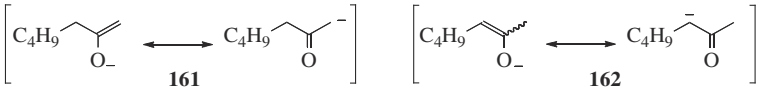
Efficient enantioselective alkylations are known,[1742] including the use a chiral base to form the enolate anion.[1743] Alternatively, a chiral auxiliary can be attached. Many auxiliaries are based on the use of chiral amides[1744] or esters.[1745] Subsequent formation of the enolate anion allows alkylation to proceed with high enantioselectivity. A subsequent step is required to convert the chiral amide or ester to the corresponding carboxylic acid. Chiral additives can also be used,[1746] and the influence of chelating ligands and hydrocarbon cosolvents has been studied for $LiN(TMS)_2$ mediated enolization reactions.[1747] The addition of triethylamine influences the (*E/Z*) selectivity of the enolate anion.[1748] Dynamic kinetic resolution has been used for the asymmetric alkylation of malonate derivatives using allenyl acetates.[1749]



When the compound to be alkylated is an unsymmetrical ketone, the question arises as to which side will be alkylated (regioselectivity). If a phenyl or a vinylic group is present on one side, alkylation goes predominantly on that side. When only alkyl groups are present, the reaction is generally not regioselective; mixtures are obtained in which sometimes the more alkylated and sometimes the less alkylated side is predominantly alkylated. Which product is found in higher yield depends on the nature of the substrate, the base,[1750] the cation, and the solvent. In any case, di- and trisubstitution are frequent[1751] and it is often difficult to stop with the introduction of just one alkyl group.[1752]

Several methods have been developed for ensuring that alkylation takes place regioselectively on the *desired* side of a ketone.[1753] Among these are the following:

1. Block one side of the ketone by introducing a removable group. Alkylation takes place on the other side; the blocking group is then removed. A common reaction for this purpose is formylation with ethyl formate (Reaction **16-86**). This generally blocks the less hindered side. The formyl group is easily removed by alkaline hydrolysis (Reaction **12-43**).
2. Introduce an activating group on one side. Alkylation then takes place on that side (Reaction **10-67**). The activating group is then removed.

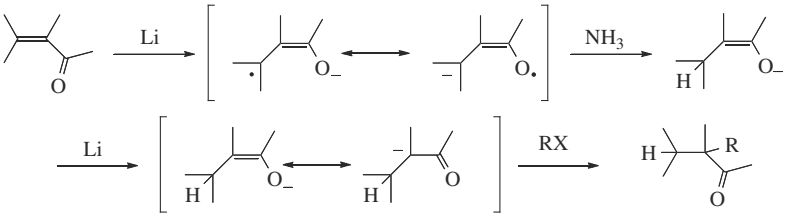
3. Prepare the desired one of the two possible enolate anions.[1754] The two ions (e.g., **161** and **162**) for



2-heptanone, interconvert rapidly only in the presence of the parent ketone or any stronger acid.[1755] In the absence of such acids, it is possible to prepare either **161** or **162** and thus achieve selective alkylation on either side of the ketone.[1756] The desired enolate anion can be obtained by treatment of the corresponding enol acetate with 2 equiv of methyllithium in 1,2-dimethoxyethane. Each enol acetate gives the corresponding enolate, for example,

The enol acetates, in turn, can be prepared by treatment of the parent ketone with an appropriate reagent.[1745] Such treatment generally gives a mixture of the two enol acetates in which one or the other predominates, depending on the reagent. The mixtures are easily separable.[1755] An alternate procedure involves conversion of a silyl enol ether[1757] (see Reaction **12-17**) or a dialkylboron enol ether[1758] (an enol borinate, see Reaction **10-73**) to the corresponding enolate anion. If the less hindered enolate anion is desired (e.g., **161**), it can be prepared directly from the ketone by treatment with LDA in THF or DME at $-78\,^{\circ}C$.[1759]

4. Begin not with the ketone itself, but with an α,β-unsaturated ketone in which the double bond is present on the side where alkylation is desired. Upon treatment with lithium in liquid NH_3, such a ketone is reduced to an enolate anion. When the alkyl halide is added, it must react with the enolate anion on the side where the double bond was.[1760] Of course, this method is not actually an alkylation of the ketone, but of the α,β-unsaturated ketone, although the product is the same as if the saturated ketone had been alkylated on the desired side.

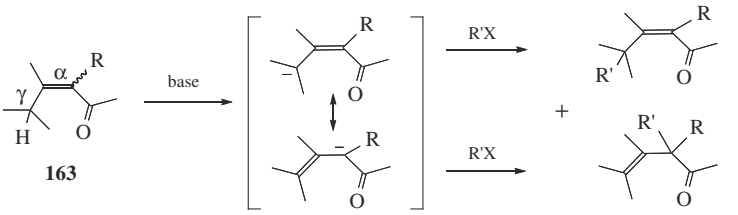
Both sides of acetone have been alkylated with different alkyl groups, in one operation, by treatment of the *N,N*-dimethylhydrazone of acetone with *n*-BuLi, followed by a primary alkyl, benzylic, or allylic bromide or iodide; then another mole of *n*-BuLi, a second halide, and finally hydrolysis of the hydrazone.[1761] Alkylation of an unsymmetrical ketone at the more substituted position was reported using an alkyl bromide, NaOH, and a calix[*n*]arene catalyst (see Sec. 4.H. category 2 for calixarenes).[1762]

Among other methods for the preparation of alkylated ketones are (1) Alkylation of silyl enol ethers using various reagents as noted above, (2) the *Stork enamine reaction* (Reaction **10-69**), (3) the acetoacetic ester synthesis (Reaction **10-67**), (4) alkylation of β-keto sulfones or sulfoxides (Reaction **10-67**), (5) acylation of $CH_3SOCH_2^-$ followed by reductive cleavage (Reaction **16-86**), (6) treatment of α-halo ketones with lithium dialkylcopper reagents (Reaction **10-57**), and (7) treatment of α-halo ketones with trialkylboranes (Reaction **10-73**).



Aldehydes can be indirectly alkylated via an imine derivative of the aldehyde.[1763] The derivative is easily prepared (Reaction **16-13**) and the product easily hydrolyzed to the aldehyde (Reaction **16-2**). Either or both R groups may be hydrogen, so that mono-, di-, and trisubstituted acetaldehydes can be prepared by this method. The R′ group may be primary alkyl, allylic, or benzylic. Imine alkylation can also be applied to the preparation of substituted amine derivatives. An amino acid surrogate (e.g., $Ph_2C{=}NCH_2CO_2R$), when treated with KOH and an alkyl halide gives the C-alkylated product.[1764] When a chiral additive is used, good enantioselectivity was observed. This reaction has also been done in the ionic liquid Bmim tetrafluoroborate (see Sec. 9.D.iii).[1765] It is possible to alkylate α-amino amides directly.[1766]

Hydrazones and other compounds with C=N bonds can be similarly alkylated.[1743] The use of chiral amines or hydrazines[1767] [followed by hydrolysis (Reaction **16-2**) of the alkylated imine] can lead to chiral alkylated ketones in high optical yields[1768] (for an example, see Sec. 4.J). Lithiated imines are generated by the treatment of an imine with a

suitable base, and reaction with an alkyl halide gives the alkylated imine.[1769] α-Magnesio imines also react with alkyl halides.[1770]

163

In α,β-unsaturated ketones, nitriles, and esters (e.g., **163**), the γ hydrogen assumes the acidity normally held by the position α to the carbonyl group, especially when R is not hydrogen and so cannot compete. This principle, called *vinylogy* (see Sec. 6.B), operates because the resonance effect is transmitted through the double bond. However, because of the resonance, alkylation at the α position (with allylic rearrangement) competes with alkylation at the γ position and usually predominates.

164

α-Hydroxynitriles (cyanohydrins), protected by conversion to acetals with ethyl vinyl ether (Reaction **15-5**), can be easily alkylated with primary or secondary alkyl or allylic halides.[1771] The R group can be aryl or a saturated or unsaturated alkyl. Since the cyanohydrins[1772] are easily formed from aldehydes (Reaction **16-52**) and the product is easily hydrolyzed to a ketone, this is a method for converting an aldehyde (RCHO) to a ketone (RCOR′)[1773] (for other methods, see Reactions **10-71**, **16-82**, and **18-9**).[1774] In this procedure, the normal mode of reaction of a carbonyl carbon is reversed. The C atom of an aldehyde molecule is normally electrophilic and is attacked by nucleophiles (Chapter 16), but by conversion to the protected cyanohydrin this carbon atom has been induced to perform as a nucleophile.[1775] The German word *Umpolung*[1776] is used to describe this kind of reversal (another example is found in Reaction **10-71**). Since the ion **164** serves as a substitute for the unavailable $R(C{=}O)^-$ anion, it is often called a "masked" $R(C{=}O)^-$ ion.

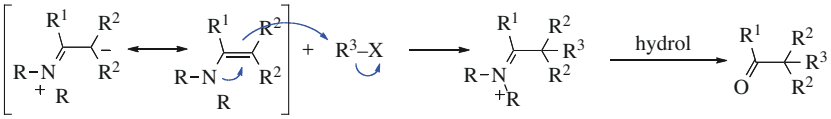
This method fails for formaldehyde (R = H), but other masked formaldehydes have proved successful.[1777] In an interesting variation of nitrile alkylation, a quaternary bromide [PhC(Br)(Me)CN] reacted with allyl bromide, in the presence of a *Grignard reagent*, to give the alkylated product [$PhC(CN)(Me)CH_2CH{=}CH_2$].[1778]

A coupling reaction of two ketones to form a 1,4-diketone has been reported, using $ZnCl_2/Et_2NH$.[1779] An interesting allylic substitution at a 3° center involves the reaction of 3° 2-bromonitriles with *i*PrMgBr and allyl bromide to give the 2-allyl nitrile.[1780]



α-Alkylation of ketones with primary alcohols is possible using polymer-associated nanoparticulate Pd.[1781]

Protonation of enolate anions is discussed in Reaction **16-34**, in connection with the aldol condensation.

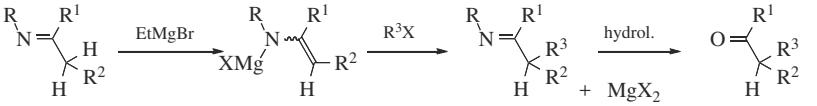
10-69 The Stork Enamine Reaction

α-Acylalkyl-de-halogenation[1782]



When enamines are treated with alkyl halides, an alkylation occurs to give an iminium salt via electron transfer from the electron pair on nitrogen, through the C=C to the electrophilic carbon of the alkyl halide.[1783] In effect, an enamine behaves as a "nitrogen enolate anion" and generally reacts as carbon nucleophiles.[1784] Hydrolysis of the iminium salt gives a ketone. Since the enamine is normally formed from a ketone (Reaction **16-13**), the net result is alkylation of the ketone at the α position. The method, known as the *Stork enamine reaction*,[1785] is an alternative to the ketone alkylation considered in Reaction **10-68**, generally giving monoalkylation of the ketone. Alkylation usually takes place on the less substituted side of the original ketone. The most commonly used amines are the cyclic amines piperidine, morpholine, and pyrrolidine. There are metal-catalyzed enamine alkylation reactions, including the use of Ir catalysts.[1786] There are reactions that are catalyzed by enamines, including asymmetric reactions.[1787]

The method is quite useful for particularly active alkyl halides, (e.g., allylic, benzylic, and propargylic halides), and for α-halo ethers and esters. Other primary and secondary halides can show sluggish reactivity. The reaction of enamines with benzotriazole derivatives has been reported.[1788] Tertiary halides do not give the reaction at all since, with respect to the halide, this is nucleophilic substitution and elimination predominates. The reaction can also be applied to activated aryl halides (e.g., 2,4-dinitrochlorobenzene; see Chapter 13), to epoxides,[1789] and to activated alkenes (e.g., acrylonitrile). The latter is a *Michael-type reaction* (**15-24**) with respect to the alkene.

Acylation[1790] can be accomplished with acyl halides or with anhydrides. Hydrolysis of the resulting iminium salt leads to a 1,3-diketone. A COOEt group can be introduced by treatment of the enamine with ethyl chloroformate (ClCOOEt;[1791] a CN group with cyanogen chloride[1792] (not cyanogen bromide or iodide, which leads to halogenation of the enamine); a CHO group with the mixed anhydride of formic and acetic acids[1791] or with DMF and phosgene;[1793] and a C(R)=NR′ group with a nitrilium salt RC≡N$^+$R′.[1794] The acylation of the enamine can take place by the same mechanism as alkylation, but another mechanism is also possible, if the acyl halide has an α hydrogen and if a tertiary amine is present, as it often is (it is added to neutralize the HX given off). In this mechanism, the acyl halide is dehydrohalogenated by the tertiary amine, producing a ketene (Reaction **17-14**), which adds to the enamine to give a cyclobutanone (Reaction **15-63**). This compound can be cleaved in the solution to form the same acylated imine salt (that would form by the more direct mechanism, or it can be isolated (in the case of enamines derived from aldehydes), or it may cleave in other ways.[1795]

N-Alkylation can be a problem, particularly with enamines derived from aldehydes. An alternative method, which gives good yields of alkylation with primary and secondary halides, is alkylation of enamine *salts*, which are prepared by treating an imine with ethylmagnesium bromide in THF:[1796]

The imines are prepared by the reaction of secondary amines with aldehydes or ketones, mainly ketones (**16-13**). The enamine salt method has also been used to give good yields of mono α alkylation of α,β-unsaturated ketones.[1797] Enamines prepared from aldehydes and

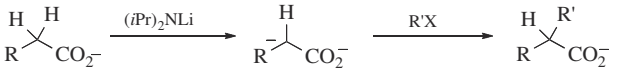
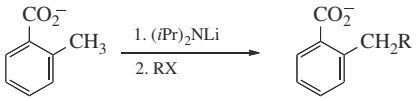
butylisobutylamine can be alkylated by simple primary alkyl halides in good yields.[1798] N-Alkylation in this case is presumably prevented by steric hindrance.



When the nitrogen of the substrate contains a chiral R group, both the *Stork enamine synthesis* and the enamine salt method can be used to perform enantioselective syntheses.[1799] The use of *S*-proline can generate a chiral enamine *in situ*, thus allowing alkylation to occur, giving alkylated product with good enantioselectivity. The reaction has been done intramolecularly.[1800]

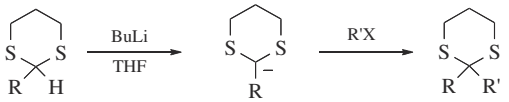
Conjugate addition (*Michael addition*) occurs when enamines react with conjugated ketones. This reaction is discussed in Reaction **15-24**.



OS **V**, 533, 869; **VI**, 242, 496, 526; **VII**, 473.

10-70 Alkylation of Carboxylic Acid Salts

α-Carboxyalkyl-de-halogenation



Carboxylic acids can be alkylated in the α position by conversion of their salts to dianions, which have resonance contributors,[1801] by treatment with a strong base (e.g., LDA).[1802] The use of Li^+ as the counterion increases the solubility of the dianionic salt. The reaction has been applied[1803] to primary alkyl, allylic, and benzylic halides, and to carboxylic acids of the form RCH_2CO_2H and RR^2CHCO_2H.[1695] Allkylation occurs at carbon, the more nucleophilic site relative to the carboxylate oxygen anion (see Sec. 10.G.vii). This procedure is an alternative to the malonic ester synthesis (Reaction **10-67**) as a means of preparing carboxylic acids and has the advantage that acids of the form $RR'R^2CCO_2H$ can also be prepared. In a related reaction, methylated aromatic acids can be alkylated at the methyl group by a similar procedure.[1804]

OS **V**, 526; **VI**, 517; **VII**, 249. See also, OS **VII**, 164.

10-71 Alkylation at a Position α to a Heteroatom

2-(2-Alkyl-thio) de-halogenation

The presence of a sulfur atom on a carbon enhances the acidity of a proton on that carbon, and in dithioacetals and dithioketals that proton $RSCH_2SR$ is even more acidic. 1,3-Dithianes can be alkylated[1805] if a proton is first removed by treatment with butyllithium in THF.[1806] Since 1,3-dithianes can be prepared by treatment of an aldehyde or its acetal (see OS **VI**, 556) with 1,3-propanedithiol (Reaction **16-11**) and can be hydrolyzed (Reaction **10-7**), this is a method for the conversion of an aldehyde to a ketone[1807] (see also, Reactions **10-68** and **18-9**):

This is another example of Umpolung (see Reaction **10-68**);[1773] the normally electrophilic carbon of the aldehyde is made to behave as a nucleophile. The reaction can be applied to the unsubstituted dithiane (R = H) and one or two alkyl groups can be introduced, so a wide variety of aldehydes and ketones can be made starting with formaldehyde.[1808] The R′ group may be a primary or secondary alkyl or benzylic. Iodides give the best results. The reaction has been used to close rings.[1809] A similar synthesis of aldehydes can be performed starting with ethyl ethylthiomethyl sulfoxide ($EtSOCH_2SEt$).[1810]

Group **A** may be regarded as a structural equivalent for carbonyl group **B**, since introduction of **A** into a molecule is actually an indirect means of introducing **B**. It is convenient to have a word for units within molecules. Such a word is *synthon*, introduced by Corey,[1811] which is defined as a structural unit within a molecule that can be formed and/or assembled by known or conceivable synthetic operations. There are many other synthons equivalent to **A** and **B** (e.g., **C**; by Reactions **19-36** and **19-3**) and **D** (by Reactions **10-2** and **16-23**).[1812]

Carbanions generated from 1,3-dithianes also react with epoxides[1813] to give the expected products. Reaction with epoxides leads to intermediates that undergo the *Brook rearrangement* (Reaction **18-44**), which is synthetically useful in what is known as *anion relay chemistry*.

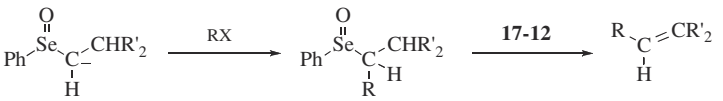
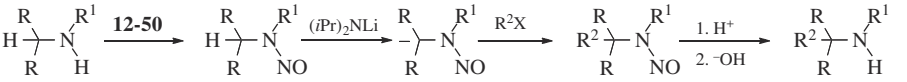
Another useful application of this reaction stems from the fact that dithianes can be desulfurated with *Raney nickel* (Reaction **14-27**). Aldehydes can therefore be converted to chain-extended hydrocarbons:[1814]



Similar reactions have been carried out with other thioacetals, as well as with compounds containing three thioether groups on a carbon.[1815]

If a stabilizing group other than sulfur is attached to the S—CH_2 unit of a thioether ($RSCH_2X$, where X is a stabilizing group), formation of the anion and alkylation can be facile. For example, benzylic and allylic thioethers ($RSCH_2Ar$ and $RSCH_2CH{=}CH_2$)[1816] and thioethers of the form $RSCH_3$ (R = tetrahydrofuranyl or 2-tetrahydropyranyl)[1817] have been successfully alkylated at the carbon adjacent to the sulfur atom.[1818] Stabilization by one thioether group has also been used in a method for the homologation of primary halides.[1819] Thioanisole is treated with BuLi to give the corresponding anion,[1820] which reacts with the halide to give the thioether, which is then refluxed with a mixture of methyl iodide and sodium iodide in DMF to give the alkyl iodide as the final product (via an intermediate sulfonium salt). By this sequence, an alkyl halide (RX) is converted to its homologue RCH_2X by a pathway involving two laboratory steps (see also, Reaction **10-64**).



Vinylic sulfides containing an α hydrogen can also be alkylated[1821] by alkyl halides or epoxides. This method is for converting an alkyl halide (RX) to an α,β-unsaturated aldehyde, which is the synthetic equivalent of the unknown $^{-}HC{=}CH{-}CHO$ ion.[1822] Even simple alkyl aryl sulfides (RCH_2SAr and $RR'CHSAr$) have been alkylated α to the sulfur.[1823]

Sulfones[1824] and sulfonic esters can also be alkylated in the α position if strong enough bases are used.[1825] Alkylation at the α position of selenoxides allows the formation of alkenes, since selenoxides easily undergo elimination (Reaction **17-12**).[1826]

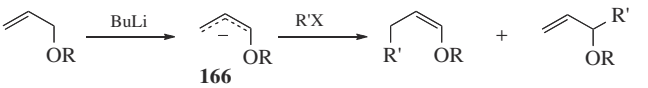
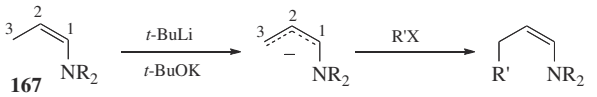
Alkylation can also be carried out, in certain compounds, at positions α to other heteroatoms,[1827] for example, at a position α to the nitrogen of tertiary amines.[1828] Alkylation α to the nitrogen of primary or secondary amines is not generally feasible because an NH hydrogen is usually more acidic than a CH hydrogen.



α-Lithiation of *N*-Boc amines has been accomplished and these react with halides in the presence of a Pd catalyst.[1829] Alkylation α to the nitrogen atom of a carbamate occurs when the carbamate is treated with a *Grignard reagent* under electrolysis conditions.[1830] α-Methoxy amides also react with allyl halides and zinc metal to give alkylation via replacement of the OMe unit.[1831] It has been accomplished, however, by replacing the NH hydrogens with other (removable) groups.[1832] In one example, a secondary amine is converted to its *N*-nitroso derivative (Reaction **12-50**).[1833] The *N*-nitroso product is easily hydrolyzed to the product amine (Reaction **19-51**).[1834] Alkylation of secondary and primary amines has also been accomplished with > 10 other protecting groups, involving conversion of amines to amides, carbamates,[1835] formamidines,[1836] and phosphoramides.[1831] In the case of formamidines (**165**), use of a chiral R′ leads to a chiral amine, in high ee, even when R is not chiral.[1837] The reaction of hydrazones with aryl halides, in the presence of a Pd catalyst leads to replacement of H with an aryl group (R'NH—N=CRH → R'NHC=NRR").[1838]

165



A proton can be removed from an allylic ether by treatment with an alkyllithium at about −70 °C (at higher temperatures the *Wittig rearrangement*, **18-22**, takes place) to give the ion **166**, which reacts with alkyl halides

to give the two products shown.[1839] Similar reactions[1840] have been reported for allylic[1841] and vinylic tertiary amines. In the latter case, enamines (**167**), treated with a strong base, are converted to anions that are then alkylated, generally at C-3.[1842] (For direct alkylation of enamines at C-2, see Reaction **10-69**.)

It is also possible to alkylate a methyl, ethyl, or other primary group of an aryl ester ($ArCO_2R$), where Ar is a 2,4,6-trialkylphenyl group.[1843] Since esters can be hydrolyzed to alcohols, this constitutes an indirect alkylation of primary alcohols. Methanol has also been alkylated by converting it to $^{-}CH_2O^{-}$.[1844]

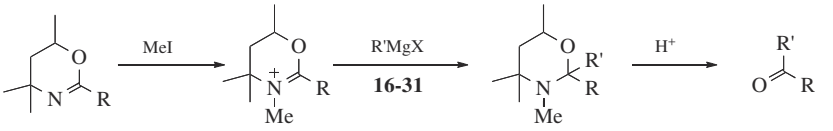
10-72 Alkylation of Dihydro-1,3-Oxazine. The Meyers Synthesis of Aldehydes, Ketones, and Carboxylic Acids



A synthesis of aldehydes[1845] developed by Meyers et al.[1846] begins with the commercially available dihydro-1,3-oxazine derivatives (**168**; A = H, Ph, or COOEt).[1847] Removal of a proton from the indicated carbon in **168** leads to the resonance stabilized and bidentate anion (**169**). Alkylation occurs regioselectively at carbon using many alkyl bromides and iodides. The R group of RX can be primary or secondary alkyl, allylic, or benzylic and can carry another halogen or a CN group.[1848] The alkylated oxazine (**170**) is then reduced and hydrolyzed to give an aldehyde containing two more carbons than the starting RX. This method thus complements Reaction **10-71**, which converts RX to an aldehyde containing

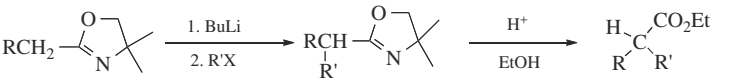
[1848] Meyers, A.I.; Malone, G.R.; Adickes, H.W. *Tetrahedron Lett.* ***1970***, 3715.



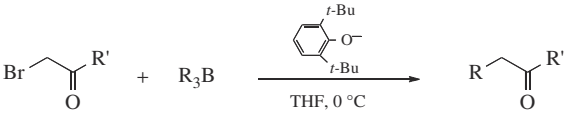
one more carbon. Since A can be H, mono- or disubstituted acetaldehydes can be produced by this method.

The ion **169** also reacts with epoxides, to form γ-hydroxy aldehydes after reduction and hydrolysis,[1849] and with aldehydes and ketones (Reaction **16-38**). Similar aldehyde synthesis has also been carried out with thiazoles[1850] and thiazolines[1851] (five-membered rings containing N and S in the 1 and 3 positions).

171 **172**

The reaction has been extended to the preparation of ketones:[1852] Treatment of a dihydro-1,3-oxazine (**171**) with iodomethane forms the iminium salt (Reaction **10-31**) which, when treated with a *Grignard reagent* or organolithium compound (**16-31**), produces **172**, which can be hydrolyzed to a ketone. The R group can be alkyl, cycloalkyl, aryl, benzylic, and so on, and R′ of the *Grignard reagent* can be alkyl, aryl, benzylic, or allylic. Note that the heterocycles **168**, **170**, or **171** do not react directly with *Grignard reagents*. In another procedure, 2-oxazolines[1853] (**173**) can be alkylated to give **174**,[1854] which are easily converted directly to the esters **175** by heating in 5–7% ethanolic sulfuric acid.

173 **174** **175**



2-Oxazolines (**173** and **174**) are thus synthons for carboxylic acids; this is another indirect method for the α alkylation of a carboxylic acid,[1855] representing an alternative to the malonic ester synthesis (**10-67**) and to Reactions **10-70** and **10-73**. The method can be adapted to the preparation of optically active carboxylic acids by the use of a chiral reagent.[1856] Note that, unlike **168**, **173** can be alkylated even if R is alkyl. However, the C=N bond of **173** and **174** cannot be effectively reduced, so that aldehyde synthesis is not feasible here.[1857]

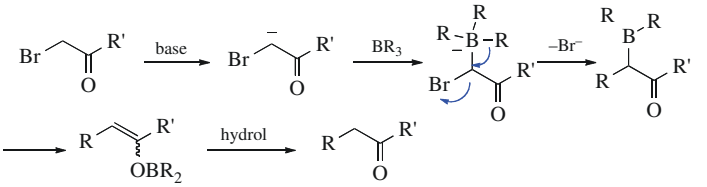
10-73 Alkylation with Boranes, Boronic Acids, and Boronates

Alkyl-de-halogenation

Trialkylboranes react rapidly and in high yields with α-halo ketones,[1858] α-halo esters,[1859] α-halo nitriles,[1860] and α-halo sulfonyl derivatives (sulfones, sulfonic esters, sulfonamides)[1861] in the presence of a base to give, respectively, alkylated ketones, esters, nitriles, and sulfonyl derivatives.[1862] Potassium *tert*-butoxide is often a suitable base, but potassium 2,6-di-*tert*-butylphenoxide at 0 °C in THF gives better results in most cases, possibly because the large bulk of the two *tert*-butyl groups prevents the base from coordinating with the R_3B.[1863] The trialkylboranes are prepared by treatment of 3 equiv of an alkene with 1 equiv of BH_3 (Reaction **15-16**).[1864] With appropriate boranes, the R group transferred to α-halo ketones, nitriles, and esters can be vinylic,[1865] or (for α-halo ketones and esters) aryl.[1866]



The reaction can be extended to α,α-dihalo esters[1867] and α,α-dihalo nitriles.[1868] It is possible to replace just one halogen or both. In the latter case, the two alkyl groups can be the same or different. When dialkylation is applied to dihalo nitriles, the two alkyl groups can be primary or secondary, but with dihalo esters, dialkylation is limited to primary R. Another extension is the reaction of boranes (BR_3) with γ-halo-α,β-unsaturated esters.[1869] Alkylation takes place in the γ position, but the double bond migrates out of conjugation with the CO_2Et unit [$BrCH_2CH{=}CHCO_2Et \rightarrow RCH{=}CHCH_2CO_2Et$]. In this case, however, double-bond migration is an advantage, because nonconjugated β,γ-unsaturated esters are usually much more difficult to prepare than their α,β-unsaturated isomers.

The alkylation of activated halogen compounds is one of several reactions of trialkylboranes developed by H.C. Brown[1870] (see also, Reactions **15-16**, **15-27**, **18-31–18-40**, etc.). These compounds are extremely versatile and can be used for the preparation of many types of compounds. In this reaction, for example, an alkene (via the BR_3) can be coupled to a ketone, a nitrile, a carboxylic ester, or a sulfonyl derivative. Note that this is still

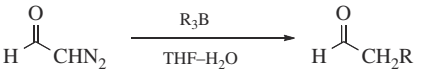
another indirect way to alkylate a ketone (see Reaction **10-68**) or a carboxylic acid (see Reaction **10-70**), and provides an additional alternative to the malonic ester and acetoacetic ester syntheses (Reaction **10-67**).

Although superficially this reaction resembles Reaction **10-57**, it is likely that the mechanism is quite different, involving migration of an R group from boron to carbon (see also, Reactions **18-23**–**18-26**). The mechanism is not known with certainty,[1871] but it may be tentatively shown as (illustrated for an α-halo ketone):

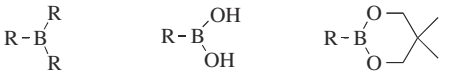


176

The first step is removal of the acidic proton by the base to give an enolate anion that combines with the borane (Lewis acid–base reaction). An R group then migrates, displacing the halogen leaving group.[1872] Another migration follows, this time of BR_2 from carbon to oxygen to give the enol borinate (**176**),[1873] which is hydrolyzed. Configuration at the alkyl group R is retained.[1874]

Alkenylboranes ($R'_2C{=}CHBZ_2$; Z = various groups) couple in high yields with vinylic,[1875] alkynyl, aryl, benzylic, and allylic halides or triflates in the presence of a Pd catalyst and a base to give $R'_2C{=}CHR$.[1876] 9-Alkyl-9-BBN compounds (Reaction **15-16**) also couple with vinylic and aryl halides,[1877] as well as with α-halo ketones, nitriles, and esters.[1878]

The reaction has also been applied to compounds with other leaving groups. Diazo ketones, diazo esters, diazo nitriles, and diazo aldehydes (**177**)[1879] react with trialkylboranes in a similar manner.



177

The mechanism is probably also similar. In this case, a base is not needed, since the carbon already has an available pair of electrons. The reaction with diazo aldehydes[1880] is

especially notable, since successful reactions cannot be obtained with α-halo aldehydes.[1881]

Boranes **Boronic acids** **Boronates**

Alkyl[1882] and aryl[1883] boronic acids [$RB(OH)_2$] react with allylic acetates to give the alkylated product in the presence of a Pd catalyst.[1884] A cyclopropylboronic acid was coupled to an allylic bromide with silver oxide/KOH and a Pd catalyst.[1885] Arylboronic acids undergo a coupling reaction with epoxides in the presence of a Pd catalyst.[1886] Alkylboronic acids can also be coupled to aromatic compounds in the presence of $Cu(OAc)_2$ and a Pd catalyst.[1887] The Pd catalyzed coupling of vinyl halides and alkylboronic acids,[1888] which gives substituted alkenes, is related to the *Suzuki coupling* (Reaction **13-12**). Vinyl zirconium reagents were coupled to alkyl halides with a Pd catalyst.[1889] Arylation of sp^3 C—H positions can be done using arylboronates and a Rh catalyst.[1890] In a related but metal-free reaction, activated epoxides and aziridines are opened by borates.[1891]

Potassium aryl- and 1-alkenyltrifluoroborates ($ArBF_3K$ and RBF_3K) are easily prepared from organoboronic acids or esters. In general, the trifluoroborates have greater air stability and greater nucleophilicity[1892] when compared to the corresponding organoboranes and organoboronic acid derivatives. Potassium alkyltrifluoroborates undergo the Pd catalyzed coupling reaction with arenediazonium tetrafluoroborates,[1893] diaryliodonium salts,[1894] aryl halides,[1895] as well as with aryl triflates. An example of the latter reaction converted **178** to diphenylmethane via coupling with phenyl triflate.[1896] Alkenyltrifluoroborates can be coupled to aryl halides.[1897]

$$\underset{\mathbf{178}}{PhCH_2BF_3K} + PhOTf \xrightarrow[9\%\ PdCl_2(dppf)\cdot CH_2Cl_2]{3\ equv\ Cs_2CO_3,\ aq\ THF} PhCH_2Ph$$

where dppf = bis(diphenylphosphino)ferrocene.

10-74 Alkylation at an Alkynyl Carbon

Alkynyl-de-halogenation

$$RX + R'C{\equiv}C^- \longrightarrow RC{\equiv}CR'$$

The reaction between alkyl halides and acetylide ions is useful, but of limited scope.[1898] Only primary halides unbranched in the β-position give good yields, although allylic halides can be used if CuI is present.[1899] If acetylene is the reagent, two different groups can be successively attached. Sulfates, sulfonates, and epoxides[1900] are sometimes used as substrates. The acetylide ion is often prepared by treatment of an alkyne with a strong base (e.g., $NaNH_2$). Magnesium acetylides (prepared as in Reaction **12-22**) are also frequently used, although they react only with active substrates (e.g., allylic, benzylic, and propargylic halides) and not with primary alkyl halides. Alternatively, the alkyl halide can be treated with a lithium acetylide–ethylenediamine complex.[1901] If 2 equiv of a very strong base are used, alkylation can be effected at a carbon α to a terminal triple bond: $RCH_2C{\equiv}CH + 2BuLi \rightarrow RCHC(C:^- + R'Br \rightarrow RR'CHC{\equiv}C:^-$.[1902] For another method of alkylating at an alkynyl carbon, see Reaction **18-26**. An alternative method for generating an alkyne anion treated a trialkylsilyl alkyne with potassium carbonate in methanol, and then methyllithium/LiBr.[1903] In the presence of an alkyl iodide, alkylation at the alkynyl carbon occurred. Terminal alkynes react with alkylzinc reagents in the presence of a Pd catalyst.[1904]

Other metalated terminal alkynes can be coupled to substrates with a leaving group, and even with other organometallics. In the presence of a Pd catalysts, an alkynyltin reagent reacts with an alkylzinc compound to give the corresponding alkyne.[1905] Terminal alkynes react with allylic bromides in the presence of a Ni catalyst.[1906] The reaction of a terminal alkyne with Zn(II) compounds allows reaction with silanes to give the 1-silylalkyne.[1907] A Re catalyzed C—H insertion reaction is known using terminal alkynes and an active methylene compound.[1908] Alkynylzinc compounds undergo Pd catalyzed cross-coupling reactions.[1909]

1-Haloalkynes react with various substrates in the presence of a metal catalyst. 1-Haloalkynes (e.g., R—C≡C—X react with $ArSnBu_3$ and CuI to give R—C≡C—Ar.[1910] Organozirconium compounds react in a similar manner.[1911] Acetylene reacts with 2 equiv of iodobenzene, in the presence of a Pd catalyst and CuI, to give 1,2-diphenylethyne.[1912]

1-Trialkylsilyl alkynes react with 1-haloalkynes, in the presence of a CuCl catalyst, to give diynes[1913] and with aryl triflates to give 1-aryl alkynes.[1914] The enolate anion derived from a β-keto ester couples with 1-bromoalkynes to give the corresponding substitution product.[1915] 1-Bromoalkynes react with nitrogen compounds (e.g., imidazole) in the presence of a Cu catalyst to give the corresponding alkyne.[1916] 1-Bromoalkynes react with *Grignard* derived reagents in the presence of an Fe catalyst.[1917]

Alkynes couple with alkyl halides in the presence of SmI_2/Sm,[1918] or a copper catalyst.[1919] Alkynes react with hypervalent iodine compounds[1920] and with reactive alkanes (e.g., adamantane) in the presence of AIBN.[1921] The reaction of benzylic amines with terminal alkynes, in the presence of copper triflate and *tert*-butylhydroperoxide, leads to incorporation of the alkyne group α to the nitrogen.[1922] A similar reaction occurs at a methyl group of *N,N*-dimethylaniline.[1923] α-Methoxycarbamates ($MeO—CHR—NR^1—CO_2R^2$) react with terminal alkynes and CuBr to give the alkynylamine.[1924] In the presence of $GaCl_3$, $ClC{\equiv}CSiMe_3$ reacts with silyl enol ethers to give, after treatment with methanolic acid, an α-ethynyl ketone.[1925]

In a related reaction, terminal alkynes react with silanes (R_3SiH) in the presence of an Ir catalyst[1926] or zinc triflate[1927] to give the 1-trialkylsilyl alkyne. Similar products are obtained when terminal alkynes react with *N*-trialkylsilylamines and $ZnCl_2$.[1928]

10-75 Preparation of Nitriles

Cyano-de-halogenation

$$RX + {}^{-}CN \longrightarrow RCN$$

The reaction between cyanide ion and alkyl halides is a convenient method for the preparation of nitriles,[1929] The reaction proceeds by a S_N2 mechanism,[1930] so primary, benzylic, and allylic halides give good yields of nitriles; secondary halides give

moderate yields. The reaction fails for tertiary halides, which give elimination under these conditions. Many other groups on the molecule do not interfere. A number of solvents have been used, but the high yields and short reaction times observed with DMSO make it a very good solvent for this reaction.[1931] In general, polar aprotic solvents are the best choice. Other ways to obtain high yields under mild conditions are to use a phase-transfer catalyst,[1932] in alternative solvents (e.g., PEG 400 (a polyethylene glycol)],[1933] or with ultrasound.[1934] This is an important way of increasing the length of a carbon chain by one carbon, since nitriles are easily hydrolyzed to carboxylic acids (Reaction **16-4**).

The cyanide ion is an ambident nucleophile (it can react via N or via C) and isonitriles (also called isocyanides, R—N≡C) may be side products.[1935] If the preparation of isocyanides is desired (see Reaction **10-40**), they can be made the main products by the use of reagents with more covalent metal–carbon bonds [e.g., silver or copper(I) cyanide,[1936] Sec. 10.G.vii, category 3]. However, the use of an excess of LiCN in acetone/THF gave the nitrile as the major product.[1937] Tosyl cyanide ($TolSO_2CN$) has been used in some cases.[1938] A radical cyanation of alkyl iodides has been reported using diethylphosphoryl cyanide[1939] (see Chap. 14).

Vinylic bromides can be converted to vinylic cyanides with CuCN,[1940] with KCN, a crown ether, and a Pd complex,[1941] or with KCN and a Ni(0) catalyst.[1942] Halides can be converted to the corresponding nitriles by treatment with trimethylsilyl cyanide in the presence of catalytic amounts of $SnCl_4$: $R_3CCl + Me_3SiCN \rightarrow R_3CCN$.[1943] Primary, secondary, and tertiary alcohols are converted to nitriles in good yields by treatment with NaCN, Me_3SiCl, and a catalytic amount of NaI in DMF—MeCN.[1944] Lewis acids have been used in conjunction with NaCN or KCN.[1945] α,β-Epoxy amides were opened to the β-cyano-α-hydroxyamide with Et_2AlCN.[1946] Cyanohydrins react with alkyl halides in some cases to give the nitrile.[1947]

Substrates that react with cyanide may contain leaving groups other than halides (e.g., esters of sulfuric and sulfonic acids, sulfates and sulfonates, respectively). Vinylic triflates

give vinylic cyanides when treated with LiCN, a crown ether, and a Pd catalyst.[1948] Epoxides give β-hydroxy nitriles. The C-2-Selectivity was observed when NaCN and $B(OMe)_3$ were reacted with a disubstituted epoxide.[1949] The use of trimethylsilyl cyanide (Me_3SiCN) and a Lewis acid generates the *O*-TMS β-hydroxy nitrile, and the use of $YbCl_3$ and a salen complex gave good enantioselectivity.[1950] Tetrabutylammonium cyanide converted a primary alcohol to the corresponding nitrile in the presence of PPh_3/DDQ.[1951] Alcohols are converted to cyanides by reaction with triphenylphosphine and cyanogen bromide.[1952]

Sodium cyanide in HMPA selectively cleaves methyl esters in the presence of ethyl esters:[1953]

$$RCOOMe + CN^- \longrightarrow MeCN + RCOO^-$$

10-76 Direct Conversion of Alkyl Halides to Aldehydes and Ketones

Formyl-de-halogenation

$$RX + Na_2Fe(CO)_4 \xrightarrow{PPh_3} \underset{\mathbf{179}}{RCOFe(CO)_3PPh_3^-} \xrightarrow{HOAc} RCHO$$

The direct conversion of alkyl bromides to aldehydes, with an increase in the chain length by one carbon, can be accomplished[1954] by treatment with sodium tetracarbonylferrate(-2)[1955] (*Collman's reagent*) in the presence of triphenylphosphine and subsequent quenching of **179** with acetic acid. The reagent $Na_2Fe(CO)_4$ can be prepared by treatment of iron pentacarbonyl [$Fe(CO)_5$] with sodium amalgam in THF. Good yields are obtained from primary alkyl bromides; secondary bromides give lower yields. The reaction is generally not satisfactory for benzylic bromides, but a good yield of the ketone was obtained using benzyl chloride and aryl iodides.[1956] The initial species produced from RX and $Na_2Fe(CO)_4$ is the ion $RFe(CO)_4^-$, which can be isolated;[1957] it then reacts with Ph_3P to give **179**.[1958]

The synthesis can be extended to the preparation of ketones in six distinct ways.[1959] These include quenching **179** with a second alkyl halide (R′X) rather than acetic acid; omitting PPh_3 with first RX and then adding the second, R′X; treatment with RX in the presence of CO,[1955] followed by treatment with R′X′; treatment with an acyl halide followed by treatment with an alkyl halide or an epoxide, gives an α,β-unsaturated

ketone.[1960] The final variations involve reaction of alkyl halides or tosylates with $Na_2Fe(CO)_4$ in the presence of ethylene to give alkyl ethyl ketones;[1961] when 1,4-dihalides are used, five-membered cyclic ketones are prepared.[1962]

Yet another approach uses electrolysis conditions with the alkyl chloride, $Fe(CO)_5$, and a Ni catalyst, which gives the ketone directly, in one step.[1963] In the first stage of methods 1, 2, and 3, primary bromides, iodides, and tosylates and secondary tosylates can be used. The second stage of the first-four methods requires more active substrates (e.g., primary iodides or tosylates or benzylic halides). Method 5 has been applied to primary and secondary substrates.

Other acyl organometallic reagents are known. An acyl zirconium reagent [e.g., RCOZr(Cl)Cp_2] reacted with allylic bromide in the presence of CuI to give the corresponding ketone, but with allylic rearrangement.[1964]

Symmetrical ketones (R_2CO) can be prepared by treatment of a primary alkyl or benzylic halide with $Fe(CO)_5$ and a phase-transfer catalyst,[1965] or from a halide RX (R = primary alkyl, aryl, allylic, or benzylic) and CO by an electrochemical method involving a nickel complex.[1966] Aryl, benzylic, vinylic, and allylic halides have been converted to aldehydes by treatment with CO and Bu_3SnH, with a Pd catalyst.[1967] Various other groups do not interfere. Several procedures for the preparation of ketones are catalyzed by Pd complexes. Alkyl aryl ketones are formed in good yields by treatment of a mixture of an aryl iodide, an alkyl iodide, and a Zn—Cu couple with CO ($ArI + RI + CO \rightarrow RCOAr$).[1968] Vinylic halides react with vinylic tin reagents in the presence of CO to give unsymmetrical divinyl ketones.[1969] Aryl, vinylic, and benzylic halides can be converted to methyl ketones ($RX \rightarrow RCOMe$) by reaction with (α-ethoxyvinyl)tributyltin [$Bu_3SnC(OEt)=CH_2$].[1970] In addition, SmI_2 can be used to convert alkyl chlorides to ketones, in the presence of 50 atm of CO.[1971]

The conversion of alkyl halides to aldehydes and ketones can also be accomplished indirectly (Reaction **10-71**). See also, Reaction **12-33**.

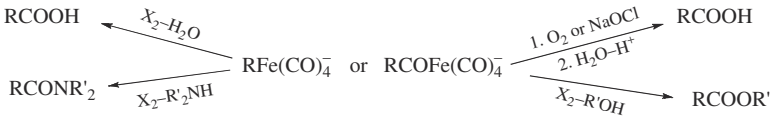
A direct method for preparing a carboxylic acid treats an alkyl halide with $NaNO_2$ in acetic acid and DMSO.[1972] Reaction of an alkyl halide with $ClCOCO_2Me$ and $(Bu_3Sn)_2$ under photochemical conditions leads to the corresponding methyl ester.[1973]

Several methods, all based on carbon monoxide or metal carbonyls, have been developed for converting an alkyl halide to a carboxylic acid or an acid derivative with the chain extended by one carbon.[1974] When an alkyl halide is treated with $SbCl_5—SO_2$ at $-70\,^{\circ}C$, it dissociates into the corresponding carbocation (Sec. 5.A.ii). If carbon monoxide and an alcohol are present, a carboxylic ester is formed by the following route:[1975]

This has also been accomplished with concentrated H_2SO_4 saturated with CO.[1976] Not surprisingly, only tertiary halides perform satisfactorily; secondary halides give mostly rearrangement products. An analogous reaction takes place with alkanes possessing a tertiary hydrogen, using $HF—SbF_5—CO$.[1977]

Carboxylic acids or esters are the products, depending on whether the reaction mixture is solvolyzed with water or an alcohol. Alcohols with more than seven carbons are cleaved into smaller fragments by this procedure.[1978] Similarly, tertiary alcohols[1979] react with H_2SO_4 and CO (which is often generated from HCOOH and the H_2SO_4 in the solution) to give trisubstituted acetic acids in a process called the *Koch–Haaf reaction* (see also, **15-35**).[1980] If a primary or secondary alcohol is the substrate, the carbocation initially formed rearranges to a tertiary ion before reacting with the CO. Better results are obtained if trifluoromethanesulfonic acid (F_3CSO_2OH) is used instead of H_2SO_4.[1981] Iodo alcohols were transformed into lactones under radical conditions (AIBN, $allylSnBu_3$) and 45 atm of CO.[1982]



Another method[1983] for the conversion of alkyl halides to carboxylic esters is treatment of a halide with nickel carbonyl [$Ni(CO)_4$] in the presence of an alcohol and its conjugate base.[1984] When R′ is primary, RX may only be a vinylic or an aryl halide; retention of

configuration is observed at a vinylic R. Consequently, a carbocation intermediate is not involved here. When R′ is tertiary, R may be primary alkyl as well as vinylic or aryl. This is thus one of the few methods for preparing esters of tertiary alcohols. Alkyl iodides give the best results, then bromides. In the presence of an amine, an amide can be isolated directly, at least in some instances.

$$RX + Ni(CO)_4 \xrightarrow[R'OH]{R'O^-} RCOOR'$$

Still another method for the conversion of halides to acid derivatives makes use of $Na_2Fe(CO)_4$. As described in Reaction **10-76**, primary and secondary alkyl halides and tosylates react with this reagent to give the ion $RFe(CO)_4^-$ or, if CO is present, the ion $RCOFe(CO)_4^-$. Treatment of $RFe(CO)_4^-$ or $RCOFe(CO)_4^-$ with oxygen or sodium hypochlorite gives, after hydrolysis, a carboxylic acid.[1985] Alternatively, $RFe(CO)_4^-$ or $RCOFe(CO)_4^-$ reacts with a halogen (e.g., I_2) in the presence of an alcohol to give a carboxylic ester,[1986] or in the presence of a secondary amine or water to give, respectively, the corresponding amide or free acid. Both $RFe(CO)_4^-$ and $RCOFe(CO)_4^-$, which are prepared from primary R, give high yields. With secondary R, the best results are obtained in the solvent THF by the use of $RCOFe(CO)_4^-$ prepared from secondary tosylates. Ester and keto groups may be present in R without being affected. Carboxylic esters (RCO_2R') have also been prepared by treating primary alkyl halides RX with alkoxides $R'O^-$ in the presence of $Fe(CO)_5$.[1987] Here $RCOFe(CO)_4^-$ is presumably an intermediate.

Palladium complexes also catalyze the carbonylation of halides.[1988] Aryl (see Reaction **13-15**),[1989] vinylic,[1990] benzylic, and allylic halides (especially iodides) can be converted to carboxylic esters with CO, an alcohol or alkoxide, and a Pd complex.[1991] The Pd catalyzed carbonylation of organoindium compounds in the presence of methanol gives methyl esters.[1992] Similar reactivity was reported with vinyl triflates.[1993] α-Halo ketones are converted to β-keto esters with CO, an alcohol, NBu_3 and a palladium catalyst at

110 °C.[1994] Use of an amine instead of the alcohol or alkoxide leads to an amide.[1995] Reaction with an amine, AIBN, CO, and a tetraalkyltin catalyst also leads to an amide.[1996] Benzylic and allylic halides were converted to carboxylic acids electrocatalytically, with CO and a Co–imine complex.[1997] Vinylic halides were similarly converted with CO and nickel cyanide, under phase-transfer conditions.[1998] Allylic *O*-phosphates were converted to allylic amides with CO and ClTi=NTMS, in the presence of a Pd catalyst.[1999] Terminal alkynes were converted to the alkynyl ester using CO, $PdBr_2$, $CuBr_2$ in methanol, and sodium bicarbonate.[2000]

Other organometallic reagents can be used to convert alkyl halides to carboxylic acid derivatives. Benzylic halides were converted to carboxylic esters with CO in the presence of a rhodium complex.[2001] Variations introduce the R′ group via an ether (R'_2O),[2002] or an Al, Ti, or Zr alkoxide.[2003] The reaction of an alkene, a primary alcohol, and CO, in the presence of a Rh catalyst, led to carbonylation of the alkene and formation of the corresponding ester.[2004] Vinyl triflates were converted to the conjugated carboxylic acid with CO_2 and a Ni catalyst.[2005] Reaction with an α,ω-diiodide, Bu_4NF, and Mo $(CO)_6$ gave the corresponding lactone.[2006]

A number of double carbonylations have been reported. In these reactions, two molecules of CO are incorporated in the product, leading to α-keto acids or their derivatives.[2007] When the catalyst is a Pd complex, best results are obtained in the formation of α-keto amides.[2008] The R group is usually aryl or vinylic.[2009] The formation of α-keto acids[2010] or esters[2011] requires more severe conditions. α-Hydroxy acids were obtained from aryl iodides when the reaction was carried out in the presence of an alcohol, which functioned as a reducing agent.[2012] Cobalt catalysts have also been used and require lower CO pressures.[2007]

CHAPTER 11

Aromatic Substitution, Electrophilic

Most substitutions at an aliphatic carbon are by nucleophiles. In aromatic systems the situation is reversed, because the high electron density at the aromatic ring leads to its reactivity as a Lewis base or a Brønsted–Lowry base, depending on the positive species. In electrophilic substitutions, a positive ion or the positive end of a dipole or induced dipole is attacked by the aromatic ring. The leaving group (the electrofuge) must necessarily depart without its electron pair. In nucleophilic substitution reactions, the chief leaving groups are those best able to carry the unshared pair: Br^-, H_2O, OTs^-, and so on (i.e., the weakest bases). In electrophilic substitution reactions, the most important leaving groups are those that can best exist without the pair of electrons necessary to fill the outer shell; that is, the weakest Lewis acids. The influence of solvents will vary with the reaction in many cases, and such details are discussed where appropriate in the reactions section (Sec. 11.F).[1]

11.A. MECHANISMS

Electrophilic aromatic substitutions are unlike nucleophilic substitutions in that the large majority proceeds by just one mechanism with respect to the substrate.[2] In this mechanism, called the *arenium ion mechanism*, the electrophile, which can be viewed as a Lewis acid, is attacked by the π electrons of the aromatic ring, which can be viewed as a Lewis base, in the first step. This reaction leads to formation of a new C—X bond and a new sp^3 carbon in a positively charged intermediate called an arenium ion, where X is the electrophile. The positively charged intermediate (the arenium ion) is resonance stabilized, but not aromatic. Loss of a proton from the sp^3 carbon that is "adjacent" to the positive carbon in the arenium ion, in what is effectively an E1 process (see Sec. 17.A.ii) is driven by rearomatization of the ring from the arenium ion to give the aromatic substitution product. A proton therefore becomes the leaving group in this overall transformation, where X replaces H. The IUPAC designation for this mechanism is $A_E + D_E$. Another mechanism, much less common, consists of the opposite behavior: a leaving group departs *before* the electrophile arrives.

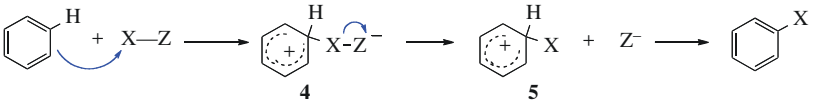
In this case, a substituent (*not* H) is attached to the aromatic ring, and the substituent is lost prior to incorporation of the electrophile. This mechanism, the S_E1 mechanism, corresponds to the S_N1 mechanism of nucleophilic substitution. Simultaneous attack and departure mechanisms (corresponding to S_N2) are not found at all. An addition–elimination mechanism has been postulated in one case (see Reaction **11-6**).

11.A.i. The Arenium Ion Mechanism[3]

In the arenium ion mechanism, the electrophilic species may be produced in various ways, but when H is replaced by X conversion of the aromatic ring to an arenium ion it is basically the same in all cases. For this reason, most attention in the study of this mechanism centers on the identity of the electrophilic entity and how it is produced.

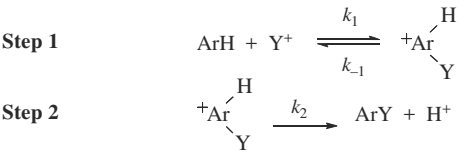


The electrophile may be a positive ion (X^+) or be a molecule that has a positive dipole. If it is a positive ion, it is attacked by the ring (a pair of electrons from the aromatic sextet is donated to the electrophile) and the product is a carbocation. This intermediate is a resonance hybrid, as shown in **1**, but is often represented as in **2**. The H atom to be replaced by X is shown in **1** for convenience. Ions of this type have been called[4] *Wheland intermediates*, σ *complexes*, but nowadays they are called *arenium ions*.[5] The inherent stability associated with aromaticity is no longer present in **1**, but the ion is stabilized by resonance. For this reason, the arenium ion is generally a highly reactive intermediate, although there are cases in which it has been isolated (see below).

Carbocations can react in various ways (see Sec. 5.A.iii), but for this type of ion the most likely pathway[6] is loss of either X^+ or H^+. In the second step of the mechanism, the reaction proceeds with loss of the proton and the aromatic sextet is restored in the final product (**3**). The second step is nearly always faster than the first, making the first rate determining, and the reaction is second order. If formation of the attacking species is slower still, the aromatic compound does not take part in the rate expression at all. If X^+ is lost, there is no net reaction, but if H^+ is lost, an aromatic substitution has taken place and a base (generally the counterion of the electrophilic species although solvents can also serve this purpose) is necessary to help remove it.

[3] This mechanism is sometimes called the S_E2 mechanism because it is bimolecular, but in this book we reserve that name for aliphatic substrates (see Chap 12).
[4] See Olah, G.A. *J. Am. Chem. Soc.* ***1971****, 94,* 808.
[5] See Brouwer, D.M.; Mackor, E.L.; MacLean, C. in Olah, G.A.; Schleyer, P.v.R. *Carbonium Ions*, Vol. 2, Wiley, NY, ***1970***, pp. 837–897; Perkampus, H. *Adv. Phys. Org. Chem.* ***1966****, 4,* 195.
[6] Also see de la Mare, P.B.D. *Acc. Chem. Res.* ***1974****, 7,* 361.

If the electrophilic species is not an ion but a molecule with a polarized covalent bond, the product must have a negative charge unless part of the dipole, with its pair of electrons, is broken off somewhere in the process, as in the conversion of **4** to **5**. Note that when the aromatic ring attacks X, Z may be lost directly to give **5**.



The electrophilic entities and how they are formed are discussed for each reaction in the reactions section of this chapter.

The evidence for the arenium ion mechanism is mainly of two kinds:

1. *Isotope Effects*. If the hydrogen ion departs before the arrival of the electrophile (S_E1 mechanism) or if the arrival and departure are simultaneous, there should be a substantial isotope effect (i.e., deuterated substrates should undergo substitution more slowly than non-deuterated compounds) because, in each case, the C—H bond is broken in the rate-determining step. However, in the arenium ion mechanism, the C—H bond is not broken in the rate-determining step, so no isotope effect should be found. Many such studies have been carried out and, in most cases, especially in the case of nitrations, there is no isotope effect.[7] This result is incompatible with either the S_E1 or the simultaneous mechanism.

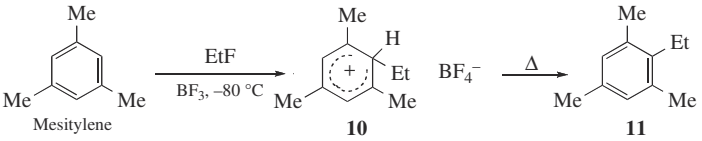
   However, in many instances, isotope effects have been found. Since the values are generally much lower than expected for either the S_E1 or the simultaneous mechanisms (e.g., 1–3 for k_H/k_D instead of 6–7), there must be another explanation. For the case where hydrogen is the leaving group, the arenium ion mechanism can be summarized:

   The small isotope effects found most likely arise from the reversibility of step 1 by a *partitioning effect*.[8] The rate at which $ArHY^+$ reverts to ArH should be essentially the same as that at which $ArDY^+$ (or $ArTY^+$) reverts to ArD (or ArT), since the Ar—H bond is not cleaving. However, $ArHY^+$ should go to ArY faster than either $ArDY^+$ or $ArTY^+$, since the Ar—H bond is broken in this step. If $k_2 \gg k_{-1}$, this does not matter; since a large majority of the intermediates go to product, the rate is determined only by the slow step ($k_2 1[ArH][Y^+]$) and no isotope effect is predicted. However, if $k_2 \leq k_{-1}$, reversion to starting materials is important. If k_2 for $ArDY^+$ (or $ArTY^+$) is $< k_2$ for $ArHY^+$, but k_{-1} is the same, then a larger proportion of $ArDY^+$ reverts to starting compounds. That is, k_2/k_{-1} (the *partition factor)* for

[7] Berglund-Larsson, U.; Melander, L. *Ark. Kemi* ***1953****, 6,* 219. See also, Zollinger, H. *Adv. Phys. Org. Chem.* ***1964****, 2,* 163.

[8] See Hammett, L.P. *Physical Organi Chemistry*, 2nd ed.; McGraw-Hill, NY, ***1970***, pp. 172–182.

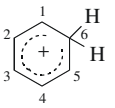
$ArDY^+$ is less than that for $ArHY^+$. Consequently, the reaction is slower for ArD than for ArH and an isotope effect is observed.



One circumstance that could affect the k_2/k_{-1} ratio is steric hindrance. Thus, diazonium coupling of **6** gave no isotope effect, while coupling of **8** gave a k_H/k_D ratio of 6.55.[9] For steric reasons, it is much more difficult for **9** to lose a proton (it is harder for a base to approach) than it is for **7**, so k_2 is greater for the latter. Since no base is necessary to remove ArN_2^+, k_{-1} does not depend on steric factors[10] and is about the same for each. Thus the partition factor k_2/k_{-1} is sufficiently different for **7** and **9** that **8** exhibits a large isotope effect and **6** exhibits none.[11] Base catalysis can also affect the partition factor, since an increase in base concentration increases the rate at which the intermediate goes to product without affecting the rate at which it reverts to starting materials. In some cases, isotope effects can be diminished or eliminated by a sufficiently high concentration of base.

Evidence for the arenium ion mechanism has also been obtained from other kinds of isotope-effect experiments, involving substitutions of the type

$$ArMR_3 + H_3O^+ \longrightarrow ArH + R_3MOH_2^+$$



where M is Si, Ge, Sn, or Pb, and R is methyl or ethyl. In these reactions, the proton is the electrophile. If the arenium ion mechanism is operating, then the use of D_3O^+ should give rise to an isotope effect, since the D—O bond would be broken in the rate-determining step. Isotope effects of 1.55–0.05 were obtained,[12] in accord with the arenium ion mechanism.

2. *Isolation of Arenium Ion Intermediates*. Very strong evidence for the arenium ion mechanism comes from the isolation of arenium ions in a number of instances.[13] For example, **7** was isolated as a solid with a

melting point of −15 °C from treatment of mesitylene with ethyl fluoride and the catalyst BF_3 at −80 °C. When **10** was heated, the normal substitution product (**11**) was obtained.[14] Even the simplest such ion, the benzenonium ion (**12**) has been prepared in $HF—SbF_5—SO_2ClF—SO_2F_2$ at −134 °C, where it could be studied

12

13

spectrally.[15] The ^{13}C NMR spectra of the benzenonium ion[16] and the pentamethylbenzenonium ion[17] give graphic evidence for the charge distribution shown in **12** (see the electron density map for the arenium ion, **13**). According to this, the 1, 3, and 5 carbons, each of which bears a positive charge of about +1/3 [note that C-1,-3,-5 (numbering from **12**) are lighter, indicating less electron density in **13**, whereas C-2,-4 are darker for higher electron density], should have a greater chemical shift in the NMR than the 2 and 4 carbon atoms, which are uncharged. The spectra bear this out. For example, ^{13}C NMR chemical shifts for **12** are C-3: 178.1; C-1 and C-5: 186.6; C-2 and C-4: 136.9, and C-6: 52.2.[16]

In Chapter 3, it was mentioned that positive ions can form addition complexes with π systems. Since the initial step of electrophilic substitution involves attack of a positive ion by an aromatic ring, it has been suggested[18] that such a complex, called a π-*complex* (represented as **14**), is formed first, and then is converted to the arenium ion (**15**).[19] Stable solutions of arenium ions or π complexes (e.g., with Br_2, I_2, picric acid, Ag^+, or HCl) can be formed.[20] For example, π-complexes are formed when aromatic hydrocarbons are treated with HCl alone, but the use of HCl plus a Lewis acid (e.g., $AlCl_3$) gives arenium ions. The two types of solution have very different properties. For example, a solution of an arenium ion is colored and conducts electricity, which shows that positive and negative ions are present, while a π complex formed from HCl and benzene is colorless and does not conduct a current. Furthermore, when DCl is used to form a π complex, no deuterium exchange takes place (because there is no covalent bond between the electrophile and the ring), while formation of an arenium ion with DCl and $AlCl_3$ gives deuterium exchange. The relative stabilities of some methylated arenium ions and π complexes are shown in Table 11.1. The arenium ion stabilities listed were

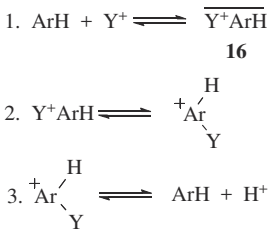
determined by the relative basicity of the substrate toward HF.[21] The π-complex stabilities are relative equilibrium constants for the reaction[22] between the aromatic hydrocarbon and HCl. As shown in Table 11.1, the relative stabilities of the two types of species are very different: The π complex stability changes very little with methyl substitution, but the arenium ion stability changes a great deal. Note that stable arenium ions have been obtained from large methylene-bridged polycyclic aromatic hydrocarbons.[23]



14 **15**

How can we tell if **14** is present on the reaction path? If it is present, there are two possibilities: (1) The formation of **14** is rate determining (the conversion of **14** to **15** is much faster), or (2) the formation of **14** is rapid, and the conversion **14** to **15** is rate determining. One way to ascertain which species is formed in the rate-determining step in a given reaction is to use the stability information given in Table 11.1. We measure the relative rates of reaction of a given electrophile with the series of compounds listed in Table 11.1. If the relative rates resemble the arenium ion stabilities, we conclude that the arenium ion is formed in the slow step; but if they resemble the stabilities of the π

[21] Kilpatrick, M.; Luborsky, F.E. *J. Am. Chem. Soc.* ***1953***, *75*, 577.

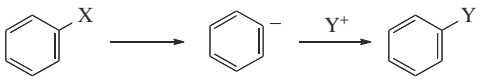
complexes, the latter are formed in the slow step.[24] When such experiments are carried out, it is found in most cases that the relative rates are similar to the arenium ion and not to the π complex stabilities. For example, Table 11.1 lists chlorination rates.[22] Similar results were obtained in room temperature bromination with Br_2 in acetic acid[25] and in acetylation with CH_3CO^+ SbF_6^-.[26] It is clear that in these cases the π complex either does not form at all, or if it does, its formation is not rate determining (unfortunately, it is very difficult to distinguish between these two possibilities).

On the other hand, in nitration with the powerful electrophile NO_2^+ (in the form of NO_2^+ BF_4^-), the relative rates resembled π complex stabilities much more than arenium ion stabilities (Table 11.1).[27] Similar results were obtained for bromination with Br_2 and $FeCl_3$ in nitromethane. These results were taken to mean[28] that in these cases π complex formation is rate determining. However, graphical analysis of the NO_2^+ data showed that a straight line could not be drawn when the nitration rate was plotted against π-complex stability,[29] which casts doubt on the rate-determining formation of a π complex in this case.[30] There is other evidence, from positional selectivities (discussed in Sec. 11.D), that *some* intermediate is present before the arenium ion is formed, whose formation can be rate determining with powerful electrophiles. Not much is known about this intermediate, which is given the nondescriptive name *encounter complex* and generally depicted as **16**. The arenium complex mechanism is therefore written as:[31]



For the reason given above and for other reasons, it is unlikely that the encounter complex is a π complex, but just what kind of attraction exists between Y^+ and ArH is not known, other than the presumption that they are together within a solvent cage (see also, Sec. 11.D). There is evidence (from isomerizations occurring in the alkyl group, as well as other observations) that π complexes are present on the pathway from substrate to arenium ion in the gas-phase protonation of alkylbenzenes.[32]

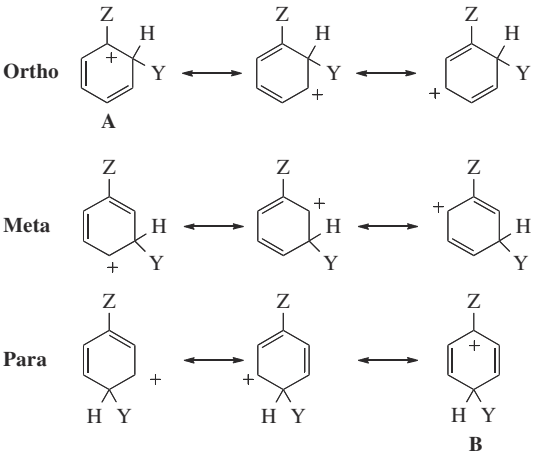
11.A.ii. The S_E1 Mechanism

The S_E1 mechanism (*substitution electrophilic unimolecular*) is rare, being found only in certain cases in which carbon is the leaving atom (see Reactions **11-33** and **11-35**) or when a very strong base is present (see Reactions **11-1**, **11-10**, and **11-39**).[33] It consists of two steps with an intermediate carbanion. The IUPAC designation is $D_E + A_E$.

Reactions **12-41**, **12-45**, and **12-46** also take place by this mechanism when applied to aryl substrates.

11.B. ORIENTATION AND REACTIVITY

11.B.i. Orientation and Reactivity in Monosubstituted Benzene Rings[34]



When an electrophilic substitution reaction is performed on a monosubstituted benzene, the new group may be directed primarily to the ortho, meta, or para position and the substitution may be slower or faster than with benzene itself.[35] The group already on the ring determines which position the new group will take and whether the reaction will be slower or faster than with benzene. Groups that increase the reaction rate are called *activating* and those that slow it are *deactivating*. Some groups are predominantly meta directing; all of these are deactivating. Others are mostly ortho–para directing; while some of these (e.g., halogens) are deactivating too, most are activating. Groups direct *predominantly*, but usually not *exclusively*. For example, nitration of nitrobenzene gave 93% *m*-dinitrobenzene, 6% of the ortho, and 1% of the para isomer.

The orientation and reactivity effects are explained on the basis of resonance and field effects of each group on the stability of the intermediate arenium ion. To understand why we can use this approach, it is necessary to know that in these reactions the product is usually kinetically and not thermodynamically controlled (see Sec. 6.F). Some of the reactions are irreversible and the others are usually stopped well before equilibrium is reached. *Therefore, which of the three possible intermediates is formed is dependent not on the thermodynamic stability of the products, but on the activation energy necessary to form each of the three intermediates.* It is not easy to predict which of the three activation energies is lowest, but it is necessary to make the assumption that the free energy profile resembles either Fig. 6.2*a* or *b*. In either case, the transition state is closer in energy to the arenium ion intermediate than to the starting compounds. Invoking the *Hammond postulate* (Sec. 6.G), assume that the geometry of the transition state also resembles that of the intermediate and that anything that increases the stability of the intermediate will

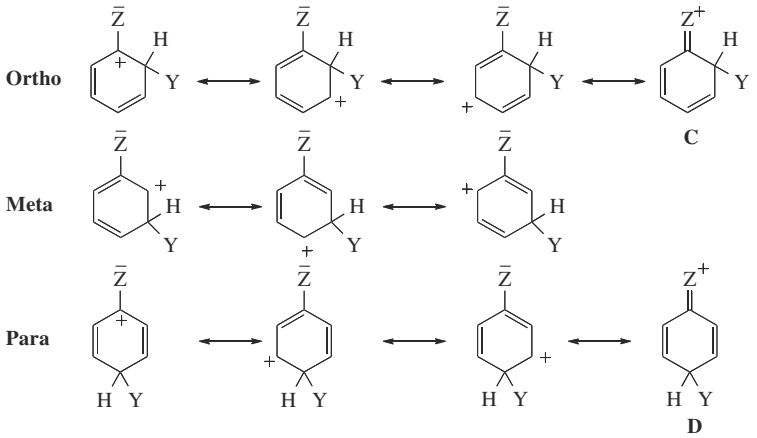
also lower the activation energy necessary to attain it. Since the intermediate, once formed, is rapidly converted to products, the relative stabilities of the three intermediates can be used as guides to predict which products will predominantly form. Of course, if reversible reactions are allowed to proceed to equilibrium, product ratios that are quite different may be obtained. For example, the sulfonation of naphthalene at 80 °C, where the reaction does not reach equilibrium, gives mostly α-naphthalenesulfonic acid,[36] while at 160 °C, where equilibrium is attained, the β isomer predominates[37] (the α isomer is thermodynamically less stable because of steric interaction between the SO_3H group and the hydrogen at the 8 position).

The three possible ions from incorporation of Y at the ortho, meta, and para positions are shown below, and each arenium ion obviously has a positive charge in the ring. It is therefore possible to predict that any group Z that has an electron-donating field effect (+*I*, Z will have a − charge or a δ− dipole in most cases) should stabilize all three ions (relative to **1**), since electron donation to a positive center is stabilizing. On the other hand, electron-withdrawing groups (−*I*, Z will have a + charge or a δ+ dipole in most cases) will increase the positive charge on the ring (like charges repel), and destabilize the arenium ion. Formation of a stabilized ion should be faster than benzene, which generates **1**, or activating, but formation of a destabilized ion should be slower, or deactivating. Such field effects should taper off with distance and are thus strongest at the carbon connected to the group Z (known as the ipso carbon). Of the three arenium ions, only the ortho and para have any positive charge at this carbon. None of the canonical forms of the meta ion has a positive charge at the ipso carbon. Therefore, +*I* groups should stabilize all three ions, but mostly the ortho and para, so they should be not only activating but ortho–para-directing as well. On the other hand, −*I* groups, by removing electron density, should destabilize all three ions, but mostly the ortho and para, and should be not only deactivating but also meta directing.



These conclusions are correct as far as they go, but they do not lead to the proper results in all cases. In many cases, there is *resonance interaction* between Z and the ring; this also

[36] Fierz, H.E.; Weissenbach, P. *Helv. Chim. Acta* ***1920****, 3,* 312.
[37] Witt, O.N. *Ber.* ***1915****, 48,* 743.

affects the relative stability, in some cases in the same direction as the field effect, in others differently.

Some substituents have a pair of electrons (usually unshared) that may be contributed *toward* the ring. Two of the three (ortho and para) arenium ions would then have a fourth resonance contributor as shown. For each ion, the same three canonical forms can be drawn as before, but now we can draw an extra form for the ortho and para ions. The stability of these two ions is increased by the extra form not only because it is another canonical form, but also because it is more stable than the others and makes a greater contribution to the hybrid. Every atom (except, of course, hydrogen) in these forms (**C** and **D**) has a complete octet, while all the other forms have one carbon atom with a sextet. No corresponding form can be drawn for the meta isomer. The inclusion of this form in the hybrid lowers the energy not only because of rule 6 (Sec. 2.E), but also because it spreads the positive charge over a larger area, out onto group Z. Groups with a pair of electrons (e.g., the halogens) to contribute would be expected, then, in the absence of field effects, not only to direct ortho and para, but also to activate these positions for electrophilic attack.

On the basis of these discussions, we can distinguish three types of groups.

1. *Groups that Contain an Unshared Pair of Electrons on the Atom Connected to the Ring*. In this category are O^-, NR_2, NHR, NH_2,[38] OH, OR, NHCOR, OCOR, SR, and the four halogens.[39] The halogens deactivate the aromatic ring to substitution (the rate of reaction is slower than that of benzene), and this effect may arise from the unique energy level of the halogen lone-pair orbital, which is higher than the

[38] It must be remembered that in acid solution amines are converted to their conjugate acids, which for the most part are meta directing (type 2). However, unless the solution is highly acidic, there will be a small amount of free amine present, and since amino groups are activating and the conjugate acids deactivating, ortho–para direction is often found even under acidic conditions.

[39] See Chuchani, G. in Patai, S. *The Chemistry of the Amino Group*, Wiley, NY, ***1968***, pp. 250–265; for ether groups see Kohnstam, G.; Williams, D.L.H. in Patai, S. *The Chemistry of the Ether Linkage*, Wiley, NY, ***1967***, pp. 132–150.

adjacent π molecular orbital of benzene (π_1).[40] The widely held explanation for this, however, is that the halogens have a $-I$ effect. The SH group would probably belong here too, except that in the case of thiophenols, electrophiles usually attack the sulfur rather than the ring, and ring substitution is not feasible with these substrates.[41] The resonance explanation predicts that all these groups should be ortho–para directing, and they are, though all except O^- are electron withdrawing by the field effect (Sec. 1.I). Therefore, for these groups, resonance is more important than the field effect. This result is especially true for NR_2, NHR, NH_2, and OH, which are *strongly* activating, as is O^-. The other groups are mildly activating, except for the halogens, which are deactivating. Fluorine[42] is the least deactivating, and fluorobenzenes usually show a reactivity approximating that of benzene itself. The other three halogens deactivate about equally. In order to explain why chlorine, bromine, and iodine deactivate the ring, even though they direct ortho–para, assume that the canonical forms **C** and **D** make such great contributions to the respective hybrids that they make the ortho and para arenium ions more stable than the meta, even though the $-I$ effect of the halogen is withdrawing sufficient electron density from the ring to deactivate it. The three halogens make the ortho and para ions more stable than the meta, but less stable than the unsubstituted arenium ion (**1**). For the other groups that contain an unshared pair, the ortho and para ions are more stable than either the meta or the unsubstituted ion. For most of the groups in this category, the meta ion is more stable than **1**, so that groups, such as NH_2 and OH, activate the meta positions too, but not as much as the ortho and para positions (see also, the discussion in Sec. 11.C).

2. *Groups that Lack an Unshared Pair on the Atom Connected to the Ring and that Are $-I$.* In this category are, in approximate order of decreasing deactivating ability, NR_3^+, NO_2, CF_3,[43] CN, SO_3H, CHO, COR, CO_2H, CO_2R, $CONH_2$, CCl_3, and NH_3^+. Also in this category are all other groups with a positive charge on the atom directly connected to the ring[44] (SR_2^+, PR_3^+, etc.) and many groups with positive charges on atoms farther away, since often these are still powerful $-I$ groups. The field-effect explanation predicts that these should all be meta directing and deactivating, and (except for NH_3^+) this is the case. The NH_3^+ group is an anomaly, since this group directs para about as much as or a little more than it directs meta.[45] The NH_2Me^+, $NHMe_2^+$, and NMe_3^+ groups all give more meta than para substitution, the percentage of para product decreasing with the increasing number of methyl groups.[46]

3. *Groups that Lack an Unshared pair on the Atom connected to the Ring and that Are ortho–para Directing*. In this category are alkyl groups,[47] aryl groups, and the COO^- group,[48] all of which activate the ring. Since aryl groups are $-I$ groups, they might seem to belong to category 2. They are nevertheless ortho–para directing and activating. This can be explained in a similar manner as in category 1, with a pair of electrons from the aromatic sextet playing the part played by the unshared pair, so that forms like **E** are generated The effect of negatively charged groups like CO_2^- is easily explained by the field effect (negatively charged groups are of course electron donating), since there is no resonance interaction between the group and the ring. The effect of alkyl groups can be explained in the same way, but, in addition, canonical forms can be drawn, even though there is no unshared pair. These, of course, are hyperconjugation forms like **F** (see above). This effect, like the field effect, predicts activation and ortho–para direction, so that it is not possible to say how much each effect contributes to the result. Another way of looking at the effect of alkyl groups, which sums up both field and hyperconjugation effects, is that (for Z = R) the ortho and para arenium ions are more stable because each contains a form (**A** and **B**) that is a tertiary carbocation, while all the canonical forms for the meta ion and for **1** are secondary carbocations. In activating ability, alkyl groups usually follow the *Baker–Nathan order* (Sec. 2.M), but not always.[49]

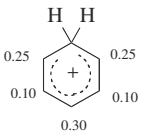
E **F**

11.B.ii. The Ortho/Para Ratio[50]

When an ortho–para directing group is on a ring, it is usually difficult to predict how much of the product will be the ortho isomer and how much is the para isomer. Indeed, these proportions can depend greatly on the reaction conditions. For example, chlorination of toluene gives an ortho/para ratio anywhere from 62:38 to 34:66.[51] Nevertheless, certain points can be made. On a purely statistical basis there would be 67% ortho and 33% para, since there are two ortho positions and only one para. However, the phenonium ion (**12**), which arises from protonation of benzene, has the approximate charge distribution shown[52] (see **13** as well). If this model were accepted for the arenium ion in aromatic substitution, a para substituent would have a greater stabilizing effect on the adjacent carbon than an ortho substituent. If other effects are absent, this would mean that >33% para and <67% ortho substitution would be found. In hydrogen exchange (Reaction **11-1**), where other effects are absent, it has been found for a number of

[47] For a discussion of the substituents effect of the methyl group, see Myrseth, V.; Sæthre, L.J.; Børve, K.J.; Thomas, T.D. *J. Org. Chem.* ***2007****, 72,* 5715.

[48] Spryskov, A.A.; Golubkin, L.N. *J. Gen. Chem. USSR* ***1961****, 31*, 833. Since the CO_2^- group is present only in alkaline solution, where electrophilic substitution is not often done, it is seldom encountered.



[49] See, however, Schubert, W.M.; Gurka, D.F. *J. Am. Chem. Soc.* ***1969****, 91,* 1443; Himoe, A.; Stock, L.M. *J. Am. Chem. Soc.* ***1969****, 91,* 1452.

[50] See Effenberger, F.; Maier, A.J. *J. Am. Chem. Soc.* ***2001****, 123*, 3429.

[51] Stock, L.M.; Himoe, A. *J. Am. Chem. Soc.* ***1961****, 83,* 4605.

[52] Olah, G.A. *Acc. Chem. Res.* ***1970****, 4,* 240, p. 248.

substituents that the average ratio of the logarithms of the partial rate factors for these positions (see Sec. 11.C for a definition of partial rate factor) was close to 0.865,[53] which is not far from the value predicted from the ratio of charge densities in **12**. This picture is further supported by the fact that meta-directing groups, which destabilize a positive charge, give ortho/para ratios >67:33[54] (of course, the total amount of ortho and para substitution with these groups is small, but the *ratios* are generally >67:33). Another important factor is the steric effect. If either the group on the attacking ring or the group on the electrophile is large, steric hindrance inhibits formation of the ortho product and increases the amount of the para isomer. An example may be seen in the nitration, under the same conditions, of toluene and *tert*-butylbenzene. The former gave 58% of the ortho compound and 37% of the para, while the more bulky *tert*-butyl group gave 16% of the ortho product and 73% of the para.[55] Some groups are so large that they direct almost entirely para.

12

When the ortho–para directing group is one with an unshared pair (this of course applies to most of them), there is another effect that increases the amount of para product at the expense of the ortho. A comparison of the intermediates involved (see above) shows that **C** is a canonical form with an *ortho*-quinoid structure, while **D** has a *para*-quinoid structure. *para*-Quinones are more stable than the ortho isomers, so it seems reasonable to assume that **D** is more stable than **C**, and therefore contributes more to the hybrid and increases its stability compared to the ortho intermediate.

It has been shown that it is possible to compel regiospecific para substitution by enclosing the substrate molecules in a cavity from which only the para position projects. Anisole was chlorinated in solutions containing a cyclodextrin, a molecule in which the anisole is almost entirely enclosed (see Fig. 3.4). With a high enough concentration of cyclodextrin, it was possible to achieve a para/ortho ratio of 21.6[56] (in the absence of the cyclodextrin the ratio was only 1.48). This behavior is a model for the regioselectivity found in the action of enzymes.

11.B.iii. Ipso Attack

Orientation has been discussed previously in the case of monosubstituted benzenes entirely in terms of attachment at the ortho, meta, and para positions, but attachment at

the position bearing the substituent (called the *ipso position*[57]) can also be important. Ipso attack has mostly been studied for nitration.[58] When attack of NO_2^+ leads to incorporation at the ipso position there are at least five possible fates for the resulting arenium ion (**17**).

Path a. The arenium ion can lose NO_2^+ and revert to the starting compounds. This results in no net reaction and is often undetectable.

Path b. The arenium ion can lose Z^+, in which case this is simply aromatic substitution with a leaving group other than H (see Reactions **11-33–11-41**).

Path c. The electrophilic group (in this case NO_2^+) can undergo a 1,2-migration, followed by loss of the proton. The product in this case is the same as that obtained by direct attachment of NO_2^+ at the ortho position of PhZ. It is not always easy to tell how much of the ortho product in any individual case arises from this pathway,[59] though there is evidence that it can be a considerable proportion. Because of this possibility, many of the reported conclusions about the relative reactivity of the ortho, meta, and para positions are cast into doubt, since some of the product may have arisen not from direct attachment at the ortho position, but from attachment at the ipso position followed by rearrangement.[60]

Path d. The ipso substituent (Z) can undergo 1,2-migration, which also produces the ortho product (although the rearrangement would become apparent if there were other substituents present). The evidence is that this pathway is very minor, at least when the electrophile is NO_2^+.[61]

Path e. Attack of a nucleophile on **17**. In some cases, the products of such an attack (cyclohexadienes) have been isolated[62] (this is 1,4-addition to the aromatic ring), but further reactions are also possible.

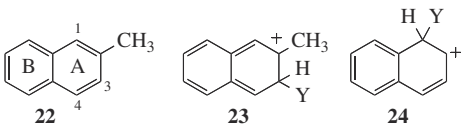
11.B.iv. Orientation in Benzene Rings with More Than One Substituent[63]

It is often possible in these cases to predict the correct isomer. In many cases, the groups already on the ring reinforce each other. Thus, 1,3-dimethylbenzene is substituted at the 4 position (ortho to one group and para to the other), but not at the 5 position (meta to both). Likewise, the incoming group in *p*-chlorobenzoic acid goes to the position ortho to the chloro and meta to the carboxyl group.

When the groups oppose each other, predictions may be more difficult, as in *N*-acetyl-2-methoxyaniline. In a case such as where two groups of about equal directing ability are in competing positions, all four products can be expected, and it is not easy to predict the proportions, except that steric hindrance should probably reduce the yield of substitution ortho to the acetamido group, especially for large electrophiles. Mixtures of about equal proportions are frequent in such cases. Nevertheless, even when groups on a ring oppose each other, there are some regularities.

1. If a strong activating group competes with a weaker one or with a deactivating group, the former controls. Thus *o*-cresol gives substitution mainly ortho and para to the *hydroxyl* group and not to the methyl. For this purpose, we can arrange the groups in the following order: NH_2, OH, NR_2, $O^- >$ OR, OCOR, NHCOR > R, Ar > halogen > meta-directing groups.
2. All other things being equal, a third group is least likely to enter between two groups in the meta relationship. This is the result of steric hindrance and increases in importance with the size of the groups on the ring and with the size of the attacking species.[64]
3. When a meta-directing group is meta to an ortho–para directing group, the incoming group primarily goes ortho to the meta-directing group rather than para. For example, chlorination of **18** gives mostly **19**. The importance of this effect is underscored by the fact that **20**, which is in violation of the preceding rule, is formed in smaller amounts, but **21** is not formed at all. This is called the *ortho effect*,[65] and many such examples are known.[66] Another is the nitration of *p*-bromotoluene, which gives 2,3-dinitro-4-bromotoluene. In this case, once the first nitro group came in, the second was directed ortho to it rather than para, even though this means that the group has to come in between two groups in the meta position. There is no good explanation yet for the ortho effect, though possibly there is intramolecular assistance from the meta-directing group.

18 **19** **20** **21**



[63] For a quantitative discussion, see Section 11.C.
[64] See Kruse, L.I.; Cha, J.K. *J. Chem. Soc., Chem. Commun.* ***1982***, 1333.
[65] This is not the same as the ortho effect mentioned at the end of Section 9.C.
[66] See Hammond, G.S.; Hawthorne, M.F. in Newman, M.S. *Steric Effects in Organic Chemistry*, Wiley, NY, ***1956***, pp. 164–200, 178–182.

It is interesting that chlorination of **18** illustrates all three rules. Of the four positions open to the electrophile, the 5 position violates rule 1, the 2 position rule 2, and the 4 position rule 3. The principal attachment is therefore at position 6.

11.B.v. Orientation in Other Ring Systems[67]

In fused ring systems, the positions are not equivalent and there is usually a preferred orientation, even in the unsubstituted hydrocarbon. The preferred positions may often be predicted as for benzene rings. Thus it is possible to draw more canonical forms for the arenium ion when attack by naphthalene leads to attachment of the electrophile at the α position than when attack by naphthalene leads to attachment of the electrophile at the β position. Therefore, the α position is the preferred site of attachment,[68] although, as previously mentioned (Sec. 11.B.i), the isomer formed by substitution at the β-position is thermodynamically more stable and is the product if the reaction is reversible and equilibrium is reached. Because of the more extensive delocalization of charges in the corresponding arenium ions, naphthalene is more reactive than benzene and substitution is faster at both positions. Similarly, anthracene, phenanthrene, and other fused polycyclic aromatic hydrocarbons are also substituted faster than benzene.

Heterocyclic compounds, too, have nonequivalent positions, and the principles are similar,[69] in terms of mechanism, and rate data is available.[70] Furan, thiophene, and pyrrole are chiefly substituted at the 2 position, and all are substituted faster than benzene.[71] Pyrrole is particularly reactive, with a reactivity approximating that of aniline or the phenoxide ion. For pyridine,[72] it is not the free base that must attack the electrophile but the conjugate acid (the pyridinium ion),[73] making the reactivity much less than that of benzene, being similar to that of nitrobenzene. The 3 position is most reactive in electrophilic substitution reactions of pyridine. However, groups can be introduced into the 4 position of a pyridine ring indirectly, by performing the reaction on the corresponding pyridine *N*-oxide.[74] Note that calculations show that the 2-pyridyl and 2-pyrimidyl cations are best represented as *ortho*-hetarynium ions, being more stable than their positional, nonconjugated isomers by as much as 18–28 kcal mol^{-1} (75–117 kJ mol^{-1}).[75]

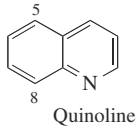
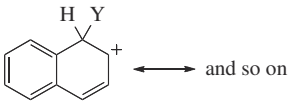
[75] Gozzo, F. C.; Eberlin, M. N. *J. Org. Chem.* ***1999****, 64,* 2188.

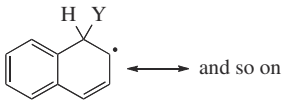


When fused ring systems contain substituents, successful predictions can often be made by using a combination of the above principles. Thus, ring A of 2-methylnaphthalene (**22**) is activated by the methyl group; ring B is not (although the presence of a substituent in a fused ring system affects all the rings,[76] the effect is generally greatest on the ring to which it is attached). Substitution is therefore expected in ring A. The methyl group activates positions 1 and 3, which are ortho to itself, but not position 4, which is meta to it. However, substitution at the 3 position gives rise to an arenium ion for which it is impossible to write a low-energy canonical form in which ring B has a complete sextet. Only forms like **23** are possible, in which the sextet is no longer intact. In contrast, substitution at the 1 position gives rise to a more stable arenium ion, for which two canonical forms (one of them is **24**) can be written in which ring B is benzenoid. We thus predict predominant substitution at C-1, and that is what is generally found.[77] However, in some cases predictions are much harder to make. For example, chlorination or nitration of **25** gives mainly the 4 derivative, but bromination yields chiefly the 6 compound.[78]

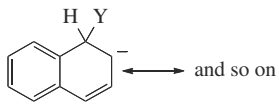
25



Indole

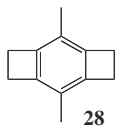


Quinoline



For fused heterocyclic systems too, predictions can be made based on the above principles, although many exceptions are known. Thus, indole is chiefly substituted in the pyrrole ring (at position 3) and reacts faster than benzene, while quinoline generally reacts in the benzene ring, at the 5 and 8 positions, and slower than benzene, though faster than pyridine.

24



26

27

In alternant hydrocarbons (Sec. 2.J), the reactivity at a given position is similar for electrophilic, nucleophilic, and free radical substitution, because the same kind of resonance can be shown in all three types of intermediate (cf. **24**, **26**, and **27**). Attachment of the electrophile at the position that will best delocalize a positive charge will also best delocalize a negative charge or an unpaired electron. Most results are in accord with these predictions. For example, naphthalene is attacked primarily at the 1 position by NO_2^+, NH_2^-, and $Ph^\bullet$, and always more readily than benzene.

When strain due to a ring fused on an aromatic ring deforms that ring out of planarity, the molecule is more reactive to electrophilic aromatic substitution.[79] This has been explained by the presence of a shortened bond for the sp^2 hybridized carbon, increasing the strain at that position. This finding is known as the *Mills–Nixon effect*.[80] There is EPR evidence (see Sec. 5.C.i) for 3,6-dimethyl-1,2,4,5-tetrahydrobenzo-bis-cyclobutene (**28**), which supports the *Mills–Nixon effect*,[81] and a theoretical study, which supports this.[82] However, *ab initio* studies of triannelated benzene rings shows *no evidence* for the *Mills–Nixon effect*, and a new motif for bond-alternating benzenes was proposed.[83] Indeed, it is argued that the *Mills–Nixon effect* is not real.[84]

11.C. QUANTITATIVE TREATMENTS OF REACTIVITY IN THE SUBSTRATE

Quantitative rate studies of aromatic substitutions are complicated by the fact that there are usually several hydrogen atoms that can leave, so that measurements of overall rate ratios do not give a complete picture as they do in nucleophilic substitutions, where it is easy to compare substrates that have only one possible leaving group in a molecule. What is needed is not, say, the overall rate ratio for acetylation of toluene versus that for benzene, but the *rate ratio at each position*. These can be calculated from the overall rates and a careful determination of the proportion of isomers formed, provided that the products are kinetically controlled, as is usually the case. The *partial rate factor* may be defined for a given group and a given reaction as the rate of substitution at a single position relative to a single position in benzene. For example, for acetylation of toluene the partial rate factors follow: for the ortho position $o_f^{Me} = 4.5$, for the meta $m_f^{Me} = 4.8$, and for the para $p_f^{Me} = 749$.[85] This means that toluene is acetylated at the ortho position 4.5 times as fast as a single position in benzene, or 0.75 times as fast as the overall rate of acetylation of benzene. A partial rate factor >1 for a given position indicates that the group in question activates that position for the given reaction. Partial rate factors differ from one reaction to another and are even different, though less so, for the same reaction under different conditions.

Once the partial rate factors are known, the proportions of isomers to be obtained when two or more groups are present on a ring can be predicted, *if the assumption is made that the effect of substituents is independent*. For example, if the two methyl groups in *m*-xylene have the same effect as the methyl group in toluene, the theoretical partial rate factors at each position can be calculated by multiplying those from toluene, so they should be as indicated.

[a]See Ref. 86.

From this, it is possible to calculate the overall theoretical rate ratio for acetylation of *m*-xylene relative to benzene, since this is one-sixth the sum of the partial rate factors (in this case 1130), and the isomer distribution if the reaction is kinetically controlled. The overall rate ratio actually is 347[86] and the calculated and observed isomer distributions are listed in Table 11.2.[86] In this case, and in many others, agreement is fairly good, but many cases are known where the effects are not additive (as in Sec. 11.B.ii).[87] For example, this treatment predicts that for 1,2,3-trimethylbenzene there should be 35% 5 substitution and 65% 4 substitution, but acetylation gave 79% 5 substitution and 21% of the 4 isomer. The treatment is thrown off by steric effects (e.g., those mentioned earlier, Sec. 11.B.iv), by products arising from ipso attack (Sec. 11.B.ii) and by resonance interaction *between* groups (e.g., **29**), which must make the results deviate from simple additivity of the effects of the groups.

29

Another approach that avoids the problem created by having competing leaving groups present in the same substrate is the use of substrates that contain only one leaving group. This is most easily accomplished by the use of a leaving group other than hydrogen. By this means, overall rate ratios can be measured for specific positions.[88] Results obtained in this way[89] give a reactivity order quite consistent with that for hydrogen as leaving group.

A quantitative scale of reactivity for aromatic substrates (fused, heterocyclic, and substituted rings) has been devised, based on the HSAB concept (Sec. 8.E).[90] From MO theory, a quantity called *activation hardness* can be calculated for each position of an aromatic ring. The smaller the activation hardness, the faster the attachment at that position; hence the treatment predicts the most likely orientations for incoming groups.

11.D. A QUANTITATIVE TREATMENT OF REACTIVITY OF THE ELECTROPHILE: THE SELECTIVITY RELATIONSHIP

Not all electrophiles are equally reactive. The nitronium ion is attacked not only by benzene but also by aromatic rings that contain a strongly deactivating group. On the other hand, diazonium ions couple only with rings containing a powerful activating group. Attempts have been made to correlate the influence of substituents with the reactivity of the group being attacked. The most obvious way to do this is with the *Hammett equation* (Sec. 8.G):

$$\log(k, k_0) = \rho\,\sigma$$

For aromatic substitution,[91] k_0 is divided by 6 and, for meta substitution, k is divided by 2, so that comparisons are made for only one position (consequently, k/k_0 for, say, the methyl group at a para position is identical to the partial rate factor p_f^{Me}). It was soon found that, while this approach worked fairly well for electron-withdrawing groups, it failed for those that are electron donating. However, if the equation is modified by the insertion of the Brown σ^+ values instead of the Hammett σ values (because a positive charge develops during the transition state), more satisfactory correlations can be made, even for electron-donating groups (see Table 9.4 for a list of σ^+ values).[92] Groups with a negative value of $\sigma_p{}^+$ or $\sigma_m{}^+$ are activating for that position; groups with a positive value are deactivating. The ρ values correspond to the susceptibility of the reaction to stabilization or destabilization by the Z group and to the reactivity of the electrophile. The ρ values vary not only with the electrophile, but also with conditions. A large negative value of ρ means an electrophile of relatively low reactivity. Of course, this approach is completely useless for ortho substitution, since the Hammett equation does not apply there.

A modification of the Hammett approach, suggested by Brown, called the *selectivity relationship*,[93] is based on the principle that reactivity of a species varies inversely with selectivity. Table 11.3 shows how electrophiles can be arranged in order of selectivity as measured by two indexes: (1) their selectivity in attacking toluene rather than benzene, and (2) their selectivity between the meta and para positions in toluene.[93] As the table shows, an

TABLE 11.3 Relative Rates and Product Distributions in Some Electrophilic Substitutions on Toluene and Benzene[a]

electrophile more selective in one respect is also more selective in the other. In many cases, electrophiles known to be more stable (hence less reactive) than others show a higher selectivity, as would be expected. For example, the *tert*-butyl cation is more stable and more selective than the isopropyl (Sec. 5.A.ii), and Br_2 is more selective than Br^+. However, deviations from the relationship are known.[94] Selectivity depends not only on the nature of the electrophile, but also on the temperature. As expected, it normally decreases with increasing temperature.

Brown assumed that a good measurement of selectivity was the ratio of the para and meta partial rate factors in toluene. He defined the selectivity S_f of a reaction as:

$$S_f = \log\left(\frac{p_f^{\mathrm{Me}}}{m_f^{\mathrm{Me}}}\right)$$

That is, the more reactive the reactive species, the less preference it has for the para position compared to the meta. If we combine the Hammett–Brown $\sigma^+\rho$ relationship with the linearity between log S_f and log p_f^{Me} and between log S_f and log m_f^{Me}, it is possible to derive the following expressions:

$$\log p_f^{\mathrm{Me}} = \left(\frac{\sigma_p^+}{\sigma_p^+ - \sigma_m^+}\right) S_f$$

$$\log m_f^{\mathrm{Me}} = \left(\frac{\sigma_m^+}{\sigma_p^+ - \sigma_m^+}\right) S_f$$

S_f is related to ρ by $S_f = \rho(\sigma_p^+ - \sigma_m^+)$

The general validity of these equations is supported by a great deal of experimental data on aromatic substitution reactions of toluene. Examples of values for some reactions obtained from these equations are given in Table 11.4.[95] For other substituents, the treatment works well with groups that, like methyl, are not very polarizable. For more polarizable groups the correlations are sometimes satisfactory and sometimes not, probably because each electrophile in the transition state makes a different demand on the electrons of the substituent group.

Not only are there substrates for which the treatment is poor, but it also fails with very powerful electrophiles. This is the reason why it is necessary to postulate the encounter complex mentioned in Section 11.A.i. For example, relative rates of nitration of *p*-xylene,

TABLE 11.4 Values of m_f^{Me}, p_f^{Me}, S_f, and ρ for Three Reactions of Toluene[a]

Reaction	m_f^{Me}	p_f^{Me}	S_f	ρ

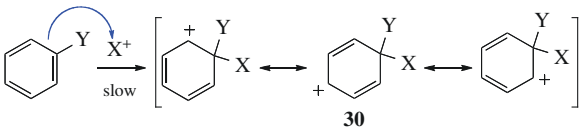
[94] See Olah, G.A.; Olah, J.A.; Ohyama, T. *J. Am. Chem. Soc.* ***1984****, 106*, 5284.

[95] Stock, L.M.; Brown, H.C. *Adv. Phys. Org. Chem.* ***1963****, 1*, 35 presents many tables of these kinds of data. See also, DeHaan, F.P.; Chan, W.H.; Chang, J.; Ferrara, D.M.; Wainschel, L.A. *J. Org. Chem.* ***1986****, 51*, 1591, and other papers in this series.

1,2,4-trimethylbenzene, and 1,2,3,5-tetramethylbenzene were 1.0, 3.7, and 6.4,[96] though the extra methyl groups should enhance the rates much more (*p*-xylene itself reacted 295 times faster than benzene). The explanation is that with powerful electrophiles the reaction rate is so rapid (reaction taking place at virtually every encounter[97] between an electrophile and substrate molecule)[98] that the presence of additional activating groups can no longer increase the rate.[99]

Given this behavior (little selectivity in distinguishing between different substrate molecules), the selectivity relationship would predict that positional selectivity should also be very small. However, it is not. For example, under conditions where nitration of *p*-xylene and 1,2,4-trimethylbenzene takes place at about equal rates, there was no corresponding lack of selectivity at positions *within* the latter.[100] Although steric effects are about the same at both positions, >10 times as much 5-nitro product was formed as 6-nitro product. It is clear that the selectivity relationship has broken down and it becomes necessary to explain why such an extremely rapid reaction should occur with positional selectivity. The explanation offered is that the rate-determining step is formation of an encounter complex (**12**, Sec. 11.B.ii).[101] Since the position of attachment is not determined in the rate-determining step, the 5:6 ratio is not related to the reaction rate. Essentially the same idea was suggested earlier[102] and for the same reason (failure of the selectivity relationship in some cases), but the earlier explanation specifically pictured the complex as a π complex, and we have seen (Sec. 11.B.ii) that there is evidence against this.



Relative rate ratios

One interesting proposal[103] is that the encounter pair is a radical pair $NO_2^{\bullet}$ $ArH^{\bullet+}$ formed by an electron transfer (SET), which would explain why the electrophile, once in the encounter complex, can acquire the selectivity that the free NO_2^+ lacked (it is not proposed that a radical pair is present in all aromatic substitutions; only in those that do not obey the selectivity relationship). The radical pair subsequently collapses to the arenium ion. There is evidence[104] both for and against this proposal.[105]

11.E. THE EFFECT OF THE LEAVING GROUP

30

In the vast majority of aromatic electrophilic substitutions, the leaving group is H^+ as indicated above, and very little work has been done on the relative electrofugal ability of other leaving groups. However, the following orders of leaving-group ability have been suggested[106]: (1) for leaving groups that depart without assistance (S_N1 process with respect to the leaving group), $NO_2{}^{+}$[107] $< i\text{Pr}^+ \sim SO_3 < t\text{-Bu}^+ \sim \text{ArN}_2{}^+ < \text{ArCHOH}^+ < NO^+ < CO_2$; (2) for leaving groups that depart with assistance from an outside nucleophile (S_N2 process), $Me^+ < Cl^+ < Br^+ < D^+ \sim RCO^+ < H^+ \sim I^+ < Me_3Si^+$. We can use this kind of list to help predict which group, X or Y, will cleave from an arenium ion **30** (see **1**, where Y = H) once it has been formed, and so obtain an idea of which electrophilic substitutions are feasible. However, a potential leaving group can also affect a reaction in another way: by influencing the rate at which attack of the original electrophile leads to attachment directly at the ipso position. Partial rate factors for electrophilic attack at a position substituted by a group other than hydrogen are called ipso partial rate factors (i_f^X).[57] Such factors for the nitration of *p*-haloanisoles are 0.18, 0.08, and 0.06, for *p*-iodo, *p*-bromo-, and *p*-chloroanisole, respectively.[108] This means, for example, that attack at the electrophile in this case leads to attachment at the 4 position of 4-iodoanisole 0.18 times as fast as a single position of benzene. Note that this is far slower than attachment at the 4 position resulting from attack of anisole itself so that the presence of the iodo group greatly slows the reaction at that position. A similar experiment on *p*-cresol showed that ipso attack at the methyl position was 6.8 times slower than attack of phenol leading to attachment at the para position.[109] Thus, in these cases, both an iodo and a methyl group deactivate the ipso position.[110]

11.F. REACTIONS

The reactions in this chapter are classified according to leaving group. Hydrogen replacements are treated first, and then rearrangements in which the attacking entity is first cleaved from another part of the molecule (hydrogen is also the leaving group in these cases), and finally replacements of other leaving groups.

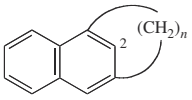
11.F.i. Hydrogen as the Leaving Group in Simple Substitution Reactions



A. Hydrogen as the Electrophile

11-1 Hydrogen Exchange

Deuterio-de-hydrogenation or Deuteriation

$$ArH + D^+ \rightleftharpoons ArD + H^+$$

Aromatic compounds can exchange hydrogen atoms when treated with acids. The reaction is used chiefly to study mechanistic questions[111] (including substituent effects), but can also be useful to deuterate (add ^2H) or tritiate (add ^3H) aromatic rings selectively. The usual directive effects apply and, for example, phenol treated with D_2O gives slow exchange on heating, with only ortho and para hydrogen atoms being exchanged.[112] Strong acids, of course, exchange faster with aromatic substrates, and this exchange must be taken into account when studying the mechanism of any aromatic substitution catalyzed by acids. There is a great deal of evidence that exchange takes place by the ordinary arenium ion mechanism. Among the evidence are the orientation effects noted above and the finding that the reaction is general acid catalyzed, which means that a proton is transferred in the slow step[113] (Sec. 8.D). Furthermore, many examples have been reported of stable solutions of arenium ions formed by attack of a proton on an aromatic ring.[5] Simple aromatic compounds can be extensively deuterated in a convenient fashion by treatment with D_2O and BF_3.[114] It has been shown that tritium exchange takes place readily at the 2 position of **31**, despite the fact that this position is hindered by the bridge. The rates were not very different from the comparison compound 1,3-dimethylnaphthalene.[115]

n = 7, 8, 10

31

Hydrogen exchange can also be effected with strong bases[116] (e.g., NH_2^-). In these cases, the slow step is the proton transfer:[117]

$$ArH + B \longrightarrow Ar^- + BH^+$$

so the S_E1 mechanism and not the usual arenium ion mechanism is operating.[118] Aromatic rings can also be deuterated by treatment with D_2O and a Rh(III) chloride[119] or Pt[120] catalyst

or with C_6D_6 and an alkylaluminum dichloride catalyst,[121] though rearrangements may take place during the latter procedure. Tritium (^3H, abbreviated T) can be introduced by treatment with T_2O and an alkylaluminum dichloride catalyst.[121] Tritiation at specific sites (e.g., >90% para in toluene) has been achieved with T_2 gas and a microporous aluminophosphate catalyst.[122]

B. Nitrogen Electrophiles

11-2 Nitration or Nitro-de-hydrogenation

$$ArH + HNO_3 \xrightarrow{H_2SO_4} ArNO_2$$

Most aromatic compounds, whether of high or low reactivity, can be nitrated, because a wide variety of nitrating agents is available.[123] For benzene, the simple alkylbenzenes, and less reactive compounds, the most common reagent is a mixture of concentrated nitric and sulfuric acids,[124] but for active substrates, the reaction can be carried out with nitric acid alone,[125] or in water, acetic acid, acetic anhydride, or chloroform.[126] Milder conditions are necessary for active compounds (e.g., amines, phenols, and pyrroles), since reaction with mixed nitric and sulfuric acids would oxidize these substrates. With active substrates, (e.g., anilines[127] and phenols,[128] nitration can be accomplished by nitrosation under oxidizing conditions with a mixture of dilute nitrous and nitric acids.[129] Trimethoxybenzenes were nitrated easily with ceric ammonium nitrate on silica gel,[130] and mesitylene was nitrated in an ionic liquid using nitric acid–acetic anhydride.[131] Phenol can also be nitrated in an ionic liquid.[132] An alternative route for the nitration of activated aromatic compounds (e.g., anisole), used a nitrate ester ($RONO_2$) with triflic acid in an ionic liquid for ortho-selective nitration.[133]

For nitration reactions of "normal" aromatic compounds, representative nitrating agents are $NaNO_2$ and trifluoroacetic acid,[134] N_2O_4/O_2 and a catalytic amount of zeolite Hβ,[135] $Yb(OTf)_3$,[136] $Bi(NO_3)_3{\cdot}5H_2O$,[137] ceric ammonium nitrate,[138] urea nitrate and nitrourea,[139] and nitronium salts.[140] A mixture of NO_2 and ozone has also been used.[141] Nitric acid, in the presence of P_2O_5 supported on SiO_2, is useful for the nitration of aromatic compounds under solvent-free conditions.[142] Nitration of styrene poses a problem since addition occurs at the C=C unit to give a 1-nitroethyl aryl.[143] Deactivated aromatic rings, as in acetophenone, were nitrated with N_2O_5 and $Fe(acac)_2$ (acac=acetylacetone).[144] Heterocycles (e.g., pyridine) are nitrated with N_2O_5 and SO_2.[145]

When anilines are nitrated under strong acid conditions, meta orientation is generally observed, because the ammonium salt is the species undergoing nitration, which is the conjugate acid of the amine. If the conditions are less acidic, the free amine is nitrated and the orientation is ortho–para. Although the free base may be present in much smaller amounts than the conjugate acid, it is far more susceptible to aromatic substitution (see also, Sec. 11.B.i). Because of these factors and because they are vulnerable to oxidation by nitric acid, primary aromatic amines are often protected before nitration by treatment with acetyl chloride (Reaction **16-72**) or acetic anhydride (Reaction **16-73**). Nitration of the resulting acetanilide derivative avoids all these problems. There is evidence that when the reaction takes place on the free amine, it is the nitrogen that is attacked to give an *N*-nitro compound (Ar—NH—NO_2), which rapidly undergoes rearrangement (see Reaction **11-28**) to give the product.[146]

Since the nitro group is deactivating, it is usually easy to stop the reaction after one group has entered the ring, but a second and a third group can be introduced if desired, especially when an activating group is also present. Even *m*-dinitrobenzene can be nitrated if vigorous conditions are applied. This has been accomplished with $NO_2^+ BF_4^-$ in FSO_3H at 150 °C.[147]

With most of the reagents mentioned, the attacking species is the nitronium ion (NO_2^+). Among the ways in which this ion is formed are

1. In concentrated sulfuric acid, by an acid–base reaction in which nitric acid is the base:

$$HNO_3 + 2H_2SO_4 \rightleftharpoons NO_2^+ + H_3O^+ + 2HSO_4^-$$

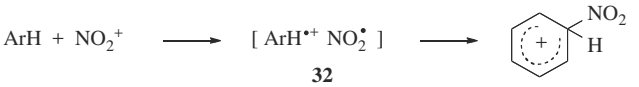
   This ionization is essentially complete.
2. In concentrated nitric acid alone,[148] by a similar acid–base reaction in which one molecule of nitric acid is the acid and another the base:

$$2\,HNO_3 \rightleftharpoons NO_2^+ + NO_3^- + H_2O$$

   This equilibrium lies to the left ($\sim 4\%$ ionization), but enough NO_2^+ is formed for nitration to occur.
3. The equilibrium just mentioned occurs to a small extent even in organic solvents.
4. With N_2O_5 in CCl_4, there is spontaneous dissociation:

$$N_2O_5 \rightleftharpoons NO_2^+ + NO_3^-$$

   but in this case there is evidence that some nitration also takes place with undissociated N_2O_5 as the electrophile.
5. When nitronium salts are used, NO_2^+ is of course present to begin with. Esters and acyl halides of nitric acid ionize to form NO_2^+.



There is a great deal of evidence that NO_2^+ is present in most nitration reactions and that it is the attacking entity,[149] for example,

1. Nitric acid has a peak in the Raman spectrum. When nitric acid is dissolved in concentrated sulfuric acid, the peak disappears and two new peaks appear, one at $1400\,cm^{-1}$ attributable to NO_2^+ and one at $1050\,cm^{-1}$ due to HSO_4^-.[150]
2. On addition of nitric acid, the freezing point of sulfuric acid is lowered about four times the amount expected if no ionization has taken place.[151] This means that the addition of one molecule of nitric acid results in the production of four particles, which is strong evidence for the ionization reaction between nitric and sulfuric acids given above.
3. The fact that nitronium salts in which nitronium ion is known to be present (by X-ray studies) nitrate aromatic compounds shows that this ion does attack the ring.
4. The rate of the reaction with most reagents is proportional to the concentration of NO_2^+, not to that of other species.[152] When the reagent produces this ion in small

amounts, the attack is slow and only active substrates can be nitrated. In concentrated and aqueous mineral acids, the kinetics are second order: first order each in aromatic substrate and in nitric acid (unless pure nitric acid is used in which case there are pseudo-first-order kinetics). But in organic solvents (e.g., nitromethane, acetic acid, and CCl_4), the kinetics are first order in nitric acid alone and zero order in aromatic substrate, because the rate-determining step is formation of NO_2^+ and the substrate does not take part in this.

