_r^{-1}\left(\frac{\partial h_y}{\partial x} - \frac{\partial h_x}{\partial y}\right)\right] - \frac{\partial}{\partial y}\left(\frac{\partial h_x}{\partial x} + \frac{\partial h_y}{\partial y}\right) = \gamma^2 h_y, \tag{35}$$

where $\mathbf{H}(x, y, z) = \mathbf{h}(x, y)\exp(-\gamma z)$. Equations 34 and 35 also satisfy the transversality constraint for the magnetic field ($\nabla \cdot \mathbf{H} = 0$). They are discretized by applying the finite-difference method on the Yee grid. A sparse matrix eigenvalue problem of the form $\mathbf{Ah} = \gamma^2\mathbf{h}$ is then obtained, which can be solved using iterative sparse eigenvalue techniques [12]. An important feature of this formulation is the absence of spurious modes in the solution [12], which is therefore robust.

Quasistatic Approximation

Several plasmonic structures have dimensions much smaller than the wavelength λ of the incident light. Under these conditions, retardation effects are negligible and the quasistatic approximation $\mathbf{E}(\mathbf{r}) = -\nabla\varphi(\mathbf{r})$ can be used for the scattered electric field, where $\varphi(\mathbf{r})$ is the electrostatic potential. The field distribution problem then reduces to solving [13]

$$\nabla \cdot \left\{\epsilon(\mathbf{r})\left[-\nabla\varphi(\mathbf{r}) + \mathbf{E}^i(\mathbf{r})\right]\right\} = 0, \qquad (36)$$

which represents the current conservation law. Equation 36 is discretized using the finite-difference method, as described above. A sparse system of linear equations of the form $\mathbf{Ax} = \mathbf{b}$ is obtained, where $\mathbf{b}$ is determined by the incident field $\mathbf{E}^i(\mathbf{r})$.

Comparison to Other Numerical Techniques

FDFD is a frequency-domain technique and can thus treat arbitrary material dispersion. Nonuniform and/or nonorthogonal grids are required in FDFD for efficient treatment of curved surfaces and rapid field variations at material interfaces. In FDFD, as in all other methods which are based on discretization of the differential form of Maxwell's equations in a finite volume, absorbing boundary conditions (ABCs) are required, so that waves are not artificially reflected at the boundaries of the computational domain. Very efficient and accurate ABCs, such as the perfectly matched layer (PML) [6, 12], have been demonstrated for FDFD. As mentioned above, FDFD results in extremely sparse systems of linear equations. Such problems can be solved efficiently if direct or iterative sparse matrix techniques are used.

FDTD is also a finite-difference method, so its performance in modeling plasmonic devices is similar to the performance of FDFD. There are many similarities between the two techniques. Both can be used to model structures with arbitrary geometries. In addition, many of the methods used in combination with FDTD (total field/scattered field method, etc.) can also be used with FDFD. However, there are some major differences. First, as already mentioned above, in time-domain methods the dispersion properties of metals have to be approximated by suitable analytical expressions which introduce substantial error in broadband calculations. In addition, the implementation of methods for dispersive materials in FDTD requires additional computational cost and extra memory storage [6, 14]. On the other hand, in FDTD it is possible to obtain the entire frequency response with a single simulation by exciting a broadband pulse and calculating the Fourier transform of both the excitation and the response [6].

The *Finite-Element Frequency-Domain* (FEFD) method is a more powerful technique than FDFD, especially for problems with complex geometries. However, FDFD is conceptually simpler and easier to program. The main advantage of FEFD is that complex geometric structures can be discretized using a variety of elements of different shapes, while in FDFD a rectangular grid is typically used leading to staircase approximations of particle shapes [12, 15]. In addition, in FEFD fields within elements are approximated by shape functions, typically polynomials, while in FDFD a simpler piecewise constant approximation is used [15]. In short, FEFD is more complicated than FDFD but achieves better accuracy for a given computational cost [15].

Future Research Directions

The dispersion properties of metals at optical frequencies are a major challenge in modeling of plasmonic devices. Frequency-domain techniques can treat arbitrary material dispersion but require a large number of simulations to obtain the broadband response. One possible future research direction could be the development of suitable fast frequency-sweep methods [12]. Such methods allow the computation of the broadband response by simulating the device only at a limited number of frequencies. Another major challenge in

modeling of plasmonic devices is the very fine discretization required to adequately resolve the rapid field decay away from metal-dielectric interfaces. Although nonuniform and/or nonorthogonal grids increase the efficiency of standard numerical methods for such problems, it would be interesting to investigate whether numerical grids could be optimized specifically for treatment of plasmonic devices. Finally, the development of efficient numerical linear algebra techniques for the solution of the sparse systems of algebraic equations resulting from FDFD is also a major challenge. While there are general-purpose iterative techniques and preconditioners, it would be interesting to investigate whether such numerical linear algebra tools could be fine-tuned for frequency-domain simulation of plasmonic devices. In conclusion, there are many exciting research opportunities in developing more accurate and more efficient methods for plasmonic devices.

Definition

Finite-difference time-domain technique is one of the most popular numerical approaches in computational nano-optics. It is a numerical solver of macroscopic Maxwell's equations on a special grid in time domain utilizing finite differences.

Overview

The field of nano-optics has been tremendously impacted by both a fast growth of laser technology

and significant advances in nanofabrication techniques in recent years. Owing to such progress, researchers now have the ability to go far beyond the diffraction limit to explore optics at the nanoscale, opening up a wide variety of applications ranging from metamaterials, through plasmonic circuitry and efficient solar energy harvesting, to biomedical applications [1]. Among those applications is the long-standing question of controlling light at the subdiffraction scale aiming for optical nanodevices and nanoscale coherent sources operating in the visible region of spectrum [2]. From the fundamental physics point of view, it is also important to understand general behavior of electromagnetic (EM) near-fields and their interaction with atoms and molecules. From that perspective, information on EM field dynamics at the subwavelength scale and the ability to predict EM field's behavior in the presence of mesoscopic materials such as metal tips, metal nanoparticles (NP), and arrays thereof are needed.

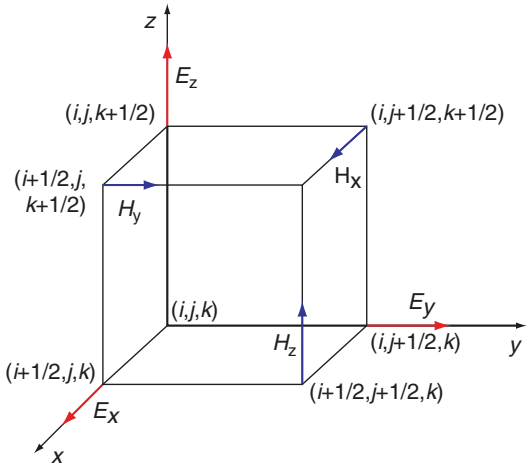
The problem of EM field dynamics in the vicinity of nanostructural materials has been the topic of both experimental and theoretical works for several years [3]. It has been realized that materials composed of metal NPs are capable of strong EM field enhancements and coherent EM energy transport in space. Although modern optical measurements are capable of capturing some near-field phenomena, they obviously lack complete physical picture of EM dynamics. It is thus important to have reliable numerical approach, which may tackle various geometries of nanomaterials and yet is relatively easy to use.

Among many numerical methods used in nano-optics, the finite-difference time-domain (FDTD) technique is considered the most easily to utilize. It has recently become a widely used tool in nano-optics due to its straightforward code implementation and the capability to accurately model complex nanostructures.

Basic Concepts

With the assumption that EM radiation can be properly described by the set of Maxwell's equations, one has the following system to solve (MKS system of units is used unless specified otherwise) [4]

$$\begin{aligned} \mu_0 \frac{\partial \vec{H}}{\partial t} &= -\nabla \times \vec{E}, \\ \varepsilon_0 \frac{\partial \vec{E}}{\partial t} &= \nabla \times \vec{H} - \frac{\partial \vec{P}}{\partial t}, \end{aligned} \tag{1}$$



$\vec{E}$ and $\vec{H}$ are electric and magnetic fields, respectively, μ_0 and ε_0 are magnetic permeability and dielectric permittivity of the free space, and $\vec{P}$ is the macroscopic polarization of the nanomaterial. In spatial regions occupied by a metal nanostructure (such as metal NP, for instance), the second equation in (Eq. 1) is modified by replacing the polarization current by a current density $\vec{J}$. The latter is needed to take into account material dispersion as discussed below.

When one writes equations (Eq. 1) replacing spatial derivatives with finite difference and then propagates the resulting system in time, the problem becomes numerically unstable for several geometries important in nano-optics. Moreover, even a simple example of plane wave propagation in free space leads to unphysical results showing numerical dispersion. The careful examination of the source of such instabilities reveals the importance of curl nature of EM waves. This problem was successfully solved by Kane Yee in 1966. In his pioneer paper, Yee proposed a new approach, which then became a basis of FDTD technique [5]. The idea is to take into account the curl nature of EM fields using a special cube, where each component of EM radiation is displaced by a half of spatial step as shown in Fig. 1. One usually introduces discrete coordinates

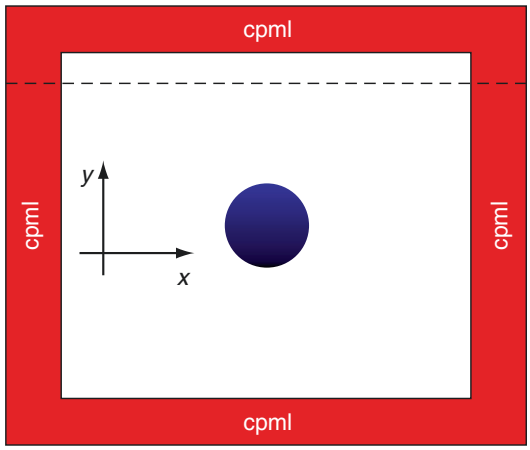
$$\begin{aligned} x_i &= x_0 + \delta x(i-1), \quad i = 1, \ldots, N_x, \\ y_j &= y_0 + \delta_y(j-1), \quad j = 1, \ldots, N_y, \\ z_k &= z_0 + \delta z(k-1). \quad k = 1, \ldots, N_z. \end{aligned} \tag{2}$$

where δx, δ_y, and δz are spatial steps. A half of spatial step $\delta x/2$ is conventionally denoted in Fig. 1 as 1/2.

It is easy to show that with such arrangement of electric and magnetic field components Gauss's

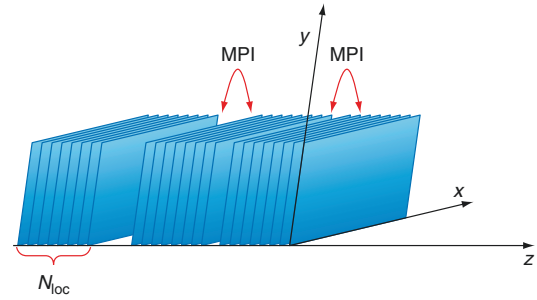
Finite-Difference Time-Domain Technique, Fig. 1 The Yee cell. The size of each side of the cube is a half of spatial step

law for electric and magnetic fields is automatically satisfied in free space. Furthermore, the boundary conditions at each grid point are automatically maintained. The latter is critical for modeling of complex structures, where other methods are particularly hard to implement due to boundaries between materials. The Yee grid has several attractive technical features, including numerical stability and availability of the magnetic field. The latter is especially important if one considers structures with sharp corners at which the tangential components of $\vec{H}$ have singularities.



In nano-optics, one usually deals with initial value problems, where initial conditions for EM fields are given and one is interested in their subsequent dynamics, i.e., scattering and absorption of laser pulses by nanomaterials. It is thus important to develop reliable and numerically stable time propagation procedure. The most efficient and hence widely used technique is the leapfrog time-stepping algorithm. Here all electric field components are updated using known magnetic field components. Next magnetic field is updated and stored in memory using updated electric field. The process is then repeated until the desired propagation time is reached. It is important to note that such procedure is non-dissipative with no artificial decay of EM waves propagated on the grid. This technique has a second order accuracy with respect to time step.

The numerical convergence sensitively depends on spatial resolution δx and temporal step δt. While the choice of the latter is usually predetermined by the dimensionality of the problem (for three-dimensional systems the conventional time step is $\delta t < c = \left(\delta x\sqrt{3}\right)$), the former has to be determined by particular fraction of the characteristic wavelength, λ_c, of nanomaterial. For silver/gold nanostructures, this results in $\delta x \leq 1.5$ nm.



For simulations of open systems, one needs to impose artificial absorbing boundaries in order to avoid numerical reflection of outgoing EM waves back to the simulation domain. From among the various approaches that address this numerical issue, the perfectly matched layers (PML) technique is considered to be the most powerful [6]. It reduces the reflection coefficient of outgoing waves at the simulation region boundary to $\sim 10^{-8}$. Essentially, the PML approach surrounds the simulation domain by thin layers of nonphysical material that efficiently absorb outgoing waves incident at any angle. The most efficient and least memory intensive method is the convolution perfectly matched layers (CPML) absorbing boundaries. It should be noted that parameters of CPML have to be carefully chosen. The latter are usually problem dependent and have to be determined for each structure independently. However, the good starting point is to begin with the following set of CPML parameters and verify whether CPML introduces no reflections of outgoing waves back into the simulation domain

$$\kappa = 20,\ \sigma = 0.75,\ \alpha = 0.24. \qquad (3)$$

Optimal number of CPML layers varies from one simulation to another; however, 20 layers is usually enough to ensure efficient absorption at almost all incident angles. It is also important to note that for periodic structures supporting high Q resonances, CPML boundaries should be placed at least two characteristic wavelengths away from the system. For example, to simulate

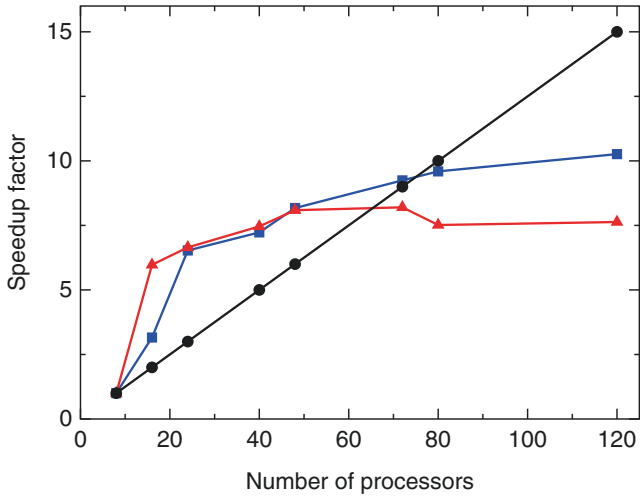
Finite-Difference Time-Domain Technique, Fig. 2 Plane wave generation. A nanostructure is placed at the center of the simulation domain. The domain is surrounded by CPML layers on all sides in order to simulate an open system. Horizontal *dashed line* represents the incident plane wave generation

Finite-Difference Time-Domain Technique, Fig. 3 Parallel implementation. Schematic parallelization of the FDTD, where N_{loc} xy-slices are carried by each processor. Send-and-receive MPI subroutines are implemented at the boundaries between each processor

properly transmission and reflection of laser radiation by a silver film (with the thickness of 100 nm) with a single subwavelength slit (with a size of 70 nm), CPML boundaries must be placed 2 μm away from the film.

Depending on particular problem, various types of incident sources have to be implemented. The most common source in nano-optics is a plane wave. There are several ways to inject plane wave into the simulation domain. If one is interested in the normal incidence case, the most efficient and less memory-consuming technique is to include artificial current source of a given direction into second equation in (Eq. 1). It is illustrated in Fig. 2. Here dashed line represents the incident plane, at which every spatial point for x-component of electric field is driven by a current source of the form

$$E_{\text{inc}}(t) = E_0 f(t) \cos(\omega t + \varphi), \tag{4}$$



where $f(t)$ is the pulse envelope, ω and φ are incident frequency and the phase. It is important to use a smooth function of time in order to avoid generation of spurious waves. The widely used pulse envelope is

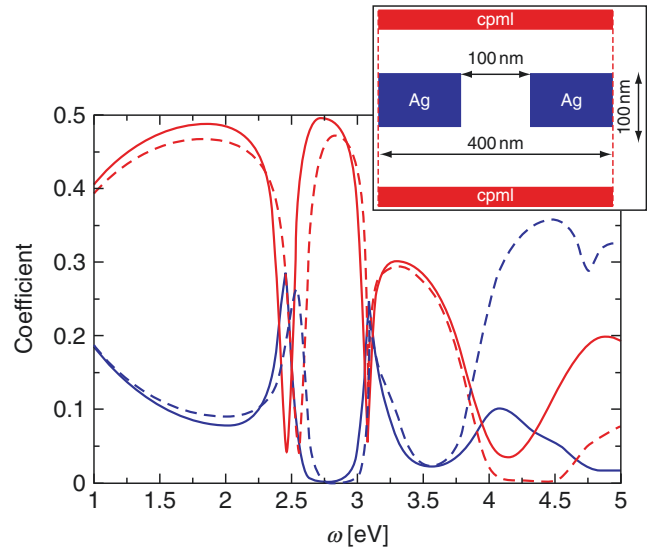
$$f(t) = \begin{cases} \sin^2\left(\pi \dfrac{t}{\tau}\right), & 0 \le t \le \tau, \\ 0, & t \ge \tau, \end{cases} \tag{5}$$

where τ is the pulse duration. Note that not only the envelope is 0 at the beginning and at the end of the pulse, but also its time derivative. It should be noted that the first term in the second equation in (Eq. 1) is also included – this ensures that the plane, at which the incident pulse is generated, is transparent for all waves that are scattered by a nanostructure. This source is referred to as soft source. Finally, both sides of the incident plane have to embedded into CPML regions as shown in Fig. 2.

One of the several advantages of FDTD is its simple finite difference layout, which allows a straightforward parallelization carried out on multiprocessor machines. As illustrated in Fig. 3, the FDTD scheme is partitioned onto a parallel grid by dividing the simulation space into M xy-slices, where M is the number of available processors. Point-to-point message passing interface (MPI) communication subroutines are implemented at the boundaries between slices. The number of xy planes in each slice denoted as N_{loc} usually varies in the range from 12 to 50. The optimal value of N_{loc} for particular problem is determined by scaling simulations – the same geometry is simulated using different number of processors.

The typical test for the parallelizability and portability of the parallelization scheme is shown in Fig. 4. The presented benchmarks of

Finite-Difference Time-Domain Technique, Fig. 4 Scaling example. Speedup factor defined in (Eq. 6) as a function of number of processors in double logarithmic scale. Ideal speedup is shown by *black circles, blue squares* represent the data obtained on ASU supercomputer Plasmon, and *red triangles* show simulations performed on NCSA cluster Abe



simulations are performed on both the Intel 64 Abe cluster at the NCSA and the Plasmon cluster – a 128-core AMD 64 Opteron–based machine that was assembled recently at ASU Polytechnic. The model tested corresponds to the scattering and absorption of an EM plane wave by a periodic array of silver NPs of 50 nm in diameter. In this problem, the two-dimensional FDTD grid has a size of 792 × 792 nm, with a step size of 1.1 nm. The number of time iterations within the leapfrog time-stepping technique is 650,000, resulting in total propagation time of 1.6 ps. An interesting observation in these studies is the vector eigenmodes of the interacting NPs. To test the efficiency of the parallelization procedure, the speedup factor is computed, defined as

$$S_n = \frac{T_8}{T_n}, \tag{6}$$

where T_8 is the execution time on eight processors and T_n is the execution time on n processors. The choice of the scaling is not arbitrary since Abe and Plasmon clusters have eight cores per node. According to Amdahl's law, the ideal speedup is $n/8$ [7].

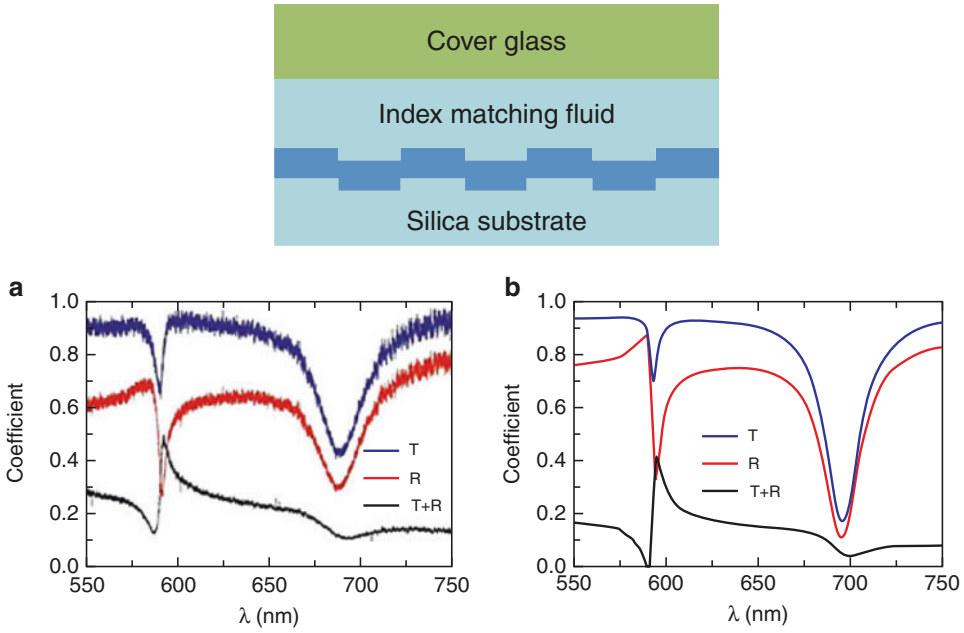
As illustrated in Fig. 4, the measured speedup factor is nearly ideal. It degrades with increasing number of processors since in the model simulations, the grid size was fixed and hence the number of layers per processor decreased with increasing number of processors, resulting in more sending-and-receiving MPI operations per iteration with consequent latency of the network. Nonetheless, the speedup for the worst case of 120 processors, where number of layers per each processor is only 6, remains good: $S_{120} = 10.26$ as compared to the ideal speedup factor of 15.06 for 120 processors. Another interesting observation is the so-called nonlinear speedup regime for small number of processors, where measured *Sn* is exceeding the ideal limit. Similar results have been obtained for full three-dimensional FDTD codes for open systems and periodic structures demonstrating efficiency of the parallelization procedure. The nonlinear deviation of the simulated speedup from its ideal value can be explained as follows. By increasing the number of processors involved in the simulations while keeping the problem size constant, one effectively decreases the amount of swapping that the code performs. In other words, for those points in Fig. 4 at which the simulated speedup is higher than its ideal value, the memory occupied by the locally propagated matrices (consisting of the EM field components) is less than the cash size of each processor.

Using the computed speedup factor, it is informative to calculate another important performance measure, namely, the F-factor that specifies the portion of simulations that cannot be parallelized, i.e., the portion of an algorithm

Finite-Difference Time-Domain Technique, Fig. 5 Comparison between Drude-Lorentz (*solid lines*) and Drude (*dashed lines*) models for the frequency-dependent transmission (*blue dark lines*) and reflection (*red bright lines*) of EM radiation by a periodic slit array. The latter is schematically depicted in the inset. Here two vertical *red dashed lines* show periodic boundaries

that is sequential in nature. The F-factor is related to the speedup factor (Eq. 6) as

$$F = \frac{n - S_n}{S_n(n-8)}. \tag{7}$$



The calculated F-factor (Eq. 7) for both open and periodic codes shows outstanding parallelization. The largest F-factor is nearly 9 %, which indicates that only 9 % of the code is sequential.

To account for material dispersion in spatial regions of a nanostructure occupied by metal or dispersive dielectric, one employs the auxiliary differential equation method [4]. In general, the dielectric response of the metal is modeled using a standard Lorentz-Drude (LD) formulation [8]

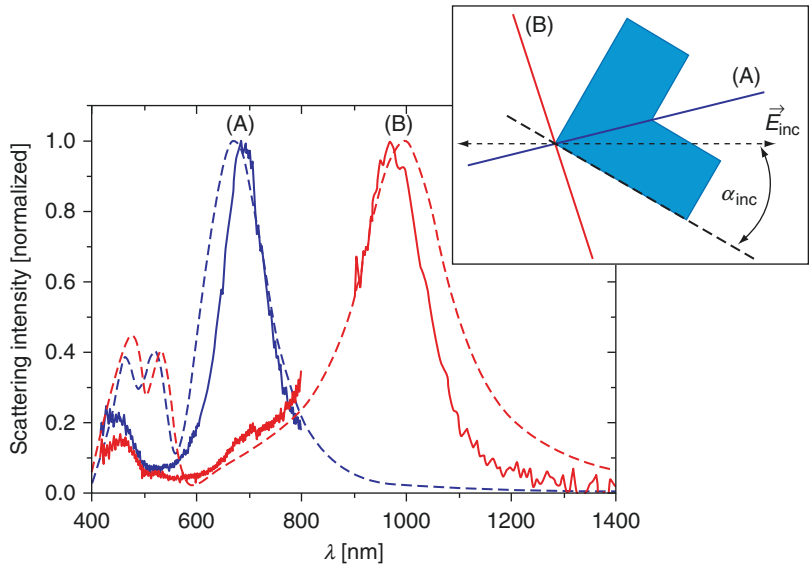
$$\varepsilon(\omega) = \left[\varepsilon_r - \frac{\Omega_p^2}{\omega^2 + i\Gamma\Omega_p}\right] + \sum_n \frac{f_n}{\left(\omega_n^2 - \omega^2\right) + i\gamma_n\omega}. \tag{8}$$

The expression in brackets represents the standard Drude model that includes the bulk plasma frequency of the electron system, Ωp, and its width (damping), Γ. The material dispersion of metals can be accurately described within this model only in the limit of high frequencies. Sometimes it is desirable to model material dispersion over a wide frequency range. Hence, it is necessary to include a more general Lorentzian model (the second term in Eq. 8) that accurately covers the optical and near-infrared wavelength region. As seen in Eq. 8 the Drude model is a special case of the Lorentzian model describing an oscillator with the zero restoring force. Finally one needs to fit Eq. 8 to the experimentally observed dielectric response of, e.g., Ag and Au in the range 0.1–5 eV [9].

Figure 5 illustrates the applicability of the Drude model and compares it with more general description Eq. 8. The performed simulations calculate transmission and reflection properties of a periodic slit array perforated on a thin silver film (see insert in Fig. 5). In order to obtain transmission and reflection as functions of the incident frequency, the system is excited by an ultra-short pulse of the duration of 0.36 fs. In the frequency domain, such pulse is almost flat for all frequencies of interest. Once the system is excited, Maxwell's equations are propagated for about 2 ps and EM field components are recorded on both input and output sides of the structure as functions of time. Subsequent Fourier transformation of the detected fields and calculations of the Poynting vector result in transmission and reflection coefficients. It should be noted that the entire spectrum is obtained via a single FDTD run. Figure 5 shows direct comparison of the Drude model and the LD

Finite-Difference Time-Domain Technique, Fig. 6 Up-down diffraction grating. Experiment (*left frame*) and FDTD (*right frame*) data for the transmission (*black lines*, lowest curves in each frame), reflection (*red lines*, curves in the middle in each frame), and transmission + reflection (*blues lines*, upper curves in each frame) as functions of the incident wavelength in nanometers. The up-down grating setup is schematically depicted in the inset, where blue regions correspond to silver. Effective thickness of the grating is 35 nm and the period is 197 nm

model. Even though results obtained within the Drude model qualitatively agree with LD simulations for low-energy part of the spectrum, the Drude approach fails at frequencies above 4 eV.



Applications

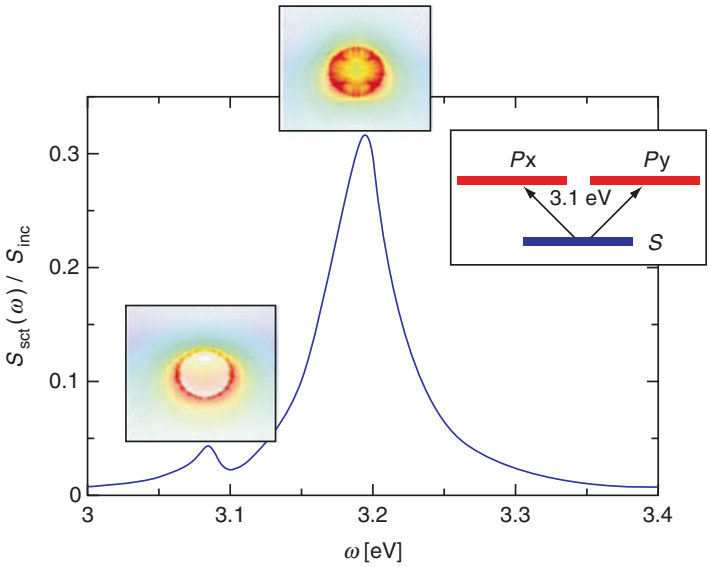
Up-Down Subwavelength Diffraction Gratings

It has been recently shown that up-down diffraction gratings produced on thin metal films may lead to high-quality optical resonances [10]. The latter have a wide variety of immediate applications ranging from surface-enhanced Raman spectroscopy to prototypes of nanoscale optical cavities for future nano-lasers. It is hence important to be able to predict optical response of such systems utilizing numerical simulations. Figure 6 demonstrates the efficiency of the FDTD technique and its ability to capture quantitatively general behavior of EM surface waves. Here experimental measurements are compared directly with FDTD data for up-down silver diffraction grating shown schematically in the inset. Due to symmetric dielectric environment, the grating exhibits two well-resolved resonant peaks corresponding to the symmetric and anti-symmetric surface modes. It should be noted that the resonance at high energy (short wavelength) becomes narrower when the effective thickness of the film decreases resulting in Q around 5,000 for thicknesses of 7 nm or smaller. The agreement between experiment and FDTD simulations is nearly ideal for the positions of these modes. Most importantly, widths and lines shapes obtained via FDTD are almost identical to those observed in the experiment.

Optical Properties of L-Shaped Nanoparticles

Several experimental groups have demonstrated that arrays of NPs with no center of inversion symmetry exhibit birefringence modifying the polarization of the incident radiation. For example, L-shaped NPs have two well-defined resonant

Finite-Difference Time-Domain Technique, Fig. 7 Scattering cross-section of a single silver L-shaped NP as a function of the incident wavelength in nanometers. FDTD simulations are shown as *dashed lines*, while experimental measurements are represented as *solid lines*. *Blue* (*dark*) color corresponds to the incident field polarized along the *blue* (*dark*) axis of symmetry (see the *inset*); *red* (*bright*) color shows the data for the polarization along the *red* (*bright*) axis. The *inset* shows the *top* view of the nanostructure



bands associated with the axes of symmetry (see the inset of Fig. 7). If the polarization of a pump pulse is not along one of these axes, the total EM field becomes elliptically polarized on the output side of the array [11]. Direct comparison of three-dimensional FDTD simulations with experimental measurements is presented in Fig. 7, again demonstrating a good agreement.

Classical Electrodynamics of Quantum Systems

All these and many other intriguing applications, however, mainly utilize linear optical response of nanomaterials. Most of the research has been centered at linear optics of metal nanostructures with several attempts to go beyond linear regime and consider nonlinear properties of materials including noble metal NPs aiming for a wide variety of nonlinear phenomena to appear. A newly emerging research field of nonlinear plasmonics follows two obvious routes, namely, combining linear metal nanosystems with highly nonlinear media or taking into account strongly inhomogeneous EM fields associated with EM surface waves that lead to spatial dependence of density of the conductive electrons in metals and hence result in nonlinear phenomena such as second harmonic generation [12]. The first approach deals with nonlinear media at the macroscopic level while even a single atom or molecule located near nanostructure at resonant conditions may be considered as a nonlinear optical system due to high EM near-fields. Thus, it is important to develop approach capable of capturing both size effects at the nanoscale and the time dynamics of EM fields. Generally speaking, such approach has to take into account Maxwell's equations and quantum dynamics of atoms or molecules in the vicinity of nanomaterials. The latter can be accomplished by coupling the Liouville equation that governs the evolution of the density matrix to Maxwell's equations via a polarization current term [13]. The resulting system of coupled equations thus contains the most accurate description of nonlinear phenomena at the nanoscale.

The goal is to couple Maxwell's equations (Eq. 1) to the equation that describes the dynamics of quantum system (such as a gas of cold atoms). In the presence of decoherence and with an assumption that the density of quantum gas is low enough to neglect Coulomb interaction between atoms, one can describe the quantum dynamics using the Liouville equation for a single atom

$$i\hbar \frac{d\hat{\rho}}{dt} = \left[\hat{H}, \hat{\rho}\right] - i\hbar\hat{\Gamma}\hat{\rho}, \tag{9}$$

Finite-Difference Time-Domain Technique, Fig. 8 Scattering cross-section of the atomic cluster as a function of the incident frequency in electron Volts. The *left inset* shows the energy level diagram. The *rightmost inset* depicts steady-state EM energy distribution associated with low-energy resonance (surface mode – analogue of the localized surface plasmon-polariton). The inset in the *middle* demonstrates the collective volume mode at 3.2 eV

where $\hat{\rho}$ is the density matrix of an atom and $\hat{H}$ is the Hamiltonian containing atom-EM field interaction. The relaxation processes are considered to be Markovian. The diagonal elements of the relaxation matrix $\hat{\Gamma}$ describe lifetime of the excited states, while nondiagonal elements take into account dephasing effects. Further assuming that EM field does not significantly change within a volume occupied by a single atom, the spatial dependence of the density matrix in (Eq. 9) is parametrical via EM field components.

To couple Eqs. 1 and 9, one needs to calculate a macroscopic polarization, $\vec{P}$, according to

$$\vec{P} = n_a \left\langle \vec{d} \right\rangle, \tag{10}$$

where n_a is the number density of atoms and $\left\langle \vec{d} \right\rangle = Tr\left(\hat{\rho}\vec{d}\right)$ is the expectation value of the atomic dipole moment, $\vec{d}$. The resulting system of coupled Maxwell-Liouville equations is then solved numerically on a computer. Note that the dipole–dipole interactions between atoms (without *nearest neighbor* approximation) are automatically included in this approach.

The numerical implementation of the proposed scheme is as follows:

1. In the regions occupied by atoms, Maxwell's equations are solved utilizing FDTD algorithm. First, magnetic field is updated according to Faraday's law. Next, using Ampere's law, electric field is updated with the macroscopic polarization current density (time derivative of Eq. 10), which uses density matrix at the previous time step.
2. With the knowledge of electric field components (stored in memory at two time steps), the density matrix is updated at each spatial point on the grid according to Eq. 9 using the fourth order Runge–Kutta scheme.
3. Finally, with the knowledge of electric field components and updated density matrix, one calculates the macroscopic polarization current at each grid point. Note that the time derivative of Eq. 10 in many cases can be written analytically, which simplifies calculations and improves numerical stability.

Figure 8 presents results of numerical integration of the coupled two-dimensional Maxwell-Liouville equations for the atomic cluster with a radius of 35 nm. The cluster is assumed to be comprised of two-level atoms with a number density corresponding to that of the ideal gas. It should be noted that in order to take into account all possible polarizations of EM field, excited states of each atom have to be doubly degenerate as depicted in the inset of Fig. 8.

The peak amplitude of the incident field is low such that the system exhibits only linear response. Maxwell-Liouville equations are propagated in time for as long as several picoseconds. The resulting EM fields are used to calculate scattering cross-section at a given incident frequency. Simulations are repeated for several frequencies. The data obtained show that the atomic cluster exhibits two resonances (unlike for an individual atom, where one would observe a single fluorescent spike) illustrating a significance of collective effects.

First-Principles Quantum Monte Carlo

Lucas K. Wagner
Department of Physics, University of Illinois, Urbana, IL, USA

Definition

A computational method that uses Monte Carlo techniques to solve many-body quantum problems. There are a number of different quantum Monte Carlo techniques, which vary from exact to approximate solution of the Schrödinger equation and can be applied to many different types of Hamiltonians.

Overview

There are many different types of quantum Monte Carlo techniques. Which one to use can be intimidating to a novice; however, there are actually only a few different concepts that are expressed in different languages for different problems.

Concept: Sampling

In a many-body quantum problem, the fundamental object is the many-body wave function $\Psi(\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \ldots)$ or, for finite temperature problems, the many-body density matrix $\rho(\mathbf{r'}_1, \mathbf{r'}_2, \ldots; \mathbf{r}_1, \mathbf{r}_2, \ldots)$. These objects are thus scalar functions on the space $\mathcal{R}^{3N}$ or $\mathcal{R}^{6N}$ in three dimensions, where N is the number of particles. Grid-based techniques require exponential numbers of points with respect to the number of particles to represent these functions, which is computationally infeasible.

The fundamental concept in QMC is that the wave function can be represented implicitly by the positions of a set of samples whose positions are chosen randomly. Observables are then measured on this set of samples, which are viewed stochastically. The central limit theorem is invoked to find the statistical error $\varepsilon = \sigma/\sqrt{N_s}$, where σ is the standard deviation of the quantity and N_s is the number of samples. The error is independent of the dimensionality of the problem. Stochastic sampling is a strategy that enables an algorithm to treat very high-dimensional spaces while potentially scaling weakly with the system size, assuming that the standard deviation σ is well controlled.

When evaluating a quantum Monte Carlo technique, one of the first objectives is to characterize what distribution the algorithm samples. This directly affects what quantities can be evaluated. The behavior of σ is also important. There are some problems for which Monte Carlo is not applicable because σ is not finite.

Concept: Monte Carlo Integration

Many high-dimensional problems can be written as an integration:

$$\int I(\mathbf{R}) d\mathbf{R}, \tag{1}$$

where $\mathbf{R}$ stands for the collective many-body coordinate $\mathbf{R} = \{r_1, r_2, \ldots\}$. If samples are generated with probability density $\rho(\mathbf{R})$, then the expectation value of any observable $A(\mathbf{R})$ on that sample set is

$$\langle A \rangle_\rho = \int A(\mathbf{R}) \rho(\mathbf{R}) d\mathbf{R}. \tag{2}$$

It is thus possible to write any integral as

$$\int I(\mathbf{R}) d\mathbf{R} = \int \frac{I(\mathbf{R})}{\rho(\mathbf{R})} \rho(\mathbf{R}) d\mathbf{R} = \left\langle \frac{I}{\rho} \right\rangle_\rho. \tag{3}$$

This equation suggests the Monte Carlo integration strategy: generate samples with some probability density ρ and accumulate the integral as the average of $\frac{I(\mathbf{R})}{\rho(\mathbf{R})}$.

There are several algorithms that can efficiently generate random samples given a density ρ. The most common is the algorithm of Metropolis, Rosenbluth, Rosenbluth, Teller, and Teller [6], often called the Metropolis algorithm.

Concept: Importance Sampling

The stochastic uncertainty ε is proportional to the standard deviation σ of the quantity $\frac{I}{\rho}$ in Eq. 3. Since ε is inversely proportional to the square root of the number of independent samples, the cost of a Monte Carlo calculation to obtain a given uncertainty rises as the variance σ^2. Because of this, the ultimate efficiency of a Monte Carlo algorithm is strongly affected by the choice of the sampled function ρ. The concept of importance sampling is to choose ρ so that σ^2 is as small as possible. This technique can increase the efficiency of a Monte Carlo method by many orders of magnitude.

One particularly spectacular example of importance sampling is the case of evaluating the expectation value of the energy giving some wave function $\Psi(\mathbf{R})$. This integral is

$$\langle E \rangle = \frac{\int \Psi^*(\mathbf{R}) \hat{H} \Psi(\mathbf{R}) d\mathbf{R}}{\int |\Psi(\mathbf{R})|^2 d\mathbf{R}} \tag{4}$$

The typical choice of ρ is

$$\rho(\mathbf{R}) = \frac{|\Psi(\mathbf{R})|^2}{\int |\Psi(\mathbf{R})|^2 d\mathbf{R}}, \tag{5}$$

which results in the integral

$$\int \frac{\hat{H}\Psi(\mathbf{R})}{\Psi(\mathbf{R})} \rho(\mathbf{R}) d\mathbf{R} \tag{6}$$

The variance of the quantity $\frac{\hat{H}\Psi(\mathbf{R})}{\Psi(\mathbf{R})}$ has the special property that for an eigenfunction of the Hamiltonian, it is a constant. Therefore, as the wave function approaches an eigenfunction, the variance approaches zero, and the efficiency of the Monte Carlo process increases as well.

Flavors of Quantum Monte Carlo

For nanotechnology, there are at least two large classes of problems that may be served using quantum Monte Carlo techniques. The first is the ab initio or first-principles problem, in which it is required that a highly accurate prediction be made using only fundamental constants and atomic positions. The second is the model problem, in which there is an approximate low-energy problem in some usually discrete Hilbert space. While the algorithms themselves are often very similar to one another in both these cases, the considerations around the applications of the algorithms and the feasibility of sophisticated methods can result in quite different calculations. This entry will focus on the most common techniques used when the Hamiltonian to be solved is the first-principles one; that is,

$$\hat{H} = -\sum_i \frac{1}{2}\nabla_i^2 - \sum_{\alpha i} \frac{Z_\alpha}{r_{i\alpha}} + \sum_{\alpha\beta} \frac{Z_{\alpha\beta}}{r_{\alpha\beta}} + \sum_{ij} \frac{1}{r_{ij}}, \tag{7}$$

where atomic units ($\hbar = 1$, $m_e = 1$, $e = 1$) are used; i, j refer to electron indices; and α, β refer to nuclear indices. Notable techniques that are not covered in this entry include full configuration interaction quantum Monte Carlo [1] (FCI-QMC) and auxiliary field quantum Monte Carlo [7] (AF-QMC). More details are available in a review article [4].

Variational Monte Carlo (VMC)

VMC is a direct application of the variational method to obtain ground states. The wave function is expressed as a function of the many-body coordinate R and some parameters P. Then the expectation value of the energy is evaluated as

$$\langle E(P) \rangle = \frac{\int \Psi^*(\mathbf{R}, P) \hat{H} \Psi(\mathbf{R}, P) d\mathbf{R}}{\int |\Psi(\mathbf{R}, P)|^2 d\mathbf{R}} \tag{8}$$

using Monte Carlo techniques as explained above. The advantage of using Monte Carlo techniques is that the integral can be evaluated for any wave function for which the value and its derivatives can be evaluated efficiently.

A paradigmatic example of a wave function enabled by the VMC method is the Slater-Jastrow form:

$$\Psi(\mathbf{R}) = \mathrm{Det}\left[\phi_i(\mathbf{r}_j)\right] \exp\left(\sum_{\alpha, i\neq j} u(r_{i\alpha}, r_{j\alpha}, r_{ij})\right). \tag{9}$$

The first term in Eq. 9 is a Slater determinant of one-particle orbitals ϕ_i. Typically these orbitals are obtained from either a Hartree-Fock or density functional theory calculation. They may be optimized as part of the VMC procedure. The second term in Eq. 9 is called the Jastrow factor and explicitly includes the electron–electron distances. Typically, the function u is expanded as follows:

$$u(r_{i\alpha}, r_{j\alpha}, r_{ij}) = \sum_k c_k^{ei} a_k(r_{i\alpha}) + \sum_k c_m^{ee} b_k(r_{ij}) + \sum_{klm} c_{klm}^{eei}\left(a_k(r_{i\alpha})a_l(r_{j\alpha}) + a_k(r_{j\alpha})a_l(r_{i\alpha})\right)b_k(r_{ij}),$$

where the Greek letters stand for the index of the nuclei and a_k/b_k are one-dimensional functions. With the Jastrow factor, Eq. 8 becomes nonseparable, and Monte Carlo is needed to numerically evaluate the integral.

There are two main options to optimize the wave function. The first is direct energy optimization. This approach is surprisingly difficult to achieve and was only fully developed in the 2000s. Modern energy optimization techniques can handle thousands of parameters efficiently. Variance optimization is an older but still effective technique to optimize wave functions. It is directly related to the zero variance principle above. The variance optimization technique minimizes the variance of the local energy $E_L(\mathbf{R}) = \hat{H}\Psi(\mathbf{R})/\Psi(\mathbf{R})$ by varying the wave function parameters. While variance optimization is typically more efficient than energy optimization, it cannot efficiently optimize parameters that change the nodes of the wave function.

Common wave function forms: MSJ, backflow, pairing.

Convergence parameters: Number of parameters, accuracy of the optimization.

Main approximation: For a given Hamiltonian and boundary conditions, the primary approximation in VMC methods is the wave function *ansatz*. If this is close to the exact wave function, then the approximation will be small. If there is important physics not contained in the parameterization, the approximation will be larger. Simpler ground states may be artificially preferred over complex ground states because they are easier to parameterize.

Exact when: The wave function parameterization includes the exact wave function in its Hilbert space.

F

Projector Monte Carlo

Diffusion Monte Carlo (DMC) and reptation Monte Carlo (RMC) are based on the so-called imaginary time Schrödinger equation

$$-\frac{d\Psi(\mathbf{R}, \tau)}{d\tau} = (H - E_0)\Psi(\mathbf{R}, \tau), \tag{10}$$

which has a steady-state solution when Ψ is an eigenfunction and E_0 is adjusted to the eigenvalue. Non-steady-state solutions converge exponentially quickly to the eigenstate Φ_0 as τ goes to infinity.

In the language of Green's functions, the propagation of $\Psi(\mathbf{R}, \tau)$ is given by

$$\Psi(\mathbf{R}, \tau + \Delta\tau) = \int G(\mathbf{R}, \mathbf{R}', \Delta\tau)\Psi(\mathbf{R}', \tau)d\mathbf{R}'. \tag{11}$$

If the function $G(\mathbf{R}, \mathbf{R}', \Delta\tau) = \langle \mathbf{R}| \exp(-\Delta\tau\hat{H})|\mathbf{R}'\rangle$ were known, then one could use Monte Carlo integration to evaluate Eq. 11. It turns out that excellent approximations exist for G when $\Delta\tau$ is small. Then, since $\exp(-\Delta\tau\hat{H}) = \exp(-\Delta\tau\hat{H}/n)^n$, any large $\delta\tau$ can be expressed as multiple nested integrals; that is,

$$\Psi(\mathbf{R}, \tau + \Delta\tau) = \int G(\mathbf{R}, \mathbf{R}_1, \Delta\tau/n)\ldots G(\mathbf{R}_{n-1}, \mathbf{R}_n, \Delta\tau/n)\Psi(\mathbf{R}', \tau)d\mathbf{R}_1\ldots d\mathbf{R}_n. \tag{12}$$

This is a very high-dimensional integration over $3N_e n$ dimensions, where a typical value for n to ensure convergence might be 100–400.

The projector Monte Carlo techniques are thus based on performing the integral in Eq. 12 using Monte Carlo techniques. The reptation or path integral ground state methods perform this operation explicitly, by sampling a random variable in the space $\mathcal{R}^{3N_e n}$ with probability proportional to the integrand in Eq. 12. It is here that one first encounters the *fermion sign problem*: for fermion particles, the integrand is not necessarily positive and cannot be represented as a probability distribution. In fact, the sign of the integrand can fluctuate wildly, which ultimately causes the variance of any observable to increase exponentially as a function of the system size. Therefore, for fermions, an approximation is needed to make the simulations feasible.

Instead of using the bare projectors in Eq. 12, one typically uses the importance-sampled ones. In this technique, the starting distribution is proportional to $\Psi_T^2(\mathbf{R})$, where Ψ_T is the trial function (typically the Slater-Jastrow wave function). The projector is then modified to become the importance-sampled Green's function:

$$\tilde{G}(\mathbf{R}, \mathbf{R}', \Delta\tau) = \Psi_T(\mathbf{R}) G(\mathbf{R}, \mathbf{R}', \Delta\tau) / \Psi_T(\mathbf{R}'). \tag{13}$$

The final distribution sampled is the mixed distribution $\Psi_T(\mathbf{R})\Phi_{FN}(\mathbf{R})$, where $\Phi_{FN}(\mathbf{R}) = \Psi(\mathbf{R}, \infty)$, as one can see by performing the integral

$$\begin{aligned} &\int \tilde{G}(\mathbf{R}, \mathbf{R}', \Delta\tau)\Psi_T^2(\mathbf{R}')d\mathbf{R}'. \\ &= \Psi_T(\mathbf{R}) \int G(\mathbf{R}, \mathbf{R}', \Delta\tau)\Psi_T(\mathbf{R}')d\mathbf{R}' \\ &= \Psi_T(\mathbf{R})\Psi(\mathbf{R}, \Delta\tau). \end{aligned} \tag{14}$$

It can be shown that $\tilde{G}$ is much more easily approximated than G for finite timesteps, if the trial function Ψ_T is accurate [3]. The importance sampling transformation also makes the *fixed-node* approximation apparent; if the nodes (zeros) of Φ_{FN} are constrained to be the same as the nodes of Ψ_T, then the final distribution $\Psi_T(\mathbf{R})\Phi_{FN}(\mathbf{R})$ is guaranteed to be positive, and there is no sign problem at the cost of an approximation.

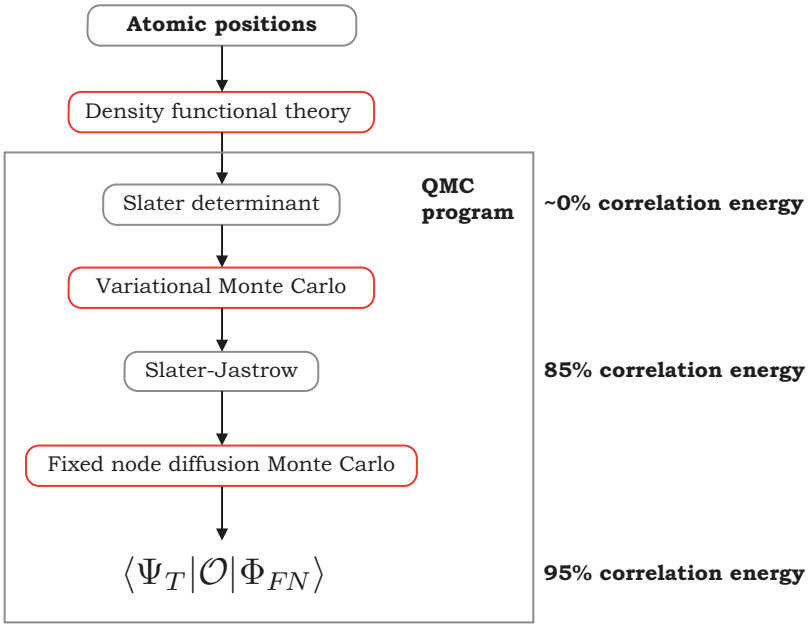
Convergence parameters: Time descretization.

Main approximation: For bosons, expectation values on the ground state can be found exactly. For small systems ($\lesssim 10$) of few fermions, the sign problem can be circumvented with sufficient computer time. For larger systems of fermions, fixed-node or similar approximations must be used.

Exact when: The ground state nodal surface is known.

Path Integral Monte Carlo

Path Integral Monte Carlo (PIMC) is closely related to the projector methods. In this case, the integrals to be evaluated are traces over the density matrix $\exp(-\beta\hat{H})$, where $\beta = 1/k_B T$, the inverse temperature. An expectation value of a local operator $\mathcal{O}(\mathbf{R})$ can be evaluated as



$$\langle \mathcal{O} \rangle = \int \langle \mathbf{R} | \exp(-\beta\hat{H}) | \mathbf{R} \rangle \, \mathcal{O}(\mathbf{R}) d\mathbf{R}. \tag{15}$$

This is very similar to Eq. 12 with $\Delta\tau = \beta$, except that the initial and final positions are the same, and there is no wave function.

Very similar considerations apply to the evaluation of Eq. 15, in terms of the sign problem and expanding the matrix elements as products of smaller steps. For lower temperature, β is larger, which corresponds to longer projection time. This then corresponds to a larger value of n, which are called "beads" in the language of PIMC.

Practical Calculations on First-Principles Models

The majority of quantum Monte Carlo calculations on first-principles models use a standard process, illustrated in Fig. 1. The most basic procedure is outlined here; there are many elaborations on this skeleton. First, a density functional theory (DFT) calculation is performed. The purpose of the DFT calculation is to generate a set of

First-Principles Quantum Monte Carlo, Fig. 1 Typical workflow for quantum Monte Carlo calculations of first-principles models

orbitals that can be used to create a Slater determinant starting wave function. The density functional itself is not relevant to the QMC calculation, other than the orbitals that it produces. Then, the Jastrow factor (Eq. 9) is added to the wave function and optimized using variational Monte Carlo techniques to form the Slater-Jastrow wave function. Finally, to improve the accuracy further, diffusion Monte Carlo is performed using the Slater-Jastrow wave function as the trial function.

Approximations in Diffusion Monte Carlo

The workflow outlined above has only a few well-defined approximations. They are summarized in Table 1. The controlled approximations can be removed in a polynomially scaling amount of time as listed. Once that is done, there are two main approximations: pseudopotentials and fixed node. Pseudopotentials are an approximation in the Hamiltonian, while fixed node is an approximation in the solution of the Hamiltonian. The relative importance of these two has been tested on small molecules by removing the fixed-node error. It seems that at least half of the error is due to fixed node, if Hartree-Fock pseudopotentials are used.

First-Principles Quantum Monte Carlo, Table 1 Approximations in the procedure outlined in Fig. 1

Approximation	Resolution
Controllable	
Timestep	Reduce the factor $\Delta\tau/n$ in Eq. 12 until the properties are converged
Finite size	In periodic models of infinite systems, increase the cell size used to simulate the system
Finite population	Use large numbers of walkers to perform the calculation
Uncontrolled	
Fixed node	Use a higher accuracy trial function
Pseudopotential	Test the pseudopotential carefully

What Can Be Calculated Using Quantum Monte Carlo Techniques

The fixed-node diffusion Monte Carlo can calculate expectation values of the following form:

$$\langle \Psi_T | \mathcal{O} | \Phi_{FN} \rangle, \tag{16}$$

where $\mathcal{O}$ is a quantum operator, Ψ_T is the trial function, and Φ_{FN} is the fixed-node wave function. This is called the mixed estimator. For the calculation of energies, this equates to the pure estimator

$$\langle \Psi_T | \hat{H} | \Phi_{FN} \rangle = \langle \Phi_{FN} | \hat{H} | \Phi_{FN} \rangle. \quad (17)$$

For other quantities, the mixed estimator is not exact, but can be corrected using the extrapolated estimator:

$$\langle \Phi_{FN} | \mathcal{O} | \Phi_{FN} \rangle \simeq 2 \langle \Psi_T | \mathcal{O} | \Phi_{FN} \rangle - \langle \Psi_T | \mathcal{O} | \Psi_T \rangle. \quad (18)$$

The mixed estimator can be written as follows:

$$\frac{\int \Psi_T^*(\mathbf{R}, P) \mathcal{O} \Phi_{FN}(\mathbf{R}, P) d\mathbf{R}}{\int \Psi_T^*(\mathbf{R}) \Phi_{FN}(\mathbf{R}) d\mathbf{R}}. \quad (19)$$

The final probability distribution of a diffusion Monte Carlo calculation is

$$\frac{\Psi_T^*(\mathbf{R}, P) \Phi_{FN}(\mathbf{R})}{\int \Psi_T^*(\mathbf{R}) \Phi_{FN}(\mathbf{R}) d\mathbf{R}}. \quad (20)$$

Performing some algebra, one can then obtain that

$$\langle \Psi_T | \mathcal{O} | \Phi_{FN} \rangle = \left\langle \frac{\mathcal{O} \Psi_T(\mathbf{R})}{\Psi_T(\mathbf{R})} \right\rangle_{\Phi_{FN} \Psi_T}. \quad (21)$$

Therefore, any static quantity can be calculated from the set of diffusion Monte Carlo walkers simply by calculating the operation of the quantum operator on the trial function and averaging over configurations.

It is a common practice to use an excited Slater determinant as a trial function to access excited states. If an appropriate symmetry can be identified that separates the ground and excited state, then this procedure results in a rigorous upper bound to the excited state energy [3]. Even in the cases where this does not occur, this method has been shown to obtain accurate estimates of the first excited state energies of solids and molecules [4, 5].

Implementations

There are a number of open-source or free-to-use packages that implement quantum Monte Carlo algorithms. Notable implementations are CASINO, QMCPACK, and QWalk, each of which has a user community.

Notable Applications

The applications listed here are chosen to give a sample of what these methods can be used to do. It is not exhaustive.

Homogeneous Electron Gas

One of the first applications of the diffusion Monte Carlo method was to compute the ground state energy of the interacting homogeneous electron gas as a function of density [2]. Because the sign problem in this system is relatively small, it was possible to obtain very accurate energies. These energies form the basis of all modern density functional theories.

High Accuracy Thermodynamics

When calculating thermodynamical quantities, one must evaluate the energy differences between different nuclear configurations. Typically these quantities are dominated by the change in internal energy, which is calculated by electronic structure methods. However, the error in these methods from the true ground state is often much larger than the change in internal energy. The methods rely on cancelation of errors, that is, that the error in the ground state of the atomic systems is approximately the same as the error in the condensed system. The projector methods, such as diffusion Monte Carlo, often obtain the lowest variational energies attainable for large systems. There is thus less error to cancel, and accuracy is much higher.

Strongly Correlated Systems

The Monte Carlo methods also occupy a unique niche which is ideal for strongly correlated condensed matter systems. They explicitly simulate the electron interactions, which can qualitatively change the physics in these materials and can treat periodic models of materials.

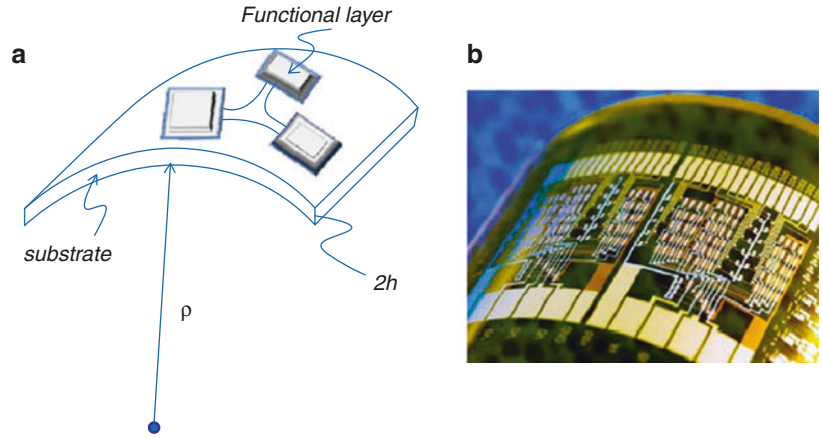
Definition of Flexible Electronics

Traditional electronics like integrated circuits or solar cells are generally built on thick inflexible substrates. Instead, flexible electronics – built on substrates like plastic or metallic foil – can be folded, wrapped, rolled, and twisted with negligible effect on its electronic function. Flexible electronics is typically composed of a bilayer of thin passive substrate (e.g., plastic, textile, etc.) topped with a second layer of active electronic components. In some applications, additional layers may be used for encapsulation and packaging. If the substrate is both flexible and stretchable for better conformal fit to highly curved surfaces, the system belongs to the broader class of "stretchable electronics" (Fig. 1). When flexible substrate is made of woven fibers like silk, some use a more descriptive term of "textile electronics" [1]. And finally, if both the electronics and substrate are made of optically transparent material – such as graphene or network of carbon nanotubes [2] on glass – it may be referred to as "transparent electronics" (Fig. 1).

History

Although the cables and connectors – thin metallic wires coated by plastic insulation – have always been flexible, it took the emergence of conductive polymers (doped organic



semiconductors) and development of doped α-Si in the 1970s for applications in photocopier, solar cells, and displays to pave the way for flexible electronics. The 1990s saw several demonstrations of the flexible electronics and optoelectronic components and systems based on various types of organic polymers. Bell Labs demonstrated fully functional flexible ICs with several thousand TFTs, and researchers at Kodak, Cavendish Laboratory, and UCSB prototyped flexible organic photovoltaics (OPVs) and organic light emitting diodes (OLEDs) on a plastic substrate. Since 2000, broad/innovative use of soft-lithography and transfer printing – originally developed in the eighteenth century to transfer images engraved in Cu plates via special paper to nonplanar porcelain substrates – has broaden the range of materials suitable for the flexible electronics. Today, transfer printing [3] can be used to create flexible electronic components based on almost any material with potentials applications like low-cost electronic readers, RF identification tags, sensors for structural integrity, etc. Bright, multicolored, flexible OLED displays from Sony and Samsung are approaching commercial viability and several companies are exploring the more difficult price/performance trade-off of OPVs. Cell phones provide a particularly interesting platform and offer many opportunities such as hinged displays and sliding keyboards. Additional applications to continuously monitor the vital signs of a patient as a part of implantable, biocompatible, and organ-conformal flexible electronics have been envisioned, but not fully realized yet.

Flexible Electronics, Fig. 1 *Landscape* of electronics showing classical, transparent, and stretchable regimes. Flexible electronics is subset of the stretchable electronics, and textile electronics is subset of the flexible electronics

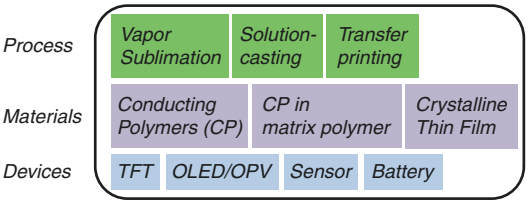
Mechanical Properties of Flexible Electronics

Flexible electronics relies on the basic premise that a substrate of thickness $2\ h$ can be bent with the radius of curvature ρ, so long the strain, $\varepsilon = \frac{h}{\rho}$, developed does not exceed the yield strain εc of the film (Fig. 2a). Actually, the physics is no different from that of three-layered composite bows used in Roman and Tartar wars that could be repeatedly stretched thousands of times without loss of function [4]. Indeed, this is why one can fold a 100 μm thick paper or plastic substrate (with elastic yield strength of 0.1 %) around a cylinder with $\rho = 10$ cm with no detrimental

Flexible Electronics, Fig. 2 (**a**) Schematic of a flexible substrate with integrated functional layer. $2\ h$ is the substrate thickness and ρ is the radius of curvature; (**b**) CNT thin-film-transistors-based circuitry printed on a flexible substrate [2]

effects [5]. Typical substrates for flexible electronics include polymers, thin foils of metal, fabrics, and even paper. In addition to flexibility, such substrates should be relatively inexpensive [6], mechanically robust (with reasonably high melting temperature, T_g) and resistant to creep, free from structural defects like pits and pinholes, thermally conductive, but electrically passive. Polymer substrates such as Kaptonz polymide, Polytetraflouroethylene (PTFE), Polyethylene terephthalate (PET), and Polyethylene naphthalate (PEN) have been used for various applications.

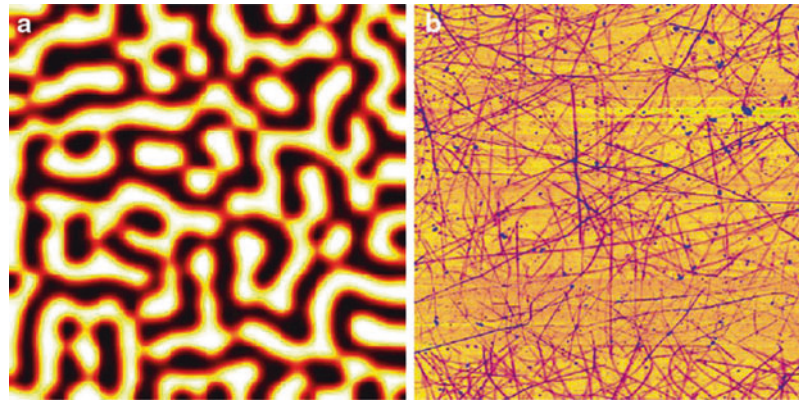
Once a thin flexible substrate with adequate structural integrity has been identified, a second layer of electronics is bonded or deposited to the substrate (Fig. 2b). Flexibility is unaffected because the active layer is only several μm thick. Delamination can be avoided if the intra-layer bonding strength γ is sufficiently strong so that the strain (ε) developed due to flexing remains below the critical strain εc of the bilayer, i.e.,



$$\varepsilon < \varepsilon = \varepsilon_p + \sqrt{2\frac{\gamma}{2L}}$$

Here, ε_P is the Poisson buckling ratio [4] and L is the linear dimension of the substrate. For a reasonable bonding strength of the substrate and electronic layers, the device may deform 20–30 times the yield strength without delamination.

Active Layer of Flexible Electronics



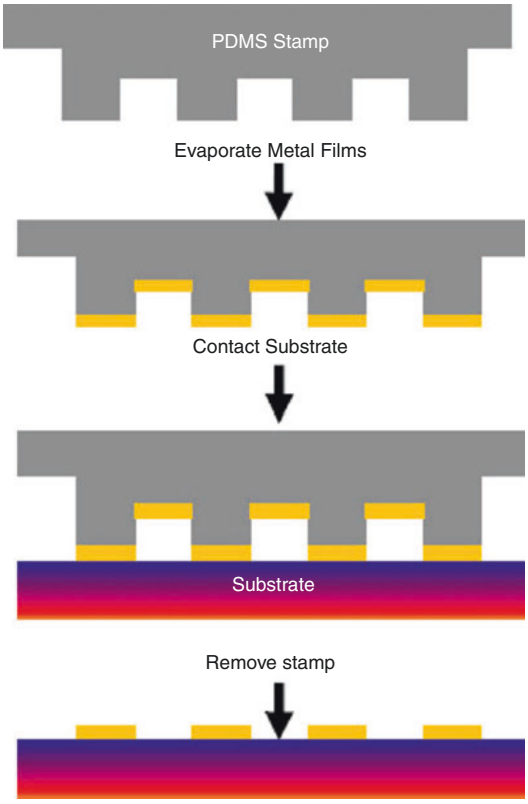
Materials and Devices in the Active Layer

The functional layer of flexible electronics may be composed of electronic and optoelectronic components like TFTs [7, 8], OPVs [9], OLEDs, batteries, sensors, etc. (Fig. 3). The simplest TFTs use active, single-carrier (hole) transport layer (i.e., p-type or acceptor) along with metal contacts and necessary interconnects. Various long-chain polymers like poly(methylmethacrylate) (PMMA), poly p-phenylene vinylene (PPV), polyaniline (PANI), poly

Flexible Electronics, Fig. 3 Processing techniques, materials, and device applications of flexible electronics

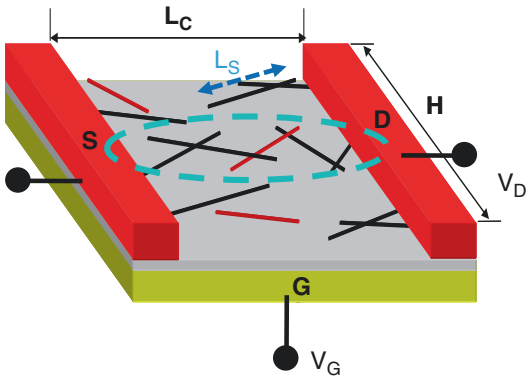
(3,4-ethylenedioxythiophene) (PEDOT), poly 3-hexylthiophene (P3HT), as well as smaller organic molecules like pentacene, rubrene, tetracene have been used for TFT applications [7, 8, 10, 11]. The organic solar cells for photovoltaic applications (OPV) are based on blended mixture of p-type and n-type polymers [9, 12], capped by transparent and reflecting electrodes (Fig. 4a). In addition to the p-type polymers discussed above, n-type (donor) polymer used in OPV applications [13] include various fullerene derivatives like (phenyl-[6, 6]-C61)-butyric acid methyl ester (PCBM). In OLEDs, donor and acceptor layers are stacked to create a p-n heterojunction diode. In many OLED applications, Aluminum tris [8-hydrooxquinoline] (Alq3) acts both as electron transport as well as light emission layer. In addition to organic polymers as discussed above, TFT, LED, and PV components of arbitrary complexity (and performance at par with single crystalline counterparts) can also be created by stacks of thin crystalline films by transfer-printing method (see below). Recently, batteries and chemical/biological sensors have been adapted to the flexible substrate. Finally, Au, Ag, and ITO are used to interconnect these active components of the functional layer. ITO films have high electrical conductivity and high optical transparency which make them a good candidate for the transparent electronic applications, but their stiffness and brittleness pose challenge for the flexible electronics. Flexible or stretchable interconnects such as conducting polymers, micro-fabricated thin films, CNT-ionic liquid gels have been explored to maintain the flexibility of the electronics [8, 14].

Flexible Electronics, Fig. 4 (**a**) Blended mixture of polymers [9, 12] (**b**) Network of carbon nanotubes as a channel region of flexible transistors using spin-casting method [13]



Fabrication of Active Layer

The key challenge in flexible electronics is that the deposition techniques for the functional layer must be compatible with the flexible substrate with low *Tg* and that the weakly bonded "van der Waal" polymers with interatomic forces decays as $\frac{1}{R^6}$ (in contrast, covalent bonding decays as inverse of square radius, i.e., $\frac{1}{R^{62}}$). These deposition techniques can be broadly classified as vapor-phase sublimation, solution casting, or solid state transfer printing (or a combination thereof). The vapor-phase sublimation (VPS) technique can deposit thin films of desired material onto the flexible substrate by thermal sublimation of a nearby (∼few cm apart) solid source. Films of arbitrary complexity can be created by changing the solid source, and intermixing of the layers can be avoided because solid diffusion is strongly suppressed at low temperature. Despite the challenges of uniformity over large areas, VPS has been used for creating large area displays. In the second approach, which is based on the solution casting, the conducting polymers (CPs) [15] are dissolved into a carrier solvent (with appropriate viscosity, surface tension, and anneal temperature) and deposited/cured onto the flexible substrate. Direct deposition of CP onto the flexible substrate (without the carrier solvent) leads to islanding and unacceptable morphology. Variants of solution processing techniques [16] include screen printing, ink-jet printing [17], spin casting, etc. Screen printing technique uses a stencil method where printable materials are first transferred to open areas of a woven mesh or screen and then printable materials are squeezed or rolled to cover the open areas leaving a desired imprint on the substrate [16]. Ink-jet printing creates desired patterns on the substrate by propelling ink droplets of different sizes, while spin casting uses centrifugal force to spin the printing material on the substrate (Fig. 4b).



Finally, the solid *transfer-printing* method enormously broadens the range of materials available for flexible electronics [5, 9]. In this technique, high-quality materials are first grown on a temporary donor substrate (Fig. 5). A silicone rubber stamp containing a replica of the desired circuit is first inked by pressing hard and then quickly lifted from the substrate. The inked pad is then softly pressed against the flexible substrate and pulled-away slowly to let the ink stay at the final substrate [3]. All sorts of materials like crystalline Si, CNT, GaAs, etc., have been transferred. Indeed, multiple transfer printing can create substrate of unprecedented complexity.

Electrical Transport of Active Layer

The active layer can be composed of (1) electrically conducting polymer (CP), (2) insulating polymers loaded with conducting fillers, and/or (3) thin films or ribbons of crystalline materials. Advances to the theoretical understanding of these soft materials have been central to the development of flexible electronics [10, 11]. The linear backbone of CP alternates between single and double C-C bonds. The sp^2 hybridization of these C–C bonds produces (1) covalent and localized σ bonds for mechanical stability and (2) out-of-plane,

Flexible Electronics, Fig. 5 Steps of the solid transfer-printing technique [3]

Flexible Electronics, Fig. 6 Schematic of a CNT network transistor. Network of semiconducting (*black*) and metallic (*red*) tubes connecting source (*S*) and drain (*D*) electrodes of the transistor. A percolating pathway of CNTs is indicated by *dashed ellipsoid* region. Channel length (*LC*), tube length (*LS*), device width (*H*), gate voltage (*VG*), and drain voltages (*VD*) are indicated

delocalized, *pz* orbital for electrical conduction (bandwidth 1–3 eV). For long-range conduction, the electrons hop among adjacent chain via weakly coupled *pz* states (0.1 eV). Electrons in these 1D, low-dielectric constant CP interacts strongly with each other and they distort the floppy lattice as they move from site to site, therefore excitonic and polaronic effects are important. In general, the transport in the crystalline organic films could be mapped back to theory of crystalline materials with appropriate redefinition of density of states (DOS), mobility, etc., while transport in amorphous organic molecules – much like α-Si – is often described by "Gaussian disorder model" as electrons hop from one molecule to other in a landscape defined by Gaussian DOS [10].

In many applications such as spin-cast TFTs (Fig. 4b), it is easier to dope a nonconducting polymer matrix (NPM) by conducting fillers (CFs) such as carbon nanotubes (CNT) or other metallic particles. These NPM/CNT network [13, 18] conducts by percolation or hopping at amazingly small fill fraction (<0.2). CFs dictates the electrical performance, while NPM controls the solution properties for ease of printing. Specifically, for the electrical transport, the areal tube-density (*D*) must exceed the percolation threshold (D_c) so that $D > D_c = \frac{4.26^2}{\pi L_s^2}$, where *Ls* is the average length of the conducting polymer or CNTs (Fig. 6). The nonlinear multielectrode percolation theory for TFTs with CNTs or CNT-doped polymers [19] is now well developed and can be succinctly summed as

$$I_D = g\left(\frac{L_c}{L_S}, D_C L_S^2\right) \times f(V_D, V_G)$$

where *ID* is the drain current for a TFT, *VD* and *VG* are drain and gates voltages, and *LC* is the channel length and *LS* is the length of CNTs. The geometric function $g \equiv \left(\frac{L_s}{L_C}\right)^{3\left(DL_S^2\right)}$ and the voltage-dependent function $f \propto C_{ox}[(V_G - V_D)V_T - V_D^2/2]$ are given by classical long-channel TFT formula. Many of the surprises in transport through such system (e.g., (channel) length-dependent mobility!) can be attributed to non-ohmic conduction at percolation threshold.

F

For applications in organic solar cells, both n and p-type organic molecules are co-blended in a solvent and demixed by annealing (through spinodal decomposition) to produce interpenetrating donor/acceptor network [20]. The interface field at the donor/acceptor boundary dissociates the excitons before they are lost to self recombination and the percolating network shepherd electron/hole to their respective contacts. Indeed, if conductive fillers is now added so that it is miscible in n-type polymers, but not in p-type polymers, then double percolation allows further reduction in percolation threshold with a better control of overall morphology. Such double-percolating films based on poly (3octylthiophene) and ethylene-co-vinyl acetate blend has been used for TFT application and is known to percolate at <0.1 fill factors!

The third and final option for active layer involves ribbons of thin crystalline films released from the substrate by chemical etching and then grafting these films onto the flexible substrate by transfer-printing method. Theories of bulk transport apply, however, the roles of surface states and defects associated with the release process are not yet fully understood.

In addition to material used for active transport, flexible electronics demand interconnects either be vapor deposited (Au, Ag, ITO) or ink-jet printed (e.g., Ag ink) at relatively low temperature, subsequently patterned by soft-lithography or benign etching. The transport properties of such thin polycrystalline film have been investigated by many groups, although the reliability of such films under repeating flexing remains to be seen.

Conclusions

Like any other novel technology, the commercial viability of flexible electronics is hard to assess. Mechanical reliability associated with crack formation during repeated flexing, ingress of moisture, etc., and electrical reliability issues related to polymer degradation, continued phase segregation, surface passivation, contact diffusion, and low efficiency are important challenges. Many advances in integrated full color OLED displays from SONY and Samsung suggest that these technical challenges are not impossible to address, the question remains however if they can be addressed economically.

Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD)

Shinji Matsui
Laboratory of Advanced Science and Technology for Industry, University of Hyogo, Hyogo, Japan

Synonyms

Focused-ion-beam-induced deposition (FIB-ID)

Definition

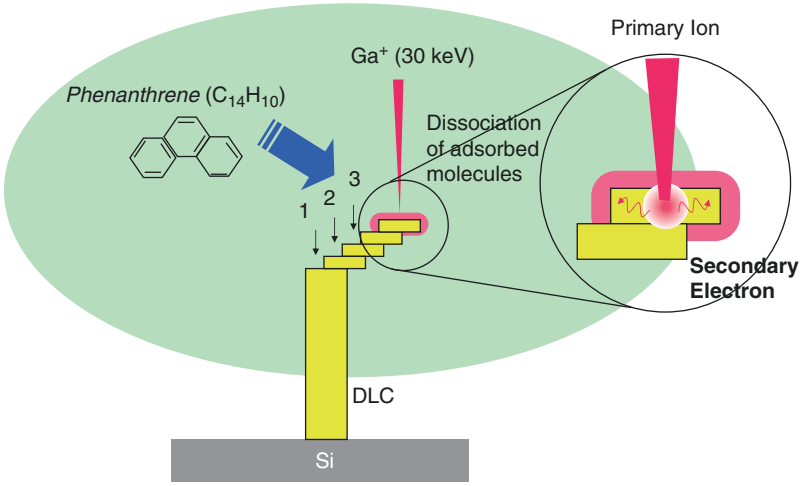
Focused ion beam (FIB) can be used as a deposition tool for fabricating nanostructures. FIB chemical vapor deposition (FIB-CVD) uses ion energy to initiate and localize chemical vapor deposition (CVD) in a specific location by a direct-writing technique. When a local gas ambient is produced near a surface, the impact of energetic ions on that surface can induce chemical reaction. The ion-induced chemistry occurs in an adsorbed layer than in the gas above the surface.

FIB-CVD Process

In 1979, Seliger et al. reported Ga ion beams down to 100-nm diameter with current density in the focal spot of 1.5 A/cm^2 [1]. In 1990, Wargner et al. demonstrated pillars and walls with high aspect ratios achieved using FIB-CVD [2]. In 2000, Matsui et al. demonstrated three-dimensional (3-D) nanostructure fabrication by FIB-CVD [3].

Matsui et al. used two commercially available FIB systems (SMI9200, SMI2050, SII NanoTechnology Inc., Tokyo, Japan) with a Ga^+ ion beam operating at 30 keV. The FIB-CVD used a precursor of *phenanthrene* ($C_{14}H_{10}$) as the source material. The beam diameter of SMI9200 was about 7 nm and that of SMI2050 was about 5 nm. The systems were equipped with the gas nozzles. The nozzles were set a distance of 40 μm from each other and positioned about 300 μm above the substrate surface. The inside diameter of a nozzle was 0.3 mm. The *phenanthrene* gas pressure during pillar growth was typically 5×10^{-5} Pa in the specimen chamber, but the local gas pressure at the beam point was expected to be much higher. The crucible of the source was heated to 85 °C. The FIB is scanned in order to be able to write the desired pattern via computer control, and the ion dose is adjusted to deposit a film of the desired thickness. The experiments were carried out at room temperature on a silicon substrate.

The deposited film was characterized by observing it with a transmission electron microscope (TEM). A thin film of carbon (200 nm thick) was deposited on a silicon substrate by 30 keV Ga^+ FIB using *phenanthrene* precursor gas. The cross sections of the structures created and its electron diffraction patterns were observed by using a 300 kV TEM. There were no crystal structures in the TEM images and diffraction patterns. It was therefore concluded that the deposited film was amorphous carbon (a-C).



Raman spectra of the a-C films were measured at room temperature with 514.5-nm line of an argon ion laser. A relatively sharp Raman band at 1,550 cm^{-1} and a broad-shouldered band at around 1,400 cm^{-1} were observed in the spectra excited by the 514.5-nm line. Two Raman bands were plotted after Gaussian line shape analysis. These Raman bands, located at 1,550 cm^{-1} and 1,400 cm^{-1}, originate from the trigonal (sp^2) bonding structure of graphite and tetrahedral (sp^3) bonding structure of diamond. This result suggests that the a-C film deposited by FIB-CVD is a diamond-like amorphous carbon, which has attracted attention due to its hardness, chemical inertness, and optical transparency.

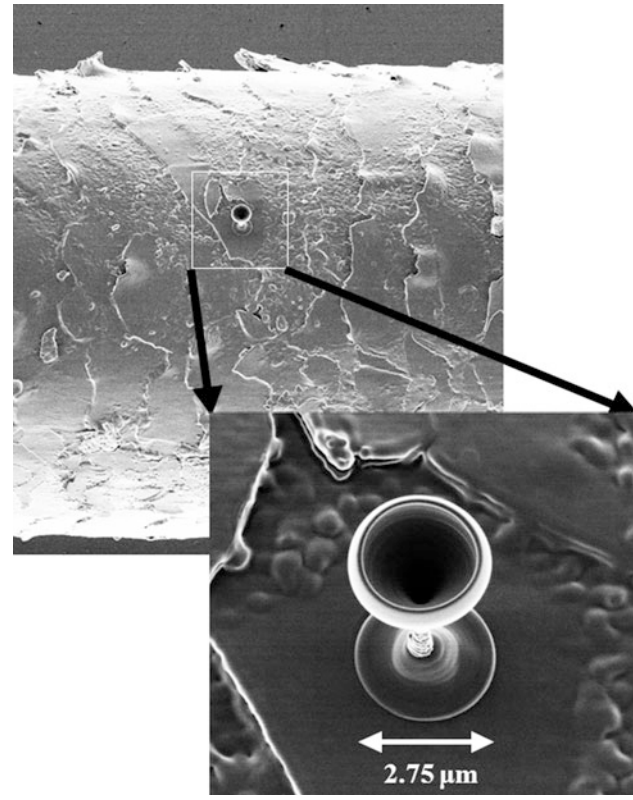
The coordination of carbon atoms in the carbon-based material formed by CVD deposition of *phenanthrene* assisted by Ga FIB was investigated by the measurement of near-edge X-ray absorption fine-structure spectra of the carbon *K*-edge over the excitation energy range 275–320 eV [4]. Novel peak observed at 289.0 eV was assigned to the 1 s → σ* transition of carbon neighboring to the residue gallium. The material formed by this method was found to be Ga-doped diamond-like carbon (DLC) that consists of a high sp^3-hybridized carbon.

The atomic fraction of the FIB-CVD DLC film has been determined as C: Ga: H = 87.4 at.%: 3.6 at.%: 9.0 at.% using Rutherford backscattering spectrometry (RBS) and elastic recoil detection analysis (ERDA) [5]. Hydrogen content of FIB-CVD DLC film was relatively lower than that of DLC films formed by other CVD methods.

Three-Dimensional Nanostructure Fabrication

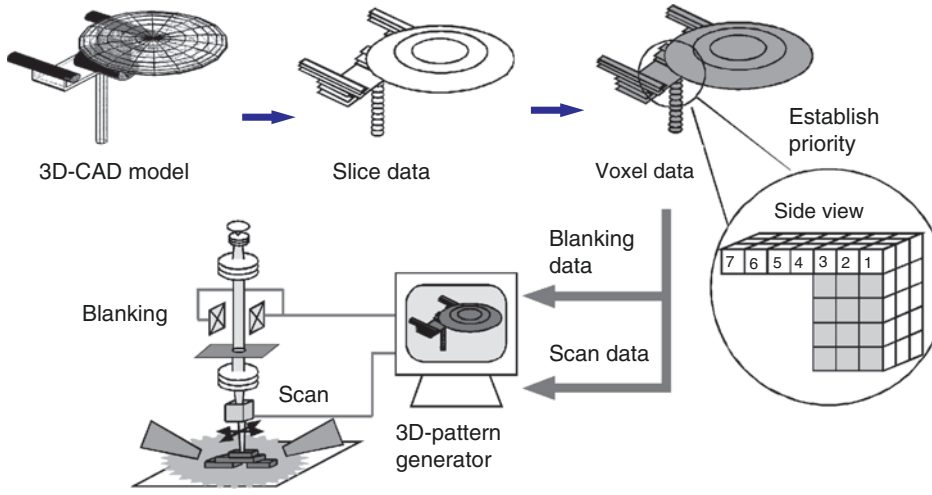
Beam-induced CVD is widely used in the electrical device industry in repair of chips and masks. This type of deposition is mainly done on two-dimensional (2-D) pattern features, but it can also be used to fabricate a three-dimensional (3-D) object. Koops et al. demonstrated a nanoscale 3-D structure construction [6] by applying electron-beam-induced amorphous carbon deposition to a micro-vacuum tube. However, FIB-CVD seems to have many advantages for the fabrication of 3-D nanostructures [3]. The key issue to realizing such 3-D nanostructures is the short penetration depth of the ions (a few tens of nm) into the target material, where the penetration depth of the ions is much shorter than that of

Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 1 Fabrication process for 3-D nanostructure by FIB-CVD



electrons (several microns). This short penetration depth reduces the dispersion area of the secondary electrons with a few eV induced by ion-beam irradiation to the molecules adsorbed on a substrate, and so the deposition area is restricted to roughly several tens nanometers.

The process of fabricating 3-D structures by FIB-CVD is illustrated in Fig. 1 [3]. In FIB-CVD processes, the beam is scanned in digital mode. First, a pillar is formed on the substrate by fixing the beam position (position 1). After that, the beam position is moved to within a diameter of the pillar (position 2) and then fixed until the deposited terrace thickness exceeds the range of the ions (a few tens nm). This process is repeated to make 3-D structures. The key point to making 3-D structures is to adjust the beam scan speed so that the ion beam remains within the deposited terrace, which means that the terrace thickness always exceeds the range of the ions. The growth in the x- and y-directions is controlled by both beam deflectors. The growth in the z-direction is determined by the deposition rate; that is, the height of structure is proportional to an irradiation time when a deposition rate is constant.



To demonstrate the possibilities of a new field called microstructure plastic arts using FIB-CVD, a "micro-wineglass" was created on a human hair as a work of microstructure plastic arts as shown in a scanting ion microscope (SIM) of Fig. 2. A micro-wineglass with an external diameter of 2.75 μm and a height of 12 μm was formed. The fabrication time was 600 s at a beam current of 16 pA. This beautiful micro-wineglass shows the potential of the field of microstructure plastic art.

The 3-D structure is built up as a multilayer structure. In the first step of this 3-D pattern-generating system, a 3-D model of the structure, designed using a 3-D CAD system (3-D DXF format), is needed. The 3-D CAD model, which is a surface model, is cut into several slices, as shown in Fig. 3. The thickness of the slices depends upon the resolution in the *z*-direction (the vertical direction). The x- and y-coordinates of the slices are then used to create the scan data (voxel data). To fabricate the overhanging structure, the ion beam must irradiate the correct positions in the correct order. If the ion beam irradiates a voxel located in midair without a support layer, the ions intended for the voxel will be deposited on the substrate. Therefore, the sequence of irradiation is determined, as shown in Fig. 3. The scan data and blanking signal therefore include the scan sequence, the dwell time, the interval time, and the irradiation pitch. These parameters are calculated from the beam diameter, x-y resolution, and z resolution of fabrication. The z resolution is proportional to the dwell time and inversely proportional to the square of the irradiation pitch. The scan data are passed to the beam deflector of the FIB-CVD as are the blanking data. The blanking signal controls the dwell time and interval time of the ion beam.

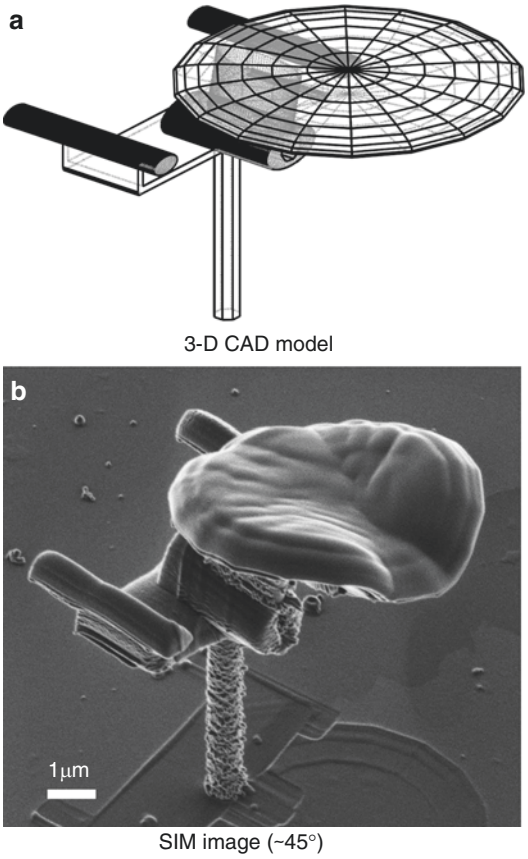


Figure 4 shows a 3-D CAD model and a SIM image of the starship Enterprise NCC-1701D (from the television series *Star Trek*) which was

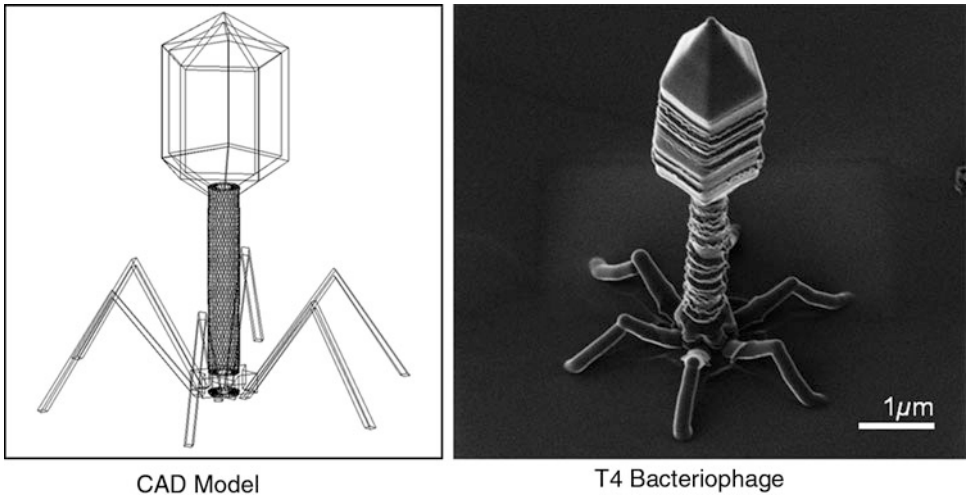
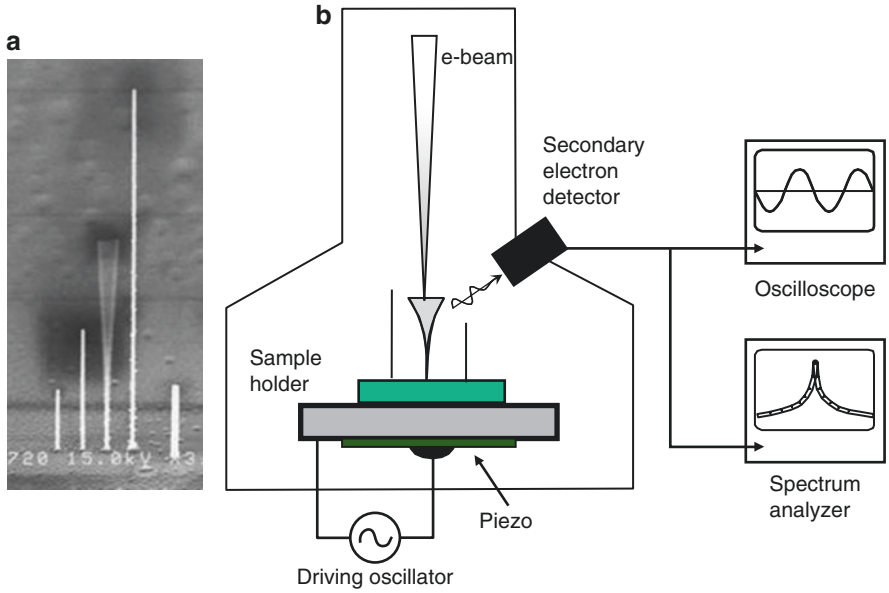
Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 4 "Micro Starship Enterprise NCC-1701D," 8.8 μm long



fabricated by FIB-CVD at 10 ~ 20 pA [7]. The nanospaceship is 8.8 μm long and was realized at about a 1:100 000 000 scale on silicon substrate. The dwell time (t_d), interval time (t_i), irradiation pitch (p), and total process time (t_p) were 80 μs, 150 μs, 2.4 nm, and 2.5 h, respectively. The horizontal overhang structure was fabricated successfully.

Figure 5 shows a 3-D CAD model and a SIM image of the "nano T4 bacteriophage," which is an artificial version of the virus fabricated by FIB-CVD on silicon surface. The size of the artificial nano "T4 bacteriophage" is about ten times as that of the real virus.



Characteristics of Materials Formed by FIB-CVD

Young's Modulus

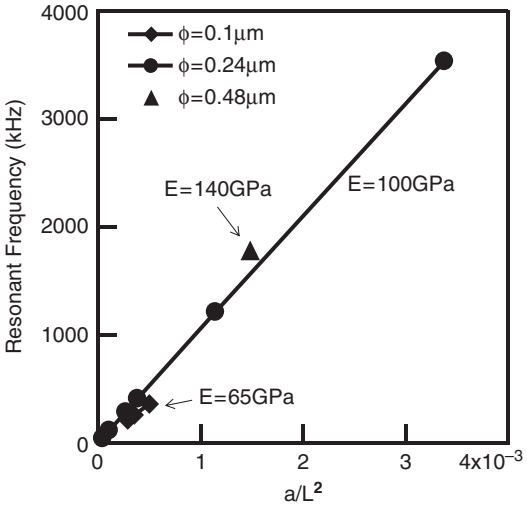
An evaluation of the mechanical characteristics of such nanostructures is needed for material physics. Buks and Loukes reported a simple but useful technique [8] for measuring the resonant frequencies of nanoscale objects using a SEM. The secondary-electron detector in the SEM can detect frequencies up to around 4 MHz, so the sample vibration is measured as the oscillatory output signal of the detector. Buks and Loukes used this

Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 5 T-4 bacteriophage fabricated by FIB-CVD

Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 6 (**a**) SEM image of the vibration. The resonant frequency was 1.21 MHz. (**b**) Schematic diagram of the vibration monitoring system

technique to evaluate the Casimir attractive force between the two parallel beams fabricated on a nanoscale. We evaluated the mechanical characteristics of DLC pillars in terms of the Young's modulus, determined using resonant vibration and the SEM monitoring technique [9, 10].

The system setup for monitoring mechanical vibration is shown in Fig. 6b. The mechanical vibration was induced by a thin piezoelectric device, 300 μm thick and 3 mm square. The piezo device was bonded to the sidewall of the SEM's sample holder with silver paste. The sample holder was designed to observe cross sections in the SEM (S5000, Hitachi) system. Therefore, the pillar's vibration was observed as a side-view image, as shown in Fig. 6a. The range of vibration frequencies involved was 10 kHz up to 2 MHz, which is much faster than the SEM raster scanning speed. Thus the resonant vibrations of the pillars can be taken as the trace of the pillar's vibration in the SEM image. The resonant frequency and amplitude were controlled by adjusting the power of the driving oscillator.



Several pillars with various diameters and lengths were fabricated. The DLC pillars with the smallest diameter of 80 nm were grown using point irradiation. Larger-diameter pillars were fabricated using an area-limited raster scan mode. The typical SEM image taken during resonance is shown in Fig. 6a. The FIB-CVD pillars seemed very durable against the mechanical vibration. This kind of measurement usually requires at least 30 min, including a spectrum analysis and photorecording, but the pillars still survived without any change in resonance characteristics. This durability of the DLC pillars should be useful in nanomechanical applications.

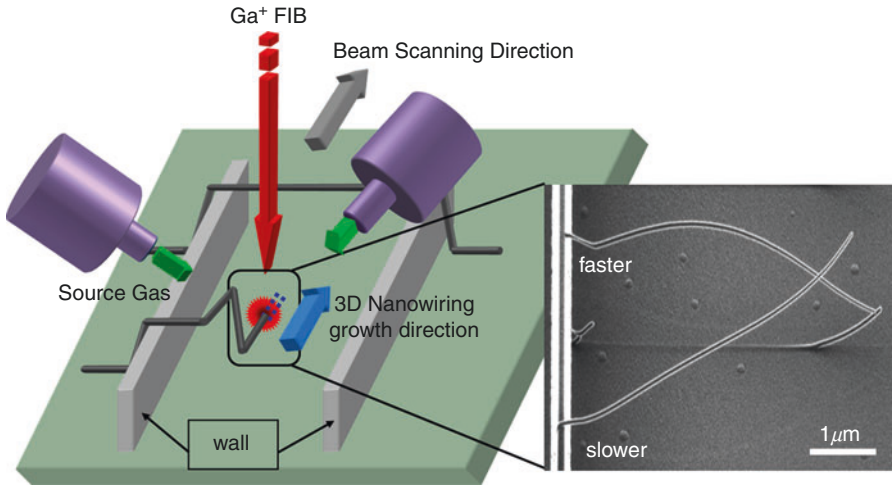
The resonant frequency f of the pillar is defined by Eq. 1 for a pillar with a square cross section and Eq. 2 for that with a circular cross section:

$$f_{\text{square}} = \frac{a\beta^2}{2\pi L^2}\sqrt{\frac{E}{12\rho}} \tag{1}$$

$$f_{\text{circular}} = \frac{a\beta^2}{2\pi L^2}\sqrt{\frac{E}{16\rho}} \tag{2}$$

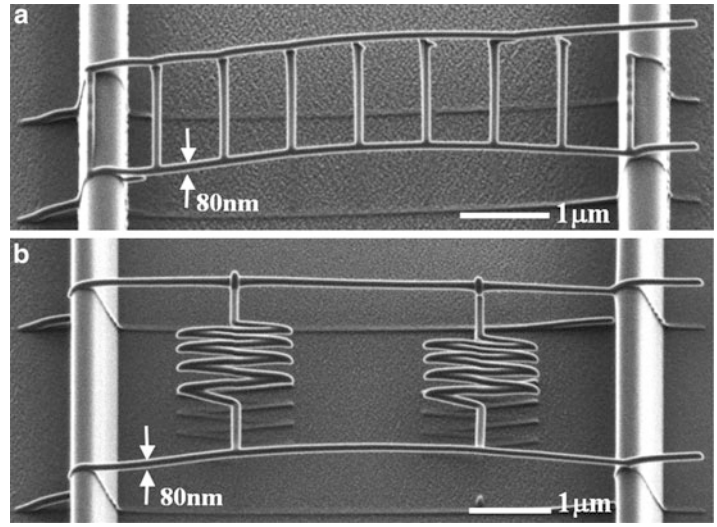
where a is the width of the square pillar and/or the diameter of the circular-shaped pillar, L is the length of the pillar, ρ is the density, and E is the Young's modulus. The coefficient β defines

Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 7 Dependence of resonant frequency on the pillar length



the resonant mode and the $\beta = 1.875$ for the fundamental mode. Equation 1 was used for pillars 240 nm wide and 480 nm wide, and Eq. 2 was used for pillars grown by point-beam irradiations. The relationship of the resonant frequency to the Young's modulus, which depends on the ratio of the pillar diameter to the squared length, is summarized in Fig. 7. All of the pillars evaluated in this figure were fabricated using the SMI9200 FIB system under rapid growth conditions. Typical growth rates were about 3 μm/min to 5 μm/min for the 100-nm diameter and 240-μm-wide pillars and 0.9 μm/min for the 480-nm-wide pillars. When calculating the line of Fig. 7, it was assumed that the density of the DLC pillars was about 2.3 g/cm^3, which is almost identical to that of graphite. The inclination of the line in Fig. 7 indicated the Young's modulus for each pillar. The Young's moduli of the pillars were distributed over a range from 65 GPa to 140 GPa, which is almost identical to that of normal metals. Wider pillars tended to have larger Young's moduli.

Electrical Resistivity

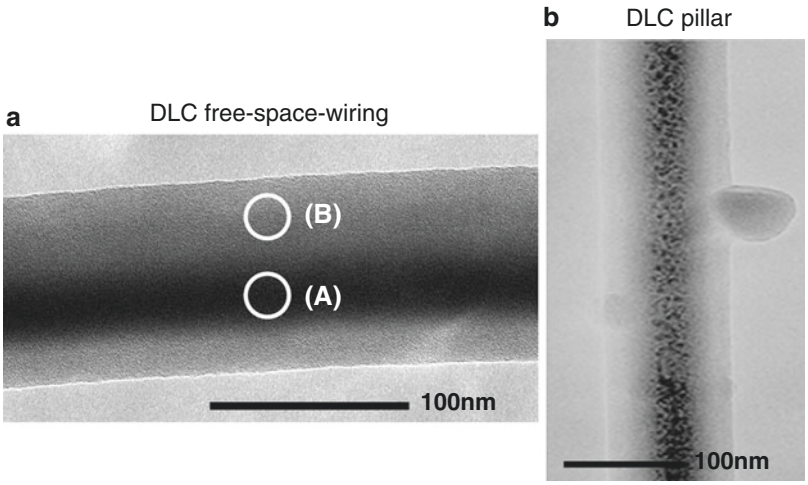


All experiments were carried out in the SMI9200 FIB system using a beam of 30 kV Ga^+ ions. The beam was focused to a spot size of 7 nm at a beam current of 0.4 pA, and it was incident perpendicular to the surface. The pattern drawing system (CPG-1000: Crestec Co., Tokyo, Japan) was added to the FIB apparatus to draw any patterns. Using the CPG, it is possible to control beam scan parameters such as scanning speed, x-y direction, and blanking of the beam, and so 3-D free-space nanowiring can be performed [11].

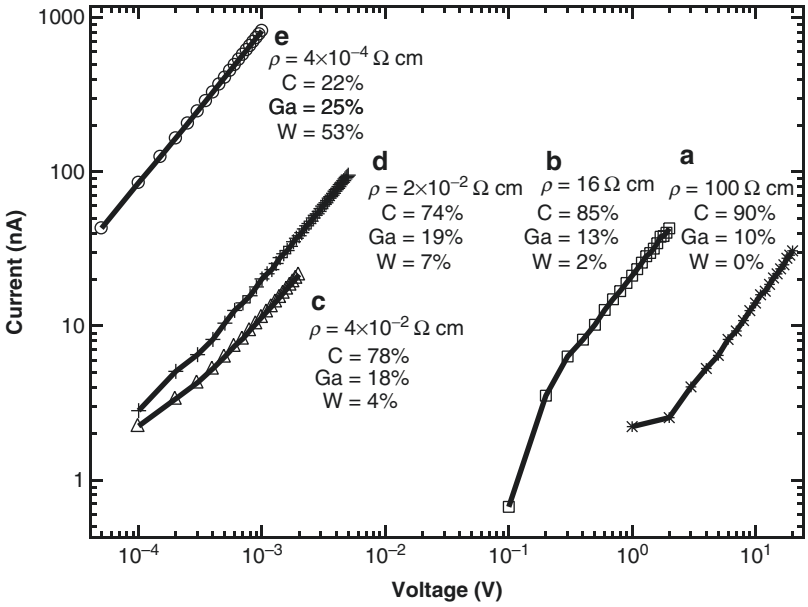
Figure 8 illustrates the free-space nanowiring fabrication process using both FIB-CVD and CPG. When *phenanthrene* ($C_{14}H_{10}$) gas or tungsten hexacarbonyl [$W(CO)_6$] gas, which is a reactive organic gas, is evaporated from a heated container and injected into the vacuum chamber by a nozzle located 300 μm above the sample surface at an angle of about 45° with respect to surface, the gas density of the $C_{14}H_{10}$ or $W(CO)_6$ molecules increases on a substrate near the gas nozzle. The nozzle system creates a local high-pressure region over the surface. The base pressure of the sample chamber is 2×10^{-5} Pa and the chamber pressures upon introducing $C_{14}H_{10}$ and $W(CO)_6$ as a source gas were 1×10^{-4} and 1.5×10^{-3} Pa, respectively. When a Ga^+ ion beam is irradiated onto the substrate, $C_{14}H_{10}$ or $W(CO)_6$ molecules adsorbed on the substrate surface are decomposed, and carbon (C) is mainly deposited onto the surface of the substrate. The direction of deposition growth can be controlling through the scanning direction of the beam.

After the two walls were formed in Fig. 8, free-space nanowiring was performed by adjusting the beam scanning speed. The x- and y-scanning directions and the beam scanning speed were controlled by the CPG. The height in the z-direction was proportional to the irradiation time. Deposition is made to occur horizontally by scanning the beam at a certain fixed speed in the direction of a plane. However, when the beam scanning speed is faster than the nanowiring growth speed, it grows downward or drops, and conversely when the scanning speed is too slow, the deposition grows slanting upward. Therefore, it is very important to carefully control the beam scanning speed when growing a nanowire horizontally. It turns out that the optimal beam scanning speed to realize a nanowire growing horizontally, using two $C_{14}H_{10}$ gas guns, is about 190 nm/s. The expected pattern resolution archived using FIB-CVD is

Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 8 Fabrication of DLC free-space wiring using both FIB-CVD and CPG



Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 9 (**a**) DLC free-space wiring with a bridge shape. (**b**) DLC free-space wiring with parallel resistances



around 80 nm, because both the primary Ga^+ ion and secondary-electron scattering occur over distances around 20 nm [9, 12].

Figure 9 shows examples of free-space nanowirings fabricated by FIB-CVD and CP-G. All of the structures shown were fabricated using $C_{14}H_{10}$ gas as a precursor gas. Figure 9a shows nanobridge free-space wirings. The growth time was 1.8 min and the wiring width was 80 nm. Figure 9b shows free-space nanowires with parallel resistances. The growth time was 2.8 min, and the wiring width was also 80 nm. From these structures, it is possible to fabricate nanowiring at an arbitrary position using FIB-CVD and CPG.

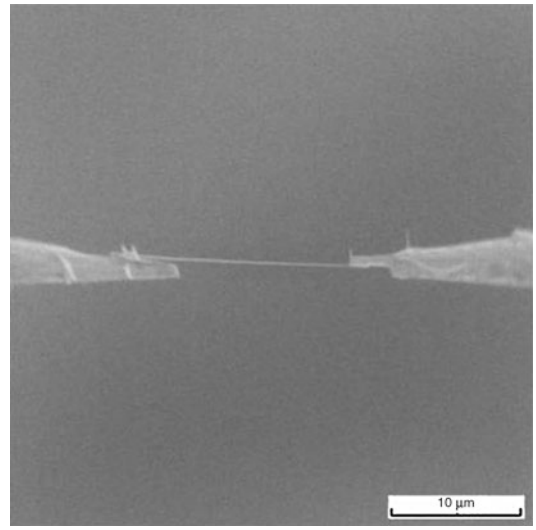
The free-space wiring structures were observed using 200 keV TEM. The analyzed area was 20 nmΦ. Figure 10a and b shows TEM images of DLC free-space wiring and a pillar, respectively. It became clear from these EDX (energy-dispersive X-ray spectroscopy) measurements that the dark part (A) of Fig. 10a corresponds to the Ga core, and the outside part (B) of Fig. 10a corresponds to amorphous carbon. This free-space wiring therefore consists of

Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 10 TEM images of (**a**) DLC free-space wiring and (**b**) DLC pillar

Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 11 Electrical resistivity measurement for nanowiring. Electrical resistivity ρ was calculated by I–V curve. Elemental contents C, Ga, W were measured by SEM-EDX

amorphous carbon with a Ga core. The center position of the Ga core is actually located below the center of the wiring. However, in the case of the DLC pillar, the Ga core is located at the center of the pillar. To investigate the difference between these core positions, the Ga core distribution in free-space wiring was observed in detail by TEM. The center position of the Ga core was about 70 nm from the top, which was 20 nm below the center of the free-space wiring. An ion range of 30 kV Ga ions into amorphous carbon was calculated using TRIM (transport of ions in matter), which was 20 nm. The calculation indicates that the displacement of the center of the Ga core in the nanowiring corresponds to the ion range.

The electrical properties of free-space nanowiring fabricated by FIB-CVD using a mixture of $C_{14}H_{10}$ and $W(CO)_6$ were measured [11]. Nanowirings were fabricated on an Au electrode. These Au electrodes were formed on a 0.2-μm-thick SiO_2 on Si substrate by an EB lithography and lift-off process. Two-terminal electrode method was used to measure the electrical resistivity of the nanowiring. Figure 11a shows

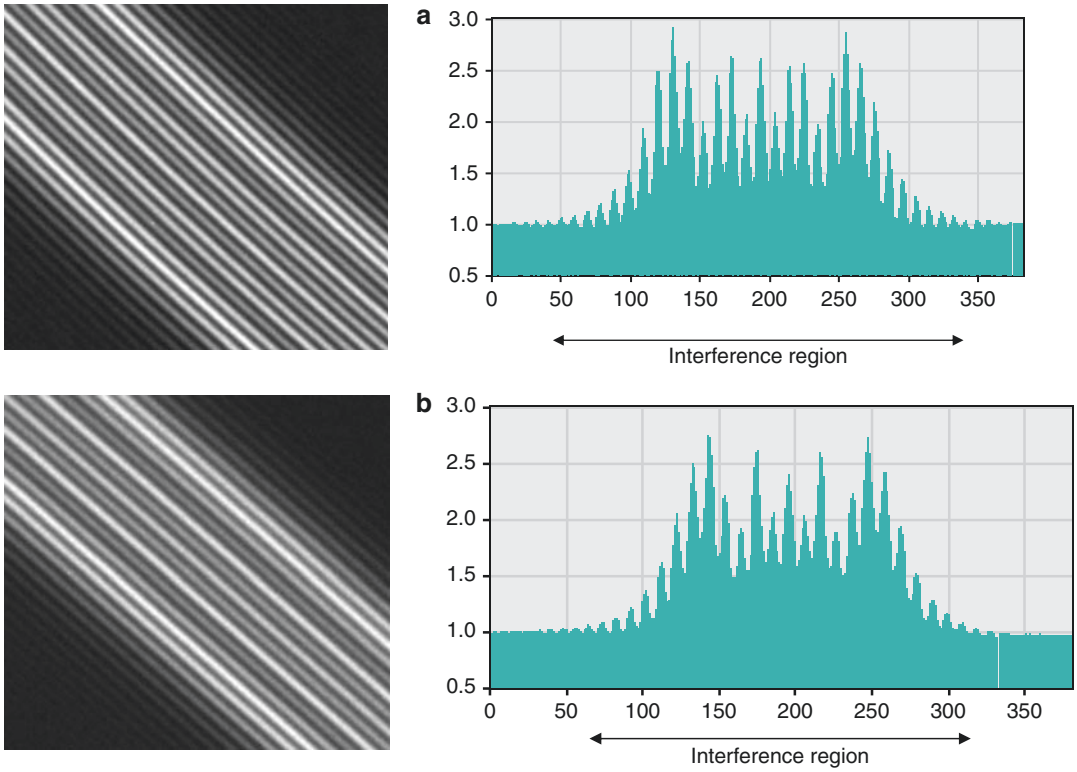


the nanowiring fabricated using only $C_{14}H_{10}$ source gas. The growth time here was 65 s and the wiring width was 100 nm. Next, $W(CO)_6$ gas was added to $C_{14}H_{10}$ gas in order to obtain a lower electrical resistivity. Figure 11b, c, and d corresponds to increasing $W(CO)_6$ contents in the gas mixture. The $W(CO)_6$ content rate was controlled by the sublimation temperature of $C_{14}H_{10}$ gas. As the $W(CO)_6$ content was increased, the nanowiring growth time and width become longer: (b) was 195 s and 120 nm, (c) was 237 s and 130 nm, and (d) was 296 s and 140 nm. Finally, the free-space nanowiring using only $W(CO)_6$ was fabricated.

The electrical resistivity of Fig. 11a fabricated using only $C_{14}H_{10}$ source gas was 1×10^2 Ωcm. The elemental contents were 90 % C and 10 % Ga, which were measured using a SEM-EDX spot beam. The *I–V* curves (b), (c), and (d) correspond to increasing $W(CO)_6$ content in the gas mixture. Increasing $W(CO)_6$ content, the electrical resistivity decreases as shown in *I–V* curves (b–d). Moreover, the Ga content also increased because the growth of nanowiring slowed down; the irradiation time of Ga^+ FIB became longer. The electrical resistivities of the *I–V* curves (b), (c), and (d) were 16×10^{-2}, 4×10^{-2}, and 2×10^{-2} Ωcm, respectively. The electrical resistivity of (e), which was fabricated by using only $W(CO)_6$ source gas, was 4×10^{-4} Ωcm. Increasing the Ga and W metallic content decreases the electrical resistivity, as shown by the SEM-EDX measurements seen in Fig. 11. These results indicate increasing the metallic content results in lower resistivity.

Examples of Applications

Electron Biprism

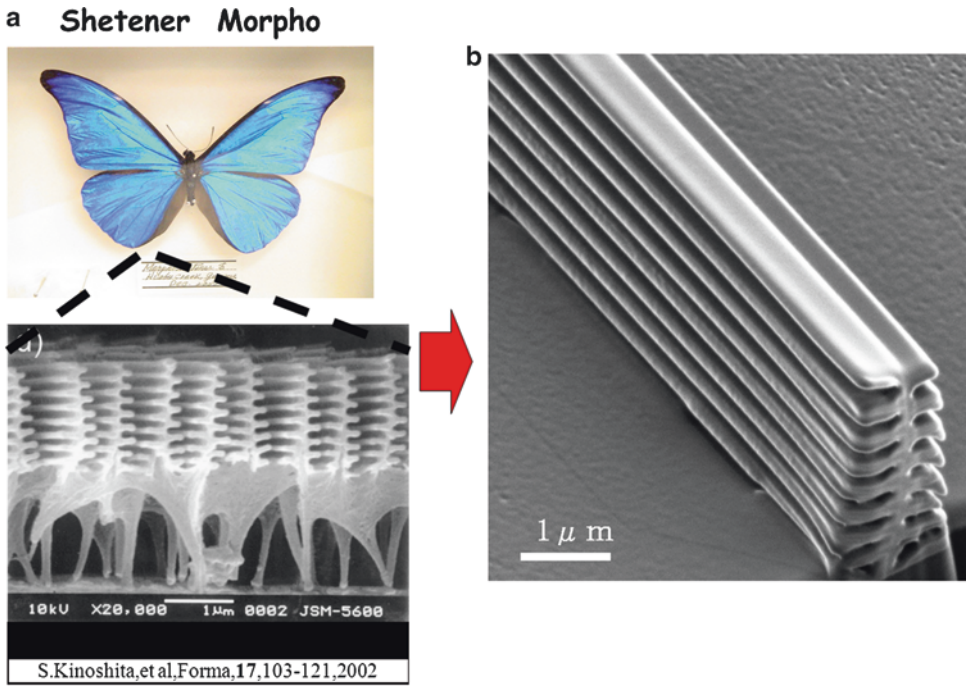


Electron holography is a useful technology for direct observation of electrical and magnetic fields at nanoscale and also has an efficient property of showing useful information by detecting the phase shift of the electron wave due to the electrical and magnetic field. The technique necessarily needs an electron biprism, which plays an important role of dividing electron wave into reference wave and objective wave. The biprism is composed of one thin filament and two ground electrodes.

Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 12 Electron biprism fabricated by FIB-CVD

It is important to fabricate a filament as narrow as possible to obtain an interference fringe with a high contrast and good fringe quality. However, fabricating the filament with a diameter below 500 nm is very difficult, because a conventional electron biprism is fabricated by pulling a melted glass rod by hand. To overcome this problem, we introduce a new fabrication technique of the electron biprism using FIB-CVD and evaluate the characteristics of the new biprism [13]. Figure 12 shows an SEM micrograph of the FIB-CVD biprism. We successfully fabricated DLC wiring with smooth surface in between W rods by free-space-wiring fabrication technology of FIB-CVD. The 80-nm DLC thin wiring works as the filament of the biprism. The diameter and length of the filament are 80 nm and 15 µm, respectively.

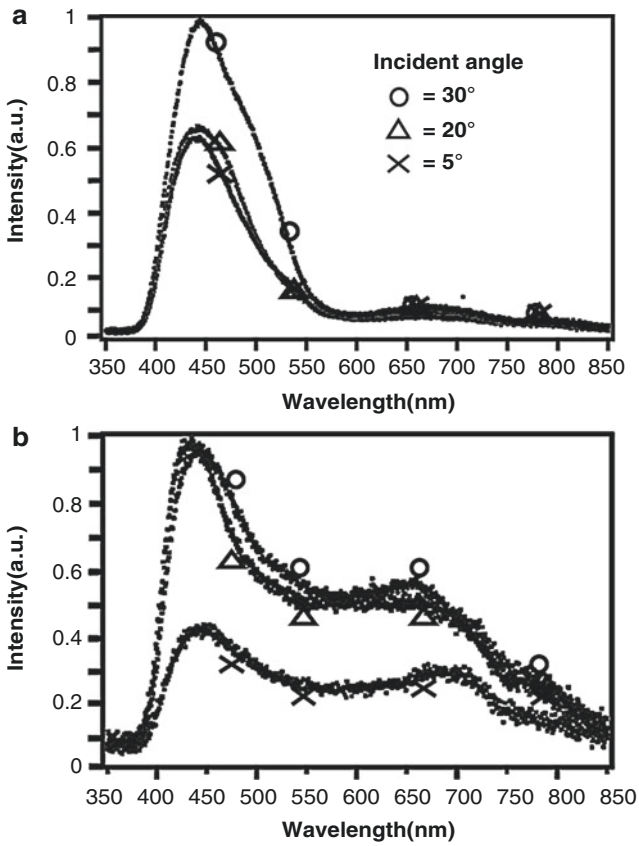
Figure 13 shows the interference fringes obtained using the biprism with a filament of



Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 13 Interference fringes and corresponding fringe profiles (**a**) obtained using the biprism with diameter of 80 nm and (**b**) obtained using the biprism with diameter of 400 nm

(a) 80-nm diameter and (b) 400-nm diameter and corresponding fringe profiles. The applied-prism voltages were 20 V. The filament with 400-nm diameter, close to the standard size used in the conventional electron biprism, was fabricated by Pt-sputter coating onto the 80-nm-diameter filament. The interference fringes were successfully obtained. Moreover, an interference region of the fringe obtained using the biprism with the 80-nm-diameter filament is larger than that of the fringe obtained using the biprism with the 400-nm-diameter filament. These results demonstrate an adequacy of the thin filament fabricated by FIB-CVD, and the new biprism will be very useful for an accurate observation with a high contrast and good fringe quality in electron holography.

Brilliant Blue Observation from a Morpho-Butterfly-Scale Quasi-Structure



The Morpho butterfly has mysteriously brilliant blue wings, and the source of this color has been an interesting scientific problem for a long time. Through an intriguing optical phenomenon, the scales reflect interfered brilliant blue color for any incidence angle of white light. This color is called a structural color, meaning that it is not caused by pigment reflection [14]. When we observed the scales with SEM (Fig. 14a), we found three-dimensional (3-D) nanostructures with 2-μm height, 0.7-μm width, and a 0.22-μm grating pitch on the scales. These nanostructures caused the optical phenomenon in the same way as the play of color is produced in an opal and iridescence is produced by a jewel beetle.

Focused-Ion-Beam Chemical-Vapor-Deposition (FIB-CVD), Fig. 14 Morpho-butterfly scales. (**a**) Top view optical microscope image of Morpho butterfly. Cross-sectional view SEM image of Morpho-butterfly scales. (**b**) Inclined-view SIM images of Morpho-butterfly-scale quasi-structure fabricated by FIB-CVD

We fabricated the Morpho-butterfly-scale quasi-structure with a commercially available FIB system (SMI9200: SII NanoTechnology Inc.) using a Ga^+ ion beam operating at 30 kV [15]. The beam diameter was about 7 nm at 0.4 pA. The FIB-CVD was done using a precursor of $C_{14}H_{10}$. Figure 14b is SIM image of the Morpho-butterfly quasi-structure fabricated by FIB-CVD using 3-D CAD data. This result demonstrates that FIB-CVD can be used to freely fabricate the quasi-structure. The Morpho-butterfly-scale quasi-structure was made of DLC. The reflectivity and transmittance of a 200-nm-thick DLC film deposited by FIB-CVD, measured by the optical measurement system at a wavelength close to 440 nm (the reflection peak wavelength of the Morpho butterfly), were 30 % and 60 %, respectively. The measured data thus indicated that the DLC film had high reflectivity near 440 nm, which is important for fabrication of an accurate Morpho-butterfly-scale quasi-structure.

We measured the reflection intensity from Morpho-butterfly scales and the Morpho-butterfly-scale quasi-structure through optical measurement and compared their characteristics. In this measurement system, white light from a halogen lamp was directed onto a sample with incident angles ranging from 5 to 45°. The reflection was concentrated by an optical microscope and analyzed by a commercially available photonic multichannel spectral analyzer system (PMA-11: Hamamatsu Photonics K.K.). The intensity of incident light from the halogen lamp had a wavelength with peak intensity close to 630 nm. Figure 15a, b, respectively, show the reflection intensity from Morpho-butterfly scales and the quasi-structure. Both had a wavelength whose peak intensity was near 440 nm and showed very similar reflection intensity spectra for the various incidence angles. We have thus successfully demonstrated that a Morpho-butterfly-scale quasi-structure fabricated by FIB-CVD can show nearly the same optical characteristics as real Morpho-butterfly scales.

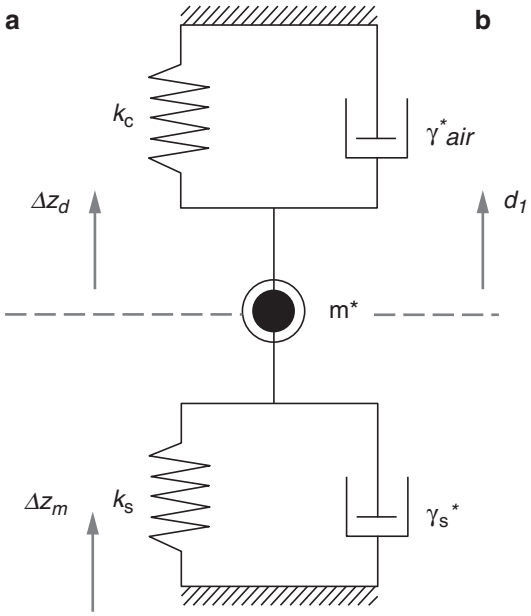
Force Modulation in Atomic Force Microscopy

Walter Arnold
Department of Material Science and Technology, Saarland University, Saarbrücken, Germany
Physikalisches Institut, Göttingen University, Göttingen, Germany

Definition

Force modulation in atomic force microscopy is a technique to measure tip–surface interactions which in turn are determined by local elastic restoring forces, by local frictional forces, and by local adhesion between a tip and the surface under inspection. The tip or sample is oscillated at a given frequency and pushed into the repulsive regime. Data on local forces can be acquired along with topography, which allows comparison of both height and material properties.



Overview

In atomic force microscopy (AFM), a microfabricated elastic beam with a sensor tip at its end is scanned over the sample surface and generates high-resolution images of surfaces. Dynamic modes, where the cantilever or the sample surface is vibrated, belong to the standard equipment of most commercial instruments. With a variety of these techniques, such as force modulation microscopy, scanning local-acceleration microscopy, scanning micro-deformation microscopy, or pulsed force microscopy, images can be obtained whose contrast depends on the elasticity, friction, and adhesion of the tip–sample contact.

The quantitative determination of the Young's modulus of a sample surface with an AFM is a challenge. Especially when stiff materials such as metals or ceramics are encountered, the image contrast due to elasticity becomes very low, because the spring constants of common AFM cantilevers, ranging from 0.01 to 70 N/m, are then much lower than the tip–sample contact stiffness. In this contribution, the various techniques are discussed to allow elasticity, anelasticity, and plastic deformation measurements or in more general terms force measurements. A number of efforts have been undertaken to combine acoustical imaging with atomic force microscopies. These are near-field imaging systems exploiting the contrast from modulation of the forces between tip and surfaces of the component under test. There is a manifold of factors determining the obtainable spatial resolution and the contrast when working in the near field of an antenna, here the tip of an AFM [1].

Force Modulation Technique

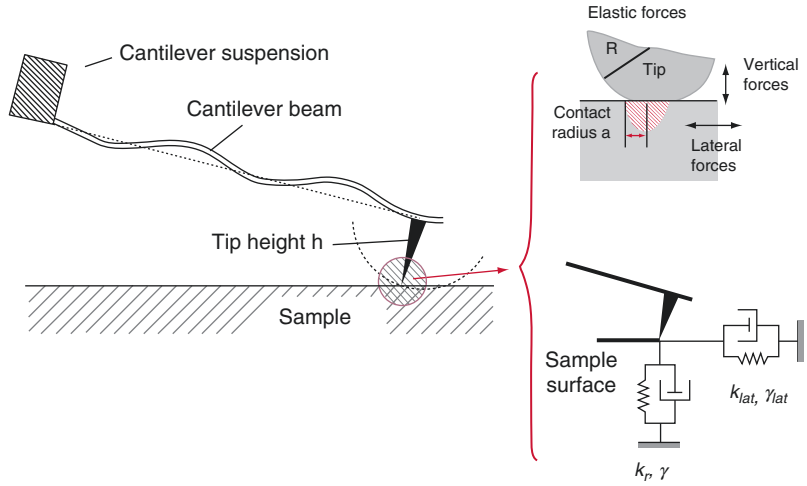
In the force modulation technique [2], the z-position of the sample is modulated with amplitudes Δz_m on the nm scale, ranging to some 10 nm (Fig. 1a). Therefore, at a constant static load applied to the cantilever, the total force exerted on the surface of the sample is modulated as well and the ensuing cantilever amplitude Δz_d depends on the local contact stiffness k_s:

Force Modulation in Atomic Force Microscopy, Fig. 1 Principle of force modulation (**a**) and scanning local-acceleration microscopy (**b**). In force modulation, the z-piezo of the AFM instrument is modulated by an amplitude Δz_m. The cantilever follows with an amplitude Δz_d which depends on the local stiffness k_s of the material and on the stiffness of the cantilever, k_c; see Eq. 1. The *dashpot* represents viscoelasticity and adhesion on the contact, as well as damping of the cantilever in air; (**b**) scanning local-acceleration microscopy (*SLAM*) [4] is identical with force modulation for frequencies below the cantilever contact-resonance frequency. For frequencies above the resonance frequency, there is a still an amplitude response of the cantilever, which is given by the accelerated mass; see Eq. 2, which corresponds to the effective mass m^* of the cantilever which is $m^* \approx m/4$ [7, 11] where m is the mass of the cantilever. In [4], the authors also discuss the cases when either the suspension of the cantilever or the cantilever itself is excited by a dynamic force inducing a corresponding cantilever amplitude

$$\frac{\Delta z_d}{\Delta z_m} = \frac{k_s}{k_s + k_c} \tag{1}$$

where k_c is the stiffness of the cantilever. In the force modulation technique, one measures the corresponding vertical photodiode output signal ΔV_m as well as the signal ΔV_d at a given static load without modulation. Using the Hertzian contact mechanics for the tip–sample contact and a calibration sample of given indentation modulus M_s, it is possible to calibrate the photodiode output signal in order to obtain the factor R [2]:

$$M_s = \frac{\sqrt{2} k_c}{a_c [R(\Delta V_m / \Delta V_d) - 1]} \tag{2}$$



Here, a_c is the contact radius, also called sample depression radius. If the experimental parameters are set such that larger depressions occur, the modulation force develops a signal at the double frequency due to the nonlinearity of a Hertzian contact [3]. Furthermore, the adhesion in the contact, as well as the viscoelasticity of the examined material, leads to a phase shift between the force excitation signal and the output signal of the AFM photodiode.

Local-Acceleration Microscopy

From a mechanical engineering point of view, the heart of an AFM consists of the cantilever and a tip in contact with the sample. Provided that the suspension of the cantilever as well as the scanning unit is infinitely stiff, the oscillations of these AFM components may be described in a simplified way. If one assigns to the cantilever an effective mass m^*, one can describe the oscillatory behavior of the whole system with the replacement model shown in Fig. 2. Neglecting the damping effects, at frequencies smaller compared to the resonance frequency of the system in contact with a sample, the amplitude d_1 of the cantilever oscillation is given by [4]

$$\frac{d_1}{\Delta z_m} = \frac{k_s}{k_s + k_c} \tag{3}$$

F

Force Modulation in Atomic Force Microscopy, Fig. 2 Mechanical model of the AFM cantilever as a rectangular elastic beam. The contact itself is described as two parallel linear springs with spring constants or contact stiffnesses k_r and k_{lat} and two damping dashpots γ and γ_{lat} for both vertical and lateral contact forces. The cantilever length is $L = L_1 + L_2$, L_2 is the distance between the tip position and the end of the cantilever, and h is the length of the tip. Due to technical reasons, the cantilever is inclined by an angle α which is $\approx 10°$. Force modulation occurs by excitation of the sample surface with vertical displacement by an attached transducer to the bottom of the sample (AFAM or CR-AFM technique) or by exciting the cantilever suspension (UAFM). The cantilever oscillation may be excited as well by a thin-film piezoelectric transducer or built-in Schottky barrier. The frequencies of the contact resonances are independent of the type of excitation; however, the cantilever amplitudes depend on the type of excitation

where Δz_m is again the excitation amplitude of the sample. Equation 3 is equivalent to Eq. 1, and it leads after calibration, using the Hertzian contact theory again, to Eq. 2, i.e., it encompasses the force modulation. Regarding the high-frequency limit above, the contact resonance of the system leads to

$$\frac{d_1}{z_m} = \frac{k_s}{m^* \omega^2} \tag{4}$$

This means that the amplitude of the cantilever is determined by the accelerated local mass; hence, the name scanning local-acceleration microscopy (SLAM) was coined. This method has no relation with the so-called scanning laser acoustic microscope whose acronym is SLAM as well [1]. There are a number of related AFM techniques based on force modulation where instead of a cantilever with its indenting tip, a capacitive load–displacement indenter is used, allowing one to perform, besides force modulation, nanoindentation at loads higher than the loads possible with an AFM [5].

Pulsed Force Microscopy

In the pulsed force microscopy, the force–distance curve is rapidly scanned through point by point at the surface, and parameters are determined which depend on elasticity, adhesion, and other surface properties [6]. For force modulation AFM caused by piezoelectricity or magnetic forces, see the entries in this volume on piezo-force microscopy and magnetic force microscopy.

Ultrasound and Atomic Force Microscopy

A more complete description of the oscillatory behavior of the core parts of an AFM can be obtained if one considers the cantilever as a finite beam with its flexural, torsional, and

lateral eigenmodes. There are several synonyms for this approach: atomic force acoustic microscopy (AFAM), ultrasonic atomic force microscopy (UAFM), contact-resonance AFM (CR-AFM), or similarly with only minimal differences in the underlying physics of the theory of operation. There are some technical differences in the realization of the various approaches which will not be discussed here, however. This holds in particular for the commercially available instruments. In these types of force modulation techniques, one measures the resonances of atomic force cantilevers with the tip contacting the specimen surface [7–11] instead of measuring amplitudes. AFAM, UAFM, and CR-AFM emerged as tools for the measurement of elastic properties of the near-surface zone of materials with nanometer resolution. In these techniques, force modulation occurs by excitation of the sample surface with vertical displacement by an attached transducer to the bottom of the sample (AFAM or CR-AFM technique) or by exciting the cantilever suspension (UAFM). The cantilever may be excited as well by a thin-film piezoelectric transducer or by a built-in Schottky barrier. The frequencies of the contact resonances are independent of the type of excitation; however, this is not the case for the amplitudes [11]. This holds for SLAM as well [4]. Furthermore, the increased dynamic stiffness of the cantilevers at the higher modes allows for quantitative measurements and imaging of stiff materials.

From such measurements, one can derive the local indentation modulus M of the sample under test, using a suitable mechanical model relating the resonance frequencies of the oscillating cantilever to the tip–sample contact stiffness $k_s{}^*$, which in turn is related to the local indentation modulus M. The indentation modulus is an elastic constant which accounts for the compressive and the shear deformations in the tip–sample contact zone between isotropic or anisotropic materials originally used for nanoindentation [8].

Vibrations of beams are treated in many textbooks of acoustics, in textbooks of engineering mechanics, and with regard to applications to AFAM, UAFM, or CR-AFM in publications, for example, in references [7, 9, 11–13]. The interaction forces normal to the sample surface are represented as a linear spring with a characteristic spring constant k_s, which is the negative derivative of the tip–sample force in the equilibrium position:

$$k_s = -\left.\frac{\partial F(z)}{\partial z}\right|_{z=z_e} \tag{5}$$

where z is the tip–sample distance, $F(z)$ is the tip–sample interaction force, and z_e is the equilibrium position. The lateral contact stiffness $k_{s,\mathrm{lat}}$ is defined analogously. The ensuing mechanical model of a vibrating cantilever in AFAM is presented in Fig. 2. The superposition of vertical and lateral tip–sample interaction forces may be represented by a set of springs and dashpots.

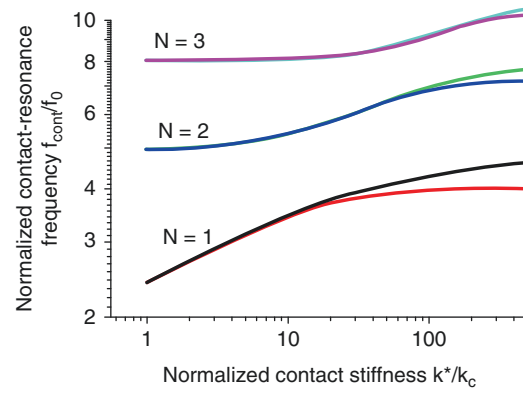
For a beam of uniform cross section, the equation of motion for flexural vibrations is a fourth-order differential equation. Taking into account the boundary conditions for an oscillating cantilever, either free or in contact with the sample, one obtains the characteristic equation from the equation of motion for which the solutions $\kappa_N L$ ($N = 1, 2, 3\ldots$) yield the wave numbers κ_N of an infinite set of flexural modes. The dispersion relations are used to calculate from the resonance frequency f_N of the N^{th} mode [7, 9, 11–13] the contact stiffness. When approaching the sample surface, the tip first senses long-range attractive forces before contact and in contact repulsive tip–sample forces. If the static load $F_0 = k_c \times d_c$, applied to the tip by a cantilever deflection d_c, is large enough, attractive forces may be neglected.

If one takes viscoelasticity of the examined materials into account, the local contact stiffness k_s^* becomes complex and can be written as [14]

$$k_s^* = k_r + ik_i = k_r + i\omega\gamma, \tag{6}$$

where γ is the contact damping. In order to obtain Q_{loc}^{-1} caused by the local contact damping from the total damping Q^{-1} of the cantilever, one has to view the cantilever as a distributed mass system where a flexural wave mode of order N propagates back and forth along the cantilever. The damping of this wave is caused (i) by internal friction in the

F



stress field of the cantilever tip extending into the sample [15], (ii) by the motion of the cantilever in the surrounding air [7], and (iii) by damping in the contact due to adhesive and frictional forces [16]. Procedures to separate the various parts are discussed in [14, 17]. For the Nth cantilever mode, the local Q_{loc}^{-1} is given by [18]

$$Q_{N,\,\text{loc}}^{-1} = \frac{M''_S}{M'_S} = \frac{\omega\gamma}{k_r} = \frac{\beta_N}{\alpha_N}\frac{L}{L_1}\frac{\omega_{c,N} \times (\kappa_N L)^2}{\omega_{\text{free},N}} \tag{7}$$

Here, M'_S is the real part of the indentation modulus of the sample, M''_S is its imaginary part, α_N and β_N are the real and imaginary parts of the wave vector κ_N describing the cantilever's motion, $\omega_{c,N}$ is the contact-resonance frequency of mode N, and $\omega_{\text{free},N}$ is the free resonance frequency of mode N. Furthermore, L is the length of the cantilever and L_1 designates the position of the cantilever tip; see Fig. 2. For the first cantilever flexural mode, Eq. 8. reduces to [18]

$$Q_{1,\,\text{local}}^{-1} \approx 3.516\frac{\beta_1}{\alpha_1}\frac{L}{L_1}\frac{\omega_{c,1}}{\omega_{\text{free},\,1}} \tag{8}$$

There is also a lateral contribution γ_{lat} to the damping in the contact [14]. The procedures described in [14, 17, 18] yield both local damping and local stiffness k_r and allow imaging of Q_{loc}^{-1}. Typical total Q-values observed are $Q \approx 100$. For the contact oscillations alone, i.e., after subtraction of the damping of the cantilever beam in air, the Q-values are higher [18]. For a spring-coupled cantilever with the ratio $k_{\text{lat}}/k_r = c_k$, and for an inclined cantilever, one obtains a characteristic equation or a dispersion curve whose solution can be found in [11–13]. A graphic display of a special dispersion curve is shown in Fig. 3. The ratio of the lateral contact stiffness to the vertical contact stiffness has been calculated for an elastic contact to be $k_{\text{lat}}/k_r = c_k = 4G^*/E^*$ [19], where E^* and G^* are the reduced Young's modulus and shear modulus of the contact zone, respectively. With a Poisson ratio of 0.4, one obtains $c_k \approx 0.85$.

Force Modulation in Atomic Force Microscopy, Fig. 3 Normalized contact-resonance frequency f_N/f_0 for the first three cantilever modes ($N = 1, 2, 3$) as a function of normalized contact stiffness k_r/k_c according to the cantilever dispersion equations (for small damping $k^* = k_r$). Due to the shape of the dispersion curve, variations in contact resonances may entail a large variation in contact stiffness and consequently in indentation modulus. Depending on the slope of the dispersion curve, higher modes ($N = 2$; $N = 3$) may become more sensitive to measure a local indentation modulus quantitatively [11]. Each dispersion curve display two values, one for $c_k = 0$ (*lower curves*) and one for $c_k = 0.85$ (*upper curves*). Parameters used for the calculations were $L_1 + L_2 = 137$ µm, $L_2 = 15.1$ µm, $h = 17$ µm, and $\alpha = 11°$ (According to M. Büchsenschütz-Göbeler, University of Göttingen, 1. Physikalisches Institut, 2010, with kind permission)

As a first step in a measurement, one obtains from the ratio $f_{\text{cont}}/f_{\text{free}}$ of the cantilever employed the normalized contact stiffness k_r/k_c, using the appropriate parameters in the dispersion curve. Knowing k_s^*, both the real and the imaginary parts, k_r and k_i, and the contact area or contact radius of the tip–sample contact, one can determine the local indentation modulus M' using the relation [8, 11, 13, 14]:

$$k_r = \frac{2}{\sqrt{\pi}}M'\sqrt{A} \tag{9}$$

$$k_i = \frac{2}{\sqrt{\pi}}M''\sqrt{A} \tag{10}$$

where A is the contact area and M' and M'' are the real and the imaginary parts of the indentation modulus. In case of an isotropic material, these

are equivalent to the reduced modulus of elasticity E^* and to the loss modulus $E^{*\prime\prime}$, respectively.

Indentation Modulus

For isotropic solids E^* is given by

$$\frac{1}{E^*} = \frac{1-\nu_s^2}{E_s} + \frac{1-\nu_{\text{tip}}^2}{E_{\text{tip}}} \tag{11}$$

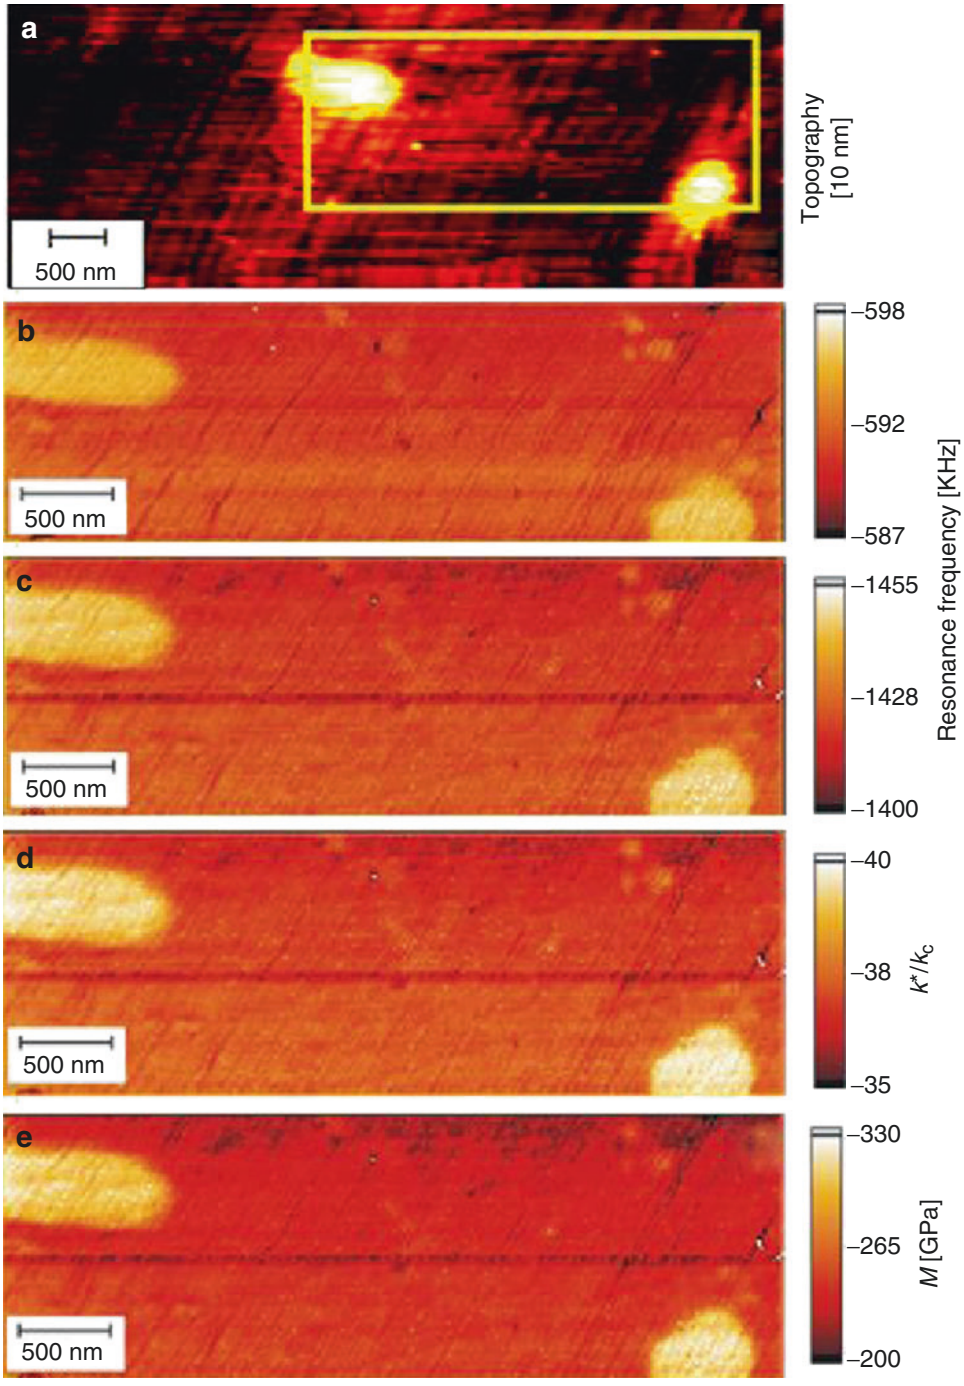
Here, $E_{s,\text{tip}}$ are the Young's modulus of the sample and of the tip, and $\nu_{s,\text{tip}}$ are the corresponding Poisson ratios. In the case of anisotropic solids, an indentation modulus M is introduced, which can be calculated from the elastic single-crystal constants in a given direction [20]. If there exists a three- or fourfold rotational symmetry axis perpendicular to the boundary, the contact area is circular. The required symmetry holds for silicon sensor tips, which are oriented in (001) crystallographic direction. In this case, Eq. 11 can be replaced by

$$\frac{1}{E^*} = \frac{1}{M_S} + \frac{1}{M_{\text{tip}}} \tag{12}$$

where M_S and M_{tip} are the indentation moduli of the sample and the tip, respectively [8]. For isotropic bodies, the indentation modulus is $M = E/(1-\nu^2)$, and Eq. 12 becomes Eq. 11.

Finally, neglecting the effect of damping, the elastic properties of the sample can be extracted by comparing measurements in order to obtain information on the contact area or the contact radius:

$$E_s^* = E_r^* \left(k_s^*/k_r^*\right)^m \tag{13}$$



Here, r and s refer to the reference sample and the unknown sample, respectively, and m describes the tip geometry. For a flat punch $m = 1$ and for a spherical tip $m = 3/2$ [8, 9, 21]. When making comparative measurements, for example, on nanocrystalline materials, on polycrystalline materials, or on metallic glasses, one may use as well elastic data from ultrasonic velocity measurements to calculate the mean macroscopic value of M_s [8, 10, 22].

An AFAM image is shown in Fig. 4 demonstrating the sequence of data evaluation. The first and the second contact-resonance spectra were obtained at every point of the area examined in a modified 9Cr–1Mo ferritic steel with $M_{23}C_6$ carbide precipitates [10]. The distribution of k_r/k_c values was derived using the contact-resonance spectra and the mechanical model shown in Fig. 2 with the appropriate dispersion curve. As can be seen, the AFAM technique is a tool for the determination of the modulus of submicron-sized precipitates with a spatial resolution of less than 10 nm in polycrystalline materials. The spatial resolution is given by the contact radius a_c (or depression radius; see above) which depends on the tip radius R_t, the applied static force F_0 acting on the tip including the forces of adhesion F_0, and the reduced elastic modulus E^* of the contact. In case of Hertzian contact with a spherical tip, this value is given by

$$a_c = \sqrt[3]{3F_0R_t/4E^*} \tag{14}$$

This resolution has been tested and exploited in several applications of contact-resonance AFM [8–10, 13, 21].

When in an AFAM setup, the amplitude of the surface vibrations is increased, and a DC offset of the cantilever develops, i.e., the sensor tip lifts off the sample surface. This rectifying effect due to the nonlinear force distance curve has been known since the early experiments combining ultrasonic technology with AFM and was exploited in ultrasonic force microscopy (UFM) [25]. The advantage of this technique compared to AFAM, UAFM, or CR-AFM is that only a low detection bandwidth of the cantilever optical detection system of the AFM is required. However, as both elasticity and adhesion contribute to the image contrast in a nonlinear fashion [11, 12, 23–25], their separation in a quantitative manner remains difficult. Also, the UFM technique can be employed to study frictional properties [26]. Using the torsional cantilever contact resonances, one can obtain data on the shear elasticity as well as on frictional properties in the contact [16]. Finally, scanning microdeformation

If the topography is too rough, the contact area A of the tip–sample contact will influence the results; see Eq. 8; (**b**, **c**) cantilever contact-resonance frequencies measured for the first ($N = 1$) (**b**) and (**c**) the second contact resonance ($N = 2$); (**d**) from the contact resonances, k_r/k_c is determined using the appropriate dispersion curve for the cantilever employed; (**e**) the indentation modulus M is determined by

microscopy [25] is analog to AFAM, UAFM, and CR-AFM in its technical realization, except that tips with larger radii are used, and hence the contact radius a_c is micrometer range instead of the nanometer range.

Subsurface Imaging

There is a lot of interest to image with atomic force microscopy subsurface features, which is difficult because AFM is a technique for surface characterization by its operational principle. Therefore, it seems straightforward to combine ultrasound with its penetrating capability with AFM for this purpose, and indeed there are efforts to achieve subsurface acoustical imaging by using various schemes of AFAM or UAFM.

Subsurface imaging with an AFM is possible if the physical quantity measured exhibits a gradient into the material within the penetration of the stress field emanating from the tip–sample contact. For example, the stiffness of the material changes at the surface when there are defects, dislocations, variations of film thicknesses, or changes of material properties within a certain depth [9, 27–29]. Cavities can be seen at depths of about 200–500 nm and having diameters of ≈300 nm. The depth range is roughly given by the extent of the stress field which the tip exerts on the surface or the stress field of the defect or their joint action and therefore on the static load. As is the case for all interior acoustical imaging techniques, the contrast determines whether an image of a given defect is obtained with an acceptable signal-to-noise ratio. Here, the ratio k_{def}/k_r of the stiffness of the defect relative to the host material determines the contrast. As a rule of thumb, one can assume that the depth range z is about three times the contact radius a_c if the Hertzian contact mechanics between tip and surface prevails, although in certain cases one can detect much deeper [29]. Recently, a subsurface imaging scheme combining ultrasound and AFM [30] called scanning near-field ultrasonic holography (SNFUH) has been reported; however, the origin of the contrast is still a matter of debate and is not further discussed here. Finally, a scheme has been reported in an AFAM setup that is meant to render possible the detection of small defects in materials much below the Hertzian stress field, using force modulation at 1 GHz [31].

Force Modulation in Atomic Force Microscopy, Fig. 4 (continued) calibration with a reference sample according to Eq. 13 in order to determine the contact area A or contact radius a_c; see Eq. 8. The reference sample may be the host material itself, and the global values for the elastic moduli for calibration may be determined by ultrasonic time-of-flight data. As can be seen in (**e**), the distribution of the indentation modulus of the $M_{23}C_6$-type carbide precipitate becomes visible as bright islands having a value of $M = 310 \pm 10$ GPa. The contact radius given in Eq. 14 determines the spatial resolution as well as the topography of the sample. Typical values range from nm to some 10 nm (Data in modified form from Kumar et al. [10] and from additional data, with kind permission by AIP and by A. Kumar, IGCAR, Kalpakkam, India)

Lateral force microscopy (LFM)

Definition

The friction force microscope (FFM) is a derivative of the atomic force microscope (AFM), which is optimized to measure the lateral forces that are acting between a sharp, nanoscopic tip and a surface during scanning of the tip. Ever since it was demonstrated that the frictional force can be measured at the atomic scale in 1987 by Mate et al. [1], this technique had a tremendous impact on understanding fundamental, molecular scale friction and lubrication processes and has been instrumental in defining the field of nanotribology.

Overview

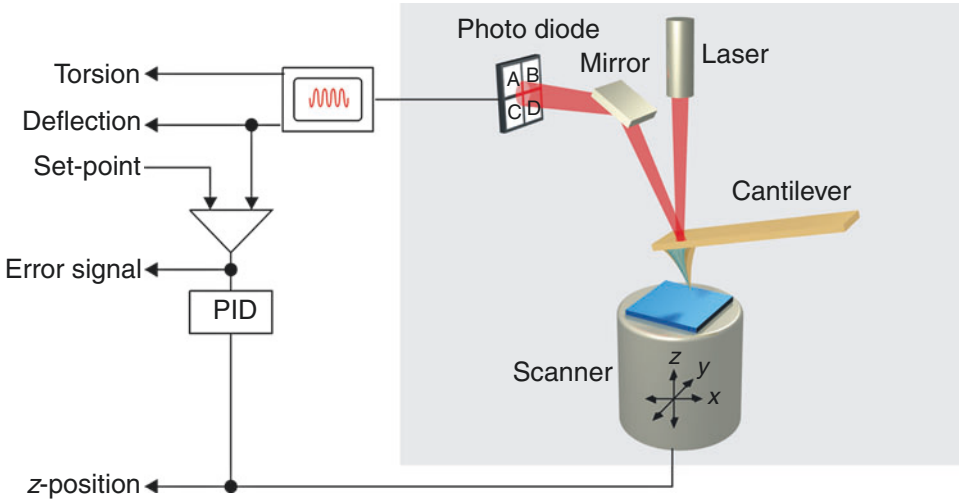
In basic physics textbooks, the frictional force F_{friction} between two bodies in contact is typically described by the following phenomenological law of friction:

$$F_{\text{friction}} = \mu F_{\text{load}}, \quad (1)$$

where F_{load} represents the external loading force and μ the friction coefficient, which depends only on the actual combination of materials in contact. This equation is essentially the condensed form of observations first noted by Leonardo da Vinci

(1452–1519). His findings had been fallen into oblivion after his death, only to be independently rediscovered by Guillaume Amontons (1663–1705), who reported them to the French Académie Royale des Sciences on December 19, 1699. Hence, Eq. 1 is commonly referred to as *Amontons' law*. It holds surprisingly well especially in the case of dry friction or Coulomb *friction*, which represents the case of sliding without lubrication between the two interacting bodies. Unfortunately, it cannot be derived from first principles up to now. Even worse, the entire understanding of the fundamental mechanisms of friction on the atomic scale is still relatively limited since most macroscopic and microscopic frictional effects are usually dominated by the influence of wear, plastic deformation, lubrication, surface roughness, and surface asperities. Macroscopic friction experiments are therefore difficult to analyze in terms of a universal theory. As this complexity of phenomena prevented the observation of pure wearless friction for many years, attempts to rigorously analyze the origins of friction on the molecular and atomic scale had been largely unsuccessful.

In the last decades, however, the field of *nanotribology* was established by introducing new experimental tools, which made the nanometer and atomic scales accessible to tribologists [2–4]. One of the basic ideas of nanotribology is that for a better understanding of friction in macroscopic systems, the frictional behavior of a single-asperity contact should be investigated first. It is the hope that once the atomic-scale manifestations of friction at such a nanometer-sized single asperity have been clarified, macroscopic friction could be explained with the help of statistics, i.e., by the summation of the interactions of a large number of small individual contacts, which form the macroscopic roughness of the contact interface.



The first important step toward such experiments at the atomic level was done when the *surface force apparatus* was equipped with special sample stages enabling the measurement of lateral forces between two molecularly smooth surfaces sliding against each other [5]. The largest step forward concerning the reduction of the asperity size, however, was accomplished with the development of the *friction force microscope* (FFM) [1]. The FFM is derived from the *atomic force microscope* (AFM) and enables the local measurement of lateral forces by moving a sharp tip, representing (approximately) a *point contact*, over a sample surface.

Technical Setup of a Friction Force Microscope

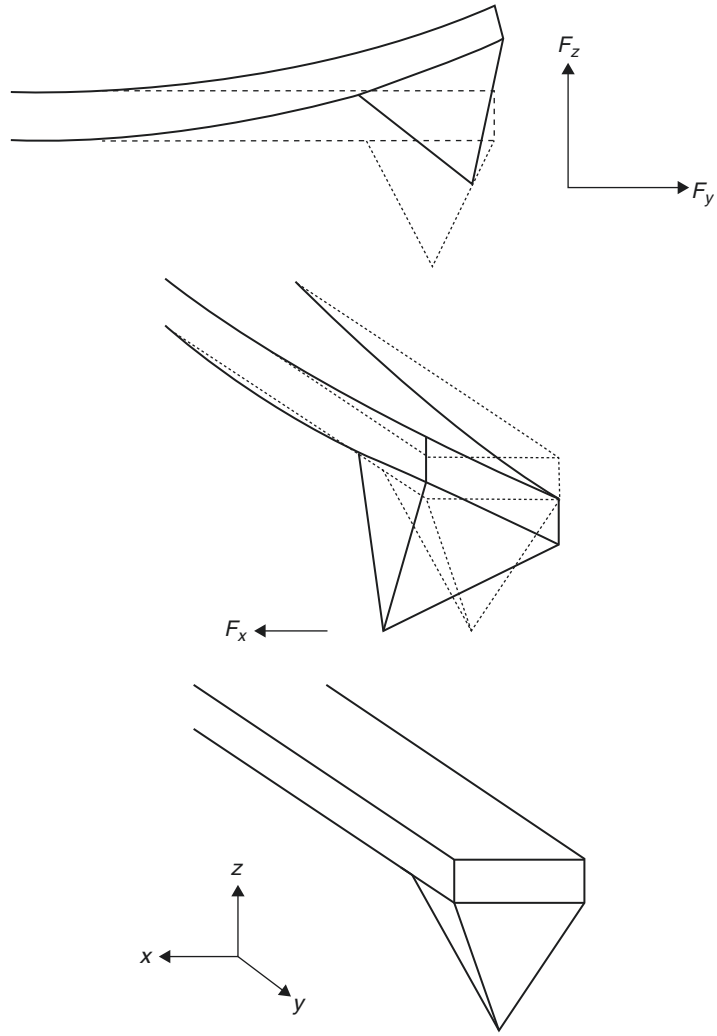
The experimental setup of an atomic or friction force microscope (AFM or FFM) is based on a simple idea. It detects forces acting between a sample surface and a sharp tip that is mounted on a soft leaf spring (the so-called cantilever). Such cantilevers are produced by standard microfabrication techniques, mostly with rectangular or V-like shapes, from silicon or silicon nitride. Spring constants for the bending of cantilevers typically used for AFM measurements are about 0.01–1 N/m. The lateral spring constants for the torsion of the cantilever are in the range between 10 and 100 N/m.

A feedback system, which controls the vertical z-position of the tip on the sample surface, keeps the deflection of the cantilever (and thus the force between tip and sample) constant. Moving the tip relative to the sample in the x-y-plane of the surface by means of piezoelectric drives, the actual z-position of the tip is recorded as a function of the lateral x-y-position with (ideally) sub-Ångström precision. The obtained data represents a map of equal forces, usually interpreted as the surface topography. The conversion of the cantilever deflection into the normal force is performed by applying Hooke's law. The data can be analyzed and visualized through computer processing. A more detailed description of the method and the generally used instrumentation can be found in the books of Meyer [6] and Bhushan [4].

The by far most widespread detection scheme for atomic force microscopy experiments is the laser beam deflection technique sketched in Fig. 1. As explained in the figure caption, not only the deflection but also the torsion of the cantilever can be measured. Atomic force microscopes that can

Friction Force Microscopy, Fig. 1 Experimental setup of an atomic force microscope/friction force microscope based on the so-called laser beam deflection method. Cantilever deflection (i.e., normal force) and torsion (friction) of the cantilever are measured simultaneously by detecting the lateral and vertical deflection of a laser beam while the sample is scanned in the *x*-*y*-plane. The laser beam deflection is determined using a 4-quadrant photodiode: If *A*, *B*, *C*, and *D* are proportional to the intensity of the incident light of the corresponding quadrant, the signal $(A + B) - (C + D)$ is a measure for the deflection and $(A + C) - (B + D)$ a measure for the torsion of the cantilever. A schematic of the feedback system is shown by *solid lines* on the *left*. The actual deflection signal of the photodiode is compared with the set point chosen by the experimentalist. The resulting error signal is fed into the PID controller ("*PID*" stands for a feedback electronics that uses a proportional, an integral, and a differential control part), which moves the *z*-position of the scanner in order to minimize the deflection signal

record bending and torsion of the cantilever simultaneously are referred to either as *friction force microscopes* (FFMs) or, alternatively, as *lateral force microscopes* (LFMs).



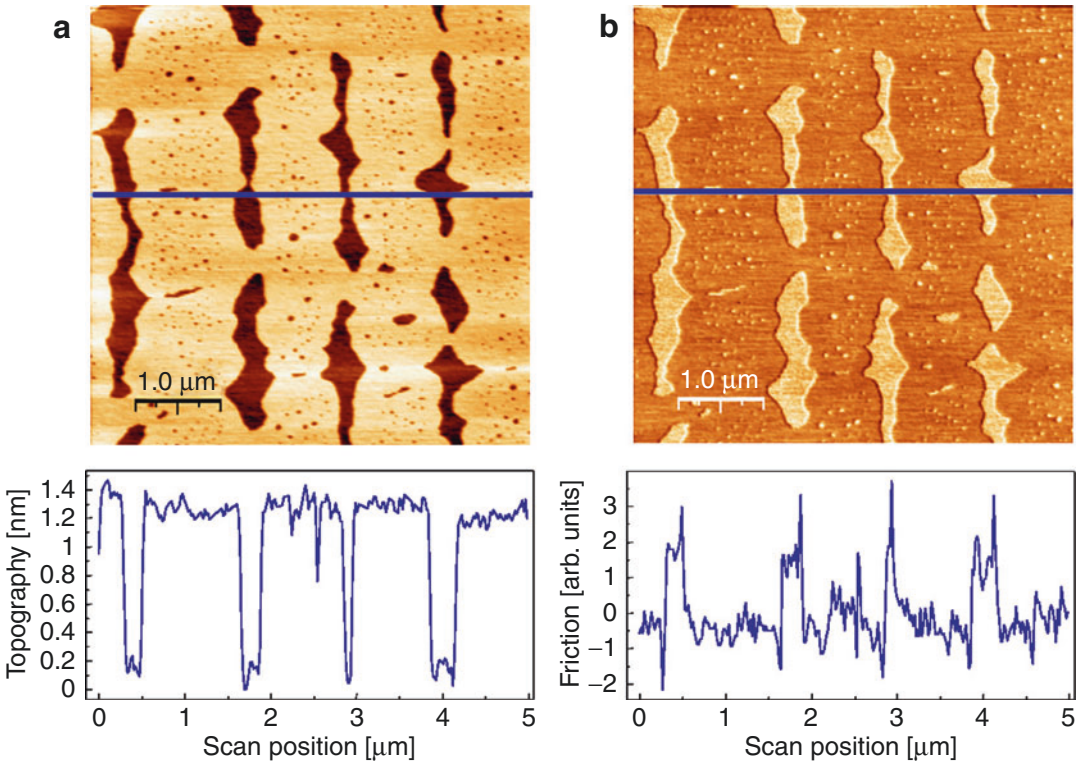
To be able to collect quantitative data, the correct calibration of the bending and the torsion of the cantilever (see Fig. 2) is an important issue. Many parameters have to be known, such as the cantilever dimensions, the elastic modulus of the cantilever material, the tip length, the exact position on the cantilever backside where the laser beam is reflected, and the sensitivity of the 4-quadrant photodiode. Different procedures for the quantitative analysis of lateral force microscopy experiments have been introduced; for a detailed review, see Munz [7].

As already mentioned in the introduction, macroscopic friction experiments are often difficult to analyze due to the complexity of the experimental system. Measurements using friction force microscopy, however, can be carried out in nearly every environment (ambient conditions, vacuum, or liquids) with well-defined tips representing approximative point contacts. Since loading forces can be kept very low, effects like wear and plastic deformation can be prevented in most cases. These features make friction force microscopy a powerful tool for nanotribology.

An example of a friction force microscopy measurement is shown in Fig. 3a, b. The images represent a measurement of a DPPC film adsorbed on a mica substrate. The lateral force was simultaneously recorded with the topography and shows a contrast between the DPPC film and the substrate. This effect can be attributed to the different frictional forces on DPPC and the mica substrate and is frequently used to obtain a chemical contrast on flat surfaces.

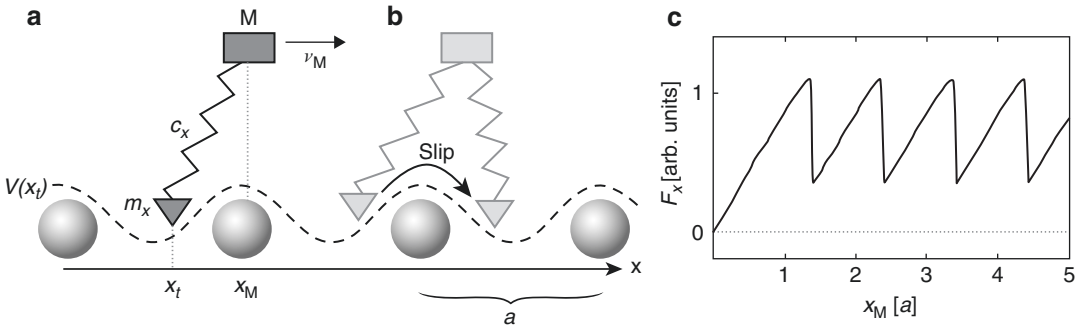
Atomic-Scale Friction and the Prandtl-Tomlinson Model

Despite the fact that much of the current knowledge on the origins of friction has been acquired during the last two decades, many of the newly



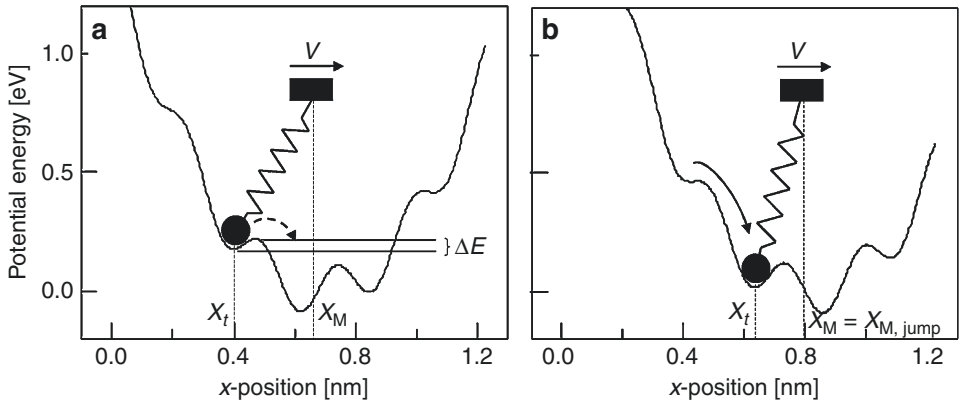
Friction Force Microscopy, Fig. 2 When the cantilever tip is sliding over the surface, there are two main modes of deflection. The *top* image shows the normal bending mode which is related to the normal forces exerted by the tip. The *middle* image shows the torsion of the cantilever beam, which is due to the lateral forces between tip and sample, i.e., the frictional forces

observed atomic-scale effects can actually be understood in the framework of a surprisingly old model, the so-called Prandtl-Tomlinson model [8, 9]. A schematic representation of this simple spring model is shown in Fig. 4. A point-like tip is elastically coupled to a main body M with a spring possessing a spring constant c_x in x-direction and interacts with the sample surface via a periodic potential $V_{\text{int}}(x_t)$, where x_t reflects the actual position of the tip. During sliding, the body M is moved in x-direction with a velocity V_{M}.



The equation of motion for the tip in the interaction potential can be written as

$$m_x \ddot{x}_t = c_x(x_{\text{M}} - x_t) - \frac{\partial V_{\text{int}}(x_t)}{\partial x_t} - \gamma_x \dot{x}_t, \qquad (2)$$



where m_x is the effective mass of the system and $x_{\text{M}} = V_{\text{M}}t$ the equilibrium position of the spring at the time t. The last term on the right side is a simple velocity-dependent damping term with a damping constant γ_x. It describes the energy dissipation of the tip independent from the exact physical nature of the actual dissipation channel (i.e., phonons or electronic excitations). The solution of this differential equation is the path of the tip $x_t(t)$. The *lateral force* F_x to move the tip in x-direction can be calculated from $F_x = c_x(x_{\text{M}} - x_t)$,

Friction Force Microscopy, Fig. 3 (**a**) Atomic force microscopy image obtained in contact mode of a monomolecular DPPC (L-*a*-dipalmitoyl-phosphatidylcholine) film adsorbed on mica. The image is color-coded, i.e., *dark areas* represent the mica substrate and *light areas* the DPPC film. (**b**) The simultaneously recorded friction image shows lower friction on the film (*dark areas*) as on the substrate (*light areas*). The graphs at the *bottom* represent single *scan lines* obtained at the positions marked by a *dark line* in the images at the *top*

Friction Force Microscopy, Fig. 4 (**a**) A simple model for a tip sliding on an atomically flat surface based on the Prandtl-Tomlinson model. A point-like tip is coupled elastically to the body M by a spring with spring constant c_x in x-direction; x_t represents its position within an external potential $V(x_t)$ with periodicity a. If $x_t = x_M$, the spring is in its equilibrium position. For sliding, the body M is moved with a velocity v_M in x-direction. (**b**) A schematic view of the tip movement in a sinusoidal interaction potential. If condition (5) holds, the tip shows a characteristic "stick-slip"-type movement, i.e., it jumps from one potential minimum to another. (**c**) If the tip moves with stick-slips over the sample surface, the lateral force F_x manifests as a sawtooth-like function

Friction Force Microscopy, Fig. 5 Potential diagram of the Prandtl-Tomlinson model at zero temperature. The indicated net potential represents the sum of a fixed sinusoidal interaction potential and a parabolic spring potential with its minimum at the position x_M, which is moving with the velocity v from *left* to *right* (cf. Eq. 3). In (**a**), where $x_M \approx 0.66$ nm, the tip is trapped in a local minimum and is separated from the next minimum to the right by an energy barrier of height ΔE. For (**b**), the tip base (and with it the minimum of the parabolic potential) has moved to the *right* ($x_M \approx 0.8$ nm). As a consequence, the energy barrier has vanished, which causes the tip to "jump" to the next local minimum. At nonzero temperature, however, there is a finite probability that even in (**a**) the tip might jump over the energy barrier due to thermal activation (*dashed arrow*)

whereas the *friction force* F_{friction} is defined as the averaged lateral force $\langle F_x \rangle$.

Within this model, the point-like tip represents the average of the actual tip-sample contact or single-asperity contact, which might include hundreds of atoms. Alternatively, the actual tip-sample contact can also be treated as a system consisting of many individual atomically sharp tips interacting through springs, which leads to more complex models. A prominent example is the model proposed by Frenkel and Kotorova [10], which is based on chains of elastically coupled atoms exposed to a periodic potential. However, here the discussion will be restricted to the simple model introduced above, which has been proven to successfully describe the tip motion for many materials.

If the sliding velocities are low, analytical solutions of Eq. 2 can be derived with the assumption that the tip is always in its stable equilibrium position, which corresponds to the actual minimum of its total energy:

$$E_{\text{tot}} = \frac{1}{2} c_x (x_t - x_M)^2 + V_{\text{int}}(x_t). \qquad (3)$$

For better clarity, the corresponding energy is plotted in Fig. 5 for two positions x_M and a sinusoidal interaction potential. In Fig. 5a, the tip is trapped in a local energy minimum. An energy barrier of height ΔE prevents the tip from reaching the next energy minimum to the right. Since the tip base M moves along the x-direction, the energy barrier diminishes with time until the local minimum vanishes at a certain position $x_M = x_{M,\text{jump}}$. As a result, the tip "jumps" to the next local minimum where it is trapped again. This situation is sketched in Fig. 5b. The "jump height," i.e., the maximum force due to spring tension just before the "slip" event occurs (cf. Fig. 4c), is a direct function of the tip-sample interaction potential V_{int}, the spring constant c_x, and the lattice constant a. Due to the periodicity of the interaction potential, this "stick" and "slip" mechanism repeats as long as the support M is scanned over the sample surface. For finite temperatures, it has to be considered that the tip might sometimes jump thermally activated over a nonvanishing potential barrier ΔE to reach the next local minimum. This case will be discussed later.

For further analysis, the two conditions for a local minimum ($\partial E_{\text{tot}}/\partial x_t = 0$ and $\partial^2 E_{\text{tot}}/\partial x_t^2 > 0$) must be considered. Then the path of the tip $x_t(x_M)$ can be determined from the solution of the equation

$$c_x(x_M - x_t) = \frac{\partial V_{\text{int}}(x_t)}{\partial x_t}. \tag{4}$$

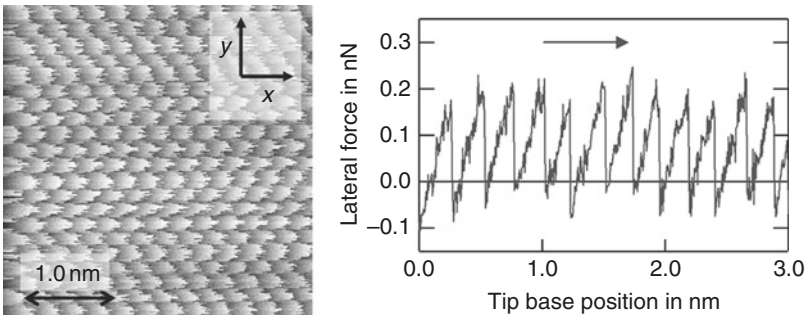
For a stiff spring, there is only one solution for all x_M, resulting in a continuous tip movement and vanishing friction, since the averaged lateral force $\langle F_x \rangle$ is zero. However, the tip movement changes dramatically if the condition

$$c_x < -\left[\frac{\partial^2 V_{\text{int}}}{\partial x_t^2}\right]_{\min} \tag{5}$$

is fulfilled. Now, the tip moves discontinuously in a "stick-slip"-type motion over the sample surface, jumping from one potential minimum to another. This specific movement of the tip results in a sawtooth-like function for the lateral force F_x (see Fig. 3c). Since the averaged lateral force $\langle F_x \rangle$ is nonzero in this case, a finite friction force F_{friction} is necessary to move the body M in x-direction.

In fact, it is exactly this behavior that frequently occurs in atomic-scale friction force microscopy experiments. Observed first by Mate et al. [1] for graphite(0001), experimentalists found atomic-scale stick-slip motion on many different materials such as mica, NaF, TeS_2, KBr, MoS_2, $MoTe_2$, as well as metal surfaces like Cu and Au. Figure 6 shows an example of stick-slip friction on highly oriented pyrolytic graphite (HOPG).

A complete transition from stick-slip to pure sliding was reported by Socoliuc et al. [11] for the NaCl(001) surface. Depending on the actual loading force of the tip, the measured lateral forces changed from a sawtooth-like shape to a continuous curve where forward and backward forces overlap. As a consequence, there is no hysteresis, and the frictional force reduces to ultralow values as expected from the above-discussed model. Assuming a simple sinusoidal potential of the form



$$V_{\text{int}} = -\frac{E_0}{2}\cos\left(\frac{2\pi}{a}x_t\right) \tag{6}$$

to describe the effective tip-sample interaction, the variation of the loading force can be inherently considered by the amplitude E_0. Inserting this potential into condition Eq. 5, it is useful to define the parameter

$$\eta = \frac{2\pi^2 E_0}{c_x a^2}. \tag{7}$$

If $\eta > 1$, condition Eq. 5 is fulfilled and stick-slip occurs. Continuous sliding and no dissipation are observed for all $\eta \leq 1$.

So far, only the jump of the tip into the immediate neighboring potential minimum was considered. However, larger slips into the next but one minimum are also possible. Furthermore, there might be more than one minimum and maximum within one unit cell. In such a case, the stick-slip behavior depends on the actual loading force since

Friction Force Microscopy, Fig. 6 On the *left side*, the lateral force signal of an FFM scan on HOPG is shown (3 × 3 nm). On the *right side*, the graph shows a single lateral force trace from the scan where the expected stick-slip behavior is clearly seen by the sawtooth-type line profile. Measurements were done under ultrahigh vacuum conditions

F

this parameter influences the height of the interaction potential.

Since stick-slip movement has been identified as the underlying mechanism for atomic-scale friction, it would be of preeminent technological importance if strategies could be found that allow to prevent or suppress this effect. It has been known for several years that the actuation of the tip-sample contact by small oscillations reduces friction. A recent study by Socoliuc et al. [12] demonstrated elegantly the possible efficiency of such an approach on the atomic scale. In their experimental setup, a small oscillatory force was added to the normal force by an external electrostatic potential applied between cantilever and sample. If that oscillatory force was modulated with a frequency equivalent to one of the vertical resonance frequencies of the tip-sample contact, the stick-slip motion of the cantilever and thus friction itself could be reproducibly switched on or off.

The original Prandtl-Tomlinson model considered only the one-dimensional movement of a tip along the x-direction. As real surfaces are two-dimensional, any somehow realistic model has to include at least the x-y-periodicity of the crystalline lattice. A two-dimensional extension of the Prandtl-Tomlinson model is discussed in detail in [13].

Thermal Activation and the Velocity Dependence of Friction

As shown above, the Prandtl-Tomlinson model and its extensions are quite successful in describing the qualitative overall behavior of atoms at nanometer-scale dry, single-asperity contacts in relative motion. This theory is based on the idea that the tip "slips" from one energy minimum to the next if the energy barrier ΔE between the current minimum and the next one vanishes because of the changes induced by the cantilever movement on the total energy Eq. 3. Since these jumps are typically much faster than the scan velocities applied in friction force microscopy, the frictional forces can be assumed to be nearly constant for scan velocities well below the slip velocities.

However, this simple picture does not hold at finite temperatures. As already indicated in Fig. 5, the tip might actually jump over a nonvanishing energy barrier ΔE due to thermal activation, leading to reduced frictional forces. Even though this effect has already been discussed in the original publication by Prandtl [8], it is still a topic of current research.

The velocity dependence on atomically flat surfaces has been measured by FFM on different surfaces; most authors report a logarithmic increase of the frictional force with velocity, which might be explained by a phenomenological "thermally activated Eyring model" [14].

Nonetheless, recent theoretical analyses of these phenomena are often based on a thermally activated Prandtl-Tomlinson model. A good starting point is the following "master equation" [15]:

$$\frac{dp(t)}{dt} = -f_0 \exp\left(-\frac{\Delta E(t)}{k_B T}\right) p(t), \qquad (8)$$

where $\Delta E(t)$ reflects the energy barrier at the time t and f_0 the resonance frequency of the tip in its actual minimum. The probability that the tip does *not jump* is denoted as $p(t)$.

For the analysis of experimental data, the variable t must be changed to the actual lateral force F_x [16]. After this transformation, one finds

$$\frac{dp(F_x)}{dF_x} = -\frac{f_0}{cxv_M} \exp\left(-\frac{\Delta E(F_x)}{k_B T}\right) p(F_x). \qquad (9)$$

The maximum of the probability for jumping can be obtained from the condition d^2p/dF_x^2 and leads to

$$\frac{\partial \Delta E}{\partial F_x} = -\frac{k_B T f_0}{c_x v_M} \exp\left(-\frac{\Delta E(t)}{k_B T}\right). \qquad (10)$$

This equation can be solved for an analytical description of ΔE. To do so, [15, 16] assumed a linear dependence of the energy barrier on F_x. However, most jumps occur very close to the

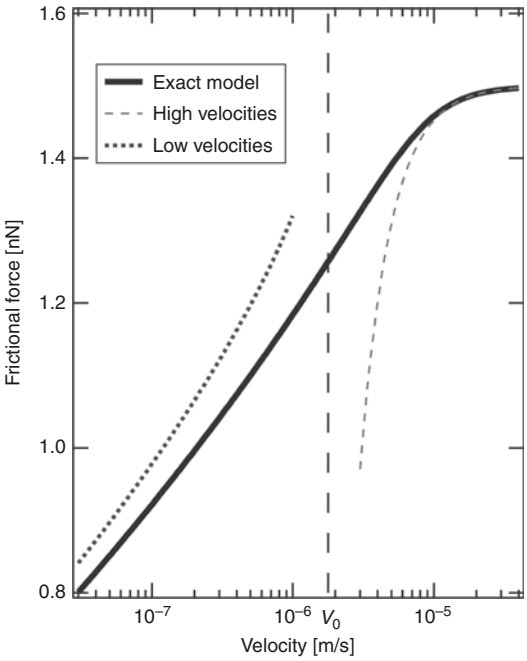
critical position, where the energy barrier is relatively small and more adequately described by a function of the type $\Delta E = \frac{1}{\beta}(F_{\max} - F_x)^{3/2}$, where $F_{\max}$ is the maximum possible lateral force occurring at zero temperature and β a constant. Introducing this relationship into Eq. 10, one gets an implicit function for the frictional force [17]:

$$\ln\left(\frac{v_0}{v_M}\right) - \frac{1}{2}\ln\left(1 - \frac{F_x}{F_{\max}}\right) = \frac{1}{\beta k_B T}(F_{\max} - F_x)^{3/2}. \quad (11)$$

Here, the parameter v_0 has been defined as

$$v_0 = \frac{2f_0\beta k_B T}{3c_x\sqrt{F_{\max}}} \quad (12)$$

and is usually referred to as the "critical velocity" [18].



The nature of v_0 as a "critical velocity" is best explored by approximating Eq. 11 for a "low-velocity" and a "high-velocity" regime relative to v_0. As shown in Ref. [18], this approach results in

$$F_{\text{low}}(v_M) = F_{\max} - \left(\beta k_B T \ln\left(\frac{v_0}{v_M}\right)\right)^{2/3} \quad (13)$$

for the low velocity limit and in

$$F_{\text{high}}(v_M) = F_{\max}\left(1 - \left(\frac{v_0}{v_M}\right)^2\right) \quad (14)$$

for the high velocity limit. Figure 7 compares the resulting force curves for the exact and approximated solutions using the parameters $T = 300$ K, $c_x = 1.0$ N/m, $f_0 = 25$ kHz, $\beta = 10^6$ N$^{3/2}$ J^{-1}, and $F_{\max} = 1.5$ nN, leading to a "critical velocity" of $v_0 = 1.78 \times 10^{-6}$ m/s. The solid line represents the exact solution of the implicit Eq. 11. Note that the frictional force increases logarithmically until it reaches a plateau for velocities higher than the critical velocity v_0. The logarithmic increase can be described by the approximation Eq. 13, while the dependence near the plateau is well reproduced by Eq. 14. Therefore, v_0 represents the velocity where the logarithmic dependence transitions toward the plateau value. The vertical dashed line in Fig. 7 labels the "critical velocity" v_0 and marks this border. A comparison of these theoretical curves to experimental force versus velocity curves for different loads on mica can be found in Ref. [17].

Friction Force Microscopy, Fig. 7 The frictional tip-sample force in the ramped creep model. The *solid line* represents the exact equation (Eq. 11). The *dotted* and *dashed lines* represent the approximations for *low* (Eq. 13) and *high* (Eq. 14) velocities, respectively

Future Research Directions

While it seems that the stick-slip processes of atomic friction are sufficiently well understood by now, the nature of the energy dissipation occurring during the "slip" event is still unclear. Usually it is assumed that phonons are excited, which eventually thermalize and thus dissipate the energy stored in the spring during the "stick" process. However, the exact underlying mechanisms are unclear. Recently several experiments

F

with the FFM have been conducted as an explicit function of the sample temperature, in order to investigate in detail the above-discussed effect of thermal activation of the friction processes. Those results point toward an even more complex situation, with a frictional enhancement effect at cryogenic temperatures [19].

Of further interest is the question, how friction depends on the true area of contact. Since the contact geometry of the tip apex is usually poorly defined, the alternative approach of nanoparticle manipulation has been developed. Here the FFM tip is used to slide well-defined nanoparticles along the surface while simultaneously measuring the lateral force signal, which in those cases is mainly due to the interfacial friction between the particle and the surface.

This allows to determine the true area dependence of friction from nano- to microscales [20].

Thus, in summary, the method of friction force microscopy has significantly advanced the understanding of microscopic friction mechanisms, which nurtures the hope that eventually the full control of frictional properties of moving surfaces in mechanical contact can be reached.

Friction-Reducing Sandfish Skin

Werner Baumgartner
Johannes Kepler University, Linz, Austria

Synonyms

Officinal skink; Sand skink; *Scincus officinalis*; *Scincus scincus*

Definition

The sandfish (*Scincus scincus*) is a lizard having the remarkable ability to move in desert sand in a swimming-like fashion over significant distances at remarkable velocities up to about 300 mm s^{-1} when submerged in sand. It is well adapted through evolution to live in loose aeolian sand by different morphological, physiological, and behavioral features. The skin of the sandfish exhibits a very small friction coefficient for sand and high abrasion resistance.

Biological Background

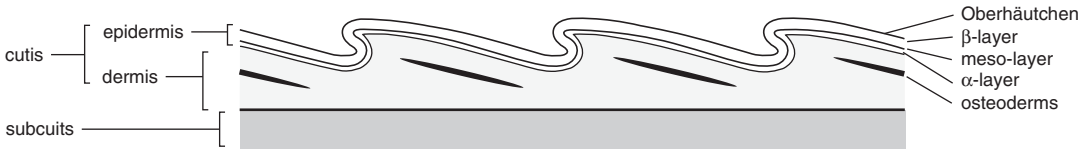
The scincid lizard genus *Scincus* [1], a group within the order Squamata, is distributed over the huge desert belt ranging from the African west coast (Morocco to Senegal) through the Sahara and the Arabian Peninsula into Jordan, Iraq, and SW Iran [1–3]. The sandfish *Scincus scincus* [1] (Fig. 1) is known for its ability to move through desert sand very fast, as if it were swimming [1–6]. This is in contrast to other desert reptiles which can bury themselves in the sand to hide from predators, but do not move in the sand over significant distances. It was found that the sandfish exhibits an in-plane meandering motion and reaches velocities of up to 300 mm s^{-1} [5, 6] when completely submerged in sand. It is currently under debate whether or not the limbs are used to propel the animal forward. Two groups did studies using different approaches and obtained different results. One group used nuclear magnetic resonance (NMR) imaging in sand [5] finding limb usage, whereas the second group used X-ray imaging in plastic granulate finding the sandfish to adpress the limbs onto the body during movement [6]. However, it might well be that both studies are right. First of all, different subspecies of *Scincus scincus* might be adapted to

Friction-Reducing Sandfish Skin, Fig. 1 An adult sandfish in the hand of the researcher. The snout-vent length (length of the animal from snout to anus) is about 120 mm

different sand types (grain size, friction coefficient, microstructure) resembling their origin from different deserts. Furthermore, the sandfish might have several different modes of locomotion, for example, fast flight from predators and normal, low energy-consuming movement. This has to be clarified in future studies.

Anyhow, the life underneath loose, aeolian sand requires morphological key adaptations, such as a shovel-shaped snout with the lower jaw wedged into the upper jaw, reduced ear openings and nostrils, a subquadrangular cross section of the body, and strongly developed limbs with fringed digits and toes. These adaptations are described by early authors [1–3]. However, other adaptations to life underneath the sharp-edged sand are subject to current research. Besides the locomotion [5, 6], the sensory system, and the breathing mechanisms [7], the integument of the sandfish, especially the scales, are of interest and have been examined in recent years. The latter cover the entire body in an imbricate manner, typical for Squamata [8].

Generally, the integument (from Latin *integere* = to cover) is the organ system that covers the body and protects it from water loss and/or damage. The integument consists of the skin and its derivatives like scales, feathers, hairs, and nails and has a variety of functions: besides mechanical protection and prevention of water loss from lower tissue layers, it serves also for temperature regulation and as a transmitter for tactile stimuli. The integument of lizards (Fig. 2) consists of several layers, the most important being the epidermis, the dermis, and the subcutis [8]. The subcutis is the connective tissue that covers the underlying muscle layers. The dermis consists of connective tissue which, in the case of some reptiles like the sandfish, contains bony plates; these plates are called *osteoderms* and resemble the shape of the covering scales. The epidermis is organized as scales and consists of an outer beta-layer mostly composed of beta-keratin, an inner alpha-layer built up by alpha-keratin, and a meso-layer separating the former two layers. The beta-layer is covered by the so-called Oberhäutchen which often exhibits particular micro- and nanostructures (microdermatoglyphics). Sandfishes, like all other squamates, renew their horny (keratinized) epidermis by periodic shedding (ecdysis). For *Scincus scincus* the ecdysis interval is of the order of 2–3 months.



Low Friction and Abrasion of Sandfish Scales

The integument and especially the scales of the sandfish exhibit some interesting properties. It was found that the friction between sand and sandfish scales is outstandingly low.

Generally, dry friction resists relative lateral motion of two solid surfaces in contact. The two regimes of dry friction are static friction between nonmoving surfaces and dynamic friction between moving surfaces. Coulomb friction [9] is an approximate model used to calculate the force of dry friction. Dynamic friction is governed by the equation:

$$F_f = \mu \cdot F_n \tag{1}$$

where F_f is the force exerted by friction, μ is the friction coefficient which is a property of the contacting materials, and F_n is the normal force exerted between the surfaces. The direction of the frictional force is opposite to the direction of motion.

Friction-Reducing Sandfish Skin, Fig. 2 Principle layered assembly of lizard skin

Friction-Reducing Sandfish Skin, Table 1 Values for friction angle Θ and friction coefficient μ for sand on different materials. *Eumeces schneideri*, the Berber skink, is a close relative of the sandfish that does not perform sand swimming. Values from [4, 10, 11] are mean values from at least 10 independent measurements; the standard deviation is below 1°

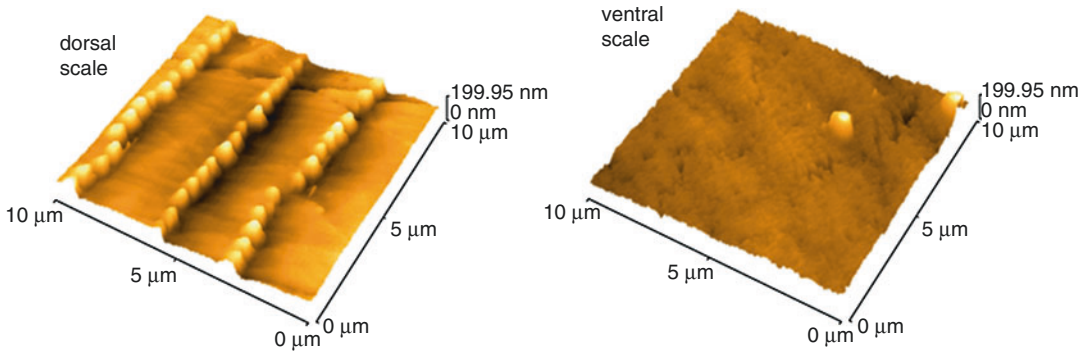
Material	Θ	μ
Sandfish scales	21°	0.38
Eumeces scales	35°	0.70
Glass	28°	0.53
Polished steel	25°	0.46
Teflon	36°	0.73
Nylon	30°	0.57

For the sandfish, the friction was quantified by determination of the so-called friction angle Θ, i.e., the lead angle of an inclined plane covered with the material under investigation at which loose sand starts to slide off. The friction angle is related to the friction coefficient μ as

$$\mu = \tan(\Theta) \tag{2}$$

As shown in Table 1, the friction angle and thus also the friction coefficient for the matching of sand and different materials are lowest for the sandfish scales when compared with technical materials or with the scales of other reptiles like a closely related but not sand-swimming lizard, the Schneider's skink (or Berber skink) *Eumeces schneideri*. Generally it was found that sand-swimming lizards show low friction similar to the sandfish, while non-sand-swimming species have significantly higher friction [12].

Determination of the friction angle is a very simple method for determining the friction of granular media on a native surface. However, one should keep in mind that a certain degree of rolling of the granules may take place leading to an underestimate of the friction coefficient. However, if one is interested in a comparison of the friction on different materials, this effect is negligible.



Hand in hand with the low friction, the scales show an impressive resistance to abrasion by sand. Hardly any engineering material can withstand abrasion through repeated interaction with fine quartz sand. However, the sandfish scales outperform Teflon, glass, and even steel in terms of abrasion resistance. This was measured by quantifying the increase of surface roughness after mild sand blasting [10, 11]. For this sand was poured through a funnel from above on the animal or material samples. The height was adjusted to 100–300 mm. While for glass some seconds of this sand blasting are sufficient to scratch the surface, the sandfish scales show no detectable scratches even after 60 min of this treatment.

This is consistent with the observation that the sandfish normally appears to have a gleaming surface. This is remarkable bearing in mind that the animal moves through sharp-edged sand at high velocities.

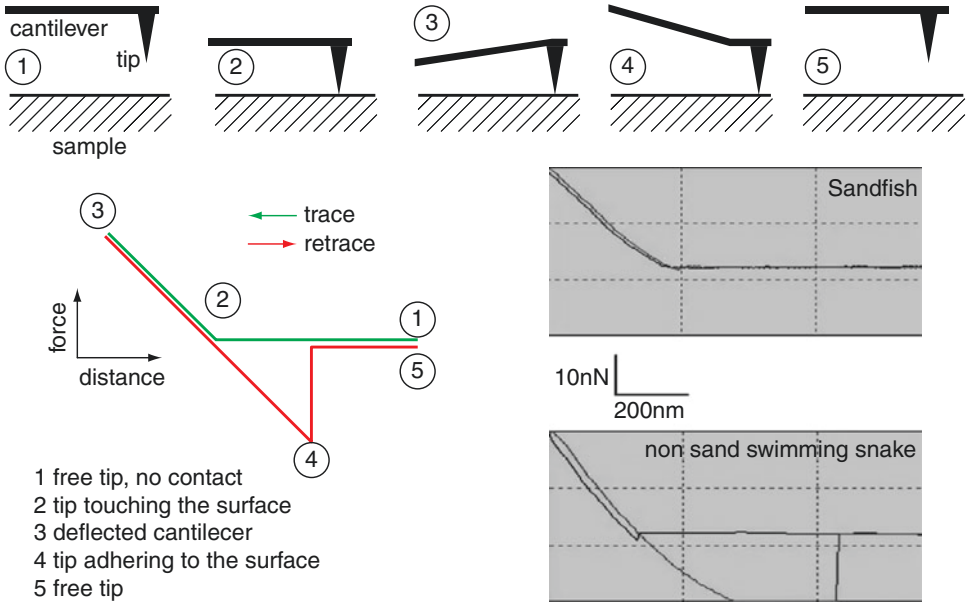
Structural Properties of Sandfish Scales

Often, the outstanding properties of biological surfaces can be understood based on their micro- or nanostructure or hierarchical surface structuring. Indeed scanning electron microscopy (SEM) as well as atomic force microscopy (AFM [13]) revealed that all dorsal scales have an interesting topography, namely, sawtooth-shaped striae with a comblike edge [4, 12] (Fig. 3). The edges are separated by ~5 μm and the step height is ~250 nm. The comblike arranged features have dimensions of approximately 50–200 nm. Although interesting, these structures were found to have nothing to do with the low friction and the abrasion resistance of the sandfish scales. These structures are less pronounced on the lateral scales and are completely absent from the ventral scales where the surface is completely flat. However, the resistance against abrasion and the friction parameters were found to be about identical on the dorsal and on the ventral scales.

Furthermore, the sawtooth-shaped striae were also found on all other Scincidae [12] investigated so far, such as the before-mentioned *Eumeces schneideri.* These animals, however, do not show the low-friction behavior like the sandfish. This indicates that the surface structure (i.e., the topography) is not responsible for the remarkable

Friction-Reducing Sandfish Skin, Fig. 3 AFM image of a dorsal and a ventral sandfish scale. Notably the dorsal scales exhibit sawtooth-shaped striae with a comblike edge while the ventral scales are mainly flat without micro- or nano-ornamentation

tribological properties but may be important for other aspects of living in the desert sand.



Several functional biomaterials like wood, arthropod cuticle, and bones reveal interesting material properties by structural anisotropies, for example, by fiber enforcement [9]. However, transmission electron microscopy and force modulation AFM [13] allow one to search for material inhomogeneities. Such studies show that the scales are more or less mechanically uniform and do not exhibit detectable anisotropies with respect to either stiffness or elastic modulus [4].

Mechanical Properties of Sandfish Scales

The stiffness and linked to this the reduced (or effective) elastic modulus can be determined by nanoindentation [13, 14]. An indenter of well-characterized shape (typically a pyramid) is pressed at known force into the surface and the total and sustaining (i.e., plastic) deformations are determined. Based on the knowledge of the indenter shape and area, load-displacement curves allow the determination of the resilience, the elastic modulus (Young's modulus) [4, 13, 14], and the hardness of the scale material of the sand skink. The elastic recovery of sandfish scales is comparable to values of other reptiles and at 70+ % exceeds standard technical materials like aluminum alloy (40 %) and steel (X6CrNi MoTi17-12-2, 44 %) [4]. The reduced elastic modulus values measured for the sandfish scale are on the order of about 0.5–1 GPa [14]. This is significantly higher than the elastic modulus of reptile scales of non-sand-swimming reptiles, but only a fraction of the reduced elastic modulus of stainless steel [4, 14]. The tensile strength is comparable to aluminum alloy.

In order to investigate the adhesive properties of sandfish scales, so-called force-distance measurements [4, 10–12, 14] were performed (Fig. 4). In this mode of operation, an AFM tip is first approached ("trace") and then retracted ("retrace") from a probe surface in a cyclic movement at a fixed lateral position. Attractive forces between tip and probe are evident from the jump-on of the tip to the probe at short distances during trace ("pull on") and from the sticking of the tip to the probe, followed by a concomitant jump-off at a critical force ("pull off"), during retrace. For a good overview of the nature of forces occurring between tip and probe, see [15].

As shown in the recorded force-distance curves [4] (Fig. 4), no interaction between the AFM tip and the sandfish scales was observed. Typically, on other surfaces, an interaction between the surface and the tip due to, e.g., van der Waals forces or electrostatic interaction takes place which yields a characteristic discontinuity (jump) in the force-distance data [13, 14]. However, this was never observed when measuring sandfish scales [4]. The interaction force, if present, cannot be distinguished from noise. This is remarkable and

Friction-Reducing Sandfish Skin, Fig. 4 Schematic of force-distance cycles and example of force-distance cycles obtained for sandfish scales and scales of the non-sand-swimming snake *Pantherophis guttatus*

in contrast to force-distance measurements on scales from related but not sand-swimming reptiles where clear adhesion-evoked jumps in the data can be observed [4]. The tips used consisted of silicon or silicon nitride, both showing the same results, resembling pretty much the properties of quartz sand. Thus, a specific property of sandfish skin is the missing adhesion with silicates, which appears to be, at least in part, responsible for the low friction of the lizard in the desert sand. Due to the nanometer-sized tip radius, it is reasonable to say that the surface structures observed, i.e., the striae and the comblike edges, are not responsible for the effect. The absence of any attractive force between tip and scale was observed on ventral, lateral, and dorsal scales taken from different animals.

Chemical Properties of Sandfish Scales

The chemical composition of sandfish scales is purely organic, lacking hard inorganic material like silicates or lime [4]. This was found using energy-dispersive X-ray spectroscopy (EDX). To stimulate the emission of characteristic X-rays from a specimen, a high-energy beam of electrons is focused onto the sample. The resulting X-rays, i.e., the *bremsstrahlung*, can be analyzed with respect to the wave lengths allowing the clarification of the atomic composition. The dominant detectable elements, i.e., the elements with atomic mass above beryllium, were carbon (83.5 $\pm$ 2 %), nitrogen (9.1 $\pm$ 1 %), oxygen (5.9 $\pm$ 1 %), and, interestingly, a rather high amount of sulfur (1.5 $\pm$ 0.3 %). The sulfur is most likely involved in a high degree of molecular cross-linkage via disulfide bonds between or within proteins. Disulfide bonds in proteins are formed between the thiol groups of cysteine residues. The other sulfur-containing amino acid, methionine, cannot form disulfide bonds. The disulfide bond stabilizes the folded form of a protein in several ways:

(i) It holds two parts of the protein covalently together, biasing the protein toward the folded topology.
(ii) The disulfide bond may form a hydrophobic core of the folded protein, i.e., local hydrophobic residues may aggregate around the disulfide bond through hydrophobic interactions.

(iii) The abovementioned two effects allow the disulfide bond to link segments of the protein chain, lowering the effective local concentration of water molecules. Water molecules attack hydrogen bonds and tend to break up some secondary structure. Thus, disulfide bonds stabilize secondary structure in its vicinity.

Thus, it is most likely that the higher sulfur content is responsible for the significantly higher stiffness of sandfish scales compared to the scales of non-sand-swimming reptiles.

The proteins are mainly β-keratins and small amounts of α-keratins and matrix proteins which are typically present in reptile scales in small amounts [8, 11, 12]. This was shown by SDS-PAGE and Western blotting. Furthermore, one corresponding gene has been sequenced recently [12]. Generally, keratin refers to a family of fibrous proteins which are a key structural material making up rigid and insoluble strong unmineralized tissues found throughout the vertebrates. The fibers, with diameters of 7–15 nm, can form networks and meshes by intermolecular interactions thereby yielding the mechanical properties. An interesting difference between keratins in the scales of sandfish and other non-sand-swimming lizards is the high glycosylation of the sandfish keratins. While non-sand-swimming reptiles exhibit only small traces of sugar side chains of the proteins, the β-keratins of the sandfish are highly and complex glycosylated [12, 14]. Sugar side chains are an extremely flexible, complex, and powerful chemical tool in protein biology used to modify the properties of proteins or protein complexes. It is evident that the sugars play an important role in the reduction of friction as sandfish scales after sugar removal show high friction toward sand [4]. It was shown that these glycans are sufficient to reduce the friction of sand to different materials like glass [11] or different polymers [14]. How exactly the sugars perform this task is still enigmatic. The exact structure, composition, and function of this sugar side chains in the sandfish scales have to be determined in future studies.

Future Directions for Research

The sandfish and closely related lizards appear to be an interesting object of research with respect to many different aspects. Of course the low friction and the high abrasion resistance of the scales are highly interesting. Detailed studies on the exact chemical composition and the 3D structure, especially of the sugar side chains of the β-keratins, might allow the development of low friction and abrasion-resistant technical surfaces. Besides this, the function of the sawtooth-shaped striae on the dorsal scales should be investigated. However, the life in aeolian sand might even hide further secrets which are worth being discovered.

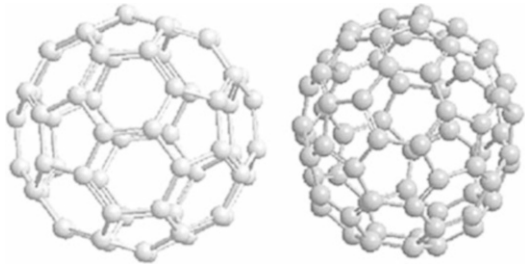
Fullerenes for Drug Delivery

Robert D. Bolskar
TDA Research, Inc., Wheat Ridge, CO, USA

Synonyms



Buckminsterfullerene; C_{60}; Metallofullerene; Nanoscale drug vector

Definition

Fullerenes are nanomolecular carbon cages that can serve as platforms for the delivery of drugs and imaging agents. There are several functional modes in which fullerenes can act as drug delivery nanomaterials. Fullerenes can have a direct bioactivity such as antioxidant activity when surface functionalized. Fullerenes can also serve as drug vectors or drug delivery scaffolds with non-covalent linkages or with covalent linkages between the fullerene and a bioactive moiety. Endohedral fullerenes are a subclass of fullerenes that contain atom(s) in their interior spaces. Endohedral fullerenes offer a robust shell that can prevent contact between the body and the entrapped atom(s), serving, for example, in contrast enhancement for magnetic resonance imaging and as a carrier for radionuclides.

Brief Introduction to Fullerenes and Endohedral Fullerenes

Fullerenes, the third allotrope of carbon after diamond and graphite, are closed-cage carbon molecules initially discovered in the gas phase during investigations of the laser desorption of graphite [1]. Fullerenes are the simplest among the newer forms of nanocarbons, as fullerenes are molecular while the other nanocarbons (including single-walled carbon nanotubes, multi-walled carbon nanotubes, carbon nanohorns, carbon onions, graphene, etc.) are decidedly not. C_{60} is the archetype fullerene of the fullerene family with its icosahedral symmetry and all-carbon cage in the shape of a soccer ball (Fig. 1). Fullerenes with larger cages, including C_{70}, C_{74}, C_{76}, C_{78}, C_{84}, etc., are termed "higher fullerenes." The fullerene cages are comprised of hexagons and pentagons, with alternating carbon–carbon bonds of double bond character (at the hexagon–hexagon junctions) and of single bond character (at the hexagon–pentagon junctions). Most known fullerene structures obey the so-called isolated pentagon rule (IPR) in which fullerenes avoid having directly adjacent pentagons to minimize cage strain. Thus, fullerenes of certain symmetries

Fullerenes for Drug Delivery, Fig. 1 Ball and stick depictions of *Ih*-C_{60} (*left*) and *D5h*-C_{70} (*right*) structures

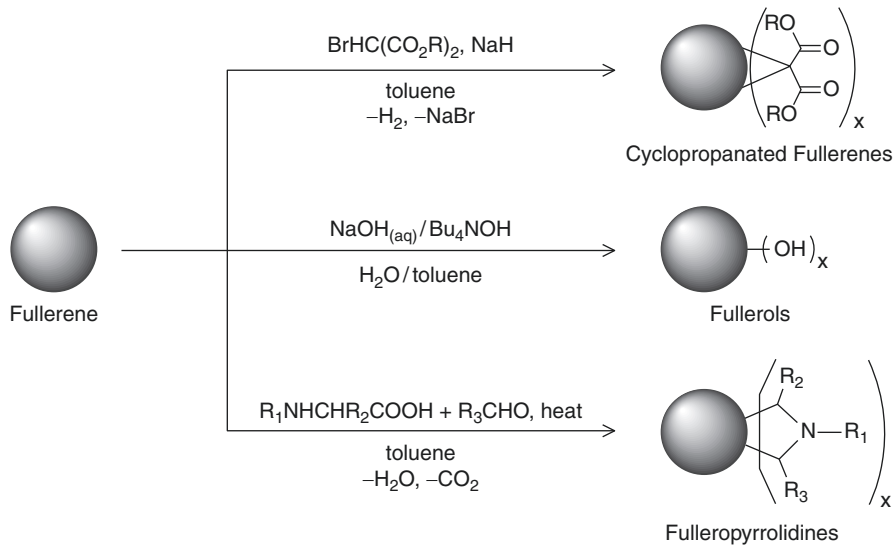
are more stable and thus more prevalent than others. The larger the fullerene cage, the greater number of possible structural isomers there are.

Several processes are now used to produce fullerenes, including the direct current arc discharge (arcing) of graphite in an inert, reduced pressure atmosphere and the combustion of hydrocarbons in sooting flames. The arc process can be used to produce fullerenes on multigram scales, while the combustion process is capable of generating far larger quantities; for example, Frontier Carbon Corporation of Japan has recently scaled up the combustion-based production of fullerenes to multiton quantities. The fullerenes are produced as mixture of the different C_{2n} combined with non-fullerene carbonaceous soot. C_{60} is the dominant fullerene product, with smaller amounts of higher fullerenes produced. Many of the fullerenes are soluble in organic solvents, particularly in methylated and halogenated arenes. The soluble C_{2n} fullerenes like C_{60} and C_{70} have large HOMO-LUMO gaps, reflective of their stability. Solvent extraction is commonly used to retrieve fullerenes from the as-produced soot matrix, and different soluble C_{2n} cages and their isomers can be separated by chromatography. There are certain fullerenes with small-HOMO-LUMO gaps that cause them to be insoluble as neutral species, including D_{3h}-C_{74} and I_h-C_{80}. Interestingly, insoluble C_{2n} fullerenes with $2n > 100$ comprise a large fraction of fullerenic combustion-produced soot. Fullerenes are generally electronegative in nature due to the effects their curved surfaces have on their electronic structures. Fullerene electronegativity has a dominating influence on their chemical reactivities. Fullerenes are redox active, with multiple reduced (negatively charged) states generally more accessible than oxidized (positively charged) states.

Besides the empty fullerenes of different cage sizes and symmetries, endohedral fullerenes comprise another major structural variant. Fullerenes, being pseudo-spherical closed-cage molecules, have a hollow interior space protected from the exterior. C_{60}, the archetypical fullerene, is about 0.7 nm in diameter, so its interior space is large enough to hold up to several atoms. Endohedral fullerenes with metals inside – the "metallofullerenes" – are the most commonly studied endohedrals [2]. Metallofullerene formulae are denoted by "M@C_{2n}," with M the metal, C_{2n} the fullerene cage, and the @ symbol indicating the encapsulation of M. Metallofullerenes are commonly produced by the carbon arc method using graphite rods doped with metals or metal oxides of Sc, Y, La, and the lanthanide series (and some actinide) elements. The metallofullerene arc product contains a mixture of empty and endohedral fullerene cages, much of which can be solvent extracted from the soot. Compared to empty fullerenes, endohedral fullerenes are produced in much smaller amounts. Whether soluble or insoluble, metallofullerenes need to be separated from the empty fullerenes having similar properties. The soluble metallofullerenes, such as M@C_{82}, can be separated from soluble C_{2n} with chromatography. The insoluble M@C_{2n} such as M@C_{60}, M@C_{70}, and M@C_{74} require different processes for access. In general, the soluble M@C_{82} species are less prevalent than the combined insoluble M@C_{2n} species. The properties, structures, and reactivities of numerous mono-metal metallofullerenes such as La@C_{82} and dimetallofullerenes such as La_2@C_{80} have been well characterized [2]. In general, the highly electropositive endohedral metal atom(s) donate electrons to the electronegative fullerene cages to form metal cations entrapped in a fullerene anion (fulleride). Lanthanides in metallofullerenes are almost always in the M^{3+} state (with several exceptions). The multi-electron donation to the fullerene cage is the reason in many cases for

why metallofullerenes have properties that are significantly different from their empty fullerene counterparts.

Some years after metallofullerenes were discovered, a new metallofullerene variant was discovered – the "trimetallic nitride templated" metallofullerenes or "TNTs" (also termed metallic nitride endohedral metallofullerenes, clusterfullerenes, trimetaspheres, etc.) [2]. These metallofullerenes contain a central nitrogen atom (nitride) bonded to three metals ions with a general formula of $M_3N@C_{2n}$. $Sc_3N@C_{80}$ was the first of its type reported, and many other $M_3N@C_{2n}$ species have since been produced and isolated with lanthanides. The electron transfer from the endohedral nitride cluster stabilizes their fullerene cages. TNTs are produced by incorporating a nitrogen source (including N_2, NH_3, cyanamide or guanidinium salts) into the process of arcing metal-doped graphite rods. The TNTs are soluble in organic solvents (similar to the $M@C_{82}$ metallofullerenes), and they can be extracted and chromatographically purified. Improvements have been found that increase the relative fraction of TNT metallofullerenes to empty fullerenes produced by the arc synthesis. Mixed-metal TNT clusters have also been produced and isolated, as well as structures with non-IPR cages.



The diversity of fullerene structures is expanding through discoveries of new cages and different endohedral contents, and exceptions to fullerene structural "rules" are becoming more prevalent. Many new empty C_{2n} and endohedrals have been isolated in minute quantities from solvent extracts of the mixed products of arc production, including non-IPR isomers and fullerenes beyond those with standard C_{2n}-only cages. Examples include $C_{2n}Cl_x$ derivatives (sub-C_{60} cages such as $C_{50}Cl_{10}$ and non-IPR cages intermediate to standard fullerenes, i.e., $C_{64}Cl_4$, $C_{72}Cl_4$, etc. recovered in small quantities via in situ chlorination reactions) and endohedrals with novel clusters ($La_2@C_{72}$, $Sc_2@C_{66}$, $Sc_3N@C_{68}$, $M_2C_2@C_{2n}$, $Sc_4C_2@C_{80}$, $M_4O_2@C_{80}$, $Sc_2(\mu_2\text{-}O)@C_{82}$, $M_2S@C_{2n}$, $Sc_3NC@C_{80}$, etc.).

Alternatively, certain metal and nonmetal endohedral fullerenes can be produced by non-arc methods. $Li@C_{60}$, an endohedral produced by ion implantation of C_{60}, was recently isolated and characterized (as a monocation salt with $SbCl_6^-$). Nonmetal endohedrals include noble gas endohedrals (produced in small quantities under very high pressures), $N@C_{2n}$, and fullerenes containing small molecules such as H_2 and H_2O that are produced via open-cage derivatives into which small molecules are inserted, followed by synthetic cage closure.

Fullerene Derivatives

A minimum level of derivatization is required to use fullerenes in drug delivery applications due to their all-carbon surfaces. Native, unmodified fullerenes are soluble in organic solvents (particularly aromatic solvents such as benzene, toluene, halogenated arenes, etc.) but they are essentially insoluble in water, the solvent of life. Soon after they were first produced in macroscopic amounts, a rich chemistry for fullerene functionalization evolved [1, 3]. Given their closed cage structures, fullerene derivatization chemistry is naturally dominated by addition reactions, and their chemistry is strongly influenced by their electronegative natures. Prominent, useful derivatization methods include polyaddition of free radicals, nucleophilic attack (attachment of anionic and neutral nucleophiles), and abundant styles of cycloaddition reactions across the fullerene cage carbon–carbon double bonds. Derivatizations adding more than one group to the fullerene surface give mixtures of isomeric products, which can be separated using chromatography.

The derivatizations can give fullerenes increased solubility in organic media or in aqueous media depending on the choice of attached functionality. Among the many water-soluble fullerene derivatives that can be synthesized [4], three main synthetic approaches have shown to be particularly valuable (Fig. 2). These three are cyclopropanation (in various forms, but particularly the Bingel–Hirsch reaction of halomalonates and base with fullerenes in organic solution, to form methanofullerenes), polyhydroxylation

Fullerenes for Drug Delivery, Fig. 2 Three commonly used fullerene derivatization reactions

(synthesis of fullerols, typically using biphasic organic/caustic media), and the cycloaddition of azomethine ylides (1,3 dipolar cycloaddition to form fulleropyrrolidines), also known as the Prato reaction.

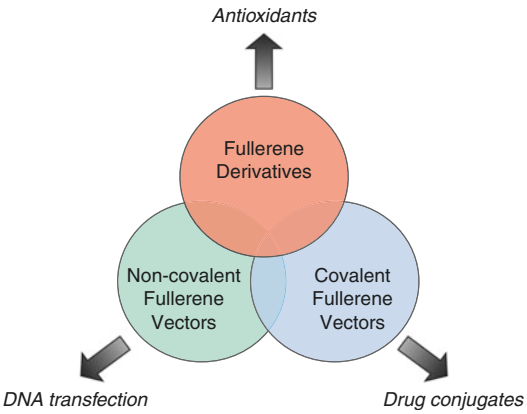
Typical solubilities for hydrophilic fullerene derivatives in water range up to ca. 100 mg C_{60} mL^{-1}. Several uncharged derivatives were synthesized having much higher aqueous solubilities (for example, malonodiserinolamide C_{60} derivatives with >240 mg C_{60} mL^{-1} and β-cyclodextrin-appended C_{60} derivatives with ca. 350 mg mL^{-1}). Water-soluble fullerene derivatives are well known to spontaneously aggregate intermolecularly. Their nanocluster aggregates have hydrodynamic diameters ranging from tens to hundreds of nm (typically with pH dependence) as determined with dynamic light scattering and other techniques.

Separately, underivatized fullerenes can be formulated in water as dispersions, suspensions, and colloidal "nanoparticle clusters," etc.; some are prepared by ultrasonication or precipitation of native C_{60} powders. Non-derivatized fullerenes have also been coaxed into water via non-covalent association with cyclodextrins and related species. With the emphasis on drug applications of functionalized derivatives, these are not generally discussed in this entry.

Drug Delivery with Nanomaterials and Fullerenes

Drug delivery with new nanotechnologies is poised to make significant improvements to human health care in the areas of selective, targeted imaging and individualized therapies [5]. The properties of nanomaterials, including their sizes, shapes, surfaces, and material compositions are well recognized to offer potentially valuable advances over traditional drug delivery. In particular, the imaging and treatment of primary and malignant cancers would benefit greatly from an improved specific drug targeting paradigm. Major goals of selective targeting of a drug agent are to increase effectiveness of the agent while decreasing nonspecific side effects, notably for the chemotherapeutics used in cancer treatment. For example, the chemotherapeutic action of the anticancer drug paclitaxel derives from its inhibition of cellular mitosis. However, the cytotoxic effects of this drug do not discriminate between cancerous cells and noncancerous

cells, which causes deleterious side effects when systemically administered. Additionally, efficient administration and circulatory delivery of otherwise hydrophobic drugs like paclitaxel is problematic. Drug delivery with carefully designed nanovectors can help to overcome poor solubility, side effects, and circulation half-life limitations of the drug molecules, along with lowering the required dosages and deliver more of the drug at the disease site (i.e., tumors, specific organs, etc.).



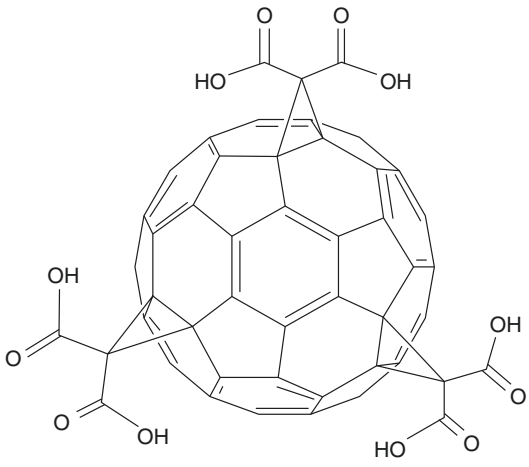
With their all-carbon surfaces, functionalization or derivatization is necessary to endow fullerenes with properties such as water solubility and bioavailability that are essential for their use in biomedicine. When suitably derivatized for water solubility, fullerenes have been shown to be relatively nontoxic both in vitro and in vivo, with toxicity generally decreasing in concert with increased surface functionalization. Biodistribution and circulation characteristics are naturally strongly affected by the composition of the derivative groups. Hydrophobic (underivatized) surface sections do remain on some fullerene derivatives, which may benefit cell membrane crossing of the fullerene with its drug payload. The attached functional groups also serve as a malleable interface for tuning the desired drug delivery and/or action.

Fullerenes as a central vector for drug delivery have valuable advantages over many of the other types of nanoparticulate and nanocrystalline systems being investigated for use in biomedicine. A distinct advantage is that in comparison to typical nanoparticulate materials, derivatized fullerenes have a reproducible nature. This is because the compositions and surface chemistries of almost all nanocrystalline and nanoparticulate materials are not precisely reproducible from particle to particle and preparation to preparation down to the level of individual atoms, as fullerenes and fullerene derivatives (with their molecular nature) are. Their relatively small size, which is regulated by derivatization, is another important advantage for in vivo applications. Fullerenes, even when derivatized, are smaller than many of the nanoparticulate and nanocrystalline systems, some of which are many tens or hundreds of nanometers in diameter. Furthermore, the sizes and shapes of fullerene derivative aggregates, when they do form in aqueous media, are reversible and fluxional in ways not possible with hard nanocrystals and nanoparticles. Fullerenes are also highly versatile in terms of cage structure, surface functionalization, and endohedral contents, making them a well-defined but flexible chemical scaffolding. These properties and advantages enable different styles of medicinal chemistry and drug delivery with fullerenes [6].

F

Exohedral Fullerene Derivatives for Biomedicine and Drug Delivery

There are at least three functional modes by which fullerene derivatives can be employed as drug delivery nanomaterials. First, the fullerene derivative alone can serve as a biomedically active agent. Secondly, the fullerene derivative can serve as a non-covalent carrier of bioactive drug species. Thirdly, the initial fullerene derivative can be secondarily derivatized via covalent attachment of drug molecule. Note that there can be overlap among these three categories with some examples of fullerene derivatives and their drug applications; the delineations are based on structure as well as function (Fig. 3). Prominent examples in these three categories of this currently young but actively developing field are discussed below.



Fullerenes for Drug Delivery, Fig. 3 The three major categories of drug delivery with fullerene derivatives

Surface-Derivatized Fullerenes with Drug Applications

This category of fullerene drug nanomaterial includes those functionalized derivatives that have a biologic action without deliberate external non-covalent association or covalent attachment of drug molecules or drug agents. These actions are derived from special physical properties inherent to fullerenes such as their size, electronegativity, reactivity, photochemistry, etc.

A highly promising biomedical application of fullerene derivatives is their use as antioxidants [7]. Fullerenes and their derivatives are electronegative and readily react with free radicals. With these properties, fullerenes efficiently scavenge the damaging reactive oxygen species (ROS) that are the targets of antioxidants. These include the superoxide radical anion $O_2^{\bullet -}$, the hydroxyl radical $HO^{\bullet}$, and singlet oxygen $^1O_2$, which are produced in settings of oxidative stress and are implicated in inflammation, cell death, neurodegeneration, ischemia/reperfusion, and other disease states.

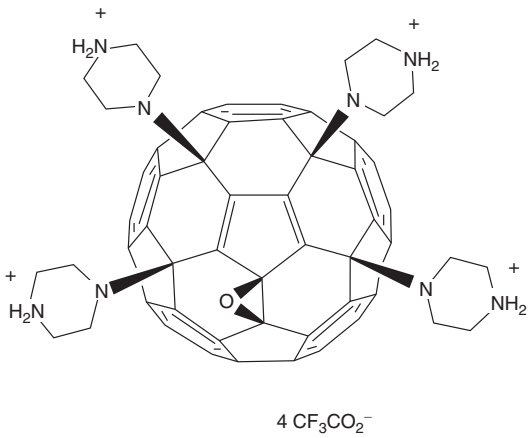
The most important antioxidant fullerene derivative studied so far is the water-soluble tris-malonate C_{60} derivative $C_{60}[C(COOH)_2]_3$ with C_3 symmetry, commonly termed "C_3" (Fig. 4). This carboxylated C_{60} derivative has been shown to have neuroprotective and life-extending effects in vivo. C_3 afforded life-extending effects in mutant rats having a type of model amyotrophic lateral sclerosis (ALS). C_3 acts as a superoxide dismutase mimetic, serving to destroy superoxide not through stoichiometric scavenging, but through catalytic action. The carboxylated fullerene C_3 also exhibits neuroprotective properties in cell cultures and has beneficial effects when administered to animals bearing neurodegenerative disorders, including Parkinsonism.

Fullerenes for Drug Delivery, Fig. 4 Depiction of C_3–$C_{60}[C(COOH)_2]_3$, a water-soluble antioxidant fullerene derivative

Also under study as antioxidants are fullerene-malonate derivatives having different numbers and arrangements of attached carboxylate groups, fullerols, dendrimer-functionalized C_{60} with terminating carboxy groups, and polyalkylsulfonated fullerenes. Dendrimer-functionalized C_{60} derivatives have been proposed as antioxidants, typically with a singly attached dendrimeric group to minimize disruption of the fullerene cage pi-electrons. The dendro-fullerene termed "DF-1" having carboxy-terminated dendritic branches was evaluated as a radioprotector in live zebrafish embryos. DF-1 afforded similar protection against overall and organ-specific ionizing radiation damage as a clinically approved drug (amifostine) does, with improved action when DF-1 was administered prior to or immediately after the radiation exposure. Tests of DF-1 in live mice showed only modest radiation protection, however, and did not show selective radiation protection in normal cells versus tumor cells. Water-soluble hexasulfobutylated C_{60} derivatives have also been studied as free radical scavengers. Factors that can influence the antioxidant activity of fullerene derivatives include the composition of the functional groups, the positioning of these groups, and their intermolecular aggregation properties. Continued studies of water-soluble fullerene antioxidants are warranted due to the high therapeutic potential of these nanomaterials; so far, the carboxy derivative C_3 has shown the greatest antioxidant utility and neuroprotective effects.

The biologically relevant properties of $C_{60}(OH)_x$ fullerols have been the subject of numerous detailed studies. In one study, the antioxidant properties of fullerols were shown to be at

least partially a result of a binding interaction that blocks glutamate receptors. The radical scavenging ability of fullerols were indicated in studies that showed reduced acute toxicity of the chemotherapeutic doxorubicin (an anthracycline DNA-intercalating anticancer drug), showing potential for mitigating doxorubicin side effects and serving as a cardioprotective agent. $C_{60}(OH)_x$ fullerols also have been shown to have tumor-inhibitory effects via immunostimulation in live mice-bearing tumor models (including activation of T-cells and macrophages) [8]. The low cytotoxicity of the fullerols indicates that the antitumor effect is not the result of direct fullerol toxicity in the cancer cells. Fullerols were also reported to inhibit tumor metastasis in mice models of mammary cancer. Further research is warranted to examine the mechanism behind the antitumor action of fullerols.



Besides antioxidant radical scavenging, fullerenes and their derivatives also can act as ROS generators upon light irradiation, due to their high, long-lived triplet state yields upon light absorption. In particular, fullerenes are promising photosensitizing agents for photodynamic therapy (PDT), with their ability to produce singlet oxygen (Type I photochemical mechanism) as well as superoxide (Type II photochemical mechanism) [9]. In vitro studies with C_{60} derivatives confirmed they can serve as PDT agents for killing cancer and other cell types, particularly with cationic pyrrolidinium derivatives. The photochemical production of ROS by fullerene derivatives is also being investigated for the photodynamic inactivation of viruses including enveloped viruses, influenza, and HIV protease, as well as in antimicrobial applications.

Fullerene Derivatives with Non-covalent Drugs and Interactions

In the second category, fullerene derivatives with drug delivery applications can be based on non-covalent association of a drug, targeting substrate, or a protein to the fullerene derivative's surface. Fullerenes and fullerene derivatives are well known to form non-covalent intermolecular complexes with species such as polyaromatics, porphyrins, and many electron-rich molecules. The types (and strengths) of these supramolecular interactions vary, and include hydrophobic interactions (particularly for underivatized fullerenes or the underivatized surface portions of lightly derivatized fullerenes), pi-pi interactions, van der Waals interactions, and electrostatic interactions, as well as hydrogen bonding between functional groups on the fullerene derivative and the substrate. Non-covalent intermolecular fullerene interactions are also evident with amphiphilic fullerene derivatives.

Non-covalent interactions can be exploited in medicinal uses of fullerene derivatives. One of the first reported examples in this category was antiviral activity, specifically HIV protease inhibition by C_{60} derivatives. The HIV protease enzyme is crucial for virus replication and ensuing infection of new cells. Its active catalytic site is a relatively hydrophobic cavity or "pocket" that is ca. 1 nm in diameter and very close in size to a C_{60} molecule. With the aid of molecular modeling, C_{60} derivatives were designed to bind in this active site (aided by van der Waals interactions between the fullerene and the cavity) and inhibit the virus [10]. In vitro tests of the first derivative confirmed binding and inhibition, prompting the design and synthesis of new C_{60} derivatives with stronger inhibitory effects [6].

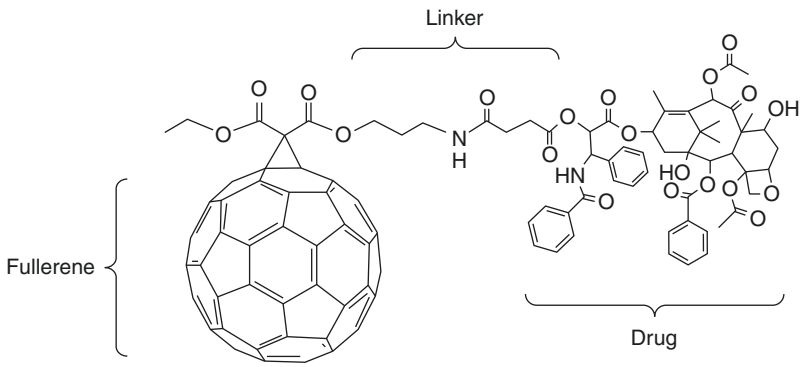
Fullerene derivatives can also be used as non-covalent carriers for the intracellular delivery of nucleic acids. There is great interest in developing new, nonviral artificial vectors for gene transfection, for both research purposes and for gene therapy and vaccination with DNA. Liposomal systems are currently used but do not have high stability in serum, making them inefficient transfection vectors. C_{60} derivatives with attached protonatable amino groups were found to condense DNA into stable nanoclusters with contribution from both electrostatic and van der Waals forces. In vitro tests indicated these fullerene-DNA nanoassemblies transfected cells with DNA at a higher efficiency than a standard liposomal agent. It was recognized that both DNA binding and releasing capabilities were needed in the fullerene derivative for it to efficiently

Fullerenes for Drug Delivery, Fig. 5 A cationic tetraamino C_{60} derivative used for in vivo DNA transfection

transfect. Using the tetra(piperazino) fullerene epoxide derivative depicted in Fig. 5, in vivo DNA transfection in mice was successfully demonstrated without acute toxicity [11]. The C_{60} derivative transfected the green fluorescent protein (GFP) gene to the lung, liver, and spleen. Transfection of an insulin-2 gene reduced the blood glucose levels of live mice. Recently, a different class of water-soluble fullerene derivatives based on cyclopropanated C_{60} structures (including neutral, cationic, and anionic functional groups) were also tested as DNA transfection agents. In vitro tests showed transfection was most efficient with the cationic derivatives. Fullerene derivatives appear to have a high potential for diagnostic and therapeutic gene transfection applications.

Non-covalent interactions between fullerenes and antibodies are also potentially useful for enacting selective targeting of fullerene derivatives. Fullerene immunoconjugates can be either covalent or non-covalent in nature, as was demonstrated in a seminal study of C_{60} immunoconjugates for selective targeting of melanoma with the murine anti-gp240 melanoma antibody ZME-018 [12]. Initially, a covalent conjugate of a C_{60} derivative to the antibody via a disulfide linker was synthesized in several different fullerene-to-antibody ratios. However, upon detailed investigation, it was found that covalent coupling between the C_{60} derivative and the antibody was not necessary to form a stable and useful immunoconjugate; it happened spontaneously upon mixing the antibody and the fullerene derivative (a highly water-soluble C_{60}-malonodiserinolamide) together. ELISA binding curves using antigen-positive cells showed that at high C_{60} derivative-to-antibody molar ratios the antibody to antigen binding is not significantly reduced (relative to the covalent C_{60}-antibody conjugate and a control nonspecific IgG antibody). Non-covalent assembly of fullerene immunoconjugates avoids difficulties inherent in synthetically designing a covalent antibody conjugate, a process that can decrease the antibody's target affinity. It should also be noted that an anti-C_{60} antibody Fab fragment and its binding to fullerene have been well characterized. Non-covalent conjugate formation between fullerene derivatives and antibodies may be a general phenomenon. Other proteins and enzymes with which there is experimental evidence of binding or interactions of C_{60} and/or derivatives include serum albumin (HSA and BSA), nitric oxide synthase, potassium ion channels, proteinases, cytochrome P450, glycosidases, and acetylcholinesterase (AChE).

Fullerene derivatives can also be employed to form non-covalent supramolecular assemblies for drug containment and delivery. As noted earlier, water-soluble fullerene derivatives typically aggregate into nanoclusters. In addition to simple, reversible aggregation, amphiphilicity has been designed into derivative structures for forming fullerene-based micelles, vesicles, and liposomes. A mixed carboxy-dendrimer/polyalkyl functionalized C_{60} amphiphilic derivative (termed AF-1) self-assembled at 70 °C into 100–200 nm vesicles suitable for encapsulating hydrophobic drug molecules inside. Paclitaxel was loaded into the hydrophobic interiors of the AF-1 liposomes, and in vitro tests showed this drug delivery system to suppress growth of MCF-7 human breast cancer cells at a level comparable to Abraxane, a clinically approved injectible formulation of (otherwise hydrophobic) paclitaxel bound to albumin. In different work, an amphiphilic C_{70} bisadduct derivative was used to



prepare stable, high-fullerene content liposomes co-formed with auxiliary membrane-forming phospholipids. These liposomes retained the fullerene molecule's antioxidant properties, including quenching of reactive oxygen species, while also inhibiting lipid peroxidation. Non-covalent delivery of drug molecules with amphiphilic fullerene structures is very promising.

Fullerene Derivatives with Covalently Attached Drugs and Bioactive Moieties

The third category includes the medicinal fullerene materials that have direct covalent connection(s) between a derivatized fullerene surface and separate, pharmaceutically active component(s). A fundamental nanoparticle drug delivery paradigm is "nanosubstrate-linker-drug." In fullerene-based covalent drug delivery assemblies, these components are (1) the fullerene cage, (2) the surface derivative groups/linker unit, and (3) the attached drug or otherwise biomedically active molecule(s). Derivatized fullerenes with covalently attached drug agents are highly amenable to introducing biofunctions such as controlled drug release while simultaneously providing for selective targeting into one overall design.

The first example of the fullerene-drug covalent conjugate class is a C_{60}-paclitaxel conjugate with slow paclitaxel release for liposomal-based aerosol drug delivery in lung cancer treatment [13]. Paclitaxel was conjugated to a C_{60} derivative via a linker having a hydrolysable ester group for slow release of the free drug (Fig. 6). The conjugate was stable in aqueous 10 % DMSO at physiological pH, and displayed a hydrolysis half-life for paclitaxel release of about 80 min upon exposure to bovine plasma. Stable C_{60}-paclitaxel conjugate liposomes with dilauroylphosphatidycholine (DLPC) were prepared and tested for their antitumor activity with human epithelial lung cancer A594 cells. The mean IC_{50} value for C_{60}-paclitaxel-DLPC (410 nM) was comparable to a paclitaxel-DLPC-only liposome (253 nM). This demonstrated viability of fullerene drug delivery, and combining this type of system with a targeting strategy (i.e., non-covalent antibody conjugation) would offer a powerful new way of delivering prodrug paclitaxel and potentially other chemotherapeutics selectively to cancer cells.

In other studies, doxorubicin was covalently conjugated to C_{60} with hydrophilic ethylene oxide linkers attached to a cyclopropanated C_{60} derivative. In vitro tests with MCF-7 human breast cancer cells showed the fullerene conjugate's cytotoxicity was comparable to native doxorubicin. One-photon confocal and two-photon fluorescence microscopies were used to image the doxorubicin-C_{60} conjugate in the MCF-7 cells. The conjugate distributed in the cytoplasm, in contrast to the localization of native doxorubicin in the cell nucleus. In different work, C_{60}-fullerols were used as the platform derivative to make covalent fullerene conjugates with releasable doxorubicin. These fullerol-doxorubicin conjugates also had co-attached poly(ethylene) glycol units and possibly residual surface hydroxyl groups. These conjugates were subjected to a

Fullerenes for Drug Delivery, Fig. 6 A "fullerene-linker-drug" conjugate assembly for drug delivery (C_{60}-paclitaxel)

variety of in vitro tests with cancer cells, including melanoma cells. Cellular uptake into the lysosomal compartment was demonstrated with fluorescent-labeled conjugates with one cell line. An in vivo test of the doxorubicin-fullerol conjugates in mice with model melanoma tumors showed increased therapeutic index for tumor inhibition and animal weight gain relative to free doxorubicin, which also inhibited tumor growth but led to decreased animal weight. When the doxorubicin-fullerol conjugate was administered to live zebrafish embryos, dose-dependent angiogenesis inhibition was noted. Angiogenesis inhibition in mice-bearing melanoma tumor models was also reported for the conjugate. The above studies with C_{60} conjugates of paclitaxel and doxorubicin indicate that fullerene-vectored delivery of chemotherapeutics will have a high potential for clinical utility with further development.

Fullerenes have been covalently attached to various other biologically relevant and drug moieties, including sugars and carbohydrates, cholesterol, adamantyl groups, the antibiotic vancomycin, viral nanoparticles, nucleosides, and photosensitizer molecules. Bone-targeted fullerene drugs for osteoporosis treatment have been studied, including C_{60} derivatives with appended bis(phosphonate) functionalities. Other potential biomedical uses of fullerene derivatives include contrast and diagnostic agents for medical imaging. Fullerene derivatization chemistry offers means to exohedrally tag fullerene cages with payloads of the active components of contrast agents and/or radioisotopic tracers. A water-soluble, nonionic hexa-iodinated C_{60} derivative was been tested as an x-ray contrast agent and it offered x-ray attenuation equivalent to that of a clinical (non-fullerene) triiodoaryl agent.

Endohedral Fullerene Derivatives for Drug Delivery

Endohedral fullerenes and metallofullerenes can carry and deliver atoms and metal ions that serve as active agents in bioimaging and therapy. Salient metallofullerene properties include a lack of exchange of their interior ion(s) with the exterior media (prohibiting transmetallation), electron transfer from the interior metal(s) to the fullerene cages to form anionic-charged cages with entrapped metal cations, and a cage derivatization chemistry similar to empty fullerenes, but with solubility and reactivity differences in some cases.

With the endohedral contents sequestered inside of the fullerene cage, metallofullerenes can participate in the same fullerene drug delivery concepts noted in Fig. 3. Metallofullerenes also can serve in applications dependent upon the metal's properties and/or derived from interactions between the fullerene cage and its contents. These include magnetic resonance imaging (MRI) contrast agents with endohedral paramagnetic ions and as radiotherapeutic agents holding radioisotopes in their interior cavities.

Metallofullerene Magnetic Resonance Imaging (MRI) Contrast Agents

Clinical magnetic resonance imaging (MRI) is a non-invasive imaging technique that uses the nuclear magnetic resonance signals of protons in tissues and organs to obtain 3-D anatomical information in patients. MRI has high spatial resolution, but has low intrinsic sensitivity. Paramagnetic contrast agents are used to increase the sensitivity of MRI via signal amplification. These agents interact with water protons via inner sphere and outer sphere mechanisms to increase the proton relaxation rates (i.e., decrease the T_1 and or T_2 relaxation times). The characteristic relaxation-enhancing potency of an agent is referred to as "relativity," and the r_1 and r_2 relaxivities vary as a function of agent concentration according to $(1/T_x)_{obsd} = (1/T_x)_d + r_x[\text{agent}]$. Clinically, r_1 is of greater interest due to its image brightening (positive contrast) effect. The paramagnetic Gd^{3+} ion, with its seven unpaired 4*f*-electrons and favorable electron spin relaxation characteristics, is the leading choice for T_1-active relaxation agents. Because the free Gd^{3+} ion is toxic, chelating molecules are required to safely hold the ion, and there are several approved Gd^{3+} chelate agents currently used in ca. 35 % of MRI scans.

A major goal in contrast agent development is increased relaxivity for both higher sensitivity (and thus smaller required dosages) and to enable advanced applications in cellular and molecular imaging. Gd-containing endohedral metallofullerenes, or "gadofullerenes," were recognized early as potential MRI contrast agents with their unique encapsulation of the Gd^{3+} ion. The MRI contrast-enhancing properties of water-solubilized gadofullerenes of $Gd@C_{82}$ and $Gd@C_{60}$ have been investigated in a number of leading studies of polyhydroxylated (fullerol) and carboxylated derivatives [14]. Note that the paramagnetism of $Gd@C_{2n}$ gadofullerenes derives not only from the encapsulated Gd^{3+} ion, but also from the unpaired electron donated by Gd to the fullerene molecular orbital (Gd donates three electrons to the fullerene). While the clinical Gd chelate contrast agents have r_1 relaxivities near 4 mM^{-1} s^{-1}, gadofullerene r_1 relaxivities are significantly higher. For example, $Gd@C_{82}(OH)_x$ and $Gd@C_{60}(OH)_x$ derivatives have reported r_1 values ranging from 20 to 98 mM^{-1} s^{-1}, and a carboxylated $Gd@C_{60}$ derivative had a r_1 maximum of 24 mM^{-1} s^{-1}. Some of the variation in r_1 values derives from the use of different measurement conditions, including temperature and magnetic field. However, solution conditions including sample pH and dissolved salt content had a strong influence on relaxivities as well.

The water-proton relaxation mechanisms of gadofullerene derivatives have recently been examined in a series of detailed experiments [15]. A strong pH dependence on relaxivity was found for the gadofullerenes, with higher relaxivities at lower pH and lower relaxivities at higher pH. Dynamic light scattering and cryo-transmission electron microscopy (TEM) measurements revealed that the gadofullerenes form intermolecular aggregates or nanoclusters with hydrodynamic diameters of ca. 700–800 nm at pH = 7.4, with larger aggregates at low pH while smaller at high pH. This trend mirrors the relaxivity trend as a function of pH, as well as the maximum relaxivity peaks seen for gadofullerenes in relaxivity measurements taken at different magnetic fields (nuclear magnetic resonance dispersion (NMRD) profiles). This latter feature, with broad relaxivity maxima at fields between 0.7 and 1.4 T, is characteristic of long rotational correlation times of larger species with slow tumbling, such as nanocluster aggregates. High dissolved salt concentrations were found to break up gadofullerene derivative nanoaggregates (and consequently decrease relaxivity), with a reported disaggregation half-life of ca. 30 min in 100 mM phosphate buffer. With inner-sphere relaxation mechanisms precluded (direct water-Gd^{3+} coordination is blocked for gadofullerenes), only outer-sphere relaxation can operate. Major factors contributing to the high gadofullerene relaxivities include large paramagnetic surface areas derivatized with hydrophilic and hydrogen-bonding functional groups, nanocluster aggregation that slows rotation, and most significantly, interstitial confinement of water molecules in the clusters. Rapid exchange of interstitial water molecules with bulk water contributes to the high relaxivities. The type of functionalization and number of attached groups employed on gadofullerene surfaces clearly has direct and strong influence on the relaxivities of gadofullerene MRI contrast agents.

Several in vitro cellular imaging studies have been conducted with $Gd@C_{2n}$ gadofullerene derivatives. In one, HeLa cells, mesenchymal stem cells (MSC), and macrophages were labeled with $Gd@C_{82}(OH)_{40}$ using protamine sulfate as a transfection agent to achieve labeling up to 4×10^7 Gd atoms/cell. With the cellular viability remaining high, MR imaging revealed excellent intracellular T_1 weighted contrast. The agents' localization in cytoplasmic endosomes was confirmed by electron microscopy. In another study, marrow stromal cells (MSC) and NIH 3 T3 stem cells were nonspecifically labeled with $Gd@C_{60}[C(COOH)_2]_{10}$, achieving an efficient 10^{11} Gd^{3+} ions per cell on average without adding a transfection agent. The cells remain viable, and an acid strip test indicated the gadofullerenes were intracellular or deep in cellular membranes. T_1-weighted imaging at 1.5 T revealed that labeled cells had MR signal intensities ca. 250 % greater than unlabeled cells. These results demonstrate that gadofullerenes can internalize into cells

and provide efficient T_1-weighted enhancement for potential in vivo cell tracking by MRI.

In vivo T_1-weighted MR imaging tests of $Gd@C_{2n}$ derivative agents have also been conducted. Tests of $Gd@C_{82}(OH)_x$ compounds in mice showed strong signal enhancements. For the compound with $x = 40$, the lung, liver, and spleen had the strongest enhancements, and for the compound reported as $x = 16$, both liver enhancement and renal excretion were seen. A different biodistribution was obtained by MRI in a rat with $Gd@C_{60}[C(COOH)_2]_{10}$. By MRI, this carboxylated derivative showed renal excretion within 1 h, less liver uptake than the gadofullerol compounds and a biodistribution similar to that of clinical Gd chelate agents. These tests indicate different biodistribution tendencies for different functionalization styles, and showed that small animals tolerated the gadofullerene agents without complications.

Gadofullerene derivatives more complex than the carboxylated and hydroxylated structures are beginning to be investigated, including $Gd@C_{82}O_6(OH)_{16}(NHCH_2CH_2COOH)_8$ and the mixed phosphonated derivative $Gd@C_{82}O_2(OH)_{16}(C(PO_3Et_2)_2)_{10}$. Toward more advanced conjugates, a mixed $Gd@C_{82}$ derivative bearing surface hydroxyl and carboxylate groups was covalently conjugated to an anti-green fluorescence protein (GFP) antibody with an amide bond. This immunoconjugate retained antibody activity and displayed a modestly higher relaxivity than the unconjugated $Gd@C_{82}$ derivative.

Water-soluble derivatives of TNT metallofullerenes with Gd ions in their endohedral metal-nitride clusters are also being investigated as MRI contrast agents, particularly with $Gd_3N@C_{80}$ [16]. Unlike lanthanide $M@C_{2n}$, $Gd_3N@C_{80}$ lacks cage-centered unpaired electron(s), so its paramagnetism comes only from the entrapped Gd^{3+} ions of the Gd_3N cluster. The mixed derivative $Gd_3N@C_{80}[DiPEG5000(OH)_x]$ (DiPEG5000 is $[COO(CH_2CH_2O)_{114}CH_3]_2$) had a r_1 maximum (at 2.4 T) of 143 mM^{-1} s^{-1} on a per C_{80} cage basis (48 mM^{-1} s^{-1} on a per Gd basis). T_1-weighted in vivo MR imaging was performed with this agent (after direct brain infusion) in a rat having a glioma tumor model. In the normal brain and tumor tissues, this $Gd_3N@C_{80}$ agent gave high contrast at relatively low concentration with better tumor margin differentiation than was obtained with a standard Gd chelate agent. Related $Gd_3N@C_{80}[DiPEG(OH)_x]$ mixed derivatives with PEG molecular weights of 350 and 750 had r_1 maxima (at 2.4 T) of 237 and 232 mM^{-1} s^{-1} on a per C_{80} cage basis (79 and 77 mM^{-1} s^{-1} on a per Gd basis), respectively.

$Gd_3N@C_{80}(N(OH)(CH_2CH_2O)_nCH_3)_x$ (n = 1,3,6; $x \approx 10$–22) derivatives were characterized, with $n = 6$ having an r_1 value of 205 mM^{-1} s^{-1} on a per C_{80} cage basis (68 mM^{-1} s^{-1} on a per Gd basis). In vivo MRI with the $n = 6$ derivative in a mouse showed this agent remained in the vasculature, as expected with its derivatization motif. $Gd_3N@C_{80}(OH)_{26}(CH_2CH_2COOM)_{16}$ (M = Na or H), with $r_1 = 207$ mM^{-1} s^{-1} on a per C_{80} cage basis (69 mM^{-1} s^{-1} on a per Gd basis), displayed a hydrodynamic diameter of ca. 160 nm and unimodal size distribution in pH = 7 water. Mixed-metal Gd/Sc TNT derivatives have also been synthesized and studied as MRI contrast agents, including $Sc_xGd_{3-x}N@C_{80}O_m(OH)_n$ (x = 1, 2; $m \approx 12$; $n \approx 26$) and a pyrrolidino $Sc_xGd_{3-x}N@C_{80}$ (x = 1, 2) derivative with functionality suited for conjugation. These are of interest for their relaxivity properties and for the greater abundance of $Sc_xGd_{3-x}@C_{80}$ (x = 1,2) as compared to $Gd_3N@C_{80}$.

With r_1 relaxivities an order of magnitude higher than the clinical chelate agents and their stable sequestration of the Gd^{3+} ion, gadofullerene derivatives show strong promise as MRI contrast-enhancing agents for intracellular labeling and in vivo imaging. Exohedral derivatization chemistry has a very strong influence on the relaxivity and intermolecular aggregation properties of the gadofullerene MRI agents. In vivo use will require a balance between relaxivity performance and biodistribution characteristics. The properties of gadofullerene MRI contrast agents are well-suited for applications requiring long circulation times (i.e., blood pool agents and targeted agents) and for multimodal imaging and theranostic agents.

Metallofullerene Radiopharmaceuticals

Nuclear medicine with endohedral radioisotopes, including radionuclear therapy and isotopic tracing and/or imaging, is also of interest with fullerenes as carriers. Metallofullerenes offer carbon-cage confinement of the radionuclide without the potential dissociation of coordinatively held isotopes in a chelate. This containment may in select cases extend to daughter radioisotopes, which is another potentially significant advantage over standard chelation.

Radioisotopic endohedral fullerenes can be generated by at least four methods, including neutron activation of metallofullerenes, direct arc synthesis with radioisotope-doped graphite rods, nuclear recoil implosion and ion implantation. In an early study of metallofullerene radiopharmaceuticals, an in vivo study was conducted with radioactive Ho metallofullerenes. Non-radioactive $^{165}Ho@C_{82}$ was neutron activated to the β-emitting $^{166}Ho@C_{82}$ species. This radio-metallofullerene was water-solubilized by polyhydroxylating its surface, and its biodistribution in mice was characterized by radiochemical methods.

Fullerene surface chemistry can be used to advantage for transport of endohedral radionuclide(s) for radionuclear therapy with both α- and β-emitting radionuclides. Toward this, carboxylate derivatives of the metallofullerene $^{212}Pb@C_{60}$ (produced by recoil following decay of a short-lived parent radioisotope) were investigated as radiocarriers suited for α-particle radioimmunotherapy [17]. TNT metallofullerenes have also been proposed for nuclear medicine agents holding endohedral ^{117}Lu, a β-emitter [18]. A mixed (poly)hydroxy/alkylcarboxy derivative of arc-generated $^{177}Lu_xLu_{(3-x)}N@C_{80}$ was conjugated to an interleukin-13 peptide, demonstrating a potentially targetable radiofullerene agent for brain cancer. In addition to the above examples, fullerene derivatives with exohedral radioisotopes have been reported. These have uses as radiotracers, but exohedral radiofullerenes do not confer the special encapsulation advantages that endohedrals do. Practical application of therapeutic radionuclear endohedrals for treating cancer, etc. will require a balance between the demands of circulation, targeting, and accumulation of a fullerene conjugate versus the inherent half-life and the amount of linear energy transfer upon decay of the chosen radioisotope.

Other Biomedical Applications of Endohedral Fullerenes

Other biomedical applications proposed for lanthanide metallofullerenes include their use as x-ray contrast agents (exploiting the x-ray absorbing properties of heavy metal ions) and as photoluminescent agents (endohedrals encapsulating fluorescing lanthanide cations, e.g., $Er_2@C_{82}$, $Er_3N@C_{80}$, $Er_2C_2@C_{82}$). Current hurdles to realizing these applications include low X-ray contrast and low photoluminescence intensities, respectively.

Metallofullerene fullerol derivatives have also been tested for antitumor activity [19]. As noted earlier, $C_{60}(OH)_x$ fullerols showed antioxidant and antitumor activities in both in vitro and in vivo tests, and related results have been reported from similar tests in small animals with $Gd@C_{82}(OH)_x$ ($x \approx 22$) materials. The derivative $Gd@C_{82}(OH)_{22}$, when compared to the chemotherapeutics CTX (cyclophosphamide) and cisplatin in vivo, exhibited a very high antitumor effect, shrinking tumors at low dose levels. These findings were unexpected because this fullerene derivative is inherently non-cytotoxic (and note that there is no toxicity from free Gd^{3+}). Spin-trapping experiments monitored with electron paramagnetic resonance spectroscopy showed $Gd@C_{82}(OH)_{22}$ scavenged reactive oxygen species and inhibited lipid peroxidation in liposomes. It was suggested that the antitumor activity may be related to the metallofullerol's ability to regulate oxidative stress (by helping to restore liver and kidney functions) and ability to stimulate Th1 cytokine-releasing immune responses. $Gd@C_{82}(OH)_{22}$ was also found to have antiangiogenic properties in live tumor-bearing mice models. Another study indicated that $Gd@C_{82}(OH)_{22}$ has potential to help reverse prostate tumor resistance to cisplatin through

restorative effects on endocytosis [20]. Comparisons of the antitumor activity of metallofullerene derivatives to empty fullerene congeners merit further study (particularly because of the greater availability of empty fullerene derivatives vs. metallofullerenes). Special properties of metallofullerenes afforded to them by the interior metal ion(s) and the electron transfer from metal to cage may be relevant to the mechanism of the observed systemic, indirect antitumor actions.

There are recent indications of greater diversity in fullerene cage and endohedral structures than was initially realized during the early years of fullerene discovery and characterization. These "new" fullerenes include those with cages smaller than C_{60}, non-IPR cages, and diverse, unsymmetrical multi-atom endohedral contents. Their physical properties such as polarity, polarizability, electronegativity, etc. may differ enough from previously known fullerenes to give substantially different attributes for medicinal chemistry and drug delivery. It remains to be seen the extent to which these special structures could contribute to biomedicine, due to the extremely small quantities in which they are produced and isolated.

Future Directions

The special physical properties of fullerenes including size, reactivity, electronegativity, endohedral encapsulation of ions, etc. present opportunities for development of novel drug action and drug delivery. Major advantages of fullerenes as nanovehicles for drug delivery include the reproducible chemistry of molecules, dimensions at the lower end of the nanoscale, diverse exterior covalent and non-covalent chemistries, and endohedral encapsulation of atoms and ions inside of the closed fullerene carbon cages. C_{60} as the "parent" fullerene has been the most investigated fullerene vector in biomedical applications, but the other fullerenes and metallofullerenes are expected to have an expanding role.

The multiverse of fullerene surface chemistry facilitates combining drug agents and therapeutic actions into a single fullerenic theranostic platform. Studies of combined imaging and therapy with multifunctional fullerene nanomaterials are currently underway in several laboratories. Still, the capabilities of fullerenes in drug delivery have only begun to be developed, as most of the examples noted in the preceding sections have not yet moved beyond the basic proof-of-concept stage. Amphiphilic fullerene structures, selective targeting (using conjugated peptides and monoclonal antibodies and their fragments), and fullerene-drug conjugates that are combined with MRI active or radionuclear endohedral fullerenes are topics that are anticipated to be productive. Binding and inhibitory interactions of fullerenes with endogenous proteins must be considered carefully when designing fullerene-based drugs intended for systemic administration in vivo. Continued emphasis on derivative design and synthesis of bioactive fullerene conjugates is needed in the near term. In vivo characterization, pharmacokinetics, long-term toxicity, and other preclinical pharmacology studies will need greater attention before the unique fullerene-based drug delivery nanomaterials can achieve clinical impact.

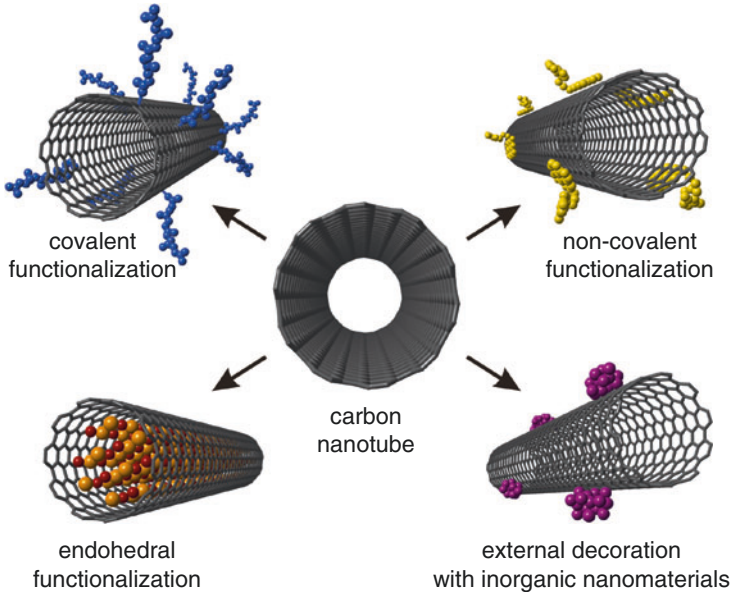
Definitions

The functionalization of carbon nanotubes consists of the attachment of organic or inorganic moieties to their tubular structure. Through the functionalization of carbon nanotubes, it is possible to modulate their physicochemical properties, increasing their ease of dispersion, manipulation, and processability, among others. The different approaches available for the modification of carbon nanotubes can be classified into four main groups: covalent functionalization, noncovalent functionalization, external decoration with inorganic materials, and endohedral filling.



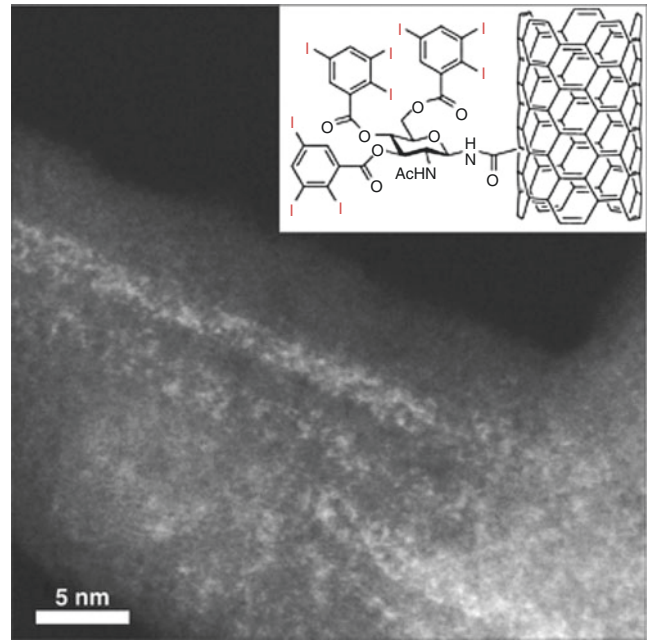
Introduction

Carbon nanotubes (CNTs) are quasi-1D structures formed by one (single-walled CNTs, SWCNTs) or more (multiwalled CNTs, MWCNTs) graphene layers rolled up forming a cylinder. The structure of a graphene layer consists of sp^2 hybridized carbon atoms in a hexagonal network with in-plane σ bonds and out of plane π-orbitals. This particular structure is responsible for CNTs' and graphene's unique properties such as their high Young's modulus, high thermal conductivity, and unique electronic properties. The length of CNTs is typically in the size of micrometers with diameters that range from about 1 to 100 nm. Defect-free CNTs are almost chemically inert. Being an advantage for some applications, this chemical inertness together with their intrinsic poor dispersibility in organic solvents and aqueous media represents a major challenge toward their practical application. Furthermore, as-produced SWCNTs and few layered MWCNTs align parallel to each other forming bundles due to van der Waals interactions, which further aggregate into entangled networks. In this context, the functionalization of CNTs is a key step toward increasing their dispersibility, reactivity, processability, and even biocompatibility [1]. The functionalization of CNTs allows the modification of the structural framework and the creation of supramolecular complexes. The main strategies employed for the modification of CNTs can be classified into four groups: covalent functionalization, noncovalent functionalization, external decoration with inorganic materials, and endohedral filling. Some of these approaches have even been applied simultaneously on a given sample of CNTs, resulting in CNTs bearing multiple functionalities. A schematic representation of these four functionalization strategies is presented in Fig. 1.

Covalent Functionalization

Covalent functionalization of CNTs has been widely used to increase their ease of dispersion, purification, conjugation with biomolecules, and anchoring to polymeric composites and to tailor their properties for specific applications [2]. A major advantage of this route is that a covalent bond is much more stable than other methods such as adsorption on the surface. Generally speaking, there are two strategies for the covalent functionalization of CNTs: direct sidewall functionalization and defect group functionalization.

On the one hand, direct sidewall functionalization is based on the rehybridization of a sp^2 carbon atom into a sp^3 configuration to form a covalent bond between the attacking species and a carbon atom of the CNT scaffold. On the other hand, defect group functionalization is based on anchoring the desired functionalities through appropriate chemical groups introduced in preexisting or intentionally created defects on the CNT scaffold. Importantly, both methods create a disturbance of the CNT tubular structure, the main difference is that defect functionalization will be primarily located (at low defect density creation) at the CNT tips where oxidation is favored compared to the sidewall, as opposed to direct sidewall functionalization where the functionalities will be installed on the CNT sp^2 network, i.e., along the outer wall. Therefore, the major drawback of both methods is the disruption of the CNT sp^2 aromatic system, leading to the modification and degradation of the intrinsic properties of the material such as the transport. Noteworthy, the creation of defects in SWCNTs arises more structural problems than in the case of



Functionalization of Carbon Nanotubes, Fig. 1 Schematic representation of different strategies for the functionalization of carbon nanotubes

MWCNTs where the inner layers sustain the mechanical integrity of the CNTs. Both strategies have been used to integrate CNTs in diverse applications such as tuning the electronic properties through the coordination with active moieties, their introduction to polymeric composites, or in the biomedical field to fabricate biosensors, drug delivery systems, or scaffolds for tissue engineering.

Defect Group Functionalization

Generally, the defect functionalization route is based on the chemical transformation of defects intrinsically present or generated through chemical oxidation. The generation of surface chemical functionalities on the sp^2 carbon network to anchor specific moieties is a challenging process since a perfect CNT is nearly a 1D cylindrical aromatic macromolecule and therefore expected to be almost chemically inert. The most common approach for the generation of defects on the CNT structure is oxidation either by liquid-phase (i.e., refluxing in HNO_3), gas-phase (i.e., O_2 plasma), or even electrochemical oxidation. It has been proved that the oxidation process starts at topological defects of the sp^2 network and the CNT tips (which ideally are two hemifullerenes) because these are more reactive toward oxidative chemical attacks than a perfect sp^2 carbon network. Hence, the oxidation process yields oxygen-bearing groups, initially in the intrinsic defects and the CNT tips, but increasing the duration or the energy of the treatment also results in the creation of new defects in the CNT scaffold. The oxidative process results in the creation of carboxylic groups and other oxygen-bearing functionalities. These functional groups created at the CNT surface serve as the starting point for further functionalization [3].

Following this approach, CNTs with carboxylic functions have been used as precursors to introduce other functional groups through esterification or amidation reactions. Generally, the carboxylic groups generated by oxidation of the CNT structure are converted to acyl chloride groups via reaction with thionyl or oxalyl chloride, followed by the addition of an alcohol or amine. An alternative approach goes via carbodiimide coupling chemistry [4]. A variety of compounds that facilitate the covalent attachment are available (cross-linking reagents), being the most commonly used the 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) and *N, N′*-dicyclohexylcarbodiimide (DCC). The role of

Functionalization of Carbon Nanotubes, Fig. 2 Z-contrast annular dark-field STEM image of a bundle of SWCNTs covalently functionalized with carbohydrates (Adapted with permission from Ref. [5]. Copyright 2007 American Chemical Society)

EDC/DCC is to transform the carboxylic group into a better leaving group through the formation of an unstable active-ester intermediate. In the final step, the ester is displaced by the amine group of the given moiety, resulting in the formation of an amide bond. For instance, the formation of amide bonds with amine-terminated proteins is of interest in the biomedical field. A Z-contrast annular dark-field scanning transmission electron microscopy (ADF-STEM) image of carbon nanotubes functionalized with carbohydrates is presented in Fig. 2. For ease of detection, carbohydrates have been tagged with iodine atoms through the addition of 2,3,5-triiodobenzoyl moieties. In Z-contrast ADF-STEM, the intensity of an element is ca. proportional to the square of its atomic number. Therefore, iodine atoms appear bright white, whereas carbon appears pale gray. The analysis of functionalized CNTs by means of electron microscopy techniques allows their visual detection down to the atomic scale and valuably complements spectroscopic techniques widely used for the characterization of organic compounds such as Raman, infrared (IR), ultraviolet (UV), and nuclear magnetic resonance (NMR), which provide information of the bulk material.

Direct Sidewall Functionalization

This functionalization strategy is based on the rehybridization of an sp^2 carbon atom of the CNT sidewall to an sp^3 configuration and the formation of a covalent bond with a chosen moiety. The amount of synthetic routes developed following this procedure during the last years is extensive [1, 6]. One of the first sidewall functionalization reactions was the fluorination, with C_2F having the highest degree of fluorination. The fluorinated CNTs serve as starting point in many reactions where fluorine atoms are replaced and derived, i.e., alkyl groups can replace the fluorine atoms using Grignard or organolithium reagents. Following the same idea, CNTs have also been chlorinated, brominated, and iodinated. Cycloaddition reactions are also being widely employed for the direct sidewall functionalization of CNTs, for instance, to render them dispersible and also for the attachment of biomolecules. These include, for instance, the carbene [2 + 1] cycloaddition to pristine CNTs, the 1,3-dipolar cycloaddition reaction, or the so-called Bingel [2 + 1] cyclopropanation. As an example of the potential application of the formation of nanohybrids, radical addition with diazonium salts has allowed the preparation of

donor–acceptor systems by decorating the CNTs with porphyrins. Both electrophilic and nucleophilic additions have also been achieved onto the CNT backbone. For instance, electrophilic addition of alkyl halides results in the formation of alkyl and hydroxyl groups, and as an example of the latter, nucleophilic addition of amine-based nucleophiles leads to amino-functionalized CNTs. Other nonconventional methods for the direct sidewall functionalization would include microwave irradiation, ball milling, ozonolysis, and plasma activation [7].

The attachment of biomolecules onto the CNT skeleton is getting an increased attention since it allows their integration in biological systems. Both defect and direct sidewall functionalization are being employed. It is also worthy to mention the use of covalently functionalized CNTs to act as fillers in polymers in order to enhance the mechanical or electrical properties of the composites. For this application it is fundamental to have a good dispersion of the CNTs in the polymeric matrix as well as an efficient load transfer from the matrix to the CNTs. Both of these requirements have been fulfilled, by both defect group and sidewall functionalization, by grafting the polymeric fibers covalently to CNTs or promoting the polymerization from CNTs covalently functionalized with monomers or initiators. These composites have potential applications where lightweight robust materials are needed, such as aerospace science and for sportive material, and are also being studied for field effect transistor devices, selective detection of gas traces, and photovoltaic devices, among others.

In summary, there has been an extensive effort in developing routes toward the covalent functionalization of CNTs at both the sidewalls and the tips. These findings in combination with the organic chemistry toolbox have lead to tailor-made properties for various applications in many fields in nanotechnology.

Noncovalent Functionalization

Carbon nanotubes' noncovalent functionalization consists of the adsorption or wrapping of various functional molecules on the tubular surface of the CNTs. This approach of functionalization is particularly interesting because it is based on π-π stacking, van der Waals, or charge–transfer interactions, and so it preserves the extended π-network of the tubes. Another characteristic of noncovalent functionalization which might be valuable for certain applications is its reversibility. The removal of the adsorbed functional moieties might be achieved by changing external conditions such as solvent, pH, temperature, light irradiation, and redox conditions [8].

Most of the research on noncovalent functionalization has aimed to achieve the dispersibility of CNTs by the exfoliation of bundles to obtain individual CNTs, which are otherwise very difficult to disperse homogeneously in solution. In the past few years, preparation of highly stable suspensions of individually dispersed nanotubes has been achieved in both aqueous and organic solutions.

Typically, the functionalization involves ultrasonication in solution followed by centrifugation and filtration steps. Ultrasonication produces a high-shear environment that results in the formation of gaps or spaces at the bundle ends. These gaps are unstable; so, in the absence of a dispersing agent, the nanotubes reattach through van der Waals attraction. However, when a dispersing agent is present in the solution, these spaces or gaps at the bundle ends are propagated by the dispersant adsorption, ultimately separating the individual nanotube from the bundle [9].

A wide range of compounds have been used for the noncovalent functionalization of carbon nanotubes, including surfactants, polymers, biomolecules, and polynuclear aromatic compounds, which has been detailed below. Besides, CNTs have also been modified with other compounds such as ionic liquids, dyes, macrocyclic host molecules, and phosphines, among others. Depending on their final application, these noncovalently functionalized CNTs have been used in some cases for further modification with biomolecules, inorganic nanoparticles, organic moieties, and others.

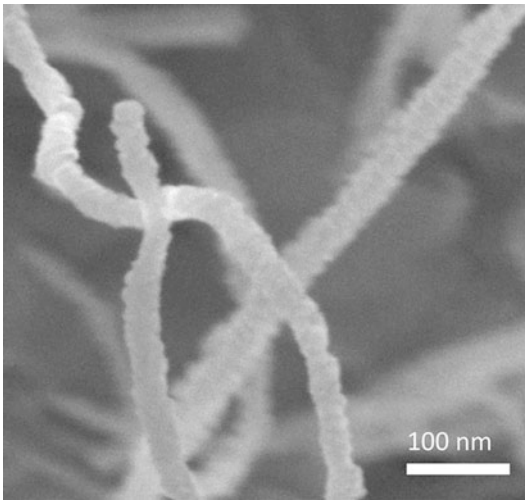
Surfactants

In general, the interaction of carbon nanotubes with surfactants takes place when hydrophilic parts of surfactants interact with the solvent and hydrophobic parts are adsorbed onto the nanotube surface, preventing the CNT aggregation into bundles and ropes and thus dispersing them. Therefore, by choosing the appropriate surfactant hydrophobic and hydrophilic groups, one can tailor the dispersibility of nanotubes to fit specific applications.

Regarding the hydrophilic groups, a range of anionic, cationic, and nonionic surfactants have been used to functionalize nanotubes. In the case of charged surfactants such as sodium dodecyl sulfate (SDS) and dodecyltrimethylammonium bromide (DTAB), negatively and positively charged, respectively, the stabilization of the dispersion is due to electrostatic repulsion between the micelles. On the other hand, for charge-neutral surfactants, such as Triton, the dispersion is achieved due to the large solvation shell created by hydrophilic tails of surfactants covering the nanotube. Therefore, for nonionic surfactants, the ability to suspend nanotubes appears to be mostly related to the size of the hydrophilic group, with heavier hydrophilic groups being capable of dispersing more nanotube material.

Hydrophobic parts of the surfactants interact directly with the nanotube surface. Surfactants with simple alkyl chains such as SDS form hydrophobic interactions with the nanotubes which are nonspecific. Therefore, the surfactant molecules are only loosely assembled around the nanotubes and the formed micelles are relatively unstable. The length and the shape of the alkyl chain are important factors, with longer and more branched alkyl groups providing better dispersions. However, too bulky hydrophobic groups show reduced debundling efficiency, since their penetration into the small spaces between the tubes is hindered. When the hydrophobic parts contain an aromatic or a naphthenic group, an especially strong interaction takes place, since the π-π stacking interactions they establish with the CNTs are more specific and directional. For instance, SDS and sodium dodecylbenzenesulfonate (SDBS) have the same length of the alkyl chain, but the latter has a phenyl ring attached between the alkyl chain and the hydrophilic group, which makes SDBS surfactant more effective for dispersing CNTs than SDS.

Although surfactants are efficient dispersants of CNTs, their use for biomedical applications is limited since they are known to permeabilize plasma membranes and have a toxicity of their own.



Polymers

Polymers are used for the preparation of CNT dispersions in both water and organic solvents and have also been shown to enable separation of nanotubes from carbonaceous and metal impurities. Both wrapping and loose adsorption of polymers around CNTs have been described. The former is driven by specific interactions which eliminate the hydrophobic interface between the tubes and the solvent.

Steric stabilization has been proposed to account for the stability of highly concentrated dispersions of polymer-coated CNTs. In the appropriate solvent conditions, polymer chains tend to avoid each other to maintain the conformational space available to each of them. Then, polymer-coated CNTs experience a repulsive force which results in a thermodynamically stable nanotube dispersion, together with the exfoliation of ropes into individual tubes.

A problem for polymers is that they might be forced into energetically unfavorable conformations due to the mechanical rigidness of CNTs. To overcome this, some polymers can wrap around nanotubes in a helical or multi-helical way, thus minimizing the conformational strain. This wrapping of the polymer ropes around the tube lattice can occur in a well-ordered periodicity.

Noncovalent polymer functionalization of CNTs has also been extensively studied for the preparation of CNT–polymer composites, since CNTs are considered ideal reinforcing materials due to their exceptional mechanical, thermal, and electrical properties. CNTs have been used to reinforce a wide variety of polymers, including epoxy, acrylates, polyelectrolytes, poly(ethylene glycol), polycarbonates, and conjugated polymers, among others [10]. Figure 3 presents a scanning electron

Functionalization of Carbon Nanotubes, Fig. 3 Scanning electron microscopy image of a sample of MWCNTs covered with polystyrene through noncovalent interactions (Reprinted with permission from Ref. [11]. Copyright 2006, American Institute of Physics)

microscopy image of MWCNTs covered with polystyrene by noncovalent interactions.

Biomolecules

The dispersion of CNT with biological molecules is desired for their integration into living systems and also for the potential use of carbon nanotubes as new types of biosensor materials. Different strategies have been used for the attachment of biomolecules to CNTs, namely direct immobilization and attachment through bifunctional linkers based, for instance, on a pyrene moiety. The biomolecules used for the direct noncovalent functionalization of CNTs include simple saccharides and polysaccharides, proteins, oligopeptides, phospholipids, and nucleic acids [6].

Proteins have a high affinity with the CNTs sidewalls. They are natural polyampholytes containing both hydrophobic and hydrophilic domains, and their hydrophilicity depends on the amino acid sequence and pH conditions. Sonication-assisted debundling and dispersion of CNT–protein hybrids in aqueous and/or polar media have been widely studied using high-molecular-weight proteins, such as streptavidin. Amphiphilic oligopeptides are also efficient dispersants of CNTs. The presence of amino acids with aromatic groups into the peptide sequence, like tryptophan, phenylalanine, or tyrosine, increases the degree of dispersion of the CNTs due to the π-π stacking interactions between the aromatic moieties of a peptide and the CNT graphitic surface. On the other hand, nucleic acids are ideal candidates to form supramolecular complexes based on π-stacking between the aromatic bases and the CNT surface. For instance, DNA strands form strong interactions with CNT by self-assembly processes, rendering stable dispersions using simple sonication procedures.

F

Polynuclear Aromatic Compounds

Condensed aromatic derivatives carrying a hydrophilic or hydrophobic moiety can disperse CNTs in aqueous and organic media, respectively. Specific π-π interactions between the aromatic system and the CNT graphitic structure lead to a strong adsorption of the polynuclear aromatic compounds onto the CNTs. The strong stacking interactions between polynuclear species and nanotubes have been used for the controlled placement of the CNTs onto various surfaces and for the subsequent attachment of biomolecules or inorganic nanoparticles.

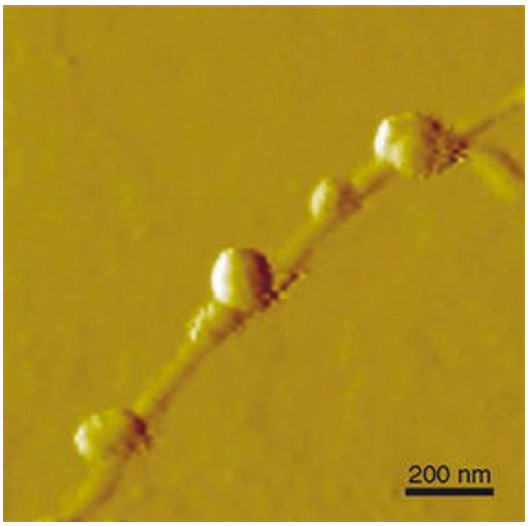
Pyrene is a molecule with a large aromatic system that forms very strong π-π interactions with nanotubes. Pyrene derivatives have been extensively used for the functionalization of CNTs in both water and organic solvents, resulting in highly stable dispersions, which, in some cases, have been subsequently used for the attachment of biomolecules. Substituted anthracenes are also useful dispersants, although their adsorption is not as strong as for pyrenes. Heterocyclic polyaromatic molecules such as porphyrins and phthalocyanines also have strong interactions with CNTs through π-stacking. However, these interactions can be weakened if a metal ion is incorporated into the porphyrin or phthalocyanine system, as the electronic state of the molecule is changed. Noncovalent attachment of porphyrins to CNTs individualized in micelles and their subsequent functionalization have shown to result in highly stable assemblies while preserving the electronic properties of the CNTs [12].

External Decoration of Carbon Nanotubes with Inorganic Nanomaterials

The interest of decorating CNTs with inorganic compounds is twofold. On the one hand, it is becoming a powerful technique for the labeling and detection of defects and functionalities on the external sidewalls. A careful study of the CNTs labeled with inorganic elements allows the determination of the exact location, distribution, and density of defects or functionalities on the CNT backbone down to the atomic scale. The most commonly used techniques for the characterization of these labeled CNTs include atomic force microscopy (AFM), scanning tunneling microscopy (STM), high-resolution transmission electron microscopy (HRTEM), and scanning transmission electron microscopy (STEM). On the other hand, and this is the area that it is actually attracting most interest, the formation of hybrid materials CNT–inorganic often results in improved performance, for a given application, with respect to the properties of each of the individual components. CNTs are excellent materials for the formation of nanocomposites due to their high surface area, mechanical strength, thermal conductivity, and chemical inertness. In general, these nanocomposites consist of inorganic nanoparticles (NPs) decorating the external CNT sidewalls either as bulk powder or vertically aligned CNTs [13]. Few examples also report on the complete coverage of the CNT by the inorganic material, thus forming coaxial carbon-inorganic nanotubes [14]. These CNT–inorganic nanocomposite materials have potential application in a wide variety of areas, including catalysis, functional components in supercapacitors and batteries, sensors, optoelectronic devices, and hydrogen storage.

Different strategies have been employed for the formation of such nanohybrids which can be classified in two main groups, depending on the stage in which the NPs are formed: (a) pre-synthesized NPs can be attached to the CNTs in the so-called ex situ approach, and (b) the NPs can be formed directly on the CNT surface in the so-called in situ approach. A key point for the further development and application of these hybrid systems resides in the development of synthetic methodologies that allow a scaling up of the production process while keeping their properties and performance reproducible.

Ex Situ Approach: Decoration of CNTs with Pre-synthesized NPs



This approach goes through several steps, namely, the preparation of the NPs, chemical modification of the CNTs and/or the preformed NPs, and finally their linkage. The formation of the NPs is carried out independently, without the presence of CNTs, and thus, their size and shape can be more easily tailored. The morphology of the resulting NPs will in turn determine their physical properties. These pre-synthesized NPs can be attached to the CNT walls by either covalent bonds or through noncovalent interactions.

In the case of covalent bonding, through organic linkers or biomolecules, the amount of NPs that can be connected to the CNT walls is controlled by the number of functionalities available on the surface. These are well-defined chemical bonds that allow the formation of stable and robust hybrids. A wide range of already reported functionalization strategies and readily available linkers can be employed to connect CNTs with NPs. As detailed above, carboxylic acid groups on the sidewalls of the CNTs are being extensively used as anchor groups for further modification of the CNT structures. Therefore, a major coupling reaction used for the attachment of pre-synthesized NPs onto the CNTs goes through the esterification or amidation of previously oxidized CNTs employing an organic linker, such as 2-aminoethanethiol or ethylenediamine. Other reactions, such as the Bingel reaction, have also been employed for the attachment of NPs onto CNTs. The linkage of NPs using biomolecules is getting an increased attention due to their high specific recognition and biocompatibility, which are relevant for the application of these hybrid materials in the biomedical field. DNA, proteins, and viruses have been used to assist the formation of hybrid structures. Inorganic NPs that have been covalently attached onto the CNTs include Au, CdSe, CdTe, PbSe, TiO_2, MnO_2, SiO_2, and MgO.

As already explained, sidewall covalent functionalization of CNTs might disrupt the structural periodicity which can cause, for instance, the lost of the intrinsic optoelectronic CNT properties. An alternative method for the formation of hybrid materials, which preserves the intrinsic CNT properties, consists of taking advantage of noncovalent interactions between the CNTs and the NPs. Although the resulting hybrid materials are not as robust as with the covalent approach, its beauty resides in the experimental simplicity. A wide variety of materials, including quantum dots (e.g., CdTe, CdSe, CdS), metals (e.g., Pt, Au, Co), and metal oxides (e.g., TiO_2, SiO_2, Al_2O_3, ZrO_2, Fe_3O_4), have been attached by noncovalent interactions. For instance, these employ polymer wrapping, including polyelectrolytes, resulting in either positively or negatively charged CNTs with improved dispersibility which can then be decorated with NPs of the opposite charge by electrostatic interactions. Absorbance of organic molecules onto the CNT surface can also enhance the interaction of CNTs with NPs either through hydrophobic interactions or $\pi - \pi$ stacking. Molecules containing conjugated π-aromatic structures such as derivatives of pyrene, porphyrins, phthalocyanines, benzyl alcohol, and triphenylphosphines have been employed for the latter.

In Situ Approach: Direct Formation of NPs onto the CNT Surface

In the in situ approach, the CNTs serve as template and stabilizer for the formation of the NPs. It is a straightforward and effective method for the preparation of these nanocomposites, allowing a large degree of NP coverage. It also avoids the presence of an organic protecting shell, commonly used in the ex situ approach for the stabilization of the NPs and their linkage to the CNTs, which might impair their performance. On the other hand, the grown NPs are not so strongly bonded to the CNTs and it is not so easy to control their shape and dimensionality which depend on the influence of the CNTs in the nucleation and growth process. A major advantage is that the inorganic compounds can be deposited to different extents going from discrete NPs to a continuous layer, resulting in the complete coverage of the CNTs with inorganic nanotubes, which in turn can either have a crystalline or amorphous structure. Several techniques have been employed for the deposition of NPs onto the CNT surfaces, including electrodeposition, sol–gel processing, hydrothermal treatment, and gas-phase deposition. The types of inorganic materials that have been grown onto the CNTs include metals (e.g., Ag, Pt, Pd, Au), metal oxides (e.g., TiO_2, Fe_2O_3, ZnO, NiO, CeO_2, Al_2O_3, SnO_2), and metal chalcogenides (e.g., CdSe, CdTe, CdS, ZnS) and few examples on metal carbides (e.g., TiC, TaC, NbC, WC) and metal nitrides (e.g., TiN, Fe_2N, Si_3N_4). Although each material and technique used for the deposition requires certain experimental conditions, a widely used protocol would consist of depositing the inorganic material directly onto previously functionalized CNTs through a chemical or electrochemical redox reaction of the precursors. Metal salts and organometallic compounds are commonly used as precursors for the in situ decoration of CNTs with inorganic materials. An AFM image of a SWCNT decorated with in situ-grown Ag nanoparticles is presented in Fig. 4.

Endohedral Functionalization: Encapsulation of Materials Inside Carbon Nanotubes

A completely different approach for the functionalization of carbon nanotubes consists of filling their inner cavities with host materials. The potential applications of filled carbon nanotubes range from nanoelectronic devices to drug delivery systems going, for instance, through functional ceramics. A bandgap modulation of carbon nanotubes has been observed upon encapsulation of different materials, thus making filled CNTs good candidates for molecular electronics. Unprecedented structures and properties compared to those of the same material in the bulk form have been reported for the confined compounds, opening up new opportunities for the development of novel functional nanocomposites. An area in which the containment of materials into CNTs is getting an increased attention is in the biomedical field since their inner cavity can be filled with therapeutic or imaging cargos, while the outer surface can be modified to improve their dispersibility, biocompatibility, and site-selectivity [16].

Back in 1992, Pederson and Broughton predicted on the basis of computer simulations that open-ended nanotubes should act as "nanostraws" and draw in molecules from vapor or fluid phases. In the following years, several works reported on the encapsulation of materials inside CNTs [17]. The inner cavities of the CNTs can be filled either during their synthesis or in a post-synthesis filling process. Since a variety of metals catalyze the synthesis of CNTs, it is possible to tune the conditions of the synthesis to encapsulate mainly metals and metal carbides inside CNTs. A much wider variety of materials has been successfully filled into CNTs in a post-synthesis process, including water, fullerenes and their derivatives, organic molecules and biomolecules, metals and alloys, metal oxides, metal halides, and metal carbides. Once encapsulated the encaged material typically forms nanoclusters or nanowires within the inner cavities of the CNTs. Recently, the formation of single-layered inorganic nanotubes in the interior of CNTs has been reported, further expanding the possibilities of these systems [18].

Functionalization of Carbon Nanotubes, Fig. 5 HRTEM image of a CNT filled with CuBr (Reproduced with permission from Nature publishing group [20])

Several methodologies allow the encapsulation of materials into CNTs which can be generally classified in the so-called gas route and liquid route [19]. The gas route is a straightforward method for filling CNTs. It consists of heating a mixture of open-ended CNTs and the material to be encapsulated above the sublimation temperature of the chosen material. This process takes place in a sealed ampoule under vacuum. Using the same experimental protocol, if the material to be encapsulated is heated up above its melting temperature, the CNTs are then filled by capillary wetting via the liquid route. A HRTEM image of a CNT filled with a metal halide using this approach is presented in Fig. 5. Another methodology also within the liquid route consists of stirring open-ended CNTs in a solution containing the chosen material, either dissolved or suspended. The solution enters into the inner cavities drawing the desired material into the CNTs. In a subsequent step, the solvent is dried leaving behind filled CNTs.

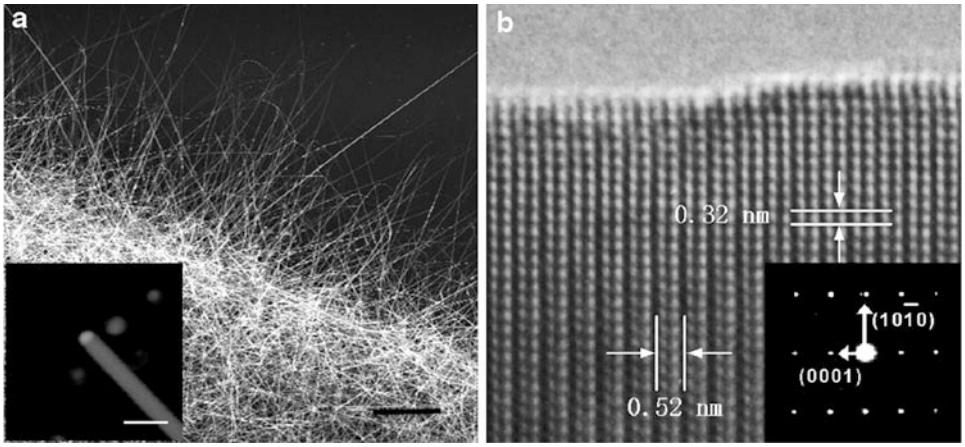
Characterizations of zinc oxide nanowires for nanoelectronic applications

Definition

Charge transport under different temperature and optical excitations in semiconducting nanowires is strongly influenced by the size confinement, surface effect, and impurity states.



Overview

When the physical size approaches fundamental length scales, such as Bohr radius or localization length, the material properties alter from their traditional bulk properties and exhibit unique characteristics. In the case of quasi-1D (Q1D) nanowire structures with high aspect ratio, there is strong fundamental interest in elucidating the charge conduction mechanisms, e.g., the effects of size confinement, surface contribution, and impurity states. This basic understanding helps to evaluate their potential as the building blocks for future nanoscale electronics. This entry presents the basic electrical transport properties correlated with the optical measurements of metal oxide nanowires, focusing on ZnO material.

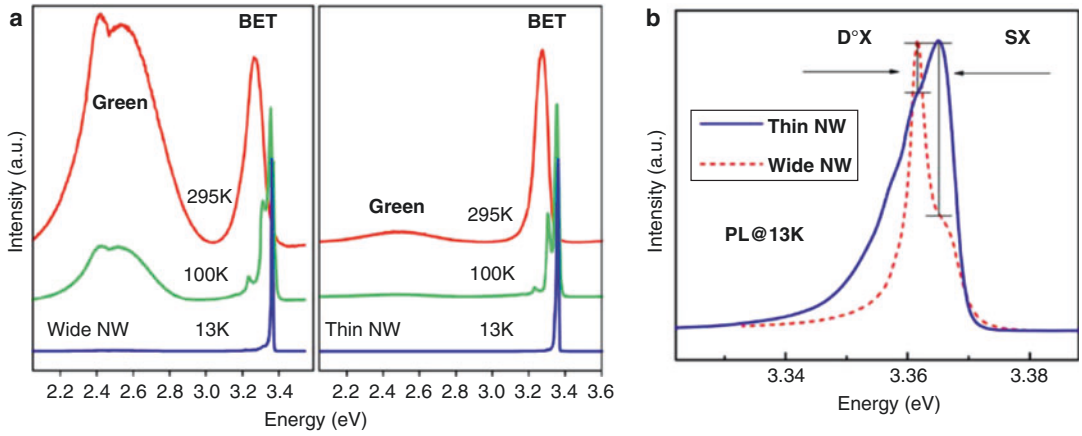
Synthesis of Single Crystalline ZnO Nanowires

ZnO has a stable wurtzite crystal structure. The zinc atoms are tetrahedrally coordinated with four oxygen atoms, which can be considered as two interpenetrating hexagonal closely packed lattices of zinc and oxygen. Single crystalline ZnO nanowires are typically synthesized via catalytic chemical vapor deposition (CVD) technique that is governed by a vapor–liquid–solid mechanism. In this process, various nanoparticles or nanoclusters are used as catalysts, such as Au, Cu, Co, Sn, etc. The formation of eutectic alloy droplet occurs at each catalyst site, followed by the nucleation and growth of solid nanowire upon the supersaturation of the liquid droplet. Incremental growth of the nanowire taking place at the droplet interface pushes the catalyst upward. The growth direction is along the crystal plane that is the most stable and has the lowest surface free energy. Figure 1a shows the scanning electron micrographs of ZnO nanowires synthesized by thermal evaporation of pure Zn powder at 700 °C in low oxygen concentration (<2 %) using Au catalyst nanoparticles [1]. Figure 1b is a high-resolution TEM image (HRTEM), and the selected area electron diffraction (SAED) pattern shown in the inset denotes single crystalline nature with [0001] growth direction.

Impurity doping is often achieved by adopting a laser ablation method in the CVD system. It can not only control the thermodynamic balance, thus influencing the crystal formation, but also tune the electron transport properties. The incorporations of Mg, Ga, In, Sn, Ni, Al, Mn, and Co in ZnO nanowires have been successfully demonstrated. One doping method places pure zinc source powder (99.99 %) in the center of the horizontal CVD furnace, while the dopant metal is loaded at the upstream of the quartz tube. The dopant source is constantly ablated by Nd:YAG (yttrium aluminum garnet) laser pulses. The doped nanowires grow via the VLS process on catalyst-coated silicon substrates. The energy dispersive X-ray (EDX) spectrum and HRTEM analyses are used to show that the impurity atoms are substitutionally doped into the wurtzite crystal lattice and the nanowires maintain the same growth direction along the *c*-axis ([0001] direction).

Fundamental Properties of Zinc Oxide Nanowires, Fig. 1 (**a**) A SEM image shows the as-grown ZnO nanowires. Inset: a ZnO nanowire with a diameter of 50 nm terminated with a Au nanoparticle (scale bar, 100 nm). (**b**) HRTEM image of a ZnO nanowire with lattice spacing 0.52 nm. The *inset* SAED indicates that the growth direction is [0001] along the *c*-axis

Material Properties of Undoped ZnO Nanowires



ZnO has a direct wide bandgap of 3.37 eV at room temperature. Compared with other wide bandgap materials, it has a larger exciton binding energy (60 meV) that ensures efficient exciton emissions at room temperature. In addition, due to the small size comparable to its Debye length, ZnO nanowire has demonstrated superior sensitivity to surface chemical adsorbents. As a result, ZnO nanostructures have attracted intensive research interest in developing nanoscale transparent electronics, sensors, actuators, optoelectronics, spintronics, and energy-harvesting devices.

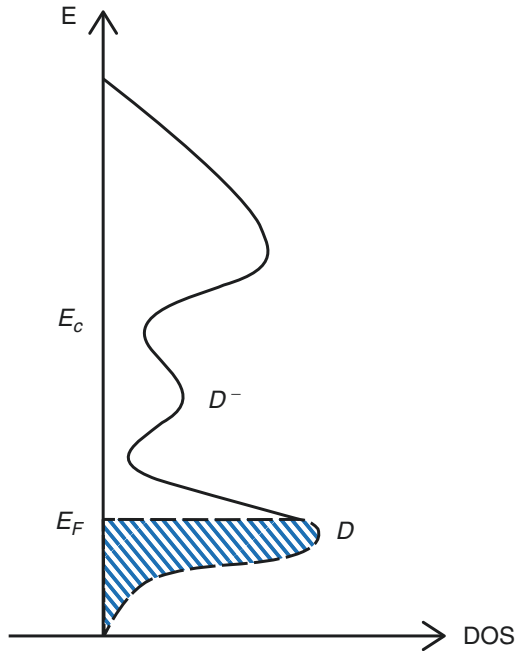
ZnO is known to be natively *n*-type doped accompanied with slight self-compensation. The electron donors originate from its native defects, such as oxygen vacancies, zinc interstitials, or incidental hydrogen [2]. They form impurity bands with shallow donor levels around 30–60 meV [3–5] and deep levels around 0.7–2.3 eV [6, 7] below the conduction band edge E_c. The impurity states have been probed by various spectroscopy techniques such as photoluminescence, cathodoluminescence, and electroluminescence.

Photoluminescence Property

Low-temperature photoluminescence (PL) measurement is one of the most sensitive tools to investigate radiative defects in materials. From the spectra peaks and decay time measurements, one can determine the different emission mechanisms, the energy bandgap, defect levels, and their relative density.

As feature sizes shrink into the nanometer scale, optical properties of metal oxide nanowires begin to reveal size effects. Comparing the ratio of the deep level to near-band-edge emission of different sized ZnO nanowires, it is found that the ratio is directly related to the wire diameter to length ratio [8, 9]. The temperature-dependent PL spectra of ZnO nanowires with different diameters (d) are shown in Fig. 2a. The green luminescence band at ~2.5 eV, originated from bulk defects, is much stronger for wide nanowire ($d >$ 100 nm) than the thinner wires ($d <$ 30 nm). Figure 2b shows the zoomed-in view of the band-edge transition (BET) emission at 13 K for different diameters. The emission from wide nanowires shows a sharp peak at 3.362 eV arising from the donor-bound excitons and a minor peak at 3.366 eV as a result of surface-bound exciton. The emission peak at 3.366 eV prevails in the

Fundamental Properties of Zinc Oxide Nanowires, Fig. 2 (**a**) PL spectra of wide (*left*) and thin (*right*) ZnO nanowires at different temperatures show that the bulk defect states (*green*) are more pronounced in wide nanowires. Intensity is normalized with respect to the band-edge transition peak. (**b**) A close-up view of band-edge transition (BET) of thin and wide nanowires at 13 K, indicating the blue shift in thinner wires due to the predominant surface-bound exciton emission



thinner wires. This blue shift is a direct result of finite size effect, due to the emerging of the surface-bound exciton emission that becomes dominant in smaller diameter nanowires.

Electrical Properties

Charge transport properties in the Q1D system are of profound interest due to the unique phenomena that occur when size reduces to nanometer scale and are also of technological importance for utilizing them as the building blocks for potential electronic devices. The contribution of surface-related properties will become increasingly important due to the enhanced surface-to-volume ratio that is inversely proportional to the nanowire radius. The optical and transport properties are closely related to the inherent native defects for the undoped nanowires and extrinsic impurities for the doped nanowires.

The underlying electronic band structure giving rise to conduction mechanisms that originate from the native *n*-type doping accompanied with self-compensation. In the case of moderate to heavy doping, the Coulomb fields arising from the ionized donors and the compensating acceptors result in the dispersion of the donor levels into impurity bands [10]. Moreover, the impurity band further splits into a lower *D* band and an upper *D* band, as depicted in the Fig. 3 [11–13]. The lower *D* band is attributed to singly charged donors, while the upper *D* band arises from neutral donors. The Fermi level, E_F, situates within the lower D band.

In order to study the electrical transport properties of the nanowires, metallic electrodes are patterned onto individual nanowires. The interface between nanowire and metal contact plays a critical role in transport behavior and device performance. Low resistance ohmic contact is necessary to elucidate the intrinsic conduction property. To reduce the contact energy barrier, titanium (Ti) with a work function of ~4.33 eV, which is close to the ZnO electron affinity of ~4.35 eV, is often selected as the adhesive layer to form ohmic contact with native *n*-type ZnO [14, 15]. The intrinsic electrical properties are determined from four-probe conductivity measurement and three-terminal field-effect transistor (FET) response [1]. Figure 4a represents the logarithmic scaled conductivity of a ZnO nanowire with diameter around 50 nm as a function of reciprocal temperature. The charge conduction consists of a combination of thermal activation and variable range hopping (VRH) conduction channels. For $T > 100$ K, the conduction shows Arrhenius behavior with thermally activated transport.

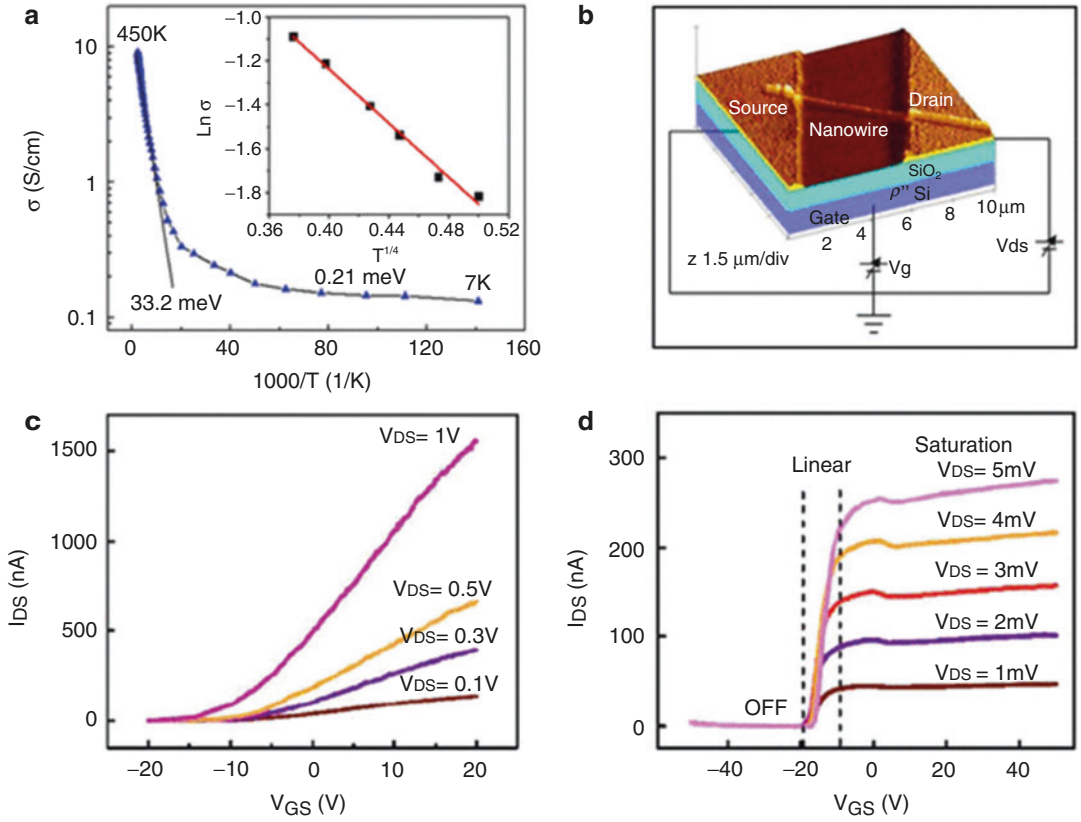
Fundamental Properties of Zinc Oxide Nanowires, Fig. 3 Band diagram depicting the density of states (DOS) in ZnO. The electronic levels below E_F (*shaded region*) are occupied, while the levels above are unoccupied

The conductivity can be expressed as $\sigma \sim \exp(-E_a/k\ T)$, where E_a is the activation energy (around 30 meV), attributed to the shallow donor levels below the conduction band edge. For $T <$ 20 K, Mott's variable range hopping model governs the transport, with conductivity modeled by $\sigma \sim A\exp(-T_0/T)^{1/(d+1)}$, where T_0 represents the characteristic temperature that depends on the localization length and the density of states at the Fermi level and d is dimensionality. The best fit yields $d = 3$, manifesting 3D conduction. For intermediate temperature range, 20 K $< T <$ 100 K, the charge transport is contributed by the activation of electrons from the Fermi level E_F to the upper D band.

Figure 4b shows an atomic force microscope (AFM) image of a ZnO nanowire FET on a SiO_2/p^{++} Si substrate. Based on simple electrostatic model, taking an infinitely long thin wire of length L and radius r ($L >> r$) located at a distance h above a conducting plane, the backgate capacitance is can be estimated to be

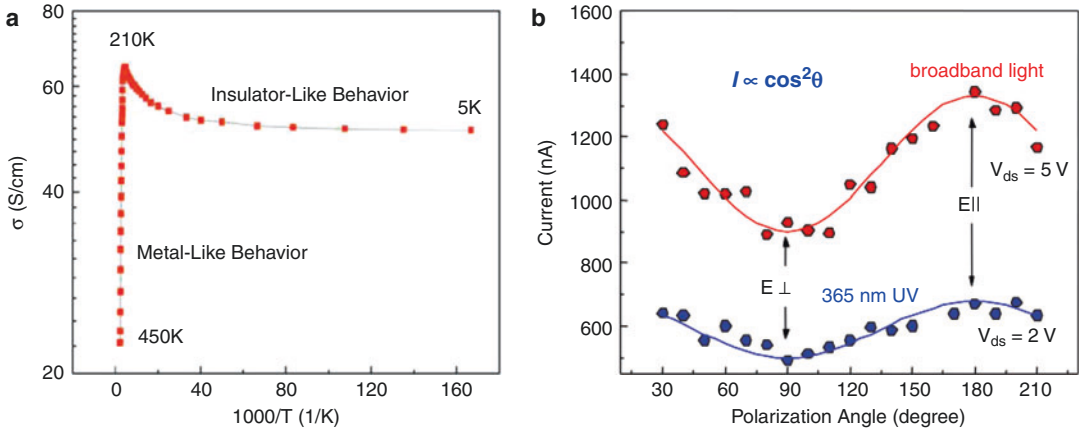
$$C = \frac{2\pi\varepsilon_0\varepsilon_r L}{\ln[(2h+r)/r]}$$

where ε_r is the effective dielectric constant for the wire between air and SiO_2 plane [16]. In general, the field-effect mobility (μ) can be expressed using the following expressions:



$$\mu = \frac{\partial I_{DS}}{\partial V_g}\frac{L^2}{CV_{DS}}$$

From the gate voltage-dependent source-drain conductance characteristics (Fig. 4c), one estimates the field-effect mobility to be around 30 cm^2/Vs and an electron concentration around $\sim 10^{18}$ cm^{-3} [17]. It is known that the surface defects act as scattering and trapping centers, thus affecting the charge transport. Surface passivation has been applied on metal oxide nanowires. Park et al. have reported an electron mobility of 1,000 cm^2/Vs after coating the nanowires with polyimide passivation layer to reduce the electron scattering and trapping at surface [18]. Later, a CMOS-compatible process is utilized to coat a SiO_2/Si_3N_4 bilayer on ZnO nanowire FETs. The results show dramatically enhanced electron mobility up to 4,000 cm^2/Vs (Fig. 4d). This performance improvement indicates that the ZnO nanowire device holds promising potential in memory and logic gate devices and other high-speed electronics application.



Photoconductance Properties

Under light illumination, the conductivity of semiconducting nanowires typically increases due to excess photogenerated charge carriers. Interestingly, pronounced metal-insulator transitions have been observed in undoped and doped ZnO nanowires. Figure 5a shows the temperature-dependent conductivity of ZnO nanowire upon continuous UV ($\lambda_{UV} = 365$ nm, $E_{UV} = 3.4$ eV) irradiation [19]. The conductivity is significantly increased by two orders of magnitude at low temperature. As temperature rises, thermally activated charge carriers contribute further to an

F

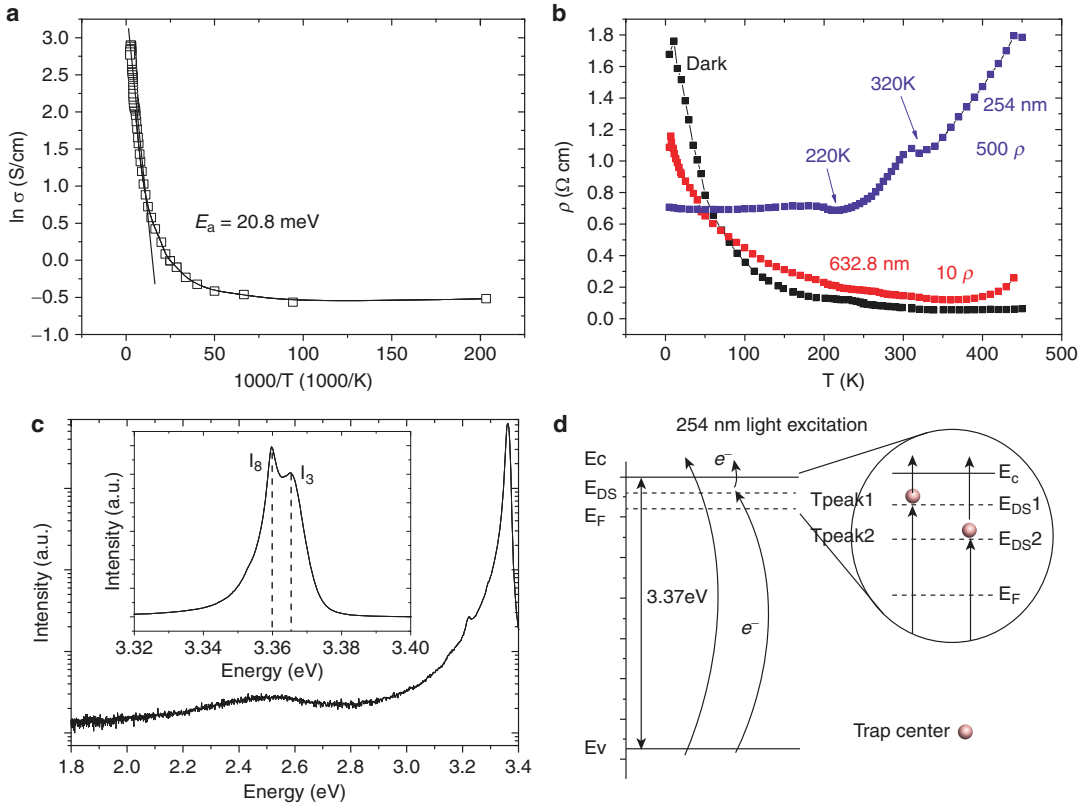
increase in conductance. Yet, as the carrier concentration approaches a critical value, an insulator-to-metal transition occurs. The strong surface scattering and Coulomb interactions among the dramatically increased charge carriers confined in the Q1D structure lead to a decrease in the conductance as the temperature rises.

In light polarization measurement, it is found that the photoconductance of ZnO nanowires is sensitive to the angle of the incident light as shown in Fig. 5b. The photocurrent is maximized when the electrical field of the incident light is parallel to the nanowire long axis and minimized at 90°. The large polarization response is attributed to the large dielectric contrast between the nanowire and surrounding air. The polarization-dependent behavior can be potentially utilized for optical switch, photodetector, and polarizer using aligned nanowire arrays.

Material Properties of Extrinsic Doped ZnO Nanowires

ZnO nanostructures have been doped with various elements, with the goal to tune their optical, electrical, and magnetic properties. Due to the abundant impurity states, the mechanisms of photoconduction are much more complex than the simple generation of electron–hole pairs across the direct bandgap. Therefore, it is challenging to elucidate the electrical properties of these individual nanowires and the contributions from impurity levels and size confinement. In addition, much more in-depth understanding is needed on the metal-to-semiconductor transitions in heavily doped systems. In this section, a study on Ga-doped ZnO (ZnO:Ga) nanowires is described below.

Electrical Properties



The electrical transport properties are investigated on single doped nanowires (~60 nm in diameter) in a three-terminal configuration, as in a typical field-effect transistor with a global backgate underneath a 500-nm SiO_2 dielectric layer on top of a Si substrate.

Photoconductance and Photoluminescence Properties

Figure 6a is the semilogarithmic plot of conductivity versus reciprocal temperature under dark condition. It is shown in the earlier section that the electrical transport of undoped ZnO nanowires at relatively high temperature range is mainly governed by thermal excitation [13, 19]. Here, the linear region shows such Arrhenius behavior fitted with $\sigma \propto e^{-E_a/kT}$, where E_a, k, and T are the activation energy, Boltzmann constant, and absolute temperature, respectively. As a result, E_a is extracted from the slope to be ~20.8 meV, corresponding to the shallow donor levels arising from the native and extrinsic defects [2, 5].

Figure 6b plots the resistivity of ZnO:Ga nanowire as a function of temperature under dark, He–Ne laser (λ_{ph} = 632.8 nm, E_{ph} = 1.96 eV), and UV (λ_{UV} = 254.0 nm, E_{UV} = 4.88 eV) illuminations. The phenomenon of persistent photoconductivity is typically observed in ZnO channels, originating from the surface band bending due to oxygen adsorption [20, 21]. The resistivity behaviors in dark and in continuous 632.8-nm laser (red curve in Fig. 6b) excitation follow the semiconducting-like behavior, i.e., resistivity decreases with the increase of temperature. In sharp contrast, under continuous UV illumination (violet curve in Fig. 6b), the temperature-dependent resistivity changes distinctively to a metallic-like behavior. The considerable conductance increase is due to both thermal excitation and photogeneration; and the resistivity increase with the increase of temperature manifests the significantly enhanced Coulomb interactions and surface scattering in the quasi-1D channels.

To calculate the charge concentration, the field-effect model shown earlier will not be strictly valid in this case of degenerate carriers. As shown in Ref. [16], the conductivity σ varies with resistance R as $d\sigma/\sigma = -(dR/R) = (2/3)(dN/N)$, where N is the total number of carriers in the wire and changes with gate voltage via $d(eN) = C\, dV_g$. The gate capacitance per unit length is estimated to be 0.42 pF/cm. From the measurements at $T = 4.9$ K and the drain source bias $V_{ds} = 0.2$ V, the carrier concentration n in

(**b**) Temperature-dependent resistivity in dark and under (632.8 and 254.0 nm) light illuminations. Note: for comparison convenience on the same plot, the resistivity data under laser and UV irradiation is multiplied by 10 and 500, respectively. (**c**) PL spectrum of ZnO:Ga nanowires measured at 13 K, showing a weak *green* luminescence band at ~2.5 eV (496 nm). *Inset*: the high-resolution plot centered at the band-edge luminescence represents donor-bound exciton emission. (**d**) Schematic band diagram of electron excitation under 254-nm UV ($E_{ph} = 4.88$ eV) illumination. Zoomed-in diagram shows the native and extrinsic impurity levels, giving rise to the corresponding resistance peaks due to trapping and detrapping processes

dark (for the wire with $L = 10$ μm and $r = 30$ nm) is calculated to be ~8.72×10^{18} cm^{-3}. From measurements on He–Ne laser ($\lambda_{ph} = 632.8$ nm, $E_{ph} = 1.96$ eV) and UV ($\lambda_{UV} = 254.0$ nm, $E_{UV} = 4.88$ eV) illuminations, the carrier concentrations are estimated to be 1.78×10^{19} cm^{-3} and 6.88×10^{19} cm^{-3}, respectively. Under irradiation, excess electrons are excited to the conduction band and form a degenerate electron gas.

In Fig. 6b, two distinct resistivity valleys are clearly displayed at 220 and 320 K, respectively. A close examination shows that the 632-nm laser illumination also induces these resistivity valleys at the same temperatures, although the effect is of much smaller magnitude than of the 254-nm UV irradiation. These two reproducible valleys signify sharp transitions at two electronic states, and they are attributed to the existence of impurity levels below the conduction band edge, leading to charge trapping and detrapping processes.

In order to verify this contribution from the impurity states, photoluminescence measurements using He–Cd laser ($\lambda = 325$ nm) incident excitation are conducted to compare with the photoconductance data. Low-temperature PL spectrum in Fig. 6c displays a weak green luminescence band at around 2.5 eV, owing to the

presence of deep lying defect states such as oxygen vacancies and structural defects [22, 23]. A weak UV emission shoulder at 3.2206 eV ($\lambda = 384$ nm) can be reproducibly observed in the PL data, which is attributed to the donor-acceptor pair emissions in ZnO [24]. An intense luminescence of donor-bound excitons around the band edge remains sharp as in undoped emission PL [23, 25], confirming that the Ga dopants have been well integrated into the ZnO lattice. With a careful examination of the bound exciton emission (inset of Fig. 6c), one sees that the peak splits into two distinct lines, manifesting that the Ga doping induces shallow donor levels [8]. The small peak at 3.3654 eV is caused by ionized donor-bound exciton, typically assigned as the I_3 line, while the prominent emission line at 3.3597 eV can be indexed to the I_8 line, attributed to the exciton emission bound to Ga donors [25, 26].

Comparing the photoconductance and photoluminescence measurements, the conduction mechanisms in ZnO nanowires can be now understood consistently. Both thermal and optical excitations contribute to the conduction in the nanowire. As a general trend under continuous UV irradiation, metallic behavior is revealed. The strong Coulomb interactions among the dramatically enhanced charge carriers confined in the Q1D nanostructure cause the resistance to increase as the temperature rises. The resistance valleys originate from the defect levels. To illustrate the process, Fig. 6d depicts the band schematic diagram and the effect under 254-nm UV illumination (4.88 eV). E_V, E_C, and E_{DS} denote, respectively, the valence band edge, the conduction band edge, and the shallow defect levels which arise from the native defects and external impurity dopants. The existence of E_{DS} levels serves as trapping and detrapping centers. At low temperatures, the photoexcited electrons from valence band get trapped in the emptied localized defects states (E_{DS} levels). As the temperature increases to ~220 K, the electrons occupied in the $E_{DS}1$ state become detrapped and thermally excited to the conduction band, inducing an increase of the electron concentration, giving rise to the first resistivity valley. The second valley occurs as temperature rises further when the trapped electrons are excited from the $E_{DS}2$ level to the conduction band. Considering the consistent valley position at 220 and 320 K, two E_{DS} levels can be estimated to be 19.0 and 27.6 meV below conduction band (Fig. 6d). In addition, the difference between the two defect levels (8.6 meV) falls in the range of the difference between the I_3 and I_8 photoemission peaks (5.7 meV). This elucidates that these resistivity valleys originate from the shallow defect states due to native and Ga donors.

Future Outlook

In the fundamental studies of ZnO nanowires, there is still much awaiting to be explored. Some important questions on the intrinsic conduction mechanisms via impurity states, surface contribution, and quantum effects remain to be answered (e.g., thermal activation, hopping conduction, weak localization, metal-insulator transition, etc.). In addition, when the diameter further reduces, scalability on the critical length scale (50 nm) and dimensional transitions from 3D, 2D, to 1D need to be thoroughly examined. Moreover, single electronic effect is expected to play an important role in low dimensions due to the strong Coulomb interactions. The quantum confinement will provide the means to manipulate individual quantized states of electrons, spins, and phonons. With a comprehensive characterization and quantitative analysis of the unique properties, one advances the knowledge necessary for device design to achieve high performance and low-power consumption based on the nanostructures.

In the trend of device miniaturization, nanowires have attracted immense interests and possess great potentials in device applications. Among various nanomaterials, ZnO nanowire has been one of the most enthralling systems due to its remarkable functionalities. With the achievements in synthesizing and characterizing high-quality nanowires, extensive research effort

has been invested on nanoscale ZnO-based device fabrications. ZnO nanowire FETs, as the elementary building blocks of next-generation transparent electronic circuitry, have been constructed with different gate configurations of back, top, side, and surrounding gate architectures. ZnO nanowire FET can be implemented into either *n*-type depletion or enhanced-mode operations that are both essential in logic circuit construction. Yet, large-scale device integration remains a crucial challenge. The realization of logic circuits based on ZnO nanowires leads toward an important step in nanoelectronics. However, cascading into multilevels of logic gates with high gain and efficient interconnection for hierarchical assembly demands additional investigations. In summary, these fascinating applications encourage further research efforts to address the technical challenges and to unravel the scientific puzzles that are vital for the meaningful development of future technology applications.

Definition

In the materials science community, the term "nanoparticle" is generally used to indicate particles with atomic domains spatially confined to less than 100 nm since the physical properties of materials start to change significantly due to a variety of confinement effects in this size range. Another commonly used concept, "cluster," indicates smaller particle with a diameter of only several nanometers, corresponding to 10^4 molecules or atoms. Sharing the same features with other types of nanostructured materials, nanoparticles also have significant atom fractions associated with interfacial environments, and interactions between their constituent domains. Gas phase particle formation refers to production of particles from individual atoms or molecules in the gas phase.

Overview

In the last several decades, intensive research has been performed on nanostructured materials, that is, materials with grain sizes less than 100 nm. Nano-sized particles are considered as the starting point for preparations of an extensive variety of nanostructured materials. Meanwhile, nanoparticles themselves have played a significant role in novel technology development [1]. As such, they have been prepared by a variety of methods and their synthesis is a crucial part of rapidly growing nanoscale research.

Gas phase synthesis technique is well known for producing a wide range of nanoparticles. Gas phase particle generation is captivating because it excludes the wet byproducts of liquid phase processes and the as-prepared product particles promptly separated from the gas stream are in high purity without post-growth treatment. The gas phase synthesis has been extensively developed and widely applied in industries. Meanwhile, the commercialization of new products has experienced a considerable progress and the commercial nanoparticles produced by this method comprise the largest share of the market. In the synthesis of nanoparticles from atomic/molecular precursors, one wants to be able to control different aspects of this condensed ensemble, in which the most important one is the size and size distribution of the resultant particles. The reason, as indicated above, is that the material parameters of a solid experience a dramatic change when cluster size becomes less than a certain threshold value. A property will be altered if the entity is confined within a space smaller than the critical length of the entity responsible for this property. Therefore, the product quality and application characteristics of nanoparticles strongly depends on the distribution of particle size and on the particle morphology. Well-controlled gas phase routes are able to synthesize nearly spherical and nonporous particles with high purity. The resulting particles are small in size with narrow size distribution.

In gas phase synthesis of nanoparticles, conditions include usual situations of a supersaturated vapor, or chemical supersaturation in which it is thermodynamically favorable for the gas phase molecules to undergo chemical reactions and condensation. If the reaction and condensation kinetics permit, particles will nucleate homogeneously when the degree of supersaturation is sufficient. Once nucleation occurs, the reaction/condensation of the gas phase molecules will occur on the resulting particles and will keep relieving the remaining supersaturation, since then the nucleation process stops. With this gas phase conversion process, particles are built all the way up to the desired size.

Gas-Phase Nanoparticle Formation, Fig. 1 Gas phase particle formation mechanism

Although the processes of gas phase nanoparticle synthesis vary from one to another, they all have in common the fundamental aspects of particle formation mechanisms. In gas phase reactors, three major formation mechanisms determine the particle formation within the first few milliseconds of the synthesis process, and will determine the final characteristics of particulate products. The influences of these mechanisms on particle formation, growth, and final morphology are shown in Fig. 1.

1. The precursor chemical reactions form product clusters by nucleation, and then the clusters grow into particles by surface growth [2].
2. Because of the sintering processes, coalescence occurs in the high-temperature zones of the reactor to reduce aggregation and enhance the formation of spherical particles [3].
3. Also, coagulation occurs inevitably in the gas phase synthesis with high particle concentrations, after the formation of particles in a gas

phase; their coagulation rate is weakly dependent on particle size and proportional to the square of particle number concentration.

If temperature is sufficiently high, the coalescence of particles is much faster than their coagulation to produce spherical particles. On the contrary, loose agglomerates are formed with open structures.

Most advances in this field closely relate to gaining better understanding and better control of particle aggregation and coalescence in order to produce nonporous particles with desired size and narrow size distribution. Gas phase synthesis is one of the best techniques in controlling nucleation-condensation growth and collecting/handling nanoparticles afterward. There are various parameters such as flame temperature, precursor residence time, ions, gas concentration, cooling rate, and additives which can affect the process of coagulation and sintering, and consequently, the characteristics of the resulting particles with respect to the size monodispersity. In addition to the particle size and size distribution, the composition of the constituent phases and the nature of the interfaces created between constituent phases are also of crucial importance if the particles are constituted by more than one material. The interplay among size, composition, and interfaces determines the properties of nanoparticles.

Specific Synthesis Methodologies

The physical and chemical processes for nanoparticle formation in gas phase are qualitatively understood. The process has been used in the formation of millions of tons of particles in nano-/submicroscale every year in different industries. Particle generation in the gas phase is carried out either by precursor gases reaction or by evaporation. To generate the high temperature for these processes, high-energy sources such as Joule heating, hydrocarbon flames, plasmas, ions, electrons, or laser beams are needed. Therefore, different kinds of furnace, flame, plasma, and laser reactors have been used to facilitate gas phase reactions and produce the desired materials.

Gas Phase Condensation (for Metal Nanoparticles)

To achieve supersaturation, the most straightforward method is to heat certain solids and evaporate them into background gases, and then reduce the temperature by mixing the vapors with cold gases. Formed by homogeneous nucleation in the vicinity of the gas source, the clusters grow in this process by gas phase coalescence of the source atoms. It has been found that the average particle size of the resulted nanoparticles increases with the increase of gas pressure and the applied inert gas mass. Experimentally, it has also been found that the particle size distribution is lognormal. This has been explained theoretically by the particle's growth mechanisms [4]. This method is also well suited for producing metal nanoparticles as for most metals, the evaporating temperature is attainable and evaporation rates are reasonable. Furthermore, compounds of the evaporated metal can be prepared by including a reactive gas in the cold gas stream [5].

In the gas-condensation process, it has been studied [6] that the formation of the atom clusters is essentially controlled by three fundamental rates:

1. The evaporation rate
2. The rate that the hot atoms lose their energy in the condensation region
3. The removal rate of the nucleated clusters from the supersaturation region

The evaporation-condensation process functions as a form of distillation. Therefore, with volatile impurities removed in this process, the purity of the material can be further improved. However, there are a few limitations for this synthesis method: (1) it is difficult to control composition in the case of synthesizing more complex materials by this method and (2) this process is restricted to materials which have low melting points or high vapor pressures.

Nanoparticle Formation in Flames

So far, in the nanoparticle synthesis, the most commercially successful approach is carrying out the synthesis process within a flame, which provides the energy to evaporate the precursors so that the heat needed to induce reaction and particle

nucleation is produced by the combustion reactions. Every year, this method alone produces millions of metric tons of nanostructured materials, such as carbon black and metal oxides. Since the flame provides oxidizing environment, it has been primarily used to make oxides materials.

High temperatures (up to 2,400 °C) can be realized in the flames and the precursor concentration in the flame can be quite high due to the high energy density. In the highest temperature region where the primary particles are formed, the residence time only ranges between 10 and 100 ms. After this region, the only things that can be influenced are the particle size and the aggregation morphology. The attainable particle sizes using flame synthesis is from a few nanometers up to 500 nm. The specific surface areas of these particles can go 400 m^2/g and higher.

Temperature profile, reactor residence time, and reactant concentration are the three crucial parameters for generating the desired particles. Unfortunately, the coupling of the flame chemistry to the nanoparticle production makes this process very complex and difficult to control. Every adjustment to the feed flow changes all three parameters simultaneously. Therefore, it is impossible to change these three parameters independently in flame reactors.

Furnace Flow (Hot-Wall) Reactor

Furnace flow systems employ tubular furnace-heated reactors for initiating the synthesis reaction. Temperatures for reaction are often set below 1,700 °C. The gas composition is freely selectable with variable concentrations. Usually, the system pressure is atmospheric, but it can also be set at other values and used as a process parameter.

With high efficiency, the reactor has a relatively simple design. The process of this technique is precisely controllable and flexible with respect to gas composition and system pressure. Therefore, it allows the production of particles with specific characteristics. It also allows different kinds of particle production in the range from atomic to micrometer dimensions. However, it often causes a high degree of aggregation at high aerosol concentrations. Moreover, compared to other methodologies, it has high energy requirements.

Plasma Reactor

Supersaturation and particle nucleation can also be achieved by injecting the precursors into thermal plasma to provide the energy needed for inducing reactions. It is quite common to deposit thin films and coatings by plasma spraying and thermal plasma vapor (chemical or physical) deposition. The most commonly used electrical methods to produce plasmas are high-intensity arcs and inductively coupled high-frequency discharge. Solid precursors are conveyed in the plasma where they are fully evaporated and decomposed into atoms in the plasma center by the high temperatures. The precursor vapors are then cooled rapidly by mixing with quenching gas at the end of the plasma. As a result of high supersaturation, ultrafine particles are obtained.

Ion Sputtering

The method of sputtering is to vaporize materials by bombarding a solid surface with inert gas ions shot in high velocities. The sputter source, for example, an ion gun, usually works in systems with of 10^{-3} mbar or even higher vacuum, since a higher pressure will block the sputtered material transportation. Electrons can be used to replace ions for the same purpose. The major advantage of sputtering is that the material being heated is mainly the target material, and thus the composition of the sputtered material is that of the target. However, this process needs to be carried out at relatively low pressures which can cause difficulties for further nanoparticles processing in gas phase.

Spark Discharge

High-current spark between two solid electrodes is used as another means of vaporizing metals. In the presence of an inert background gas, the electrode material is evaporated to produce nanoparticles until it reaches the breakdown voltage. This technique is very useful for materials with a high melting point (e.g., Si or C), which cannot be evaporated in a furnace. The spark (arc) formed across the electrodes can only vaporize a small amount of metal to produce very small amounts of nanoparticles, but this process is relatively reproducible.

Laser Ablation

Instead of evaporating certain material to produce a supersaturated vapor, a pulsed laser can be utilized to evaporate a piece of spatially confined material. The laser beams are focused onto the center of the reaction chamber where the precursor (e.g., coarse metal oxide powder) is fluidized, resulting in a power supply of a few kilowatts in a volume of only a few cubic millimeters. The precursor powder is evaporated by the focused laser, and nanoparticles are formed by the vapor condensation. This method can be used to vaporize materials that cannot readily be evaporated even though laser ablation can generally only produce small amounts of nanoparticles. For solids having high vaporization temperatures, typically ceramics and metal oxides, from which nanoparticles cannot be synthesized by standard gas phase processes, the high-power intensity of the laser opens a gate for them to be used as precursors. The nanoparticles synthesized by laser have potentials for new applications since their morphologies are significantly different from typical pyrogenic oxides due to the high cooling rates.

Nanoparticle Collection

Among the collection devices, the simplest one is a small-size pore filter for separating nanoparticles from a gas stream. The disadvantage is that impurities and defects can result from the incorporation of the filter material parts into the nanocrystallined particles. Therefore, by employing thermophoretic forces, a collection device was designed to apply a permanent temperature gradient, which results in the separation of nanoparticles from the gas that has been used. In addition, collection of the nanoparticles in liquid suspension can be used to enhance the stability of the collected nanoparticles against compositional changes, sintering, and agglomeration.

Limitation of Gas Phase Process

1. Hazardous gaseous reactants and its byproducts are apparent disadvantages of gas phase nanoparticles synthesis.
2. Nanoparticles agglomeration is inevitable in the gas phase synthesis. However, by capping the particles with appropriate ligands in the liquid phase synthesis, the dispersion of nanoparticles can be indefinitely stabilized.
3. In gas phase synthesis, it is often difficult to produce composite materials with uniform chemical compositions because heterogeneous compositions within an individual particle or from particle to particle can be caused by differences in the vapor pressures, chemical reaction rates of the reactants, and nucleation/growth rates of the products.

Engineering Applications

Nanoparticles have been applied or been evaluated for use in many fields by employing their electrical, magnetic, thermal, optical, and mechanical properties. Nanoparticles synthesized in gas phase have also emerged into engineering fields such as heterogeneous catalysis [7], biomaterials, electroceramics manufacturing, dental materials, and fuel cell membrane construction. The advantage of nanoparticle application is that it incorporates many effects related to their sizes. These effects include “the quantum size effects” (electronic effects caused by delocalized valence electron confinement), “the many-body effect” (altered cooperative atom phenomena), for example, lattice melting or vibrations, and suppression of the lattice-defect mechanisms, such as dislocation generation and migration within the confined grain sizes. The capability of engineering a large variety of useful technological applications will be impacted by possibly size-selected nanoparticle synthesis and assembling the nanoparticles into novel materials with unique and improved properties including controlled mechanical, electronic, optical, and chemical properties. Microelectronics and even medical applications [8] will profit from developing this nanoparticle formation process.

Future Research

Based on the newly arisen questions and challenges, research in this field underlines the need

for synthesizing nanoscale particles (especially mixed oxides particles) with precisely controlled characteristics. Future research includes topics such as the scale-up synthesis of particles with controlled properties, verification of mesoscopic chemistry relationships that can be applied in research, and nano-thin coated nanoparticles made in large quantities. In this endeavor, scientists and engineers should accumulate their knowledge and contribute to small particles generation, granulation, flocculation, crystallization, and classification.

Synonyms

Dry adhesion; Fibrillar adhesion

Definition

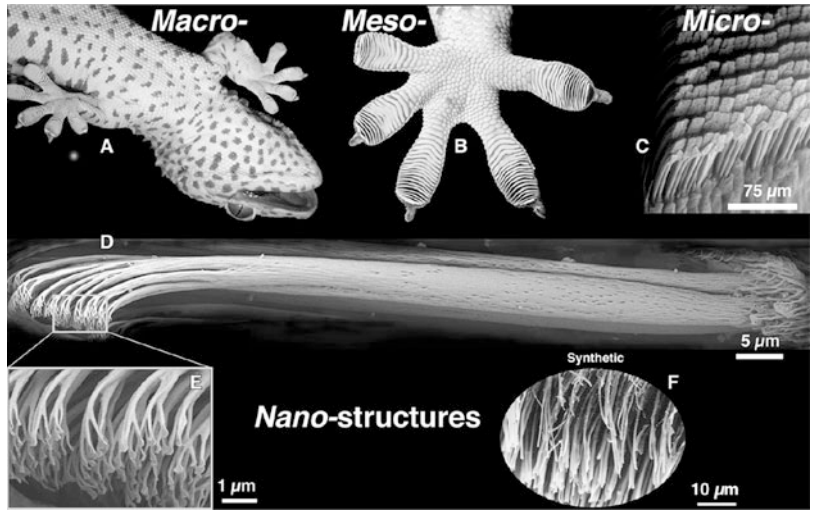
The gecko adhesion system is a dry adhesive based on a fibrillar surface pattern and allows easy, repeatable, and residue-free detachment.

Conventional Adhesives and the Gecko Adhesion System

Adhesives are an important ingredient of modern technology. Their function is to reliably connect

two different objects with each other. Although other techniques may be used to assemble two objects (e.g., screwing or welding), the application of adhesives has many benefits. For example, they provide a more uniform distribution of stresses along joints, can be applied at ambient (or moderately elevated) temperature, or can fulfill additional requirements such as acoustical damping or energy dissipation. Adhesives have also been key to new technologies, e.g., in the development of laminated fiber-reinforced materials. The need for adhesives in special applications has led to the development of more than 250,000 adhesives in use today.

Nature has also evolved adhesives for numerous purposes. A special case is a reusable adhesive in which attachment, detachment, and reattachment occur without loss in adhesion strength; insects, spiders, tree frogs, and geckos can stick to walls and ceilings, attaching and detaching their feet rapidly and repeating this for thousands of times without losing the ability to stick. Geckos belong to the heaviest animals supporting such an adhesive system, which exhibits the following characteristics:



- *High adhesion to smooth and rough surfaces based on physical interactions*: Unlike conventional adhesives, which are usually based on chemical bonds or mechanical interlocking, gecko adhesives work without pretreatment of the surface, e.g., by cleaning or roughening.
- *Adhesion barely depends on the chemical properties of the surface*: Conventional adhesives often have to be tailored to different surfaces to achieve high adhesion.
- *Directional adhesion, allowing easy detachment*: Unlike conventional adhesives, gecko adhesives enable anisotropic adhesion properties. While sticking occurs in one direction, detachment happens in another.
- *High reversibility of adhesion*: The reversibility of conventional adhesives is poor and seldom lasts more than a few attachment cycles. Gecko adhesives can attach and detach hundreds or thousands of times.
- *Residue-free detachment*: Most conventional chemistry-based adhesives leave traces of residues on the surface during removal. Note that in a recent study phospholipids were found as gecko "footprints," but the source of the lipids and their role in adhesion are not yet clear [1].
- *Self-cleaning properties*: Dust and particles, which stick to conventional adhesives, can be removed easily in gecko adhesives.

Mimicking the attachment system of geckos has attracted the attention of a worldwide research community. A successful development could lead to significant improvements in countless fields of application or even lead to new technologies. After about a decade of research, first applications begin to appear on the horizon.

History of Gecko Adhesion Research

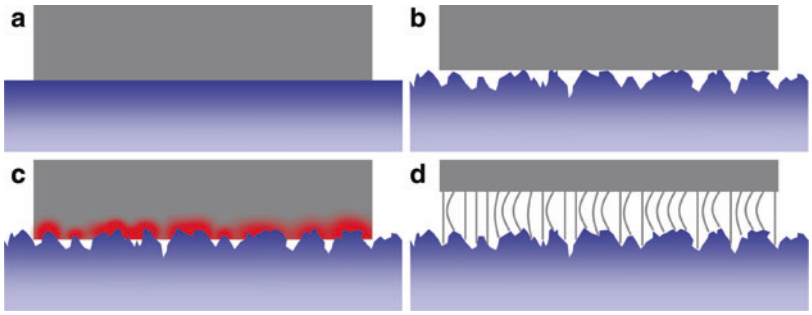
The ability of geckos to climb up walls and run along ceilings on different materials and various degrees of roughness has fascinated humans for thousands of years. Geckos were first mentioned in writing by the Greek philosopher *Aristotle* (350 B.C.), who stated in his work *Historia Animalium*: "The woodpecker [. . .] can run up and down a tree in any way, even with the head downwards, like the gecko-lizard." However, the reason behind this astonishing adhesion performance was discovered only with the development of electron microscopy in the twentieth century.

A brief study of the gecko toe structure using scanning electron microscopy was published by Hiller and Blaschke in 1967 [2]. They showed that gecko toes are covered with fine hairs (called *setae*), tens of micrometers in length and several micrometers in thickness. These *setae* branch into even finer hairs (*spatulae*) and end in plate-like tips with diameters of about 200 nanometers (nm) (Fig. 1). The results of their observation led them to the now refuted conclusion that the surface structure of the gecko toes provides high adhesion and friction due to mechanical interlocking on micro and nanorough surfaces. In 1968, Hiller found a correlation between water contact angle and attachment forces of gecko toes and corrected his statement from the

Gecko Adhesion, Fig. 1 Adhesion organ of the gecko (**a**). The toes display fine lamellae (**b**), which consist of thousands of setae (**c**, **d**). These setae branch into very fine tips, called spatulae (**e**) [4]. Similar structures can be fabricated using modern microfabrication techniques (**f**) (Reproduced with kind permission of K. Autumn and The Royal Society Publishing)

previous year by indicating that their function depends on "adhesion processes" rather than mechanical interlocking. In 1980, Stork [3] published an extensive experimental study on the beetle *Chrysolina polita*, which also suggests an adhesion system based on surface structures similar to those found in geckos. In his paper, he identified the main contribution to adhesion as molecular interactions, possibly with additional contribution from capillary forces.

Two decades later, research on the gecko adhesion system has developed to such an extent that it has become a prime topic in biomimetics. In their 2000 publication, Autumn et al. [5] measured the adhesion force of single gecko *setae*. They extrapolated that, for all *setae* in perfect contact, a single gecko foot could adhere with a shear force of approximately 100 Newton (N). Triggered by this astonishing sticking ability, many key advances have been made in recent years:



- Modern micro- and nanofabrication methods allowed bioinspired surface patterns to be produced with increasingly complex geometries.
- New methods for structural and mechanical characterization enabled extensive studies on the adhesion behavior of micropatterned surfaces.
- New micromechanical models helped explain the "gecko effect" and served as design guides for successful artificial surface patterns.
- The properties of gecko-inspired adhesives, i.e., high physical adhesion with high reversibility and repeatability, rapid and easy detachment, and self-cleaning properties, provoked interest from several application sectors, e.g., for robot locomotion, microfabrication, biomedical use, or sports articles.

While the gecko-inspired adhesion system offers the most spectacular characteristics, other adhesion systems in nature, e.g., of tree frogs, spiders, and insects, are at least as interesting as the gecko system. An overview of adhesion in nature can be found in [6].

Contact Mechanics of Patterned Surfaces

To understand the gecko attachment system in its complexity, it is necessary to apply principles of contact mechanics to the special case of patterned surfaces. The adhesive interaction between two surfaces can be investigated in a static (no movement allowed) or dynamic (movement allowed, e.g., peeling) system.

Static system for adhesion – The interplay between attractive and repulsive forces determines the strength of the adhesive force between two touching objects. Attractive forces can arise, e.g., from molecular interactions due to van der Waals forces, electrostatic or magnetic forces,

Gecko Adhesion, Fig. 2 Contact scenarios of two bodies: (**a**) two smooth surfaces with maximum contact area, (**b**) a smooth and a rough surface, both rigid, (**c**) as in (**b**) but with elastic deformation of the upper solid (high stresses are schematically indicated in *red*), and (**d**) a patterned surface which can adapt to a rough counterpart with only a small elastic energy penalty

capillary forces, or gravity. For the gecko adhesion system, the main contribution is the presence of molecular interactions as demonstrated by Stork [3]. More recent studies have shown that humidity effects also contribute to adhesion; absorbed water may reduce surface roughness [7] or influence the material properties of the gecko structures [8], both leading to increased adhesion. Repulsive forces can result, e.g., from electrostatic and magnetic repulsion or – most important in the case treated here – the energy stored in the elastically deformed bodies. If the attractive forces (positive per definition) and repulsive forces (negative) are now balanced, adhesion occurs if the attractive forces are larger than the repulsive forces. If the surfaces adhere to each other, an *external* force is necessary to detach the two surfaces. This force is defined as having a negative sign and is called pull-off force P_c.

Van der Waals forces, being the result of dipole interactions, are short range and become significant only for distances below several nanometers. Surface chemistry has only a small influence on the magnitude of the attractive forces compared to the distance and is fixed for a contact pair. Thus, the only parameter which can be modified to increase the attractive interactions is the distance between the contacting surfaces.

For illustration, consider some special cases: when perfectly smooth surfaces, e.g., the flat sides of two silicon wafers, are brought into contact, the true contact area is large and elastic deformation is unnecessary; it will then be impossible to detach the wafers from each other without damaging them (this effect is exploited in a processing step called "wafer bonding"); see Fig. 2a. However, if a stiff solid is placed onto a rough surface, the true contact area will be negligible (Fig. 2b), and it will not stick to it; a small roughness is sufficient to significantly decrease the contact area and, due to their extremely short force range, the attractive forces. In order to increase the contact area, an external force compressing the two surfaces is necessary. However, elastic deformation stores energy in the two objects and causes repulsive forces, resulting in vanishing adhesive forces (Fig. 2c).

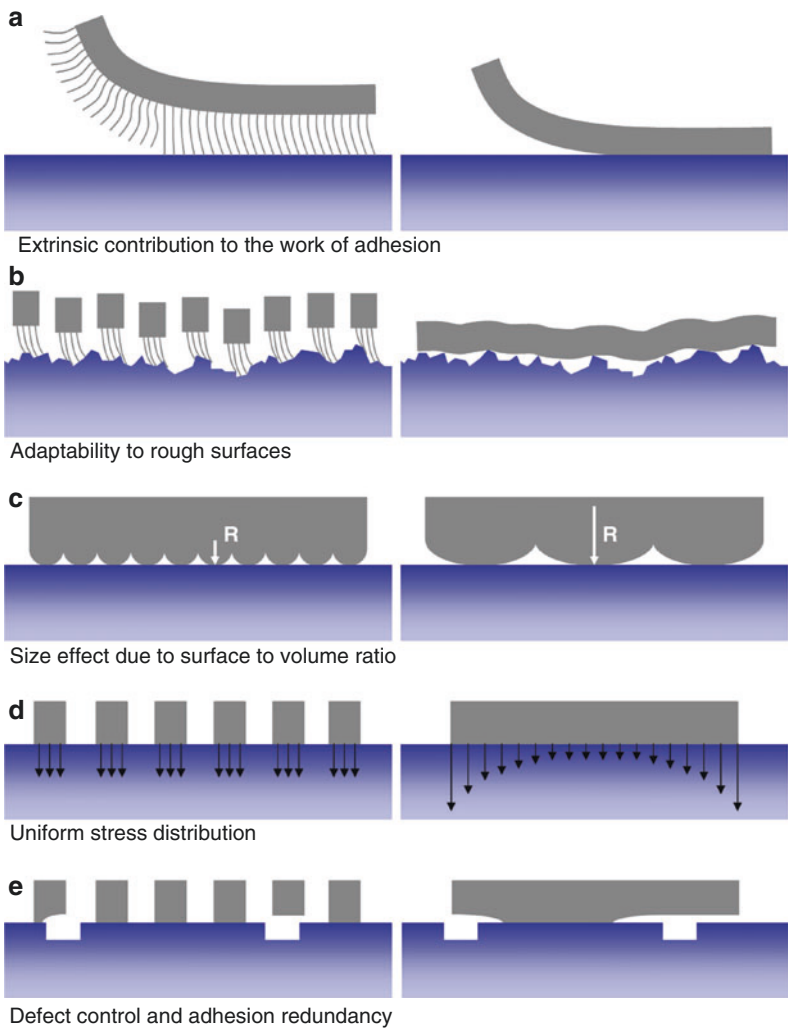
To obtain significant adhesion, it is necessary to increase the true contact area while minimizing the elastic energy penalty. This can be realized by designing an adhesive with an *effective* Young's modulus as low as possible. The pioneering adhesives scientist *Carl A. Dahlquist* defined the limiting effective Young's modulus to achieve "tackiness" to be below 100 kilopascal (kPa). Such low values may be obtained by either choosing very soft adhesives, usually soft polymeric materials, or by introducing surface structures with high aspect ratios (Fig. 2d), where the effective Young's modulus is decreased due to additional bending of the structures. Although the contact area is decreased by patterning the surface, the reduction of the repulsive forces due to the gain in compliance can be higher, thus leading to an increased adhesion force.

The fabrication of low modulus materials seems to be tempting as a complicated microstructuring process can be avoided. However, such materials have several drawbacks for reversible and repeatable attachment. First, low modulus materials usually wear quickly, which would significantly decrease the repeatability of the adhesive performance. Second, soft materials tend to transfer material to the counter surface, e.g., free oligomers in soft polymers, disqualifying them as residue-free. Third, continuous flat surfaces will contaminate easily with dust particles and dirt, necessitating a periodic cleaning process when applied in dirty environments. Fourth, due to the isotropy within the surface plane, the adhesion will be isotropic as well. Thus, there will be no preferred detachment direction, which is a key property of the gecko adhesion system to allow locomotion. And finally, under dynamic attachment and detachment conditions, the soft non-patterned surface will be inferior to patterned surfaces, which will be explained in the following paragraph.

Dynamic system for adhesion – Patterned surfaces are superior in adhesion compared to flat ones, especially when the dynamics of detachment is considered. If detachment is initiated for a flat adhesive, the elastically stored strain energy freed in the process is available to drive the detachment front further. For a disrupted surface, however, the strain energy stored in single fibrils will be lost on detachment and will not contribute to advance the detachment front (Fig. 3a). An adhesive contact can be described as a fracture problem, where the initiation of a detachment front is regarded as crack initiation and the advancing detachment corresponds to crack propagation. In fracture processes, the initiation of a crack is usually energetically more difficult than crack propagation. Once initiated, a crack will propagate easily. This analogy can be translated to flat and patterned adhesives. For a flat adhesive, the detachment front needs to be initiated only once and will subsequently propagate. However, for a patterned surface, new detachment cracks need to be initiated for each single contact, leading to an energetically more difficult detachment process.

Size Matters: The Principle of "Contact Splitting"

In 1971, Johnson, Kendall, and Roberts [9] introduced a theory of contacts between soft elastic spheres, which soon became the most highly cited publication for contacts between soft materials, now known as the JKR theory. By balancing elastic, potential, and surface energy, they obtained a theoretical expression for the external pull-off force P_c required to separate two spherical bodies:



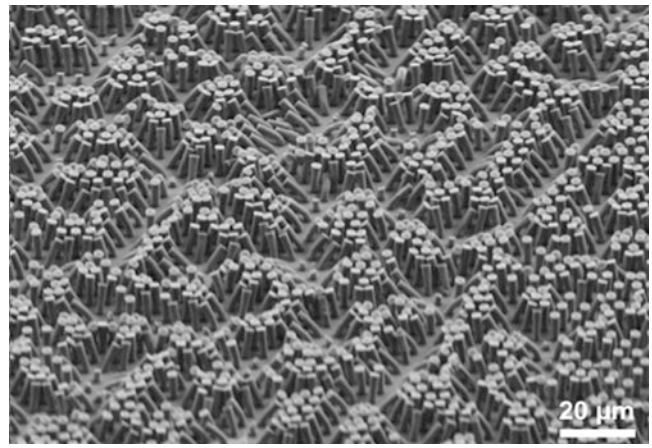
$$P_c = -\frac{3}{2}\pi\gamma R \tag{1}$$

Here, R is the relative radius of curvature defined by $1/R = 1/R_1 + 1/R_2$, R_1 and R_2 being the radii of the two contacting spheres, and γ the "work of adhesion," defined as $\gamma = \gamma_1 + \gamma_2 - \gamma_{12}$, where γ_1 and γ_2 are the surface energies of the two contacting materials, respectively, and γ_{12} is the interfacial energy. The negative sign in Eq. 1 occurs because tensile forces are defined to be negative in the contact mechanics literature. A thorough derivation of the JKR theory, additional theories for soft elastic contacts, and adhesion problems of other contact geometries such as flat contacts can be found in the books by Johnson [10] and Maugis [11].

In 2003, Arzt et al. [12] showed that Eq. 1 results in a generic size effect for adhesion: the pull-off force for a large contact is smaller than the sum of the pull-off forces for many smaller contacts together, covering the same apparent contact area. They termed this concept the "principle of contact splitting." One consequence of this principle, e.g., is the following: the number of equally sized spherical contacts n is proportional to the contact area A, which itself is proportional to the square of a length. Considering Eq. 1, it follows that the pull-off force is proportional to the square root of the number of contacts:

$$P_c \sim R \sim \sqrt{A} \sim \sqrt{n} \tag{2}$$

Thus, with increasing number of contacts, the pull-off force increases as well. Other contact



Gecko Adhesion, Fig. 3 Some theoretical explanations for the principle of "contact splitting," i.e., why arrays of small discrete contacts show increased adhesion compared to single large contacts (Schematics after [14])

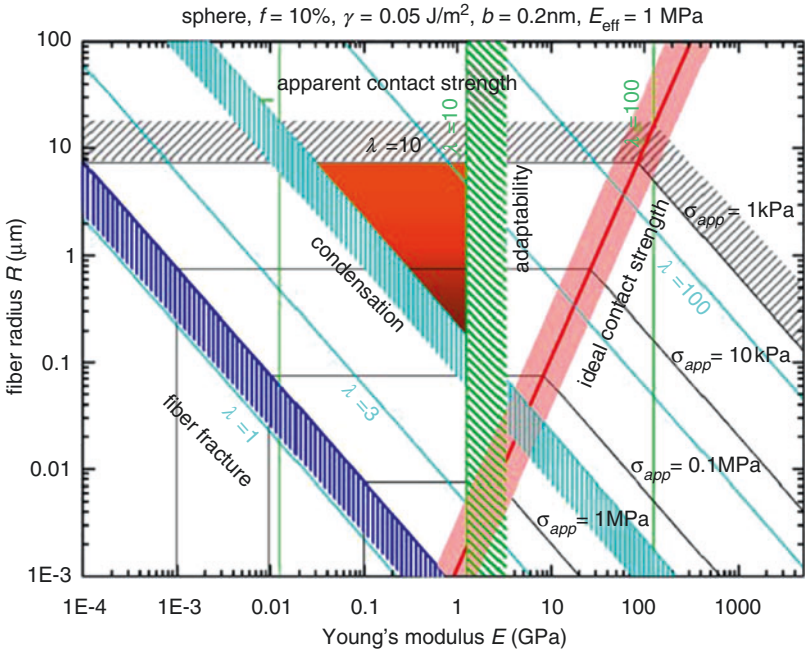
geometries than spherical contacts lead to different exponents for the number of contacts but still result in an increasing pull-off force for increasing number of contacts. This simple model offered an explanation for the experimental observation that with increasing animal body weight, the size of their contact elements decreased. Their prediction fitted well to about six orders of magnitude in animal body weight, although the effect mainly reflected the differences between different animal groups (flies, beetles, spiders, and geckos), but not within these groups. It was later pointed out by Federle [13] that the data included a transition from fluid mediated to dry adhesion, which can give rise to additional effects.

The experimental finding that smaller contacts showed increased adhesion compared to larger ones has triggered numerous theoretical explanations (Fig. 3). They may be summarized as follows (classification after [14]):

- Extrinsic contribution to the work of adhesion (Fig. 3a): Patterned surfaces are more resistant to peeling because the stored strain energy in a pillar just before detachment is not available to drive detachment to the next fibril.
- Adaptability to rough surfaces (Fig. 3b): A patterned surface with long fibrils can adapt better to rough surfaces with less storage of elastic strain energy.

Gecko Adhesion, Fig. 4 "Condensation" of polydimethylsiloxane pillars. At a certain aspect ratio of the pillars, the attractive forces between the single pillars overcome their resistance to bending, leading to a collapse of the structures (Picture reproduced with permission of C. Greiner)

- Size effect due to surface-to-volume ratio (Fig. 3c): The volume, controlling the storage of elastic energy, decreases more rapidly than the gain in surface energy, favoring smaller contacts.
- Uniform stress distribution (Fig. 3d): Below a critical size of a contact, the stress distribution within the contact area becomes uniform, resulting in adhesion strengths near the theoretical values.
- Defect control and adhesion redundancy (Fig. 3e): If the adhesion is controlled by defects, smaller contacts will be more tolerant to defects than large contacts.



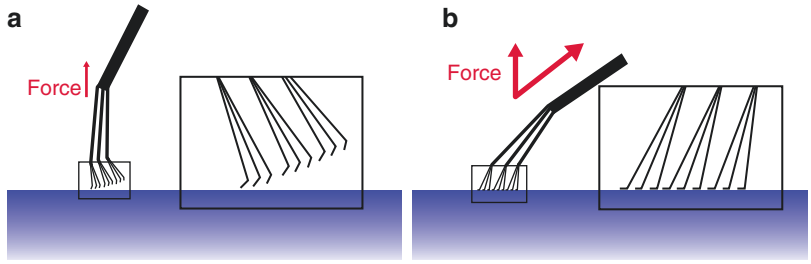
These considerations have led to the conclusion that a contact should be split into densely packed elements which should be as long and thin as possible to achieve maximum adhesion. However, if densely packed pillars exceed a critical aspect ratio (ratio between pillar length and diameter), they may become unstable with regard to "condensation" (also called "bundling" or "collapse"), as shown in Fig. 4. The reason for condensation of pillars is the low bending resistance combined with inter-pillar adhesion. This effect leads to a trade-off between pillar length, diameter, and elastic properties which can be conveniently displayed in "adhesion design maps" (Fig. 5). Illustrating the theoretical optimum in the parameter space, these maps show that, e.g., "condensation" is the overriding limitation for the refinement of a patterned adhesive. To adhere to surfaces with higher asperities, longer pillars would be needed, requiring large diameters to avoid condensation. However, there is a solution to this problem which can be found in the natural gecko adhesive: a hierarchical structure.

Role of Hierarchical Geometry for Gecko Adhesion Systems

On the macroscopic scale, a gecko has four legs with five toes each to adapt to large asperities in the range from centimeters to millimeters. On the microscopic scale, the *lamellae*, *setae*, and *spatulae* can adapt to asperities in the range of several tens of microns down to the submicrometer range. This hierarchical structure combines the advantages of small terminal contacts with stability against condensation. The influence of hierarchy on adhesion has been modeled repeatedly. Besides finite element method simulations and analytical calculations, models based on a hierarchical coupling of springs have been proposed [16].

Anisotropic Adhesion

Another key feature of geckos is their ability to rapidly detach their feet from a surface, which is a necessary feature for swift locomotion. The key to high adhesion and rapid detachment lies in the combination of their biomechanics of motion



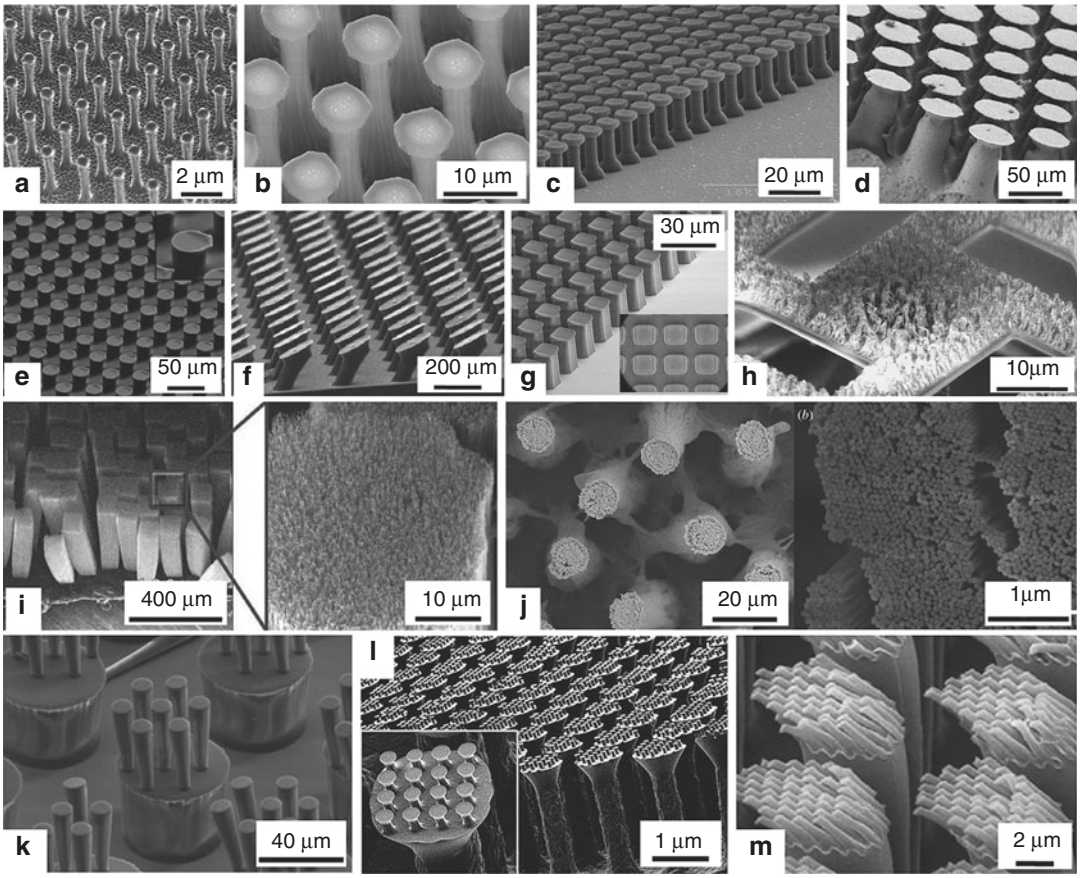
Gecko Adhesion, Fig. 5 Adhesion design map to predict successful surface patterns. The map spans a space containing material properties (Young's modulus) and geometrical parameters (radius of the fibers). Limitations are drawn in, such as fiber fracture (the adhesive strength is stronger than the material strength, causing the fiber to break rather than detach), ideal contact strength (maximum adhesion force generated by van der Waals forces), fiber condensation, and adaptability of the surface pattern. The *light blue lines* indicate the aspect ratio λ. The theoretical optimum can be found at the lower apex of the *orange triangle* [15] (Reproduced with permission of E. Arzt and Elsevier)

and the anisotropy of their adhesive structures. A closer look into their adhesive structures (Fig. 1) reveals slightly bent features with plate-like tips. When these features form contact with a surface under normal loading, the plate-like tips will be ill oriented to the surface and form insufficient contact (Fig. 6a) with low pull-off force. On application of a shear force, the structures will bend, allowing the plate-like tips to orient along the surface (Fig. 6b). The tips will then form a large contact area, enhancing adhesive forces. This so-called frictional adhesion allows the gecko to combine high sticking forces with fast detachment: orientation of the tips by pulling induces adhesion, whereas pushing or a release of the pull causes rapid pull-off. Additionally, the special anatomy of the gecko toe allows hyperextension, i.e., rolling of the toes upward, which simplifies detachment further. This shear-induced adhesion also explains the paradox that a surface provides high adhesion and, at the same time, has self-cleaning properties, i.e., no dust or particles stick to the attachment pad; the attachment organs are only adhesive if a shear force is applied. In the absence of a shear force, the adhesion is low, hindering the adhesion of dust particles to the surface structure.

Artificial Gecko Adhesives

Over the last decade, scientists around the world have tried to mimic the gecko adhesion system with artificial structures, usually fabricated from polymeric material. The fabrication methods reflect the strategies employed in microfabrication: bottom-up patterning (assembling structures from atomic or molecular materials), template-less top-down patterning (e.g., removing material from bulk), and top-down patterning

Gecko Adhesion, Fig. 6 Hierarchical gecko structures in contact with a smooth surface. If a normal force is applied, the tips of the hierarchical structures will be misaligned with the surface, leading to a low pull-off force (**a**). By applying a shear force, the structure tips become oriented, forming a large contact area and enhancing adhesion (**b**)



using a template (e.g., molding of pre-patterned surfaces). Figure 7 shows examples of recently fabricated gecko-inspired adhesives using different processes.

An example of bottom-up patterning is the fabrication of oriented carbon nanotubes on a substrate. Although carbon nanotube-based adhesives can provide high shear forces, the compressive preload necessary to trigger adhesion sometimes even exceeds the resulting normal and shear force.

Template-less top-down methods are based on either irradiation techniques to cross-link or decompose a polymer, such as UV light, lasers, and electron or ion beams, or on "mechanical" methods, i.e., cutting, writing, or melting of polymers. These techniques allow high precision in fabrication of surface structures, and features below 1 μm are accessible. Although some techniques allow the fabrication of larger areas in a short time (e.g., interference lithography), template-less top-down techniques are usually serial processes, where one structure is fabricated after another. This largely increases the fabrication time to achieve samples of feasible size.

The most widely used fabrication techniques are based on top-down structuring using a template. A template is usually fabricated by photolithography and is filled by a liquid polymer ("molding"). Although this process is usually more complex than the template-less techniques, it has a large benefit: the template may be used many times. If desired, the fabricated samples may be processed further, especially to modify the tip geometry of the pillars. Del Campo et al. [21] showed systematically in 2007 that the tip geometry of bioinspired adhesive structures is crucial to obtain high adhesive forces. They found that pillars with spherical, flat punch, or suction-cup tips showed relatively low adhesive forces, while spatular or mushroom-shaped tips showed high adhesion. To mimic the gecko adhesion system to its full extent, several of the fabrication processes presented above may be repeated to obtain hierarchical structures with controlled tip geometry. A current overview of fabrication methods to obtain patterned surfaces is given in the recently published book by del Campo and Arzt [30]. A review of recently fabricated gecko-like structures with high adhesion was published by Samento and Menon in 2010 [31]. The publication by Hu and Xia gives a nice overview about rational design of gecko-inspired surfaces, considering fabrication processes, materials selection, and concepts for switchability [32].

Although the fabrication of gecko-inspired adhesives is already well advanced in the laboratory, there is still plenty of room to improve the performance of such artificial dry adhesives. For example, experimental studies of the adhesion performance on rough surfaces – ideal territory for a gecko – are rare. In addition, surface specimens with high adhesion seldom exceeded several square centimeters in area, and the methods used are not feasible for large-scale fabrication. To establish a product based on gecko-inspired adhesives, new processes are now being developed which allow fabrication of surfaces with highly controlled structures in a cost-efficient way.

Gecko Adhesion, Fig. 7 Gecko-inspired adhesives, fabricated to achieve different structure geometry. (**a**–**d**) Symmetric structures [17–20], (**e**–**g**) asymmetric structures [21–23], and (**h**–**m**) hierarchical structures [24–29] (Reprints with kind permission of Nature Publishing Group (**a**), Elsevier (**b**, **h**), American Institute of Physics (**c**), The Royal Society Publishing (**d**), American Chemical Society (**e**, **l**), WILEY-VCH (**f**, **k**), IOP Publishing Ltd. (**g**, **j**), National Academy of Science, USA (**i**, **m**))

Applications

Possible applications of gecko-inspired adhesives can be identified by exploiting their key properties, i.e., high reversible adhesion, easy detachment, residue-free contact, and self-cleaning properties. Such adhesives are being implemented into a locomotion system for robots enabling them to overcome obstacles. Such a robot would be able to access terrain which would be difficult or dangerous for humans. Another related application would be the development of "gecko-grabbers," e.g., in fabrication plants. It is likely that gecko adhesives could find a large field of application in household or sports articles, e.g., gecko-fastening strips or goalkeeper gloves.

A true breakthrough for gecko-inspired adhesives, however, would be in the class of "intelligent materials." These new kind of adhesives would not only have the function of high reversible (and switchable) adhesion, but would combine these properties with other functions. For example, gecko-inspired adhesives could be designed in such a way that they adhere *selectively* to different materials, allow a reversible adhesion to glass, and serve as an optical coupling at the same time, or stick to skin and decompose with time, which could replace conventional plasters.

Research over the last decade has laid the foundations for such ideas; now technological development must follow to make them come true.

Nanoprobe Laboratory for Bio- and Nanotechnology and Biomimetics, The Ohio State University, Columbus, OH, USA

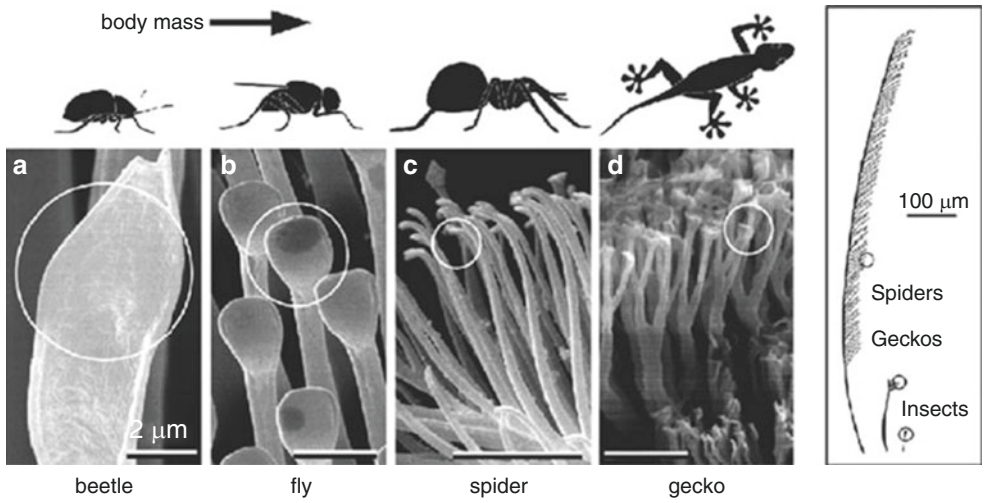
Synonyms

Gecko feet; Reversible adhesion

Definition

Geckos have the largest mass and have developed the most complex hairy attachment structures among climbing animals that are capable of smart adhesion – the ability to cling to different smooth and rough surfaces and detach at will. These animals make use of about three million microscale hairs (setae) (about 14,000/mm^2) that branch off into nanoscale spatulae, about three billion spatulae on two feet. The so-called division of contacts provides high dry adhesion. Multiple-level hierarchically structured surface construction provides the gecko with the compliance and adaptability to create a large real area of contact with a variety of surfaces.

Overview



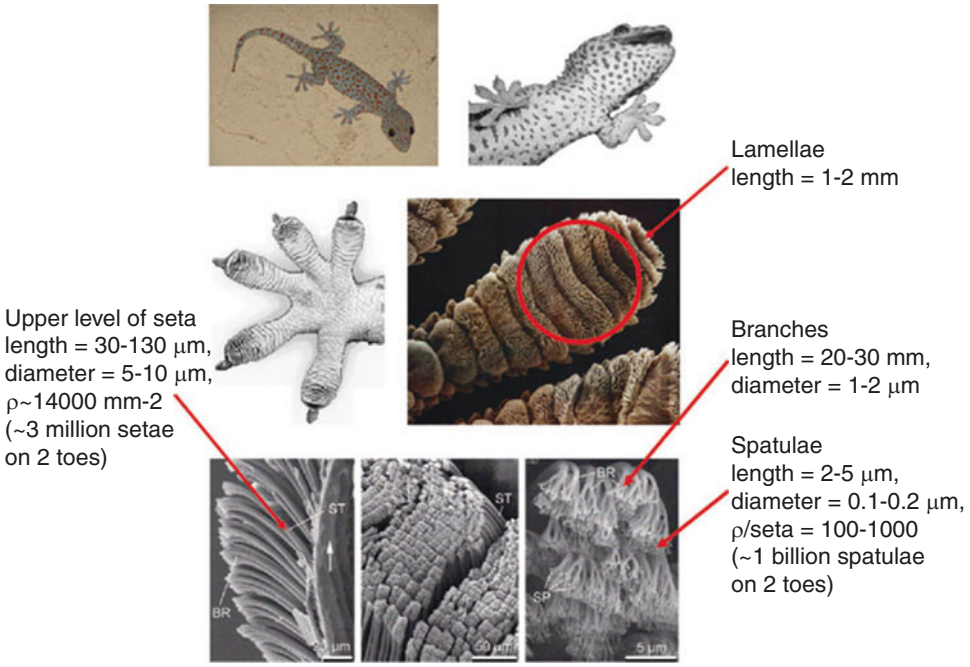
The leg attachment pads of several animals, including many insects, spiders, and lizards, are capable of attaching to and detaching from a variety of surfaces and are used for locomotion, even on vertical walls or across the ceiling [1–4]. Biological evolution over a long period of time has led to the optimization of their leg attachment systems. This dynamic attachment ability is referred to as reversible adhesion or smart adhesion [5]. Many insects (e.g., beetles and flies) and spiders have been the subject of investigation. However, the attachment pads of geckos have been the most widely studied due to the fact that they have the highest body mass and exhibit the most versatile and effective adhesive known in nature.

Although there are over 1,000 species of geckos [6, 7] that have attachment pads of varying morphology [8], the Tokay gecko (*Gekko gecko*) which is native to southeast Asia, has been the main focus of scientific research [9–11]. The Tokay gecko is the second largest gecko species, attaining lengths of approximately 0.3–0.4 m and 0.2–0.3 m for males and females, respectively. They have a distinctive blue or gray body with orange or red spots and can weigh up to 300 g [12]. These have been the most widely investigated species of gecko due to the availability and size of these creatures.

There is great interest among the scientific community to further study the characteristics of gecko feet in the hope that this information could be applied to the production of micro/nanosurfaces capable of recreating the adhesion forces generated by these lizards [2–4]. Common man-made adhesives such as tape or glue involve the use of wet adhesives that permanently attach two surfaces. However, replication of the characteristics of gecko feet would enable the development of a superadhesive tape capable of clean, dry adhesion. These structures can bind components in microelectronics without the high heat associated with various soldering processes. These structures will never dry out in a vacuum – a common problem in aerospace applications. They have the potential for use in everyday objects such as adhesive tapes, fasteners, and toys and in high technology such as microelectronic and space applications. Replication of the dynamic climbing and peeling ability of geckos could find use in the treads of wall-climbing robots.

Tokay Gecko

There are two kinds of attachment pads – relatively smooth and hairy. Relatively smooth



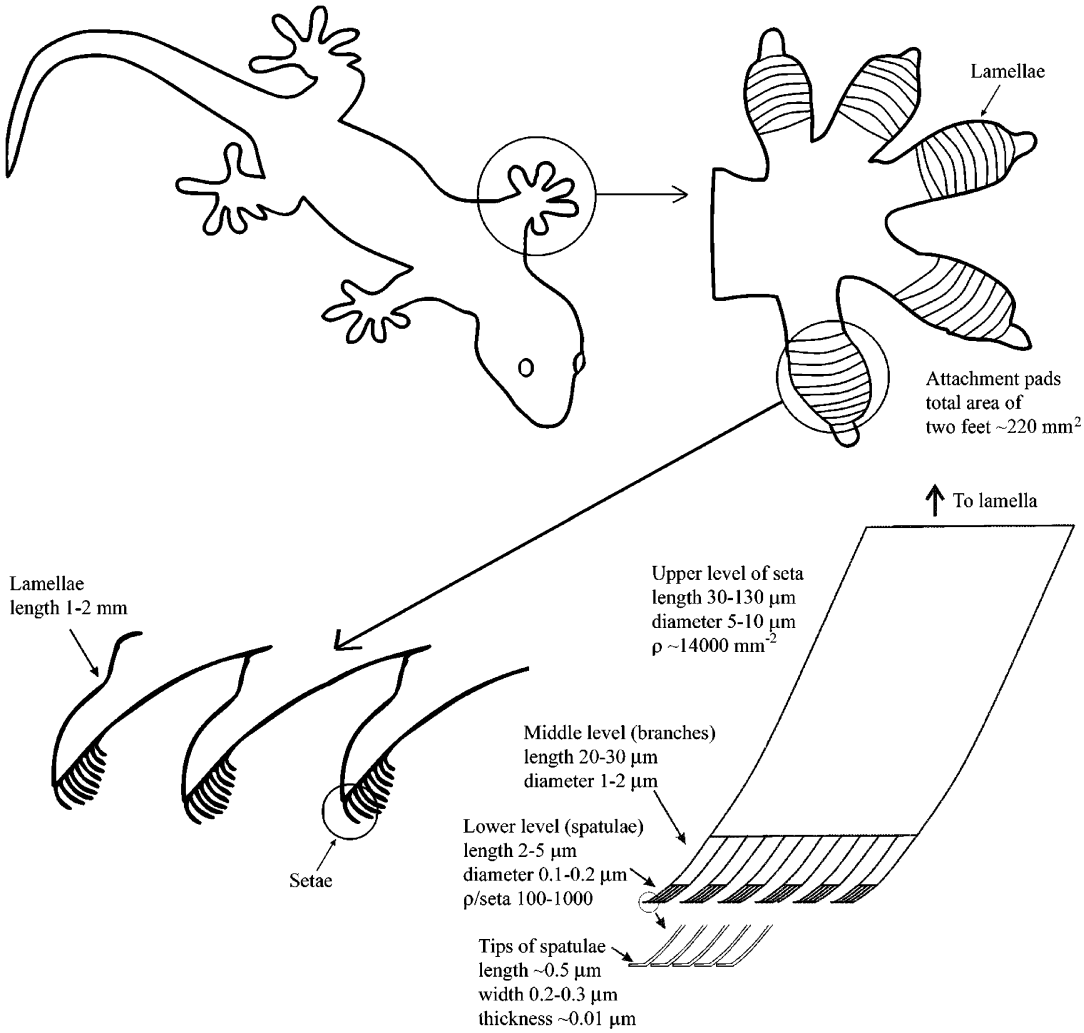
Gecko Effect, Fig. 1 Terminal elements of the hairy attachment pads of a beetle, fly, spider, and gecko shown at two different scales [13]

pads, so-called arolia and euplantulae, are soft and deformable and are found in tree frogs, cockroaches, grasshoppers, and bugs. The hairy types consist of long deformable setae and are found in many insects (e.g., beetles, flies), spiders, and lizards. The microstructures utilized by beetles, flies, spiders, and geckos have similar structures and can be seen in Fig. 1. As the size (mass) of the creature increases, the radius of the terminal attachment elements decreases. This allows a greater number of setae to be packed into an area, hence increasing the linear dimension of contact and the adhesion strength [13, 14].

The explanation for the adhesion properties of gecko feet can be found in the surface morphology of the skin on the toes of the gecko. The skin is comprised of a complex hierarchical structure of lamellae, setae, branches, and spatulae [8]. Figure 2 shows various SEM micrographs of a gecko foot, showing the hierarchical structure down to the nanoscale. Figure 3 shows a schematic of the structure, and Table 1 summarizes the surface characteristics. The gecko attachment system consists of an intricate hierarchy of structures beginning with lamellae, soft ridges 1–2 mm in length [8] that are located on the attachment pads (toes) that compress easily so that contact can be made with rough, bumpy surfaces. Tiny curved hairs known as setae extend from the lamellae with a density of approximately 14,000 per square millimeter [22]. These setae are typically 30–130 μm in length, 5–10 μm in diameter [8, 9, 19, 20], and are composed primarily of β-keratin [17, 25] with some α-keratin component [26]. At the end of each seta, 100–1,000 spatulae [8, 9] with typically 2–5 μm in length and a diameter of 0.1–0.2 μm [8] branch out and form the points of contact with the surface. The tips of the spatulae are approximately 0.2–0.3 μm in width [8], 0.5 μm in length, and 0.01 μm in thickness [21] and garner their name from their resemblance to a spatula.

The attachment pads on two feet of the Tokay gecko have an area of about 220 mm^2. About three million setae on their toes that branch off into about three billion spatulae on two feet can produce a clinging ability of about 20 N required to pull a lizard down a nearly vertical (85°) surface) [10] and allow them to climb vertical surfaces at speeds over 1 m/s with the capability to attach and detach their toes in milliseconds. In isolated setae, a 2.5 μN preload yielded adhesion of 20–40 μN, and thus the adhesion coefficient, which represents the strength of adhesion as a function of preload, ranges from 8 to 16 [27].

Typical rough, rigid surfaces are able to make intimate contact with a mating surface only over a very small portion of the perceived apparent area



Gecko Effect, Fig. 2 The hierarchical structures of a Tokay gecko foot: a gecko foot [15] and a gecko toe [11]. Two feet contain about three million setae on their toes that branch off into about three billion spatulae. Scanning electron microscope (*SEM*) micrographs of the setae and the spatulae in the bottom row [16]. *ST* seta, *SP* spatula, *BR* branch

of contact. In fact, the real area of contact is typically two to six orders of magnitude less than the apparent area of contact [4, 28, 29]. Autumn et al. [27] proposed that divided contacts serve as a means for increasing adhesion. The surface energy approach can be used to calculate adhesion force in the dry environment in order to calculate the effect of division of contacts. Adhesion force of a single contact is proportional to a linear dimension of the contact. For a constant area divided into a large number of contacts or setae, the adhesion force increases linearly with the square root of the number of contacts (self-similar scaling) [13].

Attachment Mechanisms

When asperities of two solid surfaces are brought into contact with each other, chemical and/or physical attractions occur. The force developed that holds the two surfaces together is known as adhesion. In a broad sense, adhesion is considered to be either physical or chemical in nature [3, 4, 28–34]. Chemical interactions such as electrostatic attraction charges [35] as well as intermolecular forces [9] including van der Waals and capillary forces have all been proposed as potential adhesion mechanisms in gecko feet. Others have hypothesized that geckos adhere to surfaces through the secretion of sticky fluids [36, 37], suction [37], increased frictional force [38], and microinterlocking [39].

Through experimental testing and observations conducted over the last century and a half many potential adhesive mechanisms have been eliminated. Observation has shown that geckos lack any glands capable of producing sticky fluids [36, 37], thus ruling out the secretion of sticky fluids as a potential adhesive mechanism. Furthermore, geckos are able to create large adhesive forces normal to a surface. Since friction only acts parallel to a surface, the attachment mechanism of increased frictional force has been ruled out. Dellit [39] experimentally ruled out suction and electrostatic attraction as potential adhesive mechanisms. Experiments carried out in vacuum did not show a difference between the adhesive

Gecko Effect, Fig. 3 Schematic of a Tokay gecko including the overall body, one foot, a cross-sectional view of the lamellae, and an individual seta. ρ represents number of spatulae

forces at low pressures compared to ambient conditions. Since adhesive forces generated during suction are based on pressure differentials, which are insignificant under vacuum, suction was rejected as an adhesive mechanism [39]. Additional testing utilized X-ray bombardment to create ionized air in which electrostatic attraction charges would be eliminated. It was determined that geckos were still able to adhere to surfaces in these conditions, and therefore, electrostatic charges could not be the sole cause of attraction [39]. Autumn et al. [15] demonstrated the ability of a gecko to generate large adhesive forces when in contact with a molecularly smooth SiO_2 microelectromechanical system (MEMS) semiconductor. Since surface roughness is necessary for microinterlocking to occur, it has been ruled out as a mechanism of adhesion. Two mechanisms, van der Waals forces and capillary forces, remain as the potential sources of gecko adhesion.

Multilevel Hierarchy for Adaptability to Rough Surfaces

In order to study the effect of the number of hierarchical levels in the attachment system on attachment ability, models with one [5, 40, 41],

Gecko Effect, Table 1 Surface characteristics of Tokay gecko feet (Young's modulus of surface material, keratin = 1–20 GPa[a,b])

Component	Size	Density	Adhesive force
Seta	30–130[c–f]/ 5–10[c–f] length/ diameter (μm)	~14,000[h,i] setae/mm^2	194 μN[j] (in shear) ~20 μN[j] (normal)
Branch	20–30[c]/1–2[c] length/ diameter (μm)	–	–

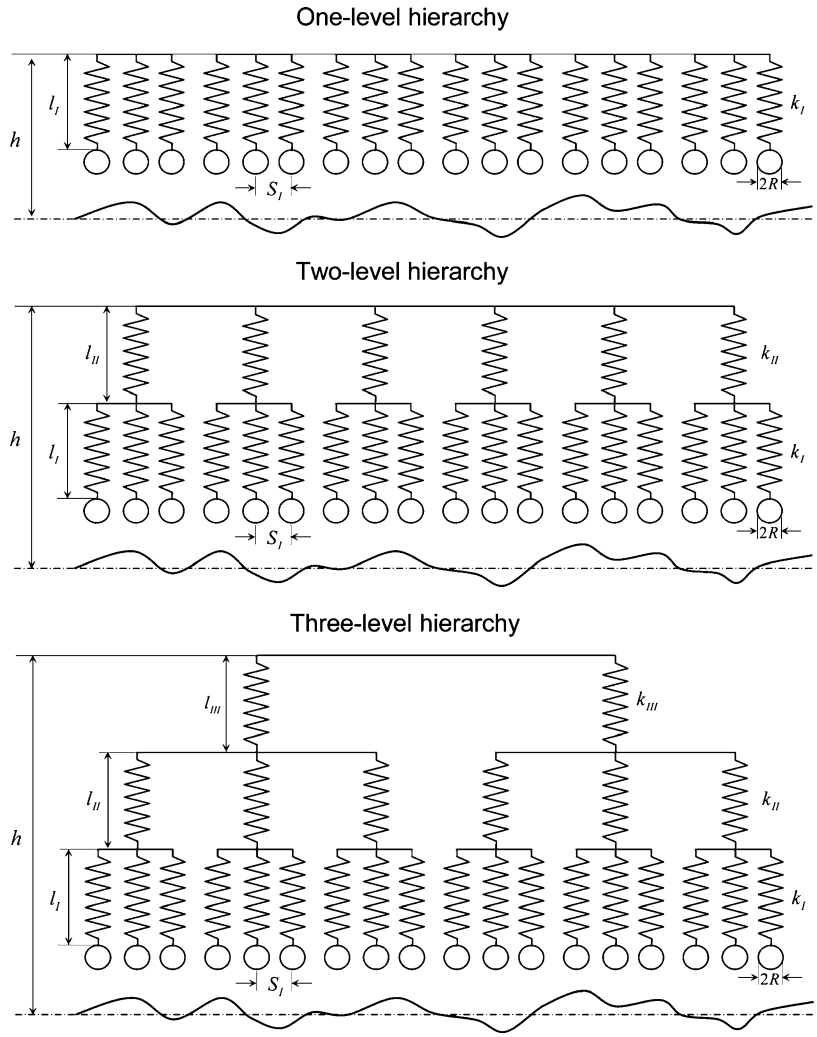
[k]Huber et al. [24]



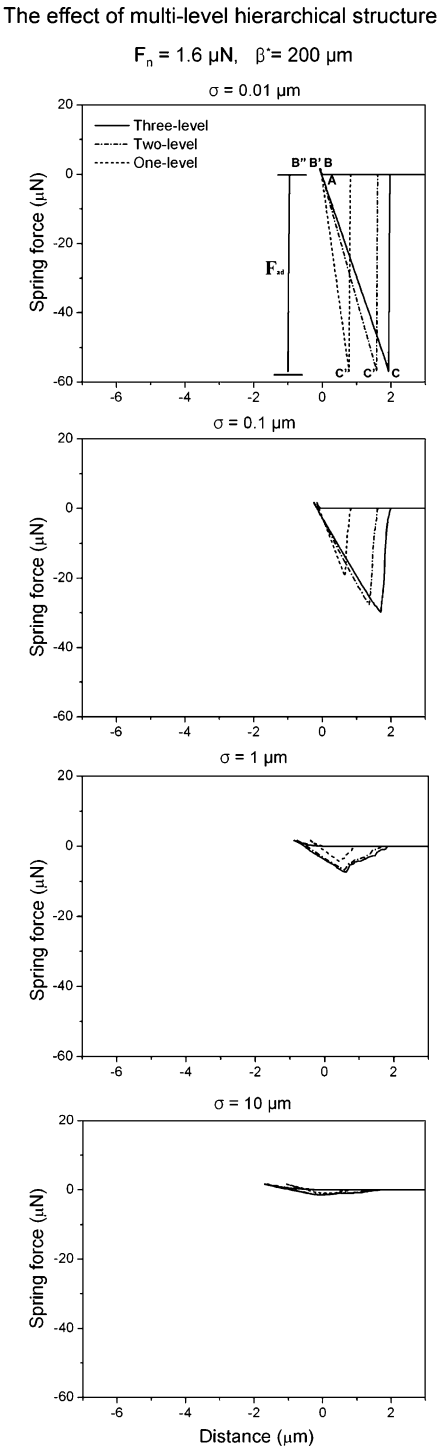
two [5, 40, 41], and three [40, 41] levels of hierarchy were simulated (Fig. 4). The random rough surfaces used in the simulations were generated by a computer program [28, 29]. Figure 5 shows the calculated spring force–distance curves for the one-, two- and three-level hierarchical models in contact with rough surfaces of different values of root mean square (RMS) amplitude σ ranging from $\sigma = 0.01$ μm to $\sigma = 10$ μm at an applied load of 1.6 μN which was derived from the gecko's weight. When the spring model is pressed against the rough surface, contact between the spring and the rough surface occurs at point A; as the spring tip presses into the contacting surface, the force increases up to point B, B′, or B″. During pull off, the spring relaxes, and the spring force passes an equilibrium state (0 N); tips break free of adhesion forces at point C, C′, or C″ as the spring moves away from the surface. The perpendicular distance from C, C′, or C″ to zero is the adhesion force. Adhesion energy stored during contact can be obtained by calculating the area of the triangle during the unloading part of the curves. The data in Fig. 5 show that adhesion forces for various levels of hierarchy are comparable when in contact with the smooth surface. However, the adhesion force for the three-level hierarchy is the largest when in contact with rough surface. Thus, multilevel hierarchy facilitates adaptability to a variety of rough surfaces.

Peeling

Although geckos are capable of producing large adhesion forces, they retain the ability to remove their feet from an attachment surface at will by peeling action. The orientation of the spatulae facilitates peeling. Autumn et al. [15] were the first to experimentally show that the adhesion force of gecko setae is dependent on the three-dimensional orientation as well as the preload applied during attachment. Due to this fact, geckos have developed a complex foot motion during walking. First, the toes are carefully uncurled during detachment. The maximum adhesion occurs at an attachment angle of 30° – the angle between a seta and mating surface. The gecko is then able to peel its foot from surfaces one row of setae at a time by changing the angle at which its setae contact a surface. At an attachment angle greater than 30°, the gecko will detach from the surface.

Self-Cleaning

Natural contaminants (dirt and dust) as well as man-made pollutants are unavoidable and have the potential to interfere with the clinging ability of geckos. Particles found in the air consist of particulates that are typically less than 10 μm in diameter while those found on the ground can often be larger [42, 43]. Intuitively, it seems that the great adhesion strength of gecko feet would cause dust and other particles to become trapped in the spatulae and that they would have no way of being removed without some sort of manual



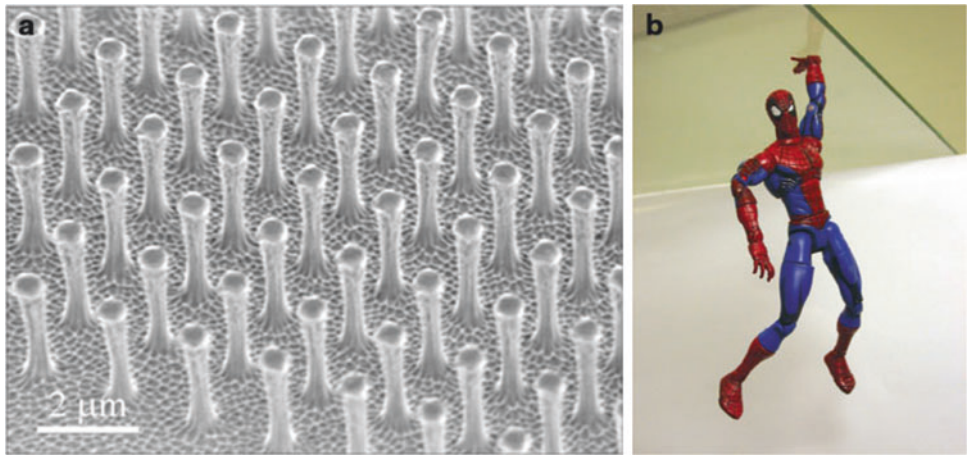
Gecko Effect, Fig. 4 One-, two-, and three-level hierarchical spring models for simulating the effect of hierarchical morphology on interaction of a seta with a rough surface. In this figure, *lI, II, III* are lengths of structures, *sI* is space between spatulae, *kI, II, III* are stiffnesses of structures, *I, II*, and *III* are level indexes, *R* is radius of tip, and *h* is distance between upper spring base of each model and mean line of the rough profile [40]

cleaning action on behalf of the gecko. However, geckos are not known to groom their feet like beetles [44], nor do they secrete sticky fluids to remove adhering particles like ants [45] and tree frogs [46], yet they retain adhesive properties. One potential source of cleaning is during the time when the lizards undergo molting, or the shedding of the superficial layer of epidermal cells. However, this process only occurs approximately once per month [47]. If molting were the sole source of cleaning, the gecko would rapidly lose its adhesive properties as it was exposed to contaminants in nature [48]. They reported that gecko setae become cleaner with repeated use – a phenomena known as self-cleaning.

Fabrication of Biomimetic Gecko Skin

Based on the studies reported in the literature, the dominant adhesion mechanism utilized by gecko and some spider attachment systems appears to be van der Waals forces. The hierarchical structure involving complex divisions of the gecko skin (lamellae-setae-branches-spatulae) enable a large number of contacts between the gecko skin and mating surface. These hierarchical fibrillar microstructured surfaces would be capable of reusable dry adhesion and would have uses in a wide range of applications from everyday objects such as adhesive tapes, fasteners, toys, microelectronic and space applications, and treads

Gecko Effect, Fig. 5 Force–distance curves of one-, two-, and three-level models in contact with rough surfaces with different σ values for an applied load of 1.6 μN



of wall-climbing robots. The development of nanofabricated surfaces capable of replicating this adhesion force developed in nature is limited by current fabrication methods. Many different techniques have been used in an attempt to create and characterize bio-inspired adhesive tapes. Attempts are being made to develop climbing robots using gecko-inspired structures [49–52].

As an example, Geim et al. [53] created arrays of polyimide nanofibers using electron-beam lithography and dry etching in oxygen plasma (Fig. 6a (left)). By using electron-beam lithography, thermal evaporation of an aluminum film, and lift-off, an array of nanoscale aluminum disks were prepared. These patterns were then transferred in the polyimide film by dry etching in oxygen plasma. A 1 cm^2 sample was able to create 3 N of adhesive force under the new arrangement. This is approximately one-third the adhesive strength of a gecko. They fabricated a Spiderman toy (about 0.4 N) with a hand covered with molded polymer nanohairs, which could support its weight Fig. 6b.

As another example, Bhushan and Sayer [54] characterized the surface roughness, friction force, and contact angle of a structured sample and compared the results to an unstructured control. The macroscale coefficient of kinetic friction of the structured sample was found to be almost four times greater than the unstructured sample. This increase was determined to be a result of the structured roughness of the sample and not the random nanoroughness. It is also noteworthy that the static and kinetic coefficients of friction were approximately equal for the structured sample. It is believed that the divided contacts allow the broken contacts of the structured sample to constantly recreate contact.

Closure

The adhesive properties of geckos and other creatures such as flies, beetles, and spiders are due to the hierarchical structures present on each creature's hairy attachment pads. Geckos have developed the most intricate adhesive structures of any of the aforementioned creatures. The attachment

Gecko Effect, Fig. 6 (**a**) An array of polyimide nanohairs and (**b**) a Spiderman toy (about 0.4 N) with a hand covered with the molded polymer nanohairs, clinging to a glass plate [53]

system consists of ridges called lamellae that are covered in microscale setae that branch off into nanoscale spatulae, about three billion spatulae on two feet. The so-called division of contacts provides high dry adhesion. Multiple level hierarchically structured surface construction plays an important role in adapting to surface roughness bringing the spatulae in close proximity with the mating surface. These structures, as well as material properties, allow the gecko to obtain a much larger real area of contact between its feet and a mating surface than is possible with a non-fibrillar material. Two feet of a Tokay gecko have about 220 mm^2 of attachment pad area on which the gecko is able to generate approximately 20 N of adhesion force. Although capable of generating high adhesion forces, a gecko is able to detach from a surface at will – an ability known as smart adhesion. Detachment is achieved by a peeling motion of the gecko's feet from a surface.

There is a great interest among the scientific community to create surfaces that replicate the adhesion strength of gecko feet. These hierarchical fibrillar microstructured surfaces would be capable of reusable dry adhesion and would have uses in a wide range of applications from everyday objects such as adhesive tapes, fasteners, toys, microelectronic and space applications, and treads of wall-climbing robots.

Genotoxicity of Nanoparticles

Fabrice Nesslany[1] and Laila Benameur[2]
[1]Laboratory of Genetic Toxicology, Institut Pasteur de Lille, Lille Cedex, France
[2]Department of Biomedical Engineering, McGill University, Montreal, QC, Canada

Definition

Genotoxicity is toxicity against cell's genetic material affecting its integrity (DNA damage). It may lead to mutagenicity and carcinogenicity in some circumstances.

Context of the Genotoxicity Assessment of Nanomaterials

As previously mentioned, the genotoxic properties of nanomaterials (NMs) are often closely linked to oxidative damage to DNA and proteins caused by oxidative stress resulting from hyper production of reactive oxygen species (ROS) and reactive nitrogen species (RNS). NM-induced oxidative stress is perhaps the most broadly developed and accepted mechanism for the potential toxic activity of NPs (nanoparticles). NP-mediated ROS and RNS production mechanisms can be classified into three groups: intrinsic production, production by interaction with cell targets, and production mediated by the inflammatory reaction. The three groups share responsibility for most of the primary (direct or indirect) or secondary genotoxic effects so far observed with NMs [1].

A critical assessment of the current knowledge about NM genotoxicity revealed that some standard models of mutagenesis and genotoxicity are either not well adapted or even not suitable for the investigation of NMs, for instance, the bacterial cell wall possibly being a barrier for many NMs; accordingly, the Ames test [2] is not relevant for assessing the mutagenicity of NMs due to a high risk of false-negative results [3–5]. The bacterial tests are probably insufficient to ensure that bacterial DNA is exposed and in consequence cannot be considered as robust. In contrast, regulatory gene mutation tests in mammalian cells [6], using rodent cells (L5178Y, CHO, V79) presenting deficiencies (weak amount of detoxification enzymes, expression of p53, etc.), may overestimate observed effects and lead to an incorrect assessment. Furthermore, their nonhuman origin could also impede their relevance as rodent cell lines are considered more susceptible to give misleading positive results [7]. Therefore, the use of such gene mutation tests is highly debatable.

For in vivo genotoxicity, the standard tests recommended by regulations in a first intention target hematopoietic cells [8, 9]. Nevertheless, the bone marrow does not represent the most exposed tissue to NMs; thus, the relevance of these tests is highly questionable. In return the in vivo comet assay and the micronucleus test appear more relevant when carried out on target organs either primary exposed, for instance, the intestine or lung [10], or exposed after translocation as the liver.

Consequently, in vitro genotoxicity tests, which so far have most frequently and successfully been used, for genotoxicity testing of NMs

were the comet assay and the micronucleus test [11, 12]. As a matter of fact, the in vitro micronucleus assay was seen to be advantageous as it is capable of detecting chromosomal damage in the form of clastogenicity (e.g., triggered by ROS) and aneugenic effects such as physical disturbance of spindles/mitotic apparatus [13]. The in vitro comet test appears to be well suited to point out primary DNA lesions.

Many other technical issues may be at the origin of drawbacks making the in vitro tests on NMs poorly predictive:

- Possible interaction of NM suspensions with the test systems, particularly with the culture medium (complex medium with the presence of protein, salts, growth factors, and other nutrients).
- The use of very high levels of doses as recommended by the corresponding OECD guidelines.
- Interferences with the methods of determination of the cytotoxicity. For example, the interference does not seem to affect the enzymatic reaction directly but lies rather in the insoluble nature of MTT – formazan; therefore, it is strongly recommended to assess cytotoxicity data with at least two or more independent test systems [14].
- To be sure that the responses are qualitatively and/or quantitatively "nanospecific," it is interesting to compare both the nano and the microscale materials in their ability to induce genotoxicity.
- Influence of cell agglomeration on genotoxicity response.
- Absence of standard positive and negative NMs allowing proofing the sensitivity and the specificity of the implemented test systems.
- Because the properties of NMs are highly dependent on how they are synthesized, their detailed characterization is necessary for accurate comparison among different studies.
- Possible secondary genotoxic effects [15, 16] etc.

Many publications show that NMs may be genotoxic in in vitro test systems [4, 5, 17]. However, the question of nonspecific responses or "false-positive" results, i.e., positive in in vitro tests but negative in in vivo assays, is often raised and should ideally be addressed. For instance, Donaldson et al. [18] concluded that in vitro genotoxicity with non-biopersistent fibers is observed only at high doses that are non-physiologically and not achievable in vivo. Following these authors, care needs to be taken in in vitro genotoxicity studies to ensure that doses used are plausible. High doses used in vitro are sufficient to cause proinflammatory, cytotoxic, and even genotoxic effects, while much lower doses attained in vivo are sufficient only to induce antioxidant defenses. Furthermore, because genotoxicity studies mainly use short-term treatments, the exposure time is insufficient for biopersistence to play a role in shortening the long fibers or dissolving them. This means that even non-biopersistent long fibers exert effects because of long fiber-type effects. This is particularly obvious with non-biopersistent glass fibers, which are found to be as genotoxic in vitro as asbestos. Following Schulz et al. [19], genotoxic effects were observed in vitro for 2 SiO_2 while these results were not reproduced in vivo. Chen et al. [20] concluded that for the genotoxicity assessment of TiO_2, in vitro test systems generated more positive results than in vivo assays. The in vitro genotoxicity may be not relevant in vivo due to antioxidant defense mechanisms [21].

Based on these observations, it was deemed useful to come back to the results generated in the field of the Nanogenotox European Project (2010–2013) entitled *Safety evaluation of manufactured nanomaterials by characterisation of potential genotoxic hazard* [22]. The goal of Nanogenotox was to build a robust methodology in terms of sensitivity and specificity with alternative test(s) for determining the genotoxic hazard of manufactured NMs.

For this purpose, preliminary physicochemical characterizations of each of the tested 14 NMs (6 MWCNT, 4 TiO_2, and 4 SiO_2) were performed, and the protocol for dispersion was determined. Then, toxicokinetics, in vitro and in vivo genotoxicity were assessed. The objective of the in vitro genotoxicity studies was to produce

in vitro data on NMs using standard tests, i.e., MLA/TK test [6] and the micronucleus test [23] and modified assays (FPG-modified alkaline comet assay), using various cell lines (human pulmonary, intestinal, dermal cells) that are theoretically representative of the target organs (i.e., primary-exposed organs or organs exposed after translocation). A round-robin test was also carried out to assess the inter-lab qualitative and quantitative reproducibility on several selected MNs using the most promising in vitro assays. Like in vitro tests, standard in vivo genotoxicity tests, i.e., micronucleus test on rat bone marrow [8] and other assays (alkaline comet assay on lung, liver, spleen, kidney, colon, and alveolar macrophages), were carried out.

The overall results obtained in in vitro genotoxicity assays (see Tables 1 and 2) show that many MNs were slightly genotoxic, possibly due to indirect mechanisms not yet fully understood. However, the genotoxicity observed in some cases (e.g., SiO_2 on Caco-2 cells) was not reproducible in an independent assay (see Table 2). Furthermore, reports from Nanogenotox European Project reach the conclusion that full-thickness 3D skin models could not be systematically recommended for MNs hazard assessment of genotoxicity and that BEAS-2B cells appear to perform somewhat better than Caco-2 cells [22]. The results obtained during the round-robin test were heterogeneous as depicted in Table 3.

Regarding results obtained in in vivo genotoxicity tests, most data indicated no genotoxic potential whatever the NM investigated even if some genotoxic effects were observed in few organs during the comet assays, without any real dose–response relationship. Few effects linked to oxidation (from FPG-modified comet assay) were observed. All NMs were negative in the micronucleus test on bone marrow except after intravenous exposure with a SiO_2 at the high dose of 20 mg/kg b.w/day (X3) with a mean of micronucleated cells of 0.00183 versus 0.00060 in the corresponding negative control. However, this increase was very slight and no dose–response relationship was observed [22]. Anyway, within the same family (SiO_2, TiO_2, and CNT), both genotoxicity and toxic injuries varied according to the NM. From these conclusions, several comments and issues appear regarding the selected endpoints, the experimental procedures, and the results.

Test Systems

Strong discrepancies were noted depending on the cell type used. For instance, all TiO_2 were found positive on NHEK cells while they were all negative on 16HBE cells. These results underline the importance of the characterization of the cell lines used (origin, antioxidant status, and their capability of internalization and externalization of NMs, etc.). Beyond this mandatory point, the conditions of culture (e.g., presence of serum), the state of cells, etc., should also be controlled. A thorough physicochemical characterization of the tested NM in the used culture media should be performed. Importantly, the efficiency and kinetics of the uptake of NMs in the selected cell type should be done.

Endpoints

From the overall in vitro results, we can wonder what is the weight of an in vitro comet assay (DNA primary damage) that is positive while the in vitro micronucleus is negative; in other words, what is the predictivity of the in vitro comet assay? At the opposite, what kind of mechanisms of action (MoA) occurs when there is no induction of DNA primary damage but chromosomal aberrations? (Aneuploidy? Other events, e.g., indirect oxidation, mitochondrial disturbance, depletion of calcium, etc.?).

Is the in vitro comet assay really well adapted for the genotoxicity assessment of NMs as such, or does it need other adaptations? If performed, which duration of treatment should be recommended or what is the relevance of a long-term treatment depending on the cell type? If not performed, which second endpoint should be investigated? As neither the Ames test nor the standard gene point mutation assays on rodent cells are appropriate, there is a real need for implementing a gene point mutation test on human cell lines.

Results

Several NMs displayed a slight genotoxic activity in vitro. As the effect was weak, it is not easily reproducible and the hypothesis of indirect mechanisms was proposed.

Otherwise, results demonstrated the lack of intra- and inter-lab reproducibility as noted during the round-robin test. One of the hypotheses is that the method of dispersion may affect the size of agglomerates, the sedimentation, the cell exposure and consequently the level of cytotoxicity, and the choice of doses for genotoxicity assessment. In any case, it shows that there is a need to reiterate the assays.

Interestingly, the production of both in vitro and in vivo data on the same NMs allowed a first comparison of in vitro versus in vivo results and the estimation of the predictivity of the in vitro genotoxicity testing (see Tables 4 and 5).

The comparison of in vitro and in vivo results displayed a weak correlation of in vitro/in vivo genotoxicity results. However, no comparison was possible for the spleen, liver, and kidney for which in vivo positive responses were observed as no in vitro tests were carried out on the corresponding specific cells.

This observation raises the question of the limits of these assays and the occurrence of "false-negative" or "false-positive" results. Many hypotheses could explain these differences:

In Vitro Positive While In Vivo Negative

- Time of treatment/exposure
  - Exposure at more long-term and at higher dose(s).
  - Intracellular dose of NM is important but depends on the mode of exposure/dispersion and on the presence or not of a dispersant. Cellular uptake could possibly serve as a measure of dose for comparison among experiments and test systems.
- Form in situ different from the one in vitro

  In cell cultures, many metal-based NMs induce weak increases in DNA damage that seem continuously formed when particles are internalized: It is unclear whether the same phenomenon could also occur in vivo and results in a low-level but prolonged genotoxic injury. Furthermore, the corona, i.e., the coating proteins, formed in vitro in culture media (and even after dispersion before instillation) is very different from that produced naturally whatever the route of entry [18]. The mechanism of genotoxic action may differ depending on the amount of proteins present in the test systems in vivo and in vitro [12]. Agglomerates of different sizes and shapes may also have different effects on cells.
- Characteristics of cell types

  The absence or a low exocytosis capability may increase the intracellular dose in vitro

Outcome: + Positive: a statistically significant increase with ≥2 doses or a statistically significant increase at high dose and a dose-dependent increase, (+) Equivocal: a statistically significant increase with 1 dose, no dose-dependent increase, – Negative

compared to the one observed in vivo. Otherwise, it is important to note that cell lines from a same origin or from different tissues could be more or less sensible to NM exposure due to variation of metabolic routes, receptors on the cell surface, antioxidant and DNA repair capabilities, the presence of different enzymes/hormones, etc. [24, 25], meaning that the final choice should be clearly argued. On the other side, the weak level of antioxidant systems could artefactually increase the level of genotoxic effect.

- Organ(s) not actually exposed in vivo

  An in vivo negative response could be expected when an in vitro positive response is observed on cells that are not representative of a target tissue because it is not exposed in vivo at least by the route of exposure.

In Vitro Negative While In Vivo Positive

In the same way, the characteristics of the cell types could be at the origin of such discrepancies if cells are not able of internalization hindering their exposure. In vivo effects were observed in tissues that were not specifically investigated in vitro (liver, kidney, spleen, etc.).

Finally, as in vitro tests are not able to display secondary genotoxicity, it may explain the difference between in vitro and in vivo results.

Conclusions

The sensitivity and the specificity of the in vitro toxicity tests should be a priority in order to increase their predictivity and to avoid unnecessary in vivo assays. In that view, all the results and hypothesis previously mentioned should be used to improve the predictivity of the in vitro genotoxicity tests and also to ensure that the whole strategy currently implemented is really appropriate for NM assessment. Thus, improvements could be found at the menu level by questioning the current strategy based on regulatory tests but also at the recipe level by bringing methodological modifications in order to obtain more specific responses.

1. Modification of the Current Strategy Based on Regulatory Testing

   First, the in vitro micronucleus test seems very interesting as it can be performed on target cells even in other than the ones recommended in standard conditions including human cells and it was considered as the most predictive in the Nanogenotox European Project [22]. However, it is mandatory to demonstrate the absorption of NMs by the cell line used.

   Otherwise, the question of the level of predictivity of the in vitro comet assay as it is currently carried out should be raised. If performed, the experimental design should take into account all the methodological considerations or modifications that could be made to the test procedure to improve its applicability or reliability for testing NMs as described in point 2 hereafter.

   Regarding gene point mutation tests, the Ames test [2] is considered as not relevant for assessing the mutagenicity of NMs due to a high risk of false-negative results. Furthermore, the MLA/TK assay [6] appears to be poorly adapted mainly as it uses rodent cell that grows in suspension. Therefore, no standard gene point mutation assays seems appropriate. However, more subtle genetic changes can also arise in response to a genotoxin such as point mutations including base substitutions, frameshifts, or small amplifications and deletions. Thus, it was suggested that mammalian mutation assays should also be considered in a test battery, particularly as it appears that the genotoxicity of some NMs failed to be revealed by the in vitro micronucleus assay [26]. There is a real need for

implementing a gene point mutation test on human cell lines but also for developing new test systems (see point 3).

Finally, the in vivo bone marrow micronucleus assay could not be systematically recommended as it detects substances that are genotoxic at a systemic level while high dose levels in bone marrow are often unlikely. In any case, negative results are relevant only when there is a proof of exposure. It would be useful to perform other in vivo tests that are applicable for NMs (in vivo micronucleus test in the lung and colon that may be target organs).

Do the in vitro genotoxicity tests as actually performed predict the in vivo genotoxicity and/or the carcinogenesis of NMs? In fact, there are very few comparative studies to answer this question but following Roller [27], there is no correlation between the probability of a positive response in vitro and the carcinogenic potency. As concluded by the Nanogenotox European Project [22], further comparative in vivo data for evaluating the performance of in vitro genotoxicity assays are needed.

Overall, this confirms the need of adaptation of the OECD guidelines for genotoxicity. This task has been initiated during the two **last WPMN meetings** (Workshop on the Genotoxicity of Manufactured Nanomaterials), held in Ottawa (November 2013) and Paris (October 2014).

2. **Methodological considerations or modifications to improve the test systems**

For the standard or new tests deemed appropriate, there are some methodological considerations or modifications that could be made to the test procedures to improve the applicability or reliability for testing NMs. This includes the following areas:

- Adoption of standard protocols for dispersion knowing that the nature of the dispersant used directly influence the quality of the suspension. For instance, NMs are very poorly dispersed in pure water and commonly form large aggregates, whereas it is not the case when using some form of protein (e.g., bovine serum albumin) to disperse NM [18]. Furthermore, a thorough physicochemical characterization of each NM in all the used culture media should also be performed.
- Selection of appropriate cell lines: The choice of the target cells could be issued from the toxicokinetics study that should define which organ(s) is(are) actually exposed and to which extent. Knowing that, the most sensitive cell system, preferably of human origin and p53 efficient, should be used. Importantly, the efficiency and kinetics of the uptake of NMs in the selected cell type should be done.
- Dose level: If determined, the extent of exposure of the target organ could be used as a basis for calculating the dose level to be actually tested. Anyway, the highest possible dose to be tested will be dictated by the dispersion protocol and the highest concentration ensuring a stable stock suspension.
- The reproducibility of the results obtained in vitro should be checked.
- The selection of appropriate positive (and negative) controls (nano and non-nanoscale) may be of particular interest to ensure the sensibility and the specificity of the test system.
- The incompatibility with some experimental conditions should be checked, e.g., simultaneous co-exposure of NMs and cytochalasin B that inhibits endocytosis [28].

3. **Development of new genotoxicity tests**

Beyond a regulatory strategy, new in vitro tests that may be particularly suitable for testing NMs should be further developed. Indeed, there may be gaps in in vitro testing, for example, the lack of detection of genotoxicity induced by secondary mechanisms. These new in vitro assays that might be considered include genomics and proteomics as related to detection of immune system effects, oxidative stress, inflammation, and other pathways. These technologies also can be used to assess pathway interactions [13].

The implementation of high-throughput platforms investigating simultaneously several

endpoints (e.g., cytotoxicity, impedance, γ-H2AX, oxidation, apoptosis, telomere length measurement, DNA damage repair system, etc.) may be of particular interest for screening rapidly and cheaply the toxicity of NMs, for instance, in the field of Safer by Design. In the same way, the QNTR (Quantitative Nanostructure–Toxicity Relationship) tools should be developed.

In any case, the rules laid down previously should also be applied for these future methods.

Synonyms

Cylindrical gold nanoparticles; Short (low aspect ratio) gold nanowires

Definition

A gold nanorod is defined as nanometer-sized gold particles that are rod shaped. These solid, cylindrical nanoparticles have uniform diameters ranging from a few nanometers to hundreds of nanometers, with aspect ratios (length/diameter) larger than 1 but typically smaller than 10. Owing to their unique physical properties, gold nanowires/nanorods have many attractive applications in several areas, such as in life science, electronic and electromechanical devices, sensors, and solar cells. In the field of nanomedicine, the typical sizes for gold nanorods were around tens of nanometers in diameters and hundreds of nanometers in lengths. The crystalline structures of these gold nanomaterials can be either polycrystals or single crystals with different orientations, depending on the growth methods and conditions.

Key Research Findings

Surface Plasmon Resonance (SPR)

One of the most remarkable features of gold nanorods (NRs) is its unique and tunable localized surface plasmon resonance (LSPR) properties. When metals are reduced to nanoscale dimensions (a few nanometers to hundreds of nanometers), interesting physical properties such as LSPR emerge due to the restrictions imposed on their electron mobility, an effect which also strongly depends on the overall shape of the metal. For nano-sized metallic particles, especially noble metal nanoparticles (such as gold, silver, platinum), they have the ability to confine resonant photons within their small particle size to induce the localized surface plasmon oscillations of conduction-band electrons. The surface plasmon is thus resonant at a specific frequency of the incident light and is called surface plasmon resonance (SPR). For spherical gold nanoparticles, the SPR properties can be described by Mie's theory [1], which has one specific SPR frequency (wavelength $\sim$ 520 nm) for strong absorption, while for nanorods, the SPR oscillates along two directions of the rods: longitudinal and transverse directions. The excitation of the surface plasmon oscillation along the short (transverse) axis induces an absorption band in the visible light region at wavelength (520–530 nm) similar to that of spherical gold nanoparticles, referred to as the transverse band. The transverse band is insensitive to the aspect ratio of the nanorods, while the excitation of the surface plasmon oscillation along the longitudinal direction induces a much stronger absorption band in the longer wavelength region, referred to as the longitudinal band. The longitudinal SPR band of gold nanorods is very sensitive to the aspect ratio of the nanorods. Slight increases in the aspect ratio greatly redshift the absorption maximum (λ_{max}, nm) of the longitudinal band from visible to the near-infrared (NIR) region with a dramatic increase in the band intensity. According to the Gans' theory [2], which is an extension of Mie's theory to treat elongated ellipsoids, the absorption maximum of the longitudinal

band is linearly dependent on the aspect ratio (R) of the nanorods by the following relationship $\lambda_{max} = 95R + 420$ [3]. This optical tunability of the nanorods in the NIR region via the varying rod aspect ratio provides great opportunities for in vivo medical applications, since the absorbance of the surrounding tissue in this region is comparatively low.