In a few cases, depending on the substrate and solvent, there is evidence that the arenium ion is not formed directly, but via the intermediacy of a radical pair (see Sec. 11.D), such as **32**.[153]

32

Arylboronic acids have been shown to react with ammonium nitrate and trifluoroacetic acid to give the corresponding nitrobenzene.[154]

11-3 Nitrosation or Nitroso-de-hydrogenation

Ring nitrosation[155] with nitrous acid is normally carried out only with active substrates (e.g., amines and phenols). However, primary aromatic amines give diazonium ions (Reaction **13-19**) when treated with nitrous acid,[156] and secondary amines tend to give *N*-nitroso rather than *C*-nitroso compounds (Reaction **12-50**); hence this reaction is normally limited to phenols and tertiary aromatic amines. Nevertheless, secondary aromatic amines can be *C*-nitrosated in two ways. The *N*-nitroso compound first obtained can be isomerized to a *C*-nitroso compound (Reaction **11-29**), or it can be treated with another equivalent of nitrous acid to give an *N,C*-dinitroso compound. Also, a successful nitrosation of anisole has been reported, where the solvent was $CF_3COOH—CH_2Cl_2$.[157]

Much less work has been done on the mechanism of this reaction than on Reaction **11-2**.[158] In some cases, the attacking entity is NO^+, but in others it is apparently NOCl, NOBr, N_2O_3, and so on, in each of which there is a carrier of NO^+. Both NOCl and NOBr are formed during the normal process of making nitrous acid (the treatment of sodium nitrite with HCl or HBr). Nitrosation requires active substrates because NO^+ is much

less reactive than NO_2^+. Kinetic studies have shown that NO^+ is at least 10^{14} times less reactive than NO_2^+.[159] A consequence of the relatively high stability of NO^+ is that this species is easily cleaved from the arenium ion, so that k_{-1} competes with k_2 (Sec. 11.A.i) and isotope effects are found.[160] With phenols, there is evidence that nitrosation may first take place at the OH group, after which the nitrite ester thus formed rearranges to the *C*-nitroso product.[161] Tertiary aromatic amines substituted in the ortho position generally do not react with HONO, probably because the ortho substituent prevents planarity of the dialkylamino group, without which the ring is no longer activated. This is an example of steric inhibition of resonance (Sec. 2.F).

OS **I**, 214, 411, 511; **II**, 223; **IV**, 247.

11-4 Diazonium Coupling

Arylazo-de-hydrogenation

$$ArH + Ar'N_2^+ \longrightarrow Ar{-}N{\equiv}N{-}Ar'$$

Aromatic diazonium ions normally couple only with active substrates (e.g., amines and phenols).[162] Many of the products of this reaction are used as dyes (*azo dyes*).[163] Presumably because of the size of the species attacked by the aromatic ring, substitution is mostly para to the activating group, unless that position is already occupied, in which case ortho substitution takes place. The pH of the solution is important both for phenols and amines. For amines, the solutions may be mildly acidic or neutral. The fact that amines give ortho and para products shows that even in mildly acidic solution they react in their un-ionized form. If the acidity is too high, the reaction does not occur, because the concentration of free amine becomes too small. Phenols must be coupled in slightly alkaline solution where they are converted to the more reactive phenoxide ions, because phenols themselves are not active enough for the reaction. However, neither phenols nor amines react in moderately alkaline solution, because the diazonium ion is converted to a diazo hydroxide (Ar—N=N—OH). Primary and secondary amines face competition from attack at the nitrogen.[164] However, the resulting *N*-azo compounds (aryl triazenes) can be isomerized to *C*-azo compounds (Reaction **11-30**). In at least some cases, even when the *C*-azo compound is isolated, it is the result of initial *N*-azo compound formation followed by isomerization. It is therefore possible to synthesize the *C*-azo compound directly in one laboratory step.[165] Acylated amines and phenolic ethers and esters are ordinarily not active enough for this reaction, though it is sometimes possible to couple them (as well as such polyalkylated benzenes as mesitylene and pentamethylbenzene) to diazonium ions containing electron-withdrawing groups in the para position, since such groups increase the concentration of the positive charge and thus the electrophilicity of the ArN_2^+. Some coupling reactions that are otherwise very slow

(in cases where the coupling site is crowded) are catalyzed by pyridine for reasons discussed in Section 11.A.i. Phase-transfer catalysis has also been used.[166]

Coupling of a few aliphatic diazonium compounds to aromatic rings has been reported. All the examples reported so far involve cyclopropanediazonium ions and bridgehead diazonium ions, in which loss of N_2 would lead to very unstable carbocations.[167] Azobenzenes have been prepared by Pd catalyzed coupling of aryl hydrazides with aryl halides, followed by direct oxidation.[168]

The mechanism of (*Z*/*E*) isomerization in Ar—N=NAr systems has been studied.[169]

OS **I**, 49, 374; **II**, 35, 39, 145.

11-5 Direct Introduction of the Diazonium Group

Diazoniation or Diazonio-de-hydrogenation

$$\mathrm{ArH} \xrightarrow[\mathrm{HX}]{2\ \mathrm{HONO}} \mathrm{ArN_2{}^+X^-}$$

Diazonium salts can be prepared directly by replacement of an aromatic hydrogen without the necessity of going through the amino group.[170] The reaction is essentially limited to active substrates (amines and phenols), since otherwise poor yields are obtained. Since the reagents and the substrate are the same as in Reaction **11-3**, the first species formed is the nitroso compound. In the presence of excess nitrous acid, this is converted to the diazonium ion.[171] The reagent (azidochloromethylene)dimethylammonium chloride [$Me_2N{=}C(Cl)N_3\ Cl^-$] can also introduce the diazonium group directly into a phenol.[172] A synthesis of solid aryldiazonium chlorides is now available.[173]

11-6 Amination or Amino-de-hydrogenation[174]

$$\mathrm{ArH} + \mathrm{HN_3} \xrightarrow{\mathrm{AlCl_3}} \mathrm{ArNH_2}$$

Aromatic compounds can be converted to primary aromatic amines in 10–65% yields, by treatment with hydrazoic acid (HN_3) in the presence of $AlCl_3$ or H_2SO_4.[175] Higher yields (>90%) have been reported with trimethylsilyl azide (Me_3SiN_3) and triflic acid (F_3CSO_2OH).[176] Treatment of an aromatic compound with tetramethylhydrazonium iodide and then ammonium also gives the aryl amine.[177] Tertiary amines have been prepared in ~50–90% yields by treatment of aromatic hydrocarbons with *N*-chlorodialkylamines; by heating in 96% sulfuric acid; or with $AlCl_3$ or $FeCl_3$ in nitroalkane solvents; or

by irradiation.[178] Treatment of an aryl halide with an amine and a Pd catalyst leads to the aniline derivative.[179]

Tertiary (and to a lesser extent, secondary) aromatic amines can also be prepared in moderate-to-high yields by amination with an *N*-chlorodialkylamine (or an *N*-chloroalkylamine) and a metallic-ion catalyst (e.g., Fe^{2+}, Ti^{3+}, Cu^{+}, Cr^{2+}) in the presence of sulfuric acid.[180] The attacking species in this case is the aminium radical ion ($R_2NH^{\bullet}$) formed by[181]

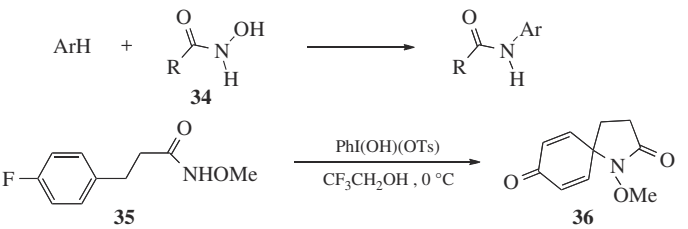
$$R_2\overset{+}{N}HCl + M^{+} \longrightarrow R_2\overset{+}{N}H^{\bullet} + M^{2+} + Cl^{-}$$

Because attack is by a positive species (even though it is a free radical), orientation is similar to that in other electrophilic substitutions (e.g., phenol and acetanilide give ortho and para substitution, mostly para). When an alkyl group is present, attack at the benzylic position competes with ring substitution. Aromatic rings containing only meta-directing groups do not give the reaction at all. Fused-ring systems react well.[182]

Unusual orientation has been reported for amination with haloamines and with NCl_3 in the presence of $AlCl_3$. For example, toluene gave predominately meta amination.[183] It has been suggested that initial attack in this case is by Cl^{+} and that a nitrogen nucleophile (whose structure is not known but is represented here as NH_2^{-} for simplicity) adds to the resulting arenium ion, so that the initial reaction is addition to a carbon–carbon double bond followed by elimination of HCl from **33**.[184]

33

According to this suggestion, the electrophilic attack is at the para position (or the ortho, which leads to the same product) and the meta orientation of the amino group arises indirectly. This mechanism is called the σ-*substitution mechanism*.



Diphenyliodonium salts react with amines in the presence of a Cu catalyst. Diphenyliodonium tetrafluoroborate, (Ph_2I^{+} BF_4^{-}), reacts with indole in DMF at 150 °C with a Cu $(OAc)_2$ catalyst (e.g., to give *N*-phenylindole).[185]

Aromatic compounds that do not contain meta-directing groups can be converted to diarylamines by treatment with aryl azides in the presence of phenol at −60 °C: $ArH + Ar'N_3 \rightarrow ArNHAr'$.[186] Diarylamines are also obtained by the reaction of

N-arylhydroxylamines with aromatic compounds (benzene, toluene, anisole) in the presence of F_3CCO_2H: $ArH + Ar'NHOH \rightarrow ArNHAr'$.[187]

Direct *amidation* can be carried out if an aromatic compound is heated with a hydroxamic acid (**34**) in polyphosphoric acid, but the scope is essentially limited to phenolic ethers.[188] Naphthol reacted with a substituted hydrazine to give the 1-amino derivative.[189] The formation of hydroindole derivatives was accomplished by reaction of a *N*-carbamoyl phenylethylamine derivative with phenyliodine (**III**) diacetate, followed by Bu_4NF.[190] Direct amidation via ipso substitution by nitrogen was accomplished when a *N*-methoxy arylethylamide (**35**) was treated with [hydroxyl(tosyloxy)iodo]benzene (HTIB) in 2,2,2-trifluoroethanol, giving a *N*-methoxy spirocylcic amide (**36**).[191]

Aromatic compounds add to DEAD, in the presence of $InCl_3—SiO_2$ and microwave irradiation, to give the *N*-aryldiamino compound [$ArN(CO_2Et)—NHCO_2Et$].[192] An interesting variation in the alkylation reaction used 5 equiv of aluminum chloride in a reaction of *N*-methyl-*N*-phenylhydrazine and benzene to give *N*-methyl-4-phenylaniline.[193]

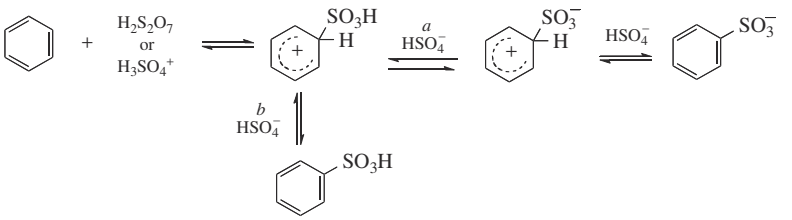
C. Sulfur Electrophiles

11-7 Sulfonation or Sulfo-de-hydrogenation



$$ArH + H_2SO_4 \longrightarrow ArSO_2OH$$

The sulfonation reaction is very broad in scope and many aromatic hydrocarbons (including fused-ring systems), aryl halides, ethers, carboxylic acids, amines,[194] acylated amines, ketones, nitro compounds, and sulfonic acids have been sulfonated.[195] Phenols can also be successfully sulfonated, but attack at oxygen may compete.[196] Sulfonation is often accomplished with concentrated sulfuric acid, but it can also be done with fuming H_2SO_4,

SO_3, $ClSO_2OH$, $ClSO_2NMe_2/In(OTf)_3$,[197] or other reagents.[198] A $FeCl_3$ based ionic liquid has been used for the sulfonation of aromatic compounds.[199] As with nitration (Reaction **11-2**), reagents of a wide variety of activity are available to suit both highly active and highly inactive substrates. Since this reaction is reversible (see Reaction **11-38**), it may be necessary to drive the reaction to completion. However, at low temperatures the reverse reaction is very slow and the forward reaction is practically irreversible.[200] Sulfur trioxide reacts much more rapidly than sulfuric acid with benzene (it is nearly instantaneous). Sulfones are often side products. When sulfonation is carried out on a benzene ring containing four or five alkyl and/or halogen groups, rearrangements usually occur (see Reaction **11-36**).

A great deal of work has been done on the mechanism, chiefly by Cerfontain and coworkers.[201] Mechanistic study is made difficult by the complicated nature of the solutions. Indications are that the electrophile varies with the reagent, though SO_3 is involved in all cases, either free or combined with a carrier. In aq H_2SO_4 solutions, the electrophile is thought to be $H_3SO_4^+$ (or a combination of H_2SO_4 and H_3O^+) at concentrations below ~80–85% H_2SO_4, and $H_2S_2O_7$ (or a combination of H_2SO_4 and SO_3) at concentrations higher than this[202] (the changeover point varies with the substrate[203]). Evidence for a change in electrophile is that in both the dilute and the concentrated solutions the rate of the reaction was proportional to the activity of $H_3SO_4^+$ and $H_2S_2O_7$, respectively. Further evidence is that with toluene as substrate the two types of solution gave very different ortho/para ratios. The mechanism is essentially the same for both electrophiles and may be shown as[202]:

The other product of the first step is HSO_4^- or H_2O from $H_2S_2O_7$ or $H_3SO_4^+$, respectively. Path *a* is the principal route, except at very high H_2SO_4 concentrations, when path *b* becomes important. With $H_3SO_4^+$ the first step is rate determining under all conditions, but with $H_2S_2O_7$ the first step is the slow step only up to ~96% H_2SO_4, when a subsequent proton transfer becomes partially rate determining.[204] The $H_2S_2O_7$ is more reactive than $H_3SO_4^+$. In fuming sulfuric acid (H_2SO_4 containing excess SO_3), the electrophile is

thought to be $H_3S_2O_7^+$ (protonated $H_2S_2O_7$) up to ~104% H_2SO_4 and $H_2S_4O_{13}$ (H_2SO_4 + 3 SO_3) beyond this concentration.[205] Finally, when pure SO_3 is the reagent in aprotic solvents, SO_3 itself is the actual electrophile.[206] Free SO_3 is the most reactive of all these species, so that attack here is generally fast and a subsequent step is usually rate determining, at least in some solvents.

11-8 Halosulfonation or Halosulfo-de-hydrogenation

$$ArH + ClSO_2OH \longrightarrow ArSO_2Cl$$

Aromatic sulfonyl chlorides can be prepared directly, by treatment of aromatic rings with chlorosulfuric acid.[207] Since sulfonic acids can also be prepared by the same reagent (Reaction **11-7**), it is likely that they are intermediates, being converted to the halides by excess chlorosulfuric acid.[208] The reaction has also been effected with bromo- and fluorosulfuric acids. Sulfinyl chlorides (ArSOCl) have been prepared by the reaction of thionyl chloride and an aromatic compound on Montmorillonite K-10 clay.[209]

OS **I**, 8, 85.

11-9 Sulfonylation

Alkylsulfonylation or **Alkylsulfo-de-hydrogenation**

$$ArH + SOCl_2 \xrightarrow{TfOH} ArSOAr \qquad ArH + Ar'SO_2Cl \xrightarrow{AlCl_3} ArSO_2Ar'$$

Diaryl sulfoxides can be prepared by the reaction of aromatic compounds with thionyl chloride and triflic acid.[210] Diaryl sulfones have also been prepared using thionyl chloride with the ionic liquid [bmim]Cl·$AlCl_3$.[211] Diaryl sulfones can be formed by treatment of aromatic compounds with aryl sulfonyl chlorides and a *Friedel–Crafts catalyst*.[212] This reaction is analogous to *Friedel–Crafts acylation* with carboxylic acid halides (Reaction **11-17**). In a better procedure, the aromatic compound is treated with an aryl sulfonic acid and P_2O_5 in polyphosphoric acid.[213] Still another method uses an arylsulfonic trifluoromethanesulfonic anhydride ($ArSO_2OSO_2CF_3$) (generated *in situ* from $ArSO_2Br$ and CF_3SO_3Ag) without a catalyst.[214] Indium tris(triflate)[215] and indium trichloride[216] leads to sulfonation of aromatic compounds with sulfonyl chlorides. Indium bromide was used

with indoles.[217] A ferric chloride catalyzed reaction with microwave irradiation has also been reported,[218] as has the use of zinc metal with microwave irradiation.[219] The reaction can be extended to the preparation of alkyl aryl sulfones by the use of a sulfonyl fluoride.[220]

Direct formation of diaryl sulfones from benzenesulfonic acid and benzene was accomplished using Nafion-H.[221] Aryl halides react with sulfinic acid salts, via a proline-promoted CuI catalyzed coupling reaction.[222] Arylboronic acids (see Reaction **10-73**) are sulfonated in ionic liquids, using a Cu catalyst.[223]

D. Halogen Electrophiles

11-10 Halogenation[224]

Halo-de-hydrogenation

$$\mathrm{ArH} + \mathrm{Br_2} \xrightarrow{\text{catalyst}} \mathrm{ArBr}$$

1. *Chlorine[225] and Bromine.[226]* Aromatic compounds can be brominated or chlorinated by treatment with bromine or chlorine in the presence of a catalyst.[227] For amines and phenols the reaction is so rapid that it is carried out with a dilute solution of Br_2 or Cl_2 in water at room temperature, or with aqueous HBr in DMSO.[228] Typically, it is not possible to stop the reaction with anilines before all the available ortho and para positions are substituted, because the initially formed haloamines are weaker bases than the original amines and are less likely to be protonated by the liberated HX.[229] For this reason, the corresponding anilides are used if monosubstitution is desired. With phenols it is possible to stop after one group has entered.[230] The rapid room temperature reaction with amines and phenols is often used as a test for these compounds. In general, for active substrates including anilines, phenols, naphthalene, and polyalkylbenzenes[231] (e.g., mesitylene and isodurene), no catalyst is needed. The overall effectiveness of reagents in aromatic substitution is $Cl_2 >$

$BrCl > Br_2 > ICl > I_2$. A mixture of $ZnBr_2$/diazene has been suggested for the regioselective para-bromination of activated aromatic substrates.[232]

When chlorination or bromination is carried out at high temperatures (e.g., 300–400 °C), ortho–para directing groups direct meta and vice versa.[233] A different mechanism operates here, which is not completely understood. It is also possible for bromination to take place by the S_E1 mechanism, for example, in the *t*-BuOK catalyzed bromination of 1,3,5-tribromobenzene.[234]

For less activated aromatic rings, iron was commonly used at one time for halogenation, but the real catalyst was shown not to be the iron itself, but rather the ferric bromide or chloride formed in small amounts from the reaction between iron and the reagent. Indeed, ferric chloride and other Lewis acids are typically directly used as catalysts, as is iodine. Many Lewis acids can be used, including thallium(III) acetate, which promotes bromination with high regioselectivity para to an ortho–para directing group.[235] A mixture of $Mn(OAc)_3$ and acetyl chloride, with ultrasound, chlorinates anisole with high selectivity.[236]

Other reagents can be used to promote chlorination or bromination. copper(II)-catalyzed chlorination has been reported using dioxygen as an oxidant.[237] *N*-Bromosuccinimide under photochemical conditions[238] brominates aromatic compounds, as does pyridinium bromide perbromide,[239] and NBS in acetic acid with ultrasound is effective.[240] Both NCS and NBS with aq BF_3 gave the respective chloride or bromide.[241] The NBS in an ionic liquid[242] gave the brominated aromatic, and para-bromination of aniline was reported by mixing aniline with the ionic liquid, bmim Br_2.[243] Similarly, hmim Br_3[244] without another reagent is a brominating agent. Bromine on silica gel[245] or with SO_2Cl_2[246] gave good yields of the brominated aromatic compound. Majetich et al.[247] reported the use of HBr/DMSO for the remarkably selective bromination of aniline. Highly para-selective bromination was accomplished using dioxane dibromide, under solvent free conditions.[248]

Other reagents have been used for chlorination and bromination. If the substrate contains alkyl groups, side-chain halogenation (Reaction **14-1**) is possible with most of the reagents mentioned, including chlorine and bromine. Since side-chain halogenation is catalyzed by light, the reactions should be run in the absence of light wherever possible. Sulfuryl chloride (SO_2Cl_2) in acetic acid chlorinates anisole derivatives,[249] and acetyl chloride with a catalytic amount of ceric ammonium nitrate also converted aromatic compounds to the corresponding chlorinated derivative.[250] A mixture of KCl and Oxone® chlorinated activated aromatic compounds.[251] Oxone and KBr gave good para-bromination of anisole,[252] as does NH_4Br/Oxone.[253] Dibromoisocyanuric acid in H_2SO_4 is a very good brominating agent[254] for substrates with strongly deactivating substituents.[255] *N*-Chlorosuccinimide in isopropyl alcohol[256] chlorinates aniline derivatives, and $KBr/NaBO_3 \cdot 4\ H_2O$ has been used for the bromination of aniline derivatives.[257] Conversion of aniline to the *N*-$SnMe_3$ derivative allowed *in situ* bromination with bromine, with high para selectivity after conversion to the free amine with aq KF.[258] Pyridinium bromochromate converted phenolic derivatives to brominated phenols.[259]

Predominant ortho chlorination[260] of phenols has been achieved with chlorinated cyclohexadienes,[261] while para chlorination of phenols, phenolic ethers, and amines can be accomplished with *N*-chloroamines[262] and with *N*-chlorodimethylsulfonium chloride ($Me_3S^+Cl\ Cl^-$).[263] The last method is also successful for bromination when *N*-bromodimethylsufonium bromide is used. Highly selective ortho chlorination of acetanilides has been reported, using a combination of P and Cu catalysts.[264] Iridium-catalyzed borylation of arenes leads to meta-halogenation.[265] Certain alkylated phenols can be brominated in the meta positions with Br_2 in the superacid solution SbF_5—HF.[266] It is likely that meta orientation is the result of conversion by the superacid of the OH group to the OH_2^+ group, which should be meta-directing because of its positive charge. Bromination and the *Sandmeyer reaction* (**14-20**) can be carried out in one laboratory step to give **37**

by treatment of an aromatic primary amine with $CuBr_2$ and *tert*-butyl nitrite, for example,[267]

37
94%

With deactivated aromatic derivatives, NBS and H_2SO_4 is an effective reagent, giving the meta-brominated product.[268] Bromination at C-6 of 2-aminopyridine was accomplished with NBS.[269] An alternative route reacted pyridine *N*-oxide with $POCl_3$ and triethylamine to give 2-chloropyridine.[270]

For reactions in the absence of a catalyst, the attacking entity is simply Br_2 or Cl_2 that has been polarized by the ring.[271]

38

Evidence for molecular chlorine or bromine as the attacking species in these cases is that acids, bases, and other ions, especially chloride ion, accelerate the rate about equally, though if chlorine dissociated into Cl^+ and Cl^-, the addition of chloride should decrease the rate and the addition of acids should increase it. Intermediate **38** has been detected spectrally in the aqueous bromination of phenol.[272]

When a Lewis acid catalyst[273] is used with chlorine or bromine, the attacking entity may be Cl^+ or Br^+, formed by $FeCl_3 + Br_2 \rightarrow FeCl_3Br^- + Br^+$, or it may be Cl_2 or Br_2, polarized by the catalyst. With other reagents, the attacking entity in brominations may be Br^+ or a species (e.g., H_2OBr^+, the conjugate acid of HOBr), in which H_2O is a carrier of Br^+.[274] With HOCl in water the electrophile may be Cl_2O, Cl_2, or H_2OCl^+; in acetic acid it is generally AcOCl. All these species are more reactive than HOCl itself.[275] It is extremely doubtful that Cl^+ is a significant electrophile in chlorinations by HOCl.[275] It has been demonstrated in the reaction between *N*-methylaniline and calcium hypochlorite that the chlorine entity is

attacked by the *nitrogen* to give *N*-chloro-*N*-methylaniline, which rearranges (as in Reaction **11-31**) to give a mixture of ring-chlorinated *N*-methylanilines in which the ortho isomer predominates.[276] In addition to hypohalous acids and metal hypohalites, organic hypohalites are reactive. An example is *tert*-butylhypobromite (*t*-BuOBr), which brominated toluene in the presence of zeolite (HNaX).[277]

Furan and thiophene are known to polymerize in the presence of strong acid, both Brønsted–Lowry and Lewis. For such highly reactive heteroaromatic systems, alternative halogenating reagents are commonly used. Furan was converted to 2-bromofuran with a bromine•dioxane complex (e.g., at $<0\,^{\circ}C$.[278] 3-Butylthiophene reacted with NBS/acetic acid to give 2-bromo-3-butylthiophene.[279] *N*-Methylpyrrole reacted with NBS and a catalytic amount of PBr_3, at $-78\,^{\circ}C \rightarrow -10\,^{\circ}C$, to give *N*-methyl-3-bromopyrrole.[280]

2. *Iodine*. Iodine is the least reactive of the halogens in aromatic substitution.[281] Except for active substrates, an oxidizing agent must normally be present to oxidize I_2 to a better electrophile.[282] Examples of such oxidizing agents used with I_2 are HNO_3, SO_3, hypervalent iodine compounds [e.g., $PhI(OTf)_2$,[283] $NaIO_4$,[284] ammonium iodide and H_2O_2,[285] ceric ammonium nitrate,[286] peroxydisulfates,[287] and a mixture of $NaIO_4$/KI/NaCl].[288] A solvent-free iodination used I_2 and $AgNO_3$.[289] The reagent ICl is a better iodinating agent than iodine itself.[290] A mixture of $ICl/In(OTf)_3$ has also been used.[291] Iodination can also be accomplished by treatment of the substrate with NCI and H_2SO_4,[292] *N*-Iodosuccinamide and trifluoroacetic acid,[293] KI/KIO_3 in aq methanol,[294] KI and H_2O_2,[295] and NaI with an iron catalyst.[296] Sodium periodate and iodine was used to iodinate β-carbolines.[297] A solvent-free iodination was accomplished using $NaICl_2$ and

an *N*-bromoammonium salt.[298] Another solvent-free iodination used I_2 with $Bi(NO_3)_3$ on silica gel.[299] A mixture of iodine/pyridine/dioxane leads to selective para-iodination of aniline derivatives.[300] Selective ortho cyanation allows the reaction with iodine to give the corresponding aryl iodide.[301] Iodination of activated aromatics has been reported using KI and ammonium peroxodisulfate.[302] *N*-Iodosuccinimide and *p*-toluenesulfonic acid give regioselective iodination of phenol and related compounds.[303]

The actual attacking species is less clear than with bromine or chlorine. Iodine itself is too unreactive, except for active species (e.g., phenols), where there is good evidence that I_2 is the attacking entity.[304] There is evidence that AcOI may be the reactive entity when peroxyacetic acid is the oxidizing agent,[305] and I_3^+ when SO_3 or HIO_3 is the oxidizing agent.[306] The I^+ ion has been implicated in several procedures.[307] For an indirect method for accomplishing aromatic iodination see (Reaction **12-31**).

3. *Fluorine*. Direct fluorination of aromatic rings with F_2 is not feasible at room temperature, because of the extreme reactivity of F_2.[308] It has been accomplished at low temperatures (e.g., -70 to $-20\,^{\circ}C$, depending on the substrate),[309] but the reaction is not yet of preparative significance. Fluorination has also been reported with acetyl hypofluorite (CH_3CO_2F, generated from F_2 and sodium acetate),[310] and with an *N*-fluoroperfluoroalkyl sulfonamide [e.g., $(CF_3SO_2)_2NF$].[311] Pyridine has been converted to 2-fluoropyridine with $F_2/I_2/NEt_3$ in 1,1,2-trichloro-1,2,2-trifluoroethane.[312] However, none of these methods seems likely to displace the *Schiemann reaction* (**13-23**; heating diazonium tetrafluoroborates) as the most common method for introducing fluorine into aromatic rings.

E. Carbon Electrophiles

A new carbon–carbon bond is formed in the reactions in this section. With respect to the aromatic ring, they are electrophilic substitutions, because a positive species attacks the ring. We treat them in this manner because it is customary. However, with respect to the electrophile, most of these reactions are nucleophilic substitutions, and what was said in Chapter 10 is pertinent to them.

11-11 Friedel–Crafts Alkylation

Alkylation or **Alkyl-de-hydrogenation**

$$\mathrm{ArH} + \mathrm{RCl} \xrightarrow{\mathrm{AlCl_3}} \mathrm{Ar{-}R}$$

The alkylation of aromatic rings, called *Friedel–Crafts alkylation*, is a reaction of very broad scope.[313] Catalytic asymmetric Friedel–Crafts alkylation reactions are known.[314] The most important reagents are alkyl halides, alkenes, and alcohols, but other types of reagent have also been employed.[313] Tertiary halides are particularly good substrates since they form relatively stable tertiary carbocations. When alkyl halides are used, the reactivity order is F > Cl > Br > I.[315] This trend can be seen in reactions of dihalo compounds (e.g., $FCH_2CH_2CH_2Cl$), which react with benzene to give $PhCH_2CH_2CH_2Cl$[316] when the catalyst is BCl_3. By the use of this catalyst, it is therefore possible to place a haloalkyl group on a ring (see also, Reaction **11-14**).[317] Di- and trihalides, when all the halogens are the same, usually react with more than one molecule of an aromatic compound; it is usually not possible to stop the reaction earlier.[318] Thus, benzene with CH_2Cl_2 gives not $PhCH_2Cl$, but Ph_2CH_2; benzene with $CHCl_3$ gives Ph_3CH. With CCl_4, however, the reaction stops when only three rings have been substituted to give Ph_3CCl. Functionalized alkyl halides [e.g., $ClCH(SEt)CO_2Et$] undergo Friedel–Crafts alkylation.[319] Montmorillonite clay-(K10) is an effective medium for alkylation reactions.[320]

Alkenes are especially good alkylating agents, generally proceeding by formation of an intermediate carbocation that reacts with the electron-rich aromatic ring, and the final product (**39**) incorporates a H and Ar from ArH to a C=C double bond. Many variations are possible. This reaction has been accomplished in an ionic liquid, using $Sc(OTf)_3$ as the catalyst.[321] Other catalysts include $Sm(OTf)_3$.[322] Intramolecular versions lead to

polycyclic aromatic compounds.[323] Benzene reacted with 1,2,3,6-tetrahydropyridine in the presence of trifluoromethanesulfonic acid to give 4-phenylpiperidine.[324]

39

When 4-methoxyphenol reacted with isobutylene (electrolysis with 3 M $LiClO_4$ in nitromethane and acetic acid), initial reaction with the phenolic oxygen generated an ether moiety and the resulting carbocation was attacked by the aromatic ring to form a benzofuran.[325] Enantioselective alkylations have been reported for pyrroles and indoles, using a chiral Pybox–Cu complex.[326]

Acetylene reacts with 2 mol of aromatic compound to give 1,1-diarylethanes, and phenylacetylene reacted to give 1,1-diarylethenes with a $Sc(OTf)_3$ catalyst.[327] Variations are possible here as well. Phenol reacted with trimethylsilylethyne, in the presence of $SnCl_4$ and 50% BuLi, at 105 °C, to give the 2-vinyl phenolic derivative.[328] A Ru catalyzed intramolecular reaction with a pendant alkyne unit led to a dihydronapthalene derivative,[329] and a Rh catalyzed reaction led to indanone derivatives.[330] An acidic fluoroantimonate(V) ionic liquid has been used as a catalyst.[331]

Alcohols are more active than alkyl halides, but if a Lewis acid catalyst is used more catalyst is required, since the catalyst complexes with the OH group. However, proton acids (e.g., H_2SO_4) are often used to catalyze alkylation with alcohols. An intramolecular cyclization was reported from an allylic alcohol, using P_2O_5, to give indene derivatives.[332] Secondary alcohols are coupled to aromatic compounds using a heterobimetallic Ir—Sn complex.[333] Molecular iodine has been used to catalyze benzylation of arenes with benzylic alcohols.[334] A "contra Friedel–Crafts" *tert*-butylation has been reported.[335] Diastereoselective alkylation is possible from alcohol precursors. High facial diastereoselectivity was reported with "chiral benzylic cations", for example.[336]

When carboxylic esters are the reagents, there is competition between alkylation and acylation (Reaction **11-17**). This competition can often be controlled by choice of catalyst, and alkylation is usually favored, but carboxylic esters are not often employed in Friedel–Crafts reactions. Other alkylating agents are ethers,[337] thiols, sulfates, sulfonates, alkyl nitro compounds,[338] and even alkanes and cycloalkanes, under conditions where these are converted to carbocations. Notable here are ethylene oxide, which puts the CH_2CH_2OH group onto the ring,[339] and cyclopropyl[340] units. For all types of reagent, the reactivity order is allylic $\sim$ benzylic $>$ tertiary $>$ secondary $>$ primary. Alkyl mesylates undergo alkylation reaction with benzene rings in the presence of $Sc(OTf)_3$.[341] Allylic acetates undergo alkylation with $Mo(CO)_6$[342] and allylic chlorides react in the presence of $ZnCl_2/SiO_2$.[343]

Naphthalene and other fused ring compounds are so reactive that they react with the catalyst, and therefore tend to give poor yields in Friedel–Crafts alkylation. Heterocyclic rings also tend to be poor substrates for the reaction. Although some furans and thiophenes have been alkylated, polymerization is quite common, and a true alkylation of a pyridine or a quinoline has never been described.[344] *N*-Methylpyrrole reacted with the C=C unit of methacrolein in the presence of a chiral catalyst (a chiral Friedel–Crafts catalyst) to give the 2-alkylated pyrrole, with good enantioselectivity.[345] Alkylation at C-5 of 2-trimethylsilylfuran was accomplished using the carbocation [$(p\text{-}MeOC_6H_4)_2CH^+$ OTf] and Proton Sponge (see Sec. 8.F, category 6).[346] The reaction of isoquinoline with $ClCO_2Ph$ and AgOTf, followed by reaction with an allylic silane, led to a 2-allylic dihydroisoquinoline.[347]

Regardless of which reagent is used, a catalyst is nearly always required.[348] Lewis acid catalysts (e.g., aluminum chloride and boron trifluoride) are the most common, but many other Lewis acids have been used,[349] and also proton acids (e.g., HF and H_2SO_4).[350] Calcium has been used to catalyze Friedel–Crafts alkylation reactions, at room temperature.[351] For active halides, a trace of a less active catalyst (e.g., $ZnCl_2$) may be enough. For an unreactive halide (e.g., chloromethane), a more powerful catalyst (e.g., $AlCl_3$) is needed, and in larger amounts. In some cases, especially with alkenes, a Lewis acid catalyst causes reaction only if a small amount of proton-donating cocatalyst is present. Catalysts have been arranged in the following order of overall reactivity: $AlBr_3 > AlCl_3 > GaCl_3$

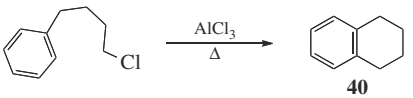
$> FeCl_3 > SbCl_5$[352] $> ZrCl_4, SnCl_4 > BCl_3, BF_3, SbCl_3$[353]; but the reactivity order in each case depends on the substrate, reagent, and conditions. Other Lewis acids have been used, of course, including $SeCl_2$,[354] $InCl_3$,[355] and enantiopure cycloalkyldialkylsilyl triflimide catalysts.[356]

Friedel–Crafts alkylation is unusual among the principal aromatic substitutions in that the entering group is activating (the product is more reactive than the starting aromatic substrate), and di- and polyalkylation are frequently observed. However, the activating effect of simple alkyl groups (e.g., ethyl and isopropyl) is only ~1.5–3 times as fast as benzene for *Friedel–Crafts alkylations*,[357] so it is often possible to obtain high yields of monoalkyl product.[358] Actually, the fact that di- and polyalkyl derivatives are frequently obtained is not due to the small difference in reactivity, but to the circumstance that alkylbenzenes are preferentially soluble in the catalyst layer, where the reaction actually takes place.[359] This factor can be removed by the use of a suitable solvent, by high temperatures, or by high-speed stirring.



It is important to note that the OH, OR, NH_2, and so on, groups do not facilitate the reaction, since most Lewis acid catalysts coordinate with these basic groups. Although phenols give the usual *Friedel–Crafts reactions*, orienting ortho and para, the reaction is very poor for aniline derivatives. However, amines can undergo the reaction if alkenes are used as reagents and aluminum anilides as catalysts.[360] In this method, the catalyst is prepared by treating the amine to be alkylated with one-third equiv of $AlCl_3$. A similar reaction can be performed with phenols, though here the catalyst is $Al(OAr)_3$.[361] Primary aromatic amines (and phenols) can be methylated regioselectively in the ortho position by an indirect method (see Reaction **11-23**). For an indirect method for regioselective ortho methylation of phenols, see Reaction **15-65**.

In most cases, meta-directing groups make the ring too inactive for alkylation. Nitrobenzene cannot be alkylated, and there are only a few reports of successful *Friedel–Crafts alkylations* when electron-withdrawing groups are present.[362] This is not because the attacking species is not powerful enough; indeed we have seen (Sec. 11.D) that alkyl cations are among the most powerful of electrophiles. The difficulty is caused by the fact that, with inactive substrates, degradation and polymerization of the electrophile occurs before it can attack the ring. However, if an activating and a deactivating group are both present on a ring, *Friedel–Crafts alkylation* can be accomplished.[363] Aromatic nitro compounds can be methylated by a nucleophilic mechanism (Reaction **13-17**).

The intermediate for *Friedel–Crafts alkylation* is a carbocation, and rearrangement to a more stable cation can be quite facile. Therefore, rearrangement of the alkyl substrate occurs frequently and is an important synthetic limitation of *Friedel–Crafts alkylation*. For example, benzene treated with *n*-propyl bromide gives mostly isopropylbenzene (cumene) and much less *n*-propylbenzene. Rearrangement is usually in the order primary → secondary → tertiary and usually occurs by migration of the smaller group on the adjacent carbon. Therefore, in the absence of special electronic or resonance influences on the migrating group (e.g., phenyl), H migrates before methyl, which migrates before ethyl, and so on (see discussion of rearrangement mechanisms in Chap 18). It is therefore not usually possible to put a primary alkyl group (other than methyl[364] and ethyl) onto an aromatic ring by *Friedel–Crafts alkylation*. Because of these rearrangements, *n*-alkylbenzenes are often prepared by *acylation* (Reaction **11-17**), followed by reduction (Reaction **19-61**).

An important use of the *Friedel–Crafts alkylation* reaction is to effect ring closure,[365] via an intramolecular process.[366] The most common method is to heat an aromatic compound with aluminum chloride having a halogen, hydroxy, or alkene group in the proper position, as, for example, in the preparation of tetralin (**40**).

40

Another way of effecting ring closure through *Friedel–Crafts alkylation* is to use a reagent containing two groups (e.g., **41**). These reactions are most successful for the preparation of six-membered rings,[367] though five- and seven-membered rings have also been closed in this manner. For other *Friedel–Crafts* ring-closure reactions, see Reactions **11-15**, **11-13**, and **11-17**. An interesting variation in this reaction showed that *N*-acyl aniline derivatives, upon treatment with $Et_2P(=O)H$ in water and a water soluble initiator (V-501) led to an intramolecular alkylation reaction to give an amide.[368]

41

As mentioned above, the electrophile in *Friedel–Crafts alkylation* is a carbocation, at least in most cases.[369] This is in accord with the knowledge that carbocations rearrange in the direction primary → secondary → tertiary (see Chap 18). In each case, the cation is

formed from the attacking reagent and the catalyst. For the three most important types of reagent these reactions are

From alkyl halides $RCl + AlCl_3 \rightarrow R^+ + AlCl_4^-$

From alcohols[370] and Lewis acids $ROH + AlCl_3 \rightarrow ROAlCl_2 \rightarrow R^+ + {}^-OAlCl_2$

From alcohols and protonic acids $ROH + H^+ \rightarrow ROH_2^+ \rightarrow R^+ + H_2O$

From alkenes (a supply of protons is usually required)

There is direct evidence, from IR and NMR spectra, that the *tert*-butyl cation is quantitatively formed when *tert*-butyl chloride reacts with $AlCl_3$ in anhydrous liquid HCl.[371] In the case of alkenes, *Markovnikov's rule* (Sec. 15.B.ii) is followed. Carbocation formation is particularly easy from some reagents, because of the stability of the cations. Triphenylmethyl chloride[372] and 1-chloroadamantane[373] alkylate activated aromatic rings (e.g., phenols and amines) with no catalyst or solvent. Ions as stable as this are less reactive than other carbocations and often attack only active substrates. The tropylium ion, for example, alkylates anisole, but not benzene.[374] Note in Section 10.F that relatively stable vinylic cations can be generated from certain vinylic compounds. These have been used to introduce vinylic groups into aryl substrates.[375] Lewis acids (e.g., BF_3[376] or $AlEt_3$[377] can also be used for alkylation of aromatic rings with alkene units.

There is considerable evidence that many *Friedel–Crafts alkylations*, especially with primary reagents, do not go through a completely free carbocation. The ion may exist as a tight ion pair with, say, $AlCl_4^-$ as the counterion or as a complex. Among the evidence is that methylation of toluene by methyl bromide and methyl iodide gave different ortho/para/meta ratios,[378] although the same ratios are expected if the same species are attacked in each case. Other evidence is that, in some cases, the reaction kinetics are third order; first order each in aromatic substrate, attacking reagent, and catalyst.[379] In these instances, a mechanism in which the carbocation is slowly formed and then rapidly attacked by the aromatic ring is ruled out since, in such a mechanism, the substrate would not appear in the rate expression. Since it is known that free carbocations, once formed, are rapidly attacked by the ring (acting as a nucleophile), there are no free carbocations here. Another possibility (with alkyl halides) is that some alkylations take place by an S_N2 mechanism (with respect to the halide), in which case no carbocations would be involved at all. However, a completely S_N2 mechanism requires inversion of configuration. Most investigations of *Friedel–Crafts* stereochemistry, even where an S_N2 mechanism might most be expected, have resulted in total racemization, or at best a few percent inversion.

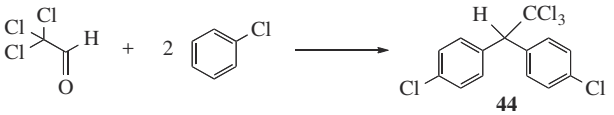
A few exceptions have been found,[380] most notably where the reagent was optically active propylene oxide, in which case 100% inversion was reported.[381]

Rearrangement is possible even with a non-carbocation mechanism. The rearrangement could occur *before* the attack on the ring takes place. It has been shown that treatment of $CH_3{}^{14}CH_2Br$ with $AlBr_3$ in the absence of any aromatic compound gave a mixture of the starting material and $^{14}CH_3CH_2Br$.[382] Similar results were obtained with $PhCH_2{}^{14}CH_2Br$, in which case the rearrangement was so fast that the rate could be measured only below $-7°$.[383] Rearrangement could also occur *after* formation of the product, since alkylation is reversible (see Reaction **11-33**).[384]



See Reaction **11-17** for *Friedel–Crafts acylation*. See Reaction **14-17** and **14-19** for free radical alkylation.

11-12 Hydroxyalkylation or Hydroxyalkyl-de-hydrogenation

When an aldehyde, ketone, or other carbonyl-containing substrate is treated with a protonic or Lewis acid, an oxygen-stabilized cation is generated. In the presence of an aromatic ring, *Friedel–Crafts type alkylation* occurs. The condensation of aromatic rings with aldehydes or ketones is called *hydroxyalkylation*.[385] The reaction can be used to prepare alcohols,[386] though more often the alcohol initially produced reacts with another molecule of aromatic compound (Reaction **11-11**) to give diarylation. For this the reaction is quite useful, an example being the preparation of 1,1,1-trichloro-2,2′-bis (*p*-chlorophenyl)ethane DDT, **44**:

44

The diarylation reaction is especially common with phenols (the diaryl product here is called a bisphenol). The reaction is normally carried out in alkaline solution on the phenolate ion.[387] Another variation involved *Friedel–Crafts coupling* of an aldehyde to an activated aromatic compound (an aniline derivative) to give diaryl carbinols that exhibited

[380] Some instances of retention of configuration have been reported; a neighboring-group mechanism is likely in these cases: see Effenberger, F.; Weber, T. *Angew. Chem. Int. Ed.* ***1987****, 26,* 142.

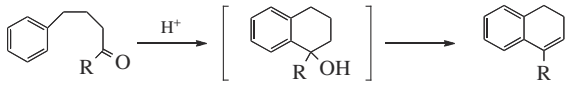
atropisomerism (see Sec. 4.C, category 5).[388] When the reaction was done with a chiral aluminum complex, modest enantioselectivity was observed.

The hydroxymethylation of phenols with formaldehyde is called the *Lederer–Manasse reaction*. This reaction must be carefully controlled,[389] since it is possible for the para and both ortho positions to be substituted and for each of these to be rearylated, so that a polymeric structure (**45**) is produced. However, such polymers, which are of the Bakelite type (phenol–formaldehyde resins, **45**), are of considerable commercial importance.

45

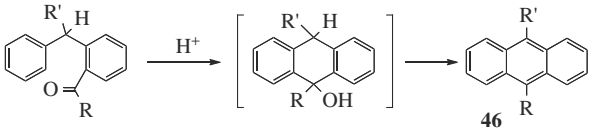


The attacking species is the carbocation ($R_2(OH)C^+$) formed from the aldehyde or ketone and the acid catalyst, except when the reaction is carried out in basic solution.

When an aromatic ring is treated with diethyl oxomalonate [$(EtOOC)_2C{=}O$)], the product is an arylmalonic acid derivative [$ArC(OH)(COOEt)_2$], which can be converted to an arylmalonic acid [$ArCH(COOEt)_2$].[390] This is therefore a way of applying the malonic ester synthesis (Reaction **10-67**) to an aryl group (see also, Reaction **13-14**). Of course, the opposite mechanism applies here: The aryl species is the nucleophile.

Two methods, both involving boron-containing reagents, have been devised for the regioselective ortho hydroxymethylation of phenols or aromatic amines.[391] Conjugated aldehydes undergo *Friedel–Crafts alkylation* with aryltrifluoroborate salts, in the presence of a catalytic amount of an imidazolidinone.[392]

OS **III**, 326; **V**, 422; **VI**, 471, 856; **VIII**, 75, 77, 80. Also see, OS **I**, 214.



11-13 Cyclodehydration of Carbonyl-Containing Compounds

As described in Reaction **11-12**, the reaction of carbonyl-containing functional groups with protonic or Lewis acids lead to oxygen-stabilized carbocations. When generated in the presence of an aromatic ring, *Friedel–Crafts alkylation* occurs to give an alcohol or an alkene, if dehydration occurs under the reaction conditions. When an

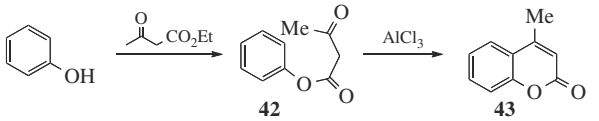
[392] Lee, S.; MacMillan, D.W.C. *J. Am. Chem. Soc.* ***2007****, 129,* 15438.

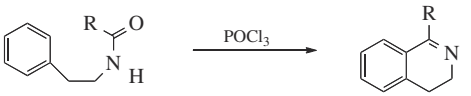


aromatic compound contains an aldehyde or ketone function in a position suitable for closing a suitably sized ring, treatment with acid results in cyclodehydration. The reaction is a special case of **11-12**, but in this case dehydration almost always takes place to give a double bond conjugated with the aromatic ring.[393] The method is very general and is widely used to close both carbocyclic and heterocyclic rings.[394] Polyphosphoric acid is a common reagent, but other acids have also been used. In a variation known as the *Bradsher reaction*,[395] diarylmethanes, which contain a carbonyl group in the ortho position, can be cyclized to anthracene derivatives (**46**). In this case, 1,4-dehydration takes place, at least formally.

46

An intramolecular cyclization of an aryl ether to the carbonyl of a pendant aryl ketone, on clay with microwave irradiation, led to a benzofuran via *Friedel–Crafts cyclization* and elimination of water.[396]

A variation of this reaction involves acylation of a β-keto ester, followed by *Friedel–Crafts cyclization* of the ketone moiety. The product is a coumarin (**43**), in what is known as the *Pechmann condensation*.[397] Isolation of esters (e.g., **42**) is not always necessary, and protonic acids can be used rather than Lewis acids. The *Pechmann condensation* is facilitated by the presence of hydroxyl (OH), dimethylamino (NMe_2), and alkyl groups meta to the hydroxyl of the phenol.[398] The reaction has been accomplished using microwave irradiation on graphite/Montmorillonite K-10.[399] *Pechmann condensation* in an ionic liquid using ethyl acetate has also been reported.[400]



42 **43**

The carbonyl unit involved in the cyclization process is not restricted to aldehydes and ketones. The carbonyl of acid derivatives (e.g., amides) also can be utilized. One of the more important cyclodehydration reactions is applied to the formation of heterocyclic systems via cyclization of β-aryl amides, in what is called the *Bischler–Napieralski reaction*.[401] In this reaction, amides of the type **47** are cyclized with phosphorous oxychloride or other reagents, including polyphosphoric acid, sulfuric acid, or phosphorus

pentoxide, to give a dihydroisoquinoline (**48**). The *Bischler–Napieralski reaction* has been done in ionic liquids using $POCl_3$.[402] The reaction has also been done using solid-phase (see Sec. 9.D.iv) techniques.[403]

47 **48**

If the starting compound contains a hydroxyl group in the α position, an additional dehydration takes place and the product is an isoquinoline.[404] Higher yields can be obtained if the amide is treated with PCl_3 to give an imino chloride ($ArCH_2CH_2N{=}CR{-}Cl$), which is isolated and then cyclized by heating.[405] In this latter case, a nitrilium ion ($ArCH_2CH_2{}^{+}N{\equiv}CR$) is an intermediate.

49

Another useful variation is the *Pictet–Spengler isoquinoline synthesis*, also known as the *Pictet–Spengler reaction*.[406] The reactive intermediate is an iminium ion (**49**) rather than an oxygen-stabilized cation, but attack at the electrophilic carbon of the C=N unit (see Reaction **16-31**) leads to an isoquinoline derivative. When a β-arylamine reacts with an aldehyde, the product is an iminium salt, which cyclizes with an aromatic ring to complete the reaction and generate a tetrahydroisoquinoline.[407] Metal-catalyzed reactions are known, including the use of $AuCl_3/AgOTf$.[408] A variety of aldehydes can be used, and substitution on the aromatic ring leads to many derivatives. When the reaction is done in the presence of a chiral catalyst, good enantioselectivity was observed.[409]

Another variation in this basic procedure leads to tetrahydroisoquinolines. When phenethylamine was treated with *N*-hydroxymethylbenzotriazole and then $AlCl_3$ in chloroform, cyclization occurred, and reduction with sodium borohydride gave the 1,2,3,4-tetrahydro-*N*-methylisoquinoline.[410]

11-14 Haloalkylation or Haloalkyl-de-hydrogenation

$$\mathrm{ArH + HCHO + HCl \xrightarrow{ZnCl_2} ArCH_2Cl}$$

When certain aromatic compounds are treated with formaldehyde and HCl, the CH_2Cl group is introduced into the ring in a reaction called *chloromethylation*. The reaction has also been carried out with other aldehydes and with HBr and HI. The more general term *haloalkylation* covers these cases.[411] The reaction is successful for benzene, and alkyl-, alkoxy-, and halobenzenes. It is greatly hindered by meta-directing groups, which reduce yields or completely prevent the reactions. Amines and phenols are too reactive and usually give polymers unless deactivating groups are also present, but phenolic ethers and esters successfully undergo the reaction. Compounds of lesser reactivity can often be chloromethylated with chloromethyl methyl ether ($ClCH_2OMe$) or methoxyacetyl chloride ($MeOCH_2COCl$).[412] Zinc chloride is the most common catalyst, but other Friedel–Crafts catalysts are also employed. As with Reaction **11-12** and for the same reason, an important side product is the diaryl compound Ar_2CH_2 (from formaldehyde).

Apparently, the initial step involves reaction of the aromatic compound with the aldehyde to form the hydroxyalkyl compound, exactly as in Reaction **11-12**, and then the HCl converts this to the chloroalkyl compound.[413] The acceleration of the reaction by $ZnCl_2$ has been attributed[414] to the raising of the acidity of the medium, causing an increase in the concentration of $HOCH_2^+$ ions.

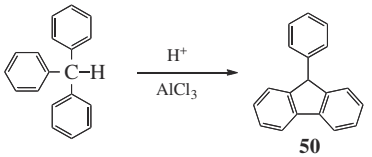
11-15 Friedel–Crafts Arylation: The Scholl Reaction



De-hydrogen-coupling

$$\mathrm{2\,ArH \xrightarrow[H^+]{AlCl_3} Ar{-}Ar + H_2}$$

The coupling of two aromatic molecules by treatment with a Lewis and a proton acid is called the *Scholl reaction*.[415] Yields are low and the synthesis is seldom useful. High temperatures and strong-acid catalysts are required, and the reaction fails for substrates that are destroyed by these conditions. The reaction becomes important with large fused-ring systems, so ordinary *Friedel–Crafts reactions* (**11-11**) on these systems are rare. For example, naphthalene gives binaphthyl under *Friedel-Crafts conditions*. Yields can be

increased by the addition of a salt (e.g., $CuCl_2$ or $FeCl_3$), which acts as an oxidant.[416] Rhodium[417] and Ru catalysts[418] have also been used.

50

Intramolecular *Scholl reactions* (e.g., formation of **50** from triphenylmethane) are much more successful than the intermolecular reaction. The mechanism is not clear, but it may involve attack by a proton to give an arenium ion of type **12** (Sec. 11.A.i, category 2), which would be the electrophile that attacks the other ring.[419] Sometimes arylations have been accomplished by treating aromatic substrates with particularly active aryl halides, especially fluorides. For free radical arylations, see Reactions **12-15**, **13-26**, **13-27**, **13-10**, **14-17**, and **14-18**.

11-16 Arylation of Aromatic Compounds by Metalated Aryls

$$\mathrm{Ar}\text{—}M \xrightarrow{\mathrm{Ar'}\text{—H}} \mathrm{Ar}\text{—}\mathrm{Ar'}$$

Many metalated aryl compounds are known to couple with aromatic compounds. Aniline derivatives react with $ArPb(OAc)_3$, for example, to give the 2-arylaniline.[420] Phenolic anions also react to form biaryls, with modest enantioselectivity in the presence of brucine.[421] A Mn(III) mediated synthesis of biaryls used microwave irradiation for the coupling reaction.[422] The homocoupling reaction of aryl *Grignard reagents* in the presence of TEMPO is known.[423]

Phenylboronates [$ArB(OR)_2$] react with electron-deficient aromatic compounds (e.g., acetophenone) to give the biaryl.[424] Arylboronates also react with π-allyl Pd complexes to form the alkylated aromatic compound.[425] Arylboronic acids are also coupled in the presence of metal catalysts.[426] Organoborates can be coupled using an oxovanadium catalyst,[427] and potassium phenyltrifluoroborates can be coupled to aromatics using a combination of Pd and Cu catalysts.[428]

11-17 Friedel–Crafts Acylation

Acylation or Acyl-de-hydrogenation

$$\mathrm{ArH} + \mathrm{RCOCl} \xrightarrow{\mathrm{AlCl_3}} \mathrm{ArCOR}$$

The most important method for the preparation of aryl ketones is known as *Friedel–Crafts acylation*.[430] The reaction is of wide scope. Reagents other than acyl halides can be used,[431] including carboxylic acids,[432] anhydrides, and ketenes. Oxalyl chloride has been used to give diaryl 1,2-diketones.[433] Carboxylic esters usually give alkylation as the predominant product (see Reaction **11-11**).[434] *N*-Carbamoyl β-lactams reacted with naphthalene in the presence of trifluoromethanesulfonic acid to give the keto-amide.[435]

The alkyl group (R in RCOCl) may be aryl as well as alkyl.[436] The major disadvantages of *Friedel–Crafts alkylation*, polyalkylation, and rearrangement of the intermediate carbocation, are not a problem in *Friedel–Crafts acylation*. Rearrangement of the alkyl group (R in RCOCl) is never found because the intermediate is an acylium ion (an acyl cation, $RC{\equiv}O^+$, see below), which is stabilized by resonance. Because the RCO group is deactivating, the reaction stops cleanly after one group is introduced. All four acyl halides can be used, though chlorides are most commonly employed. The order of activity is usually, but not always, $I > Br > Cl > F$.[437] Catalysts are Lewis acids,[438] similar to those in Reaction **11-11**, but in acylation a little >1 equiv of catalyst is required per mole of reagent, because the first mole coordinates with the oxygen of the reagent [as in $R(Cl)C{=}O^{+-}AlCl_3$].[439] A reusable catalyst [$Ln(OTf)_3$—$LiClO_4$] has been developed.[440] Ferric chloride in an ionic liquid has

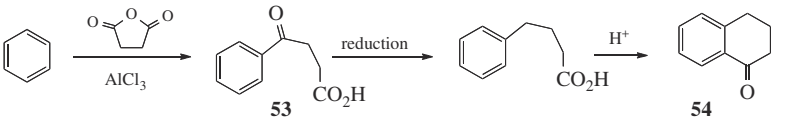
also been used.[441] The HY-Zeolite has also been used to facilitate the reaction with acetic anhydride.[442] Catalyts include a Pd catalyst, which was used with acetic anhydride,[443] $TiCl_4$,[444] SmI_2,[445] In metal,[446] acetyl chloride, and zinc powder with microwave irradiation.[447] *Friedel–Crafts acylation* using a carboxylic acid with a catalyst called Envirocat-EPIC (an acid-treated clay-based material) was reported.[448] *Friedel–Crafts acylation* was reported in an ionic liquid.[449] An interesting acylation reaction was reported that coupled trichlorophenylmethane to benzene, giving benzophenone in the presence of the ionic liquid $AlCl_3$–BPC.[450] (butylpyridiniumchloroaluminate = BPC). Acylation has been accomplished in carbon disulfide.[451] An interesting variation couples a conjugated acid chloride with benzene, in the presence of $AlCl_3$ and microwave irradiation, to give an indanone.[452]

Protonic acids can be used as catalysts when the reagent is a carboxylic acid.[453] Triflic anhydride promotes dehydrative acylation of carboxylic acids,[454] as does P_2O_5/SiO_2.[455] An aryl carboxylic acid can be converted to the acid chloride *in situ* with cyanuric chloride and $AlCl_3$, leading to *Friedel–Crafts acylation*.[456] A solvent-free method is also available using tosic acid/graphite.[457]



The mixed carboxylic sulfonic anhydrides ($RCOOSO_2CF_3$) are extremely reactive acylating agents and can smoothly acylate benzene without a catalyst.[458] With active substrates (e.g., aryl ethers, fused-ring systems, thiophenes), *Friedel–Crafts acylation* can be carried out with very small amounts of catalyst, often just a trace, or even sometimes with no catalyst at all.

The reaction is quite successful for many types of substrate, including fused ring systems, which give poor results in Reaction **11-11**. Compounds containing ortho–para directing groups, including alkyl, hydroxy, alkoxy, halogen, and acetamido groups, are easily acylated and give mainly or exclusively the para products, because of the relatively large size of the acyl group. However, aromatic amines give poor results. With amines and phenols there may be competition from *N*- or *O*-acylation; however, *O*-acylated phenols can be converted to *C*-acylated phenols by the *Fries rearrangement* (Reaction **11-27**). *Friedel–Crafts acylation* is usually prevented by meta-directing (deactivating) groups.

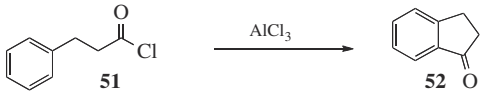
Indeed, nitrobenzene is often used as a solvent for the reaction. Many heterocyclic systems, including furans, thiophenes, pyrans, and pyrroles[459] but not pyridines or quinolines, can be acylated in good yield. Initial reaction of indole with Et_2AlCl[460] or $SnCl_4$,[461] followed by acetyl chloride leads to 3-acetylindole. By comparison, the reaction of *N*-acetylindole with acetic anhydride and $AlCl_3$ gave *N*,6-diacetylindole.[462] Acetylation at C-3 was also accomplished with acetyl chloride in the ionic liquid emimcl–$AlCl_3$.[463] Gore, in Ref. 430 (pp. 36–100; with tables, pp. 105–321), presents an extensive summary of the substrates to which this reaction has been applied.

Friedel–Crafts acylation can be carried out with cyclic anhydrides,[464] in which case the product contains a carboxyl group in the side chain (**53**). When succinic anhydride is used, the product is $ArCOCH_2CH_2CO_2H$. This can be reduced (Reaction **19-61**) to $ArCH_2CH_2CH_2CO_2H$, and can then be cyclized by an internal *Friedel–Crafts acylation* to give **54**. The total process is called the *Haworth reaction*:[465]



53 **54**

When a mixed-anhydride ($RCOOCOR'$) is the reagent, two products are possible: ArCOR and $ArCOR'$. Which product predominates depends on two factors. If R contains electron-withdrawing groups, then $ArCOR'$ is chiefly formed, but if this factor is approximately constant in R and R′, the ketone with the larger R group predominantly forms.[466] This means that *formylations* of the ring do not occur with mixed anhydrides of formic acid (HCOOCOR).

An important use of the *Friedel–Crafts acylation* is to effect ring closure.[467] This closure can be accomplished if an acyl halide, anhydride, or carboxylic acid[468] group is in the proper position. An example is the conversion of **51** to **52**. The reaction is used mostly to close six-membered rings, but has also been done for five- and seven-membered rings, which close less readily. Even larger rings can be closed by high-dilution techniques.[469] Tricyclic and larger systems are often made by using substrates containing one of the acyl groups on a ring. Many fused-ring systems are made in this manner. If the bridging group is CO, the product is a quinone.[470] One of the most

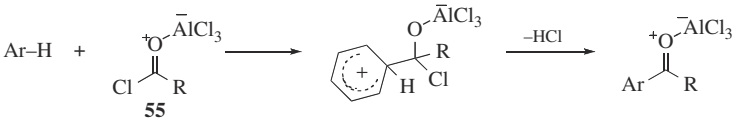
common catalysts for intramolecular *Friedel–Crafts acylation* is polyphosphoric acid[471] (because of its high potency), but $AlCl_3$, H_2SO_4, and other Lewis and proton acids are also used, though acylations with acyl halides are not generally catalyzed by proton acids.

Thioesters are coupled to arylboronic acids in the presence of a Pd catalyst, in a *Friedel–Crafts acylation*-type coupling.[472] Acyl halides are coupled to arylboronic acids under microwave irradiation.[473]



The mechanism of *Friedel–Crafts acylation* is not completely understood,[474] but at least two mechanisms probably operate, depending on conditions.[475] In most cases, the attacking species is the acyl cation, either free or as an ion pair, formed by[476]

$$RCOCl + AlCl_3 \longrightarrow RCO^+ + AlCl_4^-$$

If R is tertiary, RCO^+ may lose CO to give R^+, so that the alkyl arene ArR is often a side product or even the main product. This kind of cleavage is much more likely with relatively unreactive substrates, where the acylium ion has time to break down. For example, pivaloyl chloride (Me_3CCOCl) gives the normal acyl product with anisole, but yields the alkyl product (Me_3CPh) with benzene. In the other mechanism, an acyl cation is not involved, but the 1:1 complex (**55**) attacks directly.[477] Free-ion attack is more likely for sterically hindered R.[478] The ion CH_3CO^+ has been detected (by IR spectroscopy) in the liquid complex between acetyl chloride and aluminum chloride, and in polar solvents (e.g., nitrobenzene); but in nonpolar solvents (e.g., as chloroform) only the complex and not the free ion is present.[479] In any event, 1 molar equivalent of catalyst certainly remains complexed to the product at the end of the reaction. When the reaction is performed with RCO^+ SbF_6^-, no catalyst is required and the free ion[480] (or ion pair) is undoubtedly the attacking entity.[481] The use of $LiClO_4$ on the metal triflate catalyzed *Friedel–Crafts acylation* of methoxynaphthalene derivatives has been examined. The presence of the lithium salt leads to acylation in the ring containing the methoxy unit, whereas reaction occurs in the other ring in the absence of lithium salts.[482] Note that lithium perchlorate

forms a complex with acetic anhydride, which can be used for the *Friedel–Crafts acetylation* of activated aromatic compounds.[483]

A related reaction couples an acid chloride with an aromatic compound in the presence of a Rh catalyst, but the coupling reaction involves a decarbonylation to give a biaryl.[484]

OS **I**, 109, 353, 476, 517; **II**, 3, 8, 15, 81, 156, 169, 304, 520, 569; **III**, 6, 14, 23, 53, 109, 183, 248, 272, 593, 637, 761, 798; **IV**, 8, 34, 88, 898, 900; **V**, 111; **VI**, 34, 618, 625 **X**, 125.

Reaction **11-18** is a direct formylation of the ring.[485] Reaction **11-17** has not been used for formylation, since neither formic anhydride nor formyl chloride is stable at ordinary temperatures. Formyl chloride has been shown to be stable in chloroform solution for 1 h at $-6°$,[486] but it is not useful for formylating aromatic rings under these conditions. Formic anhydride has been prepared in solution, but has not been isolated.[487] Mixed anhydrides of formic and other acids are known[488] and can be used to formylate amines (see Reaction **16-73**) and alcohols, but no formylation takes place when they are applied to aromatic rings. See Reaction **13-17** for a nucleophilic method for the formylation of aromatic rings.

A related reaction involves a biaryl, where one ring is a phenol. Treatment with BCl_3 and an $AlCl_3$ catalyst, followed by reaction with CO and $Pd(OAc)_2$, led to carbonylation and acylation to give the corresponding lactone.[489] Carbonylation of aromatic compounds can lead to aryl ketones. Heating an aromatic compound with $Ru(CO)_{12}$, ethylene and 20 atm. of CO gave the corresponding aryl ethyl ketone.[490]

11-18 Formylation

Formylation or **Formyl-de-hydrogenation**

$$\text{Ar—H} \longrightarrow \text{Ar—CHO}$$

The reaction with disubstituted formamides (R_2N—CHO) and phosphorus oxychloride, called the *Vilsmeier* or the *Vilsmeier–Haack reaction*,[491] is the most common method

for the formylation of aromatic rings.[492] However, it is applicable only to active substrates (e.g., amines and phenols). An intramolecular version is also known.[493] Aromatic hydrocarbons and heterocycles can also be formylated, but only if they are much more active than benzene (e.g., azulenes and ferrocenes). Although *N*-phenyl-*N*-methylformamide is a common reagent, other arylalkyl amides and dialkyl amides are also used.[494] Phosgene ($COCl_2$) has been used in place of $POCl_3$. The reaction has also been carried out with other amides to give ketones (actually an example of Reaction **11-17**), but not often. The attacking species[495] is **56**,[496] and the mechanism is probably that shown to give **57**, which is unstable and easily hydrolyzes to the product. Either formation of **56** or the reaction of **56** with the substrate can be rate determining, depending on the reactivity of the substrate.[497]

When $(CF_3SO_2)_2O$ was used instead of $POCl_3$, the reaction was extended to some less-active compounds, including naphthalene and phenanthrene.[498]

In a related reaction, paraformaldehyde can be used, with $MgCl_2$-NEt_3, to convert phenol to phenol 2-carbaldehyde.[499] Another variation treated acetanilide with $POCl_3$—DMF and generated 2-chloroquinoline-3-carboxaldehyde.[500] Used in conjunction with conjugated hydroxylamines, a tandem *Vilsmeier–Beckman reaction* (see Reaction **18-17** for the *Beckman rearrangement*) leads to pyridines (2-chloro-3-carboxaldehyde).[501] A chain-extension variation has been reported in which an aryl alkyl ketone is treated with $POCl_3$/DMF on silica with microwave irradiation to give a conjugated aldehyde [ArC(=O)R → ArC(Cl)=CHCHO].[502]

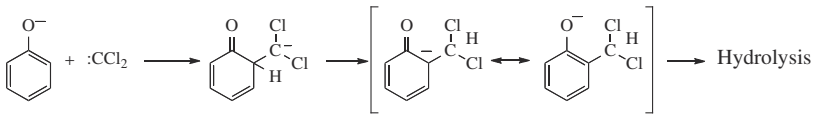
compounds. However, it cannot be applied to aromatic amines. In the original version of this reaction, the substrate was treated with HCN, HCl, and $ZnCl_2$, but the use of $Zn(CN)_2$ and HCl (HCN and $ZnCl_2$ are generated *in situ*) makes the reaction more convenient to carry out and yields are not diminished. The mechanism of the *Gatterman reaction* has not been investigated very much, but it is known that an initially formed, but not isolated nitrogen-containing product, is hydrolyzed to aldehyde. This product is presumed to be $ArCH{=}NH_2^+Cl^-$, as shown. When benzene was treated with NaCN under superacid conditions (F_3CSO_2OH–SbF_5, see Sec. 5.A.ii), a good yield of product was obtained, leading to the conclusion that the electrophile in this case was $^+C(H){=}N^+H_2$.[504] The *Gatterman reaction* may be regarded as a special case of Reaction **11-24**.

Another method, formylation with CO and HCl in the presence of $AlCl_3$ and CuCl[505] (the *Gatterman–Koch reaction*), is limited to benzene and alkylbenzenes.[506] Aryl halides are converted to aryl aldehydes with CO/H_2 in the presence of a Pd catalyst.[507]

OS **II**, 583; **III**, 549.

In the *Reimer–Tiemann reaction*, aromatic rings are formylated by reaction with chloroform and hydroxide ion.[508] The method is useful only for phenols and certain heterocyclic compounds (e.g., pyrroles and indoles). Unlike the previous formylation methods (Reaction **11-18**), this one is conducted in basic solution. Yields are generally low, seldom rising >50%.[509] The incoming group is directed ortho, unless both ortho positions are filled, in which case the attack is para.[510] Certain substrates have been shown to give abnormal products instead of or in addition to the normal ones. For example, **58** and **60** gave, respectively, **59** and **61**, as well as the normal aldehyde products. From the nature of the reagents and



58 **59** **60** **61**

from the kind of abnormal products obtained, it is clear that the reactive entity in this reaction is dichlorocarbene (CCl_2).[511] This product is known to be produced by treatment of chloroform with bases (see Reaction **10-3**); it is an electrophilic reagent and is known to

give ring expansion of aromatic rings (see Reaction **15-64**), accounting for products like **58**. The mechanism of the normal reaction is thus something like[512]:

The formation of **61** in the case of **60** can be explained by attack of some of the CCl_2 ipso to the CH_3 group. Since this position does not contain a hydrogen, normal proton loss cannot take place and the reaction ends when the CCl_2^- moiety acquires a proton.

A method closely related to the *Reimer–Tiemann reaction* is the *Duff reaction*, in which hexamethylenetetramine [$(CH_2)_6N_4$] is used instead of chloroform. This reaction can be applied only to phenols and amines; ortho substitution is generally observed and yields are low. A mechanism[513] has been proposed that involves initial aminoalkylation (Reaction **11-22**) to give $ArCH_2NH_2$, followed by dehydrogenation to ArCH=NH and hydrolysis of this to the aldehyde product. When $(CH_2)_6N_4$ is used in conjunction with F_3CCO_2H, the reaction can be applied to simple alkylbenzenes; yields are much higher and a high degree of regioselectively para substitution is found.[514] In this case too, an imine seems to be an intermediate.

OS **III**, 463; **IV**, 866

$$ArH + Cl_2CHOMe \xrightarrow{AlCl_3} ArCHO$$

Besides Reaction **11-18**, several other formylation methods are known.[515] In one of these, dichloromethyl methyl ether formylates aromatic rings with *Friedel–Crafts catalysts*.[516] The ArCHClOMe compound is probably an intermediate. Orthoformates have also been used.[517] In another method, aromatic rings are formylated with formyl fluoride (HCOF) and BF_3.[518] Unlike formyl chloride, formyl fluoride is stable enough for this purpose. This reaction was successful for benzene, alkylbenzenes, PhCl, PhBr, and naphthalene. Phenols can be regioselectively formylated in the ortho position in high yields by treatment with 2 molar equivalents of paraformaldehyde in aprotic solvents in the presence of $SnCl_4$ and a tertiary amine.[519] Phenols have also been formylated indirectly by conversion to the aryllithium reagent followed by treatment with *N*-formyl piperidine.[520] See also, the indirect method mentioned at Reaction **11-23**. Aryl halides are converted to the corresponding aldehyde in a related reaction.[521]

OS **V**, 49; **VII**, 162.

Reactions **11-19** and **11-20** are direct carboxylations[522] of aromatic rings.[523]

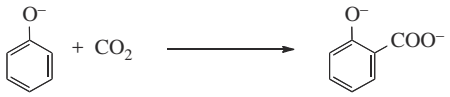
11-19 Carboxylation with Carbonyl Halides

Carboxylation or **Carboxy-de-hydrogenation**

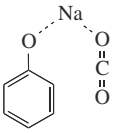
$$ArH + COCl_2 \xrightarrow{AlCl_3} ArCOOH$$



Phosgene, in the presence of *Friedel–Crafts catalysts*, can carboxylate the ring. This process is analogous to Reaction **11-17**, but the ArCOCl initially produced hydrolyzes to the carboxylic acid. However, in most cases the reaction does not take this course, but instead the ArCOCl is attacked by another ring to give a ketone ArCOAr. A number of other reagents have been used to get around this difficulty, including oxalyl chloride, urea hydrochloride, chloral (Cl_3CCHO),[524] carbamoyl chloride (H_2NCOCl), and *N*,*N*-diethylcarbamoyl chloride.[525] With carbamoyl chloride the reaction is called the *Gatterman amide synthesis* and the product is an amide. Among compounds carboxylated by one or another of these reagents are benzene, alkylbenzenes, and fused ring systems.[526]

Although mechanistically different, other methods are available to convert aromatic compounds to aromatic carboxylic acids. The Pd catalyzed reaction of aromatic compounds and formic acid leads to benzoic acid derivatives.[527] Diphenyliodonium tetrafluoroborate ($Ph_2I^+ BF_4^-$) reacts with CO and In in DMF, with a Pd catalyst, to give benzophenone.[528]

OS **V**, 706; **VII**, 420.



11-20 Carboxylation with Carbon Dioxide: The Kolbe–Schmitt Reaction

Carboxylation or **Carboxy-de-hydrogenation**

Sodium phenoxides can be carboxylated, mostly in the ortho position, by CO_2 (the *Kolbe–Schmitt reaction*). The mechanism is not clearly understood, but apparently some kind of a complex is formed between the reactants,[529] making the carbon of the CO_2 more positive and putting it in a good position to attack the ring. Potassium phenoxide, which is less likely to form such a complex, is chiefly attacked in the para position. There is evidence that, in the complex formed from potassium salts, the bonding is between the aromatic compound and the carbon atom of CO_2.[530] At least part of the potassium *p*-hydroxybenzoate that forms comes from a rearrangement of initially formed potassium salicylate (sodium salicylate does not rearrange).[531] Carbon tetrachloride can be used instead of CO_2 under *Reimer–Tiemann* (Reaction **11-18**) conditions.

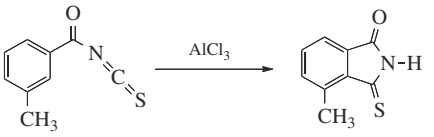
Sodium or potassium phenoxide can be carboxylated regioselectively in the para position in high yield by treatment with sodium or potassium carbonate and carbon monoxide.[532] The ^{14}C labeling showed that it is the carbonate carbon that appears in the *p*-hydroxybenzoic acid product.[533] The CO is converted to sodium or potassium formate. Carbon monoxide has also been used to carboxylate aromatic rings with Pd compounds as catalysts.[534] In addition, a Pd catalyzed reaction has been used directly to prepare acyl fluorides $ArH \rightarrow ArCOF$.[535] Molybdovanadophosphates have been used for anisole in the presence of CO and O_2.[536] A Pd catalyzed carboxylation has been reported using Ag_2CO_3 and CO.[537]

An enzymatic carboxylation was reported, in supercritical CO_2 (see Sec. 9.D.ii), in which exposure of pyrrole to *Bacillus megaterium* PYR2910 and $KHCO_3$ gave the potassium salt of pyrrole 2-carboxylic acid.[538]

OS **II**, 557.



11-21 Amidation

N-Alkylcarbamoyl-de-hydrogenation

$$ArH + RNCO \xrightarrow{AlCl_3} ArCONHR$$

N-Substituted amides can be prepared by direct attack of isocyanates on aromatic rings.[539] The R group may be alkyl or aryl, but if the latter, dimers and trimers are also obtained. Isothiocyanates similarly give thioamides.[540] The reaction has been carried out intramolecularly both with aralkyl isothiocyanates and acyl isothiocyanates.[541] In the latter case, the product is easily hydrolyzable to a dicarboxylic acid; this is a way of putting a carboxyl group on a ring ortho to one already there (**62** is prepared by treatment of the acyl halide with lead thiocyanate). The reaction gives better yields with substrates of the type $ArCH_2CONCS$, where six-membered rings are formed. An intramolecular reaction of 2-amido biaryls leads to carbazoles in the presence of Pd and Cu catalysts.[542]

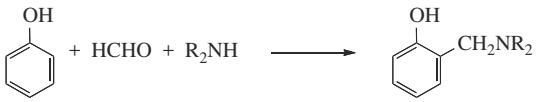
62



There are interesting transition metal catalyzed reactions that lead to aryl amides. The use of $POCl_3$ and DMF, with a Pd catalyst, converts aryl iodides to benzamides.[543] Carbonylation is another method that generates amides. When an aryl iodide was treated with a secondary amine and $Mo(CO)_6$, in the presence of 3 equiv of DBU, 10% $Pd(OAc)_2$, with microwave irradiation at 100 °C, the corresponding benzamide was obtained.[544] Aminocarbonylation is accomplished with microwave irradiation using hydroxylamine as an ammonia equivalent.[545]

OS **V**, 1051; **VI**, 465.

Reactions **11-12–11-23** involve the introduction of a CH_2Z group, where Z is halogen, hydroxyl, amino, or alkylthio. They are all *Friedel–Crafts reactions* of aldehydes and ketones and, with respect to the carbonyl compound, additions to the C=O double bond. They follow mechanisms discussed in Chapter 16.

11-22 Aminoalkylation and Amidoalkylation

Dialkylaminoalkylation or **Dialkylamino-de-hydrogenation**

Phenols, secondary and tertiary aromatic amines,[546] pyrroles, and indoles can be aminomethylated by treatment with formaldehyde and a secondary amine. Other aldehydes have sometimes been employed. Aminoalkylation is a special case of the *Mannich reaction* (**16-19**). When phenols and other activated aromatic compounds are treated with *N*-hydroxymethylchloroacetamide, *amidomethylation* takes place[547] to give **63**, which is often hydrolyzed *in situ* to the aminoalkylated product. Other *N*-hydroxyalkyl and *N*-chlorinated compounds have also been used.[379] Nitroethane in polyphosphoric acid can be used for the acetamidation of aromatic compounds.[548]

Aryl halides are aminomethylated with potassium organotrifluoroborates.[549]
OS **I**, 381; **IV**, 626; **V**, 434; **VI**, 965; **VII**, 162.

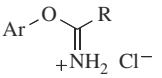
11-23 Thioalkylation

Alkylthioalkylation or **Alkylthioalkyl-de-hydrogenation**

A methylthiomethyl group can be inserted into the ortho position of phenols by heating with DMSO and 1,3-dicyclohexylcarbodiimide (DCC).[550] Other reagents can be used instead of DCC, among them $SOCl_2$,[551] or acetic anhydride.[552] Alternatively, the phenol can be treated with DMS and NCS, followed by triethylamine.[553] The reaction can be applied to amines (to give *o*-$NH_2C_6H_4CH_2SMe$) by treatment with *t*-BuOCl, Me_2S, and NaOMe in CH_2Cl_2.[554] Aromatic hydrocarbons have been thioalkylated with ethyl α-(chloromethylthio) acetate ($ClCH_2SCH_2CO_2Et$) to give $ArCH_2SCH_2CO_2Et$,[555] and with methyl methylsulfinylmethyl sulfide ($MeSCH_2SOMe$) or methylthiomethyl *p*-tolyl sulfone ($MeSCH_2SO_2C_6H_4Me$) to give $ArCH_2SMe$,[556] in each case with a Lewis acid catalyst.

OS **VI**, 581, 601.

11-24 Acylation with Nitriles: The Hoesch Reaction



Acylation or **Acyl-de-hydrogenation**

$$ArH + RCN \xrightarrow[ZnCl_2]{HCl} ArCOR$$

Friedel–Crafts acylation with nitriles and HCl is called the *Hoesch* or the *Houben–Hoesch reaction*.[557] In most cases, a Lewis acid is necessary; zinc chloride is the most common. The reaction is generally useful only with phenols, phenolic ethers, and some reactive heterocyclic compounds (e.g., pyrrole), but it can be extended to aromatic amines

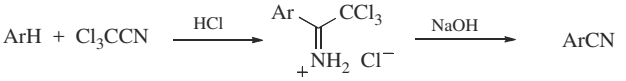
by the use of BCl_3.[558] Acylation in the case of aniline derivatives is regioselectively ortho. Monohydric phenols, however, generally do not give ketones[559] but are attacked at the oxygen to produce imino esters. Many nitriles have been used. Even aryl nitriles give good yields if they are first treated with HCl and $ZnCl_2$, and then the substrate added at 0 °C.[560] In fact, this procedure increases yields with any nitrile. If thiocyanates (RSCN) are used, thiol esters (ArCOSR) can be obtained. The *Gatterman reaction* (Reaction **11-18**) is a special case of the *Hoesch synthesis*.



An imino ester

The reaction mechanism is complex and not completely settled.[561] The first stage consists of an attack on the substrate by a species containing the nitrile and HCl (and the Lewis acid, if present) to give an imine salt (**66**). Among the possible reactive species are **64** and **65**. In the second stage, the salts are hydrolyzed to the products, first the iminium salt, and then the ketone. Ketones can also be obtained by treating phenols or phenolic ethers with a nitrile in the presence of F_3CSO_2OH.[562] The mechanism in this case is different.

OS **II**, 522.

11-25 Cyanation or Cyano-de-hydrogenation

Aromatic hydrocarbons (including benzene), phenols, and phenolic ethers can be cyanated with trichloroacetonitrile, BrCN, or mercury fulminate [$Hg(ONC)_2$].[563] In the case of Cl_3CCN, the actual attacking entity is probably $Cl_3C—C^+=NH$, formed by addition of a proton to the cyano nitrogen. Secondary aromatic amines (ArNHR), as well as phenols, can be cyanated in the ortho position with Cl_3CCN and BCl_3.[564]

Note that aryl triflates are converted to the aryl nitrile by treatment with $Zn(CN)_2$ and a Pd catalyst.[565]

F. Oxygen Electrophiles

Oxygen electrophiles are very uncommon, since oxygen does not bear a positive charge very well. However, there is one reaction that can be mentioned.

11-26 Hydroxylation or Hydroxy-de-hydrogenation

There have been only a few reports of direct hydroxylation[566] by an electrophilic process (see, however, **14-5**).[567] In general, poor results are obtained, partly because the introduction of an OH group activates the ring, which suppresses further reaction. Quinone formation is common. However, alkyl-substituted benzenes (e.g., mesitylene or durene) can be hydroxylated in good yield with trifluoroperacetic acid and boron trifluoride.[568] In the case of mesitylene, the product (**67**) is not subject to further attack.

67

In a related procedure, even benzene and substituted benzenes (e.g., PhMe, PhCl, and xylenes) can be converted to phenols in good yields with sodium perborate–F_3CSO_2OH.[569] Aromatic amines, *N*-acyl amines, and phenols were hydroxylated with H_2O_2 in SbF_5-HF.[570] Pyridine and quinoline were converted to their 2-acetoxy derivatives in high yields with acetyl hypofluorite (AcOF) at $-75\,^{\circ}C$.[571]

Another hydroxylation reaction is the *Elbs reaction*.[572] In this method, phenols can be oxidized to *p*-diphenols with $K_2S_2O_8$ in alkaline solution.[573] Primary, secondary, or tertiary aromatic amines give predominant or exclusive ortho substitution unless both ortho positions are blocked, in which case para substitution is found. The reaction with amines is called the *Boyland–Sims oxidation*. Yields are low with either phenols or amines, generally $<50\%$. The mechanisms are not clear,[574] but for the *Boyland–Sims oxidation* there is evidence that the $S_2O_8^{2-}$ ion attacks at the ipso position, and then a migration follows.[575]

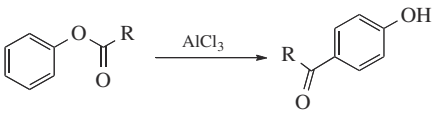
Electrolysis of benzene, in the presence of trifluoroacetic acid and triethylamine, leads to a 73% yield of phenol.[576] Photolytic hydroxylation of benzene has been reported in the presence of mesoporous TiO_2.[577] Deactivated rings (e.g., nitrobenzene) are selectively ortho hydroxylated by molecular oxygen in the presence of $H_5PV_2Mo_{10}O_{40}$ polyoxometalate.[578] Nitrous oxide has been used as an oxidant, in the presence of FeAlPO catalysts.[579]

G. Metal Electrophiles

Reactions in which a metal replaces the hydrogen of an aromatic ring are considered along with their aliphatic counterparts in Chapter 12 (Reactions **12-22** and **12-23**).

11.F.ii. Hydrogen as the Leaving Group in Rearrangement Reactions

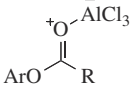


In these reactions, a group is detached from a *side chain* and then reattached the ring, but in other aspects they resemble the reactions already treated in this chapter.[580] Since a group moves from one position to another in a molecule, these are rearrangements (also see Chap 18). In all these reactions, the question arises as to whether the group that cleaves from a given molecule is attacked by the same molecule or another one; that is, Is the reaction intramolecular or intermolecular? For intermolecular reactions, the mechanism is the same as ordinary aromatic substitution, but for intramolecular cases the migrating group could never be completely free, or else it would be able to react with another molecule. Since the migrating species in intramolecular rearrangements is thus likely to remain near the atom from which it cleaved, it has been suggested that intramolecular reactions are more likely to lead to ortho products than are the intermolecular type. This characteristic has been used, among others, to help decide whether a given rearrangement is inter- or intramolecular, though there is evidence that at least in some cases, an intermolecular mechanism can still result in a high degree of ortho migration.[581]

The *Claisen* (Reaction **18-33**) and *benzidine* (Reaction **18-36**) rearrangements, which superficially resemble those in this section, have different mechanisms and are treated in Chapter 18.

A. Groups Cleaving from Oxygen

11-27 The Fries Rearrangement



1/*C*-Hydro,5/*O*-acyl-interchange[582]

[582] This is the name for the para migration. For the ortho migration, the name is 1/*C*-hydro,3/*O*-acyl-interchange.

Phenolic esters can be rearranged by heating with *Friedel–Crafts catalyst*s in a synthetically useful reaction known as the *Fries rearrangement*.[583] Both *o*- and *p*-acylphenols can be produced, and it is often possible to select conditions so that either one predominates. The ortho/para ratio is dependent on the temperature, solvent, and amount of catalyst used. Exceptions are known, but low temperatures generally favor the para product and high temperatures favor the ortho product. The R group may be aliphatic or aromatic. Any meta-directing substituent on the ring interferes with the reactions, as might be expected for a *Friedel–Crafts* process. In the case of aryl benzoates treated with F_3CSO_2OH, the *Fries rearrangement* was shown to be reversible and an equilibrium was established.[584] Transition metal catalyzed *Fries rearrangements* have been reported.[585]

Questions remain about the exact mechanism.[586] Opinions have been expressed that it is completely intermolecular,[587] completely intramolecular,[588] and partially inter- and intramolecular.[589] One way to decide between inter- and intramolecular processes is to run the reaction of the phenolic ester in the presence of another aromatic compound, say, toluene. If some of the toluene is acylated, the reaction must be, at least in part, intermolecular. If the toluene is not acylated, the presumption is that the reaction is intramolecular, though this is not certain, for it may be that the toluene is not attacked because it is less active than the other. A number of such experiments (called *crossover experiments*) have been carried out; sometimes crossover products have been found and sometimes not. As in Reaction **11-17**, an initial complex (**68**) is formed between the substrate and the catalyst, so that a catalyst/substrate molar ratio of at least 1:1 is required. In the presence of aluminum chloride, the *Fries rearrangement* can be induced with microwave irradiation.[590] Simply heating phenyl acetate with microwave irradiation gives the *Fries rearrangement*.[591] The *Fries rearrangement* has been carried out in ionic melts.[592]

The *Fries rearrangement* can also be carried out with UV light, in the absence of a catalyst.[593] This reaction, called the *photo-Fries rearrangement*,[594] is predominantly an intramolecular free radical process. Both ortho and para migration are observed.[595] Unlike the Lewis acid catalyzed *Fries rearrangement*, the *photo-Fries reaction* can be accomplished, though often in low yields, when meta-directing groups are on the ring. The available evidence strongly suggests the following mechanism involving formation of the excited state ester followed by dissociation to a radical pair[596] for the *photo-Fries rearrangement*[597] (illustrated for para attack).

The phenol ArOH is always a side product, resulting from some ArO• that leaks from the solvent cage and abstracts a hydrogen atom from a neighboring molecule. When the reaction was performed on phenyl acetate in the gas phase, where there are no solvent molecules to form a cage (but in the presence of isobutane as a source of abstractable hydrogen atoms), phenol was the chief product and virtually no *o*- or *p*-hydroxyacetophenone was found.[598] Other evidence[599] for the mechanism is that CIDNP has been observed during the course of the reaction[600] and that the ArO• radical has been detected by flash photolysis[601] and by nanosecond time-resolved Raman spectroscopy.[602]

A LDA-mediated *anionic Fries rearrangement* of aryl carbamates has been reported.[603] The so-called *anionic Snieckus–Fries rearrangement* has also been discussed.[604]

Treatment of *O*-arylsulfonate esters with $AlCl_3$—$ZnCl_2$, on silica with microwave irradiation, leads to 2-sulfonyl phenols in a *thia-Fries rearrangement*.[605] A similar reaction was reported with *O*-arylsulfonamides.[606]

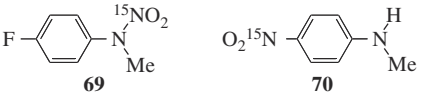
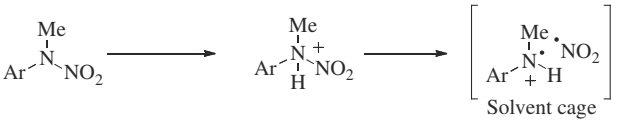
B. Groups Cleaving from Nitrogen[607]



It has been shown that $PhNH_2D$ rearranges to *o*- and *p*-deuterioaniline.[608] The migration of OH, formally similar to Reactions **11-28**–**11-32**, is a nucleophilic substitution and is treated in Chapter 13 (**13-32**).

11-28 Migration of the Nitro Group

1/ *C*-Hydro,3/*N*-nitro-interchange



N-Nitro aromatic amines rearrange on treatment with acids to *o*- and *p*-nitroamines with the ortho compounds predominating.[609] Aside from this indication of an intramolecular process, there is also the fact that virtually no meta isomer is produced in this reaction,[610] although direct nitration of an aromatic amine generally gives a fair amount of meta product. Thus a mechanism in which NO_2^+ is dissociated from the ring and then is attacked by another molecule must be ruled out. Further results indicating an intramolecular process include the observation that rearrangement of several substrates in the presence of $K^{15}NO_3$ gave products containing no ^{15}N,[611] and that rearrangement of a mixture of $PhNH^{15}NO_2$ and unlabeled *p*-$MeC_6H_4NHNO_2$ gave 2-nitro-4-methylaniline containing no ^{15}N.[612] On the other hand, rearrangement of

69 **70**

69 in the presence of unlabeled $PhNMeNO_2$ gave labeled **70**, which did not arise by displacement of F.[613] The R group may be hydrogen or alkyl. Two principal mechanisms have been suggested, one involving cyclic attack by the oxygen of the nitro group at the ortho position before the group cleaves,[614] and the other involving a cleavage into a radical and a radical ion held together in a solvent cage.[615] Among the evidence

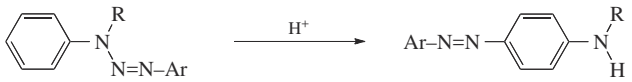
for the latter view[616] are the effects of substituents on the rate of the reaction,[617] ^{15}N and ^{14}C kinetic isotope effects that show nonconcertedness,[618] and the fact that both *N*-methylaniline and nitrous acid are produced in sizable and comparable amounts in addition to the normal products *o*- and *p*-nitro-*N*-methylaniline.[619] These side products are formed when the radicals escape from the solvent cage.

11-29 Migration of the Nitroso Group: The Fischer–Hepp Rearrangement

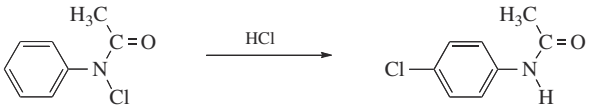


1/ *C*-Hydro-5/*N*-nitroso-interchange

The migration of a nitroso group, formally similar to Reaction **11-28**, is important because *p*-nitroso secondary aromatic amines cannot generally be prepared by direct *C*-nitrosation of secondary aromatic amines (see Reaction **12-50**). The reaction, known as the *Fischer–Hepp rearrangement*,[620] is brought about by treatment of *N*-nitroso secondary aromatic amines with HCl. Other acids give poor or no results. In benzene systems, the para product is usually formed exclusively.[621] The mechanism of the rearrangement is not completely understood. The fact that the reaction takes place in a large excess of urea[622] shows that it is intramolecular[623] since, if NO^+, NOCl, or some similar species were free in the solution, it would be captured by the urea, preventing the rearrangement.

11-30 Migration of an Arylazo Group

1/*C*-Hydro-5/ *N*-arylazo-interchange



Rearrangement of aryl triazenes can be used to prepare azo derivatives of primary and secondary aromatic amines.[624] These are first diazotized at the amino group (see Reaction **11-4**) to give triazenes, which are then rearranged by treatment with acid. The rearrangement always gives the para isomer, unless that position is occupied.

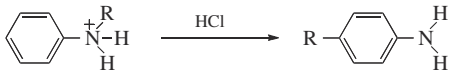
11-31 Migration of Halogen: The Orton Rearrangement



1/*C*-Hydro-5/*N*-halo-interchange

Migration of a halogen from a nitrogen side chain to the ring by treatment with HCl is called the *Orton rearrangement*.[625] The main product is the para isomer, though some ortho product may also be formed. The reaction has been carried out with *N*-chloro- and *N*-bromoamines and less often with *N*-iodo compounds. The amine must be acylated, except that $PhNCl_2$ gives 2,4-dichloroaniline. The reaction is usually performed in water or acetic acid. There is considerable evidence (cross-halogenation, labeling, etc.) that this is an intermolecular process.[626] First, the HCl reacts with the starting material to give $ArNHCOCH_3$ and Cl_2; then the chlorine halogenates the ring as in Reaction **11-10**. Among the evidence is that chlorine has been isolated from the reaction mixture. The *Orton rearrangement* can also be brought about photochemically[627] and by heating in the presence of benzoyl peroxide.[628] These are free radical processes.

11-32 Migration of an Alkyl Group[629]

1/*C*-Hydro-5/*N*-alkyl-interchange

When HCl salts of arylalkylamines are heated at ~200–00 °C, migration occurs in what is called the *Hofmann–Martius reaction*. It is an intermolecular reaction, since crossing is found. For example, methylanilinium bromide gave not only the normal products *o*- and *p*-toluidine, but also aniline and di- and trimethylanilines.[630] As would be expected for an intermolecular process, there is isomerization when R is primary.

With primary R, the reaction probably goes through the alkyl halide formed initially in an S_N2 reaction:

$$R\overset{+}{N}H_2Ar + Cl^- \longrightarrow RCl + ArNH_2$$

Evidence for this view is that alkyl halides have been isolated from the reaction mixture and that Br^-, Cl^-, and I^- gave different ortho/para ratios, which indicates that the halogen is involved in the reaction.[630] Further evidence is that the alkyl halides isolated are not rearranged (as would be expected if they are formed by an S_N2 mechanism), even though the alkyl groups in the ring are rearranged. Once the alkyl halide is formed, it reacts with the substrate by a normal *Friedel–Crafts alkylation* process (Reaction **11-11**), accounting

[630] Ogata, Y.; Tabuchi, H.; Yoshida, K. *Tetrahedron* ***1964,*** *20,* 2717.

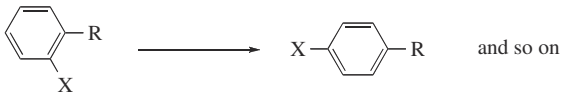
for the rearrangement. When R is secondary or tertiary, carbocations may be directly formed so that the reaction does not go through the alkyl halides.[631]

It is also possible to carry out the reaction by heating the amine (not the salt) at a temperature between 200 and 350 °C with a metal halide (e.g., $CoCl_2$, $CdCl_2$, or $ZnCl_2$). When this is done, the reaction is called the *Reilly–Hickinbottom rearrangement*. Primary R groups larger than ethyl give both rearranged and unrearranged products.[632] The reaction is not generally useful for secondary and tertiary R groups, which are usually cleaved to alkenes under these conditions.

When acylated arylamines are photolyzed, migration of an acyl group takes place[633] in a process that resembles the photo-Fries reaction (**11-27**).

11.F.iii. Other Leaving Groups

Three types of reactions are considered in this section.



1. Reactions in which hydrogen replaces another leaving group:

$$ArX + H^+ \longrightarrow ArH$$

2. Reactions in which an electrophile other than hydrogen replaces another leaving group:

$$ArX + Y^+ \longrightarrow ArY$$

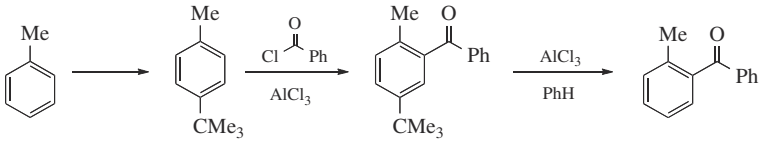
3. Reactions in which a group (other than hydrogen) migrates from one position in a ring to another. Such migrations can be either inter- or intramolecular:

The three types are not treated separately, but reactions are classified by leaving group.

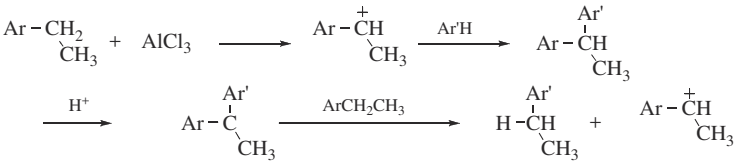
A. Carbon Leaving Groups

11-3 Reversal of Friedel–Crafts Alkylation

Hydro-de-alkylation or **Dealkylation**



$$ArR + H^+ \xrightarrow{AlCl_3} ArH$$



Alkyl groups can be cleaved from aromatic rings by treatment with proton and/or Lewis acids. Tertiary R groups are the most easily cleaved; because this is true, the *tert*-butyl group is occasionally introduced into a ring, used to direct another group, and then removed.[634] For example, 4-*tert*-butyltoluene (**71**) reacted with benzoyl chloride and $AlCl_3$ to give the acylated product, and subsequent treatment with $AlCl_3$ led to loss of the *tert*-butyl group to give **72**.[635]

Secondary R groups are harder to cleave, and primary R harder still. Because of this reaction, care must be taken when using *Friedel–Crafts catalysts* (Lewis or proton acids)

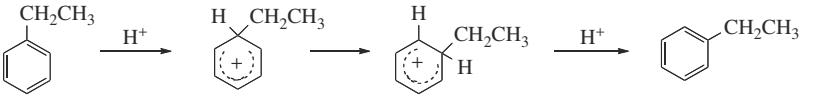
on aromatic compounds containing alkyl groups. True cleavage, in which the R becomes an alkene, occurs only at high temperatures, >400 °C.[636] At ordinary temperatures, the R group attacks another ring, so that the bulk of the product may be dealkylated, but there is a residue of heavily alkylated material. The isomerization reaction, in which a group migrates from one position in a ring to another or to a different ring, is therefore more important than true cleavage. In these reactions, the meta isomer is generally the most favored product among the dialkylbenzenes; and the 1,3,5-product the most favored among the trialkylbenzenes, because they have the highest thermodynamic stabilities. Alkyl migrations can be inter- or intramolecular, depending on the conditions and on the R group. The following experiments can be cited: Ethylbenzene treated with HF and BF_3 gave, almost completely, benzene and diethylbenzenes[637] (entirely intermolecular); propylbenzene labeled in the β position gave benzene, propylbenzene, and di- and tripropylbenzenes, but the propylbenzene recovered was partly labeled in the α position and not at all in the γ position[638] (both intra- and intermolecular); *o*-xylene treated with HBr and $AlBr_3$ gave a mixture of *o*- and *m*- but no *p*-xylene, while *p*-xylene gave *p*- and *m*- but no *o*-xylene, and no trimethyl compounds could be isolated in these experiments[639] (exclusively intramolecular rearrangement). Apparently, methyl groups migrate only intramolecularly, while other groups may follow either path.[640]



The mechanism[641] of intermolecular rearrangement can involve free alkyl cations, but there is much evidence to show that this is not necessarily the case. For example, many of them occur without rearrangement within the alkyl group. The following mechanism has been proposed for intermolecular rearrangement without the involvement of carbocations that are separated from the ring.[642]

Evidence for this mechanism is that optically active $PhCHDCH_3$ labeled in the ring with ^{14}C and treated with $GaBr_3$ in the presence of benzene gave ethylbenzene containing no deuterium and two deuterium atoms and that the rate of loss of radioactivity was about equal

to the rate of loss of optical activity.[642] The mechanism of intramolecular rearrangement is not very clear. 1,2 shifts of this kind have been proposed:[643]

There is evidence from ^{14}C labeling that intramolecular migration occurs only through 1,2-shifts.[644] Any 1,3- or 1,4-migration takes place by a series of two or more 1,2-shifts.

Phenyl groups have also been found to migrate. Thus *o*-terphenyl, heated with $AlCl_3—H_2O$, gave a mixture containing 7% *o*-, 70% *m*-, and 23% *p*-terphenyl.[645] Alkyl groups have also been replaced by groups other than hydrogen (nitro groups).

Unlike alkylation, *Friedel–Crafts acylation* has been generally considered to be irreversible, but a number of instances of electrofugal acyl groups have been reported,[646] especially where there are two ortho substituents (e.g., the hydro-de-benzoylation of **73**).[647]

11-34 Decarbonylation of Aromatic Aldehydes

Hydro-de-formylation or **Deformylation**

$$ArCHO \xrightarrow{H_2SO_4} ArH + CO$$

The decarbonylation of aromatic aldehydes with sulfuric acid[648] is the reverse of the *Gatterman–Koch reaction* (**11-18**). It has been carried out with trialkyl- and trialkoxybenzaldehydes. The reaction takes place by the ordinary arenium ion mechanism: The attacking species is H^+ and the leaving group is HCO^+, which can lose a proton to give CO or combine with OH^- from the water solvent to give formic acid.[649] Aromatic aldehydes

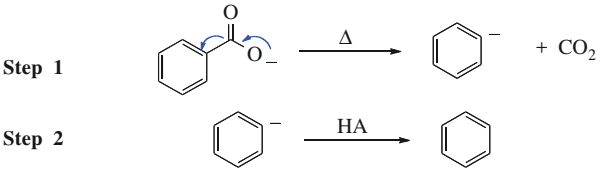
have also been decarbonylated with basic catalysts.[650] When basic catalysts are used, the mechanism is probably similar to the S_E1 process of Reaction **11-35** (see also, Reaction **14-32**).

11-35 Decarboxylation of Aromatic Acids



Hydro-de-carboxylation or **Decarboxylation**

$$\mathrm{ArCOOH} \xrightarrow[\text{quinoline}]{\text{Cu}} \mathrm{ArH} + \mathrm{CO_2}$$

The decarboxylation of aromatic acids is most often carried out by heating with copper and quinoline. However, two other methods can be used with certain substrates. In one method, the salt of the acid ($\mathrm{ArCOO^-}$) is heated, and in the other the carboxylic acid is heated with a strong acid, often sulfuric. The latter method is accelerated by the presence of electron-donating groups in ortho and para positions and by the steric effect of groups in the ortho positions; in benzene systems it is generally limited to substrates that contain such groups. In this method, decarboxylation takes place by the arenium ion mechanism,[651] with H^+ as the electrophile and CO_2 as the leaving group.[652] Evidently, the order of electrofugal ability is $CO_2 > H^+ > COOH^+$, so that it is necessary, at least in most cases, for the COOH to lose a proton before it can cleave.

When carboxylate *ions* are decarboxylated, the mechanism is entirely different, being of the S_E1 type. Evidence for this mechanism is that the reaction is first order and that electron-withdrawing groups, which would stabilize a carbanion, facilitate the reaction.[653]

Despite its synthetic importance, the mechanism of the copper–quinoline method has been studied very little, but it has been shown that the actual catalyst is cuprous ion.[654] In fact, the reaction proceeds much faster if the acid is heated in quinoline with cuprous oxide instead of copper, provided that atmospheric oxygen is rigorously excluded. A mechanism has been suggested in which it is the cuprous salt of the acid that actually undergoes the decarboxylation.[654] It has been shown that cuprous salts of aromatic acids

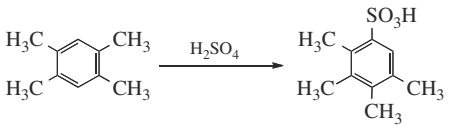
are easily decarboxylated by heating in quinoline[655] and that arylcopper compounds are intermediates that can be isolated in some cases.[656] Metallic silver has been used in place of copper, with higher yields.[657] Silver acetate has also been used to promote decarboxylation.[658] A photolytic decarboxylation also has been reported, under a dioxygen atmosphere in the presence of HgF_2.[659]

In certain cases, the carboxyl group can be replaced by electrophiles other than hydrogen (e.g., NO,[657] I,[660] Br,[661] or Hg).[662] Although closely related to reactions in Chapter 13 (Reactions **13-9**, **13-11**, and **13-12**), a decarboxylative coupling reaction of aryl halides and arylcarboxylic acids has been reported, using Pd and Cu catalysts, to give the corresponding biaryl.[663]

Rearrangements are also known to take place. For example, when the phthalate ion is heated with a catalytic amount of cadmium, the terphthalate ion (**74**) is produced:[664]



Phthalate ion **74**

In a similar process, potassium benzoate heated with Cd salts disproportionates to benzene and **74**. The term *Henkel reaction* (named for the company that patented the process) is used for these rearrangements.[665] An S_E1 mechanism has been suggested.[666] The terphthalate is the main product because it crystallizes from the reaction mixture, driving the equilibrium in that direction.[667]

For aliphatic decarboxylation, see Reaction **12-40**.

11-36 The Jacobsen Reaction

When polyalkyl- or polyhalobenzenes are treated with sulfuric acid, the ring is sulfonated, but rearrangement also takes place. The reaction, known as the *Jacobsen reaction*, is limited to benzene rings that have at least four substituents, which can be

any combination of alkyl and halogen groups, where the alkyl groups can be ethyl or methyl and the halogen iodo, chloro, or bromo. When isopropyl or *tert*-butyl groups are on the ring, these groups are cleaved to give alkenes. Since a sulfo group can later be removed (Reaction **11-38**), the Jacobsen reaction can be used as a means of rearranging polyalkylbenzenes. The rearrangement always brings the alkyl or halo groups closer together than they were originally. Side products in the case illustrated above are pentamethylbenzenesulfonic acid, 2,4,5-trimethylbenzenesulfonic acid, and so on, indicating an intermolecular process, at least partially.

The mechanism of the *Jacobsen reaction* is not established,[668] but there is evidence, at least for polymethylbenzenes, that the rearrangement is intermolecular, and that the species to which the methyl group migrates is a polymethylbenzene, not a sulfonic acid. Sulfonation takes place after the migration.[669] It has been shown by labeling that ethyl groups migrate without internal rearrangement.[670]

Isomerization of alkyl groups in substituted biphenyls has been observed[671] when the medium is a superacid (see Sec. 5.A.ii).

B. Oxygen Leaving Groups

11-37 Deoxygenation

$$\mathrm{ArOR} \longrightarrow \mathrm{ArH}$$

In a few cases, it is possible to remove an oxygen substituent directly from the aromatic ring. Treatment of an aryl mesylate (ArOMs) with a Ni catalyst in DMF, for example, leads to the deoxygenated product, Ar-H.[672]

C. Sulfur Leaving Groups

11-38 Desulfonation or Hydro-de-sulfonation

$$\mathrm{ArSO_3H} \xrightarrow[\text{dil. } \mathrm{H_2SO_4}]{135-200^\circ\mathrm{C}} \mathrm{ArH} + \mathrm{H_2SO_4}$$

The cleavage of sulfo groups from aromatic rings is the reverse of Reaction **11-7**.[673] By the principle of microscopic reversibility, the mechanism is also the reverse.[674] Dilution is generally used, as the reversibility of sulfonation decreases with increasing H_2SO_4 concentration. The reaction permits the sulfo group to be used as a blocking group to direct meta and then to be removed. The sulfo group has also been replaced by nitro and halogen groups. Sulfo groups have also been removed from the ring by heating with an alkaline solution of Raney nickel.[675] In another catalytic process, aromatic

sulfonyl bromides or chlorides are converted to aryl bromides or chlorides, respectively, on heating with an Rh catalyst.[676] This reaction is similar to the decarbonylation of aromatic acyl halides mentioned in Reaction **14-32**.

$$ArSO_2Br \xrightarrow{RhCl(PPh_3)_3} ArBr$$

OS **I**, 388; **II**, 97; **III**, 262; **IV**, 364. Also see, OS **I**, 519; **II**, 128; **V**, 1070.

D. Halogen Leaving groups

11-39 Dehalogenation or Hydro-de-halogenation

$$ArX \xrightarrow{AlCl_3} ArH$$

Aryl halides can be dehalogenated by *Friedel–Crafts catalysts*. Iodine is the most easily cleaved. Dechlorination is seldom performed and defluorination apparently never. The reaction is most successful when a reducing agent, say, Br^- or I^- is present to combine with the I^+ or Br^+ coming off.[677] Except for deiodination, the reaction is seldom used for preparative purposes. Migration of halogen is also found,[678] both intramolecular[679] and intermolecular.[680] The mechanism is probably the reverse of that of Reaction **11-10**.[681] Debromination of aromatic rings having two attached amino groups was accomplished by refluxing in aniline containing acetic acid/HBr.[682]

Rearrangement of polyhalobenzenes can also be catalyzed by very strong bases (e.g., 1,2,4-tribromobenzene) is converted to 1,3,5-tribromobenzene by treatment with PhNHK.[683] This reaction, which involves aryl carbanion intermediates (S_E1 mechanism), has been called the *halogen dance*.[684]

Removal of halogen from aromatic rings can also be accomplished by various reducing agents, among them Bu_3SnH,[685] catalytic-hydrogenolysis,[686] catalytic-transfer hydrogenolysis,[687] Na—Hg in liquid NH_3,[688] $LiAlH_4$,[689] $NaBH_4$ and a catalyst,[690] NaH,[691] HCO_2H[692] or

aq HCO_2^-[693] with Pd/C,[694] ammonium formate in aq isopropyl alcohol with a Pd catalyst,[695] and Raney nickel in alkaline solution,[696] the last method being effective for fluorine as well as for the other halogens. Aryl iodides are reduced with DMAP methiodide salt.[697] Carbon monoxide, with potassium tetracarbonylhydridoferrate [$KHFe(CO)_4$] as a catalyst, specifically reduces aryl iodides.[698] Not all of these reagents operate by electrophilic substitution mechanisms. Some are nucleophilic substitutions and some are free radical processes. Photochemical[699] and electrochemical[700] reduction are also known. Halogen can also be removed from aromatic rings indirectly by conversion to *Grignard reagents* (Reaction **12-38**) followed by hydrolysis (Reaction **11-41**).