Photoluminescence Properties

Usually bulk metals (such as gold, silver, and copper) have extremely weak fluorescence due to their rapid nonradiative electron–hole recombination. However, it has been observed that for short nanorods (aspect ratio < 3), the quantum efficiency of the photoluminescence (PL) is in the range of 10^{-4} to 10^{-3}, about six orders of magnitude greater than that found in the bulk [3]. Although the luminescence quantum efficiency of gold nanorods is several orders of magnitude lower than that of fluorescent labels such as organic dyes or semiconductor nanorods, their larger absorption cross sections compensate for their low quantum efficiency, making them high-contrast imaging agents [4]. In addition, the PL wavelength maximum is found to increase linearly with increasing aspect ratio (less than 3). The quantum efficiency increases quadratically for aspect ratios below 3 and then begins to diminish thereafter. This can be understood by the fact that, as the SPR absorption shifts to longer wavelengths as the nanorod aspect ratio (AR) is increased, the extent of the overlap between the interband processes and the SPR absorption band will be constantly changing. When less than 3, increases of AR result in greater overlap responsible for an emission enhancement. At some point, such as AR < 3.5 shown in the experimental works by Eustis and El-Sayed, further increases in AR diminish the degree of overlap resulting in an emission decline.

However, recently scientists have found that the quantum efficiency of long nanorods (length >200 nm, AR > 10) rapidly increases when the lengths are larger than 200 nm and their corresponding fluorescence intensity has been significantly enhanced [5]. In fact, the actual PL responses for metallic nanoparticles are much more complicated and could be explained as multistep processes [3, 5]. In brief, the strong dependency of photon emission on the nanorod length, combined with the fact that similar enhancements are not observed for sphere nanoparticles, provided evidences that the strong surface fields of the longitudinal surface plasmon oscillations are the origin of the fluorescence enhancement. This is also supported by the polarization of the emission being along the long rod axis [3]. Recent studies on luminescence spectrum of single nanorods with aspect ratios ranging from 1 to ~3.5 showed about an order of magnitude increase in quantum yield for nanorods with longitudinal plasmon wavelengths longer than 650 nm, compared to nanospheres. Polarization-sensitive measurements further proved that the emission is dominated by a polarized contribution that coincides with the longitudinal plasmon [4]. The excitation of interband absorption simultaneously excites the longitudinal surface plasmon of gold nanorods, resulting in enhanced local electric fields amplifying both exciting and emission fields. The enhanced fluorescence of gold nanorods thus provides opportunities for imaging and diagnostics applications.

Photothermal Properties

Unlike aforementioned radiative properties, photothermal properties of gold nanorods are nonradiative processes, in which the absorbed light is converted into heat via a series of photophysical processes [6]. Basically, these photophysical processes begin with a fast loss of phase of the coherently excited electrons on the few femtosecond timescale and then followed by energy loss to the phonon bath in the crystal lattice of gold nanorods. The relaxation process is size and shape independent and also independent for both the transverse and longitudinal surface plasmon in the nanorods. Meanwhile, the lattice cools down by passing heat to the surrounding medium via phonon–phonon relaxation of ~100 ps [3], which leads to the competitive process of cooling and heating of the whole nanorods. If the heating rate is much faster than the cooling

rate, at appropriate timescale, heat can be accumulated within the lattice causing a local temperature rise of the nanorods in a short time, which could provide an effective means for selective photothermal therapy.

Synthesis and Surface Modifications

Although the synthesis of spherical gold nanoparticles can be dated back to 1857 by Faraday, fabrication of gold nanorods with well-controlled shape and crystalline structure emerged only during past decade [3]. Five typical gold nanorod/nanowire synthesis approaches will be described here: (1) seed-mediated growth [7, 8], (2) electrochemical synthesis [9], (3) photochemical reduction [10], (4) lithographic methods [11, 12], and (5) template-assisted growth [13].

Seed-Mediated Growth

In 2001, Murphy and coworkers [7] prepared colloidal gold nanorods by the addition of citrate-capped small gold nanospheres to a bulk $HAuCl_2$ growth solution obtained by the reduction of $HAuCl_4$ with ascorbic acid in the presence of cetyltrimethylammonium bromide (CTAB) surfactant and silver ions. This method was improved by the same group with a three-step procedure in the absence of silver nitrate for larger aspect-ratio (up to 25) nanorods. In a typical procedure, the gold nanospheres/nanorods in the previous step are sequentially used as "seeds" for the next step growth. Later on, El-Sayed and coworkers further improved the method by replacing sodium citrate with a stronger CTAB stabilizer in the seed formation process and utilizing silver ions to control the aspect ratio of gold nanorods [8]. These modifications resulted in reproducible formation of nanorods with aspect ratios ranging from 1.5 to 4.5 with desired lengths. To grow longer nanorods with aspect ratios ranging from 4.6 to 10, a binary surfactant mixture composed of benzyldimethylhexadecylammonium chloride (BDAC) and CTAB was used, with appropriate silver ion concentrations. The growth of gold nanorods via seed-mediated method has been explained in two mechanisms [3]: One is the surfactant-preferential-binding-directed growth proposed by Murphy and coworkers based on high-resolution TEM (HRTEM) imaging, which showed the atomic structure of the nanorods during various formation stages. It is believed that the intrinsic structural twinning in the face-centered cubic (fcc) metallic nanoparticles causes symmetry breaking to produce anisotropic nanoparticles. And the following anisotropic growth into nanorods is due to the preferential binding of the CTA^+ head group to faceted seed nanoparticles on the {100} faces [3]. The other theory is the electric-field-directed growth mechanism proposed by Mulvaney and coworkers, in which the $AuCl^{2-}$ ions bound to cationic micelles diffused to seed nanoparticles at high curvature points due to higher electric double-layer gradient at these points and thus leads to nanoparticle growth in rod shape. Also, it might be noted that the effect of the silver ion content is not always to increase the aspect ratio of NRs. Nikoobakht et al. showed that by increasing the concentration of the $AgNO_3$ in the growth solution to more than a specific value, the length of the NRs started to decrease. The negative effect of the silver ions in higher concentration was probably due to their interaction with the bromide counterion of the surfactant monomers [8]. Finally, the size of Au nanorods can be tailored by carefully adjusting other growth conditions, such as the pH of the growth solution, the growth temperature, the compositions of the reagents, and the nanostructures of the seeds, in the seed-mediated growth process. For instance, a very recent study has demonstrated that seed-mediated growth of Au nanorods could be achieved with high yields and uniformity through the use of aromatic additives in addition to CTAB [14]. However, even if the growths follow the same protocols and procedures, the shape and size of Au nanorods may vary among different batches, which is one of major challenges that hinder the potential industrial applications of Au nanorods [15].

Electrochemical Synthesis

Gold nanorods have also been prepared via electrochemical oxidation/reduction within a simple

two-electrode type of cell [9]. A gold metal plate is used as the anode and a platinum plate is used as the cathode in the electrochemical cell. Both electrodes are immersed in an electrolytic solution consisting of a cationic surfactant, hexadecyltrimethylammonium bromide (CTAB), and a rod-inducing cosurfactant (tetraoctylammonium bromide, TOAB). The CTAB serves not only as the supporting electrolyte but also as the stabilizer for nanoparticles to prevent their further growth. During the synthesis, the bulk gold metal is converted from the anode to form gold nanoparticles mostly at the interfacial region of the cathode surface and within the electrolytic solution. A current-controlled electrolysis is used throughout the process and an appropriate amount of acetone added into the electrolytic solution is necessary [9]. The synthesis is conducted under an ultrasonication (for dissipating the nanorods away from cathode) and a controlled temperature (typically at 38 °C). It is suggested that the role of acetone is to facilitate the incorporation of cylindrical shape-inducing cosurfactant into the CTAB micellar framework and inducing the cylindrical growth to form the Au–CTAB–TOAB system [3, 9]. The typical rod-inducing cosurfactant (e.g., TOAB) employed is an overall much more hydrophobic cationic surfactant. Similarly, by inserting a silver plate into the solution and releasing silver ions, the aspect ratio of nanorods can be varied.

Photochemical Reduction

In this method, auric acid is bound to rodlike cationic micelle surfactants to form ion pairs and then excited by UV light to reduce metal ions to form metals via electron transfer from metal ions to ligands [3]. It is proposed that the rod formation is due to a two-step aggregation process [10], that is, metal nuclei aggregation to form primary particles and then primary crystal aggregation to form rodlike structures due to specific crystal face stabilization by surfactant micelles. In this method, addition of sodium chloride electrolyte, the concentration of silver ions, and the UV light wavelength/intensity can adjust the growth speed, size, and structures of the nanorods.

More recently, several other techniques have been developed based on the similar mechanisms as electrochemical or photochemical approach. Ultrasonication of growth solution containing CTAB, gold chloride, silver nitrate, and/or ascorbic acid was shown to induce rod formation. Theoretically, ultrasonic irradiation led to the formation of hydroxyl and other radicals which could reduce gold ions to form the initial nuclei necessary for rod growth [16]. Also, the radicals can be formed by irradiation of a growth solution similar to that used in photochemical synthesis [17].

Lithographic Methods

The most commonly utilized lithography technique for fabricating gold nanorods is electron-beam lithography (EBL) [11]. Nanoscale patterns written with an electron beam allow for the formation of nanometer-scale openings in the resist through which gold can be deposited. By liftoff of the remaining resist and the unwanted gold deposited on it, free-standing gold nanorods can be obtained with high-quality and well-controlled geometry. Another approach, so-called focused ion beam (FIB) lithography, utilizes a rastered ion beam to sputter away unwanted portions of a continuous film leaving behind nanostructures of the desired shape [12]. Both methods can fabricate samples with unparalleled control over the size, shape, and alignment. These two methods break the size limit of as-fabricated nanostructure compared to traditional photolithography due to diffraction limit of light. State-of-the-art electron-beam lithography systems can even fabricate Au nanorods of diameters down to ~10 nm [18]. However, unlike previous mentioned chemical/photochemical/electrochemical synthesis methods, the crystalline structure cannot be well controlled. In addition, both methods are very time consuming and expensive.

Template-Assisted Growth

Template methods involve the use of nanoporous track-etched polycarbonate or anodized aluminum oxide (AAO) membrane [13] as the template where gold atoms are deposited by electrochemical reduction of gold ion precursor in an electrochemical cell. The subsequent chemical etching of

the template membrane gives free-standing gold nanorods. The diameter of the nanorods is determined by the pore diameter of the membrane template. For AAO templates, uniform diameters ranging from tens of nanometers to hundreds of nanometers can be prepared by controlling the anodization process. The length of the rods is controlled by varying growth time and applied voltage/current (the amount of the gold deposited), and thus, the aspect ratio of the nanorods can be tuned accordingly. Similar to lithographic methods, crystalline structure is less controllable in this method. However, template method provided similar excellent control over the size (diameter, length, aspect ratio) at a much lower cost. In addition, it is possible to grow multisegment nanorods (such as Au–Ni bimetal nanorods [19]) by switching templates between different electrolyte solutions, which brings opportunities to further introduce new functions to the original gold nanorods.

In summary, the first three approaches are bottom-up methods and the latter two are considered as top-down methods. Among these, the seed-mediated growth is the most popular method for the synthesis of colloidal gold nanorods due to the simplicity of the procedure, high quality and yield of nanorods, ease of particle size/aspect ratio controlling, and flexibility for structural modifications [3]. However, this method, as well as other bottom-up methods which involve surface surfactant, usually results in a double layer of cetyltrimethylammonium bromide (CTAB), which is problematic for bio-conjugation, nonspecific absorption of DNA, cytotoxicity, and stability [20]. These factors have severely limited the use of gold nanorods in biological and nanomedicine applications. Therefore, it is necessary to apply surface modification for gold nanorods fabricated by the bottom-up methods, to increase stability, facilitating surface chemistry, tuning properties, and broadening the practical applications.

Surface Modifications

Surface modifications of gold nanorods have attracted considerable interest in recent years, and generally two types of surface modifications have been developed.

One is to introduce or exchange surface surfactant (e.g., CTAB) by other chemical or biological functional groups on nanorod surface. For example, Takahashi et al. [21] utilized phosphatidylcholine (PC) to replace the CTAB and successfully reduced the cytotoxicity. More recently, researchers applied ligand exchange and customization by using thiol group [20] and found that the functionalized nanorods had very strong binding with DNA which demonstrated potential applications in biomedical fields.

The other is to coat nanorods surface with hard inorganic materials. Firstly, gold nanorods themselves are ideal templates for further growth of other metallic nanomaterials. By further growth of silver, or platinum, or palladium thin layer(s), the surface properties of Au nanorods could be modified or improved by forming such core–shell structures. For example, silver coating can significantly enhance Raman scattering [3]. Secondly, one could also coat gold nanorod surface with iron oxide or silicon oxide hard layers. SiO_2 is of special interests since it is highly biocompatible, stable, and hydrophilic, and Au nanorods coated with a thin layer of silicon oxide can be easily adopted for further surface functionalizations [22].

Examples of Applications

Drug/Gene Delivery and Selective Release

The mechanism is to use the shape transformation and heating effect of gold nanorods under exposure to near-infrared (NIR) laser pulses to result in the drug or DNA release due to surface atom rearrangement or breaking of the chemical bonds. For example, Wijaya et al. used gold nanorods with two different lengths to carry two different DNAs [23]. When laser with appropriate wavelength is applied, selective release of DNA could be made and the releasing rate was up to 50–80 %. In the work by Wu et al. [24], the thiolated gene of enhanced green fluorescence protein (EGFP) was covalently conjugated to gold nanorods. Under laser irradiation, gold nanorods underwent significant shape transformation, resulting in the release of EGFP DNA.

Molecular Imaging

Gold nanorods can be ideal imaging probes or contrast agents for molecular imaging applications, due to their unusual optical properties at NIR region. Compared to conventional contrast agents – such as radionucleotide in PET and SPECT, gadolinium compounds in MRI, and dye molecules in optical fluorescence imaging [3] – gold nanorods can act as NIR fluorescence probe and have two main advantages: firstly, near-IR laser introduces less damage to living cells; secondly, the penetrating depth for NIR laser in biological tissues is much larger than that for visible light, up to hundreds of mm. These make near-IR imaging with gold nanorods ideal for in vivo diagnostics. For example, Durr et al. modified the surface of gold nanorods with anti-epidermal growth factor receptor (anti-EGFR) antibody and attached them onto cancel cell selectively [25]. By performing two-photon fluorescence (TPF) on the three-dimensional tissue with cancer cells, researchers found the fluorescence intensity due to gold nanorod labeling was about three orders of magnitude higher than the intensity of cancer cell fluorescence illumination [25].

Surface Plasmon Resonance Sensing

Due to the fact that the SPR frequency highly depends on the dielectric constant of the surrounding medium, increasing the dielectric constant of the surrounding medium leads to a redshift of the SPR wavelength. Therefore, the SPR wavelength either by absorption or scattering provides great opportunity to monitor the changes of the local environment of the nanoparticles and thus can be used for sensing. Compared to gold nanospheres, the unique transverse and longitudinal SPR characteristics for gold nanorods provide higher accuracy: the longitudinal SPR absorption is very sensitive to the change of surrounding environment while the transverse SPR will have no obvious redshift and can be served as a reference. In addition, the characteristic SPR responses for gold nanorods with different aspect ratios can be utilized for higher efficient diagnostics. For example, Yu et al. attached three types of antibody molecules to three different gold nanorods (with different AR), and multiplexing detection of three targets was successfully realized via the observation of three LSPR redshifts [26].

Plasmonic Nanoantenna

Plasmonic nanostructures, especially gold nanorods, possess strong light absorption and scattering capabilities and narrow line widths, so that they can control and manipulate light–matter interactions at the nanoscale and thereby act as nanoantennas [15]. As nanoantenna, far-field radiation can be captured by the gold nanorods and transferred to highly confined electromagnetic fields surrounding them, which allows for nanoscale optical signal processing. Reciprocally, gold nanoantenna can also transfer the localized near-field radiations from a nanoscale object into far-field optical signals. These far-field signals will be labeled with the characteristics of the original plasmon, such as the frequency, polarization, and spatial radiation direction, which can be modulated by the longitudinal plasmon mode or introducing hybrid nanostructures and metamaterials. Recent studies further show that 2D [27] or 3D [28] arrays of appropriately tuned gold nanorods can also function as Yagi–Uda antenna, where different sized gold nanorods work as feeds, reflectors, and directors. This nano-optical Yagi–Uda antenna can significantly improve the directionality of emission, from broad spatial distributions into a narrow forward angular cone.

Surface-Enhanced Raman Scattering (SERS)

Raman scattering has been used for biological detection since the first interpretable laser-excited Raman spectrum of lysozyme by Lord et al. in 1970 [3]. However, the small Raman scattering cross sections of most biological molecules lead to very weak Raman signal, which hinder their biomedical applications. Discovered by Fleischmann et al. in 1974, surface-enhanced Raman scattering (SERS) can enhance the Raman signal by six orders of magnitude: To maximize Raman intensity, the distance between the molecules and the metal surface and the metallic nanoparticle shape are two major considerations. For example, Nikoobaht et al. observed SERS enhancement factors on the order of 10^4–10^5 for the molecules on the nanorods

(25 nm 10 nm), while no such enhancement on the nanospheres [29]. In addition, nanorods can be synthesized with different aspect ratios so as to overlap the longitudinal surface plasmon band to the excitation source spectrum to obtain the largest enhancement [30]. As demonstrated by Jana et al., optimum length scale is 20–100 nm irrespective of nanoparticle size and shape [31].

For in vivo biosensing and biodetection, Raman-active molecule-coded nanorods are transferred to organic tissues and thereafter detected by measuring Raman scattering signals. In the study by Bhatia et al., Au nanorods were coded with several Raman-active molecules, such as IR-792 perchlorate, DTTC-765, and DTDC-655, and then injected into the mice implanted with bilateral human MDA-MB-435 tumors. Under near-infrared illumination, the Raman-active molecule-coded Au nanorods were found to give intense in vivo Raman signatures with concentrations down to attomoles. This remote sensing ability in tandem with the photothermal conversion-based therapy has made Au nanorods an excellent multiplex biomedical platform [32].

Photothermal Therapy

The recent interest in the use of gold nanorods in photothermal therapy rooted from the advantages of their small size, excellent stability, high efficiency, and tunable absorption in the biological window. Gold nanorods become very popular also because they can absorb light in the NIR window (650–900 nm) where light penetration is optimal due to minimal absorption by water and hemoglobin in the tissue as discussed earlier. In addition, these plasmonic nanoparticles could enable dual imaging and therapy functions at the same time. For example, Huang et al. provided an in vitro demonstration of gold nanorods as contrast agents for both molecular imaging and photothermal cancer therapy [3]. In their work, nanorods were conjugated to anti-epidermal growth factor receptor (anti-EGFR) monoclonal antibodies and incubated in cell cultures with a nonmalignant epithelial cell line (HaCat) and two malignant oral epithelial cell lines. The anti-EGFR antibody-conjugated nanorods binded specifically to the surface of the malignant-type cells with a much higher affinity due to the overexpressed EGFR on the cytoplasmic membrane of the malignant cells [3]. As a result of the strongly scattered red light from gold nanorods in dark field, observed using a laboratory microscope, the malignant cells were clearly visualized and diagnosed from the nonmalignant cells. It was found that, after exposure to continuous red laser at 800 nm, malignant cells require about half of the laser energy to be photothermally destroyed than the nonmalignant cells. Thus, both efficient cancer cell diagnostics and selective photothermal therapy were realized at the same time.

Future Directions

Despite the fact that gold nanorods have already exhibited a wide range of promising applications and great potentials in disease diagnosis and treatment, there remain plenty of things to be done before they can actually advance into the realm of clinical trials. First of all, although some of the biomedical applications, such as photothermal cancer therapy, have been successfully demonstrated in animal experiments, more in vivo experimental data are definitely needed in order to establish a complete set of parameters for translational research and clinical practice. Secondly, considerable refinements need to be made, for example, by further introducing hyper-structures to the nanorods, such as porous gold nanostructures, or advanced surface coatings, so that drug/gene delivery efficiency and imaging/sensing mechanisms could be correspondingly tuned. Last but not the least, rigorous studies on the long-term effects, such as distribution and fate of gold nanorods in the human body, should be carried out carefully.

Graphene

Debdeep Jena
Department of Electrical Engineering, University of Notre Dame, Notre Dame, IN, USA

Synonyms

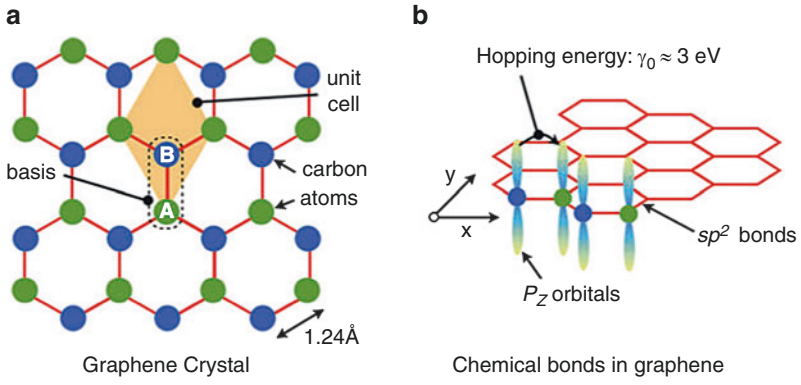
Bilayer graphene; Graphite; Nanoribbons

Definition

Graphene is defined as an atomically thin planar allotrope of carbon. Each carbon atom in this two-dimensional (2D) crystal is bonded to three other carbon atoms, forming a hexagonal structure. Graphene is the building block of graphite, carbon nanotubes, and fullerenes. It is the thinnest crystal known at this time.

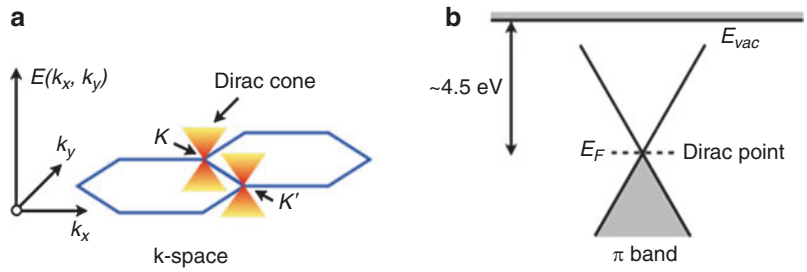
Overview

The various solid forms of carbon have been known and used since thousands of years. In three-dimensional (3D) form, charcoal is the prototype solid fuel used to sustain life through the ages. Lavoisier first showed in 1772 that diamond was composed entirely of carbon by "burning" diamond in oxygen and producing carbon dioxide. This 3D crystalline form of carbon is the hardest, electrically insulating, and most thermally conductive solid known. These properties of diamond form the basis for its many uses. Graphite is a layered solid form of carbon, and is more stable than diamond. It is remarkably different from diamond in its physical properties. It is an electrical conductor, exhibits high anisotropy in its electrical and thermal conductivities, and is very refractory. Because it is capable of carrying copious amounts of electrical current, graphite was instrumental in the discovery of the light bulb, which converts electrical energy into photons for illumination. It is still used in arc lamps and where high currents and high temperature operation is necessary. The uses of graphite are more diverse, ranging from neutron moderation in nuclear reactors to the pencil lead, which exploits its layered structure. The rich range of physical properties of the various forms of carbon emerges from seemingly minor differences in the microscopic arrangements of the carbon atoms.



With the advent of electron microscopy, it became possible to investigate the atomic structure of solids made of carbon. Lower dimensional forms of carbon were then discovered. In semiconductor heterostructures, such as those made of silicon or GaAs, man-made quantum-size effect materials were created starting from 3D bulk semiconductors to 2D quantum wells, 1D quantum wires, and 0D quantum dots. Thus, nanostructures based on semiconductor heterostructures developed from large to small. In sharp contrast, the first carbon nanostructure discovered was zero-dimensional (0D) fullerenes (C_{60}), followed by 1D carbon nanotubes. The 2D form of carbon, graphene, has been known since the 1940s to be the building block of graphite. It was also found subsequently to be the building block of fullerenes and nanotubes. But by itself, a single layer of graphene was believed to be thermodynamically unstable. Based on the Mermin–Wagner theorem in solid-state physics, the energy cost for spontaneously broken symmetries in 2D crystals is low. This means that a perfect "flat" 2D crystal can increase its entropy by forming ripples or crumples. Thus, to a certain extent, the isolation of 2D atomic crystals in 2004 was a surprise. Using scotch tape, single layer flakes of graphene were isolated from graphite, and their electronic properties were investigated [1]. More than the isolation of single

layers of graphene, the findings of the nature of electron motion in it have far-reaching consequences on the fundamental understanding of the electronic properties of solids. These findings have opened a new door to aspects of symmetry in condensed matter physics. Rapid progress has occurred in exploiting these properties in applications. To understand the origins of the peculiar properties of graphene, its atomic structure is discussed next.



Crystal Structure of Graphene

Carbon is the sixth element in the periodic table, meaning it has six protons in its nucleus. Charge neutrality requires the presence of six electrons. The six electrons fill the lowest three orbitals in the arrangement $[1s]^2[2s]^2[2p]^2$, where the $|s\rangle$ orbitals are spherically symmetric, and $|p\rangle$ orbitals are elongated along a linear axis. When carbon atoms are brought close to each other, the two electrons in the innermost $[1s]^2$ orbitals remain close to the nucleus, and do not participate in the bonding process. The outermost orbitals start interacting, and are capable of forming chemical bonds. The four electrons in the outermost $[2s]^2[2p]^2$ orbitals can be shared between atoms in a variety of ways, each leading to a different form of carbon. For example, when four nearest carbon atoms share all four electrons of a carbon atom equally, the bond is sp^3. An sp^3 bond is tetrahedral, and is inherently 3D. Carbon atoms bonded in this fashion arrange periodically in 3D space, forming the crystal structure of diamond. Carbon is rather versatile in its bonding possibilities; when combined with hydrogen atoms, electrons in carbon atoms can form sp^2 or sp bonds as well. This means carbon atoms can form 2D planar molecules (e.g., the hexagonal molecule benzene or C_6H_6), or long one-dimensional chains (e.g., in conductive polymers). This versatility of electrons in carbon is the root of the complexity of organic molecules that lead to the emergence of life itself.

When a carbon atom shares electrons with *three* nearest neighbors, the bonding is sp^2, written as $|sp^2\rangle = a|s\rangle + b|px\rangle + c|py\rangle$, where *a, b, c* are constants. This bonding leaves one electron behind for every carbon atom. The three chemical bonds are separated by 120°, and are planar. This is the crystal structure of graphene, depicted in Fig. 1. The energies of the electrons forming the sp^2 bonds bunch together into bands called the σ band. The σ band is responsible for the perfectly planar nature of graphene, and determines its structural and vibrational properties, such as its thermal conductivity and Young's modulus, among others. Thus, graphene is a 2D crystal with hexagonal arrangements of carbon atoms. The atomic spacing is $a_{cc} \sim 0.124$ nm. As indicated in Fig. 1, the smallest repeating unit that can be translated to cover the entire 2D space consists of not one, but *two nearest-neighbor carbon atoms*. Though the atoms are physically identical (they are both carbon), they are labeled as A and B in Fig. 1 since the "mechanical" symmetry can be broken by the electron wavefunction associated with them. The A-B atom combination is the two-atom "basis" of the graphene crystal, similar

to that in 3D diamond or silicon. The primitive repeating unit is shown as a parallelogram. By virtue of being 1-atom thick, graphene is the "thinnest" crystal. It is impermeable to small gas molecules. The structural and chemical rigidity of graphene is protected by symmetry: to form a chemical bond to graphene, one needs to convert sp^2 bonds to sp^3. This requires buckling of the crystal since the bonds have to change from 2D to 3D, requiring the movement of atoms. If and when this is achieved, the material is no longer graphene. In addition, carbon is the lightest in group-IV of the periodic table, and the strong σ bonds lead to the highest in-plane thermal conductivity. However, the σ band does not directly influence the electronic properties of graphene. Electrons in sp^3 bonds and bands resulting from them determine the electronic *and* structural properties in conventional 3D semiconductor crystals (e.g., Si, GaAs, diamond). In graphene, the electronic and structural properties arise from different bands. For understanding the electronic properties of graphene, attention is focused back to the *electron that was left out* in the formation of the sp^2 bond.

Electronic Properties of Graphene

The electrons left out in the chemical bonding process are from the $|p_z\rangle$ orbitals of the carbon atoms forming graphene. The linear axis of the $|p_z\rangle$ orbital protrudes outward from the plane, as shown in Fig. 1. These electrons can hop between the nearest neighbor carbon atoms. The energy characterizing this hopping is γ_0 ~3.0 eV. Thus, their wavefunctions become delocalized. Their allowed energies bunch together to form what are called π bands. Electrons in the π bands can be visualized as sliding over the hexagonal carbon atom structure of graphene. These electrons impart graphene its exceptional electrical conductivity.

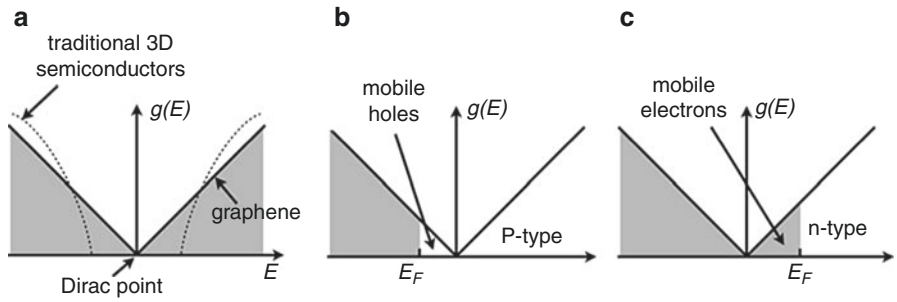
The allowed energies of the delocalized π electrons depend on their wavelength, in accordance with the rules of quantum mechanics. According to the de-Broglie relation, the wavelength is inversely proportional to momentum. The momentum is given by $\hbar k$, where $\hbar$ is Planck's constant and $k = 2\pi/\lambda$, where λ is the wavelength. The allowed energies of electrons $E(k_x, k_y)$ can be then plotted in the k-space, as shown in Fig. 2. By taking into account the basis of two atoms, the wavefunctions of electrons in graphene are represented as "spinors," which are two-component matrices of the form $\frac{exp[i\mathbf{k}\cdot\mathbf{r}]}{\sqrt{2}}\begin{pmatrix}1\\ exp[i\theta]\end{pmatrix}$, where $\mathbf{k} = \mathbf{x}k_x + \mathbf{y}k_y$, and $tan\,\theta = k_y/k_x$. Using a tight-binding procedure, the energy spectrum $E(k_x, k_y)$ is given by the equation $\hbar v_F\left(\vec{\sigma}\cdot\mathbf{k}\right)|\psi\rangle = E\left(k_x, k_y\right)|\psi\rangle$, where $\vec{\sigma} = \mathbf{x}\sigma_x + \mathbf{y}\sigma_y + \mathbf{z}\sigma_z$ is a vector composed of the three Pauli spin matrices. The term $v_F = 3a_{cc}\gamma_0/2\hbar \sim 10^8$ cm/s is a parameter characterizing the bandstructure, with dimensions of velocity. This Hamiltonian has a closer analogy to the Dirac equation rather than the Schrodinger equation used for conventional semiconductors. The Dirac Hamiltonian consists of Pauli spin matrices in the kinetic energy term, which implies that electrons have spin-like properties based

on their momentum. This property is termed "pseudo-spin," and may be pictured as a vector whose direction depends on the momentum. In traversing a path around a constant-energy circle in the Dirac cone, the wavefunction accumulates a phase of π due to the pseudospin. This phase is called Berry's phase, and has consequences on scattering and on quantum Hall effects.

The energy bandstructure obtained from this "Dirac equation" for the π band is given by $E(k_x,k_x)=E_F\pm\gamma_0\sqrt{1+4\cos\left(\sqrt{3}k_xa/2\right)4\cos\left(k_xa/2\right)+4\cos^2\left(k_ya/2\right)}$, where $a=\sqrt{3}a_{cc}$ is the lattice constant of graphene. Here, E_F is the Fermi energy, which for pristine undoped graphene is ~4.5 eV below the vacuum energy level. This is the electron affinity or the work function of pure graphene (Fig. 2). The positive sign is for the conduction band that lies above E_F, and the negative sign is for the valence band. One can note that $E(0,4\pi/3a)=E_F\pm0$ eV, which implies that there is *no energy bandgap* in the π band of graphene. The points in the k-space such as $K=(0,4\pi/3a)$ where the conduction and valence bands meet are called the Dirac points. These points form a hexagonal network in the k-space as indicated in Fig. 2, with the nearest-neighbor points labeled as K and K'. In analogy to traditional semiconductors, graphene is a direct bandgap semiconductor. Since each K point is shared between three hexagons, there are two distinct points in the smallest repeating unit cell in k-space, called the Brillouin zone. Thus, in analogy to traditional semiconductors, graphene has a valley degeneracy of 2.

The Fermi energy is at the Dirac point for pure graphene, meaning at zero temperature and in the absence of doping, all electronic states below the Dirac point are occupied, and all above it are empty. Electrical conductivity thus occurs in graphene due to transitions of electrons between allowed states close to the Dirac point. In analogy to the effective mass approximation for semiconductors, expanding the energy dispersion around the Dirac point, say around $K=(0,4\pi/3a)$, yields the rather interesting relation $E(k_x,k_x)-E_F\approx\hbar v_F\sqrt{k_x^2+k_y^2}=\hbar v_F|\mathbf{k}|$. This is the equation of a cone, and owing to its origin in the Dirac-like Hamiltonian, referred to as the Dirac cone. The conical form of the energy dispersion remains valid for energies exceeding a few eVs from the Dirac point energy, which is the range of interest for all low-energy electronic and optical properties. A few intriguing aspects of this energy dispersion can be identified by comparison with traditional semiconductors.

In traditional semiconductors, the kinetic energy of electrons near a band edge E_C is proportional to the square of the electron quasi-momentum $E(k)-E_C=(\hbar k)^2/2m^*$, with the magnitude of the kinetic energy parameterized by an effective mass distinct from the mass of free electrons. The effective mass m * is a parameter that absorbs the details of the crystal potential. It replaces the complex motion of free electrons in a crystal by that of an electron with a different mass in free space. This is a considerable simplification, one that is heavily leveraged in the design of electronic and optical devices such as transistors, light-emitting diodes, and lasers based on traditional semiconductors. In stark contrast, the kinetic energy of electrons in graphene depends on its momentum *linearly* $E(k_x,k_x)=v_F\cdot\hbar|\mathbf{k}|$, where Fermi energy at the Dirac point is used as reference. Wallace originally derived this linear form of the bandstructure of graphene in 1947 [2].



A linear dependence of kinetic energy on momentum is characteristic of light or photons. The energy dispersion of electrons in graphene is identical to that of photons, with the speed of light $c=3\times10^8$ m/s replaced by the "Fermi velocity" $v_F\approx10^6$ m/s. The maximum speed of electrons in graphene is $v_F/c=1/300$ that of light in free space. In traditional semiconductors, particularly those of small bandgaps, the velocity of carriers can also approach these speeds. A consequence of the linear energy dispersion is the difficulty in associating an effective mass to electrons in graphene. The effective mass is *defined* as the curvature of the energy dispersion. By definition, the curvature of a linear curve is zero. Thus, electrons in graphene are referred to as "massless Dirac fermions." The "massless" feature should be understood in the light of the discussion above; electrons in graphene are identical to electrons in

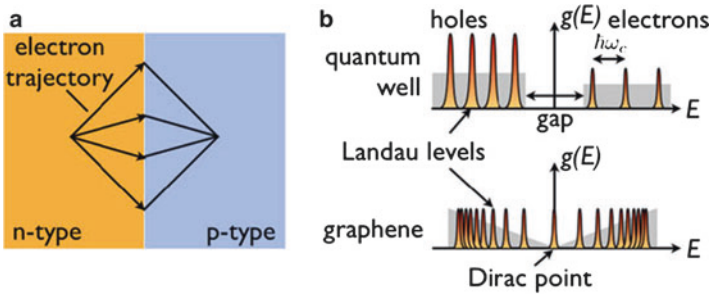
any other material. Unlike *truly massless photons*, they need external driving forces such as electric or magnetic fields to carry currents. *What is unique about graphene is the linear energy dispersion of electrons*. In the dispersion of electrons are hidden a number of symmetries, each leading to many of its unique features.

Carrier Statistics in Graphene

The absence of an energy bandgap in graphene is related to the light-like linear dispersion. The linear dispersion also implies that the transport properties of filled states in the conduction band (see Fig. 2) and empty states in the valence bands (holes) are similar. The conduction band is a mirror-reflection of the valence band. This symmetry is special. Two-dimensional electron or hole gases in semiconductor quantum wells have multiple subbands to occupy, and can be truly 2D at very low energies or at low temperatures as long as only one subband is occupied. In stark contrast, electrons and holes in 2D graphene are truly 2D at all temperatures, since there are no higher subbands near the Dirac point. Based on the energy dispersion, the density of states (DOS) of graphene is given by $g(E) = 2|E|/\pi(\hbar v_F)^2$, which is linear in energy. Three-dimensional semiconductors have density of states that depend on energy as $g(E) \sim \sqrt{E - E_0}$, whereas the density of states of 2D subbands in quantum wells are energy-independent. The DOS of 2D graphene is shown in comparison to traditional 3D semiconductors in Fig. 3. Based on the DOS, the electron and hole densities in pristine graphene are given by $n_0 = p_0 = (\pi/6) \cdot (kT/\hbar v_F)^2$, where T is the temperature and k is the Boltzmann constant. At room temperature, there are $\sim 8 \times 10^{10}/\text{cm}^2$ electrons in the conduction band due to interband thermal excitation, leaving behind an equal number of holes in the valence band. These carriers are mobile, and lead to a finite conductivity of graphene at room temperature even in the absence of intentional doping. They set the *lower limit* of mobile carrier concentration in 2D graphene: with any changes such as doping or field-effect, the net mobile carrier density can only exceed this number. The $\sim T^2$ dependence of intrinsic interband thermal generation of carriers is in stark contrast to traditional semiconductors, where the density depends on the bandgap as $\exp(-E_G/2kT)$ where E_G is the bandgap.

When graphene is electrostatically doped, the Fermi energy moves away from the Dirac point into the valence or the conduction band, making it p-type or n-type. Under these conditions, the carrier concentrations are given by $n = E_F^2/\pi(\hbar v_F)^2$. Thus, the Fermi energy changes as the square root of the carrier concentration, $E_F = \hbar v_F \sqrt{\pi n}$. At a 2D carrier concentration of $10^{12}/\text{cm}^2$, $E_F \sim 0.12$ eV from the Dirac point, and increases to $E_F \sim 0.37$ eV at $10^{13}/\text{cm}^2$. The Fermi energy is tunable over a wide range, which implies a tunable work function for 2D graphene. The electrons or holes thus formed in graphene are responsible for its electrical conductivity. The current per unit width that flows in a graphene

Graphene, Fig. 3 Density of states of pure graphene and p-type and n-type graphene. (**a**) Density of states of graphene is linear and symmetric around the Dirac point energy. It has no energy gap, unlike conventional semiconductors. (**b**) and (**c**) P-type and n-type graphene created by moving the Fermi level into the valence and conduction band, respectively



sheet in response to a voltage applied across contacts made to graphene is given by $I/W = qn\langle v\rangle$, where $\langle v\rangle$ is the ensemble-averaged velocity. In the absence of any scattering, the velocity of *all* carriers in graphene is the Fermi velocity v_F, by virtue of its linear bandstructure. However, since a net current flows only along the electric field, the effective velocity is only a fraction of the Fermi velocity obtained appropriately by angular averaging. The current drive in clean defect-free graphene is typically high, owing to the high Fermi velocity. In the presence of defects, however, the conductivity suffers due to scattering.

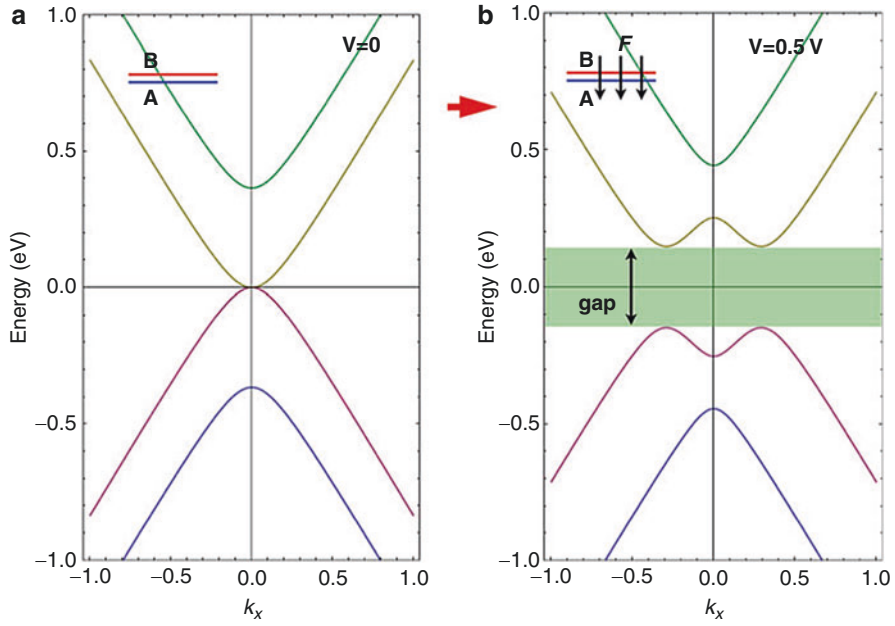
Carrier Transport in Graphene

The mobility of electrons in graphene is typically high, if the material is pure. Electron and hole mobilities well in excess of 50,000 cm^2/Vs have been measured at room temperature in the cleanest samples [3]. The high mobility is typically degraded due to scattering from impurities that are not inherent to graphene itself. For example, charged impurities located outside the plane of graphene result in Coulombic scattering of mobile carriers. Similarly, integrating a dielectric in close proximity to graphene allows electrons in graphene to excite phonon modes in them, resulting in "remote" phonon scattering [4]. When these scattering processes are suppressed, the mobility of carriers in graphene is found to increase. The high mobilities lead to long mean-free paths, and ballistic transport is possible over micrometer length scales. At high voltages, when electrons gain kinetic energies high enough to excite the intrinsic optical phonon modes of graphene, they collide with the carbon atoms and create optical phonons. By virtue of the lightness of carbon atoms, the optical phonon energy is high (~160 meV), implying that carriers cannot emit optical phonons until they acquire an equivalent kinetic energy, resulting in high velocities.

The high mobility and velocity of carriers leads to high currents in field-effect transistor-like device applications. Due to the lack of a bandgap, the demonstrated current modulation in 2D graphene typically does not exceed a factor of 10X, currently restricting the feasibility of 2D graphene in electronic digital switching. However, applications that do not require a high current modulation stand to benefit from the high current drive and the high speed. Unlike traditional semiconductors, the symmetry of the bandstructure and the absence of a bandgap implies that graphene is as conductive when p-type as when it is n-type. Thus, when the Fermi energy is tuned from the valence band to the conduction band, the current characteristics change from hole conduction to electron conduction symmetrically; this property is termed ambipolar. The ambipolar symmetry is useful for passive applications in electronic circuits such as mixers to generate higher harmonics of oscillatory signals. In most traditional semiconductors, the valence band effective mass is higher than the conduction band effective mass, and the ambipolar nature is not protected by symmetry, as in graphene.

Adjacent regions of graphene can be electrostatically gated with opposite polarity, forming p-n junctions as shown in Fig. 4. In such a case,

Graphene, Fig. 4 Electron "lensing" in graphene, and Landau levels in traditional semiconductors compared to those in 2D graphene. (**a**) Electron transport in graphene mimics light; a p-n junction behaves as a lens for electrons. (**b**) At high magnetic fields, the density of states of graphene collapses into Landau levels that are quite different from what is observed in 2D electron–hole systems in conventional semiconductors



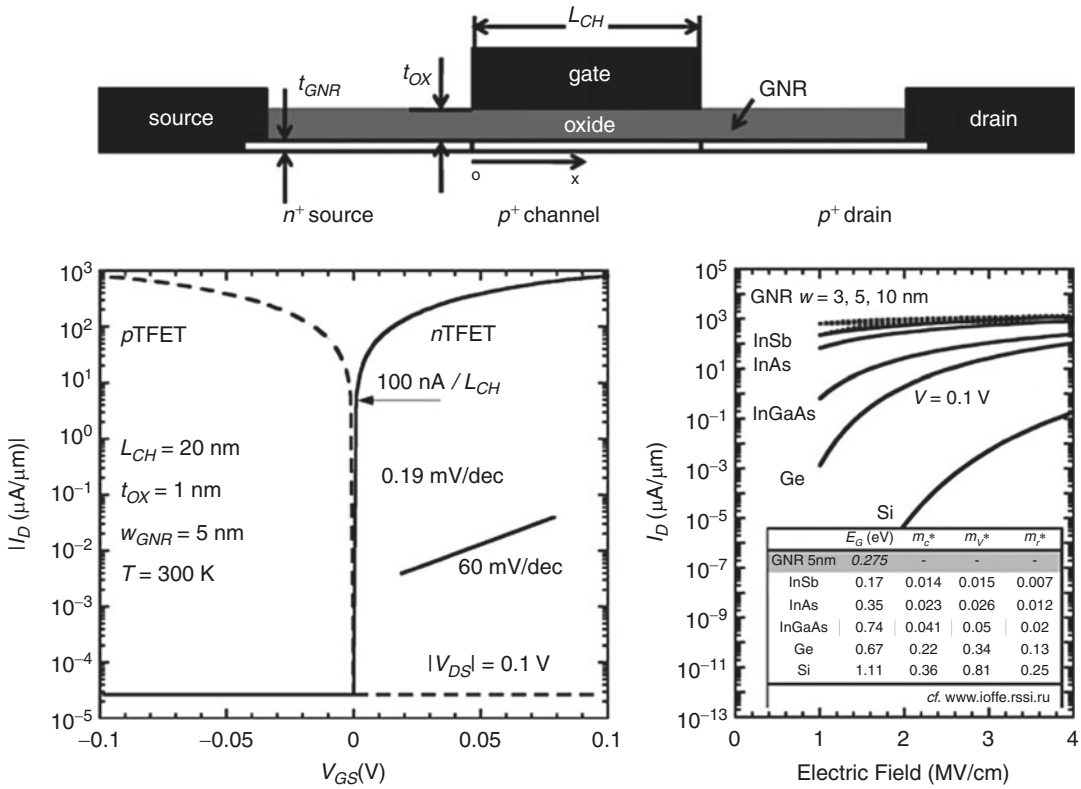
when electron waves are launched from a point in the n-region at various angles to the interface, they have to conserve energy and momentum when they enter the p-region. Since they have to tunnel from the conduction band in the n-side to the valence band in the p-side, the component of momentum parallel to the junction is flipped, resulting in the collimation of the electron waves. The tunneling process in graphene is unique owing to its Dirac dispersion, and is called Klein tunneling. This sort of electron "lensing" is a consequence of the light-like energy dispersion of graphene [5]. It requires the phase of the electron waves to be coherent throughout the transport process, and thus requires long mean free paths and low scattering. Similarly, electrons can be reflected from similar interfaces, and by combining junctions, can be "waveguided" from one region to another through all-electrical controls. The similarity of the electron energy dispersion to that of light makes such processes possible in graphene.

The quantum Hall effect in graphene offers a signature of its energy dispersion. As shown in Fig. 4, in traditional semiconductor quantum wells, 2D electron and hole gases have different effective masses, and hence different density of states. Upon the application of a high magnetic field B, the DOS collapse into uniformly spaced Landau levels, with energies peaking at $E_n = \hbar\omega c\left(n+\frac{1}{2}\right)$ for each band, where $\omega c = qB/m^*$ is the cyclotron frequency and $n = 0, 1, 2, \ldots$ is an integer. As the height of each Landau level and their separation is changed by varying the magnetic field, the Fermi level passes through peaks and minima of the Landau level, causing the longitudinal magnetoresistance to oscillate. The transverse resistance is the Hall resistance. The quantized Hall *conductance* in traditional semiconductor 2DEGs is given by $\sigma_{xy} = \frac{2q^2}{h}n$. The Landau levels of 2D graphene, on the other hand, are given by $E_n = \pm v_F\sqrt{2q\hbar B}\sqrt{n}$, bunching closer as n increases, as shown in Fig. 4. The resulting Hall conductance is given by $\sigma_{xy} = \frac{4q^2}{h}\left(n+\frac{1}{2}\right)$. For $n = 0$, there is a Landau level at the Dirac point for graphene, and the half-integer quantum Hall conductance is a signature of both the Dirac cone dispersion and the Berry phase of π for electron wavefunctions [6, 7]. The half-integer quantum Hall effect has been observed in single layer graphene grown by various methods, and the precision of the quantization is high.

Bilayer Graphene

When two layers of graphene are stacked, the mutual interaction changes the electron energy dispersion, and hence its electronic properties. Bilayer graphene should not be considered as two individual layers of graphene, but one composite electronic system. Bernal stacking is a particular type of stacking, where the A atoms in one layer (Fig. 1) are vertically above the B atoms of the other. For this form of bilayer graphene, the energy dispersion changes from the Dirac cone feature of a single layer to a parabolic bandstructure characterized by an effective mass mass $m* \approx 0.033m_0$, but still with a zero bandgap. This bandstructure is shown in Fig. 5. A remarkable phenomenon occurs upon the application of an electric field vertical to the graphene bilayer. The bandstructure deforms to that shown in Fig. 5b. An energy bandgap appears, which is tunable with the applied electric field [8]. The electric field breaks the symmetry of electron wavefunctions in the direction perpendicular to the bilayer, and this broken symmetry results in a bandgap. Such field-tunable energy bandgaps are rare in solid state systems, and can be expected to lead to novel applications. Energy bandgaps opened in this fashion up to ~0.2 eV have been experimentally measured [9].

The symmetry of the bandstructure of graphene has also led to the proposal of interlayer tunneling devices such as the BISFET [10]. This device mimics Bose-condensation of electron–hole pairs (excitons) in two graphene layers close enough to allow strong interactions, yet far enough to prevent the formation of a bilayer. It exploits collective many-body effects in an all-electronic system at room temperature. As the number of graphene layers stacked increases, the energy bandstructure evolves toward that of bulk graphite. Graphite is a



Graphene, Fig. 5 Bandstructure of bilayer graphene in the absence (**a**), and the presence (**b**) of an external field. Bilayer graphene is one of the first materials that has an electrically tunable energy bandgap

semimetal, where the conduction band minimum and the valence band maximum occur at different points in the k-space, and they overlap in energy. The semimetallic nature of graphite is responsible for its high current carrying capacity.

Graphene Nanostructures

When graphene sheets are "cut" into thin nanoscale ribbons, the size confinement results in the selection of a finite number of modes that can propagate freely along the axis of the ribbon. These structures are called graphene nanoribbons (GNRs) [11]. The edge of a GNR can be armchair or zigzag, and depending on the edge and the width, the allowed propagating modes can be metallic or semiconducting. In this aspect, GNRs are similar to carbon nanotubes (CNTs), except that the nanotube has no edges. A CNT is a rolled up GNR. Semiconducting GNRs have a bandgap $E_g \approx 1.4/W$ eV where W is the width of the GNR in nm. Since GNRs lie flat on substrates, they can dissipate heat efficiently, and are capable of high current drives. In addition, the existence of a bandgap implies they can be used for electronic switching. GNRs retain the symmetry of the bandstructure of the graphene sheet they are carved from, in the sense that the valence band of a GNR is a mirror image of the conduction band. Thus, semiconducting GNRs can be ambipolar, with a high current modulation. In the process of fabrication, if the edges of GNRs are rough, scattering from this disorder can reduce the electron mobility and carrier velocity. Nevertheless, GNRs can prove attractive for making electronic devices in the future.

If a p-n junction can be fabricated from GNRs, then the structure is very attractive for an unconventional field-effect transistor. Recently, a lot of research has focused on lowering the energy cost of digital switching by transistors. An attractive candidate for replacing conventional silicon field-effect transistor relies on the interband tunneling of electrons. The device is called a tunneling field-effect transistor or TFET; it promises digital switching of current at smaller voltages [12]. High current drives are required in transistors to maintain high performance.

Graphene, Fig. 6 Graphene nanoribbon–based tunneling field-effect transistors. Proposed device structure and predicted performance showing vast advantages over state-of-the-art silicon CMOS devices

The tunneling currents in traditional semiconductors are typically low due to the wide bandgaps. However, devices based on GNRs can deliver among the highest current drives among all homojunction TFETs [13]. Figure 6 shows the concept of the device, along with its predicted energy band diagram and switching performance. Owing to the symmetry of the bandstructure, a GNR TFET makes complementary operation feasible, a feature difficult to attain in similar devices made of traditional semiconductor heterostructures. In addition, the absence of out-of-plane bonds and the planar nature implies that GNRs and graphene are simpler to integrate with existing semiconductor technologies.

Optical Properties of Graphene

Interaction of light with graphene is understood from its energy spectrum. Single layers of graphene are found to absorb a well-defined fraction of visible light passing through them by interband excitation of electrons. This fraction is given by $\pi q^2/\hbar c = \pi \cdot \alpha \sim 2.3$ % where α is the fine structure constant [14]. The absorption coefficient is *independent* of the photon energy over a large spectral window. The photogenerated electrons and holes can lead to photocurrent, and aided by the high mobility, 2D graphene can be used for fast photodetectors that operate over a large spectral window. The ease of integration of graphene with traditional semiconductors makes it attractive for applications in optical communication devices.

Electrons in graphene can also absorb photons of very long wavelengths and small energy (in the THz spectral window). This happens by the process of free-carrier absorption, and requires momentum scattering, as in a traditional semiconductor. Since the number of photons absorbed is related to the circumference of the Fermi circle in

the k-space, by tuning the Fermi energy of graphene, the number of free carriers available for such absorption can be tuned over a large range. Thus, graphene is attractive for making THz modulators at a given frequency [15]. Further, graphene can be patterned into periodic structures similar to photonic crystals to enhance the absorption of certain modes and orientations of incident THz light. Such structures called graphene metamaterials are similar to photonic crystals made of dielectrics, and hold much promise for devices exploiting light–matter interaction.

Since graphene has zero-bandgap with a high mobility, an electromagnetic wave can create waves of electrons and holes that support its propagation. Such modes where free carriers on the surface of a conductor carry part of the electromagnetic energy of an electromagnetic wave are called surface plasmon modes. The high mobility leads to a low loss, and plasmons are thus useful for confining and controlling the flow of light in dimensions shorter than its wavelength. Such sub-wavelength waveguiding is attractive for on-chip optical communications in the future. This can enable transistors far from each other on a microprocessor chip, or between chips to exchange information by using waveguided light instead of electrons in conductors that can be lossy and have *RC* bandwidths.

Methods of Fabrication

Single-layer graphene flakes were first isolated by mechanical exfoliation from graphite. They were transferred on to substrates with ~300 nm SiO_2 on conductive silicon. The dielectric contrast of the substrate at optical wavelengths made it possible to observe the atomically thin crystal under a microscope. Since this initial breakthrough, several methods of preparing graphene have been developed [16]. Large-area single-layer graphene is formed on the surface of single crystal SiC wafers by sublimation. Under specific conditions, the few layers of Si and C on the surface dissociate, Si atoms leave the crystal, and the remaining carbon atoms rearrange to form graphene. A larger-scale method of fabricating single-layer graphene is by chemical-vapor deposition of carbon on heated copper (or other metallic) foils [17]. Owing to the low solubility of carbon in copper, it "precipitates" out, forming a single layer of graphene on the surface. The process is self-limiting, and leads to single-layer graphene of large dimensions. The graphene is subsequently transferred on to insulating substrates by removing the metallic foil. Growth and fabrication of graphene are still at their infancy. The methods used to grow graphene, and the resulting crystalline quality is expected to improve with time.

Other Applications

At present, the high conductivity of graphene and its ultrathin nature makes it attractive for transparent conductive electrodes for flexible electronics. The high in-plane thermal conductivity of graphene can be harnessed for effective heat spreading in various nanoscale structures; graphene can scale this usage of graphite down to nanoscale dimensions. The light mass of the atoms in graphene, the high bond strength, and atomically thin structure implies that microelectro-mechanical (MEMs) or nanoelectro-mechanical (NEMs) structures made from graphene can operate at very high frequencies, and extend the range of applicability of existing devices. The ease of field-effect of graphene also makes it especially conducive to the fabrication of gas and charge sensors in the field-effect geometry.

Other 2D Crystals and Future Directions

The symmetry of the bandstructure of graphene led to the proposal, and eventual discovery of a new class of materials called topological insulators [18]. These materials have a graphene-like Dirac cone energy dispersion for surface states, whereas the bulk states have energy bandgaps as in traditional semiconductors. The valley degeneracy of such materials is one, so in a sense they are "half" of graphene. Electron motion in the surface bands of topological insulators are

protected against scattering by geometric constraints, and are currently under much scrutiny.

The discovery of graphene also opened the door to the search for other 2D crystals, and a number of them have been identified. Among them, boron nitride (BN) is an excellent example. Boron and nitrogen straddle carbon in the periodic table, and is the compound semiconductor analogue of graphene. However, the broken symmetry in the crystal basis itself creates a very large bandgap, approaching ~5.4 eV. Thus, BN is an excellent insulator, and quite distinct from other insulating dielectrics since it is composed of sp^2 bonds. The absence of out-of plane or broken bonds implies that it is chemically and electronically more inert than its 3D insulating counterparts. Indeed, graphene when placed on BN in planar fashion exhibits high electron mobilities and this is attributed to the reduced electronic coupling between the two crystals. The transition-metal dichalcogenides (such as MoS_2) are an analogous family of 2D crystals that exhibit semiconducting as well as metallic properties. However, these 2D crystals are not perfectly planar, as their chemical bonds are different from sp^2; they involve d-orbitals. The presence of d-orbitals leads to a richer range of electronic phenomena, ranging from metallic, semiconducting [19], magnetic, to superconducting. Combining this rich range of electronic properties of 2D crystals in heterostructures is expected to lead to new generations of more efficient and fundamentally new devices in the future. Combining 2D crystals by stacking is expected to be simpler than 3D materials since there are no out-of-plane bonds to join, or break [20].

Graphene Nanostructures for Memristive Devices

Samuele Porro
Applied Science and Technology Department, Politecnico di Torino, Torino, Italy

Synonyms

MEM devices; Memory resistors; Memristors; Resistive switching

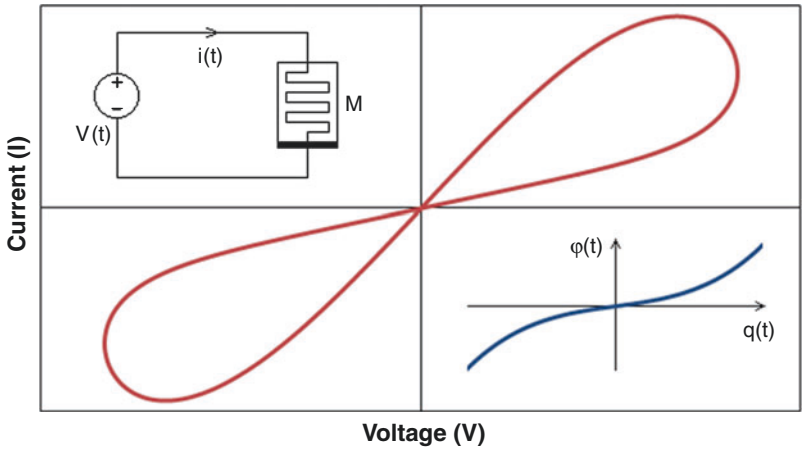
Definition

Memristive nanoscale devices can generate intense fields by the application of relatively low voltages. This peculiar property allows fast, nonvolatile, and low-energy electrical switching as well as the possibility of retaining the internal resistance state according to the history of applied voltage and current. Memristors are predicted to revolutionize the current approaches in computer electronic architecture with their application, for instance, as resistive random access memory and for neuromorphic artificial intelligence. The use of graphene nanostructures for memristive switching systems offers an exciting alternative to other classes of materials, such as transition metal oxide and organic thin films.

Overview

The development of nanoscale structures that find applications in the fabrication of devices for computer science is going to revolutionize the semiconductor industry and in general the way in which computing systems are built. A continual improvement of device performances can be obtained by their miniaturization, and the development of nanometer-sized devices allows pushing the Moore's law beyond the actual physical limits, enabling a new era for computing. Due to their high scalability down to the nanometer scale and the possibility of application in nonvolatile memory and low-power resistive switching devices, memristors perfectly fit in this scenario. Although predicting and controlling the stochastic chemical/physical mechanisms that lie behind the memristive phenomena is currently a research challenge [1], many different working devices were already reported in the recent literature. Besides the various perovskite oxide materials, binary transition metal oxides (like TiO_2, Ta_2O_5, NiO), chalcogenides, and organic materials [2, 3], in the latest years, a growing attention was directed to carbon-based devices, in particular to those based on graphene and graphene oxide [4], due to the unique properties of this class of inherently nanoscale materials.

Classification of Graphene and Graphene Oxide



After the discovery of graphene, strikingly unconventional phenomena originated by the behavior of electrons as massless relativistic particles were predicted and measured [5]. These include interdisciplinary properties, such as excellent electron mobility at room temperature, high thermal conductivity, and superior mechanical properties [6], which make these materials particularly appealing for many applications, e.g., as active material in electronic devices such as sensors, batteries, supercapacitors, and energy devices [7, 8] or as a filler in the fabrication of multifunctional nanocomposite materials, in both polymeric or inorganic matrices [9–11].

Many approaches for the synthesis of graphene and graphene-based systems have been reported up to now. The most developed include chemical vapor deposition [12], epitaxial growth via thermal decomposition of silicon carbide [13], and mechanical or liquid phase [14] exfoliation of graphite. In addition, several methods for cost-effective and large-scale production of graphene were implemented following "chemical" processing routes, which involve the exfoliation of previously oxidized bulk graphite (the Hummer's method and many variation of the same) to obtain single or few layers of graphene oxide (GO) [15]. These routes allow low-cost and high-yield production of GO, which is highly hydrophilic and thus easily dispersible in organic solvents and even in simple water (unlike graphene). Many approaches for the reduction of GO to graphene-like sheets (reduced graphene oxide, RGO) were reported, including chemical and electrochemical processes, thermal annealing, and other unconventional methods such as microwave or photo-irradiation treatments [16–18]. These methods exploit the richness of reactive oxygen functional groups on graphene oxide surfaces, by removing the oxygen-containing groups with the recovery of a conjugated structure.

The intrinsic characteristics of GO make it a suitable candidate for the fabrication of memristive devices in substitution of other thin-layered oxide structures. For example, GO sheets are heavily oxygenated presenting functional groups on their basal planes (mainly hydroxyl and epoxide) and at the sheet edges (carbonyl and carboxyl) [19]. All those oxygen functionalities randomly placed over GO sheets are responsible for GO electrically insulating behavior, with characteristics comparable to other thin-layered oxide materials, with the advantage of being atomically thin. Moreover, the two dimensionality of GO permits scaling beyond the current limits of semiconductor technology, which is a key aspect for high-density fabrication of memristive devices. In fact, being GO truly atomically thin, the scalability of GO-based devices is better than that of organic and inorganic thin-film memristors. GO sheets can readily swell and disperse in water because the surface functional groups make it strongly hydrophilic. Exploiting this property, it is possible to synthesize GO- and RGO-based printable inks [20] which can be used for the direct 2D fabrication of memristors, for example, using inkjet printing technology which is greatly advantageous compared to other techniques, as already demonstrated by several works on polymer composites [21, 22].

Background of Memristors

The memristor can be defined as the fourth two-terminal circuit fundamental passive component, as postulated by Leon O. Chua already in 1971 [23] on the basis of a simple logic deduction. Prof. Chua noticed that the four fundamental circuit variables (current I, voltage V, magnetic flux φ, and charge q) should be invariably coupled by six different mathematical relations, while at the time only five were known. The first two were given by integrating over time voltage and current, obtaining, respectively, magnetic flux and charge. Other three relations were determined by the three classical circuit elements known at the moment: the resistor, connecting I and V; the capacitor, connecting q and V; and the inductor, connecting I and φ. A sixth missing relation connecting q and φ was postulated by Chua introducing the concept of memristor, indicating a resistor with memory, through the following equations:

Graphene Nanostructures for Memristive Devices, Fig. 1 The characteristic I-V curve for the ideal memristor, representing a hysteretic loop pinched in the origin. The circuital symbol for memristor is reported in the *top left inset*. The nonlinear relationship between q and φ characteristic of memristive devices is reported in the *bottom right inset* (Reprinted with permission from Ref. [26]; copyright © 2015 Elsevier)

$$V(t) = M(q(t))I(t)$$

with

$$M(q(t)) = \frac{d\varphi(q)}{dq}$$

where the memristance M is defined in units of Ohms. Even though at an instant time t_0 the memristor acts like a normal resistor, the memristance value depends on the time integral of its current from ∞ to t_0 and, therefore, on the past history of the system, explaining the concept of "resistor with memory" which characterize the memristor. In addition, the relation between the magnetic flux and the charge must not be linear; otherwise, the memristance would become a normal resistance, losing its peculiarity.

After several conceptual works from the same author [24], the concept of memristor remained undemonstrated, and a real working device was fabricated only recently in 2008 by HP Labs, with a work that related the theoretical idea of Prof. Chua with a physically working device made of titanium dioxide [25]. Following this milestone experimental work, many other memristive materials and device architectures were developed in the latest years. The number of materials showing this technologically interesting behavior is enormous and still growing, including binary transition metal oxides, e.g., TiO_2, Cr_2O_3, FeO_x, and NiO; perovskite-type complex transition metal oxides that are variously functional, paraelectric, ferroelectric, multiferroic, and magnetic, e.g., $(Ba,Sr)TiO_3$, $Pb(Zr_xTi_{1-x})O_3$, $BiFeO_3$, and $Pr_xCa_{1-x}MnO_3$; large band gap high-k dielectrics, e.g., Al_2O_3 and Gd_2O_3; non-oxide thin-layered materials, such as higher chalcogenides (e.g., In_2Se_3 and In_2Te_3); organic materials such as intrinsically conducting polymers, e.g., polyaniline; and, finally, also graphene oxide and graphene-based materials.

Following the fact that memristors are nanoscale devices, the application of relatively low voltages can generate very intense fields, which induce a nonlinear behavior and reversible ionic transport. The evidence of this effect is increasing by reducing the thickness of memristive materials.

Among the peculiar features of memristors, one of the most relevant is that if $M(q(t)) \geq 0$ the electronic component is passive, like the resistor, which implies low power consumption in a real device application. The characteristic I-V curve of memristors is a typical frequency-dependent Lissajous figure represented by a hysteretic loop pinched in the origin (Fig. 1).

From this characteristic it is evident that the memristor can be used as a nonvolatile memory, since for $V = 0$, and also $I = 0$, that is to say that

once a particular internal state is settled, it can be conserved indefinitely if no other input signals are provided. These proprieties make the memristor an extremely powerful element which is not reproducible with a combination of the other passive components. Memristors can find applications in many fields like resistive random access memories (RRAM) [27], programmable logic [28], neural networks, and neuromorphic systems [29]. In particular, memristors are predicted to revolutionize in the near future the current approaches in computer electronics architecture, and they are indicated as the first brick to create neuromorphic devices and artificial intelligence.

The memristor exhibits two different stable resistance states, referred to as "high-resistance state" (HRS) in which the device shows low electrical conductance and "low-resistance state" (LRS) in which the device shows high conductance. The system can make a transition from HRS to LRS (or vice versa) by applying a SET (or RESET) voltage V_{SET} (or V_{RESET}). Two types of switching can be defined: the bipolar switching, where SET and RESET processes depend on the polarity of the applied voltage, and the unipolar switching, where they depend on the amplitude of the applied voltage rather than on its polarity. Finally, the performance of a memristor can be expressed in terms of retention and endurance [30]. The retention indicates how long the internal state of a device can be held when it is not powered, with typical required values for nonvolatile memory applications exceeding 10 years. The endurance indicates how many cycles can be supported by the device before reaching breakdown, with typical values between 10^3 and 10^7 cycles depending on the application.

Memristive Devices Based on Graphene Nanostructures

Memristors can be fabricated using several device structure, among which the most common is the metal/insulator/metal (MIM) structure, which applies to an extremely wide range of insulating active layers sandwiched between two metal electrodes. As previously stated, graphene oxide can be easily dispersed in common polar solvents including simple water. The stable GO solutions can be easily deposited on bottom electrode materials using many techniques with a precise control of GO layer thickness (tens of nanometers), like spin coating, drop casting, vacuum filtration, inkjet printing, or Langmuir-Blodgett deposition, usually followed by thermal annealing to improve crystallinity and uniformity, at temperatures lower than 200 °C in inert environment to avoid GO reduction. The metallic top electrode is usually deposited by thermal evaporation or sputtering through a shadow mask.

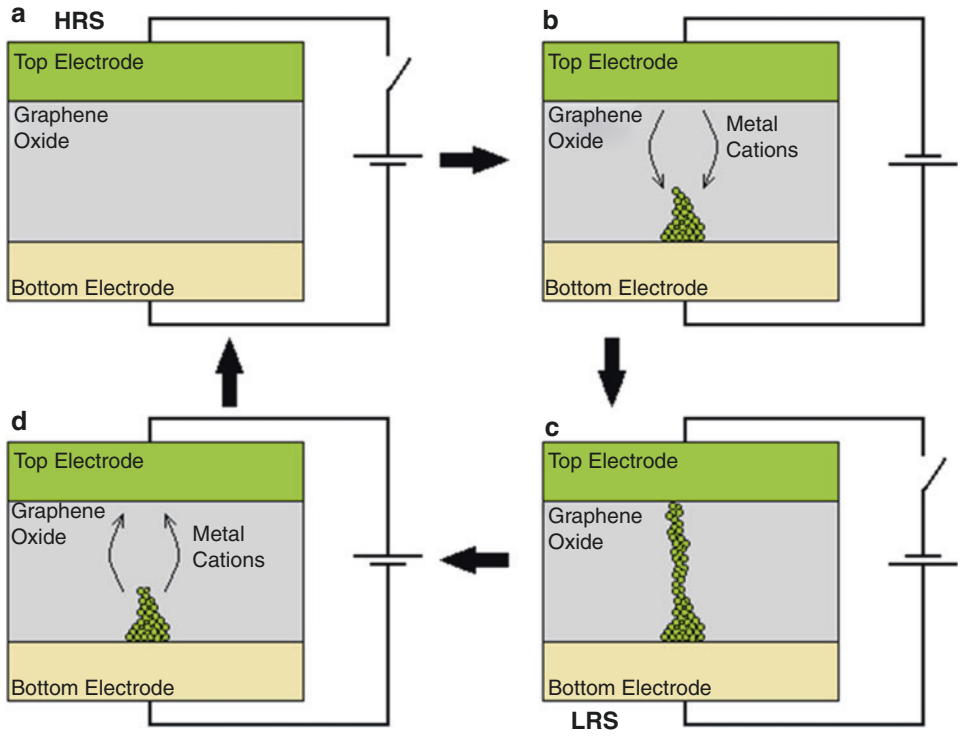
The electrical behavior of the so-fabricated graphene-based memristors can be explained following two different mechanisms [31]. The first is related to an oxygen ion diffusion driven by the electrical field and Joule heating; the second is associated to the formation of a metallike filament due to the diffusion of species from the top electrode under a bias voltage.

Switching Mechanisms

The oxygen ion diffusion is considered as the main cause of the resistance switching, therefore of the memristive behavior, in devices based on graphene oxide. However, different interpretations of the physical phenomena can be given. In fact, the memristive behavior can be related to a bulk effect, meaning a structural modification of the entire GO layer. On the other hand, the phenomenon can be localized and associated to a modification of the contact resistance with the top electrode. In the switching mechanism based on the oxygen ions drift, the contact resistance between GO and the top electrode is of fundamental importance. The device is, as fabricated, in HRS due to the presence of a thick insulating metal oxide layer. The application of a negative bias induces a migration of oxygen ions from the oxide interface layer to the GO layer. The thickness reduction causes the device to switch to LRS.

Generally, fabrication parameters, such as the choice of deposition technique for GO and top electrode, choice of electrode materials, etc., influence the hybridization state of GO, contributing to determine differences in the behavior of

devices and influencing the choice of switching mechanism.



When GO is sandwiched between two metal electrodes (e.g., aluminum) [32], it can happen that the GO layer does not participate directly in the switching phenomena, which depend on the presence of a metal oxide-insulating film at the interface with the top electrode (which creates a contact resistance). In this case GO is relegated to the role of oxygen ions reservoir. The physical adsorption of oxygen in the GO structure can explain the switching events caused by the redox reaction between GO and metal oxide layer and also the migration of oxygen ions from and to the GO layer. The memristance switching can be explained as follows. The as-fabricated device shows a thick metal oxide interface layer (HRS). After the application of a negative voltage to the top electrode, the device switches to the LRS because of the formation of metallike conductive path in the metal oxide-insulating layer, originated from the oxygen ions diffusion into the GO film. By applying a positive voltage, the back diffusion of the ions from GO restores the original resistance state. The resistive switching can also be associated to a local reversible rearrangement of a highly resistive thin region of the GO film near the interface with the metallic top electrode, rather than to the presence of a metal oxide film. This area is mainly composed of a continuous heavily sp^3 hybridized GO layer, causing the as-fabricated device to be in HRS. In the second step, the application of an external voltage causes the migration of oxygen ions, providing the formation of a sp^2 hybridized cluster filament inside the highly resistive thin region, which allows switching to LRS. On the other hand, the resistive switching can be associated with the modification of the hybridization (oxidation) state of the entire GO layer, rather than to the interface between GO and top electrode. This happens when there exists a conducting path in the GO layer due to the presence of oxygen vacancies and electron traps. In this case, the memristor in its pristine form is in LRS. Through the application of an external bias, this initial state can be altered. Applying a positive voltage, the recombination between oxygen ions and vacancies induces further oxidation of the graphene layer thus the switching from LRS to HRS. By reversing the bias polarity, back diffusion of the oxygen ions is obtained, restoring the initial high conductive state.

The oxygen ion drift model could also explain the different speed of SET and RESET operations that are often measured in these type of devices, being SET speed (typical value of 100 μs) significantly slower than the RESET speed (typical value of 100 ns) [33]. The oxygen diffusivity is strictly related to the hopping energy barrier, which depends on the injection and extraction of electrons from the GO layer, which in turns is strictly related to the electron density in the insulating layer. In particular, when a negative bias is applied to the top electrode (RESET), electrons are injected into the GO, increasing the energy barrier, thus reducing the oxygen diffusivity and speed. In the same way, when the bias voltage is reversed (SET), the electrons are extracted from the GO, reducing the energy barrier, thus increasing the ions' movement speed.

In addition to the oxygen ion drift mechanism, the memristive behavior of GO-based devices can be explained by the formation of a metal filament within the insulating layer (Fig. 2) [34]. Following this mechanism, HRS and LRS states, respectively, show nonlinear and linear resistance variations respect to temperature. During the SET process, a positive bias voltage applied to the top electrode induces a high electric field inside the device, which causes the migration of the metal ions originating from the oxidation of the top electrode to the bottom electrode through the GO film. Once metal ions arrive to the bottom electrode, they amass inducing a reduction process through the insulating layer producing the growth of a metal filament. When the grown filament reach the top electrode, the resistance state of the device switches abruptly from the HRS to the LRS. An inversion of bias voltage causes the rupture of the filament with the back diffusion of the metal ions, restoring the HRS.

Characteristics of Devices

One of the most crucial aspects in the fabrication of MIM structures is the choice of materials for both top and bottom electrodes. Many different

Graphene Nanostructures for Memristive Devices, Fig. 2 (**a**) Scheme of the switching mechanism based on metal filaments formation, with device in its pristine state. (**b**) The application of a positive bias induces the oxidation of the *top* electrode metal, originating cations that migrate toward the *bottom* electrode, where after the reduction the formation of metal filaments is promoted. (**c**) When the grown filaments reach the top electrode, a short circuit is generated and the device switches from HRS to LRS. (**d**) Inverting the external bias, the opposite process is achieved (Reprinted with permission from Ref. [26]; copyright © 2015 Elsevier)

combinations of electrode materials can be used, without absolute certainty of measuring memristive properties [35]. Usually, the memristive behavior arises from an asymmetry of the electrode's working function, being one (active electrode) lower than the other (inert electrode). However, it is worth noticing that in some cases of material choice for the electrodes, local oxidation of the electrode at the interface might play a decisive role. The formation of an oxide layer under one of the electrode could also determine an asymmetry in structure. Another parameter that may influence the memristive characteristics is the surface roughness of GO layers after the deposition. Typically, a low surface roughness of GO is obtained after deposition on smooth bottom electrodes, like indium-tin oxide (ITO) and Pt. On the other hand, materials like Au and TaN exhibit higher roughness and surface cracks, which are quite detrimental to the device characteristics. In fact, the presence of cracks at GO surface can facilitate the penetration of the bottom electrode's atoms into the active layer and hinder the switching performance. This further underlines that the contact resistance can have a great importance in determining the switching proprieties of devices.

Bottom electrodes can be fabricated also using a semiconducting material like p-doped silicon in place of metal, thus realizing a MIS (metal-insulator-semiconductor) device. Semiconductors are intrinsically rectifying, having the advantage of suppressing cross talk between adjacent memory cells, without the need of introducing any additional rectifying element (e.g., diodes) like in many MIM devices.

Most devices show a bipolar switching behavior with voltages in the order of few volts, which is

desirable for low power applications, also displaying a great retention (higher than 10^4 s) and good endurance.

Although not all devices are activated through a forming process, the initial state of GO is not fixed on a specific state, and the forming process is often required to stabilize the switching operation and to determine the consequent electrical behavior (unipolar or bipolar) [36].

The memristive properties can be maintained on flexible substrate, e.g., on polyethersulfone, and can be used for electronic flexible application, without displaying any appreciable degradation of their behavior [37].

Graphene Oxide Composite Devices

Despite the good results that can be obtained with GO-based MIM structures, the device characteristics can be further improved by the development of innovative composite materials based on polymeric matrices filled with graphene or graphene oxide, which may improve not only the electrical but also the structural characteristics of future flexible devices. In this class of materials, the formation of a covalent bonding with the polymer is achieved exploiting the oxygen functional groups normally present on surfaces [38]. The composite materials are normally used as active layer sandwiched between conductive electrodes, exhibiting the classical bistable resistive switching. The memristive property of these materials is associated to an electron transfer between graphene (graphene oxide) and the polymer molecules [39]. In particular, as-fabricated devices are generally in the HRS, since the presence of functional groups (epoxide and carbonyl) produces a reduction of the electrical conductivity due to scattering events. By applying an external voltage with adequate amplitude, the transport of electrons from the polymeric molecules (highest occupied molecular orbital, HOMO) to GO (lowest unoccupied molecular orbital, LUMO) occurs by intramolecular charge transfer. This transfer results in delocalization of electrons in the π-conjugated system, reducing the initial GO to graphene (reduced graphene oxide, RGO) and increasing the device conductivity (LRS). By reversing the voltage, the electrons are extracted from the RGO layer and returned to the polymer, restoring the initial HRS. Both states are highly stable even if the external voltage is removed or a V_{read} is applied, and high retention time values can be normally obtained ($>10^4$ s). An alternative switching mechanism for this class of materials relies on charge-trapping events [40]. When carriers coming from the metallic top electrode are injected into the composite layer and localized by an energy well, they cause the formation of space charges. The generated internal electric field interferes with the external applied field, inhibiting further charge injection and leading to the HRS. When the external field is reversed, the charges are freed and the internal field disappears, and the state of the device returns to LRS. Finally, memristive properties can be measured also on functionalized GO sheets, sandwiched between two conductive layers as in the previously described examples [41]. In this case, the switching property is attributed to the movement of the counterions of functionalized groups when immersed in an electric field, while functionalized groups remain bounded to the GO framework. During LRS, those counterions are distributed along the insulating layer inducing a high conductivity. When the voltage is reversed, the resistance of the device is increased.

Similar to previously described GO-based devices, also devices based on GO/polymer composites show bipolar switching behavior. Generally, the resistance ratio values measured on GO/polymer composite devices are higher than in other types of GO-based devices, with typical values in the order of 10^5, while other characteristics do not show relevant differences. Their good retention values indicate them for employment as memristive devices in RRAM applications.

Other Graphene-Based Structures

In addition to the various structures so far presented, a great number of other memristive systems based on graphene or other carbon-based structures such as carbon nanotubes or amorphous carbon can be implemented [42].

For example, a few layered graphene deposited on a heavily doped silicon substrate can be used. After an initial forming process, which induces a soft breakdown in the structure, a physical

nano-gap within the graphene film can be obtained, setting the device in HRS. The unipolar resistance switching can be associated to the formation/rupture of a monoatomic carbon chain connecting the two edges of graphene separated by the nano-gap [43]. A different interpretation can also be given for this behavior. The applied voltage not only induces the rupture of the graphene film but also causes a morphological alteration of the underlying SiO_2 layer, with the formation of Si nanocrystals inside the underlying insulating layer. Therefore, the switching behavior can be also associated to the reversible thermal-assisted reduction/oxidation process at the breakdown region of the SiO_2 substrate, rather than to the formation of a carbon chain in the nano-gap. The presence of the Si nanocrystals brings the device to the LRS, while its absence in the SiO_x matrix entails the HRS.

Finally, GO can be also combined with other mixed oxide materials as active layers, to create multilayer structures. This combination ensured a bipolar switching behavior even using symmetric electrodes, for instance, in a metal/GO/mixed oxide/metal configuration. The insertion of mixed oxide layers also allows obtaining stable retention at relatively high temperatures (up to 85 °C) without degradation of materials. The exchange of oxygen ions between GO and the other insulating layer is considered to be the main cause for memristive switching.

Concluding Remarks

The purpose of this entry is to give an overview of the basic principles of memristor devices and the use of graphene-based systems for their implementation. The development of reliable memristive systems is a fundamental technological innovation that will find application in artificial intelligence as resistive random access memory and neuromorphic computing. Several examples of working memristive device based on graphene systems can be fabricated, exhibiting good switching proprieties (high switching ratio and low SET and RESET voltage) as well as good retention and endurance times.

Definition

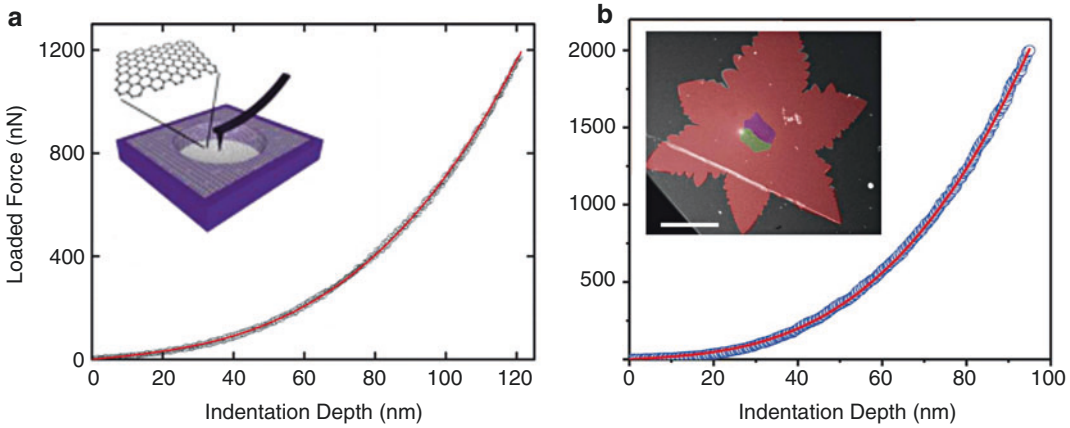
Graphene nanoelectromechanical systems (NEMS) are devices that consist of single or multilayer graphene which is free to move along the out-of-plane direction and utilize the electrical and mechanical properties of graphene for various applications, such as mass or force sensing.

Overview

Graphene, as the first two-dimensional (2D) materials that can be explicitly prepared, offers both excellent electrical and superior mechanical attributes, both of which are desired for NEMS. Shortly after the first isolation of single-layer graphene in 2004, the field of graphene NEMS was spearheaded by researchers from Cornell University in 2007: they successfully actuated and detected the motion of doubly clamped graphene mechanical resonators. In the following years, advancements in fabrication, signal transduction, and modeling have been expanding the area of graphene NEMS. Applications of graphene NEMS include self-sustained mechanical oscillators, pressure sensors, and electromechanical switches.

A graphene NEMS device is usually composed of two components: a suspended piece of graphene sheet and electrical contacts to the graphene. The electrical connections are often used to tune the electrical or mechanical properties of graphene, as well as for signal transduction. When external stimulus is applied, such as pressure or electrostatic forces, graphene will deflect statically or vibrate resonantly. Different readout schemes are developed to track the response of graphene NEMS, including optical interferometry and electrical transduction.

Graphene obtained from conventional methods, such as mechanical exfoliation, chemical vapor deposition (CVD), and epitaxial growth, can all be used to construct graphene NEMS. There is no qualitative difference in NEMS properties among those devices.



Unlike bulk materials, the thickness of the single-layer graphene cannot be measured by the distance between top and bottom surface, for which such surfaces are not well defined. However, in practice, researchers often use the interplane spacing of graphite, 0.34 nm, as the thickness of single-layer graphene. The lateral dimension of the suspended graphene, to this day, is usually from 1 to 10 μm. The separation between graphene and substrate ranges from tens of nanometers to few microns.

Various schemes can be applied to stimulate and detect the motion of graphene NEMS. Compared with other NEMS, for example, carbon nanotube (CNT)-based systems, graphene possesses the unique electrical and geometric advantages that allow simpler signal transduction. Some commonly used techniques such as capacitive transduction for MEMS resonators are demonstrated in graphene NEMS as well.

Graphene Mechanics

Since the thickness of graphene is at the atomic limit, both molecular level and continuum mechanics can be applied to model its mechanical properties. However, due to the computational expense of molecular simulations, the lateral dimension of the system is limited to tens of nanometers (few thousand carbon atoms), which is much smaller than any practical samples. Therefore, continuum mechanics with nonlinear considerations is more convenient to interpret experimental results and predict behaviors of graphene NEMS.

The most basic property of continuum mechanics is the relation between force and

Graphene NEMS, Fig. 1 Force vs displacement for circular-clamped graphene. (**a**). Experimental result of pristine graphene [1]. *Inset*: schematic of indentation setup. (**b**). Experimental result of CVD graphene [2]. *Inset*: false color dark field transmission electron microscopy (DF-TEM) images of CVD graphene; scale bar: 20 μm

displacement, commonly known as Hooke's law for bulk materials:

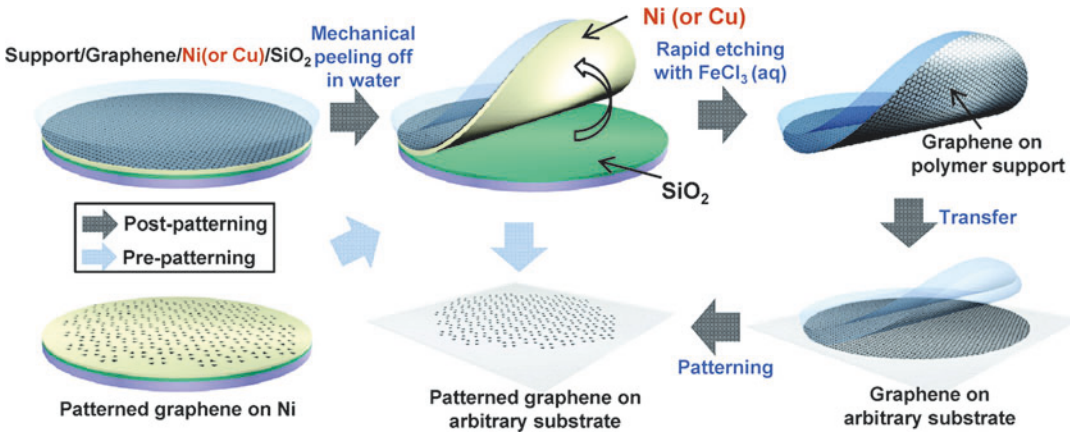
$$F = kx, \tag{1}$$

where F is the force exerted on the understudied subject, x is the corresponding deformation, and k is the spring constant. However, for graphene, profound nonlinearity emerges as the thickness approaches atomic limit; therefore, the relation between F and x takes the general nonlinear form of

$$F = Ax + Bx^3, \tag{2}$$

where A and B are linear and nonlinear coefficients, whose exact forms and values depend on the geometry and boundary conditions. For example, in the cases of doubly clamped strips and circular drums, Eq. 2 will take the form of

$$F = \left(30.78\frac{wt^2}{L^3}E^{2D} + 12.32\frac{t}{L}\sigma_0^{2D}\right)x + 2.67\frac{w}{L^3}E^{2D}x^3, \tag{3}$$



$$F = \left(1.37\frac{\pi t^2}{R^2}E^{2D} + \pi\sigma_0^{2D}\right)x + 1.06\frac{1}{R^2}E^{2D}x^3, \tag{4}$$

where w, t, and L are the width, thickness, and length of the strips, R is the radius of the drum, E^{2D} is the 2D Young's modulus, and σ_0^{2D} is the 2D pretension, both with the unit of force/length. Here, Poisson's ratio is taken as 0.165.

For exfoliated single-layer graphene, E^{2D} is experimentally determined [1] to be of 340 N/m (or equivalent 3D Young's modulus of 1 TPa), while the pretension is in the range of *O(1)* N/m. Polycrystalline graphene derived from chemical methods shows weaker mechanical strength, but if care is taken during the synthesis process, they can be as strong as pristine ones [2], as shown in Fig. 1.

From the above force versus displacement equations, it is clear that for samples with μm-size lateral dimensions, the bending rigidity (first terms with E^{2D} in the parentheses) is negligible compared to the pretension; therefore, they can be ignored. In doing so, the graphene can be modeled as membrane, whose mechanical properties such as resonant frequency are largely determined by tension/strain.

The truly unique mechanical property of graphene is its large breaking strength, i.e., the maximum strain it can sustain before breaks. In most materials, defects and flaws are abundant, and the cracks can grow and propagate from the

Graphene NEMS, Fig. 2 Schematic of transfer process of CVD graphene [6]

sites of defects easily; therefore, such imperfections dictate the maximum strength. A good example is the (intentionally introduced) notch on the plastic packages to facilitate tear opening. The inevitable existence of the defects in bulk materials weakens their breaking strength from intrinsic values of $E/9$, which is the strength of the atomic bonds [3]. Being atomically flat, graphene provides a platform of defect-free material at microscopic level. Indentation measurements, of both pristine and CVD graphene, have confirmed the breaking strength of graphene is indeed close to its intrinsic value. The breaking strength of graphene is 42 N/m, corresponding to a bulk value of 130 GPa. The measurements also reveal that the failure of graphene occurs deep into the nonlinear elastic regime, with a breaking strain of 25 %.

The large elastic modulus of graphene directly leads high resonant frequency of graphene NEMS (>10 MHz), but the atomic thinness (hence negligible bending rigidity) still allows facile frequency tuning through tension, and the large breaking strength ensures wide tuning range. Furthermore, the small mass of graphene also results in small spring constant (on the order of 1 N/m) while still maintaining high resonant frequency (high bandwidth). Such compliant system is desired for ultrasensitive applications, such as force and charge sensing.

Fabrication of Graphene NEMS

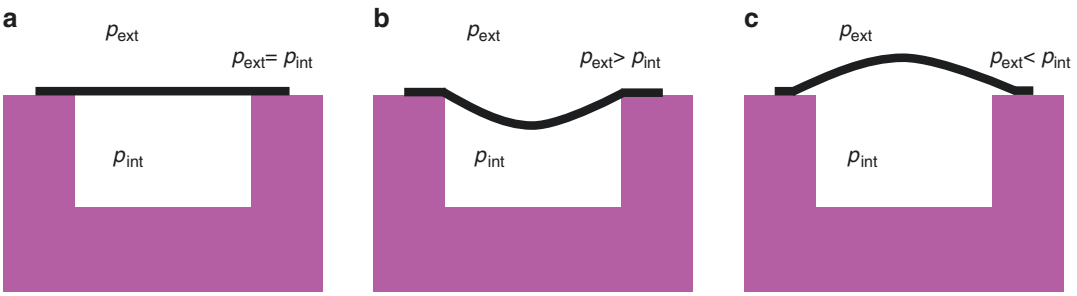
There are two major steps in graphene NEMS fabrication: graphene synthesis and release of the suspended structure. Historically, graphene can only be obtained through mechanical exfoliation from bulk graphite ("Scotch tape method"). After patterning electrodes by electron beam lithography, the silicon oxide layer below graphene is etched away by hydrofluoric (HF) acid, while the electrodes also serve as anchoring purpose. HF acid travels much faster along the interface between graphene and silicon oxide than the direction perpendicular to the interface; therefore, it is possible to release micron-size graphene structure with only tens of nanometers of graphene–substrate separation.

In 2009, few research groups developed graphene synthesis methods through CVD, using either nickel (Ni) [4] or copper (Cu) [5] as precursors, therefore enabling wafer-scale production. Cu-based CVD become more popular due to high yield and high quality. After growth, an intermediate support such as polymethyl methacrylate (PMMA) or polydimethylsiloxane (PDMS) is applied on top of the as-growth graphene/Cu foil, before the whole support/graphene/Cu foil combo is immersed into copper etchant to release the support/graphene stack. Finally, the support/graphene stack is stamped against target substrate,

followed by removal of support medium. Figure 2 shows the generic process flow of the transfer procedures. The steps to pattern and suspend CVD graphene are similar to previous described in the case of pristine graphene.

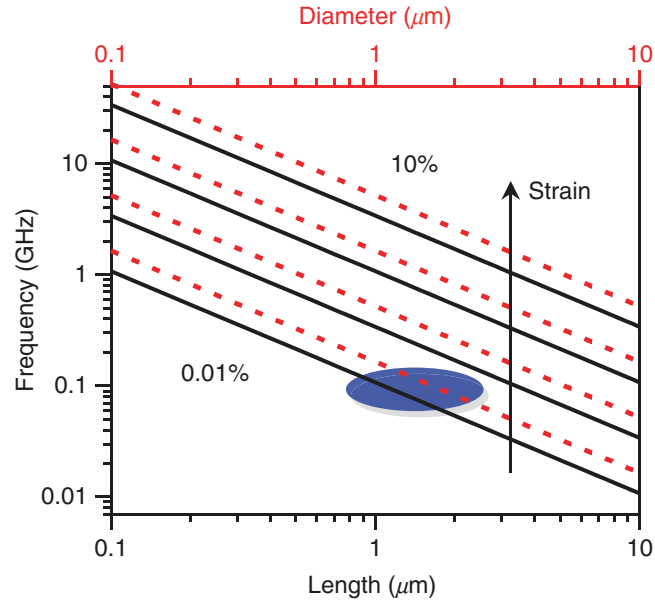
Compared to the aforementioned top-down methods, there are also bottom-up methods to prepare suspended graphene structure. In such cases, target substrates with pre-patterned trenches or holes are prepared in advance. The graphene is then placed onto the intended location with procedures similar to the CVD graphene transfer. The advantage of these top-down approaches is that the target substrates can be made through conventional photolithography process, therefore improving the device throughput. However, it is difficult to include additional wet process after the transfer without collapsing the graphene; therefore, the shapes of graphene need to be patterned beforehand.

There are hybrid techniques between the top-down and bottom-up approaches: the target substrate is pre-patterned with designed structures, but without etched trenches of holes. Only after graphene transfer and additional lithographic patterning, the graphene is finally released [7]. Such hybrid scheme combines the advantages of both top-down and bottom-up methods, but the fabrication is more laborious.



Static Graphene NEMS

Static graphene NEMS devices track the steady-state response of graphene after static deformation, where the deformation is introduced by external perturbations, such as force or pressure. These experiments are usually carried out in order to study fundamental properties of graphene; examples include indentation tests for the measurements of mechanical modulus [1, 2, 8] and "balloon/blister" tests to determine the adhesion between graphene and underlying substrate [9].



In the "balloon/blister" tests, as shown in Fig. 3, graphene and the underlying substrates form a microcavity, with gas molecules trapped inside. Since graphene is impermeable to all standard gases [10], gas can only escape the cavity through substrate, which is a slow process. Depending on the difference between the external and internal pressure of the cavity, the suspended graphene can bend either inward or outward. If the graphene is buckling outward, part of it will be peeling off away from the edge of the substrate. The peeling rate reveals that adhesion between graphene and the substrate is ultra strong, acting like liquid–solid-like interaction [9].

Applications of static graphene NEMS exploits the impermeability of graphene and the piezoresistive effect. Smith et al. demonstrated pressure sensors built from single-layer graphene [11], with gauge factor of 2.92. The device structure is very similar to the graphene balloon described above, with the cavity dimension of 64 (width) × 6 (length) × 0.64 (depth) μm, and the active area (graphene) is 64 × 6 μm.

There are preliminary studies on graphene switches [12, 13], showing switching voltage

Graphene NEMS, Fig. 3 Graphene balloon/blister, (**a**). External pressure p_{ext} equals internal pressure p_{int}, (**b**). $p_{ext} > p_{int}$, where graphene is bent inward, (**c**). $p_{ext} < p_{int}$, where graphene is buckled outward. Note that graphene is peeled from the edge of the substrate

Graphene NEMS, Fig. 4 Resonant frequencies for doubly clamped (*black solid line*) and circular dram (*red dashed line*) graphene resonators as a function of size, for strains of 0.01 %, 0.1 %, 1 %, and 10 %. The *blue* regime shows areas with experimental demonstrations [14]

smaller than 5 V. However, the reliability of such devices is not satisfying, with life cycle less than 30.

Dynamic Graphene NEMS

Given the high Young's modulus, small size, and mass, graphene is the excellent candidate for resonant NEMS. The resonant frequency of graphene resonator f_0 is given as [14]

$$f_0 \propto \frac{1}{\ell}\sqrt{\frac{E^{2D}}{\rho^{2D}}\varepsilon}, \tag{5}$$

where ℓ is the characteristic length, E^{2D} is the 2D Young's modulus, $\rho^{2D} = 7.9 \times 10^{-19}$ kg/μm^2 is the 2D mass density of single-layer graphene, and ε is the strain across the graphene sheet.

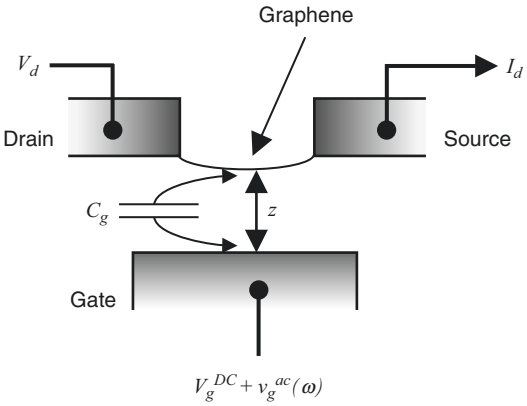
Figure 4 shows the calculated resonant frequency for doubly clamped and circular drum graphene resonators, for different sizes with various strains. For micron-size devices, it is possible to reach resonant frequency higher than 1 GHz with strain about 1 %, which is still far below the intrinsic breaking point. However, there is no deterministic method to manipulate the strain in graphene resonators yet, and the strain is largely determined from fabrication process. The blue shadow in Fig. 4 indicates the range of existing experimental achievements.

Signal transduction. The most challenging task of dynamic graphene NEMS lies in signal transduction, namely, (1) how to excite the resonant motion and (2) how to convey the mechanical vibration to easily measurable quantities (such as voltage or current) with sufficient signal-to-noise ratio (SNR).

Among these two, the actuation is relatively straightforward: graphene is being suspended over the substrate (usually conductive); therefore, they form the structure similar to parallel-plate capacitors, with geometric capacitance C_g. When both DC voltage V_g^{DC} and AC voltage $v_g^{ac}(\omega)$ at frequency ω are applied across the capacitor, the electrostatic interaction results in force exerted on graphene of

$$F \propto C_g' v_g^{ac}(\omega) V_g^{DC}, \tag{6}$$

where C_g' is the spatial derivative of the capacitance. Such capacitive drive scheme is commonly used in other MEMS and NEMS devices and works very well for graphene NEMS too. In the case when electrostatic actuation is not applicable, photothermal effect and piezo shaker (of the



whole sample) can also be used to induce mechanical vibration.

Contrary to the simplicity of actuation, the detection of resonant graphene NEMS is more difficult. Both optical and electrical techniques are employed, with details discussed below.

The optical implementation of graphene NEMS detection exploits the Fabry–Pérot cavity formed between the suspended graphene and the underlying substrate. A laser beam is directed perpendicular to the graphene membrane, part of which is reflected by graphene, with the rest being passed through and being reflected again by the substrate. The interference pattern of these two reflected signals, recorded by a fast photodiode, is sensitive to the cavity length, hence the mechanical motion of the graphene. This interferometry technique is used to demonstrate the very first graphene mechanical resonator [15].

Albeit conceptually simple, the setup of optical detection is rather complicated and stringent, and it is almost impossible to realize such scheme at integrated circuit (IC) level. Therefore, all electrical readout techniques are more preferable. However, the conventional capacitive transduction approach cannot be directly applied to graphene NEMS, due to the overwhelming parasitic capacitance (in the order of pF) compared to the active capacitance. For example, the geometric capacitance for 1 by 1 μm^2 graphene with 300 nm vacuum gap is 30 aF, which is about five orders of magnitude smaller than the parasitic capacitance. Without active noise reduction mechanism, it is very difficult to obtain adequate SNR to resolve the resonance.

The electrical detection of graphene resonator utilizes its semiconducting properties: in the schematic setup in Fig. 5, when a gate electrode is nearby to modify the carrier density n of graphene, its conductance G will change accordingly. The magnitude of such variations is enhanced by the large electronic mobility of graphene. Given the "parallel-plate capacitor" structure, the mechanical resonance will alter the geometric capacitance C_g, hence the carrier density through $Aen = C_g V_g^{DC}$, where A is the size of the graphene and e is the electron charge.

Graphene NEMS, Fig. 5 Schematic of electrical readout of graphene resonators

Therefore, the mechanical motion is imprinted to the time-varying current across graphene as

$$\frac{dI_d}{dz} = V_d V_g^{DC} \frac{dG}{dV_g^{DC}} \frac{C_g'}{C_g}. \tag{7}$$

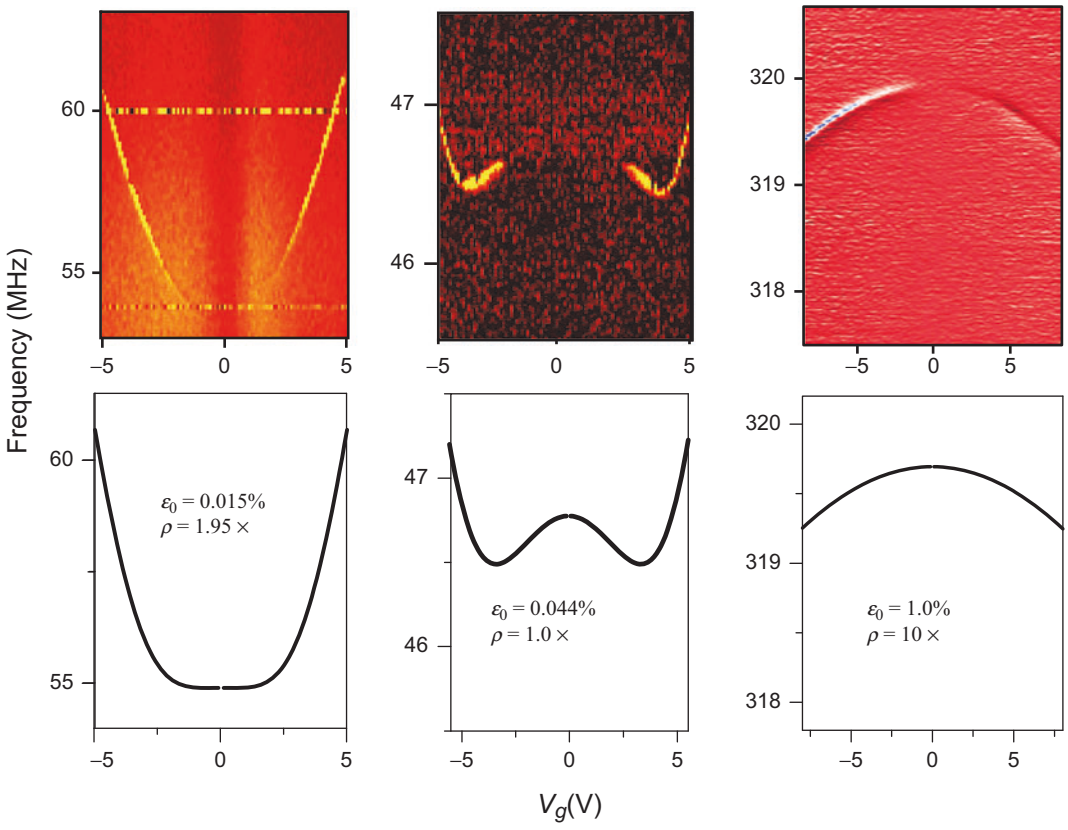
In the above equation, dG/dV_g^{DC} is proportional to the electron mobility, which in high-quality graphene can be orders of magnitude larger than other NEMS constituents.

The first demonstration of all-electrical transduction of graphene resonators [16], however, did not directly profit from Eq. 7. The authors used conductive silicon wafer as global back gate and therefore introduced inevitable large parasitic capacitance between the metal bond pads and the silicon wafer. To circumvent this limitation, the authors employed amplitude modulation (AM) frequency mixing method to down-convert the radio-frequency (RF) signal to low-frequency range ($\sim$ kHz). The amplitude of the low frequency still preserves the mechanical signature. Variations of such heterodyne techniques have since been applied for electrical detection, such as frequency modulation (FM) [17] and frequency up-conversion [18].

In order to capitalize on the simple relation outlined in Eq. 7, the critical step is to design the device structure that would minimize the capacitive cross talk. Xu et al. achieved this by employing local backgate on top of insulating

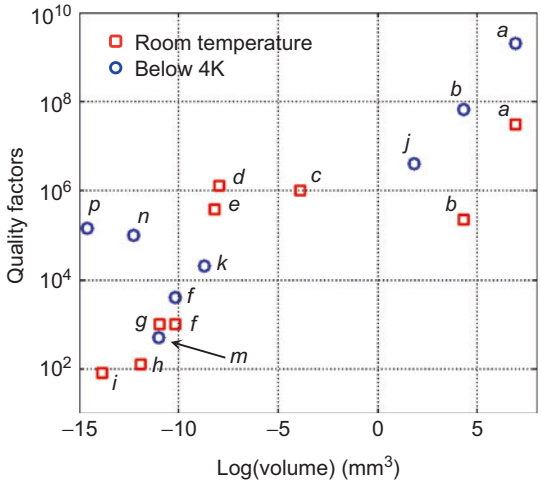
silicon substrate [19] and hence reduce the parasitic capacitance by two orders of magnitude. The RF current through the device is given as

$$I_d = j\omega C_g \left(\frac{C_{\text{tot}}}{C_g} v_g^{ac}(\omega) - V_g^{DC} \frac{C_g'}{C_g} \delta z \right) + V_d \frac{\mathrm{d}G}{\mathrm{d}V_g^{DC}} \left(v_g^{ac}(\omega) - V_g^{DC} \frac{C_g'}{C_g} \delta z \right), \quad (8)$$



where $j = \sqrt{-1}$, C_{tot} is the total capacitance of the system, including both parasitic and motional components, and δz is the vibration amplitude of the graphene membrane. Terms in the first parentheses originate purely from capacitive transduction, which are the same as the electromechanical current used in silicon-based RF MEMS. Because of the small lateral size of the graphene sample, this current is extremely small here. The two terms in the second parentheses are the immediate consequence of Eq. 7, together with electrical feedthrough. The total current I_d at different frequency ω is monitored with a vector network analyzer (VNA) and does not require any additional heterodyne mixing. The advantage of such resonant channel transistor configuration (graphene acts as the active channel) is the improvement of measurement speed, by more than three orders of magnitude compared with the frequency mixing methods.

Frequency tuning. Due to the atomic thinness, the bending rigidity of graphene can be ignored; hence, the resonant frequency is dictated by in-plane strain, according to Eq. 5. Additionally, its ability to withstand extreme large strain before breaking opens up the potential for wide-frequency tuning through strain engineering: frequency tuning up to 400 % has been demonstrated [16]. A detailed analysis [20] shows that even at atomic limit, one can still apply continuum elastic mechanics to model the dynamic response. In typical device arrangements, where the suspended graphene is partially or fully clamped, its in-plane strain can be modified through electrostatic attraction by different V_g^{DC}. For example, the spring constant k of a doubly clamped graphene resonator can be described as



$$k = \frac{16E^{2D}w}{3L}\varepsilon_0 + \frac{256E^{2D}w}{3L^3}\left[z_e\left(\varepsilon_0, V_g^{DC}\right)\right]^2 - \frac{1}{2}C_g''\left(V_g^{DC}\right)^2, \quad (9)$$

where w and L are the width and length of the suspended portion, ε_0 is the built-in strain, z_e is the maximum static deflection of graphene at equilibrium, and C_g'' is second spatial derivative of geometric capacitance. There are three contributions in Eq. 9: the first term is governed by built-in strain and is independent of V_g^{DC}. The second term reflects the effect of external strain induced by applied V_g^{DC}: with larger $|V_g^{DC}|$, the membrane will bend more toward the substrate; hence, z_e will increase. Note that the growing rate of z_e is also determined by the built-in strain ε_0. The third term describes the nonlinearity of electrostatic interaction, which will introduce spring constant softening with larger $|V_g^{DC}|$. This softening effect is commonly observed and well understood in MEMS resonators. With small built-in strain ε_0, the second term in Eq. 9 dominates, and the resonant frequency increases monotonically with $|V_g^{DC}|$; for large ε_0, the third term in Eq. 9 prevails, and the resonance decreases monotonically with $|V_g^{DC}|$. In the case of intermediate ε_0, the resonant frequency first decreases and then increases with $|V_g^{DC}|$. All the three scenarios are observed in experiments and agree well with the model prediction (Fig. 6).

Quality factor. Another important property of resonant systems is the damping rate, and it is commonly quantified by quality factor $Q = 2\pi E/\Delta E$, where E is the time-averaged energy stored in the resonator and ΔE is energy lost per cycle. Large values of Q are preferred for applications such as mass sensing and communication. However, as the size of the resonators shrinks toward nanometer size, the quality factors usually suffer, as shown in Fig. 7. The decrease in Q is mostly due to the higher surface energy dissipation, as the surface-to-volume ratio in NEMS is much bigger than MEMS. For doubly clamped graphene resonators with length less than 5 μm, the quality factors are about 10^2 at room temperature, for both mechanically exfoliated and CVD samples [16, 17]. However, the quality

Graphene NEMS, Fig. 8 Inverse quality factor Q^{-1} of graphene resonators at different operating temperatures, collected from different experiments [16, 17, 22]. *Blue* lines are merely guide to the eyes, showing different temperature dependencies

factors for circularly clamped drum-type graphene resonators show values as high as 2500 at room temperature [21]. Although the size of the drum resonators is bigger in this case (diameter of up to 25 μm), the larger values of Q still point the direction for improving quality factors by removing unclamped edges.

The quality factors of graphene resonators showed drastic increase upon cooling, reaching values higher than 10^5 when operated below 100 mK [22–24]. Its dependence on temperature, collected from experiments conducted by different research groups, is shown in Fig. 8. Between 100 K and room temperature, the energy dissipation Q^{-1} scales roughly as T^2, and below 100 K, the temperature dependence changes to approximately $T^{0.5}$. Similar trends at low temperatures [14] have been observed in carbon nanotube resonators and other NEMS resonators made from diamond and gallium arsenide; however, the explicit mechanism that can well predict the experimental results is still lacking.

The strong temperature dependence above 100 K is likely caused by thermal expansions of substrate. The samples shown in Fig. 8 are all made through HF acid under etching, as the graphene-aided diffusion of HF results in suspended metal contacts. When the temperature drops, these overhanging metals experience thermal contraction, imposing strain to the attached graphene membrane. While the in-plane strain only weakly affects the energy dissipation, it will increase the resonant frequency remarkably, hence boosting the apparent quality factor. The thermal expansion coefficients of metal become much smaller below 100 K, and the intrinsic dissipation mechanisms start to dominate.

Applications

Mass sensing. Due to the low mass and extremely large surface-to-mass ratio, graphene resonators are well suited for mass sensing applications. In general, the resonant frequency ω_0 can be written as

$$\omega_0 = \sqrt{\frac{k}{m_{\text{eff}}}}, \tag{10}$$

where m_{eff} is the effective mass. Therefore, the frequency shift $\delta\,\omega_0$ is

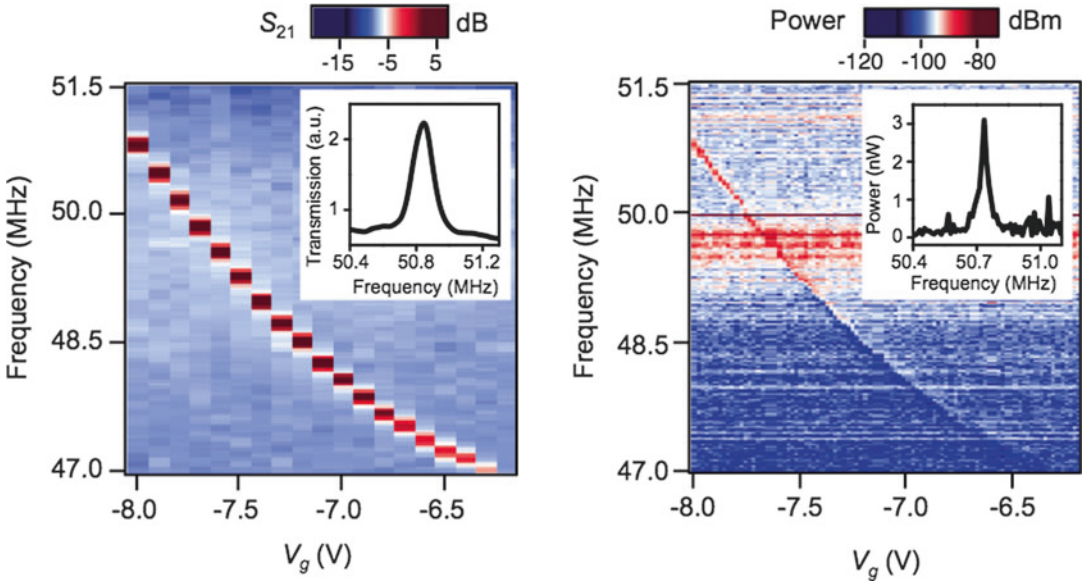
$$\delta\,\omega_0 = \frac{1}{2}\frac{\omega_0}{k}\delta k - \frac{1}{2}\frac{\omega_0}{m_{\text{eff}}}\delta m. \tag{11}$$

For bulk MEMS-based resonators, the added mass δm has little or no effect on spring constant (first term in Eq. 11); therefore, the result of mass loading is purely downshift of ω_0. However, this assumption is no longer valid for graphene resonators: the deposition of adsorbates interacts

strongly with graphene, and it causes an increase of strain, therefore resonant frequency. Study has shown that [16] at low strain limit, the resonant frequency indeed increases upon mass loading, while at high strain limit, the resonant frequency downshifts as expected. The experimentally demonstrated mass responsivity, $\Re_m = \frac{1}{2\pi}\delta\omega_0/\delta m$, which quantifies how sensitive the resonant frequency to mass change, is 1.3 Hz/zg at low strain limit and −2.1 Hz/zg at high strain limit.

The minimal resoluble mass $\delta m_{\min}$, on the other hand, also depends on the dynamic range (*DR*, in unit of dB), quality factor (Q) of the underlying resonator, and the measurement bandwidth *(BW)*. It can be approximated as

$$\delta m_{\min} \approx \Re_m^{-1} \times 10^{-DR/20}\sqrt{\frac{\omega_0}{Q}BW}. \qquad (12)$$



For a graphene resonator with resonance below 10 MHz and Q larger than 1000 at room temperature, the equivalent mass sensitivity is about 0.1 zg/Hz$^{0.5}$. Improvements of quality factors and strain engineering are expected to further enhance the mass sensitivity.

It is worth mentioning that sensors made from carbon nanotube have shown superior mass resolution [25]; however, the detection mechanism requires cryogenic environment and the measurement bandwidth is limited at kHz range. The simple implementation of graphene resonators allows for practical applications at room temperature that could achieve comparable sensitivity.

Self-sustained oscillators. The resonator structures that are considered so far all require an external AC stimulus for actuation. On the contrary, an oscillator structure that consists of a passive resonator and an active feedback component can be operated without such prerequisite. The mechanical motions are initiated by thermal noise, fed into the positive feedback loop, and the amplified output of the feedback loop is applied back to the resonator as actuation, completing the closed loop. This "ring-up" of the vibration will continue until certain nonlinearities, either of the resonator or of the amplifier, start to provide negative feedback, after which the system will oscillate around a given frequency. During these processes, only DC power supplies are needed to compensate the energy lost during each oscillation cycle, and the oscillator will return a stable AC signal output.

Barton et al. [26] have recently demonstrated self-oscillation of graphene mechanical resonators, using photothermal back-action as feedback scheme. The graphene and the substrate form a Fabry–Pérot cavity as described previously, while graphene serves as the "moving mirror." While the cavity length is modulated by the vibration of graphene membrane, so is the absorbed power of the incident laser by graphene. The absorption of light causes periodic heating and therefore changes in strain, giving rise to an induced optomechanical force parallel to the direction of vibration but with certain time delay. The time delay can be tuned by the equilibrium cavity length and laser wavelength, while the amplitude of the optomechanical force is controlled by the laser power. If the time delay is chosen such that the optomechanical force acts in-phase with damping, it will suppress the thermal motion of the membrane, resulting in optomechanical cooling. The authors showed that they are able to cool the fundamental mode of a room-temperature graphene resonator to an effective temperature of 100 K, with 2 mW of laser power. On the other hand, if the time delay causes the optomechanical force and the damping to be out of phase, it will decrease the effective energy dissipation, giving rise to larger apparent Q and higher vibrational amplitude. At sufficiently high optomechanical force, this negative damping is able to compensate for the internal energy loss, therefore inducing self-sustained oscillation without AC driving force. The oscillation frequency can also be tuned by V_g^{DC}, as shown by the authors.

Parallel to this all-optical implementation, as in the case of graphene resonators, Chen et al. [27] later reported the all-electrical realization of graphene mechanical oscillators, as shown in Fig. 9. The authors used regular radio-frequency amplifiers and phase shifter in their feedback loop, to provide adequate amplitude gain tuning and time delay control. Aside from the voltage-controlled oscillation, the benefits of electrical transduction enable direct signal processing. In this case, the

Graphene NEMS, Fig. 9 *Left panel*: open-loop response (resonator setup) shows frequency tuning through applied gate voltage V_g. *Inset*: transmission spectrum at $V_g = -8$ V. *Right panel*: closed-loop response (oscillator setup) of the same device, demonstrating the identical frequency tuning characteristics. *Inset*: power spectrum of the oscillation at $V_g = -8$ V (Figure adapted from Chen et al. [27])

graphene oscillators served as frequency modulator (FM), which up-converted audio waveform into commercial FM broadcast band. The transmitted signal was successfully demodulated and the original song track was recovered.

Optomechanical coupling with graphene resonators. The high-quality factors Q of graphene resonators (>100,000) at low temperatures triggered interests of exploiting graphene for applications in quantum regime. Recently, Weber et al. [24] reported coupling between high-Q graphene resonators (three to four layers) and high-Q microwave cavities and demonstrated detection of mechanical motion and manipulation of the coupling strength. Song et al. [28] designed similar optomechanical system and used back-action cooling to achieve 50 ± 6 mechanical quanta in a bilayer graphene resonator at 60 mK of bath temperature.

Singh et al. [23] then took one step further: by carefully preparing their microwave cavities that coupled with a 30-layer thick graphene resonator, the authors observed optomechanically induced reflection (OMIR) and optomechanically induced absorption (OMIA). The OMIA phenomena can be used for microwave photon storage. Given the high mechanical quality factor (≈220,000), the decoherence time is estimated up to 10 ms.

Ecotribology

Definition

Tribology (from the Greek word τρίβω "tribo" meaning "to rub") is the branch of science and technology concerned with interacting surfaces in relative motion and with associated matters (as friction, wear, lubrication, and the design of bearings). Green tribology is the science and technology of the tribological aspects of ecological balance and of environmental and biological impacts.

Research Areas

Green tribology deals with the ecological aspects of technology involving friction, lubrication, wear, solid surfaces, coatings, as well as applications of this technology. This makes green tribology closely related to the novel areas of tribology: nanotribology, biotribology, and biomimetics. The term "green tribology" was suggested in about 2009 by several engineers and economists. In 2010, the first scientific volume was published by Philosophical Transactions of the Royal Society [1]. A number of symposia and conference sections devoted to ecological and green tribology took place starting from approximately the same time, as well as books prepared for publication [2].

Green or environment-friendly tribology emphasizes the aspects of interacting surfaces in relative motion, which are of importance for energy or environmental sustainability or which have impact upon today's environment. This includes tribological technology that mimics living nature (biomimetic surfaces) and thus is expected to be environment-friendly, the control of friction and wear that is of importance for energy conservation and conversion, environmental aspects of lubrication (including natural oil lubrication and self-lubrication), surface modification techniques, and tribological aspects of green applications, such as wind-power turbines, tidal turbines, or solar panels. A number of tribological problems could be put under the umbrella of "green tribology," and they are of mutual benefit to one another.

Green tribology can be viewed in the broader context of two other "green" areas: green engineering and green chemistry. The U.S. Environmental Protection Agency (EPA) defines green engineering as "the design, commercialization, and use of processes and products that are technically and economically feasible while minimizing (1) generation of pollution at the source (2) risk to human health and the environment." Green chemistry, also known as sustainable chemistry, is defined as the design of chemical products and processes that reduce or eliminate the use or generation of hazardous substances.

Biomimetic and Self-Lubricating Materials/Surfaces

Biomimetic materials are also usually environmentally friendly in a natural way since they are a natural part of the ecosystem. For this reason, the biomimetic approach in tribology is particularly promising. In the area of biomimetic surfaces, a number of ideas have been suggested, including the Lotus-effect, gecko-effect, micro- and nanostructured surfaces, texturing, self-lubrication, hydrophobicity, oleophobicity, etc.

Environmental engineers have only just started paying attention to biomimetic surfaces. One research indicates that while the use phase benefits are apparent, production burdens can outweigh them when compared with other cleaning methods, so a more thoughtful and deliberate use of bio-inspiration in sustainable engineering is needed. Clearly, more studies are likely to emerge in the near future.

Biodegradable Lubrication

In the area of environment-friendly and biodegradable lubrication, several ideas have been suggested: This includes the use of natural (e.g., vegetable-oil-based or animal-fat-based) biodegradable lubricants for engines, hydraulic applications, and metal cutting applications. In particular, corn, soybean, coconut oils have been used so far (the latter is of particular interest in

tropical countries such as India). These lubricants are potentially biodegradable, although in some cases chemical modification or additives for best performance are required. Vegetable oils can have excellent lubricity, far superior than that of mineral oil. In addition, they have a very high viscosity index and high flash/fire points. However, natural oils often lack sufficient oxidative stability, which means that the oil will oxidize rather quickly during use, becoming thick and polymerizing to a plastic-like consistency. Chemical modification of vegetable oils and/or the use of antioxidants can address this problem.

Powder lubricants and, in particular, boric acid lubricants, in general, tend to be much more ecologically friendly than the traditional liquid lubricants. Boric acid and MoS_2 powder can also be used as an additive to the natural oil. Friction and wear experiments show that the nanoscale (20 nm) particle boric acid additive lubricants significantly outperformed all of the other lubricants with respect to frictional and wear performance. In fact, the nanoscale boric acid powder-based lubricants exhibited a wear rate more than an order of magnitude lower than the MoS_2 and larger-sized boric acid additive based lubricants.

Self-replenishing lubrication that uses oil-free environmentally benign powders for lubrication of critical components such as bearings used in fuel cell compressors and expanders.

Tribology of Renewable Energy Sources

The tribology of renewable sources of energy is a relatively new field of tribology. Today, there are meetings and sections devoted to the tribology of wind turbines at almost every tribology conference, and they cover certain issues specific for these applications. Unlike in the case of the biomimetic approach and environment-friendly lubrication, it is not the manufacturing or operation, but the very application of the tribological system which involves "green" issues, namely, environmentally friendly energy production. The following issues can be mentioned [1].

Wind power turbines have a number of specific problems related to their tribology and constitute a well-established area of tribological research. These issues include water contamination, electric arcing on generator bearings, issues related to the wear of the mainshaft and gearbox bearings and gears, the erosion of blades (solid particles, cavitation, rain, hail stones), etc.

Tidal power turbines are another important way of producing renewable energy, which involves certain tribiological problems. Tidal power turbines are especially popular in Europe (particularly, in the U.K.), which remains the leader in this area, although several potential sites in North America have been suggested. There are several specific tribological issues related to the tidal power turbines, such as their lubrication (seawater, oils, and greases), erosion, corrosion, and biofouling, as well as the interaction between these modes of damage.

Besides tidal, the ocean water flow energy and river flow energy (without dams) can be used with the application of special turbines, such as the Gorlov helical turbine, which provides the same direction of rotation independent of the direction of the current flow. These applications also involve specific tribological issues.

Geothermal energy plants are used in the USA (in particular, at the Pacific coast and Alaska); however, their use is limited to the geographical areas at the edges of tectonic plates. In 2007, they produced 2.7 GW of energy in the USA, with Philippines (2.0 GW) and Indonesia (1.0 GW) at the second and third place. There are several issues related to the tribology of geothermal energy sources which are discussed in the literature [1].

Principles

Nosonovsky and Bhushan [1] formulated the principles of green tribology, which belong to the three areas, suggested in the preceding section. Some principles are related to the design and manufacturing of tribological applications (3–10), while others belong to their operation (1–2 and 11–12). Tradition is followed and limited the number of principles is limited to 12.

1. *Minimization of heat and energy dissipation*. Friction is the primary source of energy

dissipation. According to some estimates, about one third of the energy consumption in the USA is spent to overcome friction. Most energy dissipated by friction is converted into heat and leads to the heat pollution of atmosphere and the environment. The control of friction and friction minimization, which leads to both the energy conservation and prevention of the damage to the environment due to the heat pollution, is a primary task of ribology. It is recognized that for certain tribological applications (e.g., car brakes and clutches) high friction is required; however, ways of effective use of energy for these applications should be sought as well.

2. *Minimization of wear* is the second most important task of tribology which has relevance to green tribology. In most industrial applications, wear is undesirable. It limits the lifetime of components and therefore creates the problem of their recycling. Wear can lead also to catastrophic failure. In addition, wear creates debris and particles which contaminate the environment and can be hazardous for humans in certain situations. For example, wear debris generated after human joint replacement surgery is the primary source of long-term complications in patients.
3. *Reduction or complete elimination of lubrication and self-lubrication*. Lubrication is a focus of tribology since it leads to the reduction of friction and wear. However, lubrication can also lead to environmental hazards. It is desirable to reduce lubrication or achieve the self-lubricating regime when no external supply of lubrication is required. Tribological systems in living nature often operate in the self-lubricating regime. For example, joints form essentially a closed self-sustainable system.
4. *Natural lubrication* (e.g., vegetable-oil based) should be used in cases when possible since it is usually environmentally friendly.
5. *Biodegradable lubrication* should also be used when possible to avoid environmental contamination.
6. *Sustainable chemistry and green engineering principles* should be used for the manufacturing of new components for tribological applications, coatings, and lubricants.
7. *Biomimetic approach* should be used whenever possible. This includes biomimetic surfaces, materials, and other biomimetic and bio-inspired approaches since they tend to be more ecologically friendly.
8. *Surface texturing* should be applied to control surface properties. Conventional engineered surfaces have random roughness, and the randomness is the factor which makes it extremely difficult to overcome friction and wear. On the other hand, many biological functional surfaces have complex structures with hierarchical roughness, which defines their properties. Surface texturing provides a way to control many surface properties relevant to making tribosystems more ecologically friendly.
9. *Environmental implications of coatings* and other methods of surface modification (texturing, depositions, etc.) should be investigated and taken into consideration.
10. *Design for degradation* of surfaces, coatings, and tribological components. Similar to green chemistry applications, the ultimate degradation/utilization should be taken into consideration during design.
11. *Real-time monitoring*, analysis, and control of tribological systems during their operation should be implemented to prevent the formation of hazardous substances.
12. *Sustainable energy applications* should become the priority of the tribological design as well as engineering design in general.

Lippmann-Schwinger integral equation method

Definition

The Green's function integral equation method (GFIEM) is a method for solving linear differential equations by expressing the solution in terms of an integral equation, where the integral involves an overlap integral between the solution itself and a Green's function. In particular, within nanotechnology the method is frequently applied to calculate scattering of light.

Overview

The Green's function integral technique can be used to solve a linear inhomogeneous differential equation in real space such as

$$\theta_0 \varphi(\mathbf{r}) = \pm f(\mathbf{r}), \tag{1}$$

where θ_0 is an operator, $\mathbf{r}$ is the position, $f(\mathbf{r})$ is a given source term, and $\varphi(\mathbf{r})$ is the function that should be calculated such that Eq. 1 is satisfied. A solution can in principle be obtained straightforwardly from a Green's function $g(\mathbf{r}, \mathbf{r}')$ of the operator θ_0. The Green's function satisfies the equation

$$\theta_0 g(\mathbf{r}, \mathbf{r}') = \pm \delta(\mathbf{r} - \mathbf{r}'), \tag{2}$$

where $\delta(\mathbf{r} - \mathbf{r}')$ is the Dirac delta function. A solution to the inhomogeneous equation (1) can be given straightforwardly by an overlap integral between the Green's function and the source term, i.e.,

$$\varphi(\mathbf{r}) = \int g(\mathbf{r}, \mathbf{r}') f(\mathbf{r}') d^3 r. \tag{3}$$

It should be recognized that there can be many solutions to Eq. 2 and thereby many possible Green's functions. Usually, it is also required that the solution $\varphi(\mathbf{r})$ must satisfy certain boundary conditions, and in many cases it is possible to choose the specific Green's function that will automatically make the expression (3) satisfy these boundary conditions. An example of the above procedure, which is usually not discussed in the context of Green's functions, is the electrostatic potential $\varphi(\mathbf{r})$ due to a distribution of charges in free space, in which case the potential must satisfy the equation [1]

$$\nabla^2 \varphi(\mathbf{r}) = -\rho(\mathbf{r})/\epsilon_0, \tag{4}$$

where $\rho(\mathbf{r})$ is the charge distribution, and ϵ_0 is the vacuum permittivity. The appropriate Green's function for finding the solution being zero at infinite distance from the source region is given by

$$g(\mathbf{r}, \mathbf{r}') = 1/4\pi \, |\mathbf{r} - \mathbf{r}'|, \tag{5}$$

which is a solution to

$$\nabla^2 g(\mathbf{r}, \mathbf{r}') = -\delta(\mathbf{r} - \mathbf{r}'), \tag{6}$$

and it satisfies the boundary condition that it becomes zero at infinity. Using Eqs. 3, 4, and 5 it is now straightforward to write up the well-known solution for the potential [1]

$$\varphi(\mathbf{r}) = \frac{1}{4\pi\epsilon_0} \int \frac{\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d^3 r'. \tag{7}$$

This may all seem very simple. However, this is only true if the Green's function is known and is in a form that is easy to use. Analytic expressions for Green's functions are usually only known for a few simple cases. Furthermore, in many cases the Green's function has a singularity that requires

special attention in a numerical solution scheme. Consider an equation of the form

$$(\theta_0 + \Delta\theta)(\varphi_0(\mathbf{r}) + \Delta\varphi(\mathbf{r})) = 0, \qquad (8)$$

where the operator $\theta_0 + \Delta\theta$ is the sum of an unmodified operator with a known Green's function having appropriate boundary conditions and a modification $\Delta\theta$. The solution $\varphi(\mathbf{r}) = (\varphi_0(\mathbf{r}) + \Delta\varphi(\mathbf{r}))$ should be in the form of the sum of a given solution $\varphi_0(\mathbf{r})$ for the case that $\Delta\theta = 0$ and a modification $\Delta\varphi(\mathbf{r})$ that must disappear when $\Delta\theta = 0$. This can be rewritten in the form

$$\theta_0(\varphi(\mathbf{r}) - \varphi_0(\mathbf{r})) = -\Delta\theta\varphi(\mathbf{r}), \qquad (9)$$

since $\theta_0\varphi_0(\mathbf{r}) = 0$. Equation 9 now has the form of an "inhomogeneous" equation, and a solution can be obtained using Eq. 3, i.e.,

$$\varphi(\mathbf{r}) = \varphi_0(\mathbf{r}) + \int g(\mathbf{r}, \mathbf{r}')\Delta\theta(\mathbf{r}')\varphi(\mathbf{r}')d^3r', \qquad (10)$$

which is an integral equation since $\varphi(\mathbf{r})$ appears on both sides. One possible solution scheme is to divide the domain in which $\Delta\theta \neq 0$ in small elements and to assume that φ is constant within each element, in which case the discretized equation (10) becomes a linear system of equations in the discrete values of φ that can be put on matrix form and solved numerically on a computer.

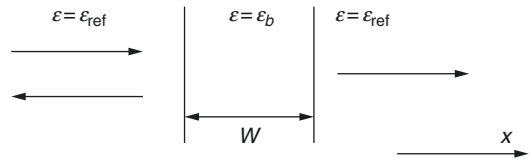
In the following, integral equations of the form (10) shall be constructed for a range of simple cases of interest for scattering problems in optics and electromagnetics. The first case that will be considered is the scalar wave equation in one and two dimensions. Then, the numerically more challenging case of the vector wave equation in three dimensions shall be considered. The examples are for the case of monochromatic light with angular frequency ω. The real solution is obtained from the complex solutions obtained in the following by multiplying with $\exp(i\omega t)$ and then taking the real part of the resulting expression. Throughout this entry the factor $\exp(i\omega t)$ will be suppressed.

Scalar Green's Function Integral Equation Method for One-Dimensional Scattering Problems

While the type of problems considered in this section can readily be solved by other methods such as, e.g., a transfer-matrix method [2], the case of a scalar one-dimensional scattering problem nevertheless provides a very instructive and transparent exemplification of the Green's function method and serves as a good introduction to the more complex cases. As an example, consider light propagating from left to right being normally incident on a dielectric barrier (Fig. 1), a case that was previously considered in Ref. [3].

The incident field $E_0(x)$ is a solution to the wave equation for a structure where the dielectric barrier is not present, i.e.,

$$\left(\frac{\partial^2}{\partial x^2} + k_0^2\epsilon_{\text{ref}}\right)E_0(x) = 0. \qquad (11)$$



A natural choice of incident field could be a plane wave propagating along the positive x-axis, i.e.,

$$E_0(x) = E_0 e^{-ik_0 n_{\text{ref}} x}, \qquad (12)$$

where $n_{\text{ref}} = \sqrt{\epsilon_{\text{ref}}}$. The equation to be solved is the wave equation for the full structure including the barrier, namely,

$$\left(\frac{\partial^2}{\partial x^2} + k_0^2\epsilon(x)\right)E(x) = 0, \qquad (13)$$

with the boundary condition that the solution must be the sum of the given incident $E_0(x)$ and a

Green's Function Integral Equation Method, Fig. 1 Illustration of scattering of light by a dielectric barrier of dielectric constant ε_b and width w. The dielectric constant of the reference medium (without the barrier) is ε_{ref}

scattered field component that propagates away from the barrier. Equations 11 and 13 can be rewritten in the form of the following "inhomogeneous" equation

$$\left(\frac{\partial^2}{\partial x^2} + k_0^2 \epsilon_{\text{ref}}\right)(E(x) - E_0(x)) = -k_0^2(\epsilon(x) - \epsilon_{\text{ref}})E(x). \tag{14}$$

The relevant Green's function for the reference medium must satisfy the equation

$$\left(\frac{\partial^2}{\partial x^2} + k_0^2 \epsilon_{\text{ref}}\right) g(x, x') = -\delta(x - x') \tag{15}$$

along with the radiating boundary condition, namely, that the solution must propagate away from the position x'. Equation 15 and this boundary condition uniquely determines the Green's function which is given by

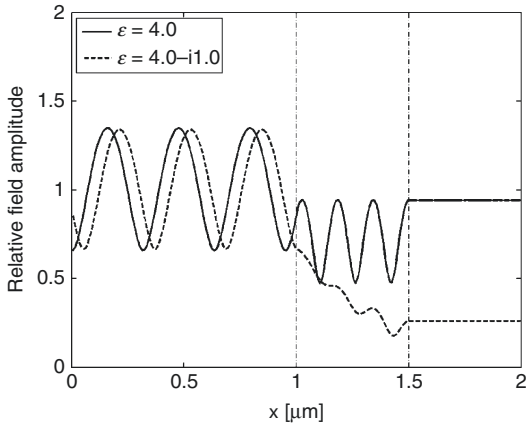
$$g(x, x') = g(x - x') = \frac{1}{2ik_0 n_{\text{ref}}} e^{-ik_0 n_{\text{ref}}|x - x'|}. \tag{16}$$

A solution of Eq. 14 can then be obtained by solving the integral equation

$$E(x) = E_0(x) + \int g(x, x') k_0^2 (\epsilon(x') - \epsilon_{\text{ref}}) E(x') dx'. \tag{17}$$

Due to the properties of the chosen Green's function, Eq. 17 will give the solution of interest since it satisfies the appropriate boundary condition, namely, that the total field must be the sum of the given incident field and a scattered field component propagating away from the scattering geometry.

An advantage in a numerical solution scheme of Eq. 17 compared with other methods, such as finite-difference methods, is that initially it is sufficient to consider only the x, x' where $\epsilon - \epsilon_{\text{ref}} \neq 0$. A simple approach is to, e.g., discretize the barrier in Fig. 1 in N elements sampled at positions $x_1, x_2, \ldots x_N$ with distance Δx between sampling points and to assume that within each element the field is constant and given by $E_1, E_2, \ldots E_N$, respectively. In that case, Eq. 17 can be approximated with the discrete linear system of equations



$$E_i = E_{0i} + \sum_j g_{ij} k_0^2 (\epsilon_j - \epsilon_{\text{ref}}) E_j \Delta x, \tag{18}$$

where $g_{ij} = g(x_i, x_j)$. This equation can be put in matrix form and readily solved on a computer. The calculated field inside the barrier can then be used in Eq. 17 to obtain the field at all other desired positions outside the barrier by direct integration over the field inside the barrier. Since a homogeneous reference medium is considered, the transmission through the barrier can, e.g., be calculated by considering $E(x)$ for a position x being larger than the barrier positions from the ratio $T = |E(x)/E_0(x)|^2$. Similarly, the reflection can be calculated by considering a position x being smaller than the barrier positions from the ratio $R = |(E(x) - E_0(x))/E_0(x)|^2$.

Finally, a few examples of calculations obtained with this method are presented that may also serve as an exercise for the reader, namely, the electric field in the case of scattering (reflection) from a dielectric barrier (Fig. 2) and reflection and transmission spectra for light incident on a layered structure or grating designed to strongly reflect red light (Fig. 3). These examples are very similar to instructive examples in Ref. [3].

Scalar Green's Function Integral Equation Method for Two-Dimensional Scattering Problems

In this section, the method from the previous section is extended to a two-dimensional scattering problem, namely, scattering of light by a very long (nano)wire (Fig. 4). Consider a situation with light propagating in the xy-plane and a wire oriented along the z-axis, and that the electric field is invariant along the z-axis and polarized along the z-axis, i.e., $\mathrm{E}(\mathbf{r}) = \hat{z}E(x, y)$. In that case the wave

Green's Function Integral Equation Method, Fig. 2 Electric field magnitude normalized relative to the incident field, i.e., $|E(x)/E_0(x)|$ for an incident wave with wavelength 633 nm (red light) on a dielectric barrier of width 500 nm and dielectric constant with and without absorption losses, namely, $\varepsilon = 4$ or a case with losses $\varepsilon = 4 - i$

equation for the electric field reduces to the following scalar wave equation:

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + k_0^2 \epsilon(x,y)\right) E(x,y) = 0, \qquad (19)$$

where $\epsilon(x, y)$ is the dielectric constant of the total structure including the wire. Outside the wire the dielectric constant is given by ϵ_{ref}. Thus, also in this case is $(\epsilon(x,y) - \epsilon_{\text{ref}})$ the modification made to a reference structure, and it is only nonzero for positions inside the wire. The boundary condition when solving the differential equation (19) is also in this case that the total field $E(x, y)$ should be the sum of a given incident field $E_0(x, y)$ and a scattered field, where the scattered field is propagating away from the scattering object. The given incident field must be a solution to the wave equation in the case when there is no nanowire, i.e.,

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + k_0^2 \epsilon_{\text{ref}}\right) E_0(x,y) = 0. \qquad (20)$$

For simplicity, the incident field can, e.g., be a plane wave propagating in the direction given by $\hat{s} = \hat{x}\cos\theta + \hat{y}\sin\theta$, i.e.,

$$E_0(x,y) = E_0 e^{-ik_0 n_{\text{ref}}(x\cos\theta + y\sin\theta)}. \qquad (21)$$

From Eqs. 19 and 20, the following equation is obtained:

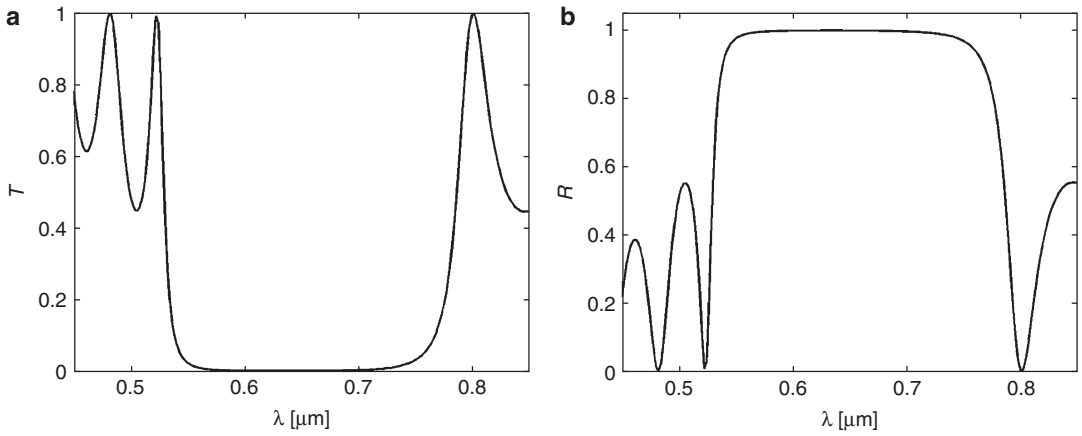
$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + k_0^2 \epsilon_{\text{ref}}\right)(E(x,y) - E_0(x,y)) = -k_0^2(\epsilon(x,y) - \epsilon_{\text{ref}})E(x,y). \qquad (22)$$

While the method can be used for wires with any geometry, examples will be given for a wire with (a) rectangular and (b) circular cross section (see Fig. 4).

The appropriate Green's function is a solution to the equation

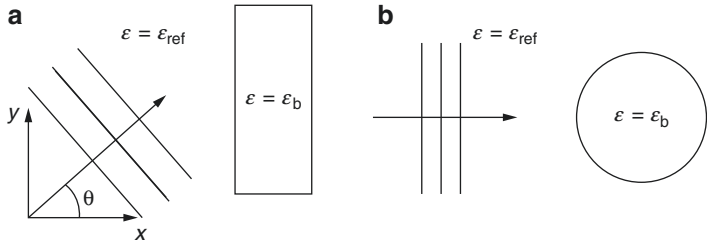
$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + k_0^2 \epsilon_{\text{ref}}\right) g(x,y;x',y') = -\delta(x-x')\delta(y-y'), \qquad (23)$$

with the boundary condition that the solution must correspond to a field propagating away from the position $\mathbf{r}' = (x', y')$. With these requirements, the Green's function is uniquely determined to be the cylindrical wave given by



$$g(\mathbf{r},\mathbf{r}') = \frac{1}{4i} H_0^{(2)}(k_0 n_{\text{ref}}|\mathbf{r} - \mathbf{r}'|), \qquad (24)$$

where $H_0^{(2)}(z)$ is the Hankel function of order 0 and second kind. From Eqs. 22 and 23, the following integral equation is straightforwardly obtained:



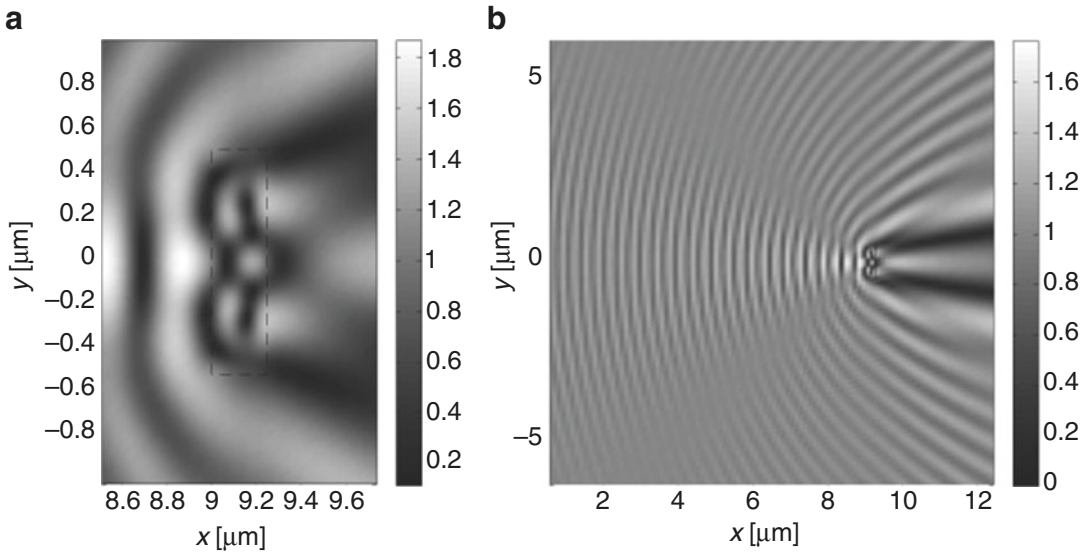
$$E(\mathbf{r}) = E_0(\mathbf{r}) + \int g(\mathbf{r},\mathbf{r}') k_0^2 (\epsilon(\mathbf{r}) - \epsilon_{\text{ref}}) E(\mathbf{r}') d^2 r', \qquad (25)$$

where the field has the desired form of the sum of the given incident field and a scattered part propagating away from the scatterer due to the properties of the chosen Green's function.

The simplest approach for solving Eq. 25 is also in this case to discretize the structure in,

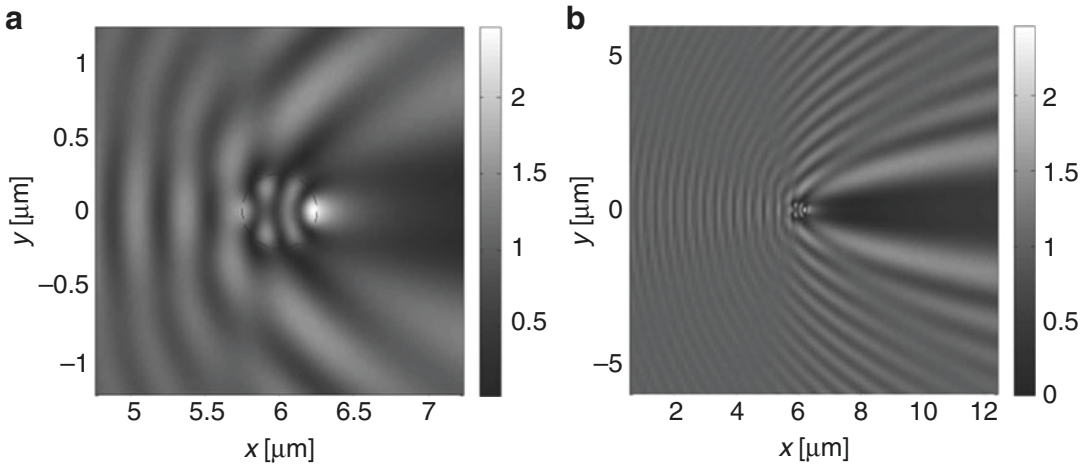
Green's Function Integral Equation Method, Fig. 3 Reflection and transmission spectra for light of wavelength λ being incident on a layered structure with alternating seven layers of high refractive index $n_H = 2.32$ and thickness 633 nm/$4n_H$ and six layers of a smaller refractive index $n_L = 1.38$ and thickness 633 nm/$4n_L$. The surrounding material is air

Green's Function Integral Equation Method, Fig. 4 Schematic of a plane wave being incident on a wire with (**a**) rectangular and (**b**) circular cross section



e.g., N square shaped area elements all having the same area ΔA and center at $\mathbf{r}_1$, $\mathbf{r}_2$, ... $\mathbf{r}_N$, respectively. As an approximation, it can be assumed that the field values are constant within each element and denoted E_1, E_2,..., E_N. Thereby, the following linear system of equations is obtained:

$$E_i = E_{0,i} + \sum_j g_{ij} k_0^2 (\epsilon_j - \epsilon_{\text{ref}}) E_j \Delta A, \qquad (26)$$



where it is, e.g., possible to use $g_{ij} = g(\mathbf{r}_i, \mathbf{r}_j)$ if $i \neq j$ and $\epsilon_j = \epsilon(\mathbf{r}_j)$. It may be slightly more accurate to use $g_{ij} = \frac{1}{\Delta A} \int_{\text{element } j} (\mathbf{r}_i, \mathbf{r}') d^2 r'$. However, this does not make a significant difference unless $i = j$. In that case, however, due to the singularity of the Green's function it is not possible to use $g_{ij} = g(\mathbf{r}_i, \mathbf{r}_j)$. Instead it can be acceptable to approximate the square element with a circular element having the same area and center, in which case the integral can be calculated analytically. The radius of the circle then is $a = \sqrt{\Delta A/\pi}$. This leads to the approximation

$$\begin{aligned} g_{ii} &\approx \frac{2\pi}{\Delta A} \int_{r=0}^{a} \frac{1}{4i} H_0^2(k_0 r) r dr \\ &= \frac{1}{2i(k_0 a)^2} \left[k_0 a H_1^{(2)}(k_0 a) - i \frac{2}{\pi} \right]. \end{aligned} \qquad (27)$$

The linear system of Eq. 26 can be formulated in matrix form and solved on a computer. As a small example that may also serve as an exercise for the reader, a few results are presented for scattering from the rectangular nanowire (Fig. 5) and a circular nanowire (Fig. 6).

Green's Function Integral Equation Method, Fig. 5 Magnitude of electric field normalized with the magnitude of the incident plane wave for a plane wave being scattered by a rectangular nanowire. The light wavelength is $\lambda = 633$ nm and the nanowire widths are 0.25 and 1.0 μm, respectively. The nanowire has dielectric constant $\varepsilon = 4$ and is located in free space with dielectric constant $\varepsilon_{\text{ref}} = 1$. The calculation was carried out with 10×40 area elements inside the scatterer

Green's Function Integral Equation Method, Fig. 6 The same as Fig. 5 except that light is incident on a circular nanowire with diameter 0.5 μm

Dyadic Green's Function Integral Equation Method for Three-Dimensional Problems

For a general three-dimensional scattering problem where light is scattered by one or more objects such as, e.g., a nanoparticle, the total electric field vector $\mathbf{E}$ must satisfy the equation

$$\left(-\nabla\nabla\cdot+\nabla^2+k_0^2\epsilon(\mathbf{r})\right)\mathbf{E}(\mathbf{r})=\mathbf{0}, \tag{28}$$

where $\epsilon(\mathbf{r})$ is the dielectric constant of the total structure consisting of a reference structure and one or more modifications representing the scattering objects. The incident field $\mathbf{E}_0$, which is the field in the case when no modification has been made to the reference structure, is a solution to the equation

$$\left(-\nabla\nabla\cdot+\nabla^2+k_0^2\epsilon_{\text{ref}}\right)\mathbf{E_0}(\mathbf{r})=\mathbf{0}. \tag{29}$$

A dyadic Green's tensor $\mathbf{G}$ for the reference medium is defined as a solution to the equation

$$\left(-\nabla\nabla\cdot+\nabla^2+k_0^2\epsilon_{\text{ref}}\right)\mathbf{G}(\mathbf{r},\mathbf{r}')=-\mathbf{I}\delta(\mathbf{r}-\mathbf{r}'), \tag{30}$$

where $\mathbf{I}$ is the unit dyadic tensor ($\mathbf{I}\cdot\mathbf{A}=\mathbf{A}$ for any vector function $\mathbf{A}$). In the case of a homogeneous reference medium (ϵ_{ref} being independent of the position) the dyadic Green's tensor can be expressed in terms of the scalar Green's function

$$g(\mathbf{r},\mathbf{r}')=\frac{e^{-ik_0n_{\text{ref}}|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} \tag{31}$$

satisfying

$$\left(\nabla^2+k_0^2\epsilon_{\text{ref}}\right)g(\mathbf{r},\mathbf{r}')=-\delta(\mathbf{r}-\mathbf{r}'). \tag{32}$$

The dyadic Green's function is for this special case given by

$$\mathbf{G}(\mathbf{r},\mathbf{r}')=\left(\frac{1}{k_0^2\epsilon_{\text{ref}}}\nabla\nabla+\mathbf{I}\right)g(\mathbf{r},\mathbf{r}') \tag{33}$$

which satisfies Eq. 30 and the radiating boundary condition that it corresponds to propagation away from the position $\mathbf{r}'$.

The resulting integral equation for the scattering problem is then given by

$$\mathbf{E}(\mathbf{r})=\mathbf{E}_0(\mathbf{r})+\int\mathbf{G}(\mathbf{r},\mathbf{r}')k_0^2(\epsilon(\mathbf{r}')-\epsilon_{\text{ref}})\cdot\mathbf{E}(\mathbf{r}')d^3r'. \tag{34}$$

An approach for solving Eq. 34 which is similar to the discrete-dipole approximation method [4] is again to discretize Eq. 34 into a number of volume elements where the electric field vector and the dielectric constant are assumed constant. This leads to the discretized version of Eq. 34 given by

$$\mathbf{E}_i=\mathbf{E}_{0,i}+\sum_j\mathbf{G}_{i,j}\cdot\left(\epsilon_j-\epsilon_{\text{ref},j}\right)\mathbf{E}_j, \tag{35}$$

where

$$\mathbf{G}_{i,j}=\int V_j^G(\mathbf{r},\mathbf{r}')k_0^2d^3r'. \tag{36}$$

The integral in Eq. 36 is rather difficult in the case when $i=j$ due to the singularity of the dyadic Green's tensor. An useful approach for calculating the integral (36) in that case is to exploit the expressions (32) and (33) and transform the volume integral into a surface integral with the surfaces placed at a distance from the singularity, i.e.,

$$\mathbf{G}_{i,j}=-\frac{\mathbf{I}}{\epsilon_{\text{ref}}}+\frac{1}{\epsilon_{\text{ref}}}\oint_{\text{surface of }V_i}(\hat{n}'\nabla'-\mathbf{I}\hat{n}'\cdot\nabla')g(\mathbf{r},\mathbf{r}')d^2r', \tag{37}$$

where $\hat{n}'$ is the surface outward unit normal vector. In the case when $i\neq j$, it might be acceptable to use

$$\mathbf{G}_{i,j}\approx\mathbf{G}\left(\mathbf{r}_i,\mathbf{r}_j\right)k_0^2V_j. \tag{38}$$

In the event that the difference in the dielectric constant in Eq. 34 is large, such as is, e.g., the case with metal particles in a homogeneous dielectric medium, the numerical solution of Eq. 34 becomes challenging. If the structure is divided into cubic volume elements, the representation of a curved surface becomes poor since it will be represented with a stair-cased approximation. In this case, convergence becomes slow at best but may not be achievable with any reasonable manageable number of discretization elements [7]. However, convergence can be achieved for this case as well if discretization elements are chosen that accurately represents the curved surfaces [7].

Further Reading

For a deeper study of the Green's function integral equation method for electromagnetic scattering problems, the reader is referred to the Refs. [5–7]. For a deeper study of the theory of Green's functions, the reader is referred to Refs. [8–10]. In the case of scattering from a two-dimensional periodic array of scatterers being, e.g., placed on a planar surface the appropriate Green's function is presented in, e.g., Ref. [11]. Another Green's function integral equation method where integrals are over the surface of scatterers instead of over the interior of the scatterers is available for two-dimensional scattering problems in, e.g., Refs. [6, 7] and more recently for three-dimensional scattering problems in Ref. [12]. The Green's function for a reference medium involving two semi-infinite homogeneous media separated by a planar interface is given in, e.g., [5, 7].

Preparation of complex oxide unidimensional nanostructures; Synthesis of multicationic 1-D oxide nanostructures

Definitions

One-dimensional (1D) oxide materials are anisotropic nanocrystals with large aspect ratios (length/diameter). Typically, they display diameters of 1–200 nm and lengths up to several tens of micrometers. Given their specific shape, 1D oxides are found in the literature under different names: nanowires, nanorods, nanotubes, nanobelts, nanofibers, whiskers, etc.

To date, different approaches have been proposed to achieve 1D growth of oxides with

different degrees of control over the growth process. These approaches are based on (i) taking advantage of the inherent anisotropic crystallographic structure of certain solids to promote the 1D growth, (ii) using organic additives or surfactants to kinetically control the oriented attachment of some crystallographic facets of a seed to finally form 1D nanostructures, (iii) using hard or soft templates (with 1D porosity) to directly grow nanowires and/or nanotubes, or (iv) controlling the condition of supersaturation to modify the tendency of seed to growth.

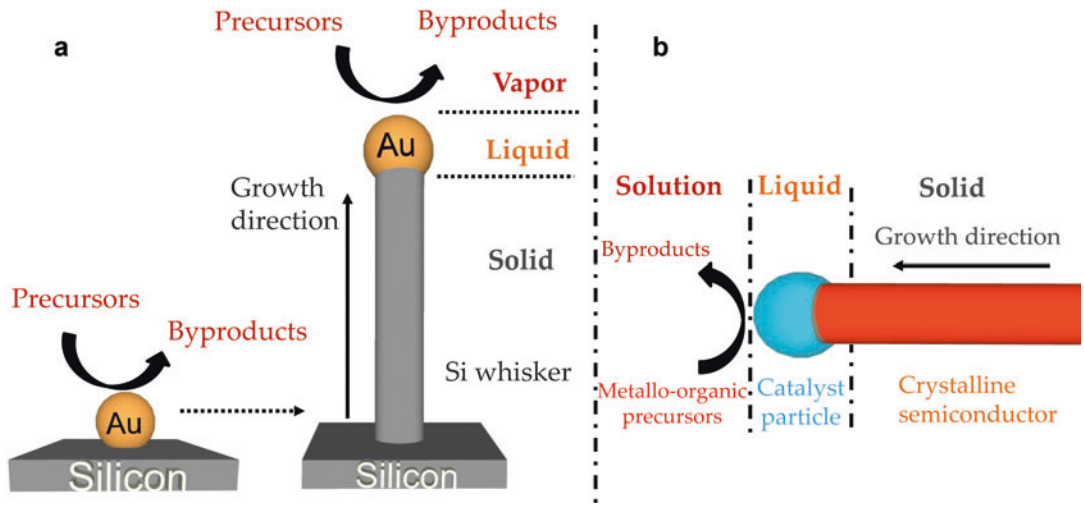
Multinary oxides, also named functional complex oxides, are materials that contain two or more metals in a precise ratio. The preparation of these oxides is to date a key challenge in materials science development.

Introduction

1D nanomaterials have attracted significant attention due to their inherent anisotropic nature, high surface area, structure-related properties resulting from confinement effects, and the possibility to be incorporated into devices. In addition, mixed-metal oxides are key components for many technological applications. These functional materials often contain one or more transition-metal elements whose oxidation states are central to define their magnetic, electronic, or redox properties. Transition-metal oxides exhibit rich physical properties expanding from insulators to semiconductors, metals, and superconductors. Their bandgap span from the visible to the ultraviolet energy regimes and their magnetic properties can be diamagnetic, paramagnetic, ferromagnetic, and antiferromagnetic. Their dielectric properties are shown to be notorious in both the low-k and high-k regimes, and they can also be ferroelectric and piezoelectric. All these properties make 1D nanostructures of complex metal oxides excellent candidates for a wide range of applications including the fabrication of advanced and more efficient devices associated with solar cells, energy storage, fuel cells, communications, information storage, sensors, catalysis and medical imaging, diagnosis, and detection. As a result, to date, different methods of synthesis are being investigated to generate 1D nanostructures of functional oxides with a precise control over their chemical composition, size, shape, and crystallinity.

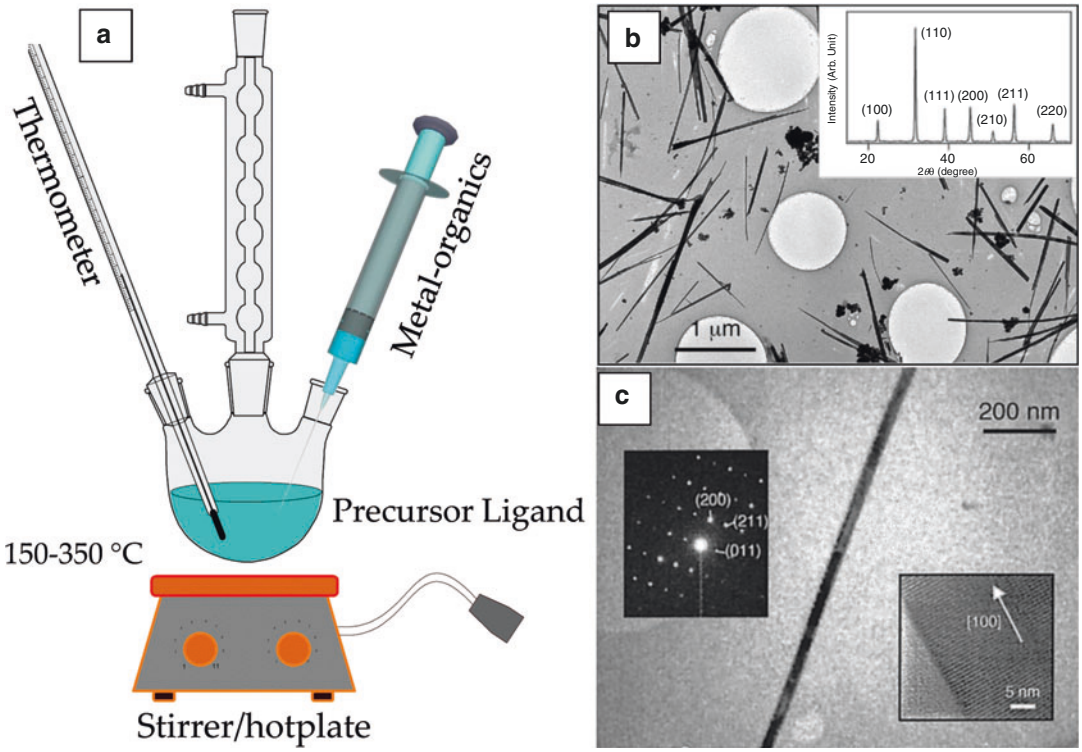
The preparation of nanostructures can be distinguished between two well-defined approaches: (i) *top-down approach* which follows conventional lithography and, more recently, new and sophisticated electron and ion beam lithography to develop such nanostructures and (ii) *bottom-up approach* where defined complex nanostructures are "built up" through self-assembly processes, i.e., they use smaller units to create the nanometer-sized features with the desired shapes and/or dimensions. Top-down techniques are usually based on patterning a given shape using lithographic methods (including photolithography, electron beam lithography, electrochemical dip-pen lithography, etc.) that are thereafter removed by wet chemical etching, focused ion beam (FIB) milling, or reactive ion etching (RIE). However, these methods tend to be rather expensive, technically challenging, tedious, time-consuming, and relatively low throughput. In contrast, bottom-up chemical synthesis methods offer an alternative strategy to produce nanostructures with large material diversity, easy setup and good control over stoichiometry and doping, and the possibility of coating large and uniform areas.

Materials with a highly anisotropic crystallographic structure grow along a well-defined crystallographic direction. As a result, the 1D morphology can be spontaneously achieved. In this context, chemical solution-based synthesis methods have been proposed as the main routes to achieve a 1D growth in oxide materials. The approaches based on chemical solutions include (i) the use of organic additives or surfactants that kinetically control the oriented attachment of some crystallographic facets of a seed to finally form 1D nanostructures, (ii) the use of oriented attachment of nanocrystals to form 1D nanostructures, (iii) the confinement of 1D growth by using a hard or soft template with 1D porosity, or (iv) the control of supersaturation to modify the tendency of the seeds growth.



Catalytic Growth of Nanowires: Vapor–Liquid–Solid (VLS) and Solution–Liquid–Solid (SLS) Methods

The synthesis of 1D nanostructures using vapor–liquid–solid (VLS) and solution–liquid–solid (SLS) methods through confinement under a liquid drop has been the center of large efforts (see Fig. 1). These methods have been especially used to prepare nanowires of semiconductors such as Si, GaAs, and ZnO [1]. Briefly, a liquid droplet is used as a catalyst seed. As a result, each liquid droplet will work as a soft template to strictly limit the lateral growth of an individual wire. The precursor is then introduced as a vapor (VLS) or as a solution (SLS) that will be dissolved into the catalyst droplet. When the droplet is supersaturated with a given dissolved species, the nanowire starts to grow. The diameter of the nanowire is consequently determined by the size of the catalyst droplet.



The VLS and SLS methods are better suited to produce single elements and binary semiconductors and oxides than complex materials such as ternary or quaternary oxides. The main reason for that is the need of more complex precursors and the corresponding difficulty in controlling the growth conditions and stoichiometry at the atomic level. Additionally, VLS or SLS growth of nanowires is restricted to systems that can form eutectic with catalysts at growth temperature. Unfortunately, for many of complex oxides, there is very limited information about the formation of eutectic liquids. In the case of multicomponent oxides, a precise control over the stoichiometric composition is possible only by chemical solution methods. Interestingly, when combined with template-mediated synthesis, it offers the possibility to produce aligned unidirectional and uniformly sized 1D oxide nanostructures over large areas which is highly attractive for device fabrication and the study of collective phenomena.

Chemical Solution Synthesis

1D complex functional oxide nanostructures can be produced, among other methods, by wet chemical methods. In this case, it is possible to obtain a large diversity of multielemental oxides with a number of cations that can exceed over four or five elements. Typically, soft chemistry provides high melting point compounds with a desired composition and structure which at low or mediate temperatures are otherwise difficult to form with a homogeneous composition. Therefore, these synthesis methods make it possible to

[3]. Copyright (2002) American Chemical Society)

control and to keep fixed the stoichiometry already present in the solution in a very reproducible way. Moreover, these methods avoid long-time calcinations at high temperatures, and, finally, they permit the production of large amounts of 1D nanostructure powders.

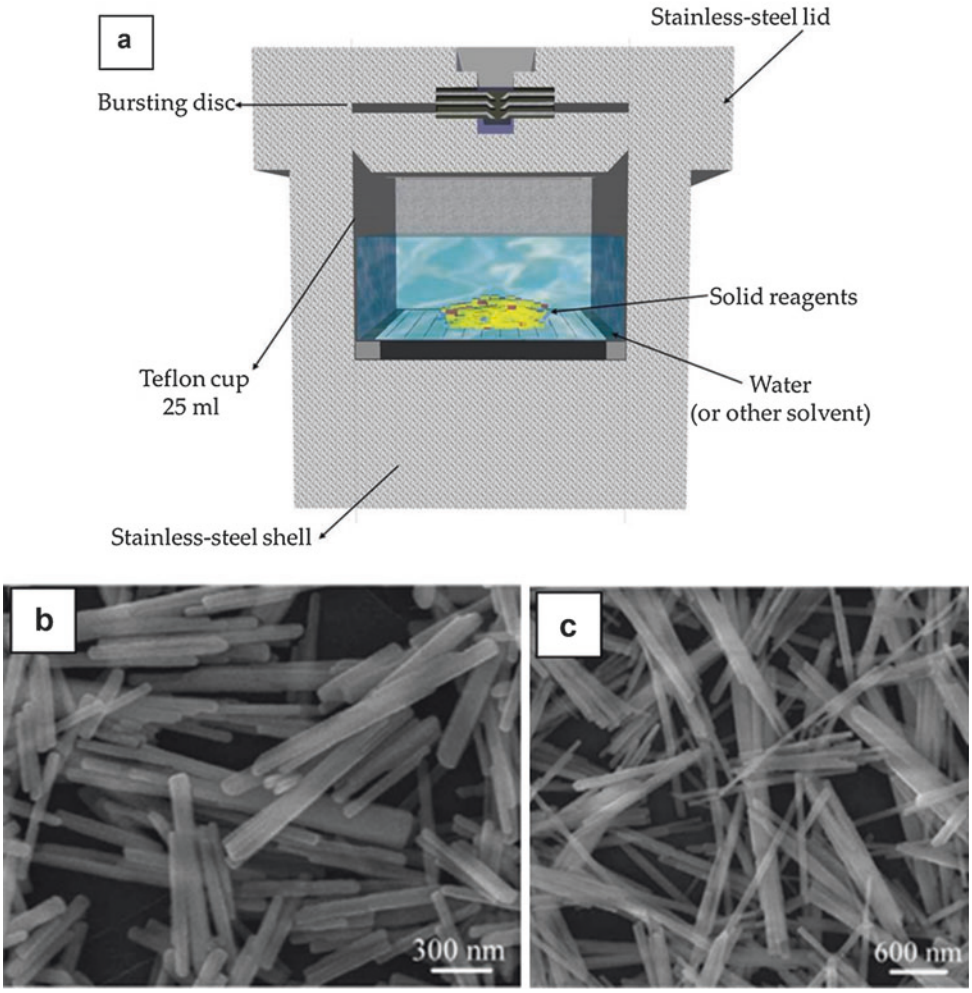
Wet chemistry includes (i) solution-phase decomposition, (ii) electrochemical techniques (including deposition and electrospinning), or (iii) hydrothermal, molten salt and template based synthesis methods. In all cases, the precursor compounds play a significant role. In this context, the fundamental purpose of wet chemistry is to design specific new precursors or to modify the existing ones in order to develop novel 1D oxide nanostructures.

Solution-Phase Decomposition Synthesis

This methodology uses the decomposition of bimetallic alkoxide precursors in the presence of coordinating ligands. As a result, it is possible to successfully obtain multicationic oxide nanowires. The main advantage of this procedure is the possibility to control the correct product stoichiometry and to avoid high-temperature treatment steps. Figure 2 shows a schematic illustration of the typical reaction apparatus involved in the synthesis of solution-phase oxide nanowires [2]. Notice that rapid injection of organometallic reagents in a hot coordination solvent produces temporally discrete homogeneous nucleation. The decomposition and nucleation occurs rapidly upon injection.

Following this approach, Urban et al. successfully synthesized [001]-$BaTiO_3$ ferroelectric nanowires [3]. The authors used an excess of H_2O_2 that was added at 100 °C to a heptadecane solution containing a 10:1 molar ratio of BaTi $[OCH(CH_3)_2]_6$ to oleic acid. The reaction mixture was then heated to 260 °C for 6 h, producing the formation of nanowires. In this case, the anisotropic growth takes place after the precursor decomposition and crystallization in a structured inverse micelle medium formed by precursors and oleic acid under the reaction conditions. These nanowires were found to be ferroelectric, exhibiting hysteresis loops with a coercive field of 7 kV/cm^{-1}.

Hydrothermal Synthesis

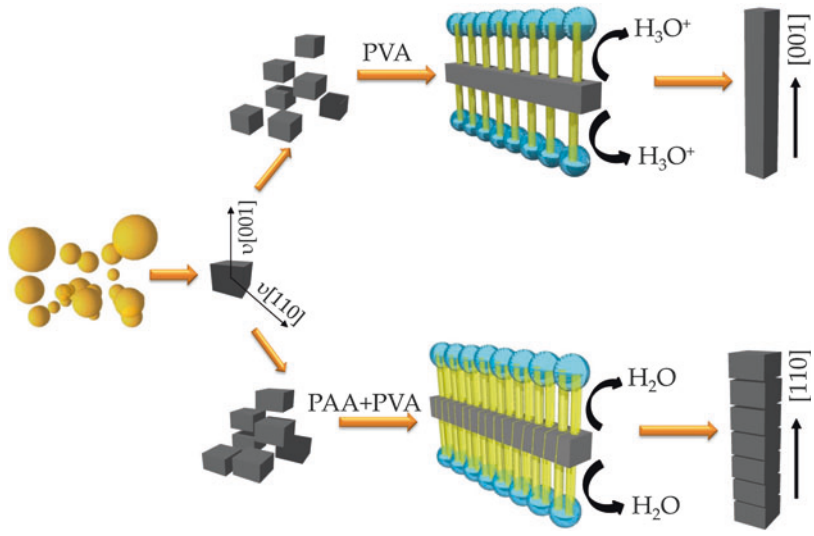


Hydrothermal synthesis is based on heating the chemical solution in a sealed vessel (autoclave). This procedure will increase the autogenous pressure inside the vessel beyond atmospheric pressure as the temperature exceeds the boiling point of the solvent [4]. As a result, the solubility and reactivity of the precursors used in the material synthesis are increased. When water is used as solvent, the process is called hydrothermal, whereas in the case of using a nonaqueous solvent, the process is termed solvothermal. Importantly, the hydrothermal synthesis exploits the enhanced solubility and reactivity of almost all inorganic substances in solvents at elevated temperatures and pressures, therefore, allowing the subsequent crystallization of the dissolved material/precursor ions from the solution under these conditions.

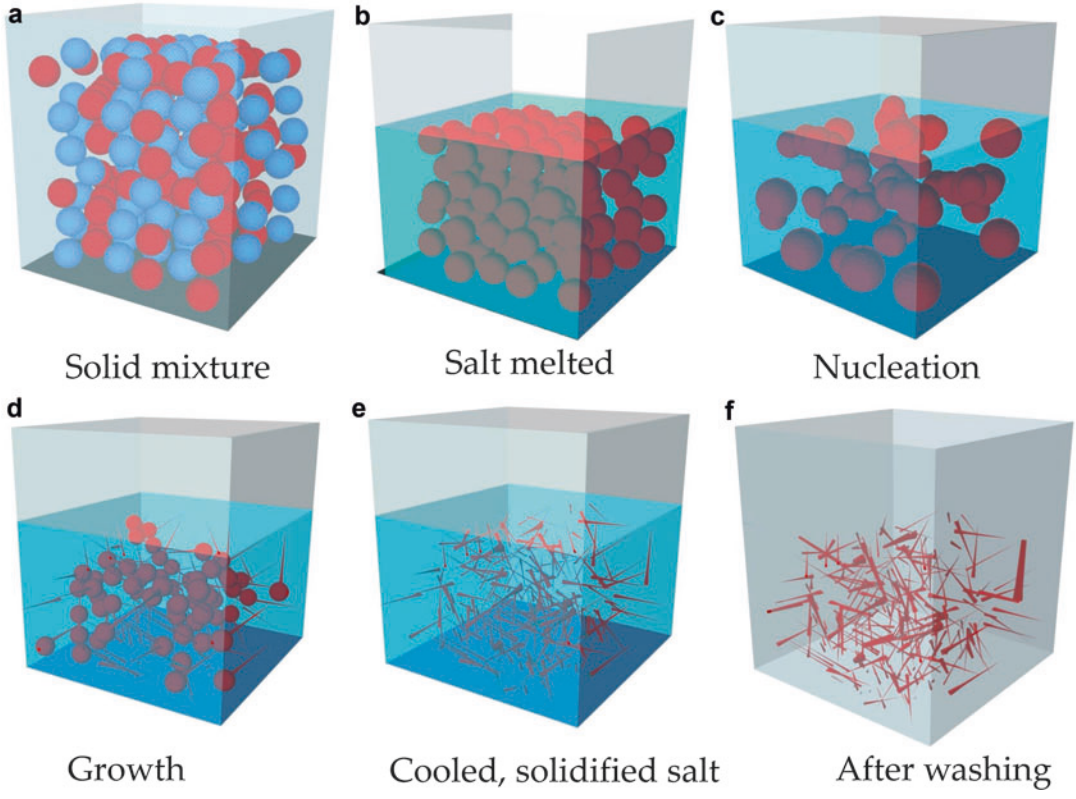
The hydrothermal synthesis is typically performed by placing the selected precursor, the mineralizer, and the additives all together with the solvent in the autoclave, as illustrated in Fig. 3. Normally, stainless steel autoclaves with a Teflon® lining are used which allows to avoid any eventual contamination from the steel. Precursors can be oxides, hydroxides, or salts of the elements required to build up the material. The autoclave is heated either by placing it in an oven or by using microwaves. The phase composition and morphology of the final product can be tuned by small changes in the chemical parameters such as the type of precursors, concentration, pH as well as process parameters like temperature and reaction time.

Only for materials with an anisotropic crystallographic structure, the 1D growth along one specific crystallographic direction can be directly obtained by hydrothermal synthesis. As an example, Fang et al. [5] were able to grow single-crystal lanthanide orthophosphate (e.g., $LaPO_4$) 1D nanowires by a simple hydrothermal synthesis route. In this case, the anisotropic crystal structure of these compounds facilitates the crystal growth along the *c*-direction. SEM images of two different synthesized $LnPO_4$ nanowires by hydrothermal treatment are displayed in Fig. 3. In most cases, and especially for materials with a cubic or pseudocubic crystal structure, the 1D directed growth approach has to be applied in order to achieve a 1D growth. This includes using precursors with a 1D nanostructure, taking advantage of appropriate organic additives (surfactants), or using the principle of oriented attachment of nonspherical nanocrystals. As an example, single-crystalline $KTa_{0.25}Nb_{0.75}O_3$ (KTN) nanorods with an orthorhombic perovskite structure were synthesized via a polymer-assisted hydrothermal method [6]. The preferred crystallographic orientation of the nanorods was found to be controllable by using different types of polymers in the process (see Fig. 4). As a result, the [001]-oriented KTN nanorods were obtained upon the use of polyvinyl alcohol (PVA), and the [110]-oriented ones were formed with the use of a combination of polyacrylic acid (PAA) and PVA. Since surfactants are capable to stabilize certain surfaces by selective adsorption, the difference in the growth rate between different crystallographic directions can be accentuated, therefore, giving rise to nanorods oriented along different growth directions.

Molten-Salt Synthesis



The molten-salt synthesis (MSS) method is straightforward and very versatile. In addition, it offers cost-effective approaches suitable for obtaining crystalline, chemically pure, and single-phase nanostructures at low temperatures. The main processing steps associated to the MSS



Growth of 1-D Oxide Nanostructures, Fig. 3 (**a**) Schematic representation of a typical stainless steel autoclave used for the hydrothermal synthesis (Adapted from Ref. [4]). method are illustrated in Fig. 5. Essentially, oxides and/or other appropriate precursors according to the desired compound are mixed with either a given salt (e.g., NaCl) or an eutectic mixture of salts (e.g., $NaNO_3/KNO_3$, NaCl/KCl). Then, they are fired at a temperature above the melting point of the salt medium to form a molten flux. At this temperature and under these specific conditions, the precursor molecules will disperse, dissociate, diffuse, and then rapidly rearrange throughout the salt. In this way, the particles of a given metal-oxide phase are formed through an initial nucleation step followed by a growth process that strongly depends on the identity of the salt species, the quantity of salt used in the reaction medium, the temperature at which the reaction is performed, and the reaction duration. After cooling down, the salt itself can be simply eliminated by washing out with an aqueous solution. Upon drying, it is unlikely to obtain agglomerated nanowires after applying the appropriate processing.

Molten-salt synthesis has been used to prepare pristine $BaTiO_3$ nanowires with diameters ranging from 50 to 80 nm and with aspect ratios ranging from 1 to larger than 25 [7, 8].

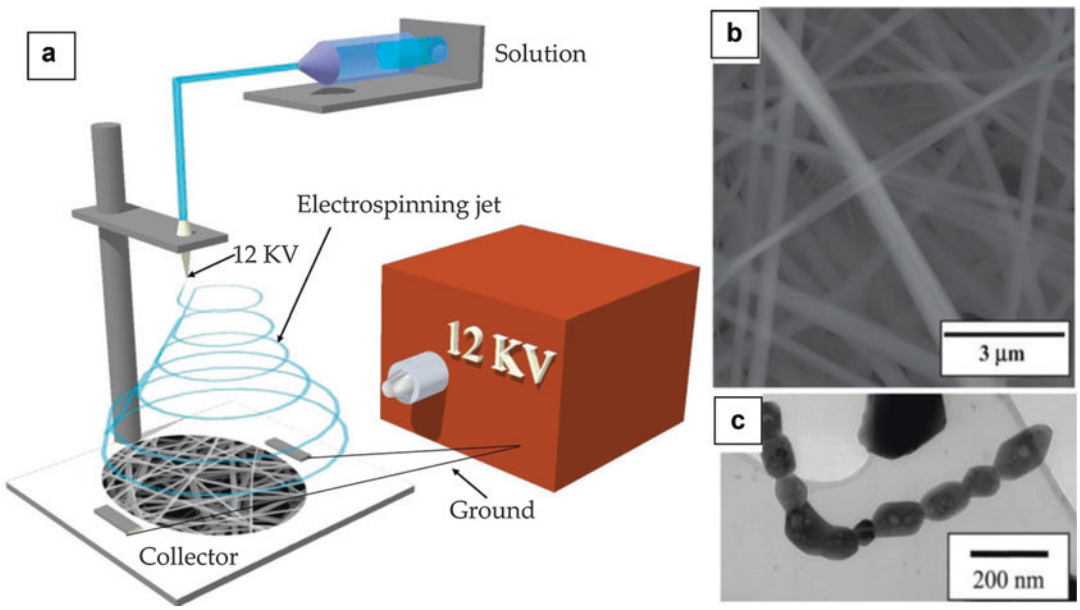
Growth of 1-D Oxide Nanostructures, Fig. 5 Schematics displaying the different steps involved in the molten-salt synthesis of metal-oxide nanowire materials (Adapted from Ref. [8])



Electrospinning Synthesis

Electrospinning is another feasible solution-based process for the synthesis of 1D nanomaterials, in particular, to obtain nanofibers with very high surface area-to-volume ratios. These nanofibers can be synthesized under different morphologies. Specifically, solid, porous, hollow, core–shell, and compoundA/compoundB type have been successfully obtained using this technique. Typically, the electrospinning setup is reader simple and requires only a syringe with a metal needle, a conductive (grounded) collector, and a high-voltage power supply [9], as displayed in Fig. 6. Briefly, a solution or melt of the desired material is placed in the syringe. The application of a sufficiently strong electric field to the needle (electrode) results in a cone-like deformation of the solution droplets, from which a jet protrudes toward the collector (counter electrode). During the ejection from the needle toward the collection plate, solid nanofibers of the material can be formed on the collection plate by either solidification of the melt or by evaporation of the reaction solvent. As-prepared fibers often require an additional thermal annealing step in order to achieve sufficiently high crystalline materials.

As an example, we show, in Fig. 6, $BaZrO_3$ nanofibers that were electrospun from a 0.25 M metal cation solution containing barium acetate and zirconium (IV) 2,4-pentanedionate dissolved in glacial acetic acid [10]. Polyvinylpyrrolidone was added to increase the solution viscosity and to further allow the formation of hollow fibers during electrospinning. The microstructural evolution during thermal annealing at temperatures between 600 °C and 1,400 °C revealed a crystal growth evolution. Strong grain coarsening was also observed above 1,200 °C, leading to linear and branched nanoparticle chains that were formed from the finer initial hollow nanofibers. The faceting of the nanoparticles took place under low-energy surfaces.

Template-Assisted Synthesis

The synthesis of 1D nanostructures using templates supposes a very convenient and

Growth of 1-D Oxide Nanostructures, Fig. 6 (**a**) Schematics of a typical electrospinning setup using a grounded static collector. Reprinted with permission from reference [9]. (**b**) Typical SEM image showing as-spun $BaZrO_3$ fibers and (**c**) TEM image of faceted $BaZrO_3$ nanoparticle chains formed after crystallization at 1,400 °C (Adapted from Ref. [10]. versatile method. This technique represents a conceptually straightforward approach to the generalized synthesis of nanostructures first introduced by Martin [11]. In this method, the template is used as scaffolds in which are possible to synthesize materials with different morphologies. The obtained material within the template's pores is composed of a nanostructure that matches that of the template's morphology. The chemical and physical properties of the template membranes (i.e., pore size and geometry) enable a high degree of control over the dimensions of the resulting 1D nanostructures.

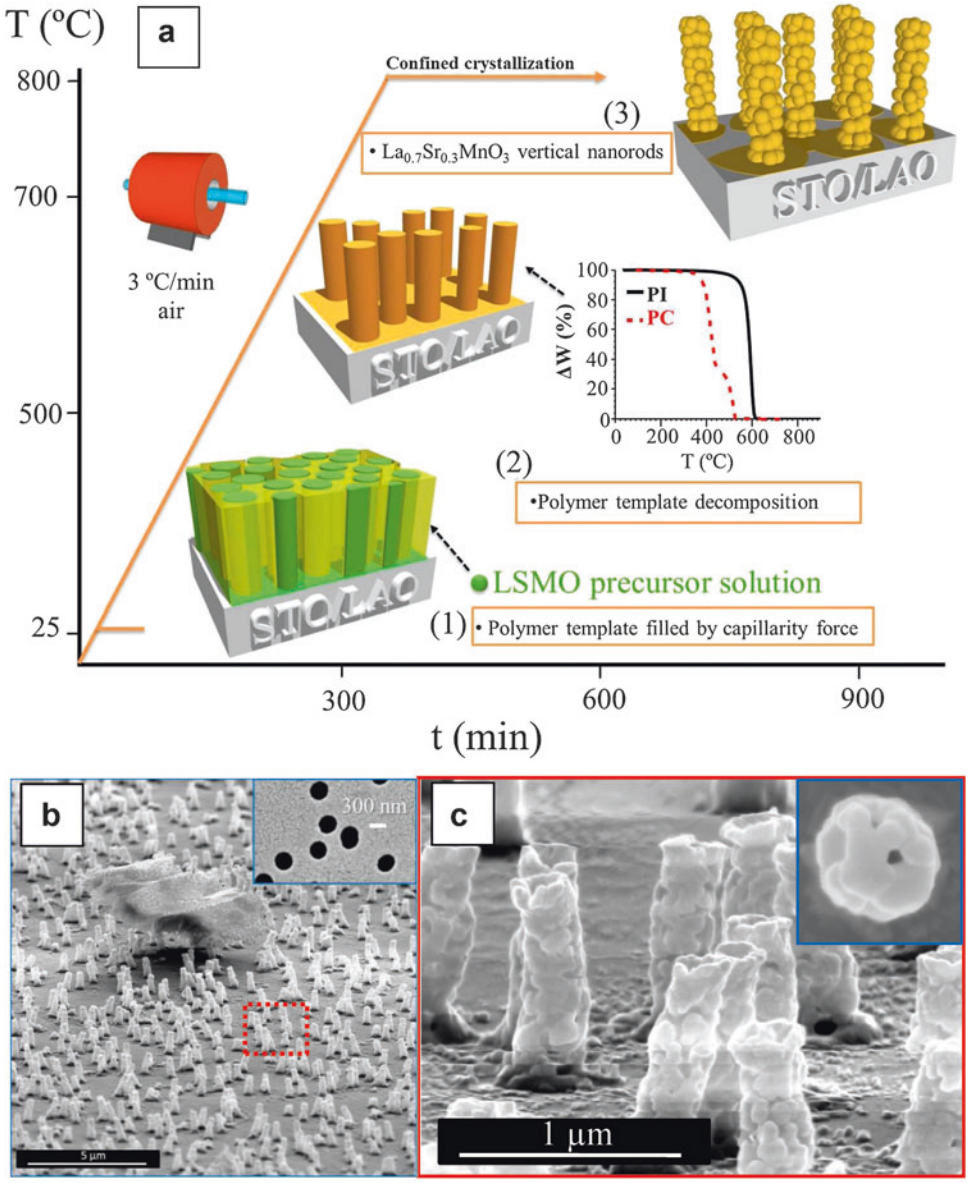
Many different types of template membranes have been successfully used, and it is generally agreed that this synthesis method is a relatively simple, reasonably high-throughput, and cost-effective procedure and, therefore, of general applicability. There are two main types of templates: "soft" templates and "hard" templates. Naturally occurring gels, micelles, and chitin scaffolds are considered as soft templates. Other soft templates include DNA strands, polymer matrices, and reverse micelles. Hard templates are typically associated with materials such as track-etched polymeric membranes and anodic alumina membranes which are both commercially available.

Direct Template Filling The direct filling of a template with a precursor solution is one of the most straightforward and versatile methods for preparing nanowires or nanorods. In the following section, we present some interesting examples on the preparation of 1D nanostructures of mixed-metal oxides by combining sol–gel processing and hard nanoporous templates.

A key issue for the synthesis of 1D nanostructures following this method is the preparation of stable starting precursor solutions which can be tuned according to the desired composition and its ability to fill the template nanopores by capillary force. Metallic nitrates which are completely soluble in water and possess long-term stability are often the precursors of choice. Good control over viscosity, wettability, stoichiometry, and stability of the precursor solution has been identified as crucial parameters for the template-mediated synthesis. In some cases, a polymerizing agent such as ethylene glycol (EG) can be used in order to reach the optimum viscosity. After template filling by capillary forces, different thermal treatments under an oxygen-rich atmosphere are further applied in a tubular oven for the ultimate phase formation and crystallization. However, the same precursor solution may have a very different wetting behavior when filling high surface tension templates such as nanoporous alumina or low surface tension track-etched porous polymer templates with low surface tension. This scenario gives rise to the formation of nanorods or nanotubes, respectively.

Anodic Aluminum Oxide Membrane Templates A recent example, showing the applicability of template-mediated synthesis, is the formation of self-standing $La_{0.7}Sr_{0.3}MnO_3$ nanotubes that were synthesized using a sol–gel precursor solution combined with porous alumina templates [12]. The nanotubes were prepared from a precursor solution containing 0.5 mol/L of lanthanum, strontium, and manganese nitrates in the proportion 07:0.3:1, respectively, in water. In this case, commercially available anodic aluminum oxide (AAO) membrane templates (Whatman®, pore diameters 100 and 200 nm) were used. The templates were immersed in the precursor solution at room temperature for different holding times ranging from 1 h to 56 h. Subsequently, the templates containing the precursor gel were heated at high temperatures by using a tubular furnace in oxygen atmosphere. The resulting nanotubes displayed outer diameters of 100 nm or 200 nm and wall thicknesses of approximately 20 nm−40 nm (see Fig. 7), depending on the template pore dimension with lengths of few micrometers. The synthesized $La_{0.7}Sr_{0.3}MnO_3$ nanotubes were polycrystalline due to the heterogeneous nucleation within the AAO pore walls and ferromagnetic with a Curie temperature of 350 K, i.e., close to the reported $La_{0.7}Sr_{0.3}MnO_3$ bulk value.

Track-Etched Polymer Templates One of the main drawbacks of using hard templates for the synthesis of 1D nanostructures relates to the ultimate template removal which is a requirement for



Growth of 1-D Oxide Nanostructures, Fig. 7 (**a**) Thermogravimetric analysis of the nitrate precursor solution, heating ramp 3 °C/min until a maximum temperature of 900 °C was reached. Schematic representation of AAO nanopore filling process and posterior nanotube formation at elevated temperatures is described. (**b**)Top view field emission SEM image of vertically aligned nanotubes obtained using an AAO membrane with 200 nm pore size (800 °C, 5 h) after partial removal of the AAO template. (**c**) TEM image of an isolated $La_{0.7}Sr_{0.3}MnO_3$ nanotube, the inset shows the corresponding selected area electron diffraction (SAED) pattern (Reproduced from Ref. [12] with permission from the Centre National de la Recherche Scientifique (CNRS) and Elsevier, with kind permission from Springer Science and Business Media)

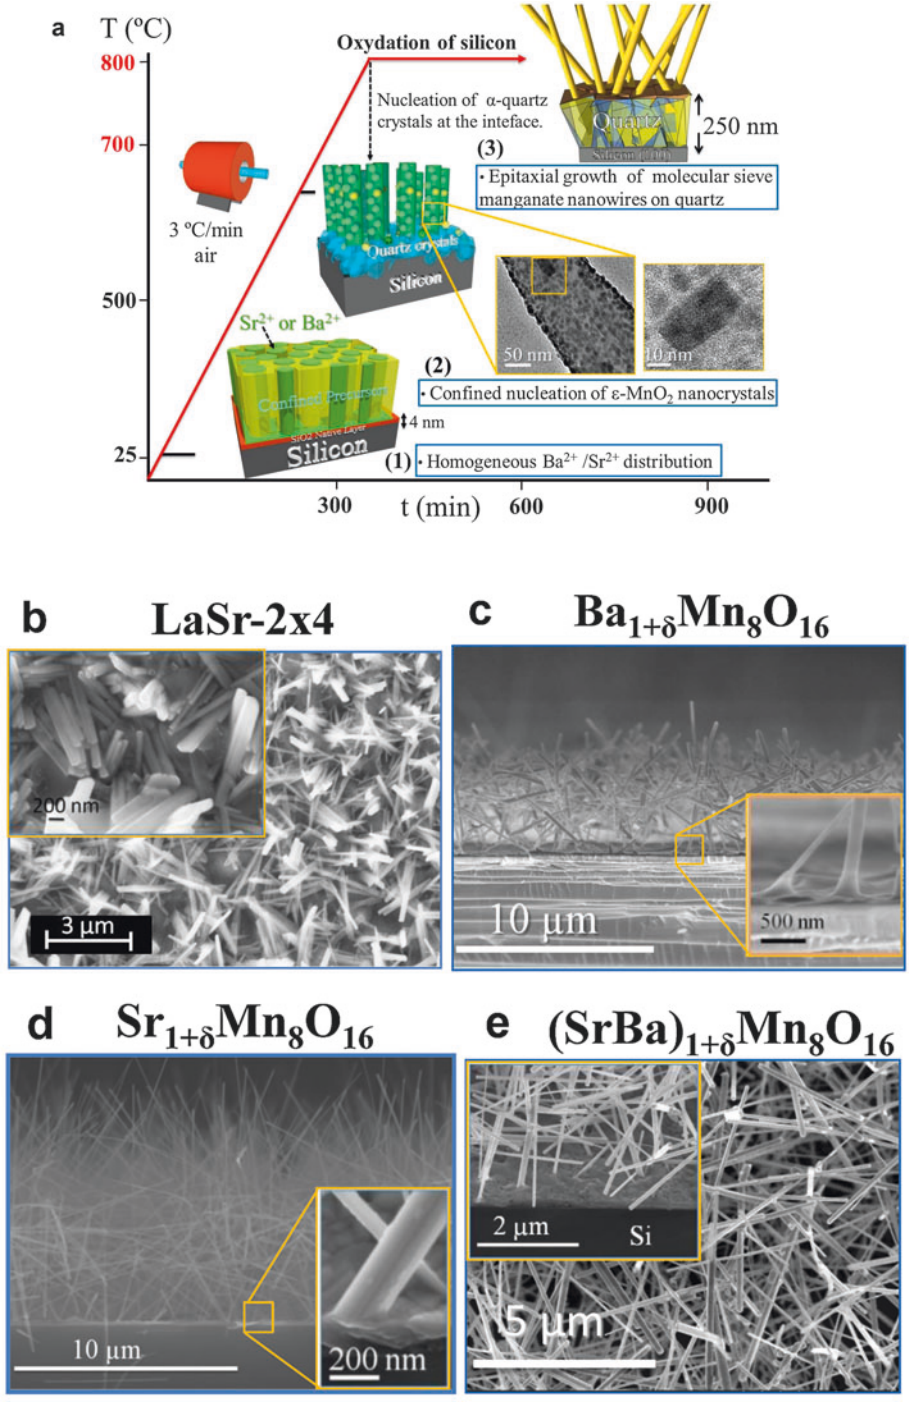
many technological applications. However, polymer templates display low decomposition temperatures (300–500 °C) which enable their easy elimination during growth processes when the right thermal conditions are chosen. In the following, we will present some examples concerning the preparation of 1D nanostructures of mixed-metal oxides by combining sol–gel processing and track-etched nanoporous polymer templates.

Vertical polycrystalline $La_{0.7}Sr_{0.3}MnO_3$ nanorods can be synthesized using chemical solution deposition assisted by polycarbonate (PC) or polyimide (PI) nanoporous templates on $SrTiO_3$ (STO) and $LaAlO_3$ (LAO) substrates [13]. In this case, the key point to maintain the verticality of the nanorods synthesized at high temperatures was the similar perovskite crystallographic structures of $La_{0.7}Sr_{0.3}MnO_3$ nanorods and substrates. The difference in the lattice parameters between $La_{0.7}Sr_{0.3}MnO_3$ and the substrates was minimal, yielding a nominal tensile lattice mismatch of $\varepsilon \approx 0.9$ % for STO and a larger but compressive magnitude of $\varepsilon \approx -2$ % for LAO substrates. Consequently, filling nanoporous track-etched polymers (≈1 μm thick) supported on STO and LAO substrates with the nitrate-based precursor solution under a thermal treatment at 800 °C resulted in a final nanostructured perovskite substrate with vertically oriented nanorods of 1 μm high, as summarized in Fig. 8.

In this case, the nanorods were polycrystalline and were indexed according to the standard

Growth of 1-D Oxide Nanostructures, Fig. 8 (**a**) Schematics of the different stages during the formation process of $La_{0.7}Sr_{0.3}MnO_3$ vertical nanorods on STO or LAO substrates. (*1*) Track-etched nanoporous polymer template supported on a LAO or STO substrate filled with the $La_{0.7}Sr_{0.3}MnO_3$ precursor solution. (*2*) At mild temperatures (500–600 °C), the polymer template is decomposed as thermogravimetric analysis indicates. Thus, surface was fully covered with vertical amorphous nanorods that kept the position of initial pores. (*3*) At high temperatures (800 °C), the crystallization on $La_{0.7}Sr_{0.3}MnO_3$ nanorods is promoted. (**b**) Tilted FEG-SEM image of $La_{0.7}Sr_{0.3}MnO_3$ vertical nanorods grown on top of a (100)-STO substrate. $La_{0.7}Sr_{0.3}MnO_3$ nanorods have a 250 nm of diameter and a density of 1×10^8 cm^{-2}. (**c**) FEG-SEM enlarged image of $La_{0.7}Sr_{0.3}MnO_3$ nanorods with a diameter of 250 nm grown on top of a STO single crystal. The inset shows a FEG-SEM image showing the top view details of $La_{0.7}Sr_{0.3}MnO_3$ nanorod grain size (Reproduced with permission from The Royal Society of Chemistry (RSC) on behalf of the Centre National de la Recherche Scientifique (CNRS) and the RSC)

rhombohedral structure and space group $R-3c$ of $La_{0.7}Sr_{0.3}MnO_3$ perovskite. They were ferromagnetic with Curie temperature (Tc) values around ~360 K, i.e., close to the reported bulk $La_{0.7}Sr_{0.3}MnO_3$ value. Altogether, these results prove the capability of the chemical solution deposition method combined with track-etched polymer templates to generate homogeneous nanostructured surfaces with vertical $La_{0.7}Sr_{0.3}MnO_3$ nanorods displaying interesting magnetic properties.



Epitaxially Stabilized Metastable Phases of 1D Oxide Nanostructures It has been shown that polymer template nanopores can be used not only as a mere physical spatial constrains but also as nanoreactors in which confined nucleation favors the stabilization of particular metastable seed nanostructures. Additionally, once the polymer template is decomposed during thermal treatment, the atomic structure of the substrate can be effectively used as a second template for phase stabilization and epitaxial growth. In the following, we present two examples of the fundamental role of the substrate as a determinant for polymorph stabilization, geometry, and orientation of the grown nanostructured oxides.

Following the same synthesis method as described above and the same precursor solution, the stabilization of a different polymorph of $La_{0.7}Sr_{0.3}MnO_3$ with highly interesting magnetic properties was achieved by using silicon substrates. In this case, the nanowire growth mechanism entails the controlled growth of an α-quartz thin film at the silicon surface which allowed octahedral molecular sieve (OMS) nanowires of different compositions to stabilize and crystallize [14, 15]. Manganese oxide OMS are 1D open framework structures with nanometric tunnel sizes. The tunnels are built up by edge-shared and corner-shared [MnO_6] octahedral units leading to different pore size materials. The shape of the tunnels is expressed as the number of constituting octahedral units ($n \times m$) and is characteristic of each porous manganese oxide.

Figure 9 shows a detailed scheme of the proposed mechanism for the formation of OMS nanowires on top of silicon substrates, based on the combination of soft chemistry routes and confined epitaxial growth. First, precursor solutions with a composition that can be tuned in order to fill the polymer template nanopores by capillary forces were used in step 1 in Fig. 9. The confinement imposed by the polymer template in high aspect ratio nanopores induced the formation of ε-MnO_2 nanoparticles at low temperatures (~500 °C) during the calcination of the precursor solution, step 2 in Fig. 9. These ε-MnO_2 phase nanoparticles served as seeds for the further growth of manganate nanowires at higher temperatures, once the polymer template has been eliminated. The synthesis of manganate structures required sufficiently high temperatures to enhance atomic mobility and, thus, to allow the diffusion of the alkaline earth and rare earth cations into the empty 1D channels of the ε-MnO_2 structure.

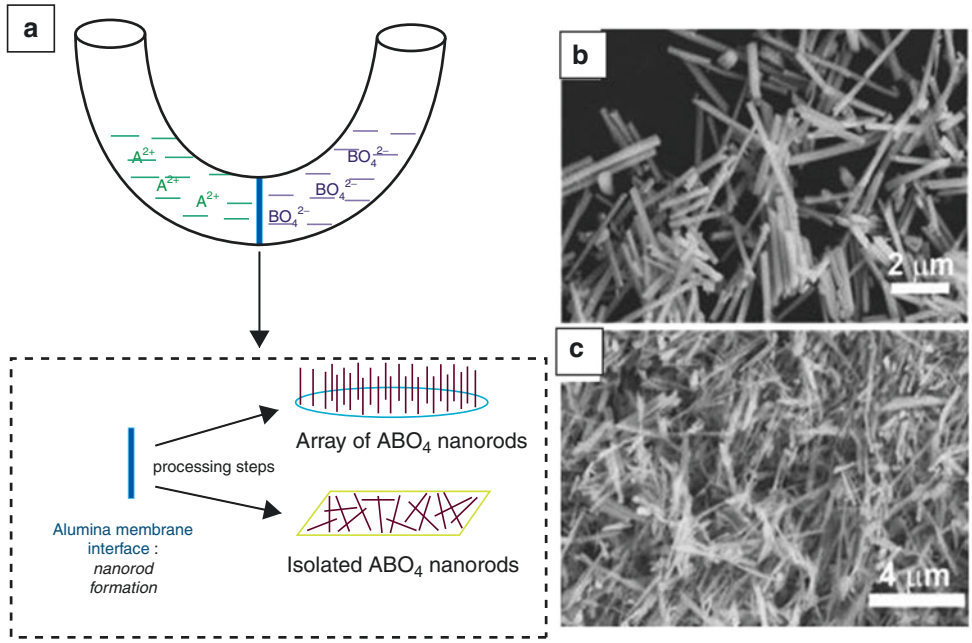
The second essential requirement for the growth of manganese oxide-based OMS nanowires on silicon is the role of the α-quartz layer acting as an epitaxial template for the stabilization of the nanowires. α-quartz thin films were obtained after thermally activated devitrification of the native amorphous silica surface layer assisted by the heterogeneous catalysis driven by alkaline earth Sr^{2+} cations present in the precursor solution [14]. This polycrystalline α-quartz film rendered the convenient interface lattice matching to the complex oxide nanostructures for the epitaxial growth of vertically oriented LaSr- 2 × 4 manganate nanowires at 800 °C, step 3 in Fig. 9, as revealed by scanning transmission electron microscopy (STEM) analysis.

The proposed unit cell of LaSr-2 × 4 nanowires based on the X-ray diffraction and STEM analysis was monoclinic with lattice parameters $a = 13.8$ Å, $b = 5.7$ Å, $c = 21.8$ Å, and $\beta = 101$ ° where the long axis of the nanowires is along the b crystallographic direction. High-resolution TEM images revealed that the orientation relationship can be described as (010) LaSr-2 × 4// (010) α-quartz and an in-plane epitaxial relationship given by [20–2] LaSr-2 × 4// [−101] α-quartz. Interestingly, these synthesized LaSr-2 × 4 nanowires exhibited ferromagnetic ordering with strongly enhanced Curie temperature ($T_c > 500$ K) that probably results from the new

Growth of 1-D Oxide Nanostructures, Fig. 9 (**a**) Schematics of the different stages of the crystallization process of single-crystalline OMS nanowires on silicon. (*1*) Track-etched nanoporous polymer template supported on a SiO_2/Si substrate filled with the chemical precursor solution allowing a homogeneous distribution of Ba^{2+} or Sr^{2+} melting agent. (*2*) At mild temperatures (500–600 °C) MnO_2 nanoparticles nucleated and stabilized due to the confinement in high aspect ratio nanopores (see *inset* HRTEM images showing the nucleation of MnO_2

crystallographic order between the La^{3+} and Sr^{2+} cations ordered inside the 2 × 4 1D channels defined by the MnO_6 octahedral and from the mixed valence of manganese [16].

This synthetic approach based on track-etched polymer templates technology combined with a chemical solution deposition route provides direct access to the monolithic integration of composition controlled vertical OMS nanowires, epitaxially grown on silicon substrates. As a result, this procedure has been successfully extended to other nanowire compositions including $Ba_{1+\delta}Mn_8O_{16}$, $Sr_{1+\delta}Mn_8O_{16}$, and $(BaSr)_{1+\delta}Mn_8O_{16}$ [17], as displayed in Fig. 9.



The directional growth of LaSr-2 × 4 nanowires when using gadolinium-doped CeO_2 substrates with the fluorite structure illustrates the determinant influence of the substrate on the nanostructure characteristics [18]. In this case, using the same growth method described above at temperatures above 1,000 °C, the system evolved toward its equilibrium state to form horizontal and oriented LaSr-2 × 4 nanowires with the [010] nanowire's longitudinal axis parallel to the [110] and [1–10] directions of the substrate. The large intrinsic anisotropy of the monoclinic LaSr-2 × 4 structure is what promoted the 1D growth along the nanowire [010] direction (the direction of the smallest interplanar distance). This fact combined with the low isotropic residual misfit along the <110> directions of the CeO_2 substrate (the estimated residual misfit is of 0.74 %) permitted the self-assembly of LaSr-2 × 4 nanowires along these directions [18].

The Template-Assisted U-Tube Method The template-assisted U-tube method is an excellent illustration on how the pores of a nanoporous hard template may act as nanoreactors. In this case, it is possible to fabricate 1D oxide materials in a more responsible and environmentally friendly manner. This approach is based on using a double-diffusion setup in which a desired membrane is sandwiched between the precursor half-cells of a U-shaped tube, as schematically shown in Fig. 10. Precursor solutions are suitably added to both sides of the so-called U-tube cell. The diffusion causes the precursor ions to enter into the pore channels where they react, thereby, forming 1D structures (nanorods or nanotubes) [19]. In this case, the template nanopores also act as nanoreactors. This technique is readily compatible with a variety of common chemical reactions, such as reduction of metal precursors or precipitation reactions, therefore, offering the possibility to synthesize a wide range of nanomaterials.

The U-tube setup has been used to grow high purity single-crystalline $BaWO_4$ nanorods and $BaCrO_4$ nanorods at large scale with different controllable size [19]. Alumina template membranes with pore sizes of 100 nm or 200 nm were mounted between the two halves of a U-tube cell. The half-cells were then filled with equimolar solutions of $Ba(NO_3)_2$ and either Na_2WO_4 or Na_2CrO_4 solutions to generate barium tungstate and barium chromate, respectively. After immersion times of up to 12 h at room temperature, the precursors diffused into the nanopores of the alumina template, resulting in the nanorods formation.

Template-Assisted Electrophoretic Deposition The use of template-based electrophoretic deposition has been demonstrated to be a very effective way to grow nanowires and nanotubes of complex oxides. Electrochemical deposition, also known as electrodeposition, involves the oriented diffusion of charged reactive species through a solution when an external electric field is applied along with the reduction of the charged growth species at the growth or deposition surface (which also serves as an electrode). A thin

Growth of 1-D Oxide Nanostructures, Fig. 9 (continued) nanoparticles in confined precursor nanorods). conducting metal film is first coated on one side of the porous membrane to serve as the cathode for the electroplating. In general, this method is only applicable to electrically conductive materials such as metals, alloys, semiconductors, and electrically conductive polymers. In the case of simple oxides, electrodeposition of the metal into the pores is followed by oxidation. Examples of this method are ZnO, In_2O_3, and SnO_2 nanowires.

However, direct electrodeposition is not suitable for multicomponent oxide nanowires as different cations would have different ionic sizes and diffusivity. Therefore, the electrophoretic deposition technique has been widely explored, particularly for the deposition of ceramic and organo-ceramic materials onto a cathode from colloidal dispersions. When dispersed in a polar solvent or an electrolyte solution, the surface of nanoparticles develops an electrical charge. Upon the application of an external electric field, charged particles are set in motion, as illustrated in Fig. 11. This type of motion is referred to as electrophoresis. Electrophoresis in the nanopores of a template offers a cost-effective and simple alternative to synthesize 1D complex oxide nanostructures.

Limmer et al. combined sol–gel preparation with electrophoretic deposition to produce nanorods of various complex oxides [20]. In this case, a conventional sol–gel processing was applied to the synthesis of various sols. By controlling the appropriate preparation of the sol, nanometer particles of a desired stoichiometric composition were formed and electrostatically stabilized by pH adjustment. Using radiation tracked-etched polycarbonate membranes with an electric field of ≈ 1.5 V/cm, they could grow nanowires with diameters ranging from 40 nm to 175 nm and lengths of 10 μm, corresponding to the thickness of the membrane. Samples were then dried at ∼100 °C for several hours and then placed in an oven and fired at 700 °C for 1–30 min. This step was set to burn off the PC membranes, to make the nanorods dense and to crystallize the material. Nanowires of many technologically important oxides like $BaTiO_3$ and $Pb(Ti,Zr)O_3$

[20])

perovskites and of the layered perovskite $Sr_2Nb_2O_7$ have been prepared by this method.

In this context, $PbZrO_3$ nanotubes where produced by using electrophoresis in AAO templates [21]. The difference in the final nanostructures may be related to the different electrochemistry, according to the type of template used.

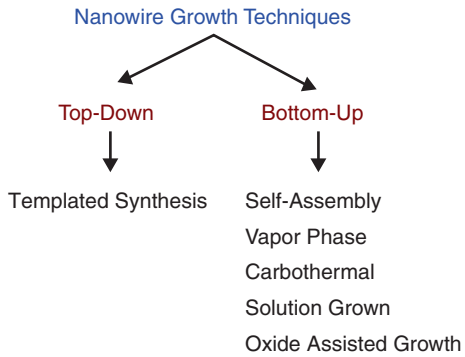
Definition

The evolution of nano (one-billionth of a meter)-sized material made of silicon and oxygen in a

wire-like morphology is referred to as growth of silica nanowires. The evolution may be from a substrate or freestanding.

Introduction

Nanotechnology continues to induce a paradigm shift in electronic, chemical, biomedical, sensor, and related industries [1]. The use of nanoscience enables (a) superior performance of the materials and devices, (b) increased sensitivity levels in sensors, (c) faster response in devices, and (d) high-density synthesis of materials and technology platforms leading to cost-effective manufacturing. These properties stem from the fact that nanostructures have enhanced surface area of volume ratios, allowing surface phenomenon to dominate inertial phenomenon. Consequently a small variation in their dimensions alters the surface area/volume ratio and leads to significant changes in physical, optical, and electrical properties, even resulting in new class of materials and devices. Additionally, the large surface-to-volume ratios and their low dimensions make them ideal candidates to probe events at submolecular and atomic scale. One of the prominent areas of research in nanotechnology is the synthesis of nanomaterials [2].



Of the numerous one-dimensional (1D) nanostructures, silica (SiO_2) nanowires are a subject of intense research [3, 4] for numerous applications such as localization of light, low-dimensional waveguides for functional microphotonics, scanning near field optical microscopy (SNFOM), optical interconnects in integrated optical microchip, sacrificial templates, biosensors, and optical transmission antennae. Silica nanowires are made up of silicon and oxygen, the two most abundant elements in the earth's crust. Their combination as bulk silica has been used in a wide variety of applications ranging from colloid chemistries to MEMS and CMOS applications [5, 6].

The surface of silica can react with various compounds such as amine, carboxyl, or thiol groups to make it functional for biosensing applications [7]. Although silica nanowires have been observed to grow at the ends of CVD reactors since the 1960s [4], they were not actively exploited till 2004. The properties of silica nanowires are unique compared to bulk or colloidal silica [8]. As nanowires would be a critical building block of any nanosystem, the ability to synthesize them at a desired location in a controlled manner is of significant importance.

This chapter reviews silica nanowire growth and the growth mechanisms. First, a general overview of the "top-down" and "bottom-up" synthesis of nanowires is presented. After brief discussion of the various growth mechanisms in "top-down" and "bottom-up" synthesis, the vapor liquid solid (VLS) technique, a preferred method to grow silica nanowires, is described in detail. Next, two new approaches in selective growth of silica nanowires using a combination of VLS and oxide-assisted growth (OAG) mechanism are presented along with a discussion on the mass manufacturing aspects of the nanoscale wires.

Nanowire Nucleation Techniques

Understanding the growth mechanism of nanowires is critical for enabling high-density and controlled synthesis of silica nanowires. The structure and morphology of the silica nanowires is dictated by the growth mechanism used. Figure 1 schematically illustrates the different techniques of growing nanowires in general. Top-down nanowires are routinely

Growth of Silica Nanowires, Fig. 1 Classification of nanowire growth methodologies

grown using templates. The preferred templates for the growth are anodized aluminum oxide (AAO), track etched polymers, and in some instances porous silicon. Bottom-up approach is an additive process, which builds on material from an atomic scale (molecule by molecule or atom by atom) to evolve one-dimensional nanostructures. Bottom-up approaches include vapor phase growth, solution-grown mechanism, oxide-assisted growth, carbothermal reduction technique, and self-assembly process. All of these growth techniques require nucleation of the wire.

Nucleation Techniques: Top Down and Bottom Up

There exist two generic methods for the growth of nanostructures, namely, the "top-down (TD)" and the "bottom-up (BU)" approach. TD approach involves machining and etching techniques to remove material from a bulk form to a nanoscale size. Templated method falls in the category of the TD approach in the formation of nanowires. On the other hand, BU approach is an additive process, which builds on material from an atomic scale (molecule by molecule or atom by atom) to evolve one-dimensional nanostructures.

Top Down: Templated Method

The "template" is a fundamental structure within which a network forms. Deposition of the material in the template and the removal of the template leaves a nanowire made from deposited material. The external morphology of the resulting nanowire can, when deposited carefully, replicate the structural details of the template. Various predefined structures such as polymer membranes, anodic alumina, and porous silicon of fixed geometry have been used as templates. Once the template is fabricated, nanowires of desired geometry (diameter dictated by the pore size and length determined by the pore length) are derived. Electrochemical methods, electroless techniques, chemical vapor deposition (CVD), sol–gel and chemical polymerization–based deposition mechanism are used to fill the pores. The porous part or the scaffold is selectively removed using appropriate etching chemistry leaving behind the nanowires. The template method is convenient and simple. Nanowires of different compounds can be easily produced harnessing the properties pertaining to specific applications. Christian [9] reported a novel iron-based surfactant to form rod-like micelle structures, which may be, used to template the formation of silica nanowires with diameters less than 5 nm. The main drawbacks of this method are the inability to produce single crystalline wires and limited geometries (i.e., fixed diameter and length).

Bottom Up: Self-assembly Process

Self-assembly process is a viable bottom-up route for manufacturing nanostructures. It is defined as the creation of material from its constituent components in a spontaneous natural manner, i.e., by an interaction between the components or by a specific rearrangement of them that proceeds naturally without any special external impetus. Kievsky and Sokolov [10] reported a novel modification of acidic synthesis of nanoporous silica fibers that assembled fibers of uniform in size and shape. Each fiber was shaped like a hexagonal cylinder of approximately 2.0 μm in diameter and approximately 4.8 μm in length. The yield of the assembled fibers was virtually 100 %.

BU: Solution-Grown Method

In this method, molecular capping agents (which control the kinetics of crystal growth by allowing selective nucleation on certain facets) along with suitable seed materials are dispersed in a solvent (a suitable chemical compound comprising material of interest) medium. The solvent is then heated and pressurized until it becomes a supercritical fluid. When the concentration of the solvent exceeds solubility limit, the seed ejects the elemental compound in the solvent as nanowires. This forms the basis of solution-grown nanowires. Kita et al. [11] successfully synthesized silicon oxide nanowires using a low-temperature hydrothermal treatment (200 °C) without the use of metallic catalysts. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) revealed nanowires having uniform distribution and straight morphology with diameters ranging from 50 to 100 nm and lengths up to ca. 60 μm. The nanowires were produced by

hydrothermal treatment based on the original concept of slow structure formation by the dissolution of bulk glass source materials (borosilicate glasses), which can be used to supply a continuous source solution.

BU: Carbothermal Reduction Technique

In this method, elevated temperatures are used which causes activated carbon to behave as a catalyst thus reducing metal oxides/nitrides/carbides to their corresponding nanowires with release of carbon monoxide. Equations 1 and 2 represent the carbothermal reduction technique.

$$\text{Metal oxide} + \text{C} = \text{Metal sub-oxide} + \text{CO} \quad (1)$$

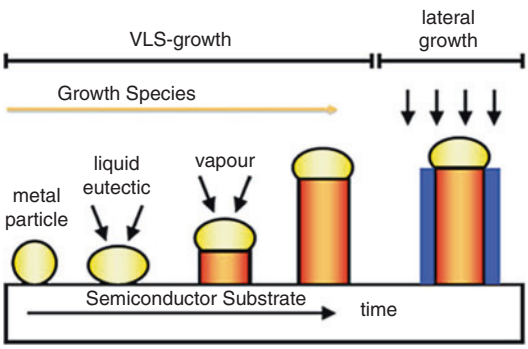
$$\text{Metal sub-oxide} + \text{O}_2 = \text{Metal oxide nanowires} \quad (2)$$

Lin and Lin [12] achieved the growth of SiO_2 nanowires via carbothermal reduction of CuO/C powders at a temperature of 1,000–1,100 °C in flowing Ar with the flow rate of 100 sccm.

BU: Oxide-Assisted Growth (OAG) Mechanism

Metal catalysts are not required for the synthesis of nanowires by this bottom-up fabrication method. Stoichiometric or non-stoichiometric silicon oxide (Si*x*O*y*) in its vapor form induces the nanowire growth. For example, the growth of SiO_2 nanowires [13] was promoted by SiO vapor derived from Si powder targets or SiO_2 thin films. Equations explaining the oxide-assisted growth mechanisms are as follows:

$$\text{Si}_x\text{O} \rightarrow \text{Si}_{x-1} + \text{SiO}(x > 1) \quad (3)$$



$$2\text{SiO} \rightarrow \text{Si} + \text{SiO}_2 \quad (4)$$

These decompositions result in the precipitation of Si nanoclusters, which act as the nuclei of the silicon nanowires covered by shells of silicon oxide.

BU: Vapor Phase Techniques

Typically, nanowires or one-dimensional nanostructures can be fabricated by promoting the crystallization of solid-state structures along one direction. This can be achieved either by the growth of intrinsically anisotropic crystal structure or the use of templates with one-dimensional morphologies directing the formation of one-dimensional nanostructures or the introduction of a liquid–solid interface thereby reducing the symmetry of a seed or by self-assembly of zero-dimensional nanostructures. The latter phenomenon forms the basis for vapor phase nucleation techniques. The growth of nanowires from the vapor phase techniques requires that the starting reactants be a gas phase species. Though there are many subcategories of vapor phase techniques, the preferred mechanism for nanowire growth referred to as the vapor liquid solid (VLS) technique will be discussed in the next section.

Vapor Liquid Solid (VLS) Mechanism Wagner and Ellis first discovered the VLS method in 1964 [14]. In the VLS method, the nanowire is grown in a desired orientation when a metal catalyst reacts with the "nanowire material" in its gaseous phase at high temperatures. This method is based on the eutectic solidification of a metal and semiconductor. The catalyst also known as a second-phase material is used to confine the crystal growth onto a specific orientation. The catalyst alloys itself with the growth material. This acts as a trap to the growth species, which results in the precipitation at the growth surface in a single direction. Figure 2 depicts a typical VLS growth.

Growth of Silica Nanowires, Fig. 2 Schematic of the VLS growth mechanism

The VLS growth is facilitated by (a) the mass transport of whisker growth species in the vapor phase to the vapor liquid phase, (b) the chemical reaction on the vapor-liquid interface, (c) the dissolution and diffusion through the liquid alloy phase, and (d) the precipitation on the solid–liquid interface.

Common conditions for a VLS mediated growth are as follows:

(a) The catalyst must form a liquid solution with the crystalline material to be grown at the deposition temperature.
(b) The distribution coefficient of the catalyst must be less than unity at the deposition temperature.
(c) The equilibrium vapor pressure of the catalyst over the liquid droplet must be very small.
(d) The catalyst or impurity must be inert chemically.
(e) The interfacial energy, i.e., the wetting characteristics, plays a very important role. For a given volume of liquid droplet, a small wetting angle results in a large growth area, leading to a large diameter of nanowires.
(f) For a compound nanowire growth, one of the constituents can serve as the catalyst.
(g) For controlled unidirectional growth, the solid–liquid interface must be well defined crystallographically.

In VLS growth, the growth species in its vapor form passes through the substrate in the presence of a catalyst (metal particle), which then diffuses into a liquid droplet. The liquid's surface has a large accommodation coefficient, so it is a preferred site for deposition. Saturated growth species in the droplet diffuse and precipitate at the interface between the substrate and liquid thus growing into a nanowire. The VLS growth method is not restricted by the type of substrate materials and catalysts, thus enabling the nanowires to be either single crystalline, polycrystalline, or amorphous. In general, the catalyst plays a key role in the VLS process.

It forms a liquid droplet as a preferred site to adsorb the vapor pieces of the source materials. The desired one-dimensional (1D) nanostructure precipitates, nucleates, and grows from the saturated liquid droplet. The selected catalysts in the VLS process should meet two demands. First, the catalyst should form the liquid eutectic alloy with a 1D nanostructure material under the growth temperature. The liquid alloy phase reduces the activation energy at the liquid–solid interface and enhances the growth rate appreciably. Second, the catalyst should be more stable than the components of the desired 1D nanostructure. This sustains the continuous growth as long as the vapor species is available.

VLS Kinetics Typically a catalytic agent is coated onto a growth substrate and is placed in a vacuum furnace of high temperature. Vapor atoms of the nanowire material are passed through it. The lowest temperature and pressure are chosen such that they cause the catalyst to form alloyed eutectic phase seeds with the lowest concentration of the growth species (GS). This causes the tip of the seed to be semi-molten. The semi-molten structure of the tip has a soft lattice and loose interatomic configurations to allow adsorption of the GS vapor.

If there is a lateral temperature gradient, or a sudden change of temperature, it leads to random breakup of the catalyst droplets. Also if there is an oversupply of the GS, it leads to oscillation of surface energies, which enables multiple nucleations. Lastly, the gas of the GS can cause hydrodynamic stress on the droplet thus causing droplet breakup. The temperature and pressure are very crucial for the VLS mechanism to succeed. The growth of the nanowires will proceed only when the concentration of the GS is above the equilibrium solubility. Although the evaporation of the catalyst does not change the composition of the saturated liquid composition, it reduces the total volume of the liquid droplet. Unless more catalyst is supplied, the volume of the liquid droplet reduces and growth will stop when all the catalyst is evaporated.

The orientation of the nanowires depends on the substrate texture and the diameter of wire. Moreover, it also depends on the nanowire composition, as materials prefer to orient in a direction minimizing their enthalpy of formation.

Silica Nanowires: A Review of Growth Investigations

Over years, silica nanowires have been synthesized using growth methodologies discussed in the previous sections. Among the various techniques, vapor phase approaches have been routinely used in applications that require mass manufacturing and high-density growth. A comprehensive review [15] on silica nanowire growth (for the past 12 years) is presented in Fig. 3.

Selective Growth of Silica Nanowires: New Approaches

Ion Implantation–Based Seeding Approach

Of the several methods used to produce nanowires, the VLS mechanism proposed by Wagner and Ellis for silicon whisker growth has proved to be very reliable for growing silica nanowires. A simulation study [16] indicated the feasibility of forming catalyst nanoclusters in silicon using ion implantation. Ion implantation is a low-temperature technique for the introduction of impurities (dopants) into semiconductors, and is preferred over diffusion. It is a process of introducing energetic and charged particles into a substrate. Implantation of ions into a target may alter the physical or chemical properties of the host via damage induced by the energy loss of the incident ions. In this surface modification technique, ions are extracted and accelerated toward the target. Before penetrating the host, the charged ions are separated according their mass-to-charge ratio. Then the desired species is directed at the target. The foreign atoms enter the crystal lattice, collide with the host atoms, lose energy, and finally come to rest at some depth within the substrate. The average penetration depth is determined by the species, substrate material, and the initial energy of the ions. This depth has some distribution, as the collisions with the target atoms are random. Figure 4 shows the ion implantation setup.

In this section, ion implantation as a new method to form catalyzing seed nanoclusters at or below the surface of Si and subsequent growth of silica nanowires is presented [17]. The ion implantation–based seeding approach possesses several advantages over conventional methods of catalyst placement such as (a) the size and distribution of the catalyst can be accurately controlled by varying the ion dose, energy, and dose rate, (b) the placement of catalyst being an integral part of the substrate lattice lends for an impurity-free nanowire growth, and (c) majority of the element across the periodic table can be implanted giving rise to hybrid nanostructures (metal/dielectric). Such an approach was demonstrated by implanting Pd ions into Si through a mask.

Methodology In this investigation, prime grade Si (100) wafers of 2″ diameter were used as substrates for Pd ion implantation performed with a metal vapor vacuum arc (MEVVA) ion implanter. The MEVVA ion source is a high current device, which can readily produce ion beam currents of several hundred milliamperes on target. Extraction potential up to 50 kV is used to implant metallic elements. Ion beams of most metallic elements either individually or in combination can be generated with a MEVVA source.

In this study, the lowest possible extraction voltage to produce a stable ion beam in the implanter (of 10 kV) was chosen to ensure maximum surface concentration of implanted Pd. Since the MEVVA ion source produces ions with multiple charge states, the energy of the ions emanating from the source depends on the charge state. For the Pd ion implantation, the energy was estimated to be 19 keV using a mean charge state of 1.9. Circular shadow mask (Al) was used to define identical and well-separated zones of ion-implanted regions. Dose was varied from 5×10^{12} to 3×10^{16} Pd ions/cm^2. The sample was introduced into the furnace around 1,100 °C and heated for the desired time (7–60 mins) in Ar followed by cooling to room temperature. Further, the growth temperature was varied.

Discussion After heating at 1,100 °C for 60 min, the ion-implanted region showed a dense growth of rather long and interwoven nanowires as shown in Fig. 5. The inset shows the unimplanted area at the same magnification confirming the absence of nanowires due to unavailability of Pd seeds.

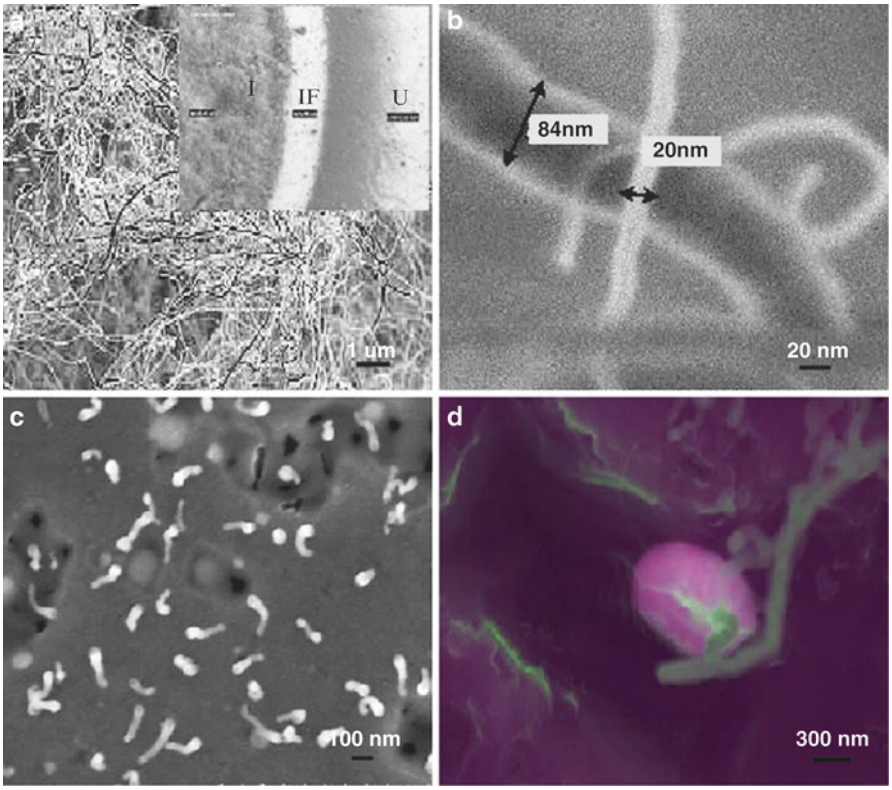
Growth of Silica Nanowires, Fig. 3 Literature review of silica nanowire growth

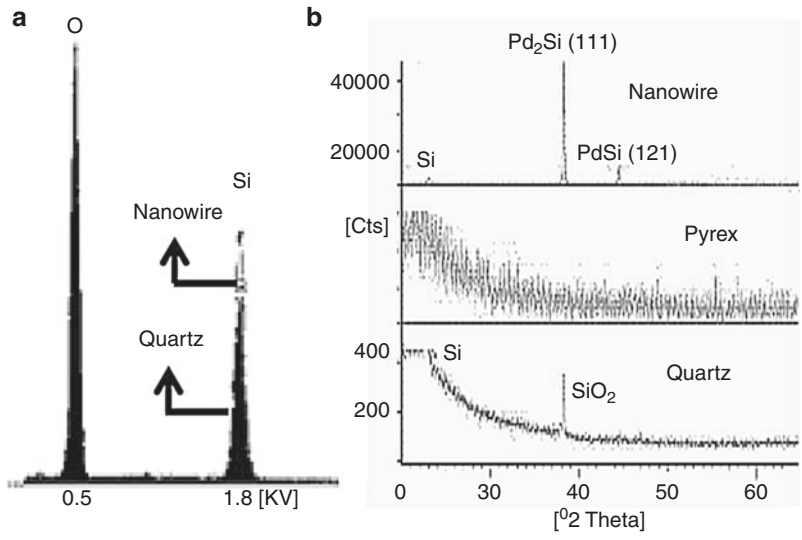


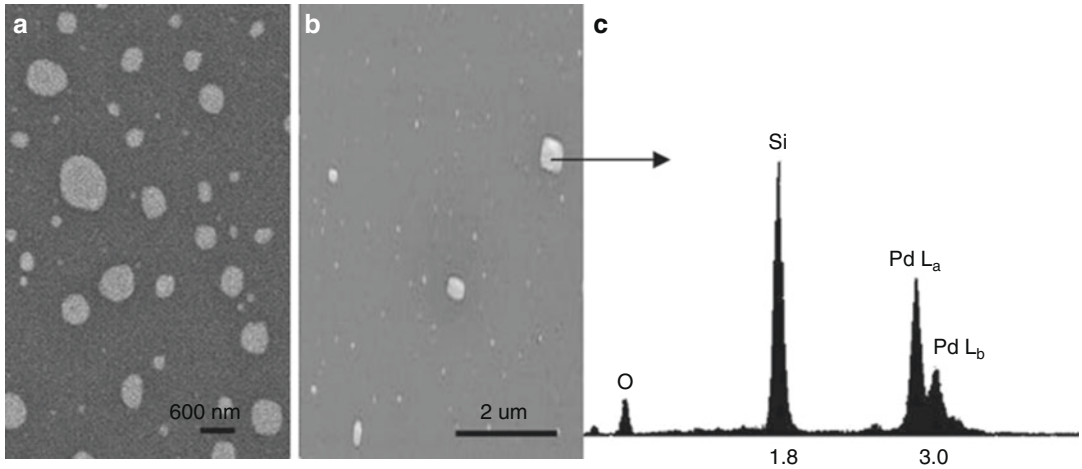
Growth of Silica Nanowires, Fig. 4 Ion implantation setup (Courtesy: Wikipedia)

Also, Fig. 5a demonstrates the selective nucleation of nanowires on the implanted region. The interface region is very narrow and sharp indicating the ability to directly locate nanowires on the implanted areas. The nanowires grow with diameters ranging from about 15 to 90 nm, as for example seen in Fig. 5b. The length of the nanowires was observed to vary up to about 50 μm corresponding to an aspect ratio of up to 3,000. The morphology of the nanowires depends on the growth time as evident from Fig. 5c (after 7 min) captured at the early stage of the growth with nanowires emanating from their parent seeds. Figure 5d is a composite constructed from an overlay of two SEM images recorded in backscattered mode (pink color) and secondary mode (green color). The pink areas therefore show atomic number contrast. The pink oval seed is confirmed to be rich in Pd by spot energy dispersive spectroscopy (EDS) measurements on and away from it.

Figure 5d therefore captures the "birth" of a silica nanowire (green color) growing from a Pd-rich seed. A much thinner nanowire can also be seen to emerge from the same seed. The composition of the nanowires was measured with EDS (at low electron energy of 5 kV to ensure that majority of X-rays come from nanowires and not from Si substrate) and compared with that of a control sample of quartz analyzed under identical EDS conditions (Fig. 6a). Thus the composition was found to be close to SiO_2 with a slight deficiency of oxygen.

The phase identification was done by X-ray diffraction (XRD) on the same sample (Fig. 6b), which did not show the peak observed in quartz sample indicating that the nanowires are amorphous. The temperature was also found to be a critical factor for the growth of nanowires. At a lower temperature of 1,010 °C for the same growth time of 60 mins, only a very early stage of nucleation and growth was observed. At still lower temperature of 910 °C (Fig. 7a), no growth of nanowires is observed. Pd ion dose was also found to be another factor critical for nucleation of Pd-rich seeds and nanowires.



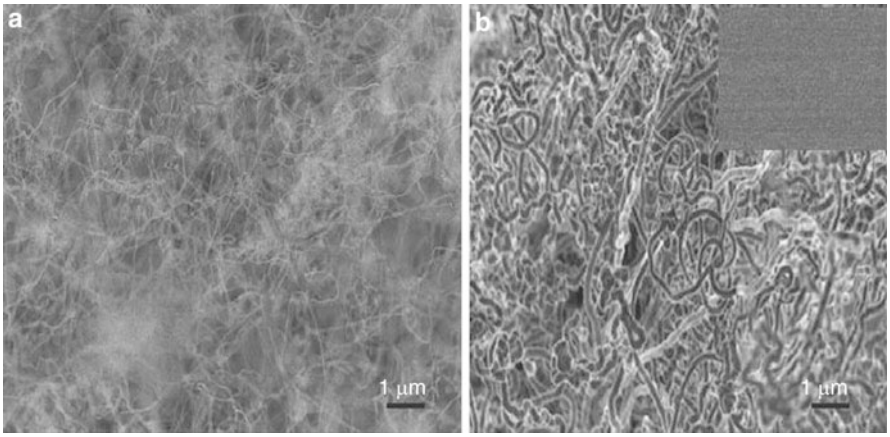


Growth of Silica Nanowires, Fig. 5 Selective growth of nanowires at a constant Pd ion dose of 3×10^{16} ions/cm^2 after heating at 1,100 °C for 60 and 7 min. (**a**) Dense wire growth after 60 min; *inset*: Selective growth on implanted regions, inset: *I* Implanted region showing nanowire growth, *IF* Interface, *U* Unimplanted region devoid of nanowire growth, (**b**) variation in morphology of wires in (**a**), (**c**) early stage of nanowire growth (after 7 min), and (**d**) composite of backscattered and scanning electron image highlights the elemental contrast between seed and wire

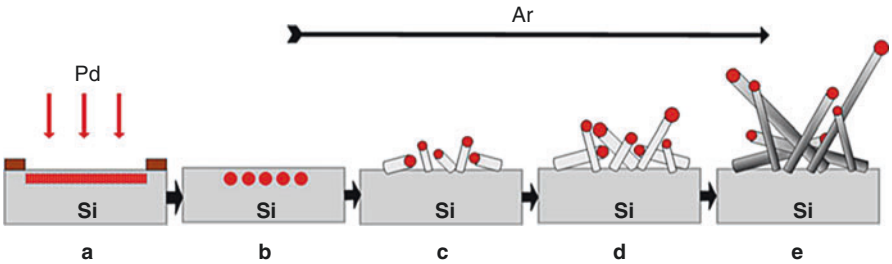
As the dose was reduced from 3E16/cm^2 (Fig. 8a) to 1E16/cm^2 (Fig. 8b), coiled nanowires of reduced density were seen. The density of the wires was estimated by counting the wires in five 4×4 μm (high dose), 7×7 μm regions (low dose) of the SEM and averaging them. The observation show an estimated 2E8 wires/cm^2 in sample implanted with a dose of 3E16/cm^2 (Fig. 8a) and 1E8 wires/cm^2 in sample implanted with at a dose of 1E16/cm^2 (Fig. 8b). These observations confirm that implantation dose is a critical factor in determining the density of the nanowires. However, at a dose of 5E12 ions/cm^2, no growth of nanowires (inset in Fig. 8b) or Pd-rich seeds was observed.

Moreover, the flow of Ar gas was found to be critical in producing growth of silica nanowires. In another experiment at 1,100 °C, the Ar gas was shut off after the furnace temperature reached 1,100 °C, and then the sample was introduced into the furnace and kept there for 60 min, after which the furnace was allowed to cool down to room temperature and the sample was taken out for further study by SEM and XRD. The SEM results showed islands of bright appearance.

Larger islands with rectangular morphology (Fig. 7b) were confirmed to be consisting of Pd_2Si composition by performing a spot EDS (Fig. 7c) on them. The composition of smaller islands could not be determined accurately because their size was much smaller compared to the excitation volume for the EDS. They appear to be the Si-rich PdSi phase. Away from islands, no Pd was found. There were no nanowires on this



Growth of Silica Nanowires, Fig. 6 Elemental composition and texture analysis of the synthesized nanowires. (**a**) Comparison of EDS spectra on quartz with EDS on nanowire sample revealing SiOx ($x < 2$) stoichiometry and (**b**) XRD showing their amorphous nature



Growth of Silica Nanowires, Fig. 7 Conditions of no nanowire growth at a constant Pd ion dose of $3 \times 10^{16}/\text{cm}^2$. sample. XRD obtained from this sample shows the presence of Pd_2Si and PdSi phases. The absence of silica nanowires proves the role of Ar as a carrier gas in transporting Si vapor to the reaction site resulting in the whisker growth by a VLS mechanism.

The physical model to explain the nanowire growth is (Fig. 9) as follows: the ion dose needs to be high enough to produce nanoclusters of Pd within the silicon matrix amorphised by ion damage. As the implanted sample is heated in Ar atmosphere, the interdiffusion at the Pd-Si interface produces two phases of PdSi and Pd_2Si, which eventually become liquid as the melting point of the silicides is approached at 972 °C or 1,331 °C, respectively. Since the maximum temperature used in the study is 1,100 °C, only liquid drops of PdSi phase are formed. These liquid drops may now coalesce to form larger sized liquid drops and migrate toward the surface of the solid Si substrate. The amorphised surface layer of silicon would also crystallize

Growth of Silica Nanowires, Fig. 8 Effect of implanted dose on the growth of nanowires heated at 1,100 °C for 60 min. (**a**) 3×10^{16} ions/cm^2 – high-density thinner nanowires and (**b**) 1×10^{16} ions/cm^2 – thicker coiled nanowires of reduced density, *inset*: 5×10^{12} ions/cm^2 – absence of nanowires

Growth of Silica Nanowires, Fig. 9 Schematic of the proposed physical model explaining ion implantation–based seeding approach. (**a**) Implanted Pd on Si (100) through a mask, (**b**) formation of PdSi cluster, and (**c**–**e**) VLS growth of silica nanowires

concurrently. When these liquid drops are exposed to the Si vapor being swept across by the carrier gas (Ar), the VLS model of whisker growth comes to play and Si nanowires begin to grow. Some nanoclusters, especially those on which nanowire growth has not yet started, agglomerate by diffusion/Oswald ripening processes, become bigger in size and nucleate wires. The growth process proceeds continuously by diffusion and precipitation of silicon atoms across the liquid-nanowire interface. Since small amount of oxygen is inevitably present in the ambient as impurity, these thin silicon nanowires may oxidize rapidly from outside and eventually get fully oxidized.

The observed oxygen deficit from the stoichiometric SiO_2 may be consistent with some unoxidized silicon around the center of the nanowires. The occurrence of selective VLS growth of nanowires only on the Pd ion–implanted regions has been validated by a careful selection of ion dose, growth temperatures, and Ar gas flow. The VLS growth can stop when either of the following conditions are met – no more vapors of Si arrive or the temperature drops below the melting point of the material of the liquid drop, or the implanted ion dose is below that required for Pd cluster formation. However, the origin of the observed morphology of silica nanowires is unclear. The nanowires are produced with a variety of diameters and have much larger lengths forming a network of entangled structures. Since the physical model is based on VLS growth of Si nanowires followed by their oxidation, one can expect the dominant growth direction to be (110) on a (100) substrate

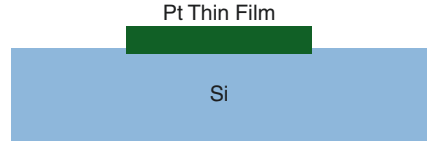
surface so that the nanowires would point out at ±45° with respect to surface plane. However, the SEM views of the early stage of growth do not show such large angles. They appear to be coming out almost along the surface at much smaller angles. This observation appears to be in agreement with recent reports of diameter-dependent growth directions of epitaxial Si nanowires grown on Si (100) substrates using Au as liquid catalyst facilitating VLS growth [18]. It was found that Si nanowires grown epitaxially on Si (100) via the VLS growth mechanism change their growth direction from <111> to <110> at a crossover diameter of approximately 20 nm.

A model has been proposed [19] for the explanation of this phenomenon. Based on this model, it can be hypothesized that most of the nanowires with diameters greater than 20 nm grow along <211> or <111> or a mixture of these growth directions and therefore lie close to the substrate plane (within about ±18°). As the diameter of the nanowires changes, so does the growth direction leading to the observed entanglement of the nanowires.

A similar change with decreasing diameter of the nanowires from <111> to <110> direction has also been observed for non-epitaxial Si nanowires. In summary, a new method for selective growth of silica nanowires on silicon wafers using ion implantation–based seeding approach is presented. Since ion implantation is compatible with the standard top-down CMOS process, this method holds a great potential for facilitating directed bottom-up growth of nanowires on silicon wafers. It may also provide an opportunity to combine the top-down and bottom-up technologies for creation of robust nanoscale devices. It may therefore open doorway to a large number of applications in wide areas of new technologies such as on-chip optoelectronics, biosensors, micro-antennae, and metallic nanotubes. The only limitation of this technique is scarce availability of ion implanters.

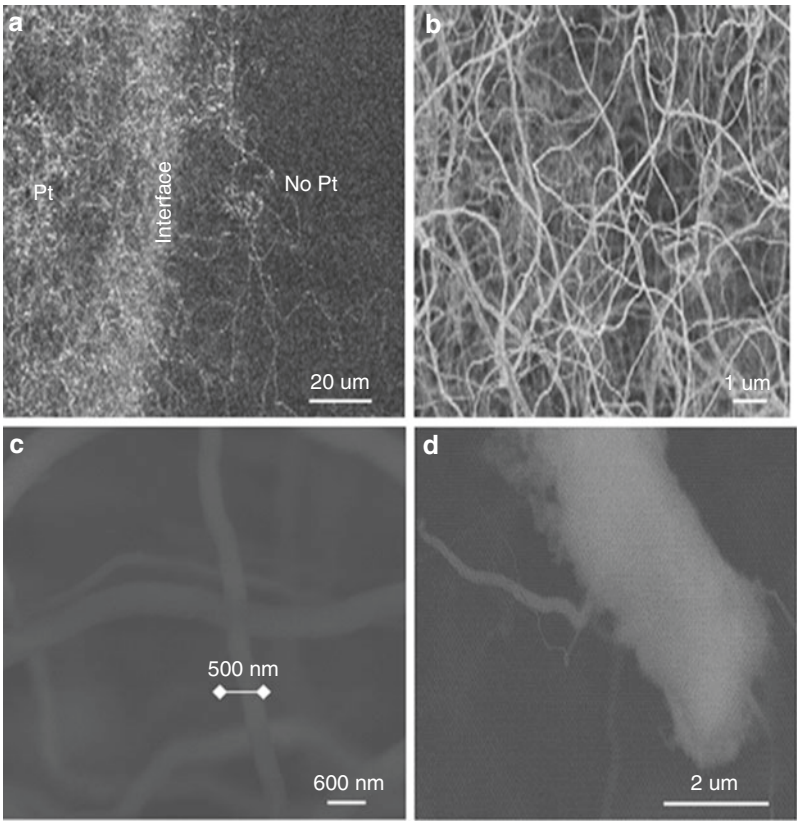
Metal Thin Film–Based Catalysis

A metal thin film catalysis–based silica nanowire growth circumvents the need for ion implantation as a tool for the placement of the catalyst. Also, the ability to produce stable nanowires at desired locations in a controlled manner on planar substrates is of critical importance for fabricating nanodevices such as nanoFETs, nanotransistors, and microphotonic nanosystems.



In this section, selective growth of silica nanowires in silicon using Pt thin film is presented [20]. This synthesis approach for localization offers several advantages such as the tunable size and distribution of the parent nanoclusters and a cost-effective solution for growing large-scale arrayable nanowires.

Methodology Prime grade 2″ n-type silicon wafers were used as substrates for subsequent Pt deposition.

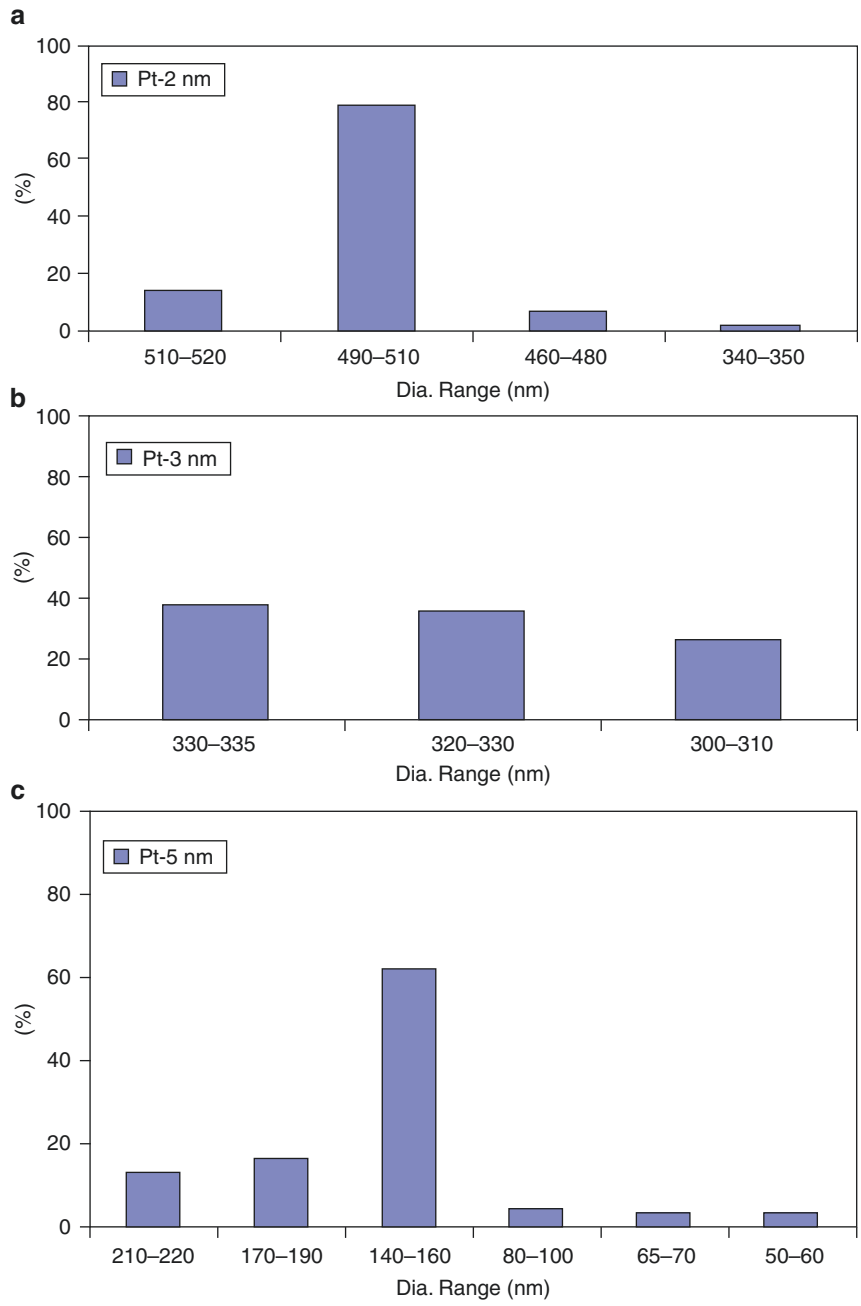


Target Pt thickness of 2, 3, 5, 10, and 100 nm was sputtered onto Si substrate (Fig. 10).

The temperature of heating is chosen based on the Pt-Si phase diagram. High-purity Ar was chosen as carrier gas and was set to 30 sccm throughout the course of the experiment. Initially the furnace was flushed with Ar to minimize interference from gaseous impurities. Then the sample is introduced into the furnace and ramped up to 1,200 °C. Once the furnace reached 1,200 °C, the heating process was timed.

Discussions After heating at 1,200 °C for an hour, regions deposited with Pt (20 nm) showed dense growth of interwoven nanowires. Figure 11a demonstrates selective growth of nanowires identifying the nucleation area and regions devoid of nanowire due to absence of Pt film. A higher magnification SEM micrograph taken in the growth region (Fig. 11b) illustrates nanowires of varying morphology. The nanowires grew at an average diameter of 200–500 nm (Fig. 11c) with lengths varying from 20 to 75 μm giving rise to high aspect ratio nanostructures for biological

Growth of Silica Nanowires, Fig. 10 Platinum thin film deposited on a silicon substrate



Growth of Silica Nanowires,

Fig. 11 Selective growth of nanowires after heating at 1,200 °C for 60 min for a Pt thickness of 2 nm. (**a**) Localized growth of nanowires, (**b**) higher magnification image in area of nanowire growth indicating the varied morphology of nanowires, (**c**) size of nanowires – diameter ranging from 50 to 500 nm, and (**d**) early stage of nanowire growth captured after heating at 1,200 °C for 15 min

applications. Figure 11d is a schematic capture of birth of several nanowires from their parent seed. The composition of these nucleated nanostructures from low-energy EDS was found to be SiO_2 closely matching with the EDS spectra of a control sample of quartz analyzed under similar test conditions. Phase identification through XRD revealed the amorphous (as compared to a quartz sample) nature of the wires along with the formation of PtSi, which acts as a seed catalyzing the nanowire growth. The thickness of platinum layer was found to be a critical factor affecting nanowire growth. As the thickness was increased to 3 nm (keeping other experimental conditions constant), the number density of the nanowires reduced. Further reduction in number density was observed when scaled up to 5 nm. At a thickness of 10 nm, silicide nanoclusters were formed indicating the absence of nanowire nucleation. When the deposited platinum thickness was around 100 nm, micron-sized clusters were seen.

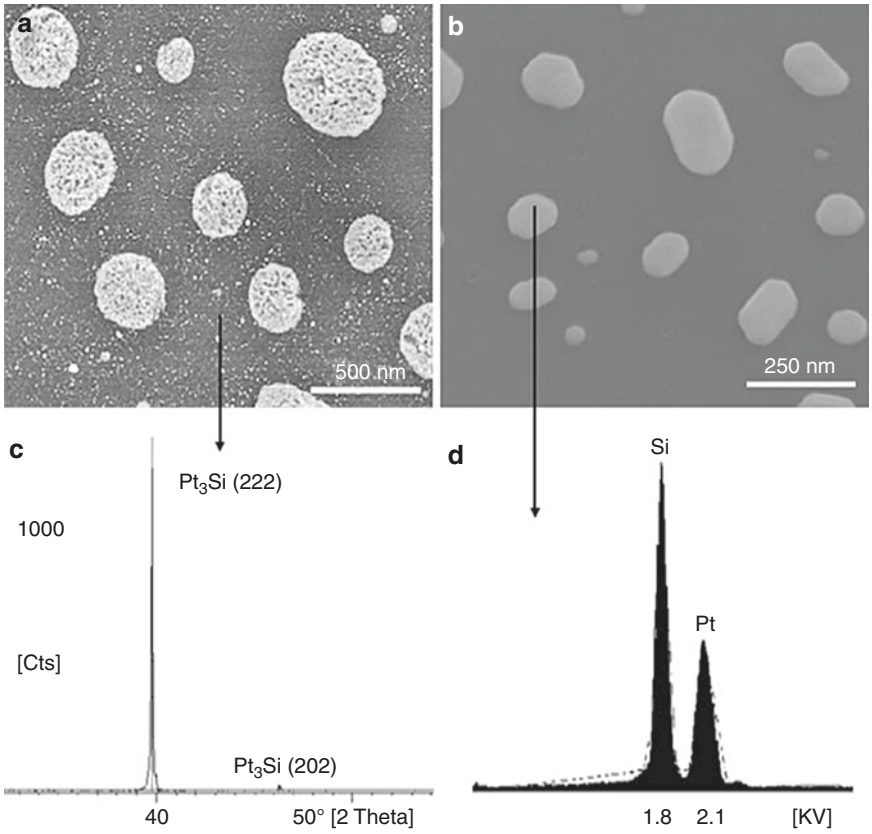


Figure 12 illustrates the statistical nature of the growth process through a frequency histogram. All the nanowire samples with different Pt thicknesses were heated to 1,200 °C for 1 h. For a Pt thickness of 2 nm, the ensemble diameter average was found to be 500 nm with a standard deviation (σ) of 6.7 over the 79 % range. A uniform distribution with an average wire diameter of 319 nm ($\sigma = 9.1$) was observed for the 3 nm Pt sample. As the platinum thickness increased to 5 nm, the nucleated nanowires exhibited a wide range of (60–220 nm) diameter variation explained by the Oswald ripening process. The average diameter was found to be 146 nm ($\sigma = 7.4$) over the 62 % range. Exploiting this selectivity of nanowire growth to platinum film thickness, a Si substrate with differential Pt coating (differential thickness achieved through repeated application of shadow mask) resulted in the nucleation of nanowires while simultaneously forming optically conducting silicide in a single furnace treatment. This would facilitate a low-loss

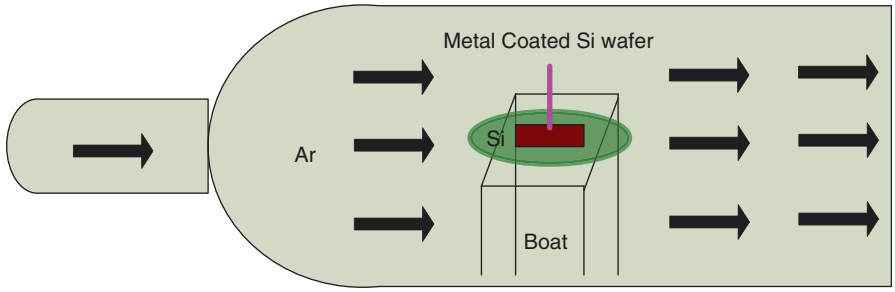
Growth of Silica Nanowires, Fig. 12 Percentage histogram indicating the statistical nature of the growth process with varying diameters for different Pt thicknesses. (**a**) Pt – 2 nm: ensemble average diameter = 500 nm, $\sigma = 6.7$; (**b**) Pt – 3 nm: ensemble average diameter = 319 nm, $\sigma = 9.1$; and (**c**) Pt – 5 nm: ensemble average diameter = 146 nm, $\sigma = 7.4$

hybrid nanointerconnect scheme in silicon for future integrated optical systems. The heating temperature was also found to be a critical factor influencing nanowire growth.

At a lower growth temperature of 950 °C for 1 h (Fig. 13a), spherical islands appeared surrounded by nanoclusters. These islands were identified as Pt_3Si particles through XRD.

Growth of Silica Nanowires, Fig. 13 Conditions of no nanowire growth for samples deposited with 2 nm Pt thickness. (**a**) 950 °C, 1 h – XRD indicating the formation of Pt_3Si (**c**) and (**b**) 1,200 °C, 1 h, No Ambient – EDX spectra revealing PtSi atomic stoichiometry of seeds (**d**)



Testing the role of ambient in nanowire growth, the flow of Ar was intentionally shut off while ramping up the furnace to 1,200 °C. When the sample was analyzed in a SEM, rectangular islands of bright appearance (Fig. 13b) were observed. Larger islands were confirmed to be PdSi by composition through an EDS on them. Smaller islands could not be resolved elementally due to limitation on the excitation volume for the EDS. The absence of silica nanowires proves the role of Ar as a carrier gas in transporting Si vapor to the reaction site resulting in the whisker growth by a VLS mechanism.

In summary, selective growth of silica nanowires on silicon catalyzed by Pt thin film was demonstrated. Platinum silicide acts as the seed facilitating the bottom-up nucleation of the oxide nanowires. The nanoscale optical wires nucleate following a VLS model validated through a careful set of growth conditions. This approach represents a simple, flexible, and cost-effective solution for synthesizing large-scale silica nanowires for wide variety of future applications that include functional microphotonics, high-density optical nanointerconnects, high-resolution optical heads, and nanoantennae. In the next section, the manufacturing aspects of silica nanowires will be discussed.

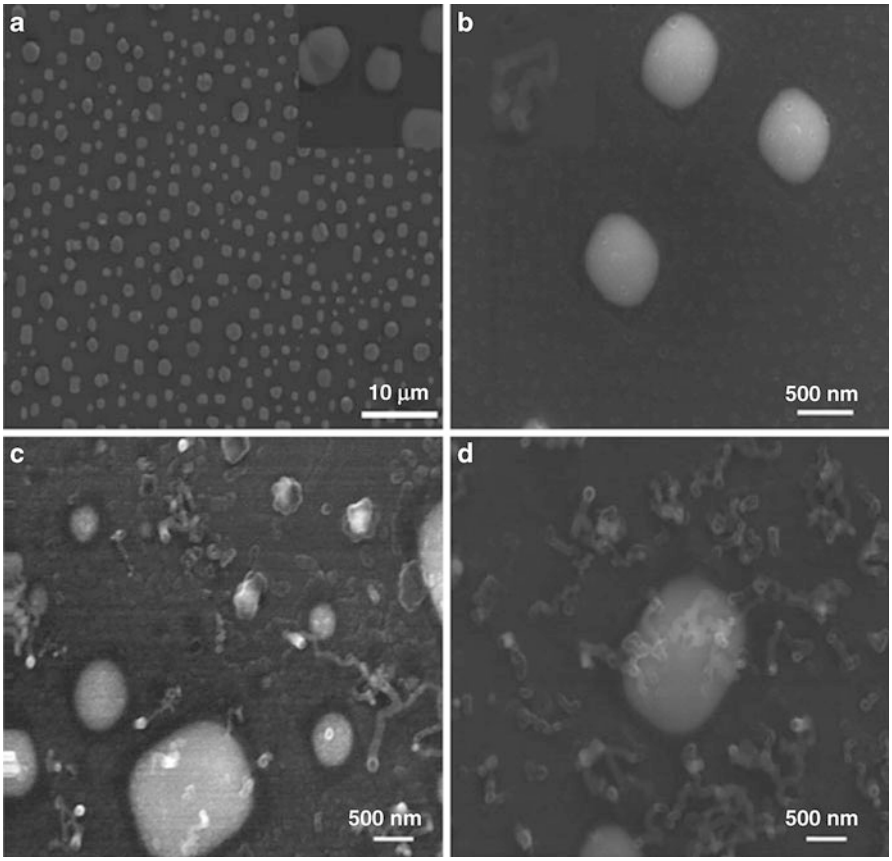
Manufacturing Aspects of Silica Nanowire Growth

Overview

Exploring the manufacturing aspects of nanostructures can enable the transition from a

Growth of Silica Nanowires, Fig. 14 Schematic of the furnace and experimental setup

laboratory-based research into a commercial product. Scalable manufacturing methods are required to harness the benefits of nanotechnology for a wide variety of applications. Understanding the manufacturing aspects of nanomaterials requires growth model and growth rate estimation. This section details on (a) a growth model derived from studying silica nanowire nucleation as a function of heating time, (b) nanowire growth rate estimation via weight differential of the Si substrate before and after growth, and (c) reusability of the Si substrate for nanowire growth. The growth mechanism of silica nanowires on Si via Pd metal thin film catalysis was investigated. A growth model was derived by sequentially varying the nanowire growth time at a constant temperature. The derived growth model for mass manufacturing nanowires was verified by a combination of experiments such as (a) annealing the metal thin film–coated silicon wafer in the absence of gas flow, (b) removing the nanowires in HF to inspect the substrate after growth, and (c) vary the Ar flow rate. In addition, the growth rate was estimated by weight differential technique while identifying distinct nanowire growth regimes. Finally, the reusability of the silicon substrate for further nanowire growth was evaluated.



Methodology

Prime grade Si wafer pieces (2 × 2 cm) were used as substrates for metal catalyst deposition. Pd of thickness of 5 nm was sputtered onto Si substrate, which served as the catalyst. The growth temperature of nanowires was chosen to be 1,100 °C based on Pd–Si phase diagram. High-purity Ar was chosen as carrier gas in an open tube furnace and was set to 30 sccm throughout the course of the experiment. Initially the furnace was flushed with Ar to minimize interference from gaseous impurities. The furnace set up with the sample for nanowire growth has been illustrated in Fig. 14.

The base support Si wafer acts as Si vapor source. Then, the heating process was timed after the furnace reached the desired temperature. The growth time was varied between 10 and 90 min in order to derive the growth model. For the estimation of growth rate, the heating time was extended up to 210 min. Further, the growth model was validated by (a) heating the metal coated Si substrate in the absence of Ar flow, (b) removing the nanowires via HF treatment and then inspecting the substrate, and (c) varying the Ar flow rate to observe the change in nanowire growth, if any. Finally, the reusability of the Si substrate was evaluated by removing the nanowires grown on Si substrate by HF solution. Then, the Si substrate was again introduced into the furnace to check for nanowire growth. After the heating experiments, the samples were observed under Hitachi S480 SEM. EDS was also performed to identify elemental compositions in addition to XRD.

Discussions

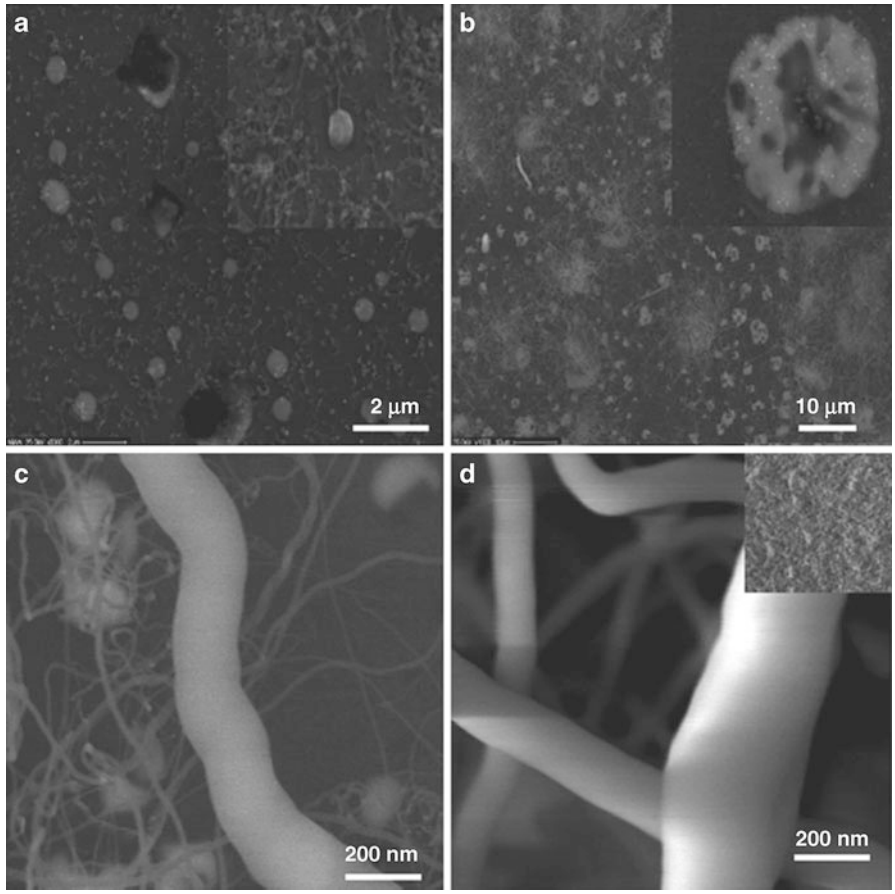


Figure 15 is a SEM composite micrograph showing the morphology of Pd coated Si substrate heated at 1,100 °C for various time intervals.

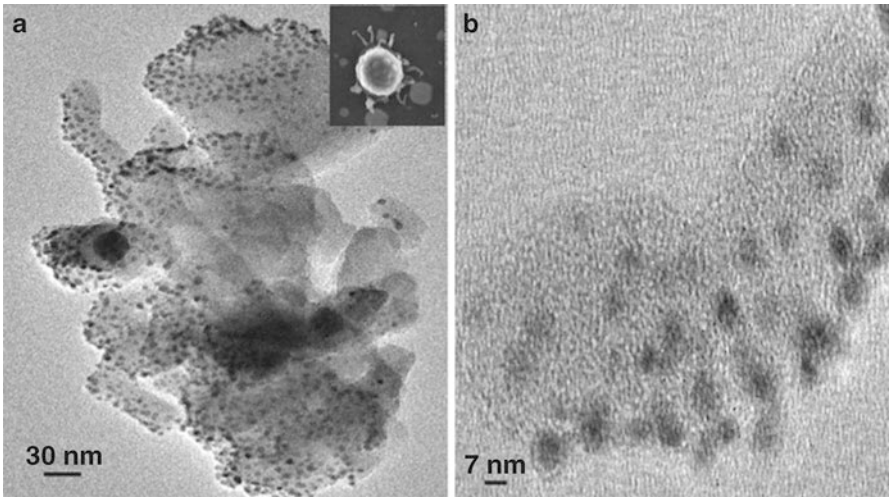
Growth of Silica Nanowires, Fig. 15 SEM micrograph illustrating the morphology of the Pd-coated Si wafer heated at 1,100 °C. (**a**) 10 min, (**b**) 15 min, (**c**) 20 min, and (**d**) 30 min

Inspecting the sample after heating 10 min, nanoclusters of various shapes and sizes were observed (shown in Fig. 15a). An EDS inspection on one of the nanoclusters indicates the presence of Pd, Si, and O. Further, the XRD data indicates the presence of crystalline Pd as well as the formation of palladium silicide. Also, a small layer (Fig. 15a inset) covering the wafer surface surrounding the island was noticed. An EDS analysis on the thin layer with quantification indicated the layer to be a SiO_2 film. The extremely low partial pressure and concentration of oxygen in high-purity Ar tank was responsible for the formation of the oxide layer at 1,100 °C. A deliberate introduction of oxygen at 0.01 sccm in addition to Ar completely oxidized the substrate without forming the islands or the nanowires. Hence, it is postulated that the thermodynamic equilibrium between the atmosphere (in an open tube furnace) and the low oxygen partial pressure in the tube is critical for nanowire growth. The sample inspected after a heating cycle of 15 min revealed surface roughening (Fig. 15b) in the form of etched pits both on the surface of Si and palladium silicide island. This has been attributed to the disassociation of the thin oxide layer to volatile SiO with continuous supply of oxygen.



A similar observation of surface roughening of a silicon wafer during annealing in argon ambient at an extremely low oxygen partial pressure was reported by Suzuki [21]. The author concluded that the surface roughening in the form of square pits occur when the oxygen partial pressure is lower than 3×10^{-5} atm. Figure 15c shows the

Growth of Silica Nanowires, Fig. 16 SEM micrograph illustrating the morphology of the Pd-coated Si wafer heated at 1,100 °C. (**a**) 45 min, (**b**) 60 min, (**c**) 75 min, and (**d**) 90 min

SEM micrograph of a sample heated for 20 min. The nucleation of nanowires could be observed along with ripening of the seeds to induce its birth. Localized Si etching was also observed along the catalyst periphery and subsequent sinking action of the nanoclusters was seen. As the eutectic alloy formation proceeds at high temperature, a tiny amount of Si diffuses from the substrate. The silicide formation consumes silicon from the surrounding which gives the appearance of Si etching. Peng et al. [22] utilized the metal-induced Si etching behavior along with nanolithography to synthesize ordered Si nanowires. As the nanoclusters vary in size distribution (several μm to nm), some of the nanowires seem to originate from silicon. The number density of nanowires increased twofold upon inspecting a sample heated at 1,100 °C for 30 min. EDS spectra on a bunch of nanowires away from the palladium nanocluster indicate Si and O composition. Extracting the stoichiometry by background subtraction and in comparison with a standard quartz substrate reveals SiOx ($1.8 < x < 2$) stoichiometry indicating a deficiency in silicon.

The number density of nanowires increased for samples heated for 45 min (Fig. 16a). Also, the inset in Fig. 16a shows the reduction in the size of nanoclusters at the expense of nanowire growth. Upon inspected by transmission electron microscope, the catalyst seems to travel up the nanowire as it grows (Fig. 17). Table 1 indicates the progressive increase in the number density of

Growth of Silica Nanowires, Fig. 17 TEM micrograph showing migration of Pd catalyst particles captured at an early growth stage (3E16 ions/cm^2, 1,100 °C, 7 min). 90	8

nanowires with increase in heating time. Figure 16b shows bunches of nanowires along with secondary nucleation (inset) from the nanocluster. High aspect ratio nanostructures were seen on samples heated to 75 min (Fig. 16c) along with size reduced parent nanoclusters. Samples heated for 90 min at 1,100 °C show intertwined nanowires Fig. 16d devoid of nanoclusters. The bushy growth of nanowires has been shown in the inset.

Next the growth rate (Fig. 18) was estimated by measuring the weight differential of Si substrate before and after nanowire growth as function of growth time. Five distinct growth regimes, namely, (1) thin oxide growth, (2) Si etch pit formation, (3) nanowire nucleation, (4) nanowire growth, and (5) nanowire growth saturation, have been demarcated.

Based on the weight differential data, it can be concluded that SiO*x* nanowires are conducive to mass manufacturing when heated at 1,100 °C for a heating time above 100 min. Further, the reusability of the substrate was investigated by etching the nanowires off the Si substrate in hydrofluoric acid (HF) and using the processed substrate again for nanowire growth (1,100 °C, 90 min). The nanowires grow at the expense of the catalyst in the sense the catalyst gets consumed inside the nanowires and the Si surface is depleted of the catalyst nanoparticles. Based on these experimental evidences, a growth model was derived and is illustrated in Fig. 19.

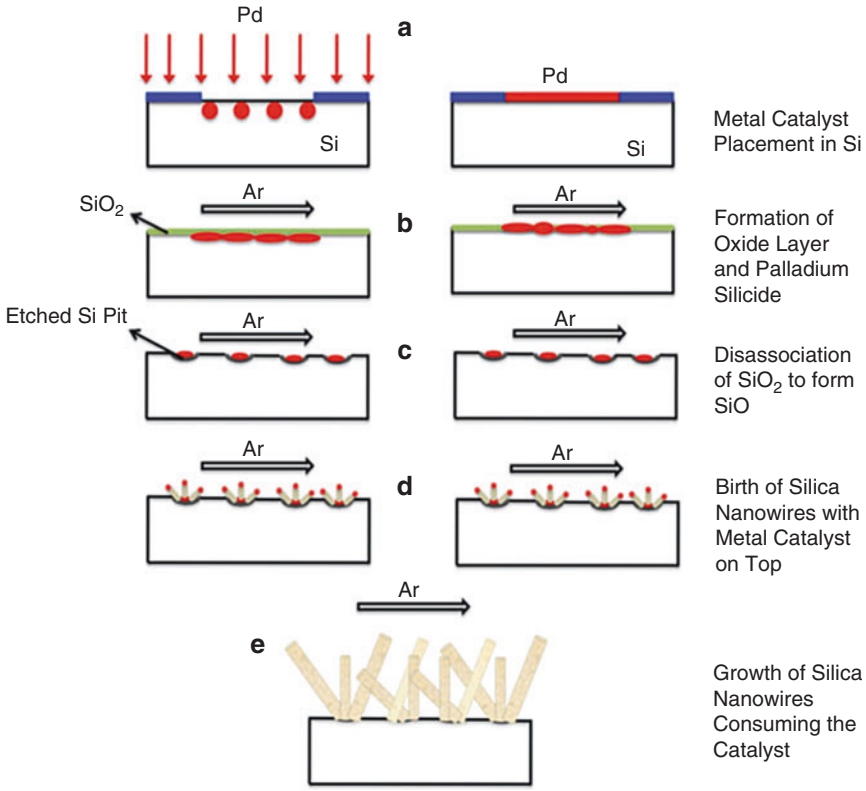
Some of the key features of silica nanowire growth via metal thin film-based catalysis and implantation-based seeding approach as inferred from the growth model are as follows:

(a) The low concentration level of oxygen in Ar is the key to the growth of silica nanowires in an open tube furnace.

Growth of Silica Nanowires, Fig. 18 Schematic illustrating the growth rate (weight differential) of silica nanowires as a function of heating time

Absence of nanowire formation was noted in the case of a minute increase in the oxygen level as mentioned earlier. Though the concentration magnitude could not be estimated, the partial pressure of oxygen must be below 3×10^{-5} atm. obtained from earlier report [19] for nanowire growth.

(b) The source of silicon originates both from the substrate (when the metal consumes Si for the alloy formation leaving exposed facets of Si) and the support wafer. Also, the initial oxide layer is transformed into silicon monoxide upon heating the sample at 1,100 °C. Presence of SiO vapor aids nanowire growth by supplying both vapor phase Si and O. Such hypothesis is concurrent with the prior investigation on thermodynamic equilibrium between Si and SiO at 1,100 °C [23].



(c) A combination of growth models governs nanowire growth. The presence of metal catalyst at the tip of nanowires, formation of silicide in tandem with the need for Ar suggests Vapor Liquid Solid (VLS) model. To rule out the Solid Liquid Solid (SLS) model, the nanowires were mechanically removed and then the substrate was inspected for any silicide nanocluster. The absence of catalyst at the sample surface negates the possibility of SLS model. Also, the formation of a thin oxide layer and role of SiO inducing nanowire growth signifies oxide-assisted growth (OAG) mechanism.

Conclusions

In summary, the manufacturing aspect of silica nanowire growth was investigated. Nanowires were found to nucleate following a combination of VLS and OAG mechanism. For a given thickness of Pd thin film and heating temperature of 1,100 °C, the nanowire growth seems to saturate after a heating time of 100 min. It has been observed that the nanowires grow at the expense of the catalyst negating the reusability for the substrate.

Summary

In this entry, silica nanowire growth was discussed in view of their potential for several

Growth of Silica Nanowires, Fig. 19 Growth model for silica nanowires on Si (**a**) metal catalyst placement in Si using ion implantation or sputtered thin film, (**b**) after sample introduction into furnace – silicide formation along with a thin oxide layer, (**c**) disassociation of oxide layer to form SiO and formation of Si etch pits with increasing heating time, (**d**) birth of silica nanowires with metal catalyst on top, and (**e**) growth of silica nanowires of high aspect ratio

unique applications such as localization of light, low-dimensional waveguides for functional microphotonics, SNFOM, optical interconnects on a futuristic integrated optical microchip, sacrificial templates, biosensors, and optical transmission antennae. The "bottom-up" and "top-down" approaches in growing nanowires were discussed with emphasis on the VLS-mediated growth. Further, the research on selective growth of silica nanowires on silicon using metal ion implantation–based seeding approach and metal thin film catalysis was presented. While the former technique has the advantage of precise placement of catalyst and near to uniform growth, the latter offers an inexpensive way to mass manufacture them. A unique feature tying both the synthesis methodologies is the use of simple open tube furnace in a high-purity Ar ambient unlike the use of harmful gases like silane or complex instrumentation such as a CVD system.

Time sequence study of the silica nanowire growth reveals a combination of VLS and OAG mechanism responsible for nanowire nucleation. Silica nanowires grown using such a combinatorial mechanism exhibit high aspect ratio (~3,000:1) and are amorphous in nature. Growth rate characteristics indicate an initiation period, prolific growth regime, and a steady state phase.

Structural characterization at a high resolution indicates catalyst metal nanoclusters along its body suggesting the formation of a hybrid (metal/dielectric) nanostructure, critical for sensing applications. Finally, a brief highlight on manufacturing aspects of silica nanowires was presented.

Future Directions

Producing an ordered array of vertically aligned nanowires is critical for many applications. In particular, the biosensing applications require silica nanowires to be grown vertically. Vertically aligned nanowires are easier to manipulate and offer greater surface coverage. Silica nanowires can be grown vertically or in an aligned fashion using electric field–assisted assembly, porous alumina templates, and self-assembly using bioengineered interfaces. Also, growing nanowires at low temperature on various substrates is critical for device applications. Apart from the growth aspects, investigating silica nanowires using Local Electrode Atom Probe (LEAP) will yield interesting results on the elemental composition and texture along the length of the wire. The atom probe is a combination of a field ion microscope and a mass spectrometer. Looking at the nanowires at their early stage of growth using LEAP will provide fundamental details on nucleation and the role of catalyst inducing growth. Moreover, these results can give an insight on the growth model.

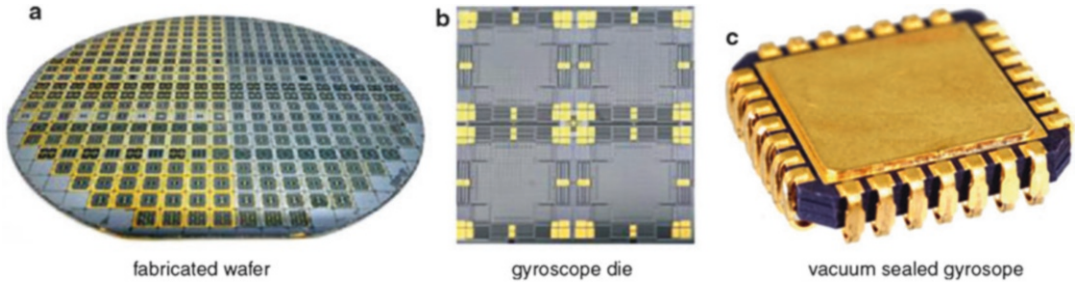
Definition

Gyroscopes are physical sensors that detect and measure the angular motion of an object relative to an inertial frame of reference. The term "gyroscope" is attributed to the mid-nineteenth century French physicist Leon Foucault who named his experimental apparatus for Earth's rotation observation by joining two Greek roots: *gyros*, rotation and *skopeein*, to see. Unlike rotary encoders or other sensors of relative angular motion, the unique feature of gyroscopes is the ability to measure the absolute motion of an object without any external infrastructure or reference signals. Gyroscopes allow untethered tracking of an object's angular motion and orientation and enable standalone Attitude Heading Reference Systems (AHRS). Combining three gyroscopes with three accelerometers in a complete 6-axis Inertial Measurement Unit (IMU) enables self-contained Inertial Navigation Systems (INS) for navigation, guidance, and dead reckoning.

All *gyroscopes* can be divided into two main categories, depending on whether the angular velocity or orientation is being measured [1]. *Rate gyroscopes* measure the angular velocity, or the rate of rotation of an object. *Angle gyroscopes*, also called *Whole Angle* or *Rate Integrating* gyroscopes, measure the angular position, or orientation of an object directly. While devices sensitive to the angular acceleration are used in some applications, these sensors are typically not referred to as gyroscopes, but rather as angular accelerometers. Essentially all currently existing Micro-Electro-Mechanical-Systems (MEMS) gyroscopes are of the rate measuring type and are typically employed for motion detection (e.g., in consumer electronics and automotive safety devices) and motion stabilization and control (e.g., in smart automotive steering and antenna/camera stabilization systems).

True INS and AHRS applications rely on the continuous tracking of the object's orientation. Measurement of the angular position can be accomplished either by numerical integration of a rate gyroscope's output, or by using an angle gyroscope which effectively integrates the rotation rate by virtue of its internal dynamics and outputs the angle information directly. When a rate gyroscope is used to track the orientation, its output signal is integrated over time together with the associated errors and noise, leading to fast buildup of the orientation angle drifts

(e.g., white noise in the angular rate signal results in $1/f^2$ drift, or random walk, of angle). Successful realization of standalone gyroscope-based INS and AHRS thus requires either angle gyroscopes or rate gyroscopes with extremely stable and low noise output.



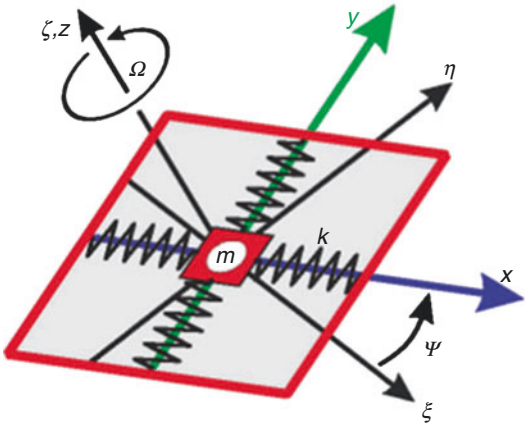
Historical Overview of Vibratory Gyroscope Technologies

Early work by Leon Foucault during the mid-nineteenth century explored two different design paradigms for angle measuring mechanical gyroscope based on either a spinning or vibrating mass. While the spinning mass approach was the dominant method of mechanical gyroscope construction from its inception well into the second half of the twentieth century, it is not well suited for MEMS implementation due to the technological limitations in the manufacturing of precision, low friction bearings. Few designs of spinning mass MEMS gyroscopes using electrostatic levitation have been reported in the literature [2, 3] without yet achieving commercial success due to the inherent instability of the mechanical system and necessity for a sophisticated control system.

The vibrating mass approach, illustrated by the popular Foucault pendulum experiment, exploits the exchange of energy between different axes of vibration due to the Coriolis effect. This architecture, at present referred to as the Coriolis Vibratory Gyroscope (CVG) [4] remained largely a scientific curiosity for almost a century until the introduction of a functional vibratory gyroscope by Sperry in the mid-twentieth century [5] followed by successful commercialization of quartz tuning fork gyroscopes by BEI Technologies in the late-twentieth century [6], and very high volume deployment of silicon MEMS CVGs in the early twenty-first century. Today, silicon vibratory rate gyroscopes with capacitive transduction comprise the majority of MEMS gyroscopes in development and production, with some research groups and manufacturers pursuing quartz devices with piezoelectric transduction or silicon devices with alternative transduction mechanisms such as inductive or electromagnetic [7]. Figure 1 shows photographs of a wafer-level batch fabricated silicon-on-insulator (SOI) gyroscope with capacitive actuation and detection designed, fabricated, and packaged at the University of California, Irvine [8].

Coriolis Vibratory Gyroscope Dynamics

In this section, the principles of operation of Coriolis vibratory gyroscopes are derived from the basic concepts of classical mechanics. While a planar, z-axis vibratory gyroscope is the focus of the explanation, the discussions are generic in nature and equally apply to devices with other architectures, including torsional, out-of-plane, and sensors with multiple modes of vibration for simultaneous detection of rotation in several axes. Let $S\xi\eta\zeta$ denote an inertial reference frame, in which a non-inertial frame $Oxyz$ is moving with a linear acceleration $A_0 = (A_0x,\ A_0y,\ A_0z)$ and an angular velocity $\Omega = (\Omega_x,\ \Omega_y,\ \Omega_z)$, where the components of the



Gyroscopes, Fig. 1 Photographs of a wafer-level fabricated silicon-on-isolator gyroscope with capacitive transduction designed, fabricated, and packaged at the University of California, Irvine MicroSystems Laboratory, http://mems.eng.uci.edu/

vectors are given with respect to the moving frame. Coordinates of a point mass in the inertial and non-inertial reference frames are given by vectors $\rho = (\xi, \eta, \zeta)$ and $r = (x, y, z)$, respectively. Newton's equation of motion of the point mass m under the action of force vector $F = (F_x, F_y, F_z)$ with respect to the inertial reference frame $S\xi\eta\zeta$ are given by $\rho'' = A_{abs} = F/m$, where the prime denotes derivative with respect to time. According to the rules of differentiation in a moving frame:

$$\begin{aligned} r'' &= A_{rel} \\ &= F/m - 2[\Omega \times r'] - (A_0 + [\Omega \times [\Omega \times r]] \\ &\quad + [\Omega' \times r]). \end{aligned} \tag{1}$$

This differential vector equation provides a mathematical foundation for the Coriolis vibratory gyroscopes. The Coriolis cross-product of the angular velocity Ω and the coordinate vector $r = (x, y, z)$ governs the coupling and exchange of energy between x, y, and z non-inertial axes. This effect allows measuring the input angular velocity Ω by observing the vibration pattern of the proof mass m relative to the non-inertial device reference frame $Oxyz$.

A theoretical model of a single axis Coriolis vibratory gyroscope is shown in Fig. 2. A point mass m forms the Coriolis sensitive proof mass and is constrained to motion in the Oxy plane under the influence of elastic forces of the suspension and inertial forces, caused by the motion of the $Oxyz$ non-inertial reference frame. To simplify the conceptual discussion, it is assumed that the proof mass suspension produces a linear field of elastic forces $Fs = (k_x x, k_y y)$. Also neglected are the projection of the gravity field on the Oxy plane, out-of-plane Oz axis dynamics, and acceleration of the origin O. These assumptions are justified by high out-of-plane stiffness of typical bulk micromachined structures and large frequency separation between the external and Coriolis accelerations. After linearization with respect to the input angular velocity vector Ω components Ω_x, Ω_y, Ω_z, Eq. 1 can be simplified to the following:

Gyroscopes, Fig. 2 Theoretical model of a single z-axis vibratory gyroscope consisting of a proof mass m suspended in the x-y plane. The xyz non-inertial frame of reference associated with the sensor is moving relative to the inertial frame $\xi\eta\zeta$ with an angular velocity $\Omega = (0, 0, \Omega_z)$. Coriolis force coupling between the x and y coordinates causes energy exchange which is used to detect the input rate Ω_z

$$\begin{aligned} x'' + x{\omega_x}^2 - y{\Omega'}_z - 2\Omega_z y' &= F_x, \\ y'' + y{\omega_y}^2 + x{\Omega'}_z + 2\Omega_z x' &= F_y, \end{aligned} \tag{2}$$

where ω_x and ω_x are the mechanical natural frequencies of the x- and y-mode, respectively. The following discussion will consider two different modes of operation of Coriolis vibratory gyroscopes – rate measuring and angle measuring.

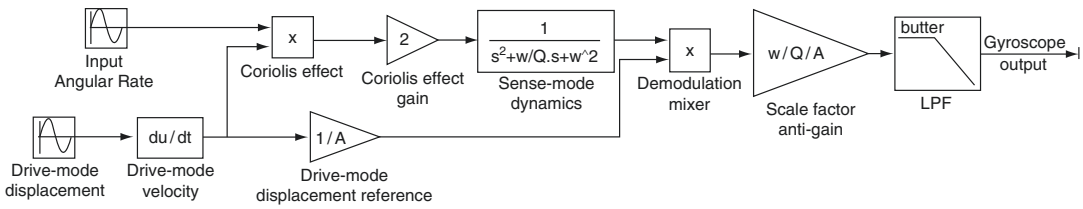
Rate Gyroscope Operation

Rate gyroscopes are operated with inherent nonsymmetry between the Ox axis, designated as the drive-mode, and the Oy axis, designated as the sense-mode. The drive-mode is operated in the forced vibrations mode, where the excitation force F_x is a sinusoidal waveform with amplitude f and angular frequency ω_d. The sense-mode of a rate gyroscope can be operated either open-loop or in a force-to-rebalance closed loop, where a feedback force is generated to suppress the sense-mode vibrations and is simultaneously used as the measure of the input rate. Dynamics of

a rate gyroscope with an open-loop sense-mode can be derived from Eq. 2 as:

$$x'' + x{\omega_x}^2 - y\Omega'_z - 2\Omega_z y' = f/m\,sin\,(\omega_d t),$$
$$y'' + y{\omega_y}^2 + x\Omega'_z + 2\Omega_z x' = 0. \tag{3}$$

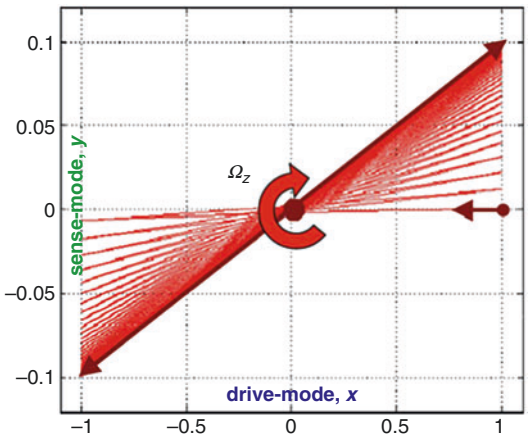
In practical implementations of vibratory rate gyroscopes, stabilization of the drive-mode velocity is desired to reduce the effect of manufacturing tolerances and operational conditions on the scale factor of the sensor. This is accomplished by an electronic feedback system which regulates the amplitude f of the driving force by means of an *Automatic Gain Control (AGC)* to maintain constant amplitude of the drive-mode motion. The frequency ωd of the drive-mode feedback force is generated by a *Phase-Lock Loop (PLL)* which locks to the drive-mode mechanical resonance frequency ωx. An alternative approach for drive-mode operation is through positive feedback of the velocity signal x', which effectively destabilizes the drive-mode and maintains resonance of the drive-mode. In the velocity feedback configuration, the need for a separate frequency source is eliminated, however often at the cost of increased jitter and noise in the Coriolis signal demodulation block. Simplified equations for a vibratory rate gyroscope with a closed-loop drive-mode and an open-loop sense-mode (see Fig. 3) are derived from Eq. 3 as:



$$x = sin\,(\omega_x t),$$
$$y'' + y'\left(\omega_y/Q_y\right) + y\omega_y^2 = -2\Omega_z x', \tag{4}$$

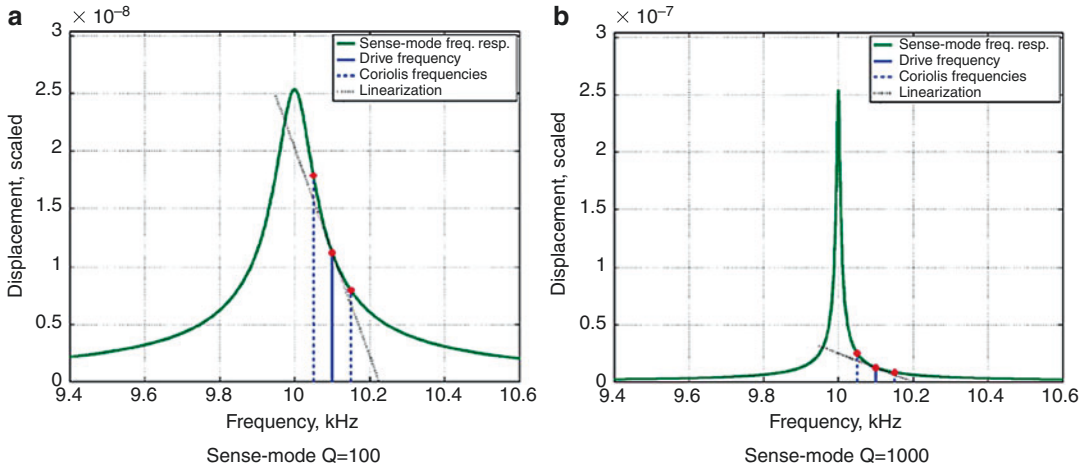
Here, an energy dissipation term, defined by the sense-mode quality factor Q_y, is now included in the sense-mode dynamics, while the term $x\Omega_z'$ is omitted assuming a slow-varying input Ω_z.

Figure 4 illustrates the motion of the proof mass relative to the device reference frame in the presence of input rotation. The drive-mode is a resonator driven to a constant amplitude of vibrations at a fixed frequency by means of a feedback system. During rotation of the device, the Coriolis effect causes coupling of energy from the drive-mode to the sense-mode. The Coriolis force applied to the sense-mode is given by the cross-product of and is proportional to the drive-mode velocity x' and the input angular rate Ω_z. Since the drive-mode velocity is a sinusoidal signal with a fixed frequency, the Coriolis effect results in the *Amplitude Modulation (AM)* of the input angular rate by the drive-mode velocity. To measure the input angular rate, displacement (or, equivalently, velocity) of the Coriolis force induced sense-mode vibrations is measured by means of an amplitude demodulation.



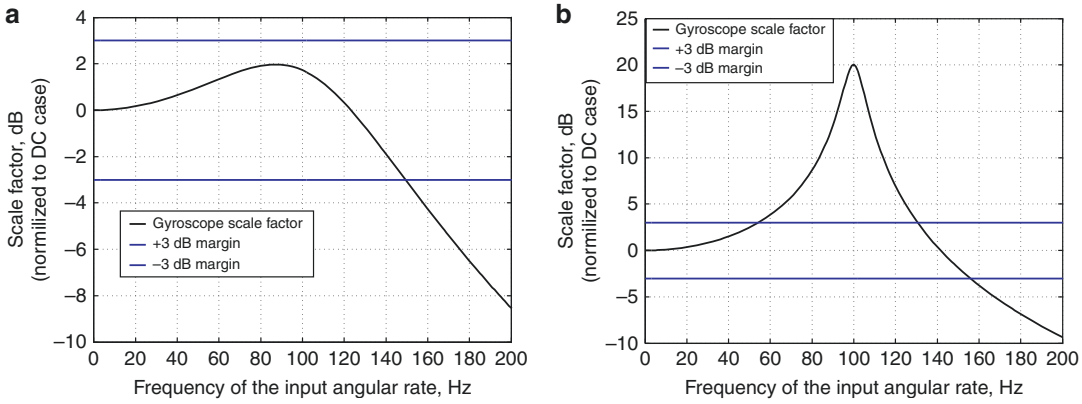
Coriolis vibratory rate gyroscopes are commonly divided into two classes depending on the relative matching or mismatching between the drive-mode and sense-mode resonant frequencies. When the drive frequency is within the bandwidth of the sense-mode resonance peak, the mechanical sensitivity of the gyroscope is maximized proportionally to the sense-mode quality factor Q_y. However, the sensitivity and *Signal-to-Noise (SNR)* advantages of this configuration come at the trade-off of the open loop rate sensor bandwidth, which in this case is inversely proportional to the sense-mode Q_y. An alternative design approach is the mismatching of the drive frequency from the sense-mode resonance by a prescribed amount.

In order to illustrate the dynamic response of a mode-mismatched rate gyroscope to a



Gyroscopes, Fig. 3 Block diagram of a Coriolis vibratory rate gyroscope with closed-loop drive- and open-loop sense-modes. Input rotation rate is amplitude modulated by the drive-mode velocity due to the Coriolis effect

time-varying input angular velocity is considered in the form of $\Omega_z = cos(\omega_{in}t)$ and the output scale factor is studied as a function of the input frequency ω_{in}. According to Eq. 4, the sense-mode is excited by $-2\Omega_z x' = \omega_d[cos((\omega_d - \omega_{in})t) + cos((\omega_d - \omega_{in})t)]$. This means that for a given $\Omega_z = cos(\omega_{in}t)$ input, the sense-mode has two forcing components of equal amplitudes at frequencies $(\omega_d \pm \omega_{in})$. This concept is illustrated with numerical modeling in Fig. 5, where the sense-mode frequency is set to 10 kHz with a quality factor of 100 and 1,000, the drive-mode frequency is 10.1 kHz (i.e., 1 % mismatching), and the input angular rate frequency is 50 Hz.



Gyroscopes, Fig. 4 Operation of a vibratory rate gyroscope is based on the excitation of the sense-mode by the Coriolis force, stemming from the cross-product of the drive-mode velocity and the input rotation rate. Sense-mode vibrations present an Amplitude Modulated (*AM*) signal of the input rotation rate with the drive-mode frequency serving as the carrier

As shown in Fig. 3, the signals at two Coriolis frequencies $(\omega_d \pm \omega_{in})$ both pass through the sense-mode dynamics and are then mapped back into a single frequency ω_{in} by the demodulation block. Figure 6 shows the input–output frequency response of a mode-mismatched vibratory gyroscope highlighting two distinct cases defined by the relationship between ω_y, Q_y, and ω_d. For a relatively low sense-mode Q_y, the gyroscope's 3-dB rate bandwidth includes the resonant peak at the $(\omega_d - \omega_y)$ frequency and the bandwidth exceeds the frequency mismatch between the drive- and sense-modes. For relatively high sense-mode Q_y, the resonant peak at the $(\omega_d - \omega_y)$ frequency escapes the gyroscope bandwidth, which in this case is given by approximately half of the drive- and sense-mode frequency mismatch. A detailed discussion on the mechanical design of vibratory rate gyroscopes is given in [9], where a multi-degree of freedom mechanical design of drive- and sense-modes is proposed as a way to increase the sensor robustness and

Gyroscopes, Fig. 5 Frequency domain representation of a mode-mismatched vibratory rate gyroscope response to a sinusoidal input angular rate with a 50 Hz frequency. Gyroscopes, Fig. 6 Input rate bandwidth of a mode-mismatched vibratory rate gyroscope. The simulation assumes sense-mode resonant frequency of 10 kHz and drive-mode excitation at 10.1 kHz. (**a**) Sense-mode at 10 kHz, Q = 100, 10.1 kHz drive (**b**) Sense-mode at 10 kHz, Q =1000, 10.1 kHz drive

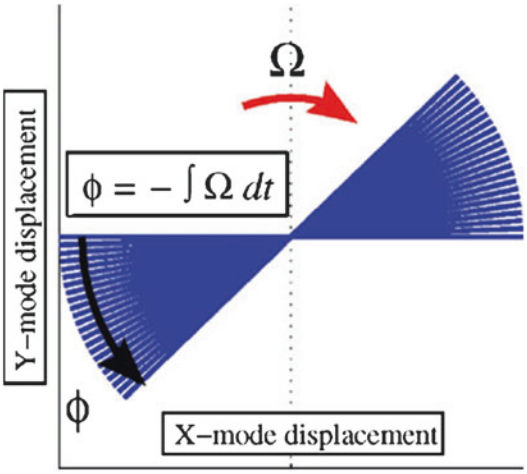
bandwidth. A different approach to resolving the quality factor versus bandwidth trade-off is the instrumentation of a vibratory gyroscope for direct angle measurements, which is based on the *x*-*y* symmetric free vibrations regime.



Angle Gyroscope Operation

The resolution and sensitivity of MEMS vibratory gyroscopes are often improved by maximizing *Q*-factors and reducing frequency separation between the two modes. Mode-matched silicon gyroscopes with *Q* of 100,000 have been demonstrated to provide sub-degree-per-hour bias stability [10]. However, mode matching of a high-*Q* rate gyroscope typically limits the open-loop sense-mode range to below 50 deg/s and rate bandwidth to 1 Hz. The traditional approach is forced-to-rebalance closed-loop operation of the sense-mode. While this approach extends the input–output bandwidth of a rate gyroscope, the signal-to-noise advantage of the high-quality factor is only preserved at low frequencies of the input angular rate. Two solutions have been proposed. The first approach is to design a relatively low-*Q* gyroscope with sub-micron capacitive gaps required for efficient transduction at a very high resonant frequency of 3 MHz [11]. The second approach is to operate an ultrahigh *Q*-factor gyroscope in the free vibrations mode, enabling direct angle measurements with mechanically unlimited sensing range and bandwidth.

Whole Angle operation dictates stringent requirements for the structural frequency and Q-factor symmetry, calling for new design architectures and fabrication methods. For example, the macroscale hemispherical resonator gyroscope (HRG) with sub-arcsecond angle resolution operates based on a mechanical element with isotropic *Q*-factors as high as 26 million [12]. Achieving the required level of damping and stiffness symmetry across process variations of conventional silicon MEMS technologies is very challenging. The latest advances in design and packaging of silicon MEMS devices enabled vibratory gyroscopes with *Q*-factors of one million [8], invigorating the development of angle measuring MEMS gyroscopes.

An ideal angle gyroscope, such as the classical Foucault pendulum, is a 2-D isotropic mass-spring system vibrating with the natural frequency ω, where $\omega = \omega_x = \omega_y$. In the presence of the inertial rotation with the rate Ω_z, the equations of motion can be derived from Eq. 2 by assuming very low dissipation and absence of any external forces as:

$$\begin{aligned} x'' + x\omega^2 - y\Omega_z' - 2\Omega_z y' = 0, \\ y'' + y\omega^2 + x\Omega_z' + 2\Omega_z x' = 0. \end{aligned} \tag{5}$$

Gyroscopes, Fig. 7 Illustration of the whole-angle mode: the orientation of the vibrations axis remains fixed in the inertial space, enabling direct angle detection

The whole-angle mode is based on the free precession of the axis of vibrations in response to the inertial rotation, Fig. 7. Orientation of the free vibrations axis remains fixed in the inertial space, providing an instantaneous orientation reference. Unlike the conventional rate measuring mode, where the axis of vibration is effectively locked to the intended drive direction, the whole-angle mode is not mechanically limited in rotation rate range or bandwidth. Changes in the precession angle Θ can be detected by monitoring x and y displacement components according to $\Theta = atan\ (y/x)$.

The above conceptual analysis of the whole-angle operating mode assumes isotropic stiffness and negligible damping. Detailed error model analysis shows that the key sources of the angle error are the frequency mismatch $\Delta\omega = \omega_x - \omega_y$ and energy dissipation time constant mismatch $\Delta(1/\tau) = 1/\tau_x - 1/\tau_y$. Minimization of the damping asymmetry drift requires very low dissipation structures with isotropic Q-factors. For instance, the damping asymmetry $\Delta(1/\tau)$ of 1e-5 rad/s with τ of 160 s (equivalently, $\Delta Q/Q$ of 0.1 %) is equivalent to the angle drift of 1 deg/h. These considerations motivate the advancement of fabrication of flat silicon structures with post-fabrication trimming and electrostatic tuning. Novel 3-D fabrication approaches for axisymmetric shell resonators with inherent smoothness and isotropy provide another promising possibility [13].

Gyroscopes, Table 1 Typical performance parameters of state-of-the-art commercial MEMS rate gyroscopes Ref. [16]

Parameter	Value
Rate resolution	5–10 deg/h/√Hz
Temperature sensitivity of bias	10 deg/h/deg C
Bias repeatability (temperature, turn on)	30 deg/h
Temperature sensitivity of scale factor	250 ppm/°C
Scale factor repeatability (temperature, turn on)	400 ppm

Historical Milestones of MEMS Gyroscopes

Since their initial introduction two decades ago in 1991 [14], the resolution of silicon micromachined gyroscopes has been improving by approximately a factor of 10 every 2 years [15]. Most recent literature on state-of-the-art vibratory MEMS gyroscopes with electrostatic/capacitive transduction reports precision on the order of 10 deg/h [16] with a trend of achieving better than 1 deg/h in controlled conditions [10] (Table 1). Despite the remarkable continuing improvement in the angular rate resolution achieved by micromachined vibratory gyroscopes, measurement repeatability, accuracy, and long-term drift still limit deployment in a variety of field applications where autonomous and repeatable operation is required over extended time and varying environments. Currently, there are several companies producing tactical grade inertial sensors and systems based on the silicon MEMS technology, Table 2; inertial grade systems are yet to be demonstrated. A comprehensive review of MEMS vibratory rate gyroscope commercialization trends are presented in [9]; here, some of the most significant milestones published in literature are reviewed.

In 2002, Analog Devices reported a surface micromachined polysilicon gyroscope with a

Gyroscopes, Table 2 Performance requirements for three grades of gyroscopes Ref. [15]

Parameter, unit	Rate grade	Tactical grade	Inertial grade
Angle random walk (ARW), deg/√h	>0.5	0.5–0.05	<0.001
ARW-equivalent rate resolution, deg/h/√Hz	>30	30–3	<0.06
Bias drift, deg/h	10–1,000	0.1–10	<0.01
Scale factor accuracy, ppm	100–1,000	10–100	<1
Full scale linear range, deg/s	50–1,000	>500	>400
Bandwidth, Hz	>70	100	100

50 deg/h random bias instability achieved at the averaging time below 1 min [17]. The single-chip integrated device was not vacuum packaged, which in combination with a 4 μm thin structural layer translates into a relatively low sense-mode quality factor on the order of 20. This family of gyroscopes has since gained a widespread acceptance and popularity in consumer and automotive markets, with new gyroscopes introduced every few years. According to Table 2, this device falls into the middle of the Rate grade category, as defined in [15]. Publication [17] also projected that the random bias can be improved by approximately 80 % by introducing new electronics design, suggesting a mechanical-thermal limit on the level of 10 deg/h. The newer generation design of the gyroscope has four electrically coupled, low quality factor surface micromachined polysilicon Coriolis vibratory gyroscopes integrated on the same die together with the electronics in order to suppress the effect of external vibrations; improvement of the bias instability was also reported.

A higher performance polysilicon micromachined gyroscope from Bosch was reported in 2007 in [18]. The device has a 1 deg/h random bias instability, showing its potential for the Tactical grade performance category, Table 2. However, this high sensitivity occurs only at a long, averaging times on the order 160 min. The minimal detectable signal at practical bandwidths was lower (30 deg/h for a 10 Hz bandwidth, and 100 deg/h for a 100 Hz bandwidth). This device was not integrated with electronics on the die level (hybrid integration of the MEMS and the electronics dies was done on a package level), and its low noise level is attributed to vacuum packaging and high sense-mode quality factor.

A 2006 publication [16] from Charles Stark Draper Laboratory provides an insightful review of performance characteristics of a few additional commercial MEMS gyroscopes. According to this paper, the uncompensated thermal sensitivity of higher performance quartz tuning fork gyroscopes from Custom Sensors and Technologies (formerly Systron Donner/BEI) was reported at 300 ppm/°C, achieved primarily due to extremely low sensitivity of the material's properties to temperature. Analog Devices' automotive grade angular rate sensor ADXRS150 scale factor uncompensated thermal sensitivity was quoted as 1,700 ppm/°C. Honeywell's dissolved wafer, single crystal silicon on glass, device based on the Draper laboratory design achieves a 250 ppm/°C scale factor temperature coefficient.

Surveying the literature confirms that in recent years performance of the commercial MEMS gyroscopes continued to improve, reaching the criteria of Tactical grade category; however, performance of these gyroscopes is still two to three orders of magnitude away from the Inertial grade. The reported progress often comes with costly refinements of the fabrication and vacuum packaging processes. Most reported commercial gyroscopes have intricate electronic compensation for such parameters as temperature drift and aging. From the mechanical structure point of view, the majority of commercial gyroscopes consist of several coupled, anti-phase-driven vibratory gyroscope elements (2- or 4-tine tuning fork architecture) to suppress external vibrations.

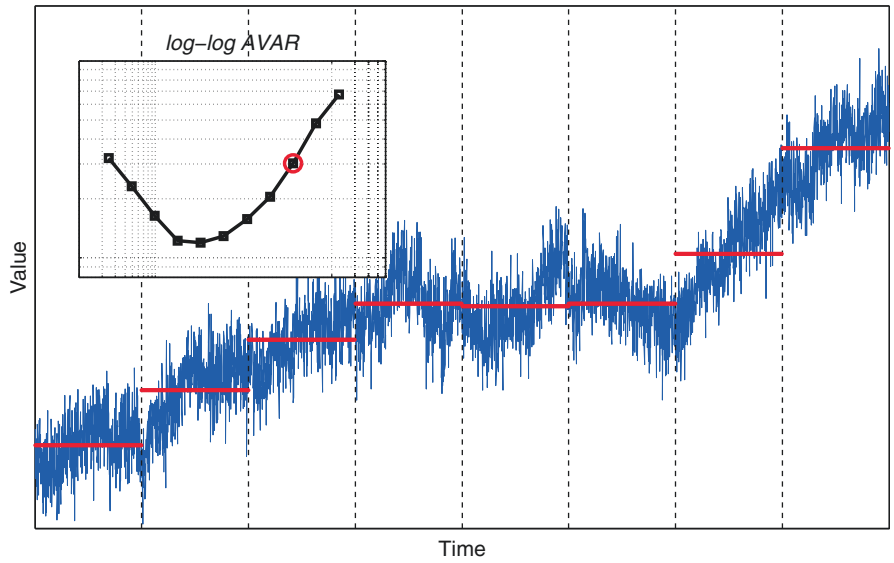
Striking breakthroughs in very large scale commercialization of very low cost (<$1 per axis) MEMS rate gyroscopes and accelerometers have been achieved during 2005–2010 by InvenSense, ST Microelectornics, and other suppliers targeting consumer electronics devices. In contrast to the automotive or defense applications with stringent requirements for reliability and high accuracy, size and price are the main drivers

for the consumer electronics applications. Current emphasis in low-cost inertial sensor commercialization is on a System-in-a-Package (SiP) and ultimately single-chip integration of 6 axis of inertial sensing augmented with a 3 axis magnetometer and a pressure sensor. Kalman filter-based sensor fusion is employed to produce useful 6-axis position and orientation information by taking advantage of the inherent sensory redundancy in the 10 degrees of freedom produced by these sensors.

Systematic Performance Parameters

In this section an explanation is provided of several most important terms used to describe and quantify the characteristics of Coriolis vibratory gyroscopes [4] with emphasis on deterministic and stochastic aspects of performance or rate sensors.

Scale factor (SF) is the ratio between the output and input signals in the linear regime of measurements. For rate gyroscopes with analog voltage output, *SF* is often expressed in V/(deg/s) or V/(deg/h). Several nonideal properties of *SF* are typically characterized, including sensitivity to temperature (in ppm/°C) and linear accelerations (in ppm/g), and *SF* turn-on repeatability (in ppm for 1-σ or 3-σ statistics). Common sources of *SF* error in MEMS gyroscopes are fabrication imperfections, drifts of drive- and sense-mode resonant frequencies and quality factors, and drifts of electronics gains, especially due to turn-on self-heating.



Bandwidth (BW) is the range of the input signal's frequencies which can be measured well by the gyroscope. BW is often specified assuming a ±3 dB margin around the gain (Scale Factor) of the gyroscope for a nonzero constant input rate. In general, the gyroscope's input–output BW should be distinguished from the individual mechanical bandwidths of the drive- or the sense-modes of vibration. A more complete picture of the gyroscopes dynamic response is given by a frequency response plot.

Bias is the apparent output of the rotation sensor for zero input rate assuming specific fixed operational conditions (e.g., temperature). For rate gyroscopes *Bias* is expressed in deg/s or deg/h units. Typical associated nonidealities are the sensitivity of bias to temperature (in deg/s/°C or deg/h/°C) and acceleration (deg/s/g or deg/h/g), *Bias* turn-on repeatability (in deg/s or deg/h for 1-σ or 3-σ statistics). A major sources of *Bias* error in MEMS gyroscopes is mechanical quadrature – the undesired sense-mode vibration caused by the fabrication imperfections. While phase-sensitive demodulation suppresses the quadrature signal by several orders of magnitude, minute phase drifts in the system cause so-called quadrature spillover error – the erroneous change of bias due to the partially unsuppressed quadrature. Even though random noise and drift effects are often referred to as bias, it is important to draw a clear distinction between systematic and random changes of output.

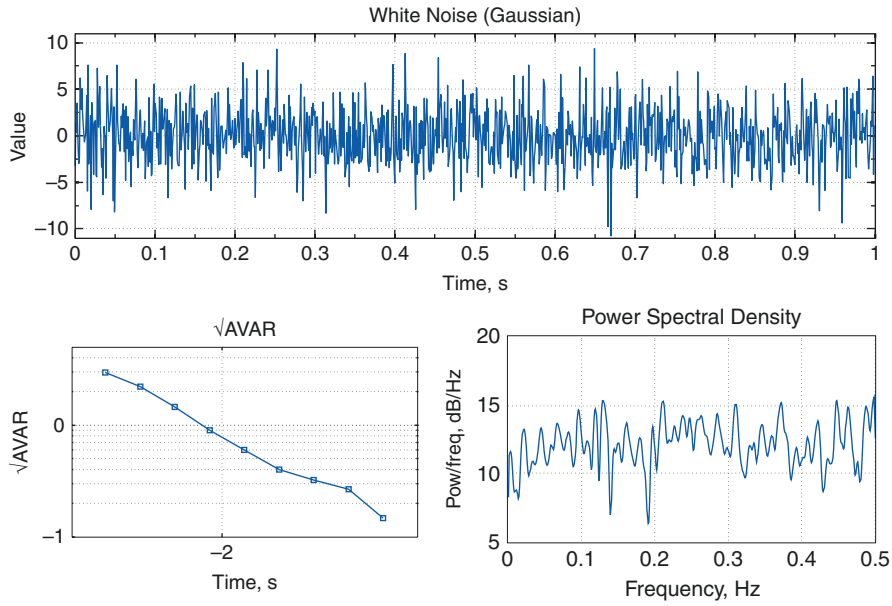
Random Noise Performance Parameters

Bias Instability (BI) refers to the additive error in the gyroscope's output with stochastic or random characteristics. Different random noise modes dominate the overall gyroscope noise level depending on the averaging time, which in turn defines the useful sensor bandwidth. The Allan deviation method is often used to identify and quantify random noise modes with different autocorrelation properties and expose their effect when the output signal is averaged or integrated over time.

Allan deviation analysis of a time domain signal $w(t)$ consists of computing its Allan deviation (also know as root Allan variance) $\sigma(\tau)$ for different integration time constants τ and then analyzing the characteristic regions and log–log scale slopes of the $\sigma(\tau)$ curve to identify different noise modes, i.e., random additive components of the signal with different autocorrelation power laws. The first step of the analysis is to acquire a time history $w(t)$ of the gyroscope's output using an experimental setup or a numerical computer simulation. The second step is to fix the integration time constant τ, divide the time history of the signal into K number of clusters of width τ, then average the

Gyroscopes, Fig. 8 Illustration of the Allan deviation analysis procedure using a simulated random process with a white noise (−1/2 slope in the Allan deviation) and a random walk component (integral of white noise, +1/2 slope in the Allan deviation)

signal over each cluster to obtain $w_{i\,=\,1\ldots K}$, and finally compute the Allan variance defined as one half of the average of the squares of the differences between the successive averaged values: $\sigma^2(\tau) = 0.5 < (w_{i+1} - w_i)^2 >$. The described sequence of steps yields an estimated value of the Allan deviation $\sigma(\tau)$ for the chosen integration time constant τ, Fig. 8. To obtain the whole $\sigma(\tau)$ curve, the computation is repeated multiple times for a sequence of τ values. Typically, the integration time constants τ are iterated through the multiples or powers of the time discretization step (inverse of the signal sampling rate). While an Allan deviation curve for a signal contains essentially the same information as the signal's power spectral density (*PSD*), it presents the information in an alternative and often more convenient way. The power laws of *PSD* and Allan deviation are related to each other in the following way:

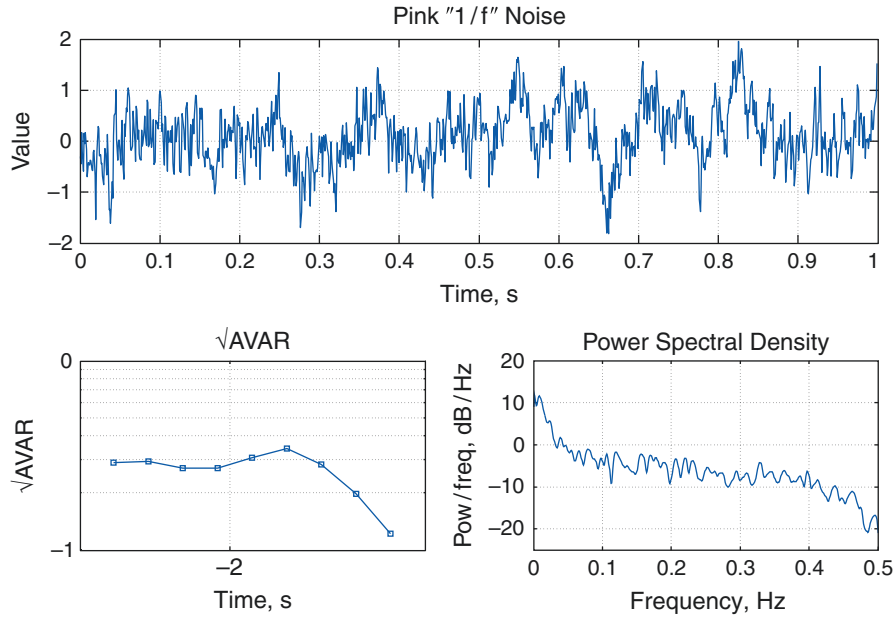


$$PSD(f) \propto f^{\alpha} \text{ is equivalent to, } \sigma(\tau) \propto \tau^{\beta}, \quad \text{where } \beta = -(\alpha + 1)/2 \text{ and } f = 1/\tau. \tag{6}$$

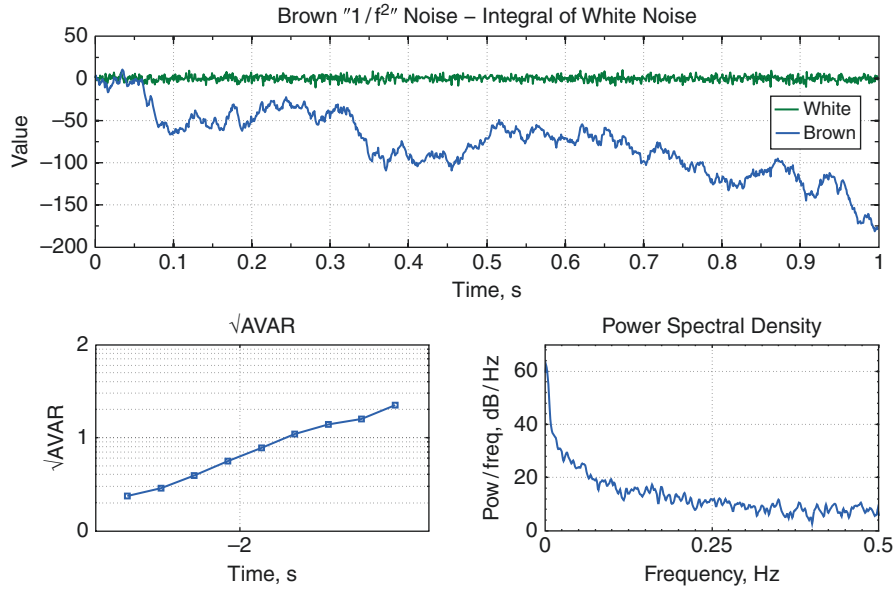
Table 3 presents a classification of the main noise components in MEMS gyroscopes based on their power spectral density and Allan deviation power laws.

White noise is a random signal with a constant power spectral density. While this definition presents a mathematical abstraction not physically possible due to its infinite total power, it gives a useful model of random processes with very short characteristic autocorrelation times. For example, the random motion of particles due to mechanical-thermal noise at room temperature has a characteristic cutoff frequency of approximately 6 THz. Important characteristic properties of a white noise type random process in time, frequency, and Allan deviation domains are shown in Fig. 9 using a simulated signal. Power spectral density of the white noise is independent of frequency, i.e., $PSD(f) \propto f^{\alpha}$ with $\alpha = 0$. As expected from Eq. 6, the numerically estimated Allan deviation of the white noise is governed by $\sigma(\tau) \propto \tau^{\beta}$ with $\beta = -1/2$. In the Allan deviation plot, the rate white noise is identified by fitting the $-1/2$ sloped part of the log-log scale curve with $y = ax^{-1/2}$ and estimating the value of a. In rate gyroscopes, the amount of white noise is quantified in terms of its power spectral density with deg/s/√Hz or deg/h/√Hz units. The value is often referred to as the *rate resolution* (same units) or *Angle Random Walk* (converted to deg/√h).

Gyroscopes, Table 3 Classification of random noise modes as applied to rate gyroscopes



Spectral type	Example sources	*PSD(f)* power law f^{α}	$\sigma(\tau)$ power law τ^{β}	Averaging over time	Associated gyroscope parameters
White	Johnson–Nyquist thermal noise	f^{0}	$\tau^{-1/2}$	Good	Rate resolution in deg/s/√Hz or deg/h/√Hz
					Angle random walk (ARW) in deg/√h
Pink	Electronics flicker	f^{-1}	τ^{0}	Neutral	Flicker, bias instability in deg/s or deg/h
Red (Brown)	White noise accumulation	f^{-2}	$\tau^{+1/2}$	Bad	Rate Random Walk (RRW) in deg/s*√Hz or deg/h*√Hz



Gyroscopes, Fig. 9 Illustration of the $1/f^{0}$ white noise properties in time, frequency, and Allan deviation domains using a numerical example

Random processes with $1/f$ *PSD* are naturally the next class of noise to consider. *Flicker noise*, commonly encountered in electronic circuits, falls into this category. Figure 10 illustrates time, frequency, and Allan deviation domain properties of $1/f$, or pink noise using a computer simulation. A pink noise can be obtained by low-pass filtering a white noise with a −3 dB per octave filter. Pink noise can be distinguished from a white noise by more visible low-frequency fluctuations. As expected from Eq. 6, Allan deviation has essentially a flat profile in the case of pink $1/f$ noise. In rate gyroscopes, $1/f$ noise often defines the smallest value of the Allan deviation, which is referred to as the *Bias Instability* and has units of deg/s or deg/h.

The third important type of random noise is red noise characterized by $1/f^{2}$ *PSD*. This type of random process is called a *Random Walk* and occurs whenever a white noise is accumulated over time. While not correct from the color spectral parallel, red $1/f^{2}$ noise is sometimes referred to as Brown noise, in honor of Robert Brown who first studied Brownian motion. Figure 11 illustrates time, frequency, and Allan deviation domain properties of $1/f^{2}$ *Random Walk* obtained

Gyroscopes, Fig. 10 Illustration of the *1/f* ("*pink*") noise properties in time, frequency, and Allan deviation domains using a numerical example

Gyroscopes, Fig. 11 Illustration of the $1/f^2$ ("red" or "Brown") noise properties in time, frequency, and Allan deviation domains using numerical example

by numerical integration of a white noise signal. Another way to obtain a random walk process is to filter white noise with a −6 dB per octave filter. Random walk signal shows strong low-frequency fluctuations. The power spectral density of a random walk is given by $PSD(\mathrm{f}) \propto f^{\alpha}$ with $\alpha = -2$ and its root Allan deviation profile is governed by $\sigma(\tau) \propto \tau^{\beta}$ with $\beta = +1/2$. In the Allan deviation

plot, the rate random walk is identified by fitting the +1/2 sloped part of the curve with $y = bx^{+1/2}$ and estimating the value of b. In rate gyroscopes, $1/f^2$ noise is typically referred to as the *Rate Random Walk* (RRW) and quantified in deg/s*√Hz or deg/h*√Hz.

When a rate gyroscope is used to track or maintain the angular orientation of an object, the rate signal is integrated over time together with the associated white noise of rate, flicker noise of rate, and random walk of rate. Upon integration, the three rate noise sources with $1/f^0$, $1/f^1$, and $1/f^2$ densities produce, respectively, drifts of angle with $1/f^2$, etc., power spectral densities. Each of these errors of angle grows fast with time, leading to degradation of angle accuracy. Angle measuring (rate integrating) micromachined gyroscope can potentially provide much better accuracy and stability since the time integration of the noise is avoided.

Definition

In nanotechnology, any fabrication process naturally introduces disorder and randomness at the nanoscale. Disorder is typically unwanted in applications, as it is associated with unpredictable degrees of freedom that are difficult to control. However, it can be demonstrated that disorder supports fascinating and counterintuitive phenomena, which can be harnessed at the nanoscale for the realization of specific functionalities.

Introduction

It is a common perception that the presence of disorder influences negatively the properties of a physical system. Nevertheless, there are several cases in which disorder plays a positive role and can be exploited to develop novel applications. In general, the introduction of disorder significantly increases the complexity of the system under examination, but, as is often seen in nature, an increase in complexity also corresponds to a richer physical scenario. As a result, in recent years, great efforts have been devoted to the possibility of harnessing complexity and controlling disorder in optical systems at the nanoscale [1–3]. An important example is provided by the study of the disorder-induced localization phenomena. Starting from the initial works of Anderson on the insulation properties of a disordered conductor [4], researchers have been able to

generalize and study the occurrence of weak and strong localization in different physical contexts involving wave propagation in complex media. In photonics, the occurrence of Anderson localization has been observed and analyzed extensively by investigating the spectral properties of disordered photonic crystals [5, 6]. At the same time, localization phenomena play a key role in the presence of metal structures. It is well known that when an electromagnetic wave impinges on a metallic surface, it can excite a distribution of surface plasmon polaritons (SPP). By tuning the geometrical properties of the plasmonic structure, the SPP distribution can be tailored to produce a strong enhancement of the electromagnetic field, whose spatial extent can go far below the diffraction limit. The generation of highly localized hotspots plays an important role in many plasmonic applications and is usually achieved by considering symmetric and regular geometries (e.g., nano-tips). However, the investigation of the effects of disorder on a plasmonic system is of great interest, and in this respect, several studies have been conducted on the localization properties of fractal clusters, particles aggregates, and disordered surfaces [7, 8]. Due to the uncertainty produced by randomness and chaos, the study of these systems requires the development of rigorous theoretical models to treat disorder and complexity. In this entry, a disordered plasmonic is modeled by considering a set of interacting cavities. Differently from previous approaches, the modeling explicitly considers the presence of radiative and dissipative losses, hence providing a model which can be easily generalized to describe many different realistic nanoscale systems. The evolution of the system is investigated by deriving a set of coupled mode (CM) equations ruling the distribution and propagation of energy among the cavities. In the stationary regime, the CM equations can be rewritten as a recursive product of real-valued matrices by applying the transfer matrix formalism. In the presence of disorder, the transfer matrices of the system become random variables, and their general properties can be determined by means of random matrix theory (RMT). By definition, a random matrix (RM) $\mathbf{M}$ is a $D \times D$ matrix whose elements M_{ij} are random variables distributed according to a given probability distribution $\mu[\mathbf{M}]$. RMs were first introduced in the 1950s to interpret the fluctuations of the nuclear energy levels, but they have rapidly become a powerful investigation tool for random processes and disordered systems [9]. Furthermore, as in the case under examination, many physical phenomena and systems involve the introduction and manipulation of products of random matrices (PRM) [10]. The localization properties of a disordered system described by a PRM are usually characterized by introducing the Lyapunov characteristic exponent (LCE) γ_m of the PRM which, in analogy with dynamical systems, determines the exponential growth or decay of the PRM eigenfunctions and, consequently, of any vector evolving according to it. By applying the theory of PRMs, one can derive an analytic expression of γ_m for the relevant case of a binary distribution of different cavities. The calculation, which is performed by considering a suitable statistical mechanics approach, allows for the detection of an optimal amount of disorder maximizing the degree of localization of the system. The results from the theoretical model can be verified by resorting to numerical ab initio simulations, in which a chain of metallic nanoparticles under external illumination plays the role of a one-dimensional set of open cavities. In the nanoplasmonic system, disorder is introduced by varying the radius of a fixed number of spheres along the chain. The relative number of different spheres depends on a probability parameter p that controls the amount of disorder. The degree of localization in the system is determined by defining a suitable localization measure for the electromagnetic energy whose value is averaged over different realizations of disorder. In very good agreement with the theoretical prediction, the numerical results confirm the existence of an optimal value of disorder which maximizes the localization of energy in the system.

This entry is organized as follows. In section "Coupled Mode Theory of a One-Dimensional Chain of Disordered Cavities," the properties of a set of coupled open cavities are modeled by defining a set of CM equations, which in the stationary regime are rewritten as a product of

real-valued transfer matrices. In section "Random Matrix Theory: Analytic Estimation of the Localization Length," following a brief introduction to random matrix theory, the analytic expression for the LCE of the system is presented, which can be used to obtain the amount of disorder maximizing the localization properties of the system. In section "Nanoplasmonic Localization: Results from FDTD Simulations," the theoretical predictions are verified by performing a large set of massively parallel finite-differences in time-domain simulations on a chain of metallic nanoparticles, whose results are in excellent agreement with the RMT model.

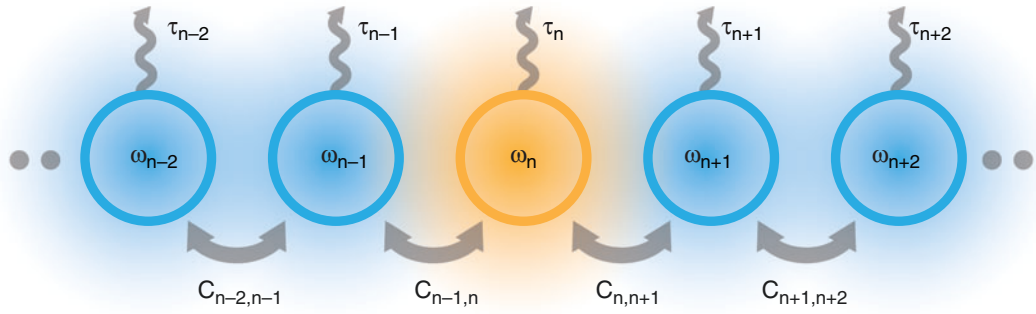
Coupled Mode Theory of a One-Dimensional Chain of Disordered Cavities

A large number of nanoscale systems can be modeled by considering a random set of interacting open cavities. A cavity, or resonator, is a structure capable of storing and accumulating energy at a given resonance frequency ω [11]. The resonance frequency corresponds to a localized mode (i.e., a standing wave) of the electromagnetic field inside the cavity. The amplitude of the localized mode is described by a complex function $a_n(t)$, in such a way that the energy stored in the cavity corresponds to $|a(t)|^2$. A cavity which can continuously lose energy by means of radiative emission is called an open cavity. A dissipative cavity, conversely, depletes energy due to internal losses (e.g., metal absorption). Radiative and dissipative losses, as can be easily understood, limit the ability of storing energy inside the cavity. A quantitative measure of the latter is provided by the quality factor Q of the cavity, which is defined as

$$Q = \frac{\omega W}{P_d} \tag{1}$$

where W is the energy stored in the cavity and P_d is the power depleted by radiative and dissipative losses. Simple arguments show that the quality factor is indeed a measure of the characteristic decay time τ of the electromagnetic energy inside the cavity, which is defined as $\tau = 2Q/\omega$. It follows that the properties of the cavity are completely determined by the oscillating frequency ω and the decay time τ, which can be grouped by defining a complex characteristic frequency

$$\Omega = \omega + i\frac{1}{\tau} \tag{2}$$



in order to simplify the notation. If one considers a set of distinct cavities with coupled resonance modes, electromagnetic energy can be further transferred among the single resonators. The exchange of energy among the cavities is described by introducing a set of coupling constants $C_{n,\,n'}$, with n, n' the indices identifying the interacting cavities. As a significant case study, one can consider the case of a one-dimensional chain of N-coupled cavities whose characteristic frequencies Ω_n are complex-valued random variables (Fig. 1). The system is chosen to be one-dimensional in order to provide a simpler notation, but all the results can be extended to higher dimensions with some algebraic effort [10, 12]. This model is particularly suitable to describe the distribution and localization of energy in a disordered plasmonic system, in which radiative and dissipative losses play an important role. Starting from an ordered chain of identical cavities, each one described by a characteristic frequency Ω_0, the presence of disorder can be introduced as a perturbation in the characteristic frequencies. As a result, the expression for the fluctuating frequencies reads

$$\Omega_n = \Omega_0 + \delta\Omega_n \tag{3}$$

where $\delta\Omega_n$ is a random variable distributed according to a given probability distribution $\mu[\delta\Omega]$. The evolution of the total system can be studied by applying coupled mode theory (CMT), which provides a set of evolution equations for the complex amplitudes of every resonator in the chain. By assuming nearest-neighbor interactions, CM equations read

$$\partial_t a_n = i\Omega_n a_n + iC_{n+1}a_{n+1} + iC_{n-1}a_{n-1}, \tag{4}$$

H

Harnessing Disorder at the Nanoscale, Fig. 1 Chain of open cavities. Every cavity is characterized by a different oscillation frequency ω_n and a different decay time τ_n. The exchange of energy along the chain is ruled by the coupling coefficients $C_{n,n'}$, which depend on the spatial coupling of the single-cavity modes

where $n \in [1, N]$ and

$$C_n = \begin{cases} 1 & n \in [1, N], \\ 0 & \text{otherwise}, \end{cases} \tag{4a}$$

C_n are coupling factors which are assumed to be constant along the chain, provided an opportune normalization of the CM equations allows for their inclusion in the complex frequencies Ω_n. Equation 4 can be rewritten in operatorial form by defining a state vector $(\mathbf{a}(t) = [a_1(t) \cdots a_N(t)]^\top$ and a tridiagonal operator $\mathbf{A}$:

$$\partial_t \mathbf{a}(t) = i\mathbf{A} \cdot \mathbf{a}(t)$$
$$\mathbf{A} = \begin{pmatrix} \Omega_1 & 1 & 0 & \cdots & 0 \\ 1 & \Omega_2 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & 1 & \Omega_N \end{pmatrix} \tag{5}$$

Given an initial condition, e.g., external illumination, the electromagnetic energy distributes along the chain of nanocavities until the system reaches a stationary state, in which the external pumping is balanced by the losses of the system. In the stationary regime $\partial_t \mathbf{a}(t) = 0$, the dynamical problem expressed by Eq. 5 becomes an eigenvalue problem for the operator $\mathbf{A}$. However, due to the introduction of radiative and dissipative losses, the operator $\mathbf{A}$ is not Hermitian, and its eigenvalues $\boldsymbol{\varepsilon}$, which are solution of the eigenvalue equation $\mathbf{A} \cdot \mathrm{a} = \boldsymbol{\varepsilon}\mathbf{a}$, are complex variables. Without losing any generality, the eigenvalue problem can be written in recursive form as

$$a_{n+1} = (\boldsymbol{\varepsilon} - \Omega_n)a_n - a_{n-1} \tag{6}$$

which is analogous to a discretized Schrödinger equation in the presence of a random complex potential. Despite the simple formulation, the real version of Eq. 6 has been extensively used to investigate localization phenomena in various physical systems. Following the standard approach and by defining the vector $\phi_n = [a_n \;\; a_{n-1}]^\top$, Eq. 6 can be rewritten in the transfer matrix formalism as

$$\phi_{n+1} = \mathbf{C}_n \phi_n, \qquad \mathbf{C}_n = \begin{bmatrix} (\boldsymbol{\varepsilon} - \Omega_n) & -1 \\ 1 & 0 \end{bmatrix} \tag{7}$$

where $\mathbf{C}_n$ is a complex-valued transfer matrix. The advantage of the transfer matrix approach is that it allows for a direct control of the propagation of energy along the chain of resonators. By iterating Eq. 7, in fact, one obtains

$$\phi_{N+1} = \mathbf{Q}_N \phi_1, \qquad \mathbf{Q}_N = \prod_{n=1}^{N} \mathbf{C}_n \tag{8}$$

where the vector ϕ_1 contains the initial conditions of the system (e.g., the input signal) and where the total transfer matrix $\mathbf{Q}_N$ is simply the product of the single-transfer matrices. It follows immediately that in the presence of disorder, the propagation of energy along the chain is ruled by a product of matrices with random elements and can be investigated by means of random matrix theory. However, the general results of random

matrix theory hold for real-valued matrices. In order to overcome this difficulty and provided the matrices $\mathbf{C}_n$ are symplectic matrices, a real-valued model can be deducted from Eq. 7 by considering separately the real and imaginary parts of the cavity amplitudes

$$a_n(t) = p_n(t) + iq_n(t) \tag{9}$$

and rewriting Eq. 4 as a system of $2N$-coupled differential equations. In the stationary regime, the evolution of the system is ruled by the following set of coupled recursive equations:

$$\begin{cases} p_{n+1} = \sigma'_n p_n - \sigma''_n q_n - p_{n-1} \\ q_{n+1} = \sigma''_n p_n - \sigma'_n q_n - q_{n-1} \end{cases} \tag{10}$$

in which the complex variable $\sigma_n = \boldsymbol{\varepsilon} - \Omega_n$ was introduced to simplify the notation and σ'_n and σ''_n are the real and imaginary parts of σ_n, respectively. Using the transfer matrix formalism, Eq. 10 can be rewritten as

$$\begin{aligned} \psi_{n+1} &= \mathbf{T}_n \psi_n, \psi_n = \begin{bmatrix} p_n \\ q_n \\ p_{n-1} \\ q_{n-1} \end{bmatrix}, \\ \mathbf{T}_n &= \begin{bmatrix} \sigma'_n & -\sigma''_n & -1 & 0 \\ \sigma''_n & \sigma'_n & 0 & -1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix}. \end{aligned} \tag{11}$$

where $\mathbf{T}_n$ is a real-valued 4×4 matrix with $\det \mathbf{T}_n = 1$. In analogy with Eq. 8, the total transmitted field reads

$$\psi_N = \mathbf{P}_{N\psi 1} \tag{12}$$

where the transfer matrix of the system

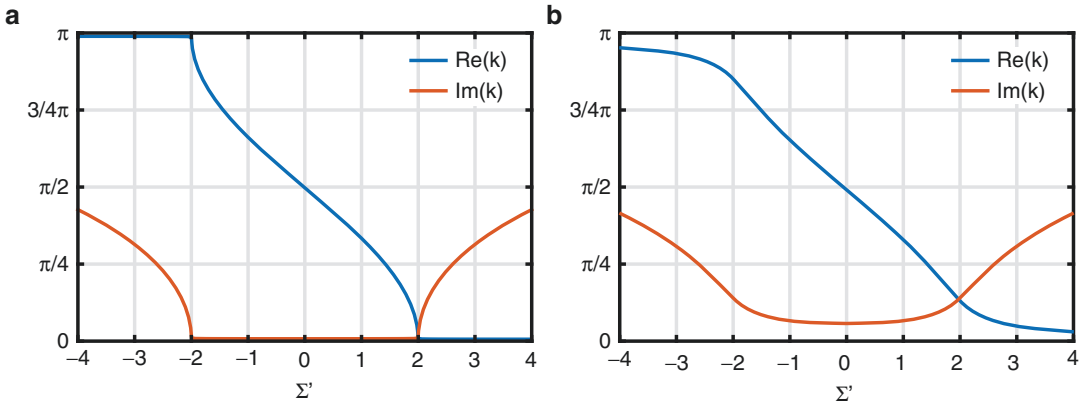
$$\mathbf{P}_n = \left[\prod_{n=1}^{N-1} \mathbf{T}_n \right] \tag{13}$$

has determinant one and is again the product of all the single-transfer matrices. In order to obtain a better insight into the physics underlying the model, one can solve Eq. 10 in the absence of disorder. By considering $\delta\Omega_n \equiv 0$, Eq. 7 can be easily solved by looking for a solution of the form

$$p_n + iq_n = Ae^{-ikn} + Be^{ikn} \tag{14}$$

where $k = k' + ik''$ is a complex wave number and A and B are complex constants depending on the boundary conditions. By substituting Eq. 14 into Eq. 10 and solving, one obtains

$$\begin{cases} \sigma' = 2\cos k' \cosh k'' \\ \sigma'' = -2\sin k' \sinh k'' \end{cases} \tag{15}$$



which corresponds to

$$\sigma' + i\sigma'' = 2\cos(k' + ik''). \tag{16}$$

Equation 16 relates the eigenvalues σ_n to the wavevector k of the corresponding eigenmodes. Therefore, it can be used to determine whether the solution associated with each value of σ_n is a propagating or exponentially localized solution. In the absence of any loss, σ_n is a purely real quantity, and, consequently, Eq. 16 has two kinds of solutions (see Fig. 2a). When $|\sigma'| \leq 2$, which is known as the allowed band of the system, the wave number k is a real quantity and the eigenmode of the total structure is a propagating wave. Conversely, when $|\sigma'| > 2$, the wave number k becomes a purely imaginary quantity, which corresponds to an exponentially attenuated eigenmode. As no propagation is possible, this condition defines the forbidden band of the structure. In the presence of losses, σ_n becomes a complex variable, whose imaginary part is always negative. The real part of σ_n is again divided into a forbidden and allowed region, but the presence of losses produces a solution which is exponentially attenuated also for values of σ'_n deep inside the allowed band $|\sigma'| \leq 2$ (see Fig. 2b).

Random Matrix Theory: Analytic Estimation of the Localization Length

In a disordered chain of cavities, the propagation and localization properties of the system depend

Harnessing Disorder at the Nanoscale, Fig. 2 Dispersion relation and energy bands of the system (**a**) in the absence of losses and (**b**) considering $\Sigma' + i\Sigma'' \equiv \sigma' + i\sigma''$ and $\sigma_n'' = -0.4$

on the amount of disorder introduced, which is directly related to the random frequency distribution $\mu[\delta\Omega]$. The transfer matrices $\mathbf{T}_n$ and the total product matrix $\mathbf{P}_N$ become random noncommutative variables, whose general properties can be studied by employing random matrix theory. As in the case of standard random variables, the global properties of a large set of RMs can be determined by means of limit theorems. In the case of a PRM, these limit theorems provide useful and universal estimates for the growth of the eigenfunctions of the final matrix and, consequently, for any state vector evolving according to it. In the presence of disorder and in analogy with chaotic dynamical systems, a generic vector $\psi_N = \mathbf{P}_N\psi_1$ will be related to the initial condition ψ_1 by an exponential growth of the form $|\psi_N| = |\psi_1|\exp(\widetilde{\gamma}N)$ when N is sufficiently large. The growth rate for a specific PRM is then given by

$$\widetilde{\gamma} = \frac{1}{N}\log\frac{|\psi_N|}{|\psi_1|} = \frac{1}{N}\log\mathrm{Tr}\mathbf{P}_N \tag{17}$$

and $\widetilde{\gamma}$ is called the Lyapunov characteristic exponent (LCE) of the PRM $\mathbf{P}_N$. Due to the random nature of the PRM, the LCE defined in Eq. 17 depends on the specific sequence of RMs composing $\mathbf{P}_N$. A general extension of Eq. 17 can be obtained by averaging over all the possible sequences of RMs and by taking the limit $N \to \infty$, namely,

$$\gamma_m \equiv \lim_{N\to\infty} \frac{1}{N}\langle\log\mathrm{Tr}\mathbf{P}_N\rangle \tag{18}$$

where γ_m is defined as the maximum LCE of the PRM and

$$\langle f[\mathbf{M_n}]\rangle = \int f[\mathbf{M}_n]\left(\prod_{n=0}^{N} \mathrm{d}\mu[\mathbf{M}_n]\right) \tag{19}$$

represents an average over the ensemble of all possible random sequences of matrices, i.e., over all the possible realizations of disorder. The properties of γ_m naturally descend from the properties of the RMs composing the product (e.g., domain of definition, sign, symmetric properties), and a general analytic expression of γ_m is known only for a limited number of RM classes. As mentioned earlier, however, if the random matrices are independent and identically distributed and their probability meets some regularity requirements, the existence conditions and the properties of γ_m can be determined by means of limit theorems. More specifically, the existence of a maximum LCE is ensured by the Furstenberg-Kesten theorem, which in the case of real random matrices with determinant, one assures that the maximum LCE always exists and is a positive nonrandom quantity, namely,

$$\gamma_m = \lim_{N\to\infty} \frac{1}{N} \langle \log \mathrm{Tr}(\mathbf{P}_N \psi) \rangle > 0 \qquad (20)$$

where ψ is a generic vector [13]. Moreover, it can be shown that the average over disorder in Eq. 20 can be performed in any statistical ensemble and γ_m is a self-averaging quantity. As already mentioned, an analytical calculation of the maximum LCE is feasible only in a limited number of cases, and generally one has to fall back to approximate methods or numerical estimates of γ_m. As an example of an exactly solvable system, one can consider the case of a finite sequence of identical matrices, which in the theoretical model corresponds to an ordered chain of identical cavities. In this case, the total transfer matrix of the system assumes the simple form $\mathbf{P}_N = \mathbf{T}^N$, and a direct computation of the LCE yields

$$\lim_{N\to\infty} \frac{1}{N} \log \mathrm{Tr} \mathbf{T}^N = \log |\mu_1| \equiv \gamma_m \qquad (21)$$

where μ_1 is the largest nondegenerate eigenvalue of the matrix $\mathbf{T}$. The proof of Eq. 21 is straightforward: as the matrix $\mathbf{T}$ is invertible and diagonalizable, it can be decomposed as $\mathbf{T} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$ where $\mathbf{D}$ is the diagonal eigenvalue matrix $\mathbf{D} = \mathrm{diag}[\mu_1, \mu_2, \mu_3, \mu_4]$ and $\mathbf{P}$ is the eigenvector matrix. Taking the n-th power yields

$$\mathbf{T}^N = \mathbf{P}\mathbf{D}\left(\mathbf{P}^{-1}\mathbf{P}\right)\mathbf{D} \ldots \mathbf{D}\mathbf{P}^{-1} = \mathbf{P}\mathbf{D}^N\mathbf{P}^{-1} \qquad (22)$$

which in the limit of large N can be rewritten as $\mathbf{T}^N \to |\mu_1|^N \tilde{\mathbf{D}}$ where $\tilde{\mathbf{D}}$ is an $O(1)$ matrix and from which trivially follows Eq. 21. Once disorder is introduced in the system, however, the equality in Eq. 20 holds only in the limit $N \to \infty$, i.e., in the case of an infinite sequence of RMs. Hence, the LCE γ_1 is a self-averaging quantity only in the thermodynamical limit, and in the case of finite sequences, the ratio $\log \mathrm{Tr}\, \mathbf{P}_n$ fluctuates around γ_1, with fluctuations which are in general related to the statistical ensemble of sequences under consideration. It is useful in these cases to define a set of generalized Lyapunov characteristic coefficients of order k, whose expressions read

$$\mathcal{G}(k) = \lim_{N\to\infty} \frac{1}{N} \log \left\langle \mathrm{Tr}(\mathbf{P}_N)^k \right\rangle \qquad (23)$$

and which are related to the maximum LCE by $\gamma_m = \partial_q \mathcal{G}(q)_{q=0}$. Equation 23 is an example of an annealed average, in contrast with the quenched average from Eq. 20 [14]. From a strict mathematical point of view, annealed averages are easier to perform, as they do not require the averaging of the logarithmic function. The problem of dealing with logarithmic averages is a well-known issue in statistical mechanics of disordered systems, and in the recent years, a wide number of theoretical approaches to their computation have been developed. These methods, which relate the generalized LCE $\mathcal{G}(k)$ to the maximum LCE of the PRM, rely on the approximation of the logarithmic function by either expanding it into a power series or considering limit identities [10]. The most immediate approach, known as the weak disorder expansion, is based on the introduction of a multiplicative control parameter ε for the fluctuating frequencies in Eq. 3. As a result, the random transfer matrices assume the form

$$\mathbf{T}_n = \mathbf{T}_0 + \varepsilon \tilde{\mathbf{T}}_n \qquad (24)$$

where $\mathbf{T}_0$ is the transfer matrix of the ordered system and $\tilde{\mathbf{T}}_n$ is a matrix containing the fluctuating frequencies. When ε is small, the total PRM and consequently the logarithm in Eq. 20 can be expressed in terms of powers of ε, and the maximum LCE can be computed up to the desired order in ε. Another standard approach to the logarithmic average is based on the replica trick, which in the random matrix case is expressed by the identity

$$\left\langle \mathrm{Tr}(\mathbf{P}_N)^k \right\rangle = \mathrm{Tr} + \left\langle (\mathbf{P}_N)^{\otimes k} \right\rangle = \mathrm{Tr}\left[\overline{\mathbf{T}_n^{\otimes k}}\right]^N \qquad (25)$$

where $\mathbf{A}^{\otimes k} = \mathbf{A} \bigotimes \mathbf{A} \cdots \bigotimes \mathbf{A}$ represents the k-th tensor power of the matrix $\mathbf{A}$ and $\overline{\cdots}$ is the average over the probability distribution $\mu[\delta\Omega_n]$. In Eq. 25, due to the direct average of the tensor product matrix, the matrix $\overline{\mathbf{T}_n^{\otimes k}}$ is a nonrandom

quantity, and by referring to Eq. 18, the generalized LCE from Eq. 23 reads

$$\mathcal{G}(k) = \log\mu_{\otimes} \tag{26}$$

where $\mu_{\otimes}$ is the largest eigenvalue in modulus of the tensor matrix $\overline{\mathbf{T}_n^{\otimes k}}$. Apart from these methods, a very good estimate of the maximum LCE can be obtained by employing the microcanonical method, which can be easily described by considering a set of RMs characterized by a binomial probability distribution:

$$\mathbf{T}_n = \begin{cases} \mathbf{T}_A & \text{with probability } p \\ \mathbf{T}_B & \text{with probability } 1-p \end{cases} \tag{27}$$

where $p \in [0,1]$. This case is very relevant because in the majority of the experiments, the system is composed of a random aggregation of two materials, such as in the case of metallic scatterers dispersed in a host medium. The results for the binomial distribution, moreover, can be easily generalized to a generic continuous probability distribution, as shown in [12]. In a random sequence of N matrices extracted with probability given by Eq. 27, N_A and N_B denote the number of occurrences of the matrices **A** and **B**, respectively. In analogy with the statistical mechanics formalism, if N_A and N_B are fixed across the different disorder realizations, then the statistical ensemble is microcanonical like, while on the contrary, if the number of occurrences is variable, it is canonical like. The microcanonical ensemble exhibits some crucial advantages over the canonical. First of all, it can be shown that the finite N fluctuations are significantly reduced. Second, in the microcanonical ensemble, the annealed average can be computed exactly by means of the binomial formula:

$$(\mathbf{T}_A + x\mathbf{T}_B) = \sum_{k=0}^{N} \binom{N}{k} \mathbf{T}_A^k (x\mathbf{T}_B)^{N-k} \tag{28}$$

where $x \in \mathbb{R}$. The product $\mathbf{P}_N$, then, is expressed by the derivative

$$\frac{\partial^{N_B}}{\partial x^{N_B}}(\mathbf{T}_A + x\mathbf{T}_B)|_{x=0} = \binom{N}{N_B} \mathbf{T}_A^{N_A}\mathbf{T}_A^{N_B} \tag{29}$$

and this allows to write the annealed average in the microcanonical ensemble as

$$\langle \mathrm{Tr}\mathbf{P}_N \rangle_m = \binom{N}{N_B}^{-1} \frac{1}{N_B!} \mathrm{Tr}\left(\frac{\partial^{N_B}}{\partial x^{N_B}}(\mathbf{T}_A + x\mathbf{T}_B)\Big|_{x=0} \right) \tag{30}$$

which follows from the commutativity of the trace operator. Provided all matrices Tn are diagonalizable, Eq. 30 can be simplified by considering

$$(\mathbf{T}_A + x\mathbf{T}_B) = \mathbf{P}\mathbf{D}_1(x)\mathbf{P}^{-1} \tag{31}$$

where $\mathbf{D}_1(x) = \mathrm{diag}[v_1(x),\ v_2(x),\ v_3(x),\ v_4(x)]$ is the diagonal matrix containing the eigenvalues $v_i\ (x)$ of the matrix $(\mathbf{T}_A + x\mathbf{T}_B)$. From Eq. 31 follows immediately (cf. Eq. 22)

$$(\mathbf{T}_A + x\mathbf{T}_B)^N = \mathbf{P}\mathbf{D}_1(x)^N\mathbf{P}^{-1} \overset{N\to\infty}{\to} v_M(x)^N\tilde{D}(x) \tag{32}$$

where v_M is the maximum eigenvalue of $(\mathbf{T}_A + x\,\mathbf{T}_B)$ and $\tilde{\mathbf{D}}(x)$ is again a $O(1)$ matrix. By substituting Eq. 32, taking the analytic continuation of x, and applying the Cauchy integral formula

$$\left.\frac{\partial^\alpha f(z)}{\partial x^\alpha}\right|_{z=z^*} = \frac{\alpha!}{2\pi i}\oint_c \mathrm{d}z \frac{f(z)}{(z-z^*)\alpha+1} \tag{33}$$

where $\mathcal{C}$ is a closed contour surrounding $z = 0$, the annealed average reads

$$\langle \mathrm{Tr}\mathbf{P}_N \rangle_m = \binom{N}{N_B}^{-1} \mathrm{Tr}\left(\oint_c \frac{\mathrm{d}z}{z}\tilde{D}(x)\exp\left[N\log\frac{v_M(x)}{z^{(1-p)}}\right] \right) \tag{34}$$

Due to the presence of the exponential function, in the limit $N \to \infty$, the complex contour integral can be evaluated by means of the stationary phase method:

$$Z = \lim_{N\to\infty} \oint_c \mathrm{d}z\ f(z)e^{NS(z)} \propto e^{NS(w)} \tag{35}$$

where w is the solution of the saddle point equation $\partial_z S(z) = 0$. In the case of Eq. 34, the final expression for the annealed average reads

$$\langle \mathrm{Tr}\mathbf{P_N}\rangle_m \propto \binom{N}{N_B} \exp[N\log v_M(w) - (1-p)\log w] \tag{36}$$

where, again, w_p is the solution of

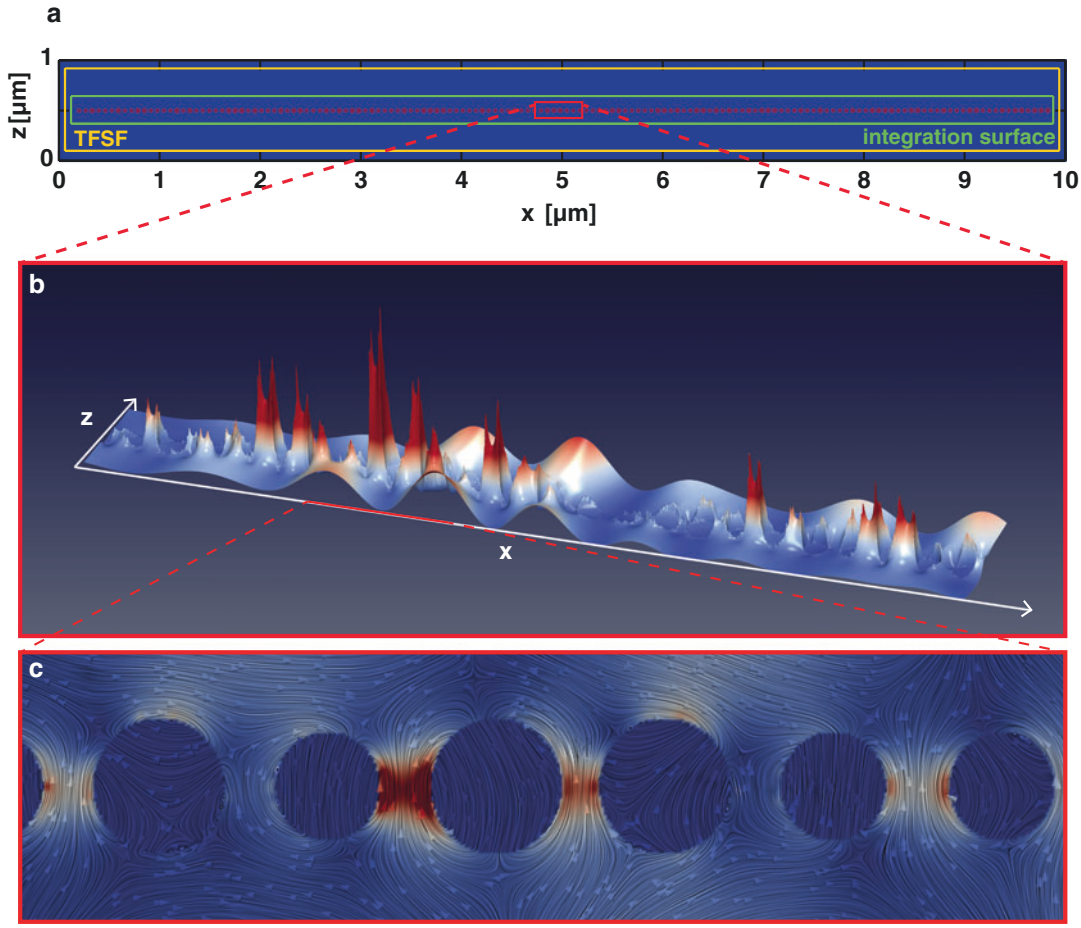
$$\left.\frac{\partial \log v_M(z)}{\partial \log z}\right|_{z=w_p} = (1-p). \tag{37}$$

Substituting into Eq. 20, one finally obtains

$$\widetilde{\gamma}_m = \lim_{N\to\infty}\frac{1}{N} = (1-p)\log(1-p) + p\log(p) + \log v_M(w_p) - (1-p)\log w_p \tag{38}$$

where the binomial coefficient is expressed using the Stirling approximation formula. As shown in [12], the LCE of the starting PRM is very close to the real part of $\widetilde{\gamma}_m$. Hence, Eq. 38 allows for a precise calculation of the LCE in the microcanonical ensemble. More than that, the availability of an analytic estimate for γ_m opens up interesting perspectives. As an example, Eq. 38 can be used to determine the optimal degree of disorder for the localization of the system. Once the structure of the matrices $\mathbf{T}_A$ and $\mathbf{T}_B$ has been determined, the amount of disorder is controlled by the probability p, with $p = 0$ corresponding to N matrices of type $\mathbf{T}_B$ and $p = 1$ corresponding to N matrices of type $\mathbf{T}_A$. By finding the zeros of the derivative

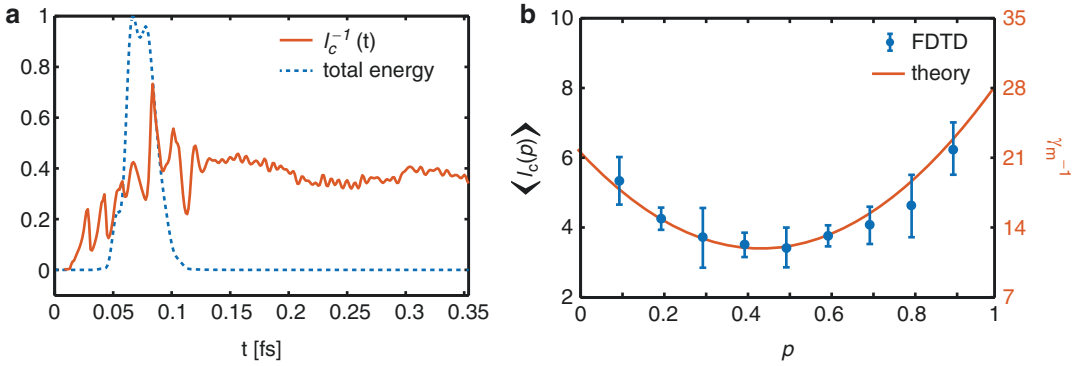
$$\frac{\partial \widetilde{\gamma}_m}{\partial p} = 2\tan^{-1}(1-2p) - \log\omega_p, \tag{39}$$



one obtains that in the case of a binomial distribution, the LCE γ_m has a single minimum for $p = p_c$. As the minimum in the LCE corresponds to a maximum in the localization length $l_c = \gamma_m^{-1}$, the system will exhibit the maximum degree of localization at the critical probability [15].

Nanoplasmonic Localization: Results from FDTD Simulations

The propagation of energy across a stationary one-dimensional set of open cavities can be simulated by considering a chain of metallic nanoparticles under external illumination. The transfer matrices for this system can be obtained by assimilating every nanoparticle with a hertzian dipole. By expressing the dipole equations in the Fourier domain, the amplitudes a_n of the elements of the chain evolve according to Eq. 7 with a transfer matrix of the form



$$\mathbf{C}_n = \begin{bmatrix} \frac{1}{\gamma\alpha_n^2}\left(\omega^2 - \omega_0^2 - i\left[\frac{\omega}{\tau_e} - \frac{\omega^3}{\tau_R\omega_0}\right]\right) & -1 \\ 1 & 0 \end{bmatrix} \tag{40}$$

where ω is the oscillation frequency of the dipoles, ω_0 is the plasma frequency of the metal, $\tau_{e,R}$ are the electronic and radiative decay times, γ is a polarization-dependent term, and α_n are coupling constants depending on the relative position of the nanoparticles [16, 17]. The evolution of the electromagnetic fields in such system can be rigorously investigated by employing the finite-differences in time-domain (FDTD) algorithm [18]. The FDTD algorithm allows for the solution of Maxwell's equations simultaneously in space and time with arbitrary precision. Due to the presence of the curl operator in Maxwell's equations, the components of the electric **E** and magnetic **H** fields are staggered on a specifically designed Yee grid, and the computation proceeds in time according to a leapfrog scheme. The simulations included in this entry have been performed using the massively parallel FDTD simulator NANOCPP, which has proved to be able to scale up to hundreds of thousands of processors [2, 19]. The computational domain was organized as follows. The computational grid was set as a two-dimensional (x, z) box with dimensions 10 × 1 μm and discretized on a 10,000 × 1000 regular mesh (resolution 1 nm) with UPML boundary conditions simulating an open space (Fig. 3a). A one-dimensional chain of

N equidistributed Ag nanoparticles was placed along the axis $z = 0.5$ μm, and the metallic nanochain was illuminated on the long side by an impinging plane wave, represented by means of the total-field/scattered-field formalism (yellow box), and whose polarization was chosen to be parallel to the axis of the chain (TM polarization). As requested by the microcanonical hypothesis, for every value of the probability p, the nanochain was formed as a random permutation of $N_A = pN$ nanoparticles of radius 25 nm and $N_B = N - N_A$ nanoparticles of radius 20 nm. In order to excite all the plasmonic resonances of the metallic nanospheres, the waveform of the incident wave was taken as a Gaussian pulse with waist $\Delta\lambda = 200$ nm and centered in $\lambda = 400$ nm. Due to the presence of a broadband excitation, the permittivity of the Ag nanoparticles was represented using a broadband critical-point (CP) model with a set of four complex-conjugate Lorentz-Drude poles, which is implemented in the FDTD code using an unconditionally stable auxiliary equation algorithm [20, 21]. In a typical

The IPR (*orange line*) tends to a stationary value once the external excitation leaves the system. The total energy (*blue line*) is reported for the sake of completeness. (**b**) Localization length as a function of the amount of disorder p. For each value, 20 different realizations of disorder were considered. The FDTD results (*blue dots*) are in strong agreement with the theoretical results from Eqs. 38 to 40 (*orange line*)

H

simulation, the incident wave travels across the computational domain, exciting the plasmonic resonances of the nanoparticles composing the metallic chain, which behave as resonant cavities. As the incident wave leaves the computational domain, the excited modes of the nanoparticles start interacting. A first insight on the dynamics of the system can be obtained by computing the electromagnetic energy:

$$\mathcal{E} = \int dx \ \varepsilon \mathbf{E}^2 + \mu \mathbf{H}^2. \tag{41}$$

Figure 3b shows the typical distribution of energy in a small region of a disordered chain with $p = 0.4$. As can be easily evinced from the figure, part of the energy is localized in proximity of the nanospheres, while a large amount of energy rapidly leaves the system due to radiative emission. In the presence of disorder, however, the system tends to create highly localized hotspots. The transfer of energy can be analyzed by computing the Poynting vector $\mathbf{S} = \mathbf{E} \times \mathbf{H}$, whose distribution in proximity of a localized hotspot is shown in Fig. 3c. The degree of localization of the system can be measured by computing the normalized inverse participation ratio $\langle l_c \rangle^{-1}$ (IPR), which is inversely proportional to the localization length l_c and which is defined as

$$\langle l_c(p) \rangle = \left\langle \frac{1}{V} \frac{\left(\int \mathrm{d}x \ \mathcal{E} \right)^2}{\int \mathrm{d}x \ \mathcal{E}^2} \right\rangle_p \tag{42}$$

where $\langle \cdots \rangle_p$ represents an average over different realizations of the sequence at fixed p [9]. The integral in Eq. 41 is performed over a surface containing the nanochain (Fig. 3a, green box). Figure 4a reports the typical evolution of the localization length (orange line) and of the total energy in the integration surface (blue line) for a disordered chain of $N = 150$ nanoparticles with $p = 0.4$. As can be evinced from the total energy evolution, the incident wave enters the integration region at $t = 0.05$ fs and leaves it at $t = 0.1$ fs. In the presence of the external excitation, the IPR has strong oscillations related to the excitation of the plasmon modes on the spheres. Once the incident radiation leaves the integrating region, however, the IPR converges to a stable value. The final IPR for the single realization can then be computed by averaging over time. In order to verify the presence of a single minimum in the localization length of the disordered chain, a large set of massively parallel simulations was performed for different values of the probability p. The results of the simulation campaign are shown in Fig. 4. In order to compute the average IPR, 20 different realizations of disorder were considered for each

value of the probability p. In order to verify the theoretical model, the maximum LCE of the system (orange line) was computed using Eqs. 38 and 40 and considering the parameters from [16]. Remarkably, the FDTD results are in strong agreement with the theoretical model, and in both cases, the localization length $\langle l_c \rangle^{-1}$ exhibits a single minimum in proximity of the critical probability $p_c = 0.4$. It is worthwhile remarking that n does not contain any fit parameter and the theoretical calculation of γ_m depends only on the physical parameters of the system.

Conclusions

In this work, it was shown how a generic nanoscale system can be studied by considering a set of interacting open cavities, whose evolution is expressed in terms of a real-valued transfer matrix formalism. In the presence of disorder, the localization properties of the system can be evaluated by resorting to random matrix theory. By employing the microcanonical approach, an analytic expression for the localization length of a binary set of cavities was obtained as a function of the amount of disorder. Such analytic expression allowed to obtain an optimal degree of disorder which provides the higher degree of localization in the system. The existence of such an optimal degree of disorder has been verified by simulating a one-dimensional chain of metallic nanoparticles using the FDTD algorithm. This system, which can be described exactly with the transfer matrix approach, is analogous to a one-dimensional chain of open cavities, and the localization length can be estimated by computing the IPR of the system. The numerical results, which show a very good agreement with the theoretical predictions, represent an interesting example of how an accurate theoretical model, coupled with a rigorous treatment of the disorder in the system, can provide quantitative insights into the localization properties of a nanoplasmonic system. The existence of an optimal degree of disorder, moreover, opens up interesting perspectives for any plasmonic application requiring highly localized hotspot distributions.

Definition

Thermal conduction is heat transfer by microscopic motions of matter. Phonon is a quantized form of atomic vibrations, and phonon transport is responsible for thermal conduction in crystalline materials such as silicon.

Overview (Physical Principles)

Heat naturally flows from hot to cold, as governed by the Second Law of Thermodynamics. The heat flow by microscopic motions in solids is known as thermal conduction, which is described by the Fourier Law:

Heat Transfer in Semiconductor Nanostructures, Fig. 1 The thermal conductivity ranges about four orders of magnitude for common solid materials. Silicon may have about two orders of magnitude change in the thermal conductivity from bulk to nanostructures. In other words, silicon can be considered as a good thermal conductor or a good thermal insulator depending on the size

$$q = -k\nabla T \tag{1}$$

where q is the heat flux [W/m^2], k is the thermal conductivity [W/mK], and T is the temperature [K]. The heat flux is the rate of thermal energy passing through a unit area that is perpendicular to the heat flow direction. The thermal conductivity is a fundamental material property, which represents material's ability of transferring heat by conduction. The Fourier Law indicates that the thermal conductivity governs heat flows and temperature variations in solids. Thermal conduction in solid materials is normally carried by electrons and phonons, and the thermal conductivity can be expressed as

$$k = k_e + k_p \tag{2}$$

where k_e is the electron thermal conductivity and k_p is the phonon thermal conductivity. The electron thermal conductivity represents heat transport by electrons and is important in metals, semimetals, and degenerate semiconductors. Since the same electrons carry both electricity and heat, the electron thermal conductivity is proportional to the electrical conductivity according to the Wiedemann-Franz Law:

$$k_e = \sigma LT \tag{3}$$

where σ is the electrical conductivity [S/m], L is the Lorenz number [W/S-K^2], and T is the temperature [K]. The Wiedemann-Franz Law allows thermal conduction studies in metallic materials to take advantage of rich information known about electron transport. Phonon transport physics is relatively not well understood but responsible for thermal conduction in most semiconductors and insulators. With focus on thermal conduction in silicon nanostructures, the thermal conductivity in this entry strictly refers to the phonon thermal conductivity. The thermal conductivity can be simply expressed as

$$k = \frac{1}{3}Cv\Lambda \tag{4}$$

where C is the heat capacity [J/m^3-K], v is the group velocity [m/s], and Λ is the mean free path [m]. The heat capacity describes amount of thermal energy carriers per unit volume, and the group velocity describes how fast they are traveling. The one-third factor accounts for the average group velocity in three-dimensional geometric space. The mean free path is the average distance the thermal energy carriers travel before collision. The thermal conductivity is an intrinsic material property, which is independent of geometry, but this is only true when the dimensions are greater than the mean free path. Nanomaterials or bulk materials with nanoscale features that are comparable or smaller than the mean free path present strong size dependence. While the thermal conductivities of solid materials range about four orders of magnitude, silicon may have about two orders of magnitude change in the thermal conductivity from bulk to nanostructures (Fig. 1).

Thermal Conductivity Derivation Using Kinetic Theory

The thermal conductivity expression Eq. 4 is derived from the kinetic theory of gases.

Assuming ideal gas particles under a temperature gradient, the particle flux in the positive x-direction (ϕ_x) can be expressed as

$$\phi_x = \frac{1}{2} n v_x \tag{5}$$

where n is the particle density, v_x is the average velocity component, and the factor 1/2 accounts for the half of particles traveling in the negative x-direction. The particle flux can be converted to energy flux by accounting for the particle energy. As a particle travels from a position with the temperature T to another position with the temperature $T + \Delta T$, the particle absorbs the energy $c\Delta T$ where c is the heat capacity per particle. The energy flux (q) is a product of the particle flux and the energy absorption per particle. For particles traveling the opposite direction, from $T + \Delta T$ to T, the same amount of energy is released:

$$q_{x(T\to T+\Delta T)} = \frac{1}{2} n v_x c \Delta T \tag{6a}$$

$$q_{x(T+\Delta T\to T)} = -\frac{1}{2} n v_x c\Delta T \tag{6b}$$

The particles fluxes are identical in both directions, and there is no net flux of particles. There is a net flux of energy by particles under the temperature gradient, and the energy flux in the direction of heat flow can be expressed as

$$q_x = q_{x(T+\Delta T\to T)} - q_{x(T\to T+\Delta T)} = -n v_x c\Delta T \tag{7}$$

Assuming the particles thermalize and experience the temperature change (ΔT) through collisions over the average distance (Λ), the temperature change can be expressed as

$$\Delta T = \Lambda \frac{dT}{dx} \tag{8}$$

where the average distance between collisions is known as the mean free path. For an isotropic case, where the average velocity in all directions has the same speed, the group velocity can be expressed as

$$v^2 = v_x^2 + v_y^2 + v_z^2 = 3v_x^2 \tag{9}$$

where v_x, v_y, and v_z are the average velocity of particles in three-dimensional space. With Eqs. 8 and 9 and using the volumetric heat capacity term ($C = nc$), the energy flux expression takes the form:

$$q_x = -\frac{1}{3} C v \Lambda \frac{dT}{dx} \tag{10}$$

Based on the Fourier Law in Eq. 1, the simple thermal conductivity expression can be derived from the kinetic theory:

$$k = -\frac{1}{3} C v \Lambda \tag{11}$$

Thermal Conductivity Derivation Using Boltzmann Transport Equation

While the simple thermal conductivity model may provide essence of thermal conduction in bulk materials, thermal conduction in nanostructures requires rigorous thermal conductivity modeling based on the Boltzmann transport equation [1–5]. The Boltzmann transport equation (BTE) considers phonons as particles with energy and momentum. The BTE model describes the conservation of the number of particles using a distribution function $f(x,p,t)$, which is a function of geometric space (x), momentum space (p), and time (t). The general form of the BTE can be expressed as

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f + \frac{F}{m} \cdot \nabla_p f = \left(\frac{\partial f}{\partial t}\right)_{\text{collision}} \tag{12}$$

where the first term on the left side of the equation represents the total time rate of change of number of particles, the second term represents particle diffusion in geometric space due to phonon group velocity (v), the third term represents acceleration in momentum space due to external forces (F), and the right side of the equation represents

time rate of change of number of particles due to scattering. The first and the third terms can be dropped out in general heat transfer problems by assuming steady-state problems with no external force. The scattering term on the right-hand side of the equation can be replaced by the departure of the distribution function from equilibrium divided by a relaxation time τ, which incorporates all phonon scattering events under the relaxation time approximation. The relaxation time is the average time between collisions. The steady-state BTE with single relaxation time assumption and in the absence of any external force is given as

$$v \cdot \nabla_x f = -\frac{f - f_{\text{eq}}}{\tau} \tag{13}$$

The equilibrium function for phonons follows Bose-Einstein statistical distribution; therefore, the number of phonons with a particular frequency ω at an equilibrium temperature T is given by the equation

$$f_{\text{eq}} = \frac{1}{\exp\left(\frac{\hbar\omega}{k_B T}\right) - 1} \tag{14}$$

For small deviation from the equilibrium, $f = f_{\text{eq}} + \delta f$, it is assumed that

$$\nabla_x f \approx \nabla_x f_{\text{eq}} \tag{15}$$

Using the chain rule,

$$\nabla_x f_{\text{eq}} = \frac{\partial f_{\text{eq}}}{\partial T} \nabla_x T \tag{16}$$

Therefore, the BTE can be reduced to

$$f = f_{\text{eq}} - v\tau \cdot \frac{\partial f_{\text{eq}}}{\partial T} \nabla_x T \tag{17}$$

under the assumptions of a steady-state system with no external fields, and the departure of the system from equilibrium is small. The heat flux can be expressed as the product of group velocity and energy density integrated over all phonon frequencies:

$$q_x = \int v_x \, \hbar\omega \, D_p f \, d\omega \tag{18}$$

where v_x is the group velocity in the x-direction and D_p is the density of states. The density of states represents the number of quantized states available for phonon occupation. Assuming an isotropic case, $v_x = v_y = v_z$, the average group velocity over directions where all particles move in the x-, y-, or z-direction, each with the same speed, v_g

$$v_x^2 = \frac{v_g^2}{3} \tag{19}$$

Using the BTE expression, the heat flux equation becomes

$$q_x = \int -\frac{1}{3} \, v_g^2 \tau \, \hbar\omega \, \frac{\partial f_{\text{eq}}}{\partial T} \, D_p \, d\omega \, \frac{\partial T}{\partial x} \tag{20}$$

The equilibrium function from the BTE solution drops out of the integration because the equilibrium function contributes an equal amount of energy in all directions. Based on the Fourier Law for heat conduction, the thermal conductivity can be expressed as

$$k = \int \frac{1}{3} \, v_g^2 \tau \, \hbar\omega \, \frac{\partial f_{\text{eq}}}{\partial T} \, D_p \, d\omega \tag{21}$$

While the solution of the above equation provides the thermal conductivity of solids, the BTE model has limitations in its usage. Firstly, the solution is applicable for particles. The particle distribution function *f*(r,p,t) represents the probability of finding a particle with the position, the momentum, and the time. It is assumed that the momentum and the position are given simultaneously, which neglects quantum mechanical nature. The BTE is applicable for describing energy transport by particles, not waves. This allows the calculation of ensemble averages for particle density, current density, and energy density. Secondly, the solution is applicable for steady-state heat transfer problems or when the time scale of interest is much larger than the relaxation time of the energy carrier, in which case the first term can

be neglected. Thirdly, the solution is applicable for problems with length scale greater than the phonon mean free path.

In the case that the group velocity and the relaxation time are independent of frequency, the BTE solution reduces to the simple kinetic theory model:

$$k = \frac{1}{3} v_g^2 \tau \int \hbar\omega \frac{\partial f_{eq}}{\partial T} D_p \, d\omega \tag{22}$$

Phonon heat capacity by definition is obtained by differentiating the internal energy with respect to temperature:

$$C = \int \hbar\omega \frac{\partial f_{eq}}{\partial T} D_p \, d\omega \tag{23}$$

This reverts to the simple kinetic theory model for the thermal conductivity:

$$k = \frac{1}{3} C v_g \Lambda \tag{24}$$

Phonon Mean Free Path Modeling for Silicon Nanostructures

Thermal conductivity modeling requires computation of heat capacity, group velocity, and mean free path of energy carriers. While the heat capacity and the group velocity are based on dispersion relations, the mean free path accounts for size effects in nanostructures. The mean free path can be modeled in the framework of Matthiessen's Rule, in which scattering processes are parallel and independent from each other. The phonon mean free path in silicon can be expressed as

$$\Lambda^{-1} = \Lambda_U^{-1} + \Lambda_D^{-1} + \Lambda_B^{-1} \tag{25}$$

where Λ_U is the mean free path limited by phonon-phonon or Umklapp scattering, Λ_D corresponds to phonon-defect scattering, and Λ_B corresponds to phonon-boundary scattering.

There are two types of phonon-phonon scattering. Normal phonon-phonon scattering conserves energy and crystal momentum. The normal process redistributes crystal momentum, and there is no resistance to heat flow. Umklapp phonon-phonon scattering conserves energy but not crystal momentum. The Umklapp process, enabled by anharmonic lattices, makes phonon transport diffusive and creates thermal resistance, which is responsible for finite thermal conductivity in solids. The Umklapp scattering mean free path frequency can be expressed as

$$\Lambda_U = \frac{v_g}{A \, T \, \omega^2 \exp\left(-\frac{B}{T}\right)} \tag{26}$$

where A and B are fitting parameters. The $A = 1.4 \times 10^{-19}$ s/K and the $B = 152$ K are the fitted parameters that reproduce the bulk silicon thermal conductivity [6]. At high temperatures, the Umklapp scattering mean free path term begins to scale inversely with temperature, which corresponds to increasing population of phonons and increasing phonon-phonon scattering events. For this reason, at room temperature and above, the thermal conductivity of silicon decreases with increasing temperature. The mean free path due to phonon-defect scattering can be expressed as

$$\Lambda_D = \frac{v_g}{D \, \omega^4} \tag{27}$$

where D can be a fitting parameter. For nearly pure silicon, the parameter D mainly depends on the isotope concentration and has been determined as $D = 1.32 \times 10^{-45}$ s^3. For doped silicon, dopant species affect the thermal conductivity depending on their physical properties, and this can be expressed as [7]

$$D = \frac{nV^2}{4\pi v_g^3} \left(\frac{\Delta M}{M}\right)^2 \tag{28}$$

where n is the dopant concentration, V is the atomic volume of the host material, M is the atomic mass of the host material, and ΔM is the mass difference between the host and the dopant atoms. The mass differences between silicon and phosphorus and boron, and arsenic atoms are 2.89, 17.27, and 46.84 g/mol, respectively [4].

Therefore, arsenic is expected to cause the largest thermal conductivity reduction followed by boron and phosphorus for a given doping concentration. The frequency dependence resembles Rayleigh scattering, in which phonon waves do not interfere with defects that are much smaller than the wavelength. This scattering becomes important at low temperatures when Umklapp process diminishes, but when temperature is low enough that phonons have wavelength greater than defects and the defect scattering becomes less important. The phonon-boundary scattering term is important for low temperatures.

Phonon-boundary scattering can have strong dependence on the sample size. In the Casimir limit [9], the mean free path limited by phonon-boundary scattering becomes equivalent to the characteristic length scale. For polycrystalline materials, the characteristic length scale corresponds to the grain size. For single crystalline materials, the characteristic length scale is given by the sample size. For thin films or nanowires, the characteristic length scale may correspond to film thickness or diameter, respectively. For thin films, the phonon-boundary scattering term has been the control knob for matching thermal conductivity models with experimental data. For thin films, specular and diffuse scattering can be accounted by

$$\Lambda_B = d\left(\frac{1+p}{1-p}\right) \tag{29}$$

where d is the film thickness and p is the specular coefficient, which represents the probability of specular phonon reflection from the sample boundary ($0 \le p \le 1$). For $p = 0$, phonon-boundary scattering is assumed completely diffuse. In that case, the boundary is an entirely rough surface that diffusely, or randomly, scatters all incident phonons according to its surface temperature, similar to a blackbody emitting absorbed radiation. This effectively thermalizes the phonons, such that they contribute to the equilibrium phonon distribution. For $p = 1$, phonon-boundary scattering is assume completely specular. In that case, the boundary is a perfectly smooth surface that completely reflects all incoming phonons. The specular phonon-boundary scattering presents no thermal resistance and is applicable for bulk materials. The specular coefficient may be expressed in terms of the phonon wavelength and surface roughness for qualitative understanding [7, 8]:

$$p = \exp\left(-\frac{16\pi^3\eta^2}{\lambda^2}(\cos\theta)^2\right) \tag{30}$$

where λ is the phonon wavelength, η is the surface roughness, and θ is the angle of incidence with respect to the normal. This illustrates that a surface or interface appears rough for phonon wavelengths shorter than the average surface roughness height but smooth for phonon wavelengths much longer than the surface roughness. A given surface may diffusely reflect high-frequency phonons and specularly reflect low-frequency phonons. At low temperatures, the excited phonon modes tend to have low frequencies and long wavelengths, so a boundary appears smooth and specularly reflects some phonons. At higher temperatures, phonons occupy the more energetic modes with high frequencies and short wavelengths, so the effectively rough boundary diffusely scatters most phonons. This illustrates that a surface or interface appears rough for phonons with small incident angles but smooth for phonons with large incident angles. While the equation can be incorporated into the solution of the Boltzmann equation and integrated over all angles of incidence, the expression only for normally incident phonons is commonly incorporated in boundary scattering models for silicon films. Ziman suggested that this expression can underestimate p for incident waves at a large or glancing angle. While the expression provides qualitative understanding of wavelength and surface roughness relationship, the specular coefficient is also commonly set to a constant value to fit the thermal conductivity data for thin films.

For nanowires with completely diffuse boundaries, known as the Casimir limit [9], the average boundary scattering mean free path equals the diameter:

$$\Lambda_B = D \tag{31}$$

where D is the nanowire diameter. For rectangular nanobeams in the Casimir limit, boundary scattering mean free path can be expressed as

$$\Lambda_B = \frac{2}{\sqrt{\pi}}\sqrt{w\,t} \tag{32}$$

where w is the width and t is the thickness of the rectangular nanobeams.

For nanostructures with arbitrary heat flow directions and complex geometries, the angular dependence needs to be accounted by converting the Boltzmann transport equation solution in the frequency space (Eq. 21) into an integral in spherical coordinates. For cross-plane heat flows with vertical boundary scattering at top and bottom interfaces bounded in the length L, the average distance traveled ballistically by a phonon before hitting the top or bottom surface can be expressed as [10]

$$\Lambda_B = \frac{L}{2|\cos\theta|} \tag{33}$$

where L is the length scale in the direction of heat flow and θ spans from 0 to π. For cross-plane heat flows with lateral geometric confinement, i.e., nanowires, the average distance traveled ballistically by a phonon before hitting the side can be expressed as [10]

$$\Lambda_B = \frac{4D}{3\pi|\sin\theta|} \tag{34}$$

For nanowires with length shorter than the mean free path or superlattice nanowires, boundary scattering terms for both perpendicular and parallel interfaces are needed. The average distance traveled ballistically by a phonon before hitting the lateral dimension D or hitting the boundaries of dimension L in the direction of heat flow can be expressed as

$$\Lambda_B = \left(\left(\frac{L}{2|\cos\theta|}\right)^{-1} + \left(\frac{4D}{3\pi|\sin\theta|}\right)^{-1}\right)^{-1} \tag{35}$$

Phonon Mean Free Path Spectrum in Silicon

Phonon mean free path value facilitates thermal conductivity predictions in nanostructures and is the key parameter for evaluating scattering mechanisms. The phonon mean free path in silicon can be obtained using experimental values. One naïve approach is to use the kinetic theory (Eq. 4) with the known values for the thermal conductivity, heat capacity, and the group velocity:

$$\Lambda = \frac{3k}{Cv_g} \tag{36}$$

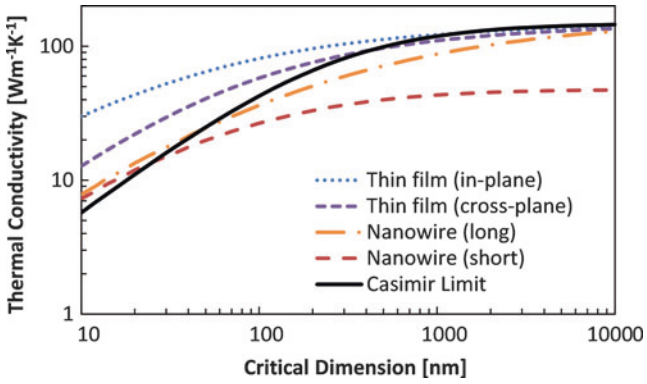
For silicon at room temperature, the specific heat is 1.66×10^6 J/m^3/K, the group velocity is 6400 m/s, and the thermal conductivity is 150 W/mK [5]. The phonon mean free path using Eq. 36 is about 40 nm. However, the thermal conductivity data for silicon thin films and nanowires show strong size dependence at dimensions much greater than 40 nm. The discrepancy is due to the severe underestimation of the phonon mean free path. Equations 4 and 36 neglect phonon frequency dependence and assume all phonons carry the same energy with the given heat capacity and the group velocity. Such a simple kinetic theory model may be a good approximation in highly disordered materials where the phonon mean free path is short and the phonon transport agrees with Einstein's minimum thermal conductivity model. However, in other materials such as silicon with broad phonon spectrum and strong frequency dependence, the heat capacity and the group velocity should be placed inside the integral, leading to

$$\Lambda_{avg} = \frac{3k}{\int Cv_g\,d\omega} \tag{37}$$

where Λ_{avg} is the average mean free path of phonons in the gray approximation. With the measured thermal conductivity value and the frequency-dependent heat capacity and the group velocity, the average mean free path is calculated to be about 250 nm. This implies

that the thermal conductivity size dependence becomes appreciable when the dimensions are 250 nm or less. The average mean free path value explains the size-dependent thermal conductivity observed in thin films and nanowires [11, 12]. Such a gray mean free path model is a good approximation in systems where the real mean free path distribution is narrow, including ideal gases and free electron gases. However, in other systems with strongly frequency-dependent scattering, the distributions can be quite broad. To better understand the potential for thermal conductivity reduction by boundary scattering, it is important to understand the range of mean free paths that contribute to heat transfer in a bulk material. The greater the fraction of heat carried by phonons with long mean free paths in bulk, the greater the thermal conductivity reduction in a given nanostructure. This effect can be quantified by rewriting the thermal conductivity expression to integrate over mean free path as the independent variable [5], leading to

$$k = \int -\frac{1}{3} C v_g \Lambda \frac{d\omega}{d\Lambda} \, d\Lambda \tag{38}$$



This expression quantifies the range of mean free path that contributes to thermal conduction. A complementary perspective is the thermal conductivity accumulation function:

$$\alpha = \frac{1}{k_{bulk}} \int_0^{\Lambda_\alpha} -\frac{1}{3} C v_g \Lambda \frac{d\omega}{d\Lambda} \, d\Lambda \tag{39}$$

which represents the fraction of the total thermal conductivity, ranging from 0 to 1, due to carriers with mean free path less than Λ_α. This calculation shows that 50 % of the heat in bulk silicon at 300 K is carried by phonons of mean free path up to 1 μm, which is greater than the average mean free path estimated from Eq. 37. The discrepancy is due to long-wavelength phonons that carry the heat in much greater distance than the short-wavelength phonons. In other words, the use of the average mean free path could underestimate the contribution of long-wavelength phonons. Furthermore, for up to 90 % of the heat, mean free paths up to 12.8 μm must be considered, and over two orders of magnitude of mean free paths are important for carrying the heat in silicon. This provides a useful guideline to the range of mean free paths that are important for heat conduction in a given system, and for silicon, the important mean free path ranges from 1 nm to 10 μm. The mean free path spectrum provides the relevant information for understanding phonon transport in nanostructures. The phonon mean free path models allow clear understanding of thermal conduction in nanoscale materials and systems and have great implications for ballistic phonon transport in silicon nanostructures (Fig. 2).

Quantum Effects and Future Directions for Research

While modeling thermal conduction in silicon nanostructures using bulk silicon dispersion relations is known to provide an accurate description of phonon transport, some experimental results do not agree well with the classical models, possibly due to quantum effects. The semiclassical models predict that the phonon scattering expressions based on the bulk dispersion relations are valid for nanowires with diameter greater than 10 nm and at temperatures higher than 40 K [3]. In very small dimensions or at very low temperatures, the phonon dispersion relations may become different from that in the bulk material. The change in the phonon dispersion relations can reduce the group velocity and results in further reduction in the thermal conductivity. The silicon nanostructures may become low-dimensional systems, in which frequency dependence of the scattering rates can be different due to confined dispersion relations. The quantum phonon transport effects, such as phonon confinement [14] or phononic bandgap formation [6], may influence heat conduction in very small dimensions or materials with nanoscale features. Recent experiments in silicon

Heat Transfer in Semiconductor Nanostructures, Fig. 2 The thermal conductivity of silicon nanostructures calculated from the solution of the Boltzmann transport equation. The critical dimension for thin films is thickness and for nanowires is diameter. For short nanowires, the length is defined as 100 nm, which may correspond to vertical interfaces with 100 nm pitch in superlattice nanowires. The Casimir limit for nanowires with completely diffuse boundary scattering yields the lowest thermal conductivity

nanostructures showed values that are much smaller than the lowest values predicted by the Boltzmann transport equation [6, 13]. These surprising results have led to theoretical investigations of whether the Casimir limit of diffuse surface scattering can be violated. Since the Boltzmann transport equation is based on particle transport, the models may fail to predict the thermal conductivity when the dimensions become comparable to phonon wavelength. Periodic features may result in phonon backscattering, which is equivalent to a negative p value [15]. Artificial spatial periodicity such as rough nanowires or phononic crystals can in principle result in the appearance of phononic bandgaps, which prohibit transport of phonons with certain frequencies. With periodic patterns, the zone folding effect may provide a low group velocity in a reduced Brillouin zone. These quantum effects on the phonon dispersion, particularly in the long-wavelength range, may be observed directly in experiments, and this requires further theoretical development. Thermal conduction in silicon nanostructures requires further investigation on whether phononic bandgap formation or another quantum effect becomes appreciable even at room temperature, which may lead to a breakthrough in phononics research and applications.

With the advance of nanotechnology and shrinking electronic devices, the thermal conductivity of silicon has renewed interest in understanding phonon transport in silicon, in particular to size effect in silicon nanostructures. The thermal conductivity of silicon thin films and nanowires has demonstrated significant reduction due to increased scattering of phonon on physical boundaries. In some cases such as rough nanowires and periodic structures, the thermal conductivity has been reported lower than the minimum thermal conductivity predicted by boundary scattering, and this calls for better understanding of phonon transport in silicon nanostructures. Understanding the mechanisms controlling the thermal conductivity at the nanoscale is of considerable importance in nanoelectronics and thermoelectrics applications.

Definition

High-energy synchrotron radiation does not have a clear and generally accepted definition. Its unique characteristic is the *high penetration into material*, and it depends on what is regarded as high penetration – millimeter or centimeter – and in what material, lightweight or comprising heavy atoms. For practical reasons which find their ways into special constructional solutions, one can regard the X-ray regime between 50 and

High Energy Synchrotron Radiation and Its Impact on Characterizing Nanoparticles, Table 1 Penetration depths for some elements plus water in the energy regime 50–150 keV

Element (atomic number)	Penetration depth at 50 keV	Penetration depth at 100 keV	Penetration depth at 150 keV
N (7)	41 m	53 m	61 m
H_2O (2/8)	3 cm	5 cm	10 cm
Si (14)	1.0 cm	2.3 cm	2.9 cm
Ti (22)	0.2 cm	0.8 cm	1.3 cm
Fe (26)	709 μm	0.37 cm	0.67 cm
Cu (29)	436 μm	0.25 cm	0.5 cm
Pd (46)	94 μm	615 μm	1648 μm
Au (79)	73 μm	101 μm	279 μm

150 keV as high-energy synchrotron radiation, thus a wavelength regime 0.08–0.24 Å. A look into the literature reveals a penetration of several 100 μm up to centimeters into most materials [1]. Table 1 lists the penetration depths (intensity falling off to e^{-1}) of some materials in the aforementioned energy regime.

With even higher energy, the gain in material penetration is usually offset by increased background Compton scattering and fluorescence radiation (also from shielding materials and slits). Visiting the home pages of (large) synchrotron radiation sources worldwide [http://www.lightsources.org/regions], one finds that they all offer corresponding specialized beamlines, i.e., experimental capabilities, for this regime. And usually, only the technical specifics of each instrument determine the lower (and likewise upper) boundary of this regime, where the limit is fluent down to even 30 keV with correspondingly lower penetration depths.

The *impact* of high-energy synchrotron radiation in *characterizing nanoparticles* is based on the general properties of X-rays interacting with matter, enhanced by the characteristics of synchrotron radiation (high brilliance and linear polarization), the details of which can be found in a number of textbooks [2, 3]. Obviously, those general properties and specific enhancements are not limited to characterizing only "nanoparticles" but also "non-nanomaterial." And indeed, this impact of high-energy synchrotron radiation is felt as a new force in many fields of materials research, physics, chemistry, and life sciences, dealing not exclusively with nanoparticles. However, this entry will stress the application of high-energy synchrotron radiation in the field of nanoparticles, their structural characterization, as well as the potential in understanding their formation, their domains of activity, and their workings in processes, e.g., catalysis.

Technical Peculiarities of High-Energy Synchrotron Radiation

There exist a number of *white beam* or *pink beam* techniques, i.e., techniques using a broad energy bandwidth out of the white synchrotron radiation beam; however, the overwhelming majority in scattering or imaging techniques relies on monochromatic beams, i.e., beams with a small energy bandwidth. They are usually created by reflection of perfect Si crystals (grating-based monochromatization for soft X-rays is omitted here). To keep the crystals perfect, they have to be cooled since the powerful synchrotron radiation sources (bending magnets, wigglers, or undulators) deposit enormous heat onto them with corresponding temperature and subsequently lattice gradients. Normally, they are kept under vacuum, and one uses two crystals in a fixed exit geometry where the reflection is in the vertical direction in order to keep the linear polarization of the synchrotron radiation (in the plane of the storage ring). Using Bragg's law "$2d \sin\Theta = \lambda$" with the lattice constant $d^{Si}_{111} = 3.135$ Å, one gets typical scattering angles of approximately 9° for an energy of 12 keV (wavelength $\lambda = 1$ Å). For 50–150 keV, the angles shrink to 2–0.8°. Hereby, the penetration length into Si is above 1 cm. Those two effects change completely the technical realization of monochromators for high-energy synchrotron radiation. (One can increase the scattering angle by choosing different lattice planes, e.g., Si(311) instead of Si(111), thereby, doubling it, but this reduces on the other hand the bandwidth and in consequence the transmitted flux.)

High Energy Synchrotron Radiation and Its Impact on Characterizing Nanoparticles,

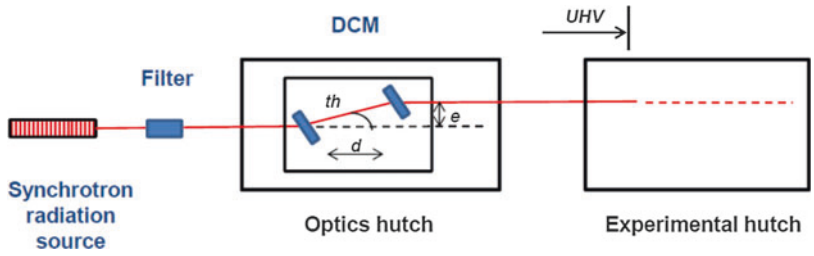

Fig. 1 Optics scheme for high-energy synchrotron radiation in top view

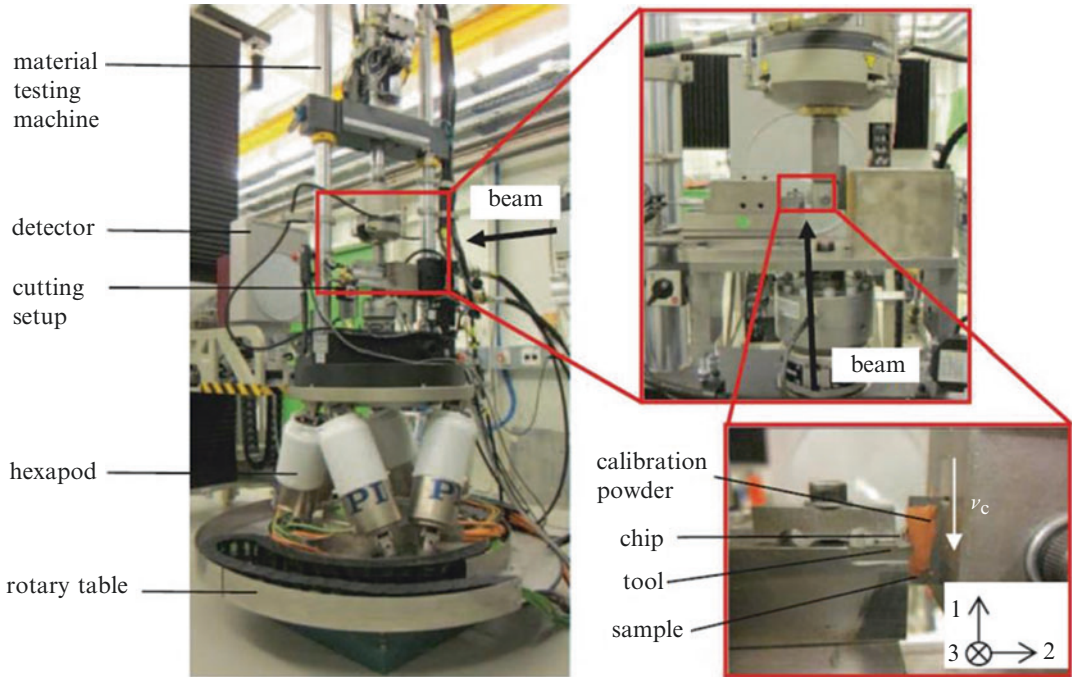
Figure 1 shows a typical optics scheme for high-energy synchrotron radiation delivery to an experiment. Small Bragg angles *th(eta)* lead to large footprints of the incoming beam, making Bragg reflection on perfect (Si) crystals prohibitively expensive. Therefore, one chooses a transmission mode, i.e., Laue geometry for the crystals (the radiation penetrates anyhow deep inside). Since the fixed exit angle *e* (between incoming white beam and monochromatic outgoing beam) is determined by external factors (construction or radiation protection), the distance *d* between the crystals gets large. For material stiffness reason, both crystals cannot any longer sit on the same rotation axis to guarantee the same scattering angle for monochromatization, so typically both crystals have separate rotation axis with the second crystal (downstream) sitting on a slide. But now some advantages make the beam delivery easier: small rotation ranges tend to be more precise and less expensive to manufacture. When concentrating on high-energy X-rays, one can filter out the lower energies by absorption; thus, the heat load onto the first crystal tremendously decreases allowing conventional water cooling (instead of liquid nitrogen) leading to a less expensive and more stable beam at the sample point. And as the bulk and not just the surface layers of the crystals is used for monochromatization, the vacuum requirements (surface contamination with water or organic deposits) are less severe, making interventions (repairs, changes) on the crystal(s) easier and faster. Actually, the high penetration of hard X-rays makes radiation delivery to the experiment easy: somewhere before the sample location normally the ultra-high vacuum (UHV) is changed to just vacuum or even air atmosphere which allows unhindered sample environment access as will be discussed later.

Another peculiarity of high-energy synchrotron radiation is that, normally, no longer a vertical scattering geometry is chosen, but a horizontal one. The reason is to keep the smaller vertical source size and to, only insignificantly, increase (through unavoidable aberration effects in the scattering plane) the much larger horizontal one. (As the linear polarization is proportional to the square of the cosine of the scattering angle *theta*, it practically stays above 90 % for theta $< 9°$ [3].)

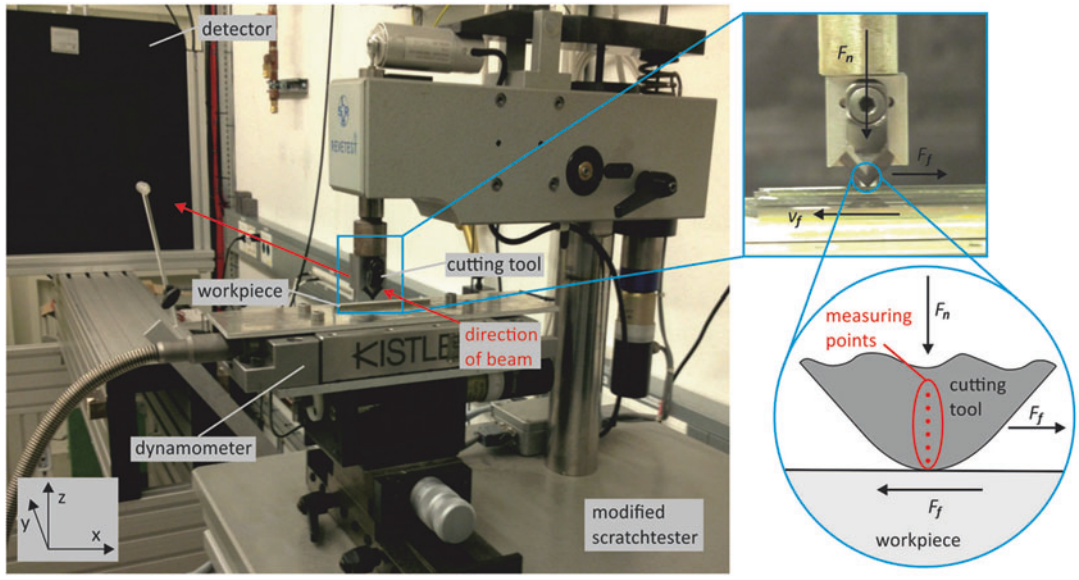
As the critical angle for total external reflection is proportional to the wavelength λ, the use of perfect mirrors for the suppression of higher harmonics is prohibitively expensive which means that a monochromator is usually the only essential optical element in bringing the hard X-ray beam to the sample. Unfortunately, sometimes higher harmonics lead to unwanted artifacts in phase analysis. Practically, one depends on the decreasing flux for higher-energy synchrotron radiation or can slightly detune the crystals to suppress higher harmonics (but then loses flux). In computational view, hard X-rays allow the use of kinematical theory and the negligence of extinction and multiple Bragg scattering effects. In order to avoid chromatic aberration, the crystals are often bent into Rowland circle geometry, and depending on the experimental requirements, there exist various schemes to push the energy resolution up into the 1 eV region or down to several hundred eV to increase the bandwidth. Usually, a channel-cut design is used for high resolution (often as a second monochromator in front of the sample), while a controlled lattice constant gradient is used for increased bandwidth, i.e., flux increase (e.g., by doping Si crystals with Ge, by bending or defining heat gradients inside the monochromator crystals, or by using multilayer crystals with a thickness gradient).

Structural Characterization In Situ



Nanoparticles are *per definitionem* characterized by their size or size distribution and their morphology being in the nm range. In contrast to characterizing methods like ▶ scanning electron microscopy (SEM), ▶ transmission electron microscopy (TEM), or atomic force microscopy (AFM), X-rays demand less effort in sample preparation, and hard X-rays are always required either if the morphology gets amorphous – short-range order requiring large reciprocal space for signal detection – or if the particles are embedded in a bulk. With small sample volumes, high-energy synchrotron radiation is then the method of choice. And as the method is destructionless, the nanoparticles are described *in their natural environment*. In a wider sense, the structural characterization comprises the phase of the material and its stress or strain state compared to a corresponding reference substance (if available).