OS **III**, 132, 475, 519; **V**, 149, 346, 998; **VI**, 82, 821.

11-40 Formation of Organometallic Compounds

$$\mathrm{ArBr + M \longrightarrow ArM}$$
$$\mathrm{ArBr + RM \longrightarrow ArM + RBr}$$

These reactions are considered along with their aliphatic counterparts at Reactions **12-38** and **12-39**.

E. Metal Leaving Groups

11-41 Hydrolysis of Organometallic Compounds

Hydro-de-metalation or **Demetalation**

$$\mathrm{ArM + H^+ \longrightarrow ArH + M^+}$$

Organometallic compounds can be hydrolyzed by acid treatment. For active metals (e.g., Mg, Li, etc.), water is sufficiently acidic. The most important example of this reaction is hydrolysis of *Grignard reagents*, but M may be many other metals or metalloids. Examples are SiR_3, HgR, Na, and $B(OH)_2$. Since aryl *Grignard* and aryllithium compounds are fairly easy to prepare, they are often used to prepare salts of weak acids (e.g., alkynes).

$$\mathrm{PhMgBr + H{-}C{\equiv}C{-}H \longrightarrow H{-}C{\equiv}C{:}^{-}{}^{+}MgBr + PhH}$$

Where the bond between the metal and the ring is covalent, the usual arenium ion mechanism operates.[701] Where the bonding is essentially ionic, this is a simple acid–base reaction. For the aliphatic counterpart of this reaction, see Reaction **12-24**.

Other reactions of aryl organometallic compounds are treated with their aliphatic analogues: Reactions **12-25**–**12-27** and **12-30**–**12-37**.

CHAPTER 12

Aliphatic, Alkenyl, and Alkynyl Substitution, Electrophilic and Organometallic

Chapter 11 pointed out that the most important leaving groups in electrophilic substitution are those that can best exist with an outer shell that is deficient in a pair of electrons. For aromatic systems, the most common leaving group is the proton. The proton is also a leaving group in aliphatic systems, but the reactivity depends on the acidity. Protons in saturated alkanes are very unreactive, but electrophilic substitutions are often easily carried out at more acidic positions [e.g., α to a carbonyl group or at an alkynyl position (RC≡CH)]. Since metallic ions are easily able to bear positive charges, organometallic compounds should be especially susceptible to electrophilic substitution, and this is indeed the case.[1] Another important type of electrophilic substitution, known as *anionic cleavage*, involves the breaking of C—C bonds; in these reactions there are carbon leaving groups (Reactions **12-40–12-46**). A number of electrophilic substitutions at a nitrogen atom are treated at the end of the chapter.

Since a carbanion is generated when an atom or group is removed as a positive species from a carbon atom, the subject of carbanion structure and stability (Chapter 5) is inevitably related to the material in this chapter. So is the subject of very weak acids and very strong bases (Chapter 8), because the weakest acids are those in which the hydrogen is bonded to carbon.

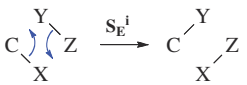
12.A. MECHANISMS

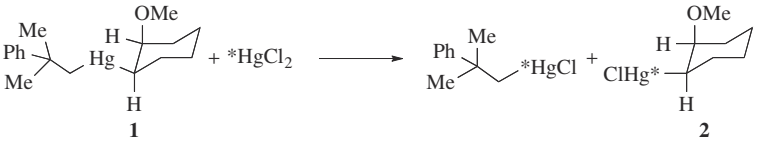


For aliphatic electrophilic substitution, at least four possible major mechanisms can be distinguished:[2] S_E1, S_E2 (front), S_E2 (back), and S_Ei. The S_E1 is unimolecular; the other three are bimolecular. Note that the term "S_EAr" has been proposed to represent electrophilic aromatic substitution, so that the term "S_E2" refers exclusively to electrophilic substitutions where a steric course is possible.[3] To describe the steric course of an aliphatic substitution reaction, the suffixes "ret" and "inv" were proposed, referring to retention and inversion of configuration, respectively.

12.A.i. Bimolecular Mechanisms: S_E2 and S_Ei

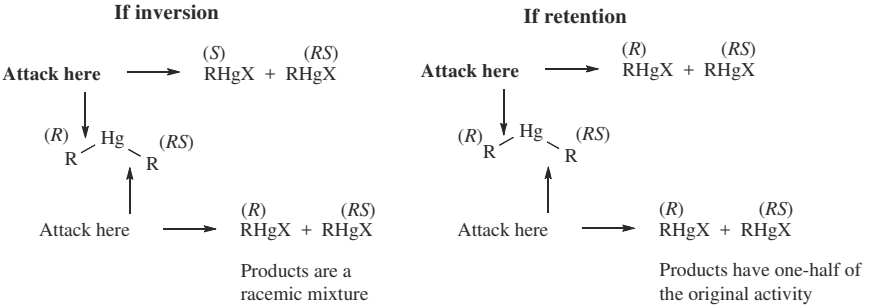
The bimolecular mechanisms for electrophilic aliphatic substitution are analogous to the S_N2 mechanism in that the new bond forms as the old one breaks. However, in the S_N2 mechanism the incoming group brings with it a pair of electrons, and this orbital can overlap with the central carbon only to the extent that the leaving group takes away its electrons; otherwise the carbon would have more than eight electrons at once in its outer shell. Since electron clouds repel, this also means that the incoming group attacks backside, at a position 180° from the leaving group, resulting in inversion of configuration. When the nucleophilic species attacks (donates electrons to) an electrophile, it brings only a vacant orbital to the substrate. Predicting the direction of the attack is not as straightforward. Two main possibilities can be imagined: delivery of the electrophile to the front, which is S_E2 (front), or delivery of the electrophile to the rear, which is S_E2 (back). The possibilities can be pictured (charges not shown):

Both the S_E2 (front) and S_E2 (back) mechanisms are designated D_EA_E in the IUPAC system. With substrates in which these possibilities may be distinguished, the former mechanism should result in retention of configuration and the latter results in inversion. The reaction of allylsilanes with adamantyl chloride and $TiCl_4$, for example, gives primarily the antiproduct via a S_E2' reaction.[4] When the electrophile reacts from the front, there is a third possibility. A portion of the electrophile may assist in the removal of the leaving group, forming a bond with it at the same time that the new C—Y bond is formed:



[2] See Abraham, M.H. *Comprehensive Chemical Kinetics*, Bamford, C.H.; Tipper, C.F.H. Eds., Vol. 12, Elsevier, NY, ***1973***; Reutov, O.A.; Beletskaya, I.P. *Reaction Mechanisms of Organometallic Compounds*, North-Holland Publishing Company, Amsterdam, The Netherlands, ***1968***; Abraham, M.H.; Grellier, P.L. in Hartley, F.R.; Patai, S. *The Chemistry of the Metal–Carbon Bond*, Vol. 2, Wiley, NY, pp. 25–149; Reutov, O.A. *Pure Appl. Chem.* ***1978***, *50*, 717; *Tetrahedron* ***1978***, *34*, 2827.

[3] Gawley, R.E. *Tetrahedron Lett.* ***1999***, *40,* 4297.



[4] Buckle, M.J.C.; Fleming, I.; Gil, S. *Tetrahedron Lett.* ***1992***, *33*, 4479.

This mechanism, which is called the S_Ei mechanism[5] (IUPAC designation: *cyclo*-$D_EA_ED_nA_n$), also results in retention of configuration.[6] Plainly, where a second-order mechanism involves this kind of internal assistance, backside attack is impossible.

1 **2**

It is evident that these three mechanisms are not easy to distinguish. All three mechanisms give second-order kinetics, and two mechanisms result in retention of configuration.[7] In fact, although much work has been done on this question, there are few cases in which one of these three can be unequivocally established to demonstrate that another is not actually taking place. Clearly, a study of the stereochemistry can distinguish between S_E2 (back) on the one hand and S_E2 (front) or S_Ei on the other. Many such investigations have been made. In the overwhelming majority of second-order electrophilic substitutions, the result has been retention of configuration or some other indication of frontside attack, indicating an S_E2 (front) or S_Ei mechanism. For example, when *cis*-**1** was treated with labeled mercuric chloride, the **2** produced was 100% cis. The bond between the mercury and the ring must have been broken (as well as the other Hg—C bond), since each of the products contained about one-half of the labeled mercury.[8] Another indication of frontside attack is that second-order electrophilic substitutions proceed very easily at *bridgehead* carbons (see Sec. 10.A.i).[9] Still another indication is the behavior of neopentyl as a substrate. The S_N2 reactions at neopentyl are extremely slow (Sec. 10.G.i), because attack from the rear is blocked and the transition state for the reaction lies very high in energy. The fact that neopentyl systems undergo electrophilic substitution only slightly more slowly than ethyl[10] is further evidence for frontside attack. One final elegant experiment may be noted.

[5] The names for these mechanisms vary throughout the literature. For example, the S_Ei mechanism has also been called the S_E2, the S_E2 (closed), and the S_E2 (cyclic) mechanism. The original designations, S_E1, S_E2, and so on, were devised by the Hughes–Ingold school.

[6] It has been contended that the S_Ei mechanism violates the principle of conservation of orbital symmetry (sec Reaction **15-60, A**), and that the S_E2 (back) mechanism partially violates it: Slack, D.A.; Baird, M.C. *J. Am. Chem. Soc.* ***1976****, 98,* 5539.

[10] Hughes, E.D.; Volger, H.C. *J. Chem. Soc.* ***1961***, 2359.

The compound di-*sec*-butylmercury was prepared with one *sec*-butyl group optically active and the other racemic.[11] This compound was prepared by treatment of optically active *sec*-butylmercuric bromide with racemic *sec*-butylmagnesium bromide. The di-*sec*-butyl compound was then treated with mercuric bromide to give 2 molar equivalents of *sec*-butylmercuric bromide. The steric course of the reaction could then be predicted by the following analysis, assuming that the bonds between the mercury and each carbon have a 50% chance of breaking. The original activity referred to is the activity of the optically active *sec*-butylmercuric bromide used to make the dialkyl compound. The actual result was that, under several different sets of conditions, the product had one-half of the original activity, demonstrating retention of configuration.

However, inversion of configuration has been found in certain cases, demonstrating that the S_E2 (back) mechanism can take place. For example, the reaction of optically active *sec*-butyltrineopentyltin with bromine (Reaction **12-40**) gives inverted *sec*-butyl bromide.[12] A number of other organometallic compounds have also been shown to give inversion when treated with halogens,[13] although others do not.[14] So far, no inversion has been found with an organomercury substrate. It may be that still other examples of backside

$$\textit{sec}\text{-BuSnR}_3 + \text{Br}_2 \longrightarrow \textit{sec}\text{-BuBr} \qquad \text{R} = \text{Neopentyl}$$

attack exist[15] but have escaped detection because of the difficulty in preparing compounds with a configurationally stable carbon–metal bond. Compounds that are chiral because of a stereogenic carbon at which a carbon–metal bond is located[16] are often difficult to resolve and once resolved are often easily racemized. The resolution has been accomplished most often with organomercury compounds,[17] and most stereochemical investigations have therefore been made with these substrates. Only a few optically active *Grignard reagents* (see Sec. **12-38**) have been prepared[18] (i.e., in which the only stereogenic center is the

[18] This was done first by Walborsky, H.M.; Young, A.E. *J. Am. Chem. Soc.* ***1964****, 86*, 3288.

carbon bonded to the magnesium). Because of this, the steric course of electrophilic substitutions at the C—Mg bond has not often been determined. However, in one such case, the reaction of both the exo and endo isomers of the 2-norbornyl *Grignard reagent* with $HgBr_2$ (to give 2-norbornylmercuric bromide) has been shown to proceed with retention of configuration.[19] It is likely that inversion takes place only when steric hindrance prevents reaction on the frontside and when the electrophile does not carry a Z group (see above).

The S_E2 (back) mechanism can be identified in certain cases (if inversion of configuration is found), but it is plain that stereochemical investigations cannot distinguish between the S_E2 (front) and the S_Ei mechanisms and that, in the many cases where configurationally stable substrates cannot be prepared, such investigations are of no help at all in distinguishing among all three of the second-order mechanisms. Unfortunately, there are not many other methods that lead to unequivocal conclusions. One method that has been used in an attempt to distinguish between the S_Ei mechanism on the one hand and the S_E2 pathways on the other, involves the study of salt effects on the rate. It may be recalled (Sec. 10.G.iv) that reactions in which neutral starting molecules acquire charges in the transition state are aided by an increasing concentration of added ions. Thus the S_Ei mechanism would be less influenced by salt effects than would either of the S_E2 mechanisms. On this basis, Abraham and Johnson[20] concluded that the reactions $R_4Sn + HgX_2 \rightarrow RHgX + R_3SnX$ (X = Cl or I) take place by S_E2 and not by S_Ei mechanisms. Similar investigations involve changes in solvent polarity[21] (see also, Sec. 12.C.i). In the case of the reaction (where R = R′ = *i*Pr and R = *i*Pr, R′ = neopentyl), the use of polar solvents gave predominant inversion, while nonpolar solvents gave predominant retention.[22]

$$\textit{sec}\text{-BuSnR}_2\text{R}' + \text{Br}_2 \longrightarrow \textit{sec}\text{-BuBr}$$

On the basis of evidence from reactivity studies, it has been suggested[23] that a variation of the S_Ei mechanism is possible in which the group Z becomes attached to X before the latter becomes detached:

This process has been called the S_EC[22] or S_E2 (co-ord)[24] mechanism (IUPAC designation $A_n + \textit{cyclo}\text{-}D_EA_ED_n$).

It has been shown that in certain cases (e.g., $Me_4Sn + I_2$) the reactants in an S_E2 reaction, when mixed, give rise to an immediate charge-transfer spectrum (Sec. 3.C.i), showing that an EDA complex has been formed.[25] In these cases, it is likely that the EDA complex is an intermediate in the reaction.

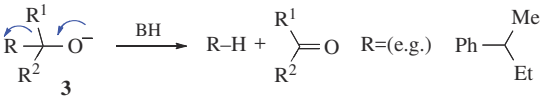
12.A.ii. The S_E1 Mechanism

The S_E1 mechanism is analogous to the S_N1. It involves two steps: A slow ionization and a fast combination.

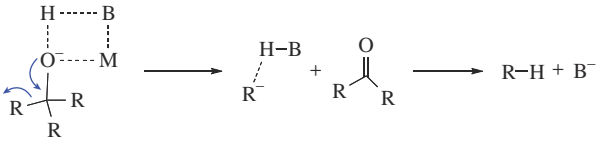
Step 1 $R{-}X \xrightarrow{\text{slow}} R^- + X^+$



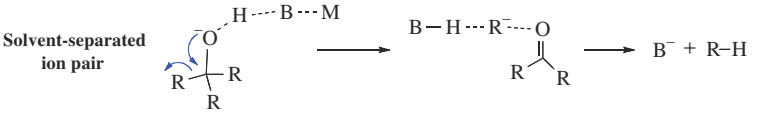
Step 2 $R^- + Y^+ \longrightarrow R{-}Y$

The IUPAC designation is $D_E + A_E$. First-order kinetics are predicted and many such examples have been found. Other evidence for the S_E1 mechanism was obtained in a study of base-catalyzed tautomerization. In the reaction, the rate of deuterium exchange was the same as the rate of racemization[26] and there was an isotope effect.[27]

It is known that S_N1 reactions do not proceed at strained bridgehead carbons (e.g., in [2.2.1]bicyclic systems, Sec. 10.A.ii) because planar carbocations cannot form at these carbons. However, carbanions not stabilized by resonance are probably not planar, and S_E1 reactions readily occur with this type of substrate. Indeed, the question of carbanion structure is intimately tied into the problem of the stereochemistry of the S_E1 reaction. If a carbanion is planar, racemization should occur. If it is pyramidal and *can hold its structure*, the result should be retention of configuration, or at least partial retention. On the other hand, even a pyramidal carbanion will give racemization if it cannot hold its structure (this means that there is pyramidal inversion as with amines, Sec. 4.C, category 3). Unfortunately, the only carbanions that can be studied easily are those stabilized by resonance, which makes them planar, as expected (Sec. 5.B.i). For simple alkyl carbanions, the main approach to deduce the structure has been to study the stereochemistry of S_E1 reactions rather than the other way around. Racemization is almost always observed, but whether this is caused by planar carbanions or by oscillating pyramidal carbanions is not known. In either case, racemization occurs whenever a carbanion is completely free or is symmetrically solvated.

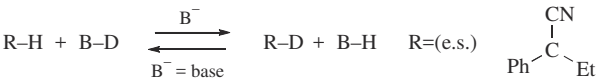


However, even planar carbanions need not give racemization. Cram found that retention and even inversion can occur in an alkoxide (see **3**) cleavage Reaction (**12-41**):

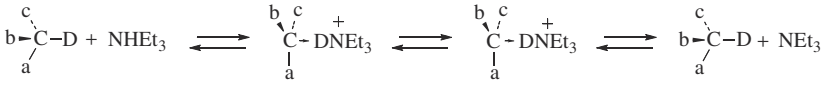


which is a first-order S_E1 reaction involving resonance-stabilized planar carbanions (here designated R^-).[28] By changing the solvent, Cram was able to produce products ranging from 99% retention to 60% inversion and including complete racemization. These results are explained by a carbanion that is not completely free, but is solvated. In nondissociating,

[26] Hsu, S.K.; Ingold, C.K.; Wilson, C.L. *J. Chem. Soc.* ***1938***, 78.
[27] Wilson, C.L. *J. Chem. Soc.* ***1936***, 1550.
[28] See Hoffman, T.D.; Cram, D.J. *J. Am. Chem. Soc.* ***1969****, 91*, 1009. For a discussion, see Cram, D.J. *Fundamentals of Carbanion Chemistry*, Academic Press, NY, ***1965***, pp. 138–158.

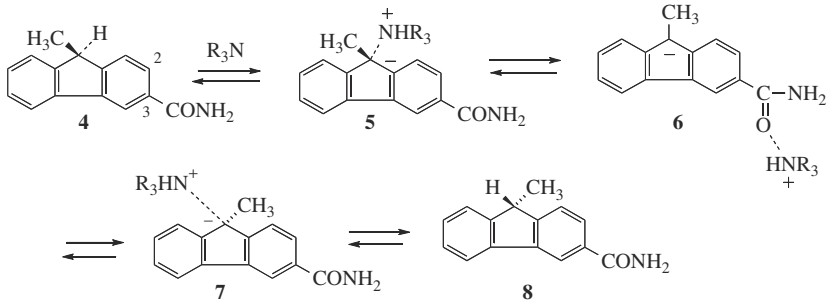


nonpolar solvents (e.g., benzene or dioxane), the alkoxide ion exists as an ion pair, solvated by the solvent BH:

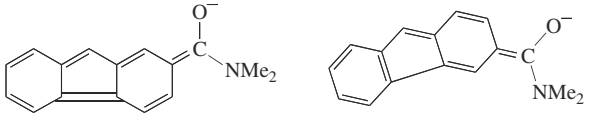


In the course of the cleavage, the proton of the solvent moves in to solvate the newly forming carbanion. This solvation is asymmetrical since the solvent molecule is already on the front side of the carbanion. When the carbanion actually bonds with the proton, the result is retention of the original configuration. In protic solvents (e.g., diethylene glycol), a good deal of inversion is found. In these solvents, the *leaving group* solvates the carbanion, so the solvent can solvate it only from the opposite side:

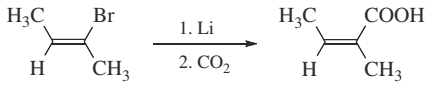
When C—H bond formation occurs, the result is inversion. Racemization occurs in polar aprotic solvents (e.g., DMSO). In these solvents, the carbanions are relatively long lived (because the solvent has no proton to donate) and is solvated symmetrically.



Similar behavior was found for carbanions generated by base-catalyzed hydrogen-exchange (Reaction **12-1**).[29] In this case, information was obtained from measurement of the ratio of k_e (rate constant for isotopic exchange) to k_a (rate constant for racemization). A $k_e k_a$ ratio substantially >1 means retention of configuration, since many individual isotopic exchanges are not producing a change in configuration. A $k_e k_a$ ratio of ~ 1 indicates racemization and a ratio of $\frac{1}{2}$ corresponds to inversion (see Sec. 10.A.i). All three types of steric behavior were found, depending on R, the base, and the solvent. As with the alkoxide cleavage reaction, retention was generally found in solvents of low dielectric constant, racemization in polar aprotic solvents, and inversion in protic solvents. However, in the proton-exchange reactions, a fourth type of behavior was encountered. In aprotic solvents, with aprotic bases like tertiary amines, the k_e/k_a ratio was found to be <0.5, indicating that racemization took place *faster* than isotopic exchange (this process is known as *isoracemization*). Under these conditions, the conjugate acid of the amine remains associated with the carbanion as an ion pair. Occasionally, the ion pair dissociates long enough for the carbanion to turn over and recapture the proton:



[29] See Roitman, J.N.; Cram, D.J. *J. Am. Chem. Soc.* ***1971****, 93*, 2225, 2231 and references cited therein; Cram, J.M.; Cram, D.J. *Intra-Sci. Chem. Rep.* ***1973****, 7(3)*, 1; Cram, D.J. *Fundamentals of Carbanion Chemistry*, Academic Press, NY, ***1965***, pp. 85–105.



Thus, inversion (and hence racemization, which is produced by repeated acts of inversion) occurs without exchange. A single act of inversion without exchange is called *isoinversion*.

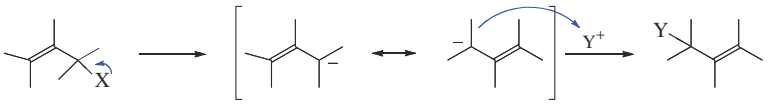
The isoinversion process can take place by a pathway in which a positive species migrates in a stepwise fashion around a molecule from one nucleophilic position to another. For example, in the exchange reaction of 3-carboxamido-9-methylfluorene (**4**) with Pr_3N in *t*-BuOH, it has been proposed that the amine removes a proton from the 9 position of **4** and conducts the proton out to the C=O oxygen (**6**), around the molecule, and back to C-9 on the opposite face of the anion. Collapse of **7** gives the inverted product **8**. Of course, **6** could also go back to **4**, but a molecule that undergoes the total process **4** → **5** → **6** → **7** → **8** has experienced an inversion without an exchange. Evidence for this pathway, called the *conducted tour mechanism*,[30] is that the 12-carboxamido isomer of **4** does not give isoracemization. In this case, the negative charge on the oxygen atom in the anion corresponding to **6** is less, because a canonical form in which oxygen acquires a full negative charge (**9**) results in disruption of the aromatic sextet in both benzene rings (cf. **10** where one benzene ring is intact). Whether the isoracemization process takes place by the conducted tour mechanism or a simple nonstructured contact ion–pair mechanism depends on the nature of the substrate (e.g., a proper functional group is necessary for the conducted tour mechanism) and of the base.[31]

It is known that vinylic carbanions *can* maintain configuration, so that S_E1 mechanisms should produce retention, which is the case. For example, *trans*-2-bromo-2-butene was converted to 64–74% angelic acid:[32]

[30] Cram, D.J.; Ford, W.T.; Gosser, L. *J. Am. Chem. Soc.* ***1968****, 90*, 2598; Ford, W.T.; Cram, D.J. *J. Am. Chem. Soc.* ***1968****, 90,* 2606, 2612. See also, Buchholz, S.; Harms, K.; Massa, W.; Boche, G. *Angew. Chem. Int. Ed.* ***1989****, 28,* 73.

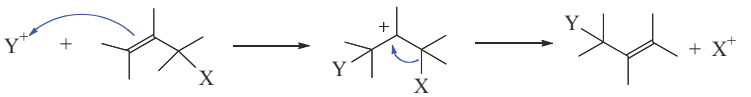
[31] Almy, J.; Hoffman, D.H.; Chu, K.C.; Cram, D.J. *J. Am. Chem. Soc.* ***1973****, 95*, 1185.

[32] Dreiding, A.S.; Pratt, R.J. *J. Am. Chem. Soc.* ***1954****, 76,* 1902. See also, Walborsky, H.M.; Turner, L.M. *J. Am. Chem. Soc.* ***1972****, 94,* 2273.



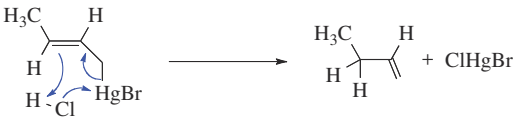
Only ~5% of the cis isomer (tiglic acid) was produced. In addition, certain carbanions in which the negative charge is stabilized by *d*-orbital overlap can maintain configuration (Sec. 5.B.ii) and S_E1 reactions involving them proceed with retention of configuration.

12.A.iii. Electrophilic Substitution Accompanied by Double-Bond Shifts

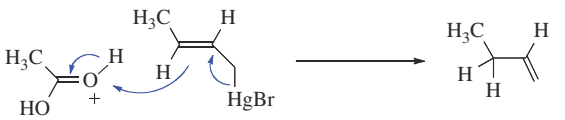


11 **12**

When electrophilic substitution is carried out at an allylic substrate, the product may be rearranged (**11** → **12**). This type of process is analogous to the nucleophilic allylic rearrangements discussed in Section 10.D. There are two principal pathways. The first of these is analogous to the S_E1 mechanism in that the leaving group is first removed, giving a resonance-stabilized allylic carbanion, which then attacks the electrophile Y.



In the other pathway, the Y group is first attacked by the π-bond, giving a carbocation, which then loses X with formation of the alkene unit.



These mechanisms are more fully discussed under Reaction **12-2**.

Most electrophilic allylic rearrangements involve loss of hydrogen, but they have also been observed with metallic leaving groups.[33] Sleezer et al.[34] found that crotylmercuric bromide reacted with HCl ~10^7 times faster than *n*-butylmercuric bromide and the product was >99% 1-butene. These facts point to an S_Ei' mechanism (IUPAC designation *cyclo*-$1/3/D_EA_ED_nA_n$):

The reaction of the same compound with acetic acid–perchloric acid seems to proceed by an S_E2' mechanism (IUPAC designation $1/3/D_EA_E$)[34]:

[33] See Courtois, G.; Miginiac, L. *J. Organomet. Chem.* ***1974****, 69*, 1.

[34] Sleezer, P.D.; Winstein, S.; Young, W.G. *J. Am. Chem. Soc.* ***1963****, 85*, 1890. See also, Kashin, A.N.; Bakunin, V.N.; Khutoryanskii, V.A.; Beletskaya, I.P.; Reutov, O.A. *J. Organomet. Chem.* ***1979****, 171*, 309.

The geometry of electrophilic allylic rearrangement has not been studied very much (cf. the nucleophilic case, Sec. 10.E), but in most cases the rearrangement takes place with antistereoselectivity,[35] although syn stereoselectivity has also been demonstrated.[36] In one case, use of the electrophile H^+ and the leaving group $SnMe_3$ gave both syn and anti stereoselectivity, depending on whether the substrate was cis or trans.[37]

12.A.iv. Other Mechanisms

Addition–elimination (Reaction **12-16**) and cyclic mechanisms (Reaction **12-40**) are also known.

Much less work has been done on electrophilic aliphatic substitution mechanisms than on nucleophilic substitutions. The exact mechanisms of many of the reactions in this chapter are in doubt. For many of them, not enough work has been done to permit us to decide which of the mechanisms described in this chapter is operating, if indeed any is. There may be other electrophilic substitution mechanisms, and some of the reactions in this chapter may not even be electrophilic substitutions at all.

12.B. REACTIVITY

Only a small amount of work has been done in this area, compared to the vast amount done for aliphatic nucleophilic substitution and aromatic electrophilic substitution. Therefore, only a few conclusions can be drawn, most of them sketchy or tentative.[38]

1. *Effect of Substrate*. For S_E1 reactions, electron-donating groups decrease rates and electron-withdrawing groups increase them. This is expected for a reaction in which the rate-determining step is analogous to the cleavage of a proton from an acid. For the S_E2 (back) mechanism, Jensen and Davis[12] showed that the reactivity of alkyl groups is similar to that for the S_N2 mechanism (i.e., Me > Et > Pr > *i*Pr > neopentyl), as is expected, since both involve backside attack and both are equally affected by steric hindrance. In fact, this pattern of reactivity can be regarded as evidence for the occurrence of the S_E2 (back) mechanism in cases where stereochemical investigation is not feasible.[39] For S_E2 reactions that proceed with retention, several studies have been made with varying results, depending on the reaction.[40] One such study, which examined the reaction $RHgBr + Br_2 \rightarrow RBr$ catalyzed by Br^-, gave the results shown in Table 12.1.[41] This data shows that branching increased the rates, while β branching decreased them. Sayre and Jensen[41]

[a]See Ref. 41.

attributed the decreased rates to steric hindrance, although attack here was definitely frontside, and the increased rates to the electron-donating effect of the alkyl groups, which stabilized the electron-deficient transition state.[42] Of course, steric hindrance should also be present with the a branched groups, so these workers concluded that if it were not, the rates would be even greater. The Br electrophile is a rather large one and it is likely that smaller steric effects are present with smaller electrophiles. The rates of certain second-order substitutions of organotin compounds have been found to increase with increasing electron withdrawal by substituents. This behavior has been ascribed[43] to an S_E2 mechanism involving ion pairs, analogous to Sneen's ion-pair mechanism for nucleophilic substitution (Sec. 10.A.iv). Solvolysis of 2-bromo-1,1,1-trifluoro-2-(*p*-methoxyphenyl)ethane in water proceeds via a free carbocation intermediate, but ion pairing influences the reaction in the presence of bromide ion.[44]

2. *Effect of Leaving Group*. For both S_E1 and second-order mechanisms, the more polar the C—X bond, the easier it is for the electrofuge to cleave. For metallic leaving groups in which the metal has a valence >1, the nature of the other group or groups attached to the metal thus has an effect on the reaction. For example, consider a series of organomercurials (RHgW). Because a more electronegative W decreases the polarity of the C—Hg bond and furthermore results in a less stable HgW^+, the electrofugal ability of HgW decreases with increasing electronegativity of W. Thus, HgR′ (from RHgR′) is a better leaving group than HgCl (from RHgCl). Also in accord with this is the leaving-group order Hg—*t*-Bu > Hg—*i*Pr > HgEt > HgMe, reported for acetolysis of R_2Hg,[42] since the more highly branched alkyl groups better help to spread the positive charge. It might be expected that, when metals are the leaving groups, S_E1 mechanisms would be favored, while with carbon leaving groups, second-order mechanisms would be found. However, the reported results have been just about the reverse of this. For carbon leaving groups the mechanism is usually S_E1, while for metallic leaving groups the mechanism is almost always S_E2 or S_Ei. A number of reports of S_E1 reactions with metallic leaving groups have appeared,[45] but the mechanism is not easy to prove and many of

these reports have been challenged.[46] Reutov and co-workers[45] expressed the view that in such reactions a nucleophile (which may be the solvent) must assist in the removal of the electrofuge and refer to such processes as $S_E1(N)$ reactions.

3. *Effect of Solvent*.[47] In addition to the solvent effects on certain S_E1 reactions mentioned earlier (Sec. 12.A.ii), solvents can influence the mechanism that is preferred. As with nucleophilic substitution (Sec. 10.G.iv), an increase in solvent polarity increases the possibility of an ionizing mechanism, in this case S_E1, in comparison with the second-order mechanisms, which do not involve ions. As previously mentioned (Sec. 12.A.ii), the solvent can also exert an influence between the S_E2 (front or back) and S_Ei mechanisms in that the rates of S_E2 mechanisms should be increased by an increase in solvent polarity, while S_Ei mechanisms are much less affected.

12.C. REACTIONS

The reactions in this chapter are arranged in order of leaving group: hydrogen, metals, halogen, and carbon. Electrophilic substitutions at a nitrogen atom are treated last.

12.C.i. Hydrogen as Leaving Group

A. Hydrogen as the Electrophile

12-1 Hydrogen Exchange

Deuterio-de-hydrogenation or Deuteriation

$$R{-}H + D^+ \rightleftharpoons R{-}D + H^+$$

Hydrogen exchange can be accomplished by treatment with acids or bases. As with Reaction **11-1**, the exchange reaction is mostly used to study mechanistic questions (e.g., relative acidities), but it can be used synthetically to prepare deuterated or tritiated molecules. When ordinary strong acids (e.g., H_2SO_4) are used, only fairly acidic protons on carbon can exchange (e.g., acetylenic and allylic). However, primary, secondary, and tertiary hydrogen atoms of alkanes can be exchanged by treatment with superacids (Sec. 5.A.ii).[48] The order of hydrogen reactivity is tertiary > secondary > primary. Where C—C bonds are present, they may be cleaved also (Reaction **12-47**). The mechanism of the exchange (illustrated for methane) has been formulated as involving attack of H^+ on the C—H bond to give the pentavalent methanonium ion, which loses

$$H_3C{-}H + H^+ \rightleftharpoons \left[H_3C\begin{matrix}H\\H\end{matrix}\right]^+ \rightleftharpoons CH_3^+ + H^2$$

Methanonium ion

[46] See Kitching, W. *Rev. Pure Appl. Chem.* ***1969****, 19,* 1.
[47] See Petrosyan, V.S. *J. Organomet. Chem.* ***1983****, 250,* 157.
[48] See Olah, G.A.; Prakash, G.K.S.; Sommer, J. *Superacids*, Wiley, NY, ***1985***, pp. 244–249; Olah, G.A. *Angew. Chem. Int. Ed.* ***1973****, 12,* 173.

H_2 to give a tervalent carbocation.[49] The methanonium ion (CH_5^+) has a three-center, two-electron bond.[50] It is not known whether the methanonium ion is a transition state or a true intermediate, but an ion (CH_5^+) has been detected in the mass spectrum.[51] The IR spectrum of the ethanonium ion ($C_2H_7^+$) has been measured in the gas phase.[52] Note that the two electrons in the three-center, two-electron bond can move in three directions, in accord with the threefold symmetry of such a structure. The electrons can move to unite the two hydrogen atoms, leaving the CH_3^+ free (the forward reaction), or they can unite the CH_3 with either of the two hydrogen atoms, leaving the other hydrogen as a free H^+ ion (the reverse reaction). Actually, the methyl cation is not stable under these conditions. It can go back to CH_4 by the route shown (leading to H^+ exchange), or it can react with additional CH_4 molecules (Reaction **12-20**) to eventually yield the *tert*-butyl cation, which is stable in these superacid solutions. Hydride ion can also be removed from alkanes (producing tervalent carbocations) by treatment with pure SbF_5 in the absence of any source of H^+.[53] Complete or almost complete perdeuteriation of cyclic alkenes has been achieved by treatment with dilute DCl/D_2O in sealed Pyrex tubes at 165–280 °C.[54]

Exchange with bases involves an S_E1 mechanism.

Step 1 $RH + B^- \longrightarrow R^- + BH$

Step 2 $R^- + BD \longrightarrow RD{-}B^-$

Of course, such exchange is most successful for relatively acidic protons (e.g., those α to a carbonyl group), but even weakly acidic protons can exchange with bases if the bases are strong enough (see Sec. 5.B.i).

Alkanes and cycloalkanes, of both low and high molecular weight, can be fully perdeuterated treatment with D_2 gas and a catalyst (e.g., Rh, Pt, or Pd).[55]

OS **VI**, 432.

12-2 Migration of Double Bonds

3/Hydro-de-hydrogenation

$$C_5H_{11}{-}CH_2{-}CH=CH_2 \xrightarrow[Me_2SO]{KNH_2} C_5H_{11}{-}CH=CH{-}CH_3$$

The double bonds of many unsaturated compounds may be isomerized[56] upon treatment with strong bases.[57] In many cases, equilibrium mixtures are obtained and the

thermodynamically most stable isomer predominates.[58] If the new double bond can be in conjugation with one already present or with an aromatic ring, the conjugated compound is favored.[59] If the choice is between an exocyclic and an endocyclic double bond (particularly with six-membered rings), endocyclic is usually preferred. In the absence of such considerations, *Zaitsev's rule* (Sec. 17.B) applies and the double bond goes to the carbon with the fewest hydrogen atoms. All these considerations lead to predictions that terminal alkenes can be isomerized to internal ones, nonconjugated alkenes to conjugated, exo six-membered ring alkenes to endo, and so on, and not the other way around.

The term *prototropic rearrangement* is sometimes used as an example of electrophilic substitution with accompanying allylic rearrangement. The mechanism involves abstraction by a base to give a resonance-stabilized carbanion, and reaction with a proton is at the position that will give the more stable alkene:[60]

This mechanism is exactly analogous to the allylic-rearrangement mechanism for nucleophilic substitution (Sec. 10.D). Ultraviolet spectra of allylbenzene and 1-propenylbenzene in solutions containing NH_2^+ are identical, showing that the same carbanion is present in both cases, as required by this mechanism.[61] The acid BH^+ protonates the position that will give the more stable product, although the ratio of the two possible products can vary with the identity of BH^+.[62] It has been shown that base-catalyzed double-bond shifts are partially intramolecular, at least in some cases.[63] The intramolecular nature has been ascribed to a *conducted tour mechanism* (Sec. 12.A.iii) in which the base leads the proton from one carbanionic site to the other (**13** → **14**).[64]

Double-bond rearrangements can also take place on treatment with acids. Both proton and Lewis[65] acids can be used. The mechanism in the case of proton acids is the reverse of the previous one; first a proton is gained, giving a carbocation and then another is lost:

Step 1 $CH_3—CH_2—CH=CH_2 + H^+ \longrightarrow CH_3—CH_2—\overset{+}{C}H—CH_3$

Step 2 $CH_3—CH_2—\overset{+}{C}H—CH_3 \longrightarrow CH_3—CH=CH—CH_3 + H^+$

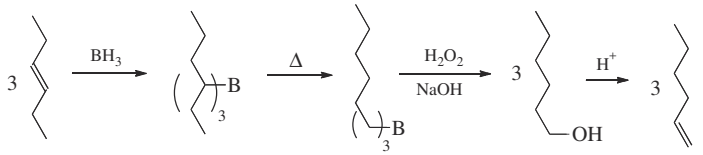
As in the case of the base-catalyzed reaction, the thermodynamically most stable alkene is the one predominantly formed. However, the acid-catalyzed reaction is much less synthetically useful because carbocations give rise to many side products. If the substrate has several possible locations for a double bond, mixtures of all possible isomers are usually obtained. Isomerization of 1-decene, for example, gives a mixture that contains not only 1-decene and *cis*- and *trans*-2-decene, but also the cis and trans isomers of 3-, 4-, and 5-decene as well as branched alkenes resulting from rearrangement of carbocations. It is true that the most stable alkenes predominate, but many of them have stabilities that are close together.

Double-bond isomerization can take place in other ways. Nucleophilic allylic rearrangements were discussed in Chapter 10 (Sec. 10.E). Electrocyclic and sigmatropic rearrangements are treated at Reactions **18-27** to **18-35**. Double-bond migrations have also been accomplished photochemically,[66] and by means of metallic ion (most often complex ions containing Pt, Rh, or Ru) or metal carbonyl catalysts.[67] With metal compounds there are at least two possible mechanisms. One of these, which requires external hydrogen, is called the *metal hydride addition–elimination mechanism*:

The other mechanism, called the π-*allyl complex mechanism*, does not require external hydrogen and proceeds by hydrogen abstraction to form the η^3-π-allyl complex **15** (see Sec. 3.C.i, category 1 and Reaction **10-60**). Another difference between the two mechanisms is that the former involves 1,2- and the latter 1,3-shifts. The isomerization of 1-butene Rh catalyzed reaction is an example that takes place by the metal hydride mechanism,[68] while an example of the π-allyl complex mechanism is found in the $Fe_3(CO)_{12}$ catalyzed isomerization of 3-ethyl-1-pentene.[69] A Pd catalyst was used to convert alkynones ($RCOC{\equiv}CCH_2CH_2R'$) to 2,4-alkadien-1-ones ($RCOCH{=}CHCH{=}CHCHR'$).[70] The reaction of an en-yne with $HSiCl_3$ and a Pd catalyst generated an allene with moderate enantioselectivity (see Sec. 4.C, category 5 for chiral allenes).[71]



15

The metal-catalysis method has been used for the preparation of simple enols, by isomerization of allylic alcohols, for example.[72] Some enols are stable enough for isolation

(see Sec. 4.Q.iv), but slowly tautomerize to the aldehyde or ketone, with half-lives ranging from 40 to 50 min to several days.[72]

No matter which of the electrophilic methods of double-bond shifting is employed, the thermodynamically most stable alkene is usually formed in the largest amount, although a few anomalies are known. An indirect method of double-bond isomerization is known, leading to migration in the other direction. This involves conversion of the alkene to a borane (Reaction **15-16**), rearrangement of the borane (Reaction **18-11**), oxidation and hydrolysis of the newly formed borane to the alcohol (**17**) (see Reaction **12-31**), and dehydration of the alcohol (Reaction **17-1**) to the alkene. The reaction is driven by the fact that with heating the addition of borane is reversible, and the equilibrium favors formation of the less sterically hindered borane, **16** in this case.

16 **17**

Since the migration reaction is always toward the end of a chain, terminal alkenes can be produced from internal ones, so the migration is often opposite to that with the other methods. Alternatively, the rearranged borane can be converted directly to the alkene by heating with an alkene of molecular weight higher than that of the product (Reaction **17-15**). Photochemical isomerization can also lead to the thermodynamically less stable isomer.[73]

See Reaction **15-1** for related reactions in which double bonds migrate or isomerize.

$$R{-}CH_2{-}C{\equiv}CH \rightleftharpoons R{-}CH{=}C{=}CH_2 \rightleftharpoons R{-}C{\equiv}C{-}CH_3$$

Triple bonds can also migrate in the presence of bases,[74] but through an allene intermediate:[75] In general, strong bases (e.g., $NaNH_2$) convert internal alkynes to terminal alkynes (a particularly good base for this purpose is potassium 3-aminopropylamide, $NH_2CH_2CH_2CH_2NHK$[76]), because the equilibrium is shifted by formation of the acetylide ion. With weaker bases (e.g., NaOH), which are not strong enough to remove the acetylenic proton, the internal alkynes are favored because of their greater thermodynamic stability. In some cases, the reaction can be stopped at the allene stage.[77] The reaction then becomes a method for the preparation of allenes.[78] The reaction of propargylic alcohols with tosylhydrazine (PPh_3) and DEAD also generates allenes.[79] In a related reaction, base

induced isomerization of propargylic alcohols leads to conjugated ketones in some cases.[80] Acid-catalyzed migration of triple bonds (with allene intermediates) can be accomplished if very strong acids (e.g., HF—PF_5) are used.[81] If the mechanism is the same as that for double bonds, vinyl cations are intermediates.

12-3 Keto–Enol Tautomerization

3/*O*-Hydro-de-hydrogenation

The tautomeric equilibrium between enols and ketones or aldehydes (keto–enol tautomerism) is a form of prototropy,[82] but is not normally a preparative reaction. For some ketones, however, both forms can be prepared (see Sec. 2.N.i, category 3 for a discussion of this and other types of tautomerism). Keto–enol tautomerism occurs in systems containing one or more carbonyl groups linked to sp^3 carbons bearing one or more hydrogen atoms. *The keto is generally more stable than the enol tautomer for neutral systems,* and for most ketones and aldehydes only the keto form is detectable under ordinary conditions. The availability of additional intramolecular stabilization through hydrogen bonding or complete electron delocalization (as in phenol), may cause the enol tautomer to be favored.

Keto–enol tautomerism is usally a slow process, but it can be catalyzed by a trace of acid or base.[83] In this equilibrium, the heteroatom is the basic site and the proton is the acidic site. For tautomerism in general (see Sec. 2.N.i),[84] the presence of an acid or a base is not necessary to initiate the isomerization since each tautomeric substance possesses amphiprotic properties.[84] Polar protic solvents (e.g., water or alcohol) may participate in the proton transfer by forming a cyclic or a linear complex with the tautomers.[85] Whether the complex formed is cyclic or linear depends on the conformation and configuration of the tautomers. In a strongly polar aprotic solvent and in the presence of an acid or a base,

the tautomeric molecule may lose or gain a proton and form the corresponding mesomeric anion or cation, which, in turn, may gain or lose a proton, respectively, and yield a new tautomeric form.[86] The structural features of the carbonyl compound influences the equilibrium.[87] Differing conjugative stabilization by CH-π orbital overlap does not directly influence stereoselectivity, and steric effects are generally not large enough to cause the several kilocalorie per mole (kcal mol^{-1}) energy difference seen between transition structures unless there is exceptional crowding.[88] Note that sterically stabilized enols are known,[89] including arylacetaldehydes.[90] Torsional strain involving vicinal bonds does contribute significantly to stereoselectivity in enolate formation.[88]

The acid base catalyzed mechanisms are identical to those in Reaction **12-2**.[91]

Acid catalyzed

Base catalyzed[92]

18

For each catalyst, the mechanism for one direction is the exact reverse of the other, by the principle of *microscopic reversibility*.[93] As expected from mechanisms in which the C—H bond is broken in the rate-determining step, substrates of the type RCD_2COR show deuterium isotope effects (of ∼5) in both the basic-[94] and the acid[95]-catalyzed processes. The keto–enol/enolate anion equilibrium has been studied in terms of the influence of β-oxygen[96] or β-nitrogen[97] substituents. The stereochemistry of enol protonation can be controlled by varying the proximal group and by changing the acidity of the medium.[98]

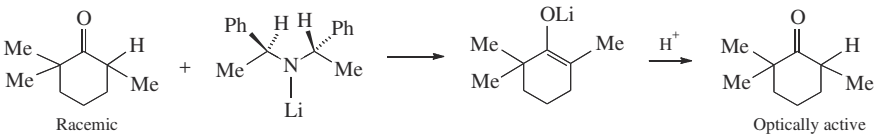
The base induced reaction generates an enolate anion rather than an enol, and the formation of and reactions of enolate anions are discussed further in Reactions **10-60**, **10-67**, **16-24**, and **16-34**. Note that ring strain plays no significant role on the rate of base-catalyzed enolization.[99] In certain cases (e.g., benzofuranones), base-induced enolate anion formation may give a transition state in which aromaticity can play a role. One study showed that aromatic stabilization of the transition state is ahead of proton transfer, and aromaticity appears to lower the intrinsic barrier to this reaction.[100] Enolizable hydrogen atoms can be replaced by deuterium (and ^{16}O by ^{18}O) by passage of a sample through a deuterated (or ^{18}O containing) gas-chromatography column.[101]

Benzofuranone

Although the conversion of an aldehyde or a ketone to its enol tautomer is not generally a preparative procedure, the reactions do have their preparative aspects. When enol ethers or esters are hydrolyzed, the initially formed enols immediately tautomerize to the aldehydes or ketones. In addition, the overall processes (forward plus reverse reactions) are often used for equilibration purposes. When an optically active compound in which the chirality is due to a stereogenic carbon α to a carbonyl group (as in **19**) is treated with acid or base, racemization results.[102] If there is another stereogenic center in the molecule, the less stable diastereomer can be converted to the more stable one in this manner. For example, *cis*-decalone can be equilibrated to the trans isomer. Isotopic exchange can similarly be accomplished at the α position of an aldehyde or ketone. In cyclic compounds, cis- to trans- isomerization can occur via the enol.[103] The role of additives (e.g., $ZnCl_2$) on the stereogenic enolization reactions using chiral cases has been discussed.[104]



19 *cis*-Decalone *trans*-Decalone

If a full equivalent of base per equivalent of ketone is used, the enolate ion (**18**) is formed and can be isolated[105] (see, e.g., the alkylation reaction in Reaction **10-68**).[106]

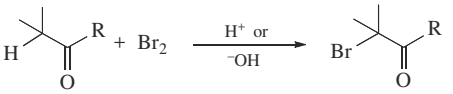
Enantioselective enolate anion protonation reactions have been studied.[107] Enolate protonation is discussed in section Reaction **16-34**. For the acid-catalyzed process, exchange or equilibration is accomplished only if the carbonyl compound is completely converted to the enol and then back, but in the base-catalyzed process exchange or equilibration can take place if only the first step (conversion to the enolate ion) takes place. The difference is usually academic. Aggregation behavior of stereoselective enolizations mediated by Mg and Ca bis(amides) have been studied.[108]

In the case of the ketone (**20**), a racemic mixture was converted to an optically active mixture (optical yield 46%) by treatment with the chiral base (**21**).[109] This happened because **21** reacted with one enantiomer of **20** faster than with the other (an example of *kinetic resolution*). The enolate (**22**) must remain coordinated with the chiral amine, and it is the amine that reprotonate **22**, not an added proton donor.



There are many enol–keto interconversions and acidification reactions of enolate ions to the keto forms listed in *Organic Syntheses*. No attempt is made to list them here.

B. Halogen Electrophiles

Halogenation of unactivated hydrocarbons is discussed in Reaction **14-1**.

12-4 Halogenation of Aldehydes and Ketones

Halogenation or **Halo-de-hydrogenation**

Aldehydes and ketones can be halogenated in the α position with bromine, chlorine, or iodine,[110] although the reaction is less successful with fluorine.[111] Sulfuryl chloride,[112] $Me_3SiCl—Me_2SO$,[113] and NCS[114] have been used as reagents for chlorination.

α-Chloroaldehydes are formed with Cl_2 and a catalytic amount of tetraethylammonium chloride.[115] Bromination methods include NBS (see Reaction **14-3**),[116] Me_3SiBr—DMSO,[117] tetrabutylammonium tribromide,[118] *in situ* generated $ZnBr_2$ in water,[119] and bromine• dioxane on silica with microwave irradiation.[120] α-Chlorination[121] and also bromination[122] have been reported in ionic liquids. Enantioselective chlorination[123] and bromination[124] methods are known, including methods that use enolate anions as intermediates.[125] Organocatalyzed asymmetric α-halogenation methods are known that can be applied to incorporation of virtually any halogen.[126] β-Keto esters and 1,3-diketones are α-brominated using bromodimethylsulfonium bromide.[127] 1,3-Diketones, β-ketoesters, and malonates are chlorinated using sodium hypochlorite or brominated using sodium hypobromite.[128]

Iodination has been accomplished by the direct reaction of ketones with molecular iodine,[129] with I_2-cerium(IV) ammonium nitrate,[130] NCS/NaI,[131] ICl/NaI/$FeCl_3$,[132] and with iodine using 1-chloromethyl-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate) in methanol.[133] Methyl ketones react with NIS and tosic acid with microwave irradiation without solvent to give the α-iodoketone.[134] An asymmetric iodination of aldehydes used NIS, with a catalytic amount of benzoic acid and a chiral biaryl amine.[135]

Although less prevalent than those noted above, several methods have been reported for the preparation of α-fluoro aldehydes and ketones,[136] including enantioselective fluorination protocols.[137] Organocatalytic α-fluorination is known for aldehydes and ketones.[138]

Selectfluor, [F–TEDA–BF_4. 1-Fluoro-4-hydroxy-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate)] has been used for the monofluorination of ketones,[139] as has a mixture of $KI—KIO_3—H_2SO_4$.[140] Active compounds (e.g., β-keto esters and β-diketones) have been fluorinated with an *N*-fluoro-*N*-alkylsulfonamide[141] (this can result in enantioselective fluorination, if an optically active *N*-fluorosulfonamide is used[142]), with $F_2/N_2—HCO_2H$,[143] and with NF_3O/Bu_4NOH.[144] Acetyl hypofluorite fluorinates simple ketones in the form of their lithium enolate anions.[145] Aldehydes have been α-fluorinated using *N*-fluorobenzenesulfonimide as an electrophilic source of fluorine and an imidazolidinone as an organocatalyst.[146] The enantioselective α-fluorination of oxindoles has been reported using *N*-fluorobenzenesulfonimide, a Pd catalyst, and a chiral ligand,[147] and also with an organocatalyst.[148]

For unsymmetrical ketones, the preferred position of halogenation is usually the more substituted: a CH group, then a CH_2 group, and then CH_3[149]; however, mixtures are frequent. With aldehydes the aldehydic hydrogen is sometimes replaced, but only when there is no α-hydrogen and the reaction is generally not very useful (see Reaction **14-4**). It is also possible to prepare di- and polyhalides. When basic catalysts are used, one α position of a ketone is completely halogenated before the other is attacked, and the reaction cannot be stopped until all the hydrogen atoms of the first carbon have been replaced (see below). If one of the groups is methyl, the haloform reaction (**12-44**) takes place. With acid catalysts, it is usually possible to stop the reaction after only one halogen has been incorporated, although a second halogen can be introduced by the use of excess reagent. In chlorination, the second halogen generally appears on the same side as the first,[150] while in bromination the α,α′-dibromo product is found.[151] Actually, with both halogens it is the α,α-dihalo ketone that is formed first, but in the case of bromination this compound isomerizes under the reaction conditions to the α,α′-isomer.[150] α,α′-Dichloro ketones are formed by reaction of a methyl ketone with an excess of $CuCl_2$ and LiCl in DMF[152] or with HCl and H_2O_2 in methanol.[153] Aryl methyl ketones can be dibrominated in high yields with benzyltrimethylammonium tribromide.[154] Active methylene compounds are chlorinated

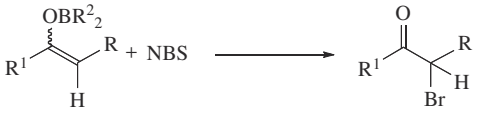
with NCS and $Mg(ClO_4)_2$.[155] Similar chlorination in the presence of a chiral copper catalyst led to α-chlorination with modest enantioselectivity.[156]

It is not the aldehyde or ketone itself that is halogenated, but the corresponding enol or enolate ion. The purpose of the catalyst is to provide a small amount of enol or enolate (Reaction **12-3**). The reaction is often done without addition of acid or base, but traces of acid or base are always present, and these are enough to catalyze formation of the enol or enolate. With acid catalysis the mechanism is

The first step, as seen in Reaction **12-3**, actually consists of two steps. The second step is very similar to the first step in electrophilic addition to double bonds (Sec. 15.A.i). There is a great deal of evidence for this mechanism: (1) the rate is first order in substrate; (2) bromine does not appear in the rate expression at all,[157] a fact consistent with a rate-determining first step;[158] (3) the reaction rate is the same for bromination, chlorination, and iodination under the same conditions;[159] (4) the reaction shows an isotope effect; and (5) the rate of the step 2–step 3 sequence has been independently measured (by starting with the enol) and found to be very fast.[160]



With basic catalysts the mechanism may be the same as that given above (since bases also catalyze formation of the enol), or the reaction may go directly through the enolate ion without formation of the enol:

It is difficult to distinguish the two possibilities. It was mentioned above that in the base-catalyzed reaction, if the substrate has two or three α halogens on the same side of

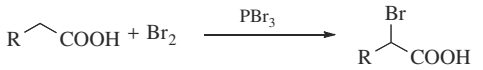
the C=O group, it is not possible to stop the reaction after just one halogen atom has entered. The reason is that the electron-withdrawing field effect of the first halogen increases the acidity of the remaining hydrogen atoms; that is, a CHX group is more acidic than a CH_2 group, so that the initially formed halo ketone is converted to enolate ion (and hence halogenated) more rapidly than the original substrate. Other halogenating agents can be used in this reaction.

An enol borinate



Regioselectivity in the halogenation of unsymmetrical ketones can be attained by treatment of the appropriate enol borinate of the ketone with NBS or NCS.[161] The desired halo ketone is formed in high yield. The appropriate lithium enolate can be brominated at a low temperature[162] (see Reaction **10-68**, category 4 for the regioselective formation of enolate ions). α-Halo aldehydes have been prepared in good yield by treatment of silyl enol ethers ($R_2C{=}CHOSiMe_3$) with Br_2 or Cl_2,[163] with sulfuryl chloride (SO_2Cl_2),[164] or with I_2 and silver acetate.[165] Silyl enol ethers generate α-chloroketones with good enantioselectivity using $ZrCl_4$ in conjunction with an α,α-dichloromalonate ester.[166] Silyl enol ethers can also be fluorinated, with XeF_2[167] or with 5% F_2 in N_2 at −78 °C in $FCCl_3$.[168] Enol acetates have been regioselectively iodinated with I_2 and either Th(I) acetate[169] or Cu(II) acetate.[170]

α,β-Unsaturated ketones can be converted to α-halo-α,β-unsaturated ketones by treatment with phenylselenium bromide or chloride,[171] and to α-halo-β,γ-unsaturated ketones by two-phase treatment with HOCl.[172] Conjugated ketones were converted to the α-bromo conjugated ketone (a vinyl bromide) using the *Dess–Martin periodinane* (see Reaction **19-3**, category 5) and tetraethylammonium bromide.[173]

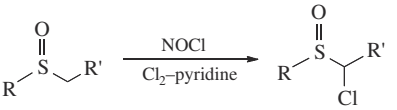
The α hydrogen atoms of carboxylic acids are replaced by bromine or chlorine using a phosphorus halide as catalyst.[174] The reaction, known as the *Hell–Volhard–Zelinskii reaction*, is not applicable to iodine or fluorine. When there are two α hydrogen atoms, one or both may be replaced, although it is often hard to stop with just one. The reaction actually takes place on the acyl halide formed initially from the carboxylic acid and the halogenating reagent. This means that each molecule of acid is α halogenated while it is in the acyl halide stage. The acids alone are inactive, except for those with relatively high enol content (e.g., malonic acid). Less than one full molar equivalent of catalyst (per molar equivalent of substrate) is required, because of the exchange reaction between carboxylic acids and acyl halides (see Reaction **16-79**). The halogen from the catalyst is *not* transferred to the α position. For example, the use of Cl_2 and PBr_3 results in α-chlorination, not bromination. As expected from the foregoing, acyl halides undergo a halogenation without a catalyst. An enantioselective α-halogenation was reported to give chiral α-haloesters via an alkaloid-catalyzed reaction of acyl halides with perhaloquinone-derived reagents.[175] So do anhydrides and many compounds that enolize easily (e.g., malonic ester and aliphatic nitro compounds). The mechanism is usually regarded as proceeding through the enol as in Reaction **12-4**.[176] If chlorosulfuric acid ($ClSO_2OH$) is used as a catalyst, carboxylic acids can be α-iodinated,[177] as well as chlorinated or brominated.[178] *N*-Bromosuccinimide in a mixture of sulfuric acid–trifluoroacetic acid can monobrominate simple carboxylic acids.[179]



A number of other methods exist for the α halogenation of carboxylic acids or their derivatives.[180] Under electrolytic conditions with NaCl, malonates are converted to 2-chloro malonates.[181] Acyl halides can be a brominated or chlorinated by use of NBS or NCS and HBr or HCl.[182] The latter is an ionic, not a free radical halogenation (see Reaction **14-3**). Direct iodination of carboxylic acids has been achieved with I_2-Cu(II) acetate in HOAc.[183] Acyl chlorides can be α iodinated with I_2 and a trace of HI.[184] Carboxylic acids, esters, and amides have been α-fluorinated at −78 °C with F_2 diluted in N_2.[185] Amides have been α-iodinated using iodine and s-collidine.[186]

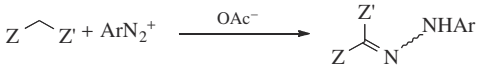
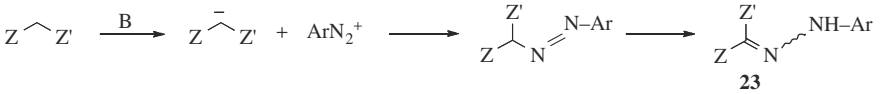
12-6 Halogenation of Sulfoxides and Sulfones

Halogenation or Halo-de-hydrogenation



Sulfoxides can be chlorinated in the α position[187] by treatment with Cl_2[188] or NCS,[189] in the presence of pyridine. These methods involve basic conditions. The reaction can also be accomplished in the absence of base with SO_2Cl_2 in CH_2Cl_2,[190] or with $TsNCl_2$.[191] The bromination of sulfoxides with bromine[192] and with NBS–bromine[193] have also been reported. Sulfones have been chlorinated by treatment of their conjugate bases (RSO_2C^-HR') with various reagents, among them SO_2Cl_2, CCl_4,[194] or NCS.[195] The α-fluorination of sulfoxides was reported via treatment with diethylaminosulfur trifluoride (Et_2NSF_3, DAST) to give an α-fluoro thioether, usually in high yield. Oxidation of this compound with *m*-chloroperoxybenzoic acid gave the sulfoxide.[196]

C. Nitrogen Electrophiles

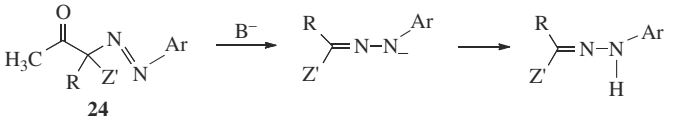


12-7 Aliphatic Diazonium Coupling

Arylhydrazono-de-dihydro-bisubstitution

If a C—H unit is acidic enough, that carbon couples with diazonium salts in the presence of a base (via the enolate anion), most often aq sodium acetate.[197] The reaction is commonly carried out on compounds of the form Z—CH_2—Z′, where Z and Z′ are as defined in Section **16-38** (e.g., β-keto esters, β-keto amides, malonic ester).

The mechanism is probably of the simple S_E1 type:



23

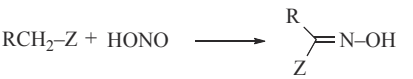
Aliphatic azo compounds in which the carbon containing the azo group is attached to a hydrogen are unstable and tautomerize to the isomeric hydrazones (**23**), which are the products of the reaction.

When the reaction is carried out on a compound of the form Z—CHR—Z′, the azo compound does not have a hydrogen that can lead to tautomerism, and at least one Z is acyl or carboxyl, this group usually cleaves:

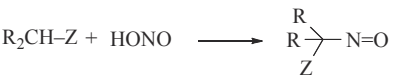
24

so the product in this case is also the hydrazone, and not the azo compound. In fact, compounds of the type **24** are seldom isolable from the reaction, although this has been accomplished.[198] The cleavage step shown is an example of Reaction **12-43** and, when a carboxyl group cleaves, of Reaction **12-40**. The overall process in this case is called the *Japp–Klingemann reaction*[199] and involves conversion of a ketone (**25**) or a carboxylic acid (**26**)



25 **26** **27**

to a hydrazone (**27**). When an acyl and a carboxyl group are both present, the leaving group order has been reported to be MeCO > COOH > PhCO.[200] When there is no acyl or carboxyl group present, the aliphatic azo compound is stable.

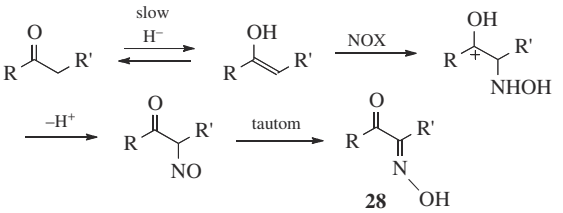


OS **III**, 660; **IV**, 633.

12-8 Nitrosation at a Carbon Bearing an Active Hydrogen

Hydroxyimino-de-dihydro-bisubstitution

Nitrosation or Nitroso-de-hydrogenation



Carbons adjacent to a Z group (as defined in Reaction **10-67**) can be nitrosated with nitrous acid or alkyl nitrites.[201] The initial product is the *C*-nitroso compound, but these are stable only when there is no hydrogen that can undergo tautomerism. When there is, the product is the more stable oxime. The situation is analogous to that with azo compounds

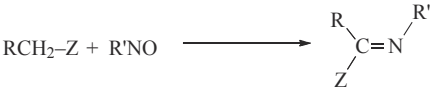
and hydrazones (Reaction **12-7**). The mechanism is similar to that in Reaction **12-7**:[202] $R–H \rightarrow R^- + {}^+N{=}O \rightarrow R–N{=}O$. The reactive species is either NO^+ or a carrier of it. When the substrate is a simple ketone, the mechanism goes through the enol (as in halogenation Reaction **12-4**):



Evidence is that the reaction, in the presence of X^- (Br^-, Cl^-, or SCN^-) was first order in ketone and in H^+, but zero order in HNO_2 and X^-.[203] Furthermore, the rate of the nitrosation was about the same as that for enolization of the same ketones. The species NOX is formed by $HONO + X^- + H^+ \rightarrow HOX + H_2O$. In the cases of $F_3CCOCH_2COCF_3$ and malononitrile, the nitrosation went entirely through the enolate ion rather than the enol.[204]

28

As in the *Japp–Klingemann reaction*, when Z is an acyl or carboxyl group (in the case of $R_2CH—Z$), it can be cleaved. Since oximes and nitroso compounds can be reduced to primary amines, this reaction often provides a route to amino acids. As in the case of Reaction **12-4**, the silyl enol ether of a ketone can be used instead of the ketone itself.[205] Good yields of α-oximinoketones (**28**) can be obtained by treating ketones with *tert*-butyl thionitrate.[206]

Imines can be prepared in a similar manner by treatment of an active hydrogen compound with a nitroso compound:

Alkanes can be nitrosated photochemically, by treatment with NOCl and UV light.[207] For nitration at an activated carbon, see Reaction **12-9**. Trialkyltin enol ethers ($C{=}C—O—SnR_3$) react with PhNO to give α-(*N*-hydroxylamino)ketones.[208]

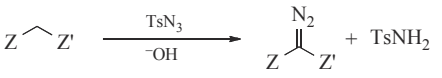
Nitration of alkanes[209] can be carried out in the gas phase at ~400 °C or in the liquid phase. The reaction is not practical for the production of pure products for any alkane except methane. For other alkanes, not only does the reaction produce mixtures of the mono-, di-, and polynitrated alkanes at every combination of positions, but extensive chain cleavage occurs.[210] A free radical mechanism is involved.[211]



Activated positions (e.g., ZCH_2Z' compounds) can be nitrated by fuming nitric acid in acetic acid, by acetyl nitrate and an acid catalyst,[212] or by alkyl nitrates under alkaline conditions.[213] In the latter case, it is the carbanionic form of the substrate that is actually nitrated. The conjugate base of the nitro compound is isolated under these alkaline conditions, but yields are not high. Of course, the mechanism in this case is not of the free radical type, but is electrophilic substitution with respect to the carbon (similar to the mechanisms of Reactions **12-7** and **12-8**). Positions activated by only one electron-withdrawing group (e.g., α positions of simple ketones, nitriles, sulfones, or *N,N*-dialkyl amides) can be nitrated with alkyl nitrates if a very strong base (e.g., *t*-BuOK or $NaNH_2$,) is present to convert the substrate to the carbanionic form.[214]

Electrophilic nitration of alkanes has been performed with nitronium salts (e.g., NO_2^+ PF_6^- and with HNO_3—H_2SO_4 mixtures), but mixtures of nitration and cleavage products are obtained and yields are generally low.[215] The reaction of alkanes with nitric acid and *N*-hydroxysuccinimide (NHS), however, gave moderate-to-good yields of the corresponding nitroalkane.[216] Similar nitration was accomplished with NO_2, NHS and air.[217] Aliphatic nitro compounds can be a nitrated [$R_2C\text{-}NO_2 \rightarrow R_2C(NO_2)_2$] by treatment of their conjugate bases $RCNO_2$ with NO_2^- and $K_3Fe(CN)_6$.[218]

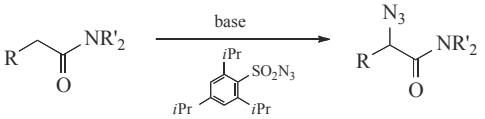
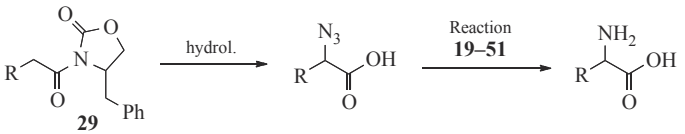
Compounds containing a CH_2 bonded to two Z groups (active methylene compounds, with Z as defined in Reaction **10-67**) can be converted to diazo compounds on treatment with tosyl azide in the presence of a base.[219] The use of phase-transfer catalysis increases the convenience of the method.[220] Sulfonyl azides also give the reaction.[221] The *diazo-transfer reaction* can also be applied to other reactive positions (e.g., the 5 position of cyclopentadiene).[222] The mechanism is probably as follows:



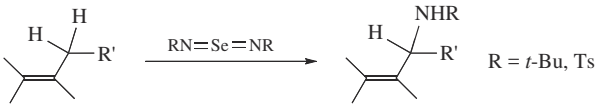
A diazo group can be introduced adjacent to a single carbonyl group indirectly by first converting the ketone to an α-formyl ketone (Reaction **16-85**) and then treating it with tosyl azide. As in the similar cases of Reactions **12-7** and **12-8**, the formyl group is cleaved during the reaction.[223]



OS **V**, 179; **VI**, 389, 414.

12-11 Conversion of Amides to α-Azido Amides

Azidation or **Azido-de-hydrogenation**



In Reaction **12-10**, treatment of $Z—CH_2—Z'$ with tosyl azide gave the α-diazo compound via diazo transfer. When this reaction is performed on a compound with a single Z group (e.g., an amide), formation of the azide becomes a competing process via the enolate anion.[224] Factors favoring azide formation rather than diazo transfer include K^+ as the enolate counterion rather than Na^+ or Li^+ and the use of 2,4,6-triisopropylbenzene-sulfonyl azide rather than TsN_3. When the reaction was applied to amides with a chiral R′ (e.g., the oxazolidinone derivative **29**), it was highly stereoselective, and the product could be converted to an optically active amino acid.[224]

12-12 Direct Amination at an Activated Position

Alkyamino-de-hydrogenation, and so on

Alkenes can be aminated[225] in the allylic position by treatment with solutions of imido selenium compounds (R—N=Se=N—R).[226] The reaction, which is similar to the allylic oxidation of alkenes with SeO_2 (see Reaction **19-14**), has been performed with R = *t*-Bu and R = Ts. The imido sulfur compound TsN=S=NTs has also been used,[227] as well as PhNHOH—$FeCl_2$/$FeCl_3$.[228] Benzylic positions can be aminated with *t*-BuOOCONHTs in the presence of a catalytic amount of $Cu(OTf)_2$.[229] Enantioselective allylic amination has been reported using organocatalyts.[230] A Rh catalyzed amination of benzylic positions has also been reported.[231]

Tertiary alkyl hydrogen can be replaced in some cases via C—H nitrogen insertion. The reaction of sulfamate ester (**30**) with $PhI(OAc)_2$, MgO, and a dinuclear Rh carboxylate catalyst, for example, generated oxathiazinane (**31**).[232] This transformation is a formal oxidation, and primary carbamates have been similarly converted to oxazolidin-2-ones.[233]

Amination of 1,3-dicarbonyl compounds can be done using functionalized dimides and an appropriate catalyst, generating the corresponding hydrazone. Enantioselective amination using this method has been reported, using a chiral guanidine catalyst.[234]

Carbonylnitrenes (:NCOW, W = R′, Ar, or OR′) are very reactive species (Sec. 5.E) and insert into the C—H bonds of alkanes to give amides (W = R′ or Ar) or carbamates (W = OR′).[235] The nitrenes are generated as discussed in Section 5.E. The order of reactivity among alkane C—H bonds is tertiary > secondary > primary.[236] Nitrenes are much more selective (and less reactive) in this reaction than carbenes (Reaction **12-17**).[237] It is likely that only singlet and not triplet nitrenes insert.[238] Retention of configuration is found at a stereogenic carbon.[239] The mechanism is presumably similar to the simple one-step mechanism for insertion of carbenes (Reaction **12-21**). Other nitrenes [e.g., cyanonitrene (NCN)[240] and arylnitrenes (NAr)[241]] can also insert into C—H bonds, but alkylnitrenes usually undergo rearrangement before they can react with the alkane. The Au(III) catalyzed insertion of nitrenes into aromatic and benzylic C—H groups has been reported.[242] *N*-Carbamoyl nitrenes undergo insertion reactions that often lead to mixtures of products, but exceptions are known,[243] chiefly in cyclizations.[244] For example, heating of 2-(2-methylbutyl)phenyl azide gave ~60% 2-ethyl-2-methylindoline (**32**).[239] Enantioselective nitrene insertion reactions are known.[245]

Ketones, carboxylic esters (including lactones),[246] and amides (including lactams)[247] can be sulfenylated[248] in the α position by conversion to the enolate anion (see Sec. 8.F, part 7), and subsequent treatment with a disulfide.[249] The reaction, shown above for ketones, involves nucleophilic substitution at sulfur. α-Phenylseleno ketones [RCH(SePh)COR′] and α-phenylseleno esters [RCH(SePh)COOR′] can be similarly prepared[250] by treatment of the corresponding enolate anions with PhSeBr,[251] PhSeSePh,[252] or benzeneseleninic anhydride [PhSe(O)OSe(O)Ph].[253] Another method for the introduction of a phenylseleno group into the α position of a ketone involves simple treatment of an ethyl acetate solution of the ketone with PhSeCl (but not PhSeBr) at room temperature.[254] This procedure is also successful for aldehydes but not for carboxylic esters. *N*-Phenylselenophthalimide has been used to convert ketones[255] and aldehydes[256] to the α- PhSe derivative. Silyl enol ethers are converted to α-alklylthio and α-arylthio ketones via a sulfenylation method, driven by aromatization of an added quinone mono-*O,S*-acetal in the presence of Me_3SiOTf.[257]

The α-seleno and α-sulfenyl carbonyl compounds prepared by this reaction can be converted to α,β-unsaturated carbonyl compounds (Reaction **17-12**). The sulfenylation reaction has also been used[258] as a key step in a sequence for moving the position of a carbonyl group to an adjacent carbon.[259]

Aldehydes, ketones, and carboxylic acids containing α hydrogen atoms can be sulfonated with sulfur trioxide.[260] The mechanism is presumably similar to that of Reaction **12-4**. Sulfonation has also been accomplished at vinylic hydrogen.

12-15 Alkylation and Alkenylation of Alkenes

Alkylation or **Alkyl-de-oxysulfonation (de-halogenation)**, **Arylation** or **Aryl-de-oxysulfonation (de-halogenation)**, and so on

Vinyl triflates (C=C—OSO_2CF_3) react with vinyl tin derivatives in the presence of Pd catalysts to form dienes, in what is known as *Stille coupling*.[261] Phosphine or bis (phosphine) ligands are most commonly used with the Pd catalyst,[262] but other ligands have been used,[263] including triphenylarsine.[264] Vinyl triflates can be prepared from the enolate anion by reaction with *N*-phenyl triflimide.[265] Vinyltin compounds are generally prepared by the reaction of an alkyne with an trialkyltin halide (see Reactions **15-17** and **15-21**).[266] *Stille cross-coupling* reactions are an important variation of the basic reaction,[267] including cross-coupling reactions of unactivated secondary halides and monoorganotin reagents.[268] Stille reactions are compatible with many functional groups. Vinyl halides can be used,[269] and allenic tin compounds have been used.[270] Intramolecular reactions are possible.[271] *Stille coupling* has been done using microwave irradiation,[272] in fluorous solvents,[273] and in supercritical carbon dioxide (see Sec. 9.D.ii).[274] *Stille coupling* using alkynes as a substrate are known.[275]

This reaction is highly stereoselective, and proceeds with a retention of geometry of the C=C units, and are usually regiospecific with respect to the newly formed C—C σ-bond. Cine substitution is known with this reaction, and its mechanism has been studied.[276] Using $ArSnCl_3$ derivatives, Stille coupling can be done in aq KOH.[277]

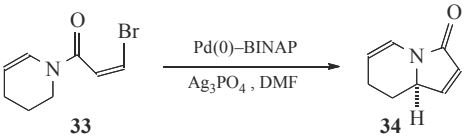
Aryl halides,[278] heteroaryl halides,[279] and heteroaryl triflates[280] can be coupled to vinyltin reagents[281] using a Pd catalyst. A Mo catalyzed variation is known.[282] A Cu catalyzed cross coupling variation[283] has been reported in ionic liquids.[284] Vinyl halides can be coupled to alkenes to form dienes.[285] The reaction of dihydrofurans with vinyl triflates and a Pd catalyst leads to a nonconjugated diene,[286] illustrating that the product is formed by an elimination step, as with the *Heck reaction* (**13-10**), and double-bond migration can occur resulting in allylic rearrangement.

The accepted mechanism for the *Stille reaction* involves a catalytic cycle[287] in which an oxidative addition[288] and a reductive elimination step[289] are fast, relative to Sn/Pd transmetalation (the rate-determining step).[290] It appears that the greater the coordinating ability of the unsaturated species is important, and a coordinated solvent molecule is likely involved in the electrophilic substitution at tin. Another mechanism has been proposed, in which oxidative addition of the vinyl triflate to the ligated Pd gives a *cis*-Pd complex that isomerizes rapidly to a *trans*-Pd complex, which then reacts with the organotin compound following an S_E2 (cyclic) mechanism, with release of a ligand.[291] This pathway gives a bridged intermediate, and subsequent elimination of $XSnBu_3$ yields a three-coordinate species *cis*-Pd complex, which readily gives the coupling product.[291] Most of the major intermediates have been intercepted, isolated, and characterized using electrospray ionization mass spectrometry.[292]



Cyclopropylboronic acids (Reaction **12-28**) couple with vinylic halides[293] or vinyl triflates[294] to give vinylcyclopropanes, using a Pd catalyst. Vinyl borates (Reaction **12-28**) were coupled to vinyl triflates using a Pd catalyst.[295] Vinyltrifluoroborates can be coupled to allylic chlorides using microwave irradiation[296] and vinyl halides react with vinyltrifluoroborates to give dienes with high stereoselectivity.[297] Stille coupling to enols has

been reported.[298] The coupling of vinyl silanes to give the symmetrically conjugated diene using CuCl and air has also been reported.[299]

Other methods are available to give Stille-like products. 1-Lithioalkynes were coupled to vinyl tellurium compounds (C=C—TeBu) using a Ni[300] or a Pd catalyst[301] to give a conjugated en-yne. 2-Alkynes (R—C≡C—Me) react with $HgCl_2$, *n*-butyllithium, and $ZnBr_2$, sequentially, and then with vinyl iodides and a Pd catalyst to give the nonconjugated en-yne.[302] Alkynyl groups can be coupled to vinyl groups to give ene-ynes, via reaction of silver alkynes (Ag—C≡C—R) with vinyl triflates and a Pd catalyst.[303] In the presence of CuI and a Pd catalyst, vinyl triflates[304] or vinyl halides[305] couple to terminal alkynes. Alkynyl zinc reagents (R—C≡C—ZnBr) can be coupled to vinyl halides with a Pd catalyst to give the conjugated en-yne.[306]

Alkyl groups can be coupled to a vinyl unit to give substituted alkenes. The reaction of vinyl iodides and EtZnBr, with a Pd catalyst, gave the ethylated alkene (C=C—Et).[307] Aliphatic alkyl bromides reacted with vinyltin compounds to give the alkylated alkene using a Pd catalyst.[308] Allylic tosylates were coupled to conjugated alkenes to give a non-conjugated diene using a Pd catalyst.[309] An internal coupling reaction was reported in which an alkenyl enamide (**33**) reacted with Ag_3PO_4 and a chiral palladium catalyst to give **34** enantioselectively.[310]

Alkenes can be acylated with an acyl halide and a Lewis acid catalyst in what is essentially a *Friedel–Crafts Reaction* (**11-17**) at an aliphatic carbon.[311] The product can arise by two paths. The initial attack is by the π bond of the alkene unit on the acyl cation (RCO^+; or on the acyl halide free or complexed; see Reaction **11-17**) to give a carbocation, (**35**).

Ion **35** can either lose a proton or combine with chloride ion. If it loses a proton, the product is an unsaturated ketone. The mechanism is similar to the *tetrahedral mechanism* in Section 16.A.i, but with the charges reversed. If it combines with chloride, the product is a β-halo ketone, which can be isolated, so that the result is addition to the double bond (see Reaction **15-47**). On the other hand, the β-halo ketone may, under the conditions of the reaction, lose HCl to give the unsaturated ketone, this time by an addition–elimination mechanism. In the case of unsymmetrical alkenes, the more stable alkene is formed (the more highly substituted and/or conjugated alkene, following *Markovnikov's rule*, see Sec. 15.B.ii). Anhydrides and carboxylic acids (the latter with a proton acid e.g., anhydrous HF, H_2SO_4, or polyphosphoric acid as a catalyst) are sometimes used instead of acyl halides. With some substrates and catalysts, double-bond migrations are occasionally encountered so that, for example, when 1-methylcyclohexene was acylated with acetic anhydride and zinc chloride, the major product was 6-acetyl-1-methylcyclohexene.[312]

Conjugated dienes can be acylated by treatment with acyl- or alkylcobalt tetracarbonyls, followed by base-catalyzed cleavage of the resulting π-allyl carbonyl derivatives[313] (π-allyl metal complexes were discussed in Sec. 3.C.i. The reaction is very general. With unsymmetrical dienes, the acyl group generally substitutes most readily at a cis double bond, next at a terminal alkenyl group, and least readily at a trans double bond. The most useful bases are strongly basic, hindered amines (e.g., dicyclohexylethylamine). Acylation of vinylic ethers has been accomplished with aromatic acyl chlorides, a base, and a Pd catalyst: $ROCH{=}CH_2 \rightarrow ROCH{=}CHCOAr$.[314]

Formylation of alkenes can be accomplished with *N*-disubstituted formamides and $POCl_3$.[315] This is an aliphatic *Vilsmeier reaction* (see Reaction **11-18**). Vilsmeier formylation can also be performed on the α position of acetals and ketals, so that hydrolysis of the products gives keto aldehydes or dialdehydes:[316] A variation

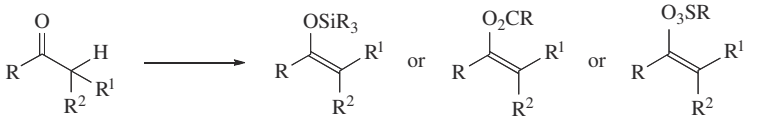
heated a 1,1-dibromoalkene with a secondary amine in aq DMF to give the corresponding amide.[317]



Acetylation of acetals or ketals can be accomplished with acetic anhydride and BF_3–etherate.[318] The mechanism with acetals or ketals also involves attack at an alkenyl carbon, since enol ethers are intermediates.[318] Ketones can be formylated in the α position by treatment with CO and a strong base.[319]

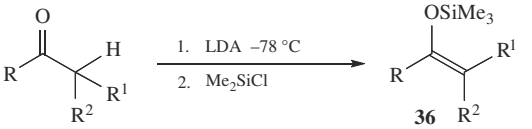
12-17 Conversion of Enolates to Silyl Enol Ethers, Silyl Enol Esters, and Silyl Enol Sulfonate Esters

3/*O*-Trimethylsilyl-de-hydrogenation



Sily enol ether | Enol ester | Enol sulfonate ester

Silyl enol ethers,[320] important reagents with a number of synthetic uses (see, e.g., Reactions **10-68**, **12-4**, **15-24**, **15-64**, and **16-36**), can be prepared by base treatment of a ketone (converting it to its enolate anion) followed by addition of a trialkylchlorosilane. Other silylating agents have also been used.[321] Both strong bases (e.g., LDA), and weaker bases (Et_3N) have been used for this purpose.[322] In some cases, the base and the silylating agent can be present at the same time.[323] Enolate anions prepared in other ways (e.g., as shown in Reaction **10-58**) also give the reaction.[324] The reaction can be applied to aldehydes by the use of the base KH in 1,2-dimethoxyethane.[325] A particularly mild method for conversion of ketones or aldehydes to silyl enol ethers uses Me_3SiI and the base hexamethyldisilazane [$(Me_3Si)_2NH$.][326] Cyclic ketones can be converted to silyl enol ethers in the presence of acyclic ketones, by treatment with Me_3SiBr, tetraphenylstibonium

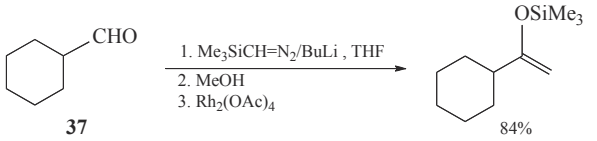
bromide (Ph_4SbBr), and an aziridine.[327] bis(Trimethylsilyl)acetamide is an effective reagent for the conversion of ketones to the silyl enol ether, typically giving the thermodynamic product (see below).[328] Silyl enol ethers have also been prepared by the direct reaction of a ketone and a silane (R_3SiH) with a Pt catalyst.[329]



36

For substituted ketones, (*E*) and (*Z*) isomers are usually formed. For **36**, the enol is (*Z*) when R^1 is the priority group, but (E) when R^2 is the priority group. In some cases, it is possible to control the selectivity to favor more of one isomer than the other. Treatment of 2-methyl-3-pentanone with LDA (THF, -78 °C), for example, gave a 60:40 mixture of the (*Z*) and (*E*) enolates.[330] The base used to generate an enolate anion, the solvent and temperature, the conjugate acid of the base used, and the nature of the carbonyl substrate will all play a role in the selectivity. In general, equilibrating (thermodynamic) conditions [protic solvents (e.g., ethanol, water, or ammonia), a base generating a conjugate acid stronger than the starting ketone, more ionic counterions (e.g., K or Na), higher temperatures and longer reaction times] are expected to give more of the (*E*)-isomer. Conversely, kinetic conditions [aprotic solvents (e.g., ether or THF), a base generating a conjugate acid weaker than the starting ketone, more covalent counterions (e.g., Li, lower temperatures), and relatively short reaction times] usually give more of the (*Z*)-isomer. It is not always easy to predict the ratio, however. Either isomer is possible from aldehydes using the proper Rh catalyst.[331]

Magnesium diisopropylamide has been used to prepare kinetic silyl enol ethers in virtual quantitative yield.[332] Reaction with Me_3SiCl/KI in DMF gives primarily the thermodynamic silyl enol ether.[333]

An interesting synthesis of silyl enol ethers involves chain extension of an aldehyde. Aldehydes are converted to the silyl enol ether of a ketone upon reaction with lithium (trimethylsilyl)diazomethane and then a dirhodium catalyst.[334] For example, initial reaction of lithium(trimethylsilyl)diazomethane [LTMSD, prepared *in situ* by reaction of butyllithium with (trimethylsilyl)diazomethane] to the aldehyde (e.g., **37**) gave the alkoxide addition product. Protonation and then capture by a transition metal catalyst, and a 1,2-hydride migration gave the silyl enol ether, (**38**). Silyl enol ethers can be prepared from acyloin derivatives (see Reaction **19-78**).[335]

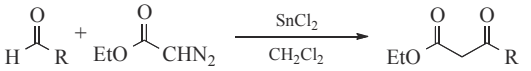
37 **38**



Enol acetates are generally prepared by the reaction of an enolate anion with a suitable acylating reagent.[336] Enolate anions react with acyl halides and with anhydrides to give the acylated product. Both C- and O-acylation are possible, but in general O-acylation predominates.[337] Note that the extent of O- versus C-acylation is very dependent on the local environment and electronic effects within the enolate anion.[338] *O*-Benzoate enols are formed in good yield from aldehydes or 1,3-diketones in the presence of CuBr and *tert*-butylhydroperoxide.[339] Silyl sulfonate esters can be prepared by similar methods, using sulfonic acid anhydrides rather than carboxylic anhydrides. A polymer-supported triflating agent was used to prepare silyl enol triflate from ketones, in the presence of diisopropylethylamine.[340]

When a silyl enol ether is the trimethylsilyl derivative ($Me_3Si—O-C=C$), treatment with methyllithium will regenerate the lithium enolate anion and the volatile trimethylsilane (Me_3SiH).[341]

12-18 Conversion of Aldehydes to β-Keto Esters or Ketones

Alkoxycarbonylalkylation or **Alkoxycarbonylalkyl-de-hydrogenation**

β-Keto esters have been prepared in moderate to high yields by treatment of aldehydes with diethyl diazoacetate in the presence of a catalytic amount of a Lewis acid (e.g., $SnCl_2$, BF_3, or $GeCl_2$).[343] The reaction was successful for both aliphatic and aromatic aldehydes, but the former react more rapidly than the latter, and the difference is great enough to allow selective reactivity. In a similar process, aldehydes react with certain carbanions stabilized by boron, in the presence of $(F_3CCO)_2O$ or NCS, to give ketones.[344]

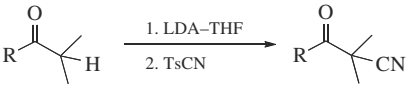
Ketones can be prepared from aryl aldehydes (ArCHO) by treatment with a Rh complex [$(Ph_3P)_2Rh(CO)Ar'$], whereby the Ar group is transferred to the aldehyde, producing the ketone (Ar—CO—Ar′).[345] In another Rh catalyzed reaction, aryl aldehydes (ArCHO) react with Me_3SnAr' to give the diaryl ketone (Ar—CO—Ar′).[346]



Acylation of aryl halides with aldehydes gives arylketones in the presence of a Pd catalyst.[347]

12-19 Cyanation or Cyano-de-hydrogenation

There are several reactions in which a C—H unit is replaced by C—CN. In virtually all cases, the hydrogen being replaced is on a carbon α to a heteroatom or functional group. There are several examples.

Introduction of a cyano group α to the carbonyl group of a ketone can be accomplished by prior formation of the enolate anion with LDA in THF and addition of this solution to *p*-TsCN at −78 °C.[348] The products are formed in moderate to high yields but the reaction is not applicable to methyl ketones. Treatment of $TMSCH_2N(Me)C{=}Nt\text{-}Bu$ with *sec*-butyllithium and $R_2C{=}O$, followed by iodomethane and NaOMe leads to the nitrile ($R_2CH—CN$).[349]

Cyanation has been shown to occur α to a nitrogen, specifically in *N,N*-dimethylaniline derivatives. Treatment with a catalytic amount of $RuCl_3$ in the presence of oxygen and NaCN leads to the corresponding cyanomethylamine.[350] Conversion of tertiary amines to the α-cyanoamine has been reported in the presence of $FeCl_2$ and *t*-BuOOH.[351]

In a different kind of reaction, nitro compounds are α-cyanated by treatment with ^{-}CN and $K_3Fe(CN)_6$.[352] The mechanism probably involves ion radicals. In still another reaction, secondary amines are converted to α-cyanoamines by treatment with phenylseleninic anhydride and NaCN or Me_3SiCN.[353,354]

Another specialized reaction converts the methyl group of arenes (e.g., toluene) into a cyano group: toluene → benzonitrile, for example.[355]

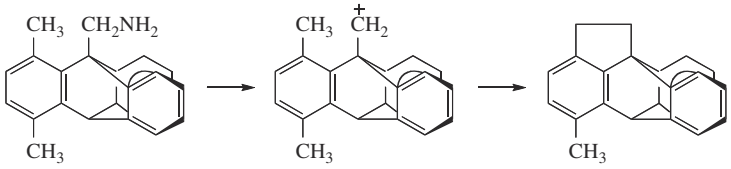
12-20 Alkylation of Alkanes



Alkylation or **Alkyl-de-hydrogenation**

$$RH + R'^{+} \longrightarrow R{-}R' + H^{+}$$

Alkanes can be alkylated by treatment with solutions of stable carbocations[356] (Sec. 5.A.ii), but the availability of such carbocations is limited and mixtures are usually obtained. In a typical experiment, the treatment of propane with isopropyl fluoroantimonate (Me_2HC^+ SbF_6^-) gave 26% 2,3-dimethylbutane, 28% 2-methylpentane, 14% 3-methylpentane, and 32% *n*-hexane, as well as some butanes, pentanes (formed by Reaction **12-47**), and higher alkanes. Mixtures arise in part because intermolecular hydrogen exchange ($RH + R'^{+} \rightarrow R^{+} + R'H$) is much faster than alkylation, so that alkylation products are also derived from the new alkanes and carbocations formed in the exchange reaction. Furthermore, the carbocations present are subject to rearrangement (Chapter 18), giving rise to new carbocations. Products result from all the hydrocarbons and carbocations present in the system. As expected from their relative stabilities, secondary alkyl cations alkylate alkanes more readily than tertiary alkyl cations (the *tert*-butyl cation does not alkylate methane or ethane). Stable primary alkyl cations are not available, but alkylation has been achieved with complexes formed between CH_3F or C_2H_5F and SbF_5.[357] The mechanism of alkylation can be formulated (similar to that shown in hydrogen exchange with superacids, Reaction **12-1**) as

It is by means of successive reactions of this sort that simple alkanes like methane and ethane give *tert*-butyl cations in superacid solutions (Sec. 5.A.ii).[358]

39 **40** 46%

Intramolecular insertion has been reported. The positively charged carbon of the carbocation (**40**), generated from the diazonium salt of the triptycene compound (**39**), reacted with the CH_3 group in close proximity with it.[359]

12-21 Insertion by Carbenes

CH-Methylene-insertion

$$RH + :CH_2 \longrightarrow RCH_3$$

The highly reactive species methylene ($:CH_2$) inserts into C—H bonds,[360] both aliphatic and aromatic,[361] although with aromatic compounds subsequent ring expansion is also possible (see Reaction **15-64**). This is effectively a homologation reaction.[362] The methylene insertion reaction has limited utility because of its nonselectivity (see Sec. 5.D.i). The insertion reaction of carbenes has been used for synthetic purposes.[363]

The carbenes can be generated in any of the ways mentioned in Chapter 5 (Sec. 5.D.ii). Alkylcarbenes usually rearrange rather than give insertion (Sec. 5.D.ii, category 4), but, when this is impossible, *intramolecular* insertion[364] is found rather than intermolecular.[365] Methylene ($:CH_2$) generated by photolysis of diazomethane (CH_2N_2) in the liquid phase is indiscriminate (totally nonselective) in its reactivity (Sec. 5.D.ii, category 2). Methylene ($:CH_2$) generated in other ways and monoalkyl and dialkyl carbenes are less reactive and insert in the order tertiary > secondary > primary.[366] Carbene insertion with certain allylic systems can proceed with rearrangement of the double bond.[367] Carbenes have been generated using ultrasound.[368] Halocarbenes ($:CCl_2$,$:CBr_2$, etc.) insert much less readily, although a number of instances have been reported.[369]

Insertion at an allylic carbon of alkenes has been reported.[370] Dirhodium catalyzed insertion into H—C^{sp2} bonds is known,[371] and also H—C^{sp} bonds.[372] Note that

cyclopropanation may compete with C—H insertion with electron-rich highly substituted alkenes.[373] Palladacycles formed by C—H insertion reactions with biphenylene have been intercepted.[374] Such species have been impicated in the *Heck reaction* (Reaction **13-10**). Insertion of diazoalkane and diazocarbonyl compounds can be catalyzed by copper compounds[375] and silver compounds[376] as well. Insertion into the α-C—H bond of an aldehyde gives an α-substituted aldehyde.[377] Intramolecular insertion at the α carbon of a ketone by a diazoketone, using $TiCl_4$, gives a bicyclic 1,3-diketone.[378] The reaction in which aldehydes are converted to methyl ketones, $RCHO + CH_2N_2 \rightarrow RCOCH_3$, while apparently similar, does not involve a free carbene intermediate and is considered in Reaction **18-9**. Note that aryl ketenes react with Me_3SiCHN_2 and then silica to give 2-indanone derivatives.[379] A three component coupling reaction of vinyl iodides, secondary amines, and diazo(trimethylsilyl)methane gives allylic amines.[380] A gold-catalyzed reaction is known that uses alkynes as an α-diazo ketone equivalent.[381]

Insertion into the O—H bond of alcohols, to produce ethers, has been reported using a diazocarbonyl compound and an $In(OTf)_3$ catalyst.[382] The Cu catalyzed insertion of a diazo ester into an oxetane gives the ring-expanded THF derivative.[383] Insertion is also possible with other ethers, including silyl ethers.[384] Metal-catalyzed silylene insertion into allylic ethers leads to allylic silanes.[385] Similar insertion at the α carbon of an ether leads to cyclic ethers, with high enantioselectivity when a chiral ligand is used with a Rh catalyst.[386]

The insertion of the diazocarbonyl unit into the C—H bond of an α-diazo amide gives the lactam shown in the reaction.[387] Insertion into a 2-pyrrolidinone derivative using $Me_3SiCH_2N_2$ followed by $AgCO_2Ph$ with ultrasound gave the ring-expanded 2-piperidone derivative.[388] Intramolecular insertion reactions are well known,[389] and tolerate a variety of functional groups.[390]

The metal carbene insertion reaction, in contrast to the methylene insertion reaction can be highly selective[391] and useful in synthesis.[392] There are numerous examples, usually requiring a transition metal catalyst.[393] The catalyst typically converts a diazoalkane or diazocarbonyl compound to the metal carbene *in situ*, allowing the subsequent insertion reaction. Intermolecular reactions are known, including diazoalkane insertion reaction with a dirhodium catalyst.[394] When chiral ligands are present good enantioselectivity is observed in the insertion product.[395]

The mechanism[396] of the insertion reaction is not known with certainty, but there seem to be at least two possible pathways.

1. A simple one-step process involving a three-center cyclic transition state:

The most convincing evidence for this mechanism is that in the reaction between isobutene-1—^{14}C and carbene the product 2-methyl-1-butene was labeled only in the 1 position.[397] This rules out a free radical or a carbocation or carbanion intermediate. If **41** (or a corresponding ion) were an intermediate, resonance would ensure that some carbene attacked at the 1 position:

Other evidence is that retention of configuration, which is predicted by this mechanism, has been found in a number of instances.[398] An ylid intermediate was trapped in the reaction of $:CH_2$ with allyl alcohol.[399]

2. A free radical process in which the carbene directly abstracts a hydrogen from the substrate to generate a pair of free radicals:

$$RH + CH_2 \longrightarrow R^{\bullet} + {}^{\bullet}CH_3$$
$$R^{\bullet} + {}^{\bullet}CH_3 \longrightarrow RCH_3$$

One fact supporting this mechanism is that among the products obtained (beside butane and isobutane) on treatment of propane with CH_2 (generated by photolysis of diazomethane and ketene) were propene and ethane,[400] which could arise, respectively, by

$$2\,CH_3CH_2CH_2^{\bullet} \longrightarrow \underset{\text{(disproportionation)}}{CH_3CH{=}CH_2 + CH_3CH_2CH_3}$$

and

$$CH_3CH_2CH_3 + :CH_2 \longrightarrow CH_3CH_2CH_2^{\bullet} + {}^{\bullet}CH_3$$
$$2\,{}^{\bullet}CH_3 \longrightarrow CH_3CH_3$$

That this mechanism can take place under suitable conditions has been demonstrated by isotopic labeling[401] and by other means.[402] However, the formation of disproportionation and dimerization products does not always mean that the free radical abstraction process takes place. In some cases, these products arise in a different manner.[403] The product of the reaction between a carbene and a molecule may have excess energy (see Sec. 5.D.ii). Therefore it is possible for the substrate and the carbene to react by mechanism 1 (the direct-insertion process) and for the excess energy to cause the compound thus formed to cleave to free radicals. When this pathway is in operation, the free radicals are formed *after* the actual insertion reaction.

The mechanism of cyclopropylcarbene reactions has also been discussed.[404]

It has been suggested[405] that singlet carbenes insert by the one-step direct-insertion process and triplets (which, being free radicals, are more likely to abstract hydrogen) by the free radical process. In support of this suggestion, CIDNP signals[406] (Sec. 5.C.i) were observed in the ethylbenzene produced from toluene and triplet CH_2, but not from the same reaction with singlet CH_2.[407] Carbenoids (e.g., compounds of the form R_2CMCl, see Reaction **12-39**) can insert into a C—H bond by a different mechanism, similar to pathway 2, but involving abstraction of a hydride ion rather than a hydrogen atom.[408]

For the similar insertion reaction of nitrenes, see Reaction **12-13**.

Many organic compounds can be metalated by treatment with an organometallic compound.[409] Since the reaction involves a proton transfer, the equilibrium lies on the side of the weaker acid.[410] For example, fluorene reacts with *n*-butyllithium to give butane and 9-fluorenyllithium. Since aromatic hydrocarbons are usually stronger acids than aliphatic ones, R is most often aryl. The most common reagent is probably butyllithium.[411] Reductive lithiation is an important method for the preparation of organolithium reagents.[412] Normally, only active aromatic rings react with butyllithium. Benzene itself reacts very slowly and in low yield, although benzene can be metalated by butyllithium either in the presence of *tert*-BuOK[413] or by *n*-butyllithium that is coordinated with various diamines.[414] Metalation of aliphatic RH is most successful when the carbanions are stabilized by resonance (allylic, benzylic, propargylic,[415] etc.) or when the negative charge is at an *sp* carbon (at triple bonds). Trimethylsilylmethyl potassium (Me_3SiCH_2K)[416] and also a combination of an organolithium compound with a bulky alkoxide (LICKOR superbase)[417] are very good reagents for allylic metalation. The former is also useful for benzylic positions. A combination of BuLi, *t*-BuOK, and tetramethylethylenediamine has been used to convert ethylene to vinylpotassium.[418] The reaction can be used to determine relative acidities of very weak acids by allowing two R—H compounds to compete for the same R′M and to determine which proton in a molecule is the most acidic.[419]

Note that organolithium compounds are aggregated species and can form hetero-aggregates containing different organic groups.[420] *N*-Lithio-*N*-(trialkylsilyl)allylamines are deprotonated in ether solvents at the cis-vinylic position to give 3,*N*-dilithio-*N*-(trialkylsilyl)allylamines.[421]

In general, the reaction can be performed only with organometallics of active metals (e.g., Li, Na, and K), but *Grignard reagents* abstract protons from a sufficiently acidic C—H bond, as in $R—C{\equiv}C—H \rightarrow R—C{\equiv}C—MgX$. This is the best method for the

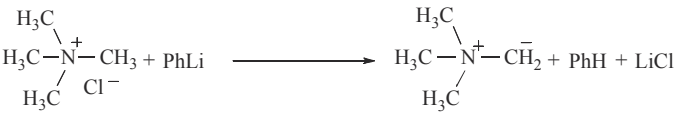
preparation of alkynyl *Grignard reagents*.[422] Lewis acids have been used to promote α-lithiation of amines.[423] Triethylgallium has been used to generate enolate anions from ketones.[424]

When a heteroatom (e.g., N, O, S,[425] or a halogen),[426] is present in a molecule containing an aromatic ring or a double bond, lithiation is usually quite regioselective.[427] It has been shown that fluorine is more effective for stabilization of carbanions when compared to the heavier halogens.[428] In such compounds, the lithium usually bonds with the sp^2 carbon closest to the heteroatom, probably because the attacking species coordinates with the heteroatom.[429] This type of reaction with compounds such as anisole are often called directed metalations.[430] In the case of aromatic rings, this means attack at the ortho position,[431] but this is considered in Reaction **13-17**.

Ref. 432

In the case of γ,δ-unsaturated disubstituted amides (**42**), the lithium does not go to the closest position, but in this case too the regiochemistry is controlled by coordination to the oxygen.[433] Cyclopropyllithium reagents are rather stable.[434]

42



The mechanism involves an attack by R'^- (or a polar R′) on the *hydrogen*[435] (an acid–base reaction) Evidence is that resonance effects of substituents in R seem to make little difference. When R is aryl, OMe and CF_3 *both* direct ortho, while isopropyl directs meta

and para (mostly meta).[436] These results are exactly what would be expected from pure field effects, with no contribution from resonance effects, which implies that attack occurs at the hydrogen and not at R. Other evidence for the involvement of H in the rate-determining step is that there are large isotope effects.[437] The nature of R′ also has an effect on the rate. In the reaction between triphenylmethane and R′Li, the rate decreased in the order R′ = allyl > Bu > Ph > vinyl > Me, although this order changed with changing concentration of R′Li, because of varying degrees of aggregation of the R′Li.[438] With respect to the reagent, this reaction is a special case of Reaction **12-24**.

Enantioselective reactions are known. The preparation of chlorodeuteriomethylithium proceeds with inversion from the corresponding enantiopure stannyl derivative.[439] Although highly reactive chemically, it is configurationally stable at temperatures up to −78 °C. Enantioselective catalytic deprotonation with chiral ligands has been used for the deprotonation of *N*-Boc amines to give chiral α-trimethylsilyl derivatives.[440] A barrier to enantiomerization has been observed for unstablized, chelated, and dipole-stabilized organolithium compounds. Studies of lithiopyrrolidines show free energies for enantiomerization in the range of 19–22 kcal mol^{-1} (79.5–92.1 kJ mol^{-1}) at 0 °C.[441]

A closely related reaction is formation of nitrogen ylids[442] from quaternary ammonium salts (see Reaction **17-8**):

Phosphonium salts undergo a similar reaction (see Reaction **16-44**).

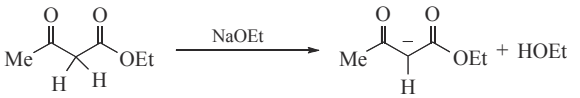
12-23 Metalation with Metals and Strong Bases



Metalation or **Metalo-de-hydrogenation**

$$2\,RH + M \longrightarrow 2\,RM + H_2$$

Organic compounds can be metalated at suitably acidic positions by active metals and by strong bases.[443] The reaction has been used to study the acidities of very weak acids (see Sec. 5.B.i). The conversion of terminal alkynes to acetylide ions is one important

application.[444] A gold-catalyst conversion of trimethylsilyl substituted esters and carbonates to the corresponding enolate anion has been reported[445]. Synthetically, an important use of the method is to convert aldehydes and ketones,[446] carboxylic esters, and similar compounds to their enolate forms,[447] for example,

for use in nucleophilic substitutions (Reactions **10-67**, **10-68**, and **13-14**) and in additions to multiple bonds (Reactions **15-24** and **16-53**). Note that the reaction of carbonyl compounds with lithium dialkylamides leads to the corresponding enolate anion. This reaction was discussed in Reaction **10-68**, in connection with the alkylation reaction of enolate anions.

OS **I**, 70, 161, 490; **IV**, 473; **VI**, 468, 542, 611, 683, 709; **VII**, 229, 339. Conversions of ketones or esters to enolates are not listed.

12.C.ii. Metals as Leaving Groups

A. Hydrogen as the Electrophile

12-24 Replacement of Metals by Hydrogen

Hydro-de-metalation or **Demetalation**

$$RM + HA \longrightarrow RH + MA$$

Organometallic compounds, including enolate anions, react with acids in reactions that replace the metal with hydrogen.[448] The R group may be aryl (see Reaction **11-41**). The reaction is often used to introduce deuterium or tritium into susceptible positions. For *Grignard reagents*, water is usually a strong enough acid, but stronger acids are also used. An important method for the reduction of alkyl halides consists of the process $RX \rightarrow RMgX \rightarrow RH$.

The organometallic compounds that are hydrolyzed by water are the ones high in the electromotive series: Na, K, Li, Zn, and so on. Enantioselective protonation of lithium enolates[449] and cyclopropyllithium compounds[450] have been reported. When the metal is less active, stronger acids are required. For example, R_2Zn compounds react explosively with water, R_2Cd slowly, and R_2Hg not at all, although the latter can be cleaved with

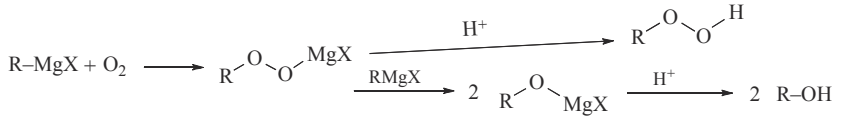
concentrated HCl. However, this general statement has many exceptions, some hard to explain. For example, BR_3 compounds are completely inert to water, and GaR_3 at room temperature cleave just one R group, but AlR_3 reacts violently with water. However, BR_3 can be converted to RH with carboxylic acids.[451] For less active metals, it is often possible to cleave just one R group from a multivalent metal. For example,

$$R_2Hg + HCl \longrightarrow RH + RHgCl$$

Organometallic compounds of less active metals and metalloids (e.g., Si,[452] Sb, and Bi), are quite inert to water. Organomercury compounds (RHgX or R_2Hg) can be reduced to RH by H_2, $NaBH_4$, or other reducing agents.[453] The reduction with $NaBH_4$ takes place by a free radical mechanism.[454] Alkyl-Si bonds are cleaved by H_2SO_4 [e.g., $HOOCCH_2CH_2SiMe_3 \rightarrow 2CH_2 + (HOOCCH_2CH_2SiMe_3)_2O$].[455]



When the hydrogen of the HA is attached to carbon, this reaction is the same as **12-22**.

This section does not list the many hydrolyses of Na or K enolates, and so on found in *Organic Syntheses*. The hydrolysis of a *Grignard reagent* to give an alkane is found at OS **II**, 478; the reduction of a vinylic tin compound at OS **VIII**, 381; and the reduction of an alkynylsilane at OS **VIII**, 281.

B. Oxygen Electrophiles

12-25 The Reaction between Organometallic Reagents and Oxygen[456]

Hydroperoxy-de-metalation; **Hydroxy-de-metalation**

Oxygen reacts with *Grignard reagents* to give either hydroperoxides[457] or alcohols. The reaction can be used to convert alkyl halides to alcohols without side reactions. With aryl *Grignard reagents*, yields are lower and only phenols are obtained, not hydroperoxides. Because of this reaction, oxygen should be excluded when *Grignard reagents* are prepared and used in various reactions.

Most other organometallic compounds also react with oxygen. Trialkylboranes and alkyldichloroboranes ($RBCl_2$) can be conveniently converted to hydroperoxides by treatment with oxygen followed by hydrolysis.[458] Dilithiated carboxylic acids (see Reaction **10-70**) react with oxygen to give (after hydrolysis) α-hydroxy carboxylic

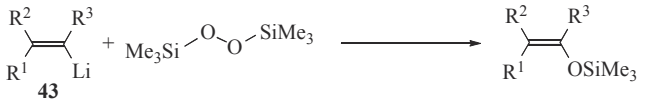
acids.[459] There is evidence that the reaction between *Grignard reagents* and oxygen involves a free radical mechanism.[460]



OS **V**, 918. See also, OS **VIII**, 315.

12-26 Reaction between Organometallic Reagents and Peroxides

tert-Butoxy-de-metalation

A convenient method of preparation of *tert*-butyl ethers consists of treating *Grignard reagents* with *tert*-butyl acyl peroxides.[461] Both alkyl and aryl *Grignard reagents* can be used. The application of this reaction to *Grignard reagents* prepared from cyclopropyl halides permits cyclopropyl halides to be converted to *tert*-butyl ethers of cyclopropanols,[462] which can then be easily hydrolyzed to the cyclopropanols. The direct conversion of cyclopropyl halides to cyclopropanols by Reaction **10-1** is not generally feasible, because cyclopropyl halides do not generally undergo nucleophilic substitutions without ring opening.

Vinyllithium reagents (**43**) react with silyl peroxides to give high yields of silyl enol ethers with retention of configuration.[463] Since the preparation of **43** from vinylic halides (Reaction **12-39**) also proceeds with retention, the overall procedure is a method for the stereospecific conversion of a vinylic halide to a silyl enol ether. Dialky ethers have been prepared from organotrifluoroborates and acetals[464].

OS **V**, 642, 924.