This harmless sounding term "embedded in their natural environment" is a consequence of the high penetration of high-energy X-rays. Another consequence of high energy or small wavelength is the fact that the scattering signal is squeezed into a small solid angle which can be captured in a single shot with the currently available large and fast two-dimensional (2D) detectors [4, 5]. And this combination makes all the difference. The brilliance of synchrotron radiation allows for a high local resolution with sub-micrometer (focused) beams and corresponding small sample volumes, the fast readout of 2D detectors down to several 100 Hz (and ever increasing) allows for a high time resolution (with no need for scanning, e.g., a diffractometer), and the high penetration generally allows for widely varying sample environments, i.e., buried structures are accessible in reaction chambers. This in situ characterization of materials is currently booming, driven by the rapid technical advances in detector development, and it comprises not only X-ray techniques but also microscopy and neutron scattering [6]. Nanoscaled materials are especially prone to fast dynamic processes as their influences propagate quickly across the intrinsically small dimensions. And this starts with the synthesis and the growth of nanostructures [7]. Figures 2, 3, and 4 exemplify the easy accessibility of high-energy synchrotron radiation for various sample environments which often can be commercially available (with none or minor modifications), here for mechanical testing of samples under load, dynamical scratch testing, and laser beam welding.



As high-energy synchrotron radiation is highly penetrating, there do not exist in principle any restrictions in characterizing *any* synthesis method with it: "breaking down of bulk material into nano-sized structures or particles" in a mill is not different in accessing with high-energy X-rays as "building up material from the bottom in atom-by-atom processes" whether in a gas phase or a liquid solution or in vacuum, independent of external temperature, pressure, or magnetic fields.

High-Energy Surface X-ray Diffraction

For nanoparticles due to their sizes, the influences of their surfaces are playing a dominant role. Understanding the interaction between the surfaces – solid, liquid, or buried – and their surroundings is thus crucial in understanding the properties of nanoparticles. And high-energy synchrotron radiation offers unique possibilities. While bulk crystalline matter leads to Bragg peaks of scattered X-rays, a surface leads to crystal truncation rods (CTRs) perpendicular to the surface. Changing in-plane periodicity leads to additional superstructures in the intensity distributions [10]. The measured intensities are several orders of magnitude less than for Bragg peaks. To gain complete information, one has to rotate the sample, i.e., rotate the Ewald sphere in reciprocal space, which for low-energy photons is time consuming. For high photon energies, 2D cuts of reciprocal space can be acquired in large 2D detectors leading to a significant speed up of data taking, approximately two orders of magnitude. Gustafson et al. [11], e.g., were thus able to measure the intensities of surface diffracted beams to follow the surface oxidation that accompanied the changes in a palladium surface during the catalytic oxidation of CO with O_2 at 85 keV in a chamber allowing the careful control of pressure, gas flow, and temperature.

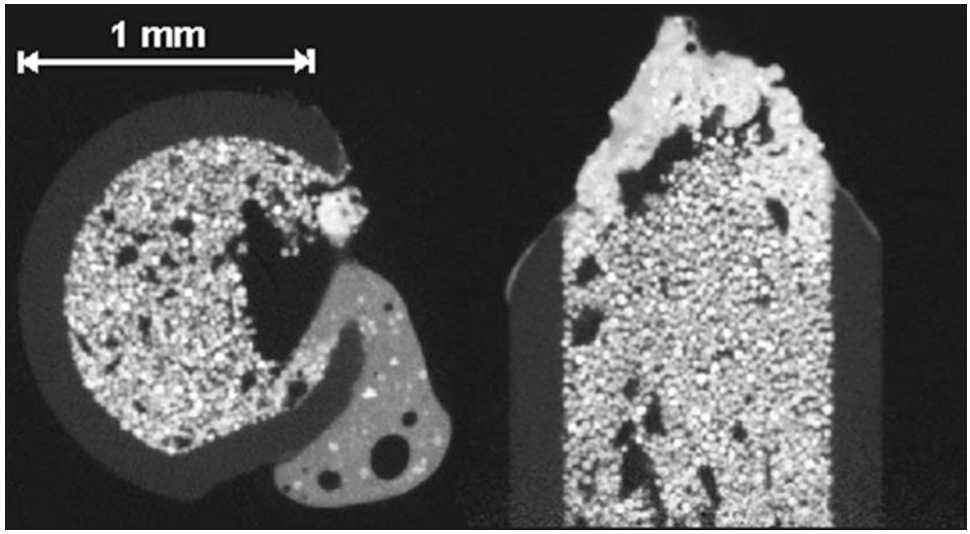
The abovementioned example does not state that surface characterization is or will be dominated by high-energy X-ray diffraction – there exists a wide range of powerful techniques that are used to characterize the surfaces of materials. The reader is referred to introductory guides in the literature [12]. On the other hand, the example shows the maturity and sensitivity reached and the complexity in process characterization with the help of high-energy synchrotron radiation diffraction.

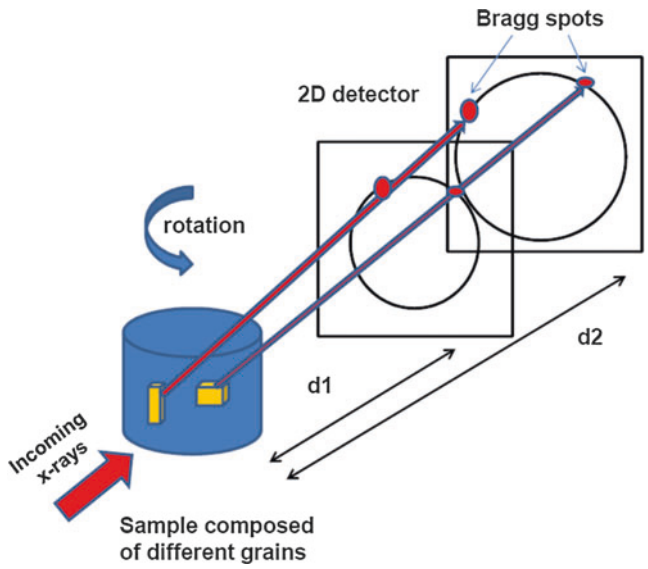


High-Energy Small-Angle X-ray Scattering

When nanoparticles are defined by their nm size or size distribution, their high-energy X-ray diffraction pattern in the here discussed regime of 50−150 keV (wavelength regime 0.08–0.24 Å) is automatically a small-angle X-ray scattering (SAXS) pattern. A more subtle definition regards SAXS as a scattering technique for structures which are much larger than the wavelength of the interacting radiation giving information about the size, shape, and orientation of those structures in a sample. The most important feature is the potential for analyzing the inner structure of disordered systems as SAXS is dependent on the average electron density difference between a particle (or a pore) and the surrounding matrix. A plethora of general [13] and specialized literature examines the method and its applications including chemical aggregation, defects, ferromagnetic correlations in magnetism, segregation, polymers, biological samples, etc.

If the particle or matrix is highly absorbing or put into a special environment (furnace, reaction chamber, stress rig, etc.), high-energy X-rays are needed to penetrate the sample (or environment) – this is the same argument as given above for wide-angle scattering.

Imaging Techniques with High-Energy X-rays



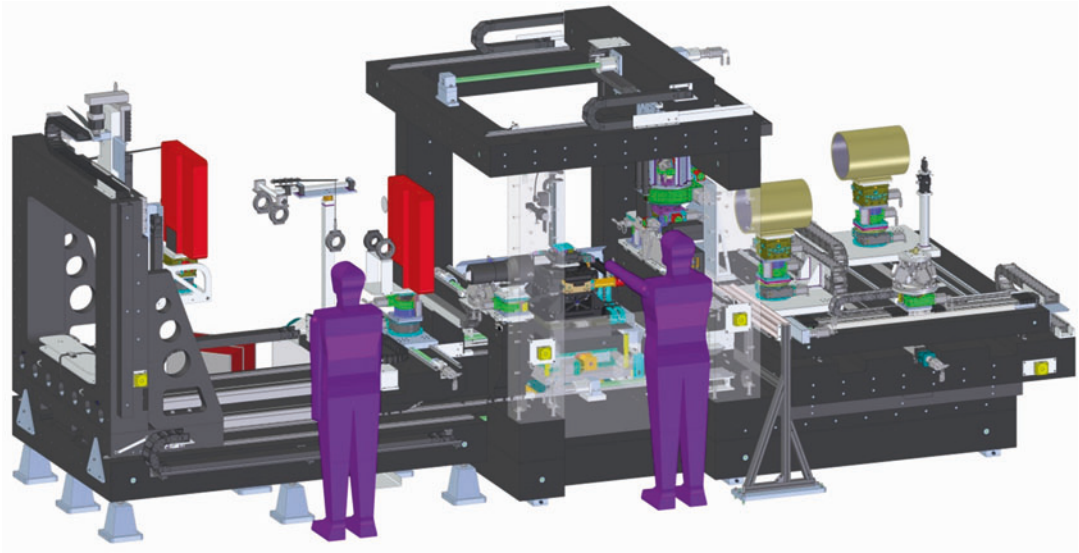
While the SAXS signal is measured as small intensity away from the trajectory of the incoming beam after interaction, caused by average electron density differences between particle and surrounding matrix, imaging techniques produce slices of a

High Energy Synchrotron Radiation and Its Impact on Characterizing Nanoparticles, Fig. 5 Feasibility study for SRμCT at 120 keV at beamline P07 at the storage ring PETRA III, DESY, Germany. The sample is a cored wire, with outer material Ni, inner particles WC/Co of 25–40 μm diameter, reconstructed volume (2.0 × 2.1 × 2.3) mm^3, pixel size 2.4 μm, and spatial resolution 5 μm. The tomogram allows the characterization of material properties in dependence of the manufacturing parameters (Courtesy F. Beckmann from Helmholtz-Zentrum Geesthacht, in cooperation with J. Nellesen, M. Abdulgader, and W. Tillmann from the Institute of Materials Engineering, Department of Mechanical Engineering, Technical University Dortmund)

scanned object to see what is inside. Most prominent is the X-ray computed tomography (X-ray CT) based on the absorption or the phase contrast of the different materials comprising the sample [14]. This technique needs generally *big data* handling as the resolution increases with the number of projection scans, and it is dependent on the accuracy of the rotation axis, i.e., its wobble which moves the sample – the smaller it is, the higher the accuracy. This has two severe consequences: the method is slower in comparison with single-shot scattering 2D images (where the information is immediately obvious), i.e., the number of "processes" to study is lower, and any sample environment is restricted in its weight. Since rotation axes are easier to handle in the vertical, high-energy synchrotron radiation tomography prefers a vertical scattering geometry as the monochromator aberration in the horizontal plane leads to artifacts of slightly different absorption when reconstructing the 3D image. Figure 5 shows a feasibility study for using synchrotron radiation micro-computed tomography (SRμCT) at 120 keV, necessary because of the high atomic number sample.

Interesting enough, one can image the inside of a sample likewise with X-ray diffraction spots, a technique labeled three-dimensional X-ray diffraction microscopy, short 3DXRD [15]. Its principle is shown in Fig. 6. Again the method is time consuming and calculation intensive, since one has to track typically 10–1000 individual grains with their distinct sizes, orientations, and strain states. The currently dedicated instruments for grain mapping (at, e.g., APS-1ID, ESRF-Id11, DESY-P07) are working in the micrometer size and resolution, but with technical detector and software development, the future capabilities will be driven to resolution in the several 10 nm range. And great efforts are under way to follow the behavior of the single grains, especially, under loading conditions to validate the widespread use of finite element (FE) models used in materials engineering. As nanoparticles often stiffen materials, this investigating technique will have applications for their characterization in the industrially important field of materials engineering.

High Energy Synchrotron Radiation and Its Impact on Characterizing Nanoparticles, Fig. 6 Scheme for 3DXRD. An incoming photon is diffracted into a specific Bragg spot which is caught in a 2D detector at different distances d1 and d2 which allows a back traction of the specific grain inside the sample. A stepwise rotation by 180° allows finally all grains to form the complete Debye-Scherrer rings in both detectors, i.e., for both distances. The individual spot (size, substructure, intensity) depends on the individual grain (size, orientation, strain, and stress) which caused the Bragg spot. Thus, one can map completely the grains inside a polycrystalline sample



Since the technical demands of SRμCT and 3DXRD are quite similar, a single experimental setup can realize both techniques, and as they are complementary, they can be combined to improve resolution and information (omitting inelastic scattering whereby a photon is either absorbed or scattered) which is done in diffraction contrast tomography (DCT) [16]. Figure 7 shows the design of a dedicated grain mapping instrument which also allows DCT [17].

Medicine and Life Sciences

Imaging techniques play a most prominent role in medicine and life sciences. Especially, radiographs are done in the energy regime 30–150 keV. Those fields are left out of this entry as the main impact is delivered in hospital environments relying on laboratory sources and not synchrotron radiation. However, leading techniques are today often developed at synchrotron radiation sources before they get a transfer to laboratory X-ray sources. In a nice reverse trend, many 2D detectors, originally designed for medical applications, find now their way to research at synchrotron radiation sources. While nanoparticles find their way, e.g., into implants, they can then be handled under the aspect of materials research with the all abovementioned impact of high-energy synchrotron radiation characterization. Likewise the importance of surfaces or chemical reactions in biology – membranes, tissue growth, etc. – can be handled by the respective topics talked about above. Even *bioreactors* can be seen as just other in situ *reaction chambers* in order not to blow up this entry.

Only one more advantage of high-energy synchrotron radiation for life sciences is given: the merit of high penetration was often stressed to give a glimpse of the many possibilities being offered to characterize processes; in life sciences, this weak interaction can have the tremendous advantage of less radiation damage, thus avoiding or at least reducing the impact of the very characterization, itself.

A final word should be given to a certain ambiguity of definition. Biomolecules and protein

High Energy Synchrotron Radiation and Its Impact on Characterizing Nanoparticles, Fig. 7 Design concept of the dedicated 3DXRD instrument at the high-energy materials science beamline P07 at the storage ring PETRA III, DESY. The beam is coming from the right and can be focused either by Kirkpatrick-Baez (*KB*) mirrors or compound reflective lenses (*CRLs*). The sample sits on a precision rotation axis in the center around which an optical microscope for alignment and the near-field X-ray detectors can be positioned – the latter allow the back tracing of single grains. The far-field detectors on an optical bench to the left allow detailed strain characterization and also SRμCT and DCT

structures are not regarded here as nanoparticles although they span the size range of nanoparticles. Thus, likewise, the field of protein crystallography is omitted which anyhow is dominated by structural characterization with X-rays below 30 keV. And, in consequence, the emerging field of structural biology with its aim to understand the connection between structure and function of biological macromolecules is omitted. Its *impact* of course is enormous; it will be developed mostly with free electron lasers in the soft X-ray regime – which is no longer classical synchrotron radiation [2]. However, there will be sources in the future which reach into the aforementioned regime of 50–150 keV with spontaneous emission [18]. But that should be another entry.

Viruses

Definition

Viruses are small biological infectious particles that can infect other biological organisms, and replicate only inside living cells [1]. They can only reproduce by invading and using host-cell machinery. Viruses infect most organisms, including animals, plants, and bacteria. Human immunodeficiency virus (HIV) is a retrovirus [2], meaning that its genetic material is in the form of RNA. To reproduce, it incorporates its genetic material into specific host cell's genome. To do this, the viral RNA must be reverse transcribed by a viral-encoded enzyme into DNA. HIV is the cause of acquired immune deficiency syndrome (AIDS) in humans [3].

Overview

The term "virus" was coined by Martinus Beijerinck in 1898, following his work on the discovery of the tobacco mosaic virus. There are estimated to be 10^{31} viruses existing on Earth, most of which are bacteriophages. It is estimated that 5000 viral genotypes are present in just 200 L

of seawater. Of the many different types of virus, over 5000 viruses have been described in detail. Currently, there are 241 recognized virus genera [1].

Whether viruses are life, or organic structures that interact with living organisms, is moot. That they possess genes, evolve by natural selection, and undergo self-assembly, suggests they are life. Yet, though they have genes, they possess no cellular structure, which is often stated a criterion that defines life. Since viruses have no metabolism, and cannot naturally reproduce outside a host cell, they are parasites that utilize life forms in order to maintain their own form of existence.

Structure

Viruses are the smallest parasites, ranging from 20 to 300 nm in diameter (some filoviruses are up to 1400 nm in length), making them visible only by electron microscopy.

Viral particles (*virions*) consist of genetic material, made from either DNA or RNA, encapsulated in a protein coat called the capsid. Some viruses possess a cell-derived membrane from the infected host, sometimes impregnated with viral-encoded proteins as receptors for cell entry.

Virally encoded protein monomers self-assemble to form the capsid. These form the morphological virus type, of which there are four: helical, icosahedral, enveloped (these viruses are envelopes in a modified host membrane), and complex (a complex arrangement of other types, with additional structures) [1].

Genome

Viruses display more genomic diversity than plants, animals, or bacteria. Viral genomes can be circular or linear, depending on the group, and is not a function of the form of nucleic acid. Most genomes are either single-stranded or double-stranded, but some are both (Table 1).

Most RNA viruses, and some single-stranded DNA viruses, possess single strands of genetic material that is either positive sense or negative sense, defined according to whether complementary to the viral mRNA. Positive-sense viral RNA is in the same sense as viral mRNA and can be translated by the host cell. Negative-sense viral RNA requires conversion into positive-sense RNA.

HIV Quantification, Table 1 Viruses can be grouped according to the genome type they possess (DNA or RNA), if single or double-stranded, whether their RNA is messenger RNA (mRNA) (+) or complementary to mRNA (−), and if they possess reverse transcriptase (*RT*)

Group	Virus type
I	dsDNA viruses
II	ssDNA viruses
III	dsRNA viruses
IV	(+) ssRNA viruses
V	(−) ssRNA viruses
VI	ssRNA-RT viruses
VII	dsDNA-RT viruses

The viral genome size varies greatly between species; from <2 kilobases (kb) to over 1.2 megabases (Mb), which encodes over 1000 proteins. RNA viruses generally have smaller genomes than those of DNA viruses, due to a higher error-rate when replicating. To compensate for this error rate, RNA viral genomes are split into smaller molecules – reducing the possibility of replication errors which would render the virus defunct.

Viruses use the machinery of a host cell to produce multiple copies, which are assembled within the infected cell. There are six basic stages in the life cycle of viruses: attachment to the target cell, penetration into that cell, uncoating of capsid to release genetic contents, replication of viral genome, assembly of new particles, and release of new virions into extracellular fluid. The specifics of each stage vary considerably between different types of virus. RNA viruses usually replicate their genome in the cytoplasm whereas, for most DNA viruses, this occurs in the nucleus. After release of newly synthesized virions, the host cell usually dies.

Viruses and Human Disease

Viruses can be transmitted vertically (from mother to child), or through the more common horizontal (from person to person) method. They can also be transmitted by blood-sucking insects (vectors), coughing and sneezing (e.g., influenza), the

fecal-oral route (e.g., norovirus), from person to person contact, food, and water. HIV, among other viruses, can be transmitted through sexual contact and exposure to infected blood by contaminated needle sharing or transfusion, and from a pregnant woman to her baby during pregnancy, delivery, and breast feeding.

Viruses have variable "host ranges," meaning the species that they can infect. Additionally, within a specific host, the virus may only be able to infect certain cell types (e.g., CD4+ cells for HIV). Responses to viral infection are variable. Some infections cause acute illness following a brief incubation period, whereas others produce minor symptoms or are asymptomatic. The immune system can clear many viral infections, but some viruses can remain undetected in a latent state. Here, viral RNA or DNA remains in host cells up to years later without causing disease. During this "latent" period, viral infections may still be transmissible. An immunosuppressed state may reactivate the latent virus, producing symptoms. Herpes viruses and HIV are viruses that produce latent infections.

Viruses exist globally, but their infectious influence on humans is limited by genetic resistance, immunization, public health control measures, and antiviral drugs. "Zoonotic" viruses can cross species. These originated in animals, with humans as secondary or accidental hosts. Hundreds of different viruses infect humans. They usually spread via respiratory and enteric excretions, but also by blood transfer, sexual activity, and arthropod vectors.

Many human diseases are caused by viruses, from mild (e.g., chickenpox), to serious (e.g., AIDS). They cause disease at the organism, and cellular, level. For the latter, this is primarily by cell lysis. For large organisms, if enough cells are killed, the effects can lead to serious disease and death. Some viruses that can exist in a latent state, such as herpes simplex virus (HSV), are harmless to an organism in this state. However, on activation, they cause symptoms of infection. Other viruses, such as hepatitis B, cause chronic infections because they are able to evade the immune system.

Some viruses are oncogenic, causing predisposition to cancers (e.g., Hepatitis B virus and hepatocellular carcinoma). The clinical diagnosis of human viral infections can be through well-known viral syndromes (e.g., measles), epidemiologically (e.g., during influenza epidemics), or by specific laboratory diagnosis (e.g., HIV). The latter is important not only for the infected individual, but also when the agent is a public health threat.

The body's first line of defense against viruses is the innate immune system, which is the intrinsic system comprising specialized cells and proteins. This doesn't provide long-term protection since it doesn't adapt to the pathogen. The adaptive immune system, as its name suggests, *does* adapt, but, unlike the innate immune system, requires a period of time after exposure to the pathogen in order to become active. Here, specific antibodies are generated that bind to the virus rendering it non-infectious. The production and secretion of antibodies is part of the humoral immune response. This differs from the cell-mediated immune response, which involves T-cells. However, together they form the adaptive immune system. A virus may infect a specific cell type called an antigen-presenting cell (APC) (B-cell, macrophage, dendritic cell). These cells then "present" a viral component to a naïve T-cell. These become primed to activate a specific B-cell, which produces antibodies against the virus first encountered by the APC (hence, the link). Some viruses, such as HIV, can avoid the innate response and takes a hold in the host before the adaptive response is able to block infection. It is for this reason that effective vaccines are so eagerly strived for.

Prevention and Treatment

Since viruses utilize host cell metabolic pathways to replicate, the problem of eliminating them must be tackled with compounds non-toxic to the host. Currently, attempts to prevent and treat viral infections is through vaccination (for immunity), and antiviral drugs (to block the viral life cycle).

Following immunization with an inactive or dead component of a virus, the immune system is stimulated to produce antibodies against that virus. Should that individual become infected, their immune system is prepared to halt the viral

life cycle before it starts. Commonly used viral vaccines include those against influenza, measles, and mumps. Immunoglobulins (antibodies) can also be given to passively immunize susceptible or immunocompromised individuals.

Once developed, vaccines are a cheap and effective way to prevent infections. They have produced profound improvements in viral infection–associated morbidity and mortality (e.g., for polio). To date, vaccines are available to prevent over 13 viral infections of humans. Vaccines may be live but attenuated virus (weakened and, therefore, not harmful), killed viruses, or viral proteins.

Significant investment and progress is being made into antiviral drug development. These drugs are directed at various phases of viral replication. Drug targets include the site of virion–host cell interaction, the uncoating process for viral nucleic acids, and viral factors required for viral replication.

Interferons are used as antiviral compounds. They are compounds released from infected host cells in response to viral or other foreign antigens. They block translation and transcription of viral RNA, and stop viral replication without disturbing host cell functions. They upregulate innate antiviral proteins, such as members of the TRIM family of proteins.

DNA analogues are the basis of typical antiviral drugs. Viruses incorporate these into their genomes during replication and, as a result, newly synthesized DNA is dysfunctional and the viral life cycle is blocked. Other drugs target different stages of the viral life cycle. For HIV, the virus-encoded protease enzyme is essential for infectivity, as it cleaves other viral proteins into active forms. Drugs called protease inhibitors inhibit this enzyme, rendering the virus, in effect, dead.

HIV

Overview

HIV is of particular interest because it is the cause of AIDS [3]. An individual can become infected with HIV by a number of possible routes: sex (vaginal, anal, oral) with an infected individual, sharing infected needles (drug use, tattoos, piercings), transfusion of infected blood, and from mother to child during pregnancy, birth, and breast feeding [3].

HIV is a virus that exists as two main types: HIV-1 and, the less virulent, HIV-2. HIV-1 was discovered in the early 1980s as the agent that causes the AIDS [4–6]. HIV-1 is thought to have zoonosed to humans from simian immunodeficiency virus (SIV_{cpz})-infected chimpanzees, perhaps through the eating of bush meat in Sub-Saharan Africa (SSA). HIV-2 zoonosed from sooty mangabeys monkeys, infected with another virus, SIV_{sm}.

HIV-1 infects 33.4 million infected individuals (2009), 27 million of who are in SSA (2/3 of all infections). Since records began, 25 million people have died from HIV-1-related complications. However, this number is probably much higher if one considers the difficulty to produce accurate numbers (considering the resources of the, mostly 3rd world, nations primarily affected) [7].

HIV is the 6th largest world cause of death, and the 4th largest in low-income countries (in 2004). In 2007, there were 2.1 million deaths (550,000 children), and 2.5 million new infections from HIV. In 2008, there were 2.0 million deaths, and 2.7 million new cases, so even after 30 years after detection of the causative agent of AIDS, the virus still presents a significant global health concern. Though in 1st world countries there is, as will be shown, efficient diagnostic and treatment measures, it is in the 3rd world where progress is essential. Indeed, it is estimated that 83 % of Kenyan cases are not diagnosed (2009). Ninety percent of global pediatric HIV is in SSA. Half of HIV-infected infants less than 18 months old in SSA will die due to AIDS.

Rather than splitting the world into social and economic groups, and evaluating the global problem on these grounds, if one considers the planet as a singular entity in which the virus can proliferate, then a more effective assault would surely ensue. Due to the nature of HIV replication, it has very high genetic variability. Unchecked in SSA, drug-resistant forms could emerge which, due to the ever-shrinking national borders, might impact

strongly on globally infected numbers. Thus, the problem of HIV is not national, but international. However, the UN published "The Millennium Development Goals Report" in 2010 [8], indicating that the global spread of HIV appears to have stabilized in most regions, and more people are surviving longer (see Fig. 1).

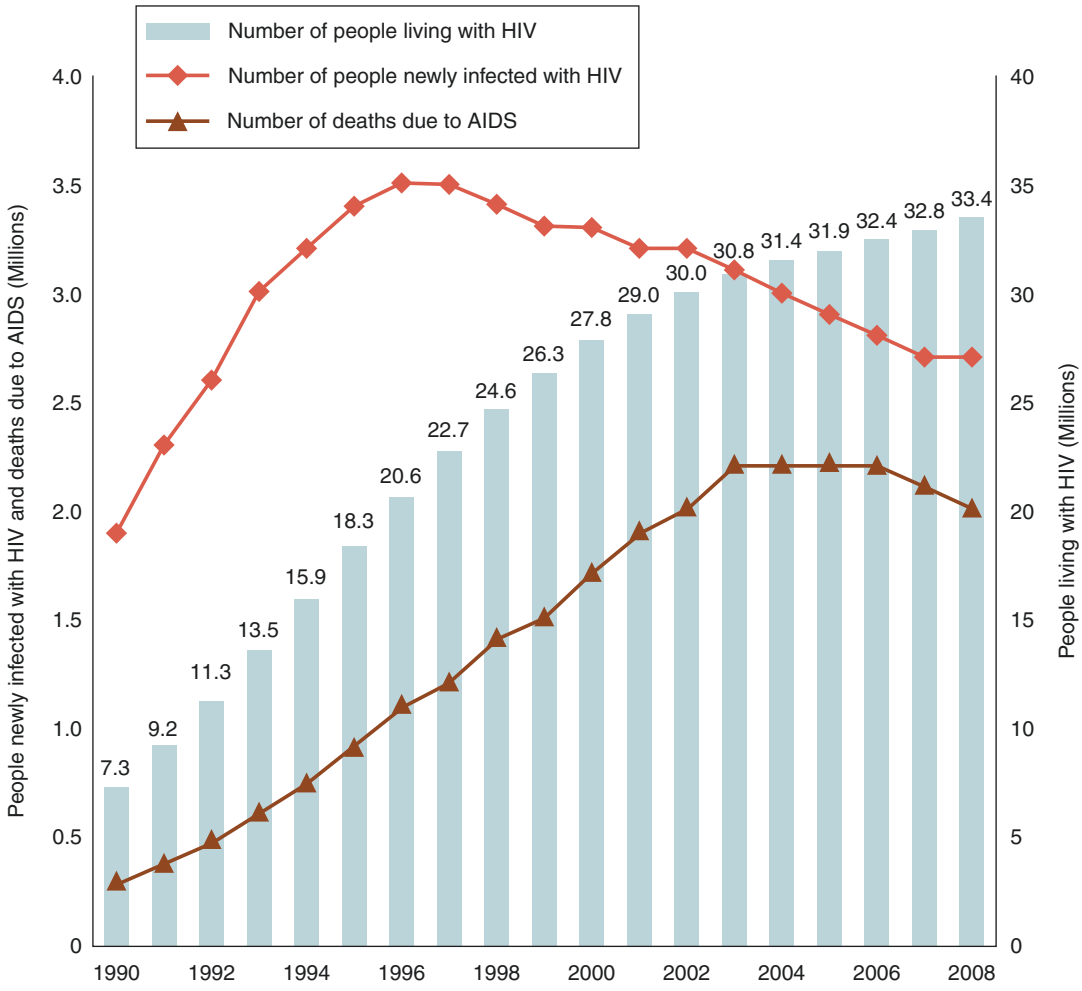
Human HIV infection is associated with social stigma. In 2004, 38 % of HIV diagnosed individuals in the USA developed AIDS in less than 1 year. Infected individuals may be reticent to seek help, and/or may do so only when symptoms are prominent (when the virus is less likely to respond favorably to antiviral drugs).

In the USA, more than one million are infected by HIV. In the UK (2005), 55,000 were infected, with an additional 20 % suspected undiagnosed. There were also high rates of drug resistance. In 2010, the number infected in the UK raised to 83,000, with 500 deaths/year. Thus, even with all facilities in place, HIV poses a problem [5, 6, 9].

Phylogenetics

HIV is a group V1 (ssRNA-RT) virus. It is a member of the family *Retroviridae*, which are the retroviruses [2]. These are RNA viruses, which replicate in a host cell using the enzyme reverse transcriptase to produce DNA from an RNA viral genome. In the *Retroviridae* subfamily *Orthoretroviridae* are the lentiviruses, including, among others, HIV and SIV. Lentiviruses are characterized by long incubation period in the infected host. HIV consists of two species, the commoner, highly virulent and highly infectious, globally prevalent, HIV-1 form, and HIV-2, which is less virulent or infectious, and is prevalent in West Africa.

HIV-1 is divided into three main groups based on the sequence of the entire viral genome. Group M ("major") accounts for more than 90 % of HIV/AIDS worldwide. Group N ("non-M, non-O") occurs only in Cameroon. Group O ("outlier") is not usually seen outside West-central Africa.



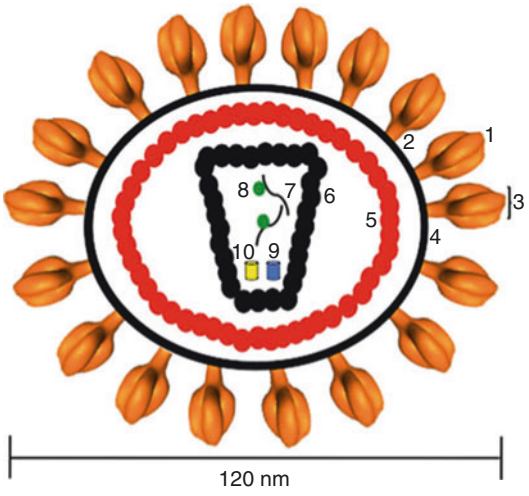
Group M is further classified into clades (subtypes), again based on the whole sequence. Clade A is common in West Africa. B is the dominant form in Europe, the Americas, Japan, Thailand, and Australia. C is the dominant form in Southern Africa, India, and Nepal, and accounts for nearly half of all worldwide HIV. There are also, Clades D, E, F, G, H, I, J, K. In addition, there are circulating recombinant forms (CRF), such as CRF02, which is clade A/G. These CRFs show genetic characteristics of more than one clade.

Since HIV has a very high genetic variability, it demonstrates huge diversity. This is a result of its fast replication cycle, generating about 10^{10} virions every day, and high mutation rate (about 3×10^{-5} per nucleotide base per cycle of replication). Thus, there are more individual variants of HIV in one infected individual than all variants of influenza in a population during an epidemic. It is this variation that makes it such a difficult agent to tackle with vaccines [10], and antiviral drugs [5, 9].

Genome and Structure

The diploid HIV-1 genome consists of two (+) RNA molecules of about 9 kilobases (kb) in length. These genomic RNAs are packaged into nascent HIV-1 particles and become reverse transcribed in infected cells to generate viral DNA for integration into the host genome. The genome encodes proteins, which are expressed from different spliced forms of a single RNA transcript, and are essential for infection. The same 9 kb HIV-1 proviral genome produces 3 mRNA transcripts encoding all the proteins necessary for the viral life cycle. As the transcripts are made from three different frames of the genome, the virus maximizes the information encoded in its genome.

The 55 kDa Gag polyprotein consists of the proteins MA (matrix), CA (capsid), spacer protein p2, NC (nucleocapsid), spacer peptide p1, and the p6 protein. Gag cleavage produces the individual proteins and occurs after virus assembly through maturation. Pol is made as a 160 kDa Gag-Pol protein, which is cleaved to produce Gag fused to protease (PR), reverse transcriptase (RT), and integrase (IN). The Env protein is cleaved into gp120, the surface protein (SU), and gp41, the transmembrane protein (TM). These proteins are essential for attachment to, and infection of, host cells. They exist together as a trimeric spike assembly. Additional auxiliary proteins



HIV Quantification, Fig. 1 Graph showing the number of people living with HIV, number of people newly infected with HIV, and number of AIDS deaths worldwide, 1990–2008 (Millions)

encodedare Vif (viral infectivity factor), Vpr (viral protein R), Vpu (viral protein unique), Rev (regulator of virion expression), Tat (transactivator of transcription), and Nef (negative factor). These serve additional functions to perpetuate the life cycle: Vif blocks innate antiviral proteins, Vpr enhances infectivity, whereas Nef and Vpu downregulate CD4.

An individual HIV-1 particle is near spherical and 100–120 nm in diameter. It consists of an outer membrane of infected host cell composition (acquired when budding from the host cell) impregnated with approximately 5–50 gp120/41 glycoproteins (for further infections) arranged as trimeric spikes. This surrounds a protein core of about 5000 p24 CA monomers arranged as a genome-housing cocoon, called the core. About 5000 MA proteins fill the space between the CA and membrane. The two RNA genomes are arranged in the core with about 250 copies each of IN, PR, RT, and variable quantities of auxiliary proteins [9] (Fig. 2).

Life Cycle

HIV-1 cell entry starts by trimeric spike binding to the susceptible cell's CD4 receptor. Further interaction with co-receptors (CCR5 or CXCR4) leads to fusion of the host cell and viral membrane,

HIV Quantification, Fig. 2 Schematic representation of a typical HIV-1 particle. *1* gp120 surface glycoprotein, *2* gp41 transmembrane glycoprotein, *3* trimeric spike (trimer of 1 + 2), *4* infected cell–derived viral membrane, *5* matrix protein, *6* p24 capsid core, *7* viral RNA genome (two copies), *8* reverse transcriptase enzyme, *9* integrase enzyme, *10* protease enzyme

involving the viral gp41. Following fusion, the CA core enters the cytoplasm and undergoes uncoating to reveal the viral genome. These two single-stranded (+) RNAs are copied into one strand of dsDNA by RT. The viral DNA is transported to the nucleus and is integrated into the host genome by the IN. Proviral transcripts encoding Rev and Tat are spliced, and their mRNAs are exported for protein synthesis in the cytoplasm. Imported back into the nucleus, these ensure efficient viral transcription and transcript export to the cytoplasm. The viral mRNAs are translated into Gag, GagPol, and Env proteins and full-length viral genome RNA is packaged into virions. Assembly and budding of new virus is mediated by host cell machinery (ESCRT-I/II/III) at the plasma membrane. Once released, HIV-1 undergoes a maturation process where protease can cleave Gag and produces cone shaped capsids within a glycoprotein/membrane cover for further infection [6].

HIV is of such interest because of the disease, AIDS, it causes. It is a disease of the immune system, such that infection leads to a progressive reduction in its effectiveness. Unchecked infections produce an ever-increasing susceptibility of the individual to opportunistic infections and tumors. Indeed, infections that would pose no threat to healthy immune systems are a potential risk to the life of those whose immune system has been compromised by HIV.

How HIV Causes Disease

Though it is widely known that HIV causes AIDS, the specifics of how it incapacitates the immune system is more specialized knowledge. It achieves this in a number of ways: primarily, since HIV infects CD4+ cells (helper T-cells, dendritic cells (DC), and macrophages), the effect on the immune system is mediated through the removal of the required amount of CD4+ cells to maintain efficient functionality. Macrophages and DCs function as, among other things, antigen-presenting cells (APCs). These internalize antigen (such as a virus), by phagocytosis or receptor-mediated endocytosis, then display a fragment of it bound to a class II major histocompatibility complex (MHC) molecule, on their membrane. Specific, naïve, CD4+ T-cells recognize and bind this complex and become activated, proliferate, and release cytokines. Later, the T-cell may bind a specific B-cell presenting the same antigen and, through a similar interaction, stimulate its conversion into an antibody-producing plasma cell. These antibodies bind to, and result in the destruction of, the virus. Thus, removal of the CD4+ cells removes the ability of antiviral (or any pathogen) antibody production.

HIV-infected cells release new virus and, as a result, this lyses and kills the cell. Thus, the specific infection allows the production of new virus, but also the destruction of the cell enabling its production. The integration of the viral genome into the host cell genome stimulates (auto) killer signals within the cell, and also downregulates anti-apoptotic signals, both promoting infected cell death. Infected cells may present viral fragments associated with MHCI. This presentation of viral component in infected cells causes cell destruction of those cells by cytotoxic CD8+ T-cells. The virus accessory proteins Nef and Vpu decrease CD4 levels in infected cells, rendering those cells ineffective APC mediators.

This effect presumably evolved to prevent other HIV particles in the infected host infecting an already infected cell.

It serves no purpose for an organism to evolve that infects another organism and kills it before the infecting organism can effectively survive. Hence, though HIV destroys cells it infects, it doesn't kill the organism for up to many months (even when non-treated), and during this time can pass to other individuals by the means described. Indeed, even if treated with drugs, or if the immune system is able to remove all serum virus (e.g., by CD8+ T-cell-mediated effects), the latent virus can be reactivated to restore serum levels and enable infection of other cells and individuals.

Prevention and Treatment

HIV differs from many viruses in that it evades the immune system by constantly changing the amino acid sequence of its glycoprotein envelope. This is essential for viral survival because the glycoprotein is on the external surface of the virus, and "visible" to the immune system, and is necessary for entry into susceptible cells.

The rapid replication of HIV, married with the high error rate, produces a large number of different particles. This results in particles whose glycoproteins differ too. Some particles will be ineffective at binding CD4 and infecting cells, rendering that virus replication–defective. Some may be replication-competent, but may present glycoproteins of a structure that are detected by neutralizing antibodies that have developed in the infected host. These antibodies block further virus–CD4 interaction by this virus. Some viruses may be produced with an envelope spike structure that the neutralizing antibody cannot recognize. These viruses can infect and result in the production of many viruses resistant to neutralization.

Thus far, the only effective neutralizing antibodies that have been produced have been isolated from HIV-infected individuals (e.g., 4E10). No comparably effective neutralizing antibodies have been produced from individuals immunized with components of an HIV particle. In effect, no effective vaccine has been produced [10].

Though clade A viruses are prevalent in Asia, C in SSA, and B in Europe and the USA, any vaccine would ideally be able to block multiclade viral infection. This is far from simple, in part due to the variability in the spike structure and the immune evasion techniques the virus has evolved.

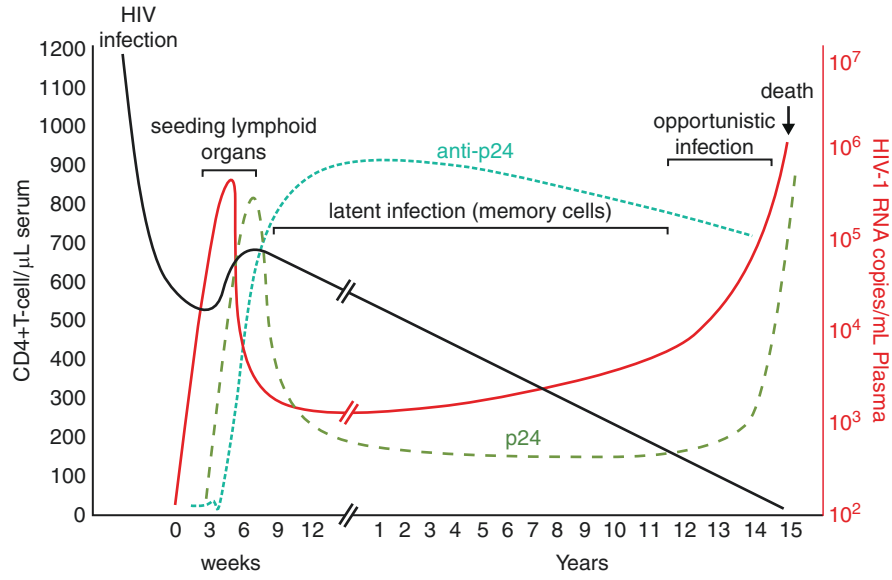
HIV vaccine development differs from that of other classic vaccines for a number of reasons: classic vaccines mimic natural immunity against reinfection. AIDS patients tend not to recover. Classic vaccines tend to be dead whole organisms, or those that are attenuated. HIV-1 is not antigenic if killed, and a live virus vaccine is unsafe. Since HIV may remain latent for long periods before causing AIDS, it can present as a hidden target, unlike those of classic vaccines. High-risk individuals may encounter HIV every day, and in different forms, whereas classic vaccines tend to protect against rarely encountered pathogens, which are less variable in sequence. Finally, the site of infection that most classic vaccines protect against is the respiratory and gastrointestinal tract. HIV rarely uses these routes [10].

Interestingly, live attenuated simian immunodeficiency virus (SIV) vaccines can confer effective protection against wild-type SIV challenge. Therefore, mindful of the positives gained from the primate effectiveness of vaccines, it is essential that one understands the early immune response to HIV-1 to enhance the possibility of generating efficient human vaccine designs. It is estimated that after initial infection there are less than 10 days in which virus-infected cells can be eradicated. After that, the virus spreads, integrates, and generates non-eradicable reservoirs of latent virus. Thus, only if the virus is prevented from infecting *any* host cells can the individual evade a successful infection.

Immunogens based on the gp120 envelope antigen represent, logically, ideal vaccine targets. gp120 stimulates a humoral immune response, including weak neutralization of the HIV strain from which it is derived. However, vaccines based on this target might conceivably be worse than useless, as they could elicit antibodies that enhance infection by targeting macrophages and dendritic cells via components of the immune system (complement and Fc receptors)

[6]. Additionally, MHCII presentation of the vaccine gp120 would result in, from the perspective of preventing HIV infection, unwanted induced proliferation of the HIV target CD4+ T-cells. However, the spike is the ideal vaccine target since it is the one whose blockage would prevent initial infection and the production of latent viral reservoirs.

Once HIV infected, the individual's prognosis is determined, somewhat, by antiretroviral drug therapy intervention. These can be broadly classified by the phase of the viral life cycle that the drug addresses. Nucleoside and nucleotide reverse transcriptase inhibitors (NRTI) inhibit reverse transcription by incorporation into newly synthesized viral DNA. This prevents further elongation. Non-nucleoside reverse transcriptase inhibitors (NNRTI) bind and inhibit RT directly. Protease inhibitors (PIs) bind and inhibit protease, which is essential for the assembly of new virions through its function of cleaving nascent viral proteins. Another target is integrase. Integrase inhibitors bind and inhibit the enzyme, preventing integration of viral DNA into the infected cell genome. Entry (or fusion) inhibitors block viral binding to target cells. Maturation inhibitors act at the stage of the viral life cycle where the capsid polyprotein is cleaved into mature capsid protein (p24). Thus, the core assembly is blocked, resulting in primarily non-infectious particles.



Highly active antiretroviral therapy (HAART) is the name given to the combination of antiretroviral drugs used to treat HIV infection. In the USA, there are different regimens (2009): an NRTI and NNRT1 are given in combination, or an NRTI and an integrase inhibitor or protease inhibitor. The choice and combination of the increasing number of drugs to choose from is often a combination of national guidelines together with the specific doctor-patient case. However, in resource-limited settings (such as SSA), the World Health Organization (WHO) has defined that HIV-infected adults should start drug therapy when HIV infection has been confirmed and one of the following conditions is present:

- There is clinically advanced HIV disease
- There is WHO Stage IV HIV disease (irrespective of the CD4+ T-cell count)
- There is WHO Stage III disease (consider CD4 + T-cell counts to assist decision – if less than 350/μL (mm^3) serum then start therapy)
- There is WHO Stage I or II HIV disease (CD4 T-cell counts less than 200/μL serum)

Of the 35+ million people infected with HIV, only 1.3 million of these people receive antiretroviral treatment. Drug treatment and diagnostics are closely linked. The decision on any rational treatment regimen starts when particular markers of infection (e.g., CD4+ T-cell count) reach a certain value. Diagnostic techniques determine these values. HAART drug regimens cannot completely eradicate HIV infection (latent infection is impervious to drugs). HAART, if adhered to, and with appropriate lifestyle choices (if applicable), can suppress HIV to levels below detection levels of standard clinical assays. This can be maintained for many years. Yet, if HAART is withdrawn, virus levels quickly rise and CD4+ T-cell levels fall (see Fig. 3), leading to AIDS.

Memory cells are a subset of CD4+ T-Cells. An HIV-infected individual, even if on successful HAART, is likely to possess memory cells with genome-integrated HIV. These long-lived cells possess the latent virus for the duration of their lifetime (many years, even decades). Thus, an infected individual could, theoretically, become free from HIV with effective HAART treatment until the latent memory cell population died. This, however, is unlikely.

The prognosis of an infected individual depends on many factors: HIV subtype, treatment, time treatment starts after infection, immune system fitness, age, location, resources, and so on. However, without treatment, the median survival time after infection with HIV is about 10 years, and the median survival rate after diagnosis of AIDS in resource-limited settings where treatment is not available ranges between 6 and 19 months. HAART has reduced the HIV-related death rate by 80 %, and raised life expectancy for newly diagnosed HIV-infected person to 20–50 years.

HIV Quantification, Fig. 3 The clinical determinant for antiretroviral therapy is the CD4+ T-cell count and the viral load. CD4+ T-cells are quantified by FACS, and virus by the genome levels. Other components of HIV infection are also measured. Serum viral p24 protein, and anti-24 antibody levels in serum are measured as indicators of the extent of, and response to, infection

Nanotechnological Methodologies for HIV Detection/Quantification

In addition to vaccine and antiretroviral drug development, there is a powerful need for cheap and accurate HIV diagnostic sensors. Nanotechnological methods are increasingly associated with designs of such devices. To fit all potential markets (e.g., hospitals, doctor's surgeries, and developing countries), such devices should rapidly, and accurately, diagnose and monitor HIV in resource-limited environments. In developing countries electricity may not be available. Thus, battery (such as mobile phone batteries), or solar-powered devices are advantageous.

The need for accurate diagnostics married to limited access to fully functional diagnostic clinics is driving the development of point-of-care (POC) technologies for early diagnostics. Early diagnosis reduces the risk of onward transmission from people who are not aware of their infection, and provides important information on the dynamics of epidemic, transmission networks to guide public health intervention programs. In the developing world, antiretroviral drugs are used without monitoring, leading to resistance and compromising the full potential of such drugs. The development of affordable, portable, HIV diagnostics, and smart monitoring devices, will benefit millions of HIV-infected individuals.

The main clinical virological marker is "viral load" (copies of RNA/mL plasma); p24 is another. The immunological markers are HIV-specific antibodies (against gp120 and p24). The CD4+ T-cell count is the main immunological marker against which drug therapy is judged, since it is an indicator of the immune system's response to infection (see Fig. 3).

Currently, POC enzyme-linked immunosorbent assay (ELISA) tests identify HIV infection through blood from thumb pricks, and can be used in non-hospital settings. These are insensitive and lack specificity. Well-funded laboratories perform HIV diagnoses by HIV antibodies and p24 in serum, to ensure detection of the early stages (first 2–4 weeks) of infection when p24 antigen is present. POC tests are limited to detection of antibody (at present).

HIV viral load is measured using real-time polymerase chain reaction (RT-PCR). For the CD4+ T-cell count, fluorescent-activated cell

sorting (FACS) and microscopy are used. Both require sophisticated instrumentation, sample preparation, amplification steps, and experienced personnel. This is expensive, so monitoring is restricted to tertiary centers.

Point-of-care HIV devices have not yet been implemented, both because of the apparent poor compatibility of gold standard methodologies (RT-PCR, FACS, ELISAs, each requiring specialized reagents and instrumentation), and because of the significant challenges imposed by resource-limited environments: tests should be robust, simple to operate, require a minimum sample volume, yet provide a rapid answer. There should be a low probability of false positive or false negative results. The device and reagents should tolerate variable storage conditions (certain settings may not possess refrigerators and freezers), yet be affordable. Microfluidic PCR systems have been developed. Devices which perform on-chip RT-PCR (incubation with RT, PCR components, and thermocycling) and chemiluminescent detection of the amplicon, all carried out within 1 h have been demonstrated [11]. However, such devices are relatively expensive. Certain microfluidic PCR platforms under development, using isothermal amplification, do not require thermocycling or the use of RT. So far, they have been qualitative in their amplification. The use of integrated optical detection could aid quantification and robustness of these devices as well as reduce cost. There is scope for an HIV context here.

Since the gold standards for evaluating HIV infection are the viral load (measured by qPCR of the viral genome), and flow cytometric counting of CD4+ T-cells, even if a POC device does not measure these specific virological and immunological aspects of an HIV infection, the aspects they *do* measure should quantitatively correlate to these values, such that the data obtained will be as useable in an HAART response context. For example, if one chooses to use the viral envelope spike to quantify viruses in the POC device, it must give readouts that are quantitatively correlative to the value that would be obtained if one were to perform qPCR on the same sample.

In addition to FACS, ELISA, and qPCR, current laboratory diagnostic techniques used for HIV status measurements include western blotting (a type of ELISA, but which can signify the target protein's mass). Simple POC lateral flow tests are available; these are chromatography techniques that rely on capillary action to drive the flow of sample. These are simple devices, which use strips with an absorbent layer coated with specific antibodies. A small drop of fluid sample causes antibody-antigen pairs to diffuse to a detection zone, providing an optical indication and a diagnosis. Though cheap and simple, their use for HIV is limited, especially in terms of sensitivity and quantification. Saliva and urine tests are also used, but carry the disadvantages of ELISAs and lateral flow tests, as well as the fact that HIV levels are low in these fluids compared to serum [11].

The recent advances in microelectronics have delivered chips with nanometer-sized features comparable with a single HIV virion (*circa* 120 nm). This convergence in the size of natural "bottom-up" self-assembled systems and "top-down" fabricated objects offers tremendous opportunities to probe pathogens with unprecedented sensitivity.

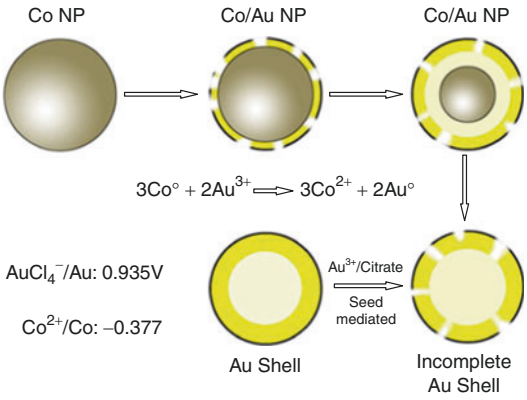
Definition

Spherical gold nanoparticles with a hollow interior. This class of photothermal conducting nanomaterials has found applications in photothermal ablation therapy, drug delivery, photoacoustic imaging, and surface-enhanced Raman scattering spectroscopy.

Key Principles



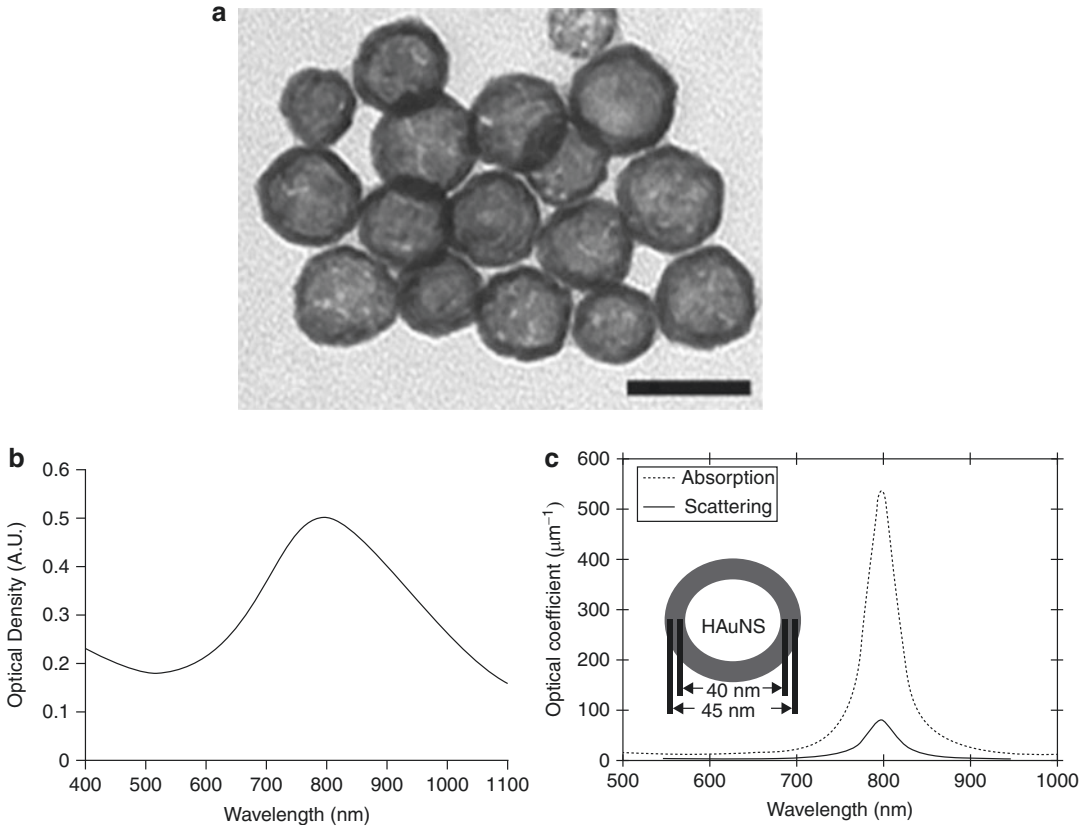
Noble metal (e.g., gold and silver) nanomaterials possess novel optical and electronic properties useful for various potential biomedical applications, including sensing, imaging, drug delivery, and therapy. In particular, their strong surface plasmon resonance (SPR) absorption and high photothermal conversion efficiency are well suited for photothermal ablation (PTA) therapy application. Ideal metal nanostructures for PTA should not only have strong and tunable SPR, especially in the near-infrared (NIR) range, for better tissue penetration but also be easy to deliver, have low toxicity, and be amenable to bioconjugation for actively targeting specific cancer cells. Several different types of gold nanostructures have been utilized for PTA therapy, including nanorods, nanoshells, nanocages, nanoprisms, and hollow nanospheres. Among these structures, hollow gold nanospheres (denoted as HAuNS or HGNs) represent second-generation gold nanostructures with unique structural features, optimal optical properties, and efficient photothermal profiles. These HAuNS are utilized in a variety of applications, including as photothermal-converting agents for PTA therapy, as contrast agents for photoacoustic imaging, as substrate for surface-enhanced Raman scattering (SERS), and as drug carriers for light-activatable delivery of anticancer agents and small interfering RNA (siRNA).

HAuNS have the unique combination of small size (outer diameter 30–50 nm), spherical shape, hollow interior, and a strong and tunable absorption band at a NIR-region wavelength as a result of their highly uniform structure. These properties make HAuNS ideally suited for targeted delivery after systemic administration. Small size is important because smaller particles extravasate more easily out of tumor blood vessels. The optimal size for intracellular uptake is about 50 nm for gold nanoparticles. Strong light absorption and a narrow absorption band are important for PTA because these properties directly affect heat-conversion efficiency. Tunable absorption is useful for matching the selected laser wavelength and minimizing the absorption of NIR light by normal tissues.

Synthesis and Characterization

HAuNS are synthesized by the cobalt nanoparticle–mediated reduction of chloroauric acid (Fig. 1) [1]. Briefly, cobalt template nanoparticles were synthesized by adding 2500 μL of sodium borohydride (1 M) into 1000 mL of deoxygenated aqueous solution of sodium citrate (2.8 mM) and cobalt chloride (0.4 mM). The slightly pink solution turned brown upon the addition of sodium borohydride, indicating the formation of cobalt nanoparticles. The solution was allowed to stand at room temperature for 45 min under constant argon flow until complete hydrolysis of the sodium borohydride. In a separate vial, 600 mL of an aqueous solution of chloroauric acid (0.04 mM) was deoxygenated by bubbling with argon gas. Subsequently, 800 mL of cobalt nanoparticle solution was transferred to the chloroauric acid solution under argon protection and magnetic stirring. The cobalt immediately reduced the chloroauric acid to gold ions that adhered to the surface of cobalt nanoparticles, while at the same time, it was oxidized to cobalt oxide. Any remaining cobalt core was further oxidized by air, resulting in the final formation of the HAuNS.

HAuNS synthesized from sodium citrate are coated with citric acid and are negatively charged. Polyethylene glycol (PEG) is normally conjugated to the surface of HAuNS to improve the colloidal stability of the nanoparticles. A transmission electron microscopy (TEM) image of PEG-HAuNS shows that the nanoparticles had a mean outer diameter of 43–46 nm and a mean shell thickness of 2–4 nm (Fig. 2a). The resonance absorbance of these nanoparticles was tuned to peak at 800 nm (Fig. 2b). According to the Mie theory and the plasmon resonance theory [2], the optical absorption coefficient of gold nanoshells increases, while the optical scattering coefficient decreases, with decreasing diameter of the core. The peak wavelength experiences a red shift (increase in wavelength) with decreasing shell thickness. Figure 2c shows the calculated optical absorption and scattering coefficients of HAuNS

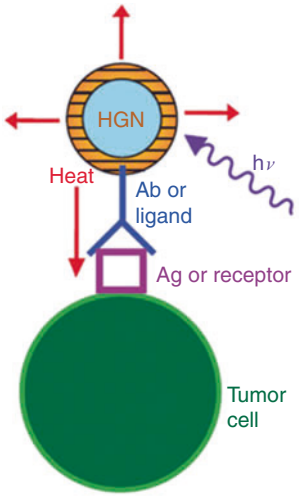


Hollow Gold Nanospheres, Fig. 1 Schematic illustration of the synthesis scheme, in which Co metal nanoparticles (*NP*) are used as a template for making HAuNS via the redox reaction shown in the *middle* of the figure

(i.e., absorption and scattering cross sections per unit volume). With an outer diameter of 45 nm and shell thickness of 2.5 nm, HAuNS have an absorption coefficient of ~540 μm^{-1} at 800 nm. The extinction of HAuNS is dominated by absorption, owing to their small size. The theoretical dimensions of HAuNS match well with the measured dimensions shown in the TEM image (Fig. 2a).

Femtosecond (fs) hole-burning studies have been carried out to understand how the HAuNS structure can be affected by pulsed laser excitation, which is important for the study of HAuNS as potential drug carriers with light as a trigger for release [3]. It was found that upon irradiation with an fs laser in the NIR (e.g., ~800 nm), HAuNS can be affected by two possible processes: (1) conversion of NIR-absorbing HAuNS to bluer light–absorbing HAuNS and (2) breakdown of NIR-absorbing HAuNS directly into solid Au nanoparticles. The branching ratio between these two processes depends on the peak power of the fs laser pulses, with a higher peak power favoring the second process.

The surface chemistry of Au is extremely versatile, which results in the formation of Au-S bonds when gold nanoparticles are mixed with molecules containing a mono-sulfhydryl (SH) group or molecules with multiple thiol



Hollow Gold Nanospheres, Fig. 2 (**a**) TEM image of PEG-HAuNS (Bar = 50 nm). The average outer diameter was 45 nm, and thickness of the shell was 2.5 nm. (**b**) Experimental absorbance spectrum of PEG-HAuNS in water, which peaked at 800 nm. (**c**) Theoretically calculated absorption and scattering spectra of PEG-HAuNS with water core having a dielectric permittivity of 1.77. The inner core radius was 20 nm, and the gold shell thickness was 2.5 nm, which are consistent with the values shown in (**a**) (Reproduced with permission from Ref. [12])

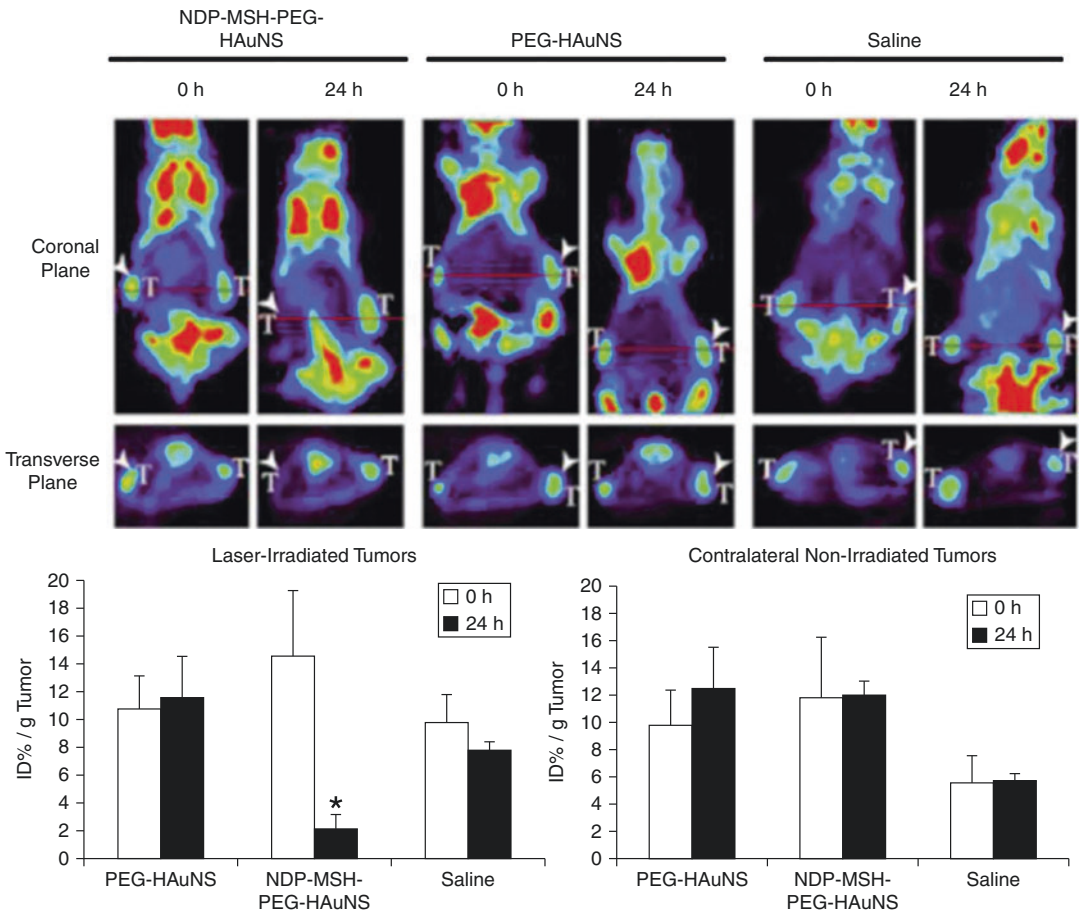
groups that act as anchoring ligands. HAuNS can also be coated with molecules attached to thioctic acid (TA), also known as alpha-lipoic acid, a naturally occurring compound [4]. TA is particularly well suited for gold surface modification because as a cyclic disulfide-containing compound, it gives added stability by providing two gold-sulfur bonds per molecule in surface-functionalized gold. Various molecules have been successfully attached to HAuNS, including the radiometal chelation agents diethylenetriamine pentaacetic acid (DTPA) and 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA), fluorescent dye, and siRNA, owing to the Au-S chemistry [5–7].

Applications

Targeted Photothermal Ablation Therapy

The basic principle behind photothermal ablation therapy (PTA) is illustrated in Fig. 3. HAuNS target cancer cells via specific interactions, such as antibody-antigen or ligand-receptor binding. Upon absorption of NIR radiation, HAuNS quickly release heat that destroys the cancer cells bound to them locally. Strong optical absorption and quick and highly efficient photothermal conversion at the cancer site are critical to the high efficacy of PTA. Mechanisms of heat-induced cell death that have been proposed in previous studies include heat shock of proteins, inactivation of

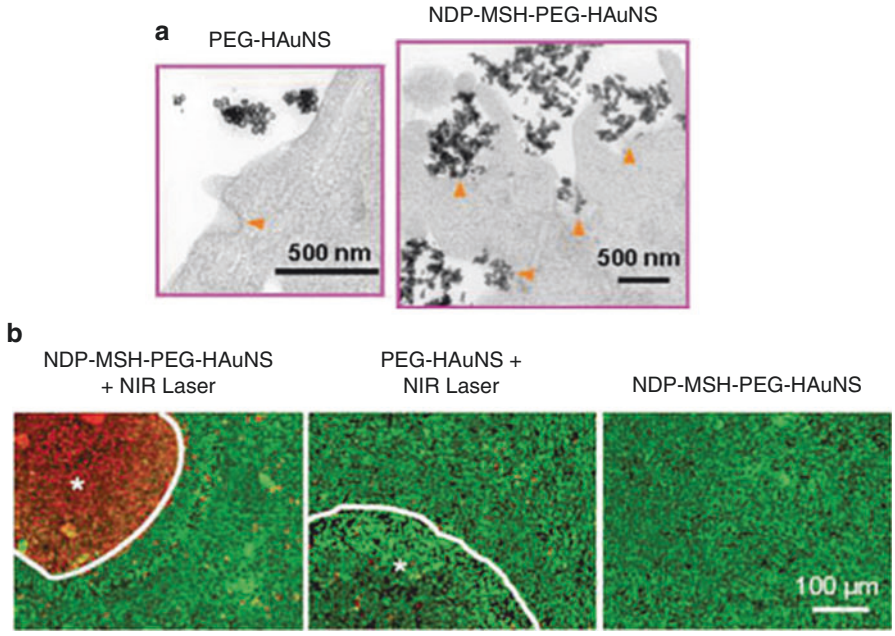
Hollow Gold Nanospheres, Fig. 3 Illustration of the principle of PTA. HAuNS target cancer cells via antibody (*Ab*)-antigen (*Ag*) interaction. Quick release of local heat by HAuNS upon absorption of light destroys the cancer cells bound to the HAuNS



membrane proteins and mitochondria, depolymerization of cytoskeletal filaments, membrane blebbing, and plasma membrane disruption due to cavitation effect, which was also suggested to be responsible for bubble formation. The high effectiveness of PTA indicates that the local temperature at or near the metal nanostructure surface is likely much higher than the average temperature usually measured using thermocouples. Photothermal coupling agents can increase the efficiency of PTA, reducing the required energy dose of laser light and thereby lowering the potential for damage to surrounding normal tissues. Among the candidates for photothermal coupling agents are gold nanostructures.

One of the major challenges in using gold nanostructures for PTA is how to maximize the efficiency of their in vivo delivery to the target sites after systemic administration. The feasibility of tumor targeting using HAuNS has been demonstrated by studies in which HAuNS were coated with antibodies, [7] peptides, [5], and small-molecular-weight organic compound [6]. To demonstrate the feasibility of using HAuNS to target epidermal growth factor receptor (EGFR)–expressing cells, HAuNS were covalently conjugated to an antibody directed against EGFR, cetuximab (C225) [7]. The resulting C225-HAuNS conjugate was selectively bound to A431 human squamous carcinoma cells that overexpress EGFR. Selective cell killing was observed in the cells treated with C225-HAuNS and NIR laser but not in the cells treated with C225-HAuNS alone, NIR laser alone, or IgG-HAuNS plus NIR laser. C225-HAuNS had significantly higher uptake in the vicinity of tumor microvessels than did IgG-HAuNS control after intravenous injection into nude mice bearing subcutaneous A431 tumors. Because monoclonal antibodies are large-molecular-weight compounds, dispersion of C225-HAuNS into the tumor mass after the nanoparticles were extravasated outside the tumor vasculature was limited, and the difference in uptake between C225-HAuNS and IgG-HAuNS in A431 tumors was not statistically significant. In contrast, conjugating HAuNS to a small-molecular-weight peptidyl analog of α-melanocyte-stimulating hormone, [Nle4,D-Phe7]α-MSH (NDP-MSH, molecular weight 1769 Da) targeting melanocortin type-1 receptor (MC1R), led to a remarkably high tumor uptake value (~12.6%ID/g) (Fig. 4). Successful PTA of melanoma in mice was demonstrated using a laser energy dose as low as 30 J/cm^2 with HAuNS targeted to MC1R, [5] supporting the use of HAuNS as an efficient, targetable photothermal conducting agent.

A number of in vitro studies, including TEM and cell viability studies, have been conducted to better understand the fundamental interactions between HAuNS and cells. For example, in the in vitro PTA study of melanoma cells, the HAuNS were selectively taken up by B16/F10 cells via MC1R receptor-mediated endocytosis [5]. The conjugate NDP-MSH-PEG-HAuNS coated with an MC1R agonist NDP-MSH peptide was critical for selectivity (Fig. 5).



Drug Delivery

HAuNS-mediated temperature elevation may be used to modulate the release of cytotoxic and genetic agents contained in HAuNS and

Hollow Gold Nanospheres, Fig. 4 In vivo photothermal ablation with targeted NDP-MSH-PEG-HAuNS induced selective destruction of B16/F10 melanoma in nude mice. [^{18}F]fluorodeoxyglucose positron emission tomography (*PET*) imaging shows significantly reduced metabolic activity in tumors after photothermal ablation in mice pretreated with NDP-MSH-PEG-HAuNS, but not in mice pretreated with PEG-HAuNS or saline. [^{18}F]fluorodeoxyglucose PET was conducted before (0 h) and 24 h after near-IR laser irradiation (0.5 W/cm^2 at 808 nm for 1 min), which was commenced 4 h after i.v. injection of HAuNS or saline. *Arrowheads* in the figure indicate tumors (*T*) irradiated with near-IR light. [^{18}F]fluorodeoxyglucose uptake (%ID/g) before and after laser treatment is shown graphically at the *bottom*. microspheres [8, 9]. To evaluate the feasibility of NIR light–modulated drug release from microspheres, biocompatible, biodegradable poly(lactic acid-co-glycolic acid) (PLGA) microspheres containing paclitaxel (PTX) and HAuNS (PTX/HAuNS microspheres) were prepared using a modified water-in-oil-in-water (W1/O/W2) double-emulsion solvent evaporation method. The resulting PTX/HAuNS microspheres had the same concentration as HauNS alone and so were able to elevate the temperature of water to the same extent, indicating that the PLGA polymer matrix did not prevent NIR light from reaching HAuNS embedded in the microspheres. Significantly, PTX released from these PLGA microspheres could be modulated by controlling the laser output power and the HAuNS content in the microspheres. Figure 6a shows the characteristics of PTX release from PTX/HAuNS microspheres and from microspheres containing PTX alone using various NIR laser output powers. The microsphere solution (10 mg/ml)

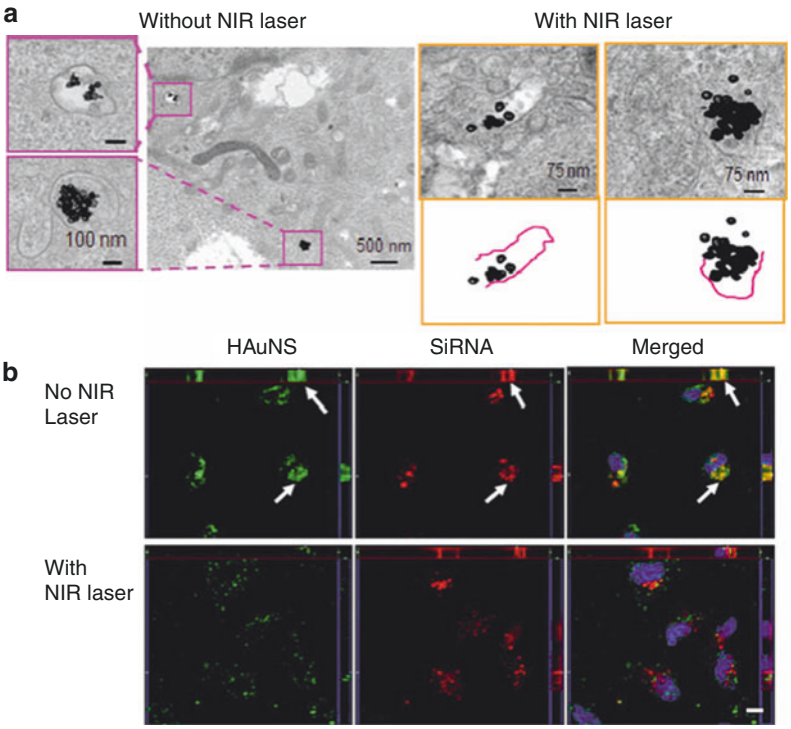
Hollow Gold Nanospheres, Fig. 5 (**a**) Transmission electron micrographs of B16/F10 melanoma cells showing selective cellular uptake of NDP-MSH-PEG-HAuNS. NDP-MSH-PEG-HAuNS were seen in coated pits (*arrowheads*) and endosomes (data not shown). Non-targeted PEG-HAuNS were found only outside the cell membrane. (**b**) Cell viability after NIR irradiation. B16/F10 cells were treated with NDP-MSH-PEG-HAuNS plus NIR light (808 nm, 32 W/cm^2, 3 min) (*left*), PEG-HAuNS plus NIR laser (*middle*), or NDP-MSH-PEG-HAuNS alone (*right*). Viable cells were *stained green* with calcein AM; dead cells were *stained red* with EthD-1. [5])

was irradiated repeatedly using an NIR laser over a period of 5 min, followed by a 1.5-h interval with the laser turned off. Rapid release of PTX from PTX/HAuNS-MS was observed when the NIR laser was on, whereas little PTX was released when the laser was turned off. The percentage of accumulated release of PTX over the course of the experiment approached 40 % when PTX/HAuNS-MS were irradiated using the NIR laser four times for 5 min each. In comparison, when PTX-MS was subjected to the same treatment protocol, the percentage of accumulated release of PTX was less than 7 % over the entire experimental period. Unirradiated PTX-MS had a 3.6 % accumulated release of PTX. These data indicate that the release of PTX from PTX/HAuNS-MS can be triggered by irradiation with an NIR laser, with excellent temporal and spatial control.

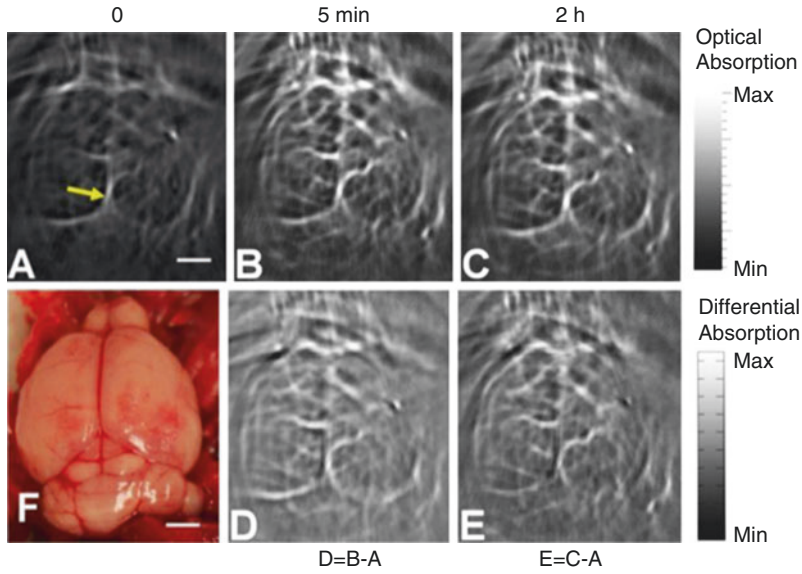
A significant difference in the cell-killing effect of PTX/HAuNS-MS with and without NIR irradiation was found (Fig. 6b). For example, 86.5 % and 67.4 % of the cells were viable after 72 h of incubation with PTX/HAuNS-MS alone at microsphere concentrations of 1 mg/ml and 10 mg/ml, respectively. However, when PTX/HAuNS-MS was combined with NIR irradiation, only 38.8 % and 3.9 % of the cells survived treatment at microsphere concentrations of 1 mg/ml and 10 mg/ml, respectively. Furthermore, about 90 % of the cells were viable after treatment with MS containing HAuNS alone and no PTX (HAuNS-MS) at the low concentration range (0.05–4.0 mg/ml) regardless of NIR exposure. At the high concentration range (6.0–10.0 mg/ml), combined treatment with HAuNS-MS and the NIR laser resulted in a significant cell-killing effect (Fig. 6b), which can be



Hollow Gold Nanospheres, Fig. 6 *NIR light triggered release of PTX from PTX/HAuNS-MS. Red lines* represent the 5-min period during which the microspheres were irradiated with NIR laser. (**a**) PTX release profiles from PTX/HAuNS-MS containing 2.0×10^9 HAuNS/mg polymer at NIR output power of 7 W/cm^2 (), 4 W/cm^2 (), and 2 W/cm^2 (o), and PTX release profiles from PTX-MS (without HAuNS) at NIR output power of 7 W/cm^2 (Δ) and without NIR exposure (●). (**b**) *Cytotoxicity in the presence and absence of NIR irradiation*. MDA-MB-231 breast tumor cells were incubated with various MS formulations for 72 h. For NIR treatment, cells were irradiated with NIR laser four times at an output power of 2 W/cm^2 for 3 min each. Cancer cells were killed primarily by PTX released from PTX/NS-MS triggered by an NIR laser at low MS concentration, while efficient cell killing was achieved with combined PTX/HAuNS-MS and NIR irradiation at higher MS concentrations mediated by both increased free PTX released from the MS and increased photothermal effect (Reproduced with permission from Ref. [8])

Hollow Gold Nanospheres, Fig. 7 Hollow gold nanospheres with strong surface plasmon absorption in the near-infrared region formed stable complexes with doxorubicin, with an extremely high payload (Reproduced with permission from Ref. [9])

attributed to the photothermal effect of HAuNS-MS at high microsphere concentrations owing to increased local temperatures. These results demonstrate that the combination of photothermal effect and chemotherapy is more efficient than thermal ablation alone in killing tumor cells over a wide range of microsphere concentrations.



In addition to the comixing of HAuNS and drugs in the matrix of microspheres, anticancer drugs can also be directly incorporated into HAuNS and their release modulated with NIR light. For example, as high as 63 % doxorubicin (DOX) by weight (~1.7 μg DOX/μg Au) could be loaded onto PEG-coated HAuNS because DOX adhered to both the outer and the inner surfaces of HAuNS (Fig. 7). Irradiation with an NIR laser induced photothermal conversion, which triggered rapid DOX release from the DOX-loaded HAuNS [9]. The release of DOX was also pH dependent, with more DOX released in aqueous solution at a lower pH. Similar to microspheres containing HAuNS and PTX, significantly greater

Hollow Gold Nanospheres, Fig. 8 Endolysosomal escape of HAuNS-siRNA after NIR irradiation. (**a**) TEM images show F-HAuNS-siRNA nanoparticles located in the intact endocytic vesicles in HeLa cells not exposed to NIR light. After laser treatment, parts of the vesicle membranes disappeared, resulting in nanoparticle escape. (**b**) Z-stack images show dissociation of $siRNA_{NF-\kappa B}$ from HAuNS after laser irradiation. In cells without NIR irradiation, the siRNA colocalized with HAuNS (*arrows*). *Red*, Dy547-labeled siRNA; *green*, scattering signal from HAuNS visualized under a dark field; *blue*, cell nuclei counterstained with DAPI. Bar, 10 μm (Reproduced with permission from Ref. [6])

cell killing was observed when MDA-MB-231 cells incubated with DOX-loaded HAuNS were irradiated with NIR light, which was attributable to both HAuNS-mediated photothermal ablation and the cytotoxicity of released free DOX.

The excellent photothermal-conducting properties of HAuNS also provide a unique opportunity for mediating controlled release of siRNA**C** [6]. Termed "photothermal transfection," this novel siRNA delivery technology involves three steps: (1) internalization of siRNA-coated HAuNS through receptor-mediated endocytosis; (2) selective thermal disruption of the endolysosomal membrane and escape of the siRNA-coated HAuNS from endolysosomes upon NIR laser irradiation; and (3) detachment of siRNA from the nanoparticle carrier and release of free siRNA into the cytosol. Unlike traditional nanoparticulate polyelectrolyte-mediated RNAi, NIR laser-induced RNAi is confined to the illuminated area, which should reduce off-target effects. In addition, unlike UV/Vis light–induced RNAi, NIR laser–induced RNAi is translatable to the clinic because NIR can penetrate 3–5 cm into soft tissues. In a proof-of-concept study (Fig. 8), it was demonstrated that HAuNS coated with folic acid and loaded with NF-κB p65 siRNA were located in the endocytic vesicles in HeLa cells expressing folate receptors with intact membranes. However, when the cells were irradiated with an NIR laser, the endocytic membrane was disrupted, resulting in escape of the nanoparticles into the cytoplasm and detachment of the NF-κB siRNA from the HAuNS. A significant reduction in NF-κB p65 protein expression was demonstrated both in vitro and in vivo and sensitization

Hollow Gold Nanospheres, Fig. 9 Noninvasive PAT imaging of a mouse brain in vivo employing PEG-HAuNS and NIR light at a wavelength of 800 nm. to chemotherapy through enhanced apoptotic response upon laser irradiation [6]. Thus, it is possible to create multifunctional HAuNS with laser-activatable release of anticancer agents and siRNA molecules.

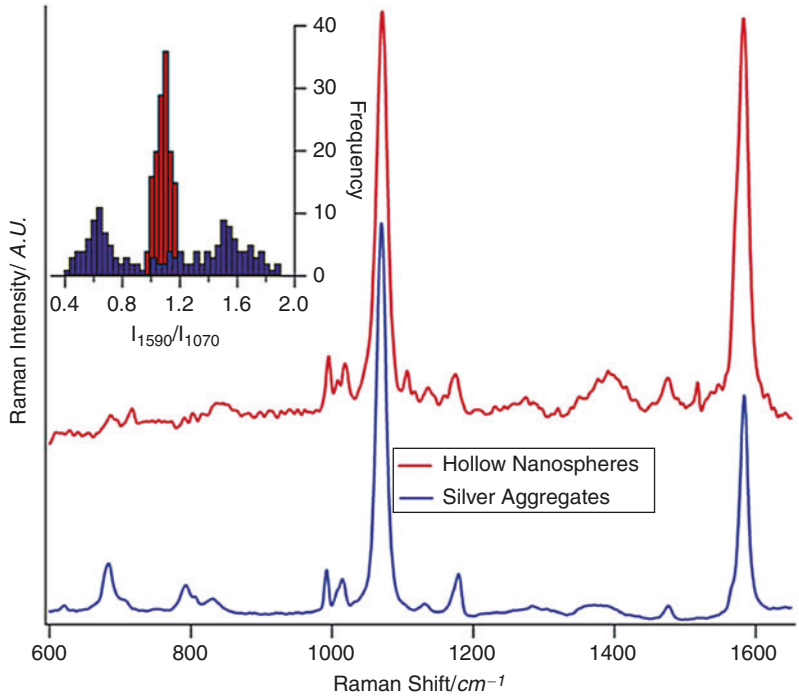
Photoacoustic Imaging

Noninvasive molecular and functional imaging techniques show promise for detecting and monitoring various physiological and pathological conditions in animals and, ultimately, humans. Among these imaging modalities, photoacoustic imaging offers higher spatial resolution and allows deeper tissues to be imaged than most optical imaging techniques [10, 11]. Photoacoustic tomography (PAT), also referred to as optoacoustic tomography (OAT), is a novel, hybrid, nonionizing imaging modality that combines the merits of both optical and ultrasonic imaging methods. PAT detects absorbed photons ultrasonically through the photoacoustic effect: A short-pulsed laser irradiates biological tissues and induces wideband ultrasonic waves (photoacoustic waves) as a result of transient thermoelastic expansion. Because HAuNS display strong resonance absorption tuned to the NIR range, HAuNS are a naturally efficient contrast agent for photoacoustic imaging. To demonstrate the utility of PEG-HAuNS as a photoacoustic contrast agent, PAT images of the cerebral cortex of a mouse before and after a single injection of PEG-HAuNS are presented in Fig. 9 [12]. Because of the low intrinsic absorption of oxyhemoglobin and deoxyhemoglobin at 800 nm, the photoacoustic signal was weak, with a low signal-to-noise ratio that showed only large vessels distributed along the mouse brain cortical surface, such as the middle cerebral artery (Fig. 9a, *arrow*). However, 5 min after the injection of PEG-HAuNS, the PAT image revealed the brain vasculature with much greater clarity, especially small blood vessels (Fig. 9b). This enhanced clarity was attributed to the strong photoacoustic signal generated with PEG-HAuNS. The circulating PEG-HAuNS enhanced the contrast between the

blood vessels and the brain parenchyma. This is better appreciated in a differential image (Fig. 9d) obtained by subtracting the preinjection image (Fig. 9a) from the postinjection image (Fig. 9b) pixel by pixel. At 2 h postinjection, the photoacoustic images remained essentially unchanged, indicating a significant amount of PEG-HAuNS circulating in the blood (Fig. 9c, e). Compared with PAT images based on the intrinsic optical contrast in nude mice, the PAT images acquired within 2 h after intravenous administration of PEG-HAuNS showed the brain vasculature with greater clarity and detail. The image depicted brain blood vessels as small as $\sim$ 100 μm in diameter using PEG-HAuNS as the contrast agent. These results indicate that PEG-HAuNS is a promising contrast agent for PAT, with high spatial resolution and enhanced sensitivity.

Surface-Enhanced Raman Scattering (SERS)



Another important application of HAuNS is surface-enhanced Raman scattering (SERS), an extremely useful method of chemical and biochemical analysis and detection. SERS is based on the enhancement of Raman scattering of an analyte molecule near or on a roughened metal substrate surface. The origin of the Raman enhancement has been largely attributed to an enhanced electromagnetic (EM) field at the metal surface due to increased absorption of the incident light. Normal Raman scattering has the key advantage of molecular specificity or selectivity that allows for the identification of unique samples but has the major limitation of very small signal or low quantum yield of scattering (on the order of 10^{-7}) [13]. SERS, discovered in the mid-1970s, has made Raman scattering more popular for practical applications by offering the combined advantages of molecular specificity *and* a large signal [14, 15].

SERS spectra are very sensitive to the metal substrate. The size and shape, as well as the morphology, of the metal substrate will affect the sensitivity and the consistency of SERS measurement. Much effort has been put into improving SERS spectra consistency in practical measurement by developing metal substrates that are uniform or monodisperse in size and shape. HAuNS have been demonstrated to be an excellent SERS substrate in this regard [1]. The unique optical and structural properties of HAuNS afford several advantages for SERS application, including small size, spherical shape, and tunable and narrow absorption from the visible to near-IR region [1]. Furthermore, compared to aggregates or nanoparticles with inhomogeneous distribution of size and shape, the HAuNS afford SERS spectra that are highly consistent, measured by the peak ratio of SERS spectra of single HAuNS. This consistency is a direct result of the narrow surface plasmon absorption band and high structural uniformity of HAuNS. Figure 10 shows a comparison of SERS spectra of mercapto benzoic acid (MBA) obtained using HAuNS vs. normal silver nanoparticle aggregates. The inset shows a histogram detailing the distribution of the peak ratio of two SERS peaks for the two different substrates. The HAuNS show a much narrower, and thus better, distribution (red), indicating a highly uniform structure and narrow SPR, and thereby, consistent SERS for a single nanostructure [16].

While the HAuNS are indeed very uniform and show highly consistent SERS, they afford a relatively weak SERS signal compared to Ag nanoparticles [16]. Ideally, one would produce hollow silver, instead of gold, nanospheres to improve SERS sensitivity. To achieve this, HAuNS have been used as seed templates and coated with a thin layer of Ag on the outer surface [17]. This approach has resulted in the successful generation of unique hollow gold-silver double nanoshells that show a significantly shifted and broadened plasmon band. These double nanoshells have shown greatly increased Raman enhancement over HAuNS, which is attributed to a combination of the increased volume of metal and the improved enhancement factor of silver.

Future Directions

Multifunctional HAuNS combined with PTA therapy, drug delivery, or RNAi capability provide a great opportunity for multimodal therapy of

Hollow Gold Nanospheres, Fig. 10 Single-particle SERS spectrum of MBA on HAuNS (*red trace*, *top*) and silver aggregates (*blue trace*, *bottom*). [16])

a variety of solid tumors. Future effort should be focused on the clinical translation of this innovative therapeutic approach. A number of hurdles must be overcome before these nanoparticles are administered to patients. In particular, the acute and long-term toxicity of PEG-HAuNS needs to be carefully documented. Selective delivery of a sufficient amount of HAuNS should lead to a more selective photothermal effect localized to the tumor. The integration of imaging probes into the HAuNS to make it possible to visualize these nanoparticles using noninvasive imaging techniques such as magnetic resonance imaging and nuclear imaging may help monitor the spatiotemporal distribution of the HAuNS in solid tumors and, thus, enable accurate pretreatment thermal dose calculation. To improve the photothermal conducting efficiency of HAuNS, the SPR band should be further reduced. The SPR bandwidth directly impacts PTA efficiency; HAuNS with a narrower band have higher overall photothermal conversion and improved PTA performance. It is also desired to improve the synthesis to make it more easily reproducible and on large scales. For example, PVP has been found to improve the synthesis reproducibility of NIR-absorbing NAuNS significantly when used as a stabilizing agent to slow down the HAuNS growth [18]. Scaling up the synthesis is another important direction for further work in the future.

Definition

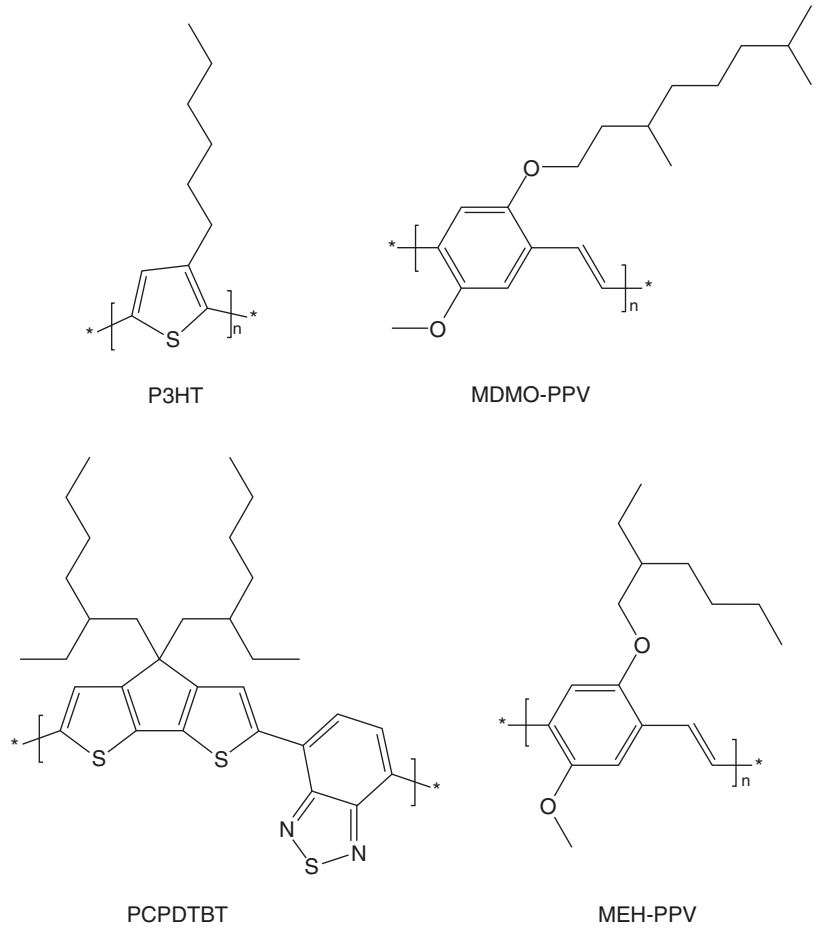
A hybrid solar cell is a photovoltaic device relying on charge transfer at the interface between two semiconductors, one being organic and the other being inorganic.

Principles of Operation

A prototypical hybrid photovoltaic device is composed of an organic semiconductor and an inorganic semiconductor. The interface between these two materials forms a type II heterojunction, where the polymer typically serves as the electron donating material and the inorganic semiconductor is the electron acceptor. In a device, these materials form a layered stack that is sandwiched between two electrodes. An opaque metallic electrode forms the back contact and a conductive semitransparent material, such as indium tin oxide (ITO), permits light to enter the front side of the device (Fig. 1).

The principle of operation is similar in nature to both a dye-sensitized solar cell and a polymer-fullerene organic photovoltaic (OPV) (see also ▶ Organic Photovoltaics: Basic Concepts and Device Physics). As in OPV devices, the conjugated polymer layer is primarily responsible for light absorption. Photons of energy greater than the optical band gap of the organic semiconductor are absorbed to create an excited state particle, known as an exciton. Consisting of a Coulombically bound electron–hole pair, excitons carry no net charge and move in a random walk uninfluenced by internal electric fields. Due to a short lifetime, excitons diffuse only a few nanometers (5–15 nm) within the organic layer before recombining [1]. By introducing a high electron affinity material, such as an inorganic semiconductor, charge separation becomes energetically favorable. An exciton reaching an organic–inorganic interface during its lifetime may dissociate by electron transfer to the inorganic semiconductor. It is also possible for excitons generated in the inorganic to dissociate at the heterojunction interface via hole transfer to the organic material. In either case, these charges tend to recombine unless they can be further separated. The driving force for separation comes from diffusion or the built-in electric field within the device. The donor/acceptor phases then serve the dual purpose of transporting charge (see also ▶ Conduction Mechanisms in Organic Semiconductors) to the respective electrodes – hole transport occurs via the highest occupied molecular orbital of the organic semiconductor, and electron transport via the conduction band of the inorganic semiconductor. Carrier transport out of the device must be sufficiently fast to compete with recombination between charges at the interface of adjacent materials. High charge carrier mobility is therefore an important parameter to ensure efficient device operation. Several recent reviews on hybrid solar cells provide further details on the physics of device operation [1–5].

Hybrid Solar Cells, Fig. 1 Schematic depiction of a planar heterojunction (or bilayer) organic–inorganic hybrid device (*left*). Light absorption by the polymer generates excitons (shown in the detail to the *right*), which diffuse approximately 5–15 nm to the heterojunction interface. After electron transfer to the conduction band of the inorganic semiconductor, electrons traverse the acceptor layer for collection at a transparent conducting electrode, typically indium tin oxide (ITO) (see also ▶ Electrode–Organic Interface Physics). Holes remain in the organic layer for transport to and collection by a metallic back contact. A hole transport layer (*HTL*) may be employed to modify the properties of the electrode, such as work function or surface roughness



H

Materials

Organic semiconductors used in hybrid devices are typically the same as those found in OPV devices and similar processing methods and material properties are required in hybrid devices. For many polymeric semiconductors, such as regioregular P3HT, proper ordering of the conjugated backbone is needed to yield optimum charge carrier mobility (10^{-2} to 10^{-3} cm^2/Vs, measured in P3HT thin film transistors). During deposition of the organic, interactions at the polymer–substrate and polymer–metal oxide interface play an important role in controlling polymer order. Interfacial modification with SAMS (see ▶ Self-assembled Monolayers) of various organic compounds can be employed to influence polymer ordering [6]. Processing parameters such as solvent evaporation rate, post-deposition thermal and solvent annealing treatment, also strongly influence the properties of organic semiconductors. Due to a high absorption coefficient ($\sim 10^5$ cm^{-1}), light absorption by the organic component is generally good; however, absorption bands tend to be narrow and typically peak in the visible spectrum, leaving much of the red to NIR portion of spectrum unabsorbed. Much effort continues to be devoted to broadening the absorption profile and decreasing the optical bandgap by way of synthetic modification of the polymer backbone. Shown in Fig. 2, PCPDTBT is an example of one such low bandgap polymer that has been developed in recent years. In terms of energy-level requirements, most p-type organic materials have a much smaller electron affinity than the inorganic electron acceptor, ensuring a sufficient energetic offset for exciton dissociation between the two materials. Of course, a low bandgap donor material also imposes new constraints on the conduction band energy level of the acceptor to ensure sufficient driving force for charge separation.

For laboratory-scale devices, deposition of organic semiconductors is most often carried out by spin casting films from solution. Large area deposition is possible using other solution processing techniques such as slot-die coating, screen printing, and spray coating. In the case of donor-acceptor blends or bulk heterojunctions, additional thermal or solvent annealing steps are employed to optimize donor–acceptor phase separation. The molecular structure for several commonly used organic semiconductors is shown in Fig. 2.

For the inorganic component, materials selection is used to optimize light absorbance and maximize charge carrier mobility. Deposition of inorganic materials can be carried out by numerous methods. Using sol–gel chemistry, dense

polycrystalline films can be processed from solution and thermally cured. In another common preparation method, soluble nanoparticles of various shapes can be dispersed in polymer solutions and spin cast as a two-component solution. Ordered inorganic nanostructures can be grown using hydrothermal techniques followed by solution phase or melt infiltration of the organic material. Similarly, ordered nanostructures can be templated using block copolymers or deposited using a variety of vapor growth methods. Below is a list of many inorganic semiconductors that have been employed in hybrid devices in varying capacities:

- CdS
- CdSe

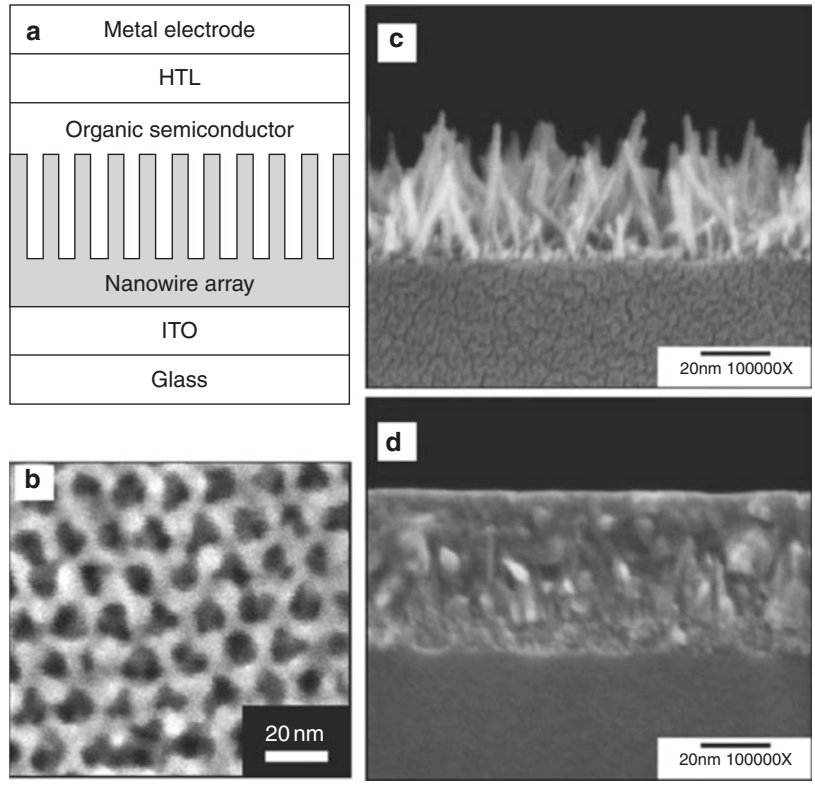
During the synthesis of inorganic nanoparticles, chemical methods can be employed to tailor nanoparticle size, aspect ratio, and type of branching [2]. Colloidal nanoparticles, such as CdSe, can be nucleated from organometallic precursors in a high-temperature (250–350 °C) mixture of surfactants. Nanoparticles are typically capped with organic ligands that passivate surface

Hybrid Solar Cells, Fig. 3 (**a**) Schematic representation of an organic-nanoparticle bulk heterojunction photovoltaic device. The nanocrystalline acceptors are frequently spherical particles, but may be also synthesized in a variety of high aspect ratio shapes, such as nanorods or tetrapods, to improve electron transport properties. (**b**) External quantum efficiency (or spectral response) for a hybrid nanocrystalline bulk heterojunction device employing nanorod acceptors of increasing aspect ratio. Photocurrent collection is enhanced as the number of hopping steps between particles is reduced. (Reprinted with permission from [9]. Copyright 2002 Science/AAAS)



states and ensure a stable dispersion when mixed with a polymer in organic solvents. Unfortunately, many solubilizing ligands also act as insulating shells that disrupt particle–particle electronic communication. After nanoparticle synthesis, residual surfactants can be stripped away to improve contact to the nanoparticles surface. The presence of residual surfactant influences charge transfer efficiency, nanoparticles aggregation, and charge transport, ultimately limiting the performance of organic–inorganic composite photovoltaic devices.

Planar, Bulk Heterojunction, and Nanostructured Architectures

The need for nanoscale features in hybrid photovoltaics stems from the fact that exciton diffusion is limited to a few nanometers. Excitons generated further than a diffusion length from the organic–inorganic interface will not contribute to photocurrent generation. In a bilayer or planar heterojunction (see Fig. 1), the optical absorption depth is a factor of 10 greater than the exciton diffusion length in most semiconducting polymers. The fraction of absorbed light near the heterojunction interface in a bilayer is too low; hence, devices based on this architecture cannot achieve useful power conversion efficiencies.

A significant development to this technology came with the fabrication of the bulk heterojunction (Fig. 3a), which is the basis for most high efficiency all-organic photovoltaic devices [7, 8]. A bulk heterojunction is comprised of a bi-continuous interpenetrating network of the electron accepting and donating material, ideally with length scales on the order of an exciton diffusion length. In principle, an exciton generated anywhere within the polymer phase will be able to reach a heterojunction interface within its lifetime.

Although the nanoparticle–polymer bulk heterojunction dramatically enhances interfacial area, high-efficiency devices also require effective charge transport of the electron to the electrode. Spherical nanoparticles provide an electron percolation pathway; however, charges encounter multiple hopping events between discrete nanoparticles, reducing overall carrier mobility. By increasing the aspect ratio of the particle, electrons encounter fewer hops during extraction from

Hybrid Solar Cells, Fig. 4 (**a**) Ideal ordered nanostructure where the spacing between nanowires is approximately an exciton diffusion length and the thickness of the organic layer is sufficient to absorb 100 % of the incident light. (**b**) Scanning electron microscopy (*SEM*) image showing a TiO_2 mesoporous lattice, deposited using a block-copolymer templating techniques. (**c**) SEM image depicting a hydrothermally grown ZnO nanowire array. (**d**) A ZnO nanowire array after infiltration with an organic semiconductor (Figure 4b reprinted with permission from [11]. the active layer. As shown in Fig. 3b, high aspect ratio nanoparticles have been shown to significantly increase the photocurrent generation in hybrid devices due to their higher effective mobility [9]. Unfortunately, unbound nanorods suffer from poor morphological arrangement where most rods orient parallel to the substrate. Using synthetic techniques, it is possible to form nanoparticles in the shape of a tetrapod [2]. One arm of the tetrapod, which is always normal to the substrate, will provide a high-mobility pathway away from the center of the device reducing the number of particle–particle hops before collection by the electrode.

A variant of the bulk heterojunction is possible using nanofabrication techniques. Instead of a randomly formed percolating inorganic network, one can intentionally deposit inorganic semiconductors to form rigid, three-dimensional networks. As shown in Fig. 4, arrays of inorganic nanowires or nanotubes are ideally separated by an exciton diffusion length and long enough to achieve maximum light absorption by an infiltrated polymer layer [10]. The nanorods provide a high-mobility charge transport pathway along a single crystal of inorganic material. Similarly, block copolymers can be used as a structure-directing template to form an inorganic semiconductor into a continuous three-dimensional lattice (Fig. 4b) [11]. In both cases, the polymeric donor can be filled or infiltrated with either polymer solutions or solid polymer that is softened by thermal processing.

Advantages of Hybrid Technology

Inorganic acceptor materials display desirable characteristics that hold promise for increasing the overall performance of low-cost, solution-processed photovoltaics. The inorganic semiconductors that form the electron transport networks found in hybrid cells provide significantly higher (often orders of magnitude) charge carrier mobility compared to most n-type organic semiconductors. Many of these materials can be synthesized

and deposited from solution, and processing steps occur at temperatures compatible with polymeric substrates. Material toxicity and abundance are important factors to consider for large-scale deployment of hybrid photovoltaics. Many *n*-type materials being investigated for hybrid cells, such as TiO_2 and ZnO, are nontoxic and derived from highly abundant precursors.

Ordered inorganic nanostructures afford the opportunity for various types of interfacial modification. Inorganic nanostructures can be modified by coating with thin films, such as another inorganic layer or by an organic SAM [3]. This is unique to the hybrid system where the nanostructured inorganic forms a rigid scaffolding that is amenable to chemical modification specifically at the charge separation interface. The polymeric donor is then infiltrated or back-filled as normal. Organic interfacial treatments have been shown to enhance polymer morphology at the charge separation interface [6]. Other SAM layers establish interfacial dipoles that influence charge transfer efficiency [12]. Thin inorganic interfacial layers may be instrumental in the passivation of surface states and act as barriers to recombination. With better understanding of interfacial effects, modification of the heterojunction may become an important route to optimize the efficiency of hybrid devices.

A significant advantage of hybrid technology comes from the enhanced absorption spectrum of the acceptor material compared to that of fullerene derivatives typically used in OPV devices, which exhibit negligible absorption in the visible spectrum. Many inorganic materials under investigation for hybrids are direct bandgap semiconductors with high extinction coefficients. Devices utilizing low bandgap inorganic particles (such as CdTe) demonstrate light absorption by the acceptor phase that contributes to photocurrent generation beyond that of the donor alone. In this way, the complementary absorption spectra can maximize the absorption overlap with the solar spectrum. Additionally, quantum confinement effects in nanoscale inorganic materials can also be exploited in hybrid solar cells [4]. When the Bohr radius of an exciton (the distance between the bound electron–hole pair) exceeds the diameter of the nanocrystal, material properties are dominated by quantum effects. By further reducing the particle size, one can systematically increase the size of the bandgap of the semiconductor relative to the bulk material. This permits tuning of both the peak absorption and the energy levels for charge transport. Manipulation of the particle size may become an important tool for ensuring the necessary driving force for charge separation as well as optimizing absorption of the solar spectrum.

Challenges and Future Research Directions

Despite significant progress in understanding the fundamental mechanisms at work in hybrid photovoltaics, in practice the power conversion efficiency of hybrid devices remains low. The record efficiency for polymer-fullerene OPV devices measures 8.3 %, while hybrid devices remain below the 3 % mark. Several areas have been identified as key to improving device efficiency. The first issue concerns a discrepancy in the magnitude of the charge carrier mobility in nanoparticle thin films. Despite high mobilities generally known for inorganic semiconductors, measurements for films of pure nanoparticles or nanostructured features indicate mobilities are several orders of magnitude lower than typical bulk values. Phenomena taking place in nanostructured films, such as multiple interparticle hopping events or charge trapping, may lead to detrimental transport properties. In addition, attention to the carrier mobility of the organic semiconductor is important to achieve higher device efficiency. Carrier mobility of the polymer is vulnerable to changes induced by interaction with the surface of the inorganic as well as polymer chain confinement after infiltration of the polymer within ordered nanostructures.

Second, charge transfer events occurring at organic–inorganic heterojunctions remain poorly understood. A great deal of research seeks to understand how parameters, such as polymer order, spatial orientation, surface dipoles, and bonding, influence the efficiency of interfacial charge separation. A better understanding of these

organic–inorganic interface effects will likely lead to improved exciton dissociation efficiency and decrease interfacial recombination rates.

Finally, as is the case for OPV, in order to reach maximum efficiency one has to achieve control over the donor–acceptor phase-separated network as well as develop reliable methods to characterize these networks on the nanometer scale [13]. To date, the largest improvements in device efficiency originate with methods that increase the donor–acceptor interfacial area. Although current hybrid solar cell efficiencies lag behind those produced with other material systems, the attractive material properties and desirable processability of inorganic semiconductors help maintain interest for further development of hybrid cells.

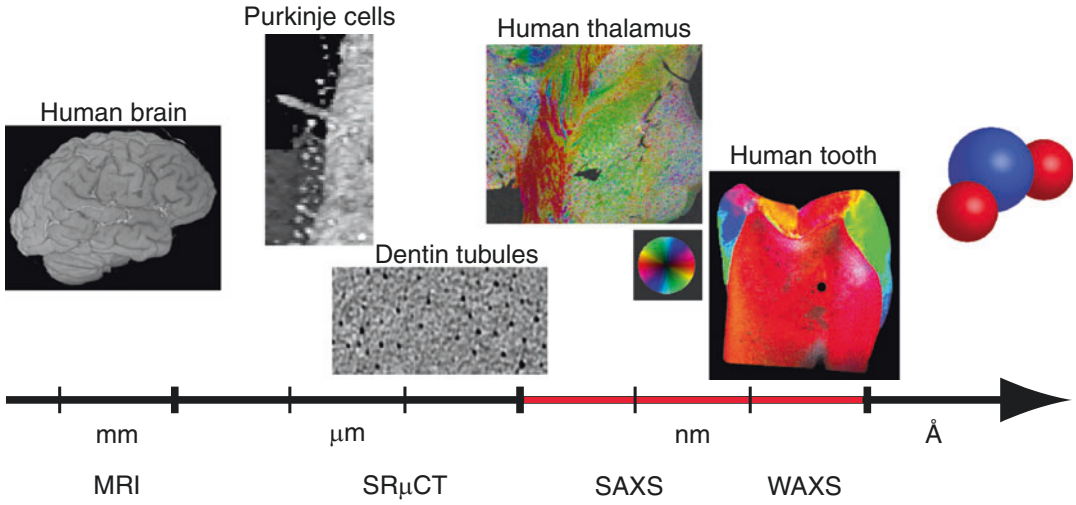
Imaging the Human Body Down to the Molecular Level

Hans Deyhle, Georg Schulz and Bert Müller
Biomaterials Science Center (BMC), University of Basel, Basel, Switzerland

Synonyms

Three-dimensional imaging of human tissues

Definition



The human body consists of nanometer-sized units including proteins, apatite crystallites, collagen, and myelin fibers. Imaging, here, means the identification, localization, and quantification of these units within the human body.

Overview

The human body consists of about 10^{27} molecules. This number is so huge that it is impossible to determine their location or even only to store this amount of data. Using a logarithmic scale (see Fig. 1), one realizes that a biological cell with an extension of about 10 μm includes as many molecules like the human body biological cells. Even the number of cells within the human body is huge and beyond our imagination. The number of stars in the Milky Way, for example, is thousand times smaller than this number. Therefore, for imaging the human body on the nanometer scale, one has to restrict to predefined parts of the body or to take advantage of symmetries or periodicities as known from the atomic view of single crystals in solid-state physics.

Three-dimensional (3D) imaging in daily clinical practice of well-equipped hospitals reaches a spatial resolution of a fraction of a millimeter, as indicated by the magnetic resonance imaging (MRI) in Fig. 1. Hence, the spatial resolution of medical imaging facilities is far from the molecular scale. In engineering and research, however, methods are known that allow imaging structures down to the world of atoms. As shown in the overview of Fig. 1, micro-computed tomography (μCT) is well established in materials science and yields a spatial resolution as low as a fraction of a micrometer in real space. The necessary dose for the subcellular level, however, is so high that only postmortem studies are permitted. Although the spatial resolution is high enough to visualize individual biological cells, the contrast is, contrary to hard tissues, too low. Monochromatic X-ray beams, as applied in synchrotron radiation-based μCT (SRμCT), provide much better contrast.

Imaging the Human Body Down to the Molecular Level, Fig. 1 The selected imaging techniques (MRI, SRμCT, SAXS/WAXS) cover length scales down to the molecular level

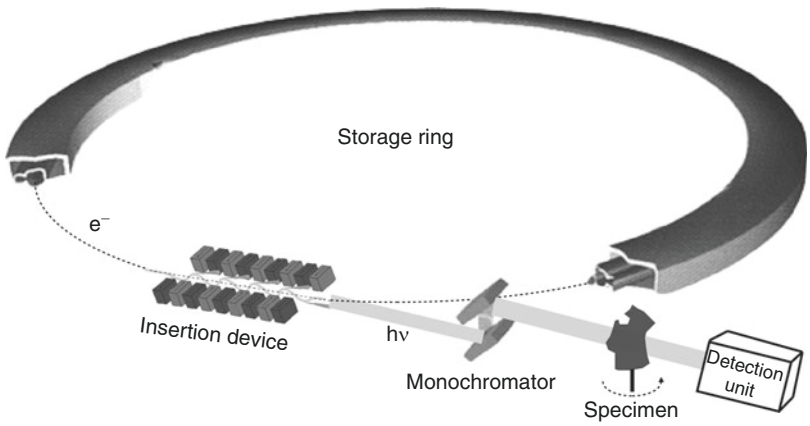
Therefore, SRμCT has allowed visualizing individual cells in human tissue after appropriate staining [1]. Grating-based phase-contrast SRμCT has been shown to give rise to even orders of magnitude better contrast for human tissues [2]. Here, non-stained, individual Purkinje cells located in the brain come to light (see Fig. 1). In order to make visible nanostructures between 1 nm and 100 nm in real space, however, X-ray optics have to be integrated into the setup and the accessible volumes become as small as for electron-based techniques.

Diffraction and scattering methods are established techniques to quantitatively characterize the arrangement of atoms or molecules in reciprocal space [3]. Therefore, they give rise to average values within the illuminated volume. The combination of small probing beams and scanning provides spatially resolved data for the nanometer range and below. X-ray-based methods are especially suitable for human tissues. They are termed scanning small-angle X-ray scattering (scanning SAXS) and scanning wide-angle X-ray scattering (scanning WAXS). While SAXS covers the entire nanometer range, WAXS depicts the interatomic distances on the sub-nanometer scale (see Fig. 1).

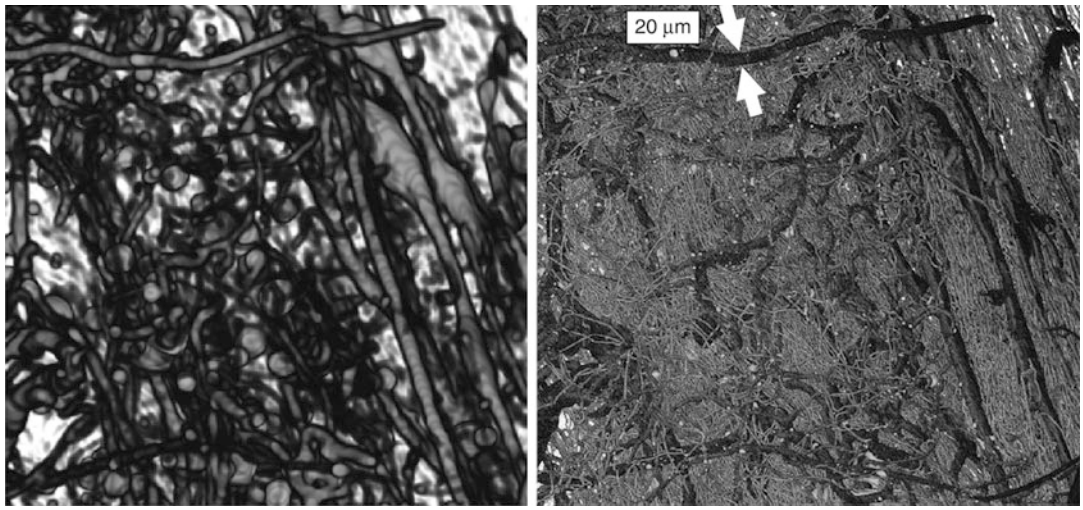
Basics

X-ray computed tomography (CT) is a widespread imaging technique in radiology. Multi-slice CT (MSCT), for example, is used to identify tumors and to plan radiation therapy treatments. In dental medicine, cone-beam computed tomography (CBCT) is a standard imaging technique. The 3D images are used, for instance, to decide if enough bone is present for implant placements. Figure 2 shows, as an example, the 3D rendering of a part of a human skull acquired with the Accuitomo 80 CBCT system (Morita, Kyoto, Japan) recorded with an acceleration voltage of 70 kV and a beam current of 4 mA. 512 radiographs were acquired over 360°. The voxel size of the tomography data was $0.25 \times 0.25 \times 0.16\ \text{mm}^3$.

To improve the spatial and density resolution of the X-ray-based imaging techniques, dangerous doses are required, and in vivo measurements become impossible. Hence methods such as μCT are rather found in the field of materials science than medicine. Nevertheless, postmortem studies are common in many research laboratories and provide exhaustive morphological information on the micrometer scale. Several μCT systems are built at synchrotron radiation facilities, which



provide highly brilliant X-rays for different kinds of imaging purposes. The main components of such a facility are schematically represented in Fig. 3. The highly energetic electrons or positrons circulate in the storage ring and through insertion devices, where the intense X-ray beams are generated. The insertion devices are classified as bending magnet (first generation), wiggler (second generation), undulator (third generation), and free-electron laser (fourth generation). The difference of the insertion devices is – besides the increasing intensity – inter alia, the incoherent (first and second generations) and coherent (third and fourth generations) interference of the produced X-rays. The high intensity of synchrotron light allows realizing a tunable X-ray source. For that, a monochromator selects the predefined photon energy. The μCT end station contains the sample manipulator and the detector.



Imaging the Human Body Down to the Molecular Level, Fig. 2 The 3D rendering of a human skull generated from CBCT data impressively shows the hard tissues of the teeth and bone

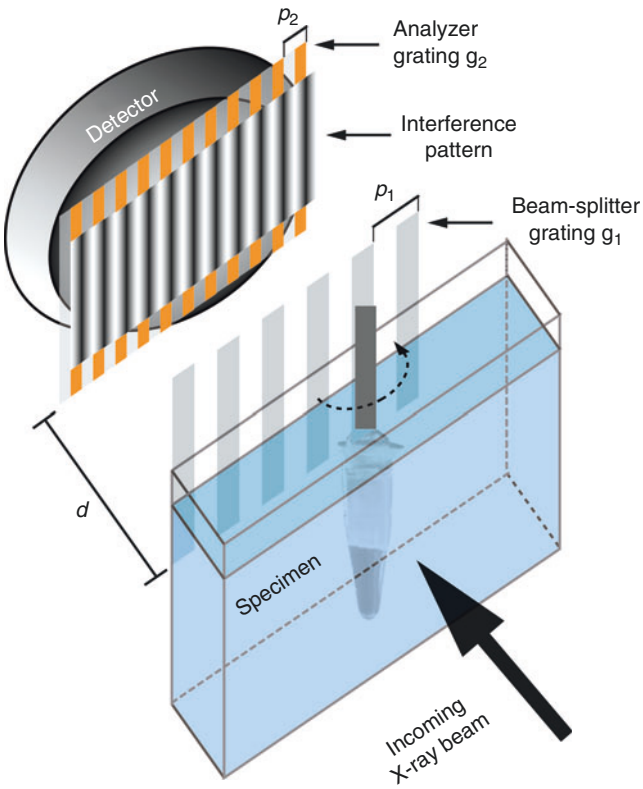
The high X-ray intensity allows pushing the resolution of tomography at synchrotron radiation sources toward the sub-micrometer range, at the cost, however, of a reduced field of view. Figure 4 illustrates the SRμCT imaging capabilities for a polymer cast of the vascular system from a human C51 tumor, acquired at the TOMCAT beamline (Swiss Light Source, Paul Scherrer Institut, Switzerland) at a photon energy of 15 keV. In the top image, the isotropic voxel length corresponds to 5.9 μm. With these settings the whole tumor could be imaged. Capillaries with a diameter smaller than 10 μm, however, are not identified. Therefore, local tomography is often performed as demonstrated on the image of the same tumor below. Here, only a part of the specimen is scanned. The voxel length corresponded to 0.74 μm, and even the smallest capillaries having a diameter below 4 μm can be recognized.

Absorption tomography, as described above, is particularly suited for hard tissues like the bone or teeth, as these provide enough contrast in the X-ray images. For soft tissues, e.g., the human

Imaging the Human Body Down to the Molecular Level, Fig. 3 Layout of a synchrotron radiation facility consisting of a storage ring, an insertion device, and the end station for tomographic imaging

Imaging the Human Body Down to the Molecular Level, Fig. 4 Cast of the vascular network of a C51 tumor visualized by SRµCT – top global tomography; bottom local tomography

brain, absorption-contrast SRµCT has a limited success, because the different soft tissues generally present very similar X-ray absorption properties. For this kind of tissue, phase-contrast SRµCT promises excellent results where, contrary to the absorption contrast, the real part of the refractive index often expressed in terms of its decrement from unity $\delta(x,y,z)$ is measured. For X-ray energies far away from the absorption edges, it relates to the electron density distribution $\rho_e(x,y,z)$:



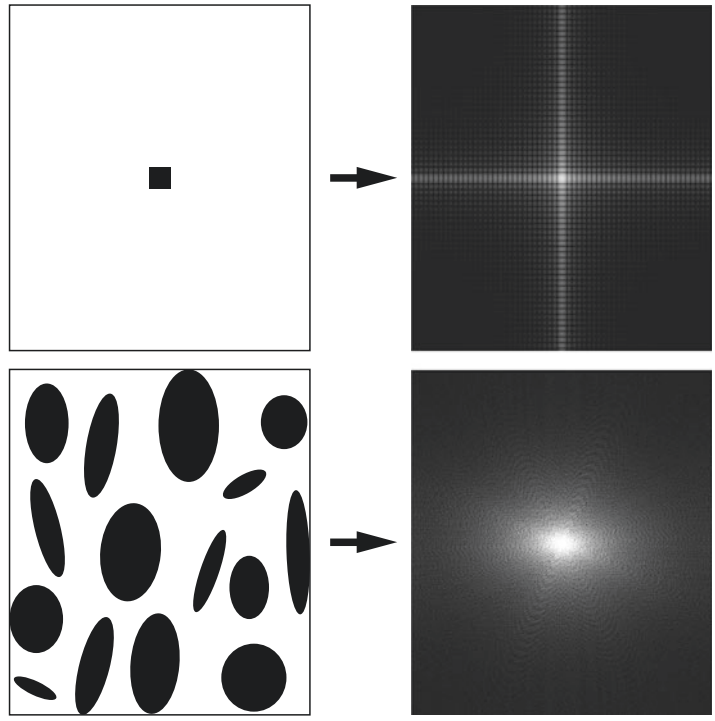
$$\delta(x,y,z) = \frac{r_e \lambda^2}{2\pi} \rho_e(x,y,z) \qquad (1)$$

where r_e denotes the classical electron radius and λ the X-ray wavelength [4]. In particular, a very high sensitivity can be reached by the recently developed grating-based, phase-contrast SRµCT [4]. A schematic view of the setup is given in Fig. 5. The grating interferometer is composed of a beam-splitter grating g_1 consisting of silicon stripes with periodicity p_1 and an analyzer grating g_2 consisting of strongly X-ray-absorbing stripes, often gold, with periodicity p_2. The periodicity of the grating g_2 has the half value of p_1. The grating g_1 induces a periodic fringe pattern in the X-ray wave-front intensity distribution with extreme values of the contrast at so-called Talbot distances from the beam-splitter grating. The Talbot distances are found at

$$d_n = \frac{n p_1^2}{8\lambda}, \qquad (2)$$

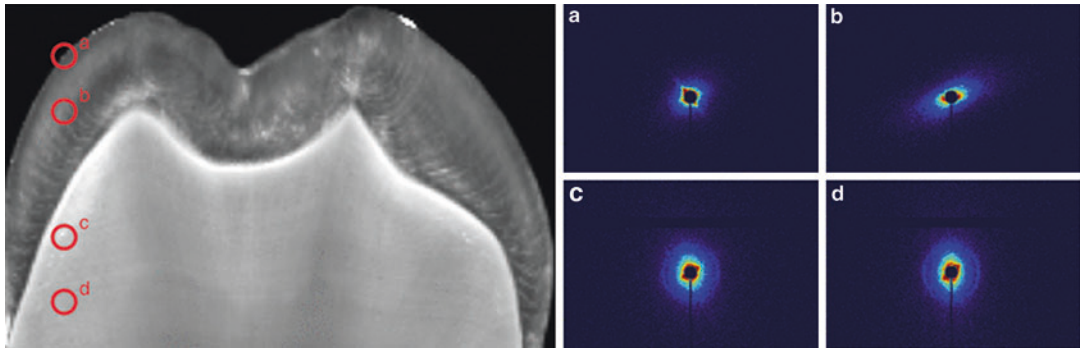
where n is a positive integer. The intensity difference between fringe maxima and minima is largest at the odd Talbot distances from the beam-splitter grating, while it is vanishing at even Talbot distances [5]. When performing a phase-contrast µCT experiment, the distance between g_1 and g_2 is adjusted to a Talbot distance with odd Talbot order. A specimen in the beam slightly deflects the incoming X-rays according to its refractive indices and leads to a disturbed fringe pattern. The analyzer grating permits detecting these changes using the phase-stepping method, where several images at different grating g_2 positions are recorded [4]. The quantitative relation between the local beam propagation $\alpha(y,z)$, the wave phase shift $\Phi(y,z)$, and the decrement of X-ray refractive index $\delta(x,y,z)$ can be obtained by the equation

$$\alpha(y,z) = \frac{\lambda}{2\pi} \frac{\partial \Phi(y,z)}{\partial y} = \int_{-\infty}^{\infty} \frac{\partial \delta(x,y,z)}{\partial y} dx. \qquad (3)$$



Imaging the Human Body Down to the Molecular Level, Fig. 5 Scheme of a grating-based interferometer for X-ray imaging at a third-generation synchrotron radiation source

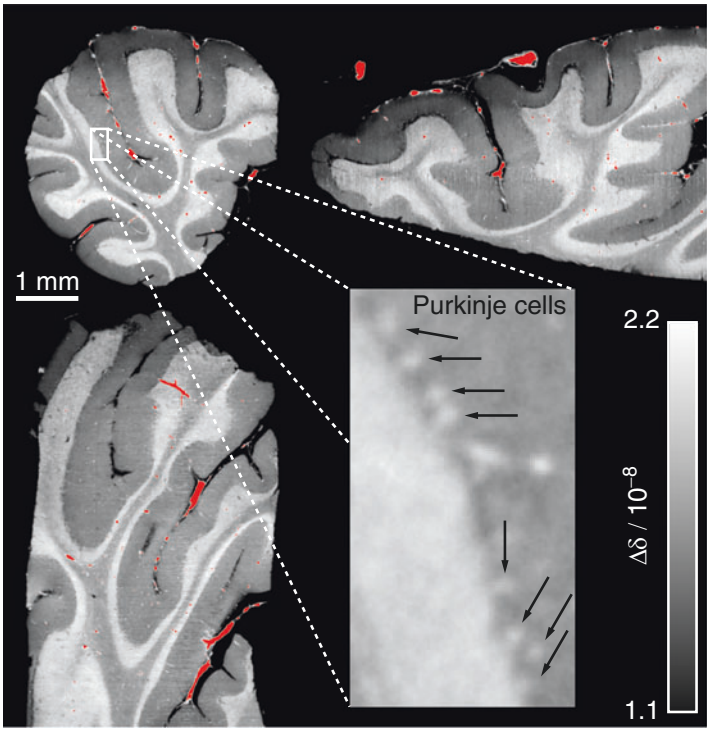
The investigation of human tissues in the nanometer range by means of X-rays is available through scattering experiments, which belong to the reciprocal imaging techniques (see also ▶ Small-Angle Scattering of Nanostructures and Nanomaterials). In SAXS experiments, a focused X-ray beam is scattered to small angles between approximately 0.2 and 20 mrad. In order to record these angles with enough precision, the distance between the specimen and detector amounts to several meters. The scattering signal is closely related to the Fourier transform of the electron density distribution of the specimens [3]. Figure 6 shows a schematic representation of the relationship between specimens (on the left) and scattering signal (on the right). In the first example of Fig. 6, the particle that causes the scattering signal cannot easily be recognized from the scattering pattern. The information concerning particle shape, size, and orientation, however, can be extracted. When different particles scatter simultaneously, the generated signal contains contributions from all of them, yielding a mean value from the illuminated volume.



The continued improvement in detector technology [6] enables the acquisition of several tens of scattering patterns per second, allowing collecting scattering data over macroscopic areas in short time with a scanning approach [7]. Figure 7 elucidates the principle of scanning SAXS. A micro-focus X-ray beam is raster scanned along *x*- and *y*-directions, while the scattering signal is recorded. Scanning with steps of several 10 μm, the nanostructure of the specimen in reciprocal space is revealed with micrometer resolution in real space.

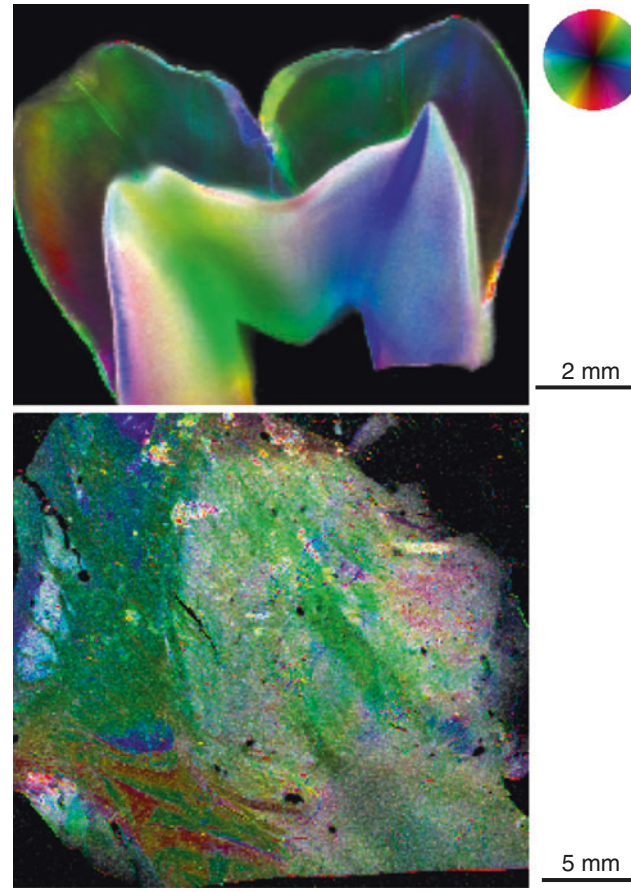
Key Research Findings

Grating-based phase-contrast SRμCT provides excellent measurement sensitivity for soft tissues. Figure 8 shows three virtual cuts of a human cerebellum acquired at the beamline ID19



Imaging the Human Body Down to the Molecular Level, Fig. 6 Schematic representation of the information obtained from small-angle X-ray scattering measurements

Imaging the Human Body Down to the Molecular Level, Fig. 7 Principle of scanning SAXS, elucidated on a tooth slice. The specimen is raster scanned through the beam, and at each raster point a SAXS pattern is recorded. On the *right*, the scattering patterns corresponding to points a through d are shown



(European Synchrotron Radiation Facility, France) [8] in phase-contrast mode with a photon energy of 23 keV. For the experiment, the specimen was fixated in 4 % formalin solution. The period of the beam-splitter grating p_1 was 4.785 µm and that of the analyzer grating p_2 2.400 µm. The experiment was carried out at the ninth Talbot distance; thus a distance d of 479.4 mm between the two gratings was adjusted. The Eppendorf container with the cerebellum in formalin solution was fixed on the high-precision rotation stage and immersed in a water bath (see Fig. 5) in order to minimize artifacts owing to X-ray phase curvature induced by the container surface. For the detection, a lens-coupled scintillator and charge-coupled device (CCD) system using a FReLoN 2 K (Fast-Readout, Low-Noise, ESRF Grenoble, France) CCD with 2048 × 2048 pixels with the effective pixel size of 5.1 µm was used. Four phase-stepping images

Imaging the Human Body Down to the Molecular Level, Fig. 8 Three orthogonal virtual cuts of a human cerebellum acquired at the beamline ID19 (European Synchrotron Radiation Facility, France) using grating-based phase-contrast SRμCT. The red-colored structures correspond to blood vessels. The inset illustrates the visualization of individual, non-stained Purkinje cells having diameters of around 50 μm

were taken over one period of the interferometer fringe pattern at each projection angle. With an exposure time of 1 s per image, 1501 radiographs were recorded over a range of 360°. The spatial resolution of the experimental data was estimated by means of Fourier analysis. The calculation resulted in (16.5 ± 0.5) μm for the processed projections and (20 ± 1) μm for the reconstructed tomogram. Figure 8 demonstrates that the phase-contrast results allow for a clear differentiation between white (inner gray-colored layer) and gray matter and even a distinction within the gray matter, namely, the stratum moleculare (dark region of the gray matter) and the stratum granulosum (bright region of the gray matter). The red-colored regions correspond to blood vessels. The inset in Fig. 8 illustrates the visualization of individual Purkinje cells, which underlines the performance of the technique in postmortem brain imaging. The detection of individual Purkinje cells with spherical diameters of 40–70 μm in the surrounding soft tissues without the application of any stain or contrast agent is a novelty in CT imaging [2].

Human tissues often exhibit strong structural anisotropies of their nanometer-sized components, which are usually related to their function. SAXS allows inspecting hard and soft tissues [9–12], as illustrated in Fig. 9, where processed data from a slice of a human molar (top image, scattering from 162 to 183 nm features) and of a human thalamus (bottom image, scattering from 98 and 110 nm features) are shown. The mean orientation of the scattering signal is according to the color wheel. The brightness relates to the abundance of nanostructures in the corresponding ranges, while color saturation codes the nanostructures anisotropy (cp. Chapter "Nanodentistry"). The tooth was scanned at a photon energy of 18.6 keV with 50 μm raster scan steps in both *x*- and *y*-directions, while the thalamus data were acquired at 11.2 keV with a step width of 75 μm. For both experiments, the distance between the specimen and detector was set to 7.1 m. The scanning SAXS measurements reveal a high degree of anisotropy on the nanometer level in the tooth hard tissues. The orientation of the calcium phosphate crystallites in the

Imaging the Human Body Down to the Molecular Level, Fig. 9 Processed SAXS data of slices of a human molar in the range corresponding to 162 to 183 nm and of a human thalamus in the range between 98 and 110 nm

enamel is found to be mainly perpendicular to the tooth surface, thus pointing in the direction of maximal mechanical load. The crystallites in dentin are, however, mainly oriented parallel to the tooth surface. It is assumed that this organization is responsible for the extraordinary mechanical performance and lifetime of the human teeth. The bright region on the right-hand side of the brain slice of Fig. 9 is the thalamus, which consists mainly of gray matter, and the so-called nuclei, which belong to the central nervous system. Within the thalamus, only a few small regions containing highly oriented nanostructures can be found. In contrast to gray matter, white matter consists of long myelinated nerve cells (axons), which transfer the nerve impulses between the nuclei. This tissue can be seen on the left-hand side of the brain slice, where the colors are saturated.

Future Research Directions

The human body is fascinating because of its huge complexity. Clinical CT facilities reach a resolution of a fraction of a millimeter. This limit will not be much shifted toward true micrometer scale, as (i) the amount of data has to be (semi-) automatically analyzed and (ii) the dose becomes dangerous for the patient. Dose reduction has been one of the major research topics in clinical CT. For postmortem visualization, μCT in absorption-contrast mode has been developed to a standard technique. The contrast for soft tissues is so weak that phase-contrast methods are required. Fine-tuning of the most advanced systems is a prerequisite to reveal cellular structures within the organs of the human body. For the visualization of the nanostructures, however, scattering methods seem to be much better suited.

Besides the well-established 2D projection data, several approaches for the 3D tomographic reconstruction of tissue anisotropy and orientation were recently presented [13–16]. These techniques require sophisticated reconstruction algorithms and extended data acquisition times in the order of tens of hours. The wealth of information obtained from such data will however warrant increased interest in these techniques, leading to the development of optimized, faster, and more powerful acquisition protocols.

The structural information of the human body down to the nanometer level will provide a sound basis for developing nature analogue biomaterials and biomimetic implants [17] to be launched for the benefit of patients. These biomimetic products will exhibit micro- and nanostructures including their preferential orientation (anisotropy) as found in nature and revealed by highly advanced imaging techniques applying sophisticated software tools for data treatment and medical image analysis. Learning from nature will lead to solutions of health problems in our aging society.

Immersion Lithography

Roger H. French
Department of Materials Science and Engineering, Case Western Reserve University, Cleveland, OH, USA

Synonyms

High index fluid immersion; Liquid Immersion lithography; Optical lithography by liquid immersion

Definition

Immersion lithography utilizes liquids with refractive indices >1 (the index of air) to enable sub-45-nm feature size (or half-pitch) patterning for semiconductor integrated circuits. An alternative to conventional "dry" optical lithography offering finer features, this method employs innovative materials at both the photomask and imaging stack levels.

Overview

In addition to the entry on ▶ Immersion Lithography Materials, herein, the reader is directed to two recent review papers which surveyed the state of the art in immersion lithography, including photomasks and wafer level materials [1] and immersion lithography tools [2].

Basic Methodology

A modern immersion lithography tool, a scanner, is shown schematically in Fig. 1 such that the different basic elements are visible. The illuminator, which prepares the ArF excimer laser light (the light source for 193.6 nm lithography) is on the right, the photomask (which contains the desired circuit layout pattern) is on the left above the large cylindrical projection lens, and the dual wafer stages are shown below. The left wafer stage undergoes alignment procedures while the right wafer stage, under the last lens element of the projection lens, is exposing the fields of the wafer in water immersion conditions. Once the wafer completes its exposure, the two wafer stages exchange positions, and exposure of the second wafer stage begins.

Microfabrication and Immersion Lithography

Microfabrication – first developed for integrated circuit processing – has relied on photolithography as a critical pattern transfer process. From the first transistor in 1947 and the first integrated circuit (IC) or semiconductor device in 1959, the basic microfabrication process steps have been deposition, etch, implant, and patterning [3]. Patterning has included photolithography in either contact or proximity modes (where the photomask and the IC have the same 1:1 feature size ratio) as well as the now dominant projection mode (where there is a 4:1 or 5:1 optical reduction of the mask features to the IC feature sizes). Rayleigh's equations provide a simple relationship between the stepper/scanner optical parameters (such as the lithographic wavelength (λ), the lens numerical aperture (NA), and the imaging medium's refractive index (1 for air and higher for immersion fluids)) and the feature size (FS) and depth of focus (DOF) which can be achieved. These equations also include a process latitude factor (k) where k_1 corresponds to the *FS* (Eq. 1) and k_2 to the *DOF* (Eq. 2), and where the scanner's numerical aperture is defined as $NA_{\text{System}} = NA_{\text{Dry}}\, n_{\text{imaging Medium}}$.[4] Microfabrication's progression down this feature size path (as presaged by Moore's Law [5]) for complementary metal oxide semiconductor (CMOS) devices has been enabled by technological advances in optics, usable lithographic wavelengths, and, most recently, immersion fluids to allow projection lens numerical apertures above 1. During this

Immersion Lithography, Fig. 1 ASML TwinScan XT:1950i Scanner showing the illuminator, the reticle (photomask) and reticle handler, the projection lens and the wafer stages. The numerical aperture of this water immersion stepper is 1.35, and the productivity is >140 wafers per hour imaged (Image courtesy of ASML Inc., Veldhoven, Netherlands)

evolution, microfabrication and optical lithography have also expanded beyond semiconductor ICs to include flat panel displays, microelectronic machines and devices, photovoltaic solar cells, and other applications, further driving the motivation to improve optical lithography's capabilities. In addition, as IC feature sizes have decreased, physical limits on materials and processes have led to new materials and device architectures, such as the IC interconnect conversion from aluminum to dual damascene copper metallization, the transition from silica interconnect dielectrics and gate dielectrics, and new gate architectures (such as the strained gate or 3D gate geometries of FinFET devices [6]). Microfabrication's widening applications, and the incorporation of new materials, process technologies, and architectures into IC fabrication, demonstrate the broad platform that microfabrication represents in materials research, as well as the large technology base it provides to the semiconductor, display, and photovoltaic industries. See Table 1 for lithographic half-pitch generations with technology options and imaging parameters.

$$FS = k_1 \lambda / NA \tag{1}$$

$$DOF \approx k_2 \lambda / NA^2 \tag{2}$$

Key Research Findings or Key Attributes and Advantages

Phase Shift Photomasks

With the advent of subwavelength lithography, the photomask's (see Fig. 2) imaging properties (i.e., the "object" in the scanner which is imaged into the photoresist [7]) have attained critical importance, such that full 3D imaging codes are used, and the opaque chrome film used in binary intensity masks (BIM) has changed to become

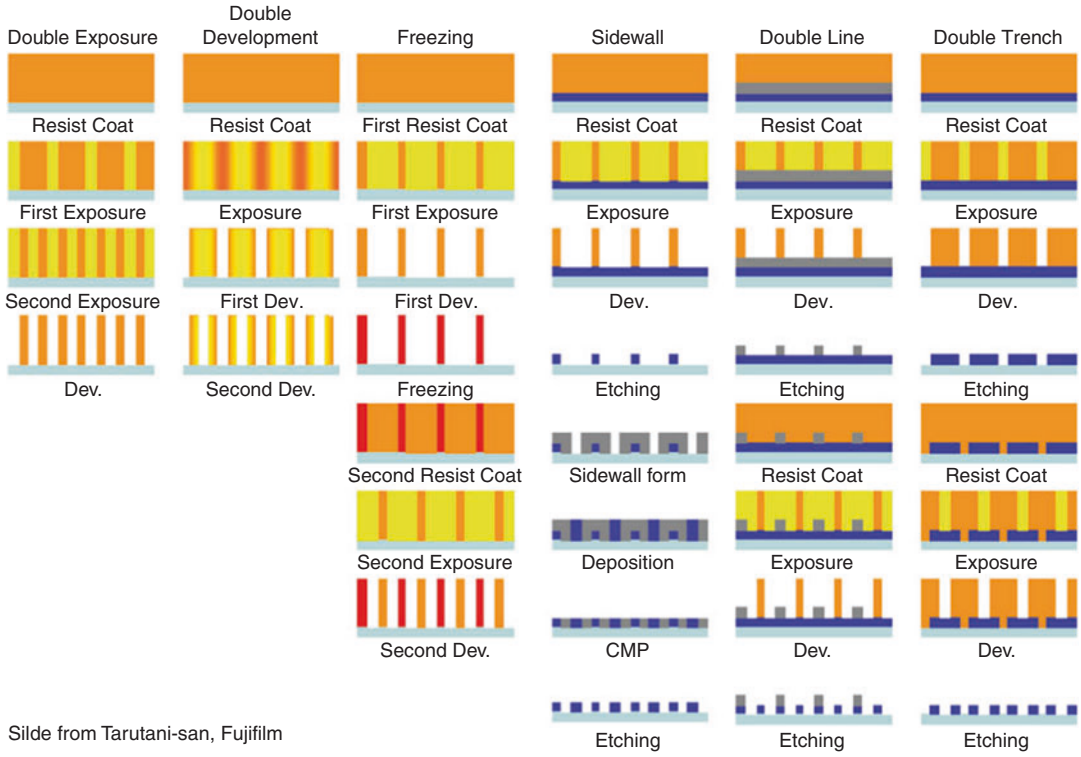
both thinner and more opaque. In addition, introduction of resolution enhancement techniques such as phase shift masks (PSM) and optical proximity corrections (OPC) have broken the simple and long-standing idea that the mask (object) is a replica of the desired circuit layout (image). Instead, the full scanner imaging must now be considered, including the properties of both the object and the image stack. This results in a complex optimization that is tied to the desired circuit pattern (such as contact layer, gate, interconnect), the particular scanner used, the particular photomask and type (BIM, Attenuating PSM, Alternating PSM, etc.), and the wafer level imaging stack. Lithography has now become computationally intensive, with iterative refinements needed to achieve accurate fidelity and yield in the fabrication facility ("fab"). These requirements lead to detailed thin film optimization of binary and phase shift masks, and of the pellicle's effects on lithographic imaging (e.g., optical proximity corrections), and also on overall mask flatness. In the 1970s or 1980s, before these advances, imaging was considered simple; now, mask and wafer level materials development must be closely coupled to lithographic image modeling to achieve the desired effects, while minimizing undesirable artifacts.

Pellicles: Dust Protectors for Photomasks

Pellicles are thin polymer membranes supported on aluminum frames and mounted on a photomask's patterned film side – typically 6 mm above the masking film (Fig. 2). They assure that any dust particles falling onto the photomask are out of the object plane of the objective lens, and therefore are not present in the image formed in the photoresist layer by the photomask. Pellicles are one of the critical elements that permit defect-free lithographic printing.

Development and Performance of Immersion Lithography

Immersion lithography has led to radical changes in lithography tools, that is, the design of the

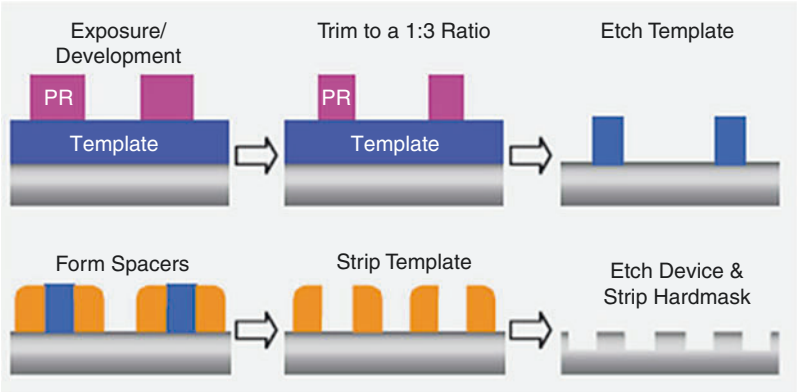


Immersion Lithography, Fig. 2 Two photomasks with pellicles. The *upper* mask is a conventional binary intensity mask with the mask pattern and the pellicle on the *lower* surface of the 6″ × 6″ ultrahigh purity fused silica photomask substrate. Round Rock Texas)

optical scanner, so that the immersion fluid can be contained between the projection lens' last lens element and the photoresist coated silicon wafer, thereby permitting the high wafer stage translation speeds needed to produce high process throughput (greater than 120 wafers per hour). Scanner manufacturers (ASML [8], Nikon [9, 10], and Canon) have chosen water as the first-generation immersion fluid and have evaluated many different approaches to immersion lithography's technical challenges. For example, different immersion fluid containment methods were considered, including a fluid bath in which the wafer would reside, a showerhead in which the fluid would continuously flow and would be deposited and removed from the wafer, and another in which the fluid would be deposited on the wafer but flow over the wafer edges to a drain. The final solution seems to be the showerhead where the fluid is flowing continuously, with the water temperature maintained to very high precision to minimize any imaging artifacts arising from water's refractive index change with temperature (i.e., dn/dT). Another critical aspect, necessary to control the number of immersion-specific defects per wafer, is to carefully control the showerhead's movement over the wafer's edge. Another important consideration is the track: the wafer processing and development system directly attached to the photolithographic scanner, which is used to coat the imaging stack (a bottom antireflection coating (BARC), the photoresist layer, and sometimes a topcoat) and perform any necessary post-apply thermal bake steps. The track then supplies the wafers into the scanner at a rate of more than 120 wafers an hour, and receives the exposed wafers back for postexposure bake, development in TMAH (Tetramethyl ammonium hydroxide), and spin drying. Typically, photoresist is removed from a small rim around the wafer's edge, using an edge bead remover in the original photoresist coating process, since the wafer's high speed and fast acceleration, relative to the stationary showerhead, can lead to particulate delamination from the wafers edge, generating immersion defects on the final imaged wafer.

Ongoing immersion lithography materials research has included developing next generation immersion fluids [11] (beyond immersion fluids for use in 157 nm lithography [12]), which have higher refractive indices than water, and so further increase the scanner's numerical aperture.

Double Exposure Immersion Lithography



Strategies to further increase resolution by optical means alone may have been exhausted, since decreasing the wavelength beyond 193 nm leads to extreme ultraviolet (EUV; see "► EUV Lithography" herein) lithography (also known as "soft-x-ray projection lithography"; see below). Also, increasing the numerical aperture to 1.55 with high index fluids will only allow single patterning down to 32 nm half pitch, even at the most aggressive k factors. The most likely alternative would be some form of double patterning, where in one variation the desired patterns are split between two masks, such that more facile feature printing

Immersion Lithography, Fig. 3 Approaches for double patterning lithography, going from least complex in terms of processing steps (but most material demanding) on the *left*, to most complex process (but least material demanding) on the *right* (After Ref. [13])

is done at twice the pitch. The second mask would be aligned so that the second feature set is printed between the first set, providing final features with target dimensions at the desired half pitch. For example, if one wanted to print 30 nm lines and spaces, one would start by printing 30 nm lines with 90 nm spaces, then print another set of 30 nm lines with 90 nm spaces over the original image, but aligning the exposures with a 60 nm offset. One can imagine that the costs associated with double patterning lithography would be substantial given the extra processing steps and materials required, yet today some chip makers are contemplating triple and quadruple patterning.

However, since EUV lithography has not progressed as quickly as initially expected, and optical lithography with water or high index fluid immersion has shown much potential, applying some double patterning method to immersion lithography would provide a means to improve resolution to keep pace with integrated circuits' leading edge feature size requirements. Several industrial laboratories and academic institutions are developing their own approaches for accomplishing this double patterning task. A few of these approaches are shown schematically in Fig. 3 [13]. The last two columns depict the double patterning method described above, where two exposure steps, two development steps, and two etching steps are required for pitch doubling. This method's costs have prompted researchers to scout other alternatives that could eliminate some of the extra steps. The most challenging approach is a double exposure method shown in the first column. In this method, the two mask patterns are exposed consecutively into the same material, providing better overlay accuracy (since the wafer is not removed from the scanner chuck). This requires a material that can behave in an optically nonlinear manner, and to date no such material exists, although some conceptual and simulation work has been reported.

Immersion Lithography, Fig. 4 Generic process flow for positive tones (*lines*) spacer mask patterning (From Ref. [14])

Another alternative uses a self-aligned double patterning (SADP) technique, or sidewall spacer technique, to achieve pitch doubling [14]. In this process, shown schematically in Fig. 4, the first optical exposure pattern is etched into a sacrificial layer. Another material (e.g., silicon nitride) is then deposited conformally on this spacer's sides to a thickness that defines the final pattern. In positive tone spacer processes, the first sacrificial layer is removed and the pattern formed by the deposited material is etched into the final hard mask or substrate. Excellent quality lines down to 22 nm half pitch have been obtained [15]. Although this process involves only a single resist application, it does add a number of process steps, contributing to the approach's complexity. As with the double development approach, this technique may not find general use, since it is applicable only to uniformly periodic structures.

Future Directions Beyond Optical Lithography

Nanofabrication

During photolithographic patterning's ongoing development for microfabrication, there have been parallel efforts on novel new technologies to displace photolithography. For example, x-ray proximity lithography, ion beam and e-beam projection, and e-beam direct write lithography have all been the focus of large and substantial research and development efforts. However, other than the critical role that e-beam direct write has played in photomask patterning for optical lithography, none of these technologies has succeeded in displacing optical projection lithography. E-beam direct write has been pursued in both single e-beam and massively parallel multibeam modes – the latter to improve the technology's pattern transfer rate and to compete with projection optical lithography's productivity.

Soft Lithography

There has been much recent work on "soft lithography": imprint lithography whereby either stamping with an elastomeric patterned mask, or hard mask contacting into either photo or thermally polymerizable materials, allows direct pattern transfer [16]. This nanoimprint technology, discussed in an article in this volume by Willson, has shown the ability to make very fine feature sizes. There is also recent work on dip pen lithography, or scanning probe lithography, which (like e-beam direct write) utilizes an atomic force microscope tip to directly write the pattern, either with a single probe, or with a probe array. In addition, there is much research on both self-assembly of small molecules and oligomers, as well as "templated growth": using small structural features (which may be introduced by patterning), to construct complex functional materials or devices using materials growth on the template.

EUV Lithography

There has been substantial research in the past 15 years on soft-x-ray projection lithography

(now called EUV lithography) using 13.4 nm light and multilayer reflective mirror optics; this is now considered a "next generation lithography" to replace optical projection lithography.

It appears that the next generation lithography, determined when it is successfully brought to commercial-scale IC fabrication, will be either EUV lithography, imprint lithography, or massively parallel e-beam direct write [16]. But it is certain that 193 nm lithography will be extended as far and as long as it is commercially viable; this ongoing extension will make use of as many optical enhancements (phase shift, polarization) and variations such as double (and perhaps triple or quadruple) patterning, thus providing an ongoing set of R&D challenges for materials scientists.

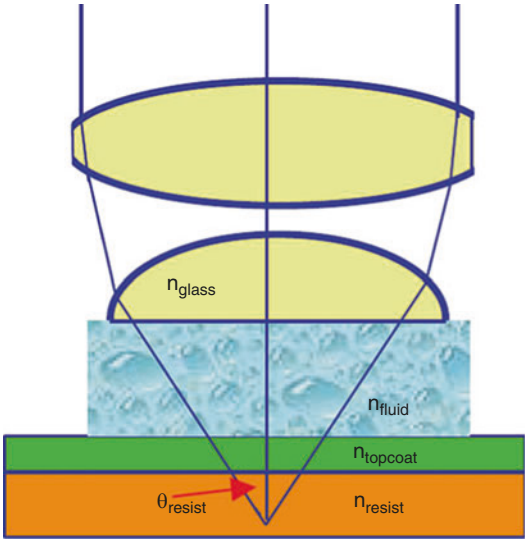
Immersion Lithography Materials

Roger H. French
Department of Materials Science and Engineering, Case Western Reserve University, Cleveland, OH, USA



Definition

Immersion lithography utilizes liquids with refractive indices >1 (the index of air) to enable sub-45-nm feature patterning for semiconductors. An alternative to conventional dry optical lithography offering finer features, this method employs innovative materials at all imaging stack levels.

Overview

In addition to the entries on Lithography and Immersion Lithography, herein, the reader is directed to two recent review papers which surveyed the state of the art in immersion lithography, including photomasks and wafer-level materials [1] and immersion lithography tools [2].

Using optical lithography in semiconductor fabrication, the main materials development has traditionally been polymeric photoresists, which changed substantially each time the lithographic wavelength decreased: from 436 nm (G-line), to 365 nm (I-line), to 248 nm (DUV), and now to 193 nm. For example, the shift to DUV (KrF excimer laser) coincided with the introduction of chemically amplified resists. The transition to 193 nm (ArF excimer laser), along with a failed transition to 157 nm (F_2 excimer laser), expanded greatly the number and type of materials needed above and below the projection lens in lithographic scanners. These new materials include both photomask materials as well as new types of wafer-level materials, such as immersion fluids, top coats, and photoresists (Fig. 1). These new materials – photomasks, pellicles, photoresists, bottom antireflection coatings, and topcoats – coupled with the introduction of immersion lithography, have enabled much larger optical scanner numerical aperture lenses (up to 1.35 NA with water as the immersion fluid), enabling 45 nm half-pitch feature printing using 193 nm light.

Immersion Lithography Materials, Fig. 1 Immersion lithography imaging stack showing the projection lens optics including the last lens element contacting the immersion fluid, a topcoat layer on *top* of the photoresist layer (From [8])

Immersion lithography materials have become a broad, diverse, and complex family developed to help the industry's advance to 32 nm half-pitch feature sizes. At the same time, the possible uses of second-generation immersion fluids, double or triple patterning, and novel resist processes indicate that the need for new and optimized materials will not be reduced in the future.

Types of Materials Used

Photomasks are typically transparent fused silica blanks covered with a pattern defined in a chrome metallic absorbing film.

Pellicles are a thin transparent film membrane stretched over a frame that is glued over one side of the photomask to serve as a dust protector.

Photoresist is a light-sensitive polymer formulation which is spin coated onto a silicon wafer and used to define features in an integrated circuit.

Bottom antireflection coatings are an inorganic or organic thin film used between the photoresist and the silicon wafer so as to control the reflectance of light from the wafer back into the photoresist.

Topcoats are a polymer coating used above the photoresist layer to reduce interactions between the photoresist and the immersion fluid.

Key Attributes and Advantages

Attenuating Phase Shift Photomasks

Attenuating phase shift masks (AttPSM) have been widely accepted in lithography for providing phase contrast imaging without the extra process steps (e.g., trim masks) needed for strong phase shifting approaches such as alternating phase shift masks. Attenuating phase shift photomasks have been developed for I-line, DUV, and 193-nm lithography; the I-line masks met with commercial acceptance, while thin films based on molybdenum and silicon ("MoSi") have become the dominant materials used at DUV and 193-nm wavelengths. In these photomasks, the thin film attenuates the light to 6 % or 9 % of the mask's illuminating intensity, and also phase shifts this light by 180° relative to the light transmitted through the openings (the mask's lines) in the thin film. This attenuated phase shifted light then destructively interferes with the light transmitted by the lines, thereby reducing the lithographically printed line width.

AttPSMs for 248 and 193 nm lithography use essentially two component materials mixed in a microstructure so as to produce broadly tunable optical materials. Compositionally graded films of MoSi (more accurately, compounds of Mo and Si with O, N, and C) have become the accepted materials at these lithography wavelengths. An alternative AttPSM consisting of multilayer films of AlN with TiN (optical superlattices) produced by sequential multilayer ion-beam deposition, where the bilayer thickness was kept to less than λ/20 (i.e., bilayer thicknesses smaller than 10 nm), was also developed but not commercialized. These films were optically homogeneous, and behaved optically as uniform films, even though the AlN and TiN amounts in each bilayer were the variables used to produce optical tenability [3]. This material family produced APSMs with transmissions from 6 % to 20 % with 180° phase shift for both 248 and 193 nm. Materials design of new APSMs continues as a research active field [4].

Polymers for Photomask Pellicles

In G-line or I-line lithography, the pellicle membranes were initially fabricated from high molecular weight nitrocellulose polymers, with the membrane prepared by spin coating from a polymer solution onto a glass plate. The aluminum frame was then adhesively attached to the polymer membrane, followed by membrane release from the glass plate, then trimming the membrane edges at the frame and optical inspection of the pellicle for any defects. The pellicle thickness is chosen so that the membrane's interference fringes give a maximum transmission, such that the pellicle serves as an optical element with ∼100 % transmission. With the advent of DUV, lithograph amorphous fluoropolymers such as Teflon AF [5] or Cytop [6] were developed, because their optical absorption edges are at much shorter wavelengths than nitrocellulose, which was no longer sufficiently transparent. The pellicle membrane's thickness can be optimized to give its peak interference transmissions at multiple wavelengths; for example, a thickness on the order of 0.8 μm can be used for I-line and DUV lithography.

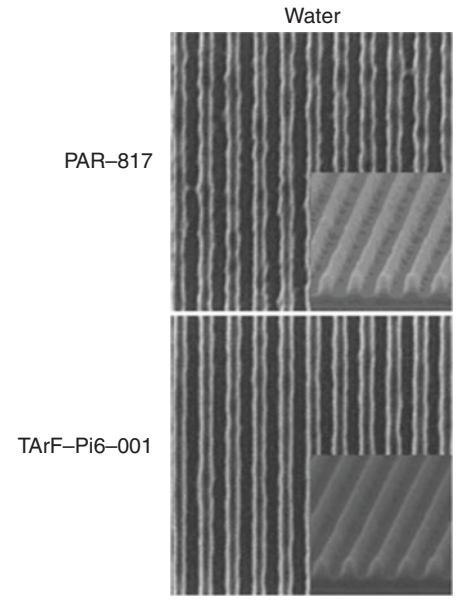
Materials in the Lithographic Imaging Stack

The immersion lithography materials required on the image side (i.e., below the projection lens) also span a wide variety of materials and classes. These materials include the immersion fluids, topcoats (used to separate the fluid from the imaging photoresist film), the photoresist layer, and an antireflection layer underneath. These are discussed in order below.

Immersion Fluids

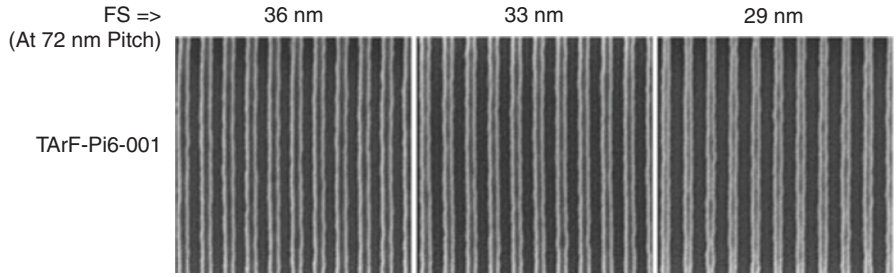
Immersion fluids give enhanced imaging performance in the same way that water or oil

immersion techniques improve an optical microscope's resolution. When imaging is performed in a fluid which has a refractive index >1 (the value for air), the light's wavelength is effectively reduced by the fluid's index. The fluids must be optically transparent (i.e., have a low optical absorbance at the lithography wavelength) and have a high refractive index. The first immersion fluids studied were to be used to extend 157-nm lithography [6], but it is immersion lithography at 193 nm (using water) that has been successfully commercialized.



Water-based immersion lithography using 193 nm ArF illumination provides optical solutions as far as the 45-nm node (with a k_1 of 0.31), but is not able to achieve the 38- or 32-nm nodes as currently defined. Achieving these lithographic nodes will require new, higher refractive index fluids to replace the water used in first-generation immersion systems. Therefore, there has been extensive research to develop second- ($1.44 < n_{193nm} < 1.65$) and third-generation ($1.65 < n_{193\ nm} < 1.8$) 193 nm immersion fluids. A number of such second-generation high-index fluids have been developed for immersion lithography at 193 nm, with low optical absorbance and refractive indices up to 1.664. To understand different fluid classes' behavior and performance, spectral index measurements are used to characterize the index dispersion, coupled with Urbach [7] absorption edge analysis and Lorentz Oscillator modeling [8].

Immersion Fluid–Resist Interactions



Using water or another higher index-matching liquid between the last lens element and the photoresist introduces new issues not previously encountered in conventional "dry" lithography. Much of the early work identified the key issues related to imaging under water immersion, and later, the same issues were addressed for the higher index organic liquids [9]. Of particular concern is the extent of resist components' extraction from the resist film into the immersion liquid. Components in the resist formulation such as photoacid generators (PAGs) and their photogenerated acids, dissolution modifiers, and bases may all leach from the film. The amount of leaching is of course a function of the resist film's component concentration, the rate of the components' diffusion into the liquid, the solubility of the components, and the time of fluid/resist contact. Leaching has two effects. First, the resist's imaging properties, such as sensitivity, are changed, and performance is usually degraded. Secondly, leached components, especially photoacid generators, may undergo further photochemistry and adsorb onto the system optics [10], a topic of particular concern to the stepper manufacturers – which has led to their setting maximum tolerable PAG limits on the order of $1.0–5.0 \times 10^{-12}$ mol/cm^2-s. The PAG amount detected in water for some commercially available resists has either come very close to or exceeded this limit. This result has prompted further work on designing immersion topcoats or topcoatless resists (vide infra) to slow or prevent leaching. It has also led to work to pre-rinse the resist surface with water (since most of the PAG leaching occurs in the first few seconds of contact), which has been reported to remove over 90 % of the PAG at the water/resist interface [11]. With second-generation immersion fluids, very little PAG leaching has been detected, reportedly about two orders of magnitude lower than the recommended limit.

Another key immersion imaging issue is the effect of fluid penetration into the resist film. Sub-surface immersion liquid may modify the kinetics of the acid-catalyzed deprotection reaction (especially if water carries with it species that can quench photoacid). It can also act as a polymer film plasticizer (especially true for organic liquids diffusing into organic resist polymers), changing the film's mechanical properties and diffusion-related properties. With water as the immersion fluid, quartz crystal microbalance and optical reflectance techniques have shown that 200 nm films may swell up to 5 nm in thickness. There is also some evidence that second-generation immersion fluids cause up to 2 nm in initial swelling and 10 nm of dissolution of some commercial resists. Despite these observations, there seem to be only subtle effects on sub-45-nm line and space interference imaging of some commercially available resists with both water and second-generation immersion fluids (vide infra).

Resist component extraction into the immersion fluid and fluid permeation into the resist may each cause unwanted defects in the final resist image, and much work has been done to quantify and reduce the new defect types seen under immersion imaging. These defect types may be classified into five general categories: process-induced defects, "watermark" defects, defects arising from bubbles in the fluid, drying stain defects, and particle-borne defects. Defects related to processing may originate from fluid carrying particles from the wafer edge, especially if the topcoat, resist, or BARC peels at the edge, and the fluid is scanned beyond this edge point. Steps to rinse and clean the bevel have shown marked improvement in defect counts. Fluids that permeate into the resist film can generate "watermark" defects, which include swelling of lines and T-topping. Bubbles (which could originate from gaseous by-products from the resist or entrapment of bubbles from fast scanning at the advancing edge of the fluid/resist interface) may be a source of undeveloped resist regions. Resist component leaching into the fluid, in conjunction with fluid droplet evaporation, may lead to drying stain defects. This is also possible if the fluid is not pure, with evaporation leading to surface residues. Finally, fluid or environmental particles can cause printed defects if present during exposure. What is clear is that optimization in both processing and immersion-related materials are necessary to improve defect performance. These improvements have resulted in defect densities below 0.06/cm^2 for water immersion. Water immersion lithography printing of 36 nm lines and spaces (i.e., 72-nm pitch) is shown in Fig. 2, using a 2-beam interference lithography tool, and shows good imaging performance with some line edge roughness. Current commercial photoresists on production immersion lithography perform even better than this. For high-index immersion, preliminary defect studies have concentrated on both the high-index fluids, cleanliness and fluid misted droplets' interaction with several commercially available dry and water immersion photoresists [12]. Imaging under a second-generation immersion fluid, with an index of refraction at 193 nm of ~1.64 is shown

in Fig. 3 with increasing exposure doses producing photoresist lines from 36 nm down to 29 nm. The dramatic ability of immersion lithography to enable the printing of such sub-resolution features can be seen by considering that 36 nm lines printed with 193 nm light correspond to imaging at λ/5, a resolution limit far beyond the diffraction limit. See Table 1 for a broad summary of lithographic half-pitch generations with technology options and imaging parameters.

Immersion Topcoats and Topcoatless Photoresists

Fears of lens contamination, increased defects, and resist performance degradation with water immersion lithography prompted much research activity on novel topcoats, and the so-called topcoatless photoresists. Topcoats are designed to reduce both water permeation into the photoresist as well as resist component leaching (especially PAG), and also to increase water's receding contact angle at fast scan speeds (to reduce water droplet formation that may lead to imaging defects). More hydrophobic topcoats provide the increased receding contact angle to allow higher scanning velocities before droplet formation occurs. Topcoats showing over 100° receding contact angles will enable speeds up to 900 mm s^{-1}. Ideally, the topcoat would dissolve in the same aqueous base developer (TMAH; tetramethyl ammonium hydroxide) used in the resist development step, but some topcoat versions were designed for nonaqueous solvent development, which adds an extra processing step. Many topcoats incorporate fluorine-containing functional groups for their increased hydrophobicity, as well as the same compound types used effectively for absorbance reduction in 157 nm technology [13]. These fluoropolymers have also been used in water immersion resist materials – either as additives to current 193 nm materials or as block copolymers [14]. These systems are designed so that a topcoat is not necessary, but instead incorporate the topcoat's hydrophobic properties directly into the photoresist, eliminating an extra topcoat spinning step. These topcoatless resists depend on the self-segregation of low surface energy fluoro-components to the air interface during spinning and baking, providing the required hydrophobicity for water immersion imaging. A novel method to make the block copolymers relies on RAFT polymerization to make the first block composed of 193 nm photoresist monomers, followed by a second block composed of a fluorinated monomer. Blends of this block copolymer (even at very small fractions) with a standard non-fluorinated methacrylate terpolymer show high receding contact angles. One variant to this system, which could further reduce the defect levels, is by modifying the fluorinated block to be developer soluble – which would also help with developer wettability.

Future Directions

As shown here, immersion lithography materials research has defined the critical application requirements and the nature and properties of the materials, which have been developed and commercialized into today's production immersion lithography. Materials which were not successfully commercialized have been included to show how successful technological developments have followed "failed" technology research efforts. An in-depth understanding of the intrinsic and extrinsic contributions to both the optical absorbance and the refractive index (or more generally, the complex index of refraction) of inorganic, polymeric, and molecular materials in the UV and VUV spectral regions has been developed. This scientific basis is essential to future successful development and commercialization of optimized materials and technology.

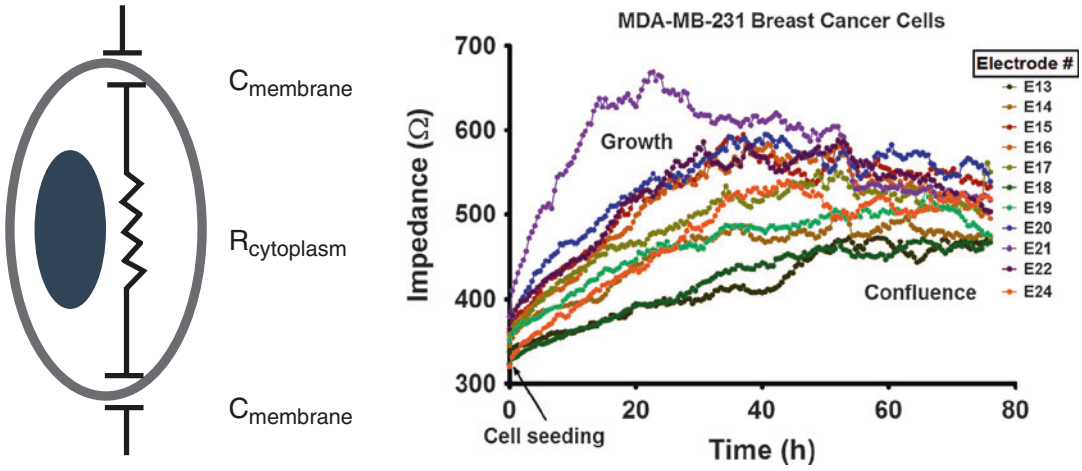
Definition

The use of electrical impedance as a means of detecting biological events or samples of interest

in microdevices for biomedical applications. Examples include electric cell-substrate impedance sensing (ECIS), electrochemical sensing of analytes in biofluids, and cell impedance cytometry.



Introduction

The advent of microfabrication tools and techniques coupled with the increasing need for low-cost, rapid sensing platforms for medical diagnostics has paved the way for a new field that we have come to know as biomedical microdevices. Research in this field has made significant headway aided by collaborations between engineers, scientists from the life sciences, and physicians who will be the end users of this technology. There are many features that make this technology promising for widespread use in the future. These devices are inexpensive to manufacture and hence can be disposed after single use which is standard in hospitals and clinics to avoid cross-contamination. Low cost also ensures low-income people as well as patients in developing countries can have ready access to this technology. Also, the sample and reagent volumes are extremely small compared to conventional tests performed in the laboratory due to the small size of the device. This not only reduces costs but also makes the reaction time much lower enabling rapid analyses. In addition, high-throughput devices which can screen samples in parallel can be manufactured using this technology that will further lower analysis times or increase sample capacity. The technology has been used to create faster and more efficient miniaturized devices for multiple existing assays in the lab. But the real success of this technology is seen in the numerous research reports on new techniques, assays, and platforms for studying and detecting a wide variety of biological samples. This chapter specifically focusses on using impedance sensing within these devices as a means to capture biological events or analytes in the sample.

Impedance refers to the resistance offered to the flow of electric current. Mathematically, it is a complex number where the real part is the electrical resistance (in ohms) and the imaginary part is the reactance (also in ohms) which is a function of the frequency (in hertz) at which the measurement is made. It can also be expressed in polar format as a magnitude and a phase angle. Impedance is typically measured using an electrode pair made of a highly conductive material such as gold or platinum. These are the metals of choice because they are inert and do not adversely affect biological cells. The impedance of biological samples is a function of their size, composition, and proximity to the electrodes. Hence, it is common to treat the surface of the gold electrodes to capture the sample or analytes of interest thereby increasing its sensitivity. In order to measure the impedance, a constant voltage is supplied by an impedance analyzer or spectroscope, and the corresponding current is measured. Conversely, it is also possible to supply a constant current and measure the voltage drop across the electrode pair. These instruments also have the capability to generate these signals over a range of frequencies enabling what is called impedance spectroscopy or the analysis of impedance over a spectrum of frequencies. The following sections discuss some of the ways impedance sensing can be successfully employed as a detection strategy in microdevices for biomedical applications.

Electric Cell-Substrate Impedance Sensing

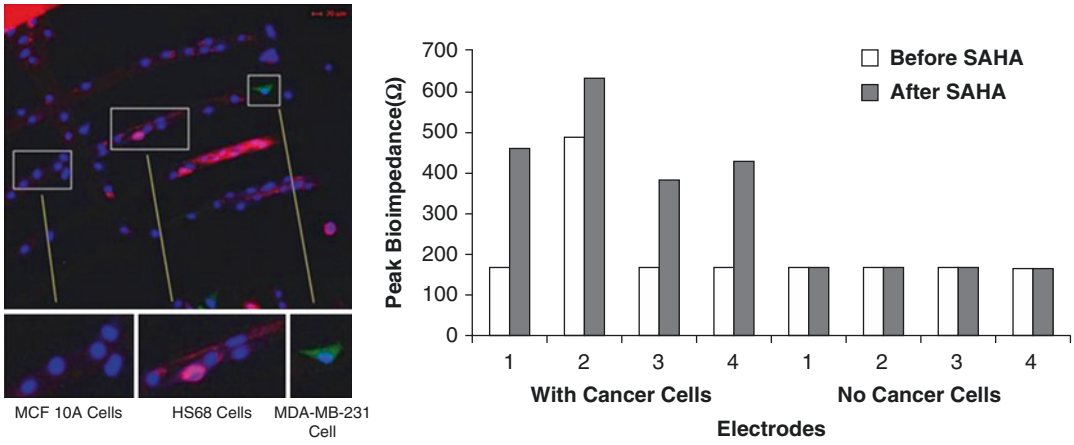
Electrical cell-substrate impedance sensing or ECIS is a technique that is used to monitor live biological cells in tissue culture. The term was coined by the inventors of the technique, Ivar Giaever and Charles R. Keese, and is currently the trademark of Applied Biophysics [1]. The electrical impedance signals are recorded from cells that are adherent on the surface of planar microelectrodes. These electrodes can be on the surface of regular treated polystyrene petri dishes or well plates used for tissue culture or on any other surface suitable for cell culture like glass or silicon with an appropriate chamber to hold media during measurements. The technique can be used to make measurements from any animal cell line

Impedance Sensing Techniques for Biomedical Microdevices, Fig. 1 The equivalent circuit model for a single cell (*left*) and the changes in electrical impedance magnitude as live breast cancer cells attach and grow on microelectrodes (*right*)

that grows as a monolayer by attachment. ECIS is based on the ability of cells to block the flow of electric current when attached to a conductive surface. The dominant current paths through the cell monolayer vary in different ranges of the frequency spectrum. The cell membrane is made of a phospholipid double layer which acts like a capacitor, and the cytoplasm of the cell is mainly made of a conductive gel-like substance which can be modeled as a resistor as shown in Fig. 1. At lower frequencies, the current passes through the cell-substrate gap and the space between adjacent cells called the cell-cell junction region. However, at higher frequencies the current can couple through the cell and thus probe the electrical properties of the cell membrane and the interior. The ECIS impedance measurements can be made continuously at a single frequency or multiple frequencies at regular time intervals.

Measurements are always made from a pair of electrodes, and they come in different configurations. For instance, the electrode pair can have one very large counter electrode which is ten times or more larger in area than one very small sensing electrode. A number of different shapes including circular, square, rectangular, branch, and other shapes have been used for the sensing and counter electrode design in ECIS devices. Another commonly used configuration is the interdigitated electrode pair in which two identical comb-shaped electrodes are interlocked with each other as shown. In this configuration, both electrodes play the role of sensing and counter electrodes. There are other commercial systems on the market that employ these electrodes in making impedance measurements from cell monolayers.

The impedance values recorded are directly related to the cell coverage on the electrodes. This makes it suitable for measuring the growth and proliferation of cells in culture. Using the impedance values recorded, it is possible to infer the rate of growth, the doubling time, and the time when the culture reaches confluence. So, one of the applications of ECIS is the remote monitoring of cell growth. To ensure good cell attachment, the electrodes are typically treated with oxygen plasma in a plasma cleaner followed by coating with extracellular matrix proteins like collagen or fibronectin just before the addition of cells. Alternately, cell culture medium can be added to the electrodes and the serum proteins in the medium self-adsorb onto them providing the same effect. However, for long-term monitoring, it is desirable to pre-coat the electrodes before adding cells to them. Figure 1 shows the characteristic change in the impedance profile as cells attach and grow on microelectrodes. The baseline impedance is the impedance when there are no cells on the



electrode. As they grow, the impedance increases as the number of cells on the electrode increases. When the area on the electrodes is completely filled with cells, the impedance saturates to a maximum value indicating they have reached confluence.

On the same note, if cells begin to die, they become rounded, and their attachment to the electrodes decreases till they completely detach from them. When this happens, it results in a drop in the impedance values which in essence is a reversal in the rise seen due to cell attachment. This is the basis for the use of ECIS to monitor events like apoptosis or programmed cell death. This mechanism of detection can also be used to measure the cytotoxicity of drugs or compounds in culture. It is particularly useful in screening for the optimal drug concentration or dose that should be used in treatments.

The technique also lends itself to a host of other applications since many cellular events are attachment based. For example, cell motility or the movement of cells in culture can be measured using ECIS which lets us compare closely related cell lines for activity in culture. Wound healing assays have also been developed in which the cells on top of the electrode are removed by electroporation and subsequent cell migration to the wounded site is measured. A short pulse of a higher voltage or current spanning a few minutes is applied which kills the cells located on the electrode causing them to detach accompanied by a fall in the impedance value. When the surrounding cells migrate onto this newly available free area on the electrode, the impedance measurements pick it up by reflecting a rise in the values recorded. Alternately, cell adhesion on the electrode area is actively prevented by applying a pulsating electric field. When the area around the electrode has a confluent cell culture, the electric field is turned off, and the impedance is monitored as cells migrate into this region. Electroporation when used on smaller timescales can result in the enlargement of pores in the cell membrane causing cells to take up molecules, particles, and compounds from the surrounding medium that normally would not make their way into the cell interior. Electroporation assays have been developed in conjunction with ECIS that measure the optimal electroporation conditions that allow for the uptake of larger molecules of drugs or nanoparticles with fluorophores for imaging. Other applications such as monitoring the binding of certain molecules to the receptors on the cell surface resulting in specific cellular events can also be done through real-time ECIS measurements.

In the last few decades, ECIS has become a useful tool to study the electrical properties of cancer cells. Although it is believed that there are biological, chemical, or physical differences between normal and cancer cells, the depth of our knowledge with respect to the similarities and differences in their electrical properties was quite limited. It has become increasingly clear, as more reports on the electrical properties of various types of cancers are published, that the impedance of cancer and normal cells are indeed different. Recently, an assay for cancer cell detection in a simulated biopsy sample was reported which employs the use of an anticancer agent called suberoylanilide hydroxamic acid (SAHA) that specifically targets the cancer cell cytoskeleton and causes an increase in the cell area on the electrode which can be captured through ECIS measurements. Figure 2 shows an electrode with normal fibroblast cells found in the extracellular matrix of tissues and normal and cancerous breast cells simultaneously cultured on it. It also displays the impedance changes recorded on electrodes with and without cancer cells demonstrating detection using this mechanism. Cancer cell invasion through a confluent layer of endothelial cells has also been monitored using real-time ECIS measurements. As mentioned before, the technique can also be used to screen the efficacy and optimal dose of anticancer agents on different types of cancer cells. These tests, in the future, could be carried out on patient samples to provide individualized reports of drug effectiveness which can then be used to make treatment plans for the patient.

Thus, ECIS is a label-free, noninvasive method that can be used to monitor live cell cultures in real-time. A number of cellular events based on cell attachment can be detected using

Impedance Sensing Techniques for Biomedical Microdevices, Fig. 2 Image of an electrode (*left*) with fluorescently stained normal fibroblast cells (*orange*) found in the extracellular matrix of tissues and normal (*red*) and cancerous (*green*) breast cells. Impedance changes (*right*) recorded on electrodes with and without cancer cells under the influence of an anticancer agent (suberoylanilide hydroxamic acid) (Srinivasaraghavan V, Strobl J, and Agah M (2012) Bioimpedance rise in response to histone deacetylase inhibitor is a marker of mammary cancer cells within a mixed culture of normal breast cells. this technique. It has become an easy and useful approach to study the electrical properties of cancer cells and also lends itself for integration into existing devices and technologies which need a detection mechanism for cell attachment-based events.

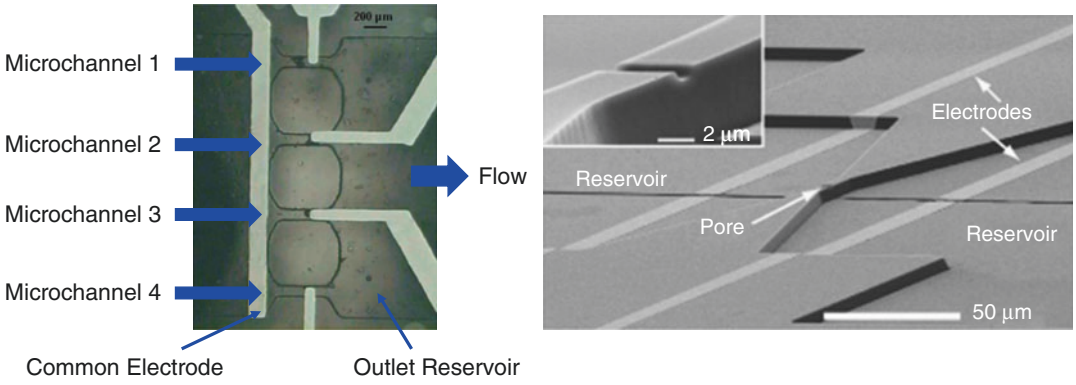
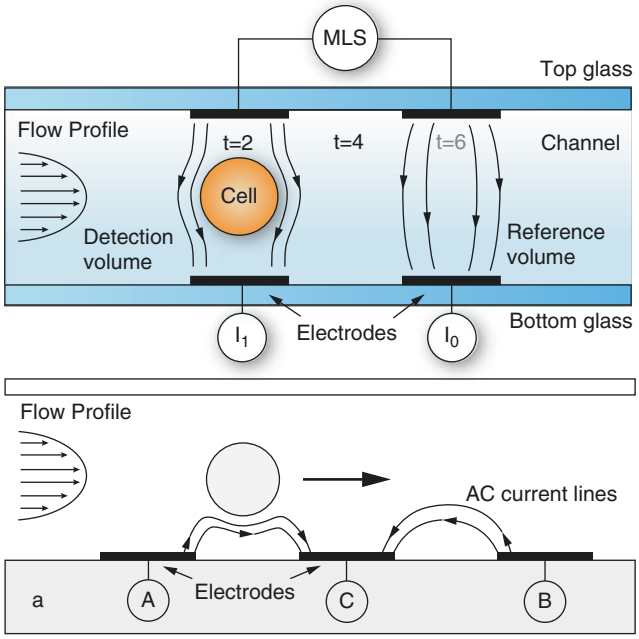
Impedance Cytometry



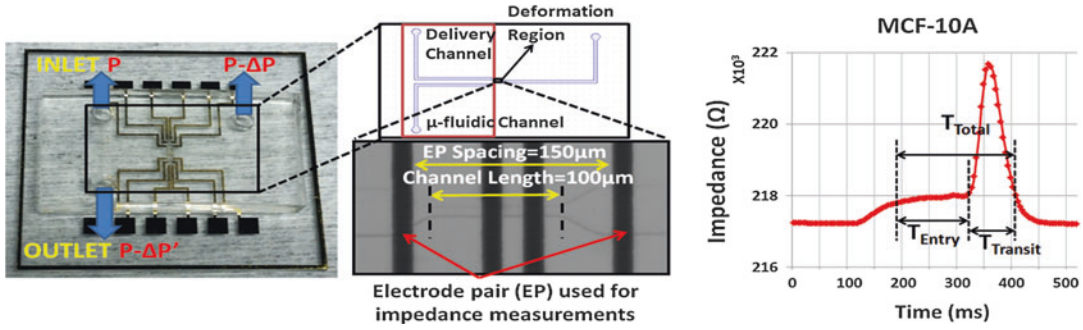
The general meaning of cytometry is making measurements from cells. Impedance measurements from flowing or suspended single cells can be used as a sensing mechanism to count and measure relative size and dielectric properties of cells [2]. Unlike ECIS, this method does not require the cells to be attached to the electrodes. Another difference is the analysis of single cells as opposed to cell populations as seen before. Measurements from single cells greatly increase the speed of measurements and also provide insight into the heterogeneity of the cell population. A number of devices that we will discuss in this part of the chapter fall under the category of microfluidics. Microfluidic channels in devices are usually fabricated using a process called soft lithography. In this process, the channel is first fabricated on a silicon wafer using standard lithography techniques with a thick photoresist like SU-8 to obtain the replica of the patterns of the microfluidic channel network. Since the channels in the final device need to be hollow to allow for liquid flow, the silicon replica, also referred to the master or the mold, has the channels that stand out from the surface of the wafer and look like they have been embossed. A moldable polymer such as PDMS can then be poured on the silicon master, cured, and peeled off to obtain the microfluidic device in PDMS. Of course, this device needs to be bonded to a glass slide or coverslip so the channels can be sealed with the openings to the channels punched out. A strong, irreversible bond between glass and PDMS is obtained by treating the surfaces with oxygen plasma.

There exist different types of electrodes that can be incorporated in the design of these devices. The first is the Ag/AgCl electrodes that have been used in electrochemical cells for many years now. They can either be purchased as wires commercially and just immersed into the reservoirs to apply a voltage or fabricated in the lab by evaporating a layer of Ag on a glass substrate and electrochemically growing a layer of AgCl.



Another commonly used technique is to integrate metal electrodes usually made of gold at the bottom of the channel by evaporation. This is the preferred method because it easily integrates into the fabrication process flow. Another interesting alternative is the use of liquid metal electrodes integrated into microdevices for impedance measurements.

One of the first examples of a cytometer is the Coulter counter in which two chambers are connected by a small orifice with one large electrode in each chamber. The chambers are filled with a conductive liquid with particles or cells. As these particles move between the chambers through the orifice, the impedance measured increases. Also, a larger particle would block the current more when moving through the orifice resulting in a higher impedance change. Conversely, a smaller particle will not occupy as much space in the orifice and therefore block lesser current causing a lower change in impedance. A smaller orifice will have more sensitivity and can detect smaller particles as well. One of the limiting factors of the traditional Coulter counter is that the measurements are made only with a DC supply. The first microscale Coulter counters designed work on the same principle, but on a smaller scale, and were fabricated on silicon, glass, and PDMS. These devices had a sensing pore region instead of an orifice for detection. As these devices have evolved, although they use the same principle of detection, they no longer adhere strictly to the design of the Coulter counter. A number of different designs have been used including higher-throughput devices with multiple channels each with its own set of test electrodes to increase the number of particles analyzed and a channel with a flow-based programmable pore size that enables testing samples of different sizes on the same devices and tuning the sensitivity based on application. Figure 3 shows some examples of microfluidic devices based on the concept of the Coulter counter used for bioparticle analyses. Using the microscale Coulter counter and its design variants, a number of different samples of interest have been analyzed. Examples include mammalian cells, red and white blood cells, and nanoparticles that capture specific antibodies even single-molecule analyses of DNA, RNA, and others.



When the above concept is extended to include AC impedance measurements at multiple frequencies, the devices can be used to probe the dielectric properties of the cells. Figure 4 shows an example of such a device where the cells are flowing through a microfluidic channel that is larger than their size and gold electrodes integrated into the channel measure the changes as single cells pass them. The electrodes can be positioned laterally on the same surface or on opposite surfaces in the microchannel. In both cases, an impedance change is recorded due to the change in the current path as shown in the schematic in Fig. 4. It also needs to be reiterated that the sensitivity of the impedance measurements is related to the frequency at which they are made. At lower frequencies, the current path bends around the cell causing the measurements to be sensitive to size of the cell. However, at higher frequencies, the currents pass through the cells and are thus sensitive to cell membrane and cytoplasm properties. The technique has been proven to be sensitive enough to differentiate between cells of different sizes like red and white blood cells and closely matched cells like healthy and diseased red blood cells as wells as normal and cancer cell lines of the same tissue. Although the flow in microfluidic channels is planar and it is possible to measure the impedance of single cells without any additional design, active focusing and trapping mechanisms are often incorporated into the design to decrease any clogging issues and increase the rate and confidence of single-cell measurements. For instance, two auxiliary channels are present on either side of the input channel and flow to focus the cells coming from the input channel as a row of single cells. Another strategy is to apply a negative pressure through a tiny pore located between the electrodes to ensure that a single cell is positioned right in the middle of the electrodes. This also ensures that there are no discrepancies in the measurements due to the cell position being partial in one direction toward one of the electrodes. Dielectrophoretic trapping has also been used to position single cells between the

measurement electrodes by incorporating more electrodes through which the electric fields required for dielectrophoresis can be supplied. Figure 5 shows a device that has electrodes integrated into the narrow microfluidic channel that is smaller than the size of the cell, in which impedance measurements can be used to simultaneously measure the mechanical and the electrical properties of single cells. A constant negative pressure is applied at one end of the channel which forces the cells to deform and travel through it. The width of the impedance profile gives the time that single cells take to traverse through the channel which in turn is a measure of the mechanical properties of these cells. Additionally, the impedance measurements made in such a channel are more sensitive to the internal properties of the cell, especially at higher frequencies, because the leakage current around the cell is minimized.

Hence, impedance cytometry can be integrated into the microfluidic platform to generate a wide array of microdevices that have applications over a wide spectrum ranging from particle counting, size determination, and single-cell and molecule analyses.

Electrochemical Sensors

The working principle of electrochemical sensors is the same as what we have seen so far. In essence, when the analyte of interest is in the sensing region of the device, the impedance measurements change, and it is detected. However, we discuss this here separately to provide a summary of the strategies that one can use to add a sensing layer on top of the electrodes to effectively sensitize them to specific analytes of interest [3]. Figure 6 shows an illustration summarizing the idea. Self-assembled monolayers are used, for instance, to immobilize the biorecognition element on the electrode surface. Thiol end groups spontaneously chemisorb and form well-organized monolayers on gold electrodes. Thus, the recognition compound can be functionalized chemically to self-assemble on the surface. Polymer and polyelectrolyte films capable of binding to biomolecules have also been used successfully to capture target analytes. The field of biosensors for immunosensing has grown largely using this detection mechanism. The selective binding between antibody and antigen is exploited, and either the antibody or the antigen that complements the antigen or antibody in solution is immobilized on the surface of the electrode. When the complementary molecule binds to the antibody or antigen, the impedance changes, and detection is achieved. In some sensors, selected enzymes are deposited on the surface of electrodes by combining them with other materials or compounds. The catalytic action of the enzyme on the biomolecule of interest results

in detection through a change in the measurement from the electrode. It is also possible to analyze DNA concentration or base-pair mismatches using electrochemical sensors by comparable strategies. Similarly, in the detection of cancer cells which overexpress certain receptors, the ligand that binds to these receptors is immobilized on the electrodes in an effort to sensitize these electrodes to cancer cells. Electrochemical sensors have also been developed for the detection of glucose and urea levels in samples obtained from patients.

To increase the overall sensitivity of electrodes to impedance measurements, a common strategy is to increase the surface area of the electrode by depositing or growing carbon nanotubes (CNTs), coating the surface with conductive nanoparticles or composites of them. These coatings have shown to be effective in improving the sensitivity of measurements from neurons, electrochemical sensors for analysis of human body fluids as well as cancer cells. Figure 6 shows an example of an electrode that is coated with CNTs and the improvement in performance compared to uncoated control electrodes from neuronal recordings.

Conclusion

This chapter gives an overview of the impedance sensing techniques than can be incorporated into biosensors for medical applications. This technique can be used to analyze a wide variety of bioanalytes like single biomolecules, DNA or RNA strands, compounds like glucose and urea, and single mammalian cells and cell populations. Immobilization of biorecognition molecules on the surface of the electrode can be used to further sensitize them to target analytes. Impedance sensing is a noninvasive, label-free, highly sensitive, inexpensive, and rapid technique that can be used as a detection strategy in hand held biomedical microdevices for point-of-care diagnostics. It can be used to automate many measurements made conventionally with bulky and expensive microscopes and can be used by existing medical professionals and staff with minimal training. It can also be easily integrated within the existing framework of smartphones and computers which enables faster transfer of information obtained, for faster results and prompt care for patients. This new field which is at the

intersection of engineering, chemistry, medicine, and biology holds tremendous promise and potential to solve the challenges and problems in healthcare in the twenty-first century.

Overview

The National Academy of Engineering, in its Grand Challenge on "making solar energy economical," places emphasis on this statement, "However advanced solar cells become at generating electricity cheaply and efficiently, a major barrier to widespread use of the sun's energy remains: the need for storage" [1].

For energy storage devices, such as the battery and the supercapacitor, the most common problems are shelf/cycle life, lower efficiency, and high leakage current [2, 3]. These are tremendous challenges for an integrated circuit (IC) industry seeking greater IC functionality, smaller component size, and low power consumption using standard supercapacitors, ultracapacitors, or electrochemical capacitors for on-chip energy storage. In addition, the continuous need to reduce the component size of IC elements has not only begun to challenge the capabilities of traditional photolithography, but has prompted intense research to incorporate nanometer scale structures into current semiconductor technologies.

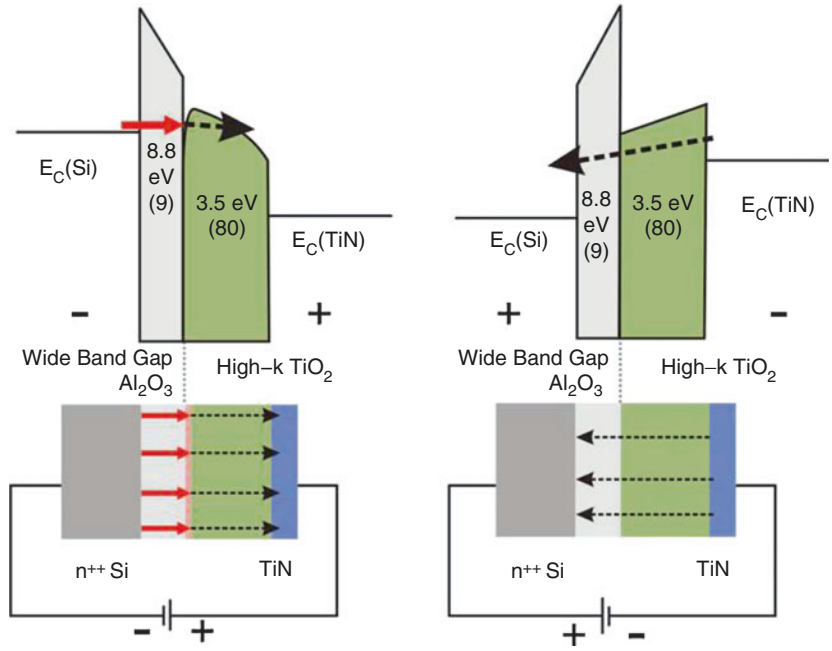
Nanostructures have unique and attractive characteristics, consisting of spatial arrangement, high surface area and density, and versatile shapes. Nanostructures have several forms: nanowires, nanochannels, nanotubes, nanobeams, nanopores, nanofilms, nanofibers, and nanolaminates. The atomic sizes for these structures vary from 0.1 to 100 nm or 5 to 1,000 atoms. In the past 10 years, nanostructures, particularly nanolaminates, have received significant attention for employability in supercapacitors/energy storage systems. Limitations of these energy storage systems have been plagued by nonconforming layers, pin holes, high leakage currents, low dielectric constants, and cost; all of which are directly related to the selection and quality processing of the materials and the nanostructure architecture. In an effort to address these limitations, researchers have employed alternating nanolaminate layers of high-k dielectric and wide bandgap materials (e.g., hafnium oxide (HfO_2), aluminum oxide (Al_2O_3), titanium oxide (TiO_2)) in energy storage systems to achieve higher capacitance density, higher breakdown

voltage, and lower leakage current. The high payoff for energy storage is improved equivalent planar capacitance (EPC) performance for existing supercapacitors/energy storage systems.

Equivalent planar capacitance (EPC) is the normalized planar footprint area of a capacitor (capacitance per planar area) and allows comparison between different capacitor structures. Capacitor structures being planar, embedded, or even trenched.

Theory

A nanolaminate, or nanolayered coating, consists of two or more alternating layers of dielectric films consisting of ultrathin oxide multilayers having individual layer thickness ranging from 0.1 to 100 nm. Nanolaminates have also been referred to as nanocomposites of materials with distinct properties, e.g., brittle/soft or high-k/wide bandgap materials. Particularly, nanolaminates of high-k dielectric materials have been investigated for energy storage applications [4]. Dielectric materials exhibiting high dielectric constants have recently gained considerable attention for their potential applications in microelectronics, such as capacitors and memory devices [5–8].



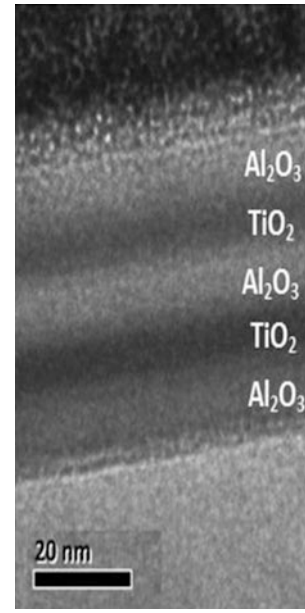
Currently studied high-k materials involve oxides of both transition or lanthanide metals and their alloys, including representative transition metal oxides such as TiO_2, Al_2O_3 [9, 10], and HfO_2 and rare-earth oxides, such as La_2O_3 and Y_2O_3. For applications of solid state supercapacitors in microchip-embedded devices, the higher the dielectric constant, the larger the energy can be stored. Excellent candidates as high dielectric materials include single oxides (e.g., HfO_2, ZrO_2, Ta_2O_5, TiO_2), binary oxides (e.g., $Ti_xAl_{1-x}O_y$, $Hf_xAl_{1-x}O_y$), and perovskite oxides (e.g., $BaTiO_3$, $SrTiO_3$).

By combining and complementing the desirable properties from several materials, ALD-enabled nanolaminates of alternating high dielectric constant (k) and wide bandgap (Eg) materials, theoretically, can achieve low leakage, higher breakdown, and a very high dielectric constant based on the Maxwell–Wagner (M-W) interfacial dielectric effect [10, 11]. When we adapt the analogy of the M-W approach, we can apply electron injection and charge accumulation, as in a depletion region, in a nanolaminate stack of wide bandgap (Al_2O_3) and high-k (TiO_2) material. A negative bias is applied to a Si substrate, and there is enhanced electron tunneling through the Al_2O_3/TiO_2 nanolaminate dielectric stack as indicated by the solid red line in Fig. 1. The electrons reach the interface at a lower E_f and cause higher leakage and low breakdown. When we apply the negative bias to the TiN, there is less direct electron tunneling, because the barrier height of the Al_2O_3 at 8.8 eV is 5.3 eV higher than the TiO_2 (3.5 eV); therefore, it is probable the leakage will be lower and the breakdown higher.

In 2007, Shi at al. proposed a configuration in which Al_2O_3 and TiO_2 have been investigated as high-k materials to replace SiO_2 as a gate oxide and a high-capacitance oxide-based capacitor for electronics [9]. High dielectric constants, in the range of 100–1,000, were achieved with planar Al_2O_3/TiO_2 nanolaminate layers [10, 11], as those featured in Fig. 2. Argonne National Labs investigated these Al_2O_3/TiO_2 nanolaminates, and results for dielectric constant measurements approached a k of 1,000 [12]. In an effort to reduce leakage and expand the range of operation, an interfacial Al_2O_3 layer was deposited prior to the top electrode. The Al_2O_3/TiO_2 nanolaminates on Si were compromised by charge injection. It should be noted that interfacial behavior dominates the ability of the multiple material lamina to reach peak performance.

Nanolaminate interfaces can be between materials of distinct properties, and in designing the laminates, the selection of materials should consider these properties, such as modulus, permittivity, conductivity, bandgap, and dielectric constant. Particularly, interfaces with structural defects, e.g., voids, cracks, and delamination, can lead to very leaky/lossy devices. Even though these defects may not propagate throughout the nanolaminate stack, but be localized, there could still be impacts on device performance.

In addition to alternating nanolaminates in a planar configuration, an alternative way to achieve high-capacitance capacitors is to increase



Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 1 Energy band diagram of nanolaminate stack of Al_2O_3/TiO_2 with the Maxwell–Wagner effect (Reproduced with permission from AIP Publishing LLC [10])

the effective surface area by fabricating 3D structures, such as porous structures with high aspect ratios, or trenches. The formation of high-aspect-ratio nanostructures can be attained through the use of non-lithographically self-organized nanotemplates, such as porous anodic aluminum oxides (AAO) [13]. Nanostructured electrodes for electrochemical double layer capacitors were fairly effective in enhancing capacitance, which was attributed to an increase in the surface areas [14].

Energy storage technologies span from conventional capacitors to batteries, inclusive of a region of supercapacitors. Supercapacitor technology has emerged with the potential to enable major advances in energy storage by utilizing higher-surface-area electrode materials and thinner dielectrics to achieve capacitances several orders of magnitude larger than conventional capacitors [2].