12-27 Oxidation of Trialkylboranes to Borates

The reaction of alkenes with borane, monoalkyl, and dialkylboranes leads to a new organoborane (see Reaction **15-16**). Treatment of organoboranes with alkaline H_2O_2 oxidizes trialkylboranes to esters of boric acid.[465] This reaction does not affect double

or triple bonds, aldehydes, ketones, halides, or nitriles that may be present elsewhere in the molecule. There is no rearrangement of the R group itself, and this reaction is a step in the hydroboration method of converting alkenes to alcohols (Reaction **15-16**). The mechanism has been formulated as involving initial formation of an ate complex when the hydroperoxide anion attacks the electrophilic boron atom. Subsequent rearrangement from boron to oxygen,[465] as shown, leads to the B—O—R unit.

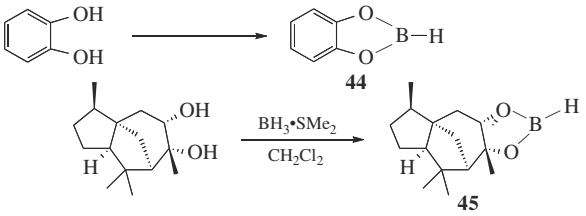
Similar migration of the other two R groups and hydrolysis of the B—O bonds leads to the alcohol and boric acid. Retention of configuration is observed in R. Boranes can also be oxidized to borates in good yields with oxygen,[466] with sodium perborate ($NaBO_3$)[467] and with trimethylamine oxide, either anhydrous[468] or in the form of the dihydrate.[469] The reaction with oxygen is free radical in nature.[470]

OS **V**, 918; **VI**, 719, 852, 919.

12-28 Preparation of Borates and Boronic Acids

$$\text{R-M} \longrightarrow \text{R-B(OH)}_2$$

$$\text{Ar-M} \longrightarrow \text{Ar-B(OH)}_2$$



$$\text{R-OH} + \text{BX}_3 \quad \text{or} \quad \text{B(OH)}_3 \longrightarrow \text{B(OR)}_3$$

Alkylboronic and arylboronic acids [$RB(OH)_2$, and $ArB(OH)_2$], respectively, are increasingly important in organic chemistry. The Pd catalyzed coupling reaction of aryl halides and aryl triflates with arylboronic acids (the *Suzuki–Miyaura reaction*, **13-12**) is probably the most notable example. A simple synthesis involves the reaction of a *Grignard reagent* (e.g., phenylmagnesium bromide) with an alkyl borate to give phenylboronic acid.[471] Alkylboronic acids are similarly prepared.[472] Note that boronic acids are subject to cyclic trimerization with loss of water to form boroxines. Tetrahydroxydiboron has been used to prepare allylboronic acids, as well as potassium trifluoro(allyl)borates.[473]

Trimethylborate [$B(OMe)_3$] can be used in place of tri-*n*-butyl borate.[474] Newer methods involve the Pd mediated borylation of alcohols with bis(pinacolato)diboron[475] or pinacolborane,[476] but deprotection of the boronate esters can be a problem. Diolboranes (e.g., catecholborane **44**)[477] are prepared by the reaction of a diol with borane.

Cedranediolborane (**45**, prepared from the cedrane-8,9-diol[478] by treatment with borane•dimethyl sulfide) can be coupled to aryl iodides with a palladium catalyst, and generates the free boronic acid by treatment with diethanolamine and then aq acid.[479] Boronate esters are often prepared as a means to purify the organoboron species, but some of these esters are hydrolytically unstable and difficult to deal with upon completion of the reaction.[480]

Alkeneboronic esters and acids are also readily available, as in the addition of vinylmagnesium chloride[481] to trimethyl borate below −50 °C, followed by hydrolysis.[482] A nonaqueous workup procedure has been reported for the preparation of arylboronic esters [ArB(OR′$_2$)].[483] Uncontrollable polymerization or oxidation of much of the boronic acid occurred during the final stages of the isolation procedure, but could be avoided by *in situ* conversion to the dibutyl ester by adding the crude product to 1-butanol. The Sm(III) catalyzed hydroboration of olefins with catecholborane is a good synthesis of boronate esters.[484]

Trialkyl borates (sometimes called orthoborates) can be prepared by heating the appropriate alcohol with boron trichloride in a sealed tube, but the procedure works well only for relatively simple alkyl groups.[485] Heating alcohols with boron trioxide (B_2O_3) in an autoclave at 110–170 °C give the trialkyl borate.[486] Boric acid can be used for the preparation of orthoborates[487] by heating with alcohols in the presence of either hydrogen chloride or concentrated sulfuric acid. Removal of water as an azeotrope with excess alcohol improves the yield,[488] and good yields can be obtained. for trialkyl borates[489] and even for triphenyl borate.[490] This method is unsuccessful for those borates whose parent alcohols do not form azeotropes with water and for the tertiary alkyl borates,[489] impure samples are usually obtained.[491]

Potassium organotrifluoroborates (RBF_3K) are readily prepared by the addition of inexpensive KHF_2 to a variety of organoboron intermediates.[492] They are monomeric, crystalline solids that are readily isolated and indefinitely stable in the air. These reagents can be used in several of the applications where boronic acids or esters are used (Reactions **13-10–13-13**).[493] Note that vinylboronic acid and even vinylboronate esters are unstable to polymerization,[494] whereas the analogous vinyltrifluoroborate is readily synthesized and completely stable.[495]

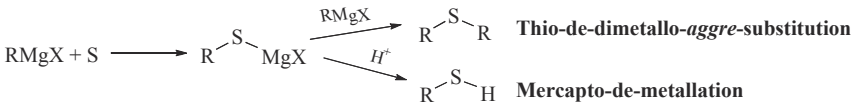
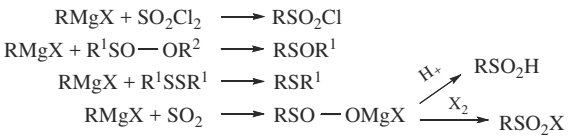
12-29 Oxygenation of Organometallic Reagents and Other Substrates to O-Esters and Related Compounds



$$R-M \longrightarrow R-OOCR' \qquad R-Y \longrightarrow R-OOCR'$$

In some cases, it is possible to oxygenate a nonaromatic carbon atom using various reagents, where the product is an *O*- ester rather than an alcohol. In one example, a vinyl iodonium salt was heated with DMF to produce the corresponding formate ester.[496]



C. Sulfur Electrophiles

12-30 Conversion of Organometallic Reagents to Sulfur Compounds

Thiols and sulfides are occasionally prepared by treatment of *Grignard reagents* with sulfur.[497] Analogous reactions are known for selenium and tellurium compounds. *Grignard reagents* and other

organometallic compounds[498] react with sulfuryl chloride to give sulfonyl chlorides,[499] with esters of sulfinic acids to give (stereospecifically) sulfoxides,[500] with disulfides to give sulfides,[501] and with SO_2 to give sulfinic acid salts,[502] which can be hydrolyzed to sulfinic acids or treated with halogens to give sulfonyl halides.[503]

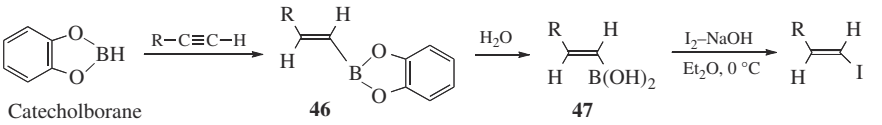
OS **III**, 771; **IV**, 667; **VI**, 533, 979.

D. Halogen Electrophiles

12-31 Halo-de-metalation

$$RMgX + I_2 \longrightarrow RI + MgIX$$

Grignard reagents react with halogens to give alkyl halides. The reaction is useful for the preparation of iodo compounds from the corresponding chloro or bromo compounds. The reaction is not useful for preparing chlorides, since the reagents RMgBr and RMgI react with Cl_2 to give mostly RBr and RI, respectively.[504]



Most organometallic compounds, both alkyl and aryl, also react with halogens to give alkyl or aryl halides.[505] The reaction can be used to convert acetylide ions to 1-haloalkynes.[506] Vinyliodonium tetrafluoroborates were converted to vinyl fluorides by heating.[507] Similarly, vinyl trifluoroborates were converted to the vinyl iodide with NaI and chloramine-T in aq THF.[508] The reaction of an alkene with $CuO{\cdot}BF_4$, iodine and triethylsilane gave the 2-iodoalkane.[509] Vinylzirconate reagents react with I_2 to give the corresponding vinyl iodide.[510]

Enolate anions can be converted to the corresponding vinyl phosphate, and subsequent reaction with triphenylphosphine dihalide leads to the vinyl halide.[511]

Trialkylboranes react rapidly with I_2[512] or Br_2[513] in the presence of NaOMe in methanol, or with $FeCl_3$ or other reagents[514] to give alkyl iodides, bromides, or chlorides,

respectively. Combined with the hydroboration reaction (Reaction **15-16**), this is an indirect way of adding HBr, HI, or HCl to a double bond to give products with an *anti-Markovnikov* orientation (see Reaction **15-1**). Trialkylboranes can also be converted to alkyl iodides by treatment with allyl iodide and air in a free radical process.[515] *trans*-1-Alkenylboronic acids (**47**), prepared by hydroboration of terminal alkynes with catecholborane to give **46**[516] (Reaction **15-16**), followed by hydrolysis, react with I_2 in the presence of NaOH at 0 °C in ethereal solvents to give *trans*-vinylic iodides.[517]

Treatment with ICl also gives the vinyl iodide.[518] This is an indirect way of accomplishing the *anti-Markovnikov* addition of HI to a terminal triple bond. The reaction cannot be applied to alkenylboronic acids prepared from internal alkynes. However, alkenylboronic acids prepared from both internal and terminal alkynes react with Br_2 (2 molar equivalents of Br_2 must be used) followed by base to give the corresponding vinylic bromide, but in this case with *inversion* of configuration; so the product is the *cis*-vinylic bromide.[519] Alkenylboronic acids also give vinylic bromides and iodides when treated with a mild oxidizing agent and NaBr or NaI, respectively.[520] Treatment of **47** (prepared from terminal alkynes) with Cl_2 gave vinylic chlorides with inversion.[521] Vinylic boranes can be converted to the corresponding vinylic halide by treatment with NCS or NBS.[522] Vinylic halides can also be prepared from vinylic silanes[523] and from vinylic copper reagents. The latter react with I_2 to give iodides,[524] and with NCS or NBS at −45 °C to give chlorides or bromides.[525] The reaction of an aryl alkyne with $HInCl_2/BEt_3$ and then iodine leads to a (*Z*)-vinyl iodide with respect to the aryl group and the iodine atom.[526] Boronic acids can be fluorinated in a reaction mediated by Ag(I) triflate.[527]

For the reaction of lithium enolate anions of esters with I_2 or CX_4, see Reaction **12-5**.

The conversion of terminal alkynes to 1-iodo-1-alkynes was reported using NaI under electrochemical conditions.[528] 1-Bromo-1-alkynes were converted to the 1-iodo-1-alkyne

with CuI.[529] 1-Trialkyldisilylalkynes were converted to the corresponding 1-bromoalkyne via reaction with NBS and AgF.[530] Terminal alkynes react with (diacetoxyiodo)benzene, KI, and CuI to give 1-iodo-alkynes.[531] Trichloroisocyanuric acid has been used to convert terminal alkynes to 1-chloroalkynes.[532]

It is unlikely that a single mechanism suffices to cover all conversions of organometallic compounds to alkyl halides.[533] In a number of cases, the reaction has been shown to involve inversion of configuration (see Sec. 12.A.i), indicating an S_E2 (back) mechanism, while in other cases retention of configuration has been shown,[534] implicating an S_E2 (front) or S_Ei mechanism. In still other cases, complete loss of configuration as well as other evidence demonstrated the presence of a free radical mechanism.[534,535]

E. Nitrogen Electrophiles

12-32 The Conversion of Organometallic Compounds to Amines

Amino-de-metalation

$$RLi \xrightarrow[MeLi]{MeONH_2} RNH_2$$

There are several methods for conversion of alkyl- or aryllithium compounds to primary amines.[536] The two most important are treatment with hydroxylamine derivatives and with certain azides.[537] In the first of these methods, treatment of RLi with methoxyamine and MeLi in ether at $-78\,^{\circ}C$ gives RNH_2.[538] *Grignard reagents* from aliphatic halides give lower yields. The reaction can be extended to give secondary amines by the use of *N*-substituted methoxyamines (CH_3ONHR').[539] There is evidence[540] that the mechanism involves the direct displacement of OCH_3 by R on an intermediate $CH_2ONR'^-$ ($CH_2ONR'^-Li^+ + RLi \rightarrow CH_3OLi + RNR'^-Li^+$). Tosyl azide ($TsN_3$) is a highly useful azide.[541] The initial product is usually RN_3, but this is easily reduced to the amine (Reaction **19-51**). With some azides (e.g., azidomethyl phenyl sulfide, $PhSCH_2N_3$), the group attached to the N_3 is a poor leaving group, so the initial

product is a triazene (in this case ArNHN=NCH_2SPh from ArMgX), which can be hydrolyzed to the amine.[542]

$$R_3B \xrightarrow{NH_3-NaOCl} 2\,RNH_2 + RB(OH)_2$$

Organoboranes react with a mixture of aq NH_3 and NaOCl to produce primary amines.[543] It is likely that the actual reagent is chloramine (NH_2Cl). Chloramine itself,[544] hydroxylamine-*O*-sulfonic acid in diglyme,[545] and trimethylsilyl azide[546] also give the reaction. Since the boranes can be prepared by the hydroboration of alkenes (Reaction **15-16**), this is an indirect method for the addition of NH_3 to a double bond with *anti-Markovnikov* orientation. Secondary amines can be prepared[547] by the treatment of alkyl- or aryldichloroboranes or dialkylchloroboranes with alkyl or aryl azides.

$$RBCl_2 + R'N_3 \longrightarrow RR'NBCl_2 \xrightarrow[^-HO]{H_2O} RNHR'$$

$$R_2BCl + R'N_3 \xrightarrow[2.\ H_2O]{1.\ Et_2O} RNHR'$$

The use of an optically active R*BCl_2 gave secondary amines of essentially 100% optical purity.[548] Aryllead triacetates [$ArPb(OAc)_3$] give secondary amines (ArNHAr′) when treated with primary aromatic amines $Ar'NH_2$ and $Cu(OAc)_2$.[549]

Secondary amines have been converted to tertiary amines by treatment with lithium dialkylcuprate reagents: $R_2CuLi + NHR \rightarrow RNR'_2$.[550] The reaction was also used to convert primary amines to secondary, but yields were lower.[551]

Terminal alkynes reacted with chlorodiphenylphosphine (Ph_3PCl) and a Ni catalyst to give the 1-diphenylphosphino alkyne (R-C≡C-PPh_2).[552] Alkynyl halides can be used for a similar reaction. Treatment of methyl carbamates with KHMDS and CuI, followed by 2 equiv of 1-bromophenylacetylene gave the *N*-substituted alkyne, Ph-C≡C-N(CO_2Me)R.[553]

Metal-catalyzed amination reactions are increasingly important in organic methodology. In a typical reaction, an amine is coupled to an alkyl, vinyl, or aryl halide (or with a different leaving group) in the presence of a transition metal, usually Pd. Presumably, the amination occurs via reaction with a transient organometallic species. Amination of aromatic compounds via this approach is discussed in section Reaction **13-5**. Aliphatic

and vinyl substrates are treated here. In one example, a vinyl triflate is converted to an enamine via reaction with pyrrole in the presence of a Pd catalyst.[554]

OS **VI**, 943.

F. Carbon Electrophiles

12-33 The Conversion of Organometallic Compounds to Ketones, Aldehydes, Carboxylic Esters, or Amides

Acyl-de-metalation, and so on

Symmetrical ketones[555] can be prepared in good yields by the reaction of organomercuric halides[556] with dicobalt octacarbonyl in THF,[557] or with nickel carbonyl in DMF or certain other solvents.[558] The R group may be aryl or alkyl. However, when R is alkyl, rearrangements may intervene in the $CO_2(CO)_8$ reaction, although the $Ni(CO)_4$ reaction seems to be free from such rearrangements.[559] Divinylic ketones (useful in the *Nazarov cyclization*, **15-20**) have been prepared in high yields by treatment of vinylic mercuric halides with CO and a Rh catalyst.[559] In a more general synthesis of unsymmetrical ketones, tetraalkyltin compounds (R_4Sn) are treated with a halide R′X (R′ = aryl, vinylic, benzylic), CO, and a Pd complex catalyst.[560] Similar reactions use *Grignard reagents*, $Fe(CO)_5$, and an alkyl halide.[561]

Grignard reagents react with formic acid to give good yields of aldehydes. Two molar equivalents of RMgX are used; the first converts HCO_2H to $HCOO^-$, which reacts with the second equivalent to give RCHO.[562] Alkyllithium reagents and Grignard reagents react with CO to give symmetrical ketones.[563] An interesting variation reacts CO_2 with an organolithium, which is then treated with a different organolithium reagent to give the unsymmetrical ketone.[564] α,β-Unsaturated aldehydes can be prepared by treatment of vinylic silanes with dichloromethyl methyl ether and $TiCl_4$ at $-90\,^\circ C$.[565]

α,β-Unsaturated esters can be prepared by treating boronic esters (**27**) with CO, $PdCl_2$, and NaOAc in MeOH.[566] The synthesis of α,β-unsaturated esters has also been

accomplished by treatment of vinylic mercuric chlorides with CO at atmospheric pressure and a Pd catalyst in an alcohol as solvent, for example,[567]

Alkyl and aryl *Grignard reagents* can be converted to carboxylic esters with $Fe(CO)_5$ instead of CO.[568]

Amides have been prepared by the treatment of trialkyl or triarylboranes with CO and an imine, in the presence of catalytic amounts of cobalt carbonyl[569]:

In another method for the conversion RM → RCONR, *Grignard reagents* and organolithium compounds are treated with a formamide ($HCONR'_2$) to give the intermediate $RCH(OM)NR'_2$, which is not isolated, but treated with PhCHO or Ph_2CO to give the product $RCONR'_2$.[570]

Direct conversion of a hydrocarbon to an aldehyde (R—H → R—CHO) was reported by treatment of the hydrocarbon with $GaCl_3$ and CO.[571]

For carbonylation reactions of aryl halides, see Reaction **13-15**.

OS **VIII**, 97.

12-34 Cyano-de-metalation

$$\text{R-M} + \text{CuCN} \longrightarrow \text{R-CN}$$

Vinylic copper reagents react with ClCN to give vinyl cyanides, although BrCN and ICN give the vinylic halide instead.[572] Vinylic cyanides have also been prepared by the reaction between vinylic lithium compounds and phenyl cyanate (PhOCN).[573] Alkyl nitriles (RCN) have been prepared, in varying yields, by treatment of sodium trialkylcyanoborates with NaCN and lead tetraacetate.[574] Vinyl bromides reacted with KCN, in the presence of a Ni complex and Zn metal to give the vinyl nitrile.[575] Vinyl triflates react with LiCN, in the presence of a Pd catalyst, to give the vinyl nitrile.[576]

OS IX, 548

G. Metal Electrophiles

12-35 Transmetalation with a Metal

Metalo-de-metalation

$$RM + M' \rightleftharpoons RM' + M$$

Many organometallic compounds are best prepared by this reaction, which involves replacement of a metal in an organometallic compound by another metal. The RM′ compound can be successfully prepared only when M′ is above M in the electromotive series, unless some other way is found to shift the equilibrium. That is, RM is usually an unreactive compound and M′ is a metal more active than M. Most often, RM is R_2Hg, since mercury alkyls[556] are easy to prepare and mercury is far down in the electromotive series.[577] Alkyls of Li, Na, K, Be, Mg, Al, Ga, Zn, Cd, Te, Sn, and so on, have been prepared this way. An important advantage of this method over Reaction **12-38** is that it ensures that the organometallic compound will be prepared free of any possible halide. This method can be used for the isolation of solid sodium and potassium alkyls.[578] If the metals lie too close together in the series, it may not be possible to shift the equilibrium. For example, alkylbismuth compounds cannot be prepared in this way from alkylmercury compounds.

OS **V**, 1116.

12-36 *Transmetalation with a Metal Halide*

Metalo-de-metalation

$$RM + M'X \rightleftharpoons RM' + MX$$

In contrast to Reaction **12-35**, the reaction between an organometallic compound and a metal *halide* is successful only when M′ is *below* M in the electromotive series.[579] The two reactions considered together therefore constitute a powerful tool for preparing all kinds of organometallic compounds. In this reaction, the most common substrates are *Grignard reagents* and organolithium compounds.[580]

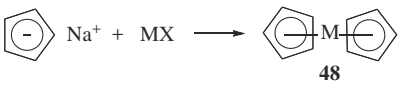
Also see, Schlosser, M. *Angew. Chem. Int. Ed.* ***1964****, 3*, 287, 362; *Newer Methods Prep. Org. Chem.* ***1968****, 5,* 238.

[580] See Wakefield, B.J. *Organolithium Methods,* Academic Press, NY, ***1988***; Wakefield, B.J. *The Chemistry of Organolithium Compounds*, Pergamon, Elmsford, NY, ***1974***.

The MgX of *Grignard reagents*[581] can migrate to terminal positions in the presence of small amounts of $TiCl_4$.[582] The proposed mechanism consists of metal exchange (Reaction **12-36**), elimination–addition, and metal exchange:

The addition step is similar to Reactions **15-16** or **15-17** and follows *Markovnikov's* rule, so the positive titanium goes to the terminal carbon.

Among others, alkyls of Be, Zn,[583] Cd, Hg, Al, Sn, Pb, Co, Pt, and Au have been prepared by treatment of *Grignard reagents* with the appropriate halide.[584] The reaction has been used to prepare alkyls of almost all nontransition metals and even of some transition metals. Alkyls of metalloids and of nonmetals, including Si, B,[585] Ge, P, As, Sb, and Bi, can also be prepared in this manner.[586] Except for alkali-metal alkyls and *Grignard reagents*, the reaction between RM and M′X is the most common method for the preparation of organometallic compounds.[587] In the presence of Ir,[588] or Pd catalysts,[589] aromatic compunds react with boranes to give the corresponding arylborane.



Lithium dialkylcopper reagents are prepared from 2 molar equivalents of RLi with 1 molar equivalent of a cuprous halide in ether at low temperatures:[590] The formation of organocuprates of this type are discussed in more detail in Reaction **10-58**, in connection with the coupling reaction of organocuprates with alkyl halides.

$$2\,RLi + CuX \longrightarrow R_2CuLi + LiX$$

Another way is to dissolve an alkylcopper compound in an alkyllithium solution. Higher order cuprates can also be prepared, as well as "non-ate" copper reagents.[591]

Metallocenes (**48**, see Sec. 2.I.ii) are usually made by this method. Among others, metallocenes of Sc, Ti, V, Cr, Mn, Fe, Co, and Ni have been prepared in this manner.[592]

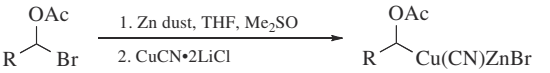
12-37 Transmetalation with an Organometallic Compound

Metalo-de-metalation

$$RM + R'M' \rightleftharpoons RM' + R'M$$

This type of metallic exchange is used much less often than Reactions **12-35** and **12-36**. It is an equilibrium reaction and is useful only if the equilibrium lies in the desired direction. Usually the goal is to prepare a lithium compound that is not prepared easily in other ways,[594] for example, a vinylic or an allylic lithium, most commonly from an organotin substrate. Examples are the preparation of vinyllithium from phenyllithium and tetravinyltin and the formation of α-dialkylamino organolithium compounds from the corresponding organotin compounds[595]

$$RR'NCH_2SnBu_3 + BuLi \xrightarrow{0\,^\circ C} RR'NCH_2Li + Bu_4Sn$$



The reaction has also been used to prepare 1,3-dilithiopropanes[596] and 1,1-dilithiomethylenecyclohexane[597] from the corresponding mercury compounds. In general, the equilibrium lies in the direction in which the more electropositive metal is bonded to that alkyl or aryl group that is the more stable carbanion (Sec. 5.B.i). The reaction proceeds with retention of configuration;[598] an S_Ei mechanism is likely.[599]

"Higher order" cuprates[600] (see Reaction **10-58**) have been produced by this reaction starting with a vinylic tin compound:[601]

$$RSnR_3' + Me_2Cu(CN)Li_2 \longrightarrow RCuMe(CN)Li_2 + MeSnR_{3-}{}' \qquad R = \text{A vinylic group}$$

These compounds are not isolated, but used directly *in situ* for conjugate addition reactions (Reaction **15-25**). Another method for the preparation of such reagents (but with Zn instead of Li) allows them to be made from α-acetoxy halides:[602]

OS **V**, 452; **VI**, 815; **VIII**, 97.

12.C.iii. Halogen as Leaving Group

The reduction of alkyl halides can proceed by an electrophilic substitution mechanism, but it is considered in Chapter 19 (Reaction **19-53**).

12-38 Metalo-de-halogenation

$$RX + M \longrightarrow RM$$

Alkyl halides react directly with certain metals to give organometallic compounds.[603] The most common metal is Mg, and of course this is by far the most common method for the preparation of *Grignard reagents*.[604] The *Grignard reaction* with aldehydes or ketones is discussed in Reaction **16-24**. The order of halide activity is I > Br > Cl. This reaction can be applied to many alkyl halides primary, secondary, and tertiary and to aryl halides, although aryl *chlorides* require the use of THF or another higher-boiling solvent instead of the usual ether, or special entrainment methods.[605] Aryl iodides and bromides can be treated in the usual manner. Allylic *Grignard reagents* can also be prepared in the usual manner (or in THF),[606] although in the presence of excess halide these may give *Wurtz-type coupling* products (see Reaction **10-56**).[607] Like aryl chlorides, vinylic halides require higher-boiling solvents (see OS **IV**, 258). A good procedure for benzylic and allylic halides is to use magnesium anthracene (prepared from Mg and anthracene in THF)[608] instead of ordinary magnesium,[609] although activated magnesium turnings have also been used.[610] Alkynyl *Grignard reagents* are generally prepared by the method in Reaction **12-22**.

Dihalides[611] can be converted to *Grignard reagents* if the halogens are different and are at least three carbons apart. If the halogens are the same, it is possible to obtain

dimagnesium compounds [e.g., $BrMg(CH_2)_4MgBr$].[612] 1,2-Dihalides give elimination[613] rather than *Grignard reagent* formation (Reaction **17-22**), and the reaction is seldom successful with 1,1-dihalides, although the preparation of *gem*-disubstituted compounds [e.g., $CH_2(MgBr)_2$], has been accomplished with these substrates.[614] α-Halo Grignard reagents and α-halolithium reagents can be prepared by the method given in Reaction **12-39**.[615] Alkylmagnesium fluorides can be prepared by refluxing alkyl fluorides with Mg in the presence of appropriate catalysts (e.g., I_2 or EtBr) in THF for several days.[616] Nitrogen-containing *Grignard reagents* have been prepared.[617]

The presence of other functional groups in the halide usually affects the preparation of the *Grignard reagent*. Groups that contain active hydrogen (defined as any hydrogen that will react with a *Grignard reagent*, e.g., OH, NH_2, and CO_2H), can be present in the molecule, but only if they are converted to the salt form (O^-, NH^-, COO^-, respectively). Groups that react with *Grignard reagents* (e.g., C=O, C≡N, NO_2, CO_2R) inhibit *Grignard* formation entirely. In general, the only functional groups that may be present in the halide molecule without any interference at all are double and triple bonds (except terminal triple bonds) and OR and NR_2 groups. However, β-halo ethers generally give β elimination when treated with Mg (see Reaction **17-24**), and *Grignard reagents* from α-halo ethers[618] can only be formed in THF or dimethoxymethane at a low temperature, for example,[619]

$$EtOCH_2Cl + Mg \xrightarrow[-30\ ^\circ C]{THF\ or\ CH_2(OMe)_2} EtOCH_2MgCl$$

because such reagents immediately undergo α elimination (see Reaction **12-39**) at room temperature in ether solution.

Because *Grignard reagents* react with water (Reaction **12-24**) and with oxygen (Reaction **12-25**), it is generally best to prepare them in an anhydrous nitrogen atmosphere. *Grignard reagents* are generally neither isolated nor stored; solutions of *Grignard reagents* are used directly for the required synthesis. *Grignard reagents* can also be prepared in benzene or toluene, if a tertiary amine is added to complex with the RMgX.[620] This method eliminates the need for an ether solvent. With certain primary alkyl halides it is even possible to prepare alkylmagnesium compounds in hydrocarbon solvents in the absence of an organic base.[621] It is also possible to obtain *Grignard reagents* in powdered form, by complexing them with the chelating agent tris(3,6-dioxaheptyl)amine [$N(CH_2CH_2OCH_2CH_2OCH_3)_3$].[622]

Next to the formation of *Grignard reagents*, the most important application of this reaction is the conversion of alkyl and aryl halides to organolithium compounds,[623] but it has also been carried out with many other metals (e.g., Na, Be, Zn, Hg, As, Sb, and Sn). With Na, the *Wurtz Reaction* (**10-56**) is an important side reaction. In some cases, where the reaction between a halide and a metal is too slow, an alloy of the metal with K or Na can be used instead. The most important example is the preparation of tetraethyl-lead from ethyl bromide and a Pb—Na alloy.

The efficiency of the reaction can often be improved by use of the metal in its powdered[624] or vapor[625] form. These techniques have permitted the preparation of some organometallic compounds that cannot be prepared by the standard procedures. Among the metals produced in an activated form are Mg,[626] Ca,[627] Zn,[628] Al, Sn, Cd,[629] Ni, Fe, Ti, Cu,[630] Pd, and Pt.[631]

The mechanism of *Grignard reagent* formation involves free radicals,[632] and there is much evidence for this, from CIDNP[633] (Sec. 5.C.i) and from stereochemical, rate, and product studies.[634] Further evidence is that free radicals have been trapped,[635] and that experiments that studied the intrinsic reactivity of MeBr on a magnesium single-crystal surface showed that *Grignard reagent* formation does not take place by a single-step insertion mechanism.[636] The following SET mechanism has been proposed:[633]

$$\mathrm{R{-}X + Mg \longrightarrow R{-}X^{\bullet -} + Mg_s^{\bullet +}}$$

$$\mathrm{R{-}X^{\bullet -} \longrightarrow R^{\bullet} + X^{-}}$$

$$\mathrm{X^{-} + Mg_s^{\bullet +} \longrightarrow XMg_s^{\bullet}}$$

$$\mathrm{R^{\bullet} + X\mathit{M}^{\bullet}g_s \longrightarrow RMgX}$$

Other evidence has been offered to support a SET initiated radical process for the second step of this mechanism.[637] The species $R—X^{\bullet -}$ and $Mg^{\bullet +}$ are radical ions.[638] The subscript "s" is meant to indicate that the species so marked are bound to the surface of the magnesium. It is known that this is a surface reaction.[639] It has been suggested that some of the $R^{\bullet}$ radicals diffuse from the magnesium surface into the solution and then return to the surface to react with the $XMg^{\bullet}$. There is evidence both for[640] and against[641] this suggestion. Another proposal is that the fourth step is not the one shown here, but that the $R^{\bullet}$ is reduced by Mg^{+} to the carbanion R^{-}, which combines with MgX^{+} to give RMgX.[642]

There are too many preparations of *Grignard reagents* in *Organic Syntheses* for us to list here. Chiral *Grignard reagents* are rare, since they are configurationally unstable in most cases. However, a few chiral *Grignard reagents* are known.[643] Use of the reaction to prepare other organometallic compounds can be found in OS **I**, 228; **II**, 184, 517, 607; **III**, 413, 757; **VI**, 240; **VII**, 346; **VIII**, 505. The preparation of unsolvated butylmagnesium bromide is described at OS **V**, 1141. The preparation of highly reactive (powdered) magnesium is given at OS **VI**, 845.

12-39 Replacement of a Halogen by a Metal from an Organometallic Compound

Metalo-de-halogenation

$$RX + R'M \longrightarrow RM + R'X$$

The exchange reaction between halides and organometallic compounds occurs most readily when M is Li and X is Br or I,[644] although it has been shown to occur with Mg.[645] The R′ group is usually, although not always, alkyl, and often butyl; R is usually aromatic.[646] Alkyl halides are generally not reactive enough, while allylic and benzylic halides usually give *Wurtz coupling*. Of course, the R that becomes bonded to the halogen is the one for which RH is the weaker acid. Despite the preponderance of reactions with bromides and iodides, it is noted that the reaction of 1-fluorooctane with 4–10 equiv of Li powder and 2–4 equiv of DTBB (4,4′-di-*tert*-butylbiphenyl) in THP (THP=tetrahydropyran) at 0 °C for 5 min, was shown to give a solution of the corresponding 1-octyllithium.[647] Vinylic halides

react with retention of configuration.[648] The reaction can be used to prepare α-halo organolithium and α-halo organomagnesium compounds[649] Carbon tetrachloride reacts with butyllithium to give lithiotrichloromethane ($Cl_3C—Li$), for example.[650] Such compounds can also be prepared by hydrogen–metal exchange, for example,[651]

$$Br_3CH + i\text{PrMgCl} \xrightarrow[-95\,^\circ C]{\text{THF–HMPA}} Br_3C—MgCl + C_3H_8$$

This is an example of Reaction **12-22**. However, these α-halo organometallic compounds are stable (and configurationally stable as well[652]) only at low temperatures (ca. -100 °C) and only in THF or mixtures of THF and other solvents (e.g., HMPA). At ordinary temperatures, they lose MX (α elimination) to give carbenes, which then react further, or carbenoid reactions. The α-chloro-α-magnesio sulfones [$ArSO_2CH(Cl)MgBr$] are exceptions, being stable in solution at room temperature and even under reflux.[653] Compounds in which a halogen and a transition metal are on the same carbon can be more stable than the ones with lithium.[654]

There is evidence that the mechanism[655] of the reaction of alkyllithium compounds with alkyl and aryl iodides involves free radicals.[656]

$$RX + R'M \rightleftharpoons \underset{\text{Solvent cage}}{[R^\bullet, X, M, R'^\bullet]} \rightleftharpoons RM + R'X$$

Among the evidence is the fact that coupling and disproportionation products are obtained from $R^\bullet$ and $R'^\bullet$ and the observation of CIDNP.[656,657] However, in the degenerate exchange between PhI and PhLi the ate complex $Ph_2I^-\ Li^+$ has been shown to be an intermediate,[658] and there is other evidence that radicals are not involved in all instances of this reaction.[659]

In a completely different kind of process, alkyl halides can be converted to certain organometallic compounds by treatment with organometalate ions, for example,

$$RX + R_3'SnLi \longrightarrow RSnR_3' + LiX$$

[648] For examples of exchange, R = vinylic, see Miller, R.B.; McGarvey, G. *Synth. Commun.* ***1979****, 9*, 831; Sugita, T.; Sakabe, Y.; Sasahara, T.; Tsukuda, M.; Ichikawa, K. *Bull. Chem. Soc. Jpn.* ***1984****, 57*, 2319.

Most of the evidence is in accord with a free radical mechanism involving electron transfer, although an S_N2 mechanism can compete under some conditions.[660] Electrochemically genrated zinc has been used to prepare organozinc bomide from the corresponding alkyl halide.[661]

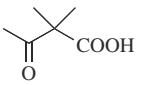
12.C.iv. Carbon Leaving Groups

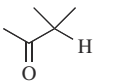
In these reactions (**12-40**–**12-48**), a carbon–carbon bond cleaves. The substrate is the side that retains the electron pair; hence the reactions are considered electrophilic substitutions. The incoming group is hydrogen in all but one (Reaction **12-42**) of the cases. The reactions in groups A and B are sometimes called *anionic cleavages*,[662] although they do not always occur by mechanisms involving free carbanions (S_E1). When they do, the reactions are facilitated by increasing stability of the carbanion.

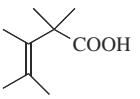
A. Carbonyl-Forming Cleavages These reactions follow the pattern:

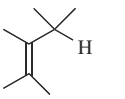
The leaving group is stabilized because the electron deficiency at its carbon is satisfied by a pair of electrons from the oxygen. With respect to the leaving group the reaction is elimination to form a C=O bond. Retrograde aldol reactions (**16-34**) and cleavage of cyanohydrins (**16-52**) belong to this classification but are treated in Chapter 16 under their more important reverse reactions. Other eliminations to form C=O bonds are discussed in Reaction **17-32**.

12-40 Decarboxylation of Aliphatic Acids









Hydro-de-carboxylation

$$RCOOH \longrightarrow RH + CO_2$$

Many carboxylic acids can be successfully decarboxylated, either as the free acid or in the salt form, but not simple aliphatic acids.[663] An exception is acetic acid, which as the acetate, heated with base, gives good yields of methane. Malonic acid derivatives are the most common substrates for decarboxylation, giving the corresponding monocarboxylic acid. Decarboxylation of 2-substituted malonic acids has been reported using microwave irradiation.[664] Aliphatic acids that do undergo successful decarboxylation have certain functional groups or double or triple bonds in the α or β position. Some of these are shown in Table 12.2.

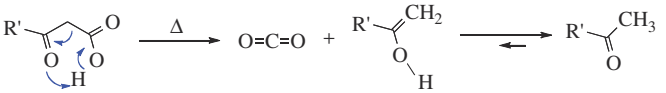
TABLE 12.2 Some Acids That Undergo Decarboxylation Fairly Readily[a]

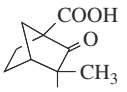
Acid Type	Decarboxylation Product
	
	
	
	
	
	
	

[a]Others are described in the text.

For decarboxylation of aromatic acids, see Reaction **11-35**. Decarboxylation of an α-cyano acid can give a nitrile or a carboxylic acid, since the cyano group may or may not be hydrolyzed in the course of the reaction. In addition to the compounds listed in Table 12.2, decarboxylation can be carried out on α,β-unsaturated[665] and α,β-acetylenic acids. Glycidic acids give aldehydes on decarboxylation. The following mechanism has been suggested:[666]



The direct product is an enol that tautomerizes to the aldehyde.[667] This is the usual last step in the *Darzens Reaction* (**16-40**).



Decarboxylations can be regarded as reversal of the addition of carbanions to carbon dioxide (Reaction **16-82**), but free carbanions are not always involved.[668] When the carboxylate *ion* is decarboxylated, the mechanism can be either S_E1 or S_E2. In the case of the S_E1 mechanism, the reaction is of course aided by the presence of electron-withdrawing

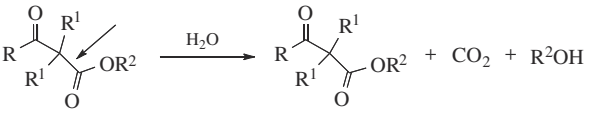
groups, which stabilize the carbanion.[669] Decarboxylation of carboxylate ions can be accelerated by the addition of a suitable crown ether, which in effect removes the metallic ion.[670] The reaction without the metallic ion has also been performed in the gas phase.[671] Some acids can also be decarboxylated directly and, in most of these cases, there is a cyclic, six-center mechanism:

Here too there is an enol that tautomerizes to the product. The mechanism is illustrated for the case of β-keto acids,[672] but it is likely that malonic, α-cyano, α-nitro, and β,γ-unsaturated acids[673] behave similarly, since similar six-membered transition states can be written for them. Some α,β-unsaturated acids



49

are also decarboxylated by this mechanism by isomerizing to the β,γ-isomers before they actually decarboxylate.[674] Evidence is that **49** and similar bicyclic β-keto acids resist decarboxylation.[675] In such compounds, the six-membered cyclic transition state cannot form for steric reasons,[676] and if it could, formation of the intermediate enol would violate *Bredt's rule* (Sec. 4.Q.iii).

Some carboxylic acids that cannot form a six-membered transition state can still be decarboxylated, and these presumably react through an S_E1 or S_E2 mechanism.[677] Further evidence for the cyclic mechanism is that the reaction rate varies very little with a change from a nonpolar to a polar solvent (even from benzene to water[678]), and is not subject to acid catalysis.[679] The rate of decarboxylation of a β,γ-unsaturated acid was increased $\sim 10^5$–10^6 times by introduction of a β-methoxy group, indicating that the cyclic transition state has dipolar character.[680] Rate constants for decarboxylation reactions have been calculated using no barrier theory.[681]

β-Keto acids[682] are easily decarboxylated, but such acids are usually prepared from β-keto esters, and the esters are easily decarboxylated themselves on hydrolysis without isolation of the acids.[683] This decarboxylation of β-keto esters involving cleavage on the carboxyl side of the substituted methylene group (arrow) is carried out under acidic, neutral, or slightly basic conditions to yield a ketone. When strongly basic conditions are used, cleavage occurs on the other side of the CR_2 group (Reaction **12-43**). β-Keto esters can be decarbalkoxylated without passing through the free-acid stage by treatment with boric anhydride (B_2O_3) at 150 °C.[684] The alkyl portion of the ester (R′) is converted to an alkene or, if it lacks a β hydrogen, to an ether (R′OR′). Another method for the decarbalkoxylation of β-keto esters, malonic esters, and α-cyano esters consists of heating the substrate in wet DMSO containing NaCl, Na_3PO_4, or some other simple salt.[685] In this method too, the free acid is probably not an intermediate, but here the alkyl portion of the substrate is converted to the corresponding alcohol. α-Amino acids have been decarboxylated by treatment with a catalytic amount of 2-cyclohexenone.[686] Amino acids are decarboxylated by sequential treatment with NBS at pH 5 followed by $NaBH_4$ and $NiCl_2$.[687] Certain decarboxylations can also be accomplished photochemically.[688] See also, the decarbonylation of acyl halides, mentioned in Reaction **14-32**. In some cases, decarboxylations can give organometallic compounds: $RCOOM \rightarrow RM + CO_2$.[689] The Cu catalyzed decarboxylation of 2-alkynoic acids to terminal alkynes has been reported.[690]

Decarboxylative alkylation and arylation reactions are known. In the presence of a Ru catalyst and a B-phenyl borinate, decarboxylation of proline esters leads to 2-phenylpyrrolidine derivatives.[691] In the presence of a Pd catalyst, esters undergo decarboxylation with coupling between the alkyl groups on the carbonyl and the ester oxygen to give the corresponding hydrocarbon fragment.[692]

Some of the decarboxylations listed in *Organic Syntheses* are performed with concomitant ester or nitrile hydrolysis and others are simple decarboxylations.

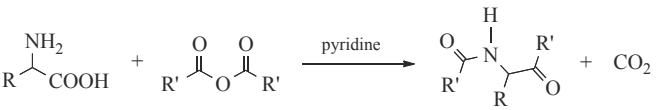
12-41 Cleavage of Alkoxides

Hydro-de-(α-oxidoalkyl)-substitution



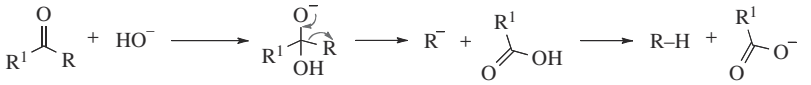
Alkoxides of tertiary alcohols can be cleaved in a reaction that is essentially the reverse of addition of carbanions to ketones (Reaction **16-24**).[693] The reaction is unsuccessful when the R groups are simple unbranched alkyl groups (e.g., the alkoxide of triethylcarbinol). Cleavage is accomplished with branched alkoxides (e.g., the alkoxides of diisopropylneopentylcarbinol or tri-*tert*-butylcarbinol).[694] Allylic,[695] benzylic,[696] and aryl groups also cleave (e.g., the alkoxide of triphenylcarbinol gives benzene and benzophenone). Studies in the gas phase show that the cleavage is a simple one, giving the carbanion and ketone directly in one step.[697] However, with some substrates in solution, substantial amounts of dimer R—R have been found, indicating a radical pathway.[698] Hindered alcohols (not the alkoxides) also lose one R group by cleavage, also by a radical pathway.[699] The so-called retro-aldol (see Reaction **16-34**) is another example.

The reaction has been used for extensive mechanistic studies (see Sec. 12.A.ii).

OS **VI**, 268.

12-42 Replacement of a Carboxyl Group by an Acyl Group

Acyl-de-carboxylation



When an α-amino acid is treated with an anhydride in the presence of pyridine, the carboxyl group is replaced by an acyl group and the NH_2 becomes acylated. This is called the *Dakin–West reaction*.[700] The mechanism involves formation of an oxazolone.[701] The reaction sometimes takes place on carboxylic acids even when an a amino group is not present. A number of *N*-substituted amino acids [RCH(NHR′)COOH] give the corresponding N-alkylated products.

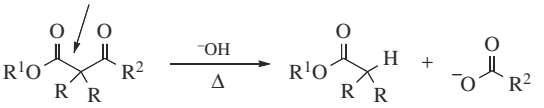
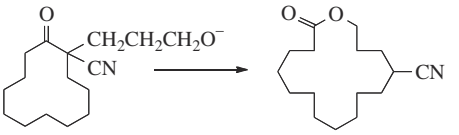
B. Acyl Cleavages



In these reactions (**12-43**–**2-46**), a carbonyl group is attacked by a hydroxide ion (or an amide ion), giving an intermediate that undergoes cleavage to a carboxylic acid (or an amide). With respect to the leaving group, this is nucleophilic substitution at a carbonyl group and the mechanism is the tetrahedral one discussed in Section 16.A.i.

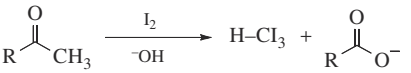


With respect to R this is of course electrophilic substitution. The mechanism is usually S_E1.

12-43 Basic Cleavage of β-Keto Esters and β-Diketones

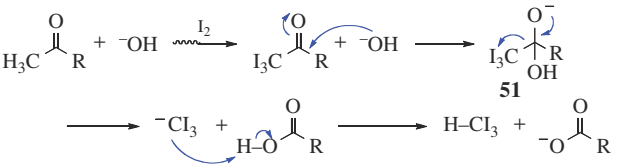
Hydro-de-acylation

When β-keto esters are treated with concentrated base, cleavage occurs, but on the keto side of the CR_2 group (arrow) in contrast to the acid cleavage mentioned in Reaction **12-40**. The products are a carboxylic ester and the salt of an acid. However, the utility of the reaction is somewhat limited by the fact that decarboxylation is a side reaction, even under basic conditions. β-Diketones behave similarly to give a ketone and the salt of a carboxylic acid. With both β-keto esters and β-diketones, $^-$OEt can be used instead of $^-$OH, in which case the ethyl esters of the corresponding acids are obtained instead of the salts. In the case of β-keto esters, this is the reverse of *Claisen condensation* (Reaction **16-85**). The related cleavage of cyclic α-cyano ketones, in an intramolecular fashion, has been used in a synthesis of macrocyclic lactones (e.g., **50**).[702]



50

Activated F^- (from KF and a crown ether) has been used as the base to cleave an α-cyano ketone.[703] Treatment with ceric ammonium nitrate led to cleavage of β-diketones to give a carboxylic acid.[704]

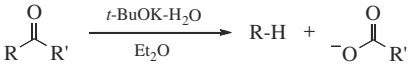


OS **II**, 266, 531; **III**, 379; **IV**, 415, 957; **V**, 179, 187, 277, 533, 747, 767.

12-44 Haloform Reaction

[702] Milenkov, B.; Hesse, M. *Helv. Chim. Acta* ***1987****, 70*, 308. For a similar preparation of lactams, see Wälchli, R.; Bienz, S.; Hesse, M. *Helv. Chim. Acta* ***1985****, 68,* 484.
[703] Beletskaya, I.P.; Gulyukina, N.S.; Borodkin, V.S.; Solov'yanov, A.A.; Reutov, O.A. *Doklad. Chem.* ***1984****, 276*, 202. See also, Mignani, G.; Morel, D.; Grass, F. *Tetrahedron Lett.* ***1987****, 28,* 5505.
[704] Zhang, Y.; Jiao, J.; Flowers II, R.A. *J. Org. Chem.* ***2006****, 71,* 4516.

In the *haloform reaction*, methyl ketones (and the only methyl aldehyde, acetaldehyde) are cleaved with halogen and a base.[705] The halogen can be bromine, chlorine, or iodine. What takes place is actually a combination of two reactions. The first is an example of Reaction **12-4**, in which, under the basic conditions employed, the methyl group is trihalogenated. Then the resulting trihalo ketone is attacked by hydroxide ion to give tetrahedral intermediate (**51**).[706] The X_3C^- group is a sufficiently good leaving group (not HX_2C^- or H_2XC^-) that a carboxylic acid is formed, which quickly reacts with the carbanion to give the final products. Primary or secondary methylcarbinols also give the reaction, because they are oxidized to the carbonyl compounds under the conditions employed.



As with Reaction **12-4**, the rate-determining step is the preliminary enolization of the methyl ketone.[707] A side reaction is α halogenation of the non-methyl R group. Sometimes these groups are also cleaved.[708] The reaction cannot be applied to F_2, but ketones of the form $RCOCF_3$ (R = alkyl or aryl) give fluoroform and $RCOO^-$ when treated with base.[709] Rate constants for cleavage of X_3CCOPh (X = F, Cl, Br) were found to be in the ratio $1 : 5.3 \times 10^{10} : 2.2 \times 10^{13}$, showing that an F_3C^- group cleaves much more slowly than the others.[710] In the past, the haloform reaction was used as a test for methylcarbinols and methyl ketones. Iodine was most often used as the test reagent, since iodoform (HCI_3) is an easily identifiable yellow solid. The reaction can be used for synthetic purposes. Methyl ketones ($RCOCH_3$) can be converted directly to methyl esters (RCO_2CH_3) by an electrochemical reaction.[711] Trifluoromethyl ketones have been converted to ethyl esters via treatment with NaH in aq DMF followed by reaction with bromoethane.[712]

OS **I**, 526; **II**, 428; **III**, 302; **IV**, 345; **V**, 8. Also see, OS **VI**, 618.

12-45 Cleavage of Nonenolizable Ketones

Hydro-de-acylation

Ordinary ketones are generally much more difficult to cleave than trihalo ketones or β-diketones. However, nonenolizable ketones can be cleaved by treatment with a 10:3 mixture of *t*-BuOK—H_2O in an aprotic solvent [e.g., ether, DMSO, 1,2-dimethoxyethane

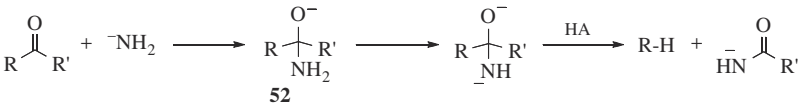
(glyme),[713] or with solid *t*-BuOK in the absence of a solvent].[714] When the reaction is applied to monosubstituted diaryl ketones, that aryl group preferentially cleaves that comes off as the more stable carbanion, except that aryl groups substituted in the ortho position are more readily cleaved than otherwise because of the steric effect (relief of strain).[714,715] In certain cases, cyclic ketones can be cleaved by base treatment, even if they are enolizable.[716]



OS **VI**, 625. See also, OS **VII**, 297.

12-46 The Haller–Bauer Reaction

Hydro-de-acylation

Cleavage of ketones with sodium amide is called the *Haller–Bauer reaction*.[717] As with Reaction **12-45**, which is exactly analogous, the reaction is usually applied only to non-enolizable ketones, most often to ketones of the form $ArCOCR_3$, where the products R_3CCONH_2 (after hydrolysis) are not easily attainable by other methods. However, many other ketones have been used, although benzophenone is virtually unaffected. It has been shown that the configuration of optically active alkyl groups (R) is retained.[718] The NH_2 loses its proton from the tetrahedral intermediate (**52**) before the R group is cleaved.[719]

52

An extension of this cleavage process involves the reaction of α-nitro ketones ($O{=}C{-}CHRNO_2$) with a primary amine, neat, to give the corresponding amide, $O{=}C{-}NHR'$.[720]

OS **V**, 384, 1074.

C. Other Cleavages

12-47 The Cleavage of Alkanes

Hydro-de- *tert-* butylation, and so on

The C—C bonds of alkanes can be cleaved by treatment with superacids (Sec. 5.A.ii). For example, neopentane in $FSO_3H{-}SbF_5$ can cleave to give methane and the *tert*-butyl cation. The C—H cleavage (see Reaction **12-1**) is a competing reaction and, for example,

[720] Ballini, R.; Bosica, G.; Fiorini, D. *Tetrahedron* ***2003****, 59*, 1143.

neopentane can give H_2 and the *tert*-pentyl carbocation (formed by rearrangement of the initially formed neopentyl cation) by this pathway. In general, the order of reactivity is tertiary C—H > C—C > secondary C—H ≫ primary C—H, although steric factors cause a shift in favor of C—C cleavage in such a hindered compound as tri-*tert*-butylmethane. The mechanism is similar to that shown in Reactions **12-1** and **12-20** and involves attack by H^+ on the C—C bond to give a pentavalent cation.

Catalytic hydrogenation seldom breaks unactivated C—C bonds (i.e., $R—R' + H_2 \rightarrow RH + R'H$), but methyl and ethyl groups have been cleaved from substituted adamantanes by hydrogenation with a Ni-Al_2O_3 catalyst at ~250 °C.[721] Certain C—C bonds have been cleaved by alkali metals.[722]

The C—C bond of 2-allyl-2-arylmalonate derivatives was cleaved, with loss of the allylic group to give the 2-arylmalonate, by treatment with a Ni catalyst.[723]

12-48 Decyanation or Hydro-de-cyanation

$$RCN \xrightarrow{Na—NH_3 \text{ or } Na—Fe(acac)_3} RH$$

The cyano group of alkyl nitriles can be removed[724] by treatment with metallic Na, either in liquid ammonia,[725] or together with tris(acetylacetonato)iron(III) [$Fe(acac)_3$][726] or, with lower yields, titanocene. The two procedures are complementary. Although both can be used to decyanate many kinds of nitriles, the Na—NH_3 method gives high yields with R groups (e.g., trityl, benzyl, phenyl, and tertiary alkyl), but lower yields (~35–50%) when R = primary or secondary alkyl. On the other hand, primary and secondary alkyl nitriles are decyanated in high yields by the Na—$Fe(acac)_3$ procedure. Sodium in liquid ammonia is known to be a source of solvated electrons, and the reaction may proceed through the free radical $R^\bullet$ that would then be reduced to the carbanion R^-, which by abstraction of a proton from the solvent, would give RH. The mechanism with $Fe(acac)_3$ is presumably different. Another procedure,[727] which is successful for R = primary, secondary, or tertiary, involves the use of potassium metal and the crown ether dicyclohexano-18-crown-6 in toluene.[728]

α-Amino and α-amido nitriles $RCH(CN)NR'_2$ and $RCH(CN)NHCOR'$ can be decyanated in high yield by treatment with $NaBH_4$.[729]

12.C.v. Electrophilic Substitution at Nitrogen

In most of the reactions in this section, an electrophile bonds with the unshared pair of a nitrogen atom. The electrophile may be a free positive ion or a positive species attached to a carrier that breaks off in the course of the attack or shortly after:

53

Further reaction of **53** depends on the nature of Y and of the other groups attached to the nitrogen.

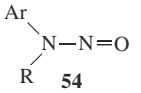
12-49 The Conversion of Hydrazines to Azides

Hydrazine-azide transformation

Monosubstituted hydrazines treated with nitrous acid give azides in a reaction exactly analogous to the formation of aliphatic diazo compounds mentioned in Reaction **13-19**. Among other reagents used for this conversion have been N_2O_4[730] and nitrosyl tetrafluoroborate ($NOBF_4$).[731]

OS **III**, 710; **IV**, 819; **V**, 157.

12-50 N-Nitrosation



***N*-Nitroso-de-hydrogenation**

When secondary amines are treated with nitrous acid (typically formed from sodium nitrite and a mineral acid),[732] *N*-nitroso compounds (also called nitrosamines) are formed.[733] The reaction can be accomplished with dialkyl-, diaryl-, or alkylarylamines, and even with mono-*N*-substituted amides: $RCONHR' + HONO \rightarrow RCON(NO)R'$.[734] Tertiary amines have also been *N*-nitrosated, but in these cases one group cleaves, so that the product is the nitroso derivative of a secondary amine.[735] The group that cleaves appears as an aldehyde or ketone product. Other reagents have also been used (e.g., NOCl), which is useful for amines or amides that are not soluble in an acidic aqueous solution or where the *N*-nitroso compounds are highly reactive. *N*-Nitroso compounds can be prepared in basic solution by treatment of secondary amines with gaseous N_2O_3, N_2O_4,[736] or alkyl

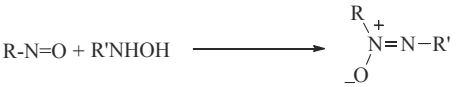
nitrites,[737] and, in aqueous or organic solvents, by treatment with $BrCH_2NO_2$.[738] Secondary amines are converted to the *N*-nitroso compound with H_5IO_6 on wet silica.[739]

54

The mechanism of nitrosation is essentially the same as in Reaction **13-19** up to the point where **54** is formed. Since this species cannot lose a proton, it is stable and the reaction ends there. The attacking entity can be any of those mentioned in Reaction **13-19**. The following has been suggested as the mechanism for the reaction with tertiary amines:[740]



The evidence for this mechanism includes the facts that nitrous oxide is a product (formed by $2HNO \rightarrow H_2O + N_2O$) and that quinuclidine, where the nitrogen is at a bridgehead and cannot give elimination, does not react. Tertiary amines have also been converted to nitrosamines with nitric acid in Ac_2O[741] and with N_2O_4.[742]

Amines and amides can be *N*-nitrated[743] with nitric acid,[744] or NO_2^+,[745] and aromatic amines can be converted to triazenes with diazonium salts. Aliphatic primary amines can also be converted to triazenes if the diazonium salts contain electron-withdrawing groups.[746] *C*-Nitrosation is discussed at Reactions **11-3** and **12-8**.

12-51 Conversion of Nitroso Compounds to Azoxy Compounds

In a reaction similar to **13-24**, azoxy compounds can be prepared by the condensation of a nitroso compound with a hydroxylamine.[747] The position of the oxygen in the final product is

determined by the nature of the R groups, not by which R groups came from which starting compound. Both R and R′ can be alkyl or aryl, but when two different aryl groups are involved, mixtures of azoxy compounds (ArNONAr, ArNONAr′, and Ar′NONAr′) are obtained[748] and the unsymmetrical product (ArNONAr′) is likely to be formed in the smallest amount. This behavior is probably caused by an equilibration between the starting compounds prior to the actual reaction ($ArNO + Ar'NHOH \rightarrow Ar'NO + ArNHOH$).[749] The mechanism[750] has been investigated in the presence of base. Under these conditions both reactants are converted to radical anions, which couple:

These radical anions have been detected by ESR.[751] This mechanism is consistent with the following result: When nitrosobenzene and phenylhydroxylamine are coupled, ^{18}O and ^{15}N labeling show that the two nitrogen atoms and the two oxygen atoms become equivalent.[752] Unsymmetrical azoxy compounds can be prepared[753] by combination of a nitroso compound with an *N,N*-dibromoamine. Symmetrical and unsymmetrical azo and azoxy compounds are produced when aromatic nitro compounds react with aryliminodimagnesium reagents [$ArN(MgBr)_2$].[754]

12-52 N-Halogenation

N-Halo-de-hydrogenation

$$RNH_2 + NaOCl \longrightarrow RNHCl$$

Treatment with sodium hypochlorite or hypobromite converts primary amines into *N*-halo- or *N,N*-dihaloamines. Secondary amines can be converted to *N*-halo secondary amines. Similar reactions can be carried out on unsubstituted and *N*-substituted amides and on sulfonamides. With unsubstituted amides the *N*-halogen product is seldom isolated but usually rearranges (see Reaction **18-13**); however, *N*-halo-*N*-alkyl amides and *N*-halo imides are quite stable. The important reagents NBS and NCS are made in this manner. *N*-Halogenation has also been accomplished with other reagents (e.g., sodium bromite, $NaBrO_2$),[755] benzyltrimethylammonium tribromide ($PhCH_2NMe_3{}^+Br_3{}^-$),[756] NaCl with Oxone,[757] and NCS.[758] Sodium hypohalite in the presence of *tert*-butanol and acetic acid is

an efficient method for the preparation of *N*-haloamines.[759] Amides are *N*-chlorinated with trichloroisocyanuric acid.[760] The mechanisms of these reactions[761] involve attack by a positive halogen and are probably similar to those of Reactions **13-19** and **12-50**.[762] *N*-Fluorination can be accomplished by direct treatment of amines[763] or amides[764] with F_2. Fluorination of *N*-alkyl-*N*-fluoroamides [RRN(F)COR′] results in cleavage to *N,N*-difluoroamines (RNF_2).[764,765] Trichloroisocyanuric acid converts primary amines to the *N,N*-dichloroamine.[766]

12-53 The Reaction of Amines With Carbon Monoxide or Carbon Dioxide

***N*-Formylation** or ***N*-Formyl-de-hydrogenation**, and so on

Three types of product can be obtained from the reaction of amines with CO, depending on the catalyst. (1) Both primary and secondary amines react with CO in the presence of various catalysts [e.g., $Cu(CN)_2$, Me_3N-H_2Se, and Rh or Ru complexes] to give *N*-substituted and *N,N*-disubstituted formamides, respectively.[767] Primary aromatic amines react with ammonium formate to give the formamide.[768] Tertiary amines react with CO and a Pd catalyst to give an amide.[769] (2) Symmetrically substituted ureas can be prepared by treatment of a primary amine (or ammonia) with CO[770] in the presence of Se[771] or S.[772] The R source can be alkyl or aryl. The same thing can be done with secondary amines, using $Pd(OAc)_2$—I_2—K_2CO_3.[773] Primary aromatic amines react with β-keto esters and a Mo—ZrO_2 catalyst to give the symmetrical urea.[774] Treatment of a secondary amine with nitrobenzene, selenium and carbon monoxide leads to the unsymmetrical urea.[775] (3) When $PdCl_2$ is the catalyst, primary amines yield isocyanates.[776] Isocyanates can also be obtained by treatment of CO with azides: $RN_3 + CO \rightarrow RNCO$,[777] or with an aromatic

nitroso or nitro compound and a Rh complex catalyst.[778] Primary amines react with di-*tert*-butyltricarbonate to give the isocyanate.[779]

Lactams are converted to the corresponding *N*-chloro lactam with $Ca(OCl)_2$ with moist alumina in dichloromethane.[780] Ring-expanded lactams are obtained from cyclic amines via a similar reaction[781] (see also, Reaction **16-22**). Intramolecular carbonylation of amines also leads to lactams.[782]

A fourth type of product, a carbamate ($RNHCOOR'$), can be obtained from primary or secondary amines, if these are treated with CO, O_2, and an alcohol ($R'OH$) in the presence of a catalyst.[783] Primary amines react with dimethyl carbonate in supercritical CO_2 (see Sec. 9.D.ii) to give a carbamate.[784] Carbamates can also be obtained from nitroso compounds, by treatment with CO, $R'OH$, $Pd(OAc)_2$, and $Cu(OAc)_2$,[785] and from nitro compounds.[786] When allylic amines ($R_2C{=}CHRCHRNR'_2$) are treated with CO and a Pd–phosphine catalyst, the CO inserts to produce the β,γ-unsaturated amides ($R_2C{=}CHRCHRCONR'_2$) in good yields.[787] Silyloxy carbamates ($RNHCO_2SiR'_3$) can be prepared by the reaction of a primary amine with carbon dioxide and triethylamine, followed by reaction with triisopropylsilyl triflate and tetrabutylammonium fluoride.[788]

Carbon dioxide reacts with amines ($ArNH_2$) and alkyl halides, under electrolysis conditions, to give the corresponding carbamate ($ArNHCO_2Et$).[789] Secondary amines react with all halides and an onium salt in supercritical CO_2 (see Sec. 9.D.ii) to give the carbamate.[790] *N*-Phenylthioamines react with CO and a palladium catalyst to give a thiocarbamate ($ArSCO_2NR'_2$).[791] Urea derivatives were obtained from amines, CO_2, and an antimony catalyst.[792]

Aziridines can be converted to cyclic carbamates (oxazolidinones) by heating with carbon dioxide and a chromium–salen catalyst.[793] The reaction of aziridines with LiI, and then CO_2 also generates oxazolidinones.[794]

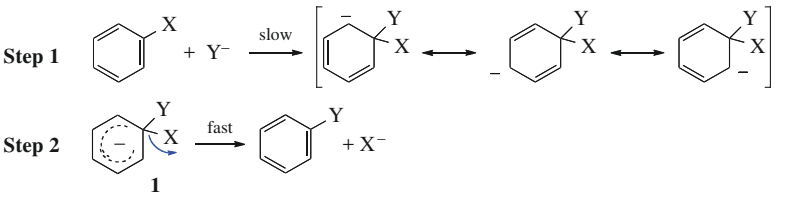
CHAPTER 13

Aromatic Substitution: Nucleophilic and Organometallic

In Section 10.G, category 2, it was pointed out that nucleophilic substitutions proceed so slowly at an aromatic carbon that the reactions of Chapter 10 are not feasible for aromatic substrates. There are, however, exceptions to this statement, and these exceptions form the subject of this chapter.[1] Reactions that *are* successful at an aromatic substrate are largely of five kinds: (1) reactions activated by electron-withdrawing groups ortho and para to the leaving group; (2) reactions catalyzed by very strong bases and proceeding through aryne intermediates; (3) reactions initiated by electron donors; (4) reactions in which the nitrogen of a diazonium salt is replaced by a nucleophile; and (5) coupling reactions catalyzed by transition metals, primarily Pd,[2] Cu, Ni, and so on. Note that solvent effects can be important.[3] The transition metal catalyzed coupling reactions are included because they involve replacement of a leaving group on an aromatic ring.

13.A. MECHANISMS

There are four principal mechanisms for aromatic nucleophilic substitution.[4] Each of the four is similar to one of the aliphatic nucleophilic substitution mechanisms discussed in Chapter 10.



13.A.i. The S_NAr Mechanism[5]

By far the most important mechanism for nucleophilic aromatic substitution consists of two steps, attack of the nucleophilic species at the ipso carbon of the aromatic ring

(the carbon bearing the leaving group in this case), followed by elimination of the leaving group and regeneration of the aromatic ring.

The first step is usually, but not always, rate determining. It can be seen that this mechanism greatly resembles the tetrahedral mechanism discussed in Chapter 16 and, in another way, the arenium ion mechanism of electrophilic aromatic substitution discussed in Chapter 11. In all three cases, the attacking species forms a bond with the substrate, giving an intermediate (e.g., **1**) and then the leaving group departs: This mechanism is the S_NAr mechanism.[6] The IUPAC designation is $A_N + D_N$ (the same as for the tetrahedral mechanism; cf. the designation $A_E + D_E$ for the arenium ion mechanism). This mechanism is generally found where activating groups are present on the ring (see Sec. 13.B.i).

There is a great deal of evidence for the mechanism.[4] Probably the most convincing evidence was the isolation, as long ago as 1902, of the intermediate **2** in the reaction between 2,4,6-trinitrophenetole and methoxide ion.[7] Intermediates of this type are stable salts, called *Meisenheimer* or *Meisenheimer–Jackson salts*,[8] and many more have been isolated.[9] The structures of several of these intermediates have been proved by NMR[10] and by X-ray crystallography.[11] Further evidence comes from studies of the effect of the leaving group on the reaction. If the mechanism were similar to either the S_N1 or S_N2 mechanisms described in Chapter 10, the Ar—X bond would be broken in the rate-determining step. In the S_NAr mechanism, this bond is not broken until after the rate-determining step (i.e., if step 1 is rate

determining). There is some evidence that electron transfer may be operative during this process.[12] If the S_NAr mechanism is operating, a change in leaving group should not have much effect on the reaction rate. In the reaction of dinitro compound **3** with piperidine, when X was Cl, Br, I, SOPh, SO_2Ph, or *p*-nitrophenoxy, the rates differed only by a factor of ~5.[13] This behavior would not be expected in a reaction in which the Ar—X bond is broken in the rate-determining step. The rates are not expected to be *identical*, because the nature of X affects the rate at which Y attacks.[14] An increase in the electronegativity of X causes a decrease in the electron density at the site of attack, resulting in a faster attack by a nucleophile. Thus, in the reaction just mentioned, when X = F, the relative rate was 3300 (compared with I = 1). The very fact that fluoro is the best leaving group among the halogens in most aromatic nucleophilic substitutions is good evidence that the mechanism is different from the S_N1 and the S_N2 mechanisms, where fluoro is by far the poorest leaving group of the halogens. This is an example of the element effect (Sec. 10.F).

The pattern of base catalysis of reactions with amine nucleophiles provides additional evidence. Bases only catalyze these reactions when a relatively poor leaving group (e.g., OR) is present (not Cl or Br) and only when relatively bulky amines are nucleophiles.[15] Bases could not catalyze step 1, but if amines are nucleophiles, bases can catalyze step 2. Base catalysis is found precisely in those cases where the amine moiety cleaves easily, but X does not, so that k_1 is large and step 2 is rate determining. This is evidence for the S_NAr mechanism because it implies two steps. Furthermore, in cases where bases *are* catalysts, they catalyze only at low-base concentrations: A plot of the rate against the base concentration shows that small increments of base rapidly increase the rate until a certain concentration of base is reached, after which further base addition no longer greatly affects the rate. This behavior, based on a partitioning effect (see Sec. 11.A.i), is also evidence for the S_NAr mechanism. At low-base concentration, each increment of base, by increasing the rate of step 2, increases the fraction of intermediate that goes to product rather than reverting to reactants. At high-base concentration, the process is virtually complete: There is very little reversion to reactants and the rate becomes dependent on step 1. Just how bases catalyze step 2 has been investigated. For protic solvents, two proposals have been presented. One is that step 2 consists of two steps: rate-determining deprotonation of **4** followed by

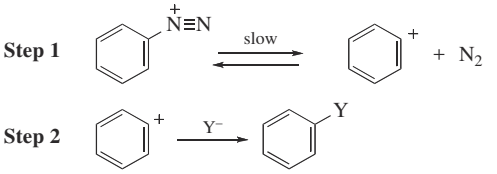
rapid loss of X, and that bases catalyze the reaction by increasing the rate of the deprotonation step.[16] According to the other proposal, loss of X assisted by BH^+ is rate determining.[17] Two mechanisms, both based on kinetic evidence, have been proposed for aprotic solvents (e.g., benzene). In both proposals, the ordinary S_NAr mechanism operates, but in one the attacking species involves two molecules of the amine (the *dimer mechanism*),[18] while in the other there is a cyclic transition state.[19] Further evidence for the S_NAr mechanism has been obtained from $^{18}O/^{16}O$ and $^{15}N/^{14}N$ isotope effects.[20]



Step 1 of the S_NAr mechanism has been studied for the reaction between picryl chloride (as well as other substrates) and ^-OH ions (Reaction **13-1**), and spectral evidence has been reported[21] for two intermediates, one a π complex (Sec. 11.A.i), and the other a radical ion–radical pair.

As with the tetrahedral mechanism at an acyl carbon, nucleophilic catalysis (Sec. 16.A.i) has been demonstrated with an aryl substrate, in certain cases.[22] There is also evidence of an interaction of anions with the π-cloud of aromatic compounds.[23]

13.A.ii. The S_N1 Mechanism

For aryl halides and sulfonates, even active ones, a unimolecular S_N1 mechanism (IUPAC: $D_N + A_N$) is very rare; it has only been observed for aryl triflates in which both ortho positions contain bulky groups (*tert*-butyl or SiR_3).[24] It is in reactions with diazonium salts[25] that this mechanism is important[26]:

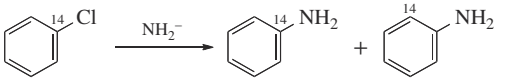
[26] Aryl iodonium salts Ar_2I^+ also undergo substitutions by this mechanism (and by a free radical mechanism).

Among the evidence for the S_N1 mechanism[27] with aryl cations as intermediates,[28,29] is the following:[30]

1. The reaction rate is first order in diazonium salt and independent of the concentration of Y.
2. When high concentrations of halide salts are added, the product is an aryl halide, but the rate is independent of the concentration of the added salts.
3. The effects of ring substituents on the rate are consistent with a unimolecular rate-determining cleavage.[31]
4. When reactions were run with substrate deuterated in the ortho position, isotope effects of ~1.22 were obtained.[32] It is difficult to account for such high secondary isotope effects in any other way except that an incipient phenyl cation is stabilized by hyperconjugation (see Sec. 2.M),[33] which is diminished when hydrogen is replaced by deuterium.

5. That the first step is reversible cleavage[34] was demonstrated by the observation that when $Ar^{15}N^+ \equiv N$ was the reaction species, recovered starting material contained not only $Ar^{15}N^+ \equiv N$, but also $Ar^{15}N^+ \equiv N$.[35,36] This could arise only if the nitrogen breaks away from the ring and then returns. Additional evidence was obtained by treating $PhN^+ \equiv N^{15}N$ with unlabeled N_2 at various pressures. At 300 atm, the recovered product had lost ~3% of the labeled nitrogen, indicating that PhN_2^+ was exchanging with atmospheric N_2.[36]

There is kinetic and other evidence[37] that step 1 is more complicated and involves two steps, both reversible:



$$ArN_2^+ \rightleftharpoons \underset{\mathbf{5}}{[Ar^+N_2]} \rightleftharpoons Ar^+ + N_2$$

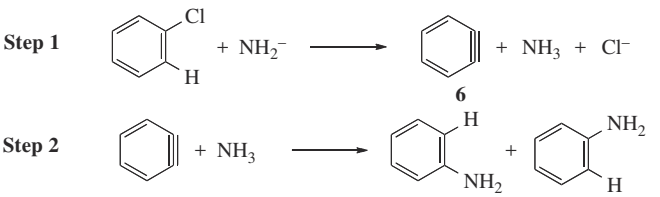
Intermediate **5**, which is probably some kind of a tight ion–molecule pair, has been trapped with carbon monoxide.[38]



13.A.iii. The Benzyne Mechanism[39]

Some aromatic nucleophilic substitutions are clearly different in character from those that occur by the S_NAr mechanism (or the S_N1 mechanism). These substitutions occur with aryl halides that have no activating groups; stronger bases are required than those normally used; and the incoming group does not always take the position vacated by the leaving group. The validity of the latter statement was elegantly demonstrated by the reaction of 1-^{14}C-chlorobenzene with potassium amide:

The product consisted of almost equal amounts of aniline labeled in the 1 and 2 positions.[40]

A mechanism that can explain all these facts involves elimination followed by addition. In step 1, a suitable base removes the ortho hydrogen, with subsequent (or concomitant) loss of the chlorine (leaving group) to

generate symmetrical intermediate **6**[41] called benzyne[42] (see below).[43] In step 2, benzyne is attacked by the NH_3 at either of two positions, which explains why about one-half of the aniline produced from the radioactive chlorobenzene was labeled at the 2 position. The fact that the 1 and 2 positions were not labeled equally is the result of a small isotope effect. Other evidence for this mechanism follows:

1. If the aryl halide contains two ortho substituents, the reaction should not be able to occur. This is indeed the case.[38]

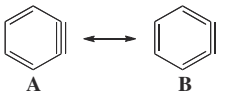
Microwave spectroscopy can be used to detect benzynes: see Godfrey, P.D. *Austr. J. Chem.* ***2010***, *63,* 1061.

2. It had been known many years earlier that aromatic nucleophilic substitution occasionally results in substitution at a different position. This is called *cine substitution*[44] and can be illustrated by the conversion of *o*-bromoanisole to *m*-aminoanisole.[45] In this particular case, only the meta isomer is formed. The reason a 1:1 mixture is not formed is that the intermediate **7** is not symmetrical and the methoxy group directs the incoming group meta, but not ortho (see Sec. 13.B.i). However, not all cine substitutions proceed by this kind of mechanism (see Reaction **13-30**). A study of the influence of structure on the formation of substituted benzynes, along with rate studies, has been reported.[46]

7



3. The fact that the order of halide reactivity is Br > I > Cl > F (when the reaction is performed with KNH_2 in liquid NH_3) shows that the S_NAr mechanism is not operating here.[40]

In the conversion of the substrate to **7**, either proton removal or subsequent loss of halide ion can be rate determining. In fact, the unusual leaving-group order just mentioned (Br > I > Cl) stems from a change in the rate-determining step. When the leaving group is Br or I, proton removal is rate determining and the rate order for this step is F > Cl > Br > I. When Cl or F is the leaving group, cleavage of the C—X bond is rate determining and the order for this step is I > Br > Cl > F. Confirmation of the latter order was found in a direct competitive study. *meta*-Dihalobenzenes in which the two halogens are different were treated with $^-NH_2$.[47] In such compounds, the most acidic hydrogen is the one between the two halogens; when it leaves, the remaining anion can lose either halogen. Therefore a study of which halogen is preferentially lost provides a direct measure of leaving-group ability. The order was found to be I > Br > Cl.[47,48]

Species, such as **6** and **7**, are called *benzynes* (sometimes *dehydrobenzenes*), or more generally, *arynes*.[49] The mechanism in which such species are intermediates is known as the *benzyne mechanism*. Benzynes are very reactive, and neither benzyne nor any other aryne has yet been isolated under ordinary conditions,[50] but benzyne has been isolated in an Ar matrix at 8 K,[51] and its IR spectrum is observed. In addition, benzynes can be trapped (e.g., they undergo the *Diels–Alder reaction*, See Reaction **15-60**). Note that the extra pair of electrons does not affect the aromaticity. However, evaluation by a series of aromaticity indicators, including magnetic susceptibility anisotropies and exaltations,

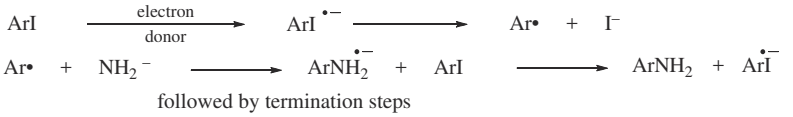
nucleus-independent chemical shifts (NICS), aromatic stabilization energies, and valence bond Pauling resonance energies point to the *o*-benzyne > *m*-benzyne > *p*-benzyne aromaticity order.[52] The relative order with respect to benzene depends on the aromaticity criterion.[48] Note that tunable reactivity for *m*-benzynes has been demonstrated.[53] The aromatic sextet from the aromatic precursor functions as a closed ring, and the two additional electrons are merely located in a π orbital that covers only two carbons. Benzynes do not have a formal triple bond, since two canonical forms (**A** and **B**) contribute to the hybrid. The Ir spectrum, mentioned above, indicates that **A** contributes more than **B**. Not only benzene rings, but also other aromatic rings[54] and even non-aromatic rings (Sec. 10.F) can react through this kind of intermediate. Of course, the non-aromatic rings do have a formal triple bond. When a benzyne unit is fused to a small ring, strain induced regioselectivity was observed in its reactions.[55]

A **B**



13.A.iv. The $S_{RN}1$ Mechanism

When 5-iodo-1,2,4-trimethylbenzene (**8**) was treated with KNH_2 in NH_3, **9** and **10** were formed in the ratio 0.63:1. The presence of an unactivated substrate, a strong base, and the occurrence of cine substitution along with normal substitution are strong indications of a benzyne mechanism. Yet if that were so, the 6-iodo isomer of **8** should have given **9** and **10** in the same ratio (because the same aryne intermediate would be formed in both cases), but in this case the ratio of **9** to **10** was 5.9:1 (the chloro and bromo analogues did give the same ratio (1.46:1), showing that the benzyne mechanism may be taking place there).

8 **9** **10**

To explain the iodo result, it has been proposed[56] that in addition to the benzyne mechanism, a free radical mechanism is also operating here:

[56] Kim, J.K.; Bunnett, J.F. *J. Am. Chem. Soc.* ***1970***, *92*, 7463, 7464.

This is called the $S_{RN}1$ mechanism,[57] and many other examples are known (see Reactions **13-3**, **13-4**, **13-6**, and **13-14**). The IUPAC designation is $T + D_N + A_N$.[58] Note that the last step of the mechanism produces $ArI^{\bullet -}$ radical ions, so the process is a chain mechanism[59] (see Sec. 14.A.i). An electron donor is required to initiate the reaction. In the case above, it was solvated electrons from KNH_2 in NH_3. Evidence was that the addition of potassium metal (a good producer of solvated electrons in ammonia) completely suppressed the cine substitution. Further evidence for the $S_{RN}1$ mechanism was that addition of radical scavengers, which would suppress a free radical mechanism, led to **9:10** ratios much closer to 1.46:1. Numerous other observations of $S_{RN}1$ mechanisms that were stimulated by solvated electrons and inhibited by radical scavengers have also been recorded.[60] Further evidence for the $S_{RN}1$ mechanism in the case above was that some 1,2,4-trimethylbenzene was found among the products. This could easily be formed by abstraction by $Ar^{\bullet}$ of H from the solvent NH_3. Besides initiation by solvated electrons,[61] $S_{RN}1$ reactions have been initiated photochemically,[62] electrochemically,[63] and even thermally.[64]

The $S_{RN}1$ reactions have a fairly wide scope. The efficiency of the reaction has been traced to the energy level of the radical anion of the substitution product.[65] There is no requirement for activating groups or strong bases, but in DMSO haloarenes are less reactive as the stability of the anion increases.[66] The reaction has also been done in liquid ammonia, promoted by ultrasound (Sec. 7.B),[67] and ferrous ion has been used as a catalyst.[68] Alkyl, alkoxy, aryl, and COO^- groups do not interfere, although Me_2N, O^-, and NO_2 groups do interfere. Cine substitution is not found.

13.A.v. Other Mechanisms

There is no clear-cut proof that a one-step S_N2 mechanism, so important at a saturated carbon, ever actually occurs with an aromatic substrate. The hypothetical aromatic S_N2 process is sometimes called the *one-stage* mechanism to distinguish it from the *two-stage* S_NAr mechanism. A "clean" example of a $S_{RN}2$ reaction has been reported, the

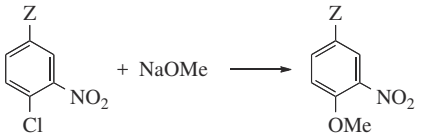
conversion of **11** to **12** in methanol.[69] Both $S_{RN}1$ and $S_{RN}2$ reactions have been reviewed.[70]

Some of the reactions in this chapter operate by still other mechanisms, among them an addition–elimination mechanism (see Reaction **13-17**). A new mechanism has been reported in aromatic chemistry, a reductively activated "polar" nucleophilic aromatic substitution.[71] The reaction of phenoxide with *p*-dinitrobenzene in DMF shows radical features that cannot be attributed to a radical anion, and it is not $S_{RN}2$. The new designation was proposed to account for these results.

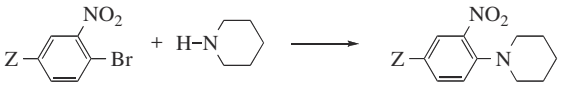
11 **12**

13.B. REACTIVITY



13.B.i. The Effect of Substrate Structure

In the discussion of electrophilic aromatic substitution (Chapter 11), equal attention was paid to the effect of substrate structure on reactivity (activation or deactivation) and on orientation. The question of orientation was important because in a typical substitution there are four or five hydrogen atoms that could serve as leaving groups. This type of question is much less important for aromatic nucleophilic substitution, since in most cases there is only one potential leaving group in a molecule. Therefore attention is largely focused on the reactivity of one molecule compared with another and not on the comparison of the reactivity of different positions within the same molecule.



S_NAr Mechanism. These substitutions are accelerated by electron-withdrawing groups, especially in positions ortho and para to the leaving group[72] and hindered by electron-attracting groups. This is, of course, opposite to the effects of these groups on electrophilic substitutions, and the reasons are similar to those discussed in Section 11.A.i. When attached to a benzene ring, the rate of reaction depends on the substituent.[73] Activating groups include 2-nitro,[74,75] N_2^+, NO, or C=N units with stong nucleophiles and when a nitro group is attached to SO_2Me, NMe_3 CF_3 CN, CHO, COR CO_2H, SO_3, halogen, H, Me, or OMe activate.[73] Table 13.1 contains a list of groups arranged approximately in order of activating or deactivating ability.[73–76] Nitrogen

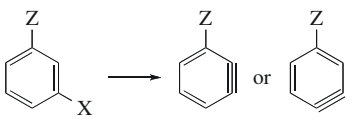
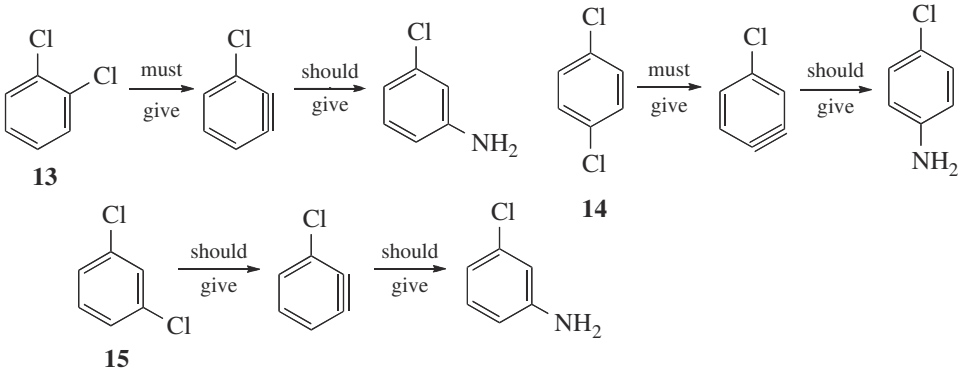
[b]The comments on the left are from Bunnett and Zahler.[76]



atoms are also strongly activating (especially to the α and γ positions) and are even more so when quaternized.[77] Both 2- and 4-chloropyridine, for example, are often used as substrates. Heteroaromatic amine *N*-oxides are readily attacked by nucleophiles in the 2 and 4 positions, but the oxygen is generally lost in these reactions.[78] The most highly activating group (N_2^+) is seldom deliberately used to activate a reaction, but it sometimes happens that in the diazotization of a compound (e.g., *p*-nitroaniline or *p*-chloroaniline), the group para to the diazonium group is replaced by OH from the solvent or by X from $ArN_2^+ X^{-\bullet}$ untouched. By far, the most common activating group is the nitro group and the most common substrates are 2,4-dinitrophenyl halides and 2,4,6-trinitrophenyl halides (also called picryl halides).[79] Polyfluorobenzenes[80] (see **11**) also undergo aromatic nucleophilic substitution quite well.[81] Benzene rings that lack activating substituents are generally not useful substrates for the S_NAr mechanism, because the two extra electrons in **1** are in an antibonding orbital (Sec. 2.A). Activating groups, by withdrawing electron density, are able to stabilize the intermediates and the transition states leading to them. Reactions taking place by the S_NAr mechanism are also accelerated when the aromatic ring is coordinated with a transition metal.[82]

Just as electrophilic aromatic substitutions were found more or less to follow the *Hammett relationship* (with σ^+ instead of σ; see Sec. 9.C) so do nucleophilic substitutions, with σ^- instead of σ for electron-withdrawing groups.[83]

Benzyne Mechanism. Two factors affect the position of the incoming group, the first being the direction in which the aryne forms.[84] When there are groups ortho or para to the leaving group, there is no choice:



but when a meta group is present, the aryne can form in two different ways:

[77] Miller, J.; Parker, A.J. *Aust. J. Chem.* ***1958***, *11,* 302.

In such cases, the more acidic hydrogen is removed. Since acidity is related to the field effect of Z, it can be stated that an electron-attracting Z favors removal of the ortho hydrogen while an electron-donating Z favors removal of the para hydrogen. The second factor is that the aryne, once formed, can be attacked at two positions. The favored position for nucleophilic attack is the one that leads to the more stable carbanion intermediate. This in turn also depends on the field effect of Z. For -*I* groups, the more stable carbanion is the one in which the negative charge is closer to the substituent. These principles are illustrated by the reaction of the three dichlorobenzenes (**13-15**) with alkali metal amides to give the predicted products shown. In each case, the predicted product was the one chiefly formed.[85] The observation that *m*-aminoanisole is obtained, mentioned in Section 13.A.iii, is also in accord with these predictions.

13.B.ii. The Effect of the Leaving Group[86]

The common leaving groups in aliphatic nucleophilic substitution (halide, sulfate, sulfonate, NR_3^+, etc.) are also common leaving groups in aromatic nucleophilic substitutions, but the groups NO_2, OR, OAr, SO_2R[87], and SR, which are not generally lost in aliphatic systems, *are* leaving groups when attached to aromatic rings. Surprisingly, NO_2 is a particularly good leaving group.[88] An approximate order of leaving-group ability is[89] $F > NO_2 > OTs > SOPh > Cl,\ Br,\ I > N_3 > NR_3^+ > OAr,\ OR,\ SR,\ NH_2$. However, this depends greatly on the nature of the nucleophile, as illustrated by the fact that $C_6Cl_5OCH_3$ treated with NH_2^- gives mostly $C_6Cl_5NH_2$; that is, one methoxy group is replaced in preference to five chlorines.[90] As usual, OH can be a leaving group if it is converted to an

inorganic ester. Among the halogens, fluoro is generally a much better leaving group than the other halogens, which have reactivities fairly close together. The order is usually Cl > Br > I, but not always.[91] The leaving-group order is quite different from that for the S_N1 or S_N2 mechanisms. The most likely explanation is that the first step of the S_NAr mechanism is usually rate determining, and this step is promoted by groups with strong $-I$ effects. This would explain why fluoro and nitro are such good leaving groups when this mechanism is operating. Fluoro is the poorest leaving group of the halogens when the second step of the S_NAr mechanism is rate determining or when the benzyne mechanism is operating. The four halogens, as well as SPh, NMe_3^+, and $OPO(OEt)_2$, have been shown to be leaving groups in the $S_{RN}1$ mechanism.[60] The only important leaving group in the S_N1 mechanism is N_2^+.

13.B.iii. The Effect of the Attacking Nucleophile[92]

It is not possible to construct an invariant nucleophilicity order because different substrates and different conditions lead to different orders of nucleophilicity, but an overall approximate order is $^-NH_2 > Ph_3C^- > PhNH^-$ (aryne mechanism) $> ArS^- > RO^- > R_2NH > ArO^- > {}^-OH > ArNH_2 > NH_3 > I^- > Br^- > Cl^- > H_2O > ROH$.[93] As with aliphatic nucleophilic substitution, nucleophilicity is generally dependent on base strength and nucleophilicity increases as the attacking atom moves down a column of the periodic table, but there are some surprising exceptions (e.g., ^-OH), a stronger base than ArO^-, is a poorer nucleophile.[94] In a series of similar nucleophiles (e.g., substituted anilines), nucleophilicity *is* correlated with base strength. Oddly, the cyanide ion is not a nucleophile for aromatic systems, except for sulfonic acid salts and in the *von Richter* (**13-30**) and *Rosenmund–von Braun* (**13-8**) reactions, which are special cases. Studies on the nature of the nucleophile continue. Indeed, the second-order rate constants for vicarious nucleophilic substitution reactions of some carbanions were measured to define electrophilicity parameters for electron-deficient heteroarenes.[95]

13.C. REACTIONS

In the first part of this section, reactions are classified according to attacking species, with all leaving groups considered together, except for hydrogen and N_2^+, which are treated subsequently. Finally, a few rearrangement reactions are discussed.

13.C.i. All Leaving Groups Except Hydrogen and N_2^+

A. Oxygen Nucleophiles

13-1 Hydroxylation of Aromatic Compounds

Hydroxy-de-halogenation

$$ArBr + {}^{-}OH \rightarrow ArOH$$

Direct hydroxylation of aryl halides to give phenols generally requires the presence of activating groups or exceedingly strenuous reaction conditions.[96] When the reaction is carried out at high temperatures, cine substitution is observed, indicating a benzyne mechanism.[97] However, phenols are prepared from aryl halides using KOH and a Pd catalyst at 100 °C.[98] Formation of phenols is possible using $AgNO_3$ with microwave irradiation,[99] or CuI.[100] There is a hydrogen peroxide promoted hydroxylation of aryl halides with metal hydroxide salts.[101] Other microwave-promoted phenol-forming reactions are known.[102]

A slightly related reaction involves the amino group of naphthylamines where can be replaced by a hydroxyl group after treatment with aq bisulfite.[103] The scope is greatly limited; the amino group, with very few exceptions may be NH_2 or NHR and must be on a naphthalene ring. The reaction is reversible (see **13-6**), and both the forward and reverse reactions are called the *Bucherer reaction*.

$$ArMgX \xrightarrow{B(OMe)_3} ArB(OMe)_2 \xrightarrow[H_2O_2]{H^+} ArOH$$

An indirect method for conversion of an aryl halide to a phenol involves initial conversion to an organometallic, followed by oxidation to the phenol. For the conversion of aryl *Grignard reagents* to phenols, a good procedure is the use of trimethyl borate followed by oxidation with H_2O_2 in acetic acid[104] (see Reaction **12-31**). Phenols have been obtained from unactivated aryl halides by treatment with borane and a metal (e.g., lithium), followed by oxidation with alkaline H_2O_2.[105] Arylboronic acids [$ArB(OH)_2$] are oxidized by aq H_2O_2 to give the corresponding phenol.[106] The reaction of an aromatic compound

with a borane in the presence of an Ir catalyst, followed by oxidation with aq Oxone, gave the corresponding phenol.[107] Aryllithium reagents have been converted to phenols by treatment with oxygen.[108] In a related indirect method, arylthallium bis(trifluoroacetates) (prepared by Reaction **12-23**) can be converted to phenols by treatment with lead tetraacetate followed by triphenylphosphine, and then dilute NaOH.[109] Diarylthallium trifluoroacetates undergo the same reaction.[110]

OS **I**, 455; **II**, 451; **V**, 632. Also see, OS **V**, 918.

13-2 Alkali Fusion of Sulfonate Salts

Oxido-de-sulfonato-substitution

$$ArSO_3^- \xrightarrow[300-320\ ^\circ C]{\text{NaOH fusion}} ArO^-$$

Aryl sulfonic acids can be converted, through their salts, to phenols, by alkali fusion. In spite of the extreme conditions, the reaction gives fairly good yields, except when the substrate contains other groups that are attacked by alkali at the fusion temperatures. Milder conditions can be used when the substrate contains activating groups, but the presence of deactivating groups hinders the reaction. The mechanism is not clear, but a benzyne intermediate has been ruled out by the finding that cine substitution does not occur.[111]

OS **I**, 175; **III**, 288.

13-3 Replacement by OR or OAr

Alkoxy-de-halogenation

$$ArBr + RO^- \longrightarrow ArOR$$

This reaction is similar to **13-1** and, like that one, generally requires activated substrates.[96,112] With unactivated substrates, side reactions predominate, although aryl methyl ethers have been prepared from unactivated chlorides by treatment with MeO^- in HMPA.[113] This reaction gives better yields than **13-1** and is used more often. A good solvent is liquid ammonia. Aryl chlorides react with phenol and KOH with microwave irradiation to give the diaryl ether.[114] Potassium phenoxide reacts with iodobenzene in an ionic solvent at 100 °C with CuCl.[115] Sodium methoxide reacted with *o*- and *p*-fluoronitrobenzenes $\sim 10^9$ times faster in NH_3 at −70 °C than in MeOH.[116] Phase-transfer catalysis

has also been used.[117] Phenols reacted with aryl fluorides[118] or aryl chlorides[119] to give the diaryl ether. Intramolecular versions are known that produce benzofurans.[120] Heating aryl iodides and phenols in an ionic liquid forms ethers.[121] In addition to halides, leaving groups can be other OR, or even OH.[122]

For aroxide nucleophiles, the reaction is promoted by Cu salts,[123] and activating groups need not be present. This method of preparation of diaryl ethers is called the *Ullmann ether synthesis*[124] and should not be confused with the *Ullmann biaryl synthesis* (**13-11**). The reactivity order is typical of nucleophilic substitutions, despite the presence of the Cu salts.[125] Copper-catalyzed coupling is known using ligand and additive-free conditions.[126] Because aryloxycopper(I) reagents (ArOCu) react with aryl halides to give ethers, it has been suggested that they are intermediates in the Ullmann ether synthesis.[127] Indeed, high yields of ethers can be obtained by reaction of ROCu or ArOCu with aryl halides.[128] Aryl halides are converted to aryl ethers with aliphatic alcohols in the presence of suitable Cu salts.[129]

An increasingly important variation of this reaction couples an alkoxide and an aryl halide to give aryl ethers in the presence of a Pd catalyst and a suitable ligand.[130] Ligand effects are important in such reactions.[131] A Pd catalyzed, intramolecular displacement of an aryl halide with a pendant alkoxide unit leads to dihydrobenzofurans.[132] Nickel catalysts have also been used.[133] Aryl iodides react with phenols in the presence of K_2CO_3, CuI, and Raney nickel alloy.[134] An Fe catalyzed etherification reaction is known.[135]

In a related reaction, acid salts ($RCOO^-$) are sometimes used as nucleophiles.[136] Unactivated substrates have been converted to carboxylic esters in low-to-moderate yields under oxidizing conditions.[137] The following chain mechanism, called the $S_{ON}2$ mechanism,[138] has been suggested[138]:

OS **I**, 219; **II**, 445; **III**, 293, 566; **V**, 926; **VI**, 150; **X**, 418.

B. Sulfur Nucleophiles

13-4 Replacement by SH or SR

Mercapto-de-halogenation	$ArBr + SH^-$	$\longrightarrow ArSH$
Alkylthio-de-halogenation	$ArBr + SR^-$	$\longrightarrow ArSR$

Aryl thiols and thioethers can be prepared by reactions that are similar to **13-1** and **13-3**.[139] Activated aryl halides generally give good results, but side reactions are occasionally important. Some reagents give the thiol directly. 4-Bromonitrobenzene reacts with Na_3SPO_3, in refluxing methanol, to give 4-nitrothiophenol, for example.[140]

Diaryl sulfides can be prepared by the use of ^-SAr.[141] Even unactivated aryl halides react with ^-SAr if polar aprotic solvents (e.g., DMF,[142] DMSO[143] 1-methyl-2-pyrrolidinone,[144] or HMPA)[145] are used, though the mechanisms are still mostly or entirely nucleophilic substitution. 2-Iodothiophene reacts directly with thiophenol to give 2-(phenylthio)thiophene.[146]

Metal-catalyzed reactions of aryl halides and thiols lead to thioethers. Perhaps the most common metal used nowadays is Pd.[147] Copper catalysts have been used,[148] including

catalysis in aqueous media,[149] and also Ni[150] or In[151] catalysts. Copper-catalyzed coupling is known using ligand- and additive-free conditions.[152] Aryl iodides react with dialkyl disulfides and a nickel catalyst to give aryl alkyl sulfides.[153] Diaryl sulfides can also be prepared (in high yields) by treatment of unactivated aryl iodides with ArS^- in liquid ammonia under irradiation.[154] The mechanism in this case is probably $S_{RN}1$. The reaction (with unactivated halides) has also been carried out electrolytically, with a Ni catalyst.[155] In the presence of a Pd catalyst, thiophenols react with diaryliodonium salts ($Ar_2I^{+-}BF_4$) to give the unsymmetrical diaryl sulfide.[156]

Other sulfur nucleophiles also react with activated aryl halides:

$$2\,ArX + S_2^{2-} \rightarrow Ar{-}S{-}S{-}Ar \qquad ArX + SCN^- \rightarrow ArSCN$$
$$ArX + SO_3^{2-} \rightarrow Ar{-}SO_3^- \qquad ArX + RSO_2^- \rightarrow Ar{-}SO_2{-}R$$

Arylboronic acids [$ArB(OH)_2$] react with thiols and copper(II) acetate to give the corresponding alkyl aryl sulfide.[157] Arylboronic acids also react with *N*-methylthiosuccinimide, with a Cu catalyst, to give the aryl methyl sulfide.[158]

Aryl sulfones have been prepared from sulfinic acid salts, aryl iodides, and CuI.[159] A Pd catalyzed arylation of sulfenate anions leads to aryl sulfoxides.[160]The copper-catalyzed reaction of NaO_2SMe and aryl iodides give the aryl methyl sulfone,[161] and aryl sulfones have been prepared from arylboronic acids using a Cu catalyst.[162] A similar synthesis of diaryl sulfones has been reported using a Pd catalyst.[163]

Aryl selenides (ArSeAr and ArSeAr') can be prepared by similar methodology. Symmetrical diaryl selenides were prepared by the reaction of iodobenzene with diphenyl diselenide (PhSeSePh), in the presence of Mg and a Cu catalyst.[164] Aryl halides react with tin selenides ($ArSeSnR_3$), with a Cu catalyst, to give the diaryl selenide,[165] and a CuS—Fe catalyst was also used.[166]

Thiocyanates have been generated from unactivated aryl halides using charcoal supported copper(I) thiocyanate.[167]

C. Nitrogen Nucleophiles

13-5 Replacement of Halogen by NH_2, NHR, or NR_2

Amino-de-halogenation

Amido-de-halogenation

$$\underset{R=H}{R_3N} + Ar{-}X \xrightarrow[\text{alkyl}(1^\circ \text{ and } 2^\circ)]{} R_2N{-}Ar$$

Activated aryl halides react with ammonia and primary and secondary amines to give the corresponding arylamines. Primary and secondary amines usually give better results than ammonia, with piperidine especially reactive. Picryl chloride (2,4,6-trinitrochlorobenzene) is often used to form amine derivatives. 2-Chloronitrobenzene also reacts with aniline derivatives directly with microwave irradiation.[168] Other leaving groups in this reaction may be NO_2,[169] N_3, OSO_2R, OR, SR, N=NAr (where Ar contains electron-withdrawing groups)[170] and even NR_2.[171] Aryl triflates react directly with secondary amines in *N*-methylpyrrolidine solvent using microwave irradiation.[172] Aniline derivatives react with activated aromatic rings, in the presence of tetrabutylammonium fluoride and under photolysis conditions, to give a *N,N*-diarylamine.[173] Arylation of amines with aryl halides has also been done in ionic liquids[174] and in supercritical CO_2.[175] Flow reactor technology has been used for the direct, uncatalyzed amination of 2-chloropyridine.[176]

Aryl halides can be converted to amines by the use of $NaNH_2$, NaNHR, or $NaNR_2$.[177] Lithium dialkylamides also react with aryl halides to give the *N*-arylamine.[178] With amide base reagents, the benzyne mechanism generally operates, so *cine* substitution (Sec. 13.A.iii, category 2) is often found. The amide base is usually generated by reaction of the amine with an organolithium reagent, but other bases may be used. The reaction of an amine, an aryl halide, and potassium *tert*-butoxide generates the *N*-aryl amine.[179] Triarylamines have been prepared in a similar manner from ArI and Ar'_2NLi, even with unactivated ArI.[180]

Aryl fluorides react in the presence of KF–alumina and 18-crown-6 in DMSO.[181] Aryl fluorides react with amines in the presence of potassium carbonate/DMSO and ultrasound,[182] and aryl chlorides react on basic alumina with microwave irradiation.[183]

2-Fluoropyridine reacts with R_2NBH_3Li to give the 2-aminoalkylpyridine.[184] 2,4-Dinitrofluorobenzene, known as *Sanger's reagent,* is used to tag the amino end of a peptide or protein chain.[185]

The reaction of amines with aryl halides can be done under milder conditions using a catalyst to initiate or mediate the reaction. Both amines (aliphatic and aniline derivatives)[186] and amide bases[187] have been coupled to aryl halides using Pd catalysts and an appropriate ligand.[188] A considerable amount of work[189] has been done to vary the nature of the ligand and the Pd catalyst, as well as the base.[190] Work to discern the mechanism of this reaction has also received considerable attention.[191] This amination has come to be called the *Buchwald–Hartwig Cross-Coupling Reaction*.

Polymer-supported Pd catalysts,[192] polymer-bound phosphine ligands used in conjunction with a Pd catalyst,[193] and polymer-bound amines[194] have been used for *N*-arylation. These reactions have been done in ionic liquids using a Pd catalyst.[195] Palladium-catalyzed amination of aryl halides has been reported using microwave irradiation.[196] Catalysts are available for the amination of aryl halides in aqueous media.[197] The Pd-catalyzed amination of aryl substrates is not limited to halides, and the reaction with mesylates lead to arylamines.[198] Arylamines with chiral substituents on nitrogen can be prepared using a Pd-catalyst with optically active ligands.[199]

Aniline derivatives have been prepared by the reaction of aryl chlorides with silylamines (Ph_3SiNH_2) using lithium hexamethyldisilazide and a Pd catalyst.[200] Amines react with

$Ph_2I^+BF_4^-$, in the presence of Pd catalysts,[201] or a CuI catalyst[202] to give the *N*-phenyl amine. Aminoalkylation of heteroaromatic rings is possible, as in the reaction of 3-bromothiophene with a primary amine and a Pd catalyst.[203] 2-Halopyridines react to give the 2-aminoalkyl pyridine.[204]

Copper catalysts have been used for the reaction of amines or aniline derivatives with aryl halides.[205] The selectivity of *O*- versus *N*-arylation for reactions of amino alcohols has been discussed.[206] Copper-catalyzed amination reactions can be done in aqueous media using 2-dimethylaminoethanol as a ligand.[207] Ammonium salts serve as a nitrogen source in some cases.[208] In the *Goldberg reaction*, an aryl bromide reacts with an acetanilide in the presence of K_2CO_3 and CuI to give an *N*-acetyldiarylamine, which can be hydrolyzed to a diarylamine: $ArBr + Ar'NHAc \rightarrow ArAr'NAc$.[209]

Nickel catalysts have been used in the reaction of aryl halides with *N*-alkyl aniline derivatives[210] and also with aliphatic amines.[211] *N*-Arylation was also accomplished with butyllithium and a secondary amine using Ni/C-diphenylphosphinoferrocene (dppf).[212] An intramolecular reaction of a pendant aminoalkyl unit with an aryl chloride moiety, catalyzed by Ni(0) gave a dihydroindole.[213] An arylbismuth reagent reacts with aliphatic amines, in the presence of copper(II) acetate, to give an *N*-arylamine.[214] Diarylzinc reagents give the *N*-aryl amine in the presence of a Cu[215] or a Ni catalyst[216]. Aryl halides also react with $Zn(NTMS_2)_2$ in the presence of a Pd catalyst to give arylamines.[217] Iron-catalyzed arylation reactions are known.[218] A $Mo(CO)_6$ mediated, Pd catalyzed reaction is known for allylamines and aryl halides.[219]

Intramolecular versions of this reaction generate bicyclic or polycyclic amines.[220] An example is the conversion of **16** to the tetrahydroquinoline.[221] Larger ring amines can be prepared using this approach: 8- and even 12-membered.

Arylboronic acids react with aliphatic amines[222] or aq ammonia[223] in the presence of a Cu catalyst. *N*-Aryl imides have been prepared by similar methodology, from arylboronic acids.[224] Trifluoroarylboronates react with copper(II) acetate and then an aliphatic amine to give the *N*-phenylamine.[225] Primary aromatic amines ($ArNH_2$) were converted to diaryl amines (ArNHPh) by treatment with $Ph_3Bi(OAc)_2$[226] and a Cu powder catalyst.[227]

The metal-catalyzed reaction with ammonia or amines likely proceeds by the S_NAr mechanism.[228] This reaction, with phase-transfer catalysis, has been used to synthesize triarylamines.[229] In certain cases, the $S_{RN}1$ mechanism has been found (Reaction **10-26**). When the substrate is a heterocyclic aromatic nitrogen compound, still a different mechanism [the S_N(ANRORC) mechanism], involving opening and reclosing of the aromatic ring, has been shown to take place.[230]

There are a number of indirect approaches for the preparation of aryl amines. Activated aromatic compounds can be directly converted to the *N*-aryl amine in high yield with hydroxylamine in the presence of strong bases.[231] Aryl halides can be converted to the corresponding *Grignard reagent* (Reaction **12-38**). Subsequent reaction with allyl azide followed by hydrolysis leads to the corresponding aniline derivative.[232] Aryl *Grignard reagents* react with nitroaryl compounds to give, after reduction with $FeCl_3/NaBH_4$, a diaryl amine.[233] Aryl halides can be converted to the aryllithium via halogen–lithium exchange or hydrogen–lithium exchange (Reactions **12-38** and **12-39**).

The use of transition metal catalysts allows aryl halides to react with the nitrogen of amides or carbamates to give the corresponding *N*-aryl amide or *N*-aryl carbamate.

Amides react with aryl halides in the presence of a Pd[234] or a Cu catalyst.[235] *N*-Aryl lactams are prepared by the reaction of a lactam with an aryl halide in the presence of a Pd catalyst.[236] β-Lactams also react.[237] The reaction of 2-oxazolidinones with aryl halides in the presence of a Pd catalyst gave the *N*-aryl-2-oxazolidinone.[238] *N*-Aryl amides are prepared from amides using $PhSi(OMe)_3/Cu(OAc)_2/Bu_4NF$.[239] *N*-Boc hydrazine derivatives ($BocNHNH_2$) gave the *N*-phenyl derivative [$BocN(Ph)NH_2$] when reacted with iodobenzene and a catalytic amount of CuI and 10% of 1,10-phenanthroline.[240] 3-Bromothiophene was converted to the 3-amido derivative with an amide and CuI-dimethylethylenediamine.[241] *N*-(2-Thiophene)-2-pyrrolidinone was similarly prepared from 2-iodothiophene, the lactam, and a copper catalyst.[242] *N*-Arylation of urea is possible using a Cu catalyst.[243]

The transition metal catalyzed couplings of primary or secondary phosphines with aryl halides or sulfonate esters to give arylphosphines is known.[244] The Pd catalyzed conversion of aryl halides to aryl phosphines using (trimethylsilyl)diphenylphosphine tolerates many functional groups (not those that are easily reducible, e.g., aldehydes, because Zn metal[245] is often used as a coreagent), but it is mainly limited to aryl iodides.[246] Diphenylphosphine reacts with aryl iodides and a copper catalyst to give the triarylphosphine.[247] Aryl iodides also react with a secondary phosphine and 5% Pd/C to give the *P*-arylphosphine.[248] Tertiary phosphines can be used via aryl–aryl exchange, as in the reaction of an aryl triflate and triphenylphosphine and a Pd catalyst, for example, gave the arylphosphonium salt ($ArPPh_3$).[249] Aryl iodides can also be used.[250]

13-6 Replacement of a Hydroxy Group by an Amino Group

Amino-de-hydroxylation

The reaction of naphthols with ammonia and sodium bisulfite is called the *Bucherer reaction.* Primary amines can be used instead of ammonia, in which case *N*-substituted naphthylamines are obtained. In addition, primary naphthylamines can be converted to secondary ($ArNH_2 + RNH_2 + NaSO_3 \rightarrow ArNHR$), by a transamination reaction. The mechanism of the *Bucherer reaction* amounts to a kind of overall addition–elimination, via **18** and **19**.[251]

The first step in either direction consists of addition of $NaHSO_3$ to one of the double bonds of the ring, which gives an enol from **17** (or enamine from **20**) that tautomerizes to the keto form **18** (or imine form, **19**). The conversion of **18** to **19** (or vice versa) is an example of Reaction **16-13** (or **16-2**). Evidence for this mechanism was the isolation of **18**[252] and the demonstration that for β-naphthol treated with ammonia and HSO_3^-, the rate of the reaction depends only on the substrate and on HSO_3^-, indicating that ammonia is not involved in the rate-determining step.[253] If the starting compound is a β-naphthol, the intermediate is a 2-keto-4-sulfonic acid compound, so the sulfur of the bisulfite in either case attacks meta to the OH or NH_2.[254]

Hydroxy groups on benzene rings can be replaced by NH_2 groups if they are first converted to aryl diethyl phosphates. Treatment of these with KNH_2 and potassium metal in liquid ammonia gives the corresponding primary aromatic amines.[255] The mechanism of the second step is $S_{RN}1$.[256]

It is possible to replace a halogen on an aromatic ring by another halogen[257] if the ring is activated. In such cases, there is equilibrium, which is usually shifted in the desired direction by the use of an excess of added halide ion.[258] A phenolic hydroxy group can be replaced by chloro with PCl_5 or $POCl_3$, but only if the ring is activated. Unactivated phenols give phosphates when treated with $POCl_3$: $3\ ArOH + POCl_3 \rightarrow (ArO)_3PO$. Phenols, even unactivated ones, can be converted to aryl bromides by treatment with Ph_3PBr_2[259] (see Reaction **10-47**) and to aryl chlorides by treatment with $PhPCl_4$.[260]

Halide exchange is particularly useful for putting fluorine into a ring, since there are fewer alternate ways of doing this than for the other halogens. Activated aryl chlorides give fluorides when treated with KF in DMF, DMSO, or dimethyl sulfone.[261] Reaction of aryl halides with Bu_4PF/HF is also effective for exchanging a halogen with fluorine.[262]

Halide exchange can also be accomplished with copper halides. Since the leaving-group order in this case is $I > Br > Cl \gg F$, which means that iodides cannot normally be made by this method, the S_NAr mechanism is probably not operating.[263] However, aryl iodides have been prepared from bromides, by the use of Cu supported on charcoal or Al_2O_3,[264] with an excess of NaI and a Cu catalyst,[265] and by treatment with excess KI and a Ni catalyst.[266] Interestingly, aryl chlorides have been prepared from aryl iodides using 2 molar equivalents of $NiCl_2$ in DMF, with microwave irradiation.[267] Aryl and vinyl triflates can be converted to the corresponding bromide or chloride using a Pd catalyst.[268]

Aryl iodides[269] and fluorides can be prepared from arylthallium bis(trifluoroacetates) (see Reaction **12-23**), indirectly achieving the $ArH \rightarrow ArI$ and $ArH \rightarrow ArF$ conversions. The bis(trifluoroacetates) react with KI to give ArI in high yields.[270] Aryllead triacetates [$ArPb(OAc)_3$] can be converted to aryl fluorides by treatment with BF_3–etherate.[271] Treatment of $PhB(OH)_2$ with NIS gives iodobenzene.[272] Arylboronic acids (Reaction **12-28**) can be converted to the corresponding aryl bromides by reaction with

1,3-dibromo-5,5-dimethylhydantoin and 5 mol% NaOMe.[273] Other aryl halides can be prepared using 1,3-dihalo-5,5-dimethylhydantoins.