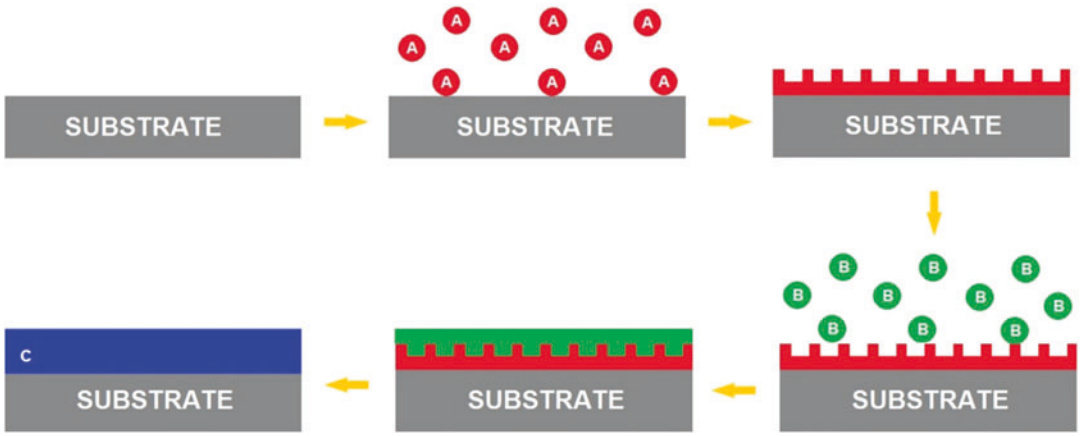
In principle, supercapacitors have higher power density than batteries and a charging time

Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 2 Cross-sectional TEM of alternating Al_2O_3 and TiO_2 nanolaminates

that is ten times shorter than a battery [1, 2]. However, supercapacitors are not as efficient as batteries in energy storage, as they tend to draw high leakage current. Despite this drawback, supercapacitors can be fabricated to make their energy densities more comparable to batteries; high energy density can be achieved when the ratio of the effective surface area to the electrode volume is high.

A combination of two processing techniques can be used to enhance surface-to-volume ratios, atomic layer deposition (ALD) and anodic aluminum oxide (AAO). Arrays of nanocapacitors using ultrathin oxide layers or nanolaminates can create a high-power-density energy storage device. It is worth noting that this combination of self-assembly, ordering, uniformity, and conformality on a nanoscale level is extremely advantageous for future ICs.

Key Processes



Atomic Layer Deposition (ALD). ALD is the technique of choice for depositing highly conformal thin films and enabling nanoscale device fabrication. The benefits of ALD are its unique ability for depositing ultrathin films on complex-shaped substrates with a thickness control at the atomic level and high conformality [15, 16]. Other processes used for nanolaminate formation include physical vapor deposition (PVD), dip coating, doctor blading, spray deposition, Langmuir–Blodgett, or chemical vapor deposition (CVD) methods. PVD methods, inclusive of evaporation and sputtering, have limited ability to coat structures with high aspect ratios and poor step coverage. CVD methods have problems with gas-phase reactions and impurities that interfere with nucleation or form defect voids during material growth. The ALD deposition technique is based on surface self-limiting reaction and deposition occurrences through alternating exposure of precursors and reactants, which provides precise control of the deposition thickness, even in ultrathin films and high-aspect-ratio holes and trenches [15–17]. As trench aspect ratio development continues to increase from 1:25 to greater than 1:200, ALD remains the most effective technique for deposition into the trenches.

ALD has basic characteristics of self-assembly, in which the surface reactions drive atoms and molecules to arrange themselves into functional structures. The ALD film growth process takes place in cycles, one cycle consisting of the following five steps, which are repeated until the desired thickness is obtained: (a) a self-terminating reaction of the first reactant A (precursor exposure), (b) an evacuation or purge to remove the non-reacted reactants and reaction products, (c) a self-terminating reaction of the second reactant/precursor B, (d) an evacuation or purge, and (e) after the reaction being terminated and all the by-products removed, a formation of monolayer of material C (Fig. 3). It is obvious that the self-termination feature enables extraordinary control over film thickness and also quality (pin holes, defects, and clustering are strongly reduced due to the selective interaction at the A/B interface). Another central advantage is the ability to coat 3D features with a conformal layer [17, 18].

ALD has emerged in the semiconductor industry as the technique to deposit very thin, highly insulating (high-*k*) oxides to serve as dielectrics in trench capacitor structures. ALD has been successfully applied to the depositing of oxide materials, including insulators and other ultrathin metal-oxide films for device applications. Currently the most investigated materials are HfO_2, ZnO, TiO_2, and/or Al_2O_3, because of their electrical and mechanical properties. Furthermore, for nanolaminates, the material property of interest is the dielectric constant, k, and the bandgap, as seen in Table 1.

ALD has been used to process layer deposition of alternating high-k dielectrics (needed for high capacitor density) and wide bandgap material (needed for low capacitor leakage) stacks of TiO_2 and Al_2O_3 of 3 nm layer thickness. Leakage and charge storage are not only dependent upon the material composition but is directly impacted by the nanolaminate stack thickness as well. TEM of a TiO_2 and Al_2O_3 stack indicates good uniformity, no pin holes, or interface spacing, as in Fig. 4.

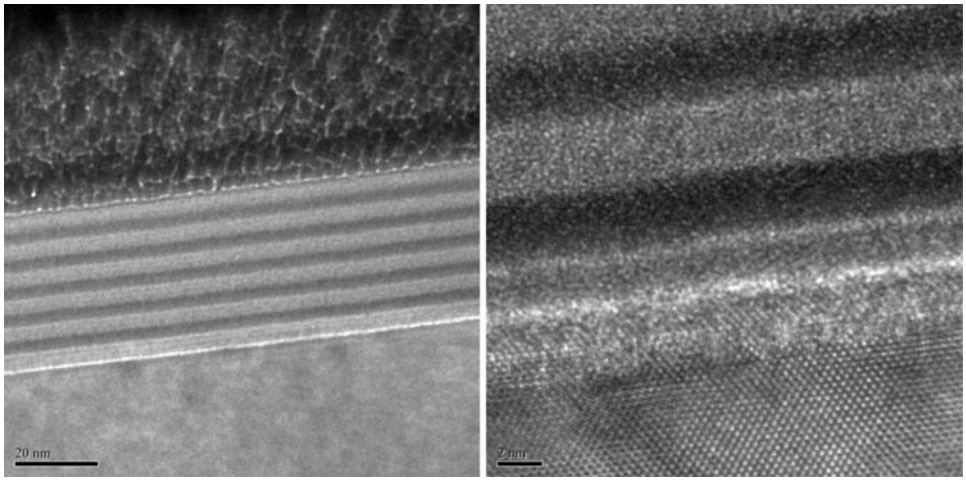
Aluminum Anodic Oxide (AAO) Processing. Anodization is an electrolytic

Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 3 Atomic layer deposition process illustrating the surface nucleation of thin film A and thin film B conforming to patterned layer

Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Table 1 List of ALD material parameters of high-k dielectrics

Materials	Dielectric constant	Bandgap (eV)	Growth rate (nm/cycle)
TiO_2	70	3.5	0.03
HfO_2	25	5.8	0.1
Al_2O_3	9	8.8	0.05
ZnO	2.5	3.33	0.08
AlN	9	6.2	

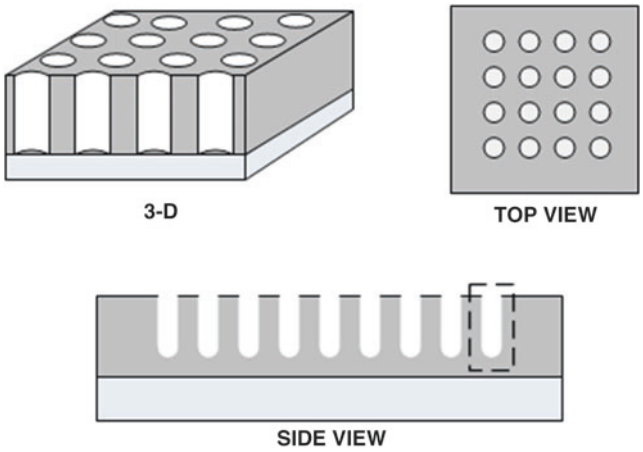
oxidation process in which the metal surface is converted primary to an adherent oxide coating having a desirable thickness and structure. Aluminum anodic oxide (AAO) templates, formed on aluminum by anodizing in acid electrolytes, are prepared following a chemical process. The AAO nanotemplates typically consist of densely packed high-aspect-ratio pores aligned almost perfectly to each other as in Fig. 5. The first published work in the field was Masuda et al. [13]. These papers describe the procedure to fabricate AAO pores on Al foil with ordered hexagonally parallel nanotubes using a two-step anodization technique.



Parameters governing the successful preparation of an ideal ordered porous structure are:

1. Anodization voltage and current, which determines pore diameter, cell dimension, and pore distribution. The voltage applied in the electrodes is constant during the whole process.
2. Electrochemical bath temperature.
3. Type and concentration of electrolyte.

A two-step anodization method is used to create AAO templates:



1. In the first step of the process, a thick porous alumina layer gradually grows over a very thin dense barrier oxide layer, which acts as an interface between the pure Al surface and porous alumina oxide layer. In the next step the pore array is created, which means that pore diameter is a function of the first anodization. Also, AAO pore diameter increases linearly with the anodization time (characterization must be made in order to find the limiting time in which the ordered array starts to dissolve).
2. The porous oxide layer that is formed is removed and leaves behind an ordered concave textured structure on the surface. The second step begins the Al anodized process again under the same conditions. This acts on the concave sites and forms a deep uniform pore growth, which means that pore height is a function of the second anodization.

The AAO template allows controllability of inner pore distance, pore diameter, and pore depth by changing the anodization conditions. A large-area AAO template can be generated

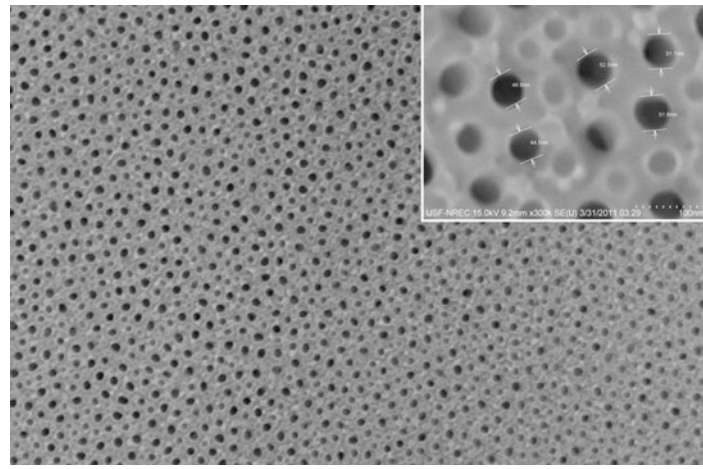
Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 4 ALD stacks of Al_2O_3 (*white*) and TiO_2 (*dark*) of 3 nm thickness

Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 5 Schematic layout of ideal AAO porous structure

using pure aluminum (99.99 wt% pure metal) foil of 0.1 mm thickness. Aluminum foil can be ultrasonically cleaned in ethanol and methanol and dried at 100 °C. Using a solution of phosphoric acid H_3PO_4 (85 wt%), sulfuric acid H_2SO_4 (98 wt %), and water H_2O (2:2:1 by volume), the foil needs to be electrochemically polished at a constant voltage of 10 V for 14 min at room temperature to remove micro-roughness from the surface, which can affect the final quality of the films. A solution of 0.3 M oxalic acid (C_2H2O_4) can be used to perform an initial anodization at a voltage of 40 V for 90 s. After anodization the aluminum template may exhibit a surface roughness due to the internal stress of the different atoms during the anodization process, which may lead to a defective formation of the structures in the porous alumina template. The as-prepared AAO template is placed in an aqueous mixture of phosphoric acid (6 wt%) and chromic acid (0.2 M) to remove anodic oxide formed in the initial anodization. Table 2 gives processing details to be used to form an AAO template. Finally, the sample can be further anodized under the same conditions as the initial anodization for 1 h to create deeper pores of high aspect ratio as in Figs. 6 and 7.

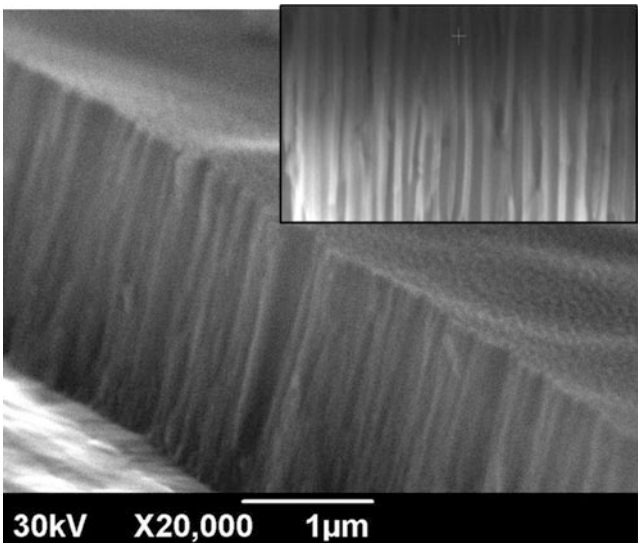
Since aluminum foil is a very flimsy substrate material, it is very difficult to go through the photolithography process without bending/damaging the AAO template. In order to fabricate devices on the AAO templates, an anodic bonding technique should be used to attach the aluminum structure to a borosilicate glass [19] as in Fig. 8.

High-purity, mechanically polished aluminum foils (99.99 % metal basis) and borosilicate glass are recommended. Aluminum pieces can be mechanically polished using alumina particles of 1 μm diameter. The pieces are then ultrasonically cleaned with methanol and dried at 100 °C. To secure bonding, the Al/glass are set between two plates of stainless steel (electrodes) and heated to 380 °C. After reaching the desired temperature, a dc voltage of 950 V was applied for 20 min. Subsequently, the setup is cooled down to room temperature to avoid cracking of the glass.



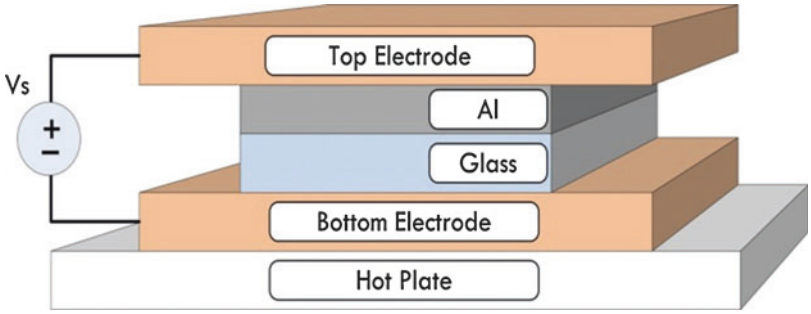
Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Table 2 Processing parameters for AAO template

Process parameters	**Range/ values**
Voltage – determines pore diameter, distribution	35 ∼ 45 V
1st anodization time – contributes to pore size and cell dimension	90–120 s
2nd anodization time – contributes to pore size and cell dimension	1 h
Pressure	Atmosphere
Temperature	RT
Electrolyte mixture	**Range/ values**
Phosphoric acid – contributes to the removal of anodic oxide	6–8 wt%
Chromic acid – contributes to the removal of anodic oxide	0.2 M
Oxalic acid – contributes in the initial formation of pores	0.3 M



Photolithography Processing (PR). A five-level mask can also be used to fabricate nanocapacitors using alternating nanolaminates. Test structures on the mask set are necessary to characterize and analyze the nanocapacitors of planar and trench configuration per Fig. 9.

A top-down view of planar nanolaminate capacitors can be seen in Fig. 10.



A deep reactive-ion etching (DRIE) system can provide advantages when used for the processing of high-aspect-ratio trenches. The DRIE has the ability to efficiently etch vertical structures in Si wafers with high aspect ratios. DRIE technology is based on the Bosch process, which uses high-density plasma to alternatively etch silicon. Some of the DRIE process advantages include high resolution and cleanliness, process control, use of small amounts of chemicals, and the avoidance of handling acids and solvents. However, in some structures, there can be a residual etch-resistant polymer that remains on the sidewalls, which could impact the trench width uniformity throughout the depth of the trench. SEM or TEM of a

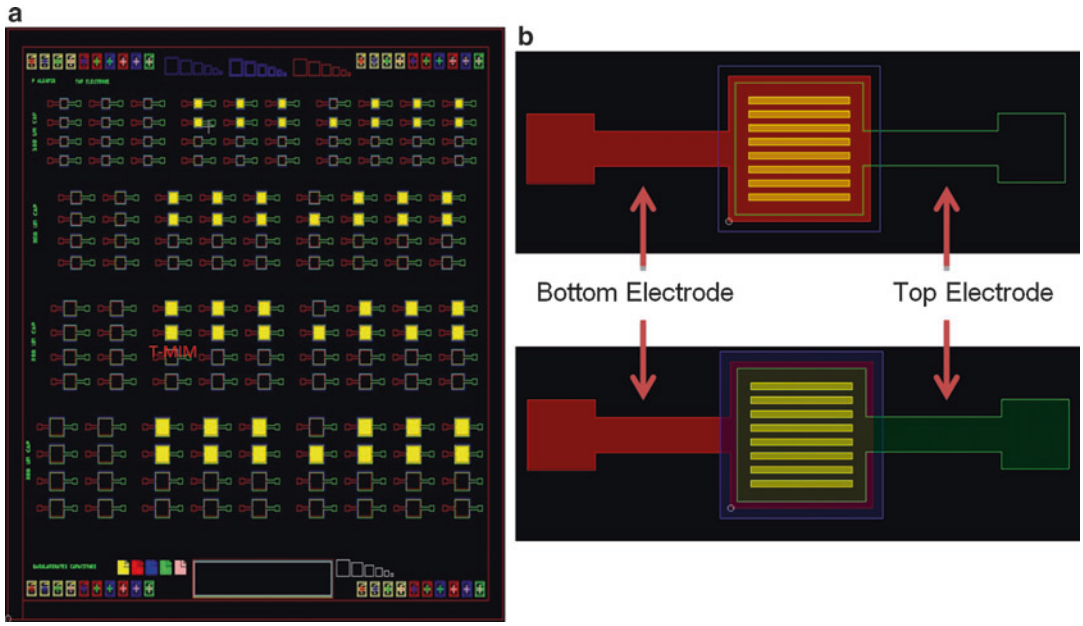
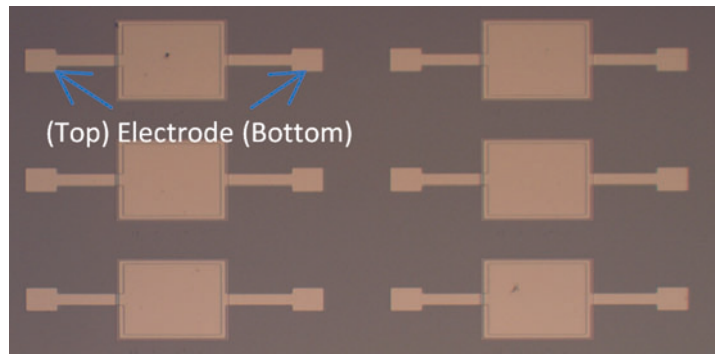
Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 7 Cross-sectional SEM image of aluminum foil after two-step anodization process (pore height ~2 µm)



Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 8 Schematic of anodic bonding setup

cleaved etched wafer can provide measurements to determine aspect ratios. Figure 11 shows high AR trenches fabricated in Si ranging in width from 5 microns to 11 microns and in height from 65 microns to 90 microns.

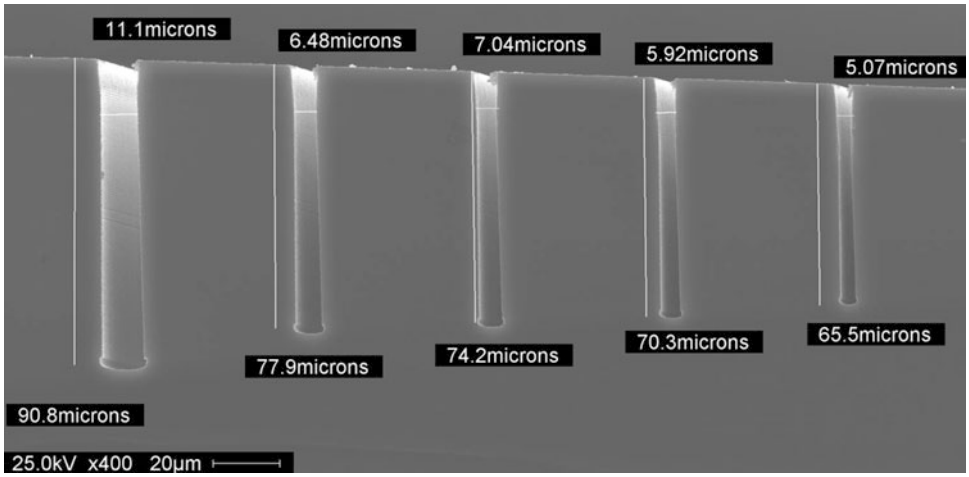


Future Directions

Nanolaminate development for nanocapacitor structures requires the integration of multiple disciplines, from materials to physics to chemistry to engineering. Since nanolaminates capitalize on superior properties of each lamina, these structures have the potential to serve as the basis for the next-generation energy storage devices that make use of densely packed interfaces (multilayer/nanolaminates) and have the capability of delivering power to renewable energy sources. These nanostructures are becoming increasingly important for ICs due to properties such as high surface area and downscaling of the technology (achieving densely packed structures from thin films).

When fabricated within a high-aspect-ratio template (AAO or PR processing) using ALD nanolaminates, nanocapacitors filled with alternating high-k and wide bandgap materials will have the ability to simultaneously achieve high capacitance density, high breakdown voltage, and lower leakage current, as compared to a planar capacitor or single layer filled trench capacitor.

Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 9 (**a**) Top-down view of nanocapacitor layout with test structures. (**b**) Layout of bottom electrode (*red*), top electrode (*green*), and trench design (*yellow*)



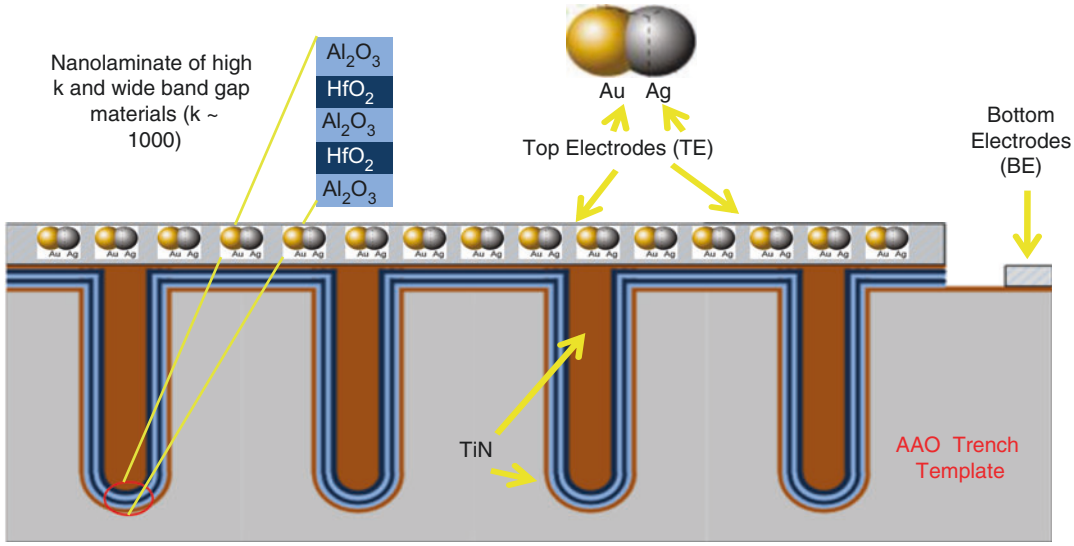
Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 10 Top-down view of patterned nanolaminate stack

ALD processing of trench-refilled capacitors have shown an incremental increase in the capacitance per unit area of 10 μF cm^{-2} and 100 μF cm^{-2} [4]. This significantly exceeds previously reported values for capacitors in porous templates [14].

Nanocapacitors with ALD nanolaminates enhance surface-to-volume ratios, improve energy storage properties, and maintain high power density. As systematic research and development continues, the fabrication of nanolaminates opens a new way to fabricate high dielectric constant materials for energy storage applications.

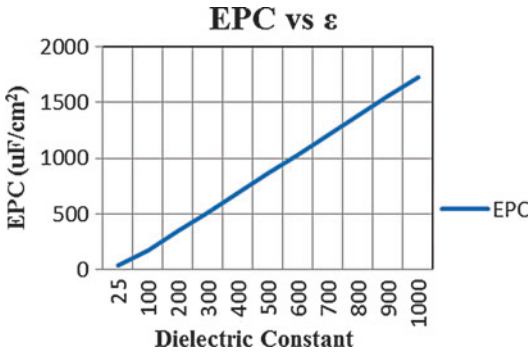
Creation and implementation of nanolaminate nanocapacitor structures has the potential to transform the life span and cost efficiency of energy storage devices for global solutions by 10 times. ALD and AAO technologies can address the current challenge of material reliability/durability, lower processing cost, and novel utilization of alternating nanolaminates in a trench structure. The high payoff for energy storage will improve

Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 11 Trench etch using DRIE of 2,400 W RF power



current equivalent planar capacitance (EPC) performance of existing supercapacitors by one order of magnitude from 100 μF cm^{-2} up to ~1,000 μF cm^{-2} using a high-aspect-ratio nanolaminate trench design. EPC can be estimated knowing the dimensions of a porous AAO structure and the thicknesses of the bottom electrode and nanolaminate (insulator) layers.

It has been studied that supercapacitors that use very large surface area electrodes have increased capacitances. The capacitance and energy density of a supercapacitor scales linearly with electrode surface area. Most of the work has been concentrated on the use of carbon-based materials in electrochemical supercapacitors. Carbon-based materials, like graphene, which is conductive, noncorrosive, thermally stable, inexpensive, and potentially high in surface, have been used as electrodes. Gomez et al. used a graphene nanocomposite to achieve a capacitance of 300–500 F/g. Other forms are carbon aerogels, carbon nanotubes, and carbon black particles. Therefore, a carbon-based material that has large surface area, such as graphene, may increase capacity. Two issues that must be addressed include high-temperature processing of the carbon-based materials and conformality.



In an effort to implement enhanced electrodes that will conform to a nanocapacitor nanolaminate structure, ALD processing of metal electrodes can be performed. Several materials can be considered as potential choices to be used in fabricating the electrodes, such as platinum (Pt), nickel (Ni), aluminum nitride (AlN), ruthenium (Ru), titanium nitride (TiN), carbon nanotubes (CNTs), or nanoparticles.

Through the utilization of a trenched structure, nanolaminates, and enhanced metal electrodes, a trench metal-insulator-metal nanocapacitor structure can be achieved. Modeling the effect of area on the capacitance using geometrical parameters of the structure leads to the normalization of capacitance per planar area using the following EPC equation $EPC = D * \frac{2\pi\kappa\varepsilon_0 L}{In\left(\frac{b}{a}\right)} + \frac{\kappa\varepsilon_0}{t_i}$ where D is the pore density, k is the dielectric constant of the insulator, ε_0 is the permittivity of free space, L is the pore depth, and t_i is the thickness of the insulator. Constants, a and b, are dependent upon the thickness of the ALD layers and the radius of the pores [4].

Therefore, based on the EPC formula given for a capacitor formed using AAO pores, a calculated theoretical EPC value for a trenched configuration filled with alternating nanolaminates and having advanced electrodes (Fig. 12) can potentially yield a capacitor density up to ~1,000 μF cm^{-2} as presented in Fig. 13.

Implementing Alternating Nanolaminates in Trenched Energy Storage Systems, Fig. 13 Theoretical EPC values plotted as a function of dielectric constant (25–1,000) for trench capacitor of alternating nanolaminates

Challenges that persistent in the technology are the need for material modeling of inter- and intrafacial behavior at the molecular level, profiling of nanolaminate stack performance, and implementing inexpensive, scalable manufacturing of these versatile structures. When these challenges are met, technological advancements using nanolaminates will progress toward a new generation of nanocapacitors for 3D electronic device energy storage and implantable biomedical system-on-a-chip energy storage.

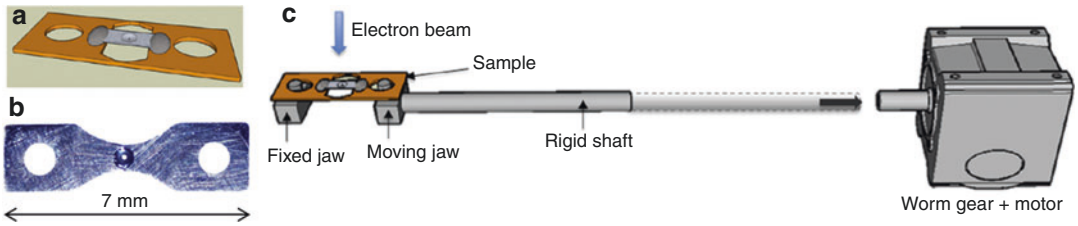
Definition

In situ transmission electron microscopy (TEM) mechanical testing is a technique used to measure the mechanical properties and behavior of small structures while simultaneously imaging them using a TEM.

Introduction

The transmission electron microscopy (TEM) is one of the most powerful tools used in materials science to unveil the structural and compositional properties of materials [1]. The coupling of conventional TEM with complimentary techniques, which are used to further investigate TEM samples directly inside the TEM chamber during imaging, has led to a broad field of "in situ TEM" that spans areas that include electrical, thermal, electrochemical, optical, and mechanical testing. The latter area of in situ TEM mechanical testing takes advantage of the high spatial resolution of the TEM to characterize strain and deformation in materials down to atomic scales, while providing measurements of force and stress acting on the samples under a number of different mechanical loading configurations. Although this field has been significantly expanded recently

due to advancements in the miniaturization of mechanical testing systems, the first implementation of this class of techniques was in the 1950s through the application of simple straining holders that enabled mechanical strain to be applied to materials while being imaged under the TEM electron beam [2]. For a comprehensive in-depth and historical review of the field of in situ TEM mechanical testing, the reader is referred to the recent review article by Legros [2].



Since its inception several decades ago, in situ TEM mechanical testing has made notable advances to enable quantitative mechanical testing configurations, which include (i) tension and compression, (ii) nanoindentation, (iii) bending, and (iv) friction and wear testing [3–5]. These various mechanical testing configurations, executed within the full view of the TEM, have enabled a detailed understanding of the mechanics of materials with micro- and nano-confined structures elucidating a number of size-scale phenomena. By conducting mechanical testing in situ TEM, researchers can take advantage of the many analytical materials characterization techniques allowed by TEM to study materials properties, such as local atomic resolution imaging of dislocations and defects, selected area electron diffraction (SAED) to identify crystalline structure, and x-ray energy-dispersive spectroscopy (XEDS) and electron energy loss spectroscopy (EELS) to identify local elemental composition and electronic structure [1]. Notable applications include the in situ TEM study of 1D nanotubes and nanowires [6], indentation of nanograined materials [4], deformation of 2D ultrathin films, tensile properties of carbon-based fibers, and tribology of hard coatings [7]. Toward advancing in situ TEM mechanical testing, a number of key challenges and limitations continue to be considered and addressed when developing testing techniques. These include constraints on sample size and geometry, electron beam-induced sample modification and deposition effects, electron beam energy constraints, limits on the rate of TEM image acquisition, and environmental limitations. For example, the traditional limitation of conducting TEM experiments only in a high-vacuum environment has been addressed recently by the emergence of high-resolution environmental TEMs as well as in situ TEM liquid cells for conducting experiments under a variety of controlled environmental conditions.

The following sections detail in situ TEM mechanical testing devices and characterization techniques as well as the most prominent mechanical testing modes and important mechanical phenomena that they have unveiled to date.

In Situ Mechanical Testing Devices and Techniques

A wide range of mechanical testing techniques have been developed to allow for tension, compression, indentation, shearing, and bending of materials in situ a TEM with real-time visualization of strains, dislocations, and deformation mechanisms. When forces can also be measured, these methods allow for fundamental understanding of the constitutive behavior of materials at the nanoscale.

Relatively basic mechanical testing has been performed in situ TEM imaging using traditional tensile stages where a sample is fixed at one end and loaded in tension by moving the other gripped end of the sample. One of the first in situ TEM tensile tests was performed on 300 μm thick aluminum foils by Wilsdorf. In these experiments, a TEM holder was modified such that a sample could be gripped between a stationary pin on the holder and a pin attached to a moving shaft internal to the shaft of the TEM holder [8]. The shaft could be driven manually by a screw device or through a hydraulic system allowing for the application of tension to a dogbone-shaped specimen (Fig. 1). While this setup provided for the first time the direct visualization of dislocations moving through a foil being deformed in situ the TEM, it did not allow for the measurement of forces. Gatan has since developed commercial straining holders that allow for the deformation of films clamped by pins at two ends, using screw-driven actuator to pull one side of the film, also with no direct measurement of force. In situ TEM tensile testing can also be conducted on 1D nanostructures, such as nanotubes and nanowires,

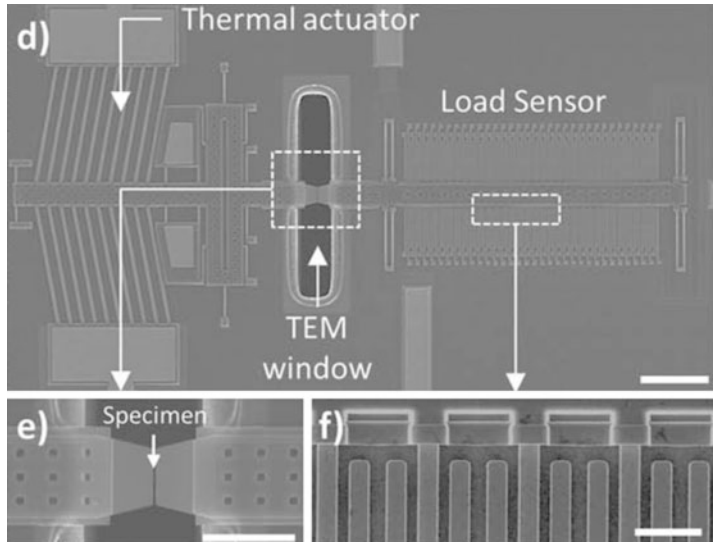
using in situ TEM 3-axis nanomanipulators (e.g., nanofactory) with integrated atomic force microscopy (AFM) like force sensors. These systems allow for the straining of the sample using a piezo-driven manipulator and the measurement of forces using either the direct measurement of deflection of the force sensor beam via TEM images or through electronic piezoresistive force sensor readouts. Similar in situ TEM manipulators with integrated scanning tunneling microscopy (STM) probes can also be used for in situ TEM friction and wear measurements.

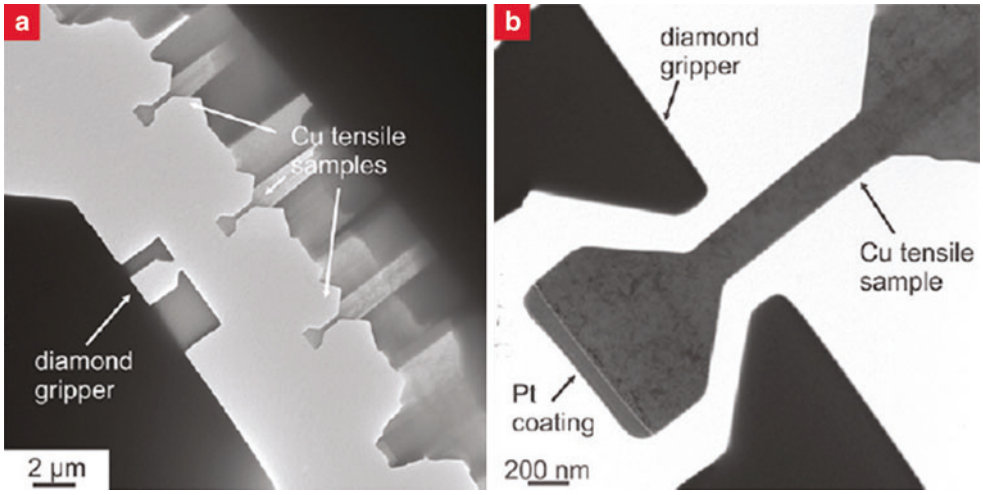
Both passive and active microelectromechanical systems (MEMS)-based devices have been developed to apply deformation to, and measure loads through, 1D and 2D materials. Haque and Saif developed MEMS-based devices consisting of opposing shuttles across which to mount a sample [9]. Tension is applied to the sample by connecting one end of the MEMS chip, and thus one shuttle, to a piezoelectric actuator. The other shuttle is connected to a set of folded silicon beams of known stiffness, fixed to the TEM holder. Sample displacements are measured by the relative motion of the opposing shuttles, and the forces are calculated by measuring the deflection of the folded silicon beams of known stiffness.



Lu and coworkers developed a push-to-pull micro-mechanical silicon-based device that converts the compression actuation of a nanoindenter to a tensile load on a sample of interest (Fig. 2) [10]. The device consists of opposing shuttles across which a sample is mounted. The shuttles are attached to oppositely pointing chevron beams, which are connected to an outer frame. Once the sample spans the shuttles, a nanoindenter compresses the outer frame, pushing the shuttles apart and applying a tensile load to the sample. The displacement can be directly measured in the TEM, and the force can be calculated by subtracting the force due to the stiffness of the device from the forces measured.

Espinosa and coworkers have developed two types of active MEMS-based tensile and compressive testing stages [6]. Both basic types consist of two opposing shuttles across which the sample is mounted. One of the shuttles is attached to a set of interdigitating combs that act as a capacitive force sensor, while the other shuttle is attached to an actuator. The actuator in one type of device types is an electotrostatic comb drive in which a voltage is applied between the stationary comb and the movable comb attached to the shuttle, in order to provide a displacement to the nanosample. The second type of actuator consists of chevron beams attached to the actuating shuttle (Fig. 3). The chevron beams are heated up via Joule heating as an electrical current is sent through the beams, causing them to elongate. For tensile loading, the chevron beams are pointed such that as they expand, they pull the shuttle away from the force sensing shuttle, and for compressive loading, they are pointed toward the force sensor so that as they heat up, they compress or indent the sample. Displacements on the order of 1 nm can be applied to the sample, with resolutions in load of approximately 12 nN depending on the stiffness of the force sensor.

Commercial TEM holders that allow for the indentation of samples or the application of



In Situ Transmission Electron Microscopy: Mechanical Testing, Fig. 2 SEM image of push-to-pull MEMS-based testing system. The sample is mounted across the two pointed shuttles highlighted in the inset. The nanoindenter is shown coming from the top of the image. When the nanoindenter moves downward and impinges on the top bar of the frame, the oppositely pointing chevron beams push the shuttles apart, applying tension to the mounted sample (Image from [10])

compressive loads in situ the TEM have been developed. Nanofactory developed a modified TEM holder that allows for indentation into a sample and the measurement of force through a micromachined two-plate capacitive load sensor [3]. However, in this configuration the depth of the indenter is not calculated. Hysitron developed a commercially available picoindenter. The sample is mounted to a fixed end of the holder, and the nanoindenter tip moves during the test. The holder has 3-axis coarse positioning as well as a three-dimensional piezoelectric actuator for fine positioning. The Hysitron design incorporates load sensing through a capacitive

(**b**) Higher-resolution TEM image showing the configuration of the sample and gripper before testing (Image from [11])

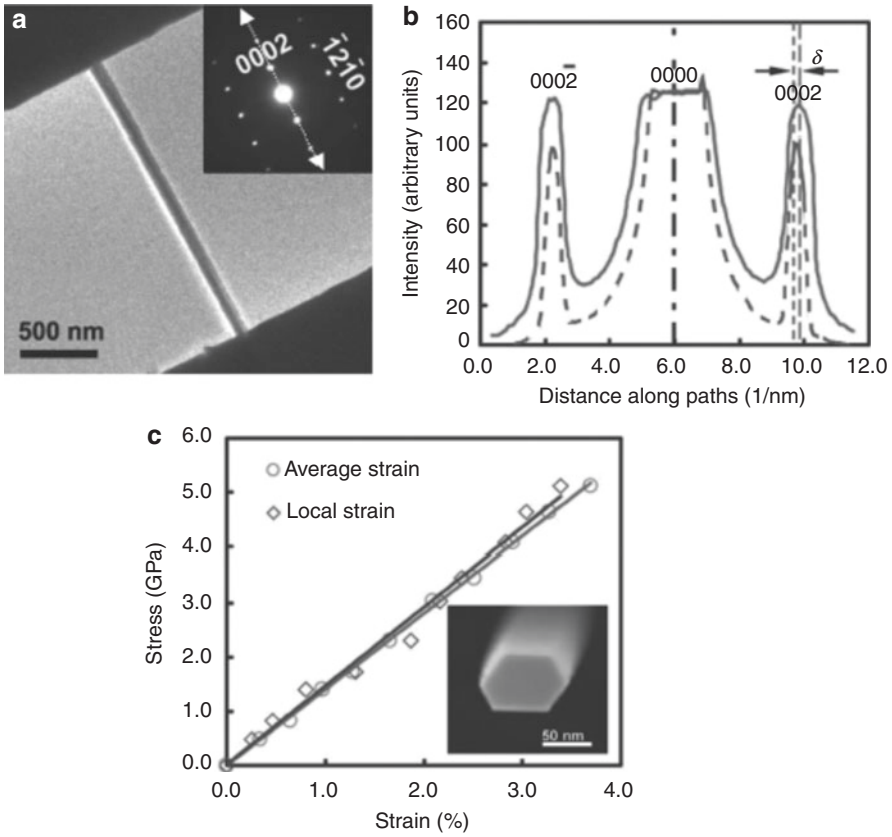
transducer, which consists of an electrostatic load generator to apply force and a capacitive displacement sensor that measures the depth into the sample that the tip has traveled [3]. Hysitron has also developed a push-to-pull MEMS-based device, which can be used to convert the compressive load of the nanoindenter into a tensile load across opposing shuttles. While these devices may be used to indent samples using traditional Berkovich-shaped tips, the tips can be replaced by flat punches to compress materials. In addition, Kiener and Minor modified the Hysitron nanoindenter tip using focused ion beam milling to machine a conductive diamond grip to engage and pull on the shoulders of a traditional dogbone-shaped tensile sample, allowing for the device to also be used to probe tensile properties of nanomaterials (Fig. 4) [11].

Indirect testing modes have also been used in situ TEM to measure mechanical behavior including beam-induced heating deformations and beam-induced resonating of suspended structures. The heating of the beam itself has been used to induce film bending, thereby applying strains. The first such experiment was performed by Hirsch, Horne, and Whelan in 1956, in which they watched dislocations move through aluminum as their aluminum film was deformed due to thermal strains. The electron beam has also been used to induce resonant oscillations of nanostructures such as CNTs and nanowires. In this case, the amplitude of the oscillation of the free end of the nanostructure with one end fixed to the sample holder can be measured to determine the elastic modulus [2].

Simultaneous TEM Characterization Tools

One of the most beneficial aspects of in situ TEM mechanical testing is the ability to obtain high-resolution TEM (HRTEM) images of specimen under deformation during mechanical testing. This enables a direct identification of any changes in structure, the nucleation and movement of dislocations, the presence of defects, as well as fracture behavior. Figure 5 shows an example of HRTEM images recorded during the mechanical testing of a cold weld between two gold nanowires. The crystalline structure of both the gold nanowires and the cold-welded region between the two nanowires is clearly observed in the atomically resolved TEM images. The insets in Fig. 5 show fast Fourier transforms (FFT)

In Situ Transmission Electron Microscopy: Mechanical Testing, Fig. 5 HRTEM images of a cold-welded gold nanowire before (*left*) and after (*right*) mechanical pulling experiment to break the cold-welded bond between the nanowires. Scale bars: 5 nm (Images and caption adapted from [12])



calculated for the images revealing the diffraction patterns that can be used to identify the crystalline structure and measure the lattice spacing.

Diffraction of materials subjected to in situ TEM mechanical testing can also be obtained directly using selected area electron diffraction patterns collected by TEM. In this TEM mode, a parallel beam of electrons is passed through the sample and an aperture inserted in the electron beam path is used to select the area of the sample for which the diffraction pattern is desired. Local diffraction measurements of the specimen under study can be used to determine the crystalline structure and the lattice spacing and identify defects. For in situ TEM mechanical testing, local diffraction patterns can be very useful in particular for measuring the local atomic strain at different regions of the deformed specimen. Figure 6 shows an example of a local strain measurement conducted for in situ TEM tensile testing of ZnO nanowires [6].

Elemental and chemical analysis, as well as electronic structure, of specimen subjected to mechanical deformation can also be conducted using in situ TEM mechanical testing combined with XEDS and EELS [1]. XEDS detects the x-rays generated when the electron beam interacts with the sample allowing for the determination of the relative elemental constituents of the sample based on the characteristic energies of the emitted x-rays [1]. EELS, on the other hand, detects the energy distribution of electrons that have passed through a sample allowing for a determination of the chemical bonding and electronic structure of the sample by analysis of the spectrum of the electron energies and in particular the energy lost to inelastic scattering [1]. With application to in situ TEM mechanical testing, EELS has been used, for example, to study changes in the electronic structure of carbon-based nanostructures such as carbon nanotubes that are subjected to bending deformations [5]. EELS has also been used to identify changes in the ratio of sp^2 vs. sp^3 bonding in diamond-like carbon films subjected to mechanical sliding between a tungsten tip and the films in situ TEM [7].

Tensile Testing Applications

Tensile testing in situ TEM observation has been performed on a variety of materials including 1D nanostructures and 2D films, providing real-time observation of dislocations and deformation mechanisms with applied force.

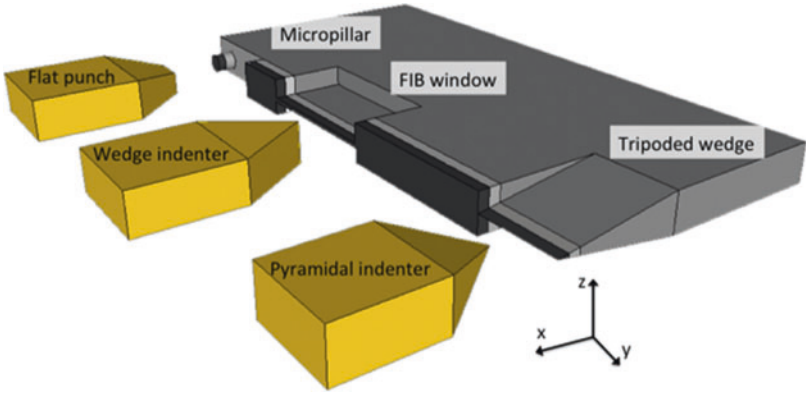
In Situ Transmission Electron Microscopy: Mechanical Testing, Fig. 6 Use of diffraction capabilities in the TEM to perform mechanical characterization. Figures (**a**–**c**) correspond to uniaxial testing of ZnO nanowires. Figure (**a**) shows the TEM image of the nanowire being pulled at two ends and its diffraction pattern. An intensity profile along the indicated path is shown in (**b**). The peaks indicate the position of the diffraction spot, which shifts by a reciprocal distance δ as a result of strain. Local strain can be computed from measurement of δ. Comparison of this local strain with the average strain (**c**) allows discarding slippage effects in the grips of the tensile testing device (Figure and caption adapted with permission from [6])

The commercial Gatan straining holder has been used to elucidate the deformation mechanisms in bulk metallic glass with dimensions on the order of 100 nm, showing that on this scale, these materials deform similar to crystalline materials. That is, they do not deform via the predominant shear banding or nanocrystallization seen in bulk metallic glasses, which have much reduced ductility with respect to their nanoscale counterparts [13]. It has also been used to investigate the deformation mechanics of freestanding nanocrystalline nickel films, showing that dislocation motion is the major mechanism for deformation, with evidence of dislocations in 20 nm grains [14]. MEMS devices have also been applied to study thin films. Haque and Saif co-fabricated MEMS devices and aluminum thin films to circumvent problems with sample transfer and mounting. With this technique, they measured the loading and unloading behavior of the films and experimentally showed reverse Hall–Petch behavior as the yield strengths decreased with reduced grain size [15]. They also noted the absence of dislocations in the samples with grain sizes of 50 nm or less, pointing to a possible grain boundary-based deformation and failure mechanism.

Tensile testing has been applied to a wide variety of 1D nanostructures in situ TEM including CNTs and metallic and semiconducting nanowires [6]. Cumings and Zettl performed

some of the first tensile experiments on single multiwalled carbon nanotubes (CNTs) by attaching a nanomanipulator to one end of a CNT and pulling the inner shells out. They did not measure forces but demonstrated that the inner shells could be pulled out and pushed back in multiple times without inducing damage in the CNT shells, concluding that the interactions between CNTs are low friction and wear-free [6]. MEMS-based tensile testing techniques have been used to measure mechanical properties and deformation mechanisms in 1D nanowires and nanotubes. For example, Lu et al. utilized their push-to-pull MEMS chip with a nanofactory nanoindenter to perform a tensile test on a single nickel nanowire, demonstrating the translation of their original tests in the SEM to in situ TEM testing to allow for acquisition of structural information. The MEMS devices developed by Espinosa et al. have also been used to conduct tensile testing on CNTs, CNT bundles, carbon nanofibers, as well as semiconducting and metallic nanowires [6]. Peng et al. used a MEMS-based testing stage to measure the strength of multiwalled carbon nanotubes (CNTs). Through the direct measurement of the CNT structures during testing, an average fracture strength of over 100 GPa for a single CNT shell was measured, which agrees with theoretical calculations for the strength of pristine CNTs [6]. In addition, a unique strain hardening mechanism was demonstrated for penta-twinned silver nanowires via in situ TEM observation of dislocation nucleation and propagation during tensile testing [6].

Ultrathin 2D films have also been recently studied via in situ electron microscopy tensile testing. Zhang and coworkers measured the fracture toughness of graphene [16] using a MEMS-based device similar to that described in [10]. They performed in situ scanning electron microscope (SEM) tensile tests on graphene that had been pre-cracked by micromachining a crack using FIB, showing that Griffith's fracture theory of brittle fracture applies to graphene, whose fracture toughness was measured to be 4.0 ± 0.6 MPa $\times$ $m^{0.5}$. Although the tensile experiments were performed in the SEM, imaging in the TEM was critical to confirm the structure of the graphene on the device and to determine when monolayer or bilayer graphene was tested [16]; furthermore, the approach for testing 2D films can, in principle, be extended for direct in situ testing in TEM.



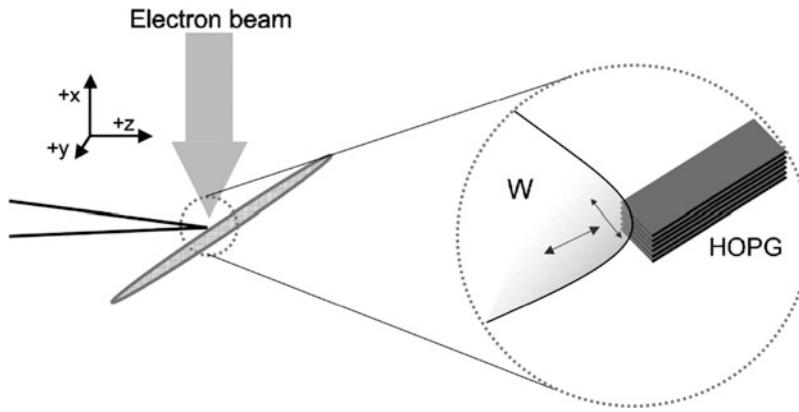
In an alternative tensile testing configuration, by using an adapted Hysitron nanoindenter in which the indenter tip was machined to interface with tensile samples, Kiener and Minor deformed 100–200 nm copper single crystals in two different orientations [11]. They showed that in the sub-micrometer size range, spiral defect sources were operational as was the gradual loss of defects, and both contributed to the hardening behavior of the single crystals. This was contrary to prior studies that proposed either one of the two mechanisms as possible hardening mechanisms, but not both simultaneously.

Indentation/Compression Testing Applications

Indentation and compression testing has been performed using nanoindentation of pillars, local indentation of films and grains, and compression of spherical particles (Fig. 7).

The pioneering micropillar compression tests were performed by Uchic et al., on 0.5–40 μm diameter pillars of nickel and nickel alloys in the SEM using nanoindentation. In this work, they clearly showed a size dependence of plasticity [17]. This work has since been extended to micro/nanopillars in situ the TEM to further elucidate size-dependent plasticity behavior and deformation mechanisms at even smaller length scales.

Shan and coworkers performed compression of nanopillars of nickel, which had diameters on the order of 100–200 nm. Using a TEM holder with a capacitive displacement sensor, they were able to correlate features in the compressive stress–strain curve with real-time experimental observations of dislocation motion. They showed that mechanical annealing was present, meaning that as mechanical force was applied, dislocations left the pillars, resulting in dislocation-free structures. Subsequent deformation was irregular as dislocation sources were activated and then



In Situ Transmission Electron Microscopy: Mechanical Testing, Fig. 7 Configurations for indentation of pillars using a flat punch, and thinned bulk materials, or films using a wedge indenter or pyramidal indenter (Figure adapted with permission from [2])

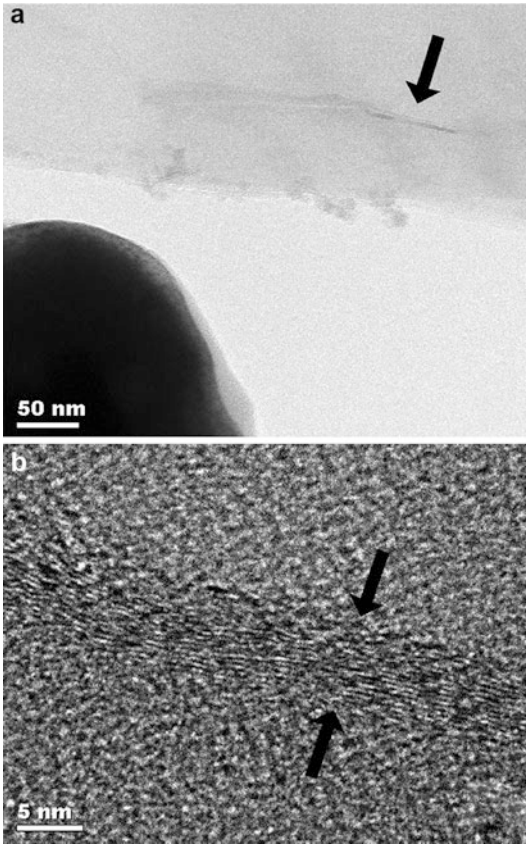
exhausted. Yu et al. performed compression tests on titanium alloy single crystal pillars and showed that deformation twinning was the dominant mechanism until the sample size decreased below 1 μm, at which point deformation twinning was no longer active and dislocation plasticity dominated the deformation [18].

Although a great deal of the in situ TEM indentation studies has focused on pillars, several other structures have also been studied. For example, Deneen and coworkers used a custom nanoindentation holder to perform in situ compression of silicon nanospheres, where they clearly visualized elastic, plastic, and fracture behavior of the silicon [19]. Minor and coworkers performed nanoindentation on individual grains in polycrystalline aluminum [20]. By measuring the forces and directly visualizing dislocations, they found that the submicron aluminum grains that were plastically deformed through nanoindentation to a nonzero dislocation density of approximately 10^{14} m^{-2} were able to support shear stresses approaching the theoretical shear strength of aluminum. These results are in stark contrast to the previously held understanding in mechanics that in order to achieve theoretical shear strengths, a material would need to be dislocation-free.

Friction/Wear Testing Applications

One of the greatest challenges in studying friction and wear of single asperity contacts at the micro- and nanoscale is obtaining a detailed knowledge of the size, geometry, and structure of the tribological contact. The application of atomic force microscopy (AFM) has enabled measuring friction forces and imaging surface wear tracks at the nanoscale; however, the shape, size, and structure of the AFM probe is not usually well known. In order to address this limitation, in situ TEM techniques have been developed that enable high-resolution imaging of a tribological contact before, during, and after sliding. The in situ TEM techniques for investigating friction and wear typically use a scanning tip in either a scanning tunneling microscopy (STM) or scanning probe microscopy (SPM) configuration within the TEM chamber. This allows for a feedback signal that controls the interaction between the tip and surface to establish contact and, in the case of SPM, measure the forces acting on the tip during sliding. Of the two configurations, STM is the most straightforward to implement inside TEM as it utilizes a ridged tip and only requires electrical measurements of the tunneling current between the tip and sample. While it does allow for TEM imaging of a sliding contact, it cannot provide quantitative lateral force measurements. SPM, on the other hand, can provide quantitative force measurement; however, the force sensors are more difficult to integrate into the TEM chamber. In particular, beam deflection AFM which is often used for ex situ nanoscale friction and wear measurements requires a flexible cantilever beam, four-quadrant photodetector, laser beam, and optical alignment system to all be integrated into the small available space within

In Situ Transmission Electron Microscopy: Mechanical Testing, Fig. 8 STM-TEM holder schematic. A tungsten STM tip is shown on the left in contact with a graphite (HOPG) sample with the contact region exposed to the TEM electron beam. Nanomanipulation allows for microstructural characterization during sliding and indentation (Figure and caption reproduced with permission from [22])



the TEM chamber. While technically difficult, beam deflection AFM in situ TEM has been achieved with dedicated instrumentation [21]. In addition, the application of in situ TEM friction and wear studies requires overcoming the key challenge of having an electron transparent contact. This is accomplished by orienting the contact at an angle with respect to the TEM electron beam and utilizing thin samples as can been seen in Fig. 8.

In situ TEM STM can be used to study the friction and wear of a number of materials including, but not limited to, graphite, diamond-like carbon, and metal films [5, 22]. Figure 9 shows an example of an in situ TEM friction and wear study conducted on graphite. The sharp tungsten STM probe is used as a sliding contact on the graphite surface. Figure 9a shows the sharp tip and a wear track on the graphite samples after 100 cycles. The great benefit of high-resolution in situ TEM imaging is demonstrated in Fig. 9b which shows a TEM image of the same wear track in which the layered atomic structure of the graphite sample is revealed. Metal thin films and diamond-like carbon films studied in situ TEM using the same STM techniques have also shown evidence of mechanical sliding-induced structural changes. In the case of polycrystalline metal films, in situ TEM sliding can result in recrystallization and grain growth, whereas sliding on diamond-like carbon films can result in graphitization of the carbon films which changes the tribological properties [7].

As mentioned above, in addition to qualitatively investigating friction and wear in situ TEM, quantitative force measurements of sliding contacts can also be achieved using integrated force sensors. This has been achieved by both AFM force measurements in situ TEM and MEMS-based force sensing in situ TEM. Beam deflection AFM has been used to measure the lateral forces acting on sliding contacts (e.g., Si-Si contacts) in situ TEM for which the contact size and sliding distance can be directly measured from the simultaneously recorded HRTEM images [21]. Despite the limited progress to date quantitative friction and wear testing, in situ TEM remains a promising area for further technological development.

Future Directions for Research

New directions of in situ TEM mechanical testing include extending the existing tools to additional mechanical testing configurations that are different to those already discussed above. For example, the

In Situ Transmission Electron Microscopy: Mechanical Testing, Fig. 9 In situ TEM friction/wear measurements of graphite. Bright field (**a**) and high-resolution (**b**) images of the wear track after 100 passes with the tungsten probe (Figure and caption adapted with permission from [22])

in situ TEM nanomanipulator-based techniques with integrated force sensors that have previously been used primarily for tensile testing have recently been utilized to study the interfacial properties layered 2D materials, such as molybdenum disulfide, via in situ TEM nanomechanical cleavage of atomic layers [23]. Further implementations of the MEMS-based testing devices described in the previous sections applied to 2D materials in situ TEM, which can characterize fracture properties, for example, are also desired. In addition to applying the techniques to other mechanical testing modes, there is a motivation to improve the functionality of the current testing configurations. Two particular directions that are of great interest are improving the temporal resolution of in situ TEM mechanical testing and controlling the testing configurations. With regard to testing configurations, in situ TEM MEMS-based tensile testers with integrated feedback control schemes are being explored, which would enable displacement controlled tensile testing of nanostructures. With regard to temporal resolution, one of the major current limitations for in situ TEM mechanical testing is that conventional TEM imaging is often restricted to ~1 ms temporal acquisition [24]. This can be a major disadvantage to in situ TEM mechanical testing as often deformations in the materials (e.g., the nucleation and propagation of dislocations) can evolve at very high rates. In addition, the slow capture of TEM images limits the capabilities of the technique to study high strain rate mechanisms, which can play an important role in the mechanics of many material types. Recent developments in dynamic TEM (DTEM) have enabled temporal resolution of TEM imaging on the order of ~1 μs to 1 ns between subsequent image captures for studying dynamic processes (i.e., nucleation/growth and phase transformation) which are envisioned to be integrated with in situ mechanical testing in the future [24].

Definition

Silver nanoparticles (Ag-nps): Any shaped particle that has silver as its majority constituent and one dimension ranging from 1 to 100 nm; its surface may be modified with intricate or conjugated complexes.

Nanotechnology has enabled the incorporation of silver nanoparticles (Ag-nps) into hundreds of products used as antimicrobial agents in both professional and personal healthcare fields. The quantity of Ag-nps produced annually is rapidly

increasing and fueled by the growing markets for products that incorporate them. This increased usage will lead to the accumulation of Ag-nps in the air, water, soil, and within organisms. Additionally, possible human and environmental toxicological risks associated with Ag-np exposure may arise during material fabrication, handling, usage, and waste disposal. For example, up to 100 % of the Ag-nps incorporated into socks to kill the bacteria associated with foot odor may leak out during washings [1]. These released Ag-nps have the potential to harm helpful bacteria in wastewater treatment facilities or endanger aquatic organisms in lakes and streams, and hand washings increase the risks associated with human interactions. Consequently, due to the increasing contact between these products and the human body, it is important to determine the potential risks Ag-nps pose in order to adequately impose policies and regulations on their product inclusion.

In the United States, the Environmental Protection Agency (EPA) regulates all self-identified antimicrobials under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). However, regulation is currently challenged by insufficient characterization and standardized test methodology due to the highly varied synthesis methods for Ag-nps. In an effort to assess current hazards, exposure and risk information pertaining to nanomaterials including Ag-nps, the European Union (EU) has established the project "Engineered Nanoparticles: Review of Health and Environmental Safety (ENRHES)." Regarding Ag-nps, the goal of both of these agencies is to consider the various sources, pathways of exposure, and impacts on health and the environment in order to generate information and data suitable for risk assessment. With this in mind, the aim of this article is to provide an overview of Ag-np uses, potential health hazards, in vitro and in vivo studies, mechanism of toxicity, and pharmacokinetics.

Evolution of Silver Use

In its bulk form, silver (Ag) has been used for thousands of years in jewelry, currency, dental alloys, and photography and, most importantly, as an antimicrobial agent. Ancient Phoenicians were known to place silver coins into their water jugs as a preservative. Until the advent of penicillin, solutions of Ag nitrate formed the mainstay of antibiotics, specifically efficacious for preventing bacterial growth in open wounds and burns. Even today, Ag sulfadiazine creams remain the standard of care in burn wards to place on a patient's denuded skin for the prevention of antibacterial infections. Solutions of microparticle colloidal solutions have been incorporated into water purification filters. At the nanoscale, the technologically important and unique magnetic, electrical, and optical properties of Ag have given rise to products for targeted drug delivery, diagnosis, detection, and imaging. However, the enhanced antibacterial activity of Ag at the nanoscale has been most valuable in the professional and personal healthcare fields through the incorporation of Ag-nps into hundreds of products, including surgical and food-handling tools, clothing, cosmetics, contact lens cases and toothbrushes, catheters, and even children's toys. In fact, according to the database of the Project on Emerging Nanotechnologies of the Woodrow Wilson International Center for Scholars, Ag-nps have consistently been identified as the most abundantly used material in all nanotechnology consumer products since 2006 and are still the most common in 2014 [2]. According to this database, the concentration of Ag-nps within consumer products from dietary supplements to cosmetics is in the range of <6–10,000 ppm. Currently, three trials on Ag-nps are registered as completed, and at least two are ongoing at the repository of clinical trials maintained at the National Institutes of Health (www.ClinicalTrials.gov). The completed studies have tested their benefits against the growth of microorganisms of a nanosilver-containing gel for hand cleaning (SilvaSorb®) and a central venous catheter embedded with nanosilver wall (AgTive®), as well as assessing the toxicity of ingested 10 and 32 ppm Ag-np solutions. Ongoing studies are focused on the incorporation of Ag-nps into fluoride dental rinses for the remineralization of teeth and reduction of dental biofilms in pediatric populations.

Silver Nanoparticles

As is the case for most nanoparticles, Ag-nps exhibit unique physicochemical properties that differ from, and provide distinct advantages over, those of their bulk metallic constituent. These augmented properties are likely due to the increased surface area to volume ratio at the nanoscale. A key reason for the ubiquitousness of Ag-nps is the ease of their generation which may be achieved by several different methods including spark discharging, electrochemical reduction, chemical reduction, solution irradiation, laser ablation, and cryochemical synthesis [3]. Depending on the method of synthesis, Ag-nps may take on a variety of different shapes such as spheres, rods, cubes, hollow tubes, multifacets, and films.

In its bulk metallic form, Ag is inert and exerts no biocidal action, but ionizes in the presence of water or tissue fluids to release antimicrobial Ag ions. Unlike other heavy metals, the speciation of Ag does not seem to play a large part of its toxicity; while Ag^{+} is highly reactive, the toxicity of Ag^{3+} or Ag^{2+} is unlikely due to the transient nature of these forms of Ag, particularly in an aqueous environment. Furthermore, there is no discernable difference between Ag ions released from nanoparticles and those generated by any other source such as through electrolysis or dissolution of ions from Ag salts. However, the rate of Ag ion production, as well as the distribution of Ag in tissue, may differ substantially between Ag-nps and other sources of Ag ions due to the ability of Ag-nps to release ions into specific tissues, cell membranes, or cells. Additionally, once a nanoparticle is located within a site, it has the ability for protracted release of Ag ions, thus increasing the potential toxic impact. Furthermore, agglomeration of multiple Ag-nps may change the rate of Ag ion offloading from their surface.

The driving force for Ag ion dissolution depends on the metal solubility within a given environment as well as the concentration gradient between the particle surface and the bulk solution phase. A nanoparticle with higher solubility such as ZnO may be more cytotoxic than one with low solubility, such as TiO_2 [4]. The rate of nanoparticle dissolution is considered to be proportional to the specific surface area, but additional factors such as surface curvature, roughness, nanoparticle aggregation, functionalization and surface modification, and the solution in which they are suspended may also be involved. Additionally, ionization of Ag or Ag compounds is enhanced by electric currents. In particular cases, it may be possible to moderate the dissolution of Ag-nps and their toxic effects via the coating on the surface [5]. Axiomatically, the functionalization and surface coating of Ag-nps will affect their endocytosis and exocytosis potentials and mechanisms, intracellular location, and agglomeration/aggregation status.

Antimicrobial Activity

Ag-nps are an effective killing agent against a broad spectrum of both Gram-positive and Gram-negative bacteria and also against antibiotic-resistant bacterial strains and a variety of fungi. Gram-negative bacterial species are responsible for nosocomial infections and include *Acinetobacter*, *Escherichia*, *Pseudomonas*, *Salmonella*, and *Vibrio.* Gram-positive bacterial strains include *Bacillus*, *Clostridium*, *Enterococcus*, *Listeria*, *Staphylococcus*, and *Streptococcus*. Antibiotic-resistant bacteria that have been killed by Ag-nps include strains such as *Enterococcus faecium* and methicillin-resistant and vancomycin-resistant *Staphylococcus aureus.*

The antimicrobial activity of Ag-nps may be explained by several mechanisms: (1) excessive binding of Ag ions and Ag-nps may prevent the uptake of essential nutrients to the cell, ultimately leading to cell death; (2) Ag ion entry into the cell by competitive binding with essential metals such as Ca^{2+}, Mg^{2+}, and Mn^{2+}; or (3) Ag transport and irreversible accumulation in the cell could occur by complexation with ligands or substrates. Once inside the cells, Ag ions can inhibit respiration or bind and condense DNA. Ultimately, the biocidal activity of Ag ions is likely caused by a synergistic effect between the binding of Ag ions to the cell wall, Ag uptake and subsequent accumulation in the cell, and Ag interference with critical biomolecules within the cell. The Ag ions released from Ag-nps, as well as the Ag-nps themselves, bind to the electron-donor receptors present on the

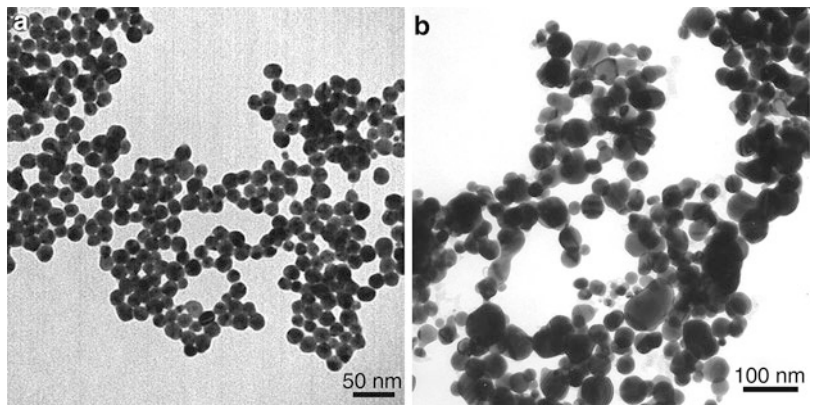
bacterial cell membranes such as disulfide, amino, imidazole, carbonyl, and phosphate. Inactivation of membrane-related enzymes like phosphomannose isomerase results in denaturation of the bacterial cell envelope and its functional capacity to regulate the inward diffusion of nutrients and limits the effusion of essential electrolytes and metabolites. The predominant intracellular effect of Ag probably lies in its ability to impair key intracellular enzyme systems by replacing trace metals and electrolytes, leading to defective respiratory pathways and RNA and DNA replication.

In a study by Samberg et al., Ag-nps of different sizes, surface conditions, and synthesis methods were evaluated in *Escherichia coli*, Ag-resistant *Escherichia coli*, *Staphylococcus aureus*, methicillin-resistant *Staphylococcus aureus* (MRSA), and *Salmonella* sp. [6]. The study yielded a range of minimal inhibitory concentrations and was based mainly on whether the Ag-nps solutions were contaminated by particle synthesis reducing agents. While freshly synthesized Ag-nps were toxic to all bacterial strains at concentrations between 3.0 and 8.0 ppm, the washed Ag-nps and the carbon-coated Ag-nps were toxic to all bacterial strains at concentrations between 64.0 and 1,024.0 ppm [6]. The results were supported by others that show size-dependent antimicrobial activity of Ag-nps with diameters ranging from 1 to 450 nm against both Gram-negative and Gram-positive bacterial strains [7]. In addition to size and concentration, shape-dependent antimicrobial activity of Ag-nps shows that between spherical, rod-shaped, and truncated triangular nanoplates, the truncated triangular Ag-nps displayed the strongest antibacterial activity [7]. The majority of the data suggests that most pathogenic organisms are killed in vitro at Ag ion concentrations of 10–40 ppm, with particularly sensitive organisms susceptible to 60 ppm Ag ions [8].

For maximal antimicrobial efficacy, it is therefore a critical function of Ag-nps to release a steady amount of Ag ions from their surface. Generally, the smaller the nanoparticle, the larger the surface area to volume ratio, which provides a more efficient means for antibacterial activity even at very low concentrations [9, 10].

In Vitro Toxicity

Ideally, the concentration of Ag-nps required to inhibit and eradicate microbial growth should be less than the concentration required for human cell cytotoxicity. The physicochemical and structural properties of Ag-nps play a major role in their interactions with cells, and variations in these properties among different Ag-nps may result in different toxicological effects. Therefore, it is strongly recommended that the physicochemical properties of Ag-nps, an important component of the study design, are reported in any risk assessment and health study. Manufactured Ag-nps have many physicochemical characteristics that include their size and size distribution, shape, surface area, porosity, zeta potential, solubility, crystallinity, purity, degree of agglomeration, surface functionalization (e.g., inorganic or organic coatings, etc.), surface chemical adsorption, and stability.



Several techniques that can be used to determine the size and size distributions of Ag-nps include atomic force microscopy (AFM), transmission electron microscopy (TEM), scanning electron microscopy (SEM), and dynamic light scattering (DLS). DLS may also be used to measure the zeta potential of Ag-nps. The size of Ag-nps is often reported from the nominal primary particle size as defined by the manufacturer. However, as was found in our study that investigated the cytotoxicity and inflammatory potential of Ag-nps of various sizes, synthesis methods, and surface conditions to human epidermal keratinocytes (HEK) in vitro and to porcine skin in vivo, as well as their antibacterial efficacy against a range of both Gram-positive and Gram-negative bacteria, the size of Ag-nps is not always correctly reported and may be observed in Table 1 [6, 11].

Due to various factors, Ag-nps tend to agglomerate in suspension and often have a larger hydrodynamic diameter when measured by DLS as compared to their physical diameter as measured by TEM. An example of a few of the Ag-nps investigated in previously mentioned studies may be observed in Fig. 1, and uniformity differences between Ag-nps of varying synthesis method may be noted [6, 11]. Therefore, it is

important to use multiple techniques to fully characterize Ag-nps prior to their testing. The Brunauer, Emmett, and Teller (BET) technique is useful in characterization by measuring the surface area and porosity of Ag-nps through the adsorption of gas molecules onto the surface of the nanoparticle.

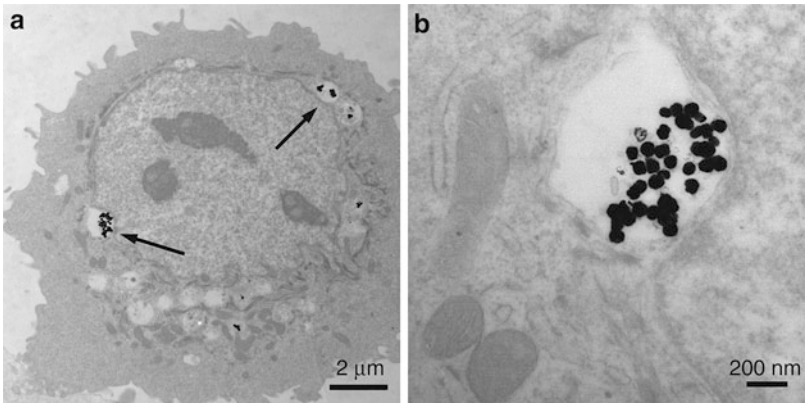
The most commonly used method to assess the cytotoxicity of Ag-nps is by cell viability. In general, the percentage of dead cells is directly proportional to the toxicity of Ag-nps. Cell viability assays are typically chemical based and depend on differential inclusion, exclusion, or conversion of a dye or dye precursor which can only be

enzymatically converted to detectable dye in living cells but not dead cells. In this case, the toxicity can be evaluated by quantitating colorimetric or fluorescent dyes that include MTT, MTS, 96 AQueous One (96AQ), alamarBlue, lactate dehydrogenase (LDH), Live/Dead, and neutral red assays. Since nanoparticles are capable of adsorbing chemicals onto their surface, they may interact and interfere with the ability of the assay dye to react appropriately and produce false results [12, 13]. Ag-nps above 1 ppm of various sizes and surface conditions were shown to interfere with MTT, 96AQ, and alamarBlue assays, with alamarBlue having the least interaction. Therefore, prior to initiating a study and selecting a particular assay as a viability biomarker, it is important to investigate any potential interactions between the nanoparticle and assay dye.

Presently, there is no consensus on the cytotoxicity of Ag-nps; however, the majority of publications do show reduced cell viability following Ag-np exposure. The variability of the cytotoxicity is linked to several characteristics, such as the synthesis method and purity of the Ag-nps, the concentration of released Ag ions from the nanoparticle, and the physicochemical properties of the nanoparticles such as size, shape, and surface functionalization. In vitro cell studies have demonstrated size-dependent Ag-np cytotoxicity and the generation of reactive oxygen species (ROS) and pro-inflammatory cytokines to various Ag-nps in a variety of human cell lines such as colon carcinoma, fibrosarcoma, skin carcinoma, lung fibroblast, glioblastoma, hepatoma, alveolar, and keratinocyte [7, 11, 14, 15]. Confocal laser scanning microscopy measurements confirmed what has been observed in many studies, that smaller Ag-nps ($\leq$20 nm) easily penetrated the cells causing significantly more damage, whereas larger Ag-nps ($\geq$40 nm) were only rarely internalized, resulting in lower toxicity [15]. Ag-nps of 20 nm were shown to be toxic to human hepatoblastoma C3A cells, following exposure to 2.5 $\mu g/cm^2$ for 24 h [16]. At sublethal concentrations, Ag-nps affected hepatocyte homeostasis by reducing albumin release and increasing mRNA expression of IL-8, IL-1RI, TNF-α, and intercellular adhesion molecule 1 (ICAM-1). Exposure of 15 and 100 nm Ag-nps to rat liver cells for 24 h at 5–10 ppm resulted in a significant decrease in mitochondrial function and membrane integrity. Additional toxic responses seen in vitro are glutathione depletion, mitochondrial changes, and destruction of cell membranes. However, Ag-np cytotoxicity does not always correlate to other stress-related effects. Contrary to other studies, exposure of human peripheral blood mononuclear cells to 1–2.5 nm diameter Ag-nps at $\geq$15 ppm for 72 h resulted in a decrease in proliferation but suppression of IFN-γ, TNF-α, and IL-5 [17].

Contaminants, stabilizers, or residual impurities created during the synthesis of Ag-nps, on their surface or in their surrounding solution, can significantly influence their cytotoxicity. Impurities may be the major contributor to the toxicity of the Ag-nps, which may cause misleading assumptions regarding the actual toxicity of the Ag-nps. Therefore, the purity of the Ag-nps should be evaluated using inductively coupled plasma-mass spectroscopy (ICP-MS) or high-performance liquid chromatography (HPLC). In the previously mentioned study by Samberg et al., freshly synthesized Ag-nps were shown to contain formaldehyde at 5.55 mg/ml in their solution and were solely responsible for toxicity in HEK [11]. In addition, an amorphous carbon matrix that effectively coated the Ag-nps was found to alleviate these cytotoxic effects.

The mechanism responsible for eukaryotic cell toxicity to Ag-nps is similar to the mechanism responsible for its antibacterial effects. It is likely to involve bound forms of oxidized Ag-nps on the surface of a target cell, the uptake and release of high concentrations of Ag ions into the cell and within cellular compartments, the disruption of integral cellular processes through catalytic or physical processes (such as protein or enzyme binding and subsequent denaturation), and the generation of ROS and induced oxidative stress. Under normal conditions, mitochondria generate ROS at low frequencies which are easily neutralized by antioxidants such as glutathione. The dissolution of Ag ions from the Ag-np surface is accompanied by the generation of ROS by disruption of the electronic and ionic flux, perturbation



of the permeability transition pores, and depletion of glutathione. A state of oxidative stress may occur and result in adverse biological consequences such as membrane and DNA damage, protein denaturation, and apoptosis. The Ag cations released from Ag-nps bind strongly to electron-donor groups of biological molecules containing sulfur, oxygen, and nitrogen. The Ag ion absorbed into cells induces synthesis of cysteine-rich metal-binding protein metallothionein. Ag avidly binds these proteins to form stable complexes. Increased metallothionein favors the uptake of the key trace elements zinc and copper which in turn promote RNA and DNA synthesis, cell proliferation, and tissue repair. Metallothionein thus provides a double action: to protect tissues against the potential toxic effects of a xenobiotic metal and to promote healing.

To define the mechanism of Ag-nps toxicity, the cellular uptake and subcellular localization of Ag-nps must be understood. The cytotoxicity may be caused by Ag-np cellular uptake and the subsequent interaction of Ag-nps with individual cellular components, which leads to cell malfunction and ultimately death. Because Ag-nps are electron dense, their localization within cells is easily observed using TEM without secondary staining. The cellular uptake of Ag-nps has been shown in many different cell types, with endocytosis as the primary mechanism for cellular uptake. Our study investigated the cytotoxicity, inflammatory potential, and cellular uptake into HEK following 24 h exposure to 25 and 35 nm carbon-coated Ag-nps, as well as to either freshly synthesized or thoroughly washed 20, 50, and 80 nm Ag-nps at concentrations ranging from 0.00054 to 1.7 ppm [11]. Although cytotoxicity was only observed for the freshly synthesized Ag-nps, small agglomerates of each of the Ag-nps were observed within cytoplasmic vacuoles. Another study showed that sets of naked or silica-coated Ag-nps ranging in size from 20 to 120 nm in diameter acquired different protein coronas depending on the serum proteins they were exposed to [18]. These coronas affected their uptake into HEK compared to control Ag-nps not exposed to serum proteins and bring to question how in vitro assays using naked Ag-nps should be interpreted relative to what would be expected to occur in vivo. An example of the endocytosis of 80 nm washed Ag-nps is seen in Fig. 2.

In Vivo Toxicity

Although in vitro toxicity studies are an important first step toward assessing the potential risks associated with Ag-np exposure, the test conditions in vitro do not correspond to the actual conditions within an organism and may lead to results that do not reflect the interactions that will arise in vivo. In vivo studies allow for the investigation of long-term effects of Ag-np exposure, systemic and local distribution in serum and tissues, retention, excretion, and any histological changes in tissues. Therefore, these studies provide more relevant information regarding Ag-np toxicity in humans that is not available through in vitro studies.

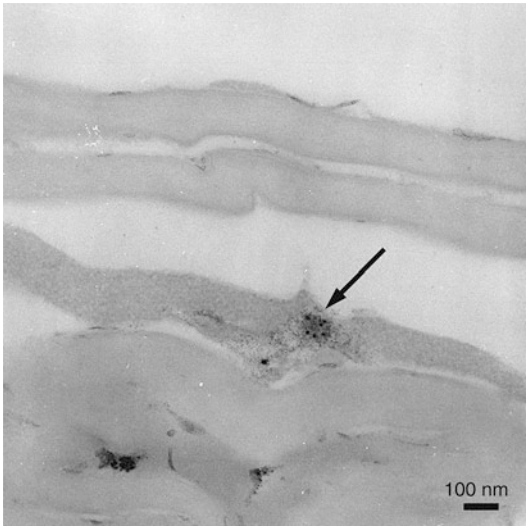
The wide variety of uses of Ag-nps allows exposure through various routes of entry into the body. Due to their size, Ag-nps have the potential to impact the respiratory tract, gastrointestinal tract, and skin and enter the systemic circulation or even the central nervous system. Target cell and organ uptake of various nanoparticles have been investigated recently, and it is indicated that several factors influence the ability of Ag-nps to produce toxic effects in vivo, such as their solubility, their ability to bind to biological sites, and the degree to which complexes are formed and sequestered or metabolized and excreted [9]. Theoretically, Ag can be deposited in any tissue of the human body, but the skin, brain, liver, kidneys, eyes, and bone marrow have received the greatest attention. Ag absorbed into human tissues from antiseptic respiratory sprays, implanted medical devices, wound dressings, or indwelling catheters can reach systemic circulation, primarily as a protein complex. The most common health effects associated with chronic exposure to Ag are a permanent gray or blue-gray discoloration of the skin known as argyria, found primarily in sun-exposed areas. Biochemical transformations in the body can affect Ag bioavailability, toxicity, and risk. Although chronic Ag ingestion produces argyrial deposits in the skin, it has been suggested that they are secondary particles and not translocated primary particles. For centuries, the prevailing view is that the use of Ag compounds

In Vitro and In Vivo Toxicity and Pharmacokinetics of Silver Nanoparticles, Fig. 2 Transmission electron micrographs depicting cellular uptake of Ag-nps into HEK: (**a**) 80 nm washed Ag-nps within cytoplasmic vacuoles of an HEK; (**b**) higher magnification of the 80 nm washed Ag-nps within the cytoplasmic vacuole. *Arrows* point to Ag-nps

and Ag-nps in products is safe, because Ag in any form has not shown toxicity or carcinogenicity to the immune, cardiovascular, nervous, or reproductive systems.

Ingestion is one of the primary routes for entry for Ag compounds, colloidal Ag, and Ag-nps. Ag-nps are routinely ingested as dietary supplements for the homeopathic treatment of allergies, arthritis, chronic fatigue, colitis, dermatitis, diabetes, gastrointestinal distress reliever, Lyme disease, pneumonia, shingles, skin cancer, sore throat, syphilis, tonsillitis, tuberculosis, and warts. Normal dietary intake of Ag from drinking water and trace amounts in foods is estimated at 70–90 µg/day. Additionally, Ag-nps may be introduced into the gastrointestinal tract after being shed from coatings on food-handling machinery or directly from Ag-nps sprayed onto produce for the prevention of food-spoiling bacteria [19]. The homeopathic ingestion of Ag-nps has led to various in vivo studies; generally, exposure to Ag and Ag-nps over time leads to distribution in various tissues without causing toxicity. Oral exposure to 10 ppm (5–10 nm, 100 µg/day) or 32 ppm (25–40 nm, 480 µg/day) of commercial Ag-np solution for 3–14 days did not cause clinical changes in human metabolic profiles [20]. Chronic symptoms from prolonged intake of low doses of Ag salts are fatty degeneration of the liver and kidneys as well as changes in blood cells [7]. IV injection in rats with 4, 10, 20, and 40 mg/kg of Ag found that the highest concentration of 40 mg/kg caused significant increases in liver enzymes and blood serum ROS levels and Ag-np deposition in the liver and kidney, concluding that a dose of >20 mg/kg was toxic to rats [21].

The respiratory system is a major portal of entry for Ag-nps. When inhaled, Ag-nps may be deposited in any region of the respiratory system, be taken into cells, enter the bloodstream, and circulate to potentially sensitive target organs. Inhalation of dusts or fumes containing Ag occurs primarily in occupational settings, such as industrial plants involved in Ag chemical manufacturing, jewelry manufacturing, Ag reclamation, and production of tableware. Due to the small diameter of Ag-nps, Brownian diffusion results in deep penetration of Ag-nps into the lungs and diffusion to the high lung surface area presented in the alveolar region. Several 28-day and 90-day inhalation studies with rats have demonstrated that inhalation of Ag-nps of approximately 15 nm resulted in slight increases in neutral mucins, with some hepatic necrosis and Ag-np accumulation in the lung and liver [7]. Oropharyngeal aspiration exposure to pristine Ag-nps at 20 µg once a week for 5 weeks showed an increase in neutrophils in the bronchoalveolar lavage fluid of mice. However, no adverse effects were found in mice



exposed to the same amount of Ag-nps embedded in a paint matrix [22]. Inhalation of 15 nm Ag-nps (179 μg/m^3) 6 h/day for 4 days in rats caused a 175-fold increase in neutrophils, an increase in cellular markers, a fivefold increase in cytokines, and a 1.5-fold increase in glutathione in the lungs 24 h postexposure, all of which disappeared by 7 days postexposure. In contrast, no adverse effects were observed after exposure to a similar mass of 410 nm Ag-nps (179 μg/m^3), suggesting a clear size-dependent effect after inhalation of Ag-nps [23].

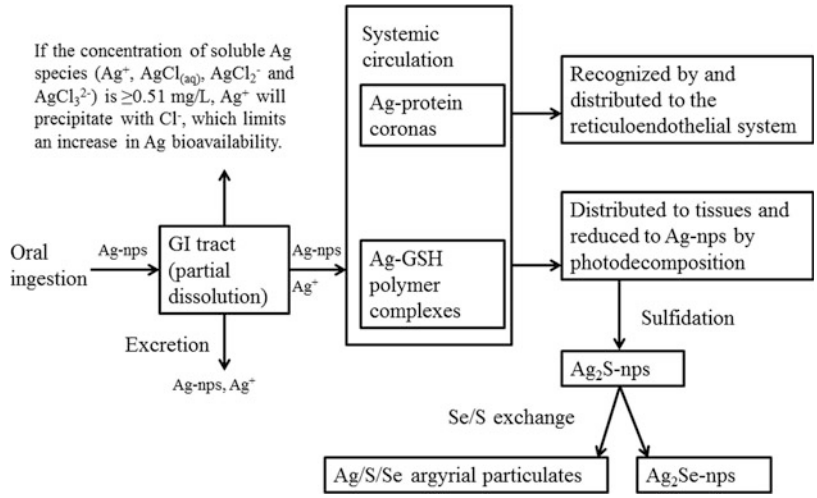
Another major route of exposure is the skin. Skin exposure to Ag-nps is particularly high due to their increasing inclusion into textiles, burn wound creams, jewelry, acupuncture needles, catheters, coatings onto high-contact surface areas, and disinfectant sprays. Although Ag compounds have long been used in wound dressings, the incorporation of Ag-nps into wound dressings is on the rise. The release of Ag ions from the wound dressings is generally triggered by wound fluids and tissue exudates. While it has been deemed that 10–40 ppm is required for appropriate antimicrobial action, the Ag content of dressings currently available varies from $<$0.1 mg/cm^2 to more than 1 mg/cm^2 with the amount of Ag ions released ranging from $<$1 to $>$70 ppm. Several studies have evaluated the toxicity of Ag from Ag-np-containing wound dressings and have shown elevated serum and liver enzyme levels as well as argyria [7]. However, absorption through intact skin is low ($<$1 ppm) since much of the free ion is precipitated as Ag sulfide in the superficial layers of the stratum corneum. Daily repetitive dosing for 14 days with both freshly synthesized and thoroughly washed 20 and 50 nm Ag-nps topically applied onto the backs of pigs showed Ag-np penetration only in the superficial layers of the stratum corneum [11]. Ultrastructural studies with TEM and confirmed by EDS detected Ag within the stratum corneum as observed in Fig. 3 [11].

When Ag-nps pass the barriers of the lung, intestine, or skin to reach systemic circulation, further tissue distribution may occur. Once Ag-nps reach systemic circulation and are exposed to biological fluids, they adsorb onto their surface amino acids, proteins, sugars, or salts within biological environments due to the surface reactivity of Ag-nps and may also undergo biochemical transformations. The adsorption of molecules onto the surface of Ag-nps influences cellular interactions and may also eliminate toxic potency of Ag-nps. Ag absorbed from the intestines accumulates in a transitory fashion in the liver, kidneys, brain, lungs, and bone marrow with minimal to no risk. Ag absorption from the gastrointestinal tract or from antiseptic sprays can accumulate in the cornea of the eye and skin to present as argyria in these tissues upon exposure to UV radiation. Argyrosis and argyria attributable to fine deposits of Ag metal or Ag sulfide are permanent, but not life threatening. Additionally, night vision problems, bowl pain, respiratory trouble, reduced creatinine clearance, and tarnished corneas have been associated with workers exposed to Ag dust [24]. In the liver and kidneys, Ag granules accumulate in the cytoplasm of phagocytic cells, hepatocytes, and renal tubular epithelium bound mostly in lysosomes. Ag is released into bile ducts and urinary ducts for excretion in the feces and urine, respectively. Greater concern relates to the influence of chronic Ag ingestion or Ag sulfadiazine therapy on the bone marrow and circulating neutrophils. For therapeutic applications of Ag-nps targeted to brain disorders, Ag-nps must be able to cross the blood-brain barrier (BBB) without harming the integrity of the brain. Several studies have been conducted using murine models and have shown localized edema to the brain 24 h after Ag-np systemic exposure, indicating the need for further research [24].

Pharmacokinetics

The potential and degree of in vivo toxicity of Ag-nps primarily depend on their pharmacokinetic characteristics and target organ dosimetry [25, 26]. The pharmacokinetics of Ag-nps has been shown to be dose, exposure route, species, and gender dependent [26]. For example, citrate-coated 7.9 nm Ag-nps showed a plasma half-life of 99 h (1 mg/kg) after IV injection and 30 h (10 mg/kg) for oral exposure in rats [27], whereas in rabbits after IV administration, the half-lives

In Vitro and In Vivo Toxicity and Pharmacokinetics of Silver Nanoparticles, Fig. 3 Transmission electron micrograph depicting 20 nm washed Ag-nps only in the superficial layers of the stratum corneum following a 14-day repetitive in vivo topical dosing. *Arrow* points to Ag-nps



were 11.7 and 16.3 days in the 5 and 0.5 mg/kg groups, respectively [28]. The fact that the half-life of citrate-coated 7.9 nm Ag-nps is three to four times shorter in rats than in rabbits could be explained, in part, by the longer transit time in the systemic circulation of larger animals than in smaller rodents, which modulates the extent of nanoparticle biocorona formation, which is supported by pharmacokinetic models [29, 30]. Interestingly, following IV injection of 120 mg/kg 90.5 nm Ag-np agglomerates, the half-life was 15.6 h in male mice and 29.9 h in females, indicating a sex difference [31].

While exposure routes for Ag-nps may include oral, dermal, and inhalational exposures, it should be noted that the bioavailability is generally low and depends on the particle size, dose, surface coating, and soluble fraction. Following a single oral exposure in rats, the bioavailability of citrate-coated 7.9 nm Ag-nps was 1.2 % and 4.2 % in the 1 and 10 mg/kg, respectively [27]. For dermal exposure, a study showed skin penetration of 25 nm Ag-nps in both intact and damaged in vitro human skin in static diffusion cells but with a low flux compared to the absorption rate for metal powders. TEM confirmed the presence of Ag-nps in the stratum corneum and outermost surface of the epidermis but not in the dermis suggesting a small fraction of the Ag-nps had dissolved and diffused through the skin layers as elemental Ag [32]. The metabolic pathways for Ag-nps following oral exposure are depicted in Fig. 4 [26, 33]. Briefly, in the stomach, Ag-nps can be ionized to form Ag^+, but the dissolution is incomplete due to the limited gastric residence time (10–240 min). Ag^+ and other soluble complexes [AgCl(aq), $AgCl_2^-$, and $AgCl_3^{2-}$] can be absorbed by the gastrointestinal tract into the systemic circulation, where Ag^+ can bind to proteins with thiol groups such as serum albumin and small thiol molecules like glutathione (GSH). These complexes generate H^+ and GS-Ag which then produce Ag-GSH complexes which then distribute throughout the body. Ag-thiol complexes are reduced to Ag-nps upon UV photodecomposition or at a slower rate with visible light. Besides thiols, Ag-nps can be sulfidated to form Ag_2S-nps, which can react with selenium (Se) to generate Ag_2Se-nps and Ag/S/Se argyrial secondary particulates and not the primary particles [33].

As previously mentioned, the biodistribution of Ag-nps is size dependent and primarily to the liver, followed by the kidneys, spleen, and other organs, regardless of exposure routes [26]. In the liver, Ag-np deposition has been detected in several cell types, including Kupffer cells, hepatocytes, and sinusoidal endothelium cells [16]. In the kidney, Ag-nps were observed in all regions of the cortex, medulla, inner medulla, and cortical glomeruli [34]. For Ag-nps larger than 80 nm, the distribution to the spleen has been shown to be high [31, 35]. Ag-nps up to 110 nm could be distributed to and persistent in the brain for 2 months following oral exposure [36].

Available evidence suggests that the biliary pathway is the major elimination route for Ag-nps. Following a single IV injection of citrate-coated 7.9 nm Ag-nps in rabbits, the 7-day cumulative fecal excretion amounts were 8.3 % and 16.7 % of the injected dose in the 5 and 0.5 mg/kg groups, respectively, whereas only <0.05 % of the injected dose was excreted via the urine for both dose groups [28].

Physiologically Based Pharmacokinetic Models

One approach that can be used to correlate the external exposure dose and observed toxicity with pharmacokinetics and target organ dosimetry, thereby establishing a dose-response relationship for Ag-nps, is physiologically based pharmacokinetic (PBPK) modeling. PBPK modeling is a computational technique that simulates the absorption, distribution, metabolism, and elimination (ADME) of chemicals, drugs, or nanoparticles in the body using mathematical equations. The advantages of PBPK models include their exposure dose-, route-, and species-extrapolation power and the ability to predict target organ concentrations. In addition, PBPK models allow the inclusion of species-dependent and nanoparticle-specific mechanistic information to more accurately simulate the pharmacokinetics. This is particularly important for nanoparticles because the pharmacokinetics of nanoparticles could be affected by multiple factors, including size, surface coating, surface charge, protein binding, exposure route, dose, and species.

Currently, there are two PBPK models for Ag-nps [35, 37]. Lankveld et al. developed the first PBPK model for 20, 80, and 110 nm Ag-nps in rats following daily IV injections for 5 days [35]. The model was composed of five compartments: blood, liver, spleen, kidneys, and remaining tissues. Distribution of Ag-nps in the liver, kidney, and spleen was described by two state variables: one is freely available for exchange between tissues and blood, and the other is irreversibly bound to tissues. Model simulations were well correlated with experimental data used for model calibration. No apparent relationship was found between key parameter values and corresponding nanoparticle diameters, suggesting that not only the size but other properties such as surface chemistry and protein absorption may be involved. Although this model was not validated with external data, it provides a valuable foundation for subsequent PBPK model development.

Bachler et al. reported a comprehensive and validated PBPK model for ionic Ag and 15–150 nm Ag-nps [37]. It consisted of 12 compartments (blood, brain, spleen, bone marrow, testes, muscles, heart, lungs, liver, skin, kidneys, and intestines) and simulated 4 exposure routes (IV, dermal, oral, and inhalation). The model described uptake of Ag-nps from the blood to the organs using transfer functions based on organ-specific mechanisms (i.e., the GSH concentration, capillary wall type, and phagocytosis efficiency) and used a same release rate to describe the transport from the tissue to the blood for all organs, except the brain and testes, for which smaller uptake and release rates were used. The model adequately predicted most of available pharmacokinetic data for Ag-nps, and model simulations offered valuable mechanistic insights into

the pharmacokinetics of Ag-nps across various exposure scenarios. Notably, this model was successfully extrapolated from rats to humans and was used to predict internal exposures based on five different human exposure scenarios. The predicted results were shown to be helpful for exposure and risk assessment of Ag-nps in humans. While being a useful model, it was built based upon a number of assumptions and there remained larger uncertainties. As proposed by Bachler et al., additional experimental studies are still needed to further refine this model [37].

The application of nanoparticles in personal and healthcare fields has the potential to have a positive effect on human wellness. Accordingly, Ag-nps are becoming widely used components in medical devices, healthcare products, and personal care items to provide antibacterial and antifungal action. While experience has shown that metallic Ag and Ag compounds are generally safe in use and effective in controlling pathogenic organisms, Ag-nps are capable of unprecedented entry into cellular compartments with protracted release of Ag ions. This ability makes Ag-nps particularly useful in eliminating harmful microbes, but also potentially harmful to humans. While some in vitro and in vivo studies have shown toxicity related to Ag-nps, others have also shown an overall lack of toxicity, and this may be due to the synthesis method, dose, exposure paradigm, various physicochemical properties of particular Ag-nps, in vivo pharmacokinetics and target organ dosimetry, species, or even type of assay used to assess the toxicity. Therefore, it is important for future studies to determine the physicochemical properties of Ag-nps that make them toxic. Additionally, because toxicity of Ag-nps is highly correlated with their pharmacokinetics, it is critical to further investigate the pharmacokinetics of Ag-nps and the influences of various physicochemical properties. PBPK models of Ag-nps have shown to be helpful in predicting target organ concentrations following a variety of exposure scenarios and in human risk assessment. New PBPK models with fewer modeling assumptions and less uncertainty in model parameters remain to be developed. Manufacturers of new products incorporating Ag-nps should envisage providing a balance between Ag ions released for antimicrobial purposes while maintaining a minimal human toxicity threshold.

Definition

Carbon nanotubes (CNT) are cylinders of one or several (up to 20) concentric graphite layer(s) (single- or multiwall carbon nanotubes respectively – SWCNT and MWCNT). Their diameter is in the order of the nanometer, and they can measure up to several micrometers in length.

Introduction

Carbon nanotubes (CNT) represent emblematic nanomaterials, which have generated a worldwide and highly competitive scientific research activity. They are a family of materials featuring a large range of diameter, length, number of walls (single- and multiwalled CNT; SWCNT and MWCNT, respectively), and metallic impurities coming from the catalyst used. Since their description in 1991, the understanding of their unique physicochemical properties, including mechanical, thermal, and electrical conductivity, led to the actual and potential development of applications in many areas such as aerospace, automobile, nanoelectronics, and medicine. Because of this increasing amount of applications, the question of potential health effects consequent to CNT exposure has been rapidly raised. In this chapter, what is currently known about in vivo toxicity of CNT will be exposed, particularly at the respiratory level, as well as the general underlying mechanisms proposed in the literature, highlighting what are the potential determinants of CNT toxicity. Finally, the remaining issues regarding the understanding of CNT in vivo toxicity will be exposed.

General Overview of CNT Toxicity In Vivo

As for other manufactured nanomaterials, studies aimed to evaluate in vivo toxicity of CNT have been mainly conducted after pulmonary exposure. This is motivated by the fact that lungs are one of the three commonly considered ports of entry for nanomaterials journey into the human body (with skin and intestinal tract), because of their direct contact with the environment. The existing literature regarding health effects of CNT related to respiratory exposure is relatively new, as the first study came out in 2004 [1]. Since then, there have been an always-increasing number of studies dealing with respiratory toxicity of CNT, mainly after exposure of mice or rats to either SWCNT or MWCNT. Initially, animals have been exposed by intratracheal administration, but intrapharyngeal and, more recently, inhalation have been now adopted as pulmonary route of administration for CNT. A large range of doses has been used so far: 10–500 μg/mouse for intratracheal administration, 0.3–30 mg/m^3 for inhalation exposure, for

example, and the duration of exposure has also been wide (from 24 h to 6 months). The majority of these studies have focused on selected specific immediate and/or long-term responses of lung tissue to the presence of CNT: the occurrence of pulmonary inflammation, the formation of granulomas, and the development of lung fibrosis. Therefore, they are not necessarily representative of the entire set of modifications that occur in exposed lungs. This does not facilitate a precise and exact understanding of CNT toxicity. However, general facts can be established.

The induction of an inflammatory response has been frequently described after pulmonary exposure to CNT. This inflammation is an early event, occurring as early as 6–24 h after the initial exposure, with the recruitment of neutrophils in the bronchoalveolar lavage (BAL) fluid [2]. Such neutrophil-driven infiltration is transient, and usually resolved within 15 days after the initial exposure. This acute-phase inflammation is accompanied by the release of pro-inflammatory cytokines, including tumor necrosis factor (TNF) alpha, interleukin (IL) -1ß, -6, monocyte chemoattractant protein (MCP) -1, or macrophage inflammatory protein (MIP) -2 (or CXCL-2) [2–4]. This increased production of inflammatory mediators is observable at the level of the BAL fluid, as well as in whole lung tissue homogenates (RNA and protein levels). This robust acute-phase inflammation, consistent with a foreign body response, is often followed by the formation of multifocal granulomas. The granulomas contain macrophages, and are usually surrounding CNT clusters, but can also appear distal, where dispersed CNT are believed to be present. The presence of granulomas has been documented to be a persistent event following CNT administration; granulomas can be still observable 6 months after the initial exposure [2]. The third biological consequence of CNT exposure that is well documented in the current literature is the development of pulmonary fibrosis. This pathological event can occur both within granulomas and as diffuse interstitial and septal fibrosis distal to granulomas. Fibrosis development has been suggested to appear as soon as 15 days after the initial exposure to CNT, and the fibrotic lesions can still be persistent after 6 months [4, 5]. The histological alteration is accompanied by the expression of markers of extracellular matrix deposition such as collagen I and III or increase in hydroxyproline lung content, as well as the production of profibrotic mediators such as transforming growth factor (TGF) beta.

Oxidative stress, defined by an imbalance between oxidants production and antioxidants defense, in favor of oxidants, is proposed to be a major mechanism underlying CNT's biological effects. This has been demonstrated by several means, in various experimental settings. For example, biomarkers of oxidative stress such as lung protein thiols or malone dialdehyde (MDA) content are increased as soon as 24 h after the initial exposure to CNT [6, 7]. Moreover, the total lung content in 4 hydroxynonenal (4-HNE), a product of lipid peroxidation, is rapidly increased after pharyngeal aspiration of SWCNT in mice [4], as well as protein carbonyls [7]. The importance of oxidant generation has been further confirmed by studies using mice on a vitamin E deficient diet. This diet led to a decreased antioxidant defense. Exposure of such mice to CNT induced a higher cellular inflammatory response (total cell count in BAL, as well as total neutrophil content), accompanied by an increased secretion of two major inflammatory cytokines, TNF and IL-6. Moreover, mice on vitamin E deficient diet developed an exaggerated fibrosis response, as demonstrated by increased TGF beta levels in the lungs, and increased thickness of alveolar walls [6]. Finally, the use of $gp91^{phox-/-}$ mice confirmed the implication of oxidants in CNT biological effects, as the absence of a functional NAD(P)H oxidase in these mice was associated to a diminished induction of collagen deposition, footprint of fibrosis development, in response to SWCNT administrated by pharyngeal aspiration 28 days earlier [8].

Beside these well-documented effects of CNT after pulmonary administration, more recent studies not especially focused on these selected specific immediate and/or long-term responses of lung tissue to the presence of CNT have been published. A few studies describe systemic effects of CNT after administration via pulmonary route.

After inhalation via whole body exposure, 0.3, 1 or 5 mg/m^3, 6 h a day, for 7 or 14 days, Mitchell and collaborators [9] have demonstrated that systemic immunity was affected, despite an absence of pulmonary effects in terms of inflammation, granuloma formation or fibrosis, and tissue injury. In this study, the authors demonstrate that spleen-derived T cells show a suppressed T cell–dependent antibody response, a decreased proliferation of T cells following stimulation, and an altered natural cell killer cell killing activity. This was the first evidence of systemic effects induced by CNT secondary to pulmonary exposure. Because of the experimental setting utilizing a whole body exposure, an ingestion of CNT because of the cleaning of the animal's fur and skin and the subsequent access of CNT to the systemic circulation cannot be ruled out. Other studies, utilizing a less physiologically relevant route of exposure (pharyngeal aspiration, intratracheal administration) allow concluding with better certainty on extrapulmonary effects of CNT. Indeed, it has been described, as soon as 4 h after the initial exposure, the presence of increased systemic levels of inflammatory proteins (IL-1ß, CXCL1, CXCL2, IL-8rß, S100a8, Mac-1) as well as stress response markers (hypoxia-inducible factor 3 (HIF-3a), matrix metalloproteinase (MMP)-9, arginase II, osteopontin, colony stimulating factor-1 (CSF-1), and insulin growth factor receptor 1 (IGF-1R)) [10]. These markers were detected in lung as well as total blood and/or in serum, but, interestingly, some of them were not detected in the lungs of the exposed animals. In addition, total and active levels of plasminogen activator inhibitor 1 (PAI-1), a procoagulant acute-phase protein which is involved in inhibition of the fibrinolytic cascade, were significantly increased in the lungs as well as in the plasma of CNT-exposed animals. This study demonstrates that 4 h after CNT deposition in the lungs, local and systemic inflammatory as well as prothrombotic responses are activated [9, 10]. Of importance, this kind of systemic response, if it is chronic and persistent, may trigger or exacerbate cardiovascular dysfunction and disease, such as atherosclerosis. Unfortunately, no evaluation of the presence of CNT outside the lungs of the animals was performed. Therefore, no conclusion can be made on the necessity or not for CNT to translocate outside the lung to have systemic effects.

A limited number of studies have considered the carcinogenic potential of CNT. A study performed on mice exposed to SWCNT by inhalation showed the occurrence of mutation in the k-ras oncogene locus within the first week of exposure, and until the end of the experiment 4 weeks later. These findings were not confirmed in a study using the pharyngeal aspiration route of exposure, implying that exposure route is a critical parameter to consider in terms of influencing the biological effects of CNT [3]. Due to the physical and chemical durability and fibrous shape of CNT, concerns have been raised that they may exhibit potentially significant health hazards similar to asbestos, such as the development of mesothelioma. To date, no such effects of CNT have been described in response to pulmonary exposure of laboratory animals. However, intraperitoneal as well as intrascrotal administration of MWCNT in mice or rats have been described to lead to the formation of abdominal and/or thoracic mesothelioma [11, 12]. Moreover, it has been recently described that CNT can rapidly reach the pleura after pulmonary exposure to CNT by inhalation of pharyngeal aspiration. From these studies, it is clear that more toxicological research is necessary to determine the effective carcinogenic potential of CNT, and that some of the studies suggest proceeding with caution.

Finally, more recent studies investigated the effect of CNT exposure in the context of existing pathologies such as asthma or bacterial infections, or along with exposure to environmental contaminants such as ozone. Indeed, exposure to CNT occurring concomitantly with an installed pulmonary disease or pathogenic infections may modify (and potentially enhance) the natural pathological response. In murine models of asthma, SWCNT as well as MWCNT have been described to increase the early inflammation and the susceptibility to develop airway fibrosis compared to CNT alone or ovalbumin sensitization only. Moreover, CNT induced an increased expression of immunoglobulins (Ig) related to allergic response in blood [13, 14]. Effects of an exposure to CNT concomitantly

with bacterial infection have been explored using Gram positive (*Listeria monocytogenes*) and Gram negative (lipopolysaccharide) bacteria. In both cases, CNT exposure in combination with bacterial infection was able to induce an increased airway fibrosis as compared to bacterial infection alone [15, 16]. An increased inflammatory acute and/or chronic response is less reproducibly evidenced. Interestingly, pharyngeal administration of SWCNT following an exposure to *Listeria monocytogenes* induced a decreased bacterial clearance. Altogether, these studies demonstrate that CNT may interfere with existing allergies and with natural responses against pathogenic infections.

Determinants of CNT Biological Effects In Vivo

Several processes are commonly used for CNT synthesis: arc discharge, chemical vapor deposition (CVD), and laser ablation. These methods share in common that energy (which can be either electrical, thermal, or high intensity light) is supplied to a carbon source (carbon monoxide, alcohols or hydrocarbons for example), which enables the further production of carbon atoms that recombine together to result in the generation of CNT. CNT synthesis is therefore a complex process resulting in a heterogeneous population of CNT presenting a whole set of various physical and chemical characteristics. Moreover, post-manufacturing processes such as (partial) removal of residual catalyst content may lead to further altered physicochemical characteristics of the initially produced CNT. From the existing literature concerning biological effects of CNT, it clearly appears that several factors mainly related to the physicochemical characteristics of CNT are major determinants of their subsequent biological effects. The exact physicochemical determinant(s) conditioning CNT biological effects is/are unknown for now, but these factors include, for example, the length, catalytic residues nature and content, surface properties, etc., of CNT. As a general comment, and before going further into details, care must be taken regarding the experimental design of the studies aimed to determine the importance of (a) specific physicochemical determinant(s), in particular concerning the origin of the CNT utilized to perform the study. Indeed, as exposed earlier, fabrication processes for CNT synthesis are highly complex, and can lead to the production of a large variety of CNT. Therefore, trying to compare results obtained with CNT issued from different origins (producers, fabrication process) can be hazardous when it comes to giving straightforward conclusions.

Length has been accepted to influence fiber clearance, because it dictates the ability of phagocytic cells in general, and macrophages in particular, to completely internalize and further process the fibers. The influence of CNT length on their biological effects has been therefore assessed in a few studies, and from these data, it appears that shorter CNT have less biological effects than long CNT, in terms of reactive oxygen species production, inflammatory mediators release, and inflammatory cell recruitment [17, 18]. Longer CNT promote frustrated phagocytosis, with a failure of macrophages to entirely engulf CNT. This has been demonstrated for CNT longer than 5 μm [19]. However, several issues must be raised concerning the effect of length in CNT biological effects, apart from those mentioned above. First of all, due to technical issues, it is very difficult to measure accurately CNT length. Indeed, they have a tendency to entangle and aggregate, which complicates the measurement. Therefore, microscopy techniques (usually transmission electron microscopy, TEM) are often used to demonstrate (but not quantify) the differences of CNT length. Moreover, shortening of CNT is often obtained by grinding raw CNT materials, by the use of an agate ball mill, a process which can introduce structural defects in CNT [20]. This would lead to the modification of not only the length of CNT, but also other physicochemical characteristics of the CNT. Interestingly, Wako and collaborators recently demonstrated that grinding CNT could modify inflammatory response in terms of localization of macrophages infiltrates [21]. Indeed, they showed that

intratracheal administration of ground MWCNT in rats lead to the infiltration of MWCNT-laden macrophages in the alveoli, whereas unground MWCNT-laden macrophages accumulated in the pulmonary interstitium. This was associated with the formation of smaller aggregates in the case of ground MWCNT, as compared to unground MWCNT.

The question of the dispersion and subsequent potency for CNT to form aggregates in solution is often proposed as an important determinant of their biological effects. What is currently believed is that well-dispersed CNT preferentially induce the development of fibrosis, whereas less dispersed CNT lead to the formation of granuloma. Better dispersion of CNT can be achieved by the use of dispersing agents (such as surfactants), solvents, attachment of functional groups to CNT's surface (functionalization process), or mechanical treatment, such as grinding or sonication. Moreover, the administration mode can also have an impact on CNT dispersion, as seen in a study by Li and coworkers demonstrating the formation of small aggregates after inhalation of CNT, as compared to the formation of larger aggregates consequent to intratracheal instillation of similar amounts of CNT [22].

Finally, and directly resulting from their production process, the amount of residual catalyst particles present in CNT is believed to play an important role in determining CNT biological effects. Iron, nickel, and cobalt are the most common catalyst particles primarily used during CNT manufacture. Their amount in the final CNT product varies with the manufacturing process, as well as the posttreatments undertaken to purify as produced raw CNT. Several studies aimed at understanding the role of CNT metal content in their biological effects suggest that the metal content (and particularly that of iron) of CNT can contribute to these effects probably via the induction of an oxidative stress. However, these studies are not consistent in their conclusions, as some show that a high content in catalyst residues is associated to increased biological effects, and some others report the opposite findings. Differences between studies may relate to the bioavailability of the catalyst residues in the various CNT samples; some catalyst residues are engulfed inside the carbon structure of CNT, although in some other cases, catalyst residues are present at the surface of the carbon structure, being therefore more accessible and prone to play a role in CNT's biological effects. Finally, the purification process (high temperature, strong acidification process) used to get (at least partly) rid of catalyst residues may introduce other physicochemical modifications in the so-called purified CNT, and therefore complicate the interpretation of the results.

Remaining Issues Regarding CNT Toxicity

Several specific end points have been either not or only poorly considered until now regarding CNT toxicity. This essentially concerns the translocation of CNT as well as their further processing after pulmonary exposure. If it is quite clear given the actual literature on the subject that CNT can have extrapulmonary effects after pulmonary administration (whatever the exposure route chosen), the underlying mechanisms are quite unclear, particularly regarding the need of the translocation of CNT to systemic circulation or other organs to have an extrapulmonary effect. There are some evidences of biopersistence of CNT after pulmonary exposure; Muller and collaborators early demonstrated that 60 days after the initial intratracheal administration, roughly 80 % of MWCNT were found inside the lungs of the exposed rats [5]. Interestingly, only 36 % of the initial dose of MWCNT was found inside the lungs when the authors considered ground MWCNT. Unfortunately, no indication on the localization (organ, body fluids) of the CNT has been achieved in this study. When considering the biodistribution of CNT, it is important to have in mind that observation of CNT in a biological context is a complex matter. Optical and conventional electronic microscopy observations are of limited interest, especially in the case of small diameter SWCNT, because of limitations related to the spatial resolution of these techniques and to

the low contrast of these materials [23]. One possibility is to graft a functionalized group to the raw CNT, but this could affect the intrinsic physicochemical characteristics of the CNT, therefore modifying their biological effects. Another possibility is to take advantage of the residual catalyst present in the CNT. However, it requires highly demanding techniques, such as synchrotron-based X-ray fluorescence microscopy (μXRF) [24], not convenient to use on a routine basis.

Another important remaining issue in the comprehensive understanding of CNT's biological effects is the question of their *devenir* and potential biotransformation in a biological context, despite the earlier-mentioned indications of biopersistence, along with evidences of CNT penetration inside cells. Such data are very important to obtain since CNT biotransformation products could have their own biological effects and therefore participate in CNT's reactivity and further toxicity. A few groups have demonstrated, essentially in test tubes, the possible modifications of SWCNT [25, 26]. However, more extensive research is clearly needed regarding this matter.

Conclusions

The analysis of the existing literature regarding biological effects following respiratory exposure to CNT allows to conclude that CNT per se can induce inflammatory response, granuloma formation, and development of pulmonary fibrosis. CNT can also modulate biological response to preexisting pathologies such as asthma and bacterial infections. The exact determinants of these effects still remain to be clearly identified, although intrinsic physicochemical characteristics of CNT such as length, catalyst residues nature and content, and dispersion state (along with aggregation potential and distribution pattern) seem to be of importance.

Several critical issues remain, and the development of analytical tools for the detection and characterization of CNT should be able to bring some further insights in the understanding of CNT biological effects.

Nanoparticles toxicity examined in vivo in animals

Definition

This topic examines the effect in animals of exposure to titanium dioxide and gold nanoparticles. The effects on different organs are examined along with an analysis of the involved mechanisms.

Introduction

This chapter examines the in vivo toxicity of titanium dioxide (TiO_2) and gold nanoparticles (NPs), the former being representative of metal oxide NPs. This emanates from the finding that research has been primarily performed using these NPs, and thus they have the richest database of information relating to their toxicity.

The effects of the different NPs will be described taking into account the way of exposure.

In Vivo Effects of TiO_2 NPs

Introduction

Metal oxide NPs can be composed of a variety of diverse materials, including titanium, zinc, cerium, aluminum, and iron oxides. When considering metal oxide particles, most available studies have focused on the toxicity of TiO_2 due to its widespread exploitation involving their photocatalytic, dielectric, and optical properties. TiO_2 is a component of sunscreens, pigments and paints, solar panels, and catalyst supports [1].

Titanium dioxide exists in a variety of crystal structures. The most actively investigated are its rutile, anatase, and brookite forms. All are studied for their photocatalytic and photoelectrochemical applications; however, the difference between their performances in applications is often related to the crystal structure. In the bulk form, rutile is the most stable, while, in the NP form, anatase appears to be the most stable structure. The surface energy of anatase is lower than for rutile and brookite. Such surface energy considerations have been used to accurately predict structural phase transformations at the nanoscale between the three systems. The cytotoxic properties of TiO_2 NPs are also dependent on their phase composition. Hence, Sayes et al. [2] demonstrated that anatase TiO_2 NPs (3–10 nm) were 100 times more toxic than an equivalent sample of rutile TiO_2. Moreover, reactive oxygen species (ROS) generation under UV illumination correlated well with the observed biological responses. The reason for these differences may be that anatase TiO_2 possesses a higher efficiency in the generation of ROS [3]. While the latter studies does not rule out particle size as a parameter that can influence in vitro toxicity of NPs, it appears that size is less or equally important than phase composition in the specific case of TiO_2 NPs (see below for further discussion).

Systemic Effects

Skin Penetration

Kiss et al. [4] investigated the in vivo penetration of TiO_2 NPs via human skin transplanted to immunodeficient mice. Furthermore, they measured the in vitro effects of nanoparticles on various functional properties of numerous epidermal and dermal cells in culture. Using various nuclear microscopy methods, the authors provided evidence that TiO_2 NPs in vivo do not penetrate through the intact epidermal barrier. However, they also report that TiO_2, when exposed directly to cell cultures in vitro, exerts significant and cell type–dependent effects on such cellular functions as viability, proliferation, apoptosis, and differentiation.

Since TiO_2 is included in some sunscreen formulations to physically block ultraviolet radiation,

Sadrieh et al. [5] conducted a dermal penetration study in minipigs with three TiO_2 particles (uncoated submicron-sized, uncoated nano-sized, and dimethicone/methicone copolymer-coated nano-sized) applied 5 % by weight in a sunscreen. These and control formulations were topically applied to minipigs at 2 mg cream/cm^2 skin (4 applications/day, 5 days/week, 4 weeks). Each cream was applied uniformly beginning at the neck and covered the entire dorsal surface and ventral abdomen ending at the base of the tail. Skin (multiple sites), lymph nodes, liver, spleen, and kidneys were removed, and the TiO_2 content was determined (as titanium) using inductively coupled plasma mass spectroscopy. An increase in titanium in the left inguinal lymph nodes following treatment with uncoated nano-TiO_2 and an increase in the right inguinal lymph nodes of minipigs treated with submicron TiO_2 was observed. When the data were combined for left and right inguinal lymph nodes for the same minipig, there were statistically significant increases in titanium from 0.758 μg/g in the control group to 1.133 and 1.232 μg/g in the submicron and uncoated nano-TiO_2 treatment groups, respectively. This pattern of increased titanium was not evidenced in the other lymph nodes analyzed. There were no statistical differences in the titanium levels in the prescapular or submandibular lymph nodes taken from any of the TiO_2-treated minipigs. When all the lymph node data were combined, there were no statistical differences in the lymph node titanium concentrations between the treatment groups. Titanium levels in liver from treated animals were not increased over the values in control animals. These data and the data from lymph nodes suggest an absence of transdermal passage of the particles. The epidermis from minipigs treated with sunscreens containing TiO_2 showed elevated titanium. Increased titanium was detected in abdominal and neck dermis of minipigs treated with uncoated and coated nanoscale TiO_2. Using electron microscopy energy-dispersive X-ray analysis, all three types of TiO_2 particles were found in the stratum corneum and upper follicular lumens in all treated skin samples (more particles visible with coated nanoscale TiO_2). Isolated titanium particles were also present at various locations in the dermis of animals treated with all three types of TiO_2-containing sunscreens; however, there was no pattern of distribution or pathology, suggesting the particles could be the result of contamination. At most, the few isolated particles represent a tiny fraction of the total amount of applied TiO_2. The authors conclude that there is no significant penetration of TiO_2 nanoparticles through the intact normal epidermis.

Adachi et al. [6] morphologically investigated animal skin exposed to water/oil emulsion containing 10 wt% TiO_2 NPs. After 4 h, exposed skin was investigated by light microscopy, confocal laser scanning microscopy, and electron microscopy with energy-dispersive X-ray spectrometry (EDX). Light microscopic evaluation was also performed on the exposed skin after 24, 72, and 168 h. Light microscopy did not show any morphological and immunohistochemical changes in the skin. Electron microscopy revealed that the most TiO_2 particles were localized in the interfollicular stratum disjunctum and the keratinized layer of follicular infundibulum. No TiO_2 particles were detected in the viable skin, which was confirmed by EDX. Furthermore, the authors demonstrated a specific TiO_2 affinity to the follicular opening area by light microscopy and low-vacuum scanning electron microscopy with EDX. The authors conclude that TiO_2 particles neither penetrate into viable cell layers nor biologically cause any cellular changes.

Apart from the isolated particles found by Sadrieh et al. [5] in the dermis, these studies do not demonstrate that TiO_2 NPs can penetrate through the intact epidermal barrier. However, the penetration across an altered skin must be still investigated.

Central Nervous System Accumulation and Effects

Wang et al. [7] investigated the distributions of nano- and microparticles (diameters 80 and 155 nm respectively) in the olfactory bulb of mice after nasal instillation (500 μg of TiO_2 nanoparticles suspension every other day for 30 days). These authors demonstrated that both types of TiO_2 particles were taken up by the olfactory bulb via the primary olfactory neurons and then accumulated in the olfactory nerve layer, olfactory ventricle, and granular cell layer of the olfactory bulb. The TiO_2 content was increased in

all investigated brain regions (olfactory bulb, cerebral cortex, hippocampus, and cerebellum), with the most significant increases seen in the hippocampus. The presence of TiO_2 in hippocampus was furthermore accompanied by changes in neuron morphology and increased amount of GFAP-positive cells in the CA4 region. Signs of oxidative stress were documented in all regions of the brain. Interestingly, in general, anatase TiO_2 gave rise to stronger effects than the rutile form. Similar results were observed with other NPs, including gold NPs [8]. As stated by Simkó and Mattsson [9], it seems that NPs can translocate to the nervous system through sensory nerves. Translocation of 20 nm particles is 2–10 times higher in the human olfactory bulb than in rats. Thus, the translocated nanoparticles in humans can enter into the deeper brain structures in short exposure time. However, based on the limited data available, it is presently difficult to assess to what extent accumulation in the brain via axonal transport is a realistic possibility.

Since synaptic plasticity in hippocampus is believed to be associated with certain high functions of CNS, such as learning and memory, Gao et al. [10] investigated the effects of developmental exposure to TiO_2 NPs on synaptic plasticity in rat's hippocampal dentate gyrus (DG) area using in vivo electrophysiological recordings. The input/output (*I*/*O*) functions, paired-pulse reaction (PPR), field excitatory postsynaptic potential, and population spike amplitude were measured. The results of the study show that the *I*/*O* functions, PPR, and long-term potentiation were all attenuated in lactation TiO_2 NPs-exposed offspring rats compared with those in the control group. However, in the pregnancy TiO_2 NPs exposure group, only PPR was attenuated significantly. These findings suggest that developmental exposure to TiO_2 NPs could affect synaptic plasticity in offspring's hippocampal DG area in vivo, which indicates that developmental brains, especially in lactation, are susceptible to TiO_2 NPs exposure.

Effects on Liver

Ma et al. [11] investigated the effects of TiO_2 NPs in liver after intraperitoneal administration in mice. In this study, the authors injected TiO_2 NPs (5 nm diameter, anatase) into the abdominal cavity of ICR mice for consecutive 14 days, and liver inflammatory response was investigated. The results showed the obvious TiO_2 accumulation in liver along with DNA damage, histopathological changes, and hepatocytes apoptosis. These findings were associated with an impaired function (only in the case of the higher doses of TiO_2). TiO_2 NPs significantly altered the mRNA and protein expressions of several inflammatory cytokines, including NF-κB, macrophage migration inhibitory factor, TNF-α, Il-6, Il-1β, Il-4, and Il-10. The authors conclude that the inflammatory responses and liver injury may be involved in TiO_2 NPs-induced liver toxicity.

Pulmonary Exposure to TiO_2 NPs

Different studies investigated pulmonary effects of TiO_2 NPs (see [12] for review). For clarity purposes, they are classified into those examining inflammation and those examining carcinogenesis.

Lung Inflammatory Responses to TiO_2 NPs

Grassian et al. [13] examined the acute pulmonary toxicity of TiO_2, with a primary particle size of 2–5 nm, in vivo using a murine model. Mice exposed to an aerosol of 0.77 or 7.22 mg/m^3 NPs demonstrated minimal lung toxicity or inflammation. At a higher dose, 8.88 mg/m^3, negative health effects were observed immediately as well as at week 1 or 2 postexposure: higher counts of total cells and alveolar macrophages in the bronchoalveolar fluid compared with controls, but after 3 weeks postexposure the mice recovered.

Warheit et al. [14] studied pulmonary toxicity in rats exposed, by intratracheal instillation, to two forms of nano-sized rutile TiO_2 particles (uf-1 or uf-2, similar diameter about 100 nm), and one 80/20 anatase/rutile TiO_2 particle (uf-3, diameter about 25 nm). The authors ranked the pulmonary inflammation/cytotoxicity/cell proliferation and histopathological responses as follows: uf-3 > uf-1 = uf-2. The exposure to a positive control (quartz) and to a lesser degree, anatase/rutile TiO_2 (uf-3) produced the most significant effects. It was concluded that anatase structure could be linked to the adverse effects and that inhaled rutile TiO_2 NPs particles are

expected to have a low-risk potential for producing adverse pulmonary health effects.

Since the translocation of NPs from the pulmonary airways into other pulmonary compartments or the systemic circulation is controversially discussed in the literature, Muhlfeld et al. [15] investigated the distribution of TiO_2 NPs in rat lung after pulmonary exposure. Animals were exposed during 1 h to a Spark-generated aerosol of TiO_2 NPs (median diameter 22 nm). The authors found that NPs distribution within four compartments (air-filled spaces, epithelium/endothelium, connective tissue, capillary lumen) was not random at 1 h or at 24 h after exposure. At 1 h, the connective tissue was the preferential target of the particles. At 24 h, the NPs were preferentially located in the capillary lumen. It was established that the studied NPs can from move from one compartment to another with relative ease but that this does not happen randomly. The authors propose that a small fraction of nano-TiO_2 are rapidly transported from the airway lumen to the connective tissue and subsequently released into the systemic circulation.

Geiser et al. [16] quantified the uptake of TiO_2 NPs (20 nm) by lung macrophages at 1 h and 24 h after a 1 h aerosol inhalation. After 1 h, four particles were found in three macrophage profiles, and 47 particles in 27 macrophage profiles at 24 h. Model-based data analysis revealed an uptake of 0.06–0.12 % TiO_2 NPs by lung-surface macrophages within 24 h. These results are in line with the sporadic and rather unspecific uptake of nano-TiO_2 by macrophages and the fact that phagocytosis plays an insufficient role for clearance in peripheral lungs.

Since exposure to ambient NPs is associated with increased risk of childhood and adult asthma, Scuri et al. [17] investigated whether the exposure to TiO_2 NPs is associated with events involved in asthma pathophysiology. They focused on neurotrophin-driven airway responses because these molecules are key regulatory elements of neuronal development and responsiveness of airway sensory neurons. Indeed, changes in their expression are associated with bronchoconstriction, airway hyperresponsiveness, and airway inflammation, which are hallmarks of asthma. The results of the study show that in vivo exposure to an aerosol of TiO_2 NPs (12 mg/m^3; 5.6 h/day for 3 day) produced upregulation of lung neurotrophins in weanling (2-week-old) and newborn (2-day-old) rats but not in adult (12-week-old) animals compared to controls. This effect was associated with increased airway responsiveness and upregulation of growth-related oncogene/keratine-derived chemokine (GRO/KC; CXCL1, rat equivalent of human interleukin [IL]-8) in bronchoalveolar lavage fluid. These data show for the first time that exposure to nanoparticles upregulates the expression of lung neurotrophins in an age-dependent fashion and that this effect is associated with airway hyperresponsiveness and inflammation. The authors conclude about the presence of a critical window of vulnerability in response to TiO_2NPs exposure in earlier stages of lung development, which may lead to a higher risk of developing asthma.

Lung Carcinogenic Effects of TiO_2 NPs

TiO_2 has recently been reclassified by the IARC as group 2B carcinogen: "possibly carcinogenic to humans." The reason for this new classification stems from the fact that high concentrations of micro and nano ($<$2.5 μm and $<$100 nm respectively) TiO_2 dust can cause respiratory tract cancer in exposed rats (see Ref. [18] for review). Tumors associated with experimental exposure carcinogenic agents are generally of two types: those originating from alveolar type II cells, which are called *bronchoalveolar tumors*, and squamous or epidermoid tumors, which are associated with bronchiolarization and considered to arise from areas with squamous metaplasia. In general, the tumors induced by TiO_2 exposure include bronchioloalveolar adenomas, non-keratinizing and keratinizing squamous cell tumors, bronchioloalveolar carcinomas, squamous cell carcinomas, and adeno-squamous carcinomas. However, it should be noted that epidemiologic studies of workers exposed to pigment-grade TiO_2 conducted thus far have not been able to detect an association between occupational exposure to TiO_2 and an increased risk for lung cancer (see Ref. [18] for a review).

Mechanisms of Action of TiO_2

Two recent studies investigated mechanisms of the main adverse effects of TiO_2 NPs: inflammation and carcinogenesis.

Two studies demonstrated that TiO_2 particles induce inflammation via a cellular signaling pathway know as "inflammasome." Yazdi et al. [19] showed that TiO_2 and SiO_2 NPs, but not ZnO NPs, activate the NLR pyrin domain containing three (Nlrp3) inflammasome, leading to IL-1β release and, in addition, induce the regulated release of IL-1α. Unlike other particulate Nlrp3 agonists, TiO_2 NPs-dependent-Nlrp3 activity does not require cytoskeleton-dependent phagocytosis and induces IL-1 α/β secretion in non-phagocytic keratinocytes. Pulmonary exposure to TiO_2 NPs in mice provoked lung inflammation, which was strongly suppressed in IL-1R- and IL-1α -deficient animals. The authors concluded that the inflammation caused by TiO_2 in vivo is largely caused by the biological effect of IL-1α. Similar results were described concerning micrometric TiO_2 particles [20], suggesting that the effects of TiO_2 on the inflammasome are not strictly related to the nano size.

Troullier et al. [21] investigated TiO_2 NPs (21 nm diameter, 75 % anatase, 25 % rutile)-induced genotoxicity, oxidative DNA damage, and inflammation in a mice model. The authors treated wild-type mice with TiO_2 NPs in drinking water and determined the extent of DNA damage using the comet assay, the micronuclei assay, and the gamma-H2AX immune-staining assay and by measuring 8-hydroxy-2′-deoxyguanosine levels and, as a genetic instability endpoint, DNA deletions. They also determined mRNA levels of inflammatory cytokines in the peripheral blood. The main results of this study show that TiO_2 NPs-induced 8-hydroxy-2′-deoxyguanosine, gamma-H2AX foci, micronuclei, and DNA deletions. The formation of gamma-H2AX foci, indicative of DNA double-strand breaks, was the most sensitive parameter. Inflammation was also present as characterized by a moderate inflammatory response. Together, these results describe TiO_2 NPs-induced genotoxicity in vivo in mice possibly caused by a secondary genotoxic mechanism associated with inflammation and/or oxidative stress.

Conclusion

All together, the different described articles show that TiO_2 NPs can induce inflammation and genotoxicity in vivo in rodents. They can also translocate from one organ to other (from nose to central nervous system, for example) and elicit a systemic response from a localized way of exposure (inflammatory markers in blood after oral exposure for example). In studies, when comparison between anatase and rutile NPs was performed, the former appear as more toxic than the latter TiO_2 NPs. These data suggest that there is matter of concern about a potential risk of inflammation, cancer, or genetic disorders, especially for people occupationally exposed to high concentrations of TiO_2 NPs and that it might be prudent to limit ingestion of TiO_2 NPs through nonessential drug additives, food colors, etc.

In Vivo Effects of Gold NPs

Introduction

In contrast with TiO_2, gold has different medical applications. Gold salts such as sodium gold thiomalate are still considered important as disease modifying antirheumatic agents (see Ref. [22] for a review). The precise modes of action of gold compounds in rheumatoid arthritis have not been clarified, but an interaction with thiol groups on proteins and cell membranes is thought to be important. However, long-term accumulation of gold salts in the body may result in adverse or toxic effects. On the other hand, intra-articular delivery of gold NPs (13 nm) was recently shown to have therapeutic potential for ameliorating collagen-induced arthritis in rats, a model that mimics the clinical and histologic features of human rheumatoid arthritis [23]. Gold NPs were shown to exert anti-angiogenic activities in this animal model, which could contribute to the attenuation of arthritis. These findings are in agreement with other studies showing that that gold NPs (5 nm) are able to bind specifically to certain growth factors such as vascular endothelial growth factor (VEGF), presumably through cysteine residues of the heparin-binding domain, resulting in inhibition of angiogenesis in a mouse model [22].

In addition to their anti-inflammatory effect, gold NPs are used often as drug carriers [24]. The relative stability of the ligand-gold bonding outside the cell combined with its decreased stability within cells, partially owing to the high intracellular concentrations of glutathione, also contributes to making gold NPs good candidates for drug delivery and drug release. This kind of NPs is a hybrid material featuring an inorganic core typically surrounded by an organic monolayer.

The physical properties of the core NP such as the size can influence its organ distribution. However, the organic monolayer of the NP is fundamentally important in modifying the interactions of the NP with its environment. The monolayer acts as a barrier between the NP core and the environment, and effectively protects and stabilizes the core's integrity. Furthermore, the reactivity and solubility of the NPs are dictated by the chemical nature of the monolayer periphery.

There is currently limited information available regarding the in vivo toxicity of gold NPs. In the main, the available studies focus on the tissue distribution of gold NPs following intravenous or intratracheal administration. Moreover, the study using gold NPs in collagen-induced arthritis in rats cited above did not investigate their toxicity and their distribution and elimination from the body [23]. One can argue that gold NPs should be poorly toxic in vivo since studies of gold NPs (35 nm) in vitro have demonstrated their low toxicity, at least for murine RAW 264.7 macrophages, with no hampering of cell functionality [25]. However, studies on in vivo toxicity of gold NPs need to be performed.

Gold Distribution After Intravenous Administration

Semmler-Behnke et al. [26] observed that 24 h following the intravenous administration of gold NPs (18 nm diameter), they were completely removed from the blood and were preferentially located within the liver and spleen. However, 1 nm NPs were excreted within urine (8.6 %) and feces (5 %), with a lower level of accumulation of particles within the spleen and liver, when compared to their larger counterparts, and a proportion of particles (3.7 %) remained within the blood at 24 h. Consequently, it is apparent that particle size influences the behavior of particles within the body. Although the percentages seem small, it is relevant that they may equate to a large number of particles (depending on particle size), which may be capable of exerting toxicity at secondary target sites.

Sonavane et al. [27] evaluated the tissue distribution of gold NPs (15, 50, 100, and 200 nm) within mice, 24 h following intravenous exposure (at a dose of 1 g/kg). For all particle sizes, the highest accumulation of particles was observed within the liver, with a smaller fraction localized within the lung, kidney, and spleen. However, 15 and 50 nm NPs were distributed to a greater extent and were even observed within the brain, indicating that they have the potential to cross the blood–brain barrier or that they have the potent to gain access to the brain via neuronal transport. The size of NPs also impacted on the extent of particle distribution so that there was a greater accumulation of smaller particles within organs when compared to their larger counterparts. The translocation of 200 nm particles was observed to be minute.

Similarly, de Jong et al. [28] investigated the distribution of gold particles (10, 50, 100, and 250 nm) within rats, 24 h following intravenous injection. As observed previously, the preferential site of particle (of all sizes) accumulation was the liver and spleen. The 10 nm particles were also observed to be more widely distributed within a variety of organs, with the distribution of larger particles restricted to the liver and spleen.

Gold Distribution After Intratracheal Administration

Semmler-Behnke et al. [26] observed that following the intratracheal administration, 1 nm gold NPs are observed to cross the air/blood barrier of the lungs much more efficiently than 18 nm gold NPs. The NP accumulation pattern in the secondary target organs differs strongly from those seen after direct intravenous injection. From this it can be concluded that the route of exposure determines gold NPs accumulation in various organs.

Another study showed that inhaled 20 nm nanogold NPs (2×10^6 particles/cm^3) can accumulate in the olfactory bulb of rats [8]. The exposure for 5 days resulted in a significant increase of gold NPs in the olfactory bulb (8 ng Au/g body weight). After 15 days of exposure, significant accumulations of gold particles were detected in the septum and entorhinal cortex. Both brain structures receive direct neuronal projections from the olfactory bulb and are important in attention and new memory formation.

Conclusion

Overall, these studies show that gold NPs size is able to influence the distribution of particles following intravenous exposure. In some studies [27], the dose administered was high, and it is therefore necessary to evaluate if particles actually accumulate within the suggested target organs to a great extent at lower, more relevant doses. In addition, it is necessary to determine if particle accumulation has toxicological consequences for the different secondary target sites.

General Conclusion

The main difference between TiO_2 and gold NPs are related to the know toxicity of TiO_2 NPs in some circumstances, whereas this effect seems less important in the case of gold NPs. However, more studies are needed to clearly precise the determinants of such effects in order to protect workers and consumers to an accidental exposure to NPs used for industrial applications and to improve utilization of these NPs in nanomedicine.

Definition

Nanoscience has recently evolved as a major research direction of our modern society resulting from an ongoing effort to miniaturize at the

nanoscale processes that currently use microsystems. Toward this end, it is well admitted that the bottom-up approach is more and more replacing the classic top-down one, a strategic move that is common to several areas of the nanosciences including optoelectronics, sensing, medicine, and catalysis. The latter discipline certainly is a key for the development of starting chemicals, fine chemicals, and drugs from raw materials.

Unique properties, different from the bulk materials, can be achieved when the sizes of particles reach the nanometer scale. As it will be shown, for nanometer-scaled metals, the electronic structure is changed. Metal clusters of a few nanometers in sizes show dielectric properties with the discrete electronic structure. These changes in electronic structure drastically change the catalytic properties of metallic nanoclusters. Catalysis by metallic nanoclusters on metal oxide surfaces plays an increasing role in the modern technology. The oxidation of carbon monoxide at around room temperature is the most famous reaction known for gold catalysts. Haruta's group discovered in 1987 that gold is a unique catalyst for this reaction if the gold metal particles are smaller than 5 nm and if they are on oxide supports. Since then, extensive and intensive fundamental works have been published, and new applications, reaching from air purification (gas masks, gas sensors, indoor air quality control) to hydrogen purification for fuel cells, have been developed. However, the CO oxidation mechanism is not yet elucidated in spite of the huge number of papers being published.

Another class of materials, the wide band gap semiconductors represented by metal oxides, made rapid and significant advances in a series of applications. The tendency in the development of the nanomaterial's technology is the shift from application of the passive nanostructures, which are designed to perform only one task, to a system of multitasking nanostructures, like actuators and sensors, and, further, to integrated nano-systems which can contain thousands of interacting components. The combination of experimental methods of surface structure studies such as SEM, AFM, STM, and spectroscopic techniques XPS, UPS, and AES (auger electron spectroscopy), as well as SIMS and TPD (temperature-programmed desorption) with theoretical modeling methods, creates a very powerful instrument for the reconstruction of real surfaces and for the understanding of their roles in catalysis, including the role of irregularities such as defects or additional species acting as promoters or inhibitors.

It should be taken into account that a photocatalytic transformation is essentially a dynamical process in which typical time intervals lie in the nanoscale level.

Defects of various types can play very important roles in enhancing the photocatalytic activity, by creating additional electron levels that take positions between the valence and the conduction bands. Defects create local changes in potential energy, which can be considerated as quantum well (or quantum dot), where an excess electron can occupy additional levels of energy. Oxygen vacancies and various dopants (metallic and nonmetallic) inclusions are examples of such defects. Taking the lattice relaxation into account, the size of these defects is in nanometer range.

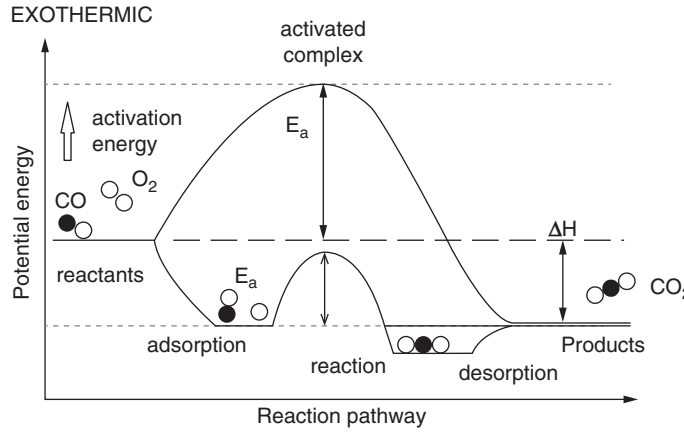
Introduction

Unique electronic and chemical properties can be manifested in solids when they reach the nanometer scale. These changes, which include the appearance of discrete electronic structures, the modification of the crystal structure, and the alteration of chemical reactivities manifests themselves as new physical and chemical properties not observed in the "bulk" form of the material, so far. The development of understanding and the ability to control the key features of nanometer-scaled catalysts is one of the main scientific challenges, which could lead to the long-sought goals of optimum catalytic activities combined with highly specific selectivities. It is well established that ultrasmall metal clusters deposited on solid substrates have catalytic properties distinct from known properties of large bulk-like particles, as illustrated by the selective oxidation of propylene to propylene oxide by the usage of gold clusters, alkene and arene hydrogenation catalysis, and CO

oxidation. In these examples, the catalytic properties improve as the clusters become smaller.

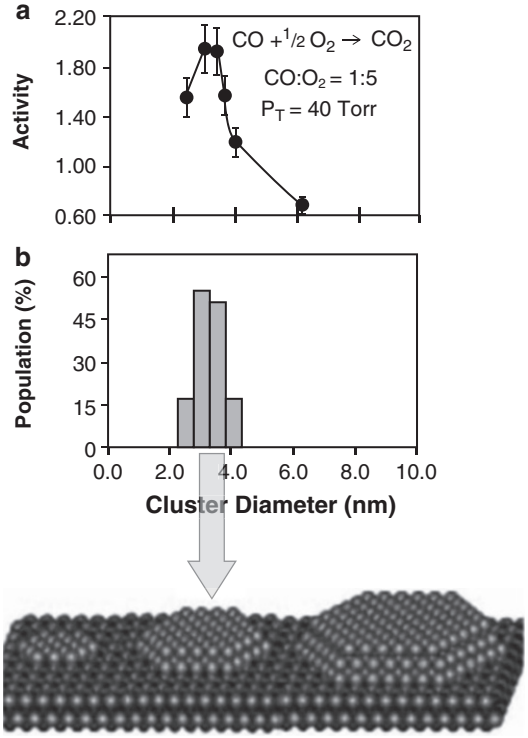
Wide band gap semiconductors represented by metal oxides opened tremendous opportunities in science and technology because of the new properties exhibited by these nanomaterials. However, there are challenging problems in theoretical physics associated with these new properties.

Furthermore an important aspect of the photocatalysis is that the photocatalytic transformation is essentially a dynamic process [1, 2]. In this process, an initial excitation of the catalyst surface or the adsorbed molecule is provoked by the adsorption of photons, which is a very fast process (10^{-15} s), followed by the internal conversion of energy (10^{-14}–10^{-13} s) and the de-excitation by fluorescence (10^{-9}–10^{-5} s) and/or intersystem crossing (10^{-6} s) of the energy or the transportation of electrons and holes created during primary excitation to the surface. The dynamic equilibrium is the factor that determines the efficiency of the photocatalytic processes.



Technology of Nanomaterials and Catalysis

In order to show how surface science can be of help in the understanding of catalytic and, as a particular case, photocatalytic processes, it is useful to consider what the essence of catalysis is. Here a heterogeneous catalysis will be considered where different environment gas or liquid and a solid surface interact. A reaction in heterogeneous catalysis is a cyclic event in which molecules adsorb on the surface react on the active centers of the surface and in which, finally, products of the reaction desorb from the surface. The latter is recovered in its original form at the end of the cycle. As an example the transformation of carbon oxide into carbon dioxide can be considered ($CO + 1/2O_2 \rightarrow CO_2$). This reaction is important in automotive exhaust catalysis and usually carried out over a platinum or a palladium catalyst. Figure 1 shows the potential energy diagrams for non-catalytic and catalytic pathways explaining how catalysts accelerate the reaction between CO and O_2.



The non-catalytic reaction occurs when CO and O_2 molecules collide with sufficient energy to overcome the high potential barrier of the O–O bond of oxygen molecule splitting ($E_{splitt} \approx 498$ kJ/mol). In the initial stage of the catalytic reaction, CO and O_2 species adsorb to the catalyst loosing entropy and lowering the free energy because the adsorption is an exothermic process. Upon adsorption on the metallic surface, the O_2 molecule dissociates spontaneously for two reasons: firstly, the electrons from metal fill antibonding orbitals of the O_2 molecule and, secondly, the bonding of two O atoms to the surface is energetically more favorable than that of one O_2 molecule. In the next stage, the reaction between CO and O atoms occurs on the surface of the catalyst, however, with an energy barrier that is significantly lower than that for the non-catalytic reaction. In the final stage, the product CO_2 desorbs from the catalyst, making the surface available for another reaction cycle.

Recent results on the catalytic oxidation of carbon oxide by Au clusters [3, 4] on a TiO_2 surface can further illustrate the influence of the cluster size and the substrate on the catalytic activity. Figure 2 shows the activity of the CO oxidation at 350 K as a function of the size distribution of Au clusters in the range of 2.0–4.0 nm that are specifically two atoms thick. The sizes of the Au clusters deposited onto a TiO_2 (110) – (1 × 1) single crystal were measured by scanning tunnelling microscopy (STM) in parallel with the kinetic rate of the $CO \rightarrow CO_2$ reaction. For each point in Fig. 2, a particular Au cluster size was prepared [4]. The data of cluster sizes and surface coverage obtained from STM were then used to calculate the turnover frequency (TOF) expressed as (product molecules–CO_2) × (total Au atoms on surface sites)$^{-1}$sec^{-1} [4]. As it can be seen in Fig. 2, the activity of the Au/TiO_2 catalysts exhibits a maximum activity at an average Au cluster size of ~3.5 nm.

Electronic structure of Au clusters is of great importance for catalytic activity and has been studied by scanning tunnelling spectroscopy (STS) [4]. Figure 3 shows a plot of the band gap measured by STS over the cluster surfaces used for the $CO \rightarrow CO_2$ reaction. There is a clear correlation between

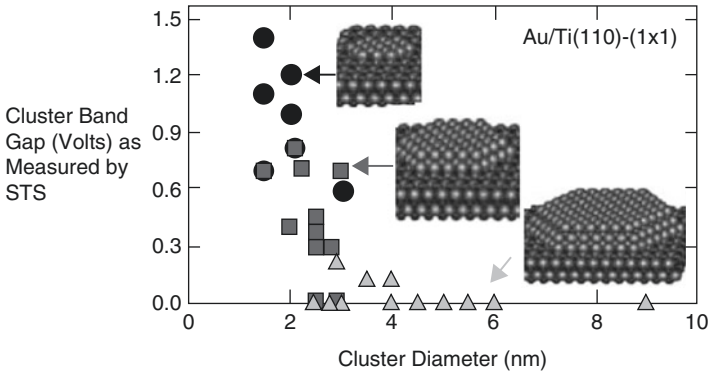
Influence of Defects in Photocatalysis, Fig. 2 (**a**) The activity for CO oxidation at 350 K as a function of Au cluster size supported on TiO_2 (110). A 1:5 $CO:O_2$ mixture was used at a total pressure of 40 Torr. Activity is expressed as (product molecules) × (total Au atoms)$^{-1}$ × sec^{-1} (**b**) (From Goodman [4]. © 2004 Marcel Dekker, Inc)



the onset of the catalytic activity and the observed metal – nonmetal transition in the supported Au clusters [4]. The STS-measured band gaps of this group of clusters range from 0.2 to 0.6 V.

From XPS measurements, it was also concluded that for adsorbed Au, the Au d bands are much closer to the Fermi level (E_f) because of a charge polarization in the interfacial region and a subsequent increase of the potential in the ad layer. Such a large energy shift of the Au 5*d* band toward the E_f should strongly alter the chemical surface properties of Au/TiO_2 from those of a clean bulk Au surface [3, 4]. At this point, an importance of the material of the substrate can be emphasized because this shift can be different for various materials.

Surface Science and Photocatalysis

Heterogeneous photocatalysis differs from catalysis by the usage of light as a special source of energy for the initial excitation of the system that is followed by the subsequent electron transfer and/or energy transfer to a reactive center. A reactive center can be a molecule or a surface reactive site. The subsequent de-excitation processes lead to chemical reactions in heterogeneous photocatalytic processes.

Various semiconductors and wide band gap semiconductors were studied, since in 1972; Fujishima and Honda discovered the photocatalytic splitting of water on TiO_2 electrodes [5]. Numerous research efforts in understanding the fundamental processes and in enhancing the efficiency of semiconductor-based

Influence of Defects in Photocatalysis, Fig. 3 Cluster band gaps were measured by STS as a function of Au cluster size supported on TiO_2 (110). I

photocatalysts were undertaken by chemists, physicists, and chemical engineers.

It is generally accepted that the theoretical model of photocatalysis on TiO_2 surface consists of different consecutive steps where each one is essential for the activity and the efficiency of the photocatalyst [1, 2]. The initial step of the photocatalytic process consists in the generation of electron–hole pairs upon irradiation of the material with photons of energies that are at least equal to those of the band gap values. In this step, parameters like the relation between adsorption/reflection coefficients and the quantum efficiency of the electron–hole generation are very important. The ability to measure the actual absorbed light is very difficult in heterogeneous systems due to the scattering of light by the semiconductor surface. Due to the high absorbance coefficient for $\lambda < 400$ nm ($E_{phot} \sim \Delta_{Egap}$), it is usually assumed that all the light is absorbed.

In the second step, the formed electron–hole pairs can either recombine in the bulk or diffuse to the surface, where they can participate in chemical reactions. In this step, the lifetime and the velocity of the electron–hole recombination are crucial. Charge carrier traps are used to promote the trapping of electrons and holes at the surface leading to recombination suppressing and to more efficient charge transfer processes.

The next step is the creation of $H^{\bullet}$* and $OH^{\bullet}$* radicals as a result of the electron–hole interaction with water and, finally, a probable multiple step reaction of organic compounds with active radicals. In this step, the hydrophilic properties of the photocatalytic surfaces are crucial. The electron transfer process is more efficient if the species are pre-adsorbed on the surface. The cyclic process of photocatalysis beginning with electron–hole excitation by light is shown in Fig. 4, schematically.

An important issue in heterogeneous photocatalysis is the role of surface defects in determining the activity and the selectivity of the transition metal oxide-based catalysts. The existence of reduced surface centers and, hence, the presence of oxygen vacancies are sometimes necessary for any activity. Ultimately, the potential of transition metal oxides in an application is related to the ability of the metal atoms to assume multiple oxidation states. For example, on TiO_2 surfaces, various unsaturated Ti^{3+},Ti^{2+},Ti^{+} cations can be generated by vacuum annealing, Ar^{+} sputtering, chemical reduction (using H_2), or high-energy ball milling. Oxygen vacancies at the oxide surfaces and in the bulk alter the geometric and electronic structure and, thus, the chemical properties of these oxides. The expectation that the understanding of fundamental properties in the microscopic scale of these defects will

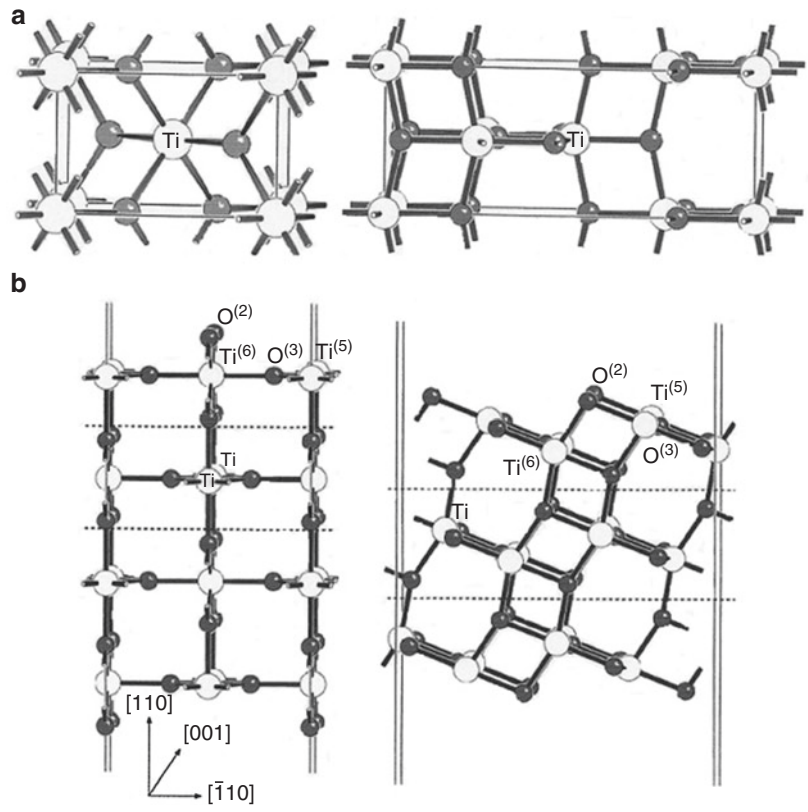
Influence of Defects in Photocatalysis, Fig. 4 Schematic photoexcitation and de-excitation events during photocatalysis

help to elucidate their effects on the catalyst functionality has been the driving force of experimental and theoretical studies of reduced materials.

There are two basic approaches developed over last decades – the first is based on AFM, STM, SXRD (surface X-ray diffraction), and LEED (low-energy electron diffraction) methods to understand the reconstruction of various facets and defects containing surfaces in the atomic scale [6, 7] and – the second is based on the obtained data from this reconstruction, by using DFT (density functional theory) to acquire the knowledge about the electronic structures of these surfaces [8].

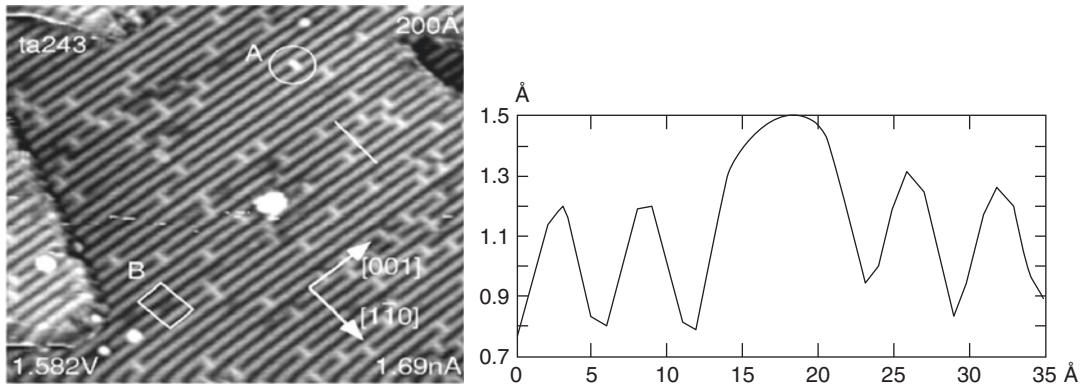
Titanium dioxide crystallizes in three major different structures – rutile (tetragonal, D_{4h}^{14} – $P4_2/mnm$, a = b = 4.584 Å, c = 2.953 Å), anatase (tetragonal, D_{2h}^{19} – $I4_1/amd$, a = b = 3.782 Å, c = 9.502 Å), and brookite (rhombohedral, D_{2h}^{15} – Pbca, a = 5.436 Å, b = 9.166 Å, c = 5.135 Å) [6]. Other structures exist as well; however, only rutile and anatase play significant roles in applications of TiO_2. Both TiO_2 structures are wide band gap semiconductors. The energy gap for rutile is equal ~3.0 eV and for anatase is 3.4 eV. In both structures, the basic building block consists of a titanium atom surrounded by six oxygen atoms in more or less distorted octahedral

configurations. In each structure, the two bonds between the titanium and the oxygen atoms at the vertices of the octahedrons are slightly longer. The total energy of periodic TiO_2 slabs was calculated (see [6] and references therein) using a self-consistent ab initio method. The (110) surface has the lowest surface energy, and the (001) surface the highest. The thermodynamic stability of the (100) surface was found to be stable with the respect to forming (110) facets and the (001) surface was found almost unstable with the respect to the formation of macroscopic (1×1) (011) facets. TiO_2 (110) facet reconstruction is now well accepted as quintessential model of oxide surface and is being used routinely as a starting point for exploring new phenomena on oxides. The combination of spectroscopic, diffraction, and imaging techniques, applied by many different groups worldwide over the course of last decades, has delivered a very complete picture of the rutile (110) surface. The stoichiometric surfaces and many of the different configurations of defects are now well characterized [6, 7]. Other orientations of rutile and of anatase TiO_2 are still less well understood. For anatase, the (101) and the (100)/(010) surface planes are found in powder materials, together with some (001) planes. The anatase (101) surface was calculated to have the lowest surface energy, even lower than the rutile (110) surface [6]. Figure 5 shows the bulk truncated (110) and (101) oriented (1×1) surfaces of rutile and anatase [8].



Both surfaces have sixfold- and fivefold- coordinated Ti atoms ($Ti^{(6)}$ and $Ti^{(5)}$), as well as threefold- and twofold-coordinated O atoms ($O^{(3)}$ and $O^{(2)}$). The removal of the latter, so-called bridging oxygen atoms, is the subject of much interest and debate [8].

Experimental Results on Oxygen Vacancies



Experimentally, it was found that the titanium–oxygen phase diagram is very rich with a variety of crystal structures [6, 7]. The defect structure of TiO_{2-x} is a complex issue because a family of stable Magnéli phases is found to occur between Ti_2O_3 and TiO_2. At low concentrations of oxygen vacancies ($x < 10^{-4}$), they appear as point defects, while for higher degrees of reduction, crystallographic shear (CS) planes are formed. Reduction of TiO_2 occurs by heating in vacuum accompanied by color changes that are attributed to conduction electrons trapped at Ti sites forming EPR(electron paramagnetic resonance)-active Ti^{3+} species. The characteristic EPR signal attributed to Ti^{3+} ions was also observed after excitation of anatase TiO_2 samples with UV light. Reduced TiO_2 crystals exhibit n-type conductivity. There are overwhelming spectroscopic and chemical evidences of presence of oxygen defects in samples of rutile and anatase annealed in vacuum. They are attributed to vacancies of bridging oxygen atoms with concentrations of several percents. Anatase surfaces show, however, fewer tendencies to release of lattice oxygen atoms. As an example the (110) surface of rutile obtained by STM [6] is shown in Fig. 6.

There are two kinds of atomic scale features [5]. These appear as short bright features centered on dark rows (label A) and connecting neighboring bright rows and as dark spots on the bright rows (label B). The feature labeled A have a density of (7 ± 3) % per surface unit cell, consistent with the O vacancy density estimated from spectroscopic results [6]. The size of the bright spots is of order ~5 Å. When the sample was exposed to oxygen atmosphere, the density of the bright spots (A) decreased. This leads to the assumption that the bright spots can be attributed to oxygen vacancies. The dark features (B) are less common (surface concentration of ~(1–2) %) than oxygen vacancies, and their nature is yet unclear [6].

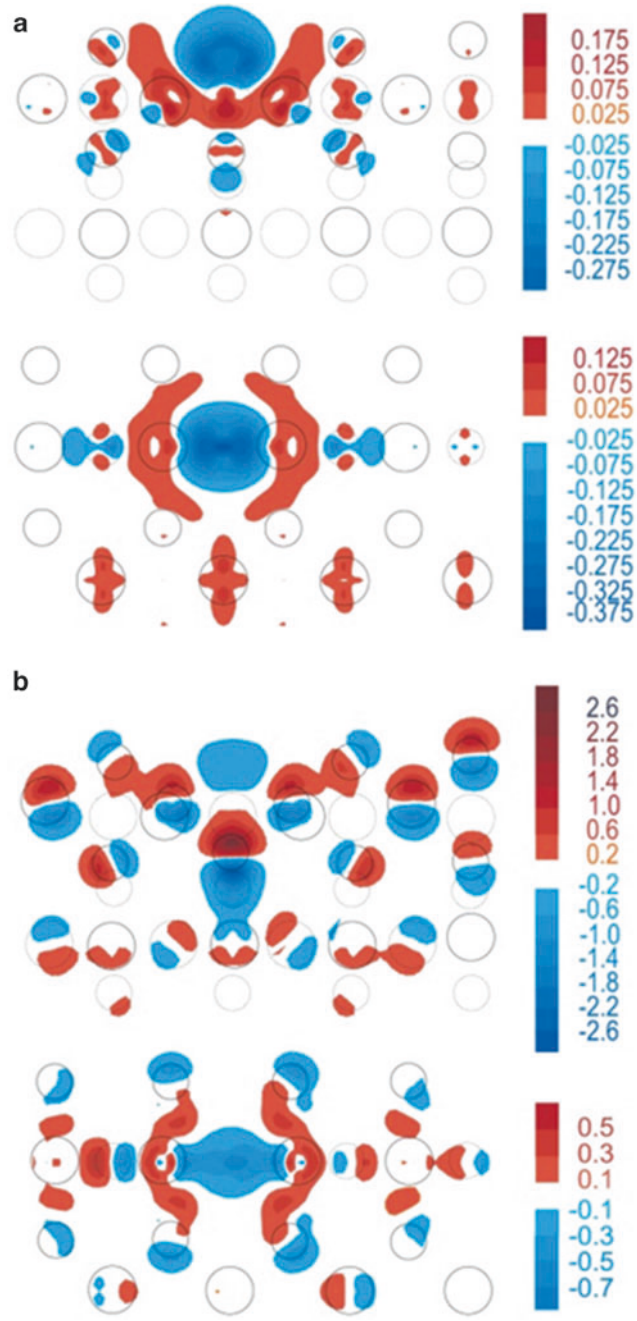
The ultraviolet photoemission spectroscopy (UPS) spectra of single crystal surfaces contain a band gap feature at ~1 eV below the conduction band edge which has been interpreted in terms of occupied Ti 3d states that can be supported by resonant behavior of UPS across the range of photon energies corresponding to the Ti 3p–3d excitation threshold [8] (and references therein). Moreover, UPS measurements on (110) rutile surface reduced by Ar bombardment showed a band gap state at 0.7–0.9 eV below the conducting band for low defect concentrations, moving toward the bottom of the conducting band as the defect concentration increases [8]. Furthermore, a shoulder

Influence of Defects in Photocatalysis, Fig. 5 (**a**) Bulk structures of rutile (*left*) and anatase (*right*) TiO_2 phases. (**b**) The bulk truncated (110) and (101) surfaces of rutile (*left*) and anatase (*right*), respectively. Shown are four- and three-layer (1 ×) slabs, respectively. The dotted lines indicate the repeating unit (one-layer) in the direction perpendicular to the surface (From Ganduglia-Pirovano et al. [8]. © 2007 Elsevier B.V)

Influence of Defects in Photocatalysis, Fig. 6 STM image (200 × 200 Å) of a TiO_2 (110) surface, sputtered and annealed in UHV to 1,100 K for 10 min, showing point defects. Features labeled "A" have been assigned as oxygen vacancies. The position of the line scan shown is indicated in the image (From Diebold [6].© 2002 Elsevier Science B.V)

in the Ti 2p XPS spectra can be attributed to Ti^{3+} ions, and the lack of surface conductivity can be interpreted as the localized nature of the additional electrons.

Now, when the key experimental features on the properties of the reduced systems are mentioned, one question of fundamental interest is what is the electronic structure of reduced



TiO_{2-x} system? In other words, when neutral oxygen atoms are removed, which states do the electrons, left in the system, and populate? What is the energy required to form the oxygen defects?

Theoretical (Numerical) Approaches on Reduced Systems

Here, some principal results obtained for reduced TiO_2 surfaces will be mentioned. Detailed information on the application of modern numerical methods of electronic structure calculations can be seen in [8] (and references therein). There are basically two different approaches to study solids, bulk, and surfaces. One is when the Schrödinger equation is numerically solved for the atoms of a unit cell containing a fixed number of atoms with periodic boundary conditions. Surfaces are modeled by repetition of a two dimensional periodic slab of the crystal together with a sufficiently thick vacuum layer. The presence of a point defect in the surface unit cell results in its periodic repetition and as a consequence leads to a high concentration of surface defects ($\Theta_{def} = 1$ that means the presence of a defect in each unit cell) that is much higher than those encountered in experiments [8]. Increasing the size of the unit cell in the surface plane reduces the defect concentration ($\Theta_{def} < 1$). Another approach is the use of cluster models where only a finite number of atoms is considered to describe a part of a solid system whereas the rest of the crystal is treated by embedding techniques. In this approach an infinite dilution of defects can be achieved. Density functional theory (DFT) is a widely used technique for the calculations of the properties of solids and molecules and can be used in both periodic and cluster approaches. Various exchange-correlations functional were used, including local density approximation (LDA), generalized gradient approximation (GGA), and hybrid functional such as Becke–Lee–Yang–Parr (B3LYP) and the Hartree–Fock (HF) along with other approaches that also have been used. There are some known failures in calculations caused by an application of LDA and GGA functional such as underestimation of band gaps, the gross overestimation of electron delocalization and metallic character, the underestimation of energy barriers for molecular reactions, etc. [8]. These problems are a consequence of employing approximations to the unknown exchange–correlation functional and the lack of knowledge about exact cancellation of the Coulomb self-interaction. These inadequacies can be partly removed by applying hybrid functional like B3LYP (or HSE03 and PBE0, see [8]). Compared to LDA and GGA functional, more accurate descriptions of the electronic structure have been achieved.

Reduced TiO_2 Rutile (110) Surface

There are two possible types of states that the electrons can occupy in TiO_2 upon reduction, namely, delocalized conduction band states formed by Ti 3d states, which leads to a metallic ground state, or localized 3d states in the band gap connected with insulating ground states that corresponds to the experimental observations (Ti^{4+} ions in TiO_2 are in d^0 state and Ti^{3+} ions formed by oxygen removal are in the d^1 state) [8]. There is an important aspect in the numerical approaches consisting in the consideration of the relaxation of the surface structure upon reduction. The surface model contained layers that all were allowed to relax, which means that all atoms can be displaced from the positions occupied in nonreduced model (these displacements are usually of about ~0.1 Å). The term *layer* is used for the repeating O – Ti_2O_2 – O unit (1 L) shown in Fig. 5. An increase in the computational resources allows to consider thicker (up to 7 L) slabs and lower defect concentrations (down to $\Theta_{def} = 1/6$). Among all periodic studies on reduced TiO_2 (110) that used gradient-corrected functional and ultrasoft pseudopotentials, here, the most systematic done by Rasmussen et al. (Ref. [18] in [8]) can be mentioned. The spin-polarized hybrid PW91 functional was used for calculations and investigated defect concentrations in the range $1/6 < \Theta_{deff} < 1/2$ using slabs of varying thickness (3L – 6L) and (1 × 6), (1 × 4), (1 × 3), and (1 × 2) and c(2 × 6), c(2 × 4), and c(2 × 2) unit cells [8]. The centered cells correspond to $\Theta_{def} = 1/6$, 1/4, and 1/2, respectively. The use of both primitive and centered cells of increasing sizes allowed for estimation of defect interactions

Influence of Defects in Photocatalysis, Fig. 7 Change in the charge density upon creation of a single defect in a $p(1 \times 4)$ cell with (**a**) unrelaxed and (**b**) relaxed geometries as calculated using PW 91. *Top* is a cut through the slab along the bridging oxygen rows. *Bottom* is a top view. The induced charge densities were integrated over the perpendicular direction to the plane shown, units are electrons/Å^2 (From Ganduglia-Pirovano et al. [8]. © 2007 Elsevier B.V)

along and across the bridging rows. The geometry of relaxations was also considered in detail [8]. Rasmussen et al. evaluated the actual changes in charge density upon defect creation and found that important changes in the electronic structure are strongly related with structural rearrangements. Figure 7a shows the induced charge density changes upon reduction for the (1×4) structure ($\Theta_{def} = 1/4$) with unrelaxed atom positions. The excess electrons distributed relatively near the defect site mostly at two closest surface located Ti atoms.

However, when atoms were allowed to relax, the excess electrons spread out (see Fig. 7b). The delocalization of the excess electrons increased upon relaxation; however, a significant amount still localized at the nearby Ti atoms. The calculated density of states of the reduced systems shows a defect-related occupied state right below the Fermi level, however, *not* separated by a gap from the conduction band as was found for other types of exchange– correlation functional [8]. The use of different approximations to exchange and correlation leads not only to considerable disagreements in the calculated electronic structure but also to considerable differences in defect formation energy [8]. Despite of these considerable variations, the most appropriate value of single defect formation energy at the rutile TiO_2 (110) can be estimated of ~3 eV [8].

Reduced TiO_2 Anatase Surfaces

Relative to the rutile (110) surface much less is known about anatase surfaces despite the much more applications in photocatalysis as a highly active substance. In correspondence to the rutile (110) surface, the reduced anatase (101) surface obtained by removal of twofold-coordinated oxygen atoms ($O^{(2)}$ in Fig. 5) was theoretically studied; however, hybrid studies have not yet been reported [8]. For such a study a partially reduced (101) surface using a 2L slab and a (1 × 3) unit cell with the spin-polarized PW91 functional was used [8]. One of the bridging oxygen atoms on the surface was removed, ($\Theta_{def} = 1/6$). The term *layer* corresponds to O_2-Ti_4O_4-O_2 unit (see Fig. 5). Atomic relaxations were allowed with the six outermost TiO_2 units fixed at their bulk positions [6]. The calculated defect formation energy was 4.7 eV (calculations that were represented by other groups lead to the values 4.38 and 4.4 eV). The relaxation produced distribution of the excess electrons similar to the results in Fig. 7 for the rutile (110) surface.

Some conclusions can be made from the above mentioned theoretical approaches to describe properties of the most stable surfaces of rutile (110) and anatase (101). Firstly, the relaxation patterns are complex for the rutile and anatase. For the rutile TiO_2 (110) surface, for example, atomic displacements are up to ~0.3 Å perpendicular to the surface as was found with gradient-corrected functionals [8]. Sizable relaxations extend up to the two outermost slab layers and lead to a *wider* defect site. This defect site can be considered as nano-sized object where excess electronic density can play an important role for catalytic and photocatalytic activity. Secondly, the energy of defect formation was estimated of about 2.7–3 eV for rutile and about 4.4–4.7 eV for anatase that are consistent with the experimentally observed lower tendency of anatase to release atomic oxygen under reducing conditions. Thirdly, the TiO_2 surface defect interactions are repulsive and are fairly strong along the [001] direction in rutile (110) surface. That corresponds to the fact that oxygen vacancies are observed as solitary nano-sized objects (see Fig. 6). Fourthly, it should be mentioned, however, that spin-polarized DFT (periodic) within the LDA or GGA approximations *fails* to correctly describe the experimentally observed localized nature of the excess electrons in reduced TiO_2 systems [8]. For the rutile TiO_2 (110) surface in particular, the localization of the excess electrons is consistent with theoretical studies at the Hartree–Fock (HF) level (periodic) and with hybrid approaches, namely, HFLYP and B3LYP, and one that combines an empirically fitted percentage of exact exchange with LDA (13 % Fock). Both B3LYP and the hybrid LDA +13 % Fock give the position of the occupied Ti 3d states upon reduction below the bottom of the conduction band (0.6–1.1 eV) that is close to the experiment [8].

In conclusion of this part, a hierarchical difference between two parts of modern knowledge about the properties of TiO_2 surfaces can be emphasized. There are sufficiently well-established reconstructions for the most stable surfaces of rutile and anatase, especially, the rutile (110) surface, including surfaces containing various surface defects [6, 7]. The results of theoretical modeling of the electronic properties of these surfaces, basically rutile (110) and anatase (101), are still dependent on the functionals used for modeling [8]. However, this situation is a point for the next step of studies of surface chemistry of various species adsorbed on TiO_2 surfaces.

Surface Chemistry of TiO_2

This field of the surface chemistry of TiO_2 is very active, with a recent emergence of theoretical calculations of adsorbate studies on various species – metals and nonmetals on TiO_2. It is evident that any modification of the TiO_2-based photocatalysts resulting in an improving of their efficiencies will represent a breakthrough in the field. For this purpose, many scientific works have appeared during recent years. A thorough analysis of the different approaches is beyond the scope of this issue and can be found, for example, in [6, 9, 10] (and reference therein); only some selected results will be summarized below.

One class of the reports is on the doping of TiO_2 with various transition metals (V, Cr, Mn, Fe, Co, Ni, Au, Ag, Pt, Nb, Cu, W, etc.) to lower the band gap energy. It was shown by ab initio band calculations based on the density functional theory (DFT) that an electron-occupied level occurs and electrons are localized around each dopant. As the atomic number of the dopant increases the localized level shifts to lower energy, thus, for Co the energy level is sufficiently low to be at the top of the valence band while other metals produce mid-gap states. In some experimental studies, it was shown that doping with metal ions such as V^{5+}, Cu^{2+}, Fe^{3+}, and W^{6+} leads to an enhanced photoactivity, whereas in other studies it was shown to lead to a reduction of the photoactivity. This fact reflects the situation that this area of modern research is not yet well established with common approaches.

Another class of reports is on the TiO_2 doping with nonmetals such as N, S, F, C, Br, or Cl. The main idea of nonmetals doping is to create electron–hole trapping centers or charge separating surfaces, as well as, to shift the optical absorption into the visible region.

A third class of reports is dealing with the increase of the adsorption of organic molecules by increasing the hydrophilicity under UV light illumination. It can be can supposed that, for example, on TiO_2:Fe surfaces, both of these mechanisms can be activated.

Metal and Metal Oxide Overlayers on TiO_2

It has been pointed out that metal reactivity toward oxygen is a very important parameter for metal overlayer or metal clusters growth on single-crystalline TiO_2 surfaces [6]. Generally, if a metal M is deposited onto TiO_2, then M should reduce the substrate and turn to be oxidized if the reaction

$$M + TiO_2 \rightarrow MO_x + TiO_{2-x}$$

is thermodynamically favorable (if the change of standard free energy ΔH_f^0 is negative). The formation of lower oxidation states from TiO_2 to Ti_2O_3 and from Ti_2O_3 to TiO is possible and ΔH_f^0 is equal to – 364 kJ/mol and – 483 kJ/mol for these reactions, correspondingly [6]. Thus, the ΔH_f^0 per mole of oxygen of oxide formation should be more negative than the above mention values, for such a reaction to take place. The heats of oxide formations were compiled by Campbell and are reproduced in Table 1 [6].

The strength of the reduction reaction scales with the reactivity of the metallic overlayer. Such a solid-state oxidation/reduction reaction was observed for Co but not for Ni (the heat oxide formation of ~250 kJ/mol, see Table 1). It should be taken into account that the values ΔH_f^0 for the TiO_2 to Ti_2O_3 and the Ti_2O_3 to TiO transformations were taken for the bulk values, so for the surface experiments, the smaller value can be acceptable. The oxidation/reduction reactions at the interface result in a substantial rearrangement of atomic positions and/or charge redistribution. Ionization of the overlayer metal introduces band gap states, or like in case of alkali metals, it leads to the formation of gap states [6]. Up to date only very few theoretical calculations of reactive metal adsorption on TiO_2 were done (see references in [6]). However, these studies took into account only one adsorption site (on top of fivefold coordinated Ti atoms) and no relaxation, which can be very important as it can be seen from the above discussions, in clear contradiction with the experimental results.

Growth morphology is an important subject of discussions about the mechanism of metal growth that can proceed in layer-by-layer fashion

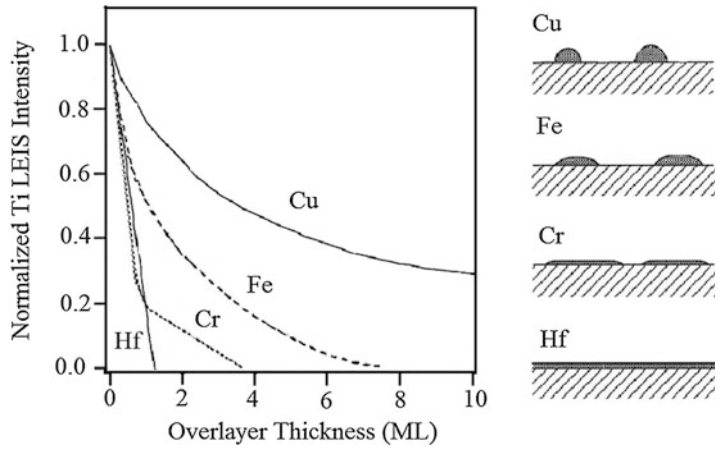
Influence of Defects in Photocatalysis, Table 1 Heat of formations of the most stable oxide of the metal

ΔH_f^0 in kJ/mol of O	Metal
>0	Au
0 to −50	Ag, Pt
−50 to −100	Pd
−100 to −150	Rh
−150 to −200	Ru, Cu
−200 to −250	Re, Ni, Co, Pb
−250 to −300	Fe, Mo, Sn, Ge, W
−300 to −350	Rb, Cs, Zn
−350 to −400	K, Cr, Nb, Mn
−400 to −450	Na, V
−450 to −500	Si
−500 to −550	Ti, U, Ba, Zr
−550 to −600	Al, Sr, Hf, La, Ce
−600 to −650	Sm, Mg, Th, Ca, Sc, Y

(Frank–van de Merwe growth mode) or in cluster fashion growth (Volmer–Weber growth mode). Very rough simplification for understanding which mechanism will be preferable is comparing the difference between the surface free energy of the clean substrate, $F_{substrate}$, and surface free energy of the metal, F_{metal}, with interfacial free energy $F_{interface}$. If $F_{interface} > (F_{substrate} - F_{metal})$, cluster growth should take place. Because the surface energy of virtually all clean metals is higher than that of TiO_2 ($\sim$0.35 J/m^2), hence, cluster growth should occur [6]. The tendency to wet the substrate should also correlate with the numbers given in Table 1. The various types of morphology are shown in Fig. 8. The growth morphologies at the right side of the figure were deduced from combined XPS and LEIS (low-energy ion scattering) measurements [4].

The correlation between heat of oxide formation, interfacial reaction, and growth mode is very simple but neglect several important details. The growth modes discussed above are valid at thermodynamic equilibrium, but normally metal deposition is performed at low temperatures (mostly at room temperature) of the substrate for the vacuum evaporation technique. The substrate is considered rigid and its structure and stoichiometry stable upon metal deposition. Atomically sharp interface are assumed, while highly reactive metals clearly extract oxygen from the substrate. So that different morphology of metallic layers can be obtained by usage of different methods of deposition, chemical vapor deposition (CVD), for example.

Inorganic Molecules



The interaction of TiO_2 with molecules of hydrogen, water, oxygen, carbon monoxide, carbon dioxide, and a lot of other species is a very important subject of studies for catalysis and photocatalysis. Here only limited important cases will be considered, and for more comprehensive review, [6, 10] (and references therein) can be recommended.

Hydrogen

The reduction of metal oxide powders in H_2 atmosphere is typically employed in catalysis. It was shown, however, that TiO_2 surfaces do not interact strongly with molecular hydrogen. High doses of H_2 (10^5 L) at room temperature caused additional emission peaks in the valence band region in ultraviolet photoemission spectra (UPS) [6, 7]. It was also noted that oxygen vacancies act as special adsorption sites for hydrogen. Despite the weak interaction between molecular hydrogen and TiO_2, reduction reactions occur when a TiO_2 surface is annealed in H_2 atmosphere. In contrast to molecular hydrogen, atomic H sticks to the TiO_2 surface at room temperature.

Water

Water vapor, in the ambient, interacts with TiO_2 surfaces, and surface hydroxyls can easily affect adsorption and reaction processes. The problem of the rutile 110 surface activity was recently studied both experimentally and theoretically. Based on the experimental results, it has been variously proposed that water (a) adsorbs molecularly on the 110 surface and only dissociates at defect sites, (b) adsorbs dissociatively at low coverages and, thereafter, molecularly, and (c) either adsorbs molecularly or dissociatively depending on temperature [6]. One point of consensus is that if dissociation does occur, it only occurs at small concentrations. It was recently calculated using the first principles of density functional method (DFT) that a monolayer of H_2O on the rutile 110 surface would contain water in both

Influence of Defects in Photocatalysis, Fig. 8 Trends for the attenuation of the Ti LEIS signals for four selected overlayers on TiO_2 (110) and schematic drawing of the initial stages of film growth for Cu (3D clusters), Fe (flat islands), Cr (2D islands followed by 3D growth), and Hf (formation of a continuous overlayer) (From Diebold [6].© 2002 Elsevier Science B.V)

molecular and dissociated forms. Based on these results, it is possible to conclude that the rutile (110) surface should be photocatalytically active. This photocatalytic activity that is lower than that for anatase was confirmed experimentally. However, these calculations do not reproduce other experimental results. Placing an H_2O molecule in a bridging oxygen vacancy did not lead to spontaneous dissociation on the TiO_2 (110) surface. Also it was concluded that single OH groups are not stable on TiO_2 (110) surfaces [6].

The adsorption of water on anatase surfaces has so far been mostly studied theoretically using DFT and first-principle molecular dynamic calculations. It was found by Selloni and coworkers (see reference [70] in [6]) that water adsorbs molecularly on an anatase (101) surface. Thermal-programmed desorption (TPD) and XPS studies confirm this prediction. Calculations of water adsorption on the anatase (001) surface predict dissociative adsorption, but they have not yet been confirmed by experiment.

Carbon Monoxide and Carbon Dioxide

Adsorption of CO on metal-promoted (covered with nano-sized Au clusters) TiO_2 surfaces is of particular interest in the context of low-temperature CO oxidation to CO_2 that has been discussed above. In contrast to metal-promoted surfaces, the adsorption of CO on the clean TiO_2 (110) surface is far less studied experimentally. It was found that oxygen vacancies can be special adsorption sites for H_2 and CO. The adsorption of CO on TiO_2 (110) was treated with different computational techniques, and the results are summarized in [6, 11]. It was found that adsorption with C-end down is energetically much more favorable than the alternative orientation. Throughout these calculations the C–O bond distances are rather similar, but the adsorption energies vary considerably from experimental results, being on the lower end of the given range [6, 11].

Carbon dioxide interacts only weakly with a clean rutile (110) surface. On the clean surface, CO_2 was found to bind to oxygen vacancies slightly more strongly than to regular lattice sites, with desorption temperatures in TPD at ~166 K, and ~137 K, respectively [6]. CO_2 adsorption is blocked by water; when H_2O is dosed on a CO_2-covered surface, the CO_2 is displaced.

Concluding this part of issue, it can be noted that hierarchically theoretical understanding of the interaction of surface with metals and even simple inorganic molecules is still, at present, less powerful for predictions, although this theory is based on detailed knowledge on surface structure and on less detailed knowledge about electronic structure of surface.

Heterogeneous Photocatalysis on TiO_2 Surface

General Considerations

In a heterogeneous photocatalysis system, photo-induced molecular transformations or reactions

take place at the surface of a catalyst. The reactions accomplished through photocatalysis can involve oxidation and oxidative cleavages, reduction, isomerization, polymerization, etc. Photocatalysis can be generally divided into two classes of processes [1, 2]. When the initial photoexcitation occurs in an adsorbed molecule, which then interact with surface in the ground state, the process is referred to as catalyzed photoreaction. When the initial photoexcitation take place in the catalyst surface and photo-excited catalyst then transfers an electron or energy into a ground state of molecule, the process is referred to as a sensitized photoreaction [1]. The initial excitation of the system is followed by electron transfer and/or energy transfers to the adsorbed molecule and subsequent de-excitation via chemical reactions in the heterogeneous photocatalysis process. Schematically this process is shown in Fig. 4.

The primary excitation process results in electron in the conducting band and a hole in the valence band. When TiO_2 is in contact with an electrolyte, the Fermi level equilibrates with the redox potential of the redox couple. The resulting Schottky barrier drives the electron and the hole in different directions. Electrons and holes when transferred across the interface are capable of reducing and oxidizing adsorbed species, forming a singly oxidized electron donor and a singly reduced electron acceptor illustrated by following reactions [6, 12]:

$$TiO_2 + h\nu \rightarrow TiO_2(e^-, h^+)$$

$$TiO_2(h^+) + RX_{ads} \rightarrow TiO_2 + RX_{ads}^{\bullet +}$$

$$TiO_2(h^+) + H_2O_{ads} \rightarrow TiO_2 + OH_{ads}^{\bullet} + H^+$$

$$TiO_2(h^+) + OH_{ads}^- \rightarrow TiO_2 + OH_{ads}^{\bullet}$$

$$TiO_2(e^-) + O_{2,ads} \rightarrow TiO_2 + O_2^{\bullet -}$$

$$TiO_2(e^-) + H_2O_{2,ads} \rightarrow TiO_2 + OH^- + OH_{ads}^{\bullet}$$

These processes result in anion or cation radicals which can undergo further reactions. Hydroxyl radicals are generally considered the most important species in photocatalytic degradation of organics. It is generally accepted that hole captures occur directly through OH_{ads}^- and not via water. It has been observed that photocatalytic activity of TiO_2 can be completely suppressed in absence of an electron scavenger such as molecular oxygen. In the absence of suitable electron or hole scavenger (adsorbed species as charge carrier trapping site), the charge carriers recombine at the surface (cf, path A1/A2 of Fig. 4) and/or in the bulk of the semiconductor (cf, path B of Fig. 4) to dissipate (heat) energy. On the other hand, when a suitable scavenger is available, the charges migrate to the surface of the TiO_2 particle and initiate interfacial redox reaction with the adsorbed species. Thus, TiO_2 photosensitizes the reduction of an electron acceptor (A) and the oxidation of an electron donor (D) forming anionic (A−) (cf, path C1 of Fig. 4) and cationic (D+) (cf, path C2 of Fig. 4) species. In nanostructured semiconductors, the surface-to-volume ratio is very high, and hence the reactive surface is also higher in nanomaterial regimes. Therefore, the surface adsorption and interfacial redox reaction can be enhanced by using nanostructured semiconductors. This semiconductor-assisted redox reaction is at the core of the heterogeneous photocatalysis. Because the conduction band of TiO_2 is almost completely isoenergetic with reduction potential of oxygen in inert solvents, adsorbed oxygen serves as an efficient trap for photogenerated electrons. The resulting species, superoxide, $O_2^{\bullet -}$, is highly active and can react with other adsorbed molecules [6]. The electron–hole recombination occurs very fast, resulting in low quantum efficiency that is one of the main impediments for use of TiO_2.

Dynamics of Photocatalytic Processes

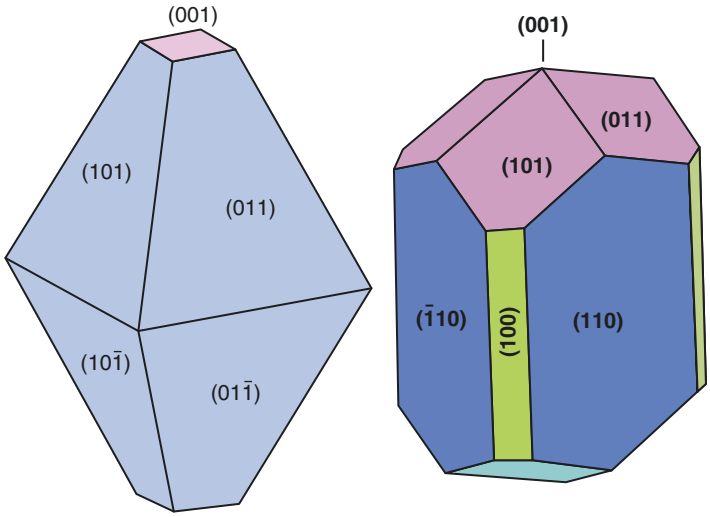
In an aqueous solution, picoseconds and nanosecond laser photolysis was employed to study the dynamics of charge carrier trapping and recombination in ~60 Å colloidal particles of TiO_2 (see Ref. [30] in [1]). The trapping of the conduction band electrons is a very fast process and occurs within 30 ps. By contrast, the trapping of the valence band holes is a much slower process and takes about 250 ns. The recombination of trapped

electrons with free or trapped holes takes place in the 10^{-11} s to 10^{-6} s time interval. At low charge carrier concentrations, the mean lifetime of a single electron – hole pair – is ~30 ns in a TiO_2 particle, and the hole trapping can compete with recombination process [1]. In the trapped state, holes are relatively less reactive in comparison with trapped electrons. At a high concentration of electron–hole pairs, the charge carriers recombine within ~1 ns. Therefore, the interfacial carrier trapping should be very rapid in order to achieve effective photochemical conversion. This can only happened when the electron and hole trapping species are pre-adsorbed on the catalyst surface.

Photocatalysis on Single-Crystalline TiO_2

In UHV-based (UHV – ultra-high vacuum) photocatalytic studies, vacancies in the bridging oxygen positions of TiO_2 (110) play a major role [6, 7]. As discussed above, these vacancies serve as adsorption sites for O_2 molecules. Depending on surface preparation, two different defect states, termed "α_1" and "α_2" state, can be created on the TiO_2 (110) surface, which are both active for CO to CO_2 oxidation. The threshold for photoexcitation is 3.1 eV, indicating that excitations within the TiO_2 substrate are important.

Nanostructured TiO_2 Materials



Numerous applications require TiO_2 to be in contact with a solid, liquid, or gaseous electrolyte; consequently, TiO_2 becomes a prime candidate for the development of nanoscale architectures. The properties of TiO_2 permit to use this material quite well to building tiny structures in all the sorts of sizes and shapes [13–15]. For example, TiO_2 nanopowder (size ~10 nm) of anatase crystal modification is typically produced in sol-gel process, where a titanium alkoxide or halide ($TiCl_4$, TiF_4) is hydrolyzed, often in presence of a template such as nano-spheres, nano-rods, or porous media.

Nanopowders

Based on the calculations of surface energies of various orientations and knowledge about thermodynamic stability, the equilibrium shape of macroscopic TiO_2 crystals was constructed for rutile and anatase crystals, as shown in Fig. 9.

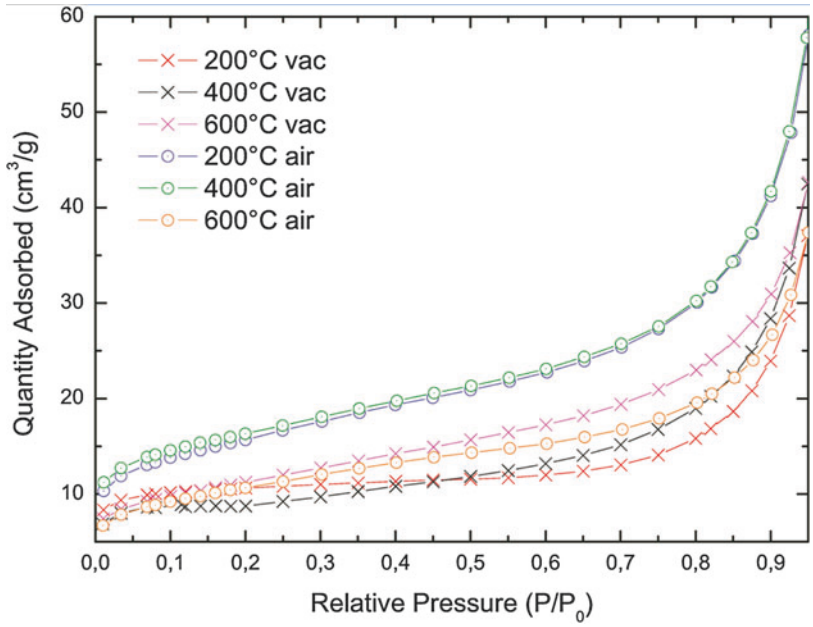
The relation between bulk and surface energy in nanomaterials is different from that for the crystalline materials of macroscopic size, being surface energy comparable with that of bulk for nanoparticles. As a result the shape of nanoparticles can be different from that of macro-crystals shown in Fig. 9; however, some low-energy terminals should be present. TiO_2 nanoparticles have specific advantages in the enhancement of light and molecule adsorption due to the large fraction of surface atoms. The particle size at which the interface enhancement of the adsorption becomes significant is around 20 nm. Specific surface area can be calculated by using the Brunauer, Emmet, and Teller (BET) equation through nitrogen adsorption isotherms collected at 77 K. Typical specific areas for TiO_2 particles ranged from ~100 to 50 m^2/g, for the particle sizes from ~1 to 20 nm correspondingly. The surface and bulk irregularities naturally occur during the preparation process, and they present very different types. The nature of surface defect sites depends on the method of the chemical preparation. One of the most often used in photocatalysis is the industrially prepared powder Degussa P25. The technology of preparation of P25 is the gas-flame synthesis. Degussa P25 TiO_2 powder consists of particles with average size of the particles ~20 nm and represents a mixture of the anatase/rutile and amorphous forms with very different photocatalytic activities with the anatase form being much more active than the rutile form.

It is known that nanopowder particles are complex objects and contain pores of various sizes that can be classified as mesopores and as micropores. An adsorption measurement exhibits several structural features. It is possible to conclude the particle shape from the shape of the isotherm and the porous structure from the type of the hysteresis. Porous structures of nanoparticles strongly depend on conditions of heat treatment. A strong increase of adsorbed gas molecules occurs up to a relative pressure of $p/p(0) = 0.05$ where a monomolecular coverage is reached. The higher the quantity of adsorption is at this point, the bigger is the specific

Influence of Defects in Photocatalysis, Fig. 9 The equilibrium shape of a macroscopic TiO_2 crystals, anatase (*left*) and rutile (*right*) (From Diebold [6].© 2002 Elsevier Science B.V)

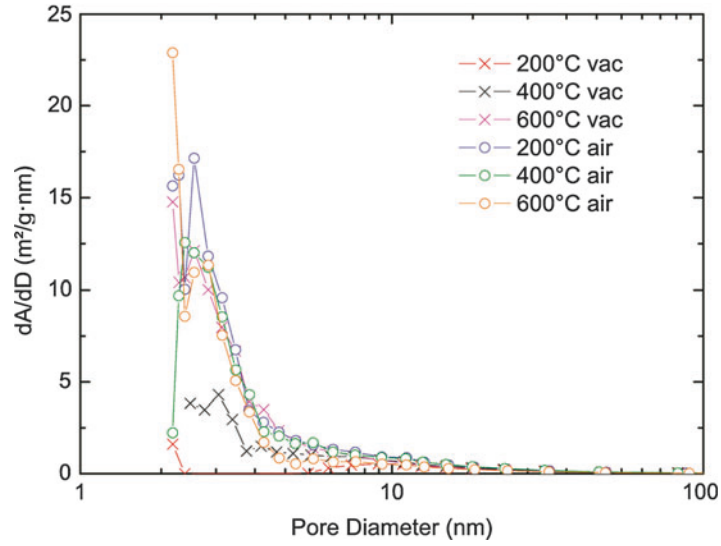
surface area. Typical adsorption branches are shown in Fig. 10.

At higher relative pressures the adsorption branches consist of a small increase up to p/p (0) = 0.7. The slope of the curve depends on the mesoporous structure. In mesopores it is possible to build up a multimolecular coating, while in micropores it is not. The curve of the powder treated at 600 °C in vacuum shows a bigger slope than the 200 °C in vacuum. The conclusion is that powders annealed at higher temperatures include more mesopores, which is also illustrated in Fig. 11.



At relative pressures near 1, structural information for the external surface area and macropores is included, because only for these structures a further adsorption is possible. The pore size distribution, Fig. 11, shows a maximum of pores between 1.7 and 4 nm. The air-treated powders up to 600 °C contain a higher amount of detectable micropores, between 1.7 and 2.0 nm diameter, as well as mesopores.

Modified Nanopowders



As it can be seen in Fig. 4, only an ultraviolet part of solar spectrum can be used for photocatalytic applications. In order to increase the limited optical adsorption of TiO_2 under sunlight, there have been persistent efforts to vary the chemical composition of TiO_2 by adding controlled metal or nonmetal impurities that generate intermediate donor or acceptor states in the band gap. Different from impurity incorporation, vacuum annealing that produces Ti^{3+} species in TiO_2 has also been made. Through doping, the solar adsorption characteristics of TiO_2 have been improved. However, this improvement not always was accompanied by improvement in photocatalytic activity. The optical adsorption of TiO_2 can be modified as the result of electronic transitions from the dopant 2*p* or 3*p* orbitals to the Ti 3*d* orbitals. At present, nitrogen-doped TiO_2 exhibits the greatest optical response to solar radiation.

An alternative approach to improve visible and infrared optical adsorption by engineering the disorder nanophase TiO_2 with simultaneous dopant incorporation has been developed [6]. In its simplest form, a disorder-engineered nanophase TiO_2 consists of two phases: a crystalline TiO_2 quantum dot or nanocrystal as a core and a highly disordered surface layer where dopants are introduced, Fig. 12 [6].

To introduce disorders into nanophase TiO_2, first a porous network of TiO_2 nanocrystals with a few nanometers in diameter was created. A disordered layer on the nanocrystal surface was then generated by hydrogenation [6]. A shift in the onset of adsorption in such disorder-engineered TiO_2 nanocrystals, from the ultraviolet to near-infrared, has been observed. This shift was accompanied by a dramatic color change and substantial enhancement of solar-driven photocatalytic activity.

Conclusion

In heterogeneous photocatalysis, the efficiency for chemical transformation depends on the photoactivity of the adsorbed molecules and the catalyst substrates. The catalyst only provides an ordered environment for a more efficient molecular interaction and does not participate in the chemical reaction process. The role of the semiconductor, in particularly of wide band gap TiO_2, is either to provide energy levels to mediate electron transfer between adsorbed molecules, by temporarily accommodating an electron, or behave as both electron

Influence of Defects in Photocatalysis, Fig. 12 (**a**) Schematic illustration of the structure and electronic DOS of a semiconductor in the form of a disorder-engineered nanocrystal with dopant incorporation. Dopants are depicted as black dots, and disorder is represented in the outer layer of the nanocrystal. The conduction and valence levels of a bulk semiconductor, EC and EV, respectively, are also shown, and the bands of the nanocrystals are shown at the *left*. The effect of disorder, which creases broadened tails of states extending into the otherwise forbidden band gap, is shown at the *right*. donor and electron acceptor (by photogenerated hole in the valence band). Defects of various types can play very important roles in enhancing the photocatalytic activity by creating additional electron levels that take positions between the valence and the conduction bands. Defects create local changes in potential energy, which can be considerated as quantum well (or quantum dot), where an excess electron can occupy additional levels of energy. Oxygen vacancies and various dopant (metallic and nonmetallic) inclusions are examples of such defects. Taking into account lattice relaxations, the sizes of these defects are in the nanometer range. Metallic nanoclusters on the catalyst surface are another example of nanoscaled objects where transitions between continuous and discrete electron spectra take place.

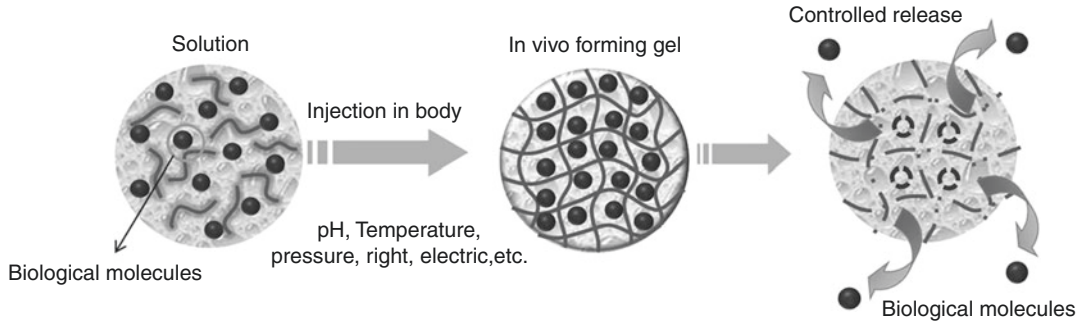
Injectable in situ forming gel

Definition

Injectable hydrogel is based on the idea that certain biomaterial could be injected as a liquid and then form an in situ solid gel.



Overview

Systemic administration of a drug in a bolus, one of the most widely used methods of medication, frequently destroy healthy cells and tissues, leading to numerous undesirable side effects, such as loss of function or reduced efficiency of various organs [1]. One means to circumvent these limitations is drug delivery using sustained-release systems, which release medication at an appropriate rate for a defined duration to a desired place in the body. While a number of sustained-release strategies have been researched, hydrogels have drawn increasing attention as a candidate delivery system for the sustained release of medication. Hydrogels are composed of hydrophilic macromolecules bridged through hydrogen bonds, covalent bonds, van der Waals interactions, or physical bonds that form a three-dimensional macromolecule network structure. Because of their hydrophilic nature, such gels can swell in an aqueous environment and are highly biocompatible, exhibiting characteristics similar to live tissue when fully hydrated.

Hydrogels designed to gel in response to a given stimulus are manufactured with a large surface area so that water-diffusion distances are short; accordingly, they exhibit very rapidly induced water-swelling characteristics. Factors that have been explored as external gelation stimuli include physical factors, such as temperature, light, electricity, pressure, and sound, as well as chemical stimuli, such as changes in ionic strength or composition, molecule recognition, and covalent binding. Hydrogels with such stimulus-induced characteristics can make a phase transition from solution to gel (sol-gel) through reversible volume changes in a matter of minutes or even seconds. Some of the stimuli described above, notably temperature, can also be applied to stimulate hydrogel formation within the human body. Hydrogels based on such a system are associated with minimal side effects and hold tremendous promise as a drug-delivery system and biomaterial for regenerative medicine applications. A large number of macromolecules have been reported as potential stimulus-induced hydrogels. The temperature-induced hydrogel can be administered as an injection and is the most widely researched in several biomedical applications. Specially, hydrogel solution at room temperature can easily incorporate various biological molecules by simple mixing and offer the advantage of simple injection procedures, thus facilitating patient compliance and quality of life via comfort (Fig. 1) [2]. This entry focuses on the types of injectable hydrogels that show a characteristic physical phase-transition response to temperature and highlights their potential human applications.