OS **III**, 194, 272, 475; **V**, 142, 478; **VIII**, 57; **81**, 98.

The reduction of phenols and phenolic esters and ethers is discussed in Reactions **19-38** and **19-35**. The reaction ArX → ArH is treated in **11-39**, although, depending on reagent and conditions, it can be nucleophilic or free radical substitution, as well as electrophilic.

E. Carbon Nucleophiles[274]

Some formations of new aryl–carbon bonds formed from aryl substrates have been considered in Reactions **10-57**, **10-68**, **10-76**, and **10-77**.

13-8 Cyanation of Aromatic Rings

Cyano-de-halogenation

Cyano-de-metalation

$$\text{Ar-X} \rightarrow \text{Ar-CN}$$

The reaction between aryl halides and cuprous cyanide is called the *Rosenmund–von Braun reaction*.[275] Reactivity of the aryl halide is in the order I > Br > Cl > F, indicating that the S_NAr mechanism does not apply.[276] Cyanides (e.g., KCN and NaCN) do not react with aryl halides, even activated ones, but this reaction has been done in ionic liquids using CuCN.[277] The reaction has also been done in water using CuCN, a phase-transfer catalyst, and microwave irradiation.[278] L-Proline has been used to promote the reaction.[279]

Aryl halides react with metal cyanides, often with another transition metal catalyst, to give aryl nitriles (aryl cyanides). Alkali cyanides convert aryl halides to nitriles[280] in dipolar aprotic solvents in the presence of Pd(II) salts[281] or Cu[282] or Ni[283] complexes. In the presence of a Pd- catalyst,[284] several cyanide-containing compounds react with aryl halides. Several different sources of cyanide may be used with the Pd catalyzed reaction, including: $Zn(CN)_2$,[285] CuCN,[286] sodium cyanoborohydride/catechol,[287]

potassium ferricyanide,[288] and KCN.[289] Microwave irradiation has been used to facilitate Pd catalyzed cyanation.[290] Aryl triflates may be used in aryl cyanation reactions, as well as aryl halides.[291] Benzylthiocyanate reacts with boronic acids to give aryl cyanides in a "cyanide-free" reaction, catalyzed by a Pd complex and mediated by Cu(I).[292] Cyanation reactions catalyzed by copper salts are common.[293] Aryl bromides react with $Ni(CN)_2$ with microwave irradiation to give ArCN.[294] A nickel complex also catalyzes the reaction between aryl triflates and KCN to give aryl nitriles.[295] Iridium-catalyzed borylation of arenes also leads to aryl nitriles.[296]

Alternative procedures are available. One uses excess aq KCN followed by photolysis of the resulting complex ion $[ArTl(CN)_3^-]$ in the presence of excess KCN.[297] Alternatively, arylthallium acetates react with $Cu(CN)_2$ or CuCN to give aryl nitriles.[298] Yields from this procedure are variable, ranging from almost nothing to 90 or 100%.

Metal-free methods have been reported. For example, conversion of an aromatic compound to the corresponding iminium salt used $POCl_3$ and DMF, and subsequent reaction with molecular iodine in aq ammonia gave the nitrile.[299] An indirect method involves the reaction of an aromatic ring with *tert*-butyllithium, particularly when there is a directing group (see Reaction **13-17**), followed by reaction with PhOCN (phenyl cyanate) to give the aryl nitrile.[300] Aromatic ethers (ArOR)[301] have been photochemically converted to ArCN.

cyclization of organolithium reagents to aromatic rings.[303] Noncatalyzed coupling reactions of aryllithium reagents and haloarenes can proceed via the well-known aryne route, but a novel addition–elimination pathway is possible when substituents facilitate a chelation-driven nucleophilic substitution pathway.[304] Such noncatalyzed coupling reactions often proceed with high regioselectivity and high yield.[304] 2-Bromopyridine reacts with pyrrolidine, at 130 °C with microwave irradiation, to give 2-(2-pyrrolidino)pyridine.[305] Aryl iodides undergo homocoupling to give the biaryl by heating with triethylamine in an ionic liquid.[306] Note that alkyl bromides are coupled to pyrrolidine by heating in an ionic liquid.[307]

Palladium-catalyzed coupling reactions that generate biaryls are increasingly important in synthesis. Aryl halides undergo homocoupling to give the biaryl with a Pd[308] or a Ni catalyst.[309] Aryl iodides have been coupled to form symmetric biphenyls with a Pd catalyst,[310] and homocoupling occurs with aryl triflates under electrolysis conditions with a Pd catalyst.[311] A recyclable Pd catalyst for use in ionic liquids has been developed.[312] Other alternative solvents include PEG.[313]

Thiophene derivatives,[314] pyrrole,[315] azoles,[316] quinoline,[317] and indolizine[318] have been coupled to aryl halides using a Pd catalyst. Fused polycyclic aromatic compounds can also be prepared from halobiaryls.[319] Trimethylsilylpyridine derivatives are coupled to aryl halides in the presence of a Pd catalyst.[320] A related reaction is the Pd catalyzed decarboxylative coupling of arylcarboxylic acids with aryl iodides.[321]

Palladium catalysts are often used in conjunction with another metal compound or complex. Arylgermanium compounds are coupled with aryl iodides using tetrabutylammonium fluoride and a Pd catalyst.[322] Homocoupling of triphenylbismuth is known,[323] as well as the coupling of arylbismuth reagents to aryliodonium salts[324] and to aryltin compounds[325] with Pd compounds or complexes. Aryl triflates were coupled to triphenylbismuth using a Pd catalyst.[326] Specialized arylbismuth compounds

have been used with a Pd catalyst to convert aryl chlorides to biaryls.[327] An aryltin–aryl halide coupling has been done in ionic liquids.[328] Aryl halides react with cyclopentadiene and Cp_2ZrCl_2 and a Pd catalyst to give pentaphenylcyclopentadiene.[329] The homocoupling of arylzinc iodides with a Pd catalyst has been reported.[330] In a related reaction, arylsulfonyl chlorides also react with $ArSnBu_3$ with Pd and Cu catalysts to give the biaryl.[331]

Aryl triflates (halides) couple with ArZn(halide) reagents in the presence of a Ni catalyst.[332] A homocoupling-type reaction was reported in which $PhSnBu_3$ was treated with 10% $CuCl_2$, 0.5 equiv of iodine, and heated in DMF to give biphenyl.[333] Similar coupling was accomplished with aryltellurium compounds.[334] A Co(II) catalyzed cross-coupling of arylcopper compounds with aryl halides gives the corresponding biaryl.[335] Another homocoupling reaction of pyridyl bromides was reported using $NiBr_2$ under electrolytic conditions. Both alkylmanganese compounds (RMnCl)[336] and Ph_3In[337] react with aryl halides or aryl triflates to give the arene. Aryl halides also react with phenols to form biaryls using a Rh catalyst.[338] Diaryliodonium salts react with $PhPb(OAc)_3$ and a Pd catalyst to give the biaryl.[339] Coupling of trialkylbismuth compounds with aryl halides leads to the arene in the presence of a Pd catalyst.[340] A cross-coupling reaction of benzylindium compounds and aryl halides in the presence of a Pd catalyst has been reported.[341]

Grignard reagents couple with aryl halides without a Pd catalyst, by the benzyne mechanism,[342] but metal-catalyzed reactions are known. Typical catalysts include Fe,[343] Ni[344] Co,[345] or Ti,[346] and Pd- catalyzed reactions are important.[347] Aryl *Grignard reagents* react with aryltrimethylammonium triflates in the presence of a Pd catalyst to give the corresponding biaryl.[348] Arylmagnesium halides couple with aryl tosylates in the presence

of a Pd catalyst to give unsymmetrical biaryls,[349] and to halopyridines to give the arylated pyridine.[350] Aryl *Grignard reagents* are coupled to aryliodonium salts, with $ZnCl_2$ and a Pd catalyst, to give the biaryl.[351]

The coupling reaction of an excess of a *Grignard reagent* (RMgX) with methoxy aromatic compounds, when the aromatic ring contains multiple alkoxy groups, proceeds with replacement of the OMe group by R.[352] Aryl sulfones were coupled with aryl *Grignard reagents* in the presence of a Ni catalyst.[353]

Unsymmetrical binaphthyls were synthesized by photochemically stimulated reaction of naphthyl iodides with naphthoxide ions in an $S_{RN}1$ reaction.[354] Methyl chloroacetate coupled with aryl iodides under electrolysis conditions, using a Ni catalyst.[355] Unsymmetrical biaryls were prepared from two aryl iodides using a CuI catalyst and microwave irradiation.[356]

It is possible to couple metalated alkyl compounds to aryl compounds. Alkyl halides[357] are coupled to aryl halide using a Ni catalyzed reductive cross coupling.[358] Organozinc compounds, available by reaction of an alkyl halide and zinc metal, are coupled to aryl halides using a Pd- catalyst.[359] Specialized alkyl indium complexes have been used with a Pd catalyst to give arenes.[360] Iron complexes have been used for coupling reactions.[361] Triarylbismuth compounds are coupled with aryl bromides in the presence of a Pd catalyst.[362] Organolithium reagents are coupled to aryl bromides in the presence of a Ni catalyst,[363] as are arylzinc compounds.[364] The lithium enolate anion of an ester was coupled to an aryl halide using a Pd catalyst.[365] Other ketones can be coupled to aryl triflates, in the presence of a Pd catalyst, and with good enantioselectivity.[366]

Arylation of alkenes[367] is an important reaction using an "arylpalladium" reagent, typically generated *in situ* from an aryl halide or other suitably functionalized aromatic compound and a Pd catalyst.[368] The Pd catalyzed aryl–alkene coupling reaction is known as *the Heck reaction*.[369] Mizoroki[370] had earlier described the coupling between iodobenzene and styrene to form stilbene in methanol at 120 °C in the presence of potassium acetate and a palladium chloride catalyst leading some to call this the *Mizoroki–Heck reaction*. The reaction works best with aryl iodides, but conditions are available for aryl bromides and aryl chlorides.[371] Aryldiazonium salts (see Reactions **13-25** and **13-26**) have also been used.[372] Activated aromatic compounds couple readily,[373] but unactivated aromatic compounds often require special reaction conditions. The *Heck reaction* can be done with heterocyclic compounds,[374] and heteroaryl halides can be used in the coupling reaction.[375] Intramolecular *Heck reactions* are increasingly important.[376] A silane-tethered, intramolecular *Heck reaction* is known.[377] Other nucleophiles can be coupled to aryl halides.[378]

Phosphine–free catalysts,[379] halogen-free reactions,[380] and base-free reactions[381] have been developed for the *Heck reaction*. Improvements to the Pd catalyst system are constantly being reported,[382] including polymer-supported[383] silca-supported,[384] and

recoverable catalysts.[385] Considerable work has been done to study and improve the ligand.[386] Efforts have been made to produce a homogeneous catalyst for the Heck reaction.[387] The *Heck reaction* can be done in aq media,[388] in perfluorinated solvents,[389] in polyethylene glycol,[390] in neat tricaprylmethylammonium chloride,[391] and in supercritical CO_2 (See Sec. 9.D.ii).[392] The reaction has been done on solid support,[393] including Montmorillonite clay,[394] glass beads,[395] on a reverse-phase silica support,[396] and using microwave irradiation.[397] A microwave irradiated *Heck coupling* was done in water using a Pd catalyst.[398] A noncatalytic reaction was reported using supercritical water.[399] The effects of high pressure have been studied.[400] The *Heck reaction* has also been done in ionic liquids,[401] and it is known that the nature of the halide is important in such reactions.[402] Ionic liquids have been shown to actually promote the *Heck reaction*.[403]

Ethylene is the most reactive alkene, and increasing substitution lowers the reactivity. Coupling generally takes place at the less highly substituted side of the double bond.[404] Unlike the diazonium coupling reaction in Reaction **13-26**, the *Heck reaction* is not limited

to activated substrates. Both electron-deficient alkenes (e.g., acrylates),[405] and electron-rich alkenes[406] undergo the *Heck reaction*. The substrate can be an unactivated alkene,[407] and the alkene can contain a variety of functional groups (e.g., esters, ether,[408] enol ethers,[409] enamides,[410] carboxyl, phenolic, or cyano groups).[411] The aryl halide or aryl triflate can be coupled to dienes,[412] allenes,[413] allylic acetates,[414] allylic silanes,[415] allylic amines,[416] vinyl phosphonate esters,[417] and with terminal alkynes.[418] Aryliodonium salts can be coupled to conjugated alkenes in a *Heck-like* manner using a Pd catalyst.[419] Double-coupling reactions have been reported, generating diaryl aromatic compounds.[420] *Heck-type reactions* have been reported with imines.[421]

Control of regiochemistry is a serious problem in the coupling to unsymmetrical alkenes. Some regioselectivity can be obtained by the use of alkenes attached to an auxiliary coordinating group,[422] or by using special ligands and acrylate or styrene as substrates.[423] Neighboring-group effects play a role in the *Heck reaction*.[424] Steric effects are thought to control regioselectivity,[425] but electronic influences have also been proposed.[426] It has been shown that the presence of steric effects generally improves 1,2-selectivity, and that electronic effects can be used to favor 1,2- or 2,1-selectivity.[427] A 1,4-Pd migration between the *o*- and *o′*-positions of biaryls has been observed in organopalladium intermediates derived from *o*-halobiaryls.[428] Migration of the double bond is a problem in some cases, and reaction conditions play a significant role in such migrations.[429] It has been

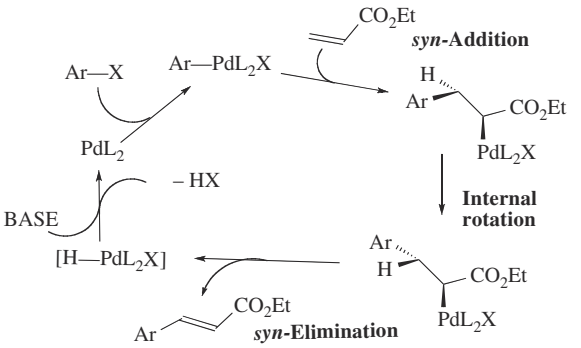
reported that double-bond isomerization can be suppressed in intramolecular *Heck reactions* done in supercritical CO_2 (see Sec. 9.D.ii).[430]

21
(89%)



The Pd catalyzed reactions are usually stereospecific,[431] yielding products expected from syn addition followed by syn elimination.[432] Because the product is formed by an elimination step, with suitable substrates, double-bond migration can occur, resulting in allylic rearrangement (as in the reaction of cyclopentene and iodobenzene to give **21**).[433] Asymmetric *Heck reactions* are known,[434] including asymmetric intramolecular *Heck reactions*.[435] Dihydrofurans react with aryl triflates and a Pd catalyst that includes a chiral ligand, to give the 5-phenyl-3,4-dihydrofuran with good enantioselectivity.[436] A similar reaction was reported for an *N*-carbamoyl dihydropyrrole.[437]

21
(89%)

An addition–elimination mechanism (addition of ArPdX followed by elimination of HPdX) operates in most cases.[438] In the conventionally accepted reaction mechanism,[439] which is shown,[440] a four-coordinate arylPd(II) intermediate (a palladacycle)[441] is formed by oxidative addition of the aryl halide to a Pd(0) complex prior to olefin addition.[442] This description suggests that cleavage of the dimeric precursor complex, reduction

of Pd^{2+}, and ligand dissociation combine to give a viable catalytic species.[443] σ-Alkyl Pd(II) intermediates are thought to be involved.[444] An analysis of reaction kinetics under dry conditions was reported.[435] In this study, the mechanism requires a first-order dependence on olefin concentration, and anomalous kinetics may be observed when the rate-limiting step is not directly on the catalytic cycle.[435] The mechanism requires a proton abstraction step, and there are substituent effects for this step.[445] A mechanistic study has been reported for the Pd catalyzed decarboxylative reaction of alkenes and arylcarboxylic acids.[446] The kinetics and mechanism of the *Heck reaction* promoted by a C—N palladacycle has been studied.[447] The mechanistic implications of asymmetric Heck reactions have been examined.[448]

There are a number of variations of this reaction, including the use of transition metal catalysts other than Pd. Rhodium-catalyzed *Heck reactions* are known,[449] and there are Co-,[450] Ru-,[451] and Ni catalyzed variations.[452] Iron-mediated arylation of alkenes has been reported,[453] and vinylgermanes are coupled to aryl halides with a Pd catalyst.[454] Aryl chlorides were coupled to conjugated esters using a $RuCl_3 \bullet 3\ H_2O$, in an atmosphere of O_2 and CO.[455] Aryl halides have been coupled to allenyltin compounds ($C{=}C{=}C\text{-}SnR_3$).[456] Divinylindium chloride [$(CH_2{=}CH)_2InCl$] reacted with an aryl iodide in aq THF with a Pd catalyst to give the styrene derivative.[457] Trialkenylindium reagents reacted similarly with

aryl halides in the presence of a Pd catalyst.[458] Arylzinc chlorides (ArZnCl) were coupled to vinyl chlorides using a Pd catalyst,[459] and vinyl zinc compounds were coupled to aryl iodides.[460] In the presence of trimethylsilylmagnesium chloride, primary alkyl halides coupled to aryl alkenes to give the substituted alkene (R′—CH=CHAr), using a Co catalyst.[461]

Potassium vinyltrifluoroborates can be coupled to aryl halides in *Heck-like* coupling reactions.[462] Likewise, the reaction of aryltrifluoroborates with vinyl halides, in the presence of a Pd catalyst, leads to the aryl alkene.[463] In a related reaction, alkyltrifluoroborates react with aryl halides in the presence of a Pd and a Rh catalyst.[464]

Although related to chemistry found in Reaction **10-57**, metal-catalyzed alkylation reactions are easily viewed as *Heck-like* reactions. For that reason, they are discussed here. Alkyl halides are coupled to alkenes to form substituted alkenes using a Co catalyst, promoted by Me_3SiCH_2MgCl.[465] Alkylation requires that the alkyl group lacks a β-hydrogen, and the reaction is successful for the introduction of methyl, benzyl, and neopentyl groups.[466] However, vinylic groups, even those possessing β-hydrogen atoms, have been successfully introduced (to give 1,3-dienes) by the reaction of the alkene with a vinylic halide in the presence of a trialkylamine and a Pd(0) catalyst.[467]

13-11 Homo-Coupling of Aryl Halides: The Ullmann Reaction

de-halogen-coupling

$$2\ \mathrm{ArI} \xrightarrow[\Delta]{\mathrm{Cu}} \mathrm{Ar{-}Ar}$$

The coupling of aryl halides with copper is called the *Ullmann reaction*.[468] The reaction is clearly related to Reaction **13-9**, but involves aryl copper intermediates. The reaction is of broad scope and has been used to prepare many symmetrical and unsymmetrical biaryls.[469] When a mixture of two different aryl halides is used, there are three possible products, but often only one is obtained. The best leaving group is iodo, and the reaction is most often done on aryl iodides, but bromides, chlorides, and even thiocyanates have been used. New ligands have been developed to promote the reaction, including an air-stable

diazaphospholane ligand.[470] The Cu catalyst has been immobilized.[471] Intramolecular reactions are known.[472] The coupling reaction can be applied to heterocyclic compounds.[473]

The effects of other groups on the ring are not easily predicted. The nitro group is strongly activating, but only in the ortho (not meta or para) position.[474] Both R and OR groups activate in all positions. Not only do OH, NH_2, NHR, and NHCOR inhibit the reaction, as would be expected for aromatic nucleophilic substitution, but so do CO_2H (but not CO_2R), SO_2NH_2, and similar groups for which the reaction fails completely. These groups inhibit the coupling reaction by causing side reactions.

The mechanism is not known with certainty. It seems likely that it is basically a two-step process, similar to that of the *Wurtz reaction* (**10-56**), which can be represented schematically by

$$\textbf{Step 1} \quad \mathrm{ArI + Cu \rightarrow ArCu}$$

$$\textbf{Step 1} \quad \mathrm{ArCu + ArI \rightarrow Ar{-}Ar}$$

Organocopper compounds have been trapped by coordination with organic bases.[475] In addition, aryl copper compounds (ArCu) have been independently prepared and shown to give biaryls (Ar—Ar′) when treated with aryl iodides (Ar′I).[476] A similar reaction has been used for ring closure[477]: Copper-catalyzed coupling of aryl halides and heterocycles has been reported.[478]

An important alternative to the *Ullmann method* is the use of certain Ni complexes.[479] Aryl halides (ArX) can also be converted to Ar—Ar[480] by treatment with activated Ni metal,[481] with Zn and Ni complexes,[482] with aq alkaline sodium formate, Pd—C and a phase-transfer catalyst,[483] and in an electrochemical process catalyzed by a Ni complex.[484]

An asymmetric *Ullmann reaction* has been reported.[485]

13-12 Coupling of Aryl Compounds with Arylboronic Acid Derivatives

Aryl-de-halogenation, and so on

Aryl-de-boronylation, and so on

$$\mathrm{Ar{-}Br} + \mathrm{Ar'B(OH)_2} \xrightarrow{\mathrm{PdL_4}} \mathrm{Ar{-}Ar'}$$

Arylboronic acids are coupled to aryl halides using a Pd catalyst to give the arene in what is called *Suzuki coupling* (or *Suzuki–Miyaura coupling*).[486] Aryl triflates react with arylboronic acids [$ArB(OH)_2$, Reaction **12-28**],[487] or with organoboranes,[488] in the presence of a Pd catalyst.[489] Even hindered boronic acids give good yields of the coupled product.[490] Homocoupling of arylboronic acids has been reported.[491] Some aromatic compounds are so reactive that a catalyst may not be required. Using tetrabutylammonium bromide, phenylboronic acid was coupled to 2-bromofuran without a catalyst.[492]

Different conditions (including additives and solvent) for the reaction have been reported,[493] often focusing on the Pd catalyst[494] or the ligand.[495] Phosphine-[496] and

ligand-free conditions[497] have been developed. Recyclable catalysts have been developed.[498] Catalysts have been developed for deactivated aryl chlorides.[499] *Suzuki coupling* has also been done in ionic liquids,[500] in supercritical CO_2[501] (see Sec. 9.D.ii), and there are solvent-free procedures.[502] Several procedures for coupling in aqueous media have been reported.[503] The reaction has been done neat on alumina,[504] and on alumina with microwave irradiation.[505] Several procedures have been reported using microwave irradiation.[506] Modifications to the basic procedure include tethering the aryl triflate[507] or the boronic acid[508] to a polymer, allowing a polymer-supported *Suzuki reaction*. Polymer-bound Pd complexes have been used.[509] There is even a Pd free cross-coupling.[510]

Arylboronic acids have been coupled to vinyl halides[511] or vinyl tosylates[512] using a Pd catalyst. Halogenated heteroaromatic compounds react, as do aryl carbamates, carbonates and sulfamates,[513] and aryl phosphoramides.[514] Aryl sulfonates have been used.[515]

Arylboronic acids couple with aryl sulfonate esters.[516] Many different heterocycles have been arylated.[517] 4-Pyridylboronic acids have been used.[518] 3-Iodopyridine reacted with NaBPh and palladium acetate, with microwave irradiation, to give 3-phenylpyridine.[519]

A variety of functional groups are compatible with Suzuki coupling, including $Ar_2P{=}O$,[520] CHO,[521] C=O of a ketone,[522] CO_2R,[523] cyclopropyl,[524] NO_2,[525] CN, and halogen substituents.[526] Vinyl halides react with arylboronic acids to give alkenyl derivatives (vinyl arenes, C=C—Ar),[527] in what is clearly a *Heck-like* reaction. In a variation, vinylboronic acids coupled to aryl halides to give the vinyl-coupling product.[528] Vinylboronic acids have been coupled to aryldiazonium salts (see Reaction **13-25**) without added base, using a Pd catalyst with an imidazolium ligand.[529]

Alkylation can accompany arylation if alkyl halides are added, as in the conversion of iodobenzene to 2,6-dibutylbiphenyl.[530] Alkyl groups may be coupled to aryls, as in the Pd catalyzed reaction of arylboronic acids with benzylic carbonates.[531] Arylboronic acids also couple with alkyl halides using either a palladium(II) acetate[532] or a Ni catalyst.[533] Conversely, arylboronic acids can be coupled to aliphatic halides.[534] Arylboronic acids can be coupled to allylic alcohols as well.[535] Benzylic phosphonates have also been used.[536] Double *Suzuki coupling* reactions are known.[537] An alkyl–alkyl coupling reaction has been classified as a *Suzuki cross-coupling* reaction.[538] The reaction of an arylboronic acid and 1,2-dibromoethane, with KOH and a Pd catalyst, leads to the styrene derivative.[539]

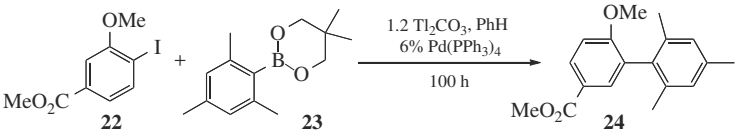
Since many biaryls are chiral due to atropisomerism (see Sec. 4.C, category 5), the use of a chiral catalyst, and/or a chiral ligand can lead to enantioselectivity in the *Suzuki coupling*.[540]



For a mechanistic viewpoint,[541] the *Suzuki coupling* proceeds via oxidative addition of areneboronic acids to give a Pd species, followed by 1,2-arene migration to an electron-deficient Pd atom, eventually leading to very fast reductive elimination to afford biaryls.[542] This mechanism is illustrated.[543] Several intermediates of the oxidative coupling process have been identified by electrospray ionization mass spectrometry.[544] Palladium peroxo complexes have been shown to be key intermediates.[545]

Other transition metals have been employed in these coupling reactions, sometimes as cocatalysts. Arylboronic acids have been coupled to conjugated alkenes to give the aryl–alkene coupling product using a Pd catalyst,[546] a Ru catalyst with copper(II) acetate,[547] a Ni catalyst,[548] or a Rh catalyst.[549] Aryl boronic acids are coupled with aryl ammonium salts to give the biaryl, with a Ni catalyst.[550] Allylic acetates have been coupled to arylboronic acids using nickel bis(acetylacetonate) and diisobutylaluminum hydride.[551] Arylboronic acids (Reaction **12-28**) were shown to react directly with benzene in the presence of $Mn(OAc)_3$.[552] Aryl halides couple with $ArB(IR'_2)$ species with a Pd catalyst.[553] Iron catalysts have been developed for coupling with alkyl halides.[554] Arylboronic

acids couple with the phenyl group of Ph_2TeCl_2 with a Pd catalyst.[555] Tributyltin aryl compounds were coupled to the aryl group of $Ar_2I^+BF_4^-$ with a Ni catalyst.[556]

Suzuki-type coupling reactions have been reported involving acyl halides. When arylboronic acids were reacted with benzoyl chloride and $PdCl_2$, the product was the diaryl ketone.[557] This coupling reaction was also accomplished using a Pd(0) catalyst.[558] Cyclopropylboronic acids couple with benzoyl chloride, in the presence of Ag_2O and a Pd catalyst, to give the cyclopropyl ketone.[559] A Ni catalyst has been used,[560] and Ph_3P/Ni/C—BuLi has also been used.[561] Arylboronic acids have also been coupled to anhydrides,[562] and the methoxy group of anisole derivatives has been replaced with phenyl using phenylboronic acid and a Ru catalyst.[563]

Arylborates (see Reaction **12-28**), $ArB(OR)_2$, can be used in place of the boronic acid.[564] The coupling reaction of aryl iodide (**22**) with boronate (**23**), for example, gave biaryl **24**.[565] Base-free conditions, using nitrogen ligands, have been reported.[566] Aryl and heteroarylboroxines (**25**) can be coupled to aryl halides using a Pd catalyst.[567] Vinylboranes have been coupled to aryl iodides to give the aryl alkene, in the presence of a Pd catalyst.[568] Organoboranes are coupled to aryl halides with a Pd catalyst.[569]

In a useful variation, aryltrifluoroborates ($ArBF_3^+ X^-$) (Reaction **12-28**), are coupled to aryl halides with a Pd catalyst to give the biaryl.[570] Alkyltrifluoroborates[571] (RBF_3K, see Reaction **12-28**) react with aryl triflates[572] aryl halides,[573] or aryliodonium salts[574] with a Pd catalyst, to give the arene. In a related reaction, vinyltrifluoroborates ($C{=}C{-}BF_3^+ X^-$ see Reaction **12-28**), are coupled to aryl halides with a Pd catalyst to give the styrene derivative.[575] *Suzuki coupling* with trifluoroborates has also been done using microwave irradiation.[576] Aryltellurides have been used in this reaction.[577] A Pd catalyzed reaction with enamino ketones, mediated by Cu(II) salts, led to coupling to give the aryl derivative.[578] Ruthenium catalysts have also been used.[579]

OS **75**, 53, 61

The coupling reactions of alkylboronic acids are covered in Reaction **13-17**.

OS CV, 102, 467; OS **81**, 89.

13-13 Aryl–Alkyne Coupling Reactions

Alkynyl-de-halogenation, and so on

$$ArI + RC{\equiv}CCu \longrightarrow ArC{\equiv}CR$$

When aryl halides react with copper acetylides to give 1-aryl alkynes, the reaction is known as *Stephens–Castro coupling*.[580] Both aliphatic and aromatic substituents can be attached to the alkyne unit, and a variety of aryl iodides have been used. Benzonitrile was shown to react with alkynyl zinc bromides, with a Ni catalyst and after electrolysis to give the diarylalkyne, where the cyano unit was replaced with an alkyne unit.[581]

$$Ar\text{-}X + RC{\equiv}CH \xrightarrow{Pd(0)} Ar\text{-}C{\equiv}CR$$

A Pd catalyzed variation is known in which an aryl halide reacts with a terminal alkyne to give 1-aryl alkynes is called *Sonogashira coupling*.[582] Terminal aryl alkynes react with aryl iodides and Pd(0)[583] to give the corresponding diaryl alkyne,[584] but monoalkynes are easily prepared.[585] Aryl iodides are more reactive than aryl fluorides.[586] Alkynes can be coupled to heteroaromatic compounds.[587] As with all of the metal-catalyzed reactions in this chapter, work has been done to vary reaction conditions, including the catalyst,[588] the ligand,[589] the solvent, and additives.[590] There are copper-[591] and ligand-free variations.[592] Transition metal free coupling has been reported using a 2,2,6,6-tetramethylpiperidine-*N*-oxyl radical as an oxidant.[593] Variations include *Sonogashira coupling* in water, without Cu,[594] and other reactions are done in aqueous media.[595] The coupling has been done in aq polyethylene glycol,[596] and in ionic liquids.[597] Microwave irradiation is an important tool in this reaction.[598] *Sonogashira coupling* was reported on microbeads,[599] with

nanoparticulate nickel powder,[600] and the aryl iodide was tethered to a polymer for a solid-state reaction.[601] Polymer-supported catalysts are known.[602] A variation scavenged the triphenylphosphine byproduct by addition of *Merrifield* resin.[603]

Coupling of the alkynes to form a diyne (see Reaction **14-16**) can be a problem is some cases, although the aryl–alkyne coupling usually predominates.[604] There are many variations. Alkyl groups are coupled to alkynes under *Sonogashira conditions*, including unactivated secondary alkyl halides.[605] Coupling propargyl bromide and an aryl iodide, in the presence of an amine, gives the aryl aminomethylalkyne.[606] 4-Chloroacetophenone reacts with 1-phenylethyne, showing that the carbonyl group is compatible with this reaction.[607] Arenediazonium salts can be used for the coupling reaction.[608] Similar Pd catalyzed coupling of bromoalkynes with heterocycles also leads to the alkynyl derivative.[609] Ynamides are coupled using cooper-free conditions.[610]

There are variations of the *Sonogashira reaction* that use other metals as catalysts or cocatalysts. A Pd free reaction is known, using Cu complexes as the catalyst.[611] An In catalyzed reaction is known that does not use Cu, Pd, or phosphine ligands.[612] Gold(I) has been used to catalyze *Sonogashira reactions*,[613] and there are Ni[614] and Fe catalyzed[615] reactions. Silver iodide has been used to catalyze the reaction.[616] Conversion of 1-lithioalkynes to the corresponding alkynyl zinc reagent allows coupling with aryl iodides when a Pd catalyst is used.[617] A 1-lithioalkyne was directly coupled to aryl bromides in the presence of $B(OiPr)_3$ and a Pd catalyst,[618] where an alkynylboronic acid was generated *in situ*. Lithium alkynyltrimethylborates are coupled to aryl chlorides as well.[619] Terminal alkynes are coupled to acylpyridinium salts in the presence of a Cu catalyst, giving a product with high enantioselectivity when a chiral ligand is used.[620] Coupling with alkynyl tin compounds is known.[621] A triphenylstibine [$Ph_3Sb(OAc)_2$] was used to transfer a phenyl group to the alkyne carbon of $PhC{\equiv}CSiMe_3$, using Pd and CuI catalysts.[622]

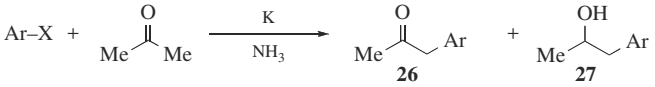
A variation of this aryl–alkyne coupling reaction reacted methylthioalkynes (R—C≡C—SMe) with arylboronic acids and a Pd catalyst to give the aryl alkyne (R—C≡C—Ar).[623] The boron trifluoride induced Pd catalyzed cross-coupling reaction of 1-aryltriazenes with areneboronic acids has been reported.[624] Aryl halides are coupled to alkynyltrifluoroboronates (R—C≡C—BF_3K, Reaction **12-28**) using a Pd catalyst.[625] Aryl iodides were also coupled to lithium alkynyl borate complexes, Li[R—C≡C—$B(OR')_3$], to give the aryl alkyne.[626]

Diaryliodonium salts react with terminal alkynes to give the phenyl alkyne.[627] A variation couples the phenyl group of $Ph_2I^+OTf^-$ with an en-yne using a Pd catalyst.[628] Aryl sulfonate esters can be coupled to terminal alkynes using a Pd catalyst in polymethylhydrosiloxane.[629]

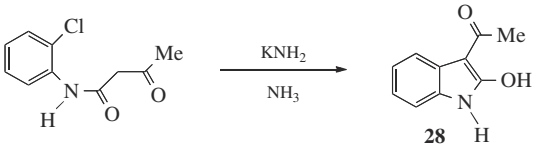


OS 11, **2009**, 234.

13-14 Arylation at a Carbon Containing an Active Hydrogen

Bis(ethoxycarbonyl)methyl-de-halogenation, and so on

The arylation of compounds of the form ZCH_2Z' is analogous to Reaction **10-67**, where Z is defined as an electron-withdrawing group (ester, cyano, sulfonyl, etc.). Activated aryl halides generally give good results.[630] Treatment with an aryl halide in liquid ammonia containing Na or K, for example, leads in the formation of **26** and **27**.[631] When the solution is irradiated with near-UV light, but Na or K is omitted, the same products are



obtained (though in different proportions).[632] In either case, other leaving groups can be used instead of halogens (e.g., NR_3^+, SAr) and the mechanism is the $S_{RN}1$ mechanism. *N*-Heterocyclic carbene ligands in the presence of alkoxide bases lead to coupling of ketones and aryl halides, at the α-position of the ketone.[633] The reaction can also take place without an added initiator. The reaction of 2-fluoroanisole and KHMDS, and 4 equiv

of 2-cyanopropane, leads to substitution of the fluorine atom by CMe_2CN.[634] β-Keto esters were coupled to aryl fluorides using CsOH and a chiral quaternary ammonium salt, leading to the aryl substitution product with good enantioselectivity.[635]

Even unactivated aryl halides can be employed if the reaction is carried out in the presence of a strong base (e.g., $NaNH_2$[636] or LDA). Compounds of the form ZCH_2Z', and even simple ketones[637] or carboxylic esters have been arylated in this manner. The reaction with unactivated halides proceeds by the benzyne mechanism and represents a method for extending the malonic ester (and similar) syntheses to aromatic compounds. The base performs two functions: It removes a proton from ZCH_2Z' and catalyzes the benzyne mechanism. The reaction has been used for ring closure, as in the formation of indole **28**.[638]

28

A similar reaction was reported using a Pd catalyst.[639] Nitroethane was converted to 2-phenylnitroethane using bromobenzene and a Pd catalyst.[640] Palladium catalysts have been developed for the α-arylation of ketones.[641] α-Arylation of esters has been accomplished using Pd catalysts.[642] Malonate esters are coupled unactivated aryl halides using a Pd catalyst.[643] Bis-(sulfones) $[CH_2(SO_2Ar)_2]$, react with aryl halides in the presence of a Pd catalyst.[644] Iron(II) salts have also been used to initiate this reaction.[645] The coupling of active methylene compounds and unactivated aryl halides can also be done with copper halide catalysts[103] (the *Hurtley reaction*).[646] Similar coupling was accomplished with $CH_2(CN)_2$ and a Ni catalyst.[647] A variation of α-arylation reacts α-halocarbonyl compounds with arylboronic acids, in the presence of a Ni catalyst.[648] Malonic and β-keto esters can be arylated at the α-carbon in high yields by treatment

with aryllead tricarboxylates [$ArPb(OAc)_3$],[649] with triphenylbismuth carbonate (Ph_2BiCO_3),[650] and other Bi reagents.[651] In a related process, manganese(III) acetate was used to convert a mixture of ArH and ZCH_2Z' to $ArCHZZ'$.[652] Arylzinc reagents have also been used.[653]

Enolate ions of ketones react with PhI in the dark.[654] In this case, it has been suggested[655] that initiation takes place by formation of a radical (e.g., **29**).

29

This is a SET mechanism (see Sec. 10.B). The photostimulated reaction has also been used for ring closure.[656] In certain instances of the intermolecular reaction, there is evidence that the leaving group exerts an influence on the product ratios, even when it has already departed at the time that product selection takes place.[657]

The reaction of the enolate anions of ketones and aldehydes, generated *in situ* by addition of a suitable base, with aryl halides can be accomplished by treatment with a Pd catalyst.[658] Formation of an enolate anion of a conjugated ketone (cyclohexenone) via reaction with LDA (see Sec. 8.F, category 7), in the presence of Ph_3BiCl_2, leads to the α-phenyl conjugated ketone (6-phenylcyclohex-2-enone).[659] An ester reacted with $TiCl_4$ and *N,N*-dimethylanline to give the para-substitution product ($Me_2N—Ar—2Et$).[660] Nickel-catalyzed α-arylation of ketone enolate anions is also known.[661] The enolate anion of lactams will react with aryl halides in the presence of a Pd catalyst via the 3-aryl lactam.[662] When the enolate anion of a ketone is generated in the presence of a Pd catalyst and a chiral phosphine ligand, the α-aryl ketone is formed with good enantioselectivity.[663]

13-15 Conversion of Aryl Substrates to Carboxylic Acids, Their Derivatives, Aldehydes, and Ketones[664]

Alkoxycarbonyl-de-halogenation, and so on

$$ArX + CO + ROH \xrightarrow[\text{Pd complex}]{\text{base}} ArCOOR$$

Carbonylation of aryl halides[665] and aryl triflates[666] with CO, an alcohol and a base (which gives an alkoxide), and a Pd catalyst, gives carboxylic esters. Similar carbonylation reactions are possible with alkyl halides. Aryl carboxylic acids were also prepared from aryl iodides by heating in DMF with lithium formate, LiCl, acetic anhydride, and a Pd catalyst.[667] Even very sterically hindered alkoxides can be used to produce the corresponding ester.[668] The use of H_2O, RNH_2, or an alkali metal or calcium carboxylate[669] instead of ROH, gives the carboxylic acid,[670] amide,[671] or mixed anhydride, respectively.[672] Ester formation via carbonylation was done is supercritical CO_2 (see Sec. 9.D.ii).[673] Microwave promoted carbonylation reactions have been reported.[674]

Variations including a silica-supported Pd reagent have been used to convert iodobenzene to butyl benzoate, in the presence of CO and butanol.[675] 2-Chloropyridine was converted to the butyl pyridine 2-carboxylate with this procedure.[676] Dicobalt octacarbonyl [$Co_2(CO)_8$] may be used as a surrogate reagent for CO.[677] Heating an aryl iodide, CO in ethanol and DBU, with a Pd catalyst, gave the ethyl ester of the aryl carboxylic acid.[678] A similar result was obtained when an aryl iodide was heated in ethanol with triethylamine, CO, and Pd/C.[679] Phenols and aryl halides react with a Pd catalyst, and carbonylation leads to the phenyl ester.[680] Arylthallium bis(trifluoroacetates) [$ArTl(O_2CCF_3)_2$, (see Reaction **12-23**], can be carbonylated with CO, an alcohol, and a $PdCl_2$ catalyst to give esters.[681] Note that seleno esters (ArCOSeAr) were prepared

from aryl iodides, CO, $PhSeSnBu_3$, and a Pd catalyst.[682] Aminocarbonylation reactions are known.[683]

Modification of this approach allows the synthesis of ketones, and aryl iodides can be converted to aldehydes.[684] Aryl ketones can be prepared from aryltrimethylsilanes ($ArSiMe_3$) and acyl chlorides in the presence of $AlCl_3$.[685] Aryllithium and *Grignard reagents* react with iron pentacarbonyl to give aldehydes ArCHO.[686] The reaction of CO with aryllithium may occur by electron transfer.[687] Aryl iodides are converted to unsymmetrical diaryl ketones on treatment with arylmercury halides and nickel carbonyl: $ArI + Ar'HgX + Ni(CO)_4 \rightarrow ArCOAr'$.[688] Aryl iodides are carbonylated to give the aryl alkyl ketone with CO and R_3In.[689] Aryl iodides are coupled with aryl acid chlorides in the presence of an In complex to form a diaryl ketone.[690] Organomercury compounds undergo a similar reaction.[691] The aryllead reagent [$PhPb(OAc)_2$] was converted to benzophenone using NaOMe, CO, and a Pd catalyst.[692] Aryl iodides containing an ortho substituent with a β-cyano group that served as the source of a carbonyl group, was converted to a bicyclic ketone with a Pd catalyst at 130 °C in aq DMF.[693]

Diaryl ketones can also be prepared by coupling aryl iodides with phenylboronic acid (Reaction **12-28**), in the presence of CO and a Pd catalyst.[694] This reaction has been extended to heteroaromatic systems, with the preparation of phenyl 4-pyridyl ketone from phenylboronic acid and 4-iodopyridine.[695] 2-Bromopyridine as coupled with phenylboronic acid, CO, and a Pd catalyst to give phenyl 2-pyridyl ketone.[696] Carbonylation of an alkyne and an aryl halide, with CO and Pd and Cu catalysts, gave the alkynyl ketone $RC{\equiv}C(C{=}O)Ar$.[697]

13-16 Arylation of Silanes

Silyl and Silyloxy-de-halogenation, Aryl-de-silylation, and so on

$$Ar{-}X + Ar'SiR_2 \rightarrow Ar{-}SiR_3$$

In the presence of transition metal catalysts (e.g., Pd), trialkoxysilanes [$HSi(OR)_3$] react with aryl halides to give the corresponding arylsilane.[698] This transformation is an alternative to the *Suzuki coupling* (Reaction **13-12**).[699] The influence of silicon substituents on the cross-coupling reaction has been studied.[700] A similar reaction was reported using a Rh catalyst.[701] Similar coupling of aryl halides with trialkylsilanes ($HSiR_3$) in the presence of a Pd,[702] or Rh catalyst,[703] or PtO_2[704] gives the arylsilane. Cyclic alkoxysilanes are prepared using Pd catalyzed cross-coupling reactions.[705] Vinylsilanes are coupled to aryl halides to give the aryl alkene.[706] Disilanes have also been employed, using a Pd catalyst.[707] Arylsilanes can be coupled to aryl iodides using a Pd catalyst[708] and in aqueous media.[709] Arylsilanes react with alkyl halides to give the corresponding arene, in the presence of a Pd catalyst.[710]

Other variations include the conversion of vinyl silanes to styrene derivatives upon treatment with Bu_4NF (TBAF), an aryl iodide and a Pd catalyst.[711] Arylsilanes were coupled to alkenes to give the styrene derivative using palladium acetate in an oxygen atmosphere,[712] or TBAF and an Ir catalyst.[713] Aryl iodides can be coupled to 1-methyl-1-vinyl- and 1-methyl-1-(prop-2-enyl)silacyclobutane with desilyation, using a Pd catalyst and TBAF, to give the corresponding styrene derivative.[714] Aryl silanes can be coupled to aryl iodides using Ag_2O and a Pd catalyst,[715] and arylsiloxanes [$ArSi(OR)_3$] are coupled to aryl halides with TBAF and a Pd catalyst.[716] 1-Trialkylsilylalkynes ($R_3Si—C\equiv C—R'$) were coupled to aryl iodides using a Pd catalyst.[717]

An alternative approach reacts aryllithium reagents with siloxanes [$Si(OR)_4$], to give the aryl derivative $ArSi(OR)_3$.[718] Biaryl derivatives are similarly prepared from

aryl halides.[719] Arylsiloxanes are similarly coupled at the ortho position of anilide derivatives.[720]

The reaction of $NaBPh_4$ (sodium tetraphenylborate) and a silyl dichloride (Ph_2SiCl_2) gives biphenyl.[721]

13.C.ii. Hydrogen as Leaving Group[722]

13-17 Alkylation and Arylation

Alkylation or Alkyl-de-hydrogenation, and so on

The alkylation of aromatic rings was introduced, in part, in Reaction **10-57**. The reaction of an aromatic ring with an organolithium reagent can give H–Li exchange to form an aryllithium. This reaction tends to be slow if there are activating substituents on the aryl halide, or in the absence of diamine additives.[723] When heteroatom substituents are present as in **30**, however, the reaction is facile and the Li goes into the 2 position (as in **31**).[724] This regioselectivity can be quite valuable synthetically, and is now known as *directed ortho metalation*[725] (see Reaction **10-57**). Subsequent reaction with a suitable electrophilic agent (e.g., D_2O) leads to **32** in this case. Aryllithium reagents give arylation. The reaction occurs by an addition–elimination mechanism and the adduct can be isolated.[726] Upon heating of the adduct, elimination of LiH occurs and an alkylated product is obtained. With respect to C-2, the first step is the same as that of the S_NAr mechanism. The difference is that the unshared pair of electrons on the nitrogen combines with the lithium, so the extra pair of ring electrons has a place to go: It becomes the new unshared pair on the nitrogen.

With TMEDA/*n*-butyllithium mediated arene lithiation reactions, the viability of directive effects (complex-induced proximate effects) has been questioned,[727] although it is not clear if this extends to other systems (particularly when there is a strong coordinating group (e.g., carbamate).[728] The 2 position is much more acidic than the 3 position (see Table 8.1), but a negative charge at C-3 is in a more favorable position to be

stabilized by the Li^+. Lithiation reactions do not necessarily rely on a complex-induced proximity effect.[729] *N,N*-Dialkyl aryl-*O*-sulfamates are substrates for ortho metalation.[730] Phenylaziridines also undergo this reaction.[731] Formation of the ortho arylmagnesium compound has been accomplished with bases of the form $(R_2N)_2Mg$.[732] A directed meta metalation has been reported, using alkali metal mediated zincation.[733] Note that the substrate-dependent mechanism of the ortho lithiation of aryloxazolines using butyllithium has been studied.[734]

Benzene, naphthalene, and phenanthrene have been alkylated with alkyllithium reagents, although the usual reaction with these reagents is Reaction **12-22**,[735] and *Grignard reagents* have been used to alkylate naphthalene.[736] The addition–elimination mechanism apparently applies in these cases too. A protected form of benzaldehyde (protected as the benzyl imine) has been similarly alkylated at the ortho- position with butyllithium.[737] The alkylation of heterocyclic nitrogen compounds[738] with alkyllithium reagents is called *Ziegler alkylation*. The reaction of 2-chloropyridine with 3 equiv of butyllithium–$Me_2NCH_2CH_2OLi$ and then iodomethane gave 2-chloro-6-methylpyridine.[739] Note that H–Li exchange can be faster than Cl–Li exchange. Treatment of 2-chloro-5-phenylpyridine with *tert*-butyllithium leads to lithiation on the phenyl ring rather than Li–Cl exchange, and subsequent treatment with dimethyl sulfate gave 2-chloro-5-(2-methylphenyl)pyridine.[740] The reaction of *N*-triisopropylsilyl indole with *tert*-butyllithium and then iodomethane gave the 3-methyl derivative.[741] Heteroaromatic compounds can be alkylated. Pyrrole, for example, reacts with an allylic halide and zinc to give primarily the 3-substituted pyrrole.[742]

Mercuration of aromatic compounds[743] can be accomplished with mercuric salts, most often $Hg(OAc)_2$,[744] to give ArHgOAc. This is ordinary electrophilic aromatic substitution and takes place by the arenium ion mechanism (Sec. 11.A.i).[745] Aromatic compounds can also be converted to arylthallium bis(trifluoroacetates) [$ArTl(OOCCF_3)_2$] by treatment

with thallium(III) trifluoroacetate[746] in trifluoroacetic acid.[747] These arylthallium compounds can be converted to phenols, aryl iodides or fluorides (Reaction **12-31**), aryl cyanides (Reaction **12-34**), aryl nitro compounds,[748] or aryl esters (Reaction **12-33**). The mechanism of thallation appears to be complex, with electrophilic and electron-transfer mechanisms both taking place.[749] Transient metalated aryl complexes can be formed that react with another aromatic compound. Aryl iodides reacted with benzene to form a biaryl in the presence of an Ir catalyst.[750] Aniline derivatives reacted with $TiCl_4$ to give the para-homo coupling product ($R_2N—Ar—Ar—NR_2$).[751]

Aromatic nitro compounds can be methylated with dimethyloxosulfonium methylid[752] or the methylsulfinyl carbanion (obtained by treatment of DMSO with a strong base)[753]:

The reactions with the sulfur carbanions are especially useful, since none of these substrates can be methylated by the *Friedel–Crafts* procedure (Reaction **11-10**).

A different kind of alkylation of nitro compounds uses carbanion nucleophiles that have a chlorine at the carbanionic carbon. The following process takes place:[754]

This type of process is called *vicarious nucleophilic substitution of hydrogen*.[755] The Z group is electron withdrawing (e.g., SO_2R, SO_2OR, SO_2NR_2, COOR, or CN); it stabilizes the negative charge. The carbanion attacks the activated ring ortho or para to the nitro group.[756] Hydride ion (H^-) is not normally a leaving group, but in this case the presence of the adjacent Cl allows the hydrogen to be replaced. Hence, Cl is a "vicarious" leaving group. Other leaving groups have been used (e.g., OMe and SPh), but Cl is generally the best. Many W groups in the ortho, meta, or para positions do not interfere. The reaction is

[746] See Uemura, S. in Pizey, J.S. *Synthetic Reagents,* Vol. 5, Wiley, NY, ***1983***, pp. 165–241.

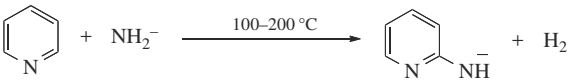
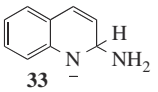
also successful for di- and trinitro compounds, for nitronaphthalenes,[757] and for many nitro heterocycles, $^{-}Z—CR—Cl$ may also be used.[758] When the nucleophile is Br_3C^- or Cl_3C^-, the product is $ArCHX_2$, which can easily be hydrolyzed to ArCHO.[759] This is therefore an indirect way of formylating an aromatic ring containing one or more NO_2 groups, which cannot be done by any of the formylations mentioned in Reaction **11-1**–**11-18**.



Replacement of an amino group is possible. When aniline derivatives were treated with allyl bromide and *tert*-butyl nitrite (*t*-BuONO), the aryl–allyl coupling product was formed ($Ar—NH_2 \rightarrow Ar—CH_2CH=CH_2$).[760]

For the introduction of CH_2SR groups into phenols, see Reaction **11-23**. See also, Reaction **14-19**.



OS **II**, 517.

13-18 Amination of Nitrogen Heterocycles

Amination or **Amino-de-hydrogenation**

Pyridine and other heterocyclic nitrogen compounds can be aminated with alkali metal amides in a process called the *Chichibabin reaction*.[761] The attack is always in the 2 position unless both such positions are filled, in which case the 4 position is attacked. Substituted alkali metal amides (e.g., RNH^- and R_2N^-), have also been used. The mechanism is probably similar to that of Reaction **13-17.** The existence of intermediate ions (e.g., **33**)

33

(from quinoline) has been demonstrated by NMR spectra.[762] A pyridyne type of intermediate was ruled out by several observations including the facts that 3-ethylpyridine gave 2-amino-3-ethylpyridine[763] and that certain heterocycles that cannot form an aryne could nevertheless be successfully aminated. Nitro compounds do not give this reaction,[764] but they have been aminated ($ArH \rightarrow ArNH_2$ or ArNHR) via the vicarious substitution principle (see Reaction **13-17**), using 4-amino- or 4-alkylamino-1,2,4-triazoles as nucleophiles.[765] The vicarious leaving group in this case is the triazole ring. Note, however, that 3-nitropyridine was converted to 6-amino-3-nitropyridine by reaction with KOH, hydroxylamine, and $ZnCl_2$.[766]

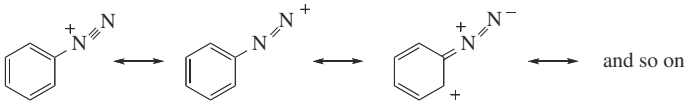
Analogous reactions have been carried out with hydrazide ions (R_2NNH^-).[767] A mixture of NO_2 and O_3, with excess $NaHSO_3$, converted pyridine to 3-aminopyridine.[768] For other methods of aminating aromatic rings, see Reaction **11-6**.

There are no *Organic Syntheses* references, but see OS **V**, 977, for a related reaction.



13.C.iii. Nitrogen as Leaving Group

The diazonium group can be replaced by a number of groups.[769] Some of these are nucleophilic substitutions, with S_N1 mechanisms (Sec. 10.A.ii), but others are free radical reactions and are treated in Chapter 14. The solvent in diazonium group reactions is usually water. With other solvents it has been shown that the S_N1 mechanism is favored by solvents of low nucleophilicity, while those of high nucleophilicity favor free radical mechanisms.[770] The N_2^+ group[771] can be replaced by Cl^-, Br^-, and CN^-, by a nucleophilic mechanism (see OS **IV**, 182), but the *Sandmeyer reaction* is much more useful (Reaction **14-20**). Transition metal catalyzed reactions are known involving aryldiazonium salts, and diazonium variants of the *Heck reaction* (**13-10**) and *Suzuki coupling* (**13-12**) were mentioned previously. As mentioned in Section 13.B.i, it must be kept in mind that the N_2^+ group can activate the removal of another group on the ring. In a few cases, nitrogen groups (e.g., nitro or ammonium) can be replaced.

13-19 Diazotization

$$\text{Ar—NH}_2 + \text{HONO} \longrightarrow \text{Ar—N+N}$$

When primary aromatic amines are treated with nitrous acid, diazonium salts are formed.[772] The reaction also occurs with aliphatic primary amines, but aliphatic diazonium ions are extremely unstable, even in solution (see Sec. 10.G.iii). Aromatic diazonium ions are more stable, because of the resonance interaction between the nitrogen atoms and the ring:

Rev.* ***1975***, *75,* 241.

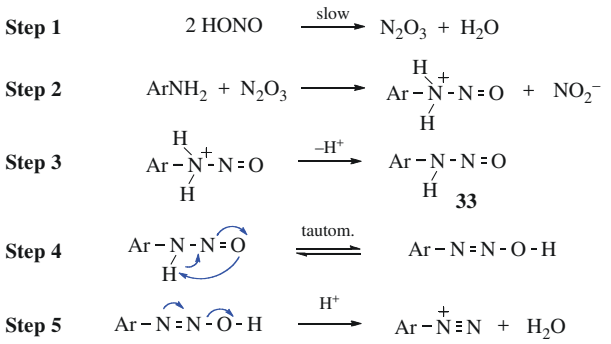
Incidentally, **34** contributes more than **35**, as shown by bond-distance measurements.[773] In benzenediazonium chloride, the C—N distance is ~1.42 Å, and the N—N distance ~1.08 Å,[774] and these values fit more closely to a single and a triple bond than to two double bonds (see Table 1.5). Even aromatic diazonium salts are unstable at temperatures other than about <5 °C. A few are more stable (e.g., the diazonium salt obtained from sulfanilic acid), which is stable up to 10 or 15 °C. Diazonium salts are usually prepared in aqueous solution and *used without isolation*.[775] While it is possible to prepare solid diazonium salts (see Reaction **13-23**), many dry diazonium salts are explosive if not handled with great care and extreme caution should be exercised. The stability of aryl diazonium salts can be increased by crown ether complexion.[776]



For aromatic amines, the reaction is very general. Halogen, nitro, alkyl, aldehyde, sulfonic acid, and so on, groups do not interfere. Since aliphatic amines do not react with nitrous acid below a pH of ~3, it is even possible, by working at a pH ~1, to diazotize an aromatic amine without disturbing an aliphatic amino group in the same molecule.[777]

$$EtOOC—CH_2—NH_2 + HONO \rightarrow EtOOC—CH{=}N{=}N^+$$

If an aliphatic amino group is α to a COOR, CN, CHO, COR, and so on, and has a hydrogen, treatment with nitrous acid gives not a diazonium salt, but a *diazo compound*.[778] Such diazo compounds can also be prepared, often more conveniently, by treatment of the substrate with isoamyl nitrite ($Me_2CHCH_2CH_2ONO$) and a small amount of acid.[779] Certain heterocyclic amines also give diazo compounds rather than diazonium salts.[780]

Despite the fact that diazotization takes place in acid solution, the actual reactive species is not the salt of the amine, but is the small amount of free amine present.[781] Because aliphatic amines are stronger bases than aromatic ones that at pH values <3 there is not enough free amine present for the former to be diazotized, while the latter still undergo the reaction. In dilute acid, the actual attacking species is N_2O_3, which acts as a carrier of NO^+. Evidence is that the reaction is second order in nitrous acid and, at sufficiently low acidities, the amine does not appear in the rate expression.[782] Under these conditions the mechanism is

Other evidence exists for this mechanism.[783] Other attacking species can be NOCl, $H_2NO_2^+$, and at high acidities even NO^+. Nucleophiles (e.g., Cl^-, SCN^-, and thiourea) catalyze the reaction by converting the HONO to a better electrophile (e.g., $HNO_2 + Cl^- + H^+ \rightarrow NOCl + H_2O$).[784]

N-Aryl ureas are converted to the aryldiazonium nitrate upon treatment with $NaNO_2$ and H_2SO_4 in dioxane[785] or with DMF—NO_2 in DMF.[786]

There are many preparations of diazonium salts listed in *Organic Syntheses*, but they are always prepared for use in other reactions. They are listed under reactions in which they are used. The preparation of aliphatic diazo compounds can be found in OS **III**, 392; **IV**, 424. See also, OS **VI**, 840.

13-20 Hydroxylation of Aryldiazonium Salts

Hydroxy-de-diazoniation

$$ArN_2^+ + H_2O \rightarrow ArOH$$

This reaction is formally analogous to **13-1**, but with a N_2^+ leaving group rather than a halide. Water is usually present whenever diazonium salts are made, but at these temperatures (0–5 °C) the reaction proceeds very slowly. When it is *desired* to have OH replace the diazonium group, the excess nitrous acid is destroyed and the solution is usually boiled. Some diazonium salts require even more vigorous treatment, for example, boiling with aq H_2SO_4 or with trifluoroacetic acid containing potassium trifluoroacetate.[787] The reaction can be performed on solutions of any diazonium salts, but hydrogen sulfates are preferred to chlorides or nitrates, since in these cases there is competition from the nucleophiles Cl^- or NO_3^-.

A better method, which is faster, avoids side reactions, takes place at room temperature, and gives higher yields consists of adding Cu_2O to a dilute solution of the diazonium salt dissolved in a solution containing a large excess of $Cu(NO_3)_2$.[788] Aryl radicals are intermediates when this method is used. It has been shown that aryl radicals are at least

partly involved when ordinary hydroxy-de-diazoniation is carried out in weakly alkaline aqueous solution.[789] Decomposition of arenediazonium tetrafluoroborates in F_3CSO_2OH gives aryl triflates directly, in high yields.[790]

OS **I**, 404; **III**, 130, 453, 564; **V**, 1130.

13-21 Replacement by Sulfur-Containing Groups

Mercapto-de-diazoniation, and so on

$$ArN_2^+ + HS^- \rightarrow ArSH$$
$$ArN_2^+ + S^{2-} \rightarrow ArSAr$$
$$ArN_2^+ + RS^- \rightarrow ArSR$$
$$ArN_2^+ + SCN^- \rightarrow ArSCN + ArNCS$$

These reactions are convenient methods for incorporating a sulfur-containing group onto an aromatic ring. With $Ar'S^-$, diazosulfides (Ar—N=N—S—Ar′) are intermediates,[791] which can in some cases be isolated.[792] Thiophenols can be made as shown above, but more often the diazonium ion is treated with EtO—CSS^- or S_2^{2-}, which give the expected products, and these are easily convertible to thiophenols. Aryldiazonium salts are prepared by the reaction of an aniline derivative with an alkyl nitrite (RONO), and when formed in the presence of dimethyl disulfide (MeS—SMe), the product is the thioether (Ar—S—Me).[793] Aryl triflates have been converted to the aryl thiol using NaST(P5) and a Pd catalyst, followed by treatment with tetrabutylammonium fluoride[794] (see also, Reaction **14-22**).

OS **II**, 580; **III**, 809 (but see OS **V**, 1050). Also see, OS **II**, 238.

13-22 Replacement by Iodine

Iodo-de-diazoniation

$$ArN_2^+ + I^- \rightarrow ArI$$

One of the best methods for the introduction of iodine into aromatic rings (see Reaction **13-7**) is the reaction of diazonium salts with iodide ions.[795] Analogous reactions with chloride, bromide, and fluoride ions give poorer results, and Reactions **14-20** and **13-23** are preferred for the preparation of aryl chlorides, bromides, and fluorides. However, when other diazonium reactions are carried out in the presence of these ions, halides are usually side products. Aniline has also been converted to fluorobenzene by treatment with *t*-BuONO and SiF_4 followed by heating.[796] A related reaction between PhN=N—NR_2 and iodine gave iodobenzene.[797]

[797] Wu, Z.; Moore, J.S. *Tetrahedron Lett.* ***1994***, *35*, 5539.

The actual attacking species is probably not only I^- if it is I^- at all. The iodide ion is oxidized (by the diazonium ion, nitrous acid, or some other oxidizing agent) to iodine, which in a solution containing iodide ions is converted to I_3^-; this is the actual attacking species, at least partly. This was shown by isolation of $ArN_2^+ I_3^-$ salts, which, on standing, gave ArI.[798] From this, it can be inferred that the reason the other halide ions give poor results is *not* that they are poor nucleophiles but *rather* they are poor reducing agents (compared with iodide). There is also evidence for a free radical mechanism.[799]

The hydroxyl group of a phenol can be replaced with iodine. The reaction of phenol with a boronic ester and a Pd catalyst, followed by reaction with NaI and chloramine-T (see Reaction **15-52**) converts phenol to iodobenzene.[800] Arylboronic acids are converted to the aryl fluoride with Selectfluor, in the presence of a Pd catalyst.[801]

OS **II**, 351, 355, 604; **V**, 1120.

13-23 The Schiemann Reaction

Fluoro-de-diazoniation (overall transformation)

$$ArN_2^+BF_4^- \xrightarrow{\Delta} ArF + N_2^+BF_3$$

Heating diazonium fluoroborates (the *Schiemann* or *Balz–Schiemann reaction*) is by far the best way to introduce fluorine into an aromatic ring.[802] In the most common procedure, the tetrafluoroborate salts are prepared by diazotizing as usual with nitrous acid and HCl and then adding a cold aqueous solution of $NaBF_4$, HBF_4, or NH_4BF_4. A precipitate forms, which is dried, and the salt is heated in the dry state. These salts are unusually stable for diazonium salts, and the reaction is usually successful (since diazonium salts are generally unstable, care should be exercised any time a diazonium salt is dried). In general, any aromatic amine that can be diazotized will form a BF_4^- salt, usually with high yields. The diazonium fluoroborates can be formed directly from primary aromatic amines with *tert*-butyl nitrite and BF_3–etherate.[803] The reaction has also been carried out on $ArN_2^+ PF_6^-$ $ArN_2^+ SbF_6^-$, and $ArN_2^+ AsF_6^-$ salts, in many cases with better yields.[804] Aryl chlorides and bromides are commonly prepared by the *Sandmeyer reaction* (**14-20**). In an alternative procedure, aryl fluorides are prepared by treatment of aryltriazenes $Ar—N{=}N—NR_2$ with 70% HF in pyridine.[805]

The mechanism is of the S_N1 type. That aryl cations are intermediates was shown by the following experiments[806]: Aryl diazonium chlorides are known to arylate other aromatic rings by a free radical mechanism (see Reaction **13-27**). In radical arylation it does not matter whether the other ring contains electron-withdrawing or electron-donating groups; in either case a mixture of isomers is obtained, since the attack is not by a charged species.

If an aryl radical were an intermediate in the *Schiemann reaction* and the reaction were run in the presence of other rings, it should not matter what kinds of groups were on these other rings: Mixtures of biaryls should be obtained in all cases. But if an aryl cation is an intermediate in the *Schiemann reaction*, compounds containing meta-directing groups (i.e., meta-directing for *electrophilic* substitutions), should be meta arylated and those containing ortho–para directing groups should be ortho and para arylated, since an aryl cation should behave in this respect like any electrophile (see Chapter 11). Experiments have shown[807] that such orientation is observed, demonstrating that the *Schiemann reaction* has a positively charged intermediate. The attacking species, in at least some instances, is not F^- but BF_4^-.[808]

OS **II**, 188, 295, 299; **V**, 133.

13-24 Conversion of Amines to Azo Compounds

N-Arylimino-de-dihydro-bisubstitution

$$ArNH_2 + Ar'NO \xrightarrow{HOAc} Ar{-}N{=}N{-}Ar'$$

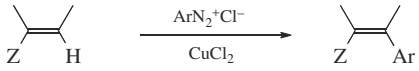
Aromatic nitroso compounds combine with primary arylamines in glacial acetic acid to give symmetrical or unsymmetrical azo compounds (the *Mills reaction*).[809] A wide variety of substituents may be present in both aryl groups. Unsymmetrical azo compounds have also been prepared by the reaction between aromatic nitro compounds ($ArNO_2$) and *N*-acyl aromatic amines (Ar′NHAc).[810] The use of phase-transfer catalysis increased the yields.

13-25 Methylation, Vinylation, and Arylation of Diazonium Salts

Methyl-de-diazoniation, and so on

$$ArN_2^+ + Me_4Sn \xrightarrow[MeCN]{Pd(OAc)_2} ArMe$$

A methyl group can be introduced into an aromatic ring by treatment of diazonium salts with tetramethyltin and a Pd catalyst.[811] The reaction has been performed with Me, Cl, Br, and NO_2 groups on the ring. A vinylic group can be introduced with $CH_2{=}CHSnBu_3$. When an aryl amine is treated with *tert*-butyl hyponitrite (*t*-BuONO) and allyl bromide, the nitrogen is displaced to give the allyl–aryl compound.[812]



Aryl diazonium salts can be used coupled with alkenes in a *Heck-like reaction* (Reaction **13-10**).[813] Other reactive aryl species also couple with aryldiazonium salts in the presence of a Pd catalyst.[814] A *Suzuki-type* coupling (Reaction **13-12**) has also been reported using arylboronic acids, aryldiazonium salts, and a Pd catalyst.[815]

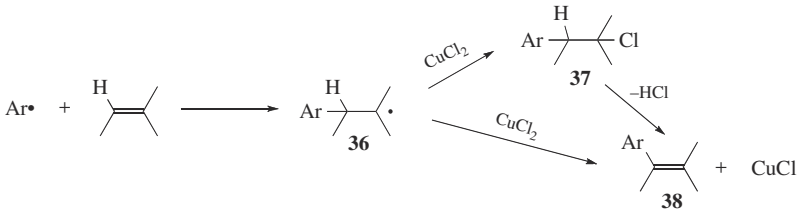
Aryltrifluoroborates (Reaction **12-28**) react with aryldiazonium salts in the presence of a Pd catalyst to give the corresponding biaryl.[816] See Reaction **13-12**. Arylborate esters also react using a Pd catalyst, and the aryl diazonium unit reacts faster than an aryl halide.[817]



13-26 Arylation of Activated Alkenes by Diazonium Salts: Meerwein Arylation

Arylation or **Aryl-de-hydrogenation**

Alkenes activated by an electron-withdrawing group (Z may be C=C, halogen, C=O, Ar, CN, etc.) can be arylated by treatment with a diazonium salt and a cupric chloride[818] catalyst. This is called the *Meerwein arylation reaction*.[819] Addition of ArCl to the double bond (to give Z(Cl)C—CHAr) is a side reaction (**15-46**). In an improved procedure, an arylamine is treated with an alkyl nitrite (generating ArN_2^+ *in situ*) and a copper(II) halide in the presence of the alkene.[820]

The mechanism is probably of the free radical type, with Ar• (**36**) forming as in Reaction **14-20**, and then halogen transfer to give **37** or elimination to give **38**.[821]

The radical **36** can react with cupric chloride by two pathways, one of which leads to addition and the other to substitution. Even when the addition pathway is taken, however, the substitution product may still be formed by subsequent elimination of HCl. Note that radical reactions are presented in Chapter 14, but the coupling of an alkene with an aromatic compound containing a leaving group prompted its placement here. Note the similarity to the *Heck reaction* in Reaction **13-10**.

When the normally acidic solution of a diazonium salt is made alkaline, the aryl portion of the diazonium salt can couple with another aromatic ring. Known as the *Gomberg* or *Gomberg–Bachmann reaction*,[822] it has been performed on several types of aromatic rings and on quinones. Yields are not high (usually <40%) because of the many side reactions undergone by diazonium salts, although higher yields have been obtained under phase-transfer conditions.[823] The conditions of the *Meerwein reaction* (**13-26**), treatment of the solution with a copper-ion catalyst, have also been used, as has the addition of sodium nitrite in DMSO (to benzenediazonium tetrafluoroborate).[824] When the *Gomberg–Bachmann reaction* is performed intramolecularly as in the formation of **39**, either by the alkaline solution or by the copper-ion procedure, it is called the *Pschorr reaction*[825] and yields are usually somewhat higher. Still higher yields have been obtained by carrying out the *Pschorr reaction* electrochemically.[826] The *Pschorr reaction* has been carried out for Z = CH=CH, CH_2CH_2, NH, C=O, CH_2, and quite a few others. A rapid and convenient way to diazotize the amine substrate uses isopropyl nitrite in the presence of sodium iodide, in which case the ring-closed product is formed in one step.[827] Palladium-catalyzed arylation of arenediazonium salts are known.[828]

39

Other compounds with nitrogen–nitrogen bonds have been used instead of diazonium salts. Among these are *N*-nitroso amides [ArN(NO)COR], triazenes,[829] and azo compounds. Still another method involves treatment of an aromatic primary amine directly with an alkyl nitrite in an aromatic substrate as solvent.[830]

In each case, the mechanism involves generation of an aryl radical from a covalent azo compound. In acid solution, diazonium salts are ionic and their reactions are polar. When they cleave, the product is an aryl cation (see Sec. 13.A.i). However, in neutral or basic solution, diazonium ions are converted to covalent compounds, and these cleave to give free radicals ($Ar^\bullet$ and $Z^\bullet$). Note that radical reactions are presented in Chapter 14, but the coupling of an aromatic ring with an aromatic compound containing a leaving group prompted its placement here. Note the similarity to the *Suzuki Reaction* in **13-12**.

$$Ar—N{=}N—Z \rightarrow Ar^\bullet + N{\equiv}N + Z^\bullet$$

Under *Gomberg–Bachmann* conditions, the species that cleaves is the anhydride (**40**).[831]

The aryl radical thus formed attacks the substrate to give the aryl cation[832] intermediate **42** (see Sec. 14.A.iii), from which the radical **41** abstracts hydrogen to give the product (**43**). *N*-Nitroso amides probably rearrange to *N*-acyloxy compounds (**44**), which cleave to give aryl radicals.[833] There is evidence that the reaction with alkyl nitrites also involves attack by aryl radicals.[834]

The Psc*horr reaction* can take place by two different mechanisms, depending on conditions: (1) attack by an aryl radical (as in the *Gomberg–Bachmann reaction*) or (2) attack by an aryl cation (similar to the S_N1 mechanism discussed in Sec. 13.A.ii).[835] Under certain conditions the ordinary *Gomberg–Bachmann reaction* can also involve attack by aryl cations.[836]

OS **I**, 113; **IV**, 718.

13-28 Aryl Dimerization with Diazonium Salts

De-diazonio-coupling; Arylazo-de-diazonio-substitution

$$2\,ArN_2^+ \xrightarrow[\text{or } Cu{+}H^+]{Cu^+} Ar{-}Ar + 2\,N_2 \quad \text{or} \quad Ar{-}N{=}N{-}Ar + N_2$$

When diazonium salts are treated with cuprous ion (or with Cu and acid, in which case it is called the *Gatterman method*), two products are possible. If the ring contains electron-withdrawing groups, the main product is the biaryl, but the presence of electron-donating groups leads mainly to the azo compound. This reaction is different from Reaction **13-27** (and from **19-14**) in that *both* aryl groups in the product originate from ArN_2^+, that is, hydrogen is not a leaving group in this reaction. The mechanism probably involves free radicals.[837]

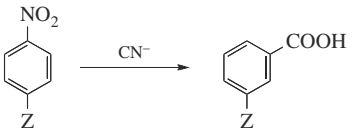
13-29 Replacement of Nitro

Alkyl-de-nitration, Hydroxy and alkoxy-de-nitration, Halo-de-nitration

$$Ar—NO_2 \rightarrow Ar—R$$

In some cases, the nitrogen group of an aromatic nitro compound can be replaced with an alkyl group. The reaction of 1,4-dinitrobenzene with potassium *tert*-butoxide in the presence of BEt_3, for example, gave 4-ethylnitrobenzene.[838]



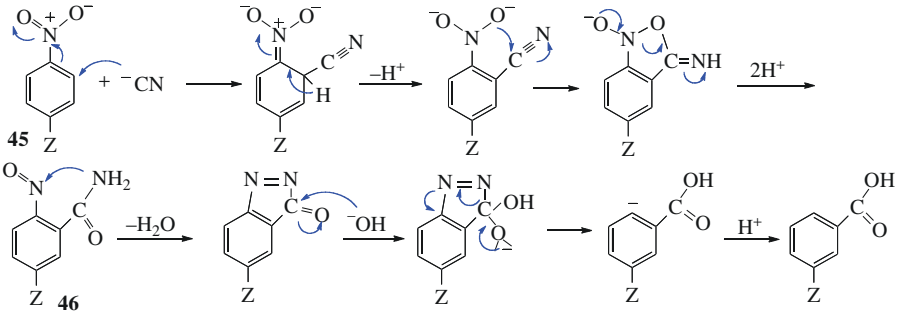
Other nucleophiles can replace a nitrogen-containing group. The reaction of hydroxide with Ar—Y, where Y = nitro,[839] azide, NR_3^+, and so on gives the corresponding phenol. This latter reaction works with alkoxide nucleophiles to give the corresponding aryl ether. The nitro can be replaced with chloro by use of NH_4Cl, PCl_5, $SOCl_2$, HCl, Cl_2, or CCl_4. Some of these reagents operate only at high temperatures and the mechanism is not always nucleophilic substitution. Activated aromatic nitro compounds can be converted to fluorides with fluoride ion.[840]

The reaction of vinyl nitro compounds (C=C—NO_2) and aryl iodide to give the styrene compound (C=C—Ar) was reported using BEt_3 and exposure to air.[841]

13.C.iv. REARRANGEMENTS

13-30 The von Richter Rearrangement

Hydro-de-nitro-*cine*-substitution



When aromatic nitro compounds are treated with cyanide ion, the nitro group is displaced and a carboxyl group enters with cine substitution (Sec. 13.A.iii), always ortho to the displaced group, never meta or para. The scope of this reaction, called the *von Richter rearrangement*, is variable.[842] As with other nucleophilic aromatic substitutions, the reaction gives best results when electron-withdrawing groups are in ortho and para positions, but yields are low, usually <20% and never >50%.

At one time, it was believed that a nitrile (ArCN) was an intermediate, since cyanide is the reagent and nitriles are hydrolyzable to carboxylic acids under the reaction conditions (**16-4**). However, a remarkable series of results proved this belief to be in error. Bunnett and Rauhut[843] demonstrated that α-naphthyl cyanide is *not* hydrolyzable to α-naphthoic acid under conditions at which β-nitronaphthalene undergoes the *von Richter rearrangement* to give α-naphthoic acid. This proved that the nitrile could not be an intermediate. It was subsequently demonstrated that N_2 is a major product of the reaction.[844] It had

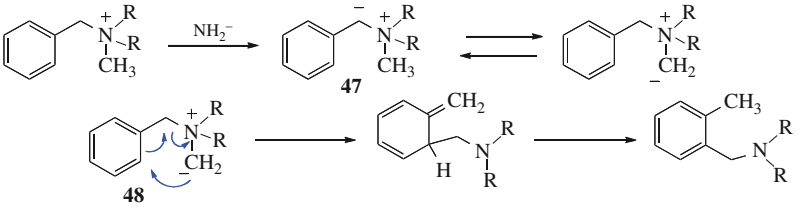
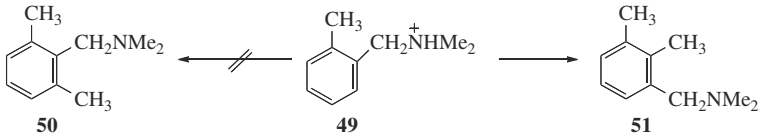
previously been assumed that all the nitrogen in the reaction was converted to ammonia, which would be compatible with a nitrile intermediate, since ammonia is a hydrolysis product of nitriles. At the same time it was shown that NO_2^+ is not a major product. The discovery of nitrogen indicated that a nitrogen–nitrogen bond must be formed during the course of the reaction. Rosenblum proposed a mechanism in accord with all the facts[843]:

Note that **46** is a stable compound: Hence, it should be possible to prepare it independently and to subject it to the conditions of the *von Richter rearrangement*. This was done and the correct products are obtained.[845] Further evidence is that when **45** (Z = Cl or Br) was treated with cyanide in $H_2{}^{18}O$, half the oxygen in the product was labeled, showing that one of the oxygen atoms of the carboxyl group came from the nitro group and one from the solvent, as required by this mechanism.[846]

13-31 The Sommelet–Hauser Rearrangement



Benzylic quaternary ammonium salts, when treated with alkali metal amides, undergo a rearrangement called the *Sommelet–Hauser rearrangement*.[847] Since the product is a benzylic tertiary amine, it can be further alkylated and the product again subjected to the rearrangement. This process can be continued around the ring until an ortho position is blocked.[848]



The rearrangement occurs with high yields and can be performed with various groups present in the ring.[849] The reaction is most often carried out with three methyl groups on the

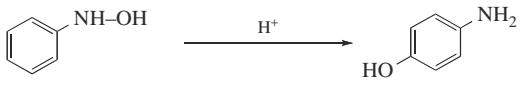
nitrogen, but other groups can also be used, though if a β-hydrogen is present, *Hofmann elimination* (Reaction **17-7**) often competes. The *Stevens rearrangement* (Reaction **18-21**) is also a competing process.[850] When both rearrangements are possible, the *Stevens rearrangement* is favored at high temperatures and the *Sommelet–Hauser* at low temperatures.[851] The mechanism is:

The benzylic hydrogen is most acidic and is the one that first loses a proton to give the ylid (**47**). However, **48**, which is present in a smaller amount, is the species that undergoes the rearrangement, shifting the equilibrium in its favor. This mechanism is an example of a [2,3]-sigmatropic rearrangement (see Reaction **18-35**). Another mechanism that might be proposed is one in which a methyl group actually breaks away (in some form) from the nitrogen and then attaches itself to the ring. That this is not so was shown by a product study.[852] If the second mechanism were true, **49** should give **50**, but the first mechanism predicts the formation of **51**, which is what was actually obtained.[853]

The mechanism as shown can lead only to an ortho product. However, a small amount of para product has been obtained in some cases.[854] A mechanism[855] in which there is a dissociation of the ArC—N bond (similar to the ion-pair mechanism of the *Stevens rearrangement*, Reaction **18-21**) has been invoked to explain the para products that are observed.



Sulfur ylids containing a benzylic group (analogous to **48**) undergo an analogous rearrangement.[856]

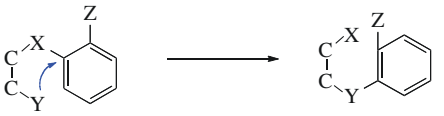
13-32 Rearrangement of Aryl Hydroxylamines

1/*C*-Hydro-5/*N*-hydroxy-interchange



Aryl hydroxylamines treated with acids rearrange to aminophenols.[857] Although this reaction (known as the *Bamberger rearrangement*) is similar in appearance to Reactions **11-28**–**11-32**, the attack on the ring is not electrophilic but nucleophilic. The rearrangement is intermolecular, with the following mechanism:

Among the evidence[858] for this mechanism are the facts that other products are obtained when the reaction is run in the presence of competing nucleophiles (e.g., *p*-ethoxyaniline) when ethanol is present, and that when the para position is blocked, compounds similar to **53** are isolated. In the case of 2,6-dimethylphenylhydroxylamine, the intermediate nitrenium ion (**52**) was trapped, and its lifetime in solution was measured.[859] The reaction of **52** with water was found to be diffusion controlled.[860]

There is a base-mediated rearrangement of aromatic hydroxamic acids to anilines.[861] OS **IV**, 148.

13-33 The Smiles Rearrangement

The *Smiles rearrangement* actually comprises a group of rearrangements that follow the pattern given above.[862] A specific example is the reaction of **54** with hydroxide to give **55**.

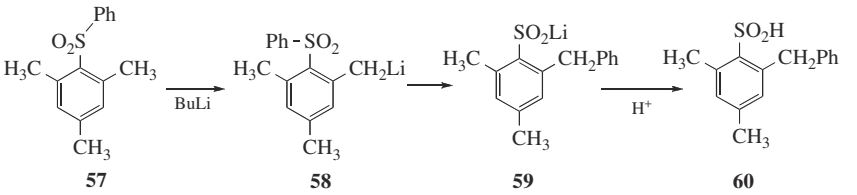
[862] See Truce, W.E.; Kreider, E.M.; Brand, W.W. *Org. React*., ***1971***, *18*, 99; Shine, H.J. *Aromatic Rearrangements,* Elsevier, NY, ***1967***, pp. 307–316; Stevens, T.S.; Watts, W.E. *Selected Molecular Rearrangements*, Van Nostrand–Reinhold, Princeton, ***1973***, pp. 120–126.



Smiles rearrangements are simply intramolecular nucleophilic substitutions. In the example given, SO_2Ar is the leaving group and ArO^- is the nucleophile. The nitro group serves to activate its ortho position. Halogens also serve as activating groups.[863] The ring at which the substitution takes place is nearly always activated, usually by ortho or para nitro groups. Here X is usually S, SO, SO_2,[864] O, or CO_2, and Y is usually the conjugate base of OH, NH_2, NHR, or SH. The reaction has even been carried out with $Y = CH_2^-$ (phenyllithium was the base here).[865]

The reaction rate is greatly enhanced by substitution in the 6 position of the attacking ring, for steric reasons. For example, a methyl, chloro, or bromo group in the 6 position of **54** caused the rate to be $\sim 10^5$ times faster than when the same groups were in the 4 position,[866] although electrical effects should be similar at these positions. The enhanced rate comes about because the most favorable conformation of the molecule can adapt to suit the bulk of the 6-substituent is also the conformation required for the rearrangement. Thus, less entropy of activation is required.

Although the *Smiles rearrangement* is usually carried out on compounds containing two rings, this need not be the case, as in the formation of **56**.[867]

In this case the, sulfenic acid (**56**) is unstable[868] and the actual products isolated were the corresponding sulfinic acid (RSO_2H) and disulfide (R_2S_2).

In the *Smiles rearrangement*, the nucleophile Y is most often the conjugate base of SH, SO_2NHR, SO_2NH_2, NH_2, NHR, OH, and OR. There are few examples where Y is a

carbanion, and the most common example is probably the *Truce–Smiles rearrangement,* where L—YH is an *o*-tolyl group.[869] The prototypical *Truce–Smiles rearrangement* requires use of a strong base to form the benzylic carbanion that undergoes the rearrangement. When sulfone (**57**) was treated with butyllithium, for example, deprotonation led to the benzylic lithium compound (**58**). *Truce–Smiles rearrangement* led to **59**, and hydrolysis gave the sulfinic acid (**60**).[870] *Truce–Smiles rearrangements* with stabilized benzylic carbanions are known,[870] and rearrangements of carbanions in general fall under this category.[871] Relatively few examples have been reported, however.[872] *Truce–Smiles rearrangements* of sulfones that proceed through a six-membered transition state have been reported.[873] In another example, displacement of an activated aryl fluoride with *o*-hydroxyacetophenone gave a product that was C-arylated adjacent to the ketone.[874]

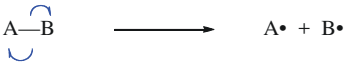
CHAPTER 14

Substitution Reactions: Radical



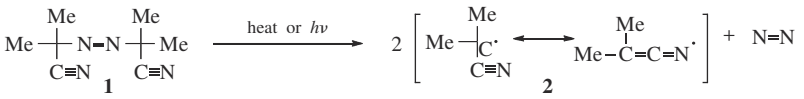
This chapter discusses many types of radical reactions, including reactions in which radicals may be intermediates. Radicals are increasingly important in organic synthesis.[1] The formation, fate, and properties of radicals were introduced in Section 5.C. Additional information concerning radicals may be found in Section 7.A, in the discussion of photochemical processes.

For the most part, this chapter discusses radical substitution reactions. Free radical additions to unsaturated compounds and rearrangements are discussed in Chapters 15 and 18, respectively. Fragmentation reactions are covered, in part, in Chapter 17. In addition, many of the oxidation–reduction reactions considered in Chapter 19 involve free radical mechanisms. Several important types of free radical reactions do not usually lead to reasonable yields of pure products and are not generally treated in this book.

14.A. MECHANISMS

14.A.i. Radical Mechanisms in General[2]

A free radical process (or just a radical process) consists of at least two steps. Any radical reaction first step involve the *formation* of free radicals, usually by homolytic cleavage of a bond; that is, a cleavage in which each fragment retains one electron:



This is called an *initiation* step. It may happen spontaneously or may be induced by heat[3] or light (see the discussion in Sec. 5.C.ii), depending on the type of bond.[4] Peroxides,

including hydrogen peroxide, dialkyl, diacyl, alkyl acyl peroxides, and peroxyacids are the most common source of free radicals. However, other organic compounds with low-energy bonds (e.g., azo compounds) are also used. Chlorine, bromine, and various ketones (see Chapter 7) are most commonly cleaved by light. Radicals can also be formed by a one-electron transfer (loss or gain) (e.g., $A^+ + e^- \rightarrow A^\bullet$). One-electron transfers usually involve inorganic ions or electrochemical processes.[5]

Dialkyl peroxides (ROOR) or alkyl hydroperoxides (ROOH) decompose to hydroxy radicals ($HO^\bullet$) or alkoxy radicals ($RO^\bullet$) when heated.[6] Cumene hydroperoxide ($PhCMe_2OOH$), bi-*tert*-butylperoxide ($Me_3COOCMe_3$),[7] and benzoyl peroxide [$(PhCO)O_2$] undergo homolytic cleavage at temperatures compatible with many organic reactions. They are also reasonably soluble in organic solvents.[8] In general, when a peroxide decomposes, the oxygen radical remains in a "cage" for $\sim 10^{-11}$ s before diffusing away. The radical can

recombine (dimerize), or react with other molecules. Azo compounds, characterized by a —N=N— bond, are free radical precursors that liberate nitrogen gas (N≡N) upon decomposition. *Azo bisi*sobutyronitrile (AIBN, **1**) is a well-known example, which decomposes to give nitrogen gas and the cyano stabilized radical (**2**).[9] Homolytic dissociation of symmetrical diazo compounds may be stepwise.[10] A derivative has been developed that decomposes at room temperature: 2,2′-*azobis*(2,4-dimethyl-4-methoxyvaleronitrile), **3**.[11] Water soluble azo compounds are known, and can be used as radical initiators.[12]

Alkyl hypochlorites (R—O—Cl) generate chlorine radicals ($Cl^\bullet$) and alkoxy radicals ($RO^\bullet$) when heated.[13] Heating *N*-alkoxydithiocarbamates is another useful source of alkoxy radicals ($RO^\bullet$).[14] Alkoxy radicals, particularly those derived from cyclic compounds, may undergo β-scission reactions to give carbonyl derivatives.[15]

It has been known for many years that boron compounds participate in radical reactions.[16] Trialkylboranes (R_3B; see Reactions **15-27** and **12-27**), such as triethylborane (Et_3B), can be used to initiate radical reactions. Indeed, Et_3B is widely used.[17] In radical reactions, Et_3B functions as both a radical initiator and also as a chain-propagation agent.[18] Reactions are usually run in open vessels exposed to oxygen or under an oxygen atmosphere. It is known that O_2 is involved in the initiation step, as shown, in this case using an atom-transfer reaction with an alkyl iodide to give the alkyl radical, ($R^{\bullet}$). Trialkylborane/water-mediated radical reactions are also known.[19]

$$Et_3B + O_2 \rightarrow Et_2BOO^{\bullet} + Et^{\bullet} \quad \textbf{Initiation}$$
$$Et^{\bullet} + R - I \rightarrow Et - I + R^{\bullet}$$

In general, the order of reactivity is $R_3B > R_2BOR > RB(OR)_2$ where R = alkyl.[20] Boronic acids are less reactive, presumably due to π-bonding between B and O.[17] However, B-alkycatecholboranes are very reactive, and highly useful for initiating radical reactions.[21] Reaction conditions usually involve addition of catecholborane (**4**, abbreviated CatBH), and the B-alkyl derivative is presumably generated *in situ* by reaction with an alkene.[22] Note that borole derivatives (the B analogue of pyrrole, **5**) have been used to initiate radical reactions.[23]

4 **5**

Aldehydes can be a source of acyl radicals ($^{\bullet}C{=}O$) via reaction with transition metal salts (e.g., Mn(III) acetate or Fe(II) compounds).[24] α,β-Unsaturated acyl radicals are subject to an isomerization that generates α-ketenyl radicals.[25] Another useful variation employs imidoyl radicals as synthons for unstable aryl radicals.[26]

An important step in radical reactions involves the *destruction* of free radicals. This usually happens by a process opposite to the first, namely, a combination of two like or unlike radicals to form a new bond:[27]

$$A^{\bullet} + B^{\bullet} \longrightarrow A{-}B$$

This type of step is called *termination* because the product of the reaction is a neutral compound and not a radical.[28] Note that this reaction constitutes a radical coupling process. The termination step rarely follows initiation because most radicals are very reactive, and there are several radical processes that occur faster than the termination step. In the usual situation, in which the concentration of radicals is low, a radical is more likely to react with a molecule rather than another radical (i.e., the radical coupling reaction is usually slower). When a radical, which has an odd number of electrons, reacts with a molecule, which has an even number, the total number of electrons in the products must be odd. In other words, the product is another radical. When a radical

6

reacts with a π bond, for example, the product is free radical (**6**). This reaction is called a *radical addition*. Another reaction constitutes an *atom-transfer reaction*. The abstraction of an atom (e.g., hydrogen atom) from an alkyl fragment gives two particles: R—H and the new radical ($R'^{\bullet}$), as shown. This type of atom-transfer reaction is called a *hydrogen-transfer reaction*.

$$R^{\bullet} + R'H \longrightarrow RH + R'^{\bullet}$$

Once again, the product is a free radical. This type of step is called *propagation*, since the newly formed radical can now react with another molecule and produce another radical, and so on, until two radicals undergo coupling and terminate the sequence. The process of initiation, propagation, and then termination constitutes what is called a *chain reaction*,[29] and there may be hundreds or thousands of propagation steps between an initiation and a termination. Two other types of propagation reactions do not involve a molecule at all. These are (1) cleavage of a radical into, necessarily, a radical and a molecule and (2) rearrangement of one radical to another (see Chapter 18). When radicals are highly reactive (e.g., alkyl radicals), chains are long, since reactions occur with many molecules; but with radicals of low reactivity (e.g., aryl radicals), the radical may be unable to react with anything until it meets another radical, so that chains are short. Alternatively, the reaction may be a nonchain process. In any particular chain process, there is usually a wide variety of propagation and termination steps so there may be many products. Such reaction are often difficult to treat kinetically.[30]

$$R{-}CH_2^{\bullet} + n\text{-}Bu_3Sn{-}H \longrightarrow R{-}CH_2{-}H + n\text{-}Bu_3Sn^{\bullet}$$
$$n\text{-}Bu_3Sn^{\bullet} + n\text{-}Bu_3Sn^{\bullet} \longrightarrow n\text{-}Bu_3Sn{-}Sn n\text{-}Bu_3$$

[27] For a review of stereochemistry, see Porter, N.A.; Krebs, P.J. *Top. Stereochem.* ***1988****, 18*, 97.
[28] Another type of termination step is *disproportionation* (see Sec. 5.C.ii).
[29] See Walling, C. *Tetrahedron* ***1985****, 41,* 3887.
[30] See Huyser, E.S. *Free-Radical Chain Reactions*, Wiley, NY, ***1970***, pp. 39–65.

Is it possible to terminate a radical reaction under controlled conditions? The answer is yes, using an atom-transfer reaction. When a carbon radical ($R^{\bullet}$) is generated in the presence of tributyltin hydride (n-Bu_3SnH), a hydrogen atom is transferred to the radical to give R—H and a new radical (n-$Bu_3Sn^{\bullet}$). The tin radical usually undergoes rapid coupling to another tin radical to give n-Bu_3Sn—Sn—n-Bu_3, which effectively terminates the chain-radical process. The carbon radical is *reduced* ($R^{\bullet} \rightarrow$ R—H) as a result of the hydrogen-atom transfer, and the tin dimer can be removed from the reaction. Again, hydrogen-atom transfer[31] is simply a variation of the radical reaction known as atom transfer. Silanes (e.g., triethylsilane, Et_3SiH), have also been used as an effective radical reducing agent.[32] The rate constants for the reaction of both tributytin hydride and $(Me_3Si)_3Si$—H with acyl radical have been measured and the silane quenches the radical faster than the tin hydride.[33] Thermolysis of bis(tri-n-butylstannyl)benzopinacolate has also been used as a source of n-$Bu_3Sn^{\bullet}$, used to mediate radical reactions.[34]

The following are some general characteristics of free radical reactions[35]:

1. Reactions are fairly similar whether they are occurring in the vapor or liquid phase, but solvation of free radicals in solution does cause some differences.[36]
2. They are largely unaffected by the presence of acids or bases or by changes in the polarity of solvents, except that nonpolar solvents may suppress competing ionic reactions.
3. They are initiated or accelerated by typical free radical sources (e.g., the peroxides or diazo compounds) noted above, or by light. In the latter case, the concept of quantum yield applies (Sec. 7.A.viii). Quantum yields can be quite high (e.g., 1000), if each quantum generates a long chain, or low, in the case of nonchain processes.
4. Their rates are decreased or the reactions are suppressed entirely by substances that scavenge free radicals (e.g., nitric oxide, molecular oxygen, or benzoquinone). These substances are called *inhibitors*.[37] Note that there are C-centered radicals in thermal equilibrium with their dimers that show poor reactivity with molecular oxygen, but good reactivity with peroxyl radicals.[38]

14.A.ii. Free Radical Substitution Mechanisms[39]

In a free radical substitution reaction

Step 1 R—X ⟶ R—Y

there must first be a cleavage of the substrate RX so that $R^{\bullet}$ radicals are produced. This can happen by a spontaneous cleavage,

Step 2 $R—X \longrightarrow R^{\bullet} + X^{\bullet}$

or it can be caused by light or heat, or, more often, there is no actual cleavage, but $R^{\bullet}$ is produced by an *abstraction* of another atom, X by the radical $W^{\bullet}$.

Step 3 $R—X + W^{\bullet} \longrightarrow R^{\bullet} + W—X$

The radical $W^{\bullet}$ is produced by adding a compound (e.g., peroxide) that spontaneously forms free radicals. Such a compound is called an *initiator* (see above). Once $R^{\bullet}$ is formed, it can go to product in this system, by another atom abstraction, such as the reaction with A—B to form R—A and a new radical $B^{\bullet}$ (atom transfer).

Step 4 $R^{\bullet} + A—B \longrightarrow R—A + B^{\bullet}$

Another reaction is coupling with another radical to form the neutral product R—Y.

Step 5 $R^{\bullet} + Y^{\bullet} \longrightarrow B—Y$

In a reaction with a moderately long chain, much more of the product will be produced by abstraction (4) than by coupling (5). Cleavage steps like (2) have been called S_H1 (H for homolytic), and abstraction steps like (3) and (4) have been called S_H2; reactions can be classified as S_H1 or S_H2 on the basis of whether RX is converted to R by (2) or (3).[40] Most chain substitution mechanisms follow the pattern (3), (4), (3), (4) $\cdots$ Chains are long and reactions go well where both (3) and (4) are energetically favored (no worse that slightly endothermic, see Sec. 14.B.i and 14.C.i). The IUPAC designation of a chain reaction that follows the pattern (3),(4) $\cdots$ is $A_rD_R + A_RD_r$ (R stands for radical).

With certain radicals the transition state in an abstraction reaction has some polar character. Consider the abstraction of hydrogen from the methyl group of toluene by a bromine atom. Since bromine is more electronegative than carbon, it is reasonable to assume that there is a separation of charge in the transition state, with a partial negative charge on the halogen and a partial positive charge on the carbon:

$$\overset{\delta+}{\text{PhCH}_2}\bullet\bullet\bullet\bullet\bullet\bullet\text{H}\bullet\bullet\bullet\bullet\bullet\bullet\overset{\delta-}{\text{Br}}$$

Evidence for the polar character of the transition state is that electron-withdrawing groups in the para position of toluene, which would destabilize a positive charge, decrease the rate of hydrogen abstraction by bromine while electron-donating groups increase it.[41] However, substituents have a smaller effect here ($\rho \approx -1.4$) than they do in reactions where a completely ionic intermediate is involved (e.g., the S_N1 mechanism, Sec. 10.A.ii). Other evidence for polar transition states in radical abstraction reactions is mentioned in Section 14.B.i, category 4. For abstraction by radicals such as methyl or phenyl, polar effects are very small or completely absent. For example, rates of hydrogen-atom abstraction from ring-substituted toluenes by methyl radical were relatively unaffected by the presence of electron-donating or electron-withdrawing substituents.[42] Those radicals (e.g., $Br^{\bullet}$) that have a tendency to abstract electron-rich hydrogen atoms are called *electrophilic radicals*.

When the reaction step $R—X \rightarrow R^{\bullet}$ takes place at a stereogenic carbon, *racemization is almost always observed because free radicals do not retain configuration*. Exceptions

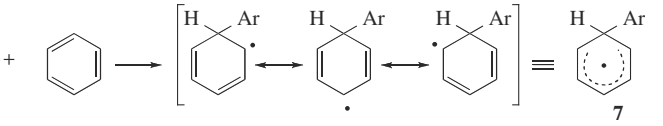
to this rule are found with cyclopropyl substrates, where both inversion[43] and retention[44] of configuration have been reported, and in the reactions mentioned in Section 14.A.iv. Enantioselective radical processes have been reviewed.[45]

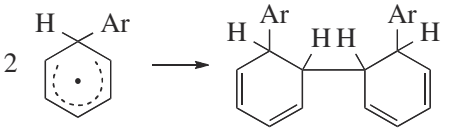
14.A.iii. Mechanisms at an Aromatic Substrate[46]



When R in reaction (1) is aromatic, the simple abstraction mechanism just discussed may be operating, especially in gas-phase reactions. However, mechanisms of this type cannot account for all reactions of aromatic substrates. In processes such as Reactions **13-27**, **14-17**, and **14-18**:

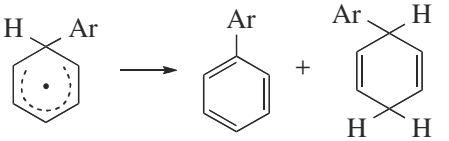
Step 6 $Ar^{\bullet} + ArH \longrightarrow Ar{-}Ar$

which occur in solution, the simple coupling of two rings by abstraction of an entire group (e.g., phenyl) to generate $H^{\bullet}$ by the free radical mechanism shown here is very unlikely (see Sec. 14.B.i).



Step 7 $Ar^{\bullet} + ArH \longrightarrow Ar{-}Ar + H^{\bullet}$

The products can be explained by a mechanism similar to that of electrophilic and nucleophilic aromatic substitution. In the first step, the radical attacks the ring in much the same way as would an electrophile or a



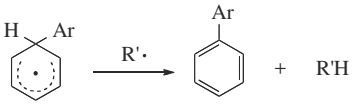
Step 8 

7

nucleophile to generate **7**. The intermediate radical (**7**) is relatively stable because of the resonance. The reaction can terminate in three ways: by simple coupling to give **8**, by disproportionation to give **9**,

Step 9 

8



Step 10 

9

or, if a species ($R'^{\bullet}$) is present that abstracts hydrogen, by abstraction to give **10**.[47]

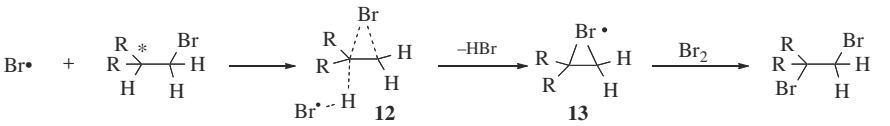
Step 11

10

Coupling product **8** is a partially hydrogenated *o*-quaterphenyl (an *o,o′*-diphenylbiphenyl). Of course, the coupling need not be ortho–ortho, and other isomers can also be formed. Among the evidence (9) and (10) was isolation of compounds of types **8** and **9**.[48] However, under the reaction conditions dihydrobiphenyls like **9** are normally oxidized to the corresponding biphenyls. Other evidence for this mechanism is the detection of the intermediate **7** by CIDNP[49] and the absence of isotope effects, expected if the rate-determining step were (7), which involves cleavage of the Ar—H bond. In the mechanism just given, the rate-determining step (8) does not involve loss of hydrogen. The reaction between aromatic rings and the $HO^{\bullet}$ radical takes place by the same mechanism. Intramolecular hydrogen-transfer reactions of aryl radicals are known.[50] A similar mechanism has been shown for substitution at some vinylic[51] and acetylenic substrates, giving the substituted alkene (**11**).[52] The kinetics of radical heterolysis reactions that form alkene radical cations has been studied.[53]

11

This is reminiscent of the nucleophilic tetrahedral mechanism at a vinylic carbon (Sec. 10.F).



There are many transition metal mediated coupling reactions of aromatic substrates that probably proceed by radical coupling. It is likely that many of these reactions do ***not*** proceed by free radicals, but rather by metal-mediated radicals or by ligand transfer at the metal. Reactions in these categories were presented in Chapter 13 for convenient correlation with other displacement reactions of aryl halides, aryl diazonium salts, and so on.

14.A.iv. Neighboring-Group Assistance in Free Radical Reactions

In a few cases, it has been shown that cleavage steps (2) and abstraction steps (3) were accelerated by the presence of neighboring groups. Photolytic halogenation (Reaction **14-1**) is a process that normally leads to mixtures of many products. However, bromination of carbon chains containing a bromine atom occurs with high regioselectivity. Bromination of

alkyl bromides gave 84–94% substitution at the carbon adjacent to the bromine already in the molecule.[54] This result may seem surprising because, as will be seen (Sec. 14.B.i, category 3), positions close to a polar group (e.g., bromine) should actually be *deactivated* by the electron-withdrawing field effect of the bromine. However, the unusual regioselectivity is explained by a mechanism in which abstraction (3) is assisted by a neighboring bromine atom, as in **12**.[55] In the normal mechanism, $Br^{\bullet}$ abstracts a hydrogen atom from RH, leaving $R^{\bullet}$. When a bromine is present in the proper position, it assists this process, giving a cyclic intermediate (a *bridged free radical*, **13**).[56] In the final step (very similar to $R^{\bullet} + Br_2 \rightarrow RBr + Br^{\bullet}$) the ring is broken. If this mechanism is correct, the configuration at the substituted carbon (marked *) should be retained. This has been shown to be the case: Optically active 1-bromo-2-methylbutane gave 1,2-dibromo-2-methylbutane with retention of configuration.[55] Furthermore, when this reaction was carried out in

the presence of DBr, the "recovered" 1-bromo-2-methylbutane was found to be deuterated in the 2 position, and its configuration was retained.[57] This is just what would be predicted if some of the **11** present abstracted D from DBR. There is evidence that Cl can form bridged radicals,[58] though ESR spectra show that the bridging is not necessarily symmetrical.[59] Still more evidence for bridging by Br has been found in isotope effects and other studies.[60] However, evidence from CIDNP shows that the methylene protons of the β-bromoethyl radical are not equivalent, at least while the radical is present in the radical pair [$PhCOO^{\bullet}$ $^{\bullet}CH_2CH_2Br$] within a solvent cage.[61] This evidence indicates that under these conditions $BrCH_2CH_2^{\bullet}$ is not a symmetrically bridged radical, but it could be unsymmetrically bridged. A bridged intermediate has also been invoked, when a bromo group is in the proper position, in the *Hunsdiecker reaction*[62] (**14-30**), and in abstraction of iodine atoms by the phenyl radical.[63] Participation by other neighboring groups (e.g. SR, SiR_3, SnR_3) has also been reported.[64]

Note that a traditional explanation for the selectivity of bromine relative to chlorine is that abstraction of hydrogen by a bromine radical has a later transition state relative to abstraction of hydrogen by a chlorine radical. In a later transition state, the relative stability of the radical plays a greater role than the strength of the C—H bond. Since a tertiary radical is more stable than a secondary, which is more stable than a primary radical, bromination favors formation of the secondary radical over the primary, and a tertiary over secondary. This analysis is supported by the relative rates of hydrogen-atom abstraction by $Br^{\bullet}$ when compared to $Cl^{\bullet}$, where there is a large difference between 1°, 2°, and 3° for $Br^{\bullet}$ and a small difference for $Cl^{\bullet}$. This effect is discussed in more detail in Section 14.B.i, categories 1–5.

14.B. REACTIVITY

14.B.i. Reactivity for Aliphatic Substrates[65]

In a chain reaction, the step that determines what the product will be is most often an abstraction (atom-transfer) step. The atom abstracted by a free radical is almost never a tetra-[66] or tervalent atom[67] (except in strained systems, see Sec. 15.B.iv)[68] and seldom a divalent one.[69] Nearly always it is univalent, and for organic compounds, it is commonly hydrogen or halogen. Further, in a reaction between a chlorine radical and ethane, formation of an ethyl radical is preferred (H atom transfer) to formation of a hydrogen-atom radical (Cl atom transfer):

$$CH_3CH_3 + Cl \begin{cases} \longrightarrow & H\text{—}Cl + CH_3CH_2^{\bullet} \quad \Delta H = -3 \text{ kcal mol}^{-1}(-13 \text{ kJ/mol}) \\ \not\longrightarrow & CH_3CH_2\text{—}Cl + H^{\bullet} \quad \Delta H = +18 \text{ kcal mol}^{-1}(+76 \text{ kJ/mol}) \end{cases}$$

The principal reason for this preference is steric. A univalent atom is much more exposed to attack by the incoming radical than an atom with a higher valence. Also, in many cases abstraction of a univalent atom is energetically more favored. For example, in the reaction given above, a C_2H_5—H bond is broken ($D = 100\,\text{kcal mol}^{-1}$, $419\,\text{kJ mol}^{-1}$, from Table 5.3) whichever pathway is taken, but in the former case an H—Cl bond is formed ($D = 103\,\text{kcal mol}^{-1}$, $432\,\text{kJ mol}^{-1}$) while in the latter case it is a C_2H_5—Cl bond ($D = 82\,\text{kcal mol}^{-1}$ $343\,\text{kJ mol}^{-1}$). Thus the first reaction is favored because it is exothermic by $3\,\text{kcal mol}^{-1}$ (100–103) [$13\,\text{kJ mol}^{-1}$ (419–432)], while the latter is endothermic by $18\,\text{kcal mol}^{-1}$ (100–82) [$76\,\text{kJ mol}^{-1}$ (419–343)].[70] However, the steric reason is more important, because even in cases where ΔH is not very different for the two possibilities, the univalent atom is chosen.[71] *Ab initio* studies have probed the transition structures for radical hydrogen abstractions.[72]

[a]See Ref. 78.

Most studies of aliphatic reactivity have been made with hydrogen as the leaving atom and chlorine atoms as the abstracting species.[73] In these reactions, every hydrogen atom in the substrate is potentially replaceable and mixtures of several products may be obtained. However, the abstracting radical is not totally unselective, and some positions on a molecule lose hydrogen more easily than others. *Ab initio* studies have studied the factors controlling hydrogen abstraction by radicals.[74] For hydrogen abstraction by the *tert*-butoxy radical (*t*-Bu—$O^{\bullet}$) the factors that influence rate in their order of importance are structure of the radical > substituent effects[75] > solvent effects.[76] The position of attack will be discussed under several headings[77]:

1. *Alkanes*. If a tertiary hydrogen atoms is present in an alkane, it is preferentially abstracted by almost any radical, with secondary hydrogen atoms being next preferred. This is in the same order as *D* values for these types of C—H bonds (Table 5.3). The extent of the preference depends on the selectivity of the abstracting radical and on the temperature. Table 14.1 shows[78] that at high temperatures selectivity decreases, as might be expected.[79] An example of the effect of radical selectivity is the comparison of fluorine atoms with bromine atoms. For the former, the ratio of primary to tertiary abstraction (of hydrogen) is 1:1.4, while for the less reactive bromine atom this ratio is 1:1600. With certain large radicals there is a steric factor that may change the selectivity pattern. For example, in the photochemical chlorination of isopentane in H_2SO_4 with *N*-chloro-di-*tert*-butylamine and *N*-chloro-*tert*-butyl-*tert*-pentylamine, the primary hydrogen atoms are abstracted 1.7 times *faster* than the tertiary hydrogen.[80] In this case, the attacking

radicals (the radical ions $R_2NH^{\bullet+}$, see Reaction **14-1**) are bulky enough for steric hindrance to become a major factor.