Key Principles

Among various macromolecules that are the subject of ongoing research are sensitive to temperature stimuli; specifically, they yield macromolecule solutions that exhibit phase-transition characteristics in response to changes in temperature. Macromolecules with hydrophilic functional groups are soluble in aqueous solutions or swell in water and generally increase in water solubility as the temperature increases. As hydrophobic components, such as methyl, ethyl, and propyl moieties, are introduced to hydrophilic functional groups, the macromolecule acquires a lower critical solution temperature (LCST), such that water solubility decreases with increases in temperature. The hydrogel produced from such macromolecules form gels at a temperature higher than the LCST; these types are called thermosensitive hydrogels. Macromolecules composed of hydrophilic and hydrophobic segments in diverse ratios exhibit a phenomenon in which the hydrophilic segments dissolve in water due to the dominance of hydrogen-bonding strength. But as the temperature rises, the cohesive strength of the hydrophobic component dominates over the hydrogen-bonding power, forming a hydrogel through cohesion. Such basic dynamics can be used to modulate LCST by controlling the length of the unit molecule, that is, by controlling the relative ratio of hydrophilic and hydrophobic segments.

Injectable Hydrogel, Fig. 1 Schematic image of injectable hydrogels

Basic Methodology

Types of Injectable Hydrogels in Synthetic Polymers

Poly(*N*-Isopropylacrylamide)

Poly(N-Isopropylacrylamide) (PNIPAAm) is a representative and widely used LCST material, exhibiting a sol-gel phase transition of 32 °C. The LCST of PNIPAAm can easily be controlled by conjugating various hydrophobic molecules. Combining highly hydrophobic copolymers reduces the LCST. For example, poly(*N*,*N*-diethylacrylamide) (PDEAAm) is a temperature-sensitive macromolecule composed of a vinyl group, an isopropylacrylamide group, and a carboxyl group that has an LCST in the range of ~25–35 °C. Poly(*N*-(L)-(1-hydroxymethyl)propylmethacrylamide) is also a temperature-sensitive macromolecule with optical activation properties. Poly(*N*-acryloyl-*N*'-alkylpiperazine) is a macromolecule that is sensitive not only to temperature but also to pH, with an LCST of approximately 37 °C. PNIPAAm and its derivatives can be utilized in various ways on demand [3].

Poloxamers

A triblock copolymer of poly(ethylene glycol) (PEG) and poly(propylene glycol) (PPG) in the form of PEG-PPG-PEG is called a poloxamer (ICI) or pluronic (BASF) [4]. The PEG/PPG ratio of poloxamers ranges from 1:9 to 8:2, and the molecular weight varies widely (from 1,100 to 14,000). An aqueous poloxamer solution exhibits a phase transition at ~4–30 °C, reflecting transition from single molecules to a micelle as the temperature increases. The poloxamer hydrogel is a structure in which the micelle is packed according to certain structural changes. Such characteristics cause the structure to easily erode in the presence of an excess of water, resulting in short-duration (~1 day) hydrogels that are not suitable for use in long-term applications. Depending on the lengths of PEG and PPG blocks, the temperature or temperature range of the sol-gel phase transition and the minimum concentration required for gel formation can be controlled.

A PEO-b-PBO copolymer, which uses poly (butylene oxide) (PBO) instead of PPO, has also been studied [5]. PBO is more hydrophobic than PPO so that the minimum threshold temperature for the copolymer is very high. Other materials, such as poly(L-lactic acid) (PLLA) and poly(D, L-lactic acid-co-glycolic acid) (PLGA), can also substitute for the PPO block.

PEG-Polyesters

PEG-PLGA-PEG was developed using the biodegradable macromolecule PLGA in place of the PPO used in a poloxamer to create a stable, long-lasting injectable gel system [6]. This triblock copolymer is in a sol state at room temperature and forms a gel at body temperature. In an aqueous solution, single PEG-PLGA-PEG molecules pack into micelles and the triblock copolymer exhibits a transition to gel as the micelles condense. As the temperature increases, the number of molecules per micelle and the size of micelles increase, and the gravitational force

between macromolecules increases to form a gel. Unlike the poloxamer, this hydrogel can decompose within the body, and the formed hydrogel can last over a month, allowing it to be used in long-term applications. The sol-gel transition temperature is very important in determining the suitability of such triblock copolymers as bioactive molecules delivery system; importantly, the transition temperature can be modulated by adjusting PLGA and PEG lengths.

One drawback of a PEG-PLGA-PEG system is that the copolymer is difficult to prepare as an aqueous solution. This limitation is largely overcome by introducing poly(caprolactone) (PCL), a biodegradable crystalline macromolecule to yield PEG-PCL [7]. An aqueous solution of PEG-PCL shows a concentration-dependent sol-gel transition as the temperature increases within a range of 20–60 °C. While the physical form of previous temperature-sensitive macromolecules is similar to that of taffy, PEG-PCL is in the form of a powder at room temperature. This valuable property allows PEG-PCL block copolymers to dissolve as an aqueous solution in a relatively short period of time. PEG-PCL has the same advantage, but because of its high degree of crystallization, it tends to harden into a gel from the sol state at room temperature within an hour. Thus, although it is easy to incorporate biologic molecules in the macromolecule aqueous solution and inject it, the entire process must be completed rapidly.

PEG-Sebacic Acid Polyester (SA)

The viscosity of most temperature-sensitive macromolecules in a gel state is ~100–10,000 Pa, making them difficult to inject in gel form. PEG-sebacic acid polyester (PEG-SA), containing SA with a flexible methylene unit and PEG as a hydrophilic component, is a soft gel system that is injectable in sol form [8]. When prepared as an aqueous solution of an appropriate concentration, PEG-SA undergoes a phase transition from sol to gel at human body temperature. When a hydrophilic drug is delivered using hydrogel, the initial amount of drug released may increase during the transition from sol to gel. Therefore, a soft gel system that is injectable in gel form can be useful in delivering hydrophilic drugs.

Polyphosphazenes

Normal organic macromolecules have a backbone composed of C–C bonds. Such macromolecules are of limited use because the short covalent bonds between carbons allow for limited motion, causing stiffness of the chain and making it difficult to maintain elasticity and flexibility over a wide temperature range. These molecules also typically have limited resistance to oxidation or high temperature and are often inflammable. In order to overcome such limitations, researchers have explored various inorganic macromolecules. One such inorganic macromolecule is polyphosphazene, which has an N-P double-bonded skeletal structure that can be substituted with various groups, has a high stability against chemicals, is not very combustible, and maintains its function over a wide range of temperatures. It also degrades within a living body, so it can be applied in various ways as a biocompatible material.

Introducing hydrophilic and hydrophobic materials to poly(dichlorophosphazene) allows the synthesis of temperature-sensitive macromolecules with LCST behavior [9]. A temperature-sensitive macromolecule in which α-amino-ω-methyl-PEG as the hydrophilic material and DL-leucine ethyl ester(LeuOeEt), L-isoleucine ethyl ester, or L-valine ethyl ester as hydrophobic amino acids were introduced into poly (organophosphazenes) has been reported. This material is a biodegradable macromolecule with LCST behavior that shows sol-gel transition as the temperature increases. Physical bridges between macromolecules in solution are formed through hydrophobic bonding between hydrophobic amino acids, resulting in the formation of a gel. By changing features of the molecule or solution conditions, such as the composition of substitution groups, types, and lengths of amino acid esters and pH, the temperature range and characteristics of the gel can easily be controlled [10].

Types of Injectable Hydrogels in Natural Polymers

Polysaccharides

Naturally occurring biopolymers such as gelatin, agarose, and gellan benzyl ester are

temperature-sensitive materials. These form a double-spiral structure in aqueous solutions, and the points of contact between spiral structure strands create the physical bridges that allow hydrogels to form. Above the melting point, these biopolymers exist as aqueous solutions; as the temperature drops, they form hydrogels.

Gelatin is the protein generated by the breakdown of the triple-spiral structure of collagen into single-stranded molecules. Gelatin in solution, unlike other polysaccharides, changes from a random coil into a triple-spiral structure, establishing physical bridges at this time to form a gel. The hydrogel formed in this way is not stable to temperature changes, so it is not suitable for biomedical application. One strategy for creating a stable hydrogel from gelatin involves the introduction of chemical bridges that prevent the molecule from forming a double-spiral structure again, even after the temperature is lowered. However, this approach raises the issue of irreversible gel formation. An alternative method that has been suggested for forming a stable yet reversible hydrogel is the introduction of chitosan to gelatin.

Chitosan has a pKa of 6.5, so it is not soluble in water at a pH greater than 6.5. But the introduction of the hydrophilic PEG (>2,000 Da) increases the solubility of chitosan in water and allows a temperature-sensitive macromolecule that remains in solution at room temperature, but forms a hydrogel at 37 °C, to be produced.

Unlike most natural macromolecules, which form gels at a low temperature, cellulose derivatives exhibit sol-gel transitions as the temperature rises. Cellulose itself is not quite soluble in water, but can be made readily water soluble by introducing a hydrophilic component. By appropriately adjusting the hydrophobic/hydrophilic ratio of such a cellulose derivative, it is possible to produce a material that can transition from sol to gel.

Artificial Polypeptides

Dual copolymers composed of a hydrophilic block of poly(L-lysine) or poly(L-glutamate) and a hydrophobic block of poly(L-Leucine) or poly(L-valine) undergo sol-gel transition as the temperature increases and form hydrogels through micelles, similar to PEO-PPO block copolymers. The main differences between such dual polymers and existing synthetic macromolecules are formations of hydrogels at a relatively low macromolecule concentration and stability at a high temperature (90 °C). Using gene recombination methods, it is possible to prepare artificial polypeptides. Elastin-like polypeptide (ELP), composed of Val-Pro-Gly-Xaa-Gly amino acid repeat units, is a temperature-sensitive macromolecule produced using such a gene recombination approach. Any amino acid except proline can take the place of Xaa, which is a "guest residue." ELP exhibits a temperature-sensitive phase transition: It is in an aqueous state below the transition temperature, but above that temperature, hydrophobic interactions cause a conglomeration phenomenon that leads to precipitation.

Key Research Findings

Injectable Hydrogels as Drug Carriers

Oral or systemic administration of anticancer drug solutions results in the spread of drug throughout the body; only a very small amount is actually delivered to the cancer tissues where anticancer activity is needed. This leads to insufficient levels of drug at the tumor site, requiring dosing strategies that increase drug concentrations in normal tissues to toxic levels, causing serious systemic side effects. In addition, anticancer drugs generally have a low bioavailability and short half-life, so they must be injected frequently. In order to overcome these limitations of conventional chemotherapy, researchers have focused on drug-delivery methods that effectively deliver the injected drugs to the cancer tissues and consistently release the appropriate amount of anticancer drugs for the desired length of time.

Dramatic improvements in injectable hydrogel drug-delivery systems have set the stage for a groundbreaking turning point in anticancer treatment. These include the recent development of a delivery system that uses biodegradable injectable hydrogels to create a drug depot under the skin or

in cancer tissues that releases hormones or chemotherapeutic agents for cancer treatment.

Because injectable hydrogels are in aqueous solution at room temperature, it is easy to mix them with various anticancer drugs. Such a solution containing drugs and temperature-sensitive, phase-transitional macromolecules can simply be injected under the skin or into the cancer tissue, immediately forming a depot for anticancer drugs. Because no surgery is required, patient pain and discomfort are minimized. Oncogel, developed by MacroMed, uses PEG-PLGA-PEG (ReGel) to produce paclitaxel anticancer drugs in aqueous solutions [11]. Clinical trials of partial injection of Oncogel for solid tumors are currently ongoing in the USA and Europe.

Various injectable hydrogels composed of MPEG-polyester containing anticancer drugs (e.g., paclitaxel, docetaxel, doxorubicin) have been produced as aqueous solutions at room temperature for injection. In the system as currently applied, the hydrogels that form in situ upon injection create an anticancer drug depot that slowly releases anticancer drugs over a long period of time, eventually decomposing within the body. Once anticancer drugs have been completely released, the injected hydrogel is excreted from the body as a degradation product that is completely harmless to the human body.

In recent years, protein drugs developed as a result of advances in molecular biological recombination technology have been shown to possess excellent selectivity and efficacy while minimizing side effects. As such, they have received considerable attention for their potential to actually cure various diseases rather than merely treat symptoms. Although these advances have made wide commercialization of such protein drugs possible, these drugs, unlike low-molecular-weight drugs, have large, complex structures and are generally very unstable within a living body. Most protein treatments are currently administered systemically as repetitive injections, because protein drugs are easily degraded by first-pass metabolism when taken orally and thus exhibit a very short half-life and low bioavailability. These characteristics of protein drugs have motivated the development of systems to overcome the limitations of existing protein delivery systems. A number of strategies are currently being explored to achieve efficient systemic delivery with reduced injection frequency. Among the approaches that have been suggested as a solution for effective protein delivery is the use of biodegradable and injectable hydrogels.

Injectable hydrogels containing bioactive molecules like proteins has developed and has confirmed their long-term release characteristics in vivo. Importantly, the incorporated proteins are relatively stable, persisting for extended periods of time within the macromolecule.

Injectable Hydrogels as Transplants in Regenerative Medicine

Individuals in modern industrial societies face the prospects of destruction or escalation of organ tissues due to a variety of causes, including accidents and congenital organ diseases, creating a demand for organ-failure solutions. The ultimate solution is organ regeneration through tissue engineering, a topic that has received considerable recent research attention. Artificial organ development through tissue engineering consists of three important factors: (1) a regenerative cell source, such as stem cells; (2) a biomaterial for the production/maintenance of the organ form; and (3) a physiologically active substance, such a as cytokine or growth factor that promotes the growth of regenerative cells. Creating artificial organs from cells incorporated into biodegradable macromolecules requires that the cell-macromolecular complex does not provoke immunorejection, that an extracellular matrix is secreted to form the new organ, and that the macromolecule is gradually biodegraded and excreted as water and carbon dioxide. Injectable hydrogels have shown particular promise as a transporter for the production of tissue-engineered, artificial organs.

The hydrogels composed of MPEG-polyester or natural materials incorporating adult stem cells derived from bone marrow, muscle, and fat have been developed. Prepared as an aqueous solution and injected into the living body, this material was observed to undergo a sol-gel transition in situ and was found to form a gelled scaffold containing growing stem cells that persisted within the body

for at least 2 months. Inclusion of a bone differentiation-promoting substance resulted in the induction of bone formation at the implantation site. Such results highlight the virtually unlimited potential of injectable hydrogels as transplant transporters in tissue engineering applications.

Future Directions of Injectable Hydrogels

Research on injectable hydrogels and related fields is in progress at various top research institutes around the world and will certainly continue to expand. The key research advances to look for in the future are the development of materials with improved curative efficacy, convenience, and absence of side effects when applied to humans. These developments can be expected to proceed hand in hand with a focus on disease cures, life extension, and investigation of basic life phenomena. Improved understanding of the structural properties of injectable hydrogels that contribute to biocompatibility and therapeutic efficacy, as well as the design and development of original synthesis technology, will facilitate these efforts. At this time, a concerted research effort by workers in various fields is urgently needed to develop and apply original technologies that might help to realize the tremendous potential of injectable hydrogels.

Inorganic Nanoparticle Radiosensitizers for Cancer Therapies

Malgorzata J. Rybak-Smith and
Helen E. Townley
Department of Engineering Science, University of Oxford, Begbroke, UK

Synonyms

Inorganic nanoparticle radioenhancers for oncology; Inorganic nanoparticle radiosensitizers for oncology

Definitions

Inorganic particles – chemical compounds that do not contain carbon.

Nanoparticles – particles sized between 1 and 100 nm.

(Inorganic) Radiosensitizers – (inorganic) chemical molecules or drugs that have the capacity to increase the therapeutic effect of irradiation when administered together with irradiation.

Cancer therapy (oncology) – treating cancer with one of the modalities, such as surgery, radiotherapy, or cancer drugs (chemotherapy, biological treatment, hormone therapies, and others). Radionuclides (radioactive metal elements) can also be used in oncology.

Radiation Therapy

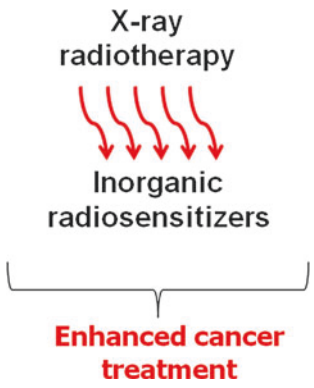
Based on information available on the World Cancer Research Fund International website, the number of expected cancer cases around the world is going to reach *21 million* by *2030* [1]. At present, surgery, radiation therapy, and chemotherapy are the most common treatments in oncology. Radiotherapy still remains a major nonsurgical modality for cancer therapy [2, 3]. It uses high-energy radiation, such as X-rays or γ-rays (external radiotherapy), to treat tumor. More than 50 % of cancer patients undergo radiation therapy during their treatment [3]. Skin cancers and cervix and lung carcinomas are examples of early cancers curable with radiation therapy alone [3]. However, most cancers (e.g., breast, bladder, and locally advanced lung carcinomas) need radiotherapy in combination with other modalities [3]. Radiotherapy achieves its therapeutic effect by inducing different types of cell death: apoptosis, necrosis, senescence (a state of permanent loss of cell proliferative capacity), autophagy, or mitotic catastrophe [3].

Tumors are usually hypoxic and in the absence of oxygen can become radioresistant [4]. Therefore, another major drawback of using radiation therapy is recurrence of tumor [4]. In the absence of oxygen, living cells surrounding tumor are less sensitive to irradiation than in the presence of oxygen [4]. Another obstacle of radiotherapy is that tumors do not receive sufficient dose of irradiation. Moreover, if the tumors are not targeted precisely, the healthy cells surrounding them can be destroyed by irradiation. Thus, the major drawback of using radiotherapy as well as other modalities in cancer therapy is destruction of healthy cells surrounding the tumor.

Radiosensitizers

Radiosensitizers can enhance radiation effects in tumors and allow a much higher dose to be delivered specifically to the tumor cells. An example of an organic tumor radiosensitizing drug is nicotinamide plus carbogen, which was found to enhance radiotherapy of experimental tumors [2]. Another approach is to use radioprotectors which can chemically protect healthy tissues. Amifostine appears to be beneficial when used in clinical trials of head and neck squamous cell carcinoma [2]. Molecules with electron affinity such as oxygen molecules or nitro compounds (nitroxyl-free radicals) are among radiosensitizers [4]. Molecular oxygen is the most well-known

radioenhancer [4]. The oxygen molecules can generate Reactive Oxygen Species (ROS) which can interact with DNA [4]. That is why the blood substitutes with increased oxygen concentration or high-pressure oxygen tanks can be used in the clinics to overcome tumor resistance. One of the most novel approaches is to use compounds (e.g., trans-sodium crocetinate – TSC) which can reoxygenate hypoxic brain tumor tissue (glioblastoma tumors) [5]. Another group of radiosensitizers are DNA-based analogues, e.g., halogenated pyrimidines, and also the membrane-active drugs [4]. The thiol reactive agents or silver salts are compounds which affect radiosensitivity and are called miscellaneous compounds [4]. Another approach to overcome the radioresistance problem is the use of hypoxic cell radiosensitizers, such as metronidazole or misonidazole [4].



For decades, researchers have tried different approaches to improve the outcome of radiotherapy [4], but there is still room for improvement. How to design the most effective radiosensitizers? The ideal radiosensitizers should not only have high radiotherapy enhancement but also have good tumor targeting capacity, good biocompatibility (appropriate size and surface properties), and efficient renal clearance. Also, they should enhance the radiation dose without being toxic, so the ideal radiosensitizers should be inert in the absence of irradiation. The majority of molecules used in radiotherapy are organic radiosensitizers. However, various inorganic nanoparticles (NPs) attracted lots of attention for their interesting physicochemical properties, such as crystal structure, various geometries or coordination numbers, etc. and therefore have great potential to be used as effective radioenhancers. It is worth mentioning that without radiation, the inorganic nanoparticle radiosensitizers would present no therapeutic value in radiotherapy.

Nanosized Metal-Based Molecules

Recently, Pottier et al. reviewed the novel use of metals as nanosized radioenhancers [6]. The nanosized metal-based molecules have potential to be used in the clinics [6]. The metals that are most commonly used in oncology are platinum, gold, and ruthenium [6]. The novel metal-based pharmaceutical compounds represent an attractive approach in oncology. Nevertheless, the main limitation of using such compounds can be their toxicity [6]. Metal oxide NPs (such as hafnium dioxide, HfO_2) represent an interesting alternative to metal NPs [6]. Organic platinum (Pt) compounds, among them cisplatin, oxaliplatin, carboplatin, tetraplatin, are leading radioenhancers [6]. Some of the organic ruthenium (Ru) complexes (e.g., Nami-A and KP1019) are currently in clinical development. Radionuclides can also be used as attractive anticancer agents [6]. The α-particle emitters, β-particle emitters, and Auger electron emitters have energies ranging from 5 to 9 MeV, 50–2,300 keV, and eV-keV, respectively [6]. BEXXAR [I-131 (β emitter) tositumomab] or ZEVALIN [Y-90 (β emitter) ibritumomab tiuxetan] are examples of commercially approved radioimmunotherapy agents [6]. The agents can treat indolent B-cell lymphoma [6].

Inorganic Nanoparticle-Enhanced X-ray Therapy

An up-to-date review of inorganic radiosensitizers is presented here. Inorganic radiosensitizers can enhance radiation effects in tumors and allow much higher dose of irradiation to be delivered specifically to the tumor cells (as schematically presented in Fig. 1). The summary of various approaches for enhancing the radiosensitization in cancer cells was recently reviewed by Kwatra et al. [7] The term *Nanoparticle Enhanced X-ray Therapy* (NEXT), which is defined as the use of nanoparticles as radiosensitizers, was introduced [7]. The most common approaches involve using metal-based NPs, quantum dots (CaF, LaF, ZnS, or ZnO), supraparamagnetic iron oxides (magnetite Fe_3O_4 and magemite γ Fe_3O_4), and nonmetal-based NPs (i. e., silicon or fullerene (C_{60})-based) [7]. The use of quantum dots is limited to superficial cancers (photodynamic therapy) [8]. The metal-/metal oxide–based nanoparticles include gold NPs (GNPs), gadolinium-based NPs, titanium-based NPs (TiO_2), silver-based NPs, and

Inorganic Nanoparticle Radiosensitizers for Cancer Therapies, Fig. 1 Inorganic nanoparticles when activated by X-rays can increase the efficacy of conventional radiotherapy

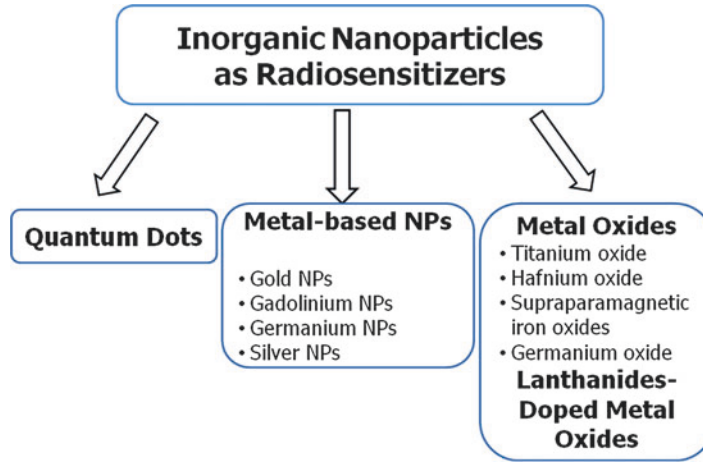
hafnium-based NPs (HfO_2) [7]. The summary of the most commonly used inorganic radiosensitizers is shown in Fig. 2.

Radiotherapy Enhancement with GNPs

High-Z elements are materials with high atomic number. For example, the Z value for gold is 79. The dose of irradiation can be increased when a high-Z material is present in the targeted cancer tissue [2]. Gold is an exceptional absorber of X-ray irradiation and therefore the most studied radioenhancer [2].

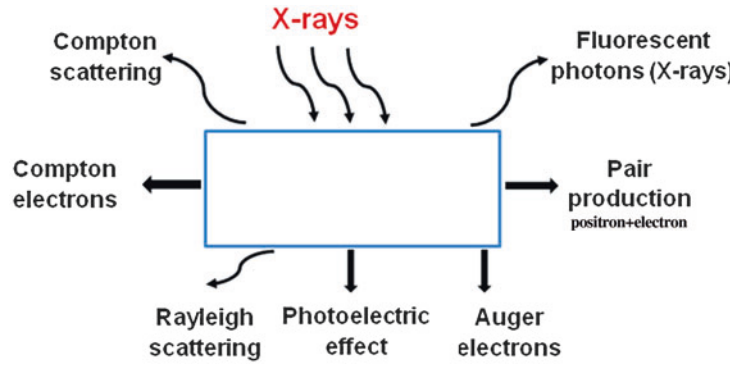
Basic Physics of Metal-Enhanced Radiotherapy

Due to X-ray interaction with matter, a number of processes can take place, including Compton scattering, fluorescent photons, Compton electrons, pair (positron–electron) production, Rayleigh scattering, photoelectric effect, and Auger electrons (Fig. 3). Photoelectric effect changes as (Z/E) [6] (E represents the incident photon energy; Z is the atomic number) [2]. Photoelectric effect is a dominant interaction of high-Z elements with matter at energies below 0.5 MeV [2]. It was estimated that the relative effect of gold (Z = 79) to soft tissue (Z = 7.4) in the energy range above gold's K-edge (80.75 keV) is approximately 1,217 [2]. Fluorescent photons can travel longer distances (up to centimeters) than Auger electrons (about 10 nm), which are weakly bound electrons [2]. In Rayleigh scattering (also called elastic), photons collide with the entire atom, not single electrons [2]. Therefore, the amount of energy transferred is insignificant. Its cross section is very small in tissues at energies above 60 keV and in gold above 200 keV. The Rayleigh scattering is elastic with no energy deposited in the tissue, and therefore it is not suitable for cancer therapy [2]. Pair production (positron and electron) occurs at high photon energies (more than 1 MeV); its cross section in tissue below 3 MeV is not significant [2].



Optimal Beam Energy in Radiotherapy

The optimal beam energy for use with a dose-enhancing contrast agent has to be taken into account in the radiotherapy [2]. Currently, most radiotherapy machines use 6–25 MV electron linacs (linear particle accelerators) for the production of X-rays [2]. This does not apply for treating superficial cancers [2].



One of the factors for selecting the optimal irradiation energy is penetration of X-rays to be effective for deep tumors (liver, brain). The advantage of using gold over iodine (Z = 53) is its greater absorption at higher energies (about three times greater than iodine at 100 eV) [2]. Some of the theoretical calculations of dose enhancement in the literature have been done using Monte Carlo calculations [2, 21].

Generation of Reactive Oxygen Species

Reactive Oxygen Species (ROS) typically include the superoxide radical ($O_2^{\cdot -}$), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($^{\cdot}OH$). Lifetimes and diffusion distances of various ROS are presented in Table 1 [9]. ROS as very reactive oxygen molecules can cause cellular damage, including oxidation of lipids, proteins, and DNA

Inorganic Nanoparticle Radiosensitizers for Cancer Therapies, Fig. 2 Examples of inorganic nanoparticles which have potential to be used for enhancing the radiosensitization in cancer therapy

Inorganic Nanoparticle Radiosensitizers for Cancer Therapies, Fig. 3 Consequences of interaction of X-rays with matter [2]

Inorganic Nanoparticle Radiosensitizers for Cancer Therapies, Table 1 Lifetimes and diffusion distances of Reactive Oxygen Species [9]

ROS	Symbol	Lifetime	Diffusion length
Hydroxyl Radical	**$HO^{\cdot}$**	100 nsec	4.5 nm
Singlet Oxygen	**$^1O_2$**	3.7 msec	82 nm
Superoxide Radical	**$O_2^{\cdot -}$**	50 msec	320 nm

resulting in apoptotic and necrotic cell death due to mitochondrial dysfunction [10]. Platinum complexes are the most commonly used compounds that have a great potential of targeting radiosensitizers to DNA [11]. However, other metals, such as palladium, rhodium, or ruthenium, can also be used for this purpose [11].

The major mechanism of radiation-induced cell death is ROS-mediated DNA damage. In a human body, ROS are generated as a consequence of the radiolysis of water. The most chemically active radical $^{\cdot}OH$, formed due to the radiolysis of water, readily reacts with biological molecules including cellular DNA to initiate radiation-induced apoptosis [10]. Metallic nanoparticles can induce the production of ROS leading to oxidative stress even in the absence of irradiation, for example, GNPs sized 1.9 nm [10]. When NPs are used in combination with ionizing radiation, they can cause enhanced ROS production [10]. GNPs are versatile NPs as they can serve as a platform for various biomedical and diagnostic purposes. Nonetheless, GNPs were found not to be inert in the absence of irradiation, which can have various biological consequences and limit their use [10].

Effect of Irradiation on Cell Cycle

Cell cycle is a vital mediator of sensitivity to the biological effects of irradiation [10]. In general, cells show different radiation sensitivity during different phases of the cell cycle [10]. Late S-phase cells are the most radioresistant, while mitotic cells are the most sensitive [10]. Cells respond to irradiation by activating cell cycle checkpoints in G1, S, and G2 phases [10]. Metal-based compounds block cells at the most radiosensitive phase: G2/M phase [11]. Lin et al. showed that nano-Germanium caused a higher level of DNA damage and cell cycle arrest in G2/M phase [12].

GNPs have been reported to cause alterations in cell cycle distributions [10]. Roa et al. demonstrated acceleration in the G0/G1 phase and accumulation of cells in G2/M phase in cells exposed to the irradiated glucose-capped GNPs [10]. Geng et al. observed an increase in the G2/M cell population for the 14 nm glucose-capped GNP-treated cells followed by irradiation at 6 MV X-rays [10]. Nuclear targeted GNPs have been shown to cause accumulation of cells in G1 phase and disruption of the G1/S transition inducing apoptosis in cancer cells [10]. These reports would suggest changes in cell cycle kinetics induced by GNPs, either additive toxicity as a result of increased sub-G1 population or accumulation in G2/M as a mechanism of GNP radiosensitization [10].

Summary of In Vitro Studies on GNPs

Jain et al. summarized results of in vitro studies of gold nanoparticle radiosensitization with ionizing radiation [13]. The impact of GNP size, concentration, and radiation energy on in vitro radiosensitization in HeLa cells was shown by Chitharni et al. [13]. The studies showed that the radiosensitization is size dependent. Three different GNPs sized 50 nm, 14 nm, and 74 nm were tested. The studies showed that the greatest radiosensitisation was observed with 50 nm GNPs with 220 kVp (peak kilovoltage (kVp) is the maximum voltage applied across an X-ray tube. It determines the kinetic energy of the electrons accelerated in the X-ray tube and the peak energy of the X-ray emission spectrum) X-rays [13]. Rahman et al. reported in vitro radiosensitizing effects of 1.9 nm GNPs (also called Aurovist) on the bovine aortic endothelial cells (BAEC) exposed to GNPs prior to irradiation with 80 kVp or 150 kVp X-rays [13].

Surface properties of NPs are a vital element in in vitro radiosensitization. Zhang et al. used 30-nm citrate or thioglucose-coated GNPs to test the GNP on the prostate cell line (DU145). The cells were irradiated with 200 kVp X-rays after 24 h exposure with the GNP [19]. As consequence, a threefold increase in GNP uptake was observed in the glucose-capped GNPs [13]. A study by Roa et al. compared thioglucose and cysteamine-capped GNPs (sized 10.8 nm) in MCF-7 breast cancer and MCF10a normal breast cells irradiated with 200 kVp, ^{137}Cs or ^{60}Co radiation [13]. A supra-additive effect with GNPs and radiation was observed with thioglucose GNPs and a single dose of irradiation [13]. Mechanisms of GNP sensitization in DU145 cells exposed to the thioglucose GNPs and irradiated with 2 Gy ^{137}Cs γ-rays was also investigated (original studies done by Roa et al.) [13]. The combination of the thioglucose GNPs and irradiation caused changes to the cell cycle compared to the untreated prostate cancer cells [13]. The proportion of the prostate cells in the G2/M phase was 29.9 % in the cells treated with the GNPs and irradiation compared to 18.4 % for untreated controls [13]. Chien et al. tested high concentrations of 20-nm GNP ranging from 50 to 400 mg ml^{-1} on the CT-26 mouse colorectal cell lines. Radiosensitizing effect with the cells in combination with 6-MeV electrons was observed [13].

Gold is a high-Z metal, therefore GNPs can absorb kilovoltage X-rays more effectively. GNPs have been shown to cause radiosensitization at kilovoltage and megavoltage photon energies. In the cancer therapy, most patients are treated with megavoltage (MV) photons produced by a clinical linear accelerator [13]. Studies by Chithrani et al. on HeLa cells and Liu et al. on CT-26 murine cancer cells have reported

in vitro GNP sensitization at megavoltage photon energies [19]. Chithrani's study used 50-nm citrate-coated GNPs [13]. The concentration of NPs also plays an important role in the observed radiosensitization [13]. Liu et al. used high concentrations of 6.1-nm PEGylated GNP [13]. Radiosensitization with 6-MeV and 12-MeV electron energies was also observed by Rahman et al. The researchers tested high concentrations (0.5 mM) of 1.9 nm GNPs in their studies [13]. More examples of in vitro studies of various GNPs with ionizing radiation can be found in the review by Jain et al. [13]. The same authors summarized in vivo studies of gold nanoparticle radiosensitization with ionizing radiation [13].

Summary of In Vivo Studies on GNPs

Hainfeld et al. reported the results of various in vivo studies on Balb/C mice bearing EMT-6 murine breast cancer tumors. In the studies, high concentrations of Aurovist were used [13]. Various approaches were tested: GNPs alone, radiation at 30 Gy alone, and combination of GNPs and radiation at 30 Gy [13]. The NPs were injected intravenously prior to irradiation [13]. The results showed that nonirradiated GNPs had no effect on tumor progression in mice. Irradiation at 30 Gy (alone) caused tumor growth delay [13]. The combination of irradiation at 30 Gy and GNPs caused a significant reduction in tumor growth [13]. In another experiment carried out by the same research group, mice were treated with two different concentrations of GNPs: 1.35 g of Au kg^{-1} or 2.7 g of Au kg^{-1} GNPs followed by irradiation at 26 Gy. About a half of mice treated with lower concentrations of GNPs and 86 % of mice treated with higher concentrations of GNPs followed by irradiation survived for 1 year. Interestingly, only 20 % of mice treated only with the irradiation at 26 Gy survived the treatment. None of the mice treated with either concentrations of GNPs survived the treatment. The GNPs were found to accumulate preferentially in the tumor periphery (EPR effect) [13]. The NPs do not accumulate in the main tumor mass [13]. Biodistribution studies by Hainfeld et al. showed that gold accumulated in tumors after 24 h. However, it was also found in the liver and spleen suggesting uptake by the RES, which may be reduced by PEGylation or active targeting [13].

The same research group carried out another experiment on mice bearing highly radioresistant murine squamous cell carcinoma, SCCVII. There were significant changes in tumor progression in mice treated with Aurovist or radiation only. The most significant tumor growth delay in mice was observed when Aurovist was combined with radiation using 68 keV photons [13].

Also, using of some coated GNPs gave very promising results in vivo. For example, 13-nm citrate-coated GNPs were tested in a mouse model with B16F10 murine melanoma cells. Significant in vivo tumor growth delay and increased survival were noted when 36 mg kg^{-1} citrate-coated GNPs were injected 24 h before irradiation at the dose of 25 Gy. There was no antitumor effect observed in control animals treated with the citrate-coated GNPs only (original studies performed by Chang et al.) [13].

However, some of the coated NPs did not show any significant difference in vivo. For example, gadolinium-coated GNPs, sized 5 nm, were tested in mice bearing MC7-L1 murine breast cancer cells (original work done by Hebert et al.) [13]. Mice were injected with GNPs 20 min before irradiation at 10 Gy [13]. Interestingly, the researchers did not report any difference in survival times in the group treated with radiation alone and the group of animals treated with GNPs and irradiation [13].

Designing the Most Effective GNP Radiosensitizer

Concentration. At higher concentrations, GNPs can be toxic. Moreover, the high concentration decreases cell growth rate [14].

Size. Large GNPs cannot be cleared by kidneys while small GNPs can be filtrated by kidneys quickly. Only GNPs sized 1–100 nm can be internalized by cells [14].

Surface properties. GNPs can be functionalized with PEG, glucose, DNA, peptides, etc. to improve

their biocompatibility. For example, glucose-functionalized GNPs can be much more effectively internalized by cells – as a consequence this enhances radiosensitivity [14].

Localization in the cell. GNPs should be localized inside the cell to improve their radiosensitivity [14].

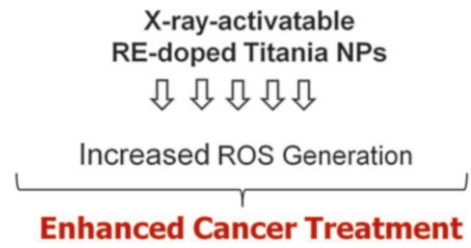
Dose of irradiation. GNPs can show radiosensitization with kV, KeV, MeV, and MV X-rays [14].

Type of cell line. Radiosensitizing effect of GNPs depends on cell type [14].

Gadolinium Nanoparticles as Theranostic Agents

Mowat et al. showed in vitro that ultrasmall (5 nm) gadolinium-based NPs can be internalized in radioresistant cancer cells (human glioblastoma cell line U87) [15]. The particles consisted of a gadolinium oxide core coated by polysiloxane shell and were functionalized by diethylenetriaminepentaacetic acid (DTPA) [15]. The U87 cells were incubated with various concentrations of the gadolinium NPs, ranging from 0 mM to 10 mM followed by irradiation at 10 Gy. It was reported that the single-cell gel electrophoresis comet assay (that measures the number of DNA damages that occur during irradiation) proved the gadolinium NPs to be effective radiosensitizers [15]. Moreover, the authors showed that the same NPs can be efficient radiosensitizers at the energy 6 MV used in clinical practice [15]. Agents that allow precise defining of the tumor target to allow enhanced radiotherapy treatment without affecting neighboring healthy tissues are called "*theranostic*" agents [16]. Sancey at al. showed that the use of theranostic gadolinium-based agents (AGuIX) can improve the outcome of radiotherapy [16]. The theranostic gadolinium-based nanoparticles were comprised of polysiloxane and surrounded by gadolinium chelates (DTPA or DOTAGA – 1,4,7,10-tetraazacyclododecane-1-glutaric acid-4,7,10-triacetic acid) covalently grafted to the polysiloxane inorganic matrix [16]. The NPs consisted of high content of Gd (15 %) and had small size distribution (<5 nm) [16]. The authors reported that the presence of several gadolinium ions in the same nanoparticle could lead to further amplification of the Auger cascade [16]. In vivo efficacy of such AGuIX NPs was reported in heterotopic and orthotopic tumors [16]. It was reported that AGuIX NPs when injected intravenously into rats bearing 9 L glioma served as theranostic agents [16].

Recently, Miladi et al. reported gadolinium-based NPs (GBNs) comprised of polysiloxane and DTPA for potential theranostic use in vivo [17]. The same authors demonstrated radiosensitizing effects of the GBNs in various radioresistant human Head and Neck Squamous Cell Carcinoma (HNSCC): SQ20B, FaDu, Cal33 cell lines [17]. The GNPs had a small size distribution, about 2.9 nm. The GBNs showed a synergistic effect combined with a 250 kV energy irradiation in vitro. As a consequence of the interaction of the GBPs with photons, Auger electrons and ROS are produced that enhance the effect of irradiation [17]. The authors reported significant ROS generation 24 h after GBN treatment combined with irradiation [17]. The same authors confirmed the radiosensitizing effect of GBNs in conjunction with irradiation in vivo. Tumor growth in SQ20B-bearing nude mice was delayed by using the GBNs and a single 10Gy dose of irradiation [17].



Rare Earth Elements

The effectiveness of radiotherapy can also be achieved by using rare earth (RE) elements [18]. The RE elements have a high Z number ranging from $Z = 57$ (lanthanum) to $Z = 71$ (lutetium) [18]. They comprise the 15 lanthanides in Mendeleev's periodic table with the addition of scandium and yttrium [18]. The improvement in delivering high dose of irradiation can be achieved by doping inorganic nanoparticles, such as titania NPs (titanium dioxide – TiO_2) with one or a combination of RE [18]. The exceptional properties of the various rare earth elements and their potential application in vivo for cancer imaging and cancer therapy were described by Townley [18].

RE-Doped Titania Nanoparticles as Radioenhancers

Titania (TiO_2) nanoparticles can have one of three crystal structures: brookite, anatase, and rutile. Anatase is the most photoactive among all the polymorphs of titania. TiO_2 can be doped with at least one lanthanide, such as Gadolinium (Gd), Europium (Er), or Erbium (Eu). Incorporation of the RE elements into the titania crystal structure (RE:TiO_2) is designed to optimize localized energy absorption from a conventional X-ray which has a maximum of absorption at 60 MeV [9]. The incorporation of the dopant into the TiO_2 can enhance the effect of radiation therapy [9]. The particulate characteristics of the doped titania NPs permits direct intratumoral administration. Tumor vasculature is hyperpermeable with pore sizes ranging from 50 to 600 nm. This allows the NPs to accumulate in a tumor tissue (passive targeting). The NPs can be well retained within the tumor due to the lack of drainage from solid tumors. RE:TiO_2 can be activated by X-ray radiation to generate Reactive Oxygen Species (ROS), which can be effective in killing cancer cells. As such, treatment with these RE-doped NPs can be used to enhance the efficacy of conventional radiotherapy. Incorporation of the NPs in to tumor tissue will permit the extension of radiotherapy to currently untreatable tumors deep within the body (as schematically presented in Fig. 4). Moreover, the short lifetimes and diffusion distances of ROS (shown in Table 1) would enable cancerous cells to be targeted with very limited damage to neighboring healthy cells [9]. Therefore, the RE:TiO_2 can serve as novel theranostic agents.

In vitro studies. Various compositions on NPs consisting of 1, 5 and 10 % of Gd as well as tridoped titania NPs consisting of 1 % of Er and Eu and various concentrations of Gd (1, 5 and 10 %) were tested on the breast carcinoma cell line (MCF-7) and the rhabdomyosarcoma (RMS) cell lines: RH30 and RD [9]. Rhabdomyosarcoma is the most common soft-tissue sarcoma among children and adolescents [9]. There are two major subtypes of RMS: the alveolar subtype (RH30) and the embryonal subtype (RD) [9].

Inorganic Nanoparticle Radiosensitizers for Cancer Therapies, Fig. 4 Rare earth elements (*RE*) doped titania (TiO_2) when activated by X-ray radiation, can increase the efficacy of conventional radiotherapy without causing additional damage to neighbouring healthy tissues. The nanoparticles ROS treatment can be extended to currently untreatable tumors deep within the body

The alveolar subtype has a poorer outcome than the embryonal subtype [9]. All tested NPs were internalized by the cancer cells [9]. However, they were unable to penetrate the nuclear membrane [9]. All tested cell lines showed reduction in cell proliferation in the presence of RE-doped titania NPs followed by X-ray irradiation except of RD cells which did not show statistically significant reductions [9]. MCF-7 cells showed significant reductions in cell proliferation for all NP compositions tested [9]. All tested RE-titania NPs were shown to be inert in the absence of irradiation [9]. Different amounts of ROS are produced by different cancer cell lines which can explain the different responses of the cell lines to the treatment [9]. The RH30 cells together with 3Gy irradiation showed statistically significant reductions in cell proliferation [9]. RH30 showed a 67 % and 66 % decrease in cell proliferation after treatment with the NPs consisting of 10 % Gd and tridoped sample containing the same molar percentage of Gd but additionally doped with 1 % Eu and 1 % Er followed by irradiation at 3Gy, respectively [9]. In the clinics, the total dose of radiation is not applied as a single dose but is fractionated. This allows the noncancerous cells some time to recover between irradiations [9]. RH30 cells were irradiated with two fractions of irradiation (two times 3Gy), and then the proliferation was determined [9]. Again, various compositions of NPs were tested, and a statistically significant

reduction in RH30 cell proliferation was reported [9]. For one of the tested samples, consisting of 5 % of Gd, 1 % Eu, and 1 % Er, there was a 75 % decrease in proliferation compared to untreated cells (control samples) [9].

In vivo studies. Preliminary preclinical studies in vivo by using tridoped RE:TiO_2 gave very promising results [19]. The tested NPs had a primary crystallite size ranging from 3 to 10 nm and were shown by XRD to be single-phase anatase [19]. Their hydrodynamic diameter of 65 nm allows the cellular uptake and effective generation of ROS [19]. The nanoparticles were silica coated to improve their biocompatibility and prevent aggregation in aqueous suspension [19]. Townley et al. found that intratumoral injection of the silica-coated three-doped titania nanoparticles (5 % Gd, 1 % Er, 1 % Eu:TiO_2@Si) can decrease A549 lung adenocarcinoma tumor volume in mice by around half when nanoparticle-augmented radiotherapy was used, compared to radiation alone [19].

Nanoparticle-Augmented Radiotherapy

Nanoparticle-augmented radiotherapy is an attractive, noninvasive, and novel method of using radiotherapy to activate NPs. The nanoparticle-augmented radiotherapy would allow fewer fractions of radiation in the clinics. Moreover, already existent hospital facilities and radiotherapy equipment could be used in the novel radiotherapy. The nano-sized particles are of a great advantage in this therapy (EPR effect), and this will avoid clearance by the kidneys and provide good particle retention in tumor. The surface of the NPS can be functionalized to improve their biocompatibility and prevent aggregation. If NPs have sizes less than 65 nm, they can enter a cell [20]. If the NPs have sizes less than 50 nm, they can enter an organelle of a cell [20]. The silica coating is thin (1–2 nm) and porous [9]. If the coating does not completely cover the surface of the metal oxide, it allows more efficient doses of irradiation to reach the molecule, generate enhanced ROS, and therefore allow a more effective radiotherapy outcome [9].

Other Inorganic Radiosensitizers

Lin et al. reported the use of *germanium* (*Ge*) *NPs* as potential radioenhancers [7]. Germanium oxide (GeO_2), Ge NPs (nano-Ge), and bis (2-carboxyethylgermanium) sesquioxide (^{132}Ge) were used in the study. The nano-Ge were found to be nontoxic to cells in the absence of irradiation [12]. ^{132}Ge did not enhance the radiosensitivity of Chinese hamster ovary (CHO) K1 cells, but inorganic Ge compounds enhanced cellular radiosensitivity [12]. The authors also reported a difference in solubility of the Ge compounds and their efficiency in cellular uptake. GeO_2 are uptaken by the cells much more efficiently than ^{132}Ge [12]. The study showed the advantage of using inorganic Ge nano-sized materials over the organic Ge compounds [12].

Chu et al. reported a radiosensitising effect of novel inorganic materials, *hydroxyapatite nanoparticles* (nano-HAPs) [21]. The NPs, sized about 50 nm, were synthesized by the sol-coagel method [21]. Nano-HAPs were tested on human glioblastoma U251 and breast tumor brain metastatic MDA-MB-231BR cells [21]. The nano-HAPS enhanced the radiosensitivity of the cells in vitro. Moreover, in a subcutaneous model, the NPs caused a larger than additive increase in tumor growth delay [21]. It was proposed that the same NPs used in an orthotopic model significantly reduced tumor growth. Moreover, the NPs extended the prolongation of survival induced by irradiation [21].

Silver NPs (Ag NPs) can also be potentially used as radiosensitizers [22]. The radiosensitising effect of various Ag NPs was reported for some cell lines, such as U231 breast cancer cells, A549 lung cancer cells, MGC803 gastric cells, and glioma cells and was size dependent [22]. For example, 20 nm and 50 nm Ag NPs performed better than 100 nm Ag NPs on the human U251 glioma cells (original work done by Xu et al.) [22]. There are few reports regarding the radiosensitizing effect of Ag NPs in vivo. One of the studies on rats bearing C6 glioma (original work done by Lin et al.) showed that the combination of a single dose of 10 Gy radiation and 10 μg and 20 μg Ag NPs had much higher survival times compared to

the animals treated with radiation alone [22]. The mechanism of Ag NP radiosensitization is not fully known yet [22].

Conclusion

The inorganic nanoparticle radioenhancers can be used as a platform for various applications of the NPs in oncology, especially in radiotherapy. The EPR effect allows the NPs to accumulate in the tumor. GNPs are the most commonly studied radiosensitizers. In practical terms, the main limitation of using GNPs in cancer therapy is their toxicity associated with the high concentrations of GNPs used. Interestingly, some inorganic compounds can be more effective radiosensitizers than the corresponding organic compounds. This was reported for germanium NPs. Another attractive alternative to improve the outcome of radiotherapy is to use metal oxides, such as titanium dioxide or hafnium dioxide, as potential radioenhancers. The titanium dioxide NPs, doped with one or more lanthanides, can enhance radiotherapy. The X-ray-activable RE-doped NPs can generate enhanced ROS production. The enhanced ROS produced can effectively damage tumor structure without affecting neighboring healthy cells. The advantage of using the NPs is that they are inert in the absence of irradiation so can serve as theranostic agents. The NP ROS treatment can be extended to currently untreatable solid tumors deep within the body. Also, as recently reported, various functionalized gadolinium NPs can be used as theranostic agents. In most studies, the NPs were found nontoxic at the concentration at which it exhibited some effect in combination with radiations and found to be effective even on radioresistant cancer cell lines.

Flapping-wing flight; Micro air vehicles (MAVs); Robotic insects

Definition

Micro air vehicles are generally considered to be blown 15 cm in characteristic dimension and weigh on the order of 10 g. Small MAVs, vehicles 1 g or less, have historically relied on insect flight for inspiration and have utilized a variety of flapping-wing morphologies.

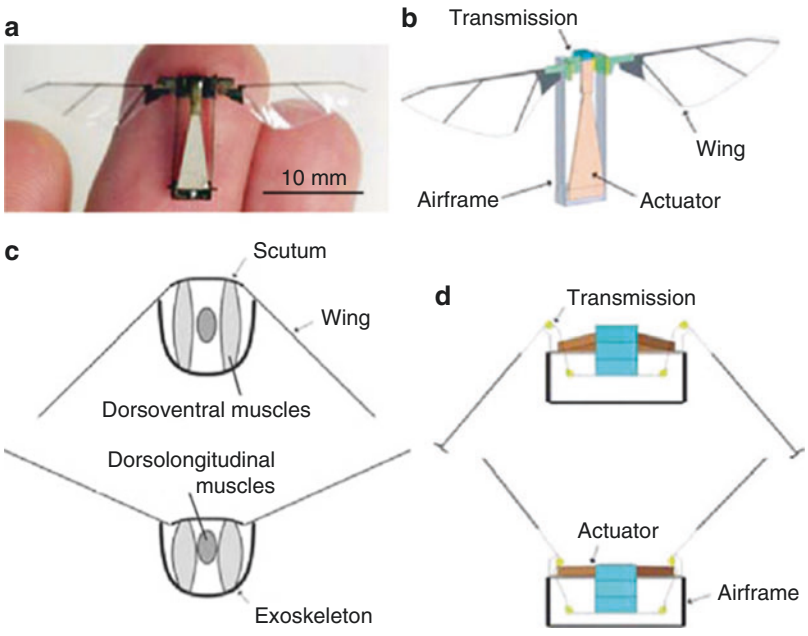
This entry discusses sub-gram MAVs inspired by flying insects.

Introduction

Many insect species are agile fliers. Yet they operate in a way fundamentally different from man-made aircraft. Although there are many, sometimes subtle, differences between the flight apparatus of individual species, in general, insects have one or two pairs of wings, driven in multiple

rotational degrees of freedom by flight musculature, and powered by metabolic processes which convert chemical energy for flight. Engineers striving to produce a robotic insect must solve similar challenges, not only for the tasks which the device could perform, but also for the open scientific questions one could use such a device to answer. Therefore, a key question is: how can one manufacture an effective replica of a flying insect? This entry describes the reproduction of some of the key functionalities of a flying insect not as an end "design," but to prove the viability of the core technologies necessary for such a robot.

The integrated circuit revolution of the 1950s and 1960s now enables the majority of the consumer electronics that are enjoyed daily. As these techniques evolved in the 1980s to include electromechanical components, an even greater space of applications emerged including sensors, optics, and even actuation [1]. Microrobots have been made using MEMS (microelectromechanical systems) surface and bulk micromachining techniques [2, 3]. However, there are many drawbacks to use integrated circuit (IC) and MEMS technologies to create robotic insects. First is the dramatic difference between the material properties of silicon and insect tissue: the former being rigid and brittle while the latter exhibits a large range of material properties, is generally quite resilient, and is approximately the density of water. Second, although the suite of techniques for high resolution machining is an appealing aspect of MEMS processes, the resulting structures are typically "2.5D," with high aspect ratio components being extremely challenging in terms of machining or requiring hinged structures [4]. Finally, although MEMS foundries exist (e.g., the Multi-User MEMS Process, www.memscapinc.com), cost and turnaround time are generally prohibitive to rapid prototyping. With the advent of "mesoscopic" manufacturing methods [5], researchers have demonstrated key components of the flight apparatus of robotic insects [6] and recently, the first demonstration of a 60 mg flapping-wing device which can produce thrust greater than its body weight [7] has proven the feasibility of creating insect-scale flying robots.



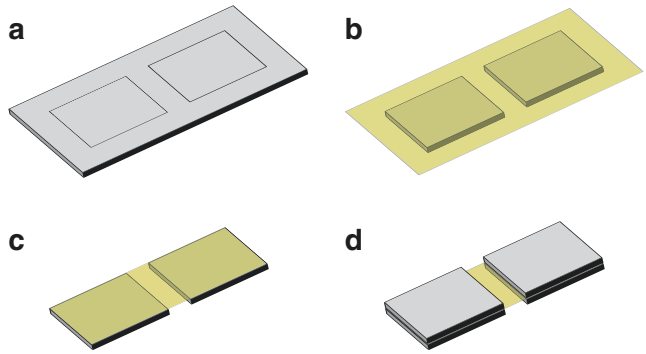
This entry discusses the challenges in developing the components necessary to achieve stable flight of a robotic insect. Topics include aeromechanics, fabrication, actuation, design, control, and power. This entry mostly considers the physical instantiation of a robotic insect. There are numerous additional aspects of a robotic insect that would be required in order for the device to perform useful tasks in natural environments. These topics will be outlined in the conclusion.

Overview of a Robotic Insect: "RoboBees"

The "RoboBee" project is aiming to build a two-wing robotic flying insect for a variety of tasks including search and rescue and assisted agriculture (e.g., pollination). This section describes the state of the art for the physical instantiation of a robotic bee which consists of composite-reinforced airfoils, a flexure-based transmission, piezoelectric actuation, and a rigid composite airframe. Key to the success of any flapping-wing design is an understanding of the aerodynamics for vehicles of this type and scale; this is discussed in section "Aerodynamics of Flapping-Wings at Low Reynolds Numbers."

Aeromechanical Components of a RoboBee

The current RoboBee prototype has four primary mechanical components: thorax, airframe, bimorph piezoelectric actuator, and a pair of airfoils [7], as shown in Fig. 1a, b. To fabricate this bee-sized robot, flexure-based structures are utilized in place of more traditional revolute bearings. A single bending actuator pushes and pulls the upper part of the mechanical thorax in a similar configuration to Dipteran dorsoventral muscles (Fig. 1c, d). This bioinspired flexure-based transmission is capable of converting small (hundreds of microns – limited by the motion of the piezoelectric actuator) actuator motions into large flapping angles (over 100° peak-to-peak) with a minimum of moving parts and with feature sizes appropriate to the scale of a bee and with extremely high transmission efficiencies. This is otherwise rather difficult, if not impossible, to



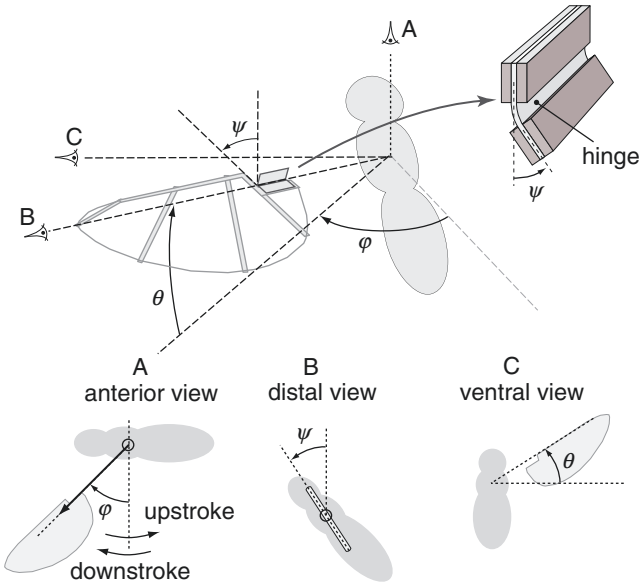
Insect Flight and Micro Air Vehicles (MAVs), Fig. 1 (**a**) A prototype RoboBee illustrating scale. (**b**) Schematic of the components of RoboBee. (**c**) Cross-sectional schematic of Dipteran thorax. (**d**) Mechanical thorax of a RoboBee

achieve with a conventional crank mechanism using a rotational motor, rotational bearings, and gears due to part size, assembly accuracy, and friction. The flexure-based structure was utilized not only for transmission hinges but also for precise fabrication and assembly of micro parts. Rigid carbon fiber frames connected with the flexure hinges were fabricated in a plane and then assembled into 3D shapes by folding. This enables precise fabrication and assembly without limiting the materials that can be utilized in the structures. The fabrication process for the flexure-based components is illustrated in Fig. 2. Rigid face sheets are laser micromachined using a diode-pumped solid-state laser from carbon fiber reinforced prepregs (preimpregnated with a catalyzed but uncured resin) with precisions and features sizes on the order of 10 μm. Thin sheets of polyimide – chosen for mechanical resilience and thermal stability – are also laser micromachined and laminated to the uncured prepreg face sheet using a vacuum tool to ensure uniform pressure distribution. The process is repeated for the opposite face sheet. Airfoils can also be created in this manner but without the need for face sheets on either side of a thin film polymer membrane. Previous versions have relied on passive flexure hinges at the base of the wing to give rise to the second degree of freedom of the wings: pronation and supination (collectively termed wing rotation). Using these techniques, prototypes as small as 60 mg (15 mm wing length) have been demonstrated [7]. Although all power electronics reside off-board the robot, this device achieved liftoff with vertical rails at a wingbeat frequency of 110 Hz.

Aerodynamics of Flapping-Wings at Low Reynolds Numbers

Flight at small scales is challenging not only in the development of the mechanism to more the airfoils, but also in the scale-dependent energetic cost of manipulating the fluid. At the scale of insects, with typical Reynolds numbers in the range of 100–10,000 [8], fluid mechanics can be dominated by viscous effects and laminar flow. For example, given a 10 mm long, 5 mm average chord wing operating in air at a 100 Hz flapping frequency with 90° stroke amplitude is operating at an average Reynolds number of approximately 500. In steady flight, these low Reynolds number conditions can dramatically reduce lift-to-drag ratios compared to larger scales and higher velocities. Therefore, there has been significant interest

Insect Flight and Micro Air Vehicles (MAVs), Fig. 2 Fabrication process for flexure-based articulated structures consisting of carbon fiber rigid plates and a polyimide hinge. First, composite face sheets are laser machined (**a**) and laminated with a polyimide film (**b**). This film is laser cut (**c**) and the structure is laminated to a second face sheet (**d**)



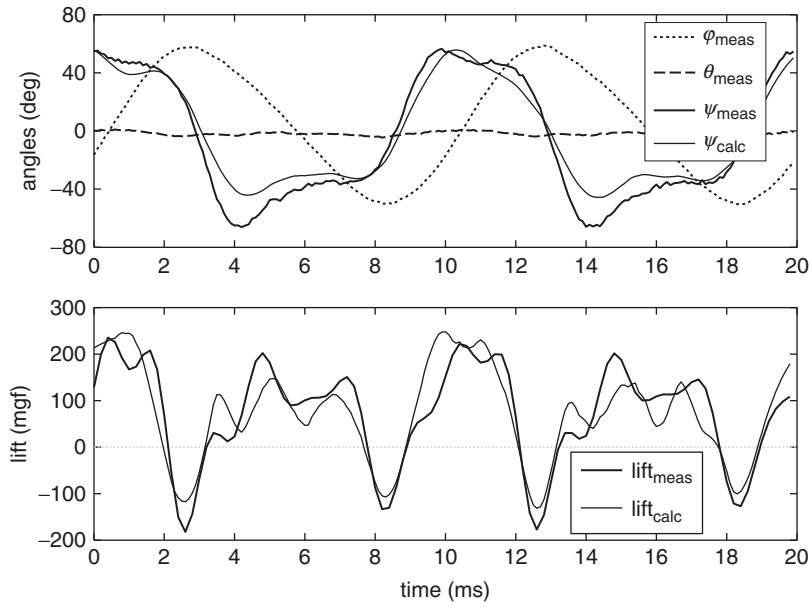
in the study of the "unsteady" mechanisms that insect use to enhance lift production [9].

Flapping kinematics are characterized by large angles of attack at midstroke and high rates of rotation during supination and pronation of the wing. Massive separation of boundary layers, possible reattachment, and strong vortex shedding at both the leading and trailing edges are possible features of this type of flow. In hover, the wing interacts with its own wake, potentially leading to significant time-dependent aerodynamic forces. Needless to say, the wing dynamics and aerodynamic effects involved are complex and the accurate prediction or measurement of forces and flow fields demands sophisticated flow simulations and precise experiments.

Many different aerodynamic effects have been identified, which are reviewed in [10]. Often, experiments attempt to explain the aerodynamics for a single wing at a single operating point, usually with the aim of identifying the important aerodynamic mechanisms for a particular insect species. Recent work by Lentink and Dickinson [11] reverses this trend; they investigate aerodynamic performance under the systematic variation of wing aspect ratio, Reynolds number (Re) and flapping amplitude using a scaled-model mechanical flapping device. As interest in flapping-wing MAVs rises, the study of flapping flight from a design, rather than biological perspective, becomes more important. Instead of studying the behavior and performance of a particular species, research must uncover the important parameters in wing configuration and flapping kinematics that most strongly influence vehicle-level performance for a range of mission profiles and vehicle sizes.

The wing design of a hovering MAV entails not only the capacity for lift generation, but, more importantly, the power required for flight. Hovering is extremely energy-intensive and aerodynamic efficiency is a primary concern. Of equal concern is minimizing the total vehicle mass. Simplification of the wing flapping mechanism and reducing the number of actuated degrees of freedom can lead to great weight savings. To this end, a successful configuration has been developed, where each wing is driven in a single flapping degree of freedom, $\Psi(t)$, allowing wing rotation to happen passively. Figure 3 illustrates a wing hinge that allows passive rotation. Clear evidence exists that some insects exhibit passive rotation [12], but there is no consensus that all insects use passive rotation, or that it is necessary for optimal flapping flight. Nevertheless, passive rotation has a demonstrated record of success in flapping-wing MAVs [7]. Prediction of wing performance, in the case of passive rotation, now becomes an aeromechanics problem, as the aerodynamic forces, wing inertia tensor and wing-hinge elastic properties jointly determine the kinematics and resulting forces.

A class of flapping-wing aerodynamic analysis techniques, the so-called blade-element methods



Insect Flight and Micro Air Vehicles (MAVs), Fig. 3 Angles used to specify wing kinematics, shown for a *left* wing and *vertical* body orientation. Current robotic insect prototypes utilize a flexure at the base of the wing (*upper right*) to allow passive rotation. The driving spar (flapping input) mounts to the *top* link of the hinge, the wing to the *bottom*

are fundamentally a form of dimensional analysis, applied in a careful and systematic fashion. The blade-element method is a quasi-static technique for applying nondimensional experimental and computational results to wings of different scales and operating conditions. The success of this method is critically limited by the quality of the accompanying force and moment coefficients and the method's quasi-static assumptions. The blade-element method begins by dividing the wing into chordwise strips along a flapping wing. The wing must be divided into strips because the relative local velocity varies linearly along the wing. Figure 3 illustrates a wing, flapping in hover, and breaks the kinematics down into flapping (Ψ), out-of-plane deviation (θ) and rotational (ψ) degrees of freedom. Using a simple expression based on dimensional analysis, for the local pressure on the wing, forces and moments arise after a straightforward integration over the entire wing. The key to the blade-element method is experimentally determining the force and moment coefficients, and ensuring that any time-dependence of these coefficients, as a result of unsteady effects, is negligible.

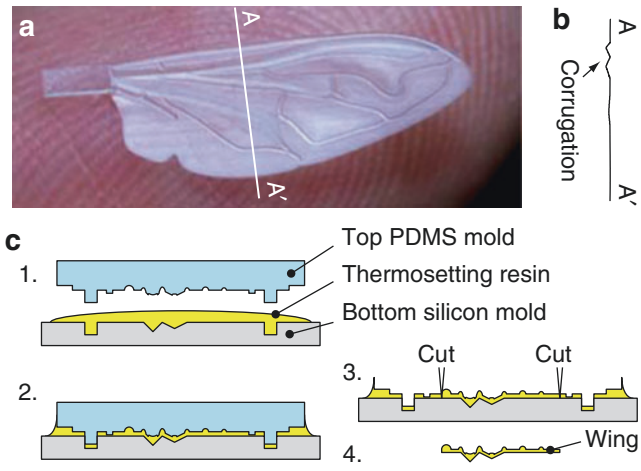
The Reynolds number (Re) for hovering insect flight is typically between 100 and 10,000. This range indicates laminar flow, and a suite of experimental and computational techniques can be employed to predict wing trajectories, deformations, and forces. Scaled-model experiments (e.g., [9]), which mechanically flap scaled-up wings in high-viscosity liquids so as to match Reynolds number, have been very successful in identifying important aerodynamic mechanisms and characterizing the performance of actual insects. However, it is not possible to match the Reynolds number (aerodynamic forces) and the inertial forces simultaneously in a scaled-model experiment. Thus, the scaled-up approaches are not appropriate for studies of passive rotation, or studies of wing deformation. Working with at-scale mechanical flapping mechanisms and micro-force sensors is an experimental challenge, but recent advances in these areas [7, 13] have enabled passive rotation and wing-deformation studies at scale.

The experiment described in [14] consists of a one-axis wing driver mounted to a capacitive force sensor. High-speed video was used to reconstruct the detailed wing trajectory. These kinematics were then used to generate blade-element force predictions, which could be compared to the experimentally measured forces. Figure 4 illustrates a comparison for one particular wing, flapping at 100 Hz. Hinge stiffness, flapping

Insect Flight and Micro Air Vehicles (MAVs), Fig. 4 Wing kinematics and lift at 100 Hz flapping (Measured and calculated). Measured kinematics are plotted unfiltered

frequency, and flapping amplitude were varied, and comparisons with blade-element predictions were made for each configuration.

Future work in support of flapping-wing MAV development will focus on continued experimental exploration of the wing design space, with a goal of minimizing the power required to generate the needed lift, under the vehicle mass and manufacturability constraints imposed by the microfabrication technology used, and the power sources available. The design and testing of flexible wings is of particular interest in the continuing quest for higher aerodynamic efficiency.



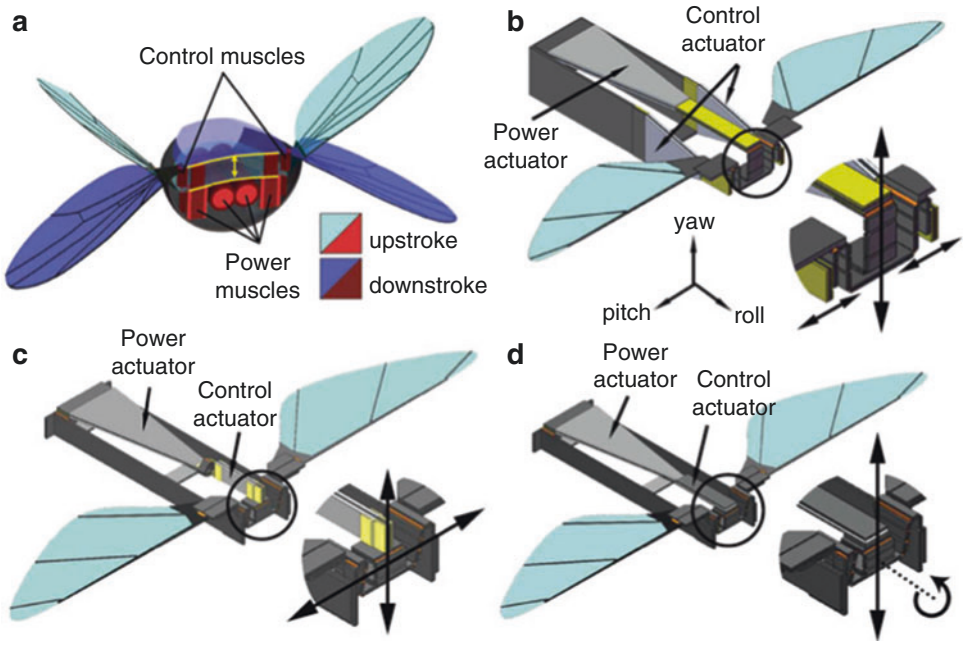
Toward Autonomy

Although a prototype RoboBee achieved takeoff along vertical guide rails, there are myriad challenges which need to be addressed to achieve full autonomy. These topics include, but are not limited to, airfoil design and fabrication, actuation and thoracic mechanics, and control. These topics will be addressed in the following sections.

Biomimetic Flexible Wings

Flexible 3D polymer wings which mimic insect wing morphologies are being developed in addition to the previous rigid carbon fiber based wings described in section "Aeromechanical Components of a RoboBee." Real insect wings are flexible and can passively deform when subject to aerodynamic load and inertia force. This flexibility is determined by the wing structure which consists of a thin cuticle membrane supported by a network of tubular cuticle veins [15]. Some insects also have 3D wing profiles such as the corrugation present in Dipteran wings. Actual effects of these wing morphologies on the aerodynamic performance of insect-sized flapping flight, however, are still unknown. By fabricating biomimetic wings, the aim is to develop an understanding of the structure-function relationship for these systems and exploit this understanding to create more effective wings for a robotic insect. Figure 5a shows a fabricated polymer wing mimicking the morphological features of a hoverfly wing [16].

As with a real hoverfly wing, the artificial polymer wings consist of veins with various thicknesses and corrugated profiles (Fig. 5b). Polymer veins and membranes with complex 3D profiles are simultaneously formed by a single molding process with a pair of molds: a bottom rigid (Silicon) mold and a top compliant (PDMS: Polydimethylsiloxane) mold (Fig. 5c). The technical challenge



Insect Flight and Micro Air Vehicles (MAVs), Fig. 5 (**a**) Photo of an artificial corrugated polymer wing. (**b**) Measured corrugated profile. (**c**) Schematic of fabrication process flow

lies in the development of molds with various 3D microscale features: veins, membranes, and corrugation. To realize arbitrary surface profiles in a mold, a custom DPSS (diode-pumped solid-state) laser machining system is used. The surface of a silicon wafer is directly etched with the scanning pulsed laser layer-by-layer to create a 3D negative mold. The spot size of the laser pulse is 10 μm and the etching rate is approximately 5 μm per layer, which is sufficient resolution for the veins and corrugation. The bottom negative mold is directly fabricated with this scanning laser ablation method, and the top PDMS mold is created by casting PDMS on another laser-ablated positive silicon mold.

The thickness of the artificial veins ranges from 50 to 125 μm and the maximum height of the corrugation is 100 μm. Since a hoverfly has vein thickness of 10–70 μm and a maximum corrugation height of 150 μm, this fabrication method enables biomimic insect wing morphologies in the same scale. The spanwise stiffness of the artificial wing, which is measured by a point-load bending test, is 2.2×10^{-7} Nm^2. This value has the same order of magnitude of that of *E. dimidiate* (from dried specimens, measured using the same point-load bending test), 5.3×10^{-7} Nm^2, which demonstrates that the artificial wing is statically similar to actual insect wings. These biomimetic wings are useful not only as airfoils for robotic insects, but also for biological studies on insect flight. Unlike experiments with live insects, microfabricated airfoils enable parametric studies of geometric features and experimentally test the relationship between geometry and performance.

Actuators and Thoracic Mechanics

Traditional fixed and rotary wing aircraft use either control surfaces (rudders, ailerons, etc.) or tail rotors to steer. Although insects may use their legs or abdomen to shift their center of mass or aerodynamic profile, their primary steering mechanism is the use of asymmetric wing kinematics [8]. While large, central "power" muscles are responsible for flapping the wings and generating the mechanical power required to stay aloft, in Dipteran insects much smaller "control" muscles at the base of each wing can cause small kinematic changes in wing motion that result in net body torques, allowing the insect to maneuver. A similar approach is used with piezoelectric actuators in the next generation prototype RoboBee (Fig. 6). The wing kinematic parameters, stroke angle ψ, rotation angle ψ, and deviation angle θ are defined in Fig. 3. Since wing dynamics are typically about an order of magnitude faster than body dynamics (i.e., it may take ten wing strokes to complete a 90° turn, although this is not always the case), variation in average parameters over the entire stroke can be sufficient to generate mean body torques. For example (to list only a few possibilities): (a) moving the mean stroke angle for both wings forward of the

Insect Flight and Micro Air Vehicles (MAVs), Fig. 6 (**a**) Cross-sectional view (artist's rendering, not anatomically correct) of a Dipteran insect thorax, (**b**) thorax design with two separate control actuators for changing stroke amplitude, (**c**) design with a "hybrid" actuator consisting of two bending piezoelectric elements, (**d**) another hybrid actuator with one bending element and one twisting element. All three designs achieve the same result of differential stroke amplitude

body's center of mass will result in a pitch torque, (b) differentially increasing the stroke amplitude of one wing to be larger than that of the opposite wing will result in a roll torque, and (c) tilting the stroke plane of one wing forward while tilting the stroke plane of the other wing backward will result in a yaw torque.

Previous prototype RoboBee designs only had one central power actuator, a bending piezoelectric cantilever. Subsequent designs included two smaller control actuators at the base of each wing, allowing controlled stroke amplitude asymmetry [17]. The systems are designed such that very small perturbations to the mechanical transmission connecting the power actuator to the wings by the control actuators can cause large changes in wing trajectory – that is, amplitude differences or stroke-plane deviations on the order of tens of degrees. Several variations of the design for controlled amplitude asymmetry are presented in Fig. 6.

While the ability to modify wing kinematics in a manner similar to that used by Dipteran insects has been verified in [17], actual torque measurements will be required to fully verify aerodynamic models and generate useful feedback control laws for vehicle stabilization and navigation. Work in this area is ongoing.

Altitude Control

To date, detailed strategies addressing the problem of altitude control of robotic insects have not been reported. Recent results obtained at the Harvard Microrobotics Laboratory show that by transforming the original problem of altitude control into one of average lift-force control, controllers capable of enforcing specified trajectories along the vertical axis can be synthesized. The main idea is that enough information about the subsystems composing the robotic insect can be gathered a priori, using well-known identification methods, such that, during constrained vertical flight, only an altitude sensor is required.

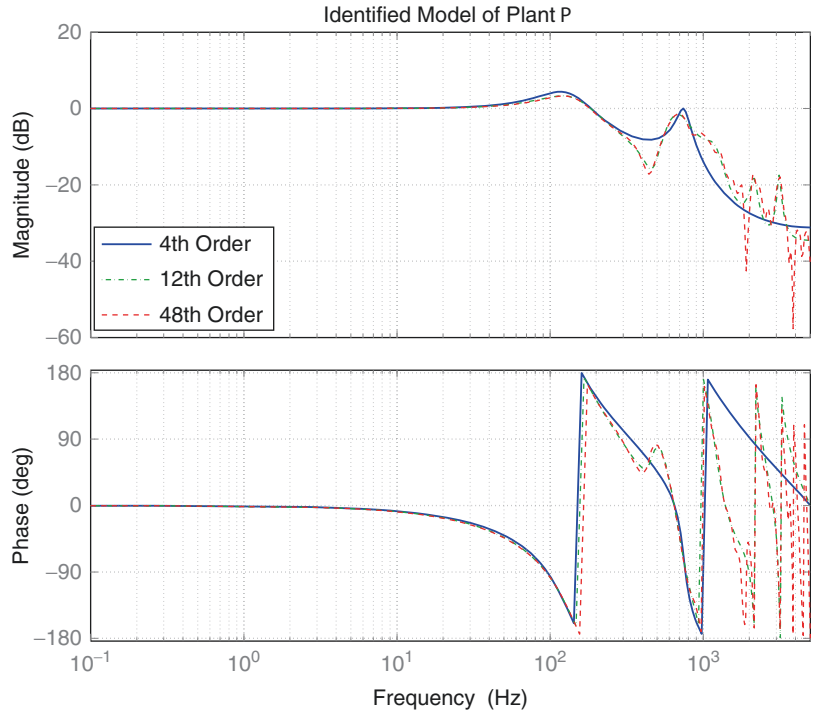
In this context, there are two subsystems relevant from a control perspective. One is the bimorph actuator, used to transduce electrical

into mechanical power, mechanically connected to the insect's airframe. The other is the mapping from the actuator tip displacement to the average lift force generated by the passive rotation of the wings, assuming a sinusoidal excitation of the bimorph actuator. Here, the first subsystem is labeled as P, such that

$$Pu + v = y, \tag{1}$$

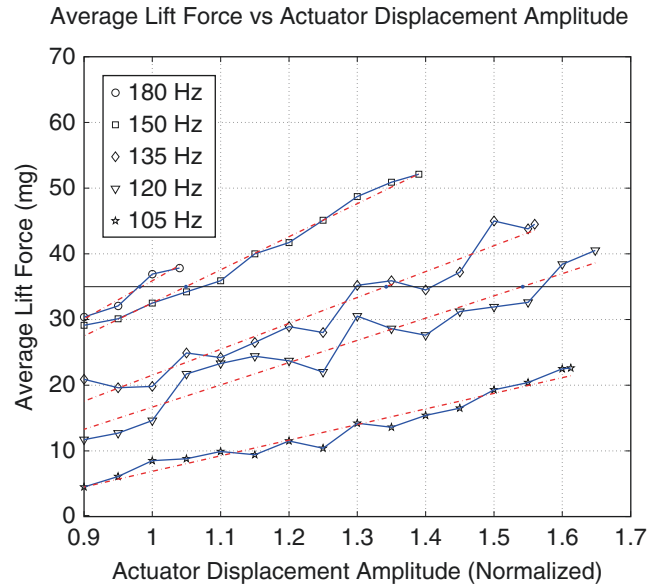
where, P is the open-loop dynamics, u is the voltage signal applied to the actuator, y is the output displacement of the actuator tip, and v is an output disturbance signal, representing the aggregated effects of all the disturbances affecting the system, including unmodeled aerodynamic forces produced by the wing flapping.

The second subsystem is a static map, labeled as Ψ, such that



$$\Psi(A, f) = \Gamma_L, \tag{2}$$

where, A and f are the amplitude and the frequency of the displacement output $y(t) = A \sin(2\pi ft)$, respectively. The signal Γ_L is the average lift force produced by the flapping of the insect's wings. Typically, instantaneous forces produced by the wings are oscillatory signals with a positive average value. Thus, hovering occurs if Γ_L is approximately equal to the weight of the robotic insect, and vertical motion occurs if Γ_L is larger than the sum of the insect's weight and the vertical aerodynamic drag. When using digital signal processors for control, Γ_L can be estimated as $\Gamma_L^{(N_L)}(t) = \frac{1}{N_L}\sum_{i=0}^{N_L-1} \gamma_L(kT_s - iT_s)$, where $\gamma_L(t)$ is the instantaneous force measured using a force sensor like the one described in [13], Ts is the sampling time, and $0 < N_L \in \mathbb{Z}^+$, is the number of samples.



With the use of an appropriate sensor to measure the actuator tip displacement, a discrete-time *linear time-invariant* (LTI) model of P, labeled as $\hat{P}$, can be found using standard system identification methods. Similarly, with the use of a force sensor, a displacement sensor and a feedback controller capable of enforcing specified trajectories $y(t)$, a lookup table with some relevant points of Ψ can be found through experiments. The estimated mapping $\hat{P}$ and the estimated lookup table associated to Ψ are contingent on a particular microrobotic flapping system, and therefore, great variability should be expected. As examples, in Figs. 7 and 8, an identified model $\hat{P}$ of P, and a graphic representation of an estimated lookup table are shown. These plots where obtained from experiments performed on a single-wing flapping microrobot, similar to the one described in [14]. In Fig. 8, the amplitudes of the signals $y(t)$ are normalized such that a constant input $u(t) = 1$ generates an output equal to 1.

The main idea for designing and implementing controllers is depicted in Fig. 9. Here, the idea is that a desired signal altitude $x_d(t)$ is arbitrarily chosen. Simultaneously, the actual altitude $x(t)$ is measured using an altitude sensor. Both signals are filtered through an *upper level control law* in order to generate a desired average lift-force $\Gamma_d(t)$ which in turn is filtered through an estimated lookup table, like the one graphically shown in Fig. 8, to generate a desired displacement of the actuator tip with the form $y_d(t) = A_d \sin(2\pi f_d t)$. Since A_d and f_d are unknown a priori, the idea of using some type of adaptive cancelation scheme is reasonable. This follows from defining $r(t) = -y_d(t)$ and the error $e_y(t) = y(t) + r(t)$, and then treating $r(t)$ as a disturbance to be rejected. Notice that under the assumption $v(t) = 0$, if $r(t)$ is completely canceled by $y(t)$, the error $e_y(t)$ vanishes and $y(t)$ follows perfectly the desired displacement $y_d(t)$. The other element to be noticed in Fig. 9 is that in order to avoid the need for a displacement sensor during flight, the identified model $\hat{P}$ is used to compute an estimate $\hat{y}(t)$ of $y(t)$, and then, an estimate of the control error, $\hat{e}_y(t) = \hat{y}(t) + r(t)$, is filtered through a *lower level adaptive control law* to generate the control signal $u(t)$ which is the input to the physical system.

To test the proposed method, a single-wing flapping microrobot, similar to the one in [14], is employed in the implementation of hardware-in-the-loop experiments. Since the main idea is to demonstrate lift control using the adaptive scheme in Fig. 9, a simple open-loop upper level control law is used. The objective is to follow an average lift-force signal, $\Gamma_L(t)$, such that a 70-mg robotic

Insect Flight and Micro Air Vehicles (MAVs), Fig. 7 Bode diagram of an identified discrete-time model $\hat{P}$ of the plant P. A 48th-order model is shown in *red*, reduced 12th and 4th-order models are shown in *green* and *blue*, respectively

insect would move from 0 to 0.3 m and then return to 0 m in no more than 3 s. Using the simple dynamical model of the insect

$$\gamma_L - mg = m\ddot{x}, \tag{3}$$

and the experimental data obtained for plotting Fig. 8, through computer simulation the complying a priori trajectory in Fig. 10 was found. Also according to the simulation, the a priori trajectory in Fig. 10 is achievable by tracking the desired

Insect Flight and Micro Air Vehicles (MAVs), Fig. 9 Control scheme

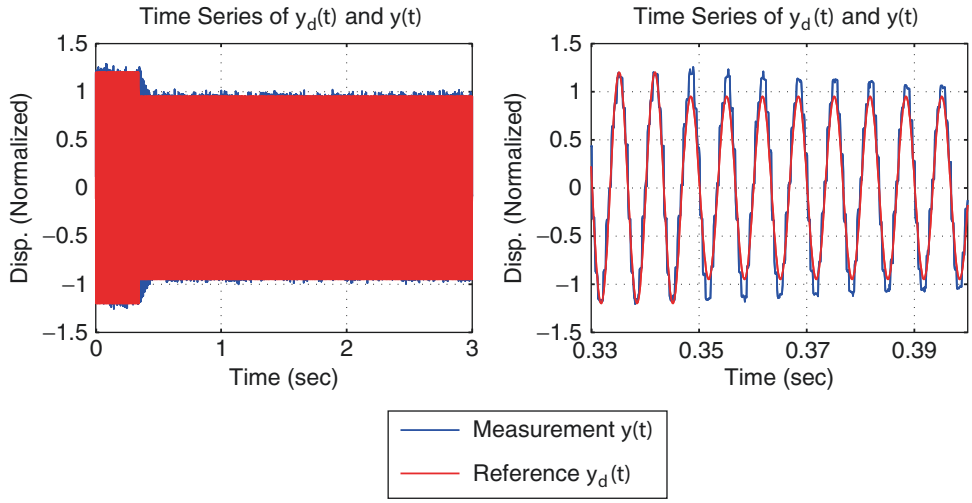
lift-force signal in red in Fig. 11, where $N_L = 1{,}000$.



The resulting experimental average lift force is plotted in blue in Fig. 11, which using the control strategy in Fig. 9, results from choosing $y_d(t) = A_d \sin(2\pi \cdot 150\ t)$, with $A_d = 1.2$ for $t \in [0, 0.347]$ s and $A_d = 0.95$ for $t \in [0.347, 5]$ s. The time series of the reference, $y_d(t)$, and output, $y(t)$, are shown in Fig. 12. Here, on the left the complete signals are compared, and on the right the transition from $A_d = 1.2$ to $A_d = 0.95$ is shown. Notice that $y(t)$ is capable of following $y_d(t)$ and that the transition is smooth, because P is under the control of the feedforward scheme in Fig. 9. According to the hardware-in-the-loop experiments, the estimated resulting *a posteriori* trajectory is shown in blue in Fig. 10.

Passive Balancing Transmission

Fully-actuated high-bandwidth control of wing trajectory is a desirable feature for an insect-scale flapping-wing robots and is a conventional approach to attaining control and stability in flight. However, mass and power constraints in

Insect Flight and Micro Air Vehicles (MAVs), Fig. 11 Reference and experimentally obtained average lift force

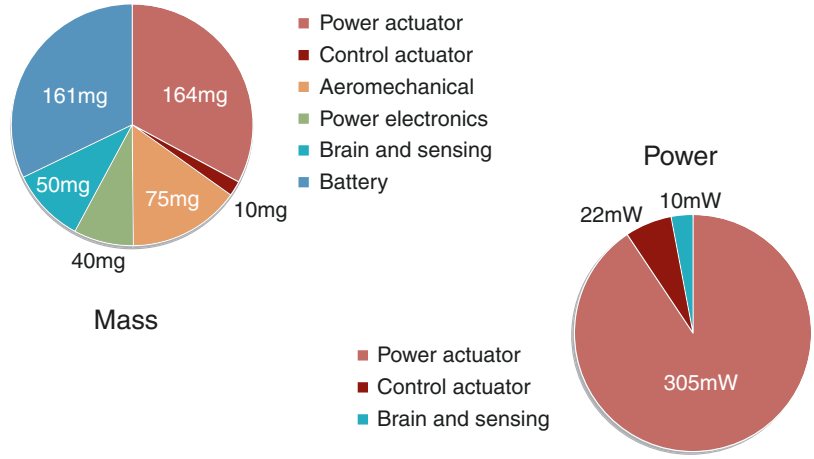
such devices motivate the investigation of unconventional control methodologies. A novel methodology, called Passive Aeromechanical Regulation of Imbalanced Torques (PARITy), relies on passive elements to achieve control objectives and has shown much promise in simplifying flight control for a flapping-wing robotic insect.

Passively compliant or under-actuated mechanisms have been used in robotic insects to reduce mechanical complexity, exemplified by the passive hinges allowing the wings of the prototype RoboBee to rotate in flight. The benefits of passive elements, however, can extend beyond reducing mechanical complexity to aid in flight control. The Drag PARITy is an example of such an under-actuated transmission and has been used successfully in the RoboBee to eliminate roll torques imparted to the airframe during operation [18].

Referring to Fig. 13, the Drag PARITy introduces a second degree of freedom to the standard 1DOF RoboBee transmission. Motion along the standard degree of freedom q_1 results in a symmetric flapping motion of the wings, while the additional degree of freedom q_2 allows differential motion between the wings, coupling the upstroke of one wing with the downstroke of the other. This additional degree of freedom is not associated with any actuator; instead, motion along q_2 is determined purely by the dynamics of the system. In this fashion, wing trajectories are passively altered in response to asymmetric wing loading,

Insect Flight and Micro Air Vehicles (MAVs), Fig. 13 (**a**) Planar kinematics of the drag PARITy transmission. Holding $q_2 = 0$ and allowing q_1 to oscillate between (**b**) negative and (**c**) positive values produces a symmetric flapping motion. Holding $q_1 = 0$ and allowing q_2 to take (**d**) negative and (**e**) positive values produces a differential flapping motion, coupling the upstroke of one wing with the downstroke of the other



resulting in a reduction in roll torque experienced by the body of the robot.

Research into PARITy is motivated by the realization that wing trajectories are not of fundamental importance to a flapping-wing device. Ideally, the wings would execute whatever trajectories are necessary to impart the desired forces and torques on the airframe. The fundamental importance of forces and torques over wing kinematics suggests the use of force and torque control instead of kinematic wing control. Passive elements such as those demonstrated by Drag PARITy can alter wing kinematic trajectories on a short timescale in response to forces and torques. In this manner, PARITy enabled devices are expected to lower performance requirements on mass and power limited active controllers.

In a PARITy system, active control is achieved not by altering the wing trajectories directly, but by modulating the dynamics of the short timescale passive systems. For example, instead of balancing roll torques, an active control input could bias the system to attain a 10 % higher reaction torque from one wing as compared to the other. It is anticipated that enabling such direct control over realized forces and torques will greatly simplify the control problem for mass-limited flapping-wing aeromechanical platforms.

Power Considerations

Power is a key challenge in achieving autonomous operation for insect-sized flapping-wing robots. The stringent weight and power requirements of insect-scale flight, especially when hovering, make it difficult to achieve autonomous operation without a thorough understanding of

Insect Flight and Micro Air Vehicles (MAVs), Fig. 14 Mass and power budgets for a hypothetical 500 mg robot

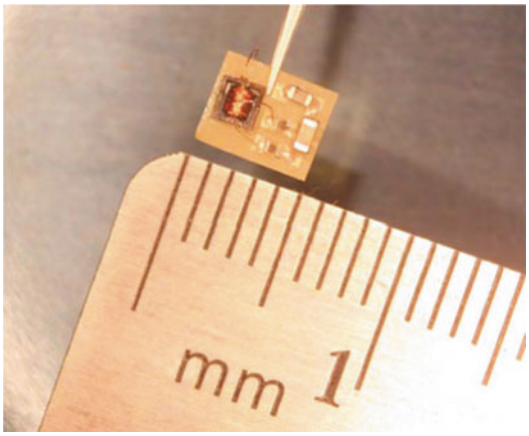
the interactions and tradeoffs between various components. There are three primary subsystems involved in flight energetics: the aerodynamic components (wings), the power actuators, and the energy source. These subsystems are linked by two transduction mechanisms: the mechanical transmission, which serves as the interface between the actuator and the aerodynamic components, and the power electronics, which serve as the interface between the energy source and the actuator. The remaining subsystems may include: structural, control electronics, sensing, communications, and energy harvesting components.

In the study of power and flight energetics, all subsystems except for the aerodynamic components, the power actuators, and the energy source are classified as payload. Payload is divided into two categories: static payload, which has a fixed mass, and proportional payload, where the mass scales as a percentage of the total mass of the robot.

Continuing advances in the design and characterization of the various subsystems have enabled system-level models of power and energy. The benefits of system-level modeling include analysis of design tradeoffs, optimization for various performance metrics (e.g., flight time), comparison to biological insects and other aerial platforms, and the ability to estimate the mass and power consumption of system components throughout the design space. For example, Fig. 14 shows the mass and power breakdown for a hypothetical 500 mg (total body mass, with all components integrated) flapping-wing robotic insect, the target vehicle of the RoboBees project [19].

Energy Source

Promising energy sources for robotic insects include batteries, fuel cells, ultracapacitors, and solar cells. At present, lithium polymer batteries are the only developed, commercially available technology that can satisfy the energy and power requirements of flapping-wing robotic insects. According to the latest models, current battery technology can yield devices that can operate for less than a minute before recharging. A number of new energy storage technologies are currently under development, including micro-solid-oxide fuel cells, lithium batteries with silicon nanowire anodes, and lithium-air batteries. Some of these technologies have the potential to exceed the energy density of current lithium polymer batteries by over an order of magnitude, which will greatly increase the operating time of insect-sized vehicles.



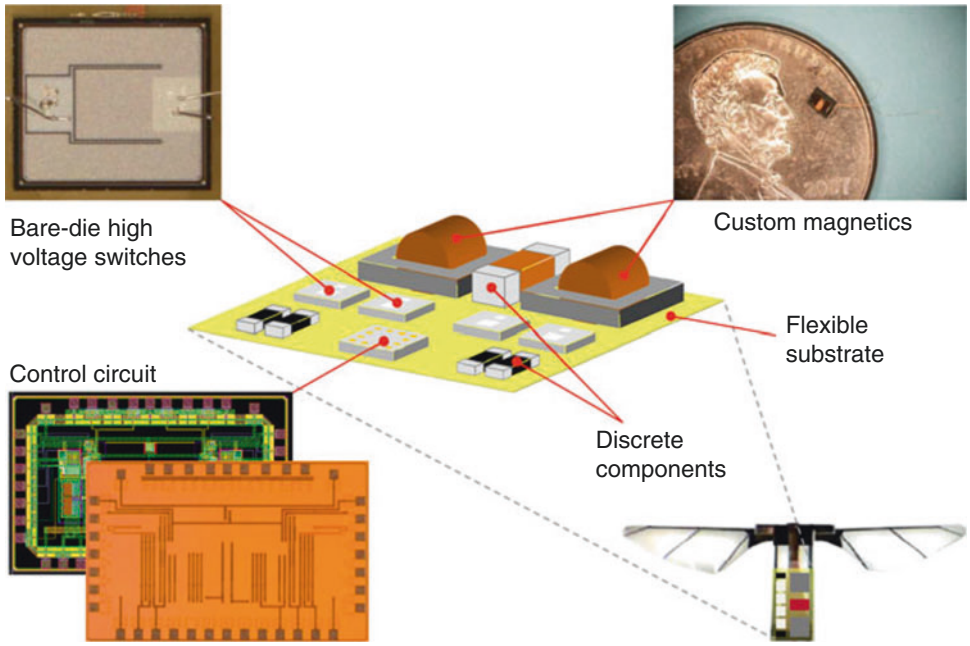
Power Electronics

The wing flapping motion in the RoboBee is powered by piezoelectric actuators, which offer robust mechanical performance, high efficiency, and high-power density at small scales, and are expected to outperform conventional actuators, such as DC motors, in insect-scale devices [6]. From the perspective of power electronic design, piezoelectric actuators present two

challenges. Firstly, only a fraction of the input electrical energy is converted to mechanical output, while the remainder is stored in the capacitive structure of the actuator and must be recovered to maximize system efficiency. Secondly, the actuators require high voltages to operate; for example, in the RoboBee, the actuators are driven in the range of 200–300 V. At the same time, prospective energy sources have output voltages below 5 V, while connecting many unit cells in series to obtain high voltage is generally not practical because the packaging overhead causes a significant reduction in energy density.

The power electronics must convert the low input voltage from the energy source into a high-voltage drive signal and recover unused energy from the actuator. Careful selection of switching circuit topologies amenable to miniaturization while retaining high efficiency has enabled milligram-scale step-up voltage converters and drive stages, such as the 20 mg voltage converter in Fig. 15. To minimize weight, the power circuits use a lightweight flexible substrate, chip-scale or bare-die semiconductors, and custom laser-micromachined magnetic components [20].

In order to drive piezoelectric actuators as efficiently as possible, a custom integrated control circuit is used to modulate the high-voltage switches in the power circuits in a way that applies the required drive signal to the actuator terminals while recovering unused electrical energy. The control circuit is manufactured in 130 nm CMOS technology and consumes less than 200 μW, resulting in a negligible effect on system efficiency. The ultimate vision for a milligram-scale power electronics package involves the integration of the power circuits with the control circuit in chip-scale or bare-die form (Fig. 16).



Insect Flight and Micro Air Vehicles (MAVs), Fig. 15 Twenty milligram voltage converter capable of stepping up a 3.7 V Li-poly battery to 200 V at 70 mW with external control functionality. The converter uses an 8 mg custom laser-micromachined flyback transformer

Conclusion

This entry has described enabling technologies for the aeromechanical platform of a flapping-wing robotic insect. This has only focused on the goal of achieving (a) thrust greater than weight, (b) power autonomy, and (c) stable hovering. There are myriad additional topics that need to be addressed in order for these devices to perform useful tasks in natural environments. Sensors for exteroception and proprioception need to be developed and migrated onboard. Low-power computer architectures for flight control and behaviors must reconcile the needs of processing sensory information and calculating actuator responses with the low available power, mass, and volume for anything beyond the flight apparatus. Finally, new methods to program these devices will need to overcome the relative simplicity of the individuals in order to create robust behaviors across a large group of robots.

Beyond the space of applications for insect-like robots, the constituent components are invaluable to help elucidate numerous open scientific questions. Examples include the use of wing fabrication techniques to study the structure-function relationship in natural airfoils and studies of control techniques for under-actuated and computation-limited systems. Various technologies are also motivated by the challenges of robotic insects. Some of these are under development, such as milligram-scale power, low-power computation, novel sensors, and batch meso and microfabrication techniques, while others are more longer-term such as energy harvesting methods.

Synonyms

Biomimetic infrared detector; Thermal infrared detector

Definition

Technical thermal infrared (IR) detectors are defined as sensors that detect incident IR by the induced increase of the temperature of a detector target. The temperature increase can be measured by many different methods, e.g., change of electrical conductivity, capacitance, and resistance. Some animals use this detection mechanism, e.g., snakes and beetles.

Overview

Biology and Behavior of Pyrophilous Insects

Fire-loving (pyrophilous) insects depend on forest fires for their reproduction. Such insects approach ongoing fires and invade the burnt area immediately after a fire. For the long-range navigation toward a fire as well as for the short-range orientation on a freshly burnt area, these insects have special sensors for smoke and infrared (IR) radiation. Whereas the olfactory receptors for smoke are located on the antennae, the IR receptors are housed in extra-antennal sensory organs, which can be found on the thorax or on the abdomen. It is suggested that smoke-derived odors and IR information converge on brain neurons which, in turn, control and direct flight toward the forest fire.

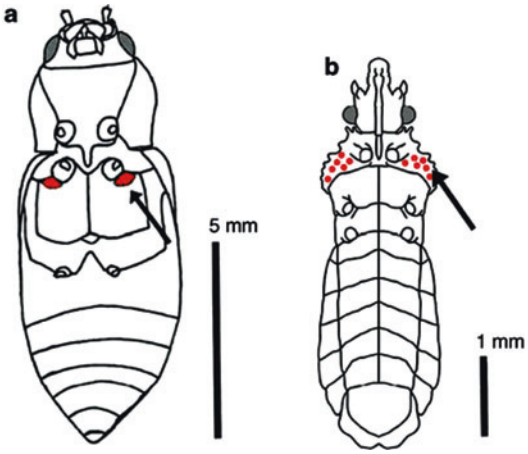
Two genera of jewel beetles (family Buprestidae) can be classified as pyrophilous: about a dozen species of the genus *Melanophila*, which are distributed nearly all over the world except for Australia [1], and the "fire beetle" *Merimna atrata*, which is endemic to Australia [2]. Despite the fact that *Melanophila* and *Merimna* show nearly the same behavior and belong to the same family of jewel beetles, their IR receptors are totally different from each other [3].

On the freshly burnt area, the males of both genera often stay on the stems of trees close to burning or glowing wood or hot ashes. As soon as they become aware of a conspecific female, they try to copulate vigorously. After mating, the females deposit the eggs under the bark of burnt trees. The main reason for the pyrophilous behavior is that the wood-boring larvae of *Melanophila* and *Merimna* can only develop in the wood of burnt trees. As a morphological specialty, both pyrophilous buprestid genera are equipped with antennal smoke receptors and thoracic or abdominal IR organs.

Another pyrophilous beetle can be found in Australia: the "little ash beetle" *Acanthocnemus nigricans* (family Acanthocnemidae). This inconspicuous beetle is only 4 mm long and highly attracted by hot ashes. However, its biology is nearly unknown. Obviously, *Acanthocnemus* also depends on fires for its reproduction and is equipped with a pair of sophisticated prothoracic IR receptors [4]. Recently, IR receptors have also been discovered in a few pyrophilous members of the flat bug genus *Aradus* (Heteroptera, Aradidae) [5]. Interestingly, the IR receptors of *Aradus* bugs are very similar to those described in *Melanophila* beetles. Consequently, fire detection is the compelling precondition for the survival of all pyrophilous insect species mentioned above. However, the outbreak of a forest fire is highly unpredictable. Therefore, pyrophilous beetles and bugs should be able to detect fires from distances as large as possible. Furthermore, when flying over a burnt area in search for a landing ground, the small insects have to avoid "hot spots" with dangerous surface temperatures above about 60 °C.

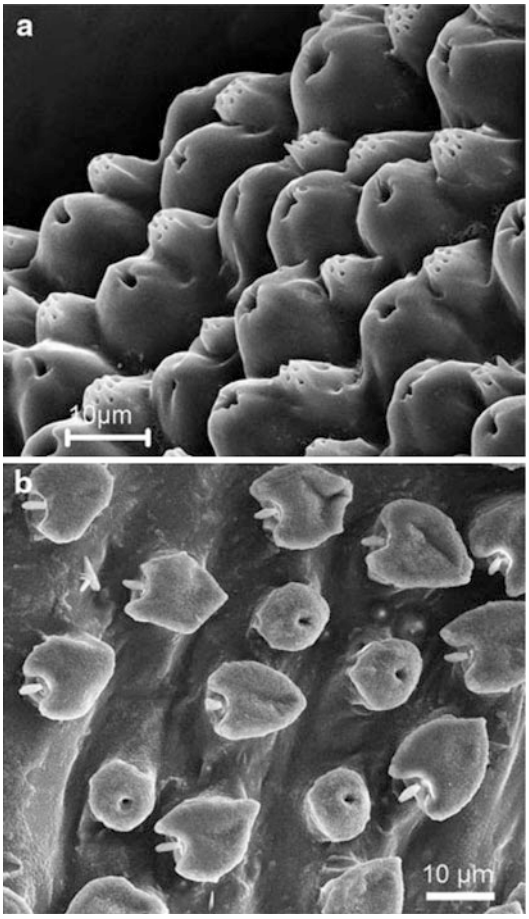
The Photomechanic IR Receptors in Pyrophilous Beetles and Bugs

Structure of Photomechanic IR Receptors



The performance of photomechanic insect IR receptors has been best studied in *Melanophila* beetles, which inhabit the Palaearctic as well as the Nearctic parts of the world. As mentioned, beetles of both sexes approach forest fires because their brood depends on burnt wood as larval food [6]. In the northern boreal forests, where most *Melanophila* species can be found, a fire statistically occurs only every 50–200 years in any one area. Therefore, it has to be postulated that the sensory organs, which are used for fire detection, have been subjected to a strong evolutionary pressure especially with regard to sensitivity. The single IR receptors (called sensilla in insects) are situated in two pit organs, which are located on the third thoracic segment (Fig. 1a). Each IR organ houses about 70 IR sensilla, which are closely packed together at the bottom of the pit [1, 7] (Fig. 2a).

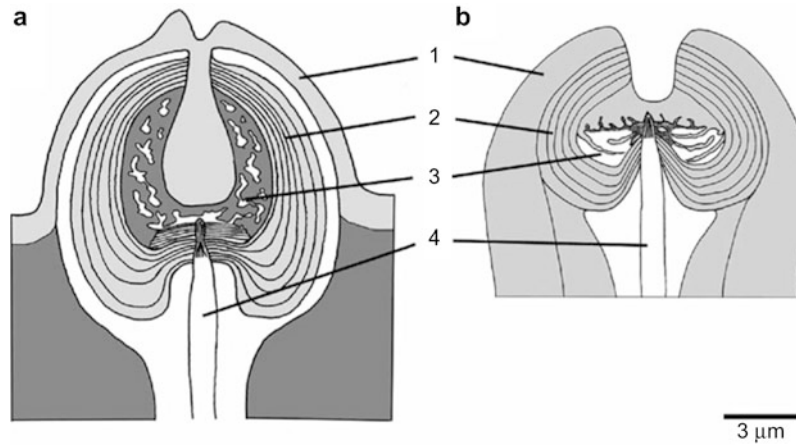
In pyrophilous bugs of the genus *Aradus*, about a dozen IR sensilla are located on the lateral sides (the so-called propleurae) of the prothorax (Fig. 1b). Here, receptors are loosely interspersed between the common hair mechanoreceptors, which cover the entire outer body surface of the bug (Fig. 2b).



From the outside, a single IR sensillum in *Melanophila* beetles and *Aradus* bugs can be recognized by a hemispherical dome with a diameter of about 12–15 μm (Fig. 2a, b). The dome consists of a thin cuticle, which represents the outer boundary of a spherical internal cavity. The cavity is almost completely filled with a tiny cuticular sphere with a diameter of about 10 μm. Based on transmission electron microscopical observations, it has been described that the internal sphere consists of at least two different zones: (1) an outer lamellated zone consisting of exocuticle – the lamellated appearance is caused by many layers of chitin fibers with a periodically changing orientation, and (2) an internal microfluidic core (Fig. 3a, b). From below, the sphere is innervated by a single sensory cell. The outermost tip of the sensory dendrite is anchored in the fluidic core. All morphological as well as all physiological data available so far have demonstrated that this cell is a ciliary mechanoreceptor [1, 5].

Receptor Function

Currently, two models of sensillum function can be found in the literature. However, these models are inconsistent with each other. (1) More than 12 years ago, a so-called photomechanic principle was established [7]. The authors proposed that the biomolecules (i.e., proteins and chitin) of the cuticular sphere strongly absorb mid-IR radiation. In a way not described in detail, the resulting thermal expansion of the cuticular sphere is measured by the mechanoreceptor. (2) Assuming the presence of a large air-filled cavity inside the sphere, Evans [8] proposed in the second model that IR radiation enters this cavity by a small apical waveguide with a diameter of about 1.5 μm. Due to the absorption of IR photons at the inner cuticular walls of the cavity, the enclosed air is heated up and expands. In a way not further specified, the resulting increase in gas pressure should stimulate the mechanoreceptor.

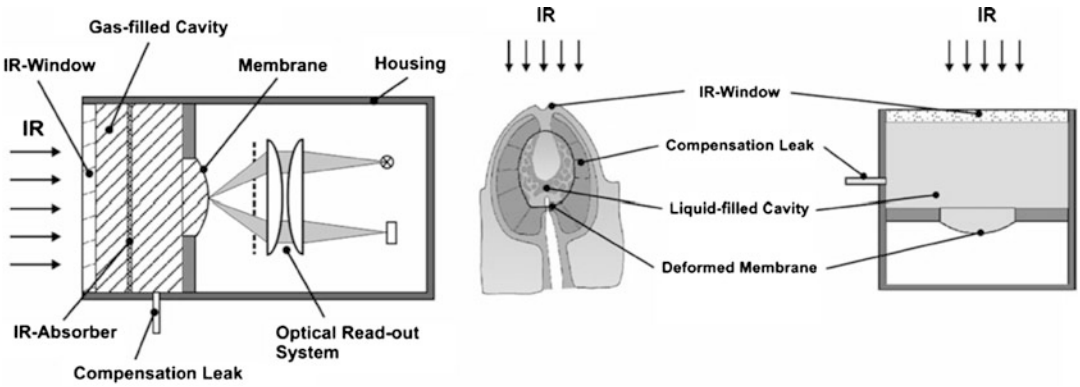


Insect Infrared Sensors, Fig. 1 Ventral view onto (**a**) *Melanophila acuminata* beetle and (**b**) *Aradus albicornis* bug. Position of IR organs and receptors are indicated by *arrows*. Legs and antenna omitted

Insect Infrared Sensors, Fig. 2 (**a**) View into an IR organ of a *Melanophila* beetle. Hemispherical IR sensilla are accompanied by porous wax glands. (**b**) IR sensilla on the propleura of an *Aradus* bug interspersed between hair mechanoreceptors with short bristles

All recent findings have clearly demonstrated that the thoracic infrared (IR) sensilla of the pyrophilous jewel beetle *Melanophila acuminata* most likely have evolved from hair mechanoreceptors (sensilla trichodea) [1]. Hair mechanoreceptors, which can be found in any insect, have a bristle of different length. In insects, the pressure-sensitive dendrite of a single mechanosensitive sensory cell innervates the base of the bristle. As a result, even a slight bending of the bristle stimulates the tip of the dendrite. To further elucidate the sensory transduction mechanism, the morphology of IR sensilla and of neighboring hair mechanoreceptors was investigated by using electron microscopical techniques (SEM, TEM) in combination with focused ion beam milling (FIB). It was assumed that any deviation from the bauplan of a hair mechanoreceptor is of special importance for the transformation of IR radiation into a mechanical stimulus. Thus, the structures supposed to be relevant for stimulus uptake and transduction were homologized. Compared to hair mechanoreceptors, minute spheres have been developed instead of bristles in photomechanic IR sensilla (see Fig. 3). Most probably, IR radiation absorbed by the proteins, the chitin fibers, and the water of the sensillum heats up the sphere, which immediately causes thermal expansion especially of the liquid inside the microfluidic core. Because the shell of the sphere consists of stiff exocuticle additionally reinforced by many layers of chitin fibers, the only compliant structure in the sphere is the membrane of the tip of the mechanosensitive dendrite. Due to the air-filled tracheal system inside the beetle's body, most of the cell body of the mechanosensitive cell always is at ambient pressure. Only the outermost tip of the sensory dendrite of the mechanosensor (cf. Fig. 3) is enclosed inside the sphere. Therefore, any increase in pressure inside the sphere will cause a cross compression of the dendritic tip which is compensated by the cell volume below the sphere. By deflection of

Insect Infrared Sensors, Fig. 3 Schematic drawings of cross sections through photomechanic IR receptors of (**a**) *Melanophila* beetles and (**b**) *Aradus* bugs (*1*): outermost layer of hard exocuticle (*2*): lamellated exocuticular shell of internal sphere (*3*): fluidic core inside the sphere (*4*): tip (dendrite) of mechanosensor



the dendritic membrane in the range of a few nanometers, stretch-activated ion channels will be opened. Accordingly, an IR sensillum acts as a microfluidic converter of infrared radiation into an increase in internal pressure inside the sphere, which is measured by the mechanosensitive neuron. In the IR sensilla of *Melanophila* beetles, fine nanocanals were found, which radially run through the outer exocuticular shell of the internal sphere (canals are too small to be shown at right dimensions in Fig. 3a). If ambient temperature slowly changes, a compensatory exchange of fluid from the inner core of the sphere prevents an unspecific stimulation of the mechanosensory cell. The principle of transforming IR radiation into a bioelectrical signal has been termed photomechanic. Although it has not been observed that the *Melanophila* beetles turn right and left in flight to search for incoming IR radiation, it has been proposed that beetles approach a fire by so-called tropotaxis (i.e., by comparing the input of two symmetrically arranged receptors on either side of their body). If the wings are used to chop incoming IR radiation has not been investigated so far.

Most probably, photomechanic IR sensilla have been developed independently in beetles and bugs. Because the products of the evolutionary process are very similar in *Melanophila* beetles and *Aradus* bugs (Figs. 2 and 3), it can be proposed that a photomechanic IR sensillum represents a highly optimized sensor for mid-IR radiation. This provides strong evidence that mechanoreceptors are promising candidates for the development of IR sensors.

Biomimetic Approach

Golay Sensor

After the clarification of the function of the biological IR sensor of the beetle, the underlying principle was analyzed mathematically to be able to design a technical sensor. For this purpose, the pneumatic Golay sensor [9] was investigated as a simple model (see Fig. 4, left). This sensor consists of an internal gas-filled cavity, which is closed on one side by a window and on the other side by a thin membrane. IR radiation enters through the window and heats up the gas by absorption. The deflection of the membrane caused by the expanding gas can be read out by an optical system [9], a capacitive detector [10], or a tunneling displacement transducer [11]. To enhance the IR absorption in the gas, the cavity is equipped with an additional absorber. Reflecting walls of the cavity are another means to enhance the absorption. The temperature changes of the gas caused by the absorbed IR radiation are in the range of mK. Because of slow variations of the ambient temperature in the range of a few K, it is absolutely necessary to integrate a leak, which compensates this influence due to an exchange of the gas with a reference volume.

Insect Infrared Sensors, Fig. 4 *Left*: principle of a gas-filled Golay sensor with optical readout. For explanations, see text. *Right*: comparison of the sensillum with the model of the sensor

Sensor Model of the IR Receptor

The model of the sensor is shown in Fig. 4, right. Similar to the sensillum, the sensor contains an internal water-filled cavity. The presence of a liquid instead of gas is a major difference between the sensillum and the Golay sensor. The cavity of the technical sensor is etched into a silicon wafer and is closed on the one side by a window (Suprasil, [12]) and on the other side by a thin silicon membrane. The IR radiation being absorbed produces a change in pressure or volume, respectively, due to the change of the state of the water. The deflection of the membrane caused by this pressure increase can be read out by, e.g., a capacitive detector or a tunneling displacement transducer.

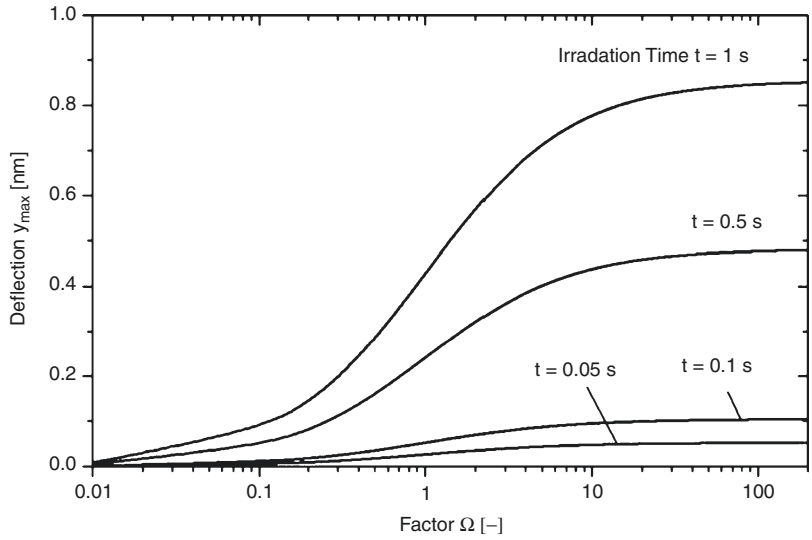
Sensor Without Compensation Leak

For calculating the change of the liquid pressure in the cavity based on the temperature profile, the equation of state must be solved. Because the pressure in the cavity depends upon the two independent variables temperature and volume, its total change is given by

$$\Delta P = \beta \cdot \Delta T_{mean} - \frac{1}{\kappa \cdot V} \cdot \Delta V \qquad (1)$$

with ΔP as the pressure increase, $\beta = (\partial \mathrm{P}/\partial \mathrm{T})_{\mathrm{V}}$ as the isochoric tension coefficient, $\Delta \mathrm{T}_{\mathrm{mean}}$ as the mean temperature increase averaged over the cavity volume, $\kappa = -(1/\mathrm{V}) \cdot (\partial \mathrm{T}/\partial \mathrm{P})_{\mathrm{T}}$ as the isothermal compression coefficient, V as the volume of the cavity, and ΔV as the volume increase. For water (25 °C, 1 bar), $\beta = 5.68 \cdot 10^5$ Pa/K and $\kappa = 4.5 \cdot 10^{-10}$ 1/Pa [13].

The increase of the volume ΔV of the cavity results in the tiny deflection of the membrane. The local deflection y of this circular membrane caused by a pressure difference can be calculated as a function of the radial distance r with the shell theory [14, 15]



$$y(r) = \frac{\Delta P}{64 \cdot D} \cdot \left(R^2 - r^2\right)^2$$
$$D = \frac{E \cdot t_P^3}{12 \cdot (1 - v^2)} \qquad (2)$$

with R as the radius of the membrane and the cavity, D as the flexural stiffness of the membrane, E as the Young's modulus of elasticity, t_P as the thickness of the membrane, and v as the Poisson's ratio.

Equation 2 is a good approximation for small membrane deflections, i.e., $y_{max}/t_p < 1$. The corresponding volume change ΔV can be calculated in relation to the pressure increase ΔP by using Eq. 2, assuming equal radius of cavity and membrane (see Fig. 5):

$$\Delta \mathrm{V} = \frac{\pi \cdot R^6 \cdot \Delta P \cdot (1 - v^2)}{16 \cdot E \cdot tp^3} \qquad (3)$$

The combination of Eqs. 1 and 3 yields a relationship for ΔP, which considers the influence of temperature and volume. It is assumed that

Insect Infrared Sensors, Fig. 5 Maximum central deflection y_{max} of a circular membrane as function of factor Ω and irradiation time for a water-filled cavity. IR power density, 10 W/m^2; diameter and height of the cavity, 0.5 mm

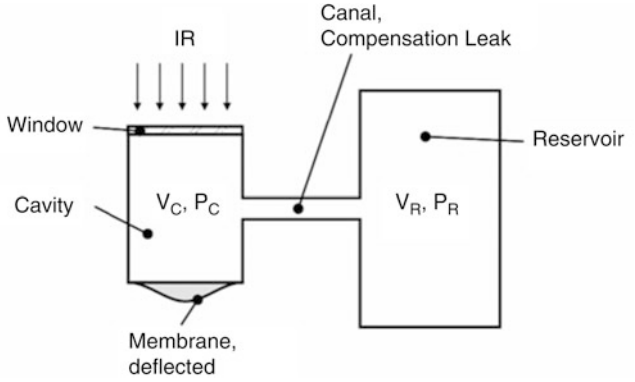
there is no additional volume change in the rest of the cavity:

$$\Delta P = \frac{\beta \cdot \Delta T_{mean}}{1 + \Omega}$$
$$\Delta T_{mean} = \frac{\int_0^{H_c} \Delta T(z) \cdot dz}{Hc} \qquad (4)$$
$$\Omega = \frac{R^4 \cdot (1 - \nu^2)}{16.E.t_{p^3}.H_c.\kappa}$$

with H_C as the height of the cylindrical cavity, ΔT(z) as the temperature as a function of the axial coordinate z of the cavity and time, and ΔT_{mean} as the mean temperature increase averaged over the cavity.

The factor Ω characterizes the change of state of the liquid inside the cavity due to a temperature increase: for $\Omega \to 0$, which corresponds to an extremely hard membrane, the change of state is isochoric with a maximal pressure increase. For $\Omega \to \infty$, as for an extremely soft membrane, the change of state is isobaric with maximal volume increase. The transition between these two cases is at $\Omega \approx 1$. The maximal deflection y_{max} of the circular membrane can be calculated as a function of the factor Ω by using the Eqs. 2 and 4:

$$y_{\max} = \frac{3 \cdot \alpha \cdot \Omega \cdot T_{mean} \cdot Hc}{1 + \Omega} \qquad (5)$$



with $\alpha = \beta \cdot \kappa$ as the isobaric thermal expansion coefficient.

Figure 6 shows the maximal deflection as a function of the factor Ω according to Eq. 5 for an IR power density of 10 W/m^2 (IR window without absorption loss assumed) for a cavity with a height and a diameter of 0.5 mm, respectively, filled with water. Obviously, the maximal deflection is achieved for the isobaric case with a very soft membrane. Due to the very low deflection of less than 1 nm, a capacitor as readout must be extremely sensitive. As an alternative, an optical readout or the use of a tunneling displacement transducer may be useful.

With regard to Eqs. 4 and 5, the maximal deflection of the membrane can be increased by using a liquid with a high thermal expansion coefficient α, e.g., $120 \cdot 10^{-5}$ 1/K for methanol versus $26 \cdot 10^{-5}$ 1/K for water, and a high mean temperature increase ΔT_{mean} due to a low product of heat capacity and density in a small cavity. Additionally, the IR window and the cavity material should have a low heat conduction to avoid heat losses during measurement.

Sensor with Compensation Leak

In the *Melanophila* IR receptor, the inner sphere is enclosed by a thin layer of fluid. Therefore, the nanocanals in the shell of the sphere allow the exchange of fluid in and out of the microfluidic

Insect Infrared Sensors, Fig. 6 Model of the IR sensor with cavity (pressure P_C, volume V_C) and reservoir (pressure P_R, volume V_R). The canal of the compensation leak has a radius R_L and a length L

compartment in the sphere. Thus, any internal pressure change which may be caused by the slowly changing ambient temperature can be compensated. Golay sensors also use such compensation leaks for compensating changes of ambient temperatures [9].

However, due to the compensation leak, the pressure increase in the cavity is reduced depending on the flow resistance of the leakage through the canal. For simulating this effect, an analysis based on the model in Fig. 5 was carried out. A mass and energy balance for the subsystem's cavity, canal, and reservoir can be used to derive the formulas for the time-dependent development of temperature and pressure in the cavity.

For a laminar flow, the volume flow in the canal can be described by a Hagen-Poiseuille flow [16]:

$$\dot{V}_L = \frac{\pi \cdot R_L^4}{8 \cdot \eta \cdot L} \cdot (P_C(t) - P_R(t)) \tag{6}$$

with $\dot{V}_L$ the volumetric flow rate, R_L the radius of canal, L the length of canal, $P_C(t)$, $P_R(t)$ the time-dependent pressure in the cavity and the reservoir, and η the dynamic viscosity.

The mass balance for the cavity and the reservoir gives

$$\begin{aligned} \frac{d}{dt} m_C &= -\rho_L \cdot \dot{V}_L \\ \frac{d}{dt} m_R &= \rho_L \cdot \dot{V}_L \end{aligned} \tag{7}$$

with m_C, m_R the mass of fluid inside cavity and reservoir, respectively, and ρ_L the mean fluid density in the canal.

The density ρ_L in the Eq. 7 is the mean value between the density in the cavity ρ_c, and the density in the reservoir ρ_R. Equation 1 for an isothermal change of state and a mass balance for the canal gives

$$\begin{aligned} \frac{\rho_C}{\rho_R} &= e^{k \cdot (P_C - P_R)} \approx 1 + k \cdot (P_C - P_R) \\ \rho_L &= \frac{(\rho_C + \rho_R)}{2} \approx \rho_R \cdot \left(1 + k \cdot \frac{(P_C - P_R)}{2}\right) \end{aligned} \tag{8}$$

It is obvious that for small pressure differences between cavity and reservoir in the order of some Pa, the density in the canal is constant due to the magnitude of the compression coefficient κ. In Eq. 7, the volume of the cavity is time-dependent due to the additional volume caused by the deflection of the membrane, so that

$$\begin{aligned} \frac{d}{dt} m_C &= \frac{d(\rho_C \cdot V_C(t))}{dt} \\ &= \frac{d\rho_C}{dt} \cdot V_C(t) + \frac{dV_C(t)}{dt} \cdot \rho_C \end{aligned} \tag{9}$$

with $V_C(t)$ the time-dependent volume of the cavity and m_C the time-dependent mass of the fluid in the cavity.

Equation 3 yields

$$\frac{dV_c}{dt} = \frac{\pi \cdot R^6 \cdot (1 - \nu^2)}{16 \cdot E \cdot t_P^3} \cdot \frac{dP_c}{dt} \tag{10}$$

Equations 6, 7, 8, 9, and 10 and the simplification $\kappa \cdot (P_C - P_R) \approx 0$, which is 10^{-8}–10^{-9} for water

and a pressure difference of some 10–100 Pa, yield two differential equations for the pressures P_C and P_R:

$$\begin{aligned}(1+\Omega).\frac{dP_C}{dt}-\beta\cdot\frac{dT_C}{dt}+\frac{P_C}{\tau_C}-\frac{P_R}{\tau_C}=0\\ \frac{dP_R}{dt}+\frac{P_R}{\tau_C}+\frac{P_C}{\tau_R}=0\end{aligned} \tag{11}$$

where the time constants τ_C and τ_R are defined as

$$\begin{aligned}\tau_C&=\frac{8\cdot\eta\cdot L\cdot V_C\cdot k}{\pi\cdot R_L^4}\\ \tau_R&=\frac{8\cdot\eta\cdot L\cdot V_R\cdot k}{\pi\cdot R_L^4}\end{aligned} \tag{12}$$

Energy Balance and Pressures for the Adiabatic Cavity

The temperature gradient in Eq. 11 can be found with an energy balance for the cavity. The first law of thermodynamics assuming an adiabatic cavity results in

$$\begin{aligned}I_0\cdot A+\frac{dW_{12}}{dt}-\rho_C\cdot\dot{V}_L\cdot C_P\cdot\Delta T_C\\ =\frac{d}{dt}(\rho_C\cdot V_C(t)\cdot C_P\cdot\Delta T_C)\end{aligned} \tag{13}$$

with A the cross section of the cavity and the IR window, W_{12} the total work of the system, $\dot{V}_L$ the volume leakage flow rate in Eq. 6, $V_C(t) = V_C + dV_C(t)$ the time-dependent volume regarding Eq. 10, V_C the initial volume of the cavity at $t = 0$, and C_P the heat capacity of the fluid in the cavity.

The total work W_{12} consists of two parts: the energy stored in the membrane due to deflection, $W_{Membrane}$, and the pressure-volume work done on the environment, W_{PV}. Here, as usual, a negative work means that the work is done by the system. The energy stored in the membrane is [15]

$$\begin{aligned}W_{Membrane}=-\frac{(P_C-P_0)^2\cdot\pi\cdot R^6}{384\cdot D}\\ \cdot\left[1+0.244\cdot\left(\frac{y_{max}}{t_P}\right)^2\right]\end{aligned} \tag{14}$$

with P_0 the ambient pressure.

The first summand in the bracket of Eq. 14 is due to the energy of bending, and the second summand considers the energy of stretching the middle plane of the membrane. For small deflections where the maximum deflection of the membrane y_{max} is smaller than its thickness t_P, the energy of stretching the middle plane can be neglected.

The pressure-volume work W_{PV} can be calculated using for dV the additional volume due to the deflection of the membrane, see Eq. 3, with

$$\begin{aligned}W_{PV}&=-\int P_0\cdot dV=-P_0\cdot\frac{\pi\cdot R^6\cdot(P_C-P_0)\cdot(1-\upsilon^2)}{16\cdot E\cdot t_p^3}\\ &=-\frac{P_E\cdot(P_C-P_0)\cdot\pi\cdot R^6}{192\cdot D}\end{aligned} \tag{15}$$

Calculating the derivatives in Eq. 13 gives

$$\begin{aligned}\frac{dW_{12}}{dt}&=-\Omega\cdot V_C\cdot k\cdot P_C\cdot\frac{dP_C}{dt}\frac{d}{dt}(\rho_C\cdot V_C(t)\cdot C_P\cdot\Delta T_C)\\ &=\rho_C\cdot C_P\cdot V_C\cdot\left[(\Omega+1)\cdot k\cdot\Delta T_C\cdot\frac{dP_C}{dt}\right.\\ &\left.+(1-\alpha\cdot\Delta T_C)\cdot\frac{dT_C}{dt}\right]\end{aligned} \tag{16}$$

With Eq. 16 and some straightforward algebra, Eq. 13 yields

$$\begin{aligned}\left[(\Omega+1)\cdot k\cdot\Delta T_C+\frac{\Omega}{\rho_C\cdot C_P\cdot H_C}\right]\cdot\frac{dP_C}{dt}\\ +(1-\alpha\cdot\Delta T_C)\cdot\frac{dT_C}{dt}\\ +\frac{k}{\tau_C}\cdot(P_C-P_R)\cdot\Delta T_C=\frac{I_0}{\rho_C\cdot C_P\cdot H_C}\end{aligned} \tag{17}$$

Obviously, because $\alpha\cdot\Delta T_C \ll 1$, it can be neglected in Eq. 17. The influence of the heat loss due to the flow in the canal is represented by the last part of the left side in Eq. 17. The heat loss increases with decreasing time constant τ_C, which means a lower flow resistance and a higher mass stream between cavity and reservoir. The heat loss relative to the irradiated IR energy, e.g., for $I_0 = 10$ W/m^2, a pressure difference of about

Insect Infrared Sensors, Table 1 Dimensions and material properties [13, 17]

Radius R of the cavity and the membrane	0.25 mm
Height H_C of the cavity	0.5 mm
Time constant τ_C of the cavity	1.9 ms
Thickness t_P of the membrane	1 μm
Length L of the canal	1 mm
Young's modulus of elasticity E of the membrane	160×10^9 N/m^2
Poisson's ratio of the membrane ν	0.279
Flexural stiffness of the membrane D	$1.45 \cdot 10^{-8}$ Nm
Isochoric tension coefficient β of the fluid	5.7×10^5 Pa/K
Isothermal compression coefficient κ of the fluid	4.5×10^{-10} 1/Pa
Isobaric thermal expansion coefficient α of the fluid	2.6×10^{-4} 1/K
Density ρ of water	998 kg/m^3
Heat capacity C_P of water	4190 J/kg·K
Dynamic viscosity η of water	10^{-3} Pa

10 Pa, a temperature difference of about 10 mK, and the values in Table 1 is

$$\frac{k \cdot \rho_C \cdot C_P \cdot H_C}{\tau_C \cdot I_0} \cdot (P_C - P_R) \cdot \Delta T_C = 10^{-6} \div 10^{-7} \tag{18}$$

Regarding this estimate, the heat loss due to the flow in the canal can be neglected also, depending on the magnitude of the time constant τ_C. The relation of the derivate of the total work dW_{12}/dt and the absorbed IR energy is about 10^{-3}–10^{-4} after one second for an adiabatic cavity without compensation canal. Therefore, the influence of the total work of the system will be not neglected.

With the simplifications and the introduction of the power density factor γ, Eq. 17 results in

$$\left[(\Omega+1) \cdot \alpha \cdot \Delta T_C + \frac{\alpha \cdot \Omega}{\rho_C \cdot C_P} \cdot P_C\right] \cdot \frac{dP_C}{dt} + \beta \cdot \frac{dT_C}{dt} = \gamma$$
$$\gamma = \frac{I_0 \cdot \beta}{\rho_C \cdot C_P \cdot H_C} \left[\frac{Pa}{s}\right] \tag{19}$$

Introducing the temperature gradient in Eq. 19 in the first differential equation of Eq. 11 can be written as

$$\left(1 + \Omega + \frac{\alpha \cdot \Omega}{\rho_C \cdot C_P} \cdot P_C\right) \cdot \frac{dP_C}{dt} + \frac{P_C}{\tau_C} - \frac{P_R}{\tau_C} = \gamma$$
$$\frac{dP_R}{dt} + \frac{P_R}{\tau_R} - \frac{P_C}{\tau_R} = 0 \tag{20}$$

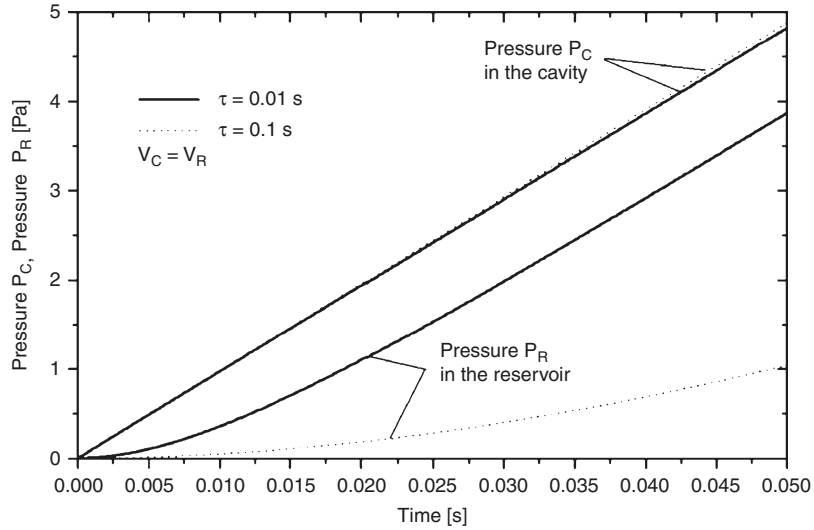
The Eq. 20 can be transformed for $\Omega = 0$ (isochoric, no deflection of the membrane) and $\gamma = 0$ (no IR power density) into the same equation published earlier [18].

For water as fluid, the magnitude $\frac{\alpha}{\rho_C \cdot C_P}$ of is about 10^{-10} [m^3/J], which can be neglected in Eq. 20.

For this case results

$$(1 + \Omega) \cdot \frac{dP_C}{dt} + \frac{P_C}{\tau_C} - \frac{P_R}{\tau_C} = \gamma$$
$$\frac{dP_R}{dt} + \frac{P_R}{\tau_R} - \frac{P_C}{\tau_R} = 0 \tag{21}$$

The analytical solution of Eq. 21 is



$$P_C(t) = \frac{\tau}{\tau_C \cdot (1+\Omega)} \cdot \left[\gamma \cdot \frac{\tau_C}{\tau_R} \cdot t + P_R(t=0) + \frac{\tau_C}{\tau_R} \cdot (1+\Omega) \cdot P_C(t=0) - \Phi + (\Delta P(t=0) + \Phi) \cdot e^{-\frac{t}{\tau}}\right]$$

$$P_R(t) = \frac{\tau}{\tau_C \cdot (1+\Omega)} \cdot [P_R(t=0) + \frac{\tau_C}{\tau_R} \cdot (1+\Omega) \cdot P_C(t=0) + \gamma \cdot \frac{\tau_C}{\tau_R} \cdot (t-\tau) - \frac{\tau_C}{\tau_R} \cdot (1+\Omega) \cdot (\Delta P(t=0) + \Phi) \cdot e^{-\frac{t}{\tau}}]$$

$$\Delta P(t=0) = P_C(t=0) - P_R(t=0)$$
$$\tau = \frac{\tau_C \cdot (1+\Omega)}{1 + \frac{\tau_C}{\tau_R} \cdot (1+\Omega)} \Phi = \gamma \cdot \tau_C \cdot \left(\frac{\tau}{\tau_R} - 1\right) \tag{22}$$

The pressure difference ΔP_{CR} between cavity and reservoir using Eq. 22 yields

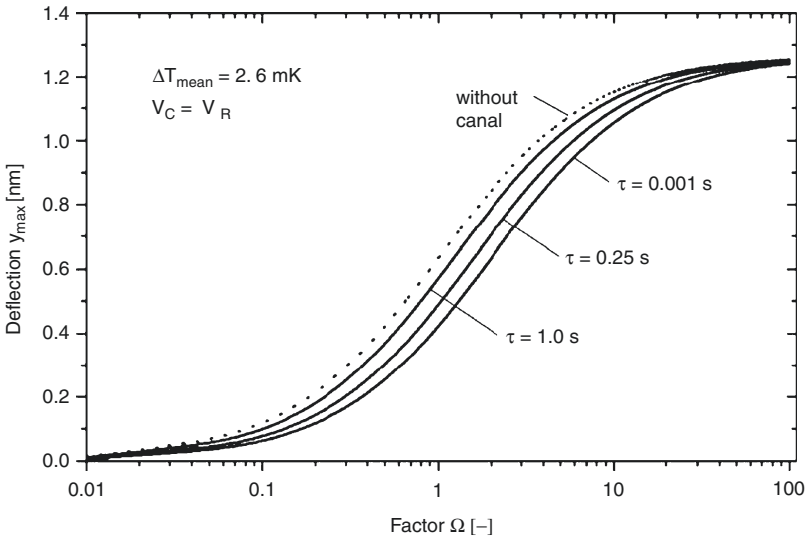
$$\Delta P_{CR}(t) = P_C(t) - P_R(t) = \frac{\tau \cdot \gamma}{1+\Omega} \cdot \left(1 - e^{-\frac{t}{\tau}}\right) \tag{23}$$

Insect Infrared Sensors, Fig. 7 Time-dependent pressure in the adiabatic cavity and the reservoir with respect to the values in Table 1 and $\Omega = 50$, $\gamma = 5000$ ($I_o = 18$ W/m^2), $\tau = 0.01$ s, and $\tau = 0.1$ s for equal size of cavity V_C and reservoir V_R

Based on the values in Table 1 for the cavity and the canal, the time-dependent pressure in the cavity and the reservoir was calculated (see Fig. 7).

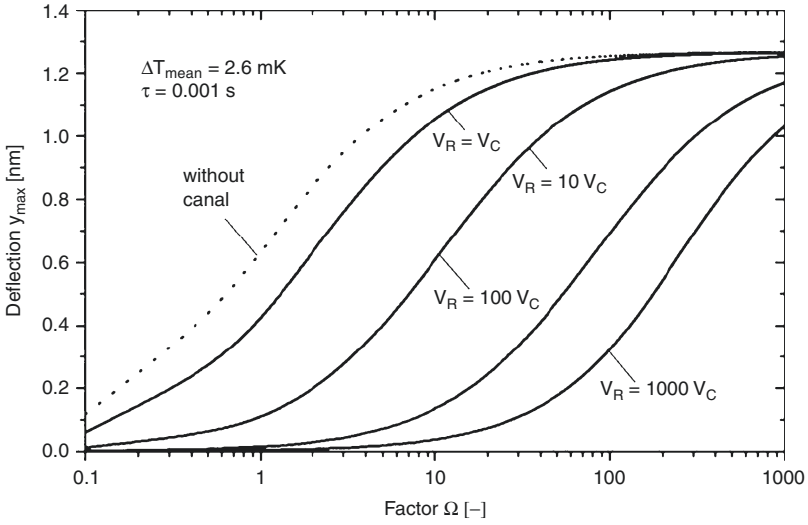
Here, the volume of the cavity V_C and the volume of the reservoir V_R are equal, and the diameter of the canal is varied, which gives two different time constants: $\tau = 0.01$ s for a larger diameter and 0.1 s for a smaller diameter, respectively. As expected, with a larger diameter of the canal, the pressure in the reservoir increases faster, and even with the larger diameter of the canal, the reduction of the pressure increase in the cavity is negligible due to the small mass stream leaving the cavity.

For an optimal readout of the sensor, the deflection of the membrane should be maximized; that means the compensation should have only a small influence on the pressure increase in the cavity. Figure 8 shows the influence of the diameter of the canal (as parameterized by the variable time constant) and the factor Ω on the maximal deflection of the membrane for equal sizes of the volumes of cavity and reservoir, respectively. For the calculation of the maximal deflection, Eq. 2 with $r = 0$ and the cavity pressure according to Eq. 22 for $t = 0.5$ s was used.



With a reduction of the flow resistance due to the increasing diameter of the canal or a shorter length of the canal (shorter time constant), the deflection is only less influenced, especially in the medium range of factor Ω from 0.1 to 10. Obviously, the change of the deflection is limited with smaller time constant, and the run of the curves does not change for time constant smaller than 0.001 s. In this case, the flow resistance is so small that no pressure difference between cavity and reservoir exists, and the two volumes act as one volume. The curve progression of the maximal membrane deflection of a cavity without canal using Eq. 5 is the limit case for a canal with a very high time constant (high flow resistance). This means the Eqs. 5 and 2 using the pressure according to Eq. 22 coincide for a time constant $\tau \rightarrow \infty$.

The maximal deflection for an increasing volume of the reservoir and a constant value of the time constant (constant flow resistance of the canal) is shown in Fig. 9. In this case, the deflection is reduced in a wide range of factor Ω, especially due to the low time constant. The reduction can be decreased by a higher time constant. In any case, the reduction is less with a high factor Ω, corresponding to a very soft membrane.



For analyzing the influencing factors on the flow rate in the canal, the Eqs. 6 and 23 are combined:

$$V_L = \frac{\pi \cdot R_L^4}{8 \cdot \eta \cdot L} \cdot \frac{\tau \cdot \gamma}{1 + \Omega} \cdot \left(1 - e^{-\frac{t}{\tau}}\right) \qquad (24)$$

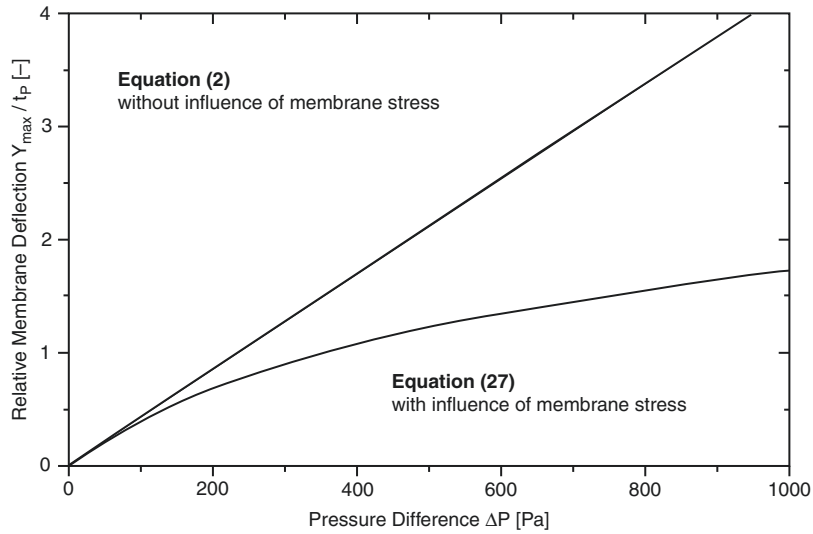
Because the power density factor γ, see Eq. 19, is proportional to the IR power density I_0, and for an

Insect Infrared Sensors, Fig. 8 Maximal deflection of the membrane as function of the factor Ω and the time constant τ (variable flow resistance in the canal) for equal volumes of cavity and reservoir, V_C and V_R, at time t = 0.5 s. γ = 3000 (I_0 = 10 W/m^2), mean temperature ΔT_{mean} = 2.6 mK

Insect Infrared Sensors, Fig. 9 Maximal deflection of the membrane as function of the factor Ω and different relations of volumes of cavity and reservoir, V_C/V_R, for equal time constant τ = 0.001 s (constant flow resistance in the canal) at time t = 0.5 s. γ = 3000 (I_0 = 10 W/m^2), mean temperature ΔT_{mean} = 2.6 mK

adiabatic cavity the relation between I_0 and the temperature change in the cavity is

$$I_0 = \frac{m \cdot C_P}{A} \cdot \frac{dT_C}{dt} \tag{25}$$



the following result is obtained:

$$\dot{V}_L \propto \frac{dT_C}{dt} \cdot \left(1 - e^{-\frac{t}{\tau}}\right) \tag{26}$$

This means, for short times $t \ll \tau$ the volumetric flow rate is about zero and the pressure increase in the cavity due to a sudden IR radiation is not influenced. For long times $t \gg \tau$ (slow ambient temperature increase), the volumetric flow rate is proportional to the temperature change in the cavity.

Compensation of Ambient Temperature Changes

The effect of the compensation will be demonstrated for a cavity based on the data in Table 1.

Insect Infrared Sensors, Fig. 10 Relative membrane deflection at r = 0 as function of applied pressure difference comparing the influence of membrane stress. The data of the membrane are taken from Table 1

For the layout of the compensation, an ambient temperature increase of 10 K in 6 h, corresponding to an IR power density I_0 of about 1 W/m^2 for an adiabatic cavity, is assumed. A cavity without temperature compensation will build up a pressure difference of at least 900 Pa during 6 h, probably higher because of the smaller deflection of the membrane due to the nonlinearity of Eq. 2. As a consequence of this high pressure bias, the membrane will be out of the linear range ($y_{max}/t_P < 1$) because the ratio of the maximal deflection y_{max} to the membrane thickness t_P is about 4 µm/1 µm, and a small pressure increase due to an incoming IR radiation will only result in a reduced additional deflection of the membrane. This effect can be explained with an improved equation compared to Eq. 2, which is also applicable for $y_{max}/t_P > 1$ [15] because it takes into account the membrane stress:

$$\frac{y_{\max}}{t_P} = \frac{\Delta P}{64 \cdot D \cdot t_P} \cdot \frac{R^4}{1 + 0.488 \cdot \left(\frac{y_{\max}}{t_P}\right)^2} \qquad (27)$$

The implicit Eq. 27 changes over to Eq. 2 with r = 0 for $y_{max}/t_P \rightarrow 0$. Figure 10 shows the comparison of the Eqs. 2 and 27. Obviously, Eq. 2 is only applicable for $y_{max}/t_P < 1$.

For the evaluation of the compensation effect a canal of 1 mm length and a diameter of 10 µm connected to a reservoir volume with constant ambient pressure, P_0 is assumed. This can be achieved, e.g., with a reservoir volume that is connected to the environment with a soft membrane so that the pressure in the reservoir is equal to the ambient pressure. A constant pressure in the reservoir is equivalent to $V_R \gg V_C$, and the time constant in Eq. 22 reduces to $\tau = \tau_C \cdot (1 + \Omega)$. With the data in Table 1 and Eq. 23, a constant pressure difference $P_C - P_0$ in the cavity of 0.1 mPa results for $t \gg \tau$. This low pressure bias results in a $y_{max}/t_P \ll 1$, and the membrane can be used in the linear range.

Assuming an increase of the pressure in the cavity of 1 Pa due to an IR source without compensation, the pressure in the cavity will increase from 900 Pa to 901 Pa, and according to Eq. 27 the maximum deflection y_{max} will only increase by about 1 nm. With compensation, the pressure will increase from 0.1 mPa to 1.0001 Pa and the deflection in the linear range is increased by 4.2 nm. This means, with an appropriate compensation the deflection of the membrane can be clearly improved, because it can operate in its linear range.

Future Directions of Research

Like in the photomechanic insect IR receptors, the technical model features very small displacements of the membrane in the sensing device in the range of 1 nm and less. The insects, however, have the advantage of possessing a very sensitive mechanoreceptor, the mechanosensitive neuron, which can detect minute deflections of its membrane [19]. It seems that this sensitivity of the beetle is difficult to achieve for a technical sensor.

For a miniaturized technical sensor, an appropriate technical readout mechanism with a high resolution of 1 nm may be necessary. So far, a sensor with a capacitor as readout is near to completion in the *Center of Advanced European Studies and Research* (caesar), Bonn. Several readout methods will be evaluated, but it has to be stressed that this search must yield a rugged and cost-effective design in order to be able to compete with existing IR sensors.

An obvious method to enhance the displacement of the membrane is to choose liquids with optimal thermal properties, e.g., high thermal expansion coefficient and low heat capacity. Here, several liquids permit an improvement. Methanol is a good candidate compared to n-pentane and toluene because of better handling during the filling process of the cavity [20].

Additionally, care has to be taken in selecting appropriate wall materials with the same low thermal conduction necessary to preserve the thermal energy inside the cell. Until now, silicon is used due to its well-known manufacturing technology for microsystems. As an alternative, microinjection molding of plastic materials with low heat conductivity are under investigation.

Insect-Inspired Visual Systems and Visually Guided Behavior

Paul Graham[1] and Andrew Philippides[2]
[1]Centre for Computational Neuroscience and Robotics, School of Life Sciences, University of Sussex, Brighton, UK
[2]Centre for Computational Neuroscience and Robotics, Department of Informatics, University of Sussex, Brighton, UK

Definition

Many insects are capable of impressive visually guided behaviors despite low-resolution vision and limited neural resources. These constraints have led to elegant neural and behavioral strategies which are of interest to engineers seeking to emulate insect-level performance with lightweight hardware. Such insect-inspired visual systems – in which engineers incorporate design principles derived from insect behavior – have consequently been adopted for many tasks, from the biomimetic design of visual hardware through to the development of parsimonious control algorithms for autonomous agent control.

Introduction

The insect world offers many examples of remarkable visually guided behavior. Two such behaviors which are no less remarkable for their familiarity are the precise, extremely fast flight control of flies and the long-distance visual navigation of bees and ants. These behaviors are all the more impressive because of the limitations that insects overcome in terms of visual resolution and available neural processing power. For the biomimetic engineer, the visual systems of insects therefore provide aspirational examples of parsimonious and economical strategies for visual tasks which can be evidently performed with minimal lightweight hardware.

Investigations of insect vision over many years and at various levels of study, from optical anatomy to behavioral observation, have shown how visually guided behaviors are the product of dedicated circuits which have evolved in specific ecological niches. This has led to the tight coupling of sensory systems, visual processing, and behavior. The basic organizational principles of insect visual systems are reviewed and at each stage it is considered how these principles might influence the design of artificial systems.

The Insect Visual Pathway

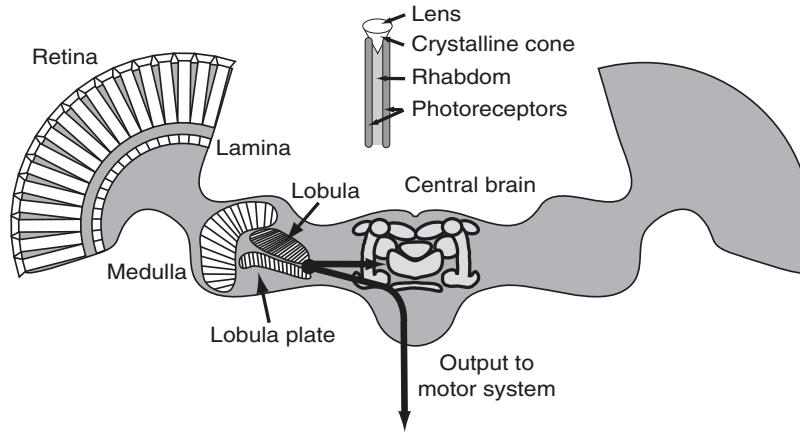
In insects the visual pathway begins with the compound eye, which differs fundamentally from simple eyes (i.e., single-lens eyes like human eyes) because there are multiple lenses with differing viewing directions but a fixed focal length (Fig. 1). There are two basic forms of compound eye [2], apposition and superposition. This entry focuses on the former as diurnal insects, the majority of which have apposition-type compound eyes, produce well-studied behaviors that have inspired engineers, such as precise and fast flight control, collision detection, and navigation.

In the apposition compound eye (Fig. 1), each lens has its own photoreceptors and this lens-photoreceptor unit is called an ommatidium ("little eye"). Compound eyes are severely constrained in terms of spatial resolution, because diffraction limits the resolution possible for a given aperture size. For instance, to replicate foveal human visual acuity, which is of the order

1 min of arc, a compound eye would have to have many more lenses and each lens would have to be much bigger, leading to a bulky sphere with a diameter of over 10 m. This limitation means that the highest visual acuity in insects is found in the large eyes of the dragonfly at about 0.5°. To mitigate this limitation, the density of ommatidia is not uniform, but is adapted to the environment, mode of locomotion, and behavior. Arthropods that move close to flat surfaces such as water or mud flats have greater acuity in the equatorial part of the visual field, which views the horizon where landmark information is to be found. Insects that fly in dense vegetation have a low density of ommatidia in the lateral parts of the eye to increase the detection of motion signals from objects moving from front to back across the eye's surface. Similarly, insects that need to resolve and track small targets, such as potential mates or rivals, have evolved specialized high-acuity eye regions adapted for encoding small and often fast-moving targets. Despite the limitations in acuity, compound eyes still offer advantages for insects and potentially engineers too. The hardware of the compound eye allows for a better temporal resolution (up to 300 Hz rather than 30 Hz for human vision) and because of the convex shape of a compound eye, insects can create a very wide field of view (FOV). These properties are particularly beneficial for processing motion information (which is discussed in section The Insect Visual Pathway).

The parallel output from the ommatidia is processed further in the lamina and medulla (Fig. 1). In these structures, information remains retinotopically organized. Although the functional organization of these structures is still not fully understood, it is generally taken that information is high-pass filtered in the lamina to emphasize dynamic components of the input, before subsequent extraction of local motion information in the medulla [3]. It is thought that motion information is extracted using correlational filters, where the signal from one point in space is correlated with time-delayed signals from adjacent points in space. These supposed filters are known as elementary motion detectors (EMDs).

One step further along the visual pathway are the lobula and lobula plate. Here there is massive convergence of the motion filtered signals from all parts of the visual field. These brain regions house a limited number of highly specialized neurons that are at the service of specific behaviors. For instance, single cells act as matched filters for particular patterns of optic flow generated in flight or for the motion of small objects against patterned backgrounds. The output of these cells often passes directly to flight muscles without further processing in the central brain. This highlights the economical, specialized nature of insects' visual circuits [1, 3].



Artificial Compound Eyes

Artificial compound eyes are desirable because they promise a wide FOV without the bulk of single-lens imaging systems. It is true that a large FOV can be achieved with multi-camera systems, panoramic mirrors, or even mirror and lens hybrid arrangements that are cheap and easy to use. Indeed, these kinds of panoramic imaging systems are widely used tools for biologists using modeling and robotic approaches to study animal visual behavior [4]. They can also be mounted on medium to large wheeled [5] and flying [6] robots for autonomous navigation. However, future miniature platforms, such as micro unmanned aerial vehicles (micro UAVs) need to minimize payload and thus require much smaller visual systems and so approaches inspired by compound eyes have been explored. Moreover, artificial compound eyes of a comparable scale to insect eyes would have many applications in space-limited situations.

There have been some successes replicating the optical arrangements of compound eyes. One approach is to use arrays of microlenses to project onto CCD or CMOS cameras. The basic result is a sandwich of a microlens array, an aperture array, and a photodetector array. These flat artificial compound eyes, which can be constructed using MEMS (microelectromechanical systems) construction technology, have the advantage of being very small and thin, but do not necessarily

I

The compound eyes of a robber fly (*Holcocephala fusca*) (Photo: Magnus Manske, used with permission under a Creative Commons license). (*Right)* A schematic of the major regions in a typical insect visual pathway (Redrawn after [1]). (*Inset)* The major components of a single ommatidium

have a large FOV. 3D microlens arrays can improve the FOV to a maximum of 180° [7]. However, a practical issue remains with systems of this type, owing to the difficulty in aligning the different components of the system.

One of the more striking attempts to create an artificial compound eye, owing to its stunning similarity to a real insect eye, comes from Jeong and colleagues [8]. They avoid the problem of aligning the components of a visual system by creating a self-aligning system. To construct their eye, they make a mold of the outer surface of a compound eye – a hemisphere consisting of thousands of bumps in a hexagonal array. This compound eye mold is filled with an epoxy resin, and when struck by a beam of light, each bump in the epoxy structure acts as a lens and focuses light on the material below, hollowing out a narrow cavity. By this technique, waveguides (similar to the rhabdom in the insect ommatidium, Fig. 1) are constructed in perfect alignment with each lens. The end product is remarkably similar in size, shape, and optical performance to a honeybee ommatidium.

The aforementioned approaches to building artificial compound eyes mainly focused on taking advantage of the optical, size, and FOV advantages that come with this eye design. A second approach to building insect-inspired eyes comes from neuromorphic engineering where conventional optics are used in tandem with hardware (VLSI or FPGA) which mimics the early stages of visual processing, most commonly motion extraction. So-called "eyes on a chip" successfully achieve the low weight and fast parallel processing required in artificial systems [1, 9]. Floreano et al. [10] have taken this approach and, by using flexible printed circuit

boards, have produced a convex artificial eye (named CurvACE) that has a hemispheric FOV. The CurvACE sensor has been shown to be well suited to the wide-field extraction of motion information which is important for many insect behaviors as discussed in the next section.

Using Motion Information

Fast, precise insect behaviors, such as the ability of flies to avoid being swatted, of hoverflies to accurately maintain their position, and of locusts to avoid predator attacks, come from the capability of insect brains to rapidly extract global patterns of local motion in behaviorally relevant ways. The pattern of visual motion experienced by an animal depends on three factors: the animal's motion, the structure of the environment, and the movement of objects in the world. This means that insects can use motion signals to extract information about their own movements as well as the structure of the environment. In this section, some basic uses of motion information are considered.

Flight Control

For flying insects, controlling flight is complicated by air currents; thus, an insect's actual movements cannot be directly inferred from its motor output. To monitor the success of an intended movement or to check for unintended displacement, insects use the pattern and amplitude of the visual motion they experience. Behavioral experiments with bees and neurophysiological experiments with flies have demonstrated the ingenious tricks employed by insects when using visual motion cues to control flight behavior.

Mandyam Srinivasan and colleagues [6] have spent many years observing bees flying through patterned tunnels. These experiments show that bees maintain a central position in a tunnel by balancing the image motion, or optic flow, perceived by each eye. The optic flow, F, generated by a simple object at a distance d from an observer moving with an instantaneous velocity v can be calculated as:

$$F = -\omega + \frac{v}{d}\sin\theta$$

where ω is the optic flow generated by self-rotation and θ is the angle of the object relative to the direction of travel. In the absence of self-rotation (often assumed to be subtracted out through measurement by gyroscopic sensors) balancing the optic flow on each side of the bee (i.e., at +/− θ) would mean that d would be the same on both sides (as v is constant for both eyes). Similarly, maintaining constant optic flow requires that if the tunnel narrows, the bee must lower its velocity. This means that in more cluttered environments, the bee automatically responds appropriately by slowing down. This simple and elegant solution of balancing optic flow thus results in a bee being able to chart a safe path through a cluttered environment *without* knowing its own speed or measuring the distance to nearby objects.

A similar control scheme is used by bees to control grazing landings on flat surfaces. When landing, bees control their forward flight speed using the angular velocity perceived in the lower part of their visual field. As the bee descends, the ground appears to move at a higher angular velocity. By controlling forward thrust to maintain a fixed angular velocity, the bee "automatically" slows as its altitude falls. When the bee finally touches down, its forward speed is zero, thus ensuring a smooth landing. This algorithm also allows the bee to maintain a constant angle of descent throughout the landing and does not require explicit measurement of flight speed, flight altitude, or estimated time to contact.

Flight Control for UAVs

The fixed-point control mechanisms observed in bee flight are clearly attractive to engineers, and following Srinivasan's work, there have been multiple instantiations of corridor-centering robots. In addition, the observation that bees use

this type of control to maintain a fixed height above a surface has led to the robust control of UAVs capable of "terrain following". Notice that in the above equation, if an insect is flying parallel to the ground, the optic flow signal from the area directly beneath it will be strong and the distance, *d*, is the height of the insect above the ground. A UAV can therefore maintain a constant height over undulating terrain by altering its forward velocity so that the optic flow measured from a downward-facing camera remains constant. This type of control has been implemented on free-flying helicopters and fixed-wing aircraft [6, 11].

Crucial to the success of these systems is the extraction of reliable optic flow signals. In general, these rely on simple hardware EMDs. However, going a stage further down the visual pathway and modeling the wide-field integration of the cells in the lobula plate has led to alternative control systems for UAVs. As described above, these cells take input from a large number of EMDs in the medulla, and electrophysiological studies indicate that they respond preferentially to particular global patterns of optic flow, such as an expanding flow field caused by pure forward motion. Individual cells therefore act as matched filters for translation and rotation about different axes providing signals that insects can use to monitor movement and correct for unintended displacements or rotations [12].

Engineers have used an analog of the lobula plate system to generate fixed-point control algorithms for both flying and wheeled robots [13]. The output of a given neuron in the lobula plate can be interpreted as a comparison between the current instantaneous flow field and the flow field that would be generated by the particular movement that the neuron is configured to detect. This can be modeled as an inner product between a template flow field pattern and the instantaneous flow field. With this technique it is possible to extract information such as forward and vertical velocity and pitch rate. Further, spatial Fourier components of appropriate filter outputs can be fed back into the system and used in fixed-point control algorithms for UAV stabilization.

Collision Avoidance

The depth cues available to insects are an impoverished subset of those that vertebrates can use. Two main cues are available: motion parallax and looming. Insects do not use these cues to generate a universal depth map. Rather, individual cues are used in specific visual circuits to control specific behaviors. For avoiding obstacles in free flight, many insects use parallax cues and have evolved a specific movement strategy to simplify the perception of parallax information. During translatory movements, objects closer to the animal move faster across the retina, but this signal can be swamped by the rotatory flow fields (where objects at all distances move across the retina with the same speed) produced by rotation. Many insects therefore move in a saccadic manner where periods of straight flight are alternated with very fast turns. In addition, small head movements are used to compensate for body rotation, such that the eyes are rotating for the least amount of time. The utility of this strategy was highlighted in a seminal piece of insect vision-inspired biorobotics [14]. Franceschini and colleagues implemented an array of electronic EMDs on the perimeter of a large wheeled robot. The EMDs were tuned to respond to the parallax generated by objects that were on a collision course. This was possible as the robot used a fixed movement direction relative to its sensors and used a saccadic movement strategy, i.e., pure translation alternated with fast pure rotation. Given these two constraints the robot was able to move rapidly around a flat environment while avoiding obstacles.

An alternative distance cue comes from looming, also known as image expansion. The mechanisms of looming detection have been well studied in the locust collision-avoidance response which is triggered by image expansion [15]. In locusts, a specialist neuron in the lobula called the lobula giant movement detector (LGMD) responds to any movement within a large visual area, but is most sensitive to objects directly approaching the eye. The firing rate of this neuron increases throughout an object's approach, but responses decrease if the approaching target

deviates from a collision course by a small amount. The response properties of the LGMD indicate that the cell is sensitive to the movement and total length of luminance boundaries in the image. All these parameters can be derived by conflating the output of EMDs in the medulla and therefore the LGMD neuron acts as a matched filter for impending collision using only a few processing stages.

Because the LGMD is able to reliably signal impending collisions without the need to explicitly represent the target object's physical size, distance, or approach speed, it represents an interesting model for collision avoidance in artificial systems. For instance, artificial neural networks have been constructed to account for the responses of the locust LGMD neurons and detect impending collisions on wheeled robots. Essentially, the edges of an expanding object trigger feed-forward excitation, followed a short time later by laterally spreading inhibition, with both excitatory and inhibitory signals converging on the LGMD. So long as the edges continue expanding rapidly enough to "outrun" the pursuing inhibitory signals, the LGMD's response continues to grow in strength. This model has been further developed and tested for collision warning systems in automobiles [16]. However, in order to produce satisfactory performance in an automobile context, the model had to be significantly augmented. This highlights a particular problem with biomimetics. In this example, the sensory environment and behavioral niche for locusts and cars are very different. In general, it should not be assumed that bioinspired systems will work perfectly in novel contexts.

Economical Visual Navigation

Efficient and robust navigation using visual cues is an important capability for many animals as well as autonomous robots. By using simple strategies, insects demonstrate excellent navigational ability albeit with small brains and low-resolution vision. The most famous example of this is view-based homing or snapshot guidance [17] in which insects navigate back to a location by remembering a retinotopic view of the world, or snapshot, stored at the goal position. Subsequent navigation is achieved by moving so as to make the current view of the world more similar to the remembered goal view. In general, algorithmic instantiations of this process work by iteratively comparing a parameterized view of the world from the agent's current position with a similarly parameterized view stored when it was at the goal location. Differences between the current and goal views are then used to derive an approximate direction to the goal. For engineers, one attraction of insect-style view-based homing is that these strategies can work without identifying objects in the world. That is, they can work using only the appearance of the world, rather than needing to identify and subsequently match features between views, vastly simplifying the visual task [18].

One of the simplest and most elegant implementations of snapshot homing for robotic navigation is the average landmark vector (ALV) model [5]. The ALV model works by first identifying visual features from a 360° panoramic view of the environment. The view of the world from that position is then represented as the average of unit vectors pointing from the agent to each identified feature, i.e., the ALV. The algorithm works since the vector difference between the current ALV and an ALV stored at the goal position points approximately back to the goal. While this approach does extract features, it does not attempt to match them and thus the feature extraction can be very coarse and has been shown to work using one feature per pixel (essentially, without feature extraction). This idea of encoding a visual scene as the visual center of mass of image features, or even the center of mass of pixel intensities, is surprisingly robust and is a general purpose method for retinotopic encoding of a visual scene.

While the ALV is a particularly parsimonious visual homing algorithm, at the heart of all algorithms of this type is the fact that, within a region local to the goal, the difference between the goal and surrounding views increases smoothly with distance from the goal until it starts to plateau [19]. The size of the region before the differences plateaus, called the catchment area of an image, is determined by the distribution of object distances.

I

To home successfully, the agent thus needs only to calculate the local gradient of the difference between current and goal images (whether processed or unprocessed) and move in the direction which decreases this difference. While the local gradient can be calculated by sampling the world, it has been shown that the gradient can also be estimated using matched filters which approximate the effects of forward and sideway movements on the current image by effectively performing the inverse of elementary optic flow calculations. This method has been shown to work robustly in natural environments and can be implemented with simple parallel processing steps and so should be amenable to hardware implementation.

As well as using visual memory to search for a discrete goal, insects can also use vision to guide long routes [20]. Unlike search for a discrete goal where an agent needs to be attracted to the goal from any location around it, when following a route an agent instead needs to set a direction that is roughly parallel to the overall direction of the route section at their current location. Because compound eyes cannot be moved relative to an insect's head, an insect's direction of movement specifies its viewing direction, and so if an insect makes similar movements when at similar locations, it will experience similar views. Thus, in practical terms, for an agent to recapitulate a route, it must simply move in the direction that appears visually most familiar to the views it experienced when it previously navigated that route [21]. This simple heuristic can be underpinned by parsimonious computational architectures [22] allied to stereotypical behaviors [23]. For instance, Baddeley et al. [24] show how during route learning the views experienced along a route can be used to update the weights in a neural network using the Infomax algorithm. After training the network can be used to gauge the familiarity of any scene presented to it and thus can be used to underpin familiarity-based route navigation.

While there are many insect-inspired navigation algorithms, the key similarity is that the agent never calculates where it is at any point but rather what it should do. This class of algorithm thus highlights how navigation can be performed without explicitly calculating position, setting it apart from map-based approaches such as simultaneous localization and mapping or SLAM [25] and allowing navigation to proceed with low computation.

Conclusion

Insects are an existence proof that low-resolution vision and a small brain are not a barrier to the production of exquisite visually guided behavior. What's more, insects provide specific design blueprints for emulating this performance in artificial systems [1]. In summary, the early stages of insect vision are massively parallel and fast, and much visual behavior is controlled by neural matched filters that integrate across many of these parallel inputs. However, a significant lesson for engineers is that insects' visual systems have been fine-tuned by evolution such that the interactions between optics, neurons, behavioral routines, and the environment are optimized for a specific ecological niche. The niche of an artificial system has to be considered when applying biomimetic design principles.

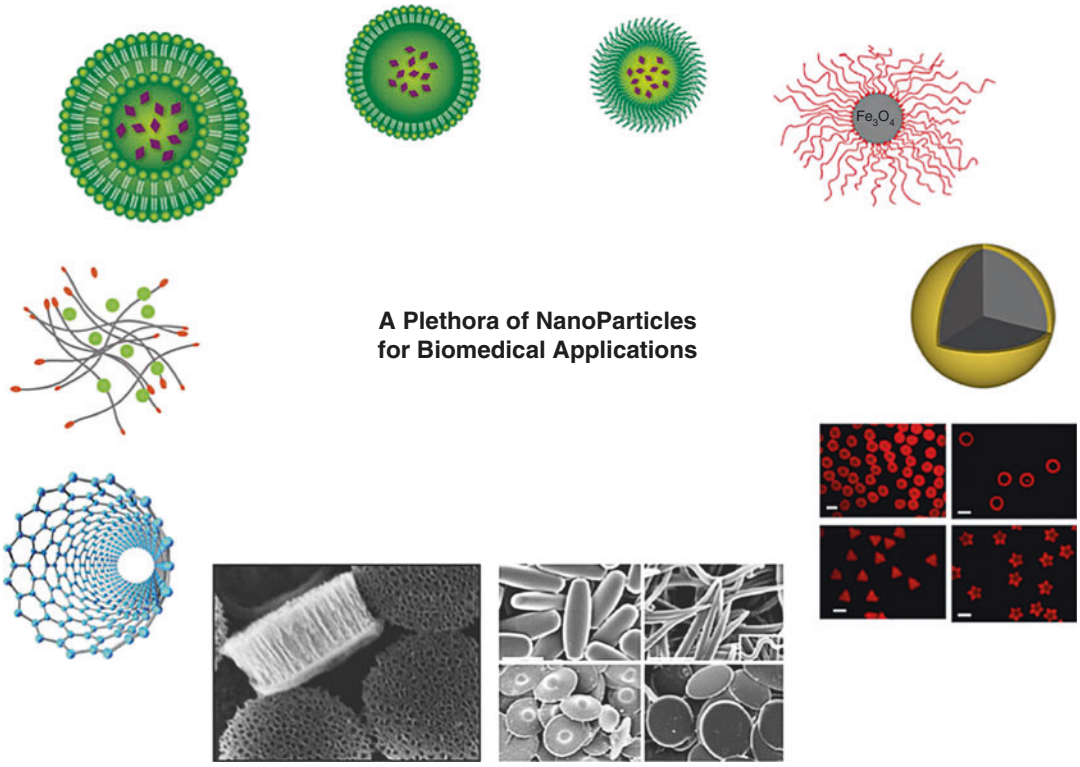
Optimization of nanoparticles

Definition

The integrated approach for the rational design (IARD) of nanoparticles is a framework combining in silico mathematical modeling, in vitro and in vivo experiments with the objective of identifying an optimal nanoparticle that can efficiently localize within the diseased tissue (tumor, atherosclerotic plaque, injured vessel, and so on) while avoiding nonspecific sequestration by the organs of the reticuloendothelial system (RES). The size, shape, surface properties, and mechanical stiffness (*4S design parameters*) are the independent design parameters to be optimized that affect the vascular, extravascular, and subcellular behavior of systemically injected nanoparticles.

Introduction

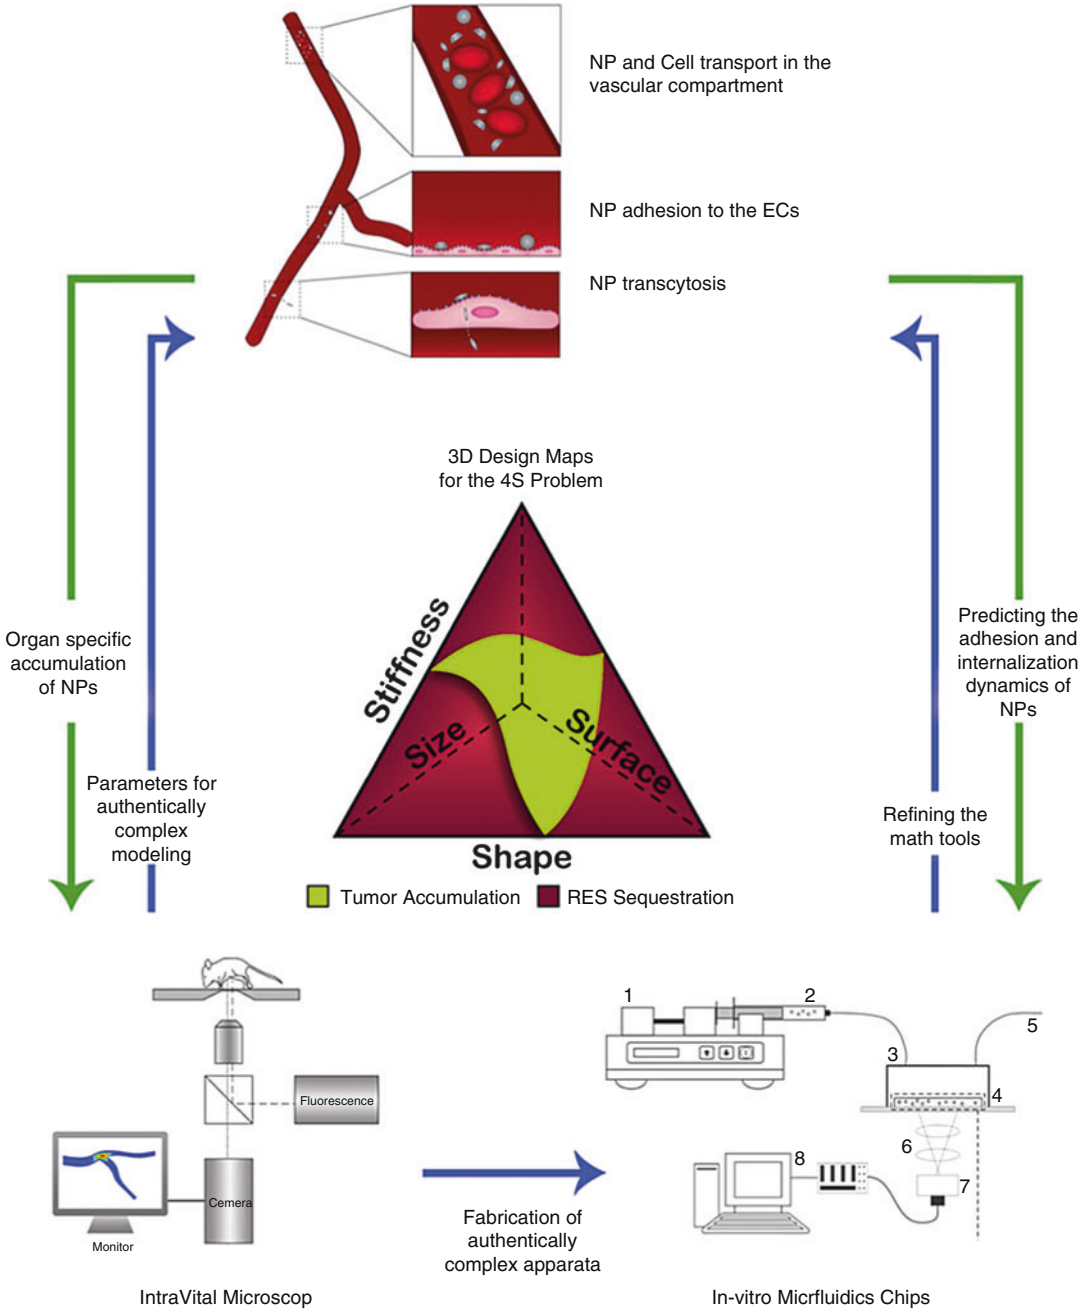


Nanoparticles (NPs) are man-made objects small enough to be injected intravascularly and navigate safely within the circulatory system and are designed to perform several crucial functions [1, 2]. They can carry multiple drug molecules and contrast agents from the site of injection to the biological target (diseased tissue) thence providing their therapeutic action and contrast enhancement. Many classes of NPs have been developed for diverse applications, including the treatment and imaging of cancer and other diseases. The advantage of using NPs over freely administered molecules is threefold: (1) *higher specificity*, increased active molecules reaching the target; (2) *multifunctionality*, loading and codelivery of several and different drug molecules and contrast agents; and (3) *engineerability*, multiple design parameters that can be properly tailored during the NP synthesis process.

Geometry, surface properties, and composition often change among the different classes of NPs. This is shown in Fig. 1 where a few representative NPs, developed over the last 20 years, are exhibited. In the top left corner, the archetypical NP – a liposome – is depicted with a spherical shape, a diameter of about 100 nm and is composed of a lipid double-layer. Proceeding in a clockwise direction, a micelle is shown which is still spherical, with a diameter of few tens of nanometers, and is composed of a lipid single-layer. Figure 1c represents a spherical polymeric NP. These NPs usually have a size varying in a wide range, from tens to a few hundreds of nanometers, and can be synthesized using several different types of polymers. Continuing, two examples of metallic NPs are presented: a superparamagnetic iron oxide (SPIO) particle (Fig. 1d), whose magnetic core is generally spherical with a characteristic size of 5–20 nm, and a gold nanoshell (Fig. 1e), comprising an inner spherical silica core (110–130 nm) coated with a thin (5–10 nm) gold film. So far, only spherical NPs have been featured which are generally obtained by the precipitation and self-assembly of salts, lipids, and polymeric chains. More recently, methods have been proposed for the synthesis of nonspherical NPs made out of different materials. These include the use of hydrogel-based templates (Fig. 1f), PRINT technology, thermoforming, and mechanical molding (Fig. 1g) for the synthesis of polymeric nano- and microparticles, offering a variety of shapes, sizes, and compositions. Nonspherical particles have been also fabricated out of silicon (Fig. 1h), combining lithographic techniques and electrochemical etching; and using gold and carbon-based materials, leading to nanorods and nanotubes, respectively (Fig. 1i). Finally Fig. 1j presents an interesting example of a hybrid NP obtained by combining bacteriophages (organic component) with gold nanospheres (nonorganic component). Clearly, the variety of size, shape, and composition is enormous and, in addition, the surface of most NPs can be decorated with multiple and diverse functional groups and polymeric chains and molecules, making the overall picture even more complex.

Size, shape, surface properties, and mechanical stiffness (*the 4S design parameters*) have been shown to affect the vascular, intravascular, and subcellular transport of NPs and their functions [3, 4]. It is imperative for the development of NPs to accurately control the 4S design parameters during manufacturing and to identify the optimal combination (or set of combinations) that would allow the systemically injected NPs to efficiently and preferentially reach the biological target. This indeed is the objective of the integrated approach for the rational design (IARD) of nanoparticles, a framework where in silico mathematical models, in vitro and in vivo experiments are used together to solve an optimization problem (Fig. 2): identify the 4S design parameters that maximize NP lodging within the diseased tissue (*efficient accumulation*) and minimize nonspecific sequestration by the organs of the reticuloendothelial system (RES) (*preferential accumulation*).

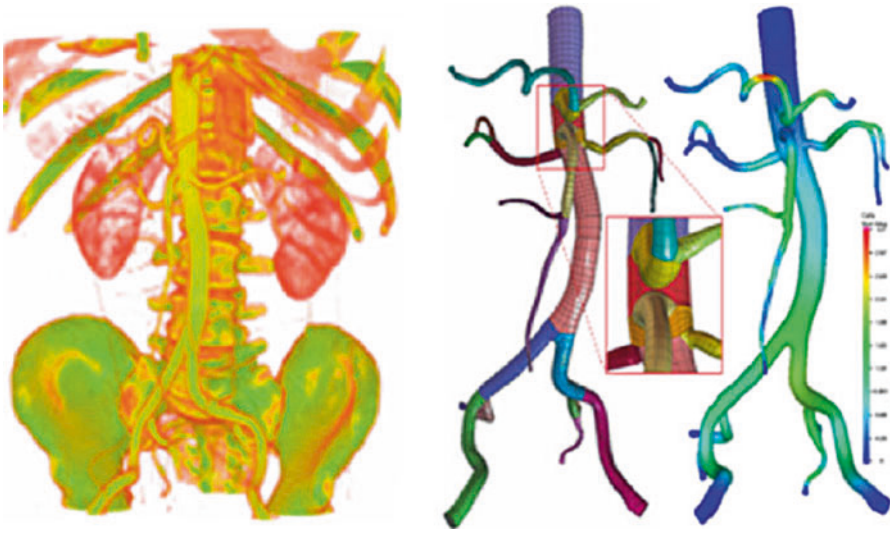
In Silico Mathematical Modeling



An intravascularly injected NP navigates the circulatory system transported by the blood flow. During the journey, NPs interact with red blood

Integrated Approach for the Rational Design of Nanoparticles, Fig. 1 A plethora of nanoparticles for biomedical applications. Over the last 20 years, nanoparticles with different size, shape, surface properties, mechanical stiffness, and composition have been developed

cells (RBCs), the most abundant cells in the circulation; with cells of the immune system, both circulating monocytes and resident macrophages, such as the Kupffer cells in the liver and the splenic macrophages; and with endothelial cells (ECs), lining the vessel walls. Different computational tools can be employed to study the vascular transport and cell/NP interaction, depending on the complexity of the problem and desired accuracy of the solution.

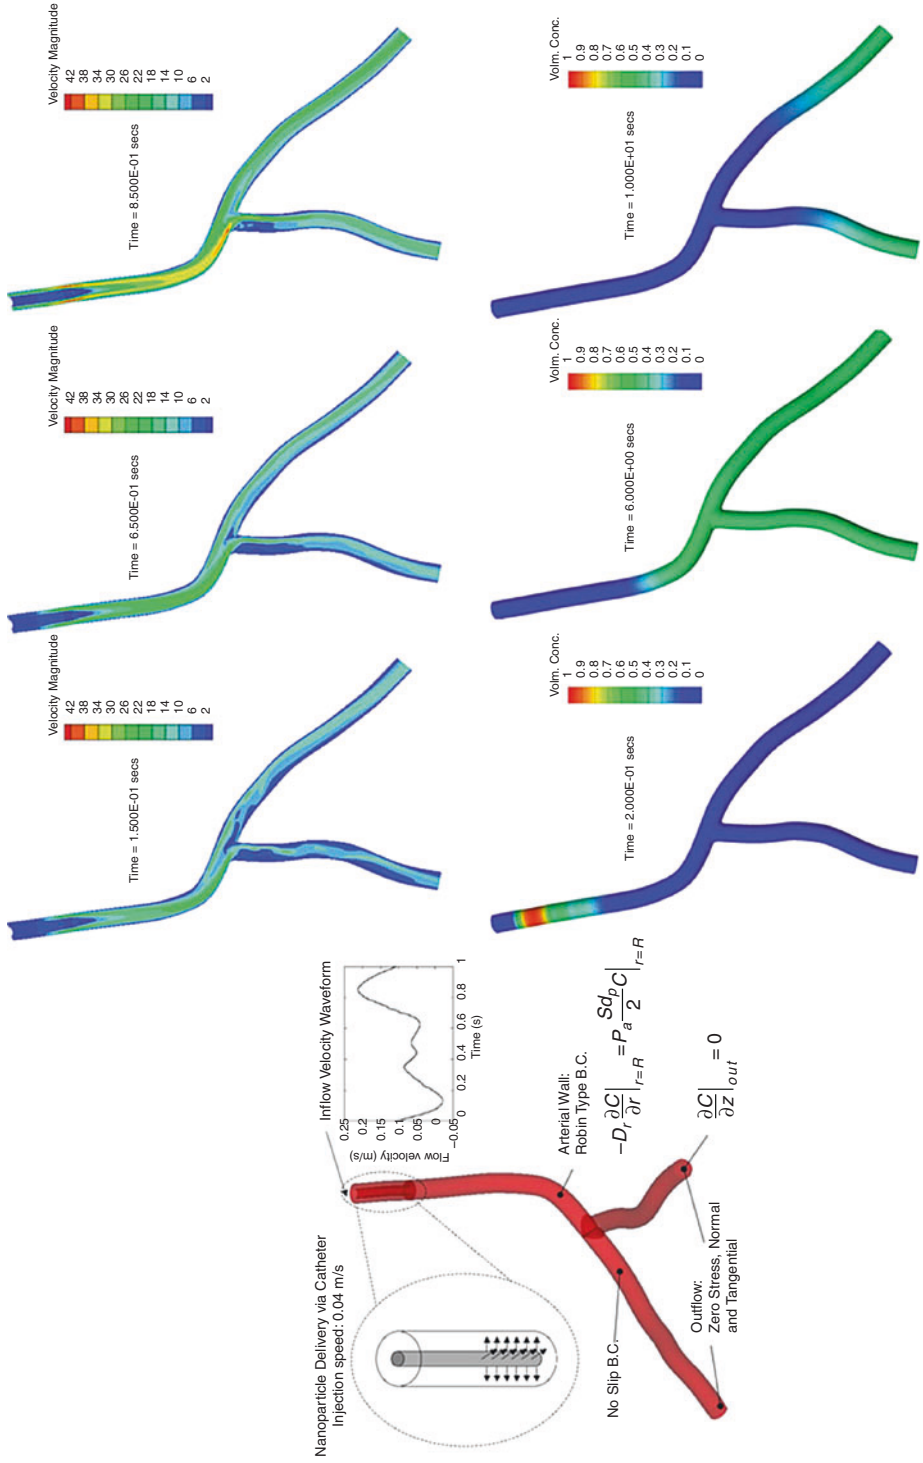


In the macrocirculation (vessel diameter >300 μm), NPs can be considered as passive scalars advecting and diffusing in a quasi-Newtonian fluid. Under these conditions, a classical computational scheme, based on finite element methods (FEMs) and finite volume methods (FVMs), can be used quite efficiently to solve the transport problem. Recently, the isogeometric analysis (IA) has been introduced as a generalization of FEM which allows one to improve the functional representation of the geometry in the computational problem, simplifying the mesh refinement and increasing the accuracy of the solution [5]. In particular, patient-specific vascular models can be accurately constructed by identifying a set of procedures to create solid NURBS-based vascular models directly from patient-specific MRI/CT data (Fig. 3) [6]. This requires four main steps: preprocessing, where the quality of the original patient-specific data is improved using imaging processing techniques; path extraction, where the skeleton of the arterial system is identified using Voronoi and Delaunay diagrams; control mesh construction, where hexahedral NURBS control meshes are generated by sweeping a templated quad mesh of a circle along the arterial path; solid NURBS construction, which allows one to generate a 3D exact representation of the patient-specific

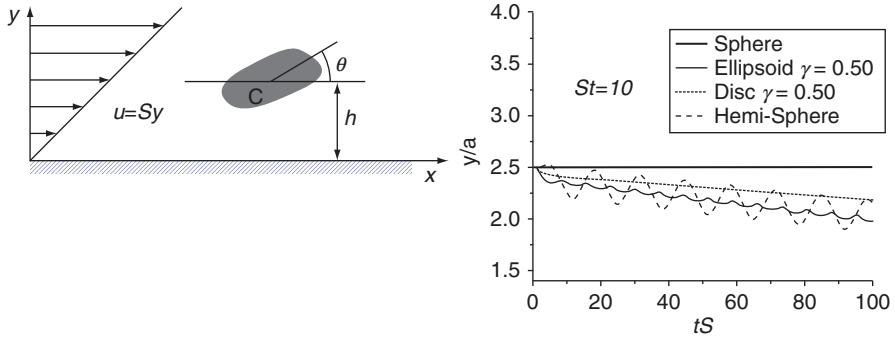
Integrated Approach for the Rational Design of Nanoparticles, Fig. 2 A schematic representation of the integrated approach for the rational design of nanoparticles. Mathematical tools, in vitro experiments, and intravital microscopy are used synergistically to solve the 4S problem, presented in the quaternary diagram in the *middle*

data, and, eventually, the reconstructed 3D geometry is used for the final numerical analysis.

The IA framework has been applied successfully to solve several nonlinear and complex physical problems. It can be effectively used to model transport problems in the macrocirculation. A 3D Navier–Stokes solver for blood flow is coupled with a linear scalar advection/diffusion



Integrated Approach for the Rational Design of Nanoparticles, Fig. 3 Patient-specific modeling of the abdominal aorta. The original image is divided into 26 patches, and each color represents one different patch. The image to the *right* presents data on the flow field within the vessels (Adapted from [6])

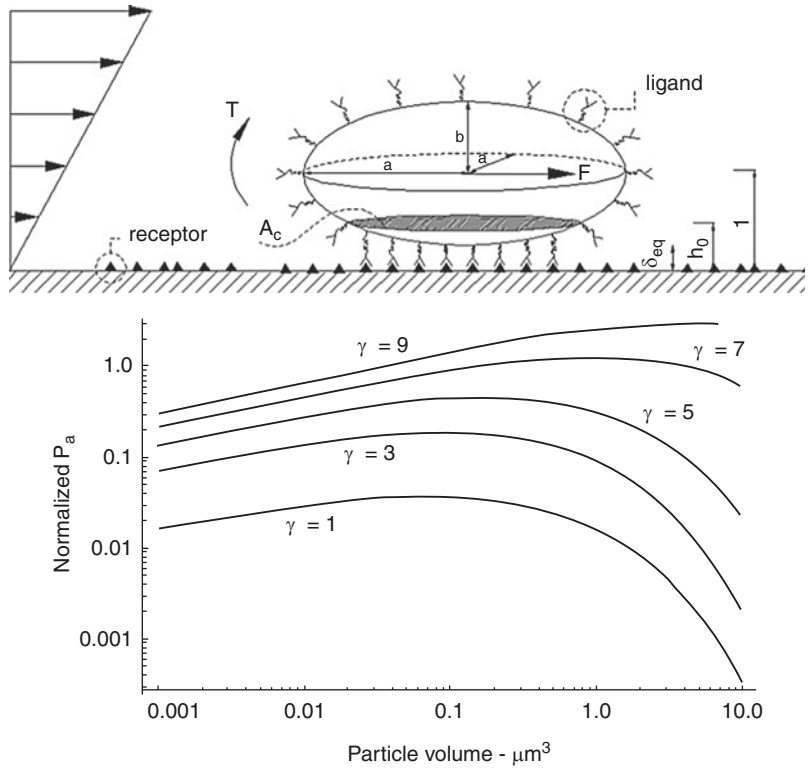


equation for studying the blood flow and transport of passive scalars within the authentically complex arterial vasculature. The spatial and temporal variations of the wall shear rate (WSR), wall shear stress (WSS), velocity profile, pressure field, and volumetric concentration of drug molecules and NPs can be estimated in patient-specific geometries. A classical problem solved within the IA framework is exemplified in Fig. 4, where a catheter is placed at the inlet of a coronary artery and releases drug molecules in the flow. The 3D Navier–Stokes solver allows one to quantify the magnitude of the velocity field within the vasculature in the presence of the catheter (top, right) at different time points. Using the derived flow field, the transport equation is solved for time and spatial evolution of the drug molecules released from the catheter (bottom, right). The IA can be implemented with an efficient parallel-solution strategy.

In the microcirculation (vessel diameter $<$300 μm), NPs interaction with RBCs and with the ECs has to be also taken into account. Different techniques have been proposed including semianalytical models [7, 8], the immersed boundary method (IBM) [9], the immersed finite element method (IFEM) [10, 11], dissipative particle dynamics (DPD) [12], and Lattice Boltzman (LB) [13] approaches. In the following, the focus will be on semianalytical methods and IFEM.

RBCs tend to preferentially accumulate in the core of the vessels leaving a "cell-free layer" in proximity of the wall where the flow is mostly laminar and linear with a shear rate S. Such a layer has a thickness varying with the vessel lumen diameter and mean blood velocity, ranging from few microns in small capillaries (10 μm and more in diameter) to few tens of microns in arterioles (100 μm and more in diameter). The dynamics of NPs moving in the cell-free layer can be effectively described using semianalytical methods. The geometry of the problem is presented in Fig. 5 (left), where an arbitrary shaped particle is immersed within a linear laminar flow in a semi-infinite 3D region bounded by an infinite flat plane at $y = 0$, reproducing the blood vessel wall [8]. In this specific example, a sphere, an ellipsoid, a discoid, and a hemisphere are considered. For the fluid motion, mass and momentum conservation are imposed, whereas the NP is required to obey Newton's law for linear and rotational motion. For the case presented in Fig. 5, it is clearly seen that nonspherical particles would drift laterally across

Integrated Approach for the Rational Design of Nanoparticles, Fig. 4 Patient-specific modeling for the transport of drug molecules in a coronary artery. The fluid velocity field (*right*, *top*) and the volumetric concentration of drug molecules (*bottom*, *right*) are shown at different time points. A typical inflow velocity profile of a beating heart is used (*left*, *inset*)

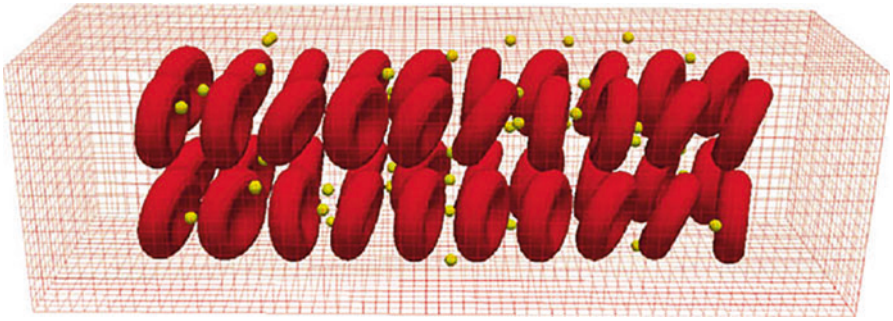


Integrated Approach for the Rational Design of Nanoparticles, Fig. 5 Shape-specific NP dynamics in proximity of a vessel wall. Schematic of the problem (*left*) and trajectory of NPs with different shapes (*right*). Nonspherical NPs are predicted to drift laterally across the streamlines toward the vessel wall (y = 0) (Adapted from [7])

the streamlines. Such a lateral drifting has been named *margination dynamics*, and it is affected by the NP size, shape, and composition and by the local hydrodynamic conditions. Also, it has been demonstrated that the smaller the aspect ratio, the larger is the drifting velocity having fixed other parameters.

Clearly, a marginating NP has a larger likelihood of interacting with the vessel walls to recognize the diseased tissue. However, this does not directly imply adhesion. The propensity for firm adhesion to the vessel walls under flow can be related to a specific mathematical quantity: the probability of adhesion P_a [14]. This is affected by biophysical parameters, such as the local hydrodynamic conditions (wall shear rate S) and the density of receptor molecules (m_r) expressed on the cell membrane, and by the size, shape, surface properties, and mechanical stiffness of the particle. The NP surface properties include the density of ligand molecules (m_l) distributed over the particle surface, the electrostatic surface charge and decoration with polymeric chains which would affect nonspecific interactions at the cell/particle interface (van der Waals, steric, double-layer electrostatic), and the ligand-receptor affinity k_a. Mechanical stiffness is relevant too because it affects the distribution of the hydrodynamic forces over the multiple interfacial molecular bonds. Using in silico models, it has been demonstrated that oblate spheroidal particles exhibit a much higher strength of adhesion (P_a) compared to spherical particles under the same biophysical conditions and for the same volume V (i.e., payload). The variation of P_a with V, for different values of the particle aspect ratio γ, is shown in Fig. 6: the P_a of a spheroid with $\gamma > 2$ is orders of magnitude larger than for a sphere ($\gamma = 1$), for a fixed V [14]. As γ increases, the oblate spheroid tends in the limit to a thin disk. The large adhesion observed is explained by the larger surface area exposed (i.e., larger number of molecular bonds) to cells and lower hydrodynamic dislodging forces of a "squashed" spheroid compare with a sphere of equivalent volume.

In order to analyze the interaction of NPs with RBCs, a more sophisticated computational approach is required, such as the immersed finite element method (IFEM). This technique was developed by integrating the concept of immersed boundary, finite element, and mesh-free methods. Following the IFEM framework, the immersed bodies (i.e., NPs and circulating cells) are modeled as flexible and highly deformable structures using a Lagrangian mesh, whereas the fluid (plasma) is solved in a fixed Eulerian mesh. The cell/cell and cell/NP interactions can be modeled using a Morse potential, and Kramer's reaction rate is employed for describing the ligand-receptor binding at the interface. Within the IFEM framework, the dynamics of immersed bodies is coupled with the surrounding incompressible viscous fluid



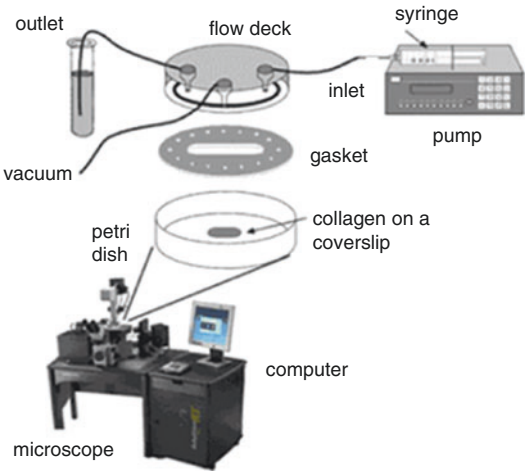
Integrated Approach for the Rational Design of Nanoparticles, Fig. 6 Shape-specific NP adhesion under flow. Schematic of the problem (*top*) and normalized probability of adhesion Pa as a function of the particle volume V and for different values of the particle aspect ratio γ (*bottom*). For a fixed volume, non spherical particles are predicted to adhere more avidly to the vessel wall under flow (Adapted from [14])

but avoiding expensive remeshing or mesh adaptivity of the fluid domain. With this approach, the dynamics of NPs can be studied in whole blood, meaning in the presence of a large group of deformable RBCs under different flow conditions. An example is presented in Fig. 7, where NPs are dispersed within a train of RBCs moving in a capillary. The relative position of the RBCs and NPs, and their orientation can be estimated at different time points as blood flows from left to right.

Finally, the cellular uptake of NPs is again affected by their size, shape, surface physicochemical properties, and mechanical stiffness. The size effect has been clearly shown for spherical particles, where the radius not only affects the uptake rate, in that the larger is the radius and the longer is the time for cell uptake, but it also affects the internalization mechanisms [15]. The characteristic time for NPs to be wrapped by a cell membrane can be related to their size, shape, and surface physicochemical properties. A mathematical model for receptor-mediated internalization based on an energetic analysis shows that a threshold radius exists below which particle uptake does not occur because it is energetically unfavorable. The same analysis shows that the surface physicochemical properties of the NP related to that of the cell membrane can dramatically increase or decrease the uptake rate [16]. A mathematical model has been developed to predict the rate of uptake for ellipsoidal particles as a function of their aspect ratio. Spherical or ovoidal particles can be more rapidly internalized by cells compared to elongated particles [17]. These results agree qualitatively well with experimental data [18].

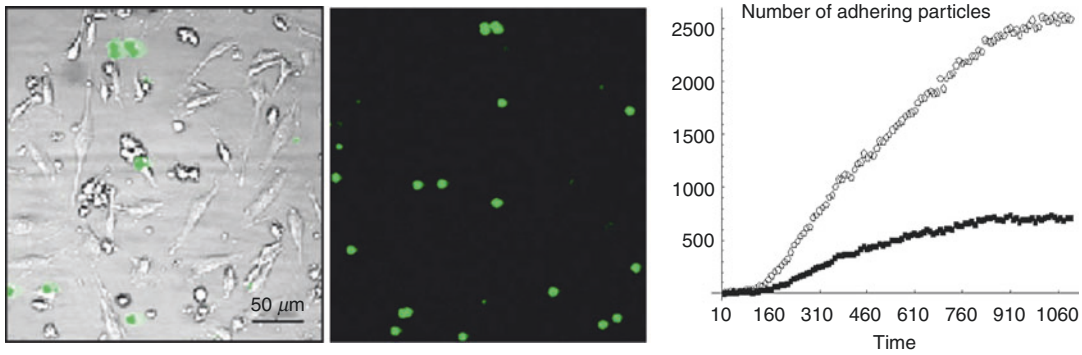
Microfluidic Chips and Intravital Microscopy

Microfluidic chips (MFCs) and intravital microscopy (IVM) analysis are used to validate and refine the mathematical models. MFCs can be effectively used in conjunction with semianalytical models and IFEM for studying the NP behavior



Integrated Approach for the Rational Design of Nanoparticles, Fig. 7 Immersed finite element modeling of NP/RBC interaction in a capillary flow

under flow. IVM is used for the final validation in vivo, for elucidating the mechanisms regulating NP dynamics, and for acquiring input parameters for the computational models. These include patient-specific data on the vascular geometry, blood flow condition, blood vessel thickness and diameter, expression of specific receptor molecules.



The microfluidic chip apparatus presented in Fig. 8 can be used to estimate the rate of rolling and adhesion of nanoparticles and circulating monocytes [19]. This consists of (1) the MFC (inlet, flow deck, gasket, coverslip, and outlet), (2) a fluorescent confocal microscope, (3) a digital camera, (4) a pumping system, (5) connecting tubings, and (6) a PC. The chip is installed over the microscope stage. An external pumping system (syringe pump) is connected to the chip through tubings and connection kits. The working fluid (physiological solution with and without RBCs) is continuously infused into the chip through a main syringe pump at a constant velocity defined by the desired wall shear rate S, whereas a bolus of the sample particles is injected within a short period of time through an additional syringe. The chip is installed on the stage of the microscope, with the transparent slide upright facing the objectives. Lenses with different magnification ratios are used depending on the size of the region of interest (ROI), varying from about $100 \times 100\ \mu m^2$ for a dry $40\times$ with digital focusing up to $2 \times 2\ \mu m^2$ with a $10\times$ objective.

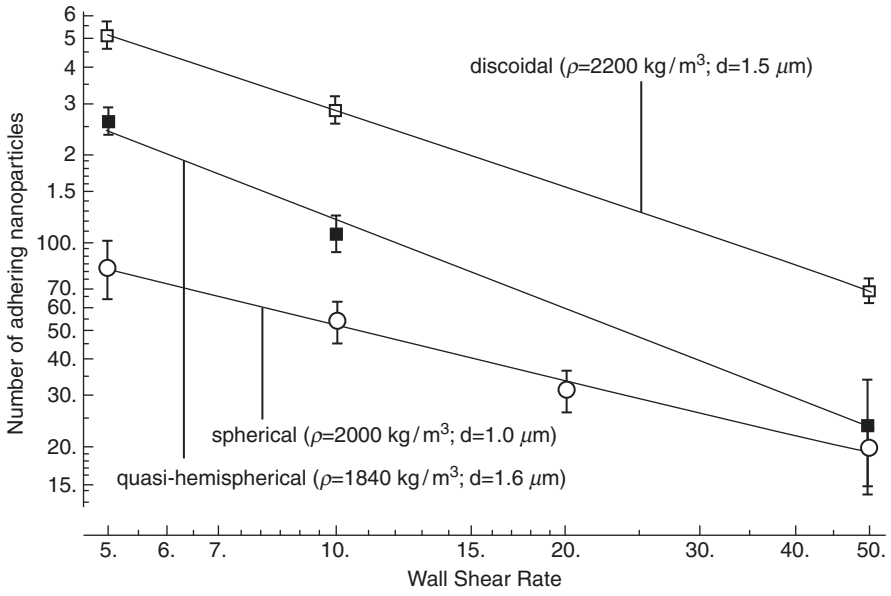
Parallel plate flow chambers have been used to characterize the behavior of circulating cells, as

Integrated Approach for the Rational Design of Nanoparticles, Fig. 8 Experimental setup for a microfluidic chip. The transport dynamics of NPs and cells can be studied under controlled biophysical conditions

leukocytes and platelets, and micro-/nanoparticles in vitro. By decorating the NP with fluorescent molecules, the transport along the chamber and the adhesive dynamics to the bottom cell layer can be analyzed over time. Based on the imaging analysis, the surface density of adhering NPs and the rate of adhesion and decohesion can be measured over time and compared with those derived theoretically. Images from a typical flow chamber experiment are given in Fig. 9, showing, from left to right, fluorescent beads adhering to the cellular layer (imaged in bright and fluorescent field) and

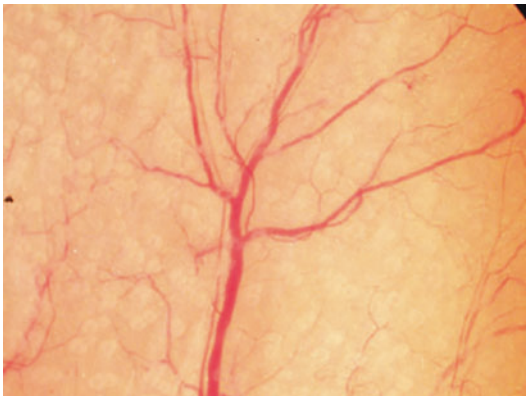
Integrated Approach for the Rational Design of Nanoparticles, Fig. 9 Outcome of a typical MFC experiment. From *left* to *right*: bright field and fluorescence image of NPs adhering to a layer of HUVECs, fluorescent image identifying the NPs, time-dependent adhesion of NPs under flow

the final result with the variation of the number of beads adhering to a cell layer over time.