14

Cyclopropylcarbinyl radicals (**14**) are alkyl radicals, but because of the cyclopropane ring with its relatively weak bonds, they undergo rapid ring opening to give butenyl radicals.[81] The rate constant for this process has been measured by picosecond radical kinetic techniques to be in the range of $10^7\ M^{-1}\ s^{-1}$ for the parent[82] to $10^{10}\ M^{-1}\ s^{-1}$ for substituted derivatives.[83] Cyclobutylcarbinyl radicals undergo the cyclobutylcarbinyl to 4-pentenyl radical process,[84] but examples are generally limited to the parent system and phenyl-substituted derivatives.[85] Cyclization of the 4-pentenyl radical is usually limited to systems where a stabilized radical can be formed.[86] The effect of substituents has been studied.[87] Note that 2-aziridinylmethyl radicals also undergo ring opening via C—N or C—C cleavage to give a nitrogen or carbon radical, respectively, and the ring opening is strongly influenced by substituents at C-1 rather than those on nitrogen.[88] An alkyl substituent at the C-1 substituent generally leads to C—N cleavage, whereas a carbonyl substituent at C-1 usually favors C—C cleavage.[88]

The rate of the ring-opening reaction of **5**,[89] and other substrates have been determined using an indirect method for the calibration[90] of fast radical reactions, applicable for radicals with lifetimes as short as 1 ps.[91] This 'radical clock'[92] method is based on the use of pyridine-2-thione-*N*-oxycarbonyl esters as radical precursors and radical trapping by the highly reactive thiophenol and benzeneselenol.[93] A number of radical clock substrates are known.[94] Other radical clock processes include: racemization of radicals with chiral conformations,[95] one-carbon

ring expansion in cyclopentanones,[96] norcarane and spiro[2,5]octane,[97] α- and β-thujone radical rearrangements,[98] and cyclopropylcarbinyl radicals or alkoxycarbonyl radicals containing stabilizing substituents,[99] and cyclobutylcarbinyl radicals.[100] *Ab initio* and density functional theory have been used to study radical clock reactions.[101]

2. *Alkenes*. When the substrate molecule contains a double bond, treatment with chlorine or bromine usually leads to addition rather than substitution, as described in Reaction **15-39**. However, for other radicals (and even for chlorine or bromine atoms when they react by hydrogen transfer) the position of attack is at the allylic carbon. Vinylic hydrogen atoms are practically never abstracted, and allylic hydrogen atoms are greatly preferred to other positions of the molecule. Allylic hydrogen abstraction from a cyclic alkene is usually faster than abstraction from an acyclic alkene.[102] This is generally attributed[103] to resonance stabilization of the allylic radical (**15**). As might be expected, allylic rearrangements (see Reaction **14-7**) are common in these cases.[104]

15

3. *Alkyl Side Chains of Aromatic Rings*. The preferential position of attack on a side chain is usually the one directly attached to the ring (the benzylic position). Both for active radicals (e.g., chlorine and phenyl) and for more selective ones (e.g., bromine), hydrogen exchange is faster than that at a primary carbon. For active radicals, hydrogen exchange at the benzylic position is slower than for tertiary positions, while for the selective ones it is faster. Two or three aryl groups on a carbon activate its hydrogen atoms even more, as would be expected from the resonance involved. These statements can be illustrated by the following abstraction ratios:[105]

	Me—H	$MeCH_2$—H	Me_2CH—H	Me_3C—H	$PhCH_2$—H	Ph_2CH—H	Ph_3C—H
Br	0.0007	1	220	19,400	64,000	1.1×10^6	6.4×10^6
Cl	0.004	1	4.3	6.0	1.3	2.6	9.5

However, many anomalous results have been reported for these substrates. The benzylic position is not always the most favored. One thing certain is that *aromatic* hydrogen atoms are seldom abstracted if there are aliphatic ones to compete (note from Table 5.3, that *D* for Ph—H is higher than that for any alkyl H bond). Several

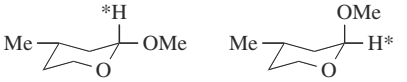
$\sigma^{\bullet}$ scales (similar to the σ, σ^{+}, and σ^{-} scales discussed in Chapter 9) have been developed for benzylic radicals.[106]

4. *Compounds Containing Electron-Withdrawing Substituents.* In halogenations, electron-withdrawing groups greatly deactivate adjacent positions. Compounds of the type $Z—CH_2—CH_3$ are attacked predominantly or exclusively at the β position when Z is CO_2H, COCl, COOR, SO_2Cl, or CX_3. Compounds, such as acetic acid and acetyl chloride, are not attacked at all, in sharp contrast to electrophilic halogenations (Reactions **12-4**–**12-6**), where *only* the α position is substituted. This deactivation of α positions is also at variance with the expected stability of the resulting radicals, since they would be expected to be stabilized by resonance similar to that for allylic and benzylic radicals. This behavior is a result of the polar transition states discussed in Section 14.A.ii. Halogen atoms are electrophilic radicals and look for positions of high electron density. Hydrogen atoms on carbon atoms next to electron-withdrawing groups have low-electron densities (because of the field effect of Z) and are therefore shunned. Radicals that are not electrophilic do not display this behavior. For example, the methyl radical is essentially nonpolar and does not avoid positions next to electron-withdrawing groups; relative rates of abstraction at the α and β carbons of propionic acid are[107]

	$CH_3—CH_2—COOH$	
Me$^{\bullet}$	1	7.8
Cl$^{\bullet}$	1	0.02

It is possible to generate radicals adjacent to electron-withdrawing groups. Radical **16** can be generated and undergoes coupling reactions with little selectivity. When **17** is generated, it rapidly disproportionates rather than couples, giving the corresponding alkene and alkane.[108] Such radicals have also been shown to have a conformational preference for orientation of the orbital containing the single electron. In such cases, hydrogen abstraction proceeds with good stereoselectivity.[109]



16 **17**

Some radicals (e.g., *tert*-butyl,[110] benzyl,[111] and cyclopropyl)[112] are *nucleophilic* (they tend to abstract electron-poor hydrogen atoms).[113] The phenyl radical appears to have a very small degree of nucleophilic character.[114] For longer chains, the field effect

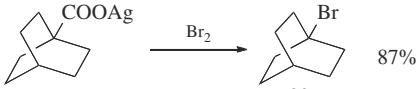
continues, and the β position is also deactivated to attack by halogen, though much less so than the α position. Note that in Section 14.A.ii the abstraction of an α hydrogen atom from ring-substituted toluenes can be correlated by the *Hammett equation*.

5. *Stereoelectronic Effects*. In Section 16.A.i, category 4, there is an example of a stereoelectronic effect. It has been shown that such effects are important where a hydrogen is abstracted from a carbon adjacent to a C—O or C—N bond. In such cases, hydrogen is abstracted from C—H bonds that have a relatively small dihedral angle (≈30°) with the unshared orbitals of the O or N much more easily than from those with a large angle (∼90°). For example, the starred hydrogen of **18** was abstracted about eight times faster than the starred hydrogen of **19**.[115]

18 **19**

The presence of an OR or SiR_3 substituent β- to the carbon bearing the radical accelerates the rate of halogen abstraction.[116] Tertiary arylcarbinyloxy radicals undergo β-scission to give a ketone:[117]



Abstraction of a halogen has been studied much less,[118] but the order of reactivity is RI > RBr > RCl ≫ RF.

There are now many cases where free radical reactions are promoted by transition metals.[119]

14.B.ii. Reactivity at a Bridgehead[120]

Many free radical reactions have been observed at bridgehead carbons, as in formation of bromide **20** (see Reaction **14-30**),[121] demonstrating that the free radical need not be planar. However, treatment of norbornane with sulfuryl chloride and benzoyl peroxide gave mostly 2-chloronorbornane, although the bridgehead position is tertiary.[122] So, while bridgehead free radical substitution is possible, it is not preferred, presumably because of the strain involved.[123]

14.B.iii. Reactivity in Aromatic Substrates

Free radical substitution at an aromatic carbon seldom takes place by a mechanism in which a hydrogen atom is abstracted to give an aryl radical. Reactivity considerations here are similar to those in Chapters 11 and 13; that is, which position on the ring will be attacked to give the intermediate **21**.

21

The obvious way to obtain this information is to carry out reactions with various Z groups and to analyze the products for percent ortho, meta, and para isomers, as has so often been done for electrophilic substitution. However, this procedure is much less accurate in the case of free radical substitutions because of the many side reactions. It may be, for example, that in a given case the ortho position is more reactive than the para, but the intermediate from the para attack may go on to product while that from the ortho attack gives a side reaction. In such a case, analysis of the three products does not give a true picture of which position is most susceptible to attack. The following generalizations can nevertheless be drawn, though there has been much controversy over just how meaningful such conclusions are[124]

1. All substituents increase reactivity at ortho and para positions over that of benzene. There is no great difference between electron-donating and electron-withdrawing groups.
2. Reactivity at meta positions is usually similar to that of benzene, perhaps slightly higher or lower. This fact, coupled with the preceding one, means that all substituents are activating and ortho–para directing; none are deactivating or (chiefly) meta directing.
3. Reactivity at ortho positions is usually somewhat greater than at para positions, except where a large group decreases ortho reactivity for steric reasons.
4. In direct competition, electron-withdrawing groups exert a somewhat greater influence than electron-donating groups. Arylation of para-disubstituted compounds (XC_6H_4Y) showed that substitution ortho to the group X became increasingly preferred as the electron-withdrawing character of X increases (with Y held constant).[125] The increase could be correlated with the Hammett σ_p values for X.
5. Substituents have a much smaller effect than in electrophilic or nucleophilic substitution; hence the partial rate factors (see Sec. 11.C) are not great.[126] Partial rate factors for a few groups are given in Table 14.2.[127]
6. Although hydrogen is the leaving group in most free radical aromatic substitutions, ipso attack (Sec. 11.B.iii) and ipso substitution (e.g., with Br, NO_2, or CH_3CO as the leaving group) have been found in certain cases.[128]

[a]See Ref. 127.

Note that interconvertible 1,4-hydrogen atom shifts are possible in radicals derived from biaryls.[129]

14.B.iv. Reactivity in the Attacking Radical[130]

As seen above, some radicals are much more selective than others (Sec. 14.B.i). The bromine atom is so selective that when only primary hydrogen atoms are available, as in neopentane or *tert*-butylbenzene, the reaction is slow; and isobutane can be selectively brominated to give *tert*-butyl bromide in high yields. However, toluene reacts with bromine atoms instantly. Bromination of other alkylbenzenes (e.g., ethylbenzene and cumene) takes place exclusively at the α position,[131] emphasizing the selectivity of $Br^{\bullet}$. The dissociation energy (*D*) of the C—H bond is more important for radicals of low reactivity than for highly reactive radicals, since bond breaking in the transition state is greater. Thus, bromine shows a greater tendency than chlorine to attack α to an electron-withdrawing group because the energy of the C—H bond there is lower than in other places in the molecule.

Some radicals (e.g., triphenylmethyl) are so unreactive that they abstract hydrogen atoms very poorly if at all. Table 14.3 lists some common free radicals in approximate order of reactivity.[132]

$$X^{\bullet} + C_2H_6 \longrightarrow X - H + C_2H_5^{\bullet} \qquad \text{Ref. 132}$$

iPr$^{\bullet}$ is $<$ $Me^{\bullet}$ and *t-Bu*$^{\bullet}$ is still less[133]

As mentioned earlier, some free radicals (e.g., chloro) are electrophilic and some (e.g., *tert*-butyl) are nucleophilic. Bear in mind that these tendencies are relatively slight compared with the electrophilicity of a positive ion or the nucleophilicity of a negative ion. The predominant character of a free radical is neutral, whether it has slight electrophilic or nucleophilic tendencies.

14.B.v. The Effect of Solvent on Reactivity[134]

As noted earlier, the solvent usually has little effect on free radical substitutions in contrast to ionic substitution reactions: Indeed, reactions in solution are often quite similar in character to those in the gas phase, where there is no solvent at all. However, in certain cases the solvent *can* make an appreciable difference. Chlorination of 2,3-dimethylbutane in aliphatic solvents gave ~60% $(CH_3)_2CHCH(CH_3)CH_2Cl$ and 40% $(CH_3)_2CHCCl(CH_3)_2$, while in aromatic solvents the ratio became 10:90.[135] This result is attributed to

22

complex formation between the aromatic solvent and the chlorine atom that makes the chlorine more selective.[136] This type of effect is not found in cases where the differences in ability to abstract the atom are caused by field effects of electron-withdrawing groups (Sec 14.B.i). In such cases, aromatic solvents make little difference.[137] Complex **22** has been detected[138] as a very short-lived species by observation of its visible spectrum in the pulse radiolysis of a solution of benzene in CCl_4.[139] Differences caused by solvents have also been reported in reactions of other radicals.[140] Some of the anomalous results obtained in the chlorination of aromatic side chains (Sec 14.B.i) can also be explained by this type of complexing, in this case not with the solvent but with the reacting species.[141] Much smaller, though real, differences in selectivity have been found when the solvent in the chlorination of 2,3-dimethylbutane is changed from an alkane to CCl_4.[142] However,

these differences are not caused by formation of a complex between $Cl^{\bullet}$ and the solvent. There are cases, however, where the rate of reaction for trapping a radical depends on the polarity of the solvent, particularly in water.[143]

14.C. REACTIONS

The reactions in this chapter are classified according to leaving group. The most common leaving groups are hydrogen and nitrogen (generally the diazonium ion); these are considered first.

14.C.i. Hydrogen as a Leaving Group

A. Substitution by Halogen

14-1 Halogenation at an Alkyl Carbon[144]

Halogenation or **Halo-de-hydrogenation**

$$R{-}H + \text{Halogenating agent} \longrightarrow R{-}X$$

Alkanes can be chlorinated or brominated by treatment with chlorine or bromine in the presence of visible or UV light, or with heat[145] These reactions require an added chemical reagent as the radical chain initiator, or exposure to light, or higher temperatures.[146] The reaction can also be applied to alkyl chains containing many functional groups. The chlorination reaction is usually not useful for preparative purposes precisely because it is so general: Not only does substitution take place at virtually every alkyl carbon in the molecule, but di- and polychloro substitution almost invariably occur even if there is a large molar ratio of substrate to halogen. Note that benzylic halogenation (e.g., the *Wohl–Ziegler bromination*) is discussed in Reaction **14-3**.

When functional groups are present, the principles are those outlined in Section 14.B.i. Tertiary carbons are most likely to be functionalized and primary are least likely. Favored positions are those α to aromatic rings, while positions α to electron-withdrawing groups are least likely to be substituted. Hydrogen atoms α to an OR group are very readily replaced. Nevertheless, mixtures are nearly always obtained. This can be contrasted to the regioselectivity of electrophilic halogenation (Reactions **12-4**–**12-6**), which always takes place α to a carbonyl group (except when the reaction is catalyzed by $AgSbF_6$). Of course, if a *mixture* of chlorides is wanted, the reaction is usually quite satisfactory. For obtaining pure compounds, the chlorination reaction is essentially limited to substrates with only one type of replaceable hydrogen (e.g., ethane, cyclohexane, and neopentane). The most common are methylbenzenes and other substrates with methyl groups on aromatic rings,

[146] Hill, C.L. *Activation and Functionalization of Alkanes*, Wiley, NY, ***1989***.

since few cases are known where halogen atoms substitute at an aromatic position.[147] Of course, ring substitution *does* take place in the presence of a positive-ion-forming catalyst (Reaction **11-10**). In addition to mixtures of various alkyl halides, traces of other products are obtained. These include H_2, alkenes, higher alkanes, lower alkanes, and halogen derivatives of these compounds. Solvent plays an important role in this process.[148]

The bromine atom is much more selective than the chlorine atom. As indicated in Section 14.B.iv, it is often possible to brominate tertiary and benzylic positions selectively. High regioselectivity can also be obtained where the neighboring-group mechanism (Sec 14.A.iv) can operate.

As already mentioned, halogenation can be performed with chlorine or bromine. Fluorine has also been used,[149] but seldom, because it is too reactive and hard to control.[150] It often breaks carbon chains down into smaller units, a side reaction that sometimes becomes troublesome in chlorinations as well. Fluorination[151] has been achieved by the use of chlorine trifluoride (ClF_3) at $-75°C$.[152] For example, cyclohexane gave 41% fluorocyclohexane and methylcyclohexane gave 47% 1-fluoro-1-methylcyclohexane. Fluoroxytrifluoromethane (CF_3OF) fluorinates tertiary positions of certain molecules in good yields with high regioselectivity.[153] For example, adamantane gave 75% 1-fluoroadamantane. Fluorine at -70 °C, diluted with N_2,[154] and bromine trifluoride at 25–35 °C[155] are also highly regioselective for tertiary positions. These reactions probably have electrophilic,[156] not free radical mechanisms. In fact, the success of the F_2 reactions depends on the suppression of free radical pathways, by dilution with an inert gas, by working at low temperatures, and/or by the use of radical scavengers. Fluorination of 1,3-dicarbonyl compounds and activated aromatic compounds was achieved under solvent-free conditions using Selectfluor™ F–TEDA–BF_4.[157]

Iodine can be used if the activating light has a wavelength of 184.9 nm,[158] but iodinations using I_2 alone are seldom attempted, largely because the HI formed reduces the alkyl iodide. The direct free radical halogenation of aliphatic hydrocarbons with iodine is significantly endothermic relative to the other halogens, and the requisite chain reaction does not occur.[159] On the other hand, when iodine ($CCl_4 \bullet 2\ AlI_3$) reacts with an alkane in

dibromomethane at −20 °C, good yields of the iodoalkane are obtained.[160] The reaction of an alkane with *tert*-butylhypoiodite (*t*-BuOI) at 40 °C gave the iodoalkane in good yield.[161] The reaction of alkanes with iodine and $PhI(OAc)_2$ generates the iodoalkane.[162] A radical protocol was developed using CI_4 with base. Cyclohexane could be iodinated, for example, with CI_4 in the presence of powdered NaOH.[163] The reaction led to the use of iodoform on solid NaOH as the iodination reagent of choice. A base-induced bromination has been reported. 2-Methyl butane reacts with 50% aq NaOH and CBr_4, in a phase-transfer catalyst, to give a modest yields of 2-bromo-2-methylbutane. α-Iodo ethers and α-iodolactones have been prepared from the parent ether or lactone via treatment with $Et_4N^{\bullet}4$ HF under electrolytic conditions.[164]

Many other halogenation agents have been employed, and a common reagent is sulfuryl chloride (SO_2Cl_2).[165]Among other agents used have been NBS (see Reaction **14-3**), CCl_4,[166] PCl_5,[167]*N*-haloamines, and sulfuric acid.[168] In all these cases, an initiator is required, usually peroxides or UV light.[169]

When chlorination is carried out with *N*-haloamines and sulfuric acid (catalyzed by either UV light or metal ions), selectivity is much greater than with other reagents.[168] In particular, alkyl chains are chlorinated with high regioselectivity at the position next to the end of the chain (the ω - 1 position).[170]Some typical selectivity values are[171]

$$\underset{1}{CH_3}-\underset{56}{CH_2}-\underset{29}{CH_2}-\underset{14}{CH_2}-CH_2-CH_2-CH_3 \qquad \text{Ref. 172}$$

$$\underset{1}{CH_3}-\underset{92}{CH_2}-\underset{3}{CH_2}-\underset{1}{CH_2}-\underset{1}{CH_2}-\underset{2}{CH_2}-\underset{0}{CH_2}-\underset{0}{CH_2}-OH \qquad \text{Ref. 173}$$

$$\underset{3}{CH_3}-\underset{72}{CH_2}-\underset{20}{CH_2}-\underset{4}{CH_2}-\underset{1}{CH_2}-\underset{0}{CH_2}-COOMe \qquad \text{Ref. 174}$$

Furthermore, di- and polychlorination are much less prevalent.Dicarboxylic acids are predominantly chlorinated in the middle of the chain,[175] and adamantane and bicyclo [2.2.2]octane at the bridgeheads[176] by this procedure. The reasons for the high ω - 1

specificity are not clearly understood.[177] Alkyl chlorides can be converted to *vic*-dichlorides by treatment with $MoCl_5$.[178] Enhanced selectivity at a terminal position of *n*-alkanes has been achieved by absorbing the substrate onto a pentasil zeolite.[179] For regioselective chlorination at certain positions of the steroid nucleus, see Reaction **19-2**.

In almost all cases, the mechanism involves a free radical chain:

Initiation $X_2 \xrightarrow{h\nu} 2X^{\bullet}$

Propagation $RH + X^{\bullet} \longrightarrow R^{\bullet} + XH$

$R^{\bullet} + X_2 \longrightarrow RX + X^{\bullet}$

Termination $R^{\bullet} + X^{\bullet} \longrightarrow RX$

When the reagent is halogen, initiation occurs as shown above.[180] When it is another reagent, a similar cleavage occurs (catalyzed by light or, more commonly, peroxides), followed by propagation steps that do not necessarily involve abstraction by halogen. For example, the propagation steps for chlorination by *tert*-butyl hypochlorite (*t*-BuOCl) have been formulated as:[181]

$$RH + t\text{-BuO}^{\bullet} \longrightarrow R^{\bullet} + t\text{-BuOH}$$

$$R^{\bullet} + t\text{-BuOCl} \longrightarrow RCl + t\text{-BuO}^{\bullet}$$

and the abstracting radicals in the case of *N*-haloamines are the aminium radical cations ($R_2NH^{\bullet+}$, Reaction **11-5**), with the following mechanism (in the case of initiation by Fe^{2+})[168]:

Initiation $R_2NCl \xrightarrow{H^+} R_2\overset{+}{N}HCl \xrightarrow{Fe^{2+}} R_2NH^{\bullet+} + \overset{+}{F}eCl$

Propagation $R_2NH^{\bullet+} + RH \longrightarrow R_2NH_2 + R^{\bullet}$

$R^{\bullet} + R_2NHCl \longrightarrow RCl + R_2NH^{\bullet+}$

This mechanism is similar to that of the *Hofmann–Löffler Reaction* (**18-40**).

The two propagation steps shown above for X_2 are those that lead directly to the principal products (RX and HX), but many other propagation steps are possible and many occur. Similarly, the only termination step shown is the one that leads to RX, but any two radicals may combine ($^{\bullet}H$, $^{\bullet}CH_3$, $^{\bullet}Cl$, $^{\bullet}CH_2CH_3$ in all combinations). Thus, products like H_2, higher alkanes, and higher alkyl halides can be accounted for. When methane is the substrate, the rate-determining step is

$$CH_4 + Cl^{\bullet} \rightarrow {}^{\bullet}CH_3 + HCl$$

since an isotope effect of 12.1 was observed at 0 °C.[182] For chlorinations, chains are very long, typically 10^4–10^6 propagations before a termination step takes place.

[a]See Ref. 183.

The order of reactivity of the halogens can be explained by energy considerations. For the substrate methane, ΔH values for the two principal propagation steps follow:

	F_2	Cl_2	Br_2	I_2	F_2	Cl_2	Br_2	I_2
	(kcal mol^{-1})				(kJ mol^{-1})			
$CH_4 + X^{\bullet} \rightarrow CH_3^{\bullet} + HX$	−31	+2	+17	+34	−132	+6	+72	+140
$CH_4 + X_2 \rightarrow CH_3X + X^{\bullet}$	−70	−26	−24	−21	−293	−113	−100	−87

In each case, *D* for CH_3—H is 105 kcal mol^{-1} (438 kJ mol^{-1}), while *D* values for the other bonds involved are given in Table 14.4 .[183] Fluorine (F_2) is so reactive[184] that neither UV light nor any other initiation is needed (total $\Delta H = -101$ kcal mol^{-1}, -425 kJ mol^{-1})[185]; while $\mathbf{Br_2}$ and $\mathbf{I_2}$ essentially do not react with methane. The second step is exothermic in all four cases, but it cannot take place before the first, and it is this step that is very unfavorable for Br_2 and I_2. It is apparent that the most important single factor causing the order of halogen reactivity to be $\mathbf{F_2 > Cl_2 > Br_2 > I_2}$ is the decreasing strength of the HX bond in the order HF > HCl > HBr > HI. The increased reactivity of secondary and tertiary positions is in accord with the decrease in *D* values for R—H in the order primary > secondary > tertiary (Table 5.3). (Note that for chlorination, step 1 is exothermic for practically all substrates other than CH_4, since most other aliphatic C—H bonds are weaker than those in $\mathbf{CH_4}$.)

[185] For F_2 the following initiation step is possible: $F_2 + RH \rightarrow R\cdot + F^{\bullet} + HF$ (first demonstrated by Miller, Jr., W.T.; Koch, Jr., S.D.; McLafferty, F.W. *J. Am. Chem. Soc.* ***1956****, 78*, 4992).

Metal mediated halogenation reactions are known. Heating alkenes with bromine in the presence of MnO_2 leads to monobromination.[186] Hydrogen peroxide–HBr in water has been used for radical bromination.[187] Bromination and chlorination of alkanes and cycloalkanes can also take place by an electrophilic mechanism if the reaction is catalyzed by $AgSbF_6$.[188] Direct chlorination at a vinylic position by an electrophilic mechanism has been achieved with benzeneseleninyl chloride [PhSe(O)Cl] and $AlCl_3$ or $AlBr_3$.[189] However, while some substituted alkenes give high yields of chloro-substitution products, others (e.g., styrene) undergo addition of Cl_2 to the double bond (Reaction **15-39**).[151] Electrophilic fluorination has already been mentioned (Sec. 14.C.i).

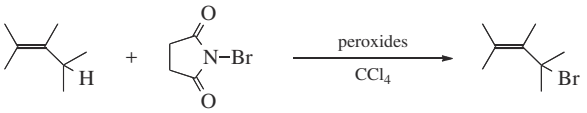
14-2 Halogenation at Silicon



Halogenation or **Halo-de-hydrogenation**

$$R_3Si-H \longrightarrow R_3Si-X$$

Just as free radical halogenation occurs at the carbon of an alkane, via hydrogen abstraction to form the radical, a similar reaction occurs at silicon. When triisopropylsilane (iPr$_3$Si—H) reacts with *tert*-butyl hypochlorite at −10 °C, the product is triisopropylchlorosilane (iPr$_3$Si—Cl).[190]

14-3 Allylic and Benzylic Halogenation

Halogenation or **Halo-de-hydrogenation**

This reaction is a special case of Reaction **14-1**, but is important enough to be treated separately.[191] Alkenes can be brominated in the allylic position and also a benzylic position by a number of reagents, of which NBS[192] is by far the most common. When this reagent is used, the reaction is known as *Wohl–Ziegler bromination*. A nonpolar solvent is used, most often CCl_4, but the reaction has been done in an ionic liquid.[193] A variation in the reaction used NBS with 5% Yb(OTf)$_3$ and 5% ClSiMe$_3$.[194] Other *N*-bromo amides have also been used. With any reagent an initiator is needed; this is usually AIBN (**1**), a peroxide (e.g., di-*tert*-butyl peroxide) or benzoyl peroxide or, less often, UV light. Boron trifluoride has been used for benzylic bromination.[195]

[195] Chen, H.; Shen, L.; Lin, Y. *Synth. Commun.* ***2010****, 40*, 998.

1,3-Dibromo-5,5-dimethylhydantoin (DBDMH) has been used for benzylic bromination in the presence of a Lewis acid (e.g., $ZrCl_4$).[196] Similarly, *N*-fluoro-2,4,6-trimethylpyridinium tetrafluoroborate, in the presence of a Pd catalyst and microwave irradiation, led to benzylic fluorides.[197]

Allylic chlorination has also been carried out[198] with NCS and either arylselenyl chlorides (ArSeCl), aryl diselenides (ArSeSeAr), or TsNSO as catalysts. Allylic chlorination has been carried out with *tert*-butyl hypochlorite[199] or $NaClO/CeCl_3 \bullet 7H_2O$.[200]

The reaction is usually quite specific at an allylic or benzylic position and good yields are obtained. However, when the allylic radical intermediate is unsymmetrical, allylic rearrangements can take place, so that mixtures of both possible products are obtained (**23** and **24**). Use of the selenium catalysts produces almost entirely the allylically rearranged chlorides in high yields. With TsNSO the products are the unrearranged chlorides in lower yields. Dichlorine monoxide (Cl_2O), with no catalyst, also leads to allylically rearranged chlorides in high yields.[201] A free radical mechanism is unlikely in these latter reactions.

23 **24**

When a double bond has two different allylic positions (e.g., $CH_3CH{=}CHCH_2CH_3$), a secondary position is substituted more readily than a primary. The relative reactivity of tertiary hydrogen is not clear, though many substitutions at allylic tertiary positions have been performed.[202] It is possible to brominate both sides of the double bond.[203] Because of the electron-withdrawing nature of bromine, the second bromine substitutes on the other side of the double bond rather than α to the first bromine. Molecules with a benzylic hydrogen (e.g., toluene) react rapidly to give α-bromomethyl benzene (e.g., $PhCH_3 \rightarrow PhCH_2Br$).

N-Bromosuccinimide is a highly regioselective brominating agent at other positions, including positions α to a carbonyl group, to a C≡C triple bond, and to an aromatic ring (benzylic position). When both a double and a triple bond are in the same molecule, the preferred position is α to the triple bond.[204]

Dauben and McCoy[205] demonstrated that the mechanism of allylic bromination is of the free radical type, showing that the reaction is very sensitive to free radical initiators and inhibitors and indeed does not proceed at all unless at least a trace of initiator is present. Subsequent work indicated that the species that actually abstracts hydrogen from the

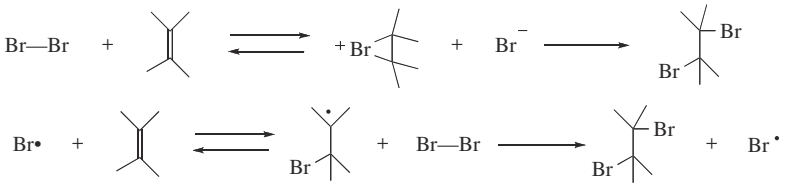
substrate is the bromine atom. The reaction is initiated by small amounts of $Br^{\bullet}$. Once it is formed, the main propagation steps are

Step 1 $Br^{\bullet} + RH \longrightarrow R^{\bullet} + HBr$



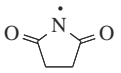
Step 2 $R^{\bullet} + Br_2 \longrightarrow RBr + Br^{\bullet}$

The source of the Br_2 is a fast ionic reaction between NBS and the HBr liberated in step 1:

The function of the NBS is therefore to provide a source of Br_2, as shown in the reaction, in a low, steady-state concentration, which effectively uses up the HBr liberated in step 1.[206] The main evidence for this mechanism is that NBS and Br_2 show similar selectivity[207] and that the various *N*-bromo amides also show similar selectivity,[208] which is consistent with the hypothesis that the same species is abstracting in each case.[209]

It may be asked why, if Br_2 is the reacting species, it does not add to the double bond, either by an ionic or by a free radical mechanism (see Reaction **15-39**). Apparently, the concentration is too low. In bromination of a double bond, only one atom of an attacking bromine molecule becomes attached to the substrate, whether the addition is electrophilic or free radical:

The other bromine atom comes from another bromine-containing molecule or ion. This result is clearly not a problem in reactions with benzylic species since the benzene ring is not prone to such addition reactions. If the concentration is sufficiently low, there is a low probability that the proper species will be in the vicinity once the intermediate forms. The intermediate in either case reverts to the initial species and the allylic substitution competes successfully. If this is true, it should be possible to brominate an alkene in the allylic position without competition from addition, even in the absence of NBS or a similar compound, if a very low concentration of bromine is used and if the HBr is



[206] See Adam, J.; Gosselain, P.A.; Goldfinger, P. *Nature (London)* ***1953****, 171*, 704; *Bull. Soc. Chim. Belg.* ***1956****, 65*, 533.

removed as it is formed so that it is not available to complete the addition step. This has indeed been demonstrated.[210]

25

When NBS is used to brominate non-alkenyl substrates (e.g., alkanes) another mechanism, involving abstraction of the hydrogen of the substrate by the succinimidyl radical[211] **25** can operate.[212] This mechanism is facilitated by certain solvents (e.g., CH_2Cl_2, $CHCl_3$, or MeCN) in which NBS is more soluble, and by the presence of small amounts of an alkene that lacks an allylic hydrogen (e.g., ethene). The alkene serves to scavenge any $Br^{\bullet}$ that forms from the reagent. Among the evidence for the mechanism involving **25** are abstraction selectivities similar to those of $Cl^{\bullet}$ atoms and the isolation of β-bromopropionyl isocyanate ($BrCH_2CH_2CONCO$), which is formed by ring opening of **25**.

Allyl silanes react with transition metals bearing chlorine ligands to give allyl chlorides, where a chlorine replaces a Me_3Si unit.[213]

OS **IV**, 108; **V**, 825; **VI**, 462; **IX**, 191.

14-4 Halogenation of Aldehydes

Halogenation or **Halo-de-hydrogenation**

$$RCHO + Cl_2 \longrightarrow RCOCl$$

The α-halogenation reaction of carbonyl compounds was mentioned in Reaction **14-2**. A different halogenation reaction is possible in which aldehydes can be directly converted to acyl chlorides by treatment with chlorine, but the reaction operates only when the aldehyde does not contain an α hydrogen and even then it is not very useful. When there is an α hydrogen, α halogenation (Reactions **14-2** and **12-4**) occurs instead. Other sources of chlorine have also been used, among them SO_2Cl_2[214] and *t*-BuOCl.[215] The mechanisms are probably of the free radical type. *N*-Bromosuccinimide, with AIBN (Sec. 14.A.i) as a catalyst, has been used to convert aldehydes to acyl bromides.[216] In the presence of benzoyl peroxide as an initiator, Br_3CCO_2Et converts aldehydes to acyl bromides under radical conditions.[217]

B. Substitution by Oxygen

14-5 Hydroxylation at an Aromatic Carbon[218]

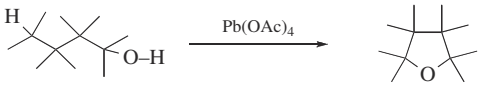
Hydroxylation or **Hydroxy-de-hydrogenation**

$$ArH + H_2O_2 + FeSO_4 \longrightarrow ArOH$$

A mixture of hydrogen peroxide and ferrous sulfate,[219] called *Fenton's reagent*,[220] can be used to hydroxylate aromatic rings, although yields are usually not high.[221] Biaryls are typical side products.[222] Among other reagents used H_2O_2 and titanous ion; O_2 and Cu(I)[223] or Fe(III),[224] a mixture of ferrous ion, oxygen, ascorbic acid, and ethylenetetraaminetetraacetic acid (*Udenfriend's reagent*)[225]; O_2 and KOH in liquid NH_3[226]; and peroxyacids (e.g., peroxynitrous and trifluoroperoxyacetic acids).

Much work has been done on the mechanism of the reaction with *Fenton's reagent*, and it is known that free aryl radicals (formed by a process, e.g., $HO^{\bullet} + ArH \rightarrow AR^{\bullet} + H_2O$) are ***not*** intermediates. The mechanism is essentially that outlined in Section 14.A.iii, with $HO^{\bullet}$ as the attacking species,[227] formed by

$$Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^- + HO^{\bullet}$$



The rate-determining step is formation of $HO^{\bullet}$ and not its reaction with the aromatic substrate.

An alternative oxidation of arene to phenol was reported using $Cu(NO_3)^{\bullet}3\ H_2O$, 30% hydrogen peroxide and a phosphate buffer.[228]

Alcohols with hydrogen in the δ position can be cyclized with lead tetraacetate.[229] The reaction is usually carried out at ~ 80 °C (most often in refluxing benzene), but can also be done at room temperature if the reaction mixture is irradiated with UV light. Tetrahydrofurans are formed in high yields. Little or no four- and six-membered cyclic ethers (oxetanes and tetrahydropyrans, respectively) are obtained even when γ and ε hydrogen atoms are present. The reaction has also been carried out with a mixture of halogen (Br_2 or I_2) and a salt or oxide of silver or mercury (especially HgO or AgOAc),[230] with iodosobenzene diacetate and I_2,[231] and with ceric ammonium nitrate (CAN).[232] The following mechanism is likely for the lead tetraacetate reaction[233]:

although **26** has never been isolated. The step marked **A** is a 1,5-internal hydrogen abstraction. Such abstractions are well known (see Reaction **18-40**) and are greatly favored over 1,4 or 1,6 abstractions (the small amounts of tetrahydropyran formed result from 1,6-abstractions).[234]

Oxidation to the aldehyde or acid (Reactions **19-3** and **19-22**) and fragmentation of the substrate sometimes compete. When the OH group is on a ring of at least seven members, a transannular product can be formed, as in the cyclization reaction of 1-octanol to **27**.[235] β-Hydroxy ethers can give cyclic acetals (e.g., **28**).[236]

14-7 Formation of Hydroperoxides

Hydroperoxy-de-hydrogenation

$$RH + O_2 \longrightarrow R{-}O{-}O{-}H$$

The slow atmospheric oxidation (*slow* meaning without combustion) of C—H to C—O—O—H is called *autoxidation*.[237] The reaction occurs when compounds are allowed to stand in air and is catalyzed by light, so unwanted autoxidations can be greatly slowed by keeping the compounds in dark places. Most autoxidations proceed by free radical chain processes that involve peroxyl radicals.[238] To suppress autoxidation, an antioxidant can be added that will prevent or retard the reaction with atmospheric oxygen.[239] Although some lactone compounds are sold as antioxidants, many radicals derived from lactones show poor or no reactivity toward oxygen.[239] The hydroperoxides produced often react further to give alcohols, ketones, and more complicated products, so the reaction is not often used for preparative purposes, although in some cases hydroperoxides have been prepared in good yield.[240] It is because of autoxidation that foods, rubber, paint, lubricating oils, and so on deteriorate on exposure to the atmosphere over periods of time. On the other hand, a useful application of autoxidation is the atmospheric drying of paints and varnishes. As with other free radical reactions of C—H bonds, some bonds are attacked more readily than others,[241] and these are the ones seen before (Sec. 14.B.i), although the selectivity is very low at high temperatures and in the gas phase. The reaction can be carried out successfully at tertiary (to a lesser extent, secondary), benzylic,[242] and allylic (though allylic rearrangements are common) R.[243] 2-Phenylpropane reacted with oxygen to give $PhMe_2C{-}OOH$, for example. Another susceptible position is aldehydic C—H, but the peroxyacids so produced are not easily isolated[244] since they are converted to the corresponding carboxylic acids (Reaction **19-23**). The α positions of ethers are also easily attacked by oxygen [RO—C—H → RO—C—OOH], but the resulting hydroperoxides are seldom isolated. However, this reaction constitutes a hazard in the storage of ethers since solutions of these hydroperoxides and their rearrangement products in ethers are potential spontaneous explosives.[245]

Oxygen itself (a diradical) is not reactive enough to be the species that actually abstracts the hydrogen. But if a trace of free radical (say $R'^{\bullet}$) is produced by some initiating process, *it* reacts with oxygen[246] to give $R'{-}O{-}O^{\bullet}$; since this type of radical *does* abstract

[237] The term autoxidation actually applies to any slow oxidation with atmospheric oxygen. See Goosen, A.; Morgan, D.H. *J. Chem. Soc. Perkin Trans. 2* ***1994,*** *557*. hydrogen, the chain is

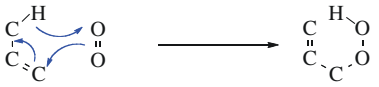
$$R'OO^{\bullet} + RH \longrightarrow R^{\bullet} + R'OOH$$
$$R^{\bullet} + O_2 \xrightarrow[\text{etc.}]{} R{-}O{-}O^{\bullet}$$

In at least some cases (in alkaline media),[247] the radical $R^{\bullet}$ can be produced by formation of a carbanion and its oxidation (by O_2) to a radical, such as allylic radical **29**.[248] Autoxidations in alkaline media can also proceed by a different mechanism: R—H + base → R^- + O_2 → ROO^-.[249]

29



When alkenes are treated with oxygen that has been photosensitized (Sec. 7.A.vi, category 6), they are substituted by OOH in the allylic position in a synthetically useful reaction.[250] Although superficially similar to autoxidation, this reaction is clearly different because 100% allylic rearrangement always takes place. The reagent here is not the ground-state oxygen (a triplet), but an excited singlet state[251] (in which all electrons are paired), and the function of the photosensitization is to promote the oxygen to this singlet state. Singlet oxygen can also be produced by nonphotochemical means,[252] for example, by the reaction between H_2O_2 and NaOCl[253] or between ozone and triphenyl phosphite.[254] Calcium peroxide diperoxohydrate ($CaO_2 \bullet 2H_2O_2$) has been reported as a storable compound used for the chemical generation of singlet oxygen.[255] The oxygen generated by either photochemical or nonphotochemical methods reacts with alkenes in the same way;[256] this is evidence that singlet oxygen is the reacting species in the photochemical reaction and not some hypothetical

complex between triplet oxygen and the photosensitizer, as had previously been suggested. The fact that 100% allylic rearrangement always takes place is incompatible with a free radical mechanism. Further evidence that free radicals are not involved comes from the treatment of optically active limonene (**30**) with singlet oxygen. Among other products is the optically active hydroperoxide **31**, though if **32** were an intermediate, it could not give an optically active product since it possesses a plane of symmetry.[257] In contrast, autoxidation of **30** gave optically inactive **31** (a mixture of four diastereomers in which the two pairs of enantiomers are present as racemic mixtures). As this example shows, singlet oxygen reacts faster with more highly substituted than with less highly substituted alkenes. The order of alkene reactivity is tetrasubstituted > trisubstituted > disubstituted. Electron-withdrawing substituents deactivate the alkene.[258] In simple trisubstituted alkenes, there is a general preference for the hydrogen to be removed from the more highly congested side of the double bond.[259] With *cis*-alkenes of the form RCH=CHR′, the hydrogen is removed from the larger R group.[260] Many functional groups in an allylic position cause the hydrogen to be removed from that side rather than the other (geminal selectivity).[261] Also, in alkyl-substituted alkenes, the hydrogen that is preferentially removed is the one geminal to the larger substituent on the double bond.[262]

Several mechanisms have been proposed for the reaction with singlet oxygen.[263] One of these is a pericyclic mechanism, similar to that of the ene synthesis (Reaction **15-23**) and to the first step of the reaction between alkenes and SeO_2 (Reaction **19-14**). However, there is strong evidence against this mechanism,[264] and a more likely mechanism involves addition of singlet oxygen to the double bond to give a perepoxide (**33**),[265] followed by internal proton transfer.[266]

33

Still other proposed mechanisms involve diradicals or dipolar intermediates.[267]

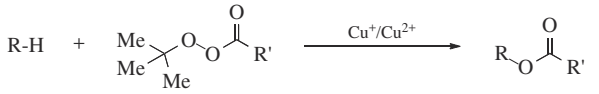
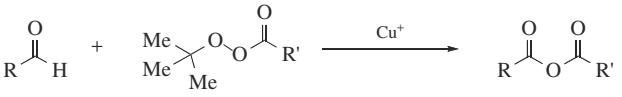
14-8 Formation of Peroxides



Alkyldioxy-de-hydrogenation

$$RH + R'OOH \xrightarrow{CuCl} ROOR'$$



Peroxy groups (ROO) can be introduced into susceptible organic molecules by treatment with a hydroperoxide in the presence of cuprous chloride or other catalysts (e.g., cobalt and manganese salts).[268] Very high yields can be obtained. The type of hydrogen replaced is similar to that with NBS (Reaction **14-3**); that is, mainly benzylic, allylic, and tertiary. The mechanism is therefore of the free radical type, involving $ROO^{\bullet}$ formed from ROOH and the metal ion. The reaction can be used to demethylate tertiary amines of the form R_2NCH_3, since the product R_2NHCH_2OOR' can easily be hydrolyzed by acid (Reaction **10-6**) to give R_2NH.[269]

14-9 Acyloxylation

Acyloxylation or Acyloxy-de-hydrogenation

Susceptible positions of organic compounds can be directly acyloxylated[270] by *tert*-butyl peroxyesters, the most frequently used being acetic and benzoic ($R' = Me$ or Ph).[271] The reaction requires a catalyst (cuprous ion is the actual catalyst, but a trace is all that is necessary, and such traces are usually present in cupric compounds, so that these are often used) and without it is not selective. Susceptible positions are similar to those in Reaction **14-6**: benzylic, allylic, and the α position of ethers and sulfides. Terminal alkenes are substituted almost entirely in the 3 position; that is, with only a small amount of allylic rearrangement, but internal alkenes generally give mixtures containing a large amount of allylic-shift product. If the reaction with alkenes is carried out in an excess of another acid ($R''CO_2H$), the ester produced is of *that* acid $ROCOR''$. Aldehydes give anhydrides:

Acyloxylation has also been achieved with metallic acetates (e.g., lead tetraacetate,[272] mercuric acetate,[273] and palladium(II) acetate).[274] In the case of the lead and mercuric acetates, not only does the reaction take place at allylic and benzylic positions and at those α

to an OR or SR group, but also at positions α to the carbonyl groups of aldehydes, ketones, or esters and at those α to two carbonyl groups (ZCH_2Z'). It is likely that in the latter cases it is the enol forms that react. Ketones can be α-acyloxylated indirectly by treatment of various enol derivatives with metallic acetates (e.g., silyl enol ethers with silver carboxylates-iodine,[275] enol thioethers with lead tetraacetate,[276] and enamines[277] with lead tetraacetate).[278] Lead tetraacetate even acyloxylates alkanes, in a slow reaction (10 days–2 weeks), with tertiary and secondary positions greatly favored over primary ones.[279] α,β-Unsaturated ketones can be acyloxylated in good yields in the α′ position with manganese triacetate.[280] Palladium acetate converts alkenes to vinylic and/or allylic acetates.[281] Acyloxylation of certain alkanes has also been reported with palladium(II) acetate.[282]

Studies of the mechanism of the cuprous-catalyzed reaction show that the most common mechanism is the following[283]:

34

This mechanism, involving a free radical $R^{\bullet}$, is compatible with the allylic rearrangements found.[284] The fact that *tert*-butyl peroxyesters labeled with ^{18}O in the carbonyl oxygen gave an ester with 50% of the label in each oxygen[285] is in accord with coupling of $R^{\bullet}$ with intermediate **34**, in which the Cu is ionically bound, so that the oxygen atoms are essentially equivalent. Other evidence is that *tert*-butoxy radicals have been trapped with dienes.[286] Much less is known about the mechanisms of the reactions with other metal acetates.[287]

Free radical acyloxylation of aromatic substrates[288] has been accomplished with a number of reagents, including copper(II) acetate,[289] silver(II) complexes,[290] and cobalt(III) trifluoroacetate.[291]

C. Substitution by Sulfur

14-10 Chlorosulfonation or Chlorosulfo-de-hydrogenation

$$RH + SO_2 + Cl_2 \xrightarrow{h\nu} RSO_2Cl$$

The chlorosulfonation of organic molecules with chlorine and sulfur dioxide is called the *Reed reaction*.[292] In scope and range of products obtained, the reaction is similar to **14-1**. The mechanism is also similar, except that there are two additional main propagation steps:

$$R^{\bullet} + SO_2 \longrightarrow R{-}SO_2^{\bullet}$$
$$R{-}SO_2^{\bullet} + Cl_2 \longrightarrow R{-}SO_2Cl + Cl^{\bullet}$$

Chlorosulfenation[293] can be accomplished by treatment with SCl_2 and UV light:

$$RH + SCl_2 \xrightarrow{h\nu} RSCl$$

D. Substitution by Nitrogen

14-11 The Direct Conversion of Aldehydes to Amides

Amination or **Amino-de-hydrogenation**

$$ArCHO \xrightarrow[NBS-AIBN]{NH_3} ArCONH_2$$

Aliphatic and aromatic aldehydes have been converted to the corresponding amides with ammonia or a primary or secondary amine, NBS, and a catalytic amount of AIBN (Sec. 14.A.i).[294] In a reaction of more limited scope, amides are obtained from aromatic and α,β-unsaturated aldehydes by treatment with dry ammonia gas and nickel peroxide.[295] Best yields (80–90%) are obtained at −25 to −20 °C. In the nickel peroxide reaction, the corresponding alcohols ($ArCH_2OH$) have also been used as substrates.

Oxidative amidation of aldehydes has been done using $AgIO_3$ in the presence of a CuI catalyst.[296] Similar oxidative amidation was accomplished using H_2O_2 and a Pd-catalyst.[297] Amides were prepared from aldehydes using NBS with a Cu catalyst.[298] Hypervalent iodine with a Fe catalyst has also been used.[299] Oxidative amidation of aromatic aldehydes using Oxone and ball milling without solvent gave the corresponding amide.[300] Amidation using nucleophilic *N*-heterocyclic carbenes leads to amidation

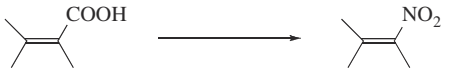
accompanied by ring opening of proximal epoxides[301] or cyclopropane moieties.[302] Aromatic aldehydes are converted to the corresponding amide by treatment with LiN $(TMS)_2$ in the presence of $LnCl_3$, and a stoichiometric reaction was reported using $(Me_3Si)_2N]_3Ln(i\text{-}Cl)Li(THF)_3$.[303]

The reaction has been performed with MnO_2 and NaCN along with ammonia or an amine at 0 °C in isopropyl alcohol.[304] Treatment of an aldehyde with iodine in aq ammonia, followed by oxidation with aq H_2O_2 generates a primary amide.[305] Secondary amines react with aldehydes to give an amide using a Pd[306] or a Rh catalyst.[307] For an indirect way of converting aldehydes to amides, see Reaction **12-32**. Thioamides ($RCSNR'_2$) have been prepared in good yield from thioaldehydes (produced *in situ* from phosphoranes and sulfur) and secondary amines.[308]

14-12 Amidation and Amination at an Alkyl Carbon



Acylamino-de-hydrogenation

When alkanes bearing a tertiary hydrogen are exposed to UV light in acetonitrile containing a heteropolytungstic acid, they are amidated.[309] The oxygen in the product comes from the tungstic acid. When the substrate bears two adjacent tertiary hydrogen atoms, alkenes are formed (by loss of two hydrogen atoms), rather than amides (Reaction **19-2**). Amidyl radicals can be generated by other means.[310]

14-13 Substitution by Nitro

Nitro-de-carboxylation

In a reaction termed a "nitro-Hunsdiecker" (see Reaction **14-30**), vinyl carboxylic acids (conjugated acids) are treated with nitric acid and a catalytic amount of AIBN (Sec. 14.A.i). The product is the vinyl nitro compound, generated via decarboxylation of a radical intermediate.[311]

Aryl halides are converted to aromatic nitro compounds via a Cu catalyzed reaction with nitrite salts ($Ar—X \rightarrow Ar—NO_2$).[312] Ceric ammonium nitrate in acetonitrile also facilitates this reaction.[313]

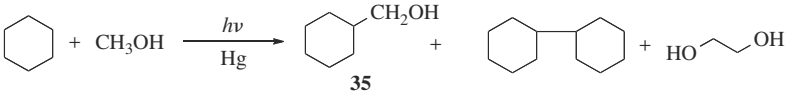
Conjugated amides were coupled via the γ-carbon to give good yields of the dimeric diamide, with an excess of samarium(II) iodide, and with modest enantioselectivity using a chiral additive.[314]

E. Substitution by Carbon

In these reactions, a new carbon–carbon bond is formed, and they may be given the collective title *coupling reactions*. In each case, an alkyl or aryl radical is generated and then combines with another radical (a termination process) or attacks an aromatic ring or alkene to give the coupling product.[315]

14-14 Simple Coupling at a Susceptible Position



De-hydrogen-coupling

$$2\,RH \longrightarrow R{-}R$$

Alkane and alkyl substrates RH are treated with peroxides, which decompose to give a radical that abstracts a hydrogen from RH to give $R^{\bullet}$, which dimerizes. Dialkyl and diacyl peroxides have been used, as well as *Fenton's reagent* (Reaction **14-5**). This reaction is far from general, although in certain cases respectable yields have been obtained. Among susceptible positions are those at a tertiary carbon,[316] as well as those α to a phenyl group (especially if there is also an α-alkyl or α-chloro group),[317] an ether group,[318] a carbonyl group,[319] a cyano group,[320] a dialkylamino group,[321] or a carboxylic ester group (either the acid or alcohol side).[322] Cross-coupling is possible in some cases. When toluene was heated with allyl bromide, in the presence of di-*tert*-butyl peroxide, 4-phenyl-1-butene was formed quantitatively.[323]

$$2\,RH \xrightarrow[Hg]{h\nu} R{-}R + H_2$$

Alkanes can be dimerized by vapor-phase mercury photosensitization[324] in a synthetically useful process. Best results are obtained for coupling at tertiary positions, but compounds lacking tertiary hydrogen atoms (e.g., cyclohexane) also give good yields. Dimerization of *n*-alkanes gives secondary–secondary coupling in a nearly statistical distribution, with primary positions essentially unaffected. Alcohols and ethers dimerize at the position α to the oxygen [e.g., 2 EtOH → MeCH(OH)CH(OH)Me].

When a mixture of compounds is treated, cross-dimerization (to give **35**) and homodimerization take place statistically. Even with the limitation on yield implied by the statistical process, cross-dimerization is still useful when one of the reactants is an alkane, because the products are easy to separate, and because of the few other ways to functionalize an alkane. The cross-coupling of an alkane with trioxane is especially valuable, because hydrolysis of the product (Reaction **10-6**) gives an aldehyde, thus achieving the conversion RH → RCHO. The mechanism probably involves abstraction of H by the excited Hg atom, and coupling of the resulting radicals.

The reaction has been extended to ketones, carboxylic acids and esters (all of which couple α to the C=O group), and amides (which couple α to the nitrogen) by running it in the presence of H_2.[325] Under these conditions it is likely that the excited Hg abstracts $H^{\bullet}$ from H_2, and that the remaining $H^{\bullet}$ abstracts H from the substrate. Radicals have also been generated at benzylic positions and shown to couple with epoxides, forming an alcohol.[326]

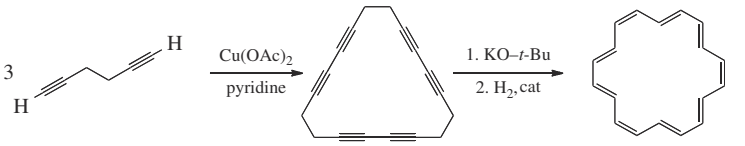
OS **IV**, 367; **V**, 1026; **VII**, 482.

14-15 Coupling at a Susceptible Position via Silanes

De-silyl-coupling

Under electrochemical conditions it is possible to couple two silanes. The reaction of **36** and allyltrimethylsilane, for example, gave the corresponding homoallylic ether.[327]

14-16 Coupling of Alkynes[328]



De-hydrogen-coupling

$$2\,R{-}C{\equiv}C{-}H \xrightarrow[\text{pyridine}]{CuX_2} R{-}C{\equiv}C{-}C{\equiv}C{-}R$$

Terminal alkynes can be coupled by heating with stoichiometric amounts of cupric salts in pyridine or a similar base. This reaction, which produces symmetrical diynes in high yields, is called the *Eglinton reaction*.[329] The large-ring annulenes (see Sec. 2.K) were prepared by rearrangement and hydrogenation of cyclic polyynes,[330] prepared by the *Eglinton reaction* with terminal diynes to give **37**, a cyclic trimer of 1,5-hexadiyne.[331] The corresponding tetramers (C_{24}), pentamers (C_{30}), and hexamers

(C_{36}) were also formed. The *Eglinton reaction* is of wide scope and many functional groups can be present on the alkyne. The oxidation is usually quite specific for triple-bond hydrogen.

37

Another common procedure is the use of catalytic amounts of cuprous salts in the presence of ammonia or ammonium chloride (this method is called the *Glaser reaction*). Atmospheric oxygen or some other oxidizing agent (e.g., permanganate or hydrogen peroxide) is required in the latter procedure. This method is not satisfactory for cyclic coupling. Hydrogen peroxide, potassium permanganate, potassium ferricyanide, iodine, or Cu(II) can be used instead of oxygen as oxidants.[332] Isolation of copper acetylide during the reaction can be avoided by doing the reaction in pyridine or cyclohexylamine, in the presence of a catalytic amount of $CuCl_2$.[333] If the *Glaser reaction* is done with a *N,N,N′,N′*-tetramethylethylenediamine–CuCl complex, the reaction proceeds in good yield in virtually any organic solvent.[334] When molecular oxygen is the oxidant, this modification of the *Glaser reaction* is known as the *Hay reaction*.

A variation couples terminal alkynes using $CuCl_2$ in supercritical CO_2 (see Sec. 9.D.ii),[335] and in ionic liquids.[336] Coupling was also achieved using $CuCl_2$ on KF—Al_2O_3 with microwave irradiation.[337] A Co catalyzed *Glaser coupling* has been reported[338] and also a transition metal free coupling.[339] A modified *Glaser coupling* has been reported using KF/Alumina.[340] Coupling has been achieved under ambient conditions using cupric acetate.[341] Copper(II) promoted homocoupling of terminal alkynes has been done in supercritical CO_2.[342] Another variation is a Ni catalyzed cross-coupling.[343] Terminal alkynes give 1,3-diynes upon treatment with Cu–iodine.[344]

Unsymmetrical diynes can be prepared by *Cadiot–Chodkiewicz* coupling[345]:

$$R{-}C{\equiv}C{-}H + R'{-}C{\equiv}C{-}Br \xrightarrow{Cu^+} R{-}C{\equiv}C{-}C{\equiv}C{-}R' + HBr$$

This may be regarded as a variation of Reaction **10-74**, but it must have a different mechanism since acetylenic halides give the reaction but ordinary alkyl halides do not,

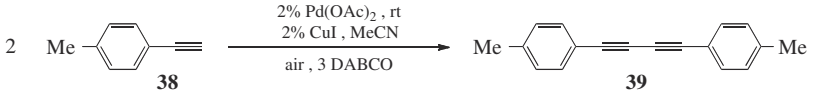
which is hardly compatible with a nucleophilic mechanism. However, the mechanism is not fully understood. One version of this reaction binds the alkynyl bromide unit to a polymer, and the di-yne is released from the polymer after the solid-state transformation.[346] Alkynes have also been coupled using CuI and a Pd catalyst.[347] A variation of the *Cadiot–Chodkiewicz method* consists of treating a haloalkyne ($R'C{\equiv}CX$) with a copper acetylide ($RC{\equiv}CCu$).[348] The *Cadiot–Chodkiewicz procedure* can be adapted to the preparation of diynes in which $R'{=}H$ by the use of $BrC{\equiv}CSiEt_3$ and subsequent cleavage of the $SiEt_3$ group.[349] This protecting group can also be used in the *Eglinton* or *Glaser* methods.[350]

The mechanism of the *Eglinton* and *Glaser reactions* probably begins with loss of a proton

$$R{-}C{\equiv}C{-}H \xrightarrow{\text{base}} R{-}C{\equiv}C^{-}$$

since there is a base present and acetylenic protons are acidic. It is known, of course, that cuprous ion can form complexes with triple bonds. The last step is probably the coupling of two radicals:



$$R{-}C{\equiv}C^{\bullet} \longrightarrow R{-}C{\equiv}C{-}C{\equiv}C{-}R$$

but just how the carbanion becomes oxidized to the radical and what part the cuprous ion plays (other than forming the acetylide salt) are matters of considerable speculation,[351] and depend on the oxidizing agent. One proposed mechanism postulated Cu(II) as the oxidant.[352] It has been shown that molecular oxygen forms adducts with Cu(I) supported by tertiary amines, which might be the intermediates in the *Glaser reaction* where molecular oxygen is the oxidant.[353] For the *Hay reaction*, the mechanism involves a Cu(I)/Cu(III)/Cu(II)/Cu(I) catalytic cycle, and the key step for this reaction is the dioxygen activation during complexation of two molecules of acetylide with molecular oxygen, giving a Cu(III) complex.[354] This mechanism is supported by isolation and characterization of Cu(III) complexes formed under the conditions of the *Glaser coupling*.

Sonogashira coupling, which involves aryl halides and terminal alkynes in the presence of a Pd catalyst, has been extended to the coupling of two alkynes.[355] Indeed, the Pd catalyzed coupling of two alkynes to form a diyne[356] is often referred to as *Sonogashira cross-coupling*, or *Sonogashira-like coupling*. An example is the

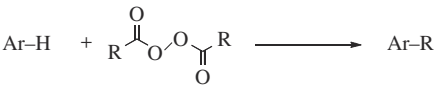
conversion of **38** to **39**.[357] Here rt = room temperature amd DABCO = 1,4-diazabicyclo [2.2.2]octane.

38 **39**

Terminal alkynes are not the only reaction partners. 1-Trimethylsilyl alkynes (R—C≡C—$SiMe_3$) give the diyne R—C≡C—C≡C—R) upon reaction with CuCl[358] or $Cu(OAc)_2/Bu_4NF$.[359]

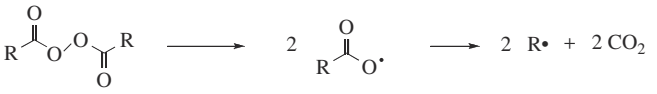


Alkynylboronates undergo homocoupling to give symmetrical 1,3-diynes in the presence of a Cu salt.[360] The Cu-catalyzed homocoupling of alkynyltrifluoroborates leads to 1,3-diynes.[361]

In related reactions, alkynyltrifluoroborates react with vinylic tellurides to give 1,3-enynes.[362] The Pd catalyzed reaction of vinyl bromides and terminal alkynes gives enynes.[363] 1,3-Dienes are prepared by the Pd catalyzed homocoupling of alkenyltrifluoroborates.[364]

OS **V**, 517; **VI**, 68, 925; **VIII**, 63.

14-17 Alkylation and Arylation of Aromatic Compounds by Peroxides



Alkylation or **Alkyl-de-hydrogenation**

This reaction is most often carried out with R = aryl, so the net result is the same as in Reaction **13-27**, though the reagent is different.[365] It is used less often than Reaction **13-27**, but the scope is similar. When R = alkyl, the scope is more limited.[366] Only certain aromatic compounds, particularly benzene rings with two or more nitro groups, and fused ring systems, can be alkylated by this procedure. 1,4-Quinones can be alkylated with diacyl peroxides or with lead tetraacetate (methylation occurs with this reagent).

The mechanism is as shown in Section 14.A.iii (CIDNP has been observed[367]); the radicals are produced by

Since no relatively stable free radical is present (e.g., $^{\bullet}O—N=N—Ar$ in Reaction **13-27**), most of the product arises from dimerization and disproportionation.[368] The addition of a small amount of nitrobenzene increases the yield of arylation product because the nitrobenzene is converted to diphenyl nitroxide, which abstracts a hydrogen atom and diminishes the extent of side reactions.[369] The Pd catalyzed methylation of aromatic rings in the presence of dicumyl peroxide is another variation.[370]

$$ArH + Ar^{I}Pb(OAc)_3 \longrightarrow ArAr^{I}$$

Aromatic compounds can also be arylated by aryllead tricarboxylates.[371] Best yields ($\sim$ 70–85%) are obtained when the substrate contains alkyl groups; an electrophilic mechanism is likely. Phenols are phenylated ortho to the OH group (and enols are a phenylated) by triphenylbismuth dichloride or by certain other Bi(V) reagents.[372] *O*-Phenylation is a possible side reaction. As with the aryllead tricarboxylate reactions, a free radical mechanism is unlikely.[373]

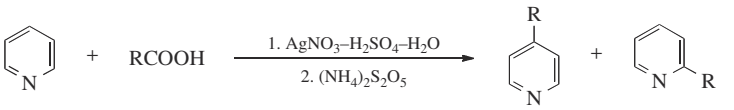
OS **V**, 51. See also, OS **V**, 952; **VI**, 890.

14-18 Photochemical Arylation of Aromatic Compounds

Arylation or **Aryl-de-hydrogenation**

$$ArH + Ar^{I}I \xrightarrow{h\nu} ArAr^{I}$$

Another free radical arylation method consists of the photolysis of aryl iodides in an aromatic solvent.[374] Yields are generally higher than in Reactions **13-27** or **14-17**. The aryl iodide may contain OH or COOH groups. The coupling reaction of iodobenzene and azulene to give a phenylazulene was reported (41% conversion and 85% yield).[375] The mechanism is similar to that of Reaction **13-27**. The aryl radicals are generated by the photolytic cleavage $ArI \rightarrow AR^{\bullet} + I^{\bullet}$. The reaction has been applied to intramolecular arylation (analogous to the *Pschorr reaction*).[376] A similar reaction is photolysis of an



[367] Kaptein, R.; Freeman, R.; Hill, H.D.W.; Bargon, J. *J. Chem. Soc., Chem. Commun.* ***1973***, 953.
[368] The mechanism is actually more complicated. See DeTar, D.F.; Long, R.A.J.; Rendleman, J.; Bradley, J.; Duncan, P. *J. Am. Chem. Soc.* ***1967****, 89,* 4051; DeTar, D.F. *J. Am. Chem. arylthallium bis(trifluoroacetate) (**12-23**) in an aromatic solvent. Here too, an unsymmetrical biaryl is produced in good yields.[377] In this case, it is the C—Tl bond that is cleaved to give aryl radicals.

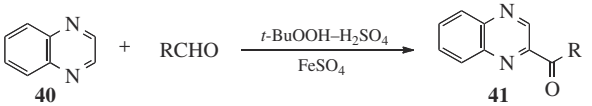
$$Ar^{I}Tl(OCOCF_3)_2 \xrightarrow[h\nu]{ArH} ArAr^{I}$$

14-19 Alkylation, Acylation, and Carbalkoxylation of Nitrogen Heterocycles[378]

Alkylation or **Alkyl-de-hydrogenation**, and so on

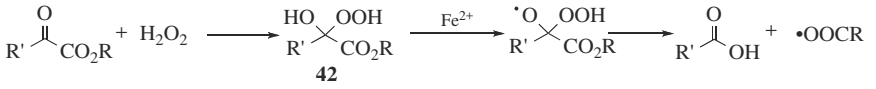


Alkylation of protonated nitrogen heterocycles (e.g., pyridines, quinolines) can be accomplished by treatment with a carboxylic acid, silver nitrate, sulfuric acid, and ammonium peroxydisulfate.[379] The R group can be primary, secondary, or tertiary. The attacking species is $R^{\bullet}$, formed by[380]

$$2\,Ag^{+} + S_2O_8^{2-} \longrightarrow 2\,Ag^{2+} + 2\,SO_4^{2-}$$
$$RCOOH + Ag^{2+} \longrightarrow RCOO^{\bullet} + H^{+} + Ag^{+}$$
$$RCOO^{\bullet} \longrightarrow R^{\bullet} + CO_2$$

A hydroxymethyl group can be introduced (ArH → $ArCH_2OH$) by several variations of this method.[381] Alkylation of these substrates can also be accomplished by generating the alkyl radicals in other ways: from hydroperoxides and $FeSO_4$,[382] from alkyl iodides and H_2O_2—Fe(II),[383] from carboxylic acids and lead tetraacetate, or from the photochemically induced decarboxylation of carboxylic acids by iodosobenzene diacetate.[384]

Protonated nitrogen heterocycles (e.g., quinoxaline, **40**) can be acylated by treatment with an aldehyde, *tert*-butyl hydroperoxide, sulfuric acid, and ferrous sulfate, in this case giving **41**.[385]



Photochemical alkylation of protonated quinoline occurred with $Ph_2Se(O_2C\text{-}c\text{-}C_6H_{11})_2$.[386]

Other positively charged heterocycles react as well. When *N*-fluoropyridinium triflate was treated with the enolate anion of acetone, 2-(2-oxopropyl)pyridine was formed in modest yield.[387]

These alkylation and acylation reactions are important because *Friedel–Crafts* alkylation and acylation (Reactions **11-11** and **11-17**) cannot be applied to most nitrogen heterocycles (see also, Reaction **13-17**).

Protonated nitrogen heterocycles can be carbalkoxylated[388] by treatment with esters of α-keto acids and *Fenton's reagent*. Pyridine is carbalkoxylated at C-2 and C-4, for example. The attack is by •COOR radicals generated from the esters via a hydroperoxide (**42**).

Similarly, a carbamoyl group can be introduced[389] by the use of the radicals $H_2N—\dot{C}=O$ or $Me_2N—\dot{C}=O$ generated from formamide or DMF and H_2SO_4, H_2O_2, and $FeSO_4$ or other oxidants.

14.C.ii. N_2 as Leaving Group[390]

In these reactions, diazonium salts are cleaved to aryl radicals,[391] in most cases with the assistance of copper salts. Reactions **13-27** and **13-26** may also be regarded as belonging to this category with respect to the attacking compound. For nucleophilic substitutions of diazonium salts (see Reactions **13-20**–**13-23**). Removal of nitrogen and replacement with a hydrogen atom is a reduction, found in Chapter 19.

14-20 Replacement of the Diazonium Group by Chlorine or Bromine

Chloro-de-diazoniation, and so on

$$ArN_2^+ + CuCl \longrightarrow ArCl$$

Treatment of diazonium salts with cuprous chloride or bromide leads to aryl chlorides or bromides, respectively. In either case, the reaction is called the *Sandmeyer Reaction*.[392] The reaction can also be carried out with copper and HBr or HCl, in which case it is called the *Gatterman Reaction* (not to be confused with **11-18**). However, a Cu catalyzed *Sandmeyer bromination* reaction is known.[393] The *Sandmeyer reaction* is not useful for the preparation of fluorides or iodides, but for bromides and chlorides it is

[392] Rate constants for this reaction have been determined. See Hanson, P.; Hammond, R.C.; Goodacre, P.R.; Purcell, J.; Timms, A.W. *J. Chem. Soc. Perkin Trans. 2* ***1994***, 691.
[393] Beletskaya, I.P.; Sigeev, A.S.; Peregudov, A.S.; Petrovskii, P.V. *Synthesis* ***2007***, 2534.

of wide scope and is probably the best way of introducing bromine or chlorine into an aromatic ring. The yields are usually high.

The mechanism is not known with certainty, but is believed to take the following course[394]:

$$ArN_2^+X^- + CuX \longrightarrow Ar^\bullet + N_2 + CuX_2$$
$$Ar^\bullet + CuX_2 \longrightarrow ArX + CuX$$

The first step involves a reduction of the diazonium ion by the cuprous ion, which results in the formation of an aryl radical. In the second step, the aryl radical abstracts halogen from cupric chloride, reducing it. CuX is regenerated and is thus a true catalyst.

Aryl bromides and chlorides can be prepared from primary aromatic amines in one step by several procedures,[395] including treatment of the amine (1) with *tert*-butyl nitrite and anhydrous $CuCl_2$ or $CuBr_2$ at 65 °C,[396] and (2) with *tert*-butyl thionitrite or *tert*-butyl thionitrate and $CuCl_2$ or $CuBr_2$ at room temperature.[397] These procedures are, in effect, a combination of Reaction **13-19** and the *Sandmeyer Reaction*. A further advantage is that cooling to 0 °C is not needed. A mixture of Me_3SiCl and $NaNO_2$ was used to convert aniline to chlorobenzene in a related reaction.[398]

For the preparation of fluorides and iodides from diazonium salts, see Reactions **13-32** and **13-31**.

$$ArN_2^+ + CuCN \longrightarrow ArCN$$

Note that the reaction of aryl diazonium salts with CuCN to give benzonitrile derivatives is also called the *Sandmeyer Reaction*. It is usually conducted in neutral solution to avoid liberation of HCN.

OS **I**, 135, 136, 162, 170; **II**, 130; **III**, 185; **IV**, 160. Also see, OS **III**, 136; **IV**, 182. For the reaction with CuCN see OS **I**, 514.

14-21 Replacement of the Diazonium Group by Nitro

Nitro-de-diazoniation

$$ArN_2^+ + NaNO_2 \xrightarrow{Cu^+} ArNO_2$$

Nitro compounds can be formed in good yields by treatment of diazonium salts with sodium nitrite in the presence of cuprous ion. The reaction occurs only in neutral or alkaline solution. This is not usually called the *Sandmeyer Reaction*, although, like Reaction **14-20**, it was discovered by Sandmeyer. Tetrafluoroborate (BF_4^-) is often used as the negative ion, since the diminished nucleophilicity avoids competition from the chloride ion. The mechanism is probably like that of Reaction **14-20**.[399] If electron-withdrawing groups

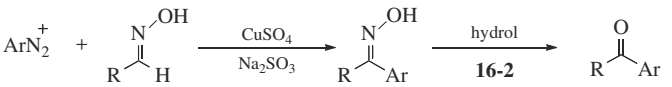
are present, the catalyst is not needed; $NaNO_2$ alone gives nitro compounds in high yields.[400]

An alternative procedure used electrolysis, in 60% HNO_3 to convert 1-aminonaphthalene to naphthalene.[401]

OS **II**, 225; **III**, 341.

14-22 Replacement of the Diazonium Group by Sulfur-Containing Groups

Chlorosulfo-de-diazoniation



$$ArN_2^+ + SO_2 \xrightarrow[HCl]{CuCl_2} ArSO_2Cl$$

Diazonium salts can be converted to sulfonyl chlorides by treatment with sulfur dioxide in the presence of cupric chloride.[402] The use of $FeSO_4$ and copper metal instead of $CuCl_2$ gives sulfinic acids ($ArSO_2H$)[403] (see also, Reaction **13-21**).

OS **V**, 60; **VII**, 508.

14-23 Conversion of Diazonium Salts to Aldehydes, Ketones, or Carboxylic Acids

Acyl-de-diazoniation, and so on

Diazonium salts react with oximes to give aryl oximes, which are easily hydrolyzed to aldehydes (R = H) or ketones.[404] A copper sulfate–sodium sulfite catalyst is essential. In most cases, higher yields (40–60%) are obtained when the reaction is used for aldehydes rather than for ketones. In another method[405] for achieving the conversion $ArN_2^+ \rightarrow$ ArCOR, diazonium salts are treated with R_4Sn and CO with palladium acetate as catalyst.[406] In a different kind of reaction, silyl enol ethers of aryl ketones ($Ar'C(OSiMe_3)=CHR$) react with solid diazonium fluoroborates ($ArN_2^+ BF_4^-$) to give ketones ($ArCHRCOAr'$).[407] This is, in effect, an arylation of the aryl ketone.

Carboxylic acids can be prepared in moderate-to-high yields by treatment of diazonium fluoroborates with carbon monoxide and palladium acetate[408] or copper(II) chloride.[409] The mixed anhydride (ArCOOCOMe) is an intermediate that can be isolated. Other mixed anhydrides can be prepared by the use of other salts instead of sodium acetate.[410] An arylpalladium compound is probably an intermediate.[368]

14.C.iii. Metals as Leaving Groups

14-24 Coupling of Grignard Reagents

De-metallo-coupling

$$2\,RMgX \xrightarrow{M} RR$$

This organometallic coupling reaction is clearly related to the *Wurtz coupling*, discussed in Reaction **10-56**, and the coupling of other organometallic compounds is discussed in Reaction **14-25**. *Grignard reagents* can be coupled to give symmetrical dimers[411] by treatment with either thallium(I) bromide[412] or with a transition metal halide (e.g., Fe compounds,[413] $CrCl_2$, $CrCl_3$, $CoCl_2$, $CoBr_2$, or $CuCl_2$).[414] The metallic halide is an oxidizing agent and becomes reduced. Both aryl and alkyl *Grignard reagents* can be dimerized by either procedure, though the TlBr method cannot be applied to R = primary alkyl or to aryl groups with ortho substituents. Aryl *Grignard reagents* can also be dimerized by treatment with 1,4-dichloro-2-butene, 1,4-dichloro-2-butyne, or 2,3-dichloropropene.[415] Vinylic and alkynyl *Grignard reagents* can be coupled (to give 1,3-dienes and 1,3-diynes, respectively) by treatment with thionyl chloride.[416] Primary alkyl, vinylic, aryl, and benzylic *Grignard reagents* give symmetrical dimers in high yield (~90%) when treated with a silver(I) salt in the presence of a nitrogen-containing oxidizing agent (e.g., lithium nitrate, methyl nitrate, or NO_2).[417] This method has been used to close rings of four, five, and six members.[418]

The mechanisms of the reactions with metal halides, at least in some cases, probably begin with conversion of RMgX to the corresponding RM (Reaction **12-36**), followed by its decomposition to free radicals.[419]

OS **VI**, 488.

14-25 Coupling of Other Organometallic Reagents[332]

De-metallo-coupling

$$R_2CuLi \xrightarrow[-78\ ^\circ C,THF]{O_2} RR$$

Lithium dialkylcopper reagents can be oxidized to symmetrical dimers by O_2 at −78 °C in THF.[420] The reaction is successful for R = primary and secondary alkyl, vinylic, or aryl. Other oxidizing agents (e.g., nitrobenzene) can be used instead of O_2. Vinylic

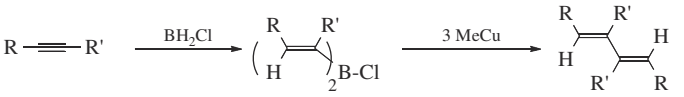
copper reagents dimerize on treatment with oxygen, or simply on standing at 0 °C for several days or at 25 °C for several hours, to yield 1,3-dienes.[421] The finding of retention of configuration for this reaction demonstrates that free radical intermediates are not involved.

The coupling reaction of *Grignard reagents* was discussed in Reaction **14-24**. There are iron-catalyzed cross-coupling reactions.[422] Lithium organoaluminates ($LiAlR_4$) are dimerized to R—R by treatment with $Cu(OAc)_2$.[423] Terminal vinylic alanes (prepared by Reaction **15-17**) can be dimerized to 1,3-dienes with CuCl in THF.[424] Symmetrical 1,3-dienes can also be prepared in high benzylic bromides to give the coupling product.[425] Coupling products are obtained by treatment of vinylic mercury chlorides[426] with LiCl and a Rh catalyst[427] and by treatment of vinylic tin compounds with a Pd catalyst.[428] Vinylic, alkynyl, and aryl tin compounds were dimerized with $Cu(NO_3)_2$.[429] Allylindium reagents were coupled to alkyl- and aryllithium compounds can be dimerized by transition metal halides in a reaction similar to Reaction **14-24**.[430]

Unsymmetrical coupling of vinylic, alkynyl, and arylmercury compounds was achieved in moderate-to-good yields by treatment with alkyl and vinylic dialkylcopper reagents (e.g., $PhCH{=}CHHgCl + Me_2CuLi \rightarrow PhCH{=}CHMe$).[431] A radical coupling reaction has been reported, in which an aryl halide reacted with Bu_3SnH, AIBN, and benzene, followed by treatment with methyllithium to give the biaryl.[432]

14-26 Coupling of Boranes

Alkyl-de-dialkylboration



Alkylboranes can be coupled by treatment with silver nitrate and base.[433] Since alkylboranes are easily prepared from alkenes (Reaction **15-16**), this is essentially a way of coupling and reducing alkenes; in fact, alkenes can be hydroborated and coupled in the same flask. For symmetrical coupling (R = R′) yields range from 60 to 80% for terminal alkenes and from 35 to 50% for internal ones. Unsymmetrical coupling has also been

carried out,[434] but with lower yields. Arylboranes react similarly, yielding biaryls.[435] The mechanism is probably of the free radical type.

Dimerization of two vinylborane units to give a conjugated diene can be achieved by treatment of divinylchloroboranes (prepared by addition of BH_2Cl to alkynes; see Reaction **15-16**) with methylcopper. (*E*,*E*)-1,3-Dienes are prepared in high yields.[436]

In a similar reaction, symmetrical conjugated diynes RC≡C—C≡CR can be prepared by reaction of lithium dialkyldialkynylborates, $Li^+ [R'_2B(C{\equiv}CR)_2]^-$, with iodine.[437]

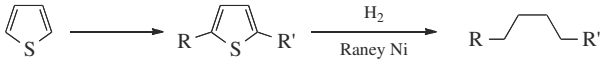
14.C.iv. Halogen as Leaving Group

The conversion of RX to RH can occur by a free radical mechanism, but is treated at Reaction **19-53**.

14.C.v. Sulfur as Leaving Group

14-27 Desulfurization

Hydro-de-thio-substitution, and so on



$$RSH \xrightarrow[Ni]{H_2} RH \qquad RSR' \xrightarrow[Ni]{H_2} RH + R'H$$

Thiols and thioethers,[438] both alkyl and aryl, can be desulfurized by hydrogenolysis with Raney nickel.[439] The hydrogen is usually not applied externally, since Raney nickel already contains enough hydrogen for the reaction. Other sulfur compounds can be similarly desulfurized, among them disulfides (RSSR), thiono esters (RCSOR′),[440] thioamides (RCDNHR′), sulfoxides, and dithioacetals. The last reaction, which is an indirect way of accomplishing reduction of a carbonyl to a methylene group (see

Reaction **19-61**), can also give the alkene if a hydrogen atom is present.[441] In most of the examples given, R can also be aryl. Other reagents[442] have also been used,[443] including Sm in acetic acid for desulfurization of vinyl sulfones.[444]

An important special case of RSR reduction is desulfurization of thiophene derivatives. This proceeds with concomitant reduction of the double bonds. Many compounds have been made by alkylation of thiophene (see **39**), followed by reduction to the corresponding alkane.

43

Thiophenes can also be desulfurized to alkenes ($RCH_2CH{=}CHCH_2R'$ from **43**) with a nickel boride catalyst prepared from nickel(II) chloride and $NaBH_4$ in methanol.[445] It is possible to reduce just one SR group of a dithioacetal by treatment with borane–pyridine in trifluoroacetic acid or in CH_2Cl_2 in the presence of $AlCl_3$.[446] Phenyl selenides (RSePh) can be reduced to RH with Ph_3SnH[447] and with nickel boride.[448]

The exact mechanisms of the Raney nickel reactions are still in doubt, though they are probably of the free radical type.[449] It has been shown that reduction of thiophene proceeds through butadiene and butene, not through 1-butanethiol or other sulfur compounds; that is, the sulfur is removed before the double bonds are reduced. This was demonstrated by isolation of the olefins and the failure to isolate any potential sulfur-containing intermediates.[450]

See Chapter 19 for other reduction reactions involving sulfur compounds.

with R = primary, secondary, or tertiary alkyl, or allylic,[453] and containing groups, such as double bonds or halogens. Dilithio compounds can be made from compounds containing two separated SPh groups, but it is also possible to replace just one SPh from a compound with two such groups on a single carbon, to give an α-lithio sulfide.[454] The reaction has also been used to prepare α-lithio ethers and α-lithio organosilanes.[451] For some of these compounds, lithium 1-(dimethylamino)naphthalenide is a better reagent than either Li or lithium naphthalenide.[455] The mechanism is presumably of the free radical type.

14.C.vi. Carbon as Leaving Group

14-29 Decarboxylative Dimerization: The Kolbe Reaction

De-carboxylic-coupling

$$2\,RCOO^- \xrightarrow{\text{electrolysis}} R{-}R$$

Electrolysis of carboxylate ions, results in decarboxylation and combination of the resulting radicals to give the coupling product R—R. This coupling reaction is called the *Kolbe Reaction* or the *Kolbe electrosynthesis*.[456] It is used to prepare symmetrical R—R, where R is straight chained, since little or no yield is obtained when there is a branching. The reaction is not successful for R = aryl. Many functional groups may be present, though many others inhibit the reaction.[456] Unsymmetrical R—R′ have been made by coupling mixtures of acid salts. The *Kolbe reaction* has been done using solid-supported bases.[457]

A free radical mechanism is involved

$$RCOO^- \xrightarrow[\text{oxidation}]{\text{electrolytic}} RCOO^\bullet \xrightarrow{-CO_2} R^\bullet \longrightarrow R{-}R$$

There is much evidence[458] for this mechanism, including side products (RH, alkenes) characteristic of free radical intermediates and the fact that electrolysis of acetate ion in the presence of styrene caused some of the styrene to polymerize to polystyrene (such polymerizations can be initiated by free radicals, see Sec. 15.B.i). Other side products (ROH, RCO_2R) are sometimes found, stemming from further oxidation of the radical $R^\bullet$ to a carbocation R^+.[459]

When the reaction is conducted in the presence of 1,3-dienes, additive dimerization can occur:[460]

$$2\,RCOO^- + CH_2{=}CH{-}CH{=}CH_2 \longrightarrow RCH_2CH{=}CHCH_2CH_2CH{=}CHCH_2R$$

The radical $R^\bullet$ adds to the conjugated system to give $RCH_2CH{=}CHCH_2^\bullet$, which dimerizes. Another possible product is $RCH_2CH{=}CHCH_2R$, from coupling of the two kinds of radicals.[461]

In a nonelectrolytic reaction, which is limited to R = primary alkyl, the thiohydroxamic esters (**44**) give dimers when irradiated at −64 °C in an Ar atmosphere:[462]

44

In another nonelectrolytic process, aryl acetic acids are converted to *vic*-diaryl compounds ($2ArCR_2COOH \rightarrow ArCR_2CR_2Ar$) by treatment with sodium persulfate ($Na_2S_2O_8$) and a catalytic amount of $AgNO_3$.[463] Photolysis of carboxylic acids in the presence of Hg_2F_2 leads to the dimeric alkane via decarboxylation.[464] Both of these reactions involve dimerization of free radicals. In still another process, electron-deficient aromatic acyl chlorides are dimerized to biaryls (Ar—Ar) by treatment with a disilane R_3SiSiR_3 and a Pd catalyst.[465]

14-30 The Hunsdiecker Reaction

Bromo-de-carboxylation

$$RCOOAg + Br_2 \longrightarrow RBr + CO_2 + AgBr$$

Reaction of a silver salt of a carboxylic acid with bromine is called the *Hunsdiecker reaction*[466] and is a method of decreasing the length of a carbon chain by one unit.[467] The reaction is of wide scope, giving good results for *n*-alkyl R from 2 to 18 carbons and for many branched R too, producing primary, secondary, and tertiary bromides. Many functional groups may be present as long as they are not a substituted. The R group may also be aryl. However, if R contains unsaturation, the reaction seldom gives good results. Although bromine is the most often used halogen, chlorine, and iodine have also

[466] This reaction was first reported by the Russian composer–chemist Alexander Borodin: *Liebigs Ann. Chem.* ***1861****, 119,* 121.
[467] See Wilson, C.V. *Org. React.* ***1957****, 9*, 332; Johnson, R.G.; Ingham, R.K. *Chem. Rev.* ***1956****, 56*, 219. Also see, Naskar, D.; Chowdhury, S.; Roy, S. *Tetrahedron Lett.* ***1998****, 39*, 699.

been used. Catalytic Hunsdiecker reactions are known,[468] and microwave enhancement has been employed.[469]

When iodine is the reagent, the ratio between the reactants is very important and determines the products. A 1:1 ratio of salt/iodine gives the alkyl halide, as above. A 2:1 ratio, however, gives the ester RCOOR. This is called the *Simonini Reaction* and is sometimes used to prepare carboxylic esters. The *Simonini reaction* can also be carried out with lead salts of acids.[470] A more convenient way to perform the *Hunsdiecker Reaction* is by use of a mixture of the acid and mercuric oxide instead of the salt, since the silver salt must be very pure and dry and such pure silver salts are often not easy to prepare.[471]

Other methods for accomplishing the conversion RCOOH → RX are[472] (1) treatment of thallium(I) carboxylates with bromine;[473] (2) treatment of carboxylic acids with lead tetraacetate and halide *ions* (Cl^-, Br^-, or I^-);[474] (3) reaction of the acids with lead tetraacetate and NCS, which gives tertiary and secondary chlorides in good yields, but is not good for R = primary alkyl or phenyl;[475] (4) treatment of thiohydroxamic esters with CCl_4, $BrCCl_3$ (which gives bromination), CHI_3, or CH_2I_2 in the presence of a radical initiator;[476] (5) photolysis of benzophenone oxime esters of carboxylic acids in CCl_4 ($RCON{=}CPh_2 \rightarrow RCl$).[477] Alkyl fluorides can be prepared in moderate-to-good yields by treating carboxylic acids (RCOOH) with XeF_2.[478] This method works best for R = primary and tertiary alkyl, and benzylic. Aromatic and vinylic acids do not react.

The mechanism of the *Hunsdiecker reaction* is believed to be as follows:

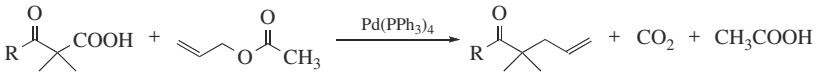
The first step is not a free radical process, and its actual mechanism is not known.[479] Compound **45** is an acyl hypohalite and is presumed to be an intermediate, though it has never been isolated from the reaction mixture. Among the evidence for the mechanism is that optical activity at R is lost (except when a neighboring bromine atom is present, see Sec. 14.A.iv); if R is neopentyl, there is no rearrangement, which would certainly happen with a carbocation; and the side products, notably R-R, are consistent with a free radical mechanism. There is evidence that the *Simonini reaction* involves the same mechanism as the *Hunsdiecker reaction*, but that the alkyl halide formed then reacts with excess RCOOAg (Reaction **10-17**) to give the ester[480] (see also, Reaction **19-12**).



Vinyl carboxylic acids (conjugated acids) were shown to react with NBS and lithium acetate in aq acetonitrile, to give the corresponding vinyl bromide (C=C—CO_2H → C=C—Br), using microwave irradiation.[481] A similar reaction was reported using Na_2MoO_4, KBr and aq H_2O_2.[482]

A related reaction reacts the sodium salt of an alkylsulfonic acid with thionyl chloride at 100 °C, to give the alkyl chloride.[483]

14-31 Decarboxylative Allylation

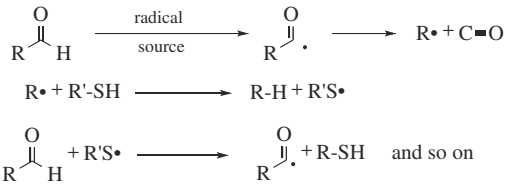
Allyl-de-carboxylation

The COOH group of a β-keto acid is replaced by an allylic group when the acid is treated with an allylic acetate and a Pd catalyst at room temperature.[484] The reaction is successful for various substituted allylic groups. The less highly substituted end of the allylic group forms the new bond. Thus, both CH_2=CHCHMeOAc and MeCH=CH-CH_2OAc gave O=C(R)-C-CH_2CH—CHMe as the product.

14-32 Decarbonylation of Aldehydes and Acyl Halides

Carbonyl-extrusion

Aldehydes, both aliphatic and aromatic, can be decarbonylated[485] by heating with a Rh catalyst[486] or other catalysts (e.g., Pd).[487] The compound $RhCl(Ph_3P)_3$ is often called



[479] When Br_2 reacts with aryl R, at low temperature in inert solvents, it is possible to isolate a complex containing both Br_2 and the silver carboxylate: see Bryce-Smith, D.; Isaacs, N.S.; Tumi, S.O. *Chem. Lett.* ***1984***, 1471.

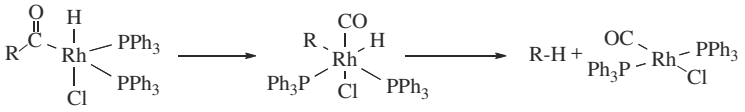
Wilkinson's catalyst.[488] In an older reaction aliphatic (but not aromatic) aldehydes are decarbonylated by heating with di-*tert*-butyl peroxide or other peroxides,[489] usually in a solution containing a hydrogen donor, such as a thiol. The reaction has also been initiated with light, and thermally (without an initiator) by heating at ~500 °C.

Wilkinson's catalyst has also been reported to decarbonylate aromatic acyl halides at 180 °C (ArCOX → ArX).[490] This reaction has been carried out with acyl iodides,[491] bromides, and chlorides. Aliphatic acyl halides that lack a hydrogen also give this reaction,[492] but if an α hydrogen is present, elimination takes place instead (Reaction **17-17**). Aromatic acyl cyanides give aryl cyanides (ArCOCN → ArCN).[493] Aromatic acyl chlorides and cyanides can also be decarbonylated with Pd catalysts.[494]

It is possible to decarbonylate acyl halides in another way, to give alkanes (RCOCl → RH). This is done by heating the substrate with tripropylsilane (Pr_3SiH) in the presence of *tert*-butyl peroxide.[495] Yields are good for R = primary or secondary alkyl and poor for R = tertiary alkyl or benzylic. There is no reaction when R = aryl. (See also, the decarbonylation ArCOCl → Ar—Ar mentioned in Reaction **14-29**.)



The mechanism of the peroxide- or light-induced reaction seems to be as follows (in the presence of thiols).[496]

The reaction of aldehydes with *Wilkinson's catalyst* goes through complexes of the form **46** and **47**, which have been trapped.[497] The reaction has been shown to give retention of configuration at a chiral R;[498] and deuterium labeling demonstrates that the reaction is

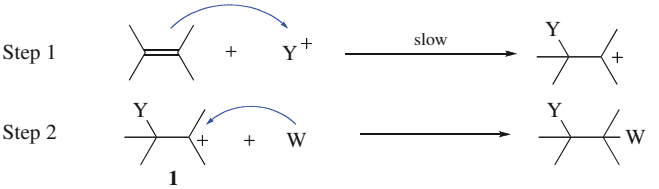
CHAPTER 15



Addition to Carbon–Carbon Multiple Bonds

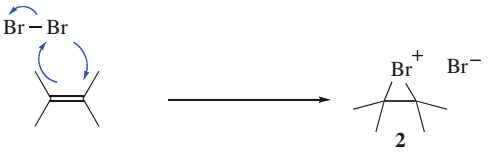
There are four fundamental ways in which addition to a double or triple bond can take place. Three of these are two-step processes, with initial attack by a nucleophile, or attack upon an electrophile or a free radical. The second step consists of combination of the resulting intermediate with, respectively, a positive species, a negative species, or a neutral entity. In the fourth type of mechanism, attack at the two carbon atoms of the double or triple bond is simultaneous (concerted). Which of the four mechanisms is operating in any given case is determined by the nature of the substrate, the reagent, and the reaction conditions. Some of the reactions in this chapter can take place by all four mechanistic types.

15.A. MECHANISMS

15.A.i. Electrophilic Addition[1]

In this mechanism, a positive species approaches the double or triple bond and in the first step forms a bond by donation of the π pair of electrons[2] to the electrophilic species to form a σ bond:

1



The IUPAC designation for this mechanism is $A_E + A_N$ (or $A_H + A_N$ if $Y^+ = H^+$). As in electrophilic substitution (Sec. 11.A.i), Y need not actually be a positive ion, but can be the

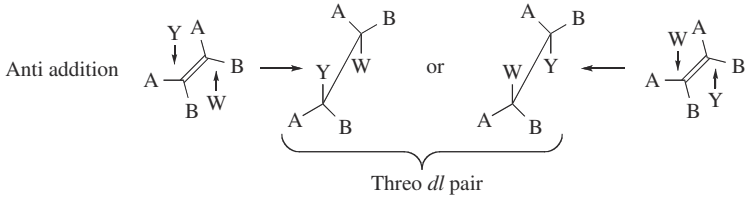
positive end of a dipole or an induced dipole, with the negative part breaking off either during the first step or shortly after. The second step is a combination of **1** with a species carrying an electron pair and often bearing a negative charge. This step is the same as the second step of the S_N1 mechanism. Not all electrophilic additions follow the simple mechanism given above. In many bromination reactions it is fairly certain that **1**, if formed at all, very rapidly cyclizes to a bromonium ion (**2**):

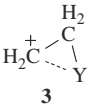


2

This intermediate is similar to those encountered in the neighboring-group mechanism of nucleophilic substitution (see Sec. 10.C). The attack of W: on an intermediate like **2** is an S_N2 step. Whether the intermediate is **1** or **2**, the mechanism is called Ad_E2 (electrophilic addition, bimolecular).

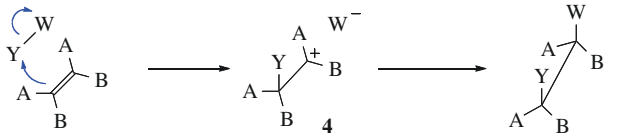
The most useful type of information for investigating the mechanism of addition to a double bond, is perhaps, the stereochemistry of the reaction.[3] The two carbons of the double bond and the four atoms immediately attached to them are all in a plane (Sec. 1.D); there are thus three possibilities. Both Y and W may enter from the same side of the plane, in which case the addition is stereospecific and syn; they may enter from opposite sides for stereospecific anti addition; or the reaction may be nonstereospecific. In order to determine which of these possibilities is occurring in a given reaction, the following type of experiment is often done: YW is added to the cis and trans isomers of an alkene of the form ABC=CBA. Using the *cis*-alkene as an example, if the addition is syn, the product will be the erythro *dl* pair, because each carbon has a 50% chance of being attacked by Y:

On the other hand, if the addition is anti, the threo *dl* pair will be formed:



Of course, the trans isomer will give the opposite results: the threo pair if the addition is syn and the erythro pair if it is anti. These diastereomers have different physical properties. In the special case, where Y = W (as in the addition of Br_2), the "erythro pair" is a meso

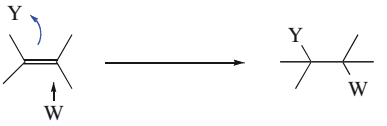
[3] See Fahey, R.C. *Top. Stereochem.* ***1968****, 3,* 237; Bartlett, P.A. *Tetrahedron* ***1980****, 36,* 2, pp. 3–15.



compound. In addition to triple-bond compounds of the type AC≡CA, syn addition results in a *cis*-alkene and anti addition in a *trans*-alkene. By the definition given in Section 4.N, addition to triple bonds cannot be stereospecific, although it can be, and often is, stereoselective.

It is easily seen that in reactions involving cyclic intermediates like **2**, addition must be anti, since the second step is an S_N2 step and must occur from the rear. It is not so easy to predict the stereochemistry for reactions involving **1**. If **1** has a relatively long life, the addition should be nonstereospecific, since there will be free rotation about the single bond. In addition, the carbocation is planar, so there is no facial bias for nucleophilic attack. On the other hand, if there is some factor that maintains the configuration, the group W may come in from the same *or* the opposite side, depending on the circumstances. For example, the positive charge might be stabilized by an attraction for Y that does not involve a full bond (see **3**). In such a case, Y is said to stabilize the positive center via back-donation.

3

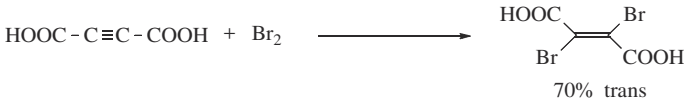


Such stabilization usually leads to anti attack of the second group. This contrasts with a circumstance that would favor syn addition: Formation of an ion pair (**4**) after the addition of Y[4]:

4

Since W is already on the same side of the plane as Y, collapse of the ion pair leads to syn addition.

Another possibility is that anti addition might, at least in some cases, be caused by the operation of a mechanism in which attack by W and Y are essentially *simultaneous*, but from opposite sides:



This mechanism, called the Ad_E3 mechanism (*termolecular addition*, IUPAC A_NA_E),[5] has the disadvantage that three molecules must come together in the transition state. Note that it is the reverse of the E2 mechanism for elimination, for which the transition state is known to possess this geometry (Sec. 17.A.i).

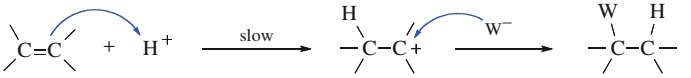
[4] Heasley, G.E.; Bower, T.R.; Dougharty, K.W.; Easdon, J.C.; Heasley, V.L.; Arnold, S.; Carter, T.L.; Yaeger, D.B.; Gipe, B.T.; Shellhamer, D.F. *J. Org. Chem.* ***1980****, 45*, 5150.

[5] See Roberts, R.M.G. *J. Chem. Soc. Perkin Trans. 2,* ***1976***, 1374; Pasto, D.J.; Gadberry, J.F. *J. Am. Chem. Soc.* ***1978****, 100*, 1469; Naab, P.; Staab, H.A. *Chem. Ber.* ***1978****, 111*, 2982.

There is much evidence that when an alkene attacks Br^+ (or a carrier of it), bromonium ion **2** is usually the intermediate and the addition is anti, so the reaction is diastereospecific. Such ions have also been isolated in reactions involving addition of a Br^+ species to a double bond.[6] Treatment of maleic acid with bromine gave the *dl* pair of 2,3-dibromosuccinic acid, for example, while fumaric acid (the trans isomer) gave the meso compound.[7] Many similar experiments have been performed with similar results. Bromination of dicarboxyacetylene gave 70% of the trans isomer.[8]

70% trans

There is other evidence for mechanisms involving **2**. As seen in Section 10.C, bromonium ions have been isolated in stable solutions in nucleophilic substitution reactions involving bromine as a neighboring group. The following is further evidence. If the two bromines approach the double bond from opposite sides, it is very unlikely that they could come from the same bromine molecule. This means that if the reaction is performed in the presence of nucleophiles, some of these will compete in the second step with the bromide liberated from the bromine. It has been found, indeed, that treatment of ethylene with bromine in the presence of chloride ions gives some 1-chloro-2-bromoethane along with the dibromoethane.[9] Similar results are found when the reaction is carried out in the presence of water (Reaction **15-40**) or of other nucleophiles.[10] *Ab initio* MO studies show that **2** is more stable than its open isomer **1** (Y = Br).[11] There is evidence that formation of **2** is reversible.[12]



However, a number of examples have been found where addition of bromine is not stereospecifically anti. For example, the addition of Br_2 to *cis*- and *trans*-1-phenylpropenes in CCl_4 was nonstereospecific.[13] Furthermore, the stereospecificity of bromine addition to stilbene depends on the dielectric constant of the solvent. In solvents of low dielectric constant, the addition was 90–100% anti, but with an increase in dielectric constant, the reaction became less stereospecific, until at a dielectric constant of ~35, the addition was completely nonstereospecific.[14] Likewise in the case of triple bonds, stereoselective anti addition was found in bromination of 3-hexyne, but both cis and trans products were obtained in bromination of phenylacetylene.[15] These results indicate that a bromonium ion

is not formed where the open cation can be stabilized in other ways (e.g., addition of Br^+ to 1-phenylpropene gives the ion $PhC^+HCHBrCH_3$, which is a relatively stable benzylic cation). In addition, there is probably a spectrum of mechanisms between complete bromonium ion (**2**, no rotation) formation and completely open-cation (**1**, free rotation) formation, with partially bridged bromonium ions (**3**, restricted rotation) in between.[16] Previously seen cases (Sec. 10.C.i, category 4) showed that cations require more stabilization from outside sources as they become intrinsically less stable themselves.[17] Further evidence for the open cation mechanism where aryl stabilization is present was reported in an isotope effect study of Br_2 addition to $ArCH{=}CHCHAr'$ ($Ar = p$-nitrophenyl, $Ar' = p$-tolyl). The ^{14}C isotope effect for one of the double-bond carbons (the one closer to the NO_2 group) was considerably larger than for the other one.[18]

When the π bond of an alkene attacks Cl^+,[19] I^+,[20] or RS^+,[21] the result is similar to that when the electrophile is Br^+; there is a spectrum of mechanisms between cyclic intermediates and open cations. As might be expected from the discussion in Section 10.C, iodonium ions compete with open carbocations more effectively than bromonium ions, while chloronium ions compete less effectively. There is kinetic and spectral evidence that at least in some cases (e.g., in the addition of Br_2 or ICl), the electrophile forms a π complex with the alkene before a covalent bond is formed.[22] There is evidence for β-chloro and β-bromocarbenium ions in some reactions.[23]

When the electrophile is a proton,[24] a cyclic intermediate is not possible, and the mechanism is the simple $A_H + A_N$ process shown before

This is an A-S_E2 mechanism (see Reaction **10-6**). There is a great deal of evidence[25] for it, including:

1. The reaction is general acid, not specific acid catalyzed, implying rate-determining proton transfer from the acid to the double bond.[26]

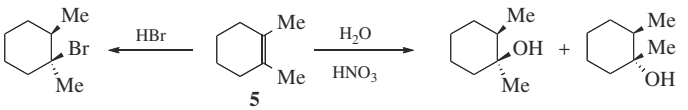
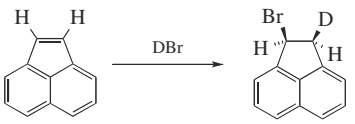
2. The existence of open carbocation intermediates is supported by the contrast in the pattern of alkyl substituent effects[27] with that found in brominations, where cyclic intermediates are involved. In the latter case, substitution of alkyl groups on $H_2C{=}CH_2$ causes a cumulative rate acceleration



until all four hydrogen atoms have been replaced by alkyl groups, because each group helps to stabilize the positive charge.[28] In addition of HX, the effect is not cumulative. Replacement of the two hydrogen atoms on one carbon causes great rate increases (primary → secondary → tertiary carbocation), but additional substitution on the other carbon produces little or no acceleration.[29] This is evidence for open cations when a proton is the electrophile.[30]

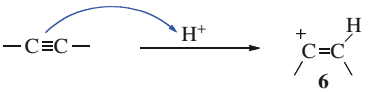


3. Open carbocations are prone to rearrange (Chapter 18). Many rearrangements have been found to accompany additions of HX and H_2O.[31]

It may also be recalled that vinylic ethers react with proton donors in a similar manner (see Reaction **10-6**).

The stereochemistry of HX addition is varied. Examples are known of predominant syn, anti, and nonstereoselective addition. It was found that treatment of 1,2-dimethylcyclohexene (**5**) with HBr gave predominant anti addition,[32] while addition of water to **5** gave equal amounts of the cis and trans alcohols:[33]

On the other hand, addition of DBr to acenaphthylene and to indene and 1-phenylpropene gave predominant syn addition, as shown:[34]



In fact, it has been shown that changing the reaction conditions can control the stereoselectivity of HCl addition. Addition of HCl to **5** in CH_2Cl_2 at −98 °C

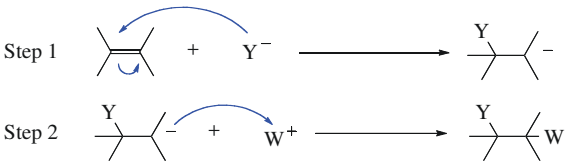
gave predominantly syn addition, while in ethyl ether at 0 °C, the addition was mostly anti.[35]



Addition of HX to triple bonds has the same mechanism, although the intermediate in this case is a vinylic cation (**6**).[36]

In all these cases (except for the Ad_E3 mechanism), it was assumed that formation of the intermediate (**1**, **2**, or **3**) is the slow step and attack by the nucleophile on the intermediate is rapid. This finding is probably true in most cases. However, some additions have been found in which the second step is rate determining.[37]

15.A.ii. Nucleophilic Addition[38]

In the first step of nucleophilic addition, a nucleophile donates a pair of electrons to one carbon atom of the double or triple bond, creating a carbanion, which reacts with a positive species in the second step:

This mechanism is the same as the simple electrophilic one shown in Section 15.A.i except that the charges are reversed (IUPAC $A_N + A_E$ or $A_N + A_H$). When the alkene contains a good leaving group (as defined for nucleophilic substitution), substitution is a side reaction (this is nucleophilic substitution at a vinylic substrate, see Sec. 10.F).

In the special case of addition of HY to a substrate of the form —C=C—Z, where Z = CHO, COR[39] (including quinones[40]), CO_2R, $CONH_2$, CN, NO_2, SOR, 2R,[41] and so on, addition nearly always follows a nucleophilic mechanism,[42] with Y^- bonding with the carbon *away* from the Z group, for example,

After the reaction with HY, the product is a resonance-stabilized enolate anion. Subsequent protonation of the enolate ion is probably at the oxygen to give an enol, which tautomerizes to the ketone (Sec. 2.N.i). Although the net result of the reaction is addition to a carbon–carbon double bond, the *mechanism* is 1,4-nucleophilic addition to the C=C—C=O (or similar) system and is thus very similar to the mechanism of addition to carbon–oxygen double and similar bonds (see Chapter 16). This mechanism is essentially that of the *Michael reaction* discussed in Reaction **15-24**, and such reactions are often called *Michael reactions* or *Michael-type reactions*. When Z is CN or a C=O group, it is also possible for Y^- to attack C of the cyano or carbonyl, which sometimes competes. When it happens, it is called 1,2-addition (see nucleophilic acyl addition in Chapter 16). 1,4-Addition to these substrates is also known as *conjugate addition*. Attack of the Y^- ion at the 3 position is very difficult, since the resulting carbanion would have no resonance stabilization.[43] Systems of the type C=C—C=C—Z can give 1,2-, 1,4-, or 1,6-addition.[44] *Michael-type reaction*s are reversible, and compounds of the type YCH_2CH_2Z can often be decomposed to YH and CH_2=CHZ by heating, either with or without alkali.

If the mechanism for nucleophilic addition is the simple carbanion mechanism outlined above for an alkene, the addition should be nonstereospecific, although it might well be stereoselective (see Sec. 4.N for the distinction). For example, the (*E*) and (*Z*) forms of an alkene ABC=CDE would give **7** and **8**. If the carbanion has

7 **8**

even a short lifetime, **7** and **8** will assume the most favorable conformation before the reaction with W. This is of course the same for both, and reaction with W will give the same product. This will be one of two possible diastereomers, so the reaction will be diastereoselective; but since the cis and trans isomers do not give rise to different isomers, it will not be diastereospecific. Unfortunately, this prediction has not been tested on open-chain alkenes. Except for *Michael-type substrates*, the stereochemistry of nucleophilic addition to double bonds has been studied only in cyclic systems, where only the cis isomer exists. In these cases, the reaction has been shown to be stereoselective, with syn addition reported in some cases[45] and anti addition in others.[46] When the reaction is performed on a *Michael-type substrate* (C=C—Z) the hydrogen does not arrive at the carbon directly, but only

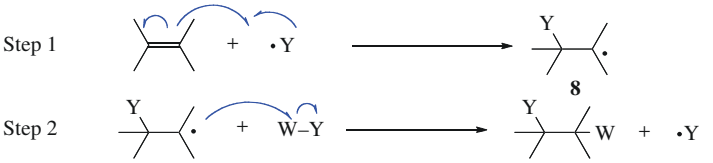
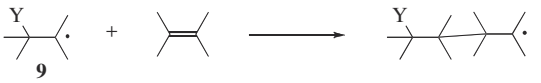
through a tautomeric equilibrium. The product naturally assumes the most thermodynamically stable configuration, without relation to the direction of original attack of Y. In one such case (the addition of EtOD and of Me_3CSD to *trans*-MeCH=CHCOOEt), predominant anti addition was found. There is evidence that the stereoselectivity here results from the final protonation of the enolate, and not from the initial attack.[47] For obvious reasons, additions to triple bonds cannot be stereospecific. As with electrophilic additions, nucleophilic additions to triple bonds are usually stereoselective and anti,[48] although syn addition[49] and nonstereoselective addition[50] have also been reported.

15.A.iii. Free Radical Addition



The mechanism of free radical addition[51] follows the pattern discussed in Section 14.A.i. The method of principal component analysis has been used to analyze polar and enthalpic effects in radical addition reactions.[52] A radical is generated by

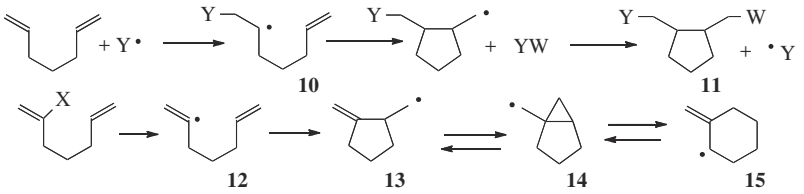
$$Y-W \xrightarrow[\text{dissociation}]{h\nu \text{ or spontaneous}} Y^{\bullet} + W^{\bullet}$$



or

$$R^{\bullet} \quad (\text{from some other source}) + YW \longrightarrow RW + Y^{\bullet}$$

For subsequent reaction with an alkene, propagation occurs by



Step 2 is an abstraction (an atom transfer), so W is nearly always univalent, either hydrogen or halogen (Sec. 14.B.i). Termination of the chain can occur in any of the ways discussed in Section 14.A.i. If **9** adds to another alkene molecule, a dimer is formed. This can add to still another alkene unit, and chains, long or short, may be built up. This is the mechanism of free radical polymerization. Short polymeric molecules (called *telomers*), formed in this manner, are often troublesome side products in free radical addition reactions.

When free radicals are added to 1,5- or 1,6-dienes, the initially formed radical (**10**) can add intramolecularly to the other bond, leading to a cyclic product (**11**).[53] When the radical is generated from a precursor that gives vinyl radical **12**, however, cyclization leads to **13**, which is in equilibrium with cyclopropylcarbinyl radical **14** via a 5-exo-trig reaction.[54] A 6-endo-trig reaction (Sec. 6.E) leads to **15**, but unless there are perturbing substituent effects, cyclopropanation should be the major process. Radicals of type **10**, generated in other ways, also undergo these cyclizations. Both five- and six-membered rings can be formed (Sec. 15.B.i).

The free radical addition mechanism just outlined predicts that the addition should be nonstereospecific, at least if **9** has any, but an extremely short lifetime. However, the reactions may be stereoselective, for reasons similar to those discussed above for nucleophilic addition to alkenes. A few free radical additions are selective. For example, addition of HBr to 1-bromocyclohexene is regioselective in that it gave only *cis*-1,2-dibromocyclohexane and none of the trans isomer (anti addition),[55] and propyne (at −78 to −60 °C) gave only *cis*-1-bromopropene (anti addition), making it stereoselective.[56] Selectivity was observed in radical cyclization reactions of functionalized alkenes, which proceeded via a trans-ring closure.[57] The most important case is probably addition of HBr to 2-bromo-2-butene under free radical conditions at −80 °C. Under these conditions, the cis isomer gave 92% of the meso product, while the trans isomer gave mostly the *dl* pair.[58] This stereospecificity disappeared at room temperature, where both alkenes gave the same mixture of products (∼78% of the *dl* pair and 22% of the meso compound), so the addition was still stereoselective, but no longer stereospecific. The stereospecificity at low temperatures is probably caused by a stabilization of the intermediate radical through the formation of a bridged bromine radical, of the type mentioned in Section 14.A.iv:

This species is similar to the bromonium ion (**2**) that is responsible for stereospecific anti addition in the electrophilic mechanism. Further evidence for the existence of such bridged

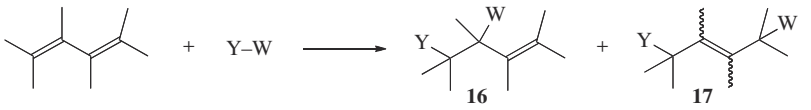
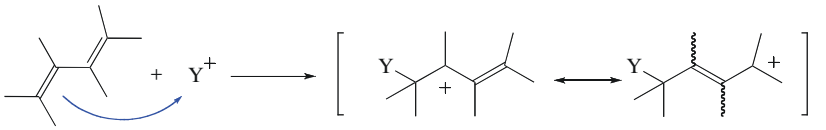
radicals was obtained by addition of $Br^{\bullet}$ to alkenes at 77 K. The ESR spectra of the resulting species were consistent with bridged structures.[59]

For many radicals, step 1 ($C{=}C + Y^{\bullet} \rightarrow {}^{\bullet}C{-}C{-}Y$) is reversible. In such cases free radicals can cause cis → trans isomerization of a double bond by the pathway[60]

15.A.iv. Cyclic Mechanisms



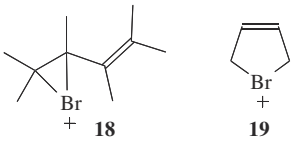
There are some addition reactions where the initial reaction is not at one carbon of the double bond, but both carbons react simultaneously. Some of these are four-center mechanisms, which follow the following pattern:



In others, there is a five- or a six-membered transition state. In these cases the addition to the double or triple bond must be syn. The most important reaction of this type is the *Diels–Alder reaction* (**15-60**).

15.A.v. Addition to Conjugated Systems

When electrophilic addition is carried out on a compound with two double bonds in conjugation, a 1,2-addition product (**16**) is often obtained, but in most cases there is also a 1,4-addition product (**17**), often in larger yield:[61]



If the diene is unsymmetrical, there may be two 1,2-addition products. The competition between two types of addition product comes about because the carbocation resulting from attack on Y^+ is a resonance hybrid, with partial positive charges at the 2 and 4 positions:

W^- may then be attacked by either position. The original reaction with Y^+ is always at the end of the conjugated system because reaction at a middle carbon would give a cation unstabilized by resonance. In the case of electrophiles like Br^+, which can form cyclic intermediates, both 1,2- and 1,4-addition products can be rationalized as stemming from an

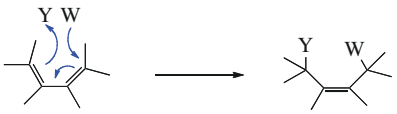
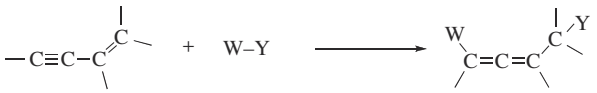
[61] Khristov, V.Kh.; Angelov, Kh.M.; Petrov, A.A. *Russ. Chem. Rev.* ***1991****, 60,* 39.

intermediate like **18**. Direct nucleophilic attack by W^- would give the 1,2-product, while the 1,4-product could be formed by attack at the 4 position, by an S_N2'-type mechanism (see Sec. 10.E). Intermediates like **19** have been postulated, but ruled out for Br and Cl by the observation that chlorination or bromination of butadiene gives trans 1,4-products.[62] If an ion like **19** were the intermediate, the 1,4-products would have to have the cis configuration.



18 **19**



In most cases, more 1,4- than 1,2-addition product is obtained. This may be a consequence of thermodynamic control of products, as against kinetic, and usually temperature dependent. In most cases, under the reaction conditions, **16** is converted to a mixture of **16** and **17** that is richer in **17**. That is, either isomer gives the same mixture of both, which contains more **17**. It was found that at low temperatures, butadiene and HCl gave only 20–25% 1,4-adduct, while at high temperatures, where attainment of equilibrium is more likely, the mixture contained 75% 1,4-product.[63] 1,2-Addition predominated over 1,4- in the reaction between DCl and 1,3-pentadiene, where the intermediate was symmetrical (except for the D label).[64] Ion pairs were invoked to explain this result, since Cl^- would attack a free ion equally well at both positions, except for the very small isotope effect.

Addition to conjugated systems can also be accomplished by any of the other three mechanisms. In each case, there is competition between 1,2- and 1,4-addition. In the case of nucleophilic or free radical attack,[65] the intermediates are resonance hybrids and behave like the intermediate from electrophilic attack. Dienes can similarly give 1,4-addition by a cyclic mechanism:

Other conjugated systems, including trienes, enynes, diynes, and so on, have been studied much less but behave similarly. 1,4-Addition to enynes is an important way of making allenes:

Radical addition to conjugated systems is an important part of chain-propagation reactions. The rate constants for addition of cyclohexyl radical to conjugated amides

have been measured, and shown to be faster than addition to styrene.[66] In additions to $RCH{=}C(CN)_2$ systems, where the R group has a stereogenic center, the *Felkin–Anh model* (Sec. 4.H, category 1) applies and the reaction proceeds with high selectivity.[67] Addition of some radicals [e.g., $(Me_3Si)_3Si^{\bullet}$], is reversible and this can lead to poor selectivity or isomerization.[68]

15.B. ORIENTATION AND REACTIVITY

15.B.i. Reactivity

As with electrophilic aromatic substitution (Chapter 11), electron-donating groups increase the reactivity of a double bond toward electrophilic addition and electron-withdrawing groups decrease it. This is illustrated in Tables 15.1 and 15.2.[69] As a further illustration, the reactivity toward electrophilic addition of a group of alkenes increased in the order $CCl_3CH{=}CH_2 < Cl_2CHCH{=}CH_2 < ClCH_2CH{=}CH_2 < CH_3CH_2{=}CH_2$.[70] For nucleophilic addition, the situation is reversed. These reactions are best carried out on substrates containing three or four electron-withdrawing groups, two of the most common being $F_2C{=}CF_2$[71] and $(NC)_2C{=}C(CN)_2$.[72] The effect of substituents is so great that it is possible to make the statement that *simple alkenes do not react by the nucleophilic mechanism, and polyhalo or polycyano alkenes do not generally react by the electrophilic mechanism.*[73] There are some reagents that attack only as nucleophiles (e.g., ammonia) and these add only to substrates susceptible to nucleophilic attack. Other reagents attack only as electrophiles, and, for example, $F_2C{=}CF_2$ does not react with these. In still other cases, the same reagent reacts with a simple alkene by the electrophilic mechanism and with a polyhalo alkene by a nucleophilic mechanism. For example, Cl_2 and HF are normally electrophilic reagents, but it has been shown that Cl_2 adds to $(N{\equiv}C)_2C{=}CHC{\equiv}N$ with initial attack by Cl^{-}[74] and that HF adds to $F_2C{=}CClF$ with initial attack by F^{-}.[75] Compounds that have a double bond conjugated with a Z group (as defined in Sec. 15.A.ii) nearly always react by a nucleophilic mechanism.[76] These are actually 1,4-additions, also discussed in Section 15.A.ii. A number of studies have been made of the relative activating abilities of various Z groups.[77] On the basis of these studies,

the following order of decreasing activating ability has been suggested: $Z = NO_2$, COAr, CHO, COR, SO_2Ar, CN, CO_2R, SOAr, $CONH_2$, and CONHR.[78]

It seems obvious that electron-withdrawing groups enhance nucleophilic addition and inhibit electrophilic addition because they lower the electron density of the double bond. Addition of electrophilic radicals to electron-rich alkenes has been reported,[79] so the reaction is possible in some cases. This is probably true, and yet similar reasoning does not always apply to a comparison between double and triple bonds.[80] There is a higher concentration of electrons between the carbons of a triple bond than in a double bond, and

Chem.* ***1982***, *47*, 775.

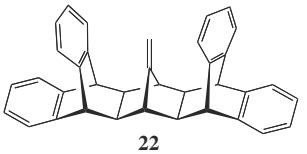
yet triple bonds are *less* subject to attack at an electrophilic site and *more* subject to nucleophilic attack than double bonds.[81] This statement is not universally true, but it does hold in most cases. In compounds containing both double and triple bonds (nonconjugated), bromine, an electrophilic reagent, always adds to the double bond.[82] In fact, all reagents that form bridged intermediates like **2** react faster with double than with triple bonds. On the other hand, addition of electrophilic H^+ (acid-catalyzed hydration, Reaction **15-3**; addition of hydrogen halides, Reaction **15-2**) takes place at about the same rates for alkenes as for corresponding alkynes.[83] Furthermore, the presence of electron-withdrawing groups lowers the alkene/alkyne rate ratio. For example, while styrene ($PhCH{=}CH_2$) was brominated 3000 times faster than PhC≡CH, the addition of a second phenyl group (PhCH=CHPh versus PhC≡CPh) lowered the rate ratio to ∼250.[84] In the case of *trans*-MeOOCCH=CHCOOMe versus MeOOCC≡CCOOMe, the triple-bond compound was actually brominated faster.[85]

As mentioned earlier, it is true that in general triple bonds are more susceptible to nucleophilic and less prone to reaction at an electrophilic site than double bonds, in spite of their higher electron density. One explanation is that the electrons in the triple bond are held more tightly because of the smaller carbon–carbon distance. Thus it is harder to donate an electron pair to an electrophile. There is evidence from far-UV spectra to support this conclusion.[86] Another possible explanation has to do with the availability of the unfilled orbital in the alkyne. It has been shown that a π∗ orbital of bent alkynes (e.g., cyclooctyne) has a lower energy than the π^* orbital of alkenes, and it has been suggested[87] that linear alkynes can achieve a bent structure in their transition states when reacting with an electrophile. Where electrophilic addition involves bridged-ion intermediates, those arising from triple bonds (**20**) are more strained than the corresponding **21**. This may be a reason why electrophilic addition by such electrophiles as Br, I, SR, and so on, is slower for triple than for double bonds.[88] As might be expected, triple bonds connected to a Z group (C≡C—Z) undergo nucleophilic addition especially well.[89]



20 **21**

Although alkyl groups in general increase the rates of electrophilic addition, as mentioned in Section 15.A.i, category 1, there is a different pattern depending on whether the intermediate is a bridged ion or an open carbocation. For brominations and other electrophilic additions in which the first step of the mechanism is rate determining, the rates for substituted alkenes correlate well with the ionization potentials of the alkenes, which means that steric effects are not important.[90] Where the second step is rate

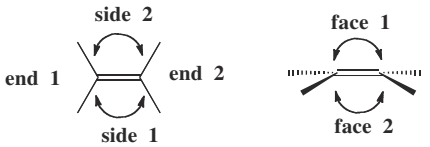
determining [e.g., oxymercuration Reaction (**15-3**), hydroboration Reaction (**15-17**)], steric effects are important.[89]

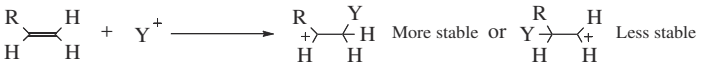
Free radical additions can occur with any type of substrate. The determining factor is the presence of a reactive free radical species. Some reagents (e.g., HBr, RSH) attack by ionic mechanisms if no initiator is present, but in the presence of a free radical initiator, the mechanism changes and the addition is of the free radical type. Nucleophilic radicals (Sec. 14.A.ii) behave like nucleophiles in that the rate is increased by the presence of electron-withdrawing groups in the substrate. The reverse is true for electrophilic radicals.[91] However, nucleophilic radicals react with alkynes more slowly than with the corresponding alkenes,[92] which is contrary to what might have been expected.[93]



22

Steric influences are important in some cases. In catalytic hydrogenation, where the substrate must be adsorbed onto the catalyst surface, the reaction becomes more difficult with increasing substitution. The hydrocarbon (**22**), in which the double bond is entombed between the benzene rings, does not react with Br_2, H_2SO_4, O_3, BH_3, **:**CBr_2, or other reagents that react with most double bonds.[94] A similarly inactive compound is tetra-*tert*-butylallene $(t\text{-Bu})_2C{=}C{=}C(t\text{-Bu})_2$, which is inert to Br_2, Cl_2, O_3, and catalytic hydrogenation.[95]

15.B.ii. Orientation



When an unsymmetrical reagent is added to an unsymmetrical substrate, the question arises: Which side of the reagent goes to which side of the double or triple bond? In other words, what is the *regioselectivity* of the reaction? *Regioselectivity is defined as one direction of bond making or breaking that occurs preferentially over all other possible directions.* The terms side and face are arbitrary, and a simple guide is shown to help understand

the arguments used here. For reaction with an electrophile, the traditional answer is given by *Markovnikov's rule: The positive portion of the reagent goes to the side of the double or triple bond that has more hydrogen atoms*.[96] Mechanistically, regioselectivity is predicted by attack of the π bond on Y^+, forming a bond to the carbon that will give the

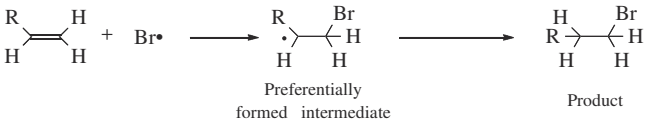
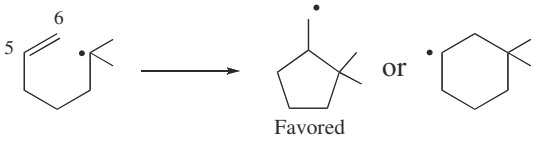
more stable carbocation. For example, secondary carbocations are more stable than primary:

This mechanism is supported by evidence from core electron spectroscopy and by theoretical analysis.[97] The *Hammond postulate* is invoked to say that the lower energy carbocation is preceded by the lower energy transition state. *Markovnikov's rule* also applies for halogen substituents, and the mechanistic rationale is that the halogen stabilizes the carbocation by resonance, so the intermediate with the positive charge on the Cl bearing carbon is more stable.



Markovnikov's rule is also followed where bromonium ions or other three-membered rings are intermediates formed in protic solvents (e.g., methanol).[98] In such a medium, attack by the nucleophile W on the three-membered ring must resemble the S_N1 (see Sec. 10.A.ii) rather than the S_N2 mechanism (and see Sec. 10.G.viii), although the overall stereospecific anti addition in these reactions means that the nucleophilic substitution step is taking place with inversion of configuration. This result suggests a tight ion pair rather than a free carbocation.



Alkenes containing strong electron-withdrawing groups may violate *Markovnikov's rule*, but formation of the more stable carbocation still controls the reaction. For example, attack at the *Markovnikov* position of Me_3N^+—CH=CH_2 would give an ion with positive charges on adjacent atoms. The compound $CF_3CH{=}CH_2$ has been reported to give electrophilic addition with acids in an *anti-Markovnikov* direction, but it has been shown[99] that, when treated with acids, this compound does not give simple electrophilic addition at all; the apparently *anti-Markovnikov* products are formed by other pathways. Molecular electrostatic potentials for the π-region of substituted alkenes were studied, with electron donating and withdrawing substituents (based on the increase or decrease in the negative character of V_{min} - most negative-valued point), and plots of V_{min} shows a good linear correlation with the *Hammett* σ_ρ *constants*, suggesting similar substituent electronic effects for substituted ethylenes and substituted benzenes.[100]

In free radical addition[101] the main effect seems to be steric.[102] All substrates $CH_2{=}CHX$ preferentially react at the CH_2, regardless of the identity of X or of the radical. With a reagent, such as HBr, which generates $Br^\bullet$ *in situ* via hydrogen-atom exchange, this means that the addition is *anti-Markovnikov*:

Thus the observed orientation in both kinds of HBr addition (*Markovnikov* electrophilic and *anti-Markovnikov* free radical) is caused by formation of the more stable secondary intermediate.

In *intramolecular* additions (radical cyclization, see Reaction **15-30**) of radicals containing a 5,6 double bond,[53] both five- and six-membered rings can be formed, but in most cases[103] the five-membered rings are greatly preferred kinetically, even (as in the case shown) where five-membered ring closure means generating a primary radical and six-membered ring closure a secondary radical. This phenomenon may be caused by more favorable entropy factors leading to a five-membered ring, as well as by stereoelectronic factors, but other explanations have also been offered.[104] Similar behavior is found when the double bond is in other positions (from the 3,4 to the 7,8 position). In each case, the smaller ring (exo-trig addition) is preferred to the larger (endo-trig addition)[105] (see *Baldwin rules*, Sec. 6.E). However, when a radical that is unsaturated in the 5,6 position contains an alkyl group in the 5 position, formation of the six-membered ring is generally favored, presumably due to unfavorable steric interactions.[106]

For conjugated dienes, attack at a positive ion, by a negative ion, or reaction with a free radical is almost always at the *end* of the conjugated system, since in each case this gives an intermediate stabilized by resonance. In the case of an unsymmetrical diene, the more stable ion is formed. For example, isoprene ($CH_2{=}CMeCH{=}CH_2$) treated with HCl gives only $Me_2CClCH{=}CH_2$ and $Me_2C{=}CHCH_2Cl$, with none of the product arising from attack at the other end. The compound $PhCH{=}CHCH{=}CH_2$ gives only $PhCH{=}CHCHClCH_3$ since it is the only one of the eight possible products that has a double bond in conjugation with the ring and that results from attack that places the proton at an end of the conjugated system.

When allenes attack electrophilic reagents,[107] *Markovnikov's rule* would predict that formation of the new bond should be at the end of the system, since there are no hydrogen

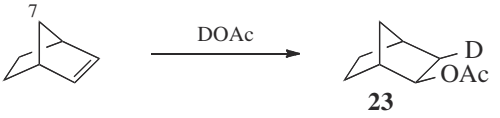
atoms in the middle. Reaction at the center gives a carbocation stabilized by resonance, but not immediately. In order for such stabilization to be in effect, the three *p* orbitals must be parallel, and it requires a rotation about the C—C bond.[108] Therefore, the stability of the allylic cation has no effect on the transition state, which still has a geometry similar to that of the original allene (Sec. 4.C, category 5). Probably because of this, reaction of the unsubstituted $CH_2{=}C{=}CH_2$ is most often at the end carbon, to give a vinylic cation, although reaction at the center carbon has also been reported. However, as alkyl or aryl groups are substituted on the allene carbons, reaction at the middle carbon becomes more favorable because the resulting cation is stabilized by the alkyl or aryl groups (it is now a secondary, tertiary, or benzylic cation). For example, allenes of the form $RCH{=}C{=}CH_2$ react most often at the end, but $RCH{=}C{=}CHR'$ usually gives reaction at the center carbon.[109] Free radicals[110] react with allenes most often at the end,[111] although reaction at the middle carbon has also been reported.[112] As with reactions that proceed via electrophilic intermediates and for the same reason, the stability of the allylic radical has no effect on the transition state of the reaction between a free radical and an allene. Again, the presence of alkyl groups increases the extent of reaction by a radical at the middle carbon.[113]

15.B.iii. Stereochemical Orientation

It has already been pointed out that some additions are syn, with both groups approaching from the same side, and that others are anti, with the groups approaching from opposite sides of the double or triple bond. For cyclic compounds steric orientation must be considered. In syn addition to an unsymmetrical cyclic alkene, the two groups can come in from the more- or from the less-hindered face of the double bond. The rule is that syn addition is usually, although not always, from the less-hindered face. For example, epoxidation of 4-methylcyclopentene gave 76% addition from the less-hindered and 24% from the more-hindered face.[114]



(76%) (24%)

In anti addition to a cyclic substrate, the initial reaction with the electrophile is also from the less-hindered face. However, many (although not all) electrophilic additions to norbornene and similar strained bicycloalkenes are syn additions.[115] In these cases reaction

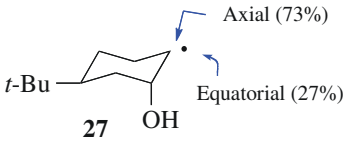
is always from the exo side, as in formation of **23**,[116] unless the exo

23

side is blocked by substituents in the 7 position, in which case endo attack may predominate [e.g., 7,7-dimethylnorbornene undergoes syn–endo epoxidation (Reaction **15-50**) and hydroboration[117] (Reaction **15-16**)]. However, addition of DCl and F_3CCO_2D to, and oxymercuration (Reaction **15-2**) of, 7,7-dimethylnorbornene proceeds syn–exo in spite of the methyl groups in the 7 position.[118] Similarly, free radical additions to norbornene and similar molecules are often syn–exo, although anti additions and endo attacks are also known.[119]



24 **25** **26**

Electronic effects can also play a part in determining which face reacts preferentially with the electrophilic species. In the adamantane derivative (**24**), steric effects are about the same for each face of the double bond. Yet epoxidation, dibromocarbene reactions (**15-64**), and hydroboration (**15-16**) all take place predominantly from the face that is syn to the electron-withdrawing fluorine.[120] In the case shown, about twice as much **25** was formed, compared to **26**. Similar results have been obtained on other substrates:[121] groups that are electron withdrawing by the field effect ($-I$) direct attack from the syn face; $+I$ groups from the anti face, for both electrophilic and nucleophilic attack. These results are attributed[122] to hyperconjugation (Sec. 2.M): For the adamantane case, there is overlap between the σ^* orbital of the newly forming bond (between the attacking species and C-2 in **24**) and the filled σ orbitals of the C_α—C_β bonds on the opposite side. This is called the *Cieplak effect*. The $LiAlH_4$ reduction of 2-axial methyl or methoxy cyclohexanones supports Cieplak's proposal.[123] In addition reactions of methanol to norbornanones, however, little evidence was found to support the Cieplak effect.[124] The four possible bonds are C-3–C-4 and C-1–C-9 on the syn side and C-3–C-10 and C-1–C-8 on the anti side. The preferred pathway is the one where the incoming group has the more electron-rich bonds on the side *opposite* to it (these are the ones it overlaps with). Since the electron-withdrawing F has its greatest effect on the bonds closest to it, the C-1–C-8 and C-3–C-10 bonds are more electron rich, and the group comes in on the face syn to the F.

It has been mentioned that additions of Br_2 and HOBr are often anti because of formation of bromonium ions and that free radical addition of HBr is also anti. When the substrate in any of these additions is a cyclohexene, the addition is not only anti but the initially formed product is conformationally specific too, being mostly diaxial.[125] This is so because diaxial opening of the three-membered ring preserves a maximum coplanarity of the participating centers in the transition state; indeed, on opening, epoxides also give diaxial products.[126] However, the initial diaxial product may then pass over to the diequatorial conformer unless other groups on the ring render the latter less stable than the former. In free radical additions to cyclohexenes in which cyclic intermediates are not involved, the initial reaction with the radical is also usually from the axial direction,[127] resulting in a diaxial initial product if the overall addition is anti. The direction from which unsymmetrical radicals react has also been studied.[128] For example, when the radical (**27**) adds to a double bond it preferentially does so anti to the OH group, leading to a diaxial trans product.[126]

27

15.B.iv. Addition to Cyclopropane Rings[129]

Section 4.Q.iv showed that cyclopropane rings resemble double bonds in some aspects of their reactivity.[130] It is not surprising, therefore, that cyclopropanes undergo addition reactions analogous to those undergone by double-bond compounds, resulting in the opening of the three-membered rings, as in the two examples shown, where Reactions **15-2** and **15-47** describe the reaction to alkene chemistry.

Reaction **15-2**

Ref. 131

Reaction **15-47**

Other examples are discussed at Reaction **15-3**, **15-15**, and **15-63**.

Additions to cyclopropanes can take place by any of the four mechanisms already discussed in this chapter, but the most important type involves attack on an electrophile.[132]

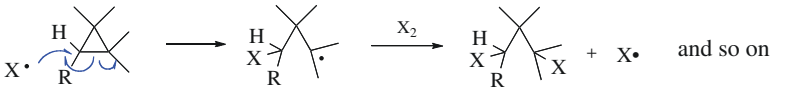
For substituted cyclopropanes, these reactions usually follow *Markovnikov's rule*, although exceptions are known and the degree of regioselectivity is often small. The application of *Markovnikov's rule* to these substrates can be illustrated by the reaction of 1,1,2-trimethylcyclopropane with HX.[133] The rule predicts that the electrophile (in this case H^+) goes to the

carbon with the most hydrogen atoms and the nucleophile goes to the carbon that can best stabilize a positive charge (in this case the tertiary rather than the secondary carbon). The stereochemistry of the reaction can be investigated at two positions: the one that becomes connected to the electrophile and the one that becomes connected to the nucleophile. The results at the former position are mixed. Additions have been found to take place with 100% retention,[134] 100% inversion,[135] and with mixtures of retention and inversion.[136] At the carbon that becomes connected to the nucleophile, the result is usually inversion, although retention has also been found,[137] and elimination, rearrangement, and racemization processes often compete, indicating that in many cases a positively charged carbon is generated at this position.

At least three mechanisms have been proposed for electrophilic addition (these mechanisms are shown for reaction with HX, but analogous mechanisms can be written for other electrophiles).



Mechanism *a* involves a corner-protonated cyclopropane[138] (**28**). Examples of such ions were seen in the 2-norbornyl and 7-norbornenyl cations (Sec. 10.C.i). Mechanism *b* involves an edge-protonated cyclopropane (**29**). Mechanism *c* consists of a one-step S_E2 type attack on H^+ to give the classical cation **30**, which then reacts with the nucleophile. Although the three mechanisms as drawn show retention of configuration at the carbon that

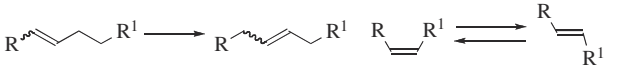
becomes attached to the proton, mechanisms *a* and *c* at least can also result in inversion at this carbon. Unfortunately, the evidence on hand at present does not allow us unequivocally to select any of these as the exclusive mechanism in all cases. Matters are complicated by the possibility that more than one edge-protonated cyclopropane is involved, at least in some cases. There is strong evidence for mechanism *b* with the electrophiles Br^+ and Cl^+[139]; and for mechanism *a* with D^+ and Hg^{2+}.[140] *Ab initio* studies show that the corner-protonated **28** is slightly more stable ($\sim$1.4 kcal mol^{-1}, 6 kJ mol^{-1}) than the edge-protonated **29**.[141] There is some evidence against mechanism *c*.[142]

Free radical additions to cyclopropanes have been studied much less, but it is known that Br_2 and Cl_2 add to cyclopropanes by a free radical mechanism in the presence of UV light. The addition follows *Markovnikov's rule*, with the initial radical reacting at the least-substituted carbon and the second group going to the most-substituted position. Several investigations have shown that the reaction is stereospecific at one carbon, taking place with inversion there, but nonstereospecific at the other carbon.[143] A mechanism that accounts for this behavior is[144]



In some cases, conjugate addition has been performed on systems where a double bond is "conjugated" with a cyclopropyl ring. An example is the formation of **31**.[145]

15.C. REACTIONS

15.C.i. Isomerization of Double and Triple Bonds

15-1 Isomerization

Without a transition metal catalyst, there is usually a rather high-energy barrier for the excited state required for (*E*/*Z*) isomerization.[146] The transition metal catalyzed

isomerization of an alkene from (*E*) to (*Z*) or (*Z*) to (*E*) is a well-studied reaction.[147] Among the metals used, Pt is widely used, and rather selective.[148] The Pd catalyzed isomerization of (*Z*)-alkenes to (*E*)-alkenes required the presence of Bu_3SnH.[149] However, a 1:1 mixture of *cis*/*trans*-styrene derivatives was isomerized to a 90% yield of the *trans*-styrene derivatives reported using a Pd catalyst.[150] Isomerization of cyclic alkenes is difficult for rings of seven members and less, but cis/trans isomerization of cyclooctene is induced photochemically.[151] Radical-induced (*E*/*Z*) isomerization is known.[152] Isomerization of the C=C units in dienes is also induced photochemically.[153]

In a different type of reaction, isomerization of alkynes to 1,3-dienes is possible using Rh or Pd catalysts.[154]

There are several reagents that lead to isomerization of a double bond to form a new alkene. In general, there is an energetic preference of an α,β- versus β,γ-double bond.[155] Allylic arenes ($Ar—CH_2CH=CH_2$) have been converted to the corresponding (*Z*)-1-propenyl arene (Ar—CH=CHMe using an Ru catalyst[156] or a polymer-supported Ir catalyst.[157] In the presence of a Rh catalyst, certain allylic amines are converted to an enamine with high selectivity for the (*Z*) isomer.[158] Double-bond migration has been observed in sulfide photoirradiation, induced by singlet oxygen.[159] Many of these reactions were discussed in Reaction **12-2**.

For conjugated carbonyl compounds that have a hydrogen atom at the γ-position (C-4), it is possible to move a double bond *out* of conjugation. Photolysis of conjugated esters, at −40 °C in the presence of *N,N*- dimethylaminoethanol, gave the nonconjugated ester.[160] Heating an *N*-allylic amide (N—C—C=C) with $Fe(CO)_5$, neat, gave the enamide (N—C=C—C).[161] Conjugated aldehydes have been isomerized using thiourea in DMF.[162]

Double bonds of atoms other than carbon are subject to isomerization. Azobenzenes (Ar—N=N—Ar) exist as (*E*) and (*Z*) isomers, and photochemical isomerization is possible.[163]

15.C.ii. Reactions in Which Hydrogen Adds to One Side

A. Halogen on the Other Side

15-2 Addition of Hydrogen Halides

Hydro-halo-addition

Any of the four hydrogen halides can be added to double bonds.[164] Alkenes react as Brønsted–Lowry bases with HI, HBr, and HF[165] at room temperature, but reaction with HCl is more difficult and usually requires heat.[24] Hydrogen Chloride adds easily in the presence of silica gel. However,[166] HF is difficult to handle, but a convenient method for the addition of HF involves the use of a polyhydrogen fluoride–pyridine solution in THF.[167]

The addition of hydrogen halides to simple alkenes, in the absence of peroxides, takes place by an electrophilic mechanism, and the orientation is in accord with *Markovnikov's rule*.[168] In other words, the π bond of the alkenes donates two electrons to the acidic proton of H—X. The addition follows second-order kinetics.[169] When peroxides are added, the addition of HBr occurs by a free-radical mechanism and the orientation is *anti-Markovnikov* (Sec. 15.B.i).[170] It must be emphasized that this is true *only* for HBr. Free radical addition of HF and HI has never been observed, even in the presence of peroxides; free radical addition of HCl has been observed only rarely. In the rare cases where free radical addition of HCl was noted, the orientation was still *Markovnikov*, presumably because the more stable product was formed.[171] Free radical addition of HF, HI, and HCl is energetically unfavorable (see the discussions in Sec. 14.B.i and 14.C.i). It is known that under some conditions *anti-Markovnikov addition* of HBr takes place even when peroxides have not been added. This happens because the substrate alkenes absorb oxygen from the air, forming small amounts of peroxides (Reaction **14-7**). *Markovnikov addition* can be ensured by rigorous purification of the substrate, but in practice this is not easy to achieve. It is more common to add inhibitors (e.g., phenols or quinones), which suppress the free radical pathway. The presence of free radical precursors (e.g., peroxides) does not inhibit the ionic mechanism, but does inhibit the more rapid radical reaction, which is a chain process. In most cases, it is possible to control the mechanism (and hence the orientation) by adding peroxides to achieve complete free radical addition, or inhibitors to achieve complete electrophilic addition, although there are some cases where the ionic mechanism is fast enough to compete with the free radical

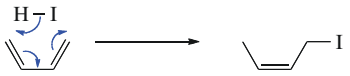
mechanism and complete control cannot be attained. *Markovnikov addition* of HBr, HCl, and HI has also been accomplished, in high yields, by the use of phase transfer catalysis.[172] For alternative methods of adding HBr (or HI) with *anti-Markovnikov orientation*, see Reaction **12-31**.



Alkynes also react as bases with acids (e.g., HX). It is possible to add 1[173] or 2 equiv of any of the four hydrogen halides to triple bonds. *Markovnikov's rule* ensures that *gem*-dihalides and not *vic*-dihalides are the products of the addition of 2 equiv.

$$—C{\equiv}C— \xrightarrow{HX} —CH{=}CX— \xrightarrow{HX} —CH_2—CX_2—$$

Chlorotrimethylsilane can be added to alkenes to give alkyl chlorides. 1-Hexene reacts with Me_3SiCl in water, for example, to give 2-chlorohexane.[174] Treatment of an alkene with KHF_2 and SiF_4 leads to the alkyl fluoride,[175] and bromotrimethylsilane adds to alkynes to give the vinyl bromide.[176]

Brønsted–Lowry acids (e.g., HX) are electrophilic reagents, and many polyhalo or polycyano alkenes do not react with them in the absence of free radical conditions. Vinylcyclopropanes, however, react with opening of the cyclopropane ring to give a homoallylic chloride.[177] When such reactions do occur, however, they take place by a nucleophilic addition mechanism, that is, initial attack is by X^-. This type of mechanism also occurs with *Michael-type substrates* (C=C—Z),[178] where the orientation is always such that the halogen goes to the carbon that does not bear the Z, so the product is of the form X—C—CH—Z, even in the presence of free radical initiators.

The reaction has been carried out with conjugated dienes, where both 1,2- and 1,4-addition are possible. Hydrogen iodide adds 1,4 to conjugated dienes in the gas phase by a pericyclic mechanism:[179]

In a related reaction, HX can be added to ketenes[180] to give acyl halides:

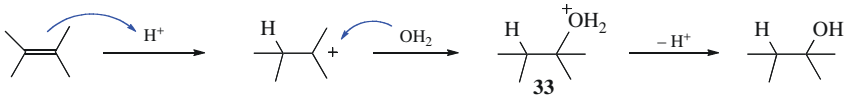
B. Oxygen on the Other Side

15-3 Hydration of Double bonds

Hydro-hydroxy-addition



Double bonds can be hydrated by treatment with water and an acid catalyst. Sulfuric acid is a common catalyst, but other acids that have relatively non-nucleophilic counterions, such as nitric, perchloric, or more commonly sulfonic acids (*p*-toluenesulfonic acid, methanesulfonic acid, etc.) can also be used. The mechanism is electrophilic and begins with attack of the π bond on an acidic proton (Sec. 15.A.i). The resulting carbocation is then attacked by negative species (e.g., HSO_4^-, or a similar counterion in the case of other acids), to give the initial product (**32**), which can be isolated in some cases. However, such compounds are rather unstable, and

32

under the conditions of the reaction are usually hydrolyzed to the alcohol (Reaction **10-4**). Under some reaction conditions, other nucleophiles are present in the reaction, either from the solvent or from added compounds. In an aqueous medium, water is a competitive nucleophile, and attack by water forms oxonium ion **33**. Products, such as **32**, are not involved when other nucleophiles react with the carbocation, and the mechanism is exactly (by the principle of microscopic reversibility) the reverse of El elimination of alcohols (Reaction **17-1**).[181] *The initial carbocation occasionally rearranges to a more stable one.* For example, hydration of $CH_2{=}CHCH(CH_3)_2$ gives $CH_3CH_2COH(CH_3)_2$. Hydration of simple alkenes leads to alcohols predicted by *Markovnikov's rule*.

33

Oxymercuration[182] (addition of oxygen and mercury) of alkenes followed by *in situ* treatment with sodium borohydride[183] (Reaction **12-24**), gives an alcohol (see example) under mild conditions, in high yields, and without rearrangement products. For example, treatment of 2-methyl-1-butene with mercuric acetate,[184] followed by $NaBH_4$, gave 2-methyl-2-butanol. Oxymercuration of alkenes has been reported in water, using cyclodextrins as phase-transfer catalysts.[185]

[185] Abreu, A.R.; Costa, I.; Rosa, C.; Ferreira, L.M.; Lourenço, A.; Santos, P.P. Te*trahedron* ***2005****, 61,* 11986.

This method, which is applicable to mono-, di-, tri-, and tetraalkyl, as well as phenyl-substituted alkenes, gives almost complete *Markovnikov addition*. Hydroxy, methoxy, acetoxy, halo, and other groups may be present in the substrate, and generally do not cause difficulties.[186] When two double bonds are present in the same molecule, changing the carboxylic acid ligand of the mercuric salt allows oxymercuration of the less-substituted one without affecting the other, with ultrasound.[187] A related reaction treats an alkene with zinc borohydride on silica gel to give a 35:65 mixture of secondary/primary alcohols.[188]

With substrates of the type C=C—Z (Z is as defined in Sec.15.A.ii) the product is almost always HO—C—CH—Z and the mechanism is usually nucleophilic,[189] although electrophilic addition gives the same product[190] since a cation CH—C—Z would be destabilized by the positive charges (full or partial) on two adjacent atoms. However, the α-hydroxy compound HC—CH(OH)Z, was obtained by treatment of the substrate with O_2, $PhSiH_3$, and a manganese-complex catalyst.[191] Addition of water to RCH=CZZ′ substrates may result in cleavage of the adduct to give an aldehyde and CH_2ZZ' (**34**).[192] The cleavage step is an example of Reaction **12-41**.

For another method of *anti-Markovnikov* hydration, see hydroboration (Reaction **15-16**).

Indirect hydration, with *anti-Markovnikov* orientation, was achieved by treatment of the alkene with a 1:1 mixture of $PhCH_2NEt_3^+$ BH_4^- and Me_3SiCl, followed by addition of an aqueous solution of K_2CO_3.[193] Reaction of alkenes with $Ti(BH_4)_3$, and then aq K_2CO_3 also leads to the *anti-Markovnikov* alcohol.[194] Alkenes react with PhO_2BH and a Nb catalyst, followed by oxidation with $NaOO^-$, to give the alcohol,[195] and Cp_2TiCl_4 can also be used.[196] Conjugated alkenes also react with $PhSiH_2$ and oxygen, with a Mn catalyst, to give an α-hydroxy ketone.[197] Alkenes react with molecular oxygen in the presence of a Co porphyrin catalyst, and reduction with $P(OMe)_3$ leads to the secondary alcohol.[198] This procedure has also been used to hydrate conjugated dienes,[199] although conjugated dienes are seldom hydrated.

The addition of water to enol ethers causes hydrolysis to aldehydes or ketones (Reaction **10-6**). Ketenes add water to give carboxylic acids ($R_2C{=}C{=}O \rightarrow R_2CO_2H$) in a reaction catalyzed by acids[200]:

OS **IV**, 555, 560; **VI**, 766. Also see, OS **V**, 818.

15-4 Hydration of Triple Bonds

Dihydro-oxo-biaddition

The hydration of triple bonds is generally carried out with mercuric ion salts (often the sulfate or acetate or even mercuric oxide) as catalysts.[201] In contrast to oxymercuration of alkenes, the organomercury intermediate from this reaction is unstable and loss of mercury *in situ* leads to an enol product. The enol tautomerizes to the ketone (see Sec. 2.N.i), so the isolated product is the ketone from either an internal or terminal alkyne (the OH unit will always be on the more substituted carbon via the more stable secondary vinyl carbocation). Only acetylene gives an aldehyde. With alkynes of the form $RC{\equiv}CR'$ both possible ketone products are usually obtained. The reaction can be conveniently carried out with a catalyst prepared by impregnating mercuric oxide onto Nafion-H (a superacidic perfluorinated resinsulfonic acid; see Sec. 5.A.ii).[202] Gold,[203] In,[204] and Ru[205] catalysts have been used to convert alkynes to the ketone. Gold(I) catalysts have also been used in the hydration of allenes.[206] Internal alkynes were treated with 2-aminophenol in refluxing dioxane using a Pd catalyst to produce the corresponding ketone.[207] Lactones have been prepared from trimethylsilyl alkenes containing a hydroxyl unit elsewhere in the molecule, when reacted with molecular oxygen, $CuCl_2$, and a Pd catalyst.[208] When a carboxylic acid that contains a double bond in the chain is treated with a strong acid, the intramolecular hydration reaction gives a γ- and/or a δ-lactone, regardless of the original position of the double bond in the chain, since strong acids catalyze double-bond shifts (Reaction **15-1**; and see **12-2**).[209] The double bond always migrates to a position favorable for the reaction, whether this has to be toward or away from the carboxyl group. The use of a chiral *Cinchonidine*

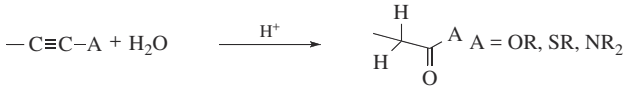
alkaloid additive leads to lactone formation with modest enantioselectivity.[210]



The first step of the mercury-mediated mechanism is formation of a complex (**35**). It is known that ions like Hg^{2+} form complexes with alkynes (Sec. 3.C.i). Water then attacks in an S_N2 type process to give the intermediate **36**, which loses a proton to give **37**. Hydrolysis of **37** (an example of Reaction **12-34**) gives the enol, which tautomerizes to the product. A spectrum of the enol was detected by flash photolysis when phenylacetylene was hydrated photolytically.[211] Note that another possibility for **35** is a mercury-stabilized carbocation rather than a formal three-membered ring complex. In such a carbocation, the carbocation is stabilized by back-donation from the metal, and nucleophilic attack is more like a S_N1 type process.

Metal-free reactions are known, often using strong acids. Phenyl acetylene was converted to acetophenone [e.g., in water at 100 °C with a catalytic amount of Tf_2NH (trifluoromethanesulfonimide)], which is a very powerful acid.[212] Simple alkynes can also be converted to ketones by heating with formic acid, without a catalyst.[213] Metal-free hydration of terminal alkynes occurs by reacting water, heated with microwave irradiation, to give the corresponding methyl ketone.[214] 1-Selenoalkynes (e.g., PhSe-C≡C-Ph) react with tosic acid in dichloromethane to give a seleno ester [PhSeC(=O)SH_2Ph] after treatment with water.[215] Allenes can be hydrolyzed to ketones using an acid catalyst.[216]

Carboxylic esters, thiol esters, and amides can be made, respectively, by acid-catalyzed hydration of acetylenic ethers, thioethers,[217] and ynamines, without a mercuric catalyst.[218]

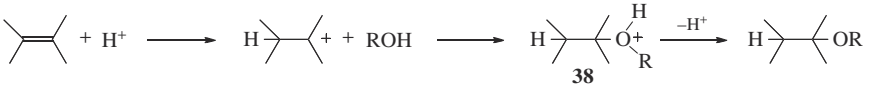
This is ordinary electrophilic addition, with rate-determining protonation as the first step.[219] Certain other alkynes have also been hydrated to ketones with strong acids in the absence of mercuric salts.[220]

Catalysts have been developed for the *anti-Markovnikov* hydration of alkynes.[221] When 1-octyne was heated with water, isopropyl alcohol and a Ru catalyst, for example, the product was octanal.[222] The presence of certain functionality can influence the regioselectivity of hydration.

A Ni catalyzed reaction has been reported between alkynes and allyl phenyl sulfides to give thioallylation.[223]



OS **III**, 22; **IV**, 13; **V**, 1024.

15-5 Addition of Alcohols and Phenols

Hydro-alkoxy-addition

Just as water adds to an alkene via hydration to form an alcohol, alcohols can also add to form an ether. Addition of alcohols and phenols to double bonds is catalyzed by acids or bases. When the reactions are acid catalyzed, the mechanism is electrophilic, where H^+ of the acid catalyst, is attacked by the π bond. The more stable carbocation is formed and subsequently attacked by a molecule of alcohol to give an oxonium ion (**38**).

38

The addition, therefore, follows *Markovnikov's rule*. Primary alcohols give better results than secondary, and tertiary alcohols are relatively inactive. This method is convenient for the preparation of tertiary ethers by the use of a suitable alkene (e.g., $Me_2C{=}CH_2$). Addition of alcohols to allylic systems can proceed with rearrangement, and the use of chiral additive can lead to asymmetric induction.[224] The uncatalyzed addition of alcohols occurs in supercritical alcohols.[225]

Metal-catalyzed addition to alkenes is a useful variation. The Pd catalyzed addition of alcohols to aryl alkenes gives the ether.[226] The Au(III)—$CuCl_2$ catalyzed reaction of alcohols and alkenes gives the ether.[227] Gold(I) catalyzed intermolecular addition of phenols leads to aryl ethers.[228]

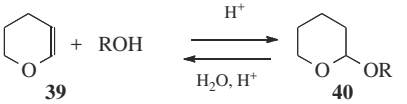
Alcohols add intramolecularly to alkenes to generate cyclic ethers, and the product often bears a hydroxyl unit,[229] but not always.[230] Cyclization is facilitated by Re,[231] Ti,[232] or Pt compounds,[233] forming functionalized tetrahydrofurans or tetrahydropyans. Intramolecular addition of alcohols to alkenes can be promoted by a Pd catalyst, but migration of the double bond in the final product is sometimes a problem.[234] Furan derivatives are available from alkene–ketones using $CuCl_2$ and a Pd[235] Cr,[236] Ag(I),[237] or lanthanide catalyst.[238] A gold catalyst was used with conjugated ketones bearing an alkyne substituent to give fused-ring furans.[239] Note that the reaction of an alkene–alcohol and NIS with a chiral Ti catalyst leads to a THF with a pendant iodoalkyl group, with modest enantioselectivity.[240]

Alcohols add to alkynes under certain conditions to give vinyl ethers. In an excess of alcohol, and in the presence of a Pt[241] or a Au catalyst,[242] internal alkynes are converted to ketals. The alcohol to alkyne addition reaction is quite useful for the preparation of heterocycles. Dihydrofurans,[243] furans,[244] benzofurans,[245] and pyran derivatives[246] have been prepared using this approach. Tetrahydrofurans bearing an exocyclic double bond (vinylidene tetrahydrofurans) were prepared from alkynyl alcohols and a silver carbonate catalyst.[247]



Allenes that react with alcohols and allenic alcohols have been converted to THF derivatives bearing a vinyl group at the α-position, using diphenyliodonium salts.[248] In the presence of allylic bromide and a Pd catalyst, allenic alcohols lead to allylically substituted dihydrofurans.[249] The intramolecular Au(I) catalyzed reaction of alcohols and allenes has been reported.[250] Intramolecular addition of alcohols to allenes leads to cyclic vinyl ethers.[251]

Functionalized ethers can be formed in the presence of other reagents. In methanol with a R—Se—Br reagent, alkenes are converted to selenoalkyl ethers (MeO—C—C—SeR).[252]

Base-catalyzed reactions are known. For those substrates more susceptible to nucleophilic attack, for example, polyhalo alkenes and alkenes of the type C=C—Z, it is better to carry out the reaction in basic solution, where the attacking species is RO^-.[253] The reactions with C=C—Z are of the *Michael type*, and OR goes to the side away from the Z.[254]

Since triple bonds are more susceptible to nucleophilic attack than double bonds, it might be expected that bases would catalyze addition to triple bonds particularly well. This is the case, and enol ethers and acetals can be produced by this reaction.[255] Because enol ethers are more susceptible than triple bonds to electrophilic attack, the addition of alcohols to enol ethers can also be catalyzed by acids.[256] One utilization of this reaction

39 **40**

involves the compound dihydropyran (**39**), which is often used to protect the OH groups of primary and secondary alcohols[257] and phenols.[258] When the desired reactions are completed, **40** is easily cleaved by treatment with dilute acids (Reaction **10-6**). In base-catalyzed addition to triple bonds, the rate falls in going from a primary to a tertiary alcohol, and phenols require more severe conditions.

Photochemical addition of alcohols to certain double-bond compounds (cyclohexenes, cycloheptenes) is possible[259] in the presence of a photosensitizer (e.g., benzene). The mechanism is electrophilic and *Markovnikov* orientation is found. The alkenes react in their first excited triplet states.[260]

The oxymercuration–demercuration procedure mentioned in Reaction **15-3** can be adapted to the preparation of ethers in what is known as *alkoxymercuration–demercuration* (*Markovnikov* orientation), if the reaction is carried out in an alcohol (ROH) solvent.[261] For example, oxymercuration of 2-methyl-1-butene in ethanol gives $EtMe_2COEt$.[262] Primary alcohols give good yields when mercuric acetate is used, but for secondary and tertiary alcohols, it is necessary to use mercuric trifluoroacetate.[263] However, even this reagent fails where the product would be a ditertiary ether. It is possible to combine the alcohol reactant with another reagent. The reaction of an alkene with iodine and allyl alcohol, in the presence of HgO, gave the *vic*-iodo ether.[264] Alkene-alcohols react with mercuric trifluoroacetate and the aq KBr (with $LiBH_4/BEt_3$) to

give a THF derivative bearing an iodoalkyl substituent [—O—C—CH(I)R].[265] Alkynes generally react under the same conditions to give acetals. If the oxymercuration is carried out in the presence of a hydroperoxide instead of an alcohol, the product (after demercuration with $NaBH_4$) is an alkyl peroxide (*peroxy-mercuration*).[266] This can be done intramolecularly.[267]

Both alcohols and phenols add to ketenes to give carboxylic esters [$R_2C{=}C{=}O + ROH \rightarrow R_2CHCO_2R$].[268] This has been done intramolecularly (with the ketene end of the molecule generated and used *in situ*) to form medium- and large-ring lactones.[269] In the presence of a strong acid, ketene reacts with aldehydes or ketones (in their enol forms) to give enol acetates. 1,4-Asymmetric induction is possible when chiral alcohols add to ketenes.[270]

15-6 Addition of Carboxylic Acids to Form Esters

Hydro-acyloxy-addition

Carboxylic esters are produced by the addition of carboxylic acids to alkenes, a reaction that is usually acid catalyzed (by Brønsted–Lowry or Lewis acids[271]) and similar in mechanism to Reaction **15-5**. Since *Markovnikov's rule* is followed, hard-to-get esters of tertiary alcohols can be prepared from alkenes of the form $R_2C{=}CHR$.[272] Carboxylic esters have also been prepared by the acyloxymercuration–demercuration of alkenes (similar to the procedures mentioned in Reactions **15-3** and **15-4**).[273] Addition of carboxylic acids to alkenes to form esters or lactones is catalyzed by Pd compounds.[274] Thallium acetate also promotes this cyclization reaction.[275] Diene carboxylic acids have been cyclized using acetic acid and a Pd catalyst to form lactones that have an allylic acetate moiety elsewhere in the molecule.[276]

Triple bonds can give enol esters[277] or acylals when treated with carboxylic acids. Mercuric salts are usually catalysts,[278] and vinylmercury compounds ($RO_2C—C=C—HgX$) are intermediates,[279] but Ru complexes have also been used.[280] Terminal alkynes ($RC\equiv CH$) react with CO_2, a secondary amine (R'_2NH), and a Ru complex catalyst, to give enol carbamates [$RCH=CHOC(=O)NR$].[281] This reaction has also been performed intramolecularly, to produce unsaturated lactones.[282] Cyclic unsaturated lactones (internal vinyl esters) have been generated from alkyne-carboxylic acids using a Pd[283] or a Ru catalyst.[284] Carboxylic esters can also be obtained by the addition to alkenes of diacyl peroxides.[285] These reactions are catalyzed by Cu and are free radical processes.

Allene carboxylic acids have been cyclized to butenolides with copper(II) chloride.[286] Allene esters were converted to butenolides by treatment with acetic acid and LiBr.[287] Cyclic carbonates can be prepared from allene alcohols using carbon dioxide and a Pd catalyst.[288] Carboxylic acids react with ketenes to give anhydrides[289] and acetic anhydride is prepared industrially in this manner [$CH_2=C=O + MeCO_2H \rightarrow (MeC=O)_2O$].

Sulfonic acids add to alkenes and alkynes. The reaction of an alkyne with *p*-toluenesulfonic acid and treatment with silica gives the vinyl sulfonate ($C=C—OSO_2Tol$).[290] Cyclic sulfonates can be generated by the reaction of an allylic sulfonate salt ($C=C—C—OSO_3^-$) with silver nitrate in acetonitrile containing an excess of bromine and a catalytic amount of water.[291] Sultones are formed when alkenes react with PhIO and 2 equiv of Me_2SiSO_3Cl.[292]

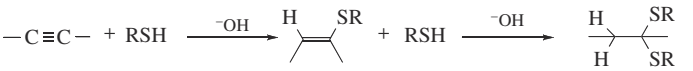
Hydrogen sulfide (H_2S) and thiols add to alkenes to give alkyl thiols or sulfides by electrophilic, nucleophilic, or free radical mechanisms.[293] In the absence of initiators, the addition to simple alkenes is by an electrophilic mechanism, similar to that in Reaction **15-5**, and *Markovnikov's rule* is followed. However, this reaction is usually very slow and often cannot be done or requires very severe conditions unless a Brønsted–Lowry or Lewis acid catalyst is used. For example, the reaction can be performed in concentrated H_2SO_4[294] or with the addition of $AlCl_3$.[295] In the presence of free radical initiators, H_2S and thiols add to double and triple bonds by a free radical mechanism and the orientation is *anti-Markovnikov*.[296] *Anti-Markovnikov* addition of thiols to vinyl ethers occurs under solvent- and catalyst-free conditions,[297] and is promoted by water.[298]



Additives can influence the regioselectivity. Styrene reacts with thiophenol to give primarily the *anti-Markovnikov* product, whereas addition of thiophenol in the presence of Montmorillonite K-10 clay gives primarily the *Markovnikov addition* product.[299] The addition of thiophenol to an alkene with a zeolite, however, leads to the *anti-Markovnikov* sulfide.[300] In fact, the orientation can be used as a diagnostic tool to indicate which mechanism is operating. Free radical addition can be done with H_2S, RSH (R may be primary, secondary, or tertiary), ArSH, or RCOSH.[301] The R group may contain various functional groups. The alkenes may be terminal, internal, contain branching, be cyclic, and have various functional groups including OH, CO_2H, CO_2R, NO_2, RSO_2, and so on. Addition of Ph_3SiSH to terminal alkenes under radical conditions also leads to the primary thiol.[302]

Alkynes react with thiols to give vinyl sulfides. With alkynes it is possible to add 1 or 2 molar equivalents of RSH, giving a vinyl sulfide[303] or a dithioketal, respectively. Thiols also add to alkynes with a Pd catalyst to give vinyl sulfides.[304] Thiols add to alkenes under photochemical conditions to form thioethers, and the reaction can be done intramolecularly to give cyclic thioethers.[305] Thiocarbonates function as thiol surrogates, converting alkenes to alkyl thiols in the presence of $TiCl_4$ and CuO.[306] Sulfonic acids add to alkynes to give vinyl sulfonates in the presence of a Au catalyst.[307] A cesium carbonate catalyzed reaction

gives the vinyl sulfide with good (*Z*)-selectivity.[308] The Rh^{-}[309] In^{-},[310] organoactinide^{-},[311] organozirconium-,[312] or Pt catalyzed[313] reaction of alkynes with thiols gives the corresponding vinyl sulfide. Similar results were obtained under solvent-free conditions using an alumina–KF system.[314] Alternative preparations are available, as in the reaction of a terminal alkyne with $Cp_2Zr(H)Cl$ followed by PhSCl to give the vinyl sulfide with the SPh unit at the less substituted position (PhCH=CHSPh).[315] The intramolecular addition of a thiol to an ene–yne, with a Pd catalyst, leads to substituted thiophene derivatives.[316] Alkenes react with diphenyl disulfide in the presence of $GaCl_3$ to give the product with two phenylthio units (PhS—C—C—SPh).[317] The reaction of an alkyne with diphenyl disulfide and a Pd catalyst leads to the bis(vinyl) sulfide (PhS—C=C—SPh).[318]

When thiols are added to substrates susceptible to nucleophilic attack, bases catalyze the reaction and the mechanism is nucleophilic. These substrates may be of the *Michael type*[319] or may be polyhalo alkenes or alkynes.[255] As with the free-radical mechanism, alkynes can give either vinylic thioethers or dithioacetals:

By any mechanism, the initial product of addition of H_2S to a double bond is a thiol, which is capable of adding to a second molecule of alkene, so that sulfides are often produced: C=C → H—C—C—S—C—C—H. As with alcohols, ketenes add thiols to give thiol esters [$R_2C{=}C{=}O + RSH \rightarrow R_2CHCOSR$].[320]

Selenium compounds (RSeH) add in a similar manner to thiols.[321] Vinyl selenides can be prepared from alkynes using diphenyl diselenide and sodium borohydride.[322] A Pd(II) catalyzed reaction of PhSeH with alkynes, in pyridine, also gives the corresponding vinyl selenide.[323]

The conjugate addition of thiols to α,β-unsaturated carbonyl derivatives is discussed in Reaction **15-31**.

D. Nitrogen or Phosphorus on the Other Side

15-8 Addition of Ammonia and Amines, Phosphines, and Related Compounds[324]

Hydro-amino-addition

Hydro-phosphino-addition

Ammonia and primary and secondary amines add to alkenes *in some cases*.[325] Ammonia and amines are much weaker acids than water, alcohols, and thiols (see Reactions **15-3**, **15-5**, and **15-7**) and since acids turn NH_3 into the weak acid, the ammonium ion (NH_4^+), this reaction does not occur by an electrophilic mechanism. The reaction tends to give very low yields, if any, with ordinary alkenes, unless extreme conditions are used (e.g., 178–200 °C, 800–1000 atm, and the presence of metallic Na, for the reaction between NH_3 and ethylene[326]). There is, however, a proton-catalyzed hydroamination reaction in which aniline derivatives add to alkenes in the presence of anilinium salts, in 20–90% yield depending on the alkene.[327]

There are many examples of transition-catalyzed addition of nitrogen compounds to alkenes, alkynes,[328] and so on. Amines can be added to certain nonactivated alkenes using Pd,[329] Rh,[330] In,[331] Ti,[332] Fe,[333] Ta,[334] Au,[335] Y,[336] Mo,[337] and various lanthanide catalysts.[338] 1,3-Dienes,[339] and also allenes,[340] undergo hydroamination in the presence

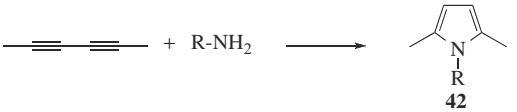
of an Au catalyst. Complexation with the metal lowers the electron density of the double bond, facilitating nucleophilic attack.[341] *Markovnikov* orientation is observed and the addition is anti.[342] Aniline reacts with dienes and a Pd catalyst to give allylic amines.[343] Diene amines react with Sm catalysts to give 2-alkenyl pyrrolidines.[344] The mechanism of the Au(I) catalyzed hydroamination reaction of alkenes has been studied.[345] It is believed to involve a ligand substitution reaction in the active Au species followed by nucleophile attack of the N-nucleophile on the activated double bond, which is followed by proton transfer from the NH_2 group to the unsaturated carbon atom.

Cyclization reactions are useful variations of this reaction. An intramolecular addition of an amine unit to an alkene to form a pyrrolidine was reported using a Pd[346] Rh,[347] Sc,[348] Sm,[349] Ti,[350] Zr,[351] or a Lu catalyst.[352] as well as a lanthanide reagent,[353] or a Y reagent.[354] An intramolecular Ca mediated reaction of amino alkenes leads to cyclic amines.[355] Alkenyl amines give cyclic amines as the major product, in good yield, when treated with *n*-butyllithium.[356] Reaction of a secondary amine with butyllithium generates an amide base, which reacts with alkenes to give alkyl amines,[357] and can add intramolecularly to an alkene to form a pyrrolidine.[358] Pyrroles can be generated in this manner.[359]



Other nitrogen compounds, among them hydroxylamine and hydroxylamines,[360] hydrazines, and amides (Reaction **15-9**), also add to alkenes. Tertiary amines (except those that are too bulky) add to *Michael-type* substrates (C=C—Z) in a reaction that is catalyzed by acids like HCl or HNO_3 to give the corresponding quaternary ammonium salts (R_3N^+—C—C—Z).[361] The tertiary amine can be aliphatic, cycloalkyl, or heterocyclic (including pyridine). The reaction of NaOH with an amine containing two distal alkene units, followed by addition of a neodymium catalyst, leads to a bicyclic amine.[362]

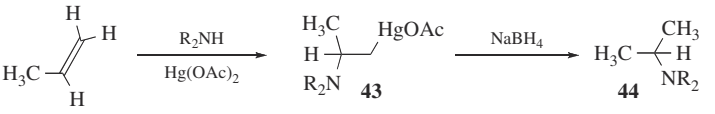
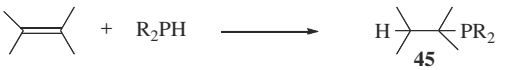
41

Primary amines add to triple bonds[363] to give enamines that have a hydrogen on the nitrogen and (analogously to enols) tautomerize (Sec. 2.N.ii, category 4) to the more stable imines (**41**).[364] The reaction has been done with a Pd,[365] a Ti,[366] a Ta,[367] a Cu,[368] or an Au catalyst.[369] An intramolecular addition of amines to an alkyne unit in the presence of a Pd catalyst generated heterocyclic or cyclic amine compounds.[370] A variation treats an alkynyl imine with CuI to form pyrroles.[371] *N,N*-Diphenylhydrazine reacts with diphenyl acetylene and a Ti catalyst to give indole derivatives.[372] Treatment of an imine of 2-alkynyl benzaldehyde with iodide gave a functionalized isoquinoline.[373] When ammonia is used instead of a primary amine, the corresponding $R_2C{=}NH$ imine product is not stable enough for isolation, but polymerizes. Ammonia and primary amines (aliphatic and aromatic) add to conjugated diynes to give pyrroles (**42**).[374] *Anti-Markovnikov* addition of alkynes is possible using a Cu catalyst.[375]



42



A related reaction of amines and alkynes, in supercritical CO_2, leads to amides.[376]

Allenes are reaction partners,[377] and amines add to allenes in the presence of a catalytic amount of CuBr,[378] Au,[379] or Pd compounds.[380] Intramolecular reaction of allene amines leads to dihydropyrroles, using a Au catalyst.[381] Cyclic imines can be prepared from allene amines using a Ti catalyst.[382]

A NH_2 or NR_2 unit can be added to double bonds (even ordinary double bonds) in an indirect manner by the use of hydroboration (Reaction **15-16**) followed by treatment with NH_2Cl or NH_2OSO_2OH (Reaction **12-32**). This produces a primary amine with *anti-Markovnikov* orientation. An indirect way of adding a primary or secondary amine to a double bond consists of aminomercuration to give **43**, followed by reduction (see Reaction **15-3** for the analogous *oxymercuration–demercuratio*n procedure) to give amine **44**.[383] The addition of a secondary amine produces a tertiary amine, while addition of a primary amine gives a secondary amine. The overall orientation follows *Markovnikov's rule*. For conversion of **43** to other products, see Reaction **15-53**.

Phosphines add to alkenes to give alkyl phosphines (**45**) and to alkynes to give vinyl phosphines. A Pd catalyzed reaction of alkenes and triarylphosphines gives alkyltriarylphosphonium salts.[384] Alkenes also react with diarylphosphines and a Ni catalyst to give the alkyl phosphine.[385] Silylphosphines ($R_3Si—PAr_2$) react with alkenes and Bu_4NF to give the *anti-Markovnikov* allyl phosphine.[386] Phosphine oxides can be prepared by the reaction of an aryl substituted alkene and diphenylphosphine oxide, $Ph_2P(=O)H$.[387] Phosphonate esters were similarly prepared from alkenes and diethyl phosphite [$(EtO)_2P(=O)H$] and an Mn catalyst in a reaction exposed to oxygen.[388] Similar addition was observed in the reaction of an alkene with NaH_2PO_2 to give the phosphinate [$RCH=CH_2 \rightarrow RCH_2CH_2PH(=O)ONa$].[389] Palladium catalysts were used for the preparation of similar compounds from alkenes[390] and the reaction of terminal alkynes with dimethyl phosphite and a Ni catalyst gave the *Markovnikov* vinyl phosphonate ester.[391]

In the presence of an Yb catalyst, diphenylphosphine added to diphenyl acetylene to give the corresponding vinyl phosphine.[392] A Pd catalyst was used for the addition of diphenylphosphine to terminal alkynes, giving the *anti-Markovnikov* vinyl phosphine, but a Ni catalyst led to the *Markovnikov* vinyl phosphine.[393] A Co catalyst has also been used.[394] Diphenylphosphine oxide also reacted with terminal alkynes to give the

anti-Markovnikov vinyl phosphine oxide using an Rh catalyst.[395] Other phosphites were added to dienes to give an allylic phosphonate ester using a Pd catalyst.[396] Diarylphosphines react with vinyl ethers and a Ni catalyst to give α-alkoxy phosphonate esters.[397]

15-9 Addition of Amides

Hydro-amido-addition

Under certain conditions, primary and secondary amides can add directly to alkenes to form *N*-alkylated amides. Sulfonamides react in a similar manner. Alkenes react with amides and related compounds in the presence of certain transition metals. The Ti catalyzed reaction of alkenyl *N*-tosylamines gives *N*-tosyl cyclic amines.[398]

The reaction can be done intramolecularly. 3-Pentenamide cyclized to 5-methyl-2-pyrrolidinone by treatment with trifluorosulfonic acid.[399] *N*-Benzyl pent-4-ynamide reacted with tetrabutylammonium fluoride to an alkylidene lactam.[400] Acyl hydrazine derivatives also cyclize in the presence of hypervalent iodine reagents to give lactams.[401] Treatment of triflamide alkenes with triflic acid gives the corresponding *N*-triflyl cyclic amine.[402] Intramolecular cyclization of sulfamate esters, catalyzed by a Rh complex, leads to cyclic sulfamates.[403]

Alkynes and allenes also react with amides. A Ru/In catalyzed addition of sulfonamides to alkynes leads to cyclic *N*-sulfonyl derivatives.[404] Palladium-catalyzed reactions give similar results,[405] and Bi and Hf have been used as catalysts.[406] Phenylthiomethyl alkynes were converted to *N*-Boc-*N*-phenylthio allenes with Boc azide and an iron catalyst.[407] Enamides are prepared by the Re[408] or Ru catalyzed[409] hydroamidation of terminal alkynes with amides. The Pd catalyzed reaction of an allene amide, with iodobenzene, leads to *N*-sulfonyl aziridines having an allylic group at C-1.[410] Other allene *N*-tosylamines similarly give *N*-tosyl tetrahydropyridines.[411]

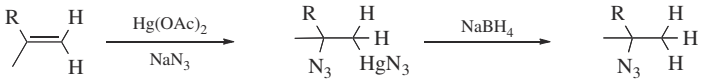
N-Bromocarbamates also add to alkenes, in the presence of $BF_3 \cdot OEt_2$ to give a *vic*-bromo *N*-Boc amine.[412] When a carbamate was treated with Bu_3SnH, and AIBN, addition to an alkene led to a bicyclic lactam.[413] Alkenyl amides and carbamates react with transition metal catalysts to form lactams or cyclic carbamates. Similar addition of a tosylamide–alkene, with a Pd catalyst, led to a vinyl *N*-tosyl pyrrolidine.[414] Both Pd[415] and Au[416] catalyzed cyclization reactions of carbamates are known, and Os compounds have been used.[417] Ionic liquids have been used to catalyze these reactions.[418]

Imides can also add to alkenes or alkynes. Phthalimide reacts with an alkene in the presence of a Pd catalyst.[419] Ethyl 2-propynoate reacted with phthalimide, in the presence of a Pd catalyst, to give ethyl 2-phthalimido-2-propenoate.[420]

Nickel-catalyzed hydrophosphinylation reactions are known, such as the reaction of an alkyne with an alkyl phosphinate to give a vinyl phosphinate ester.[421] Both H-phosphinates and secondary phosphine oxides add to alkenes in an *anti-Markovnikov* manner, induced by air in what is likely a radical reaction.[422]

15-10 Addition of Hydrazoic Acid



Hydro-azido-addition

Hydrazoic acid (HN_3) can be added to certain Michael-type substrates (Z is as defined in Sec. 15.A.ii) to give β-azido compounds.[423] The reaction apparently fails if R is phenyl. Hydrazoic acid also adds to enol ethers $CH_2{=}CHOR$ to give $CH_3{-}CH(OR)N_3$, and to silyl enol ethers,[424] but it does not add to ordinary alkenes unless a Lewis acid catalyst (e.g., $TiCl_4$) is used, in which case good yields of azide can be obtained.[424]

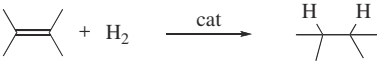
Hydrazoic acid can also be added indirectly to ordinary alkenes by azidomercuration, followed by demercuration,[425] analogous to the



similar procedures mentioned in Reactions **15-3**, **15-5**, **15-6**, and **15-8**. The method can be applied to terminal alkenes or strained cycloalkenes (e.g., norbornene), but fails for unstrained internal alkenes. A variation is the hydroazidation reaction of alkenes using a Co catalyst and *tert*-BuOOH to give the alkyl azide.[426]

E. Hydrogen on Both Sides

15-11 Hydrogenation of Double and Triple Bonds[427]

Dihydro-addition

Most carbon–carbon double bonds, whether substituted by electron-donating or electron-withdrawing substituents, can be catalytically hydrogenated, usually in quantitative or near-quantitative yields.[428] However, a transition metal catalyst is required to break apart H_2 into metal-bound hydrogen atoms before reaction can occur with the alkene. Almost all known alkenes added hydrogen at temperatures between 0 and 275 °C. The catalysts used can be divided into two broad classes, both of which mainly consist of transition metals and their compounds: (1) Catalysts insoluble in the reaction medium (*heterogeneous catalysts*). Among the most effective are Raney nickel,[429] Pd-on-charcoal (perhaps the most common),[430] $NaBH_4$ reduced nickel[431] (also called nickel boride), Pt metal or its oxide, Rh, Ru, and zinc oxide,[432] (2) Catalysts soluble in the reaction medium

(*homogeneous catalysts*).[433] An important example is chlorotris(triphenylphosphine) rhodium [$RhCl(Ph_3P)_3$],[434] **46**, *Wilkinson's catalyst*),[435] which catalyzes the hydrogenation of many alkenyl compounds without disturbing such groups as CO_2R, NO_2, CN, or COR present in the same molecule.[436] Even unsaturated aldehydes can be reduced to saturated aldehydes,[437] although in this case decarbonylation (Reaction **14-32**) may be a side reaction. In general, for catalytic hydrogenation many functional groups may be present in the molecule, for example, OH, COOH, NR_2 (including NH_2), and N(R)COR′ (including carbamates),[438] CHO, COR, CO_2R, or CN. Vinyl esters can be hydrogenated using homogeneous Rh catalyst.[439] Some of these groups are also susceptible to catalytic reduction, but it is usually possible to find conditions under which double bonds can be reduced selectively[440] (see Table 19.2). Controlling the solvent allows catalytic hydrogenation of an alkene in the presence of an aromatic nitro group.[441]

Modification of the catalyst includes a polymer bound Ru catalyst,[442] and a polymer incarcerated Pd catalyst.[443] A nanoparticulate Pd catalyst in an ionic liquid has been used for the hydrogenation of alkenes.[444]

Homogeneous catalysts have the advantages of better catalyst reproducibility and better selectivity. Apart from *Wilkinson's catalyst* (**46**), chlorotris(triphenylphosphine)hydridoruthenium(II) [$(Ph_3P)_3RuClH$][445] is an important homogeneous catalyst that is specific for terminal double bonds (other double bonds are hydrogenated slowly or not at all). Homogeneous catalysts are also less susceptible to catalyst poisoning.[446] Heterogeneous catalysts are usually poisoned by small amounts of sulfur, often found in rubber stoppers, or by thiols and sulfides.[447] Note that heterogeneous catalysts are usually easier to separate from a reaction mixture.

Using soluble, homogeneous catalysts, unfunctionalized alkenes are hydrogenated with good diastereoselectivity and enantioselectivity[448] using various metal catalysts

(e.g., Ir,[449] Pd,[450] or Zr,[451] and chiral ligands).[452] The chiral transition metal catalyst (Rh and Ru are probably the most common) is usually prepared with suitable chiral ligands prior to addition to the reaction. Alternatively, an achiral catalyst (e.g., *Wilkinson's catalyst*, **46**), is simply added along with a chiral ligand. With monophosphine chiral ligands, [453] the phosphorous may be chiral, as in **47** (called R-camp)[454] or bis(phosphine) **48** (called dipamp),[455] but pyramidal inversion at elevated temperatures (see Sec. 4.C) limits the utility of such ligands. The alternative is to prepare phosphines that contain a chiral carbon, as in **49** (known as Chiraphos),[456] but there are many variations of chiral bis(phosphine) ligands.[457] Chiral poisoning has been used as a strategy for asymmetric catalysis.[458]

46 **47** **48** **49**

Hydrogenations are carried out at room temperature and just above atmospheric pressure, in most cases, but some double bonds are more resistant and require higher temperatures and pressures. The poor reactivity is usually a function of increasing substitution and is presumably caused by steric factors. Trisubstituted double bonds require, say, 25 °C and 100 atm, while tetrasubstituted double bonds may require 275 °C and 1000 atm. Among the double bonds most difficult to hydrogenate or which cannot be hydrogenated at all are those common to two rings, as in steroid **49**. Hydrogenations, even at about atmospheric pressure, are often performed in a special hydrogenator, but this is not always necessary. Indeed, placing a hydrogen-filled balloon over the reaction flask is common for small-scale hydrogenations that do not require heat or

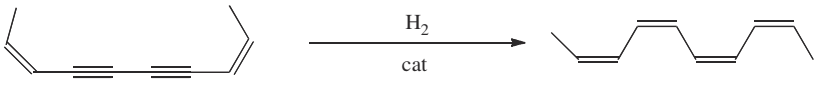
pressure. The great variety of catalysts available often allows an investigator to find one that is highly selective. For example, the catalyst Pd(salen) encapsulated in zeolites permitted the catalytic hydrogenation of 1-hexene in the presence of cyclohexene.[459] It has been shown that the pressure of the reaction can influence enantioselectivity in asymmetric catalytic hydrogenations.[460]



Triple bonds can be reduced, either by catalytic hydrogenation or by the other methods mentioned in the following two sections. The comparative reactivity of triple and double bonds depends on the catalyst. *With most catalysts (e.g., Pd), triple bonds are hydrogenated more easily*, and therefore it is usually possible to add just 1 equiv of hydrogen and reduce a triple to a double bond or to reduce a triple bond without affecting a double bond present in the same molecule.[461] A particularly good catalyst for this purpose is the *Lindlar catalyst* (Pd—$CaCO_2$—PbO),[462] which gives rather lean syn addition, and a (*Z*)-alkene. An alternative catalyst used for selective hydrogenation to *cis*-alkenes is the Pd on a barium sulfate ($BaSO_4$) catalyst, poisoned with quinoline[463] (sometimes called the *Rosenmund catalyst*). Palladium on calcium carbonate in PEG has also been used as a recyclable catalyst system.[464] Catalytic hydrogenation of alkynes leads to *cis*-alkenes with a Pd catalyst and DMF/KOH was found to be an efficient transfer-hydrogen source.[465] Hydrogenation of a C≡C unit occurs in the presence of other functional groups, including NR_2 including NH_2,[466] and sulfonyl.[467]

Conjugated dienes can add hydrogen by 1,2- or 1,4-addition. Selective 1,4-addition can be achieved by hydrogenation in the presence of CO, with bis(cyclopentadienyl)chromium as catalyst.[468] With allenes,[469] catalytic hydrogenation usually reduces both double bonds. Hydrogenation of functionalized alkenes is possible. The Rh catalyzed hydrogenation of enamines leads to amines,[470] for example. Hydrogenation of fluorinated alkenes has been reported using an Ir catalyst.[471] The hydrogenation of conjugated alkenes is discussed in Reaction **15-14**.

Most catalytic reductions of double or triple bonds, whether heterogeneous or homogeneous, have been shown to be mostly syn, with the hydrogen atoms incorporated from the less-hindered side of the molecule.[472] This selectivity depends in large part of how well the reactive intermediates are bound to the metal, and isomerization of the double bond is possible. Stereospecificity can be investigated only for tetrasubstituted alkenes (except when the reagent is D_2), which are the hardest to hydrogenate, but the results of these investigations show that the addition is usually 80–100% syn, although some of the anti-addition product is normally also found and in some cases predominates. Catalytic hydrogenation of alkynes is nearly always stereoselective, giving the *cis*-alkene (usually at least 80%), even when it is thermodynamically less stable. For example, **50** gave **51**, even though the steric hindrance is such that a planar molecule is impossible.[473] This is

50 **51**

thus a useful method for preparing *cis*-alkenes.[474] However, when steric hindrance is too great, the *trans*-alkene may be formed. One factor that complicates the study of the stereochemistry of heterogeneous catalytic hydrogenation is that exchange of hydrogen atoms takes place, as can be shown by hydrogenation with deuterium.[475] Thus deuterogenation of ethylene produced all the possible deuterated ethylenes and ethanes (even C_2H_6), as well as HD.[476] With 2-butene, it was found that double-bond migration, cis–trans isomerization, and even exchange of hydrogen with groups not on the double bond could occur (e.g., $C_4H_2D_8$ and C_4HD_9 were detected on treatment of *cis*-2-butene with deuterium and a catalyst).[477] Indeed, *alkanes* have been found to exchange with deuterium over a catalyst,[478] and even without deuterium (e.g., $CH_4 + CD_4 \rightarrow CHD_3 + CH_3D$ in the gas phase), with a catalyst. All this makes it difficult to investigate the stereochemistry of heterogeneous catalytic hydrogenation.

The mechanism of the heterogeneous catalytic hydrogenation of double bonds is not thoroughly understood because it is a very difficult reaction to study.[479] Because the reaction is heterogeneous, kinetic data, although easy to obtain (measurement of decreasing hydrogen pressure), are difficult to interpret. Furthermore, there are the difficulties

caused by the aforementioned hydrogen exchange. The currently accepted mechanism for the common two-phase reaction was originally proposed in 1934.[480] According to this, the alkene is adsorbed onto the surface of the metal, although the nature of the actual bonding is unknown,[481] despite many attempts to elucidate it.[482] In the 1934 work, the metallic site was indicated by an asterisk, but here  is used. For steric reasons it is apparent that adsorption of the alkene takes place with its less-hindered side attached to the catalyst surface, probably as an η^2 complex (Sec. 3.C.i). The fact that addition of hydrogen is generally also from the less-hindered side indicates that the hydrogen too is probably adsorbed on the catalyst surface before it reacts with the alkene. It is likely that as the H_2 molecule is adsorbed on (coordinated to) the metal catalyst, cleavage occurs to give η^1-coordinated hydrogen atoms (Sec. 3.C.i). Note that this model suggests a single metal particle for coordination of the alkene and the hydrogen atoms, but the hydrogen atoms and the alkene could be coordinated to different metal particles. It has been shown that Pt catalyzes homolytic cleavage of hydrogen molecules.[483] In the second step, one of the adsorbed (η^1-coordinated) hydrogen atoms becomes attached to a carbon atom, creating in effect, an alkyl radical, which is still bound to the catalyst although only by one bond, probably η^1-coordination. Transfer of a hydrogen atom to carbon opens a site on the metal catalyst for coordination to additional hydrogen atoms. Finally, another hydrogen atom (not necessarily the one originally connected to the first hydrogen) combines with the radical to give the reaction product, freed from the catalyst surface, and the metal catalyst that is now available for coordination of additional hydrogen atoms and/or alkenes. All the various side reactions, including hydrogen exchange and isomerism, can be explained by this type of process.[484] Although this mechanism is satisfactory as far as it goes,[485] there are still questions it does not answer, among them questions[486] that involve the nature of the asterisk, the nature of the bonding, and the differences caused by the differing nature of each catalyst.[487]

Another problem with any study of heterogeneous catalysis is that it occurs at the surface, and different types of metal particles are exposed to the medium and reactants. Maier[488] suggested the presence of **terrace-**, **step-,** and **kink**-type atoms (in Fig. 15.1)[488] on the surface of a heterogeneous catalyst. These terms refer to different atom types, characterized by the number of nearest neighbors, which correspond to different transition metal fragments, as well as to different coordination states of that metal.[489] A terrace-type atom (A in Fig. 15.1) typically has eight or nine neighbors and corresponds to a geometry shown for the ML_5 particle. The step type of atom (B) usually has seven neighbors and can

be correlated with the geometry shown for the ML_4 particle. Finally, the kink-type atom (C) has six neighbors and corresponds to geometry shown for the ML_3 particle. In general, as the particle size increases, the relative concentration of terrace atoms will increase, whereas small particle size favors the kink type of surface atoms.

The mechanism of homogeneous hydrogenation[490] catalyzed by $RhCl(Ph_3P)_3$ (**46**, *Wilkinson's catalyst*)[491] involves reaction of the catalyst with hydrogen to form a metal hydride $(PPh_3)_2RhH_2Cl$ (**52**).[492] Replacement of a triphenylphosphine ligand with two toms of hydrogen constitutes an oxidative addition. After coordination of the alkene to form **53**, transfer of hydrogen to carbon is an insertion process, presumably generating **55**, and a second insertion liberates the hydrogenated compound, and Rh species **54**, which adds hydrogen by oxidative addition to give **55**. In a different study of Pd catalyzed hydrogenations, a palladium hydride species was detected.[493] Alternatively, replacement of triphenylphosphine can lead to **53**, with two hydrogen atoms and a η^2 alkene complex. If a mixture of H_2 and D_2 is used, the product contains only dideuterated and nondeuterated

compounds; no monodeuterated products are found, indicating that (unlike the case of heterogeneous catalysis) H_2 or D_2 has been added to one alkene molecule and that no exchange takes place.[491] Although conversion of **53** to the products takes place in two steps,[494] the addition of H_2 to the double bond is syn, although bond rotation in **55** can lead to stereochemical mixtures.

The occurrence of hydrogen exchange and double-bond migration in heterogeneous catalytic hydrogenation means that the hydrogenation does not necessarily take place by straightforward addition of two hydrogen atoms at the site of the original double bond. Consequently, this method is not synthetically useful for adding D_2 to a double or triple bond in a regioselective or stereospecific manner. However, this objective can be achieved (with syn addition) by a homogeneous catalytic hydrogenation, which usually adds D_2 without scrambling[495] or by the use of one of the diimide methods (Reaction **15-12**). Deuterium can also be regioselectively added by the hydroboration–reduction procedure previously mentioned.

15-12 Other Reductions of Double and Triple Bonds

Although catalytic hydrogenation is the method most often used, double or triple bonds can be reduced by other reagents as well. These include sodium in ethanol, sodium and *tert*-butyl alcohol in HMPA,[496] lithium in aliphatic amines[497] (see also, Reaction **15-13**), zinc and acids, and $(EtO)_3SiH—Pd(OAc)_2$.[498] Trialkylsilanes (R_3SiH) in conjunction with an acid will reduce double bonds.[499] When double bonds are reduced by lithium in ammonia or amines, the mechanism is similar to that of the *Birch reduction* (Reaction **15-13**).[500] The reduction with trifluoroacetic acid and Et_3SiH has an ionic mechanism, with H^+ coming in from the acid and H^- from the silane.[289] In accord with this mechanism, the reaction can be applied only to those alkenes that when protonated can form a tertiary carbocation or one stabilized in some other way (e.g., by a OR substitution).[501] It has been

shown, by the detection of CIDNP, that reduction of α-methylstyrene by hydridopentacarbonylmanganese(I), $[HMn(CO)_5]$, involves free radical addition.[502]

Triethylamine reduces alkynes in the presence of a Pd catalyst.[503] Samarium iodide in water and a triamine additive led to reduction of alkenes.[504] Similar reduction was reported using $Co_2(CO)_8$ and an excess of water in dimethoxyethane.[505]

Another hydrogenation method is called *transfer hydrogenation*.[506] In this method, the hydrogen atom comes from another organic molecule, and that molecule is oxidized. A transition metal catalyst, heterogeneous or homogeneous, is frequently employed. A common reducing agent is cyclohexene, which, when a Pd catalyst is used, is oxidized to benzene, losing 2 molar equivalents of hydrogen. Nickel nanoparticles reduce alkenes by transfer hydrogenation using 2-propanol.[507]

Diimide (NH=NH) is a reducing agent for simple alkenes, formed *in situ* from N_2H_4 from the reaction of a mixture of hydrazine and hydroxylamine.[508] The rate of this reaction has been studied.[509] Diimide is also generated from hydrazine using a flavin catalyst in an oxygen atmosphere.[510] Although both the syn and anti forms of diimide are produced, only the syn form reduces the double bond,[511] at least in part by a cyclic mechanism:[512]

The addition is stereospecifically syn[513] and, like catalytic hydrogenation, generally takes place from the less-hindered side of a double bond, although not much discrimination in this respect is observed where the difference in bulk effects is small.[514] Diimide reductions are most successful with symmetrical multiple bonds (C=C, C≡C, N=N) and are not useful for those inherently polar (C≡N, C=N, C=O, etc.). Diimide is not stable enough for isolation at ordinary temperatures, although it has been prepared[515] as a yellow solid at −196°C.

An indirect method[516] of double-bond reduction involves formation of an alkylborane from an alkene, followed by hydrolysis of the borane (prepared by Reaction **15-16**).

Trialkylboranes can be hydrolyzed by heating to reflux with carboxylic acids,[517] while monoalkylboranes (RBH_2) can be hydrolyzed with base.[518] A mild procedure involves treatment of the alkene with 2 molar equivalents of catecholborane, a catalytic amount of $MeCONMe_2$, followed by reduction of the organoborane with 4 molar equivalents of MeOH and then treatment with air.[519] Triple bonds can be similarly reduced to *cis*-alkenes.[520] Further reduction is also possible. When an alkyne was treated with decaborane and Pd/C in methanol, 2 equiv of hydrogen are transferred to give the alkane.[521] Reduction of alkenes occurs with *tert*-butylamine • borane complex in methanol with 10% Pd/C.[522] In a related reaction, reduction occurs *in situ* when an alkene is treated with $NaBH_4$, $NiCl_2 \cdot 6 H_2O$ with moist alumina.[523] Hydrogenation with Ni_2B on borohydride-exchange resin (BER) has also been used.[524]

Metallic hydrides (e.g., lithium aluminum hydride and sodium borohydride) do not typically reduce carbon–carbon double bonds, although in special cases where the double bond is polar, as in 1,1-diarylethenes[525] and in enamines,[526] reduction can occur. Note that both $LiAlH_4$ and $NaBH_4$, as well as NaH, reduce ordinary alkenes and alkynes when complexed with transition metal salts (e.g., $FeCl_2$ or $CoBr_2$).[527] Lithium aluminum hydride reduces cyclopropenes with a pendant alcohol in the allylic position to the corresponding cyclopropane.[528] Transition metals catalyze the reduction of alkenes using $NaBH_4$. Among the metals used for this purpose are Pd,[529] and Ru.[530] A mixture of $NaBH_4$ and $BiCl_3$ also reduced certain alkenes.[531] Zinc metal catalyzes the reduction of alkenes in water in the presence of a Rh complex.[532]

The fact that ordinary double bonds are inert toward metallic hydrides is quite useful, since it permits reduction of, say, a carbonyl or nitro group, without disturbing a double bond in the same molecule (see Chap 19 for a discussion of selectivity in reduction reactions). Sodium in liquid ammonia also does not reduce ordinary double bonds,[533] although it does reduce alkynes, allenes, conjugated dienes,[534] and aromatic rings (Reaction **15-13**).

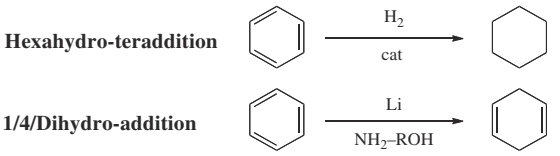
Enantioselective reduction of certain alkenes has also been achieved by reducing with baker's yeast.[535]

Catalytic hydrogenation of triple bonds and the reaction with Dibal-H (diisobutylaluminum hydride) usually give the *cis*-alkene (Reaction **15-11**). Most of the other methods of triple-bond reduction lead to the more thermodynamically stable *trans*-alkene. However, this is not the case with the method involving hydrolysis of boranes or with the reductions with activated zinc, hydrazine, or NH_2OSO_3H, which also give the cis products.



Triple bonds can also be selectively reduced to double bonds with Dibal-H,[536] with activated zinc (see Reaction **12-38**),[537] or (internal triple bonds only) with alkali metals (Na, Li) in liquid ammonia or a low-molecular-weight amine.[538] Terminal alkynes are not reduced by the Na—NH_3 procedure because they are converted to acetylide ions under these conditions. However, terminal triple bonds can be reduced to double bonds by the addition to the Na—NH_2 solution of $(NH_4)_2SO_4$, which liberates the free ethynyl group.[539] The reaction of a terminal alkyne with lithium naphthalenide and $NiCl_2$ effectively reduced the alkyne unit.[540] This reagent is also effective for the reduction of simple alkenes.[541]

Alkynes are converted to *trans*-alkenes with siloxanes [$(RO)_3SiH$] [542] and a Ru catalyst, followed by treatment with AgF, or silanes[543] and a Ru catalyst, followed by treatment with CuI and Bu_4NF. Reduction of an alkyne to an alkene can be done via an organometallic, by heating the alkyne with In metal in aq ethanol.[544] Alkynes are reduced with palladium acetate and sodium ethoxide. In methanol, the product is the alkane, whereas in THF the product is the *cis*-alkene.[545]

Reduction of just one double bond of an allene, to give an alkene, has been accomplished by treatment with Na—NH_3[546] or with Dibal-H,[547] and by hydrogenation with $RhCl(PPh_3)_3$ as catalyst.[548]

Reductions of double and triple bonds are found at OS **III**, 586, 742; **IV**, 136, 302, 887; **V**, 281, 993; **VII**, 524; **80**, 120.

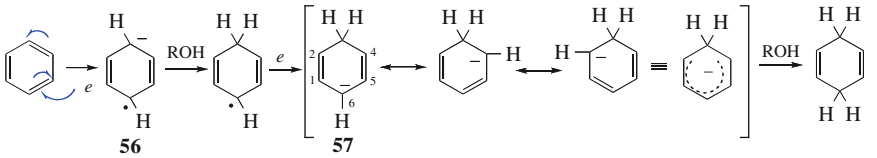
Aromatic rings can be reduced by catalytic hydrogenation,[549] but higher temperatures (100–200 °C) are required than for double bonds in alkenes.[550] Although the reaction is usually carried out with heterogeneous catalysts, homogeneous catalysts have also been used; conditions are much milder with these.[551] Hydrogenations using phase transfer catalysts often proceed under mild conditions.[552] Hydrogenation in ionic liquids is known,[553] and also hydrogenation in supercritical ethane containing water.[554] Many functional groups (e.g., OH, O^-, CO_2H, CO_2R, NH_2) do not interfere with the reaction, but some groups may be preferentially reduced. Among these are CH_2OH groups, which undergo hydrogenolysis to CH_3 (Reaction **19-54**). Phenols may be reduced to cyclohexanones, presumably through the enol. A computational study of the mechanism of hydrogenation of aromatic compounds has been reported, and it was shown that the barrier for uncatalyzed 1,4-hydrogenation is substantially lower than that for 1,2-hydrogenation, despite similar reaction enthalpies.[555]

It is usually impossible to stop the reduction of benzene rings after only one or two bonds have been reduced, since alkenes are more easily reduced than aromatic rings.[556] Thus, 1 molar equivalent of benzene, treated with 1 molar equivalent of hydrogen, gives no cyclohexadiene or cyclohexene, but one-third equivalent of cyclohexane and two-thirds equivalent of recovered benzene. This is not true for all aromatic systems. With anthracene, for example, it is easy to stop after only the 9,10-bond has been reduced (Sec. 2.I.i). Hydrogenation of phenol derivatives can lead to conjugated cyclohexenones.[557] Hydrogenation of toluene in an ionic liquid using a Ru catalyst gave methylcyclohexane.[558]



Heterocyclic compounds are often reduced by hydrogenation.[559] Furan gives THF, pyrroles[560] give pyrrolidines, and pyridines[561] give piperidines. The nitrogen-containing ring of quinolines is reduced by hydrogenation using iodine and an Ir catalyst.[562] Catalytic hydrogenation of the five-membered ring in indole derivatives using a chiral Rh catalyst gave hydroindoles with excellent enantioselectivity.[563]

When aromatic rings are reduced by Li (or K or Na) in liquid ammonia (such reductions are known as *dissolving metal reductions*), usually in the presence of an alcohol (often ethyl, isopropyl, or *tert*-butyl alcohol), 1,4-addition of hydrogen takes place and

nonconjugated cyclohexadienes are produced.[564] This reaction is called the *Birch reduction*.[565] Heterocycles (e.g., pyrroles,[566] furans,[567] pyridines,[568] and indolones[569]) can be reduced using *Birch reduction*. Ammonia obtained commercially often has iron salts as impurities that lower the yield in the *Birch reduction*. Therefore it is often necessary to distill the ammonia. When substituted aromatic compounds are subjected to the *Birch reduction*, electron-donating groups (e.g., alkyl or alkoxyl) decrease the rate of the reaction and are generally found on the nonreduced positions of the product. For example, anisole gives 1-methoxy-1,4-cyclohexadiene, not 3-methoxy-1,4-cyclohexadiene. On the other hand, electron-withdrawing groups (e.g., COOH or $CONH_2$) increase the reaction rate and are found on the reduced positions of the product.[570] The regioselectivity of the reaction has been examined.[571] The mechanism involves solvated electrons,[572] which are transferred from the metal to the solvent, and hence to the ring:[573]

The sodium becomes oxidized to Na^+ and creates a radical ion (**56**).[574] There is a great deal of evidence from ESR spectra for these species.[575] The radical ion accepts a proton from the alcohol to give a radical, which is reduced to a carbanion by another sodium atom. Finally, **57** accepts another proton. Thus the function of the alcohol is to supply protons, since with most substrates ammonia is not acidic enough for this purpose. In the absence of the alcohol, products arising from dimerization of **56** are frequently obtained. There is evidence[576] at least with some substrates (e.g., biphenyl) that the radical ion corresponding to **56** is converted to the carbanion corresponding to **56** by a different pathway, in which the order of the steps is reversed: First a second electron is gained to give a dianion,[573] which then acquires a proton, producing the intermediate (e.g., **56**).

56 **57**

Ordinary alkenes are usually unaffected by *Birch-reduction* conditions, and double bonds may be present in the molecule if they are not conjugated with the ring. However,

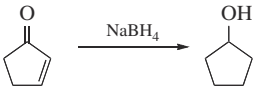
phenylated alkenes, internal alkynes (Reaction **15-12**),[577] and conjugated alkenes (with C=C or C=O) are reduced under these conditions.

Note that **56** is a resonance hybrid; that is, two additional canonical forms can be written. The question therefore arises: Why does the carbanion pick up a proton at the 6 position to give the 1,4-diene? Why not at the 2 position to give the 1,3-diene?[578] An answer to this question has been proposed by Hine,[579] who suggested that this case is an illustration of the operation of the *principle of least motion*. According to this principle, "those elementary reactions will be favored that involve the least change in atomic position and electronic configuration."[578] The principle can be applied to the case at hand in the following manner (simplified): The valence bond bond orders (Sec. 2.A) for the six carbon–carbon bonds (on the assumption that each of the three forms contributes equally) are (going around the ring) $1\frac{2}{3}$, 1, 1, $1\frac{2}{3}$, $1\frac{1}{3}$, and $1\frac{1}{3}$. When the carbanion is converted to the diene, these bond orders change as follows:

It can be seen that the two bonds whose bond order is 1 are unchanged in the two products, but for the other four bonds there is a change. If the 1,4-diene is formed, the change is $\frac{1}{3}+\frac{1}{3}+\frac{1}{3}+\frac{1}{3}$, while formation of the 1,3-diene requires a change of $\frac{1}{3}+\frac{2}{3}+\frac{2}{3}+\frac{1}{3}$. Since a greater change is required to form the 1,3-diene, the principle of least motion predicts formation of the 1,4-diene. This may not be the only factor, because the ^{13}C NMR spectrum of **111** shows that the 6 position has a somewhat greater electron density than the 2 position, which presumably would make the former more attractive to a proton.[580]

Reduction of aromatic rings with Li[581] or Ca[582] in amines (instead of ammonia: called *Benkeser reduction*) proceeds further and cyclohexenes are obtained. It is thus possible to reduce a benzene ring, by proper choice of reagent, so that one, two, or all three double bonds are reduced.[583] Lithium triethylborohydride ($LiBEt_3H$) has also been used, to reduce pyridine derivatives to piperidine derivatives.[584]



Transition metals and metal compounds can reduce aromatic rings in the proper medium. Indium metal reduces the pyridine ring in quinoline in aq ethanol solution,[585] as well as the C=C unit in the five-membered ring of indole derivatives.[586] Samarium

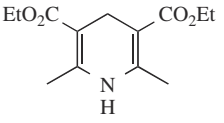
15-14 Reduction of the Double or Triple Bonds Conjugated to Carbonyls, Cyano, Nitro, and so on

(100%)



Reduction of only the C=C bond of conjugated C=C—C=O and C=C—C≡N systems[591] has been achieved by many reducing agents,[592] including catalytic hydrogenation with a Rh,[593] a Ru,[594] a Pd,[595] or an Ir catalyst,[596] and with Raney nickel alone.[597] Reagents, such as SmI_2[598] and catecholborane,[599] are effective. Conjugated ketones react with 2 equiv of Cp_2TiCl in THF/MeOH to give the corresponding saturated ketone.[600] Zinc and acetic acid has been used for the conjugate reduction of dihydropyridin-4-ones.[601] Formic acid with a Pd catalyst reduced conjugated carboxylic acids.[602] A zinc–titanocene protocol has been developed for conjugate reductions.[603] Both $NaBH_4$ in MeOH—THF[604] and $NaCNBH_3$ on a zeolite[605] reduce α,β-unsaturated nitro compounds to nitroalkanes.

In certain cases,[606] metallic hydride reagents may selectively reduce double bonds that are in conjugation with C=O bonds,[607] although the C=O bonds are also reduced in many

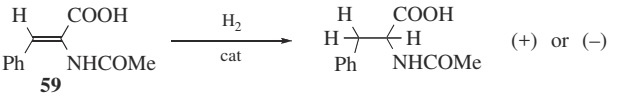
cases, as in the conversion of cyclopentenone to cyclopentanol.[608] The reagent $NaBH_4$ has a greater tendency than $LiAlH_4$ to effect this double reduction, although even with $NaBH_4$ the product of 1,2-reduction (of the C=O bond) is usually formed in larger amount than the doubly reduced product. The C=C unit proximal to the carbonyl in dienyl amides is selectively reduced with $NaBH_4/I_2$.[609] Mixed hydride reducing agents (e.g., $NaBH_4$—$BiCl_3$,[610] $NaBH_4$—$InCl_3$,[611] and Dibal-H–$Co(acac)_2$)[612] have been used. The $InCl_3$—$NaBH_4$ reagent was used to covert conjugated diene ketones (C=C—C=C—C=O) selectively to the nonconjugated alkenyl ketone (C=C—CH_2CH_2—C=O).[613] Lithium aluminum hydride also reduces the double bonds of allylic alcohols.[614]

Transfer hydrogenation can be applied to the reduction of conjugated alkenes. Reduction of the C=C unit of conjugated aldehydes is accomplished with an imidazolidinone catalyst[615] or an amino ester[616] in the presence of a *Hantzch ester* (e.g., **58**). Nitroalkenes are hydrogenated using a thiourea catalyst in the presence of **58**.[617] Palladium/carbon with microwave heating is used for the transfer hydrogenation of conjugated carboxylic acids, using 1,4-cyclohexadiene as the hydrogen-transfer agent.[618] Solvent-free transfer hydrogenation is possible using a Ru complex, with formic acid or water[619] as the hydrogen donor.[620] Palladium—P(*t*-Bu)$_3$ has been used as a mild catalyst for transfer hydrogenation.[621] Titanium-catalyzed reductions are also known.[622]



58

Silanes reduce the C=C unit in conjugated systems in the presence of Cu species.[623] An asymmetric CuH catalyzed hydrosilation reaction is known.[624] Phenylsilane ($PhSiH_3$) and

a Ni catalyst,[625] CuCl,[626] a Mn catalyst[627] or a Mo[628] catalyst have been used for hydrosilation reactions. Triphenylsilane was also used for the asymmetric reduction of nitro alkenes ($C{=}C{-}NO_2$).[629] Poly(methylhydrosiloxane) with a chiral Cu catalyst gave conjugate reduction of conjugated esters to give the saturated derivative with high enantioselectivity.[630] Polymethylhydrosiloxane, in the presence of a Co-catalyst reduces conjugated nitriles.[631] A β-bromo conjugated lactone was reduced to the β-bromolactone with modest enantioselectivity using an excess of Ph_3SiH and a CuCl catalyst with a chiral ligand.[632] Tributyltin hydride, in the presence of $MgBr_2 \cdot OEt_2$ gave 1,4-reduction of conjugated esters.[633]

59

Optically active homogeneous hydrogenation catalysts have been used to achieve the enantioselective hydrogenation[634] of many prochiral conjugated substrates.[635] For example,[636] hydrogenation of **59** with a suitable catalyst gives the (+) or (−) amino ester (depending on which enantiomer of the catalyst is used) with an ee as high as 96%.[637] Prochiral substrates that give such high optical yields generally contain functional groups (e.g., a carbonyl group,[638] amide groups, cyano groups) or combinations of such groups as in **58**.[639] The catalyst in such cases[640] is usually a Ru[641] or Rh complex[642]with chiral

phosphine ligands.[643] Good asymmetric induction[644] has been achieved using chiral Rh complexes with other chiral additives.[645] Iridium complexes have been used with excellent enantioselectivity.[646] The role of solvent has been examined.[647] A pressure-dependent enantioselective hydrogenation has been reported.[648] Asymmetric catalytic hydrogenation has been reported for conjugated carboxylic acids[649] and conjugated ketones.[650] Asymmetric hydrogenation of conjugated carboxylic acids in an ionic liquid is known using a chiral Ru complex[651]

See Reaction **19-36** for methods of reducing C=O bonds in the presence of conjugated C=C bonds.

The C=C unit of conjugated aldehydes has been reduced using $AlMe_3$ with a catalytic amount of CuBr[652] and with ammonium formate/Pd—C.[653] Polymer-supported formate has been used for the 1,4-reduction of conjugated ketones[654] and for conjugated acids using an Rh catalyst and microwave irradiation.[655] Isopropyl alcohol and an Ir catalyst gives conjugate reduction of conjugated ketones.[656] The reaction of conjugated ketones with aluminum chlorides, followed by treatment with water generates the saturated ketone.[657]

Enzymatic reduction of conjugated systems requires the reactivity with certain purified or whole cell enzymes. Baker's yeast reduces conjugated nitro compounds to nitroalkanes[658] and also the C=C unit of conjugated ketones.[659] Other enzymatic reductions are possible. A reductase from *Nicotiana tabacum* reduced a conjugated ketone to the

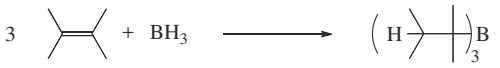
saturated ketone, with excellent enantioselectivity.[660] Enzyme YNAR-I and NADP-H reduces conjugated nitro compounds to nitroalkanes.[661] Conjugated nitro compounds are reduced in the presence of *Clostridium sporogenes*.[662]

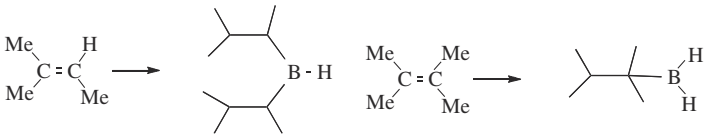
15-15 Reductive Cleavage of Cyclopropanes



Cyclopropanes can be cleaved by catalytic hydrogenolysis.[663] Among the catalysts used have been Ni, Pd, Rh,[664] and Pt. The reaction can often be run under mild conditions.[665] Certain cyclopropane rings, especially cyclopropyl ketones and aryl-substituted cyclopropanes,[666] can be reductively cleaved by an alkali metal (generally Na or Li) in liquid ammonia.[667] Similar reduction has been accomplished photochemically in the presence of $LiClO_4$.[668] This reaction is an excellent way to introduce a *gem*-dimethyl unit into a molecule. Hydrogenation of the cyclopropane ring in **60**, for example, gave the *gem*-dimethyl unit in **61** using PtO_2 (*Adam's catalyst*).[669]

60 **61**

F. A Metal on the Other Side



15-16 Hydroboration

When alkenes are treated with borane[670] in ether solvents, BH_3 adds across the double bond.[671] The alkene reacts as a base with the boron essentially reacting as a Lewis acid. Borane cannot be prepared as a stable pure compound[672] (it dimerizes to diborane, B_2H_6),

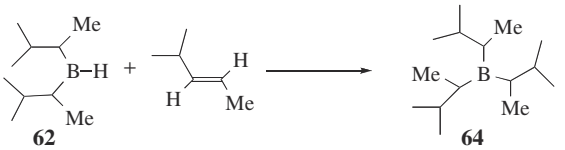
but it is commercially available in the form of "ate" complexes with THF, Me_2S,[673] phosphines, or tertiary amines. The alkenes can be treated with a solution of one of these complexes. Tetrahydrofuran–BH_3 reacts at 0 °C and is the most convenient to use and $R_3N—BH_3$ generally require temperatures of ~100 °C. The latter can be prepared as air-stable liquids or solids, while the former can only be used as relatively dilute solutions in THF and are decomposed by moisture in air) or with a mixture of $NaBH_4$ and BF_3 etherate, which generates borane *in situ*.[674] Pyridine–borane can be used for the hydroboration of alkenes at room temperature.[675] With relatively unhindered alkenes, the process cannot be stopped with the addition of one molecule of BH_3 because the resulting RBH_2 adds to another molecule of alkene to give R_2BH, which in turn adds to a third alkene molecule, so that the isolated product is a trialkylborane (R_3B). The reaction can be performed on alkenes with one to four substituents, including cyclic alkenes, but when the alkene is moderately hindered, the product *is* the dialkylborane (R_2BH) or even the monoalkylborane (RBH_2).[676] For example, **62** (*disiamylborane*) and **63** (*thexylborane*)[677] have been prepared in this manner. Monoalkylboranes (RBH_2), which can be prepared from hindered alkenes, (as above) and dialkylboranes (R_2BH) also add to alkenes, to give the mixed trialkylboranes (RR'_2B and $R_2R'B$), respectively. Surprisingly, when methylborane ($MeBH_2$),[678] which is not a bulky molecule, adds to alkenes in the solvent THF, the reaction can be stopped with one addition to give dialkylboranes (RMeBH).[679] Reaction of this with a second alkene produces the trialkylborane (RR′MeB).[680] Other monoalkylboranes (*i*$PrBH_2$, *n*-$BuBH_2$, *s*-$BuBH_2$, and *t*-$BuBH_2$), behave similarly with internal alkenes, but not with alkenes of the type $RCH=CH_2$.[681]



Disiamylborane **62** Thexylborane **63**

In all cases, the boron goes to the side of the double bond that has more hydrogen atoms (less substituted), whether the substituents are aryl or alkyl.[682] Technically, this follows *Markovnikov's rule*, since boron is more positive than hydrogen. The regioselectivity is caused mostly by steric factors, although electronic factors also play a part. Studies of the effect of ring substituents on rates and on the direction of attack in hydroboration of

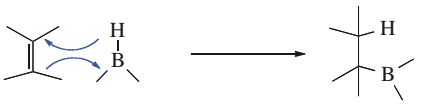
substituted styrenes showed that the reaction with boron and the alkene has electrophilic character.[683] When both sides of the double bond are monosubstituted or disubstituted, about equal amounts of each isomer are obtained. However, it is possible in such cases to make the addition regioselective by the use of a large borane molecule. For example, treatment of *i*PrCH=CHMe with borane gave 57% of product with boron on the methyl-bearing carbon and 43% of the other, while treatment with **62** gave 95% **64** and only 5% of the other isomer.[684]



62 **64**

Another reagent with high regioselectivity is 9-borabicyclo[3.3.1]nonane (9-BBN, **65**), which is prepared by hydroboration of 1,5-cyclooctadiene,[685] and has the advantage that it is stable in air. Borane is quite unselective and attacks all sorts of double bonds. Disiamylborane, 9-BBN, and similar molecules are far more selective and preferentially react at the less-hindered bonds, so it is often possible to hydroborate one double bond in a molecule and leave others unaffected or to hydroborate one alkene in the presence of a less reactive alkene.[686] For example, 1-pentene can be removed from a mixture of 1- and 2-pentenes, and a *cis*-alkene can be selectively hydroborated in a mixture of the cis and trans isomers.