The higher propensity of nonspherical particles to marginate and adhere more avidly to a substrate under flow has been also verified experimentally in vitro, as in Fig. 10, where the number of particles depositing over a layer of fibronectin under a laminar flow in a parallel plate flow chamber has been measured for three different particle geometries (sphere, quasi-hemisphere, and discoidal particles) and different shear rates S [19]. These experimental results support the notion that nonspherical particles can more effectively marginate toward the vessels and more avidly adhere under flow.

Flow chambers can be heated up to 37 °C or cooled down to 4 °C to perform internalization experiments over time under flow or in a quiescent medium. Therefore, the same apparatus can be also used to measure the uptake rates of NPs as a function of their geometrical and physicochemical properties.



Intravital microscopy (IVM) is used to collect dynamic, quantitative data in vivo with cellular and subcellular resolution. Techniques have been developed that allow the dynamics of individual cells and nanoparticles to be monitored and quantified in real time in live small animals [20]. A variety of organs can be studied acutely or longitudinally via surgical manipulations, including the aorta and arteries, the liver, spleen, and solid tumors. Nanoparticle and cell localization relative to blood vessels and specific cells of interest (as the ECs) can be visualized with the selection of appropriate vital dyes and/or transgenic animal strains. The behavior of cells and nanoparticles within the microvasculature can be correlated to local flow conditions by simultaneously tracking fluorescently tagged red blood cells in the region of interest. Cell/particle trajectory and velocity can be quantified across multiple frames.

The architecture of vascular networks can be determined using intravascularly injected fluorescent tracers, as tetramethylrhodamine isothiocyanate–labeled dextran (TRITC-dextran) with a molecular weight of 155 kDa. The tracers perfuse the vessels after tail vein injection, and images are taken at sufficiently short rates. A sample image of a vascular network from an intravital microscopy analysis is shown in Fig. 11. From the reconstructed network, the following morphological parameters can be estimated from off-line imaging analysis: volume density (volume of vessels per unit volume of tissue), vessel diameter, lineal density (length of vessels per unit volume of tissue), branch point density (number of vessel bifurcations per unit tissue volume), segment length (vessel length between branch points), and tortuosity index (segment path length/shortest distance between branch points).

The permeability of the vascular walls can be assessed by injecting calibrated fluorescent nanoparticles with increasing size, ranging from 100 nm up to 1 μm. After clearance from the

circulation, the extent of particle extravasation can be observed and the pore cutoff size determined as the range between the largest particle size that could extravasate and the smallest size that could not extravasate. In addition to this, the vascular permeability within a ROI can be quantified by analyzing the extravascular diffusion of fluorescent blood tracers, as fluorescein-labeled dextran. The permeability parameter determined through the procedures described above can be used in the mathematical models.

The dynamics of intravascularly injected NPs can be monitored in real time. In particular, the surface density of adhering particles can be measured within the ROI and compared with the mathematical predictions (Fig. 12) [20].

Future Directions

The integrated approach for the rational design (IARD) will help in developing patient-specific therapeutic and imaging agents with superior efficiency and efficacy through the use of (1) multiscale computational tools, for the analysis of the vascular and extravascular transport of nanoparticles, cells, and molecules; (2) the fabrication of sophisticated fluidic chips, resembling the biological complexity of authentic vascular networks; and (3) in vivo imaging, for tracking the dynamics of circulating agents and their performance.

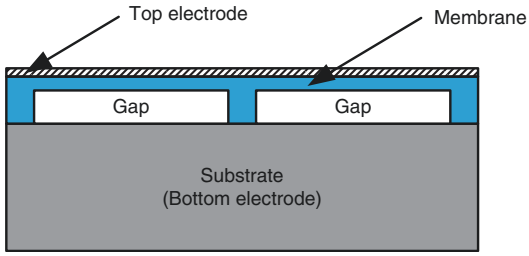
Micromachined acoustic devices

Definition

Integrated micro-acoustic devices are silicon-based acoustic transducers which are integrated with IC modules such as preamplifiers or analog-to-digital converters (ADCs).



Overview

An integrated micro-acoustic device consists of an acoustic transducer and an integrated circuit (IC) module. The functional part is the acoustic transducer, and it can either be fabricated with the IC module on the same chip or be packaged with the IC module on the same substrate. The transducer part is fabricated on a silicon wafer by MEMS techniques. The fabrication process is usually compatible with IC fabrication. Due to the adoption of semiconductor technologies, integrated micro-acoustic devices have many advantages such as small size, low cost, and high yield. In terms of applications, integrated micro-acoustic devices can be divided into micro-audio devices and micro-ultrasonic devices. The working frequency range of micro-audio devices is from 20 Hz to 20 kHz. Micro-audio devices include MEMS microphones, micro-receivers, and micro-speakers. Commercial MEMS microphones are very mature MEMS products and they have a wide variety of applications in mobile phones, MP3 and other consumer electronics. The working frequency range of micro-ultrasonic devices is typically greater than 20 kHz. They are also known as micromachined ultrasonic transducers (MUTs). Due to their miniature size and high performance, micro-ultrasonic devices have great potential to be used in medical imaging systems or distance measuring devices.

According to the transduction principle, there are three types of integrated micro-acoustic devices: capacitive, piezoelectric, and piezoresistive. Major manufacturers producing integrated micro-acoustic devices include Analog Devices, Akustica (AKU200x), Knowles Electronics, and Memstech (MSMx).

Capacitive Micro-Acoustic Devices

Capacitive micro-acoustic devices are based on electrostatic principle [1–3]. The basic structure is a parallel-plate capacitor (Fig. 1). They convert sound waves into electrical signals by moving an active membrane separated from the silicon substrate by a very thin air gap. The top electrode and the highly doped substrate are conductive, and they form a parallel-plate capacitor. When sound waves hit the membrane, it vibrates, inducing an alternating current from the capacitor. When the capacitor is applied with an alternating voltage, the active membrane will move periodically by electrostatic force and transmit sound waves.

Integrated Micro-acoustic Devices, Fig. 1 Basic structure of capacitive micro-acoustic device

According to the operation frequency, the capacitive micro-acoustic devices can be categorized as capacitive MEMS microphones and capacitive micromachined ultrasonic transducers.

Capacitive MEMS Microphones

Capacitive MEMS microphones are the most successful, commercial integrated micro-acoustic devices which work at the audio frequency (20 Hz–20 kHz). The MEMS microphones are also called microphone chips or silicon microphones. The pressure-sensitive diaphragm is formed directly on a silicon chip by MEMS or CMOS techniques and is usually accompanied with IC modules such as preamplifiers or analog-to-digital converters (ADCs). Due to the adoption of semiconductor techniques, MEMS microphones have some advantages, compared with traditional ECMs (electret condenser microphones), including greater reliability, higher tolerance to mechanical vibration, smaller footprint and digital signal output. Akustica and Knowles are the first two MEMS microphone makers reporting volume shipments. In 2006, Akustica announced a single-chip digital MEMS microphone that has a downsized die that is smaller than 1 mm^2 and Knowles announced a two-chip digital MEMS microphone that includes an ADC on its ASIC in the same year. Later in 2008, Analog Devices Inc. (ADI) and other companies started to enter the MEMS microphone market. A unique aspect of ADI's design is a particle filter constructed by perforating a silicon cover over the microphone's diaphragm. This structure can effectively prevent the dust from reaching the delicate silicon diaphragm and thus improves the performance. Due to the hot sales of smart phones and other consumer electronics, the demands of MEMS microphone increase rapidly. The Yole Développement predicts that the shipment of MEMS microphones will exceed one billion units in 2013 [4]. Now the major manufacturers producing MEMS microphones are Wolfson Microelectronics (WM7xxx), Analog Devices, Akustica (AKU200x), Infineon (SMM310 product), Knowles Electronics, Memstech (MSMx), NXP Semiconductors, Sonion MEMS, AAC Acoustic Technologies, and Omron.

Capacitive Micromachined Ultrasonic Transducers

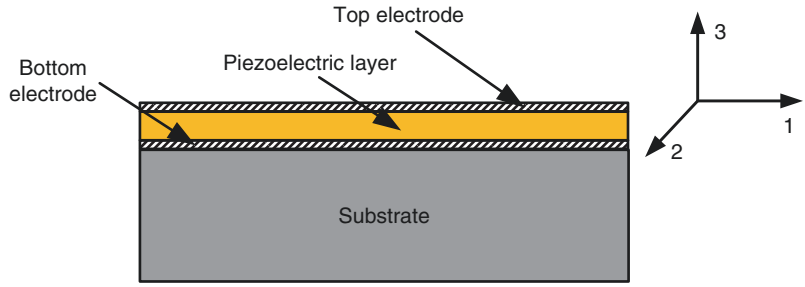
Capacitive micromachined ultrasonic transducers (cMUTs) are the kind of transducers that can convert ultrasound into electrical signal and transmit ultrasound when they are applied with an alternating voltage. cMUTs have been subject to extensive research for the last two decades. Although they were initially developed for air-coupled applications, today their main application space is medical imaging and therapy. The typical operation frequency of cMUTs used for medical imaging is from several to tens of megahertz.

cMUTs, invented in the mid-1990s by the research group of Stanford University [5], have come a long way in the last two decades and recently reached the market for medical ultrasound imaging [6]. The research team at Stanford University is still one of the most active groups in the design, fabrication, and application of cMUTs [7]. In the early years of research in this field, the main focus was on the basic device fabrication and understanding device operation. Several fabrication processes based on standard surface micromachining techniques have been developed [8–12]. An alternative cMUT fabrication method based on wafer bonding was developed later in 2003 [13]. Equivalent circuit models for CMUTs have been developed to help the design of arrays for practical applications [14–16]. Finite element analysis has been used to understand transducer characteristics (especially cross talk issues) and to optimize transducer response [17–21].

Integration of ultrasonic transducer arrays and integrated circuits is highly desired in many applications, especially for transducer arrays with small elements such as in 2D arrays and arrays for use at the end of a catheter [7]. Several methods have been developed to integrate cMUT arrays with electronic circuits including monolithic integration [22–25] and multichip integration [26, 27]. Recently, flexible cMUT arrays are successfully designed and fabricated using wafer-bonding and PDMS filling techniques [28]. Ultrasound imaging with a forward-looking 2D array and a ring array at the end of a catheter are achieved [7].

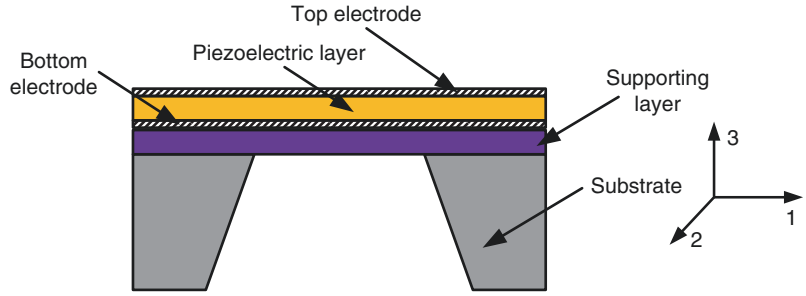
Piezoelectric Micro-acoustic Devices

Piezoelectric micro-acoustic devices are based on piezoelectricity and converse piezoelectricity [29–31]. The most widely used piezoelectric materials are lead zirconate titanate (PZT), AlN, and ZnO. Most researches of the piezoelectric micro-acoustic devices focus on the supersonic range. These devices are called piezoelectric micromachined ultrasonic transducers (pMUTs). pMUTs can convert ultrasound into electric signal and will transmit ultrasound when applied with an alternating voltage. The pMUTs working at 40–80 kHz are used in positioning or distance measuring systems, and high frequency pMUTs (typically several or tens mega Hertz) are used for medical imaging systems. In terms of vibration mode, piezoelectric micro-acoustic devices can be divided into d_{33} mode and d_{31} mode.



d_{33} Mode

A piezoelectric micromachined ultrasonic transducer working at the d_{33} mode is an acoustic resonance device. The basic structure is shown in Fig. 2. When the sound waves hit the device, the strain of the piezoelectric layer will generate charges on the electrodes due to the piezoelectricity. According to the converse piezoelectricity, the electric field in direction "3" will cause strain in direction "3," so the thickness of the piezoelectric layer will be changed periodically under a sine voltage signal, in other words, the layer vibrates. So the device will transmit sound waves under electrical stimulus. When the phase difference between the sound wave in the surface and the sound wave reflected from the bottom electrode is the multiple of 2π, the device will be in the resonance state. So the resonance frequency is decided by the thickness of the piezoelectric layer.

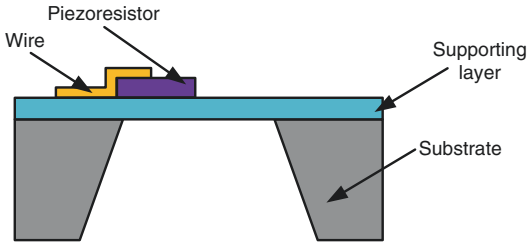


The piezoelectric layer is the key part of pMUTs. The methods to deposit piezoelectric materials include sputter, pulse laser deposition (PLD), MOCVD, Sol–gel, and bulk ceramic bonding. The piezoelectric layers formed by these methods are either very thin (less than 10 μm) or very thick (more than 100 μm). The resonance frequency of pMUTs in d_{33} mode is decided by the thickness of the piezoelectric layer which means pMUTs of certain frequency bands are very difficult to fabricate because of the thickness gap between thin-film deposition and bulk ceramics. Research group of Technical University of Denmark proposed a novel method to deposit thick piezoelectric films [32]. In their work, the piezoelectric elements are formed by deposition of PZT paste into etched features of the silicon substrate such that the depth of these features determines the element thickness and hence the resonance frequency. The process leaves a near-planar surface which is ideal for further wafer-level processing such as top electrode and interconnect formation. Using this method, they fabricated pMUTs with piezoelectric layer thicknesses ranging from 15 to 50 μm. The pulse-echo experiments on these transducers demonstrated their abilities to emit and receive ultrasound waves.

d_{31} Mode

A piezoelectric micromachined ultrasonic transducer working at the d_{31} mode is a mechanical resonance device. The basic structure of the piezoelectric micro-acoustic device at d_{31} mode is a multilayer membrane which consists of a top electrode, a piezoelectric layer, a bottom electrode, and a supporting layer (Fig. 3). The supporting layer can be either silicon or silicon dioxide. When sound waves hit the membrane, the membrane will deform. Thus there will be charges induced on the electrodes due to piezoelectricity.

Integrated Micro-acoustic Devices, Fig. 2 Piezoelectric micro-acoustic device of d_{33} mode



Integrated Micro-acoustic Devices, Fig. 3 Piezoelectric micro-acoustic device of d_{31} mode

According to the converse piezoelectricity, the piezoelectric layer will stretch or compress in direction "1" and direction "2" when it is exercised by an electric field in direction "3" with an opposite phase. So the multilayer membrane will bend periodically by an alternating voltage and transmit sound waves. The resonance frequency is determined by the thickness and size of the multilayer membrane.

d_{31} mode is widely used because its design parameter is more flexible. In the early years of research in pMUTs, SiO_2 or Si_3N_4 serves as the supporting layer. The membrane is released by bulk micromachining processing using wet etching. But it is difficult to control the thickness and residual stress of SiO_2 or Si_3N_4, and these parameters will heavily influence the resonance frequency and the performance of the pMUTs. Researchers in the Research Triangle Park and Duke University use the device layer of SOI as the supporting layer, and the membrane is released using deep reactive ion etch (DRIE) [33]. They have successfully fabricated 2D pMUTs arrays using these techniques, and obtained B-mode images of three metal wires spaced 5 mm apart. Research group of Nanyang Technological University also uses the device layer of SOI as the supporting layer, but the piezoelectric layer is formed by a PZT/silicon wafer-bonding technique, and the bulk PZT is polished down to 10 μm using chemical mechanical polishing [34]. A perforated damping backplate is employed to broaden the acoustic frequency spectrum. Since the resonance of the pMUT array for medical imaging is very high (several to tens mega Hertz), it is necessary to reduce the spacing between elements in the array. Research group of Tsinghua University proposed a new fabrication process based on an SOI/Si wafer-bonding technique [35]. Shallow pits are etched on a Si wafer, then the device layer of an SOI wafer is bonded with the Si wafer, and after removal of the handle layer of SOI, the membrane is released. The element's size and location are defined by the etched pitch. High element density and low cross talk are achieved by these techniques.

Piezoresistive Micro-Acoustic Sensors

Piezoresistive micro-acoustic sensors are based on piezoresistive effect [36–38]. This kind of

Integrated Micro-acoustic Devices, Fig. 4 Basic structure of piezoresistive micro-acoustic device

sensors cannot generate sound, they can only convert sound wave to electric signal. The basic structure of piezoresistive micro-acoustic sensors is shown in Fig. 4. The supporting layer can be either a diaphragm or a cantilever, and it will vibrate when it is hit by sound waves. The strain of the piezoresistive layer will cause the change of resistance due to piezoresistive effect. Polycrystalline Si (poly-Si) is the most common piezoresistor. Typically, a Wheatstone bridge configuration is adopted to convert resistance changes into voltage signals.

Poly-Si piezoresistors on silicon nitride (SiN) were used in early demonstrations of piezoresistive micro-acoustic sensors. However, the gauge-factor of poly-Si is relatively low compared with single-crystal silicon (sc-Si). Research group of Hong Kong University of Science and Technology proposed a novel fabrication process to substitute poly-Si with sc-Si [39]. They bond SOI with a Si wafer which is deposited with silicon nitride. Exfoliation of the handle layer of SOI is accomplished by heat-treatment at 550 C for 30 min. After that the device layer of the SOI which is sc-Si is transferred to the silicon nitride. The diaphragm is released from the front side through cavity etching holes using aqueous potassium hydroxide (KOH). This technique can effectively reduce the footprint. The mode shape and the resonance frequency of the microphone are measured and recorded using an optical vibrometer. For the fundamental mode, the resonance frequency is 520 kHz.

The piezoresistive micro-acoustic sensors can also be used to detect sound source. Researchers in Korea Advanced Institute of Science and Technology developed a piezoresistive multicantilever microphone to locate the sound source by the ITD (interaural time difference) method [40]. In their method, the device layer of SOI wafer is served as the cantilever and boron-doped silicon is used as piezoresistor. Cantilevers with different lengths have different resonance frequencies, so the piezoresistive multicantilever microphone is a broad frequency device. Experiment results show that they can successfully detect the azimuthal angle of sound sources.

Summary

Capacitive micro-acoustic devices are the most mature micro-acoustic devices, mainly because of their excellent performances and ease of integration with IC modules. The capacitive MEMS microphones have already been commercialized. And the demands of MEMS microphones grow rapidly as the conventional electret microphones are substituted. Researches of piezoelectric micro-acoustic devices are mainly focused on piezoelectric micromachined ultrasonic transducers. Although a lot of prototypes with good performance and ability for medical imaging have been fabricated by researchers, it is still not commercialized yet. This is partially because the deposition of the piezoelectric materials is not so compatible with the standard IC process. Different from the capacitive and piezoelectric micro-acoustic devices which can convert sound wave and electric signal into each other, the micro-acoustic devices based on piezoresistive effect cannot generate sound wave but can only be acoustic sensors.

Definition

Nanostructures encompass a broad class of materials with characteristic or functional lengths below 100 nm. For the purposes of this entry, nanostructures will be defined more broadly to include structures with functional dimensions at the submicron scale. The distinguishing characteristic of the materials discussed here is that their integration within a microfluidic platform is attained through a combination of microfabrication and material synthesis processes that allow the unique functionality of the structure or array of structures to be incorporated directly within the microfluidic system of interest. Generally, nanostructures or nanomaterials are considered to be zero dimensional (nanodots or nanoparticles) or one dimensional (nanowires

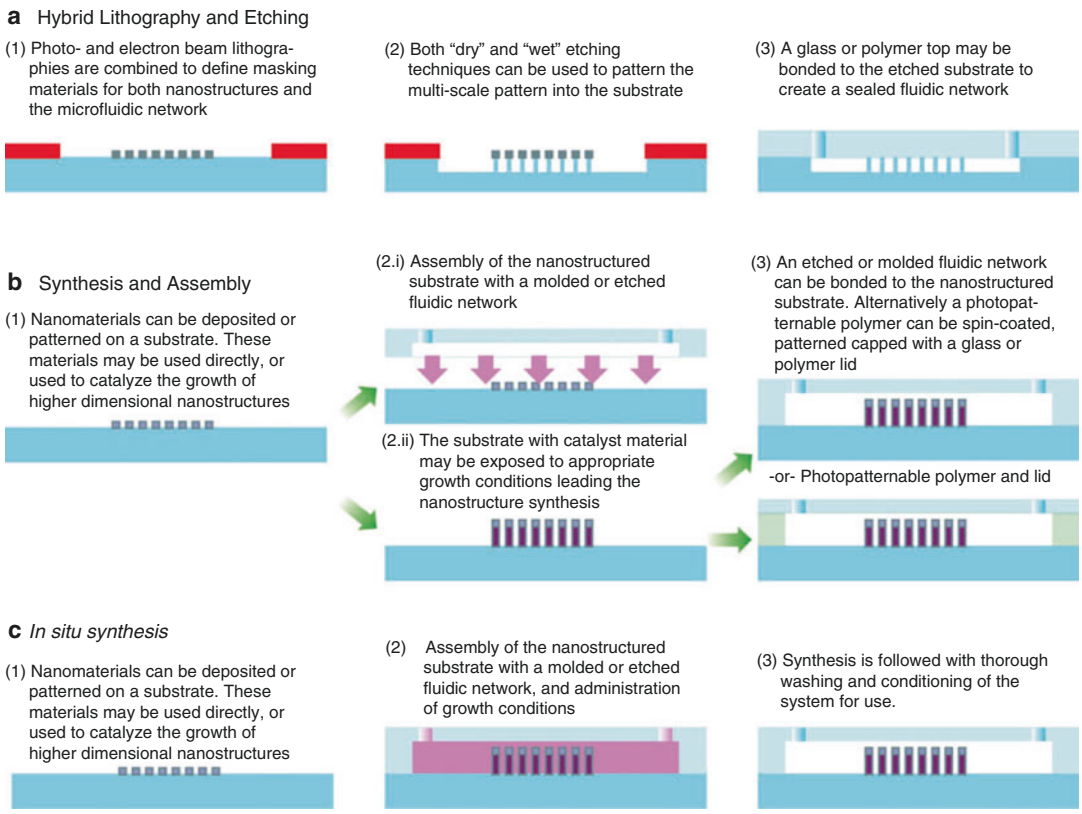
and nanorods). Conventionally two-dimensional materials, such as thin-films, are not considered nanostructures, though their synthesis is fundamental to microfabrication and nanostructure modification. This entry includes examples of nanostructured thin films or patterned thin films into discussion as well as monolithic structures that are created using a combination of nano- and microfabrication techniques.

Concepts

Nanostructured materials possess properties that are significantly different than their bulk counterparts. As a result, these materials have garnered a great deal of attention from the scientific community as well as the popular media. Increasingly, these materials are also finding their way into commercial products. Often, the material properties of these nanostructures will depend on the atomic structure of the material of interest, but are enhanced or perturbed by reductions in scale that amplify phenomena that occur at interfaces or result from material defects. Other trends in nanomaterial properties are material independent, relating to the scale of the material rather than its atomic composition. For example, the high surface area-to-volume ratio of nanostructured materials enhances the role that interfacial phenomena play in dictating the interplay between these materials and their environment. Thus, these materials are often the focus of interfacial studies that examine surface adsorption, wettability, and catalytic activity. The scale of these materials also makes them mechanically sensitive, allowing small changes in material mass to quickly impact both the static and dynamic properties of the material. One of the most captivating features of nanomaterials is that they exist and function at the same scale as the most basic elements of biological systems, providing a new approach to interfacing "hard" inorganic and "soft" biological materials. For example, nanoporous materials have pore sizes that approach the scale of biomolecules such as nucleic acids and proteins. This can facilitate both size and charge selective transport as a means of controlling or modulating chemical communication in biological systems, creating a chemical or fluid interface to biology. Because nanomaterials are smaller than most biological cells, they can also provide a model physical interface for cellular systems. The surface chemistry and physical structure of such nanostructured materials can be tuned to influence cell attachment, growth, and even differentiation.

As individual entities or disordered collections of objects, nanostructures clearly exhibit unique properties. Additional functionality can often be achieved when these materials are arranged into ordered ensembles of interacting components. For many applications, ensembles of nanostructures have been created to simply expand the overall coverage and effective size of the nanomaterial array. In such cases the result of the ensemble is to simply scale the phenomena exhibited by any one element over a larger area. Alternatively, the ensemble can exhibit new properties that one might not predict based on the behavior of a single element. Such collective phenomena are often dependent upon the arrangement of materials within the system. Interactions, exchange or coupling of materials, can be tuned or modulated through discrete patterning and assembly techniques that allow control of relative distance and orientation of nanostructures. Because the local environment can dramatically impact such exchanges, changes in the environment can affect the collective behavior of the ensemble. Thus, changes in the collective behavior of ensembles of nanostructures may be indicative of changes in the local environment, making them ideal sensors.

Because of their scale and enhanced functionality, nanostructure ensembles or arrayed nanomaterials are ideal for integration into microfluidic and Lab-on-a-chip (LOC) platforms. Their function can be particularly useful for platforms that are intended to interface with biological materials. As described above, these ensembles can be used as sensing elements to detect changes within the local fluid environment or within a biological system confined within the microfluidic platform. They can be used as passive elements to impart changes in the local environment, shaping fluid flow, molecular transport, reaction kinetics, and electromagnetic fields



within the system. Furthermore, nanostructure ensembles can be designed to undergo directed changes, respond to changes in their environment, or be actively manipulated to change their functionality. Such alterations can cause local perturbations or lasting changes within the system. Altogether, ensembles of nanostructures provide a unique path toward integrating higher level sensing and actuation into LOC and microfluidic platforms.

Methodology

One of the ongoing challenges of nanoscience is addressing the need to interface with the broad range of nanomaterials and nanoscale structures that one is capable of synthesizing. In order to take full advantage of the tremendous properties that these materials exhibit, one needs to develop technologies that allow the manipulation and interrogation of these materials at time scales that are relevant to the processes in which they are involved. Multiscale fabrication techniques combine conventional microfabrication technologies, honed through decades of integrated circuit and semiconductor manufacturing, with emerging methods for nanomaterial synthesis and assembly, to create integrated platforms in which functional nanomaterial ensembles can be created and taken advantage of.

The strategies applied to the creation of nanostructures within microfluidic devices are lumped into two categories. Top-down strategies involve the step-by-step addition, patterning, and removal of bulk materials and substrate until a desired shape is achieved. Top-down techniques include microfabrication and patterning techniques conventionally used in the semiconductor industry, encompassing both surface and bulk micromachining processes. The resolution of the patterning techniques used to facilitate these processes can be used to create nanostructures that are as small as 5–10 nm, though the true limitations of such processes are dependent on structure composition. In contrast, bottom-up strategies involve the precise placement of nanoscale building blocks, template molecules, and catalysts at molecular levels to build two- and three-dimensional structures. High temperature or solution based synthesis techniques may be involved in the growth of nanostructures or nanomaterials from a patterned catalyst or initiator. The process usually involves the self-assembly of materials into energetically favorable arrangements with a very fine resolution (sub-nanometer range). Both covalent and non-covalent bonds have been utilized to order molecules into nanostructures. The primary challenge in bottom-up approaches is that by nature of the assembly and growth processes involved, long-range order can be difficult to achieve. Typically a combination of bottom-up and top-down approaches can be combined to integrate ensembles of nanoscale structures into functional microfluidic platforms (Fig. 1).

There are three fundamental fabrication processes that are involved in the top-down approach. They are: deposition, lithography, and etching. Combination of these three processes in a layer-by-layer sequence allows for the creation of quasi-three-dimensional structures. As more layers are added, more complex architectures can be created. Deposition processes typically involve the creation of metal, dielectric, or semiconductor thin films using physical vapor deposition processes such as evaporation and sputtering, as well as chemical vapor deposition and oxidation. Common patterning techniques include photolithography, electron beam lithography, and X-ray lithography. These processes rely on the selective exposure and subsequent development of a typically polymeric "resist" material to create a protective layer for material etching processes. Emerging lithographic techniques include soft lithography, nanoimprinting and scanning probe lithography. Soft lithography and nanoimprinting are based on the use of a stamp made of elastomer or hard materials, such as etched silicon, to pattern a protective resist. These processes often require the use of a "master" or "mold" that is created using other lithographic techniques. Each of these techniques balances practical advantages and disadvantages, often sacrificing speed or up-front cost for higher resolution. Etching processes include wet chemical etching techniques and reactive dry processes, carried out in highly energetic plasmas.

Integration of Nanostructures Within Microfluidic Devices, Fig. 1 Methods for integrating nanostructures into microfluidic networks

Detailed overviews of top-down manufacturing processes are provided elsewhere [1, 2]. With respect to the creation of nanoscale structures and ensembles within microfluidic devices, top-down processes can be carried out to create monolithic structures with both micro- and nanoscale features. This is accomplished using sequential electron beam and photolithographic processes to define nanoscale features and microfluidic channels in compatible resist materials respectively. Once patterned, a single directional etch process can be used to transfer this pattern into a silicon, quartz, or glass substrate.

In contrast, bottom-up processes follow the approach of placing small components, at the molecular scale, into more complex assemblies. Predictable and well-controlled growth of nanostructures comprised of carbon (nanotubes, nanohorns, nanofibers) provides an example of such processes. In the case of nanofibers, for example, a catalyst material such as Ni is deposited on a surface. When heated and exposed to a carbon-rich environment, the carbon assembles into distinct cone-shaped sheets of graphene that stack to form nanofibers of carbon with a Nickel catalyst particle at the tip. When formed on a thin-film of Ni, these nanofibers grow as randomly arranged forests, derived from the dewetting of the Ni film and random formation of Ni catalyst particles during the initial heating process. Alternatively, top-down lithographic patterning processes can be used to pattern Ni into distinct shapes, that is, disks and lines, to confine the formation of nanofibers to specific positions. Ultimately it is this combination of top-down and bottom-up processes that provide the most promise for the integration of nanostructures into functional microfluidic devices.

Two enabling approaches to the creation of microfluidic devices with nanostructured ensembles or elements have been the alignment and patterning of SU-8 polymer and assembly of polydimethylsiloxane (PDMS) microfuidic networks, created using soft lithographic techniques [3], to create microfluidic networks that are aligned to nanomaterials synthesized or patterned on glass and silicon substrates. This approach requires careful alignment of microfluidic structures and precise control of nanostructure placement to achieve integration, making it a laborious and low-yield process. Nonetheless, it can provide the quickest route to creating multiscale fluidic systems. PDMS structures can be assembled directly on top of nanostructure ensembles, using an appropriate microscope, manipulator or steady pair of hands, and adequate alignment marks or guides. Alternatively, if the nanostructures are robust and can withstand a polymer spin-coating process, SU-8, or any other photopatternable polymer, can be spin-coated on the sample upon which the nanoscale structures are grown or deposited, and selectively exposed to yield a microfluidic network aligned to the existing nanostructure array.

Applications

A range of nanomaterials have been integrated into and used within microfluidic platforms to create complex sensing and actuation platforms for monitoring and modulating the environment within, and even around, the microfluidic or LOC device. One way to classify or examine these applications is to group them based on the use of nanomaterials as sensors, passive elements, or active modulators of their environment. The examples provided here are not intended to be comprehensive, but rather illustrative of the methods used to create these multiscale platforms, and the unique phenomena that can be taken advantage of in order to realize new levels of functionality within microfluidic platforms.

Nanostructure Arrays as Sensing Elements

The field of plasmonics, the study of charge density oscillations confined to the surface of metallic materials, has garnered a great deal of attention in recent years. Using nanostructured metal materials, including nanoparticle arrays or nanoporous thin metal films, scientists have utilized both plasmon resonance and Surface Enhanced Raman Scattering (SERS) techniques to develop highly sensitive biosensors [4]. Surface plasmon resonance results when plasmons are excited on the surface of metallic nanoparticles by an external electromagnetic field. The frequency at which adsorption, or excitation, occurs is highly dependent on particle size and distribution, particle spacing, and local refractive index. Accordingly arrays of metallic nanoparticles integrated within microfluidic devices have been used to detect the presence of specific molecules within a fluid sample. As these molecules adsorb, or are captured, onto the surfaces of arrayed nanoparticles, local changes in refractive index at the particle surface resulting in changes to the adsorption spectra of the array are indicative of the molecule's presence. Hiep et al. [5] describe the utilization of gold-capped nanoparticles and nanopore arrays to achieve a highly sensitive platform for protein and gene sensors. Chemical modification of the arrayed nanoparticles or pores makes them sensitive to the presence of specific antigens. In this case an antibody to insulin was attached to the particles, and shifts in the absorption peak were observed as insulin, in varied concentrations, was pushed through the microfluidic device. Changes in the Local Surface Plasmon Resonance (LSPR) signal were recorded over time for concentrations as low as 100 ng/mL. Nanoparticle arrays were created via a random dispersion of amine functionalized silica particles onto an oppositely charged (COO− terminated) gold-coated glass slide. A capping layer of gold was added to create the metallic nanoparticle arrays. Assembly of the capped nanoparticle arrays with a molded PDMS microfluidic channel allowed for facile production of the sensor platform. Many similar examples exist within the literature. Most of these utilize electron beam or colloidal patterning of thin metal films via lift-off or etching to create plasmonic materials comprised of metal nanostructure ensembles or porous metal films with discretely spaced and sized pores. Following production of

I

the plasmonic material, SU-8 processing or assembly with PDMS channels can be used to integrate the material into a functional sensing platform.

In an example that illustrates the power of combining top-down and bottom-up synthesis techniques, Kim et al. [6] describe the in situ synthesis of ZnO nanowire arrays by carrying out a controlled hydrothermal reaction within an assembled microfluidic device. In this process, zinc acetate dihydrate and ZnO thin films were used as texture seeds to catalyze ZnO nanowire growth within a microfluidic channel. Photolithography and lift-off processing were used to pattern ZnO seed films and local microheaters that helped drive localized formation of ZnO nanowires. Once patterning was completed, a PDMS channel was bonded to the substrate. Nanowire formation was demonstrated within the channels as either global or local heating was administered while flowing the nanowire precursor solution through the microfluidic device. Following in situ synthesis, the nanowire arrays were used to detect local changes in pH and physically trap particles against fluid flow.

Nanostructures as Passive Elements

Ensembles of nanoscale structures can be used to shape and perturb microflows, influence molecular transport and even modulate chemical reactions within microfluidic systems by simply acting as obstructions that can comprise "cages" or "sieves" within a microfluidic device. In addition to influencing physical flow within a microfluidic device, these obstructions can also be used to perturb or focus electromagnetic fields, creating field concentrations that can influence particle or cellular motion within the fluid flow. For example, Cao et al. [7] describe the use of nanoscale obstructions within a microfluidic device to improve the injection of biomolecules into sets of nanochannels, providing a transition from micro- to nanofluidics, preventing the accumulation and clumping of biomolecules at the nanofluidic inlets. Park et al. [8] developed three-dimensional interconnected pore networks inside microfluidic channels by combining single prism holographic and photolithography techniques. Arranged into a face-centered cubic lattice with a lattice constant of 650 nm, the pores continuously split and recombined the fluid flow to improve mixing efficiency by 84 %.

Hybrid lithography techniques that combine electron beam and photolithography along with anisotropic (directional) silicon etching have been used to simultaneously create arrays of nanoscale structures and microfluidic devices in silicon. These nanoscale structures include cellular-scale microreactors with nanoscale slits as well as arrays of silicon posts with controlled spacing. In both cases, modification of nanoscale structures using plasma enhanced chemical vapor deposition and vapor phase treatment with alkylsilane reagents was carried out to modulate the surface chemistry of the nanostructures and channel. Choi et al. [9] used the chemically functionalized pillar arrays to examine the effects of synthetic crowding and volume exclusion on the transport of green fluorescent protein (GFP) and "supercharged" GFP variants. Fluorescence recovery after photobleaching and computational modeling of molecular transport made it possible to quantify the effects of surface charge and molecular binding on diffusion within the nanostructured silicon post arrays. Retterer et al. [10] demonstrated the fabrication of nanoporous silicon bioreactors using hybrid lithography and etching processes, demonstrating the size selective retention of DNA and reactive enzymes within the nanostructured reactor while delivering small molecules, continuously, to the reaction system. Subsequently, Siuti et al. [11] demonstrated the use of the same reactor within a microfluidic network to carry out cell-free synthesis of GFP using cell-free extract and a GFP encoding plasmid. Protein synthesis was carried out for over 24 h under continuous flow of amino acids and ATP. Lavrik et al. [12] have used similar patterning and etching techniques to create arrays of nanopillars within microfluidic devices for use in chemical separations carried out on a microfluidic chip.

In addition to shaping physical flow and diffusion processes, arrays of insulating nanostructures can be used to shape electromagnetic fields. Arrays of nanoscale elements can be used to

"squeeze" the electric field generated through a microfluidic device into areas of high field over a short distance, creating a very high field gradient, and correspondingly high dielectrophoretic force [13]. The forces resulting from the constricted electric field can be used to concentrate bacteria for analysis or align and assemble nanostructures for further use.

Nanostructures as Actuators

Electrical and optical addressability of nanostructure arrays or ensembles makes it possible to monitor local changes within microfluidic systems by performing electrochemical measurements with nanofiber electrodes [14], monitoring the adsorption spectra of plasmonic materials [4, 15], or analyzing nanowire impedance [8]. While applications that utilize nanostructure ensembles as sensors are practical and appealing, just as intriguing is the possibility of using ensembles of nanostructures to actively and dynamically induce changes within the microfluidic system. Fletcher et al. [16] integrated patterned arrays of carbon nanofibers into microfluidic devices by patterning SU-8 microchannels onto arrays of nanofibers. Prior to patterning the SU-8 channels onto the device, an additional metal patterning step was used to create a set of electrodes that incorporated the carbon nanofibers. Subsequent electropolymerization of polypyrole onto the fibers allowed shrinking and swelling of the nanofiber profile via actuation of the polypyrole coating. Given the nanoscale gaps between the fibers, on-demand capture and release of fluorescent proteins within the microfluidic chip was demonstrated. Future work exploring the integration of functional polymer architectures that shrink or swell in response to changes in environmental factors such as pH or temperature may facilitate the development of smart systems that require no input from an outside user.

A Developing Field

The convergence of nanoscale materials and microfluidics has created a rich field in which sensors and actuators that are created at the cellular and subcellular scale can be integrated into fluid environments that are ideal for the study and manipulation of biological systems [17–19]. This has allowed the development of biological interfaces that can be used to probe cellular systems over prolonged periods under dynamic conditions that were previously impossible to create, quantify, and visualize. This has led to new insights into biological function and the emergence of a host of techniques that promise to facilitate new levels of molecular diagnostics and therapeutic strategies that can be administered within the field and at the point-of-care.

Acknowledgments The preparation of this entry was performed at the Oak Ridge National Laboratory, managed by UT-Battelle, LLC, for the US DOE under Contract No. DE-AC05-00OR22725.

Definition

In most applications of nanomedicine, nanoparticles will come into contact with the skin, the gastrointestinal tract, the bloodstream, or other tissues in the body. Therefore, the nanoparticles will interact with the immune system. Interactions range from opsonization by immune or nonimmune proteins, uptake by phagocytic cells, and likely generation of antibodies. These immune processes can cause adverse inflammatory conditions and affect the intended target and delivery of the drugs by nanoparticles. Nanotherapeutics can also be strategically designed to interact with specific components of the immune system, either to stimulate or suppress the immune responses. These properties are useful for prophylactic vaccination and treatment of inflammatory and autoimmune diseases.

Introduction

Due to their advantageous physicochemical properties and increased targeting specificity, nanoparticle-based drugs can be effective at

lower dose, with less deleterious side effects. It is, thus, understandable that nanoparticles are frequently proposed for clinical applications, especially targeted drug delivery [1, 2]. In order to be applied in clinics, the nanoparticles have to be safe for patients. Therefore, nanoparticle non-toxicity to cells and tissues is a highly discussed topic in literature. In addition, studies examining interactions of nanoparticles with the immune system and consequent immunotoxicity are on the rise currently. The immune system can significantly influence drug and tissue targeting, that can be achieved with nanotherapeutics. If the immune system is activated and phagocytic cells in tissues and blood are actively ingesting the nanoparticles, they will not be available to deliver a therapeutic to a tumor or other target. Furthermore, if the nanoparticles residing in an area cause the recruitment of immune cells, this may lead to extensive inflammation and immunopathology.

Interaction between nanoparticles and the immune system is like a double-edged sword. This can have desirable as well as detrimental consequences. In vaccination strategy, the stimulation of the immune system by nanoparticles can be exploited to increase the efficiency of the treatment. However, when the immune system is overly stimulated by the nanoparticles causing inflammation, or when the nanoparticles suppress the immune response, it would impair normal challenge to infectious agents.

The Immune System

The immune system's main task is to protect against attack from infectious non-self (viruses, bacteria, fungi, and parasites) and clear from the body altered-self such as apoptotic, necrotic, and transformed cells [3]. It uses a complex network of intercommunicating proteins, cells, and organs to recognize and eliminate a potential pathogen. Recognition of the pathogens is mediated by binding of specific surface receptors to the targets, which trigger downstream responses, ultimately leading to the elimination of the target such as pathogens, apoptotic, and tumor cells. The response of the immune system has to be carefully balanced. A weakened immune response can make the individual succumb to infection, whereas an exaggerated immune response (as in hypersensitivity reactions and autoimmune disorders) can lead to a spectrum of diseases [4].

The immune system consists of two wings: the innate and the adaptive immune system. The innate immune system operates rapidly and is broadly specific. Recognition of the pathogens is achieved by pattern recognition receptors (PRRs), which recognize molecular motifs on the targets, also referred to as PAMPs (pathogen-associated molecular patterns). PAMPs can be charge clusters, neutral sugars, vicinal hydroxyl groups, or acetyl groups. The recognition proteins of the innate immune system work through multiple low-affinity binding. PRRs can be found on cellular membranes (Toll-like receptors; TLRs), in the cytoplasm (NOD-like receptors), and free in the blood plasma (complement proteins; acute phase proteins such as C-reactive protein, serum amyloid protein, and pentraxins; collectins and ficolins).

In the adaptive immune system, the immune cells will interact with the targets through highly specific interactions leading to either antibody production via B cells, or cell-mediated immunity via macrophage activation. In both the innate and adaptive immune responses, interaction with cellular receptors will trigger the synthesis and release of cytokines by the cell and can lead to phagocytosis, and migration and activation of more immune cells. When a pathogen interacts with a dendritic cell (DC), the cell can mature toward an antigen-presenting cell (APC), which migrates to the lymph nodes where they activate T lymphocytes, with the specific receptors for the presented epitope. These T cells can either be cytotoxic T cells, specialized in killing their virus-infected cells, or stimulate B lymphocytes to produce antibodies toward the pathogen [5].

Humoral factors are essential in the immune response toward nanoparticles. Among these, the complement system is a principal player. The complement system consists of over 30 proteins, interacting in three different pathways: the classical, alternative, and lectin pathway, each of which is initiated by recognition of a different array of targets. In the classical pathway, C1q is the recognition subcomponent. In the lectin pathway, this

function is performed by mannose-binding lectin (MBL). Binding of these recognition proteins activates C4 and C2 to form C3 convertase, which is able to cleave C3 into C3a and C3b. In the alternative pathway, coating of the target with C3b is initiated by a conformational change in C3 via spontaneous hydrolysis of C3. C3b bound onto a target is an inducer of phagocytosis, also known as opsonization, and can also trigger further activation of the complement system culminating in a graded association of components C5, C6, C7, C8, and C9 forming the C5–9 or membrane attack complex (MAC), which disrupts the lipid bilayer of cells [6, 7].

Immunotoxicity

The interactions between nanoparticles and the immune system and its consequences vary greatly. The effects and the pathways involved are influenced by factors, such as size, shape, surface charge, hydrophobicity, and coating of the nanoparticles. Upon entry in the body, the nanoparticle surface changes quickly due to adsorbed proteins. This corona contains a range of proteins, which alters over time. Initially, the most abundant proteins from the serum bind to the surface, which are slowly replaced by those with the highest affinity toward the surface of the nanoparticle. In addition, several proteins will attach only onto other proteins in the corona. The physical characteristics of the resulting nanoparticle–protein complexes can be vastly different from those of the native nanoparticle, and examining these differences is essential in order to understand eventual distribution and clearance of the nanoparticles and the biological responses that follow. The binding of proteins can increase the nanoparticles' effective size and change its effective surface charge, which, in turn, will affect uptake by phagocytic cells and interactions with PRR on the cell surface.

Complement proteins are commonly part of the protein corona found on nanoparticles. As described above, these proteins are part of the innate immune response and are able to trigger phagocytosis and enhance immune responses toward the nanoparticles. Surface charge and distribution are the most important factors that influence the extent and the pathway of complement activation. Complement protein fragments, C3b and C4b, can react with nucleophilic groups (OH, NH_2, SH) on the surface of a nanoparticle. Complement fragment C3b is the main opsonizing agent in the complement cascade. Binding of large numbers of C3b molecules onto a nanoparticle will result in rapid elimination of the particles by uptake via phagocytic cells, which will limit the availability of the nanoparticle for drug delivery to the target tissue/organ. Besides opsonization and membrane lysis, complement activation supports humoral- and cell-mediated adaptive immunity through augmenting functions and activation of antigen-presenting cells such as dendritic cells, B and T cells [8]. Furthermore, by-products of the activated complement system (C3a, C4a, and C5a) are potent anaphylatoxins, which can attract cellular infiltration at the site of infection or tissue injury, exaggerating inflammation. A wide range of nanoparticles, including carbon nanotubes (CNTs), iron oxide nanoparticles, fullerenes, polymer particles, and dendrimers, have been shown to activate complement, predominantly via the classical pathway [9–11]. The complement classical pathway is initiated by binding of C1q to the target self- and nonself ligands. The most potent binders of C1q are antigen–antibody complexes. Therefore, the antibodies used for targeting via a nanoparticle platform specifically can induce complement activation via the classical pathway. Nanoparticles containing an array of antibodies or antigens in a highly organized manner can be rapidly recognized by the innate immune system, specially complement recognition subcomponents and, therefore, removed from circulation.

Various coatings have been proposed to limit the formation of a protein corona on nanoparticles, the most well-known example being polyethylene glycol (PEG). This polymer has been shown to prolong the circulation time of the nanoparticles in the blood by reducing their uptake by resident phagocytes in the spleen and liver. Steric hindrance to proteins as well as complement adsorption by PEG leading to reduced

opsonization is the most likely explanation for the reduced phagocytosis of the PEGylated nanoparticles. However, specific antibodies against PEG have been detected following exposure to PEGylated nanoparticles, which would suggest stimulation of the adaptive immune system. Whereas some PEG-derivatives reduce complement activation, other commonly used coatings such as dextran-enhanced complement activation mainly through the lectin pathway [10].

In general, neutral nanoparticles are less likely to be phagocytized than charged nanoparticles (with cationic or anionic surface charges). Larger nanoparticles (over 50 nm) are convenient targets for phagocytosis due to a greater possibility of multiple interactions between cell surface receptors and nanoparticles. The optimal size for uptake is cell-dependent. Dendritic cells (DC) preferentially take up virus-sized particles (20–200 nm), while macrophages prefer larger particles 0.5–5 μm) [12]. Following the uptake of the nanoparticles by phagocytic cells such as macrophages, the clearance route/mechanism depends mainly on the biodegradability of the nanoparticle. While biodegradable nanoparticles are digested and cleared, nonbiodegradable nanoparticles may accumulate inside the cells and tissues for extended periods. Such accumulated nanoparticles may cause granulomas and excessive inflammation that can potentially cause carcinomas. These effects have mainly been studied for carbon nanotubes (CNTs), where after inhalation, granulomas were found in the lungs [13].

Nanoparticles can also interact with other components of the immune system in addition to phagocytes and complement. Few nanoparticles have been shown to alter the cytokine levels expressed by immune cells. An example is Resovist, a dextran-coated iron oxide nanoparticle, which on its own was shown to shift the cytokine balance from helper T cell 1 (Th1) to Th2 immune response, thereby lowering IFN-γ and increasing IL-4 synthesis in cultured splenocytes. Th1 cytokine response promotes cell-mediated immunity via activation of macrophages, whereas Th2 cytokine (including IL-4, IL-5, and IL-13) promotes humoral immune response leading to the production of antibodies. Fullerenes (C_{60} derivatives) had a similar effect but did not interfere with IFN-γ production; it enhanced INF-α and suppressed IL-6 and IL-17 production, suggesting stimulation of regulatory T cells (Treg). Polyvinyl alcohol (PVA)-coated iron oxide nanoparticles interfered with antigen processing by dendritic cells, thereby limiting pro-inflammatory cytokine production and T-cell proliferation.

The immunomodulatory effects are not always clear-cut, and often, a mixed response can be observed. Both pro- and anti-inflammatory effects are induced by gold nanoparticles (AuNP). For example, it has been shown that AuNPs are able to bind IL-1β and TGF-β1 directly, thereby downregulating several important pro-inflammatory pathways. However, at the same time, it was shown that following uptake of AuNPs, dendritic cells secrete pro-inflammatory cytokines, TNF-α, IL-12, and IL-6 [14].

The process of immunomodulation by nanoparticles can be even more complex. CNTs after being administered by inhalation enhanced TGF-β production by alveolar macrophages in mice. This TGF-β was then distributed throughout the body and triggered COX and IL-10 production in the spleen, altering the antibody production by B lymphocytes [15]. In a series of studies, the interplay between complement activation by nanoparticles and the synthesized cytokines has recently been analyzed [11]. These studies showed that complement deposition considerably enhanced uptake of CNTs by immune cells known to overexpress complement receptors such as macrophages and B cells. qPCR and multiplex array analyses showed serum-dependent downregulation of TNF-α and IL-1β and upregulation of IL-12 by CNTs, revealing IL-10 as a crucial regulator during nanoparticle–immune cell interaction. It appears that CNTs offer diverse molecular patterns to the complement system and subsequent handling and immune response by antigen-capturing and antigen-presenting cells, which can shape the innate and adaptive immune axis. Factor H, a negative regulator of the alternative pathway and also known to inhibit classical pathway for certain

C1q ligands, was partly able to inhibit C1q-mediated classical pathway activation by CNTs. C1q and the recombinant globular head modules of C1q, but not factor H, enhanced uptake of CNTs by U937 macrophage-like cell line and human macrophages. Binding of C1q and its globular head modules to CNTs was able to downregulate the production of pro-inflammatory cytokines and transcriptional factor, NF-κB, and NLRP3 inflammasome.

Not only the coating of the nanoparticle can cause immunotoxicity, but the core material can also have an influence, especially when the nanoparticle is degraded inside the body or cells. An example is cadmium, which is known to cause T-cell toxicity by inhibiting proliferation. It is not clear if this effect is also caused by cadmium-containing quantum dots.

Adverse effects of immunosuppression by nanoparticles include myelosuppression, thymic suppression, and lowered immune responses to infections and cancer [16]. The increased retention time and barrier-crossing properties of nanotherapeutics could increase the myelosuppression of the nanotherapeutics. This leads to decreased production of erythrocytes, lymphocytes, and platelets in the blood.

Immunomodulation as Treatment

Specific stimulation of the immune system can be beneficial in defense against an invading pathogen or clearance of damaged self. Vaccination involves administration of an antigenic material, or an inactivated/attenuated pathogen to evoke a limited adaptive immune response and generate long-term immunological memory toward a specific pathogen. By attaching pathogen-derived antigens onto nanoparticles, their stability and immunogenicity are increased. It also enables targeted delivery of the antigens and slow release, allowing for more efficient vaccination. A limited number of nanoparticle-based vaccines have been approved for human use, and their numbers are increasing steadily [12]. The role of the nanoparticle in the vaccination can be to carry the antigen to the target cell and aid in the phagocytosis of the antigen into the cell. In addition, nanoparticles can also have an important role in activating an immune pathway that will enhance antigen processing and presentation.

The main principle of nanoparticle-based vaccination strategy is to deliver multiple copies of an antigen array mimicking the way it would be presented on a virus or pollen to the antigen-presenting cell such as DCs, inducing their maturation and subsequent effector mechanisms. Local complement activation by nanoparticles may be desirable in order to enhance the efficacy of a nanoparticle-based vaccine as an adjuvant.

Therapeutic vaccination is used for cancer treatment and has also been proposed for Alzheimer's disease and hypertension. In cancer treatment, the objective is to stimulate the host immune system to fight the cancer cells. Furthermore, several tumors have developed mechanisms/strategies to downregulate the immune response. These include secretion of anti-inflammatory cytokines such as IL-10 and TGF-β, suppression of DC maturation, or engagement/recruitment of Treg cells [14]. By reversing these escape mechanisms, the immune system can be tailored toward mounting a robust anti-cancer immune response. Prophylactic nanovaccinology is commonly applied for the prevention of infectious diseases [12]. Nanoparticles can be used to present arrays of antigens and thereby improve the immunogenic efficacy, which is also dependent on size and surface of the nanoparticles.

Gold nanoparticles (AuNPs) have been used as antigen carriers in the case of antigens for influenza A virus, respiratory syncytial virus, foot-and-mouth disease, and human immunodeficiency virus (HIV-1) [12]. Due to the nature of HIV-1, it is undesirable to inject deactivated viruses. Thus, gp120 structural motif was grafted onto AuNPs to mimic the presentation of oligomannosides by HIV-1 to DCs, ultimately inhibiting HIV-1 infection of $CD4^+$ T cells.

Virus-like particles (VLP) are frequently proposed as ideal candidates for nanovaccines. VLPs are self-assembling, biocompatible capsid proteins that form a nanocage with a virus-like structure. Therefore, VLPs naturally interact with the immune system in a similar way viruses would which gives

rise to a potent immune response, while avoiding the risks involved with natural (deactivated) viruses, especially in immunosuppressed or immunocompromised individuals.

Immunosuppression can be beneficial when nanoparticles are used to treat immune-mediated pathologies (e.g., inflammatory and autoimmune disorders) and also to prevent overactive immune responses in allergy and transplant rejections. Nanoparticle-based therapeutics have been proposed for rheumatoid arthritis, diabetes, uveoretinitis, and thyroiditis. Several nanoparticles do not need the addition of a therapeutic ligand to cause immunomodulation. Several polyamidoamine (PAMAM) dendrimers were found to have anti-inflammatory effects; the extent depended on their size and surface modifications. The effects were most likely caused by inhibition of cyclooxygenases (COX). Hydrophilic fullerenes (C_{60} derivative) were shown to inhibit type I hypersensitivity responses in mast cells and basophils and in a mouse model of anaphylaxis.

A major pathway of immunosuppression is through inhibition of T lymphocytes. This can be achieved either by inhibiting their interaction with APCs or by inhibiting T-cell proliferation. Available agents to target either the antigen presentation or IL-12-mediated signal transduction appear to have poor stability and hydrophobicity; both issues can be circumvented by the use of nanoparticle platform. Unfortunately, the specificity of T-cell suppression is not very high; therefore, undesired off-target immunosuppression can result. Improvements can be made by targeting specific subpopulations of T cells, e.g., regulatory T cells, by tuning the cytokine profile toward stimulation of the proliferation of this type. These T cells are responsible for self-tolerance and downregulation of the immune response; therefore, they can be very useful in the treatment of autoimmune disorders such as multiple sclerosis [16].

Corticosteroids are very helpful for the treatment of chronic inflammatory disorders. However, due to rapid elimination from the body, they have to be administered frequently and in high dose. Therefore, the main goal of nanotherapeutics has been to improve the circulation time of the drugs. Prolonged circulation and increased drug accumulation in inflamed tissues have been achieved with PEGylated polymeric nanoparticles loaded with betamethasone phosphate. Interestingly, liposomes filled with glucocorticoids altered the drug target from T lymphocytes to macrophages and an induced anti-inflammatory cytokine response [16].

Immune cell recruitment is one of the key factors in inflammation. By inhibiting the signaling pathways, cellular infiltration at the inflamed region can be reduced, thereby limiting the inflammation. In leukocyte migration, an essential step is the adherence of leukocytes to the endothelial cells lining blood vessels. By inhibiting this interaction, migration of leukocytes can be avoided [16].

Another approach to treat inflammatory conditions is to alter the cytokine expression profiles of immune cells. This can be achieved by delivering small interfering RNA (si-RNA) to the target cells. By altering specific gene transcription, the cells will be either stimulated to produce anti-inflammatory cytokines (e.g., IL-10) or decrease pro-inflammatory cytokine production (e.g., TNF-α). This approach does require the si-RNA to enter the cell nucleus, which adds another great challenge to the barriers to be crossed by the nanoparticles [17].

Tests

Immunomodulation is not easily monitored in vitro, as it involves many interacting pathways and long-term variations and changes. Therefore, long-term, systematic, multi-parameter in vivo studies would be required to evaluate various immunological aspects of nanotechnology. These tests are time consuming and costly. Therefore, most immunological studies presented in literature focus on single aspects of the immune response, e.g., complement activation or cytokine response by a single cell type.

Clearly, nanoparticles often do not evoke a singular immune response; often, both pro- and anti-inflammatory cytokine production are influenced by the presence of nanoparticles. This effect can be caused by the fact that nanoparticles can enter

different cells through various receptors and pathways. Therefore, in one cell type, they might evoke a pro-inflammatory response, while in another cell, an anti-inflammatory or no response can be seen [16].

No consensus has been reached about the optimal way to test the immune response induced by nanoparticles. The most applicable and internationally recognized standard available is ISO-10993, which recommends using hemolysis, thrombogenicity, and complement activation (in vitro) tests to examine hematocompatibility of medical devices. However, potentially different applications of highly variable nanoparticles available may require specific regulations. Other essential tests involve confirmation of the sterility of the nanoparticle formulation, and the absence of endotoxins, which can be achieved by LAL assays (limulus amebocyte lysate). Contaminations of the nanoparticles might evoke immune responses, which are not related to the nanoparticles. In vitro phagocytosis assays are useful for an initial prediction of the reticuloendothelial system response toward the particles and can give an indication of the distribution of the particles toward liver and spleen. Thus, in vivo studies will be essential to confirm these predictions since many other factors will influence the biodistribution and clearance of the nanoparticles.

It is widely known that nanoparticles may interfere with the outcome (both false negatives and false positives) of the test, mainly the high optical absorbance of the particles will interfere with all dye and fluorescence-based assays. Therefore, tests should be calibrated for use with the specific nanoparticles.

Conclusions

The immune systems can have a major influence on the biodistribution, efficiency of treatment, and the adverse effects caused by nanoparticles. The main parameters influencing the interactions of nanoparticles with the immune system are the size, surface charge, and chemistry of the nanoparticles. Several nanoparticles have been shown to cause significant inflammatory responses, while others seem to suppress the immune response through pathways involving the complement system.

Nanovaccinology for immunosuppression as well as immunostimulation is still in a very early stage of development. Thus, there is a clear argument to include immune responses to nanoparticles as specialized tests, leading to accurate and reproducible results, with the possibility to compare a range of nanoparticles.

Definition

Bulk acoustic wave quartz crystal resonator can be used for the investigation of the material properties such as the thickness, density, viscosity, and modulus of protein films adsorbed on their surface via self-assembly processes.

Overview

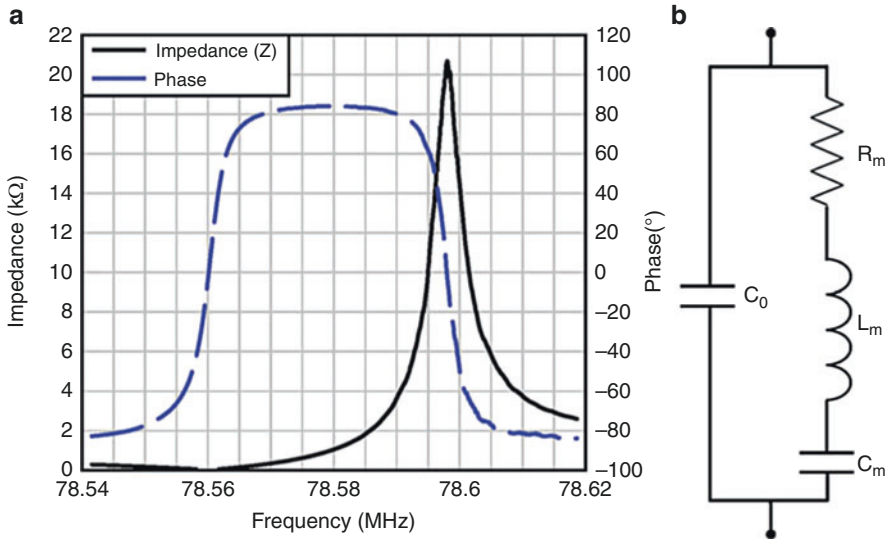
Understanding the phenomenon of the aggregation and assembly of biological molecules such as proteins, lipids, and other biomaterials at the liquid–solid interface is of enormous practical consequence and is not yet well understood. For example, protein adsorption to materials is known to mediate the foreign body response to medical implants in the body. Bacterial adhesion to biomaterials has been found to be mediated by the adsorption of proteins such as fibronectin onto the material surface, creating an interface suitable for adhesion, proliferation, and biofilm formation in medical implants [1–5]. Furthermore, what appears to be driving the host response is not only the chemistry of the material, but the microstructure of individual features within the material onto which host cells can attach. Miniaturized bulk acoustic shear wave resonators exhibit high sensitivity to viscoelastic loading within a few tens of nanometers from the electrode surface and are ideally suited for in situ monitoring of the adsorption of proteins and characterization of their viscoelastic properties. While several techniques are currently available for studying biomolecular assembly processes at interfaces such as atomic force microscopy (AFM), optical reflectometry, surface plasmon resonance (SPR), and techniques based upon protein labeling (e.g., radioactive isotopes) most of these techniques are optimized to either identifying the molecular species or characterization of simple properties such as aerial mass or number density. Acoustic wave sensing techniques based on quartz crystal microbalances (QCM), in principle, are able to characterize not only the physical properties of the layer but also viscoelastic properties of the layer. As will be

Interfacial Investigation of Protein Films Using Acoustic Waves, Fig. 1 Schematic drawing of a quartz crystal resonator showing the *top* and *bottom* electrodes. Application of a sinusoidal electrical stimulus across the electrodes sets-up a shear wave across the thickness of the quartz and resonance occurs at the frequency for which the thickness of the quartz is equal to half the acoustic wavelength

demonstrated in this article, the technique can be used to study adsorption of proteins on plane and textured surfaces with resolution approaching few angstroms to nanometers of the assembling layer.

Principle of Operation

A typical thickness shear mode quartz crystal resonator is schematically illustrated in Fig. 1. It consists of a thin slice of single-crystal, piezoelectric quartz, with very large lateral dimensions in comparison to its thickness, which is sandwiched between two metal electrodes. Application of a sinusoidal electric field using the electrodes sets up a shear wave through the thickness of the quartz. Under the assumptions of ideal free-free boundary conditions of the electrode surfaces, the device exhibits a resonance behavior when the thickness of the quartz slab is half the wavelength of the shear acoustic wave. The fundamental resonance frequency of a quartz resonator can simply be given by



$$f_0 = \frac{1}{2t_q}\sqrt{\frac{\mu_q}{\rho_q}}, \tag{1}$$

where t_q is the thickness of the quartz slice and $\mu_q = 2.947 \times 10^{10}$ kg/m-s^2 and $\rho_q = 2{,}650$ kg/m^3 are the shear modulus and density of quartz, respectively.

Figure 2a shows a typical resonance characteristic of a quartz resonator. Under the assumptions of (1) the quartz crystal is an infinitely large, thin plate, (2) shear wave traveling along the thickness of the quartz plate, (3) negligible material anisotropy, and (4) massless electrodes of negligible thickness, an equivalent circuit representation of the resonator can be realized and is shown in Fig. 2b. At resonance, the equivalent electrical circuit of the QCM is modeled as consisting of a capacitor C_0 in parallel with the motional arm of the circuit consisting of a series circuit of L_m, C_m and R_m and is commonly referred to as the Butterworth-Van Dyke (BVD) model. The values of these parameters can be derived and are given as [6].

$$\left.\begin{aligned} C_0 &= \frac{\varepsilon_{22}}{h}A \\ C_m &= \frac{8Ae_{26}^2}{\pi^2 h\mu_q} \\ L_m &= \frac{\rho_q h^3}{8Ae_{26}^2} \\ R_m &= \frac{h\eta_q\pi^2}{8Ae_{26}^2} \end{aligned}\right\} \begin{aligned} &\text{Static Capacitance} \\ &\text{Motional Arm} \end{aligned} \tag{2}$$

where $\varepsilon_{22}(=3.982 \times 10^{-11}$ F/m) is the permittivity of quartz, A is the area of the energized region of the quartz plate (electrode region), h is the thickness of the quartz plate, $e_{26}(=-0.095$ C/m$^2)$ is the piezoelectric coefficient of quartz, $\mu_q(=2.947 \times 10^{10}$ N/m) is the piezoelectrically stiffened quartz elastic constant, and $\eta_q(=3.5 \times 10^{-4}$ kg/m-s) is the viscosity of quartz.

Interfacial Investigation of Protein Films Using Acoustic Waves, Fig. 2 (**a**) Typical resonance curve obtained for a micromachined quartz resonator. The thickness of the resonator is ~21 μm. (**b**) The equivalent circuit representation of the quartz resonator at resonance shows the motional arm consisting of a series LCR circuit connected in parallel with a static capacitance C_0

The exceptionally low phase-noise characteristically exhibited by quartz resonators allows for a precision of few parts in 10^{14} and is the primary reason for their widespread use in frequency control applications. The phase noise is quantitatively specified in terms of the Q-factor defined as the half-width at the full maximum of the resonance curve or in terms of an energy dissipation factor D, which is inversely proportional to the decay time constant and is also equal to the $1/Q$-factor. The resonance frequency and the Q-factor of the resonance are significantly affected by any surface load placed on the quartz crystal. Generally speaking, loading on the resonator surface can be of three types: (1) pure elastic loads (rigid solids), (2) pure viscous loads (liquids), and (3) viscoelastic loads (polymers) and/or a sequential combination of any of these. The problem of interaction of the transverse shear wave with these surface loads has been treated using three fundamental approaches: (1) evaluation of electrical admittance characteristics upon mechanical perturbations on the resonators [7, 8], (2) using continuum mechanics with appropriate material properties and boundary conditions for each added material [9, 10], and (3) the energy transfer model in which the quartz resonator and the deposited film are treated as a compound resonator, and energy balance methods are used to evaluate the perturbed characteristics of the resonator [11]. These approaches are based on a one-dimensional treatment of the problem since the lateral size of the resonators is typically much larger than the relevant dimensions such as the penetration depth of the acoustic waves in the direction perpendicular to the surface of the resonators.

Elastic Loading

The concept of measurement of aerial mass density using a resonating quartz crystal was presented in 1959 by Sauerbrey. For an unloaded resonator with a resonance frequency of $f_0(0)$, the decrease in frequency, Δf, upon loading of a rigid mass of small thickness in comparison to the resonator thickness and under no-slip condition can be given by

$$\Delta f = -\left(\frac{2f_0^2(0)}{\sqrt{\rho_q \mu_q}}\right)\frac{\Delta m}{A} = -\left(\frac{1}{t_q^2(2\rho_q)}\sqrt{\frac{\mu_q}{\rho_q}}\right)\frac{\Delta m}{A}, \qquad (3)$$

where A is the area of the electrode on the quartz crystal and Eq. 1 has been used to simplify the formula. The most common commercially available quartz microbalances (QCMs) have a resonance frequency of 5–10 MHz and typically consist of 25.4–12 mm diameter and 333–167 μm thick AT-cut quartz discs with gold electrodes on each face and exhibit a mass sensitivity of 17.7–4.42 ng · cm^{-2} Hz, respectively. From Eq. 3 it can be seen that the sensitivity to aerial mass density of the QCM can be increased by increasing its resonance frequency. Based on empirical data, the smallest frequency noise in an AT-cut quartz resonator has been approximated to be $\sim 12 \times 10^{-2} f_0^2$. Thus, the highest aerial mass-density resolution that can be achieved by a given QCM can be calculated by dividing this expression by the mass–sensitivity factor in Eq. 3, that is,

$$\left.\frac{\Delta m}{A}\right|_{ultimate} = 0.6 \times 10^{-20} * \sqrt{\rho_q \mu_q} = 5.6 \times 10^{-15}, \quad (4)$$

where is $\left.\frac{\Delta m}{A}\right|_{ultimate}$ is given in g/cm^2. In finite electrode sized resonators, energy trapping is necessary to maintain a high Q-factor and is determined by the effectiveness of the total internal reflection of vibrations at the edge of the electrodes to confine the acoustic energy to within this region only. For the effective suppression of the spurious modes, the rule-of-thumb thickness of quartz to electrode radius ratio is given by

$$\Delta f_{pb} < 0.744 f_{q0} \frac{1}{N^2} \left(\frac{t_q}{r_q}\right)^2, \quad (5)$$

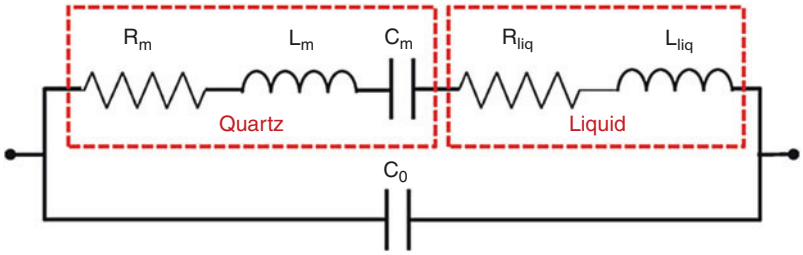
where $f_q 0$ is the expected resonance frequency of the bare quartz crystal of thickness t_q before the mass loading due the electrodes, and Δf_{pb} is the plate back frequency, that is, the frequency after the deposition of the top and bottom electrodes of radius r_q, and N is the overtone number. This implies that as the quartz resonator thickness is reduced, the electrode diameter must also be reduced in order to effectively suppress spurious modes. Excessive decrease in the electrode diameter, however, will result in acoustic energy leakage and poor confinement of energy resulting in small Q-factors. These opposing requirements entail a design compromise. Results show that for 50–90 MHz resonators with 100 nm of gold electrodes on both faces, the optimal electrode diameter ($2r_q$) to resonator thickness (t_q) ratio is ~10–20. Large deviations from this value either way result in resonators with poor characteristics.

Viscous Loading

When used for applications such as biosensing and electrochemical studies, where one of the resonator surfaces is in contact with a liquid medium, the viscous drag effects need to be considered and now determine the ultimate device performance. Behavior of quartz resonators under purely viscous loading was first reported by Kanazawa and Gordon in 1985. Under such conditions, the fundamental mode QCM frequency shift is given by

$$\Delta f = -\frac{f_0^{3/2}}{\sqrt{\pi \rho_q \mu_q}} \sqrt{\rho_{liq} \eta_{liq}}, \quad (6)$$

where ρ_{liq} and η_{liq} are the viscosity and density of the liquid, respectively. The change in the quality factor ΔQ of the resonator under viscous loading conditions can be given by



$$\Delta Q = \frac{\pi \rho_q \mu_q}{2\sqrt{\pi f_0 \rho_{liq} \eta_{liq}}} - \frac{\rho_q \mu_q^2}{2\pi f_0 \eta_q}, \quad (7)$$

For operation in liquids, the modified BVD model is shown in Fig. 3. Two additional terms arising from the liquid mass-loading and viscous damping appear in the motional arm of the circuit.

The additional equivalent circuit elements due to the liquid loading can be written as

$$\left.\begin{aligned} L_{liq} &= \frac{\omega_s L_m}{N\pi} \sqrt{\frac{2\rho_{liq}\eta_{liq}}{\omega \mu_q \rho_q}} \\ R_{liq} &= \frac{\omega_s L_m}{N\pi} \sqrt{\frac{2\omega\rho_{liq}\eta_{liq}}{\mu_q \rho_q}} \end{aligned}\right\} \quad (8)$$

The expression for the ultimate aerial mass resolution of the QCM under liquid mass loading conditions is now modified and can be given as

Interfacial Investigation of Protein Films Using Acoustic Waves, Fig. 3 The equivalent model of a quartz resonator when loaded by a liquid of density ρ_{liq} and viscosity η_{liq}. An additional resistance and inductance term appear in the motional arm representing the effect of this load on the resonator characteristics. For a typical resonator, $R_{liq} \gg R_m$ and $L_m \gg L_{liq}$

$$\left.\frac{\Delta m}{A}\right|_{ultimate} = 5.64 \times 10^{-8} \frac{\sqrt{\rho_{liq}\eta_{liq}}}{\sqrt{f_0}}, \qquad (9)$$

where all quantities are specified in SI units. For example, in pure water loading condition, the resolution now varies between 2.529 and 0.596 pg/cm^2 for a 5–90 MHz resonator. Clearly, the ultimate mass resolution in liquids is 10^2–10^3 times lower as compared to the case of mass resolution in air. In the case of liquid operation, it is quite clear that a high-frequency resonator is likely to provide a higher mass resolution. However, often in liquid applications, one is interested in measuring viscosity and density changes in liquid rather than adsorbed mass changes. In this case, the functional dependence of Δf on the density and viscosity of the liquid, can be written as [12]

$$\frac{\Delta\eta_{liq}}{\eta_{liq}} + \frac{\Delta\rho_{liq}}{\rho_{liq}} = 4 \times 10^{-7} \qquad (10)$$

for the ultimate resolution of viscosity and density using a QCM. Since most liquid experiments are accompanied by simultaneous changes in the density and the viscosity of the liquid, Eq. 10 gives the combined minimum resolution in both parameters. Furthermore, in liquid medium applications, the shear wave rapidly damps out as it travels through the thickness of the liquid, and consequently the QCM typically samples a layer of thickness equivalent to the decay length $\delta_{liq} = \sqrt{\eta_{liq}\pi\rho_{liq}f_0}$. For a commercial 5 MHz QCM, the typical decay length in water is ~250 nm, which is large in comparison to the thickness of molecular or even polymer and biomolecular (e.g., proteins) films which can be in a thickness range of 10–50 nm. As a result, a commercial QCM not only samples the adsorbed film but is also significantly affected by the viscous liquid layer above it. Small changes in the viscoelastic properties of adsorbed layers are often masked by the viscous loading from the liquid overlayer. However, if the QCM thickness is decreased, its fundamental resonance frequency increases inversely as a function of the thickness of quartz, and thus the decay length in liquid also decreases consequently. For example, if the thickness of a quartz resonator is decreased from 330 μm (commercial 5 MHz resonator) to 24 μm (miniaturized 66–69 MHz resonator), the decay length in water is reduced to ~68 nm. These factors are critical to the improved abilities of miniaturized devices for probing the viscoelastic properties of adsorbed layers compared to standard commercial QCMs.

Viscoelastic Loading in Liquid Ambient

The QCM frequency shift resulting from the deposition of viscoelastic layer in a viscous liquid ambient can be analyzed using a continuum mechanics approach, for example, as developed by Kasemo and coworkers [10]. In order to model this situation, the QCM surface is considered to be in intimate contact with a layer of continuous viscoelastic slab with an infinitely thick Newtonian liquid overlayer on one of its surfaces. Under the assumption that the thickness of the bulk liquid layer is much larger than the decay length of the acoustic wave in the liquid, the frequency,

Q-factor, and dissipation factor changes with respect to liquid loading conditions can then be written as

$$\Delta f \approx -\frac{1}{2\pi\rho_q t_q} \times \left(t_{visc}\rho_{visc}\omega - 2t_{vise}\left(\frac{\eta_{liq}}{\delta_{liq}}\right)^2 \frac{\eta_{visc}\omega^2}{\mu_{vise}^2 + \omega^2\eta_{visc}^2} \right) \tag{11}$$

$$\Delta Q \approx -2\pi f_0 \rho_q t_q \frac{\left(2t_{vise}\frac{\mu_{visc}\omega}{\mu_{visc}^2 + \omega^2\eta_{visc}^2}\right)}{\left[1 + \left(2t_{visc}\left(\frac{\eta_{liq}}{\delta_{liq}}\right)\frac{\mu_{visc}\omega}{\mu_{visc}^2 + \omega^2\eta_{visc}^2}\right)\right]}, \tag{12}$$

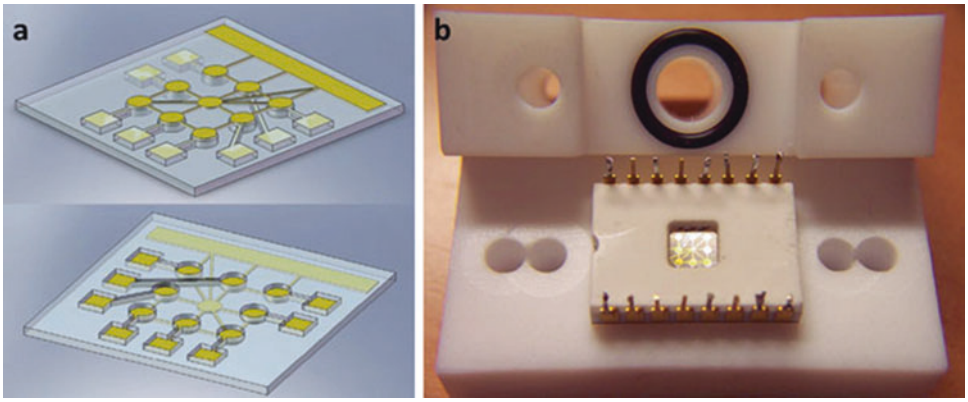
$$\Delta Q \approx \frac{1}{2\pi f_0 \rho_q t_q}\left(2t_{visc}\left(\frac{\eta_{liq}}{\delta_{liq}}\right)^2 \frac{\mu_{visc}\omega}{\mu_{visc}^2 + \omega^2\eta_{visc}^2}\right), \tag{13}$$

where μ_{visc}, η_{visc}, and ρ_{visc} are the elastic modulus, viscosity, and density of the viscoelastic layer, respectively, and t_{visc} is its thickness and δ_{liq} is the penetration depth of the acoustic wave in the liquid.

Basic Methodology

Micromachined Quartz Resonator Arrays

Figure 4a shows a schematic illustration of the fabricated resonator array with eight resonators in the array. The creation of an abrupt step in the quartz substrate for each pixel acoustically and energetically isolates each of these for the shear mode operation [13, 14]. Each resonator is individually addressed through backside (etched-side) electrodes which are extended to the rim of the sensor array chip. The top electrode is common to all the pixels of the array. In order to effectively confine the acoustic energy in each pixel, the pixel thickness to diameter of the electrodes ratio has been carefully optimized as per the conditions described in Eq. 4 [15]. The mounting and packaging of the array and the interconnection were also carefully optimized to maintain a high-quality factor of the resonators. Figure 4b shows the packaged device placed on the liquid test cell. For the fabricated 25–18 μm thick pixels, the fundamental resonance frequency is expected to be in the range of 66.72–90 MHz. Fabricated devices were mounted in a specially designed Teflon test cell capable of liquid testing experiments.



Key Research Findings

Impedance Characteristics in Air and Liquid Loading Conditions

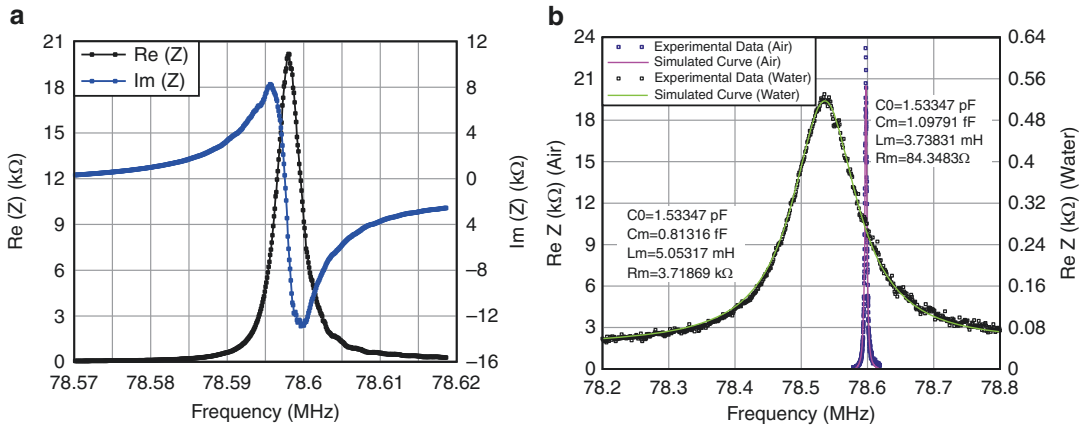


Figure 5a shows the at-resonance real and imaginary impedance curves for one of the eight pixels of the array in air. All the fabricated pixels show similar impedance characteristics. The equivalent BVD circuit model for the quartz resonator yields the following expression for the real part of the impedance (Re Z):

$$\left.\begin{aligned} \mathrm{ReZ} &= \frac{R_m}{(1 - B_0 X_m)^2 + (B_0 R_m)^2} \\ &\text{Where} \\ \mathrm{B}_0 = \omega\, C_0, &\text{ and } X_m = \left(\omega L_m - \frac{1}{\omega C_m}\right) \end{aligned}\right\}, \tag{14}$$

The 801 data points of experimentally measured Re Z near resonance was fitted to the equivalent BVD circuit model of the resonator with C_0, C_m, L_m, and R_m as parameters. Using nonlinear fitting function in Mathematica® software, the best fit was used to obtain the values of the four equivalent circuit parameters. Figure 5b shows the experimental data and the fit obtained in air and water and the values of the resonator parameters obtained using this method. As can be seen, an excellent fit was obtained using this technique and the method was followed for all concentration of water–glycerol mixtures as well. Using this method and Eq. 8 the values of the $(\rho_{liq}\eta_{liq})^{0.5}$ for the various water-glycerol concentrations has been deduced and are listed Table 1 along with the equivalent circuit parameters deduced by nonlinear fitting.

Investigation of Interfacial Layer: Protein Adsorption Studies

Micromachined quartz resonators were used to measure the changes in the frequency and the *Q*-factor of the various pixels upon adsorption for five globular proteins as a function of concentration in the solution phase. The five proteins investigated are human serum albumin (HSA), immunoglobulin G (IgG), human fibrinogen (Fib), alpha-2-macroglobulin (AMG), and immunoglobulin M (IgM) at the fundamental and the third resonance modes.

Human serum albumin (HSA), immunoglobulin G (IgG) from rabbit serum, and fibrinogen (Fib) were used as received from Sigma Aldrich and were of highest purity available (>96 %). Alpha-2-macroglobulin (AMG) and immunoglobulin M (IgM) were from MP Biomedicals

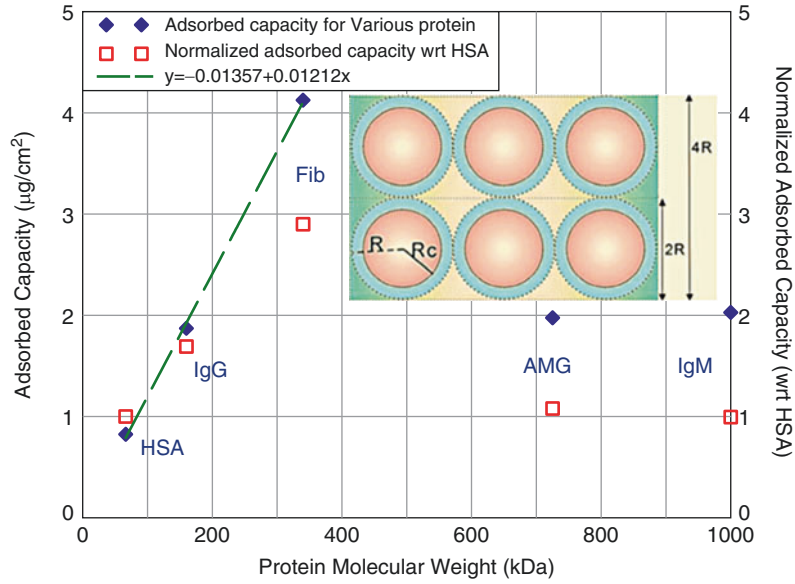
and used without further purification. Different HSA, IgG, and fibrinogen concentration solutions were made by diluting a 10 mg/ml stock solution. AMG and IgM were made by diluting a 5 mg/ml stock solution. The 10 mM phosphate buffer solution (PBS) was made by dissolving phosphate buffered saline powder (Sigma Aldrich) into 18 MΩ-cm DI water (Millipore Milli-Q system; Barnstead international). The micromachined quartz resonator pixels were cleaned by three cycles of exposure to ultraviolet (UV) light and ozone; each 15 min long and followed by thorough rinsing with ethanol and immersion in ethanol for 1 h.

The electrodes were exposed to 1 mM hexadecanethiol solution for 24 h. This procedure has been demonstrated to result in the formation of a hexadecanethiolate self-assembled monolayer (HD-SAM). Given the thin (~2 nm), chemically attached, dense nature of the HD-SAM layer, it can be considered as a rigid extension of the electrode. The adsorbed globular protein layer attaches to the HD-SAM surface via van der Waals forces with each molecule surrounded by water and in contact with the phosphate buffer saline solution. The protein layer is considered to be viscoelastic in nature whereas the surrounding PBS solution, containing only a very low-volume fraction of protein molecules, can be represented as a Newtonian fluid. Furthermore, the change in frequency as well as the change in the Q-factor at the fundamental and third mode of the resonator upon adsorption for each protein at various concentrations was measured. Experimental results show a decrease in the frequency and the Q-factor at both the fundamental mode and third overtone of operation with increasing concentration for each protein. Using expressions given by Eqs. 11, 12, and 13, the expected frequency and Q-factor changes can be calculated. In order to model the system, the thickness, density, elastic modulus, and viscosity of the protein layer are considered as parameters and varied to fit to the experimental data. Detailed results and analysis of these measurements are presented elsewhere [16]. Here, the results are briefly summarized.

Figure 6a shows a plot of the resonance frequency shift and quality factor change upon adsorption of HSA at the fundamental and the third overtone modes versus HSA solution concentration. All sets of data show a very close fit with high (>0.99) R^2 value to a sigmoidal function. The observed change in the dissipation factor ΔD versus the change in frequency Δf for various concentrations is plotted in Fig. 6b. The slopes reveal the value of $\partial D/\partial f$ in different concentration regions indicating a varying loss and rigidity of the adsorbed film assembled on the resonator electrode at different concentrations. A low value of $\partial D/\partial f$ indicates a highly rigid, low dissipation film. In contrast, a high value of $\partial D/\partial f$ indicates a soft, dissipative film. In the low-concentration region, a small value of $\partial D/\partial f$ is obtained indicative of a low dissipation. It is reasonable to suggest that the acoustic wave is very slightly damped by protein molecules in low surface coverage region. With increasing surface coverage, the damping of acoustic wave by protein molecules



Interfacial Investigation of Protein Films Using Acoustic Waves, Fig. 6 (**a**) Shows the experimentally measured frequency and quality factor shift upon adsorption of human serum albumin (*HSA*) in phosphate buffer solution on a hydrophobic CH_3-terminated surface. The experimentally measured shifts at the fundamental mode (*top*) and third overtone (*bottom*) as a function of the concentration of HSA are shown. (**b**) Shows the dissipation factor ($1/\Delta Q$-factor) plotted as a function of the frequency shift at the various concentrations of HSA. Distinct regions with different slopes can be identified indicating a change in the viscoelastic behavior of the absorbed protein film. (**c**) Langmuir model plot of adsorbed HSA mass, represented by $C/\Delta f$ versus HSA concentration (C), for the entire concentration range tested. The *long-dash line* is a linear fit to all concentration range of data. The *dotted line* is a linear fit in the low concentration region of the data. The spread in the data with respect to the linear fit indicates a deviation from the fit only be seen in the low-concentration region

continuously increases. In the high-concentration (surface coverage) region, the slope of $\partial D/\partial f$ is markedly different from its value at low concentrations. This may be interpreted as gradual conformational changes during the self-assembly process upon reaching critical intermolecular interactions amongst the molecules in the adsorbing film. The reduction of $\partial D/\partial f$ near the saturation region implies a slightly rigid HSA film upon the completion of the adsorption process. The same experiments were repeated for other globular proteins listed and the analyzed using Eqs. 11, 12, and 13.

Table 2 summarizes the physical and viscoelastic properties of the various proteins that were extracted from the QCM measurements [16]. As a simple, preliminary way to model the protein adsorption trends, the proteins can be treated as spheres with a radius $r_v = 6.72 \times 10^{-8}$ MW$^{1/3}$ where the volume of the core protein is considered to be proportional to their molecular weight [17]. For a core protein, including a shell of water molecules, the hydrated protein radius is 1.3 times the core protein radius. These values are in close agreement with the thickness per layer deduced from the QCM results. A linear

relationship between the MW of the proteins and adsorbed capacity (density x thickness (in µg/cm^2) of the protein layer) on the QCM electrode is observed for three of the five proteins, as shown in Fig. 7. Furthermore, normalization of the adsorbed capacity with respect to HSA (i.e., adsorbed capacity of given protein/adsorbed capacity of HSA) gives a simple integral number for the remaining two of the four proteins measured (see Fig. 7). HSA is known to adsorb on a surface as a single layer, which implies that the integral values obtained for two of the four proteins can be interpreted as adsorption of IgG as two layers and Fibrinogen as three layers. From the estimated value of the hydrated layer, AMG and IgM proteins are thought to adsorb as a single layer.

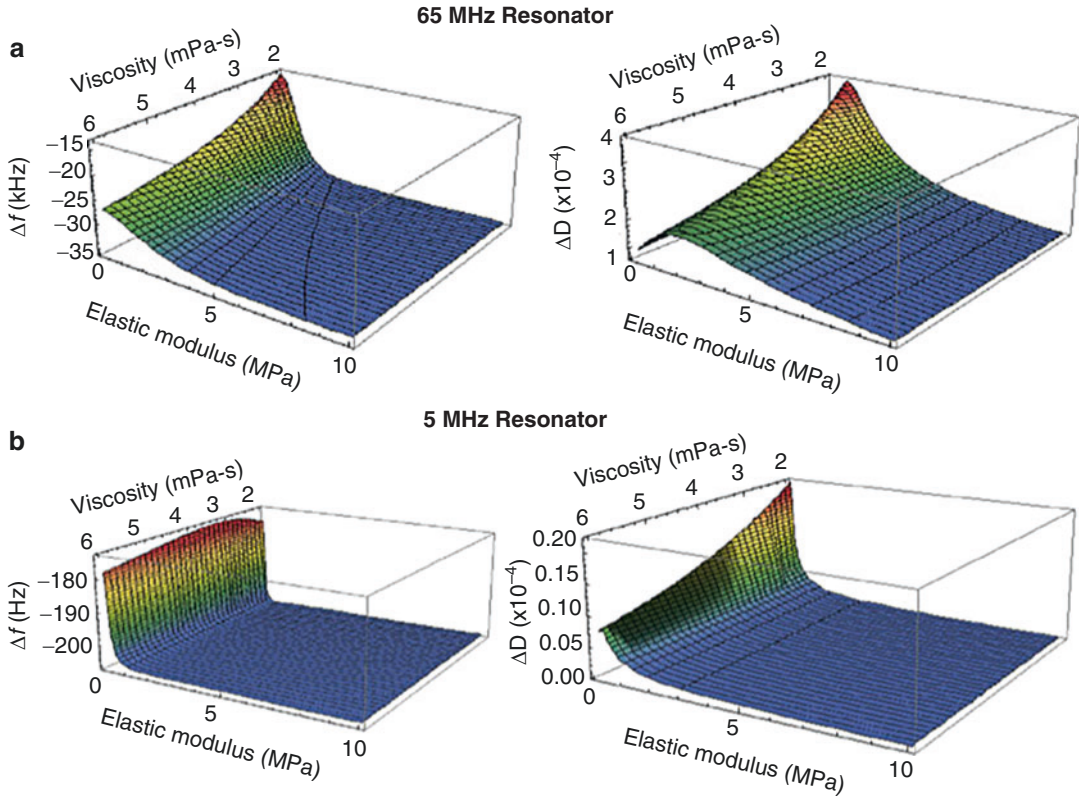
The chemical and physical properties of the interface and ambient strongly influence the degree of protein adsorption at a solid interface. The relative strength of the thermodynamic adhesion of the protein to the CH_3-SAM surface has been reported in the following order (Fib > Alb > IgG) [18]. Furthermore, the surface concentration of IgG adsorbed on SAMs has been shown to decrease in the order: $CH_3 > C_6H_5OH > COO- > NH_2 > OH$ [19]. Langmuir theory provides a general approach to discussing the adsorption kinetics of proteins by including the interactions between surface active sites and adsorbed species. However, extensive debates on the applicability of Langmuir model for protein adsorption can be found in literature. From the observed irreversibility of the macroscopic adsorption, as demonstrated by observations

that dilution of the protein solution does not lead to a corresponding desorption of the protein films, it can be concluded that a large barrier to desorption exists. For example, addition of pure PBS solution on top of an adsorbed (saturated) protein layer for as long as 24 h showed no observable frequency and Q-factor change.

Clark et al. reported similar observations where, the degree of reversibility of protein adsorption decreased with increasing contact time [20]. This desorption irreversibility has been attributed to time-dependent interfacial conformational changes of the adsorbing protein molecules which result in a strong interaction with the surface. As a consequence of this irreversibility, for any given concentration of the protein solution, the adsorption process leads to saturation coverage after long enough time. However, at low concentrations of proteins, the adsorption process is extremely slow and requires very long times to approach saturation coverage – thus giving the appearance of a concentration-dependent surface coverage akin to Langmuir isotherm. Attempted modifications to Langmuir model of protein adsorption have not been very successful at explaining the kinetics of protein adsorption processes. For now, the Langmuir type of model remains the best way to empirically analyze adsorption data and has been used to interpret the results of HSA adsorption shown in Fig. 6c. It is important to realize that the high-frequency micromachined bulk acoustic resonators described here, with reduced acoustic penetration depths, are able to resolve the interfacial effects in the adsorbed films with high sensitivity.

In the log-log plots of $C/\Delta f$ versus concentration C for HSA, it is clear that only a few data points lie on a straight line. It appears that the data can be fitted by two linear regions of different slope and intercept. The calculated K value has a large variation in the two regions of concentration. To interpret these variations in the K value, the theory needs to include not only adsorption process, but also reorientation, spreading, spatial conformations, and their kinetics at the various concentrations. The ΔD versus Δf graph, Fig. 6b, shows the dissipative effects in the adsorbing film as a function of concentration and relates more directly to reorientation, spreading, and spatial conformation effects. The presence of more than one linear region with different slopes as seen in a plot of $C/\Delta f$ versus concentration C and ΔD versus Δf suggests a competition between adsorption and dissipative processes which are expected to be determined by the native form of the protein.

To compare the effect of surface functionalization on protein adsorption process, QCM gold electrodes were functionalized to produce a high-density carboxyl-terminated hydrophilic surface by chemisorption of 16-mercaptohexadecanoic acid. Identical frequency and Q-factor change measurements and analysis were undertaken for the adsorption of three globular proteins on the COO^- terminated electrode surface. The observed results show similar overall behavior for the adsorption of the globular protein layer on to COO^- surfaces as on hydrophobic surface. The measured change in frequency and Q-factor at the fundamental and third resonance modes were once again fitted to Eqs. 11, 12, and 13 with the thickness, density, elastic modulus, and viscosity of protein layer as parameters. Table 3 summarizes the physical and viscoelastic properties of the various proteins that were extracted from these measurements. However, the parameters of each protein on hydrophobic and charged hydrophilic surfaces differ due to the differences in the interfacial packing of spherical protein molecules on the two surfaces.



Furthermore, normalization of the surface adsorbed capacity with respect to HSA (i.e., adsorbed capacity of given protein/adsorbed capacity of HSA) gives a simple integral number for the other two proteins on COO^- SAM. The two proteins on hydrophilic surface indicate three layers for IgG, and four layers for fibrinogen on hydrophilic surface.

Future Directions for Research

In conclusion, it has been demonstrated that high-frequency micromachined quartz resonators are especially suited for monitoring small changes in the viscoelastic loading in films adsorbed on their surface. Figure 8 shows the dependence of the frequency and Q-factor shift as a function of the

Interfacial Investigation of Protein Films Using Acoustic Waves, Fig. 8 Comparison of the frequency and dissipation factor sensitivity of (**a**) 65 MHz and (**b**) 5 MHz resonators to variations in the viscosity and modulus of the adsorbed films with 35 nm of thickness and 1,040 kg/m^3 density. Clearly, the 65 MHz resonator has a better resolution over wider range of values of these properties

viscosity and elastic modulus of a 35 nm thick protein film adsorbed on a commercial 5 MHz and a micromachined 65 MHz resonator. It is clear that the miniaturized resonators provide a greater resolution of these properties. A large variation in the *Q*-factor and the frequency for small changes in the viscoelastic properties of the adsorbed film is highly desirable for accurate

determination of the material properties of the films and for the observation of conformational changes in these nanometer thin films. Based on the measurement of five selected globular proteins, the sensitivities (resolution) of thickness, density, viscosity, and elastic modulus are summarized in Table 4. Careful interpretation of the frequency and *Q*-factor changes can provide a sensitive tool for the analysis and investigation of the biomolecular films in terms of film assembly, packing density, and other conformational changes.

In vivo microscopy analysis

Definition

Intravital microscopy is a type of microscopy performed upon the living organism to directly observe dynamic phenomena in high resolution enough to distinguish cellular and subcellular features.

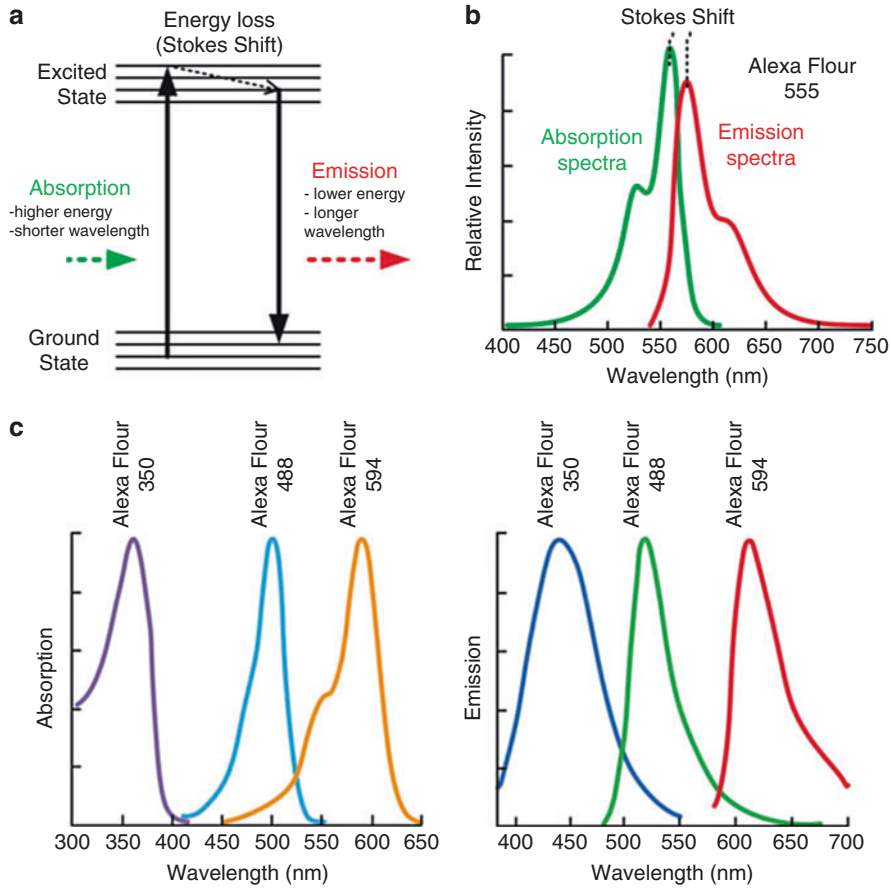
Overview

Intravital microscopy is an emerging type of microscopic imaging technique which can be performed in the living organisms to directly visualize dynamic cellular phenomena in its natural environment. During the last decade, intravital microscopy has evolved to become an indispensable technique to address key questions in a wide area of biomedical fields such as molecular biology, cell biology, immunology, neuroscience, and tumor biology. Real time direct visualization of dynamic cellular processes in action under its natural environment in vivo by intravital microscopy has provided unprecedented insights that were impossible to obtain by static observation of thinly sliced chemically fixed tissues ex vivo by conventional light microscopy (i.e., histology, immunohistochemistry). In addition, although in vitro model studies have enabled many significant findings with its flexibility and manipulability, it fails to reconstitute the cellular environment in specific tissue under physiological condition that can only be found in in vivo models, which makes the intravital microscopy analysis unique and invaluable for many biomedical investigations. For the field of nanotechnology toward biomedical applications such as nanomedicine and nanoparticles for drug delivery, the utilization of intravital microscopy that can monitor the dynamic behaviors of individual nanoparticles in vivo is highly attractive.

Principles

Intravital microscopy is defined as a type of microscopy that can directly image the living organism. In practice, categorized by the combination of key techniques to implement intravital microscopy, there are two most widely used forms of microscopies, *fluorescence confocal laser-scanning microscopy* and *fluorescence two-photon laser-scanning microscopy*. All major microscopy companies such as Carl Zeiss, Olympus, Nikon, and Leica have their own versions of these two types of microscopies and all of them share same working principles to construct image – fluorescence detection and sectioning.

Fluorescence



Currently, intravital microscopy is mostly performed by observing *fluorescence* emitted from a *fluorophore* as a contrast to create an image, which is categorized as *fluorescence microscopy* [1, 2]. It can reveal only objects of interests tagged by fluorophore from a black background, providing high selectivity, sensitivity, and

contrast. Over the past decades, tens of thousands of fluorescent probes were synthesized by organic chemists to provide a toolbox to label virtually any components in biological systems. In addition, the development of fluorescent proteins, most notably green fluorescent protein (GFP), has allowed the intrinsic endogenous tagging of numerous components in living systems by genetic engineering without the hassle of devising a labeling scheme using exogenous probes. Lastly, rapid technical advances in light sources and detectors optimized for fluorescence imaging make fluorescence microscopy to become an ideal technique for the observation of all biological specimens either alive (in vivo) or fixed (ex vivo) by allowing the detection of molecules at very small concentration with superior signal-to-background noise ratio.

Fluorescence is the emission of light from a fluorophore through after its absorption of light. Figure 1a shows typical electronic states of a fluorophore in Jablonski diagram. Each electron state has multiple vibrational states. The energy of absorbed photon makes an electron to be excited, elevating to a higher energy level. Subsequently, the electron returns to the ground state and emits a lower energy photon. Typically, the wavelength of emitted light is longer than that of absorbed light due to the energy loss involved in the vibrational state transition and the difference is called Stokes shift. This is the critical property that enables the fluorescence imaging to have high contrast and high sensitivity by completely filtering out the unwanted background light spectrally without affecting the signal emission light. Since the energy transition by absorption and emission can occur between multiple vibration states in each state, a fluorophore typically has a broadened spectrum of absorption and emission as shown in Fig. 1b. These spectral properties of a fluorophore are determined by its electronic energy structure that can be tuned to have many different emission wavelengths, that is, colors. During past decades, a variety of colorful fluorophores have developed in ultraviolet (UV), visible, and near-infrared (NIR) spectrum from 300 to 800 nm in wavelength. Fortunately, the emission spectrum of most fluorophores is spectrally narrow enough that it is possible to use multiple fluorophores with different colors at the same time as illustrated in Fig. 1c. This enables simultaneous visualization of multiple components tagged by different color fluorophores, which is extremely useful to analyze complex processes involving interaction between components, for example, interaction between a nanomaterial and a cell.

Fluorophores

Common fluorophores with different colors for multicolor imaging are summarized in Table 1. Fluorescein Isothiocyanate (FITC) and Tetramethylrhodamine (TAMRA) are traditional fluorescent dyes that have been successfully utilized for many years. The quantum yield of fluorescein is very high and its physical and chemical characteristics have been well known. But, fluorescein is very sensitive to environmental factors such as pH, changing its emission intensity. 4′,6-diamidino-2-phenylindole (DAPI) and Hoechst dyes are very popular to stain DNA and chromatin by its binding property to the double helix. And their blue fluorescence makes them to be easily combined with traditional dyes with green and red fluorescence. Alexa Fluor dyes, marketed by invitrogen™, have several improved features such as higher quantum yield than spectrally similar traditional dyes, enhanced photostability under continuous excitation and pH insensitivity. In addition, the absorption spectra of derivatives are well matched to common laser lines and water solubility is high. These advantages make the Alexa Fluor dyes to be one of the most popular dyes for many fluorescence imaging applications, but its relatively high price is the drawback. Cyanine dyes, Cy2, Cy3, Cy5, Cy5.5, and Cy7 are more environmentally stable and thus less sensitive to pH and organic media mounting samples. The cyanine dyes generally have broader absorption spectra than Alexa Fluor family, making them somewhat more versatile in the choice of laser excitation. As described before, due to the unique advantage of endogenous labeling, fluorescent proteins in various colors in blue (BFP), cyan (CFP), green (GFP), and red (RFP, DsRed) are widely used. Qdot®, marketed by invitrogen™, is

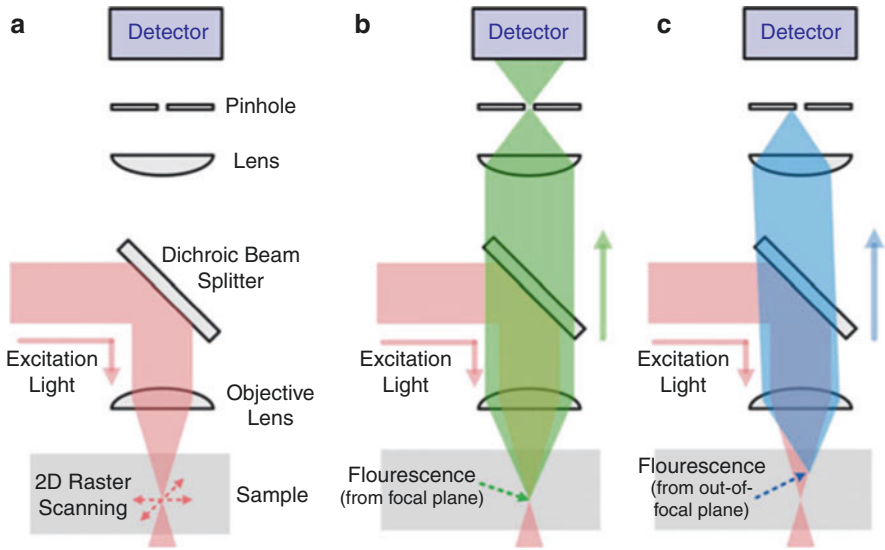
a newly emerging semiconductor quantum dot with diameter of tens of nanometers. Unlike typical organic fluorophores that have highly specific spectral absorption profiles, quantum dots have a unique absorption property that absorption efficiency continuously increases with shorter wavelength, independent of emission wavelength. Thus, multiple kinds of quantum dots of different

colors can be excited by single UV light source. Another unique feature is that the emission wavelength of quantum dot is determined by the dot size, which enables the manufacturing of quantum dot with emission at NIR range. And the photostability of quantum dot is several orders of magnitude higher than organic dyes. These exceptional properties and the reduced scattering/absorption by most biological tissue in NIR range make the NIR quantum dot to have great potential for in vivo observation of living animal models, even for clinical applications such as fluorescence-guided surgery of the human patient [3]. To perform a fluorescence imaging with a certain fluorophore, it is crucial to select a light source whose output wavelength is closely matched to the peak wavelength of absorption spectra of fluorophore. Common light sources type and output wavelengths are summarized in Table 2.

Sectioning

Traditional fluorescence microscopy with simple configuration of Kohler illumination and wide-field detection can provide excellent images of thin transparent specimen, mostly sliced tissue sample after fixation or living cell cultured in vitro [1, 2]. However, for much thicker sample such as live tissue in mouse in vivo, it fails to reveal microscopic-scale details at the focus plane due to the reduced contrast by the fluorescence arise from fluorophores in out-of-focus plane, because the entire sample is excited indiscriminately. Thus, intravital microscopy must equip with a capability that can exclusively acquire fluorescence signal only from the focus by eliminating the out-of-focus fluorescence signal, which is termed as *sectioning* and this type of microscopy is categorized as *sectioning microscopy*. The removal of unnecessary fluorescence provides a tomographic snapshot of thick living sample with greatly enhanced contrast, which enables three-dimensional (3D) reconstruction by integrating the image data at multiple focal planes computationally.



As a sectioning microscopy, there exist two major types of microscopies, *confocal microscopy* [3, 4] and *two-photon microscopy* [5, 6]. In both cases, the illumination of sample with the light source to excite a fluorophore is performed by two-dimensional (2D) raster-pattern scanning of tightly focused beam, which is termed as *scanning*. To achieve high resolution with *scanning*, it is crucial to implement light illumination that is focused to the smallest spot possible, the diffraction-limited spot at focus. This tight focusing is normally created by sending collimated beam to pass the high power, high numerical aperture (NA) objective lens that transforms the beam to converge. The higher the NA of objective lens and the shorter the wavelength of light for excitation, the smaller the spot becomes to the diffraction-limit that is calculated to 0.61 λ/NA in radius, where λ is the wavelength of the light. Although this diffraction-limited spot at the focal plane ensures the highly localized fluorescence signal generation for high-resolution information, the excitation of fluorophore happens nonselectively all along the converging and diverging beam path out of focal plane. Thus, it is necessary to implement rejection mechanism to block the fluorescence from out-of-focus plane. For example, in confocal microscopy, this is achieved by placing a pinhole in front of the detector at a plane optically conjugated to the focal plane such that pinhole aperture is aligned with the focus. This arrangement makes the only fluorescence arise from the focus exclusively pass the pinhole to reach the detector.

Confocal Microscopy

The operation principle of confocal microscopy for fluorescence imaging with sectioning is illustrated in Fig. 2. The arrangement of major components including pinhole, objective lens, sample, dichroic beam splitter, and detector as well as the path of excitation light are illustrated in Fig. 2a. The dichroic beam splitter is a specially engineered optical component that reflects shorter wavelength excitation light while transmitting longer wavelength fluorescence. Excitation light under 2D scanning is directed to the sample by the dichroic beam splitter and focused by the objective lens to create a tightly focused spot inside the sample. Figure 2b illustrates the light path of fluorescence that is emitted from the focal plane.

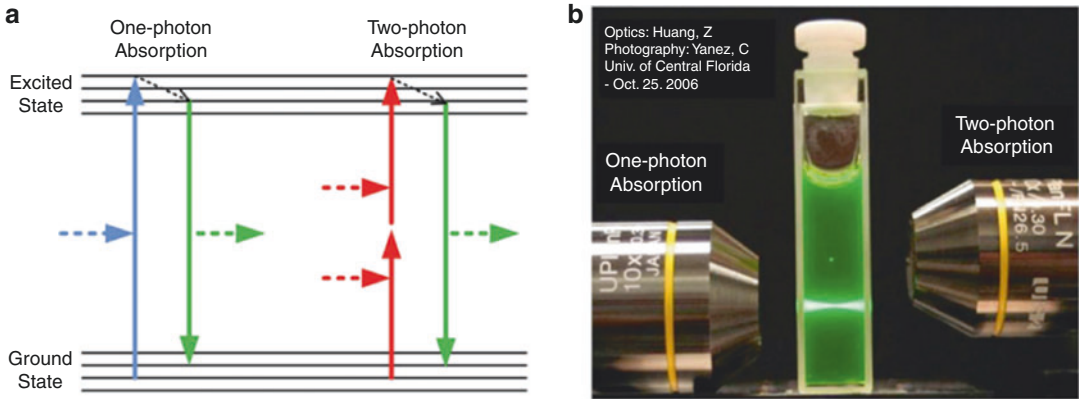
Helium-neon laser	–	–	–	543	594	633
DPSS laser	365	405	488	532	561	641
Mercury-arc lamp	365	405, 436	–	546	579	–
Xenon-arc lamp	–	–	467	–	–	–
Metal-halide lamp	365	435	495	520, 545	575	625



Intravital Microscopy Analysis, Fig. 2 Principle of confocal microscopy. (**a**) Schematic layout of confocal microscopy for fluorescence imaging with sectioning. (**b**) Light path of fluorescence emitted from the focus. (**c**) Light path of fluorescence emitted from the out-of-focus

This in-focus fluorescence signal is back-collected by the objective lens and then separated by the dichroic filter to transmit toward the detector. Then the fluorescence signal passes the pinhole of which the aperture is precisely aligned to the optical conjugation point with the focus of excitation light inside the sample and reaches the detector as illustrated in Fig. 2b. In contrast, the fluorescence emitted from the out-focus plane is focused onto the nontransparent part of the pinhole and thus fails to reach the detector as illustrated in Fig. 2c. The effectiveness of pinhole in terms of sectioning is greatly related to the size of the opening in the pinhole. Normally, for the observation of a thin specimen, it is recommended to match aperture size to the calculated spot size at focus, 0.61 λ/NA in radius (often referred to Airy Disk size). But, for in vivo observation of a thick living specimen, increasing the aperture size up to 2–4 Airy Disk size often provides a significantly brighter image with small penalty in resolution due to excessive light scattering.

Two-Photon Microscopy

On the other hand, *two-photon microscopy* achieves *sectioning* based on a nonlinear optical process between excitation light and fluorophore, two-photon absorption. It is a phenomenon that

Intravital Microscopy Analysis, Fig. 3 Principle of two-photon microscopy. (**a**) Jablonski diagram illustrating one- and two-photon absorption. (**b**) Photograph showing the spatial confinement of fluorescence generation with two-photon absorption, compared to one-photon absorption

occurs when two individual photons arrive at the same fluorophore simultaneously (within ~0.5 fs interval) and are absorbed together to combine their energy to excite the fluorophore. Since the energy of photon is inversely proportional to the wavelength, two absorbed photons substituting one photon of twice the energy should have twice the wavelength. For example, a fluorophore normally absorbing UV light at 350 nm can be excited by two-photon absorption with NIR light at 700 nm. Figure 3a illustrates the two-photon absorption along with a one-photon absorption. As depicted, once fluorophore is excited in either of absorption processes, it returns to the ground state in the exact same manner emitting a fluorescence photon. Due to the requirement that two photons hit the same fluorophore within an extremely short interval, compared to one-photon absorption, a light with about a million times higher intensity is required to generate the same level of fluorescence with two-photon absorption. In practice, to achieve this high intensity, the excitation light facilitating two-photon absorption has to be extensively concentrated not only in space by a high NA objective lens but also in time. Mode-locked Titanium-sapphire laser generating ultrashort pulse light of 10–100 fs pulse width at about 80 MHz repetition rate is the most common light source for two-photon microscopy. Even with this level of concentration in time domain, the high photon density sufficient for two-photon absorption is achieved only at the very small volume at the focus. In other words, the fluorescence excited by two-photon absorption is generated only from the focal plane as shown in Fig. 3b, which facilitates intrinsic *sectioning* without additional pinhole in front of detector like confocal microscopy. In Fig. 3b, a quartz cuvette with the solution of fluorophore, fluorescein having green fluorescence, is placed between two identical objective lenses. From the right-side objective lens ultrashort pulse light with 200 fs pulse width and 780 nm wavelength is delivered into the cuvette, demonstrating the highly confined generation of fluorescence signal by two-photon absorption. In contrast, when illumination light of 380 nm wavelength tuned for one-photon absorption is delivered through the left-side objective lens, the fluorescence is generated indiscriminately in whole illuminated volume. Table 3 summarizes the features of confocal and two-photon microscopy.

Laser Scanning

The most common method to implement a *scanning* for commercial confocal microscope is using two galvanometer-based oscillating mirrors to deflect the angle of reflected light. Typically, one mirror scans the excitation light along the "fast axis" (mostly horizontal direction) and the other

Intravital Microscopy Analysis, Table 3 Comparison between confocal and two-photon microscopy

	Confocal microscopy	Two-photon microscopy
Sectioning principle	Pinhole rejecting out-of-focus fluorescence	Nonlinear fluorescence generation exclusively in focus
Light source type	Continuous-wave laser	Femtosecond pulsed laser
Light source wavelength	360–640 nm	700–1050 nm
Excitation process	Single-photon absorption	Two-photon absorption
Pinhole before detector	Yes	No
De-scanning	Yes	No

mirror scans the "slow axis" (mostly vertical direction) in much slower speed to sequentially cover the 2D plane. Naturally, the speed of image acquisition is limited by the maximum scanning speed of the fast-axis scanner. The typical scanning speed of the galvanometer-based oscillating mirror is from 500 Hz to 1 kHz, which corresponds to 1–2 frames per second with 512 × 512 pixels. However, for the in vivo observation such as intravital microscopy, it is often very useful to have a capability of video-rate image acquisition at 24–30 frames per second. Fast dynamics such as blood circulation, muscle reflex, and neural signal are several examples. One common method to achieve video-rate scanning is to use the resonant oscillating mirror that can scan at very high speed from 7 to 14 kHz by sacrificing scanning linearity. One commercial confocal microscope employing this resonant scanning is available in market, Nikon's A1R-A1 confocal microscope. Another method is using a polygonal mirror rotating at very high speed from 400 to 900 rev/s, which corresponds to 14.4–32.4 kHz with a 36-facet polygonal mirror. In practice, for in vivo observation, the image acquisition speed often needs to be compromised to obtain a high-quality image depending on the brightness of the fluorescence signal, since the achievable signal-to-noise ratio is proportional to the square root mean of exposure time per pixel with given signal intensity and frame rate.

Applications

In the last decade, with its unique capability of visualizing cellular dynamics in vivo, intravital microscopy has become an indispensable tool for many fields of biology, such as immunology [14], cancer biology [15], neuroscience [16], and neuropathology [17]. In the field of nanotechnology, there have been tremendous amount of efforts to develop new functionalized nanoparticles for biomedical applications such as gene or drug delivery, diagnosis, and therapeutics. In the process of translation from the chemical bench to the bed in clinic, extensive analysis using experimental animal, especially mouse, to assess the efficacy and safety in vivo is commonly required. The traditional microscopy-based analysis of ex vivo tissue sample provides only static information at a single given time of animal death, like a snapshot. The intravital microscopy-based analysis of live mouse can provide dynamic information over a period of hours to weeks in a single animal, which enables direct monitoring of various biological processes involving nanoparticles introduced into the animal in chronological view, like a movie. Here, two examples of intravital microscopy-based analysis of nanoparticle behavior in a live mouse will be introduced.

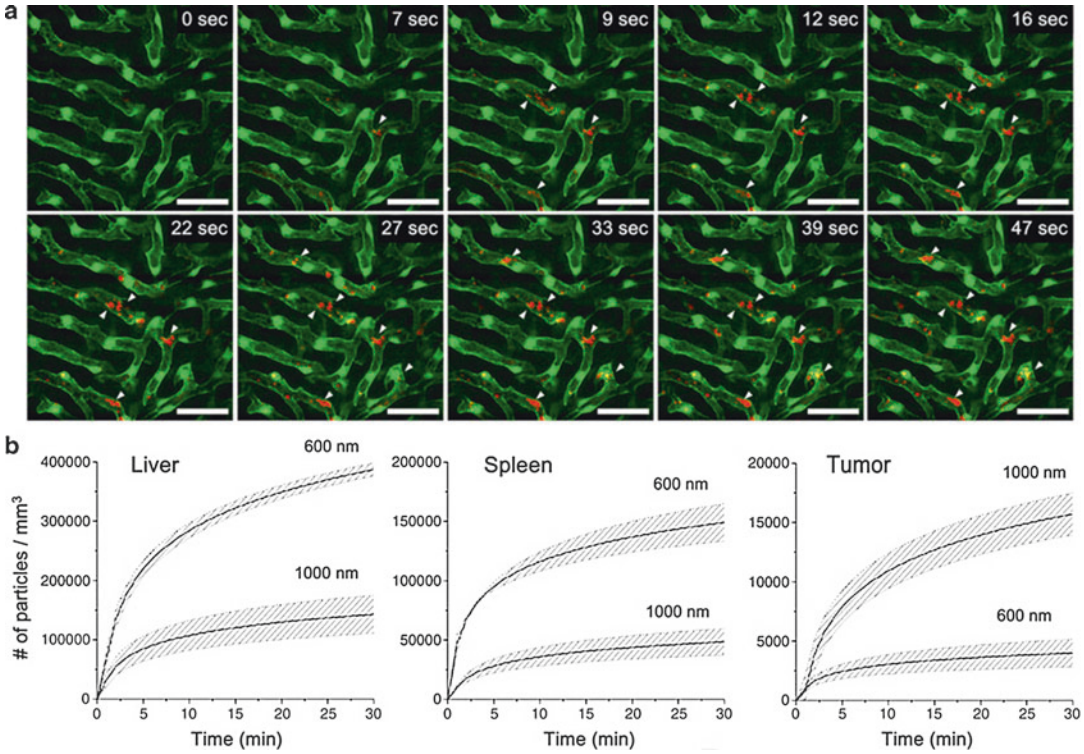
The first example is the in vivo tracking of polyplex nanomicelle administered for gene delivery to skeletal muscle over a week [7]. Skeletal muscle has been studied as an ideal target of gene delivery for therapeutic protein production, such as growth factor [8]. Since direct injection of naked plasmid DNA (pDNA) into muscle suffers very low efficacy, a virus-based gene delivery system, viral vector, has been developed. However, several fundamental limitations of utilizing the virus as a gene carrier such as the size limitation of integrated gene, the difficulty in virus manufacture, and most critically, the immunogenicity driven by virus have limited its clinical application. To overcome these limitations, a

Intravital Microscopy Analysis, Fig. 4 In vivo tracking of polyplex nanomicelle hydrodynamically administered for gene delivery to thigh muscle over a week in live mice. (**a**) Polyplex nanomicelle composed of plasmid DNA and block copolymer. (**b**) Hydrodynamic gene delivery to the thigh muscle by intravenous injection and tourniquet. (**c**) Longitudinal in vivo tracking of Cy5-labeled pDNA (*red*) distributed in the muscle fibers of Histone-GFP mice, in which every nucleus of cells expresses GFP (*green*). Scale bars are 100 μm (Modified from Ref. [7])

nonviral gene carrier, such as nanomicelle and porous nanoparticle, has been actively developed [9].

In this example, the polyplex nanomicelle is synthesized by a self-assembly process in the mixture of pDNA and block copolymer as illustrated in Fig. 4a. To image the pDNA in vivo, it is fluorescently labeled by red fluorophore, Cy5. As an experimental animal model to monitor the delivery of Cy5-labeled pDNA in vivo, a transgenic Histone-GFP fusion mouse (B6.Cg-Tg (HIST1H2BB/EGFP) 1 Pa/J, Jackson Lab) expressing GFP in the nucleus of every cell is used. To administer the nanomicelle safely, a Histone-GFP mouse is anesthetized. The blood circulation of the right foot is isolated by placing tourniquet as illustrated in Fig. 4b. Then the polyplex nanomicelle containing Cy5-labeled pDNA solution (300 μl solution with 50 μg pDNA) is injected intravenously through the Great saphenous vein in 5 s. Due to the tourniquet limiting the blood circulation, the hydrostatic pressure in the right foot is greatly increased and enhances the gene delivery. After 5 min, the tourniquet is released. For comparison, the same amount of naked pDNA is injected into another mouse as a control.

The gene delivery efficacy of naked pDNA and polyplex nanomicelle in terms of distribution in the



muscle and retention over time is monitored by intravital microscopy analysis using a custom-built video-rate confocal microscopy system [10, 11]. To evaluate the time-dependent change, each mouse is imaged at multiple time points of days 1, 3, and 7. In each in vivo imaging session, the mouse is anesthetized and placed on the heated plate of motorized XYZ stage. The thigh muscle is carefully exposed by skin incision without damaging fascia. GFP and Cy5 are excited by 491 and 635 nm continuous-wave DPSS laser, respectively, and detected by a photomultiplier tube through a 520 ± 17 nm and a 670 ± 17 nm band-pass filter, respectively. After the imaging, the skin incision is closed by 6–0 polyethylene suture for the follow-up imaging at later time point and triple antibiotic ointment is applied to avoid infection.

Figure 4c shows the representative images at each time point. On day 1, for both of naked pDNA and nanomicelle, the Cy5-labeled pDNA (red) is widely distributed, revealing no difference. With image analysis to identify the co-localization of GFP and Cy5 fluorescence, the ratio of nuclei with delivered pDNA can be assessed. For naked pDNA, the Cy5-labeled pDNA is significantly decreased on day 3 and completely disappeared on day 7. In contrast, for the nanomicelle, a much larger amount of pDNA is detectable until day 7. This intravital microscopy analysis clearly demonstrates the greatly improved gene delivery efficacy of nanomicelle over naked pDNA.

The second example is the in vivo tracking of systemically injected porous silicon nanoparticles at reticuloendothelial system (RES) organs – liver and spleen [12]. Drug encapsulating nanoparticles have been extensively developed to improve the pharmacokinetic features, safety, and selective accumulation to target site, compared to freely administered molecule. For anticancer treatment, the common strategy to maximize the accumulation of nanoparticles loaded with chemotherapeutic agents to the tumor relies on the enhanced permeation and retention (EPR) effect [13]. However, unfortunately, the RES in liver and spleen that works like a net catching blood circulating foreign materials such as bacteria take up the most of injected nanoparticle. As part of the immune system fighting against the environment, the RES functions so efficiently that it has been a major hurdle ultimately limiting the accumulation of nanoparticles to the tumor site, which rarely exceeds 1 % ID/g.

In this example, the accumulation of porous silicon nanoparticles in two major RES organs of liver and spleen is monitored in real time in vivo by intravital microscopy analysis [12]. As described in the previous example, a custom-built video-rate confocal microscopy system is used [10, 11]. Figure 5a is the image sequence taken at the liver from the very moment of intravenous injection of spherical-shaped porous silicon nanoparticles with diameter of 500 nm. To track the individual nanoparticles, it is fluorescently labeled by Alexa Flour 555. To visualize the liver sinusoid simultaneously, a transgenic Tie2-GFP mouse (STOCK Tg(TIE2GFP) 287Sato/J, Jackson Lab) expressing GFP under the direction of endothelial-specific receptor promoter Tie2 was used. To access the liver with high NA objective lens, a small incision is made on the abdominal skin and peritoneum of anesthetized Tie2-GFP mouse. Then the nanoparticle is injected into the blood stream by retro-orbital injection and image acquisition is started at the same time. After 7 s, the injected nanoparticle starts to appear in the liver, then rapidly accumulates as shown in Fig. 5a. Interestingly, a few particles initially attach to an endothelial cell of liver sinusoid, then they quickly attract many particles to aggregate as marked by arrowhead. This high spatial and temporal analysis based on intravital microscopy suggests that inhibiting the initial attachment of the nanoparticle to the endothelial cell of RES organs like the liver or minimizing the aggregation of the nanoparticle can be a good strategy to avoid these unwanted accumulations.

One approach to modulate the characteristics of nanoparticles is to modify their shape from spherical to anisotropic such as the plateloid (disk) or cylindroid (rod) shape as well as their size. As an example, the accumulation of two

Intravital Microscopy Analysis, Fig. 5 In vivo real time monitoring of time-dependent accumulation of systemically administered porous silicon nanoparticle in live mice. (**a**) Image sequence taken at the liver from the very moment of intravenous injection of the nanoparticle (*red*). Time-dependent accumulation of nanoparticles is clearly visualized in high resolution. Liver sinusoid (*green*) is simultaneously visualized by GFP expression under the direction of endothelial-specific receptor Tie2. Scale bars are 50 μm. (**b**) Time-dependent accumulation of plateloid shape porous silicon nanoparticles with two different sizes of 600 × 200 and 1000 × 400 nm in the liver, spleen, and melanoma tumor. Data is plotted as a mean curve ± 1 SD ($n = 4$ animal) (Modified from Ref. [12])

plateloid-shaped nanoparticles with different sizes of 600 × 200 and 1000 × 400 nm in the liver, spleen, and tumor is monitored by similar intravital microscopy analysis. Tumor is generated by subcutaneous injection of 10^6 mouse melanoma cells (B16F10) at the flank of live Tie2-GFP mouse, then left for 1 week to allow the tumor to grow in 3–5 mm size. Figure 5b shows the time-dependent accumulation of plateloid-shaped nanoparticles over 30 min from the systemic administration by intravenous injection. For the first 5 min, the number of accumulated nanoparticles rapidly increases and then slows down (600 nm) or begins to level off (1000 nm) in all three sites. In the RES organs, liver, and spleen, the 600 nm particles accumulate much faster than the 1000 nm particles in about three times. Interestingly, this trend becomes opposite in the tumor that the 1000 nm particles accumulate in about four times faster, later confirmed by traditional ex vivo analysis like ICP-AES or histological observation.

Perspectives

Intravital microscopy to visualize a dynamic cellular process in a living animal with submicron resolution can provide valuable new insights that are unobtainable by other analyses. During last

decade, this unique capability makes intravital microscopy to be one of most popular tool for many fields of biology, such as immunology [14], cancer biology [15], neuroscience [16], and neuropathology [17]. Naturally, in the field of nanotechnology aiming biomedical application involving living organism, it is clear that intravital microscopy analysis will emerge as a new powerful tool. As illustrated in the examples, for the fields of nanomedicine and nanoparticles for drug delivery, it is demonstrated that intravital microscopy analysis can provide new insights to improve the current understanding about interactions of nanomaterial with cellular compartments in live animal. On the other hand, for the field of intravital microscopy, nonorganic optical probes based on nanotechnology such as fluorescent quantum dot and nonlinear optical signal generating nanoparticles emerges as a novel contrast agent with highly desirable features like enhanced photostability and near-infrared emission. Combined with rapid technical advances in laser source, optical detector, and micro-optics, these new nanoprobes can greatly expand the applications of intravital microscopy.

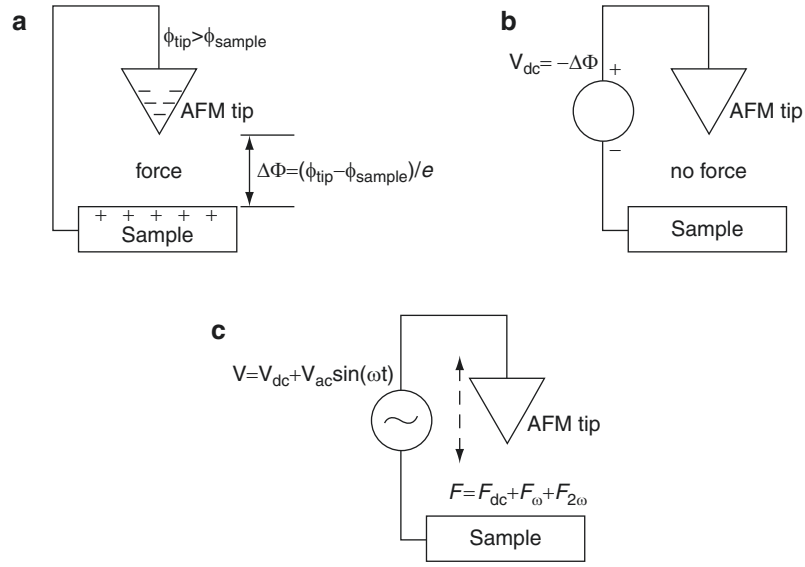
Definition

Kelvin probe force microscopy (KPFM) is an atomic force microscopy (AFM)-based technique used to measure the surface potential and work function properties of a material surface interacting with a conductive AFM probe.



Overview

The applications of atomic force microscopy (AFM) have continuously evolved to include the measurement of properties aside from surface topography. To date, the AFM is widely used for the characterization of surface/near-surface properties such as friction, adhesion, scratch, wear, fabrication/machining, electrical properties, local deformation, nanoindentation, local surface elasticity, viscoelasticity, and boundary lubrication.

The mapping of surface or near-surface electrical properties using the AFM is possible through the use of an electrically conducting tip, which acts as a movable top electrode that can locally set a potential difference between the tip and the sample of interest. As the cantilever tip is scanned above the sample, the tip can sense the response to the electrical potential. An advantage of conducting electrical AFM is that the topography and electrical properties can be obtained simultaneously during the experiment [2].

The contact, intermittent (tapping) and noncontact operating modes, along with the use of a conductive tip, extended the application of AFM from topographic imaging to electrical surface characterization [2–4, 6]. The ability to detect the surface potential difference between the tip and sample, with the tip lifted a certain distance above the sample, has led to Kelvin Probe Force Microscopy (KPFM). The ability for capacitance measurements, such as in *n*-type silicon, led to Scanning Capacitance Microscopy (SCM). Deflection detection for electromechanical response of ferroelectric films led to Piezoresponse Force Microscopy (PFM). The detection of current through oxide films led to Conductive AFM (CAFM) and on doped samples as a function of the load led to Scanning Spreading Resistance Microscopy (SSRM). The studies of current flowing into constrictions in

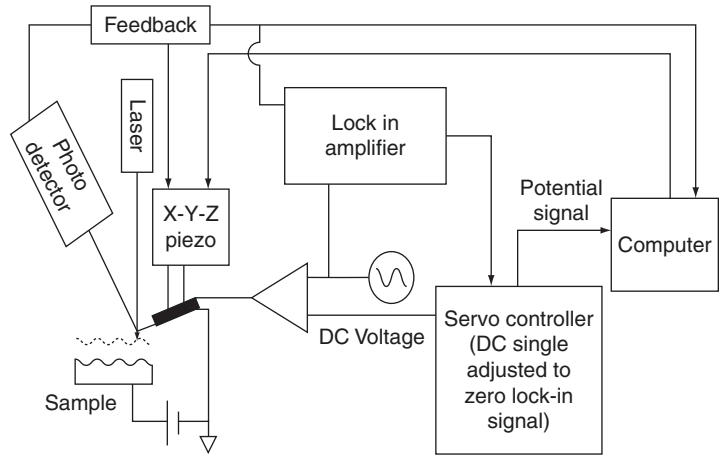
two-dimensional semiconductor structures led to Scanning Gate Microscopy (SGM). The detection of frequency dependence force applying a voltage across a sample in $BiFeO_3$ and *p*-doped silicon led to Scanning Impedance Microscopy (SIM). A recently reported new technique to map capacitance, impedance, and dielectric constant variations is called Scanning Microwave Microscopy (SMM). This technique studies the electromagnetic tip–sample interactions using a specially designed conductive probe to send and receive microwave signals up to GHz frequencies.



The focus of this entry is on Kelvin probe force microscopy. Since the surface potential measurements are highly sensitive to surface charge variations, KPFM is widely used in detecting the dopant concentration and the dopant type (either *p*-type or *n*-type) on semiconductor materials. Non-semiconductor applications of KPFM include the characterization of adsorbates on Si substrates, intermetallic grain formation on metal films, nanotribology studies, and the degradation of inorganic materials for batteries, among others.

Kelvin Probe Force Microscopy Principles

Kelvin probe force microscopy is used to measure the surface potential with the AFM in noncontact mode, and is based on the Kelvin probe principle [3, 4, 10]. To describe the operating principle behind KPFM, consider a tip and sample interaction as shown in Fig. 1. When the tip and sample are electrically connected (Fig. 1a), electrons flow from the material with the lower work function to the material with the higher work function. Due to the difference in the work function of the electrically connected tip and the sample, an electrostatic contact potential difference (or surface potential) is created between the tip and the sample. The value of this contact potential difference ($\Delta\Phi$) is given by the following equation:

$$\Delta\Phi = \frac{\Phi_{tip} - \Phi_{sample}}{e} \tag{1}$$

where Φ_{tip} and Φ_{sample} are work functions of the tip and the sample, respectively, and e is the magnitude of the charge of one electron. The contact potential difference provides material contrast information, because it is sensitive to adsorbed molecules on the surface or the presence of various phases within a given material. Electrostatic force is created between the tip and sample under the influence of this surface potential difference and the separation-dependent local capacitance C of the tip and sample. This force is given by

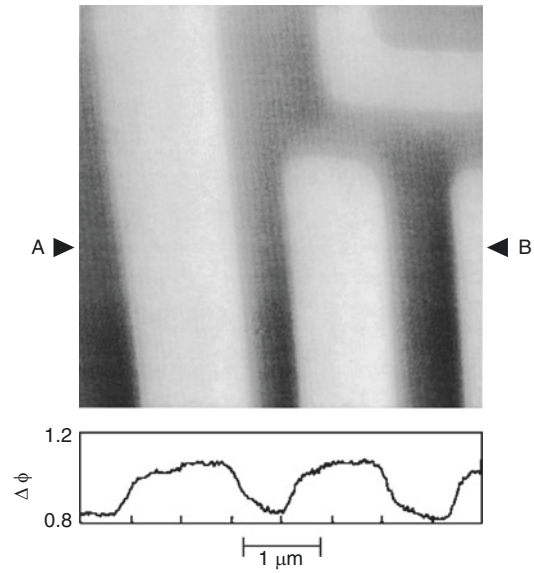
Kelvin Probe Force Microscopy,
Fig. 2 Schematic of the interleave scan method used in KPFM, where the first pass records the height profile performed in tapping mode, and the second pass in lift mode monitors the variations of electrostatic force at a constant height [12]

$$F = \frac{1}{2}(\Delta\Phi)^2 \frac{\partial C}{\partial z} \tag{2}$$

where z is the distance between the tip and sample.

In KPFM, an AC voltage signal ($V_{AC}\sin(\omega t)$) with an adjustable offset DC voltage (V_{DC}) is applied to the conducting tip (Fig. 1b and c). As shown in (Eq. 3), the electrostatic force is the sum of three components, namely, the DC force, a harmonic force with the same frequency of the AC tip bias (the first harmonic), and a harmonic force at double the frequency of the AC signal (the second harmonic):

$$\begin{aligned} F &= \underbrace{\frac{1}{2}\frac{\partial C}{\partial z}\left\{(\nabla\Phi + V_{DC})^2 + \frac{{V_{AC}}^2}{2}\right\}}_{\text{DC term}} \\ &+ \underbrace{\frac{\partial C}{\partial z}(\Delta\Phi + V_{DC})V_{AC}\sin(\omega t)}_{\omega \text{ term}} F \\ &= \underbrace{\frac{1}{4}\frac{\partial C}{\partial z}{V_{AC}}^2\cos(2\omega t)}_{2\omega \text{ term}} \end{aligned} \tag{3}$$



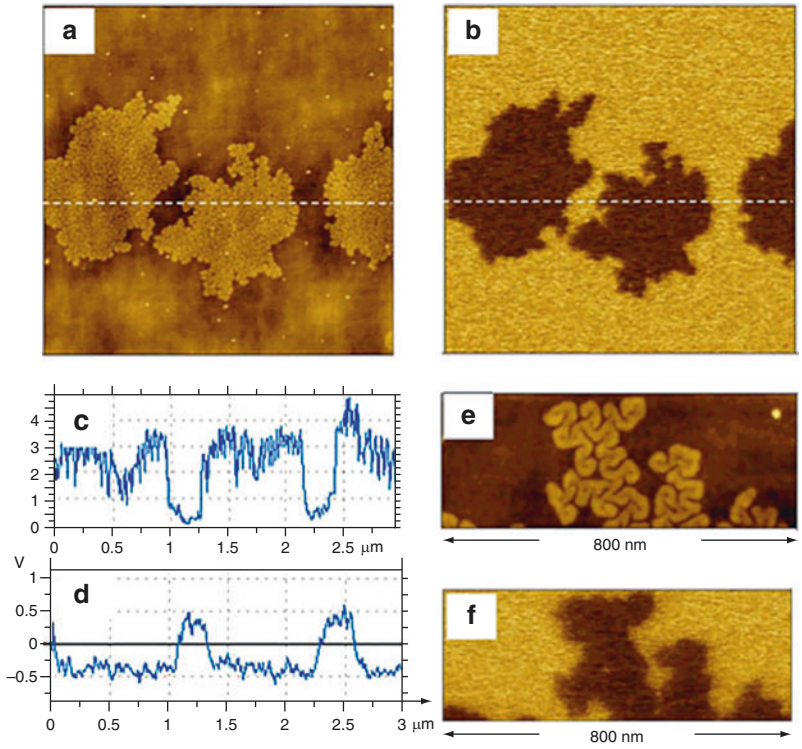
The electrostatic force is used to adjust the externally applied voltage in order to compensate the contact potential until the force between the tip and the sample is nulled. This is attained when the difference between the work functions of the tip and sample is equal to the external voltage. The presence of different materials on the sample surface leads to the formation of different material interfaces (with the tip), each having their own value of the contact potential difference. This leads to surface potential contrast [9].

In the initial implementation of KPFM, the topography and potential are measured simultaneously using two feedback circuits [13]. Subsequent modifications to the setup involve the sequential measurement of topography and potential in the so-called lift mode, which is regarded to improve on the lateral resolution of the topographic image [9]. A schematic of the two-pass lift or interleave scan method used in KPFM experiments is shown in Fig. 2. On the first pass, surface height information is recorded in the standard tapping mode where the oscillating cantilever lightly taps the surface. On the second pass, the feedback loop controlling the vertical piezo is turned off, and the tip is lifted from the surface and traced following the surface profile acquired in the first pass and at constant tip–sample separation distance [7, 8]. An oscillating potential is applied to the DC-biased tip (the tip oscillation is electrically driven). The oscillating potential frequency is equal to the cantilever's resonance frequency. An extra feedback loop is used to adjust the DC bias on the tip to nullify the first harmonic component of the electrostatic force [5, 9].

A more recent implementation of the KPFM experiment involves the detection of the surface potential using a frequency modulation technique instead of the amplitude modulation method. The main difference between these two methods is that amplitude modulation is sensitive to the

electrostatic force, while frequency modulation is sensitive to its gradient. Instead of having one feedback control/lock-in amplifier system that sequentially records the topography and surface potential, a separate lock-in amplifier is used in the frequency modulation KPFM experiment to detect surface potential. The frequency modulation method has been shown to measure a potential difference in close agreement with macroscopic measurements, and is thus regarded as a more quantitative potential measurement technique compared to amplitude modulation [16].

As mentioned earlier, KPFM is widely used in characterizing the doping of semiconductors, and it can also be utilized for non-semiconductor materials. Examples of KPFM applications are described next.



Kelvin Probe Force Microscopy, Fig. 3 Surface potential image of a silicon *pn* junction (*above*), with the *bright* and *dark areas* corresponding to the *p*-type and *n*-type regions, respectively. The cross section (*below*) refers to the scan defined by the line A-B on the image, where Δφ is the surface potential relative to the probe surface potential [11]

Applications of KPFM

An example of the applicability of KPFM to semiconductor materials is shown in Fig. 3, which is a surface potential image of a *pn* junction on a silicon wafer created through ion implantation. Below the image is a corresponding cross section of the scan defined by the line A-B on the image [11]. The contrast in the surface potential image is induced by the charge carriers introduced by the ion implantation process. The brighter features correspond to areas with a higher surface potential. In this case, the surface potential in the *p*-type region is higher than in the *n*-type region. This is attributed to the bending of energy bands at the subsurface as a result of the trapping of charge carriers in surface states [11].

KPFM has been used in the characterization of perfluoroalkyl alkanes self-assembled on substrates such as graphite, mica, and silicon. As an example, Fig. 4 shows images of $F_{14}H_{20}$ adsorbates on a Si substrate [1]. Topography and surface potential images of the adsorbate layers show clusters in Fig. 4a and b. In the surface potential image, the difference between the adsorbates and silicon shows a high contrast. In Fig. 4c and d, the profiles of the white lines marked in Fig. 4a and b are displayed. The profiles indicate that there is a large surface potential drop of ± 0.5 V within the adsorbate clusters as a result of possible repulsion of the adsorbate composition. A correlation between the surface potential and the topography image suggests that the surface potential corresponds to the adsorbate clusters. The magnified images in Fig. 4e and f also revealed a particular shape in the cluster, spiral structures. In the example KPFM images, the capacity of the technique to detect different surface potentials on the sample is shown.

Figure 5 shows a KPFM application to recognize constituent materials in a metal alloy film [14]. In this example, an alloy consisting of Al and Cu were deposited as 5 μm lines on a silicon substrate. The lines in the contact potential difference image in Fig. 5a contain features that are not present in the topographic image shown in Fig. 5b. In the potential image, the dark features contained within the lines correspond to the Al/Cu intermetallic that forms on the grain boundaries, which has a lower contact potential difference relative to the surrounding Al regions. The clear

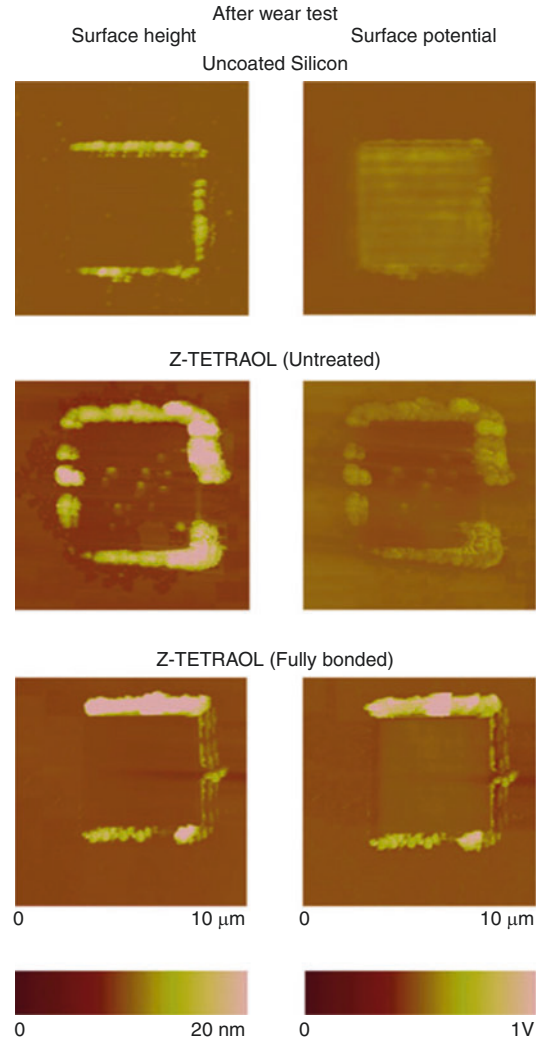
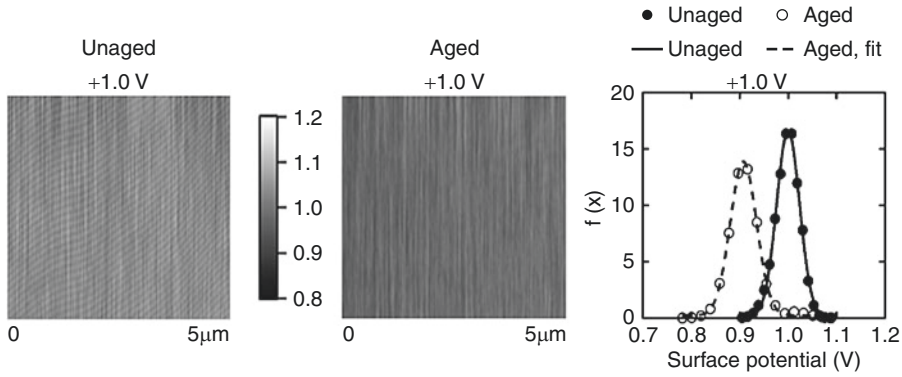
contrast between the Al/Cu and Al shows the capacity of KPFM as a technique to identify the presence of different materials on alloy surfaces at the nanoscale.



KPFM can also be applied to nanotribological studies, specifically for studies involving wear initiation. In Fig. 6, surface height and surface potential data (taken after nanoscale wear tests were performed) are shown for silicon surfaces coated with the perfluoropolyether lubricant Z-TETRAOL. The lubricant is applied using two different techniques, such that the samples are either untreated or fully bonded. Data for the uncoated silicon surface subjected to the same wear test procedure is shown for reference [15].

The surface height and surface potential images in Fig. 6 show contrast on both sets of images. Compared to the uncoated silicon surface, reduction in the debris is observed in the partially bonded samples. This indicates that the lubricant is able to provide wear protection. The pileup of debris observed in the untreated sample could be a combination of removed fragments of Si as well as the weakly bound lubricant. The untreated sample with its mobile lubricant fraction exhibits a lower surface potential change compared to the fully bonded sample, which only has immobile lubricant molecules. This is attributed to lubricant replenishment by the mobile lubricant molecules present on the untreated sample. In general, a considerable surface potential change is observed on the wear region when: (1) the lubricant has been fully removed from the substrate; (2) the native SiO_2 layer has been abraded from the surface; (3) wear has caused subsurface structural changes; and (4) charges build up as the charges are unable to dissipate into the surrounding material [15].

Finally, the application of KPFM in studying material degradation is illustrated for the aging of lithium-ion batteries. The surface potential maps of the unaged and aged $LiFePO_4$ cathode samples are shown in Fig. 7 [12]. The maps were collected by applying +1.0 V from an external DC voltage source. On the surface potential maps for both the unaged and aged sample, a small difference in the contrast is observed, suggesting an almost uniform dissipation of charge over the surface of the samples under the externally applied voltage. This



Kelvin Probe Force Microscopy, Fig. 5 KPFM study of various intermetallics in a metal alloy: (**a**) surface potential image of Al/Cu film showing contrast between Al and the Al/Cu intermetallic (*the dark points*); the scan field is 40 × 40 μm, (**b**) AFM topography image [14]

Kelvin Probe Force Microscopy, Fig. 6 Surface height and surface potential maps after wear tests for an uncoated silicon wafer and two types of Z-TETRAOL-lubricated silicon wafers (untreated and fully bonded). The *brighter areas* correspond to higher values of both the height and surface potential

indicates that under the external source the sample tends to charge uniformly even in an aged condition. The uniform charging is good for the cell as it avoids large local currents and subsequent damage to the cathode. The last column of Fig. 7 shows the distribution of the collected data points in unaged and aged cathodes. Then a normal probability density function is used to fit the histogram data. The unaged sample had mean values of the surface potential almost equivalent to the external applied voltage. The mean values of surface potential on the aged sample are lower than that of the unaged sample. Thus, even though the externally applied voltage was the same for the unaged and aged samples, the charge sustained on the surface of the aged cathode is less than that sustained on the unaged cathode [12].

The work function of the tip is constant in each surface potential map, since the same kind of tip is used in both samples. Therefore, Fig. 7 shows the

Kelvin Probe Force Microscopy, Fig. 7 Surface potential map of the unaged (*left column*) and the aged (*middle column*) $LiFePO_4$ cathode samples with external voltage of + 1 V. The *right column* shows the normal probability density distribution of the surface potential for the unaged and aged samples, indicating that the mean value of the surface potential decreases after aging

change in the work function of the aged sample relative to the unaged sample. The decreased surface potential in the aged sample is an indication of surface modification as a result of the phase change of the cathode material upon degradation [12]).

Definitions

Lab-on-a-chip (LOC) is a general term used to describe microdevices that integrate and scale down single or multiple laboratory functions and processes to a miniaturized chip format. The main characteristic of LOC devices is that they are able to handle extremely small fluid volumes down to less than pico-liters. This feature enables the analysis of very small samples in short time. LOC devices have recently been developed as micro-engineering approaches to small-size animal model research offering several advantages over conventional approaches, such as control of the microenvironment, automation, and high-throughput analysis.

Caenorhabditis elegans (*C. elegans*) is a small, transparent, nonparasitic nematode that is used as a model organism for the study of multiple biological processes such as development, genetics, and neurobiology. This is mainly due to the fact that this animal is small in size, has a rapid life cycle, and it is easy to manipulate and cultivate in controlled laboratory conditions. In addition, there are many human disease models available in this model organism providing an in vivo environment for the study of these diseases over other approaches such as cell culture.

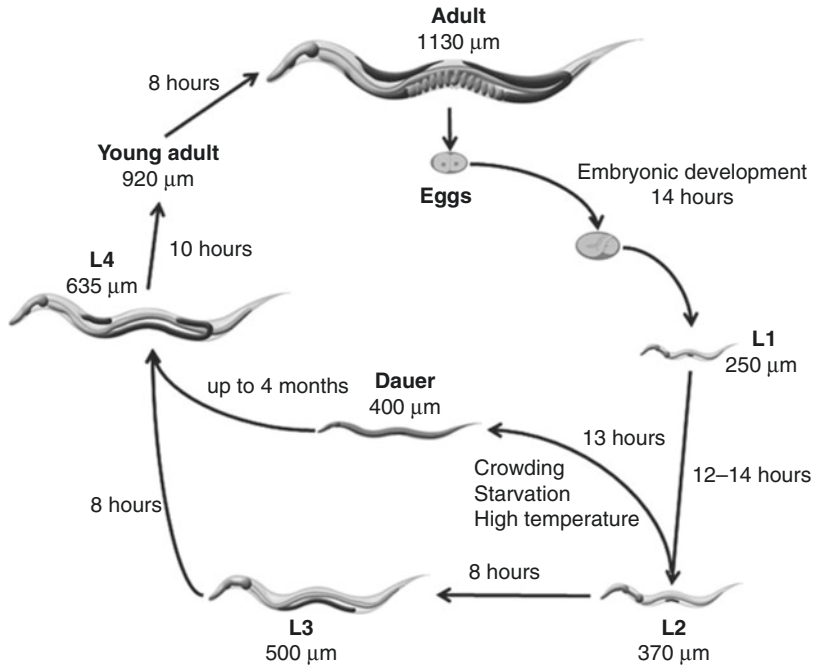
Overview

The possibility to perform laboratory operations on a small scale using miniaturized lab-on-a-chip devices has become in recent years a real tool for which biologists show an increasing interest. The use of small volume samples leads to a reduction

© Springer Science+Business Media Dordrecht 2016
B. Bhushan (ed.), *Encyclopedia of Nanotechnology*,
DOI 10.1007/978-94-017-9780-1

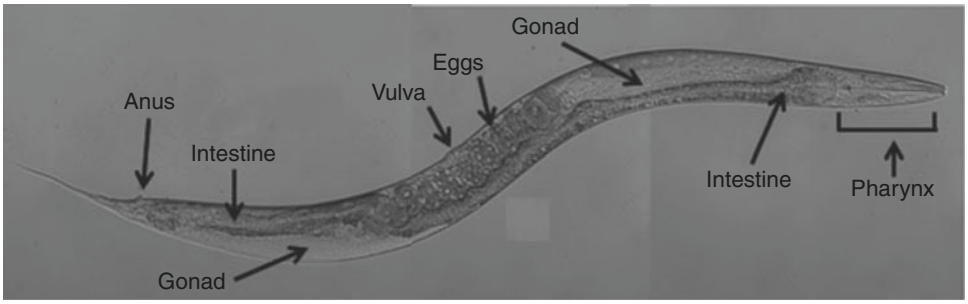
in the time taken to perform an experiment and analyze the result; it also reduces the cost of the analysis. Together with the ability to automate sample manipulation and analysis, the use of LOC devices brings with it the potential to analyze very large populations of animals and to perform high-throughput analysis, which could not be done prior to the development of these new techniques.

C. elegans has been used as a model organism for the last 40 years. The multiple characteristics that make this nematode an excellent model organism for the study of a wide range of biological processes will be discussed further in this text.



In this entry, an introduction to the use of *C. elegans* as a model organism in a range of different biological scenarios will be provided, outlining the basic requirements of LOC devices to be used for the study of multicellular organisms and highlighting the technical challenges they have had to overcome. Finally, some approaches that so far have been of particular value for the study of *C. elegans* will be shown.

Introduction to *C. elegans*



C. elegans Physiology

Caenorhabditis elegans (*C. elegans*) is a small, transparent, free-living nematode which lives in temperate soil environments feeding on bacteria and fungi. It can often be found in compost heaps, fallen fruits, and some invertebrates, but hardly anything is known about its life in the wild.

C. elegans is small. The length of the adult hermaphrodite worm is around 1.2–1.5 mm and the diameter 30–40 μm. It also has a very short life cycle (compared to other model organisms) of about 3 days under optimal conditions of food and temperature (Fig. 1). The life cycle of these

Lab-on-a-Chip for Studies in *C. elegans*, Fig. 1 Representation of the life cycle of *C. elegans*. The different stages of growth: egg, L1, L2, L3, L4, and adult are shown. Adult worms are fertile and capable of laying eggs. These are laid outside during the gastrula stage. If worms are deprived of food in larval stages or environmental conditions are not optimal they will enter a larval stage known as dauer, in which development is arrested. When food becomes available development will continue. Numbers along the *arrows* indicate the length of time the animal spends at a certain stage. The length of the animal at each stage is marked underneath the stage name in micrometers (μm) (Reproduced from [28] with permission)

Lab-on-a-Chip for Studies in *C. elegans*, Fig. 2 Anatomical features of an adult hermaphrodite *C. elegans*. *Arrows* point to the main features of the worm: the pharynx, intestine, vulva, and gonad

nematodes starts with the fertilization of the eggs within the adult hermaphrodite. The fertilized eggs are laid when they are at the gastrula stage and contain about 40 cells. Embryogenesis occurs in 12–14 h after which the animal goes through four juvenile stages (L1–L4) each of which ends in a molt. Following the final molt, the animals reach adulthood at which point they become fertile producing about 300 progeny each over the course of 3 days. When environmental conditions are not optimal (e.g., high temperature, overcrowded cultures, or starvation), the L3 stage is replaced by a dauer larval stage that corresponds to the infectious stage of parasitic nematodes. The dauer of free-living soil nematodes is sometimes associated with some invertebrates. Dauer larvae are thin and are unable to feed because their mouths are closed with a cuticle but survive high temperatures and other harsh conditions much better than adult worms. Most interestingly, they can remain viable for 3 months and resume the L4 reproductive stage when they encounter more favorable environmental conditions. Adult worms have an average life span of 2–3 weeks.

C. elegans displays two sexes: hermaphrodites and males. In culture, males are produced spontaneously at low frequency (about 0.1 %) but their frequency and crossing rate in the wild are unknown. The hermaphrodite produces both sperm and oocytes and can therefore either self-fertilize or be fertilized by a male.

The worms are cylindrical in shape. They essentially consist of an inner and outer tube separated by the pseudocoelomic space. The inner tube contains the gonad, pharynx, and intestine and the outer tube contains neurons, muscle, excretory system, hypodermis, and cuticle. Figure 2 shows a photograph of the anatomical features of a gravid adult *C. elegans* with the pharynx, intestine, and the reproductive system highlighted.

The hermaphrodite and male worms consist of a constant number of somatic cells of 959 and 1,031, respectively. The haploid genome size is relatively small (9.7×10^7 base pairs) about 30 times smaller than the human genome and contains near 20,000 genes. In 1998, *C. elegans* became the first multicellular organism to have its genome fully sequenced. About 35 % of *C. elegans* genes have human homologs. The genome consists of five pairs of autosomal chromosomes and a pair of sex chromosomes: XX in the hermaphrodite and XO in the male.

C. elegans development has been fully characterized, meaning the complete cell lineage of the worm has been recorded. All the cell divisions required to generate a specific group of differentiated cells has been documented for the whole animal [1].

C. elegans as a Model Organism

In 1974, Sydney Brenner established *C. elegans* as a model organism when working on the genetics of the animal development (including neural development), behavior, and physiology [2]. Brenner, with his exhaustive labor, set up the basis for today's worm research and as recognition for this work he was awarded the Nobel Prize in Physiology or Medicine in 2002.

There are several important features that make *C. elegans* an attractive organism not only for the study of gene regulation and gene function, but also for the study of many other different relevant biological aspects including development, cell biology, behavior, and neurobiology. *C. elegans* is easy and cheap to maintain in the laboratory. It grows on agar plates feeding on *Escherichia coli* lawns. It can also be grown in liquid cultures in large quantities. *C. elegans* is a multicellular organism which goes through a complex developmental process, including embryogenesis, morphogenesis, and growth to adulthood. As mentioned before, it has a short life cycle which is an advantage for developmental studies. It is transparent; therefore, it is possible to use fluorescent makers in order to track different cell types and tissues and to perform high-resolution microscopy.

C. elegans is one of the simplest organisms with a nervous system comprised of only 302 neurons. Nevertheless, it exhibits complex behavioral modalities, such as habituation, sensitization and conditioning in response to stimulus. *C. elegans* nervous system has been completely mapped and all neuronal connections are known. Using microfluidic platforms it has been possible to perform precise neuronal ablations and study the phenotypic and behavioral consequences of this in a high-throughput manner.

In comparison to other model organisms *C. elegans* has a relative short lifespan representing a useful model for the study of aging. Due to its small size it is possible to perform high-throughput drug screening assays. For example, *C. elegans* provides a useful model for the investigation of the mode of action of anthelmintics (group of compounds to treat infections caused by parasitic nematodes). As mentioned earlier, *C. elegans* displays a particular mode of reproduction with self-fertilizing hermaphrodites and facultative males which makes it an interesting model for population genetic studies. Males arise infrequently in *C. elegans* populations, about 0.1 %. This percentage can be increased through heat-shock of L4 hermaphrodites. Once males have been obtained, a population containing up to 50 % males can be maintained through mating.

C. elegans also has the advantage of being amenable to genetic manipulation, through mutagenesis, transgene expression, and RNA interference (RNAi) partly because of its rapid life cycle, small size, and ease of laboratory cultivation. When investigating molecular mechanisms in *C. elegans* either forward or reverse approaches can be taken. Reverse genetic techniques are hypothesis driven. Analysis of the phenotypes of mutants with specific mutations can be used to inform about the role of genes in a drug's mode of action. Alternatively, RNA interference can be used to knock down the expression of specific genes allowing, for example, the study of morphological or behavioral changes associated with the gene.

A number of microfluidic approaches that exploit several of these *C. elegans* features have been described and will be further discussed in the text.

Introduction to Worm Chip Technology

Lab-on-a-chip (LOC) devices provide the ability to perform multiple laboratory operations in a miniaturized chip format. This is mainly due to the fact that they handle extremely small fluid volumes reducing the amount of sample and time needed for a particular analysis. Worm chips, as they are commonly described, are microfabricated LOC devices capable of manipulating single worms or a population of worms and their environment in a precise and automated fashion.

The advantages provided by LOC devices depend very specifically on their applications. In general: (1) they handle very low fluid volumes reducing the cost and sample volume needed for the analysis; (2) they are very efficient systems because they provide high control of the experimental conditions (e.g., thermal control, short diffusion distances); (3) they allow high-throughput analysis because being very compact, LOC systems are capable of massive parallelization; and (4) they can be mass produced with low fabrication costs, allowing cost-effective disposable chips.

LOC devices belong to a broader group of small mechanical devices known as MEMS (Micro-Electro-Mechanical-Systems). Worm chips usually integrate MEMS components to provide flow control (microchannels, pumps, mixers, and valves) and sensing capabilities to the devices (optical or electrochemical sensors) with microfluidics platforms (to deal with and manipulate tiny volumes of fluid samples) [3].

Worm Chip Materials and Fabrication Technologies

Worm chips can be fabricated from many types of material including various polymers, glass, or silicon, or combinations of these materials. A broad variety of fabrication technologies are used for LOC device fabrication; the most frequent being single layer or multilayer soft lithography.

Soft lithography-based microfluidic devices are typically made in polydimethylsiloxane (PDMS). This polymer offers several benefits for biological research including biocompatibility, high permeability to gas, a chemical inert surface, and optical transparency down to 300 nm. The chips normally have a closed architecture as they are sealed with a glass slide, a PDMS layer, or an agar plate. Worm chips that include MEMS are normally fabricated using standard silicon and polymer micromachining processes, which requires expertise in microfabrication and access to a clean room.

Photolithography is the most common method of fabrication of microfluidic devices. Typically it consists of the transfer of a pattern into a photosensitive material by selective exposure to a radiation source such as light. Following the creation of a template (replica mold) PDMS can be cast against it to form the microfluidic devices. This process is cost effective and can be performed in any traditional laboratory setting with the mold being used repeatedly [4].

Worm Chip Technical Challenges

The study of multicellular organisms using microfluidic devices presents some technical challenges that when controlled allow high-throughput phenotyping, screening, imaging, and sorting of small animals in an automated manner. In particular, the organisms need to be handled efficiently and the microenvironment created for the experiment needs to be precisely controlled. Environment parameters, to be controlled, include temperature, nutrients, dissolved gas, and stimuli delivered to the animals.

Worm chips have been designed for the detailed analysis of single worm phenotype. The manipulation in this type of chips involves complete or partial immobilization of the worm. The movement of the worm can be restricted physically or by applying glue, cold, or CO_2. Some examples of immobilization of the worms on chip will be discussed further in section "Key Research Findings: Applications of LOC Devices to the Study of C. elegans." Other worm chips have been designed for the analysis of large populations of animals and do not restrict worm movement. These types of chips are mainly used to study worm behavior and locomotion [5].

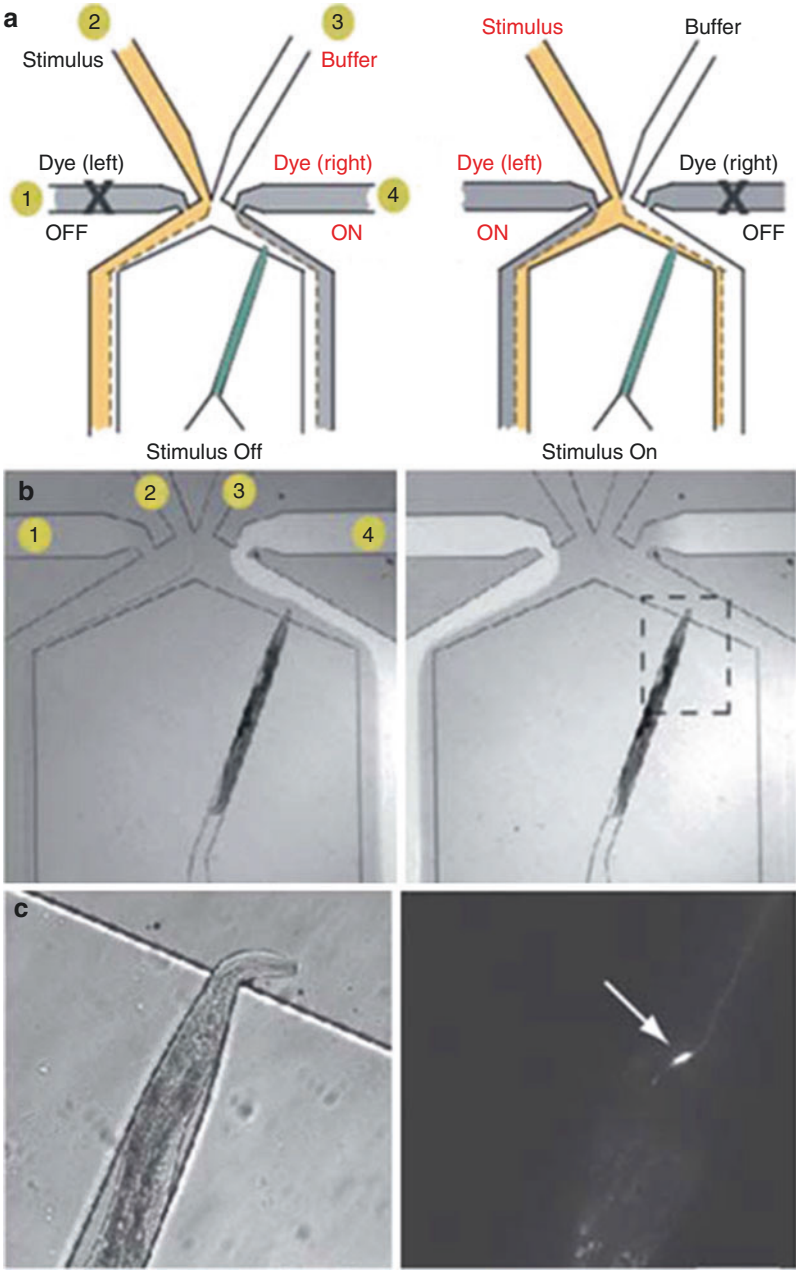
Key Research Findings: Applications of LOC Devices to the Study of *C. elegans*

The development of LOC devices for the study of small animals is a new area of research still in progress. Worm chips capable of performing high-throughput studies show great potential to provide a better understanding of key aspects of the biology of nematodes. In this section, a few examples of microfluidic devices designed to study different aspects of the worm biology will be shown and some technical challenges will be highlighted.

Immobilization of Single Animals: Suction Pipette, Glue, Physical Restraint (Worm Trap), Suction Microchannel (Aspiration)

As discussed above, one of the challenges that LOC devices have had to overcome in order to be able to study relevant aspects of the biology of *C. elegans* is the total or partial immobilization of the whole animal. *C. elegans* is a very active animal. It constantly explores the environment while searching for food (foraging behavior). In the laboratory *C. elegans* is normally cultivated on agar plates where it exhibits a sinusoidal

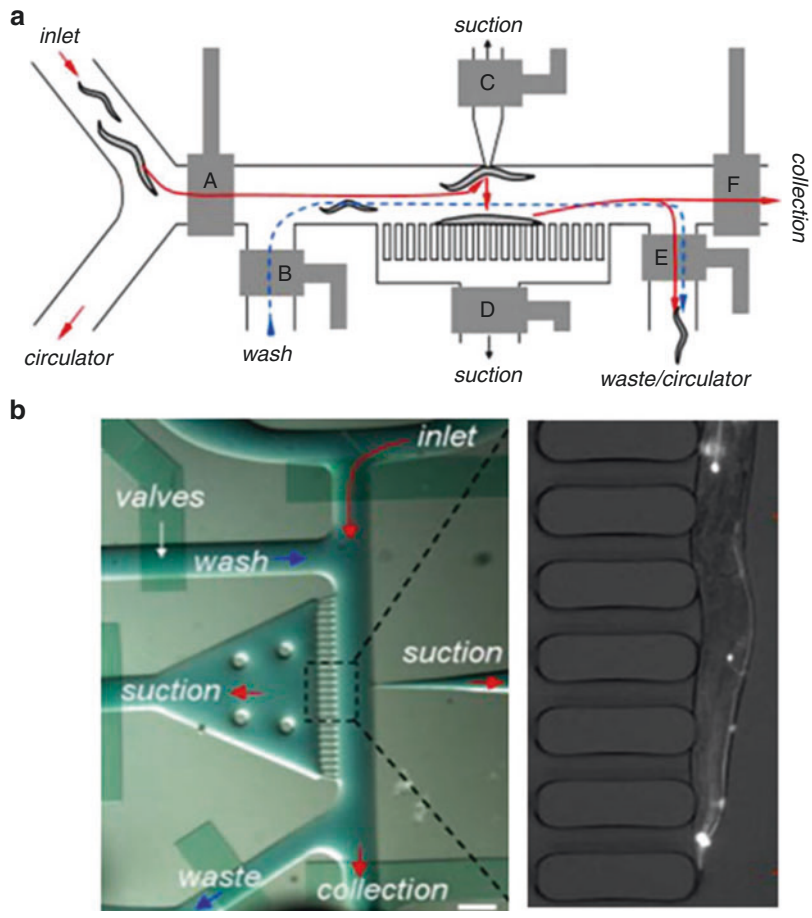
forward and backward movement of unpredictable direction. Locomotion behavior is often measured and quantified by researchers to describe the healthy status of the worm. Immobilization of the animal is a key element in order to get high-resolution images of various anatomical features or to image cellular development and gene expression. In addition, immobilization of the worm is required to precisely deliver stimuli taking control of the microenvironment conditions for the experiment, to perform laser ablations of individual neurons for studying neural networks, axon regeneration, or monitoring neuronal responses at the presence of various stimuli.



One of the first microfluidic devices developed to study biological questions using *C. elegans* addressed the issue of immobilization of the worm in a flowing solution; this was achieved by holding the animal by the tail using a suction pipette. Forward and backward movement was recorded in response to different chemical stimuli using an array of photocells connected to a multichannel chart recorder [6]. This allowed, for the first time, to control the timing of the stimulus presented to the worm and behavioral events were recorded with relatively high time resolution thus allowing the determination of changes in behavior. With this device the author demonstrated the mechanism of chemotaxis and described for the first time that the frequency of change of direction varied with stimulus intensity in the appropriate direction and the animal does adapt rapidly.

C. elegans evaluates the quality of its environment through a complex and versatile chemosensory system. Peripheral chemosensation is highly divergent between mammals and *C. elegans*, but regulatory and behavioral mechanisms appear to be more conserved across species. *C. elegans*' chemosensory behavior was tested again a few years later on a device where the worm was semi-restrained. The anterior part of the worm was glued to the substrate and the worm's behavior was recorded and analyzed quantitatively [7]. The use of mutant worms in this study provided insight into the understanding of the neural basis of behavior and represented a new technique to use in combination with genetic or neuronal manipulations.

More sophistication in the design of the LOC devices was shown by Chronis et al. In their device to measure olfactory neuron activity, the worm was physically immobilized in a narrow space (i.e., no glue or anesthetic was used) (Fig. 3). This device combined the concept of worm trap (used as well to analyze multiple worms at the same time [8]) with a microfluidic chemical delivery system and allowed to measure the activity of chemosensory neurons in response to chemosensory stimuli [9]. The same authors also designed a chip to measure neural activity in relation to behavior. In this device the worms, one at a time, were able to move forward and backward and neural activity could be measured simultaneously for the first time. The results that emerged from this study had a high biological relevance. Prior to this work, nobody had shown neural activity in real time; this revealed important finds relating to the behavior of the olfactory neurons. Olfactory neurons are activated in the absence of the stimuli (food odor) and remain deactivated when the food odor appears. The amount of activity of the neuron depends on how strong the odor is and how long it lasts.



A microsystem for high-throughput whole animal sorting and screening at subcellular resolution was developed by Rohde et al. [10]. The device was capable of isolating and immobilizing single worms for the screening of phenotypic features at subcellular resolution in live animals (Fig. 4). The animals were exposed to biochemical compounds and high-resolution time-lapse imaging of many individual worms on a single chip, without the need of anesthesia, was performed. Individual worms were capture in an immobilization chamber via suction by a microchannel held at a low pressure and imaged using high-resolution optics. After image acquisition and processing, the worm can be released and directed to the appropriate collection channels according to its phenotype.

Zeng et al. presented in 2008 an improved immobilization system for single animals that allowed performing techniques such as femtosecond-laser manipulation (laser microsurgery) and three-dimensional two-photon

Lab-on-a-Chip for Studies in *C. elegans*, Fig. 3 Lab-on-a-chip device to measure olfactory neuron activity in response to chemosensory stimuli. (**a**) The chip consists of two channels (*1* and *4*) loaded with fluorescent dyes that are used to redirect the chemical stimulus (applied in channel *2*) to the nose of the worm. (**b**, **c**) Higher magnification photographs of a worm trapped in the chip. The *arrow* points to a sensory neuron which is expressing a fluorescent marker in response to the stimulus delivered (Reproduced from [5, 9] with permission)

microscopy (which cannot be done on anesthetized animals) [11]. They described their immobilization method as fast and noninvasive because it did not require the use of anesthesia or cooling and allowed high-throughput on-chip worm manipulation at subcellular level. The device combined aspiration channels to capture and align the animals in a linear position (achieving partial immobilization) and a "sealing membrane" that flexed on top of the captured animal forming a tight seal which completely restrained the motion in a linear orientation. This method allowed highly demanding subcellular resolution imaging and manipulation techniques (such as laser microsurgery for precision ablation with minimal collateral damage and 3D two-photon microscopy

Lab-on-a-Chip for Studies in *C. elegans*, Fig. 4 Microfluidic worm sorter. (**a**) The sorter consists of control channels and valves (labeled with the letters *A–F*) that direct the flow of worms in different directions in the flow channels. Animals enter the chip through the inlet channel and can be continuously recirculated. The immobilization chamber captures one worm each time via suction by multiple microchannels held at low pressure and subsequently, the image acquisition and processing are performed. The worm is either collected or directed to the waste, depending on its phenotype. (**b**) Image of the worm sorter and a worm trapped in the system. Bright spots along the animal show mechanosensory neurons expressing a fluorescent reporter (Reproduced from [10] with permission)

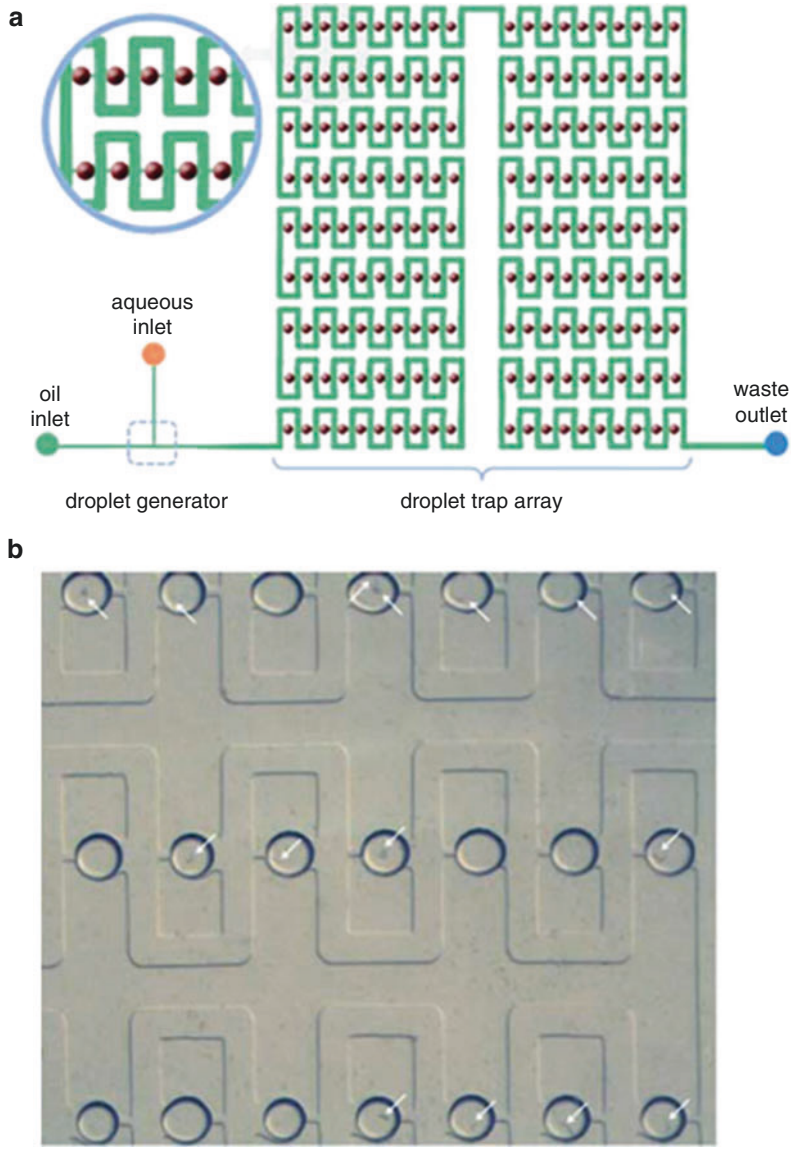
including two-photon excitation fluorescence or TPEF) that required long periods of stable immobilization.

Immobilization of Multiple Animals: Arrays of Worm Traps, Chip-Gel Hybrid

The first micro-engineered array of clamps for worms (worm trap) was designed by Hulme et al. with the purpose of investigating the physiology and behavior of large populations of worms. The immobilization of the worms in this device was achieved by an array of wedge-shape channels (clamps) where the worms were trapped and oriented by the direction of the microfluidic flow. The purpose of this work was to identify mutants affecting anatomical structure or body size distribution of a population of worms. One major advantage of this device was that the worms could be released after the analysis by reversing the flow direction. Therefore repeated sampling of the same population of worms at different times could be performed. The authors measured life span and brood size from the released worms [8]. This type of worm chip provides a high-throughput system for morphological analysis with potential to be used for extremely delicate operations such as microsurgery; and with the combination of high-resolution optical imaging could be used for fluorescence imaging. An improved modified version of this system was used to culture *C. elegans* in liquid, in separate chambers from L4 throughout the entire life span of the worm until death [12]. The device included microfluidic worm clamps to allow the temporary and reversible immobilization of each worm, making it possible to monitor changes in body size and locomotion throughout the life span of the animal.

In 2008, Chung et al. presented the first microsystem with complete automation of sample handling for high-resolution microscopy phenotyping and sorting of *C. elegans* [13]. This device could analyze and sort several hundred worms per hour using a brief and reversible immobilization by transiently cooling to 4 °C. This system in comparison with the COPAS (Complex Object Parametric Analyzer and Sorter), which is a fluorescence-activated cell sorter modified to handle small organisms, represents a much more advanced system not limited by the tissue level. The automated microsystem is capable of high-throughput high-resolution microscopy and allows sorting based on phenotype. In this case, the authors based the sorting in the expression of a reporter in neurons.

Almost simultaneously another chip to perform laser ablations was also described [14]. The nanoaxotomy chip is a microfluidic device used to sever axons in *C. elegans* using ultrashort laser pulses with high precision and monitor axonal regeneration activity. This chip presented several advantages over the chips used previously. As mentioned before, immobilization of the animal was done without the need of glue or anesthetic therefore not interfering with physiological processes. This system used a two-layer microfluidic approach with a thin membrane between the two channels. When the top layer was pressurized the membrane deflected quickly immobilizing the worm. The chip had great flexibility in terms of being able to analyze worms from L4 to adult size; furthermore, the worms did not need a recovery period after surgery, permitting immediate behavioral studies. The chip also allowed control of the sample population.



In 2009, Chokshi et al. explored the use of CO_2 to immobilize *C. elegans* on a microfluidic chip and characterized the effect of this immobilization method on worm behavior. The authors also tested mechanical immobilization through a deformable membrane of PDMS that compressed the worm to mechanically restrict its movement (compressive immobilization). They found that CO_2 immobilization was effective and efficient for up to 2 h with low photobleaching, whereas the mechanical approach was best for shorter periods of time. Locomotion was measured as well as gene reporter expression [15, 16].

In 2010, Krajniak et al. presented a chip-gel hybrid microfluidic device for developmental studies. The novelty of this device was the use of a biocompatible polymer called Pluronic F127 as the immobilization agent in combination with a microfluidic platform. This polymer was reversibly transformed into a gel in a process that depends on temperature. The gel phase was sufficient to immobilize the animals. While the animals were not imaged they were cultured in individual chambers containing media with nutrients required for development. This device allowed culturing, individual tracking and repeated imaging of *C. elegans* at high-resolution throughout development [17].

No Immobilization: Microchamber for Small Volume Liquid Culture, CD Platform, Droplet Generator, Artificial Dirt

The appearance of the first platform to maintain and monitor *C. elegans* in a microfluidic environment arrived almost 25 years after the first example of a microfluidic device for the study of the worm. This device was designed for the experimental study of *C. elegans* in space. It consisted of a chamber able to support a tiny volume of liquid culture of *C. elegans* for long periods of time with a membrane to allow gas exchange [18]. Shadow images were acquired by a camera attached at the bottom of the microchamber. The authors measured the activity of *C. elegans* as a function of temperature finding that thrashing (stroke frequency) increased with temperature validating previous results obtained with manual counting.

As an alternative to the immobilization of the animal with glue, other platforms for culture and behavioral observation have also been used. In 2007, Kim et al. [19] described a compact disc microfluidic system for the automatic cultivation of *C. elegans*. This system showed to be proficient in automated feeding, waste removal, and live-animal microscopy using centrifugal force-driven fluidics. This system could analyze and control a population of worms in one chamber (up to three generations could be monitored over time) and measure the rate of development, brood size, and

Lab-on-a-Chip for Studies in *C. elegans*, Fig. 5 Droplet-based microfluidic system for single worm analysis. (**a**) The device consists of a parallel series of microdroplets (droplet trap array) continuously generated by shearing a dispersed aqueous phase with a constant oil phase at the T-junction droplet generator; the inset shows a magnified view of ten traps with droplets. (**b**) Image of an array of droplets encapsulated with worms. The position of individual worms is indicated by *white arrows* (Reproduced from [21] with permission)

the rate of population growth. As shown previously, with other microsystems, locomotion could also be measured in single worms as an indicator of the physiological state of the worm. The CD cultivation system showed the capacity to incorporate diverse molecular, biochemical, and pharmacological assays for real-time physiological and behavioral test of live animals. This system has also been used to study the effect of hypergravity and the ability of *C. elegans* to withstand mechanical stress. The device affords an opportunity to investigate molecular pathways that transduce mechanical forces into biological regulators and to identify genetic targets of mechanical stress in the context of the whole animal [20].

Droplet-based microfluidic systems represent another type of chips for individual worm assay [21]. These systems consist of a droplet generator and a droplet trap array, which allows the encapsulation of individual worms into parallel series of droplets of tiny volumes (Fig. 5). The authors studied worm swimming behavior in response to a neurotoxin. This work represents for the first

time droplet encapsulation of small organisms. The main disadvantage is that the worms only survived for a maximum of 2 h.

Artificial dirt illustrates novel experimental microfluidic devices to study *C. elegans* neurobiology and behavior. Artificial dirt devices mimic the natural environment where *C. elegans* can be found in contrast to the planar surface of an agar plate. The authors argue that this fails to reflect the complexity of *C. elegans* natural environment with complicated stimulus delivery. Artificial dirt devices are thin and transparent and consist of microchambers and agarose-free channels that mimic the moist soil environment with rapid delivery of fluid-borne stimuli. The animals are able to crawl as they would on agar plates and are compatible with optical recording. Artificial dirt devices were made to accelerate studies of the neuronal basis of behavior in *C. elegans* [22].

Others: Live-Animal FACS, Maze, Optofluidic On-Chip Platform

A curious example of the broad applicability of worm chips is the device designed by Qin et al. to study behavioral plasticity of an animal using a microfluidic platform [23]. These authors studied the tendency of the worm to explore different environments in the presence or absence of food in one of the outlet chambers. They measured locomotion rates and compared the results obtained from mutant and wild-type worms.

Live-animal FACS (la-FACS) is a Fluorescence-Activated Cell Sorting (FACS) based method to sort live *C. elegans* larvae. Up until recently FACS only allowed sorting of *C. elegans* embryos [24]. The la-FACS is able to obtain large quantities of pure mutant populations. This method has a great potential for expanding the arsenal of high-throughput tools available in *C. elegans* [25].

There are many further examples were *C. elegans* has been used. For example in 2006, Heng et al. used *C. elegans* and a technique described as optofluidic microscopy (OFM) on chip. L1 worms were euthanized to demonstrate the feasibility of the method to perform high-resolution imaging.

Future Directions of Research

The development of LOC systems over the last few years has been spectacular. The future of microfluidic devices offers a range of interesting and new opportunities in worm research. Worm chips offer several advantages over conventional approaches including the maintenance of well-controllable microenvironments, creation of reproducible experimental conditions, and automation of tedious experimental protocols. However, some improvements are still needed in order to overcome the challenges arising from working with small volumes and multicellular living organisms such as *C. elegans*.

In addition to imaging different features of the worm, most of the microfluidic devices described so far have focused on measuring locomotion behavior. However, *C. elegans* displays many other types of behavior which have not been exploited thus far using a worm-chip platform. One example is pharyngeal pumping behavior.

The *C. elegans* pharynx is required for the ingestion and mechanical digestion of food. There is a basement membrane isolating the pharynx from the rest of the animal, making it an almost completely self-contained system. The pharyngeal nervous system coordinates the pharyngeal muscle cells allowing food to be sucked in, broken down, and passed into the intestine. This process is referred to as pharyngeal pumping. The pharyngeal pumping of *C. elegans* can either be counted optically or electrically. The method of recording pumping electrophysiologically gives what is referred to as the electropharyngeogram or EPG. This is an extracellular recording that can be performed on intact worms or on isolated pharynxes. As well as producing a readout of pump rate, this technique can also be used to provide information on neuronal activity of the pharynx. The EPG trace has excitatory and inhibitory components that can be attributed to the function of specific pharyngeal neurons. Measuring EPGs is a laborious and tedious process and it takes a long time to analyze a single worm. The possibility to perform EPG-recordings in a high-throughput and automated fashion remains to be exploited using microfluidic platforms.

RNAi represents another technique that has not been exploited using microfluidic devices yet.

RNAi is a powerful tool to investigate gene function in *C. elegans* broadly used to do worm research in many different areas such as development or aging. So far nobody has used this tool on a microfluidic platform in order to perform a genetic screen. In this scenario the combination of RNAi and a microfabricated worm sorter device would result in a very powerful platform.

Further Reading

Almost everything you want to know about *C. elegans* itself can be found online. Wormbase is a complete database about the worm with connections to data of human and other model organisms. Wormbase contains complete cell lineages as well as the genetic and physical maps and the annotated sequence of the worm. Also all web references can be found there: http://www.wormbase.org/.

The latest reviews describing microfluidic devices applied for the study of *C. elegans* are listed next: [5, 26, 27].

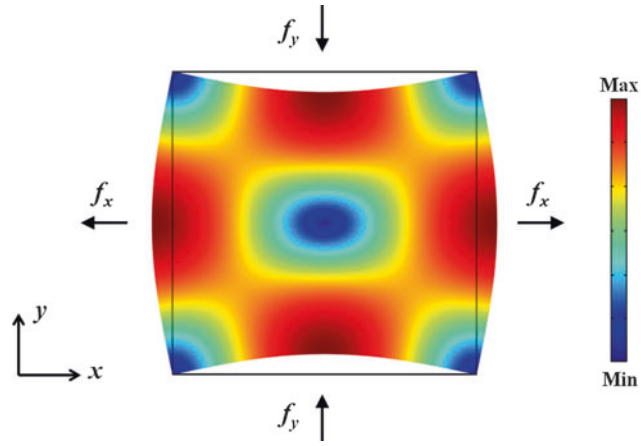
Definition

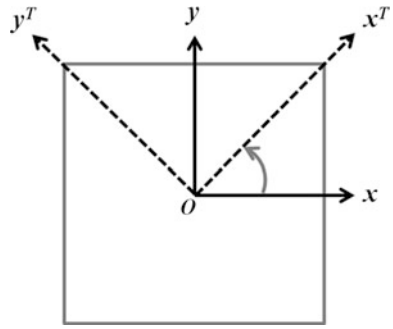
A Lamé mode MEMS resonator comprises a microscale square plate designed to be excited to vibrate in a particular lateral antisymmetric mode within the plane of fabrication. The Lamé mode can be seen as two opposite sides of the square plate expanding, while the other two opposite sides on the orthogonal axis contract. The corners of the square plate are nodes in the Lamé mode such that the square plate can be conveniently clamped for minimal anchor loss. The Lamé mode is a planar pure shear vibration mode.

Modal Analysis



As illustrated in Fig. 1, the Lamé mode is typically actuated by forces that are out of phase between adjacent sides of the square plate. Given that the plate is thin, whereby the length (L) of the plate is much greater than its thickness (H), we ignore displacements along the thickness (z-direction) of the plate. The resulting Lamé mode shape can then be mathematically defined for just the in-plane axes:

$$x-\text{direction}: \quad u(x,y) = \sin\left(\frac{\pi x}{L}\right)\cos\left(\frac{\pi y}{L}\right) \tag{1a}$$



$$y-\text{direction}: \quad v(x,y) = -\sin\left(\frac{\pi y}{L}\right)\cos\left(\frac{\pi x}{L}\right) \tag{1b}$$

Note that the amplitudes of displacement in either axis have been normalized to one. Neglecting strain components associated with the thickness z-direction assuming thin plate theory, only the lateral strain components remain. This includes the normal strains along the x and y axes denoted by ε_x and ε_y, respectively, and the shear strain in the x-y plane denoted by γ_{xy}. From Eq. 1, we obtain the lateral strain components for the Lamé mode:

$$\varepsilon_x(x,y) = -\varepsilon_y(x,y) \tag{2a}$$

Lamé Mode MEMS Resonators, Fig. 1 Illustration of the Lamé mode shape and requirement for antiphase actuation forces applied through adjacent capacitive gap electrodes

Lamé Mode MEMS Resonators, Fig. 2 Depiction of rotated planar coordinates for deriving the shear characteristics of the Lamé mode

$$\gamma_{xy}(x,y) = 0 \tag{2b}$$

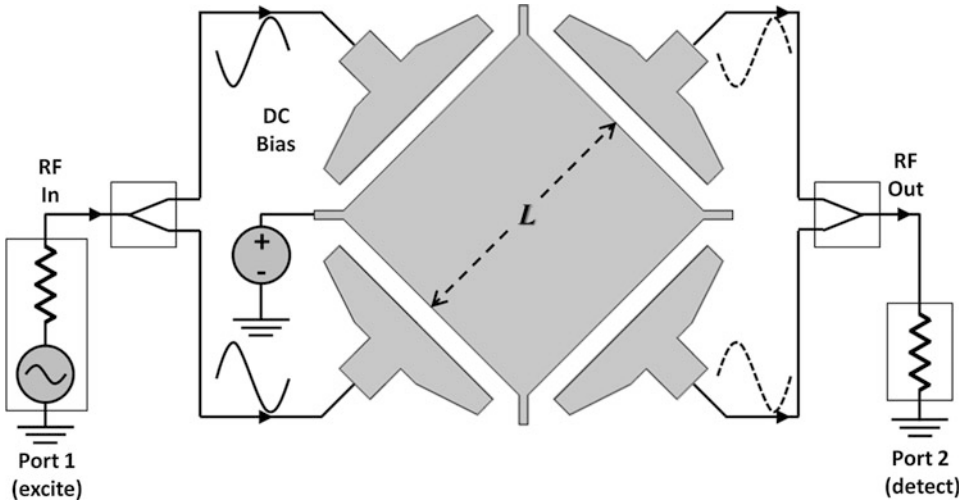
By applying planar strain coordinate transformation using Mohr's circle of strain, we find that maximum shear strain occurs at 45° to the x and y axes while the normal strains become zero. In this respect, the Lamé mode can be described as a lateral shear mode characterized by a shear wave along the diagonals of the square plate. Hence, it is convenient to perform a 45° rotation to the planar coordinates when deriving the shear characteristics of the Lamé mode as illustrated in Fig. 2. The transformed mode shape according to the rotated planar coordinates is then given by:

$$\text{Rotated } x^T - \text{direction} : u^T\left(x^T, y^T\right) = -\frac{1}{\sqrt{2}} \sin\left(\frac{\sqrt{2}\pi}{L} y^T\right) \tag{3a}$$

$$\text{Rotated } y^T - \text{direction} : v^T\left(x^T, y^T\right) = -\frac{1}{\sqrt{2}} \sin\left(\frac{\sqrt{2}\pi}{L} x^T\right) \tag{3b}$$

The superscript T denotes the transformation of a variable according to the coordinate rotation. Solving the relevant equation of motion, we obtain the lumped mechanical parameters of mass (m) and linear spring constant (k) for the Lamé mode:

$$m = \frac{1}{2}\mu H L^2 \tag{4a}$$



$$k = \pi^2 G_{x^T y^T} H \tag{4b}$$

$G_{x^T y^T}$ refers to the shear modulus with respect to the rotated coordinates, in other words along the lengths of the square plate. In addition, μ denotes the density of the structural material. From Eq. 4, we obtain the resonant frequency of the Lamé mode [1, 2]:

$$f_0 = \frac{1}{\sqrt{2}L}\sqrt{\frac{G_{x^T y^T}}{\mu}} \tag{5}$$

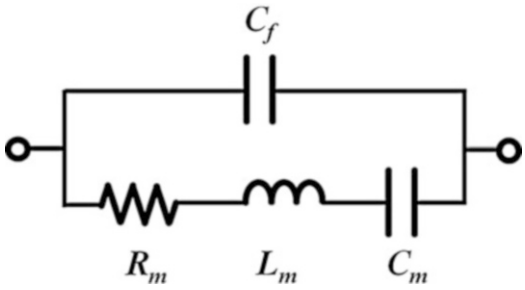
Electromechanical Transduction

The Lamé mode can be electrostatically actuated through capacitor gap electrodes fabricated on

Lamé Mode MEMS Resonators, Fig. 3 Fully differential biasing configuration to electrically excite and detect the Lamé mode using capacitive transduction

each side of the square plate. The displacement of the resonator can similarly be picked up electrically through the capacitor gaps. A commonly used configuration of electrically interfacing a Lamé mode resonator is depicted in Fig. 3. In the configuration shown in Fig. 3, a DC bias voltage is applied to the structure, while a differential pair of AC voltages is applied to adjacent electrodes. The combination of a DC bias voltage (V_{dc}) on the structure and a differential pair of AC voltages (v_{in}) generates a pair of forces that are out of phase to match the antisymmetry of the Lamé mode in order to excite the Lamé mode. The total electrostatic force imposed on the resonator from two sides, taking into account the nonuniform edge displacement of the Lamé mode, is given by

$$F = \frac{4}{\pi}\frac{\varepsilon_o HL}{g^2} V_{dc} v_{in} \tag{6}$$



The above equation approximates the length of the electrode to be the same as the length of the square plate. Note that g denotes the nominal gap of the capacitive transducer under zero displacement conditions and ε_o is the permittivity in vacuum.

The lateral amplitude displacements at the sides of the square plate, denoted by a lumped variable x, are detected through the remaining capacitive gap electrodes. As shown in Fig. 3, the same DC bias voltage is dropped across both capacitive gaps; thus the same charge is stored on both gaps when the square plate is at rest. Modulation of the gap resulting from exciting the Lamé mode results in a change in capacitance. Given that the gap change in one gap is opposite to the adjacent gap, the resulting motional currents between the two electrodes will also be out of phase. By detecting the motional currents from the two electrodes differentially, the total motional current for an amplitude displacement x at the driving radian frequency of ω is given by

$$i_{out} = \frac{4}{\pi}\frac{\varepsilon_o HL}{g^2} V_{dc} \omega x \tag{7}$$

As in the case when considering the actuation port, the above expression once again takes into account the nonuniform edge displacement of the Lamé mode.

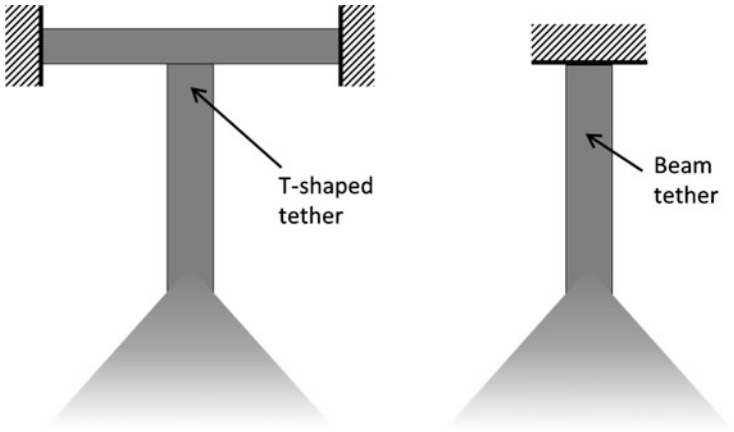
Like most other capacitive MEMS resonators, the electromechanical transfer function of the Lamé mode MEMS resonator can be represented by the Butterworth van Dyke (BVD) circuit model as depicted in Fig. 4. Note that η is the transduction factor common to each of the electromechanical lumped parameters in the BVD model. For the Lamé mode when biased with the setup shown in Fig. 3, η is given by:

Lamé Mode MEMS Resonators, Fig. 4 Butterworth van Dyke (BVD) equivalent circuit model to describe the electromechanical transfer function of a Lamé mode MEMS resonator

$$\eta = \frac{4}{\pi}\frac{\varepsilon_o HL}{g^2}V_{dc} \tag{8}$$

The equivalent circuit model depicted in Fig. 4 includes a capacitor (C_f) between the input and output ports. C_f captures the effect of feedthrough between the input and output ports through a parasitic capacitor [3]. The physical sources of C_f could include, though by no means exhaustively, the direct overlapping capacitance of the capacitive gap transducer, capacitive coupling through the substrate, interconnects, and the electrical package holding the die. Although the value of C_f may be relatively small (pF for packaged devices) [4], due to the comparatively weak electromechanical coupling for capacitive transducers, the electrical path through C_f becomes significant and could potentially obscure the output motional current. The fully differential configuration in Fig. 3 as such has the benefit of suppressing feedthrough [5] by providing feedthrough cancelation at the input and output ports, thus enhancing the electrical characterization of the MEMS resonator [6].

Quality (*Q*) Factor and Dissipation



A MEMS oscillator is realized by embedding a MEMS resonator in an amplifier loop to achieve self-sustained oscillation. MEMS oscillators have made inroads during the last decade in starting to replace quartz crystals as timing references [7]. Compared to quartz crystals, MEMS oscillators offer the advantage of small form factor and greater compatibility of their fabrication with complementary metal-oxide-semiconductor process technology. High-quality (Q) factor benefits the close-to-carrier phase noise performance of the oscillator. From the view of high Q, silicon Lamé mode resonators are highly attractive in that they exhibit Qs that are close to the fundamental material limit set by phonon-phonon interaction losses. Examples of Q in the millions for MHz silicon Lamé mode resonators have been reported in the literature [8–10]. To see what governs Q in Lamé mode resonators, we can consider the various sources of damping since the net Q of a resonator is determined by the sum of all dissipative sources:

$$\frac{1}{Q_{\text{net}}} = \frac{1}{Q_{\text{anchor}}} + \frac{1}{Q_{\text{TED}}} + \frac{1}{Q_{\text{viscous}}} + \frac{1}{Q_{\text{AKE}}} \tag{9}$$

Q_{anchor}: Clamping structures known as tethers are required to physically support the free-standing square plate to the underlying substrate. As the square plate vibrates, some of the energy propagates out through the supporting tethers and into the substrate where they are lost. This is referred to as anchor loss and is accounted for by Q_{anchor}.

Q_{TED}: As a solid deforms, regions in tension become cooler, while regions in compression become hotter. This temperature gradient results in irreversible heat flow. The energy loss due to this mechanism is known as thermoelastic damping (TED) and is accounted for by Q_{TED}. In other words, the driving mechanism for TED is a lack of thermal equilibrium associated with thermal gradients resulting from a strain field.

Q_{viscous}: As the square plate deforms, fluid between the capacitive gaps is squeezed and results in resistance to the vibration. The loss associated with squeezing fluid through the gaps and friction between the solid and air is accounted for by Q_{viscous}. Q_{viscous} is related to the pressure in which the resonator is operating in. For silicon Lamé mode resonators up to tens of MHz, it has been shown that Q increases as the pressure is reduced until about a Torr,

Lamé Mode MEMS Resonators, Fig. 5 Stick diagram illustrating two geometries of annexed tethers connecting the resonator to the anchors: (**a**) T-shaped tether and (**b**) beam tether

beyond which the pressure appears to have little effect on Q [9]. Hence in operating a Lamé mode resonator at pressures much lower than 1 Torr, Q_{viscous} is no longer a dominant factor in determining the actual Q.

Q_{AKE}: This represents the losses due to phonon-phonon interactions and constitutes the fundamental limit on Q for a given material. For silicon, Q_{AKE} is bound by the fQ product in the order of 10^{13} below 1 GHz resonance [11, 12].