65

For most substrates, the addition in hydroboration is stereospecific and syn, with attack taking place from the less-hindered side.[687] Note that organoboranes can be analyzed using ^{11}B NMR.[688] The mechanism[689] may be a cyclic four-center one:[690]

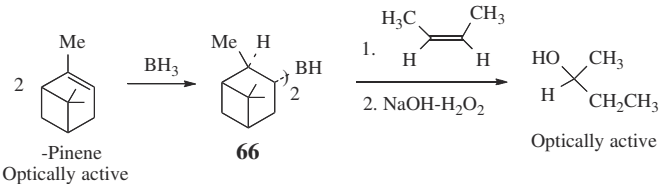
When the substrate is an allylic alcohol or amine, the addition is generally anti,[691] although the stereoselectivity can be changed to syn by the use of catecholborane and Rh complexes.[692] Because the mechanism is different, use of this procedure can result in a change in regioselectivity as well (e.g., styrene, $PhCH{=}CH_2$, gave $PhCH(OH)CH_3$).[693]

Monochloroborane[694] (BH_2Cl) coordinated with DMS shows greater regioselectivity than BH_3 for terminal alkenes or those of the form $R_2C{=}CHR$, and the hydroboration product is a dialkylchloroborane (R_2BCl).[695] For example, 1-hexene gave 94% of the *anti-Markovnikov* product (the boron is on the less substituted carbon) with BH_3—THF, but 99.2% with $BH_2Cl^-SMe_2$. Treatment of alkenes with dichloroborane–DMS ($BHCl_2$—SMe_2) in the presence of BF_3[696] or with BCl_3 and Me_3SiH[697] gives alkyldichloroboranes ($RBCl_2$). Extensions of this basic approach are possible with dihalo alkylboranes. The reaction of an alkene with allyl dibromoborane, incorporated an allyl group and the boron on adjacent carbons.[698]

An important use of the hydroboration reaction is oxidation of an organoborane to alcohols with H_2O_2 and NaOH (see Reaction **12-27**). The synthetic result is an indirect way of adding H_2O across a double bond in an *anti-Markovnikov* manner. However, boranes undergo many other reactions as well. Among other things, they react with α-halo carbonyl compounds to give alkylated products (Reaction **10-73**), with α,β-unsaturated carbonyl compounds to give *Michael-type* addition of R and H (Reaction **15-27**), with CO to give alcohols and ketones (Reactions **18-23**–**18-24**); they can be reduced with carboxylic acids (Reaction **15-11**), or they can be oxidized with chromic acid or pyridinium chlorochromate to give ketones[699] or aldehydes (from terminal alkenes),[700] dimerized with silver nitrate and NaOH (Reaction **14-26**), isomerized (Reaction **18-11**), or converted to amines (Reaction **12-32**), halides (Reaction **12-31**), or carboxylic acids.[701] They are thus useful intermediates for the preparation of a wide variety of compounds. Intramolecular hydroboration reactions are possible.[702]



Such functional groups as OR, OH, NH_2, SMe, halogen, and CO_2R may be present in the molecule,[703] but not groups that are reducible by borane (e.g., COOH). Hydroboration of enamines with 9-BBN provides an indirect method for reducing an aldehyde or ketone to an alkene, for example,[704]

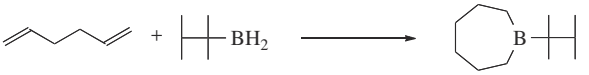
The presence of certain functional groups has directing effects on hydroboration reactions. Amides direct hydroboration reactions in alkenyl amides, for example.[705] Intramolecular hydroboration is directed by amine groups in alkenyl amines.[706] Alkenyl alcohols or ethers also undergo hydroboration, where delivery of boron is directed by the oxygen.[707]

Use of the reagent diisopinocampheylborane (**66**, prepared by treating optically active α-pinene with BH_3) results in enantioselective hydroboration–oxidation.[708] Since both (+) and (−) α-pinene are readily available, both enantiomers can be prepared. Alcohols with moderate-to-excellent enantioselectivities have been obtained



in this way.[709] However, **66** does not give good results with even moderately hindered alkenes; a better reagent for these compounds is isopinocampheylborane[710] although optical yields are lower. Limonylborane,[711] 2- and 4-dicaranylboranes,[712] a myrtanylborane,[713] and dilongifolylborane[714] have also been used. Other new asymmetric boranes have also been developed. The chiral cyclic boranes *trans*-2,15-dimethylborolanes (**67** and **68**) also add enantioselectively to alkenes (except alkenes of the form $RR'C{=}CH_2$) to give boranes of high optical purity.[715] When chiral boranes are added to trisubstituted alkenes of the form $RR'C{=}CHR''$, two new chiral centers are created, and, with **67** or **68**, only one of the four possible diastereomers is predominantly produced, in yields >90%.[715] This has been called *double-asymmetric synthesis*.[716] An alternative asymmetric synthesis of alcohols involves the reaction of catechol borane with an alkene in the presence of a chiral Rh catalyst, giving the alcohol enantioselectivity after the usual oxidation.[717]

The double bonds in a conjugated diene are hydroborated separately; that is, there is no 1,4-addition. However, it is not easy to hydroborate just one of a conjugated system, since conjugated double bonds are less reactive than isolated ones. Thexylborane[677] (**63**) is particularly useful for achieving the cyclic hydroboration of dienes, conjugated or nonconjugated, as in the formation of **69**.[718]

63 **69**

Rings of five, six, or seven members can be formed in this way. Similar cyclization can also be accomplished with other monoalkylboranes and, in some instances, with BH_3 itself.[719] One example is the formation of 9-BBN, shown above. Another is conversion of 1,5,9-cyclododecatriene to perhydro-9*b*-boraphenalene (**70**).[720]

70

Boronate esters are prepared from alkenes. The reaction of an alkene with pyridine iodoborane, followed by treatment with pinacol and NaOH, for example, leads to the pinacol boronate ester.[721]

Triple bonds[722] can be monohydroborated to give vinylic boranes, which can be reduced with carboxylic acids to *cis*-alkenes or oxidized and hydrolyzed to aldehydes or ketones. Terminal alkynes give aldehydes by this method, in contrast to the mercuric or acid-catalyzed addition of water discussed in Reaction **15-4**. However, terminal alkynes give vinylic boranes[723] (and hence aldehydes) only when treated with a hindered borane (e.g., **62**, **63**, or catecholborane, Reaction **12-31** and Sec. 14.A.i),[724] or with $BHBr_2—SMe_2$.[725] The reaction between terminal alkynes and BH_3 produces 1,1-dibora compounds, which can be oxidized either to primary alcohols (with $NaOH—H_2O_2$) or to carboxylic acids (with *m*-chloroperoxybenzoic acid).[726] Double bonds can be hydroborated in the presence of triple bonds if the reagent is 9-BBN.[727] On the other hand, dimesitylborane selectively hydroborates triple bonds in the presence of double bonds.[728] Furthermore, it is often

possible to hydroborate selectively one particular double bond of a nonconjugated diene.[729] A triple bond can be hydroborated in the presence of a ketone, and treatment with acetic acid reduces the C≡C unit to a *cis*- alkene (see Reaction **15-12**).[730] When the reagent is catecholborane, hydroboration is catalyzed by Rh complexes,[731] (e.g., *Wilkinson's catalyst*, **46**,[732] by SmI_2,[733] or lanthanide reagents).[734] Enantioselective hydroboration–oxidation has been achieved by the use of optically active Rh complexes.[735]

A chain extension variation involved the reaction of styrene with catecholborane and then Me_3SiCHN_2.[736] Subsequent oxidation with $NaOH/H_2O_2$ and the reaction with Bu_4NF gave 3-phenyl-1-propanol.

15-17 Other Hydrometalation

Hydro-metallo-addition

Metal hydrides of Groups 13 and 14 of the periodic table (e.g., AlH_3, GaH_3), as well as many of their alkyl and aryl derivatives (e.g., R_2AlH and Ar_3SnH) add to double bonds to give organometallic compounds.[737] In each case, the alkene reacts with the Lewis acid. The hydroboration reaction (**15-16**) is the most important example but, as mentioned, other important metals in this reaction are Al,[738] Sn,[739] and Zr[740] (a Group 4 metal). Some of these reactions are uncatalyzed, but in other cases various types of catalyst have been used.[741] Hydrozirconation is most commonly carried out with Cp_2ZrHCl (Cp = cyclopentadienyl),[742] known as *Schwartz's reagent*. The mechanism with Group 13 hydrides seems to be electrophilic (or four-centered pericyclic with some electrophilic characteristics) while with Group 14 hydrides a mechanism involving free radicals seems more likely. Dialkylmagnesium reagents have been obtained by adding MgH_2 to double bonds.[743]

With some reagents triple bonds[744] can add 1 or 2 equiv.[745] When 2 molar equivalents are added, electrophilic addition generally gives 1,1-dimetallic products (as with hydroboration), while free radical addition usually gives the 1,2-dimetallic products.

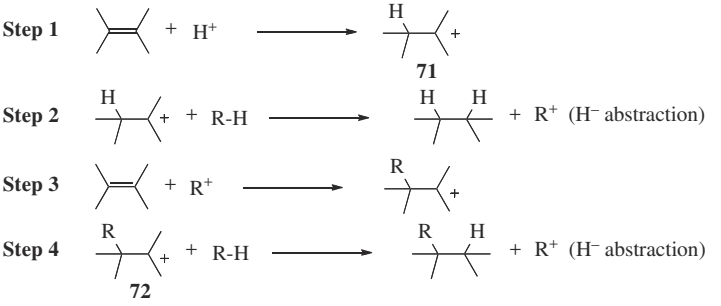
G. Carbon or Silicon on the Other Side

15-18 Addition of Alkanes

Hydro-alkyl-addition

There are two important ways of adding alkanes to alkenes: direct heating, and acid catalysis.[746] Both give mixtures, and neither is useful for the preparation of relatively pure compounds in reasonable yields. However, both are useful industrially. In the thermal method, the reactants are heated to high temperatures (~500 °C) at high pressures (150–300 atm) without a catalyst. As an example, propane and ethylene gave 55.5% isopentane, 7.3% hexanes, 10.1% heptanes, and 7.4% alkenes.[747] The mechanism is undoubtedly of a free radical type and can be illustrated by one possible sequence in the reaction between propane and ethylene:



Step 1 $CH_3CH_2CH_3 + CH_2{=}CH_2 \xrightarrow{\Delta} CH_3{-}\dot{C}H{-}CH_3 + CH_3CH_2^{\bullet}$

Step 2 $CH_3{-}\dot{C}H{-}CH_3 + CH_2{=}CH_2 \longrightarrow (CH_3)_2CHCH_2CH_2^{\bullet}$

Step 3 $(CH_3)_2CHCH_2CH_2^{\bullet} + CH_3CH_2CH_3 \longrightarrow (CH_3)_2CHCH_2CH_3 + CH_3\dot{C}HCH_3$

There is kinetic evidence that the initiation takes place primarily by steps like 1, which are called *symproportionation* steps[748] (the opposite of disproportionation, see Sec. 5.C.ii).

In the acid-catalysis method, a protonic or Lewis acid is used as the catalyst and the reaction is carried out at temperatures between –30 and 100 °C. This is a *Friedel–Crafts* process that proceeds via a carbocation mechanism[749] (illustrated for a proton acid catalyst):

[744] See Hudrlik, P.F.; Hudrlik, A.M. in Patai, S. *The Chemistry of the Carbon–Carbon Triple Bond,* pt. 1, Wiley, NY, ***1978***, pp. 219–232.

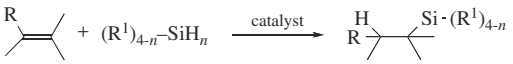
Carbocation **72** often rearranges before a hydride is transferred, explaining, for example, why the principal product from the reaction between isobutane and ethylene is 2,3-dimethylbutane. Instead of abstracting a hydride, it is also possible for **71** (or **72**) to add to another molar equivalent of alkene, so that not only rearrangement products, but also dimeric and polymeric products, are frequent. If the tri- or tetrasubstituted alkenes are treated with Me_4Si, HCl, and $AlCl_3$, protonation gives a tertiary carbocation, which reacts with the Me_4Si to give a product that is the result of addition of H and Me to the original alkene.[750] (For a free radical hydro-methyl addition, see Reaction **15-28**.) An intramolecular cyclization of 1-dodecene to cyclododecane was reported using aluminum chloride in an ionic liquid.[751]

Alkanes add to alkynes under photolysis conditions to give an alkene.[752] Tetrahydrofuran adds to alkynes to give the alkene with microwave irradiation.[753]

The reaction can also be base catalyzed, in which case there is nucleophilic addition and a carbanion mechanism.[754] Carbanions most often used are those stabilized by one or more α-aryl groups. For example, toluene adds to styrene in the presence of sodium to give 1,3-diphenylpropane:[755]

$$PhCH_3 \xrightarrow{Na} Ph\overset{+}{C}H_2 + PhCH{=}CH_2 \longrightarrow Ph\overset{+}{C}H{-}CH_2CH_2Ph \xrightarrow{solvent} PhCH_2CH_2CH_2Ph$$

Conjugated dienes give 1,4-addition.[756] This reaction has also been performed with salts of carboxylic acids in what amounts to a method of alkylation of carboxylic acids[757] (see also, Reaction **10-59**).



$$CH_3COOK \xrightarrow{NaNH_2} {}^{-}CH_2COOK + CH_2{=}CH_2 \longrightarrow {}^{-}CH_2{-}CH_2CH_2COOK$$

There are transition metal catalyzed addition reactions of alkyl units to alkenes,[758] often proceeding with metal hydride elimination to form an alkene. An intramolecular cyclization reaction of an *N*-pyrrolidino amide alkene was reported using an iridium catalyst for addition of the carbon α to nitrogen at the alkene unit.[759]

Although silanes bearing at least one Si—H unit do not generally react with alkenes or alkynes, addition occurs to give the corresponding alkyl or vinyl silane in the presence of transition metal catalysts.[760] This reaction is known as hydrosilation. The reaction of an alkylsilane and an alkene with a Ru,[761] Rh,[762] Pd,[763] Re,[764] La,[765] Y,[766] Pt[767] Cu,[768] or Sm[769] catalyst leads to addition with high *anti-Markovnikov* selectivity. Silanes add to dienes with a Pd catalyst, and asymmetric induction is achieved by using a chiral binapthyl additive.[770] Alkenes react with Li metal and t-Bu_2SiCl_2 to give a three-membered ring silane.[771]

Dienes react with zirconium compounds and silanes to produce cyclic compounds in which the silyl group has also added to one C=C unit.[772] With an Y catalyst, $PhSiH_3$ reacts with nonconjugated dienes to give cyclic alkenes with a pendant CH_2SiH_2Ph group.[773] Rhodium compounds allow silanes to add to enamides to give the α-silylamide.[774] Formation of silanes via reaction with alkenes can be followed by reaction with fluoride ion and then oxidation to give an alcohol[775] (see Reaction **10-16**; *Tamao–Fleming oxidation*). A variation of this reaction generated allylic silanes from terminal alkenes and a dianion-type zincate using a Ti catalyst.[776]

In the presence of BEt_3, silanes add to alkenes to give the alkylsilane with *anti-Markovnikov* selectivity,[777] or to alkynes to give the corresponding vinyl silane.[778] Similar selectivity was observed when a silylated zinc reagent was added to a terminal alkyne.[779] Hydrosilation of alkynes is accomplished using transition metal catalysts (e.g., Ru[780] Pt,[781] Ti,[782] or Ir).[783] Organocatalyts have been used as well.[784] Siloxanes [e.g., $(RO)_3SiH$] add to alkynes with a Ru catalyst to give the corresponding vinyl silane.[785] The reaction of Cl_2MeSiH and terminal alkynes, in ethanol–triethylamine with a Ru catalyst, to give

primarily the *Markovnikov* vinyl silane.[786] However, Et_3SiH adds to terminal alkynes with a Rh[787] or a Pt[788] catalyst to give the *anti-Markovnikov* vinyl silane. Using a 0.5 molar equivalent of $HfClO_4$ with alkynes bearing a dimethylphenylsilyl unit gave a cyclic vinyl silane with transfer of the phenyl group to carbon (see **73**).[789]

73

Silanes add to alkenes under radical conditions (using AIBN) with high *anti-Markovnikov* selectivity.[790] An alternative route to alkylsilanes reacted an alkene with Li metal in the presence of 3 equiv of chlorotrimethylsilane, giving bis-1,2-trimethylsilyl compounds after treatment with water.[791] Silanes also add to alkenes to form the *anti-Markovnikov* alkylsilane ($R_3Si—C—C—R'$) in the presence of a hyponitrite.[792]

In a reaction more related to those in Reaction **15-24**, vinyl silanes add to conjugated carbonyl compounds in the presence of a Ru catalyst,[793] or to acrylonitriles with a Co catalyst.[794] Silyl phosphines react with conjugated ynones directly to give an enone with an α-trimethylsilyl and a β-phosphine group.[795] Siloxanes of the type $(RO)_3SiH$ add to the α-carbon of enamines in the presence of a dirhodium catalyst.[796] The uncatalyzed reaction of trimethylsilyl cyanide and ynamines, however, gave an enamine with a β-trimethylsilyl and an α-cyano group.[797]

bis(Silanes) add to alkylidene malonate derivatives (see Reaction **15-24**) in the presence of a Cu catalyst to give β-silyl malonates [$RCH(SiR_3)CH(CO_2Me)_2$].[798] Alkylsilane units add using bis(trialkylsilyl)zinc reagents with a CuCN catalyst.[799] Trimethylsilyl cyanide (Me_3SiCN) adds a cyano group to α,β-unsaturated amines with a specialized Al(salen)-Y catalyst.[800]

15-20 Addition of Alkenes and/or Alkynes to Alkenes and/or Alkynes

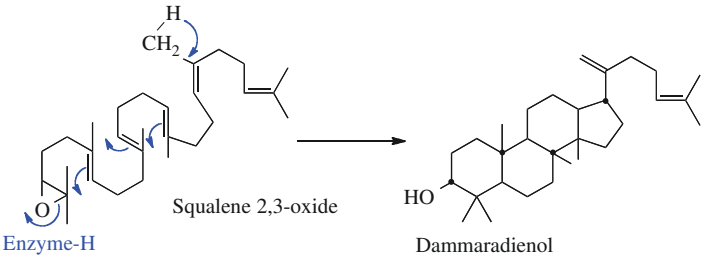
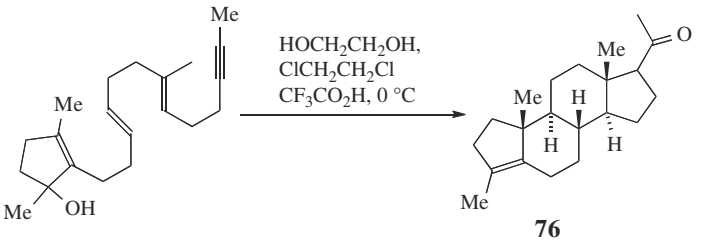
With certain substrates, alkenes can be dimerized by acid catalysts, so that the product is a dimer that contains one double bond.[801] A catalyst comprised of a combination of Zn and a $CoCl_2$ accomplished this type of coupling.[802] One alkene adds to another in the presence of a Ni catalyst.[803] α-Alkenes add to dienes in a 1,4-manner in the presence of an Fe catalyst.[804]

This reaction is more often carried out internally, as in the formation of cyclohexene (**74**). A Pd catalyzed cyclization is known, in which dienes are converted to cyclopentene derivatives (e.g., **75**).[805]



74 **75**



Ring-forming reactions are possible. A Ru catalyzed version of this reaction gave the five-membered ring with an exocyclic double bond.[806] Carbocyclization of an alkene unit to another alkene unit was reported using a Y,[807] or a Ti catalyst.[808] In some cases, internal coupling of two alkenes can form larger rings.[809] Carbocyclization was reported using Pd,[810] Rh,[811] Ru,[812] Ir,[813] or a Zr catalyst.[814] Alkene allene substrates were cyclized to form cyclic products with an exocyclic double bond using a Pd catalyst.[815] An interesting variation adds a silyl enol ether to an alkyne using $GaCl_3$ to give an unconjugated ketone (O=C—C—C=C).[816] Alkenes and alkynes can also add to each other to give cyclic products in other ways (see Reaction **15-63** and **15-65**).

Processes of this kind are important in the biosynthesis of steroids and tetra- and pentacyclic terpenes. For example, squalene 2,3-oxide is converted by enzymatic catalysis to dammaradienol. The squalene → lanosterol biosynthesis, which is a key step in the biosynthesis of cholesterol, is similar. The idea that the biosynthesis of

such compounds involves this type of multiple ring closing was proposed in 1955 and is known as the *Stork–Eschenmoser hypothesis*.[817] Such reactions can also be carried out in the laboratory, without enzymes.[818] By putting cation-stabilizing groups at positions at which positive charges develop, Johnson and co-workers[819] have been able to close as many as four rings stereoselectively and in high yield, in one operation. An example is formation of **76**,[820] by what is known as the *Johnson polyene cyclization*.[821] Lewis acids can be used to initiate this cyclization,[822] including $EtAlCl_2$ used for the coupling of an alkyne and an alkene.[823] A Pd catalyst has been used for a similar cyclization reaction.[824] A radical cyclization approach (Reaction **15-30**) to polyene cyclization using a seleno–ester anchor gave a tetracyclic system.[825]

76

The addition of alkenes to alkenes[826] can also be mediated by bases.[827] Coupling reactions can occur using transition metal catalyst systems[828] (e.g., alkylaluminum

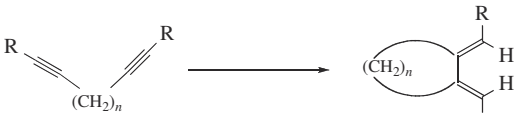
compounds, known as *Ziegler catalysts*),[829] Rh,[830] Fe,[831] or Ni[832] catalysts. The 1,4-addition of alkenes to conjugated dienes to give nonconjugated dienes[833] occurs with various transition metal catalysts, as does the dimerization of 1,3-butadienes to octatrienes.[834] A

molecule containing two distal conjugated diene units was cyclized to give a bicyclic molecule with an exocyclic double bond using a Pd catalyst.[835] A Ni catalyst converted a similar system to a saturated five-membered ring containing an allylic and a vinyl group.[836] Ethylene adds to alkenes to form a new alkene in the presence of a Ni[837] or a Zr catalyst,[838] and to alkynes in the presence of a Ru catalyst[839] to form a diene. Allenes add to alkynes to give a diene with a Ti catalyst.[840]

In the presence of cuprous chloride and ammonium chloride, acetylene undergoes self-coupling to give vinylacetylene. Alkynes are coupled to dienes to give enynes in the presence of a Ni catalyst.[841]



Another type of alkyne dimerization is the reductive coupling in which two molecules of alkyne, the same or different, give a 1,3-diene, as shown.[842] In this method, one alkyne is treated with *Schwartz's reagent* (see Reaction **15-17**) to produce a vinylic zirconium intermediate. Addition of MeLi or MeMgBr, followed by the second alkyne, gives another intermediate, which, when treated with aq acid, gives the diene in moderate-to-good yields.[843]If the second intermediate is treated with I_2 instead of aq acid, the 1,4-diiodo-1,3-diene is obtained, in comparable yield and isomeric purity. The reaction of an alkyne with a *Grignard reagent*, followed by an Fe complex and then an alkene leads to enynes.[844] A Rh catalyzed coupling reaction of alkenes and electron-deficient internal alkynes leads to 1,3-dienes.[845] A combination of Zr and Cr reagents allows the coupling of alkynes to form

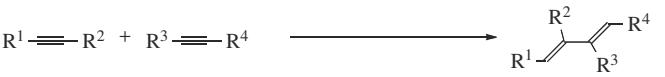
linear polyenes.[846] Alkynes can also be coupled to allylic silyl ethers with a Ru catalyst to give dienes.[847] Other alkyne–allylic coupling reactions are known to give dienes.[848]

This reaction can also be done intramolecularly, as in the cyclization of diyne **77** to (*E*, *E*)-exocyclic dienes (**78**) by treatment with a Zr,[849] Rh,[850] Ru,[851] Au,[852] or Pt complex.[853] A similar reaction was reported using a Ti catalyst from a diyne amide.[854] Rings of four, five, and six members were obtained in high yield; seven-membered rings in lower yield. When the reaction is applied to enynes, compounds similar to **78** are formed using various catalysts, but with only one double bond[855] Larger rings can be formed from the appropriate enyne, including forming cyclohexadiene compounds.[856] Spirocyclic compounds can be prepared from enynes in this manner using formic acid and a Pd catalyst.[857]



77 **78**

The Rh catalyzed cyclization of 1,6-enynes, triggered by arylboronic acids, leads to rings with an exocyclic alkylidene group.[858] Alkynes are coupled to give enynes using Ni,[859] Pd,[860] Lu,[861] and Ru[862] catalysts. Similar products are obtained by cross-coupling terminal alkynes with an allene, using a combination of Pd and CuI catalysts.[863] The reaction has been carried out internally to convert diynes to large-ring cycloalkynes with an exocyclic double bond.[864] Diynes have also been cyclized to form cyclic enynes (an endocyclic double bond) using a diruthenium catalyst with ammonium tetrafluoroborate in methanol.[865] Enynes are similarly cyclized to cyclic alkenes with an endocyclic

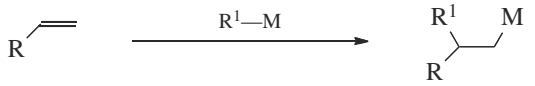
C=C unit using a dicobalt catalyst.[866]

Enynes can also be converted to cyclic and bicyclic compounds using a Au[867] Rh,[868] Fe,[869] or Pd[870] catalyst. Enynes having a conjugated alkene unit also undergo this reaction in the presence of $ZnBr_2$.[871] Using mercury(II) triflate in water, cyclization leads to five-membered rings having an exocyclic double bond, and a pendant alcohol group.[872] Enynes give cyclic compounds with an endocyclic double bond conjugated to another alkene unit (a conjugated diene) when treated with $GaCl_3$[873] or a Pt catalyst in an ionic liquid.[874] Allene–alkenes give a similar product with a Pd[875] or a Ru catalyst,[876] as do alkyne–allenes with a dirhodium catalyst.[877]



There are many useful variations. Internal coupling of an alkyne with a vinyl halide, using triethylsilane and a Pd catalyst, gave the saturated cyclic compound with two adjacent exocyclic double bonds (a 2,3-disubstituted diene).[878] Alkynes are added to propargyl acetates using Pd catalyst to give an alkyne–allene.[879] Alkyne–alkenes were formed by coupling terminal alkynes and allenes in the presence of a Pd catalyst.[880] An alkyne was coupled internally to give an allene using a Pd catalyst, to give an product that has an exocyclic methylene group and a vinyltin derivative.[881] A similar process occurred with $RhCl(PPh_3)_3$ to incorporate a vinyl chloride.[882] Allene–allylic halide systems reacted with phenylboronic acid and a Pd catalyst to give cyclopentane rings with two pendant vinyl groups, one of which contained a phenyl group.[883]

15-21 Addition of Organometallics to Double and Triple Bonds Not Conjugated to Carbonyls

Hydro-alkyl-addition

Neither *Grignard reagents* nor lithium dialkylcopper reagents generally add to ordinary C=C double bonds in the absence of a transition metal catalyst.[884] *Grignard reagents* usually add only to double bonds susceptible to nucleophilic attack (e.g., fluoroalkenes and tetracyanoethylene).[885] However, active *Grignard reagents* (benzylic, allylic) also add to the double bonds of allylic amines,[886] and of allylic and homoallylic alcohols,[887] as well as to the triple bonds of propargyl alcohols and certain other alkynols.[888] Transition metal complexes facilitate the addition of *Grignard reagents* to alkenes. Examples include Ti,[889] Mn,[890] Zr,[891] Ni,[892] Fe,[893] and Cu compounds.[894] Cyclopropenes are an exception, and an excess of a Grignard reagent will add at low temperatures.[895] Cyclopropene derivatives also react with CuI and then allyl bromide.[896]

Benzylic alkenes react with silylmethyl *Grignard reagents* in the presence of oxygen.[897] It is likely that cyclic intermediates are involved in these cases, in which the Mg coordinates with the heteroatom. Allylic, benzylic, and tertiary alkyl *Grignard reagents* also add to 1-alkenes and strained internal alkenes (e.g., norbornene), if the reaction is carried out in a hydrocarbon solvent (e.g., pentane) rather than ether, or in the alkene itself as solvent, heated, under pressure if necessary, to 60–130 °C.[898] Yields are variable.

Intramolecular addition of RMgX to completely unactivated double and triple bonds has been demonstrated.[899] The reaction of tosylates bearing a remote alkene unit and a *Grignard reagent* leads to cyclization when a Zr catalyst is used.[900] The intramolecular

addition of a CH_2Br unit to the C=C unit of an allylic ether was accomplished using PhMgBr and a Co catalyst, give a functionalized THF and incorporation of the phenyl group on the C=C unit as well.[901]

In a useful variation, vinyl epoxides react with *Grignard reagents* and CuBr to give an allylic alcohol via reaction at the C=C unit and concomitant opening of the epoxide.[902] Conjugated dienes react with arylmagnesium halides, Ph_3SiCl, and a Pd catalyst to give a coupling product involving the reaction of 2 equiv of the diene and incorporation of two $SiPh_3$ units.[903] The Cr catalyzed formation of arylmagnesium compounds[904] and the Rh catalyzed hydroarylation[905] of alkynes are also known. The Pd catalyzed hydroarylation[906] of alkynes is possible using arenediazonium salts[907] as substrates or hydroarylation of 1,3-dienes with boronic acids.[908]

Organolithium reagents (primary, secondary, and tertiary alkyl and in some cases aryl) add to the double and triple bonds of allylic and propargylic alcohols,[909] (tetramethylethylenediamine is a catalyst) and also to certain other alkenes containing hetero groups (e.g., OR, NR_2, or SR). Mixing an organolithium reagent with transition metal compounds [e.g., $CeCl_3$[910] or $Fe(acac)_3$][911] leads to addition of the alkyl group. Cyclopropane derivatives have been formed in this manner.[912] The organolithium reagents can contain heteroatoms (e.g., nitrogen) elsewhere in the molecule, and the organolithium species can be generated from an intermediate organotin derivative.[913] Organolithium reagents add to the less substituted C=C unit of conjugated dienes.[914] Addition of butyllithium to alkenes has been observed with good enantioselectivity when sparteine was added.[915]

The intramolecular addition of RLi and R_2CuLi has been reported.[916] Organolithium reagents containing an alkene[917] or alkyne[918] unit cyclize[919] at low temperatures and

quenching with methanol replaces the new C—Li bond with C—H. Tandem cyclization is possible with dienes and enynes to form more than one ring,[920] including bicyclic compounds.[921] Tandem cyclization is possible with alkyne iodides[922] or alkynes with a homoallylic CH_2Li unit.[923] The organolithium compound can be generated *in situ* by reaction of an organotin compound with butyllithium, allowing cyclization to occur upon treatment with an excess of LiCl.[924]

Unactivated alkenes or alkynes[925] react with other organometallic compounds under certain conditions. The Pt catalyzed addition to alkynes leads to functionalized alkenes.[926] Phenylboronic acids add to alkynes in the presence of a Co[927] or a Pd catalyst.[928] Trimethylaluminum reacts with 4-methyl-1-pentene, in the presence of Cl_2ZrCp_2, for example, and subsequent reaction with molecular oxygen leads to (2*R*),4-dimethyl-1-pentanol in good yield and 74% ee.[929] These reagents also add to alkynes.[930] Ruthenium catalysts have been used to mediate the addition of allylic alcohols to alkynes.[931] Samarium iodide (SmI_2) induces cyclization of a halide moiety to an alkyne unit[932] or an alkene unit[933] to form cyclized products. Copper complexes can catalyze similar cyclization to alkenes, even when an ester unit is present in the molecule.[934] Allyl manganese compounds add to allenes to give nonconjugated dienes.[935]

Organomanganese reagents add to alkenes.[936] Manganese triacetate [$Mn(OAc)_3$], in the presence of cupric acetate, facilitates intramolecular cyclization of a halide unit to an alkene.[937] Alkynes react with In reagents [e.g., $(allyl)_3In_2I_3$] to form dienes (allyl substituted alkenes from the alkyne).[938] Allylic halides add to propargyl alcohols using In metal to form the aryl organometallic *in situ*.[939] Allyltin reagents add to alkynes in a similar manner in the presence of $ZrCl_4$.[940] Alkylzinc reagents add to alkynes to give substituted alkenes in the presence of a Pd catalyst.[941] Allylzinc reagents add to alkynes in

the presence of a Co catalyst.[942] A vinyltellurium reagent adds to alkynes in the presence of $CuI/PdCl_2$.[943]

Ketones with an α-hydrogen add to alkenes intramolecularly when heated in a sealed tube with $CuCl_2$ and a Pd catalyst.[944] A similar reaction was reported using $Yb(OTf)_3$ and a Pd catalyst[945] or an In catalyst.[946] Keto esters add to alkynes using 10% benzoic acid and a Pd catalyst,[947] or an In catalyst.[948] 1,3-Diketones add to dienes (1,4-addition) using a Pd catalyst,[949] a $AuCl_3/AgOTf$ catalyst,[950] and this addition has been done intramolecularly using 2.4 molar equivalents of $CuCl_2$ and a Pd catalyst.[951] The intermolecular addition of diesters (e.g., malonates) to alkynes was accomplished in acetic acid and a Pd catalyst under microwave irradiation.[952] The enolate anion derived from the reaction of a nitrile with potassium *tert*-butoxide added to the less substituted carbon of the C=C unit of styrene in DMSO.[953] Silyl enol ethers add to alkynes using a W catalyst.[954] Malonate derivatives add to alkenes in the presence of an $Al(OR)_3$ catalyst.[955] 1,3-Dicarbonyl compounds add to allenes in the presence of a Pd catalyst.[956]

Aryl iodides add to alkynes using a Pt complex in conjunction with a Pd catalyst.[957] A Pd catalyst has been used alone for the same purpose,[958] and the intramolecular addition of a arene to an alkene was accomplished with a Pd[959] or a $GaCl_3$ catalyst.[960] Alkyl iodides add intramolecularly to alkenes with a Ti catalyst,[961] or to alkynes using In metal and additives.[962] The latter cyclization of aryl iodides to alkenes was accomplished with In and I_2[963] or with SmI_2.[964]

Aromatic hydrocarbons (e.g., benzene) add to alkenes using a Ru catalyst[965] a catalytic mixture of $AuCl_3/AgSbF_6$,[966] or a Rh catalyst,[967] and Ru complexes catalyze the addition

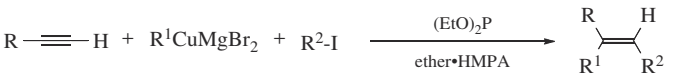
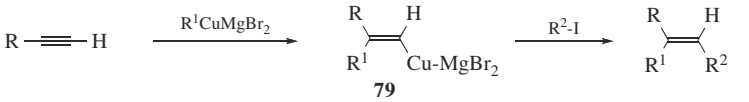
of heteroaromatic compounds (e.g., pyridine) to alkynes.[968] Such alkylation reactions are clearly reminiscent of the *Friedel–Crafts* reaction (**11-11**). Palladium catalysts can also be used for the addition of aromatic compounds to alkynes,[969] and Rh catalysts for addition to alkenes (with microwave irradiation).[970] Note that vinylidene cyclopropanes react with furans and a Pd catalyst to give allylically substituted furans.[971]



Arylboronic acids (see Reaction **13-13**) add to alkynes to give the substituted alkene using a Rh catalyst.[972] Allenes react with phenylboronic acid and an aryl iodide, in the presence of a Pd catalyst, to give a substituted alkene.[973] 2-Bromo-1,6-dienes react with phenylboronic acid with a Pd catalyst to give a cyclopentane with an exocyclic double bond and a benzyl substituent.[974]

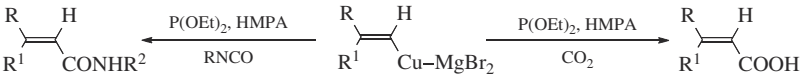
An indirect addition converts alkynes to an organozinc compound using a Pd catalyst, which then reacts with allylic halides.[975] Similarly, the reaction of an alkyne with $Ti(OiPr)_4$/2 *i*PrMgCl followed by addition of an alkyne leads to a conjugated diene.[976]

OS 81, 121.



15-22 The Addition of Two Alkyl Groups to an Alkyne

Dialkyl-addition



Two different alkyl groups can be added to a terminal alkyne[977] in one laboratory step by treatment with an alkylcopper–magnesium bromide reagent (called *Normant reagents*)[978] and an alkyl iodide in ether–HMPA containing triethylphosphite.[979] The groups add stereoselectively syn. The reaction, which has been applied to primary[980] R′ and to primary, allylic, benzylic, vinylic, and α-alkoxyalkyl R′, involves initial addition of an intermediate alkylcopper reagent,[981] followed by a coupling reaction (**10-57**):

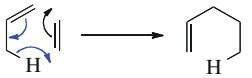
79

Acetylene itself (R = H) undergoes the reaction with R_2CuLi instead of the *Normant reagent*.[982] The use of R′ containing functional groups has been reported.[983] If the alkyl iodide is omitted, the vinylic copper intermediate (**79**) can be converted to a carboxylic acid by the addition of CO_2 (see Reaction **16-30**) or to an amide by the addition of an isocyanate, in either case in the presence of HMPA and a catalytic amount of triethyl phosphite.[984] The use of I_2 results in a vinylic iodide.[985]



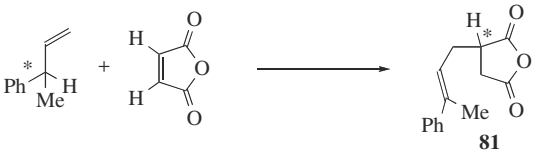
Similar reactions, in which two alkyl groups are added to a triple bond, have been carried out with trialkylalanes (R_3Al) and zirconium complexes as catalysts.[986] Internal alkynes undergo bis(allylation) using a Ni catalysts and triallylindium.[987] Allyl ethers and iodobenzene have also been added using a Zr complex.[988] Similarly, allyl ethers and allyl chlorides have been added.[989]

Arylboronic acids (see Reaction **13-13**) react with alkynes and 1 equiv of an aryl iodide, with a Pd catalyst, to add two aryl groups across the triple bond.[990]

OS **VII**, 236, 245, 290.

15-23 The Ene Reaction

Hydro-allyl-addition



80

An interesting addition of RH to a double bond involves the reaction of alkenes with an alkene having an allylic hydrogen (**80**), and is called the *ene reaction* or the *ene synthesis*.[991] The reaction proceeds without a catalyst, but one of the components must

be a reactive dienophile (reacts with a diene; see Reaction **15-60** for a definition of this word), such as maleic anhydride, but the other (which supplies the hydrogen) may be a simple alkene (e.g., propene) as long as there is an allylic hydrogen atom. Rather high reaction temperatures (250–450 °C) are common unless the substrates are very activated, but steric acceleration of the uncatalyzed ene reaction is known.[992] The reaction is compatible with a variety of functional groups that can be appended to the ene and dienophile. N,N-Diallyl amides give an ene cyclization, for example.[993] There has been much discussion of the mechanism of this reaction, and both concerted pericyclic (as shown above) and stepwise mechanisms have been suggested. The mechanism of the ene reaction of singlet ($^1\Delta_g$) oxygen with simple alkenes was found to involve two steps, with no intermediate.[994] A retro-ene reaction is known with allylic dithiocarbonate.[995] An intramolecular ene reaction between oxazolones and enol ethers leads to functionalized oxazolones.[996] The reaction between maleic anhydride and optically active PhCHMeCH=CH_2 gave an optically active product (**81**),[997] which is strong evidence for a concerted rather than a stepwise mechanism.[998] The reaction can be highly stereoselective.[999]

81

The reaction can be extended to less-reactive enophiles by the use of Lewis acid catalysts, especially alkylaluminum halides.[1000] Titanium catalysts,[1001] Sc,[1002] $LiClO_4$[1003] Y,[1004] In,[1005] Pd,[1006] Co,[1007] Ni catalysts,[1008] as well as a combination of Ag and Au catalysts[1009] have also been used. A magnesium–ene cyclization stereochemically directed by an allylic oxyanionic group has been reported.[1010] The Lewis acid catalyzed reaction

probably has a stepwise mechanism.[1011] An Ir catalyzed ene reaction has been done in an ionic liquid.[1012] An ene reaction of arynes with alkynes leads to aryl allenes.[1013] An *aza–ene reaction*[1014] has been used in a synthesis of enantioenriched piperidines, using two different imines as starting materials.[1015] Ene reactions of imines are sometimes called *imino–ene reactions*.[1016]

The *carbonyl–ene reaction*[1017] is also very useful, and often gives synthetically useful yields of products when catalyzed by Lewis acids.[1018] Scandium triflate[1019] and chromium complexes[1020] are useful Lewis acids in this reaction. Asymmetric catalysts[1021] for enantioselective carbonyl ene reactions have been reported using chiral Sc catalysts[1022] In,[1023] or chiral Ni catalysts.[1024] Ketoester ene reactions with silyl enol ethers occurs in the presence of Pd and Ag catalysts.[1025] Carbonyl–ene cyclization has been reported on silica gel at high pressure (15 kbar).[1026] Ene reactions with imines,[1027] nitrile oxides,[1028] as well as nitroso–ene reactions are known.[1029] Vinyl boronates have been prepared via a Ru catalyzed ene reaction.[1030]

OS **IV**, 766; **V**, 459. See also, OS **VIII**, 427.

15-24 The Michael Reaction

Hydro-bis(ethoxycarbonyl)methyl-addition, and so on

Compounds containing electron-withdrawing groups (Z is defined in Sec. 15.A.ii as an electron-withdrawing group) add to alkenes of the form C=C—Z in the presence of bases.[1031] This is called the *Michael reaction* and is formally a conjugate addition.[1032] The

product formed, RCH_2Z or $RCHZZ'$, can include aldehydes,[1033] ketones,[1034] esters,[1035] diesters,[1036] diketones,[1037] keto-esters,[1038] carboxylic acids, dicarboxylic acids,[1039] nitriles,[1040] vinyl sulfones,[1041] nitro compounds (see below),[1042] and others of the form ZCH_3, ZCH_2R, $ZCHR_2$, and $ZCHRZ'$. [1043] In the most common examples, a base removes the acidic proton from the substrate adding to C=C—Z and the mechanism is as outlined in Section 15.A.ii. *Michael addition* is known to be catalyzed by phosphines,[1044] as well as other organocatalysts.[1045] Catalysts are known that are compatible with an aqueous medium.[1046] A double *Michael* process is possible, where conjugate addition to an alkynyl ketone is followed by an intramolecular *Michael reaction* to form a functionalized ring.[1047] Vinylogous *Michael* reactions are well known, using a variety of nucleophilic species[1048] (see Sec. 6.B for vinylogy). 1,6-Additions are also known.[1049] Arylsilanes add to conjugated esters and amides in the presence of a Rh catalyst.[1050] Nitro compounds add to conjugated ketones via *Michael addition*.[1051] Niroalkenes are *Michael* acceptors[1052] for the enolate anions of β-keto esters[1053] or malonate derivatives with a Ni catalyst[1054] or

an organocatalyst.[1055] Other substrates have been added to nitroalkenes via *Michael addition*.[1056] Malonate derivatives also add to conjugated ketones,[1057] and keto esters add to conjugated esters.[1058] Vinyl sulfones undergo *Michael addition*.[1059]

It is known that 1,2-addition (to the C=O or C≡N group) often competes and sometimes predominates (Reaction **16-38**).[1060] In particular, α,β-unsaturated *aldehydes* seldom give 1,4-addition.[1061] The *Michael reaction* generally gives better yields with fewer side reactions by conversion of the nucleophile to its enolate form (a *preformed enolate*).[1062] Phase-transfer catalysts have been used,[1063] and ionic liquids have been used in conjunction with phase-transfer catalysis.[1064] Transition metal compounds Ce,[1065] Yb,[1066] Bi,[1067] Fe,[1068] Ni,[1069] Cu,[1070] La,[1071] Ru,[1072] or Sc[1073] also induce the reaction Conjugate addition has also been promoted by Y-zeolite,[1074] and water-promoted *Michael additions* have also been reported.[1075] Acylsilanes, when treated with fluoride ion, add to conjugated amides under certain conditions.[1076] Addition to the meta-position of phenolic compounds leads to bicyclic ketones.[1077] Conjugate addition of nitrones using SmI_2 has

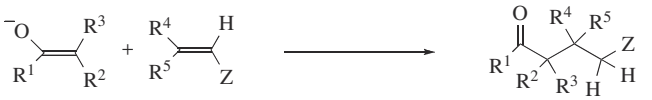
been reported.[1078] Cyanide ion adds to *Michael* acceptors, and TMSCN also adds in a *Michael reaction*.[1079]

Intramolecular versions of *Michael addition* are known.[1080] The intramolecular *Michael addition* of an α-chloro ketone enolate anion, formed *in situ* using DABCO, leads to formation of a bicyclo[4.1.0] diketone.[1081]



82 **83**

An important cyclization procedure involves the acid-catalyzed addition of dieneketones (e.g., **82**), where one conjugated alkene adds to the other conjugated alkene to form cyclopentenones (**83**). This is called the *Nazarov cyclization*.[1082] While it may be categorized in Reaction **15-20** because one alkene unit adds to another, the addition is formally a *Michael addition*, and so is placed here. Structural variations are possible that prepare a variety of cyclopentenones. The steric influence of substituents has been discussed,[1083] and the rate-accelerating influence observed in N- and S-heterocycles.[1084] Substituents on the C=C units lead to cyclopentenones that bear those substituents. Gold[1085] and V catalyzed[1086] cyclizations have been reported, as well as a Sc catalyzed cyclization in water.[1087] Heating dienones in DME or an ionic liquid has been shown to give the *Nazarov* product without addition of a Lewis acid.[1088] Allenes participate in *Nazarov cyclization* reactions.[1089] A vinylogous *Nazarov reaction* is involved in the cyclization of cross-conjugated trienes[1090] (see Sec. 6.B for vinylogy). The use of a chiral ligand gave the cyclopentenone with modest enantioselectivity.[1091] Reductive cyclization can also give the nonconjugated five-membered ring.[1092] Note that a *retro*-Nazarov is possible with α-bromocyclopentanones.[1093] In one variation using an Al complex, a

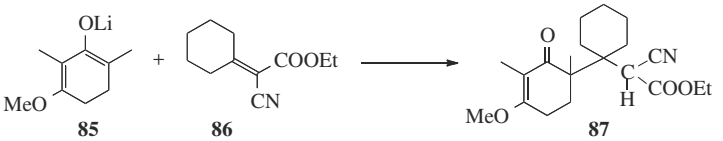
cyclohexenone was formed.[1094] There is a so-called interrupted *Nazarov*, in which an amine is trapped after cyclization to give an α-amino conjugated cyclopentenone.[1095] Spirocycles have been prepared via a tandem *Nazarov–Wagner–Meerwein* sequence.[1096]



84

In a *Michael reaction* with suitably different R groups, two new stereogenic centers may be created (see **84**). In a diastereoselective process, one of the two pairs is formed exclusively or predominantly as a racemic mixture.[1097] When either or both of the reaction components have a chiral substituent, the reaction can be enantioselective (only one of the four diastereomers formed predominantly).[1098] There are many examples of catalytic enantioselective Michael additions,[1099] often by the use of a chiral catalyst[1100] or by using optically active enamines instead of enolates.[1101] Common chiral catalysts used with carbonyl substrates include Ru,[1102] Ni,[1103] Sr,[1104] and Al(salen) complexes.[1105] Chiral organocatalysts[1106] (e.g., oxazolidinones)[1107] have been developed and chiral imines have also been used.[1108] Certain antibodies have been used to facilitate chiral, intramolecular *Michael addition* reactions.[1109] Enzymes have been used as for asymmetric *Michael reactions*.[1110] Addition of chiral additives to the reaction (e.g., metal–salen complexes,[1111] proline derivatives,[1112] or (−)-sparteine[1113]) lead to product formation with good-to-excellent asymmetric induction. Ultrasound has been used to promote

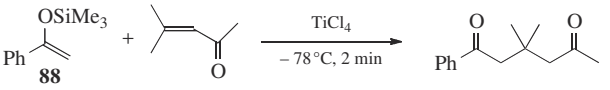
asymmetric *Michael reactions*.[1114] In reactions of enolate anions, both the enolate anion and substrate can exist as (*Z*) or (*E*) isomers. With enolates derived from ketones or carboxylic esters, the (*E*) enolates gave the syn pair of enantiomers (Sec. 4.G), while (*Z*) enolates gave the anti pair.[1115]

When the substrate contains *gem*-Z groups, (e.g., **86**), bulky groups can be added, if the reaction is carried out under aprotic conditions. For example, addition of enolate **85** to **86** gave **87** in which two adjacent quaternary centers have been formed.[1116]

85 **86** **87** (98%)



In certain cases, *Michael reactions* can take place under acidic conditions.[1117] *Michael-type* addition of radicals to conjugated carbonyl compounds is also known.[1118] Radical addition can be catalyzed by $Yb(OTf)_3$,[1119] but radicals add under standard conditions as well, even intramolecularly.[1120] Electrochemical-initiated Michael additions are known.

Alkynes are reactive, and *Michael reactions* are sometimes applied to substrates of the type C≡C—Z, where the coproducts are conjugated systems of the type C=C—Z.[1121] Terminal alkynes add to conjugated systems.[1122] Due to the greater susceptibility of triple bonds to nucleophilic attack, it is even possible for nonactivated alkynes (e.g., acetylene), to be substrates in this reaction.[1123]

Silyl enol ethers (e.g., **88**) add to α,β-unsaturated ketones and esters when catalyzed[1124] by $TiCl_4$[1125] or $InCl_3$.[1126] Aluminum compounds also catalyze this reaction[1127] and the reaction has been done in neat tri-*n*-propylaluminum.[1128] A solid-state version of the reaction used alumina•$ZnCl_2$.[1129] Tin-enolates have been used.[1130] This reaction has been performed with good diastereoselectivity,[1131] and silyl enol ethers have been used

15-25 1,4-Addition of Organocuprates and Other Organometallic Compounds to Activated Double Bonds

Hydro-alkyl-addition

Lithium dialkylcopper reagents (R_2CuLi reagents,[1133] also known as *Gilman reagents*, see Reaction **10-57**) add to α,β-unsaturated aldehydes[1134] and ketones (R′ = H, R, Ar) and other systems of the form C≡C—C=O[1135] to give conjugate addition products[1136] in a reaction closely related to the *Michael reaction*. α,β-Unsaturated esters are less reactive,[1137] and the corresponding acids do not react at all. The R group can be primary alkyl, vinylic,[1138] or aryl. If Me_3SiCl is present, the reaction takes place much faster and in higher yield; in the example given, the product is the silyl enol ether of **89** (see Reaction **12-17**).[1139] The use of Me_3SiCl also permits good yields with allylic R groups.[1140] Conjugated alkynyl-ketones also react via 1,4-addition to give substituted alkenyl-ketones.[1141] Solvent effects are important for the reactivity of organocuprates,[1142] which

influence aggregation and aggregation state of the dialkyl cuprate.[1143] Organocuprate reactions have been shown to undergo oscillations in complexation.[1144]

An excess of the cuprate reagent relative to the conjugated substrate is often required. In general, only one of the R groups of R_2CuLi adds to the substrate; the other is wasted with respect to the conjugated substrate. This can be a limitation where the precursor (RLi or RCu, see Reaction **12-36**) is expensive or available in limited amounts, particularly if an excess of the reagent is required. The difficulty of group transfer can be overcome by using one of the mixed reagents [R(R′C≡C)CuLi,[1145] R(O-*t*-Bu)CuLi,[1146] R(PhS)CuLi[1147] each of which transfers only the R group. Mixed reagents are easily prepared by the reaction of RLi with R′C≡CCu (R′ = *n*-Pr or *t*-Bu), *t*-BuOCu, or PhSCu, respectively. A further advantage of the mixed reagents is that good yields of addition product are achieved when R is tertiary, so that use of one of them permits the introduction of a tertiary alkyl group. The mixed reagents R(CN)CuLi[1148] (prepared from RLi and CuCN) and $R_2Cu(CN)Li_2$[1149] also selectively transfer the R group.[1150] With mixed cuprates, one of the ligands may be less prone to transfer than the other, as $R(R'Se)Cu(CN)Li_2$, leading to selective transfer of the R group.[1151] This less transferable ligand is sometimes referred to as a "dummy ligand". The selectivity of ligand transfer depends on two factors, thermodynamics of groups (e.g., alkyl or thioalkyl) and kinetic reactivity of groups (e.g., silylalkyl or vinyl).[1152] The selectivity arises in the Cu(III) intermediate formed by complexation of the cuprate and the unsaturated carbonyl compound.[1150,1153] A Cu(III) complex has been detected using rapid injection NMR.[1154]

Various functional groups (e.g., OH and unconjugated C=O groups) may be present in the substrate when organocuprates are employed.[1155] There is generally little or no competition from 1,2-addition (to the C=O). However, when R is allylic, 1,4-addition is observed with some substrates and 1,2-addition with others.[1156] The R_2CuLi group also adds to α,β-unsaturated sulfones,[1157] but not to simple α,β-unsaturated nitriles.[1158] Organocopper reagents (RCu) as well as certain R_2CuLi add to α,β-unsaturated and acetylenic sulfoxides.[1159] The reaction has been carried out[1160] with α,β-acetylenic ketones,[1161] esters, and nitriles. Conjugate addition to α,β-unsaturated and acetylenic

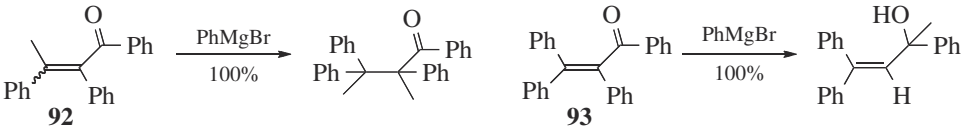
acids and esters, as well as ketones, can be achieved by the use of the coordinated reagents $RCu \bullet BF_3$ (R = primary).[1162] Amine units have been transferred using α-lithio amides, CuCN, and various additives, which gave conjugate addition of an amidomethyl unit [$—CH_2N(Me)Boc$].[1163] Other amino-cuprates are known to give conjugate addition reactions.[1164]

89 **90**

Conjugate addition of the cuprate to the α,β-unsaturated ketone leads to an enolate ion (**89**), as noted above. It is possible for this enolate anion to react with an electrophilic species (*tandem vicinal difunctionalization*), in some cases at the O and in other cases at the C.[1165] For example, if an alkyl halide R^2X is present (R^2 = primary alkyl or allylic), the enolate (**89**) can be alkylated directly to give **90**.[1166] Thus, by this method, both the α and β positions of a ketone are alkylated in one synthetic operation (see also, Reaction **15-22**).



91

79% [84% ee, (*S*)]

As with the *Michael reaction* (**15-24**) the 1,4-addition of organometallic compounds has been performed diastereoselectivity[1167] and enantioselectively.[1168] The influence of solvent and additives on yield and selectivity has been examined.[1169] Addition of chiral ligands to the organocuprate conjugate addition reaction leads to alkylation with good-to-excellent enantioselectivity.[1170] The conjugate addition of dimethyl cuprate in the presence of a chiral ligand (e.g., **91**) is an example.[1171] Chiral bis(oxazoline) copper catalysts have been used for the conjugate addition of indoles to α,β-unsaturated esters.[1172] In the presence of a chiral additive and a Cu catalyst, conjugate addition to trisubstituted cyclohexeneones leads to the formation of stereogenic quaternary centers.[1173] Enantioselectivity was improved by the addition of styrene in the conjugate addition reactions of

α-halo enones.[1174] Enantioselectivity is effectively controlled by the choice of ligand and its interaction with the copper compound, where different ligands on the metal may lead to differences in selectivity.[1175] Chiral templates have also been used with *Grignard reagents*, directly[1176] and in the presence of $AlMe_2Cl$.[1177]

Other organometallic compounds add to conjugated systems. *Grignard reagents* add to conjugated substrates (e.g., α,β-unsaturated ketones, cyano-ketones,[1178] esters, and nitriles),[1179] but 1,2-addition may seriously compete:[1180] The extent of 1,4-addition of *Grignard reagents* can be increased by the use of a Cu catalyst [e.g., CuCl and $Cu(OAc)_2$],[1181] forming a magnesium cuprate *in situ*. Formation of the conjugate addition product is often controlled by steric factors. Thus **92** with phenylmagnesium bromide gives 100% 1,4-addition, while **93** gives 100% 1,2-addition. In general, substitution at the carbonyl group increases 1,4-addition, while substitution at the double bond increases 1,2-addition. In most cases, both products are obtained, but α,β-unsaturated *aldehydes* nearly always give exclusive 1,2-addition when treated with *Grignard reagents*. *Grignard reagents* mixed with $CeCl_3$ generates a reactive species that gives primarily 1,4-addition.[1182] It is likely that alkylcopper reagents, formed from RMgX and Cu^+ (cupric acetate is reduced to cuprous ion by excess RMgX), are the actual reactive species in these cases.[1134] Alkylidene malonic ester derivatives [$C{=}C(CO_2R)$] increase the facility of 1,4-addition with the two electron-withdrawing groups.[1183]

A dialkyl copper–magnesium iodide complex ($R_2Cu \cdot MgI$) has been used for conjugate addition to chiral α,β-unsaturated amides.[1184] Catalytic enantioselective conjugate addition has been reported with Grignard reagents.[1185]

Organolithium reagents[1186] generally react with conjugated aldehydes, ketones, and esters by 1,2-addition,[1187] but 1,4-addition was achieved with esters of the form

C=C—CO_2Ar, where Ar was a bulky group (e.g., 2,6-di-*tert*-butyl-4-methoxyphenyl).[1188] Alkyllithium reagents can be made to give 1,4-addition with α,β-unsaturated ketones[1189] and aldehydes,[1190] if the reactions are conducted in the presence of HMPA.[1191] Among organolithium reagents that have been found to add 1,4 in this manner are 2-lithio-1,3-dithianes (see Reaction **10-71**),[1192] vinyllithium reagents,[1193] and α-lithio allylic amides.[1194] Lithium–halogen exchange (**12-22**) generates an organolithium species that adds intramolecularly to conjugated esters to give cyclic and bicyclic products.[1195] A reagent based on RMgX—3 MeLi gave conjugate addition with α,β-unsaturated amides and carboxylic acid derivatives.[1196] 1,4-Addition of alkyllithium reagents to α,β-unsaturated aldehydes can also be achieved by converting the aldehyde to a benzothiazole derivative (masking the aldehyde function),[1197] from which the aldehyde group can be regenerated. α,β-Unsaturated nitro compounds undergo conjugate addition with aryllithium reagents, and subsequent treatment with acetic acid gives the α-aryl ketone.[1198]

If the organolithium reagent is complexed, 1,4-addition is more successful. The reaction of an aryllithium reagent with $B(OMe)_3$, for example, led to a Rh catalyzed conjugate addition with excellent enantioselectivity when a chiral ligand was employed.[1199] Allylic Te reagents that are treated with lithium diisopropyl amide and then conjugated esters give the 1,4-addition product, which cyclizes to form the corresponding cyclopropane derivative.[1200]

Organozinc compounds add to conjugated systems, especially dialkyl zinc compounds (R_2Zn). Many dialkylzinc compounds can be used, including vinylzinc compounds.[1201] The use of chiral ligands is effective for conjugate addition of dialkylzinc compounds to α,β-unsaturated ketones, esters, and so on,[1202] including conjugated lactones.[1203] The addition of a chiral complex to dialkylzinc compounds leads to enantioselective conjugate addition in conjunction with $Cu(OTf)_2$[1204] CuCN,[1205] or

other copper compounds.[1206] Chiral ionic liquids have also been employed.[1207] Diethylzinc adds to conjugated nitro compounds in the presence of a catalytic amount of Cu $(OTf)_2$ to give the conjugate addition product.[1208] 1,6-Addition of dialkylzinc compounds has been reported, in the presence of a Rh catalyst.[1209] Other transition metal compounds can be used in conjunction with dialkylzinc compounds[1210] or with arylzinc halides (ArZnCl).[1211] Reaction of alkyl iodides with Zn/CuI and ultrasound generates an organometallic that adds to conjugated esters.[1212] Diarylzinc compounds (prepared with the aid of ultrasound) in the presence of nickel acetylacetonate, undergo 1,4-addition not only to α,β-unsaturated ketones, but also to α,β-unsaturated aldehydes.[1213] Mixed-alkylzinc compounds also add to conjugated systems.[1214] Functionalized allylic groups can be added to terminal alkynes with allylic halides, zinc, and ultrasound, to give 1,4-dienes.[1215] Internal alkynes undergo 1,4-addition to conjugated esters using a combination of zinc metal and a Co complex as catalysts.[1216]

Trialkylalanes (R_3Al) add 1,4 to α,β-unsaturated carbonyl compounds in the presence of nickel acetylacetonate[1217] or $Cu(OTf)_2$.[1218] In the presence of aluminum chloride, benzene reacts with conjugated amides to add a phenyl group to C-4.[1219] Alkyl halides react via conjugate addition using BEt_3 or $AlEt_3$.[1220] Other metals are known to catalyzed conjugate addition of alkyl or aryl groups, including Co.[1221] An In/Cu mediated conjugate addition reaction is known using unactivated alkyl iodides.[1222]

Terminal alkynes add to conjugated systems when using a Ru,[1223] Pd,[1224] Ni,[1225] or a Rh catalyst.[1226] Intramolecular addition of terminal alkynes, in the presence of

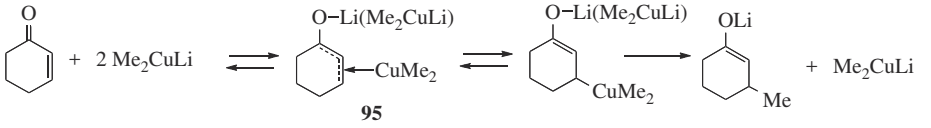
phenylboronic acid and a Rh catalyst, leads to cyclic compounds.[1227] Lithium tetraalkylgallium reagents give 1,4-addition.[1228] Trimethyl(phenyl)tin and a Rh catalyst gives conjugate addition of a methyl group[1229] and tetraphenyltin and a Pd catalyst adds a phenyl group.[1230] Triphenylbismuth (Ph_3Bi) and a Rh catalyst give conjugate addition of the phenyl group upon exposure to air.[1231] Similar reactivity is observed with a Pd catalyst in aqueous media.[1232] Allyltin compounds add an allyl group in the presence of a Sc catalyst.[1233] Benzylic bromides add to conjugated nitriles using a 2:1 mixture of $CrCl_3$ and Mn metal.[1234] Aryl halides add in the presence of $NiBr_2$.[1235] Vinyl Zr complexes undergo conjugate addition when using a Rh catalyst.[1236]

94



In certain cases, *Grignard reagents* add 1,4 to *aromatic* systems to give **94** after tautomerization (Sec. 2.N.i) of the initial formed enol.[1237] Such cyclohexadienes are easily oxidizable to benzenes (often by atmospheric oxygen), so this reaction becomes a method of alkylating and arylating suitably substituted (usually hindered) aryl ketones. A similar reaction has been reported for aromatic nitro compounds where 1,3,5-trinitrobenzene reacts with excess methylmagnesium halide to give 2,4,6-trinitro-1,3,5-trimethylcyclohexane.[1238]

The mechanisms of most of these reactions are not well known. The 1,4-uncatalyzed *Grignard reaction* has been postulated to proceed by the cyclic mechanism shown, but there is evidence against it.[1239] The R_2CuLi[1240] and copper-catalyzed *Grignard additions* may

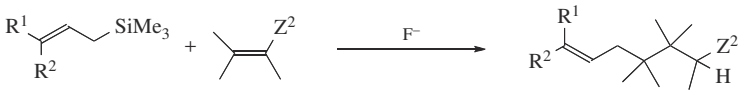
involve a number of mechanisms, since the actual attacking species and substrates are so diverse.[1241] A free radical mechanism of some type (perhaps SET) has been suggested[1242] although the fact that retention of configuration at R has been demonstrated in several cases completely rules out a free $R^{\bullet}$ radical.[1243] For simple α,β-unsaturated ketones (e.g., 2-cyclohexenone and Me_2CuLi), there is evidence[1244] for this mechanism:



95 is a *d*, π* complex, with bonding between copper, as a base supplying a pair of *d* electrons, and the enone as a Lewis acid using the π* orbital of the allylic system.[1242] The ^{13}C NMR spectrum of an intermediate similar to **95** has been reported.[1245]

15-26 The Sakurai Reaction

Allylic silanes ($R_2C{=}CHCH_2SiMe_3$) can be added to conjugated systems rather than silyl enol ethers in what is known as the *Sakurai reaction*.[1246] For example, an allyl group can be added to α,β-unsaturated carboxylic esters, amides and nitriles, with $CH_2{=}CHCH_2SiMe_3$ and F^- ion (see Reaction **15-47**).[1247] This reagent gave better results than lithium diallylcuprate (Reaction **15-25**). Catalytic *Sakurai reactions* are known.[1248] The Pd catalyzed reaction of conjugated ketones with $PhSi(OEt)_3$ and $SbCl_3$ and Bu_4NF in acetic acid gave the 1,4-addition product.[1249] A similar reaction was reported using $PhSi(OMe)_3$ with a Rh catalyst.[1250] Silver fluoride was used to catalyze the reaction with allyl (trimethoxy)silane.[1251] In a related reaction, Ph_2SiCl_2, NaF, and a Rh catalyst gives conjugate addition of a phenyl group to α,β-unsaturated ketones.[1252] An interesting Rh catalyzed, conjugate addition of a phenyl group was reported using a siloxane polymer

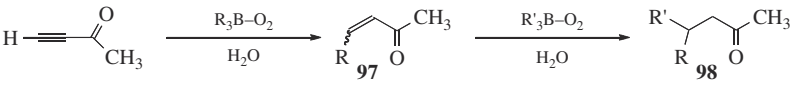
bearing Si—Ph units.[1253] The *Sakurai reaction* has been used in multi-component reactions.[1254]

15-27 Conjugate Addition of Boranes to Activated Double Bonds

Hydro-alkyl-addition (overall transformation)



Just as trialkylboranes add to simple alkenes (Reaction **15-16**), they rapidly add to the double bonds of acrolein, methyl vinyl ketone, and certain related derivatives in THF to give enol borinates (also see Reaction **10-68**), which can be hydrolyzed to aldehydes or ketones.[1255] If water is present in the reaction medium from the beginning, the reaction can be run in one laboratory step. Since the boranes can be prepared from alkenes (Reaction **15-16**), this reaction provides a means of lengthening a carbon chain by three or four carbons, respectively. Compounds containing a terminal alkyl group [e.g., such as crotonaldehyde ($CH_3CH{=}CHCHO$) and 3-penten-2-one], fail to react under these conditions, as does acrylonitrile, but these compounds can be induced to react by the slow and controlled addition of O_2 or by initiation with peroxides or UV light.[1256] A disadvantage is that only one of the

three R groups of R_3B adds to the substrate, so that the other two are wasted. This difficulty is overcome by the use of a β-alkyl borinate (e.g., **96**),[1257] which can be prepared as shown. Borinate (**96**, R = *tert*-butyl) can be made by treatment of **96** (R = OMe) with *t*-BuLi. The use of this reagent permits *tert*-butyl groups to be added. β-1-Alkenyl-9-BBN compounds β-RCH=CR′-9-BBN (prepared by treatment of alkynes with 9-BBN or of RCH=CR′Li with β-methoxy-9-BBN[1258]) add to methyl vinyl ketones to give, after hydrolysis, γ,δ-unsaturated ketones,[1259] although β-R-9-BBN, where R = a saturated group, are not useful here, because the R group of these reagents does not preferentially add to the substrate.[1253] Transition metals catalyze the addition of trialkylboranes to conjugated systems (e.g., the addition of allylboranes in the presence of a Ni catalyst).[1260] The Ni catalyzed addition was enhanced by the addition of methanol.[1261]

The corresponding β-1-alkynyl-9-BBN compounds also give the reaction.[1262] Since the product **97** is an α,β-unsaturated ketone, it can be made to react with another BR_3, the same or different, to produce a wide variety of ketones (**98**).

Vinyl boranes add to conjugated ketones in the presence of a Rh catalyst (with high asymmetric induction in the presence of BINAP).[1263] Alkynyl-boranes also add to conjugated ketones, in the presence of BF_3.[1264]

Other boron reagents add to conjugated carbonyl compounds.[1265] Tetraphenylborates add to conjugated alkynes in the presence of a Pd catalyst in a reaction known as hydrophenylation.[1266] Alkynyl boronate esters (Reaction **12-28**) give conjugate addition[1267] in the presence of boron trifluoride etherate,[1268] as do arylboronic acids (Reaction **12-28**) with a Rh,[1269] Pd,[1270] or a Bi catalyst.[1271] Diethylzinc has also been used.[1272] Aryl boronic acids add to the double bond of vinyl sulfones in the presence of a Rh catalyst.[1273] Vinylboronic acids add directly to conjugated ketones.[1274] An Ir catalyzed 1,6-addition of arylboronic acids is known.[1275] Conjugated alkynes undergo conjugate addition with arylboronic acids in the presence of a Cu catalyst.[1276] Organocatalysts have also been used for the conjugate addition of arylboronic acids to conjugated systems.[1277] Potassium vinyltrifluoroborates (see Reactions **10-59**, **13-10**, and **13-13**) give 1,4-addition with a Rh catalyst,[1278] as do

aryltrifluoroborates.[1279] The Rh catalyzed addition of vinyl tetrafluoroborates has been reported.[1280]

In the presence of a Rh catalyst, $LiBPh(OMe)_3$ gave conjugate addition of the phenyl group to α,β-unsaturated esters.[1281] The fact that these reactions are catalyzed by free radical initiators and inhibited by galvinoxyl[1282] (a free radical inhibitor) indicates that free-radical mechanisms are involved.

15-28 Radical Addition to Activated Double Bonds

Hydro-alkyl-addition

In a reaction similar to **15-25**, alkyl groups can be added to alkenes activated by such groups as COR′, CO_2R', CN, and even Ph.[1283] This is a radical addition reaction.[1284] In the method illustrated above, the R group comes from an alkyl halide (R = primary, secondary, or tertiary alkyl; X = Br or I) and the hydrogen from the tin hydride (H atom transfer agents). The reaction of tert-butyl bromide, Bu_3SnH and AIBN (Sec. 14.A.i), for example, adds a tert-butyl group to a conjugated ester via 1,4-addition.[1285] An alkene is converted to an alkylborane with catecholborane (Reaction **12-28**) and when treated with a conjugated ketone and O_2, radical conjugate addition leads to the β-substituted ketone.[1286] The Bu_3SnH can also be generated in situ, from R_3SnX and $NaBH_4$. Like Reaction **15-27**, these additions have free radical mechanisms. The reaction has been used for free radical cyclizations of the type discussed in Reaction **15-30**.[1287] Such cyclizations normally give predominant formation of five-membered rings, but large rings (11–20 members) have also been synthesized by this reaction.[1288]

A BEt_3 (see Sec. 14.A.i) initiated reaction of conjugated amides with an alkyl iodide, in the presence of Bu_3SnH and O_2, leads to conjugate addition of the alkyl group.[1289] Enantioselective radical addition has been reported.[1290]

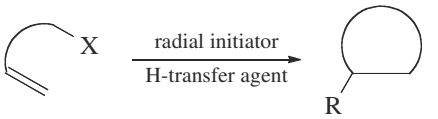
Conjugate addition is possible using photolysis. The photoinduced 1,4-addition of indoles to enones proceeds when irradiated at 350 nm.[1291]

OS **VII**, 105.

15-29 Radical Addition to Unactivated Double Bonds[1292]

Alkyl-hydro-addition

Radical addition to alkenes is usually difficult, except when addition occurs to conjugated carbonyl compounds (Reaction **15-24**). An important exception involves radicals bearing a heteroatom α to the carbon bearing the radical center. Such radicals are much more stable and can add to alkenes, usually with *anti-Markovnikov* orientation, as in the radical induced addition of HBr to alkenes (Reaction **15-2**).[1293]



Examples of this type of reaction include the use of alcohol-, ester-,[1294] amino-, and aldehyde-stabilized radicals.[483] The alkyl group of alkyl iodides adds to alkenes with BEt_3/O_2 as the initiator and in the presence of a tetraalkylammonium hypophosphite.[1295] The radical generated from $(EtO)_2POCH_2Br$ adds to alkenes to generate a new phosphonate ester.[1296] α-Bromo esters add to alkenes in the presence of BEt_3/air to give a γ-bromo ester.[1297] α-Bromo amides add the Br and the acyl carbon to an alkene using $Yb(OTf)_3$ with BEt_3/O_2 as the radical initiator.[1298] α-Iodo amides add to alkenes using a water-soluble azobis initiator (see Sec. 14.A.i) to give the iodo ester, which cyclizes under the reaction conditions to give a lactone.[1299] β-Keto dithiocarbonates [RC(=O)—C—SC(=S)OEt] generate the radical in the presence of a peroxide and add to alkenes.[1300] 2-Fluoropyridyl derivatives of allylic alcohols react with xanthates in the presence of lauroyl peroxide to give alkenes.[1301] Malonate derivatives add to alkenes in the presence of a mixture of Mn/Co catalyst, in oxygenated acetic acid.[1302]

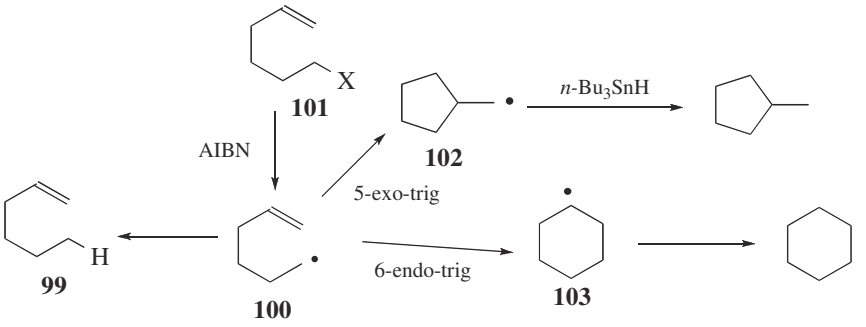
Other radicals can add to alkenes, and the rate constant for the addition of methyl radicals to alkenes has been studied.[1303] The rate of radical additions to alkenes in general has also been studied.[1304] The kinetic and thermodynamic control of a radical addition regiochemistry has also been studied.[1305] Alkynes are generally less reactive than alkenes in radical coupling reactions.[1306] Nonradical nucleophiles usually react faster with alkynes than with alkenes, however.[1307]



15-30 Radical Cyclization[1308]

Alkyl-hydro-addition

ω-Haloalkenes generate radicals upon treatment with radical initiator reagents (e.g., AIBN) or under photolysis conditions,[1309] and the radical carbon adds to the alkene to form cyclic compounds.[1310] This intramolecular addition of a radical to an alkene is called *radical cyclization*. In a typical example, haloalkene (**101**) reacts with the radical produced by AIBN to give radical **100**. The radical can add to the more substituted carbon to give **102** via a 5-exo-trig reaction (Sec. 6.E).[1311] If the radical adds to the less substituted carbon, **103** is formed via a 6-endo-trig reaction.[1312] In both cases, the product is another radical, which must be converted to an unreactive product. This is generally accomplished by adding a hydrogen-transfer agent[1313] [e.g., tributyltin hydride (Bu_3SnH)], which reacts with **102** to form methylcyclopentane and $Bu_3Sn^{\bullet}$, or with **103** to give cyclohexane. The $Bu_3Sn^{\bullet}$ formed in both cases usually dimerizes to form $Bu_3SnSnBu_3$. Cyclization can compete with hydrogen transfer[1314] from Bu_3SnH to **100** to give **99**, the reduction product. Atom-transfer cyclization is possible with other atoms (e.g., halogen), catalyzed by $InCl_3$[1315]or CuBr.[1316] Tin-free radical cyclizations are known using peroxyacids.[1317]

In general, formation of the five-membered ring dominates the cyclization, but if addition to the C=C unit is relatively slow, the reduction product is formed preferentially. Radical rearrangements can also diminish the yield of the desired product.[1318] Given a choice between a larger and a smaller ring, radical cyclization generally gives the smaller ring,[1319] but not always.[1320] Formation of other size rings is possible of course. A 4-exo-trig radical cyclization has been studied,[1321] selectivity in a 7-endo versus 6-exo cyclization,[1322] and also an 8-endo-trig reaction.[1323] In radical cyclization to form large rings, 1,5- and 1,9-hydrogen atom abstractions can pose a problem[1324] Ring expansion during radical cyclization is possible when the terminal intermediate is a cyclobutylcarbinyl radical.[1325]

The mechanism of this reaction has been discussed.[1326] Cyclization via 5-endo-dig transition states require reorientation of the radical orbital needed to reach the in-plane acetylene π orbital in the bond-forming step, with accompanying loss of conjugative stabilization, and an increase in the activation energy. Therefore, many 5-endo cyclizations undergo H abstraction or equilibration with an isomeric radical.[1327]

In cases where hydrogen atom transfer gives primarily reduced products, one solution to promote cyclization generates the radical by photochemical cleavage of $Bu_3Sn—SnBu_3$ and the resulting carbon radical can cyclize (see Reaction **15-46**).[1328] A halogen atom transfer agent (e.g., iodoethane) is used rather than a hydrogen-transfer agent, so the final product is an alkyl iodide.

A mixture of a *Grignard reagent* and $CoCl_2$ has been used to initiate aryl radical cyclizations.[1329] Titanium(III)-mediated radical cyclizations are known,[1330] and SmI_2

mediated reactions are possible in the presence of a Ni catalyst.[1331] Organoborane-mediated radical cyclizations are known (see Sec. 14.A.i).[1332] The influence of the halogen atom on radical cyclization has been studied.[1333]

Both phenylthio[1334] and phenylseleno groups[1335] can be used as "leaving groups" for radical cyclization, where S or Se atom transfer leads to formation of the radical. A seleno ester ($R_2N—CH_2C(—O)SeMe$) has also been used with $(Me_3Si)_3SiH$ (tristrimethylsilylane, TTMSS) and AIBN to generate $R_2NCH_2^{\bullet}$.[1336] *O*-Phosphonate esters have also served as the leaving group.[1337] *N*-(2-bromophenylbenzyl)methylamino have been used as leaving groups for formation of a radical.[1338]

Radical cyclization reaction often proceeds with high diastereoselectivity[1339] and high asymmetric induction when chiral precursors are used. Internal alkynes are good substrates for radical cyclization,[1340] but terminal alkynes tend to give mixtures of *exo/endo-dig* products (Sec. 6.E).[1341] Radical cyclization has been used to transfer asymmetry from transient atropisomers to form lactams.[1342]

Radical cyclization is compatible with the presence of other functional groups, and heterocyclic rings may be formed via radical cyclization.[1343] Aryl radicals participate in radical cyclization reactions when the aromatic ring has an alkene or alkyne substituent. *o*-Iodo aryl allyl ethers cyclize to benzofuran derivatives, for example, when treated with AIBN, aq H_3PO_2 and $NaHCO_3$ in ethanol.[1344] Cyclization of vinyl radicals[1345] and allenyl radicals[1346] are also well known. Treatment of $XCH_2CON(R)—C(R^1)=CH_2$ derivatives (X = Cl, Br, I) with Ph_3SnH and AIBN led to formation of a lactam via radical cyclization.[1347] Cyclization of *N*-iodoethyl-5-vinyl-2-pyrrolidinone led to the corresponding bicyclic lactam,[1348] and there are other examples of radical cyclization with molecules containing a lactam unit[1349] or an amide unit.[1350] β-Lactams can be produced by radical

cyclization, using $Mn(OAc)_3$.[1351] Radical cyclization occurs with enamines as well.[1352] Radical cyclization occurs with oximes to form the corresponding heterocyclic ring.[1353] Phenylseleno *N*-allylamines led to cyclic amines.[1354] ω-Iodo acrylate esters cyclize to form lactones,[1355] and allylic acetoxy compounds of the type $C{=}C{-}C{-}O_2C{-}CH_2I$ cyclize in a similar manner to give lactones.[1356] Iodolactonization (see Reaction **15-41**) occurs under standard radical cyclization conditions using allylic acetoxy compounds[1357] and $HGaCl_2/BEt_3$ has been used to initiate the radical process.[1358] α-Bromo mixed acetals give α-alkoxy THF derivatives[1359] and α-iodoacetals cyclize to give similar products.[1360] The reaction of an *o*-alkynyl aryl isonitrile with AIBN and 2.2 equiv of Bu_3SnH gave an indole via 5-exo-dig cyclization.[1361] Indole derivatives have also been prepared from *o*-iodoaniline derivatives, using AIBN and TTMSS.[1362] Samarium(II) has been used to initial 5-exo-trig ketyl-alkene coupling, and the mechanism of the reaction has been examined.[1363]

Acyl radicals can be generated and they cyclize in the usual manner.[1364] Molecular orbital calculations have shown that acyl, as well as silyl radicals, simultaneously use SOMO–LUMO (SOMO = singly occupied molecular orbital and LUMO = lowest unoccupied molecular orbital) and LUMO–HOMO interactions in reactions with alkenes.[1365] A polyene-cyclization reaction generated four rings, initiating the sequence by treatment of a phenylseleno ester with Bu_3SnH/AIBN to form the acyl radical, which added to the first alkene unit.[1366] The newly formed carbon radical added to the next alkene, and so on. Acyl radicals generated from Ts(R)NCOSePh derivatives cyclize to form lactams.[1367]

Radical cyclization of iodo aldehydes or ketones, at the carbon of the carbonyl, is effectively an acyl addition reaction (**16-24** and **16-25**). This cyclization is often reversible, and there are many fewer examples of addition to an alkene or alkyne. In one example, a δ-iodo aldehyde was treated with BEt_3/O_2 to initiate formation of the radical, and in the presence of Bu_3SnH cyclization gave a cyclopentanol.[1368] The reaction of an

aldehyde-alkene with AIBN, 0.5 $PhSiH_3$ and 0.1 Bu_3SnH generated a radical from the alkene, which cyclized at the aldehyde to give cyclopentanol derivatives.[1369] An aldehyde–*O*-methyloxime generated a radical adjacent to nitrogen under standard conditions, which cyclized at the carbonyl to give a cyclic α-hydroxy *N*-methoxyamine.[1370] Alternatively, an α-bromoacetal–*O*-methyl oxime cyclized at the C=NOMe unit under electrolytic conditions in the presence of cobaloxime.[1371] Alkynyl-imines are cyclized to the imino carbon to form alkylidene lactams under radical conditions in the presence of CO.[1372]

The attacking radical in radical cyclization reactions is not limited to a carbon, and a number of heterocycles can be prepared.[1373] Amidyl radicals are known and give cyclization reactions.[1374] Aminyl radical cyclizations have been reported.[1375] *N*-Chloroamine-alkenes give an aminyl radical when treated with $TiCl_3{\cdot}BF_3$, and cyclization gave a pyrrolidine derivative with a pendant chloromethyl group.[1376] *N*-(*S*-substituted) amines give similar results using AIBN/Bu_3SnH.[1377] Oxime-alkenes cyclize to imines when treated with PhSSPh and TEMPO (Sec. 5.C.i).[1378] An oxygen radical can be generated under photochemical conditions, and they add to alkenes in a normal manner.[1379] Note that radical substitution occurs, and reaction of Ph_3SnH/AIBN and an *O*-amidyl compound having a phosphonate ester elsewhere in the molecule gave cyclization to a THF derivative.[1380]

15-31 Conjugate Addition with Heteroatom Nucleophiles

Heteroatom nucleophiles add to conjugated systems to give *Michael-type* products. Conjugated carbonyl compounds react via conjugate addition with amines to give β-amino derivatives (See Reaction **15-31**)[1381] Conjugate addition of nitrogen-containing compounds is often called the *aza-Michael reaction*.[1382] Amines add to conjugated systems in the presence of In,[1383] Pd,[1384] Sm,[1385] Bi,[1386] Cu,[1387]

Ce,[1388] La,[1389] or Yb compounds[1390] to give β-amino derivatives. This reaction can be initiated photochemically[1391] or with microwave irradiation.[1392] Aniline derivatives add to conjugated aldehydes in the presence of a catalytic amount of DBU,[1393] and indeed, DBU promotes the *aza-Michael reaction*.[1394] Lithium amides add to conjugated esters to give the β-amino ester.[1395] Amidocuprates add to conjugated systems to give β-nitrogen compounds, and a β-silyl group has an activating effect of the amidocuprate.[1396] A solvent-free conjugate addition of amines occurs on alumina in the presence of a Ce catalyst.[1397] Boric acid has been used as a catalyst of *aza-Michael reactions* in water.[1398] An intramolecular addition of an amine unit to a conjugated ketone in the presence of a Pd catalyst, or photochemically, led to cyclic amines.[1399] Amines add to conjugated thiolactams.[1400]

There are asymmetric versions of the *aza-Michael reaction*,[1401] and high enantioselectivity is possible using an organocatalyst.[1402] Chiral catalysts lead to enantioselective reactions.[1403] Chiral additives (e.g., chiral Cinchona alkaloids[1404] or chiral naphthol derivatives)[1405] have also been used. Chiral imines add in a highly stereoselective manner.[1406] Chiral catalysts have been used for the conjugated addition of carbamates.[1407] Indoles add to nitro alkenes in the presence of an organocatalyst.[1408] Other N-heterocycles add with good enantioselectivity in the presence of an organocatalyst.[1409]

Lactams have been shown to add to conjugated esters in the presence of $Si(OEt)_4$ and CsF.[1410] Phthalimide adds to alkylidene malononitriles via 1,4-addition with a Pd catalyst, and the resulting anion can be alkylated with an added allylic halide.[1411] Alkylidene

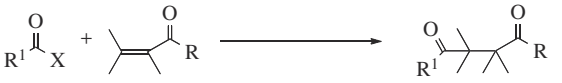
amido-amides, C=C(NHAc)CONHR, react with secondary amines in water to give the β-amino amido amide.[1412] Amines also add in a conjugate manner to alkynyl phosphonate esters, C≡C—$PO(OEt)_2$, using a CuI catalyst.[1413] Hydroxylamines add to conjugated nitro compounds to give 2-nitro hydroxylamines.[1414] *N,O*-Trimethylsilyl hydroxylamines add to conjugated esters, via nitrogen, using a Cu catalyst.[1415] Trimethylsilyl azide with acetic acid reacts with conjugated ketones to give the β-azido ketone.[1416] Sodium azide adds to conjugated ketones in aq acetic acid and 20% PBu_3.[1417] An interesting variation involves a double *Michael addition* of amido amines, amido alcohols or amido thiols to conjugated alkynes, forming pyrrolidine, oxazolidine, or thiazolidine derivatives.[1418]

The nitrogen of carbamates adds to conjugated ketones with a Pt,[1419] Pd,[1420] Cu,[1421] or with a bis(triflamide) organocatalyst.[1422] The amine moiety of a carbamate adds to conjugated ketones with a polymer-supported acid catalyst,[1423] or with $BF_3 \cdot OEt_2$.[1424] The reaction of ammonium formate with 1,4-diphenylbut-2-en-1,4-dione, in PEG-200 and a Pd catalyst under microwave irradiation, gave 2,5-diphenylpyrrole.[1425]

Phosphines react similarly to amines under certain conditions. Conjugate addition of R_2PH and a Ni catalyst give conjugate addition to α,β-unsaturated nitriles.[1426] A Pd catalyzed addition of diarylphosphines proceeds with good enantioselectivity to give chiral phosphines.[1427] Phosphites add to nitroalkenes in the presence of a chiral organocatalyst to give the corresponding nitro phosphite compound.[1428]



Alcohols add to conjugated ketones with a PMe_3 catalyst to give the β-alkoxy ketone.[1429] This reaction is called an *oxy-Michael reaction*.[1430] Alcohol addition is catalyzed by *N*-heterocyclic carbenes[1431] and other organocatalysts,[1432] often with enantioselectivity.[1433] The conjugate addition of peroxide anions (HOO^- and ROO^-) to α,β-unsaturated carbonyl compounds is discussed in Reaction **15-48**. An intramolecular variation is known that produces dihydropyrones.[1434]

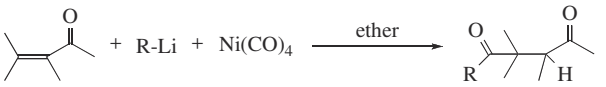
Thiophenol and butyllithium (lithium phenylthiolate) adds to conjugated esters.[1435] Similar addition is observed with selenium compounds (RSeLi).[1436] Thiols react with conjugated amides via 1,4-addition with the addition of 10% $Hf(OTf)_4$ or other lanthanide triflates[1437] or to conjugated ketones in ionic solvents.[1438] Alkyl thiols add to conjugated carbonyl compounds with high enantioselectivity using an organocatalyst.[1439] Iron(III)-catalyzed addition of thiols occurs under solvent-free conditions.[1440] Thiols add without a catalyst in water[1441] in PEG,[1442] or in ionic liquids.[1443] Thiol addition is also catalyzed by iodine under solvent-free conditions.[1444] Ceric ammonium nitrate promotes the conjugate addition of thiols.[1445] Thioaryl moieties can be added in the presence of Yb[1446] or a catalytic amount of $(DHQD)_2PYR$ (a dihydroquinidine, see Reaction **15-48**).[1447] Thioalkyl units (e.g., BuS—) add to conjugated ketones using BuS—SnBu and In—I.[1448] Addition of conjugated lactones is possible to produce β-arylthiolated lactones.[1449] Dithiocarbamates are prepared by the reaction of an amine, CS_2, and a conjugated carbonyl compound.[1450] α,β-Unsaturated sulfones undergo conjugate addition of a cyano group using Et_2AlCN.[1451]

15-32 Acylation of Activated Double Bonds and of Triple Bonds



Hydro-acyl-addition

Under some conditions, acid derivatives add directly to activated double bonds. Acetic anhydride, Mg metal, and Me_3SiCl react with conjugated esters to give a γ-keto ester.[1452] Similar reaction with vinyl phosphonate esters leads to a γ-keto phosphonate ester.[1453] Thioesters undergo conjugate addition to α,β-unsaturated ketones in the presence of SmI_2.[1454] Using DBU and a thioimidazolium salt, acyl silanes, $Ar(C{=}O)SiMe_3$, add in a

similar manner.[1455] Under microwave irradiation, aldehydes add to conjugated ketones using DBU/Al_2O_3 and a thiazolium salt.[1456] The conjugate addition of acyl zirconium complexes in the presence of $BF_3{\cdot}OEt_2$ is catalyzed by palladium acetate.[1457]

104

An acyl group can be introduced into the 4 position of an α,β-unsaturated ketone by treatment with an organolithium compound and nickel carbonyl[1458] to give a 1,4-diketone (**104**). The R group may be aryl or primary alkyl. The reaction can also be applied to alkynes, which need not be activated, in which case 2 molar equivalents add and the product is also a 1,4-diketone (e.g., $R'C{\equiv}CH \rightarrow RCOCHR'CH_2COR$).[1459] In a different procedure, α,β-unsaturated ketones and aldehydes are acylated by treatment at −110°C with $R_2(CN)CuLi_2$ and CO. This method is successful for R = primary, secondary, and tertiary alkyl.[1460] For secondary and tertiary groups, R(CN)CuLi, which does not waste an R group, can be used instead.[1461]

105

The reaction of an aldehyde and cyanide ion (See Reaction **16-52**) in a polar aprotic solvent (e.g., DMF or DMSO) leads to a cyanohydrin, which generates a diketone via loss of HCN.[1462] This method has been applied to α,β-unsaturated ketones, esters, and nitriles to give the corresponding 1,4-diketones, γ-keto esters, and γ-keto nitriles, respectively (see also, Reaction **16-55**). The initial product of this reaction is ion **105**, which is a synthon for the unavailable $R^-C{=}O$ anion (see Reaction **10-68**). It is a masked $R^-C{=}O$ anion that upon reaction with the conjugated carbonyl gives **104** after loss of HCN from the cyanohydrin addition product. Other masked carbanions that have been used in this reaction are the $RC^-(CN)NR$ ion,[1463] the EtSCRSOEt ion,[1464] the $CH_2{=}C^-OEt$ ion,[1465] $CH_2{=}C(OEt)Cu_2Li$,[1466] $CH_2{=}CMe(SiMe_3)$,[1466] and the $RC^-(OCHMeOEt)CN$ ion.[1467] In the last case, best results are obtained when R is a vinylic group. Anions of 1,3-dithianes

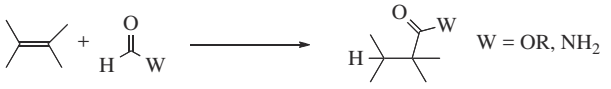
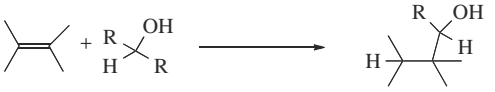
(Reaction **10-71**) do not give 1,4-addition to these substrates (except in the presence of HMPA, see Reaction **15-25**), but add 1,2 to the C=O group instead (Reaction **16-38**).

Interestingly, acylation occurs at the α-position of an enone when and α,β-unsaturated ketone is treated with an acid chloride and Et_2Zn in the presence of a Rh catalyst.[1468]



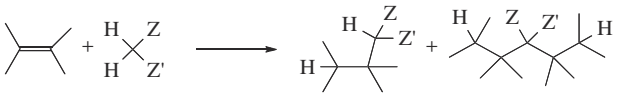
In another procedure, acyl radicals derived from phenyl selenoesters (ArCOSePh) (by treatment with Bu_3SnH) add to α,β-unsaturated esters and nitriles to give γ-keto esters and γ-keto nitriles, respectively.[1469]

OS **VI**, 866; **VIII**, 620.



15-33 Addition of Alcohols, Amines, Carboxylic Esters, Aldehydes, and so on

Hydro-acyl-addition, and so on



Formates, primary and secondary alcohols, amines, ethers, alkyl halides, compounds of the type $Z—CH_2—Z'$, and a few other compounds add to double bonds in the presence of free radical initiators.[1470] This is formally the addition of RH to a double bond, but the "R" is not just any carbon, but one connected to an oxygen or a nitrogen, a halogen, or to two Z groups (defined as in Sec. 15.A.ii). Formates and formamides[1471] add similarly:

Alcohols, ethers, amines, and alkyl halides add as follows (shown for alcohols):

The ZCH_2Z' compounds react at the carbon bearing the active hydrogen[1472]:

Similar additions have been successfully carried out with carboxylic acids, anhydrides,[1473] acyl halides, carboxylic esters, nitriles, and other types of compounds.[1474]

Similar reactions have been carried out on acetylene.[1475] In an interesting variation, thiocarbonates add to alkynes in the presence of a Pd catalyst to give a β-phenylthio α,β-unsaturated ester.[1476] Aldehydes add to alkynes in the presence of a Rh catalyst to give

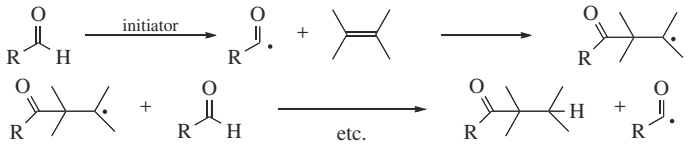
conjugated ketones.[1477] In a cyclic version of the addition of aldehydes, 4-pentenal was converted to cyclopentanone with a Rh complex catalyst.[1478] An intramolecular acyl addition to an alkyne was reported using silyl ketones, acetic acid, and a Rh catalyst.[1479] Formamides add to alkynes in the presence of a Pd catalyst to form conjugated amides.[1480]

OS **IV**, 430; **V**, 93; **VI**, 587, 615.



15-34 Addition of Aldehydes

Alkyl-carbonyl-addition

In the presence of metal catalysts (e.g., Rh[1481] or Yb[1482]), aldehydes can add directly to alkenes to form ketones. Additives play an important role in such reactions.[1483] The reaction of ω-alkenyl aldehydes with a Rh catalyst leads to cyclic ketones,[1484] with high enantioselectivity if chiral ligands are employed. A carbene organocatalyst was used for an enantioselective intramolecular reaction.[1485] β,γ-Unsaturated ketones are prepared by the Rh catalyzed addition of aldehydes to dienes.[1486] The addition of aldehydes to activated double bonds, mediated by a catalytic amount of thiazolium salt in the presence of a weak base, is called the *Stetter reaction*,[1487] An internal addition of an alkynyl aldehyde, catalyzed by a Rh complex, led to a cyclopentenone derivative.[1488] These reactions are not successful when the alkene contains electron-withdrawing groups (e.g., halo or carbonyl groups). A free radical initiator is required,[1489] usually peroxides or UV light. The mechanism is illustrated for aldehydes, but is similar for the other compounds:

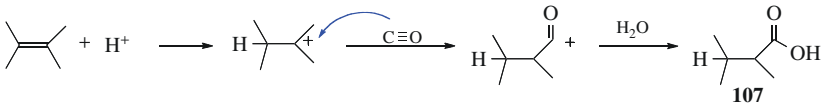
In the presence of BF_3 and a Ag salt, aldehydes add to alkynes to give the corresponding conjugated ketone.[1490] Polymers are often side products. Photochemical addition of aldehyde to conjugated C=C units can be efficient when a triplet sensitizer (Sec. 7.A.vi, category 5, e.g., benzophenone) is used.[1491]

A variation that is more of an acyl addition (Reaction **16-25**) involves the reaction of an allylic alcohol with benzaldehyde. With a Ru catalyst and in an ionic liquid, the C=C unit reacts with the aldehyde, with concomitant oxidation of the allylic alcohol unit, to give a β-hydroxy ketone, $PhCHO + C{=}C{-}CH(OH)R \rightarrow PhCH(OH){-}CH(Me)COR$.[1492] In another variation, formate esters add to alkenes using a Ru catalyst to give an alkyl ester via a formylation process.[1493]

15-35 Hydrocarboxylation

Hydro-carboxy-addition



The acid-catalyzed hydrocarboxylation of alkenes (the *Koch reaction*) can be performed in a number of ways.[1494] In one method, the alkene is treated with CO and water at 100–350°C and 500–1000-atm pressure with a mineral acid catalyst. However, the reaction can also be performed under milder conditions. If the alkene is first treated with CO and catalyst and then water added, the reaction can be accomplished at 0–50°C and 1–100 atm. If formic acid is used as the source of both the CO and the water, the reaction can be carried out at room temperature and atmospheric pressure.[1495] The formic acid procedure is called the *Koch–Haaf reaction* (the Koch–Haaf reaction can also be applied to alcohols, see Reaction **10-77**). Nearly all alkenes can be hydrocarboxylated by one of these procedures. However, conjugated dienes are polymerized under these conditions. Hydrocarboxylation can also be accomplished under mild conditions (160°C and 50 atm) by the use of nickel carbonyl as catalyst. Acid catalysts are used along with the nickel carbonyl, but basic catalysts can also be employed.[1496] The $Ni(CO)_4$ catalyzed oxidative carbonylation with

CO and H_2O as a nucleophile is often called *Reppe carbonylation*.[1497] The toxic nature of nickel tetracarbonyl has led to development of other catalysts.[1498] Indeed, variations in the reaction procedure include the use of Pd,[1499] Pt,[1500] and Rh[1501] catalysts. This reaction converts alkenes, alkynes, and dienes and is tolerant of a wide variety of functional groups. When the additive is alcohol or acid, saturated or unsaturated acids, esters, or anhydrides are produced (see Reaction **15-36**). The transition metal catalyzed carbonylation has been done enantioselectively, with moderate-to-high optical yields, by the use of an optically active palladium-complex catalyst.[1502] Alkenes also react with $Fe(CO)_5$ and CO to give carboxylic acids.[1503] Electrochemical carboxylation procedures have been developed, including the conversion of alkenes to 1,4-butanedicarboxylic acids.[1504] A reductive carboxylation of alkenes with CO and cesium carbonate has been reported.[1505]

When applied to triple bonds, hydrocarboxylation gives α,β-unsaturated acids under very mild conditions. Triple bonds give unsaturated acids and saturated dicarboxylic acids when treated with CO_2 and an electrically reduced Ni complex catalyst.[1506] Alkynes also react with $NaHFe(CO)_4$, followed by $CuCl_2 \cdot 2\,H_2O$, to give alkenyl acid derivatives.[1507] A related reaction with CO and Pd catalysts in the presence of $SnCl_2$ leads to conjugated acid derivatives.[1508] Terminal alkynes react with CO_2 and $Ni(cod)_2$ (cod = 1,5-cyclooctadiene), and subsequent treatment with DBU gives the α,β-unsaturated carboxylic acid.[1509]

When acid catalysts are employed, in the absence of nickel carbonyl, the mechanism[1510] involves initial attack on a proton, followed by attack by CO on the resulting carbocation to give an acyl cation, and subsequent reaction with water gives the product **107**. *Markovnikov's rule* is followed, and carbon skeleton rearrangements and double-bond isomerizations (prior to attack by CO) are frequent.

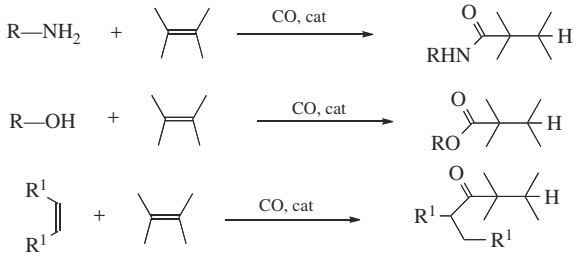
For the transition metal catalyzed reactions, the nickel carbonyl reaction has been well studied and the addition is syn for both alkenes and alkynes.[1511] The following is the accepted mechanism:[1511]



Step 3 is an electrophilic substitution. The principal step of the mechanism, step 4, is a rearrangement.

An indirect method for hydrocarboxylation involves the reaction of an alkene with a borate [$(RO)_2BH$] and a Rh catalyst. Subsequent reaction with $LiCHCl_2$, and then $NaClO_2$, gives the *Markovnikov* carboxylic acid ($RC{=}C \rightarrow RC(CO_2H)CH_3$.[1512] When a chiral ligand is used, the reaction proceeds with good enantioselectivity.

15-36 Carbonylation, Alkoxycarbonylation, and Aminocarbonylation of Double and Triple Bonds

Alkyl, Alkoxy, or Amino-carbonyl-addition

In the presence of certain metal catalysts, alkenes and alkynes can be carbonylated or converted to give an amide or an ester.[1513] There are several variations. The reaction of an alkyl iodide and a conjugated ester with CO, $(Me_3Si)_3SiH$, and AIBN in supercritical CO_2 (Sec. 9.D.ii) gave a γ-keto ester.[1514] Terminal alkynes react with

CO and methanol in the presence of $CuCl_2$ and $PdCl_2$ to give a β-chloro-α,β-unsaturated methyl ester.[1515] Conjugated dienes react with thiophenol, CO and $Pd(OAc)_2$ to give the β,γ-unsaturated thioester.[1516] Allene reacts with CO, CH_3OH, and a Ru catalyst to give methacrylic acid.[1517] Alkynes react with thiophenol and CO with a Pd[1518] or Pt[1519] catalyst to give a conjugated thioester. Terminal alkynes react with CO and CH_3OH, using a combination of a palladium(II) halide and a copper(II) halide, to give a conjugated diester, $MeO_2C—C{=}C—CO_2Me$.[1520] A similar reaction with alkenes using a combination of a Pd and a Mo catalyst led to a saturated diester ($MeO_2C—C—C—CO_2Me$).[1521] Alkenes were converted to the dimethyl ester of 1,4-butanedioic acid derivatives with CO/O_2 and a combination of $PdCl_2$ and CuCl catalysts.[1522] Note that alkenes primarily are converted to the *anti-Markovnikov* ester upon treatment with arylmethyl formate esters ($ArCH_2OCHO$) and a Ru catalyst.[1523] Terminal alkynes react with tosyl azide, water, and a catalytic amount of CuI to give an *N*-tosyl amide.[1524]

A bicyclic ketone was generated when 1,2-diphenylethyne was heated with carbon monoxide, methanol and a dirhodium catalyst.[1525] 2-Iodostyrene reacted at 100 °C with CO and a Pd catalyst to give the bicyclic ketone 1-indanone.[1526] Another variation reacted a conjugated allene–alkene with 5 atm of CO and a Rh catalyst to give a bicyclic ketone.[1527] An intermolecular version of this reaction is known using a Co catalyst, giving a cyclopentenone[1528] in a reaction related to the *Pauson–Khand reaction* (see below). The reaction of a conjugated diene having a distal alkene unit and CO with a Rh catalyst led to a bicyclic conjugated ketone.[1529] When a *Stille coupling* (Reaction **12-15**) is done in a CO atmosphere, conjugated ketones of the type C=C—CO—C=C are formed,[1530] suitable for a *Nazarov cyclization* (Reaction **15-20**). Alkynes were converted to cyclobutenones using $Fe_3(CO)_{12}$ to form an initial complex, followed by reaction with copper(II) chloride.[1531] An interesting variation treated cyclohexene with 5 molar equivalents of Oxone and a $RuCl_3$ catalyst to give 2-hydroxycyclohexanone.[1532]

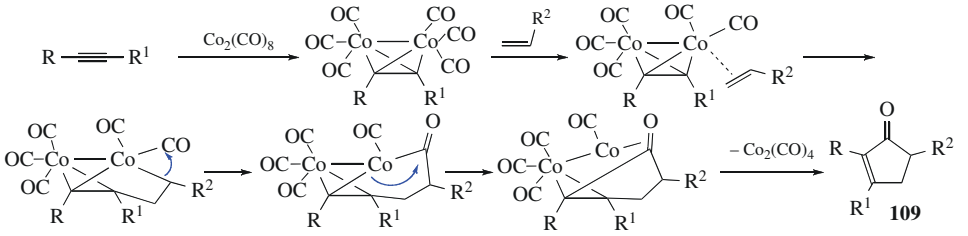
The reaction of dienes, diynes, or enynes with transition metals[1533] (usually Co)[1534] forms organometallic coordination complexes. Rhodium,[1535] Ti,[1536] Mo,[1537] and W[1538] complexes have been used for this reaction. In the presence of CO, the metal complexes derived primarily from enynes (alkene–alkynes) generate cyclopentenone derivatives in what is known as the *Pauson–Khand reaction*.[1539] This reaction involves (1) formation of a hexacarbonyldicobalt–alkyne complex and (2) decomposition of the complex in the presence of an alkene.[1540] A typical example is the preparation of **108**.[1541] Cyclopentenones can be prepared by an intermolecular reaction of a vinyl silane and an alkyne using CO and a Ru catalyst.[1542] Carbonylation of an alkene–diene using a Rh catalyst leads to cyclization to an α-vinyl cyclopentanone.[1543] An yne–diene can also be used for the *Pauson–Khand reaction*.[1544]



108

The reaction can be promoted photochemically[1545] and the rate is enhanced by the presence of primary amines.[1546] Coordinating ligands also accelerate the reaction,[1547] polymer-supported promoters have been developed[1548] and there are many possible variations in reaction conditions.[1549] The *Pauson–Khand reaction* has been done under heterogeneous reaction conditions,[1550] with Co nanoparticles,[1551] and in water.[1552] A

dendritic Co catalyst has been used.[1553] Ultrasound promoted[1554] and microwave promoted[1555] reactions have been developed. Polycyclic compounds (tricyclic and higher) are prepared in a relatively straightforward manner using this reaction.[1556] Asymmetric *Pauson–Khand reactions* are known.[1557]

The *Pauson–Khand reaction* is compatible with other groups or heteroatoms elsewhere in the molecule. These include ethers and aryl halides,[1558] esters,[1559] amides,[1560] alcohols,[1561] diols,[1562] and an indole unit.[1563] A silicon-tethered *Pauson–Khand reaction* is known.[1564] Allenes are reaction partners in the *Pauson–Khand reaction*.[1565] This type of reaction can be extended to form six-membered rings using a Ru catalyst.[1566] A double-*Pauson–Khand process* was reported.[1567] In some cases, an aldehyde can serve as the source of the carbonyl for carbonylation.[1568]

The accepted mechanism was proposed by Magnus and Principe,[1569] shown for the formation of **109**,[1570] and supported by Krafft's work.[1571] It has been shown that CO is lost from the *Pauson–Khand* complex prior to alkene coordination and insertion.[1572] Calculations

concluded that the LUMO of the coordinated alkene plays a crucial role in alkene reactivity by determining the degree of back-donation in the complex.[1573]

Other carbonylation methods are available. Carbonylation occurs with conjugated ketones to give 1.4-diketones, using phenylboronic acid (see Reaction **13-12**), CO and a Rh catalyst.[1574] A noncarbonylation route treated a conjugated diene with an excess of *tert*-butyllithium, and quenching with CO_2 led to a cyclopentadienone.[1575] When quenched with CO rather than CO_2, a nonconjugated cyclopentenone was formed.[1576] Note that a carbonylation reaction with CO, a diyne, and an Ir[1577] or a Co catalyst[1578] provided similar molecules.

With any method, if the alkene contains a functional group (e.g., OH, NH_2, or $CONH_2$), the corresponding lactone (Reaction **16-63**),[1579] lactam (Reaction **16-74**), or cyclic imide may be the product.[1580] Titanium,[1581] Pd,[1582] Ru,[1583] and Rh[1584] catalysts have been used to generate lactones. Allenic alcohols are converted to butenolides with 10 atm of CO and a Ru catalyst.[1585] Larger ring conjugated lactones can also be formed by this route using the appropriate allenic alcohol.[1586] Propargylic alcohols lead to β-lactones[1587] or to butenolides with CO/H_2O and a Rh catalyst.[1588] Allenic tosyl-amides are converted to *N*-tosyl α,β-unsaturated pyrrolidinones using 20 atm of CO and a Ru catalyst.[1589] Conjugated imines are converted to similar products with CO, ethylene, and a Ru catalyst.[1590] Propargyl alcohols generate lactones when treated with a chromium pentacarbonyl carbene complex.[1591] Amines add to allenes, in the presence of CO and a Pd catalyst, to form conjugated amides.[1592]

The reaction of a secondary amine, CO, a terminal alkyne, and *t*-$BuMe_2SiH$ with a Rh catalyst led to a conjugated amide bearing the silyl group of the C=C unit.[1593] Reaction of a molecule containing an amine and an alkene unit was carboxylated with CO in the presence of a Pd catalyst to give a lactam.[1594] A similar reaction with a molecule containing an amine and an alkyne also generated a lactam, in the presence of CO and

a Rh catalyst.[1595] An intramolecular carbonylation reaction of a conjugated imine, with CO, ethylene and a Ru catalyst, led to a highly substituted β,γ-unsaturated lactam.[1596]

15-37 Hydroformylation

Hydro-formyl-addition

Alkenes can be hydroformylated[1597] by treatment with CO and hydrogen over a catalyst, usually a Co carbonyl (see below for a description of the mechanism) or a Rh complex,[1598] but other transition metal compounds have also been used. Cobalt catalysts are less active than the Rh type, and catalysts of other metals are generally less active.[1599] Commercially, this is called the *oxo process*, but it can be carried out in the laboratory in an ordinary hydrogenation apparatus. The order of reactivity is straight-chain terminal alkenes > straight-chain internal alkenes > branched-chain alkenes. With terminal alkenes, for example, the aldehyde unit is formed on both the primary and secondary carbon, but proper choice of catalyst and additive leads to selectivity for the secondary[1600] or primary product.[1601] Alkylidenecyclopropane derivatives undergo hydroformylation to give aldehydes with a quaternary center.[1602]

Good yields for hydroformylation have been reported using Rh catalysts in the presence of certain other additives.[1603] Among the side reactions are the *aldol Reaction* (**16-34**), acetal formation, the *Tischenko Reaction* (**19-82**), and polymerization. In one case using a Rh catalyst, 2-octene gave nonanal, presumably via a η^3-allyl complex (Sec. 3.C).[1604] Conjugated dienes give dialdehydes when Rh catalysts are used[1605] but saturated monoaldehydes (the second double bond is reduced) with cobalt carbonyls. Both 1,4- and 1,5-dienes may give cyclic ketones.[1606]

Hydroformylation of triple bonds proceeds very slowly, and few examples have been reported.[1607] However, in the presence of a Rh catalyst, the triple bond of a conjugated

enyne is formylated.[1608] The Rh catalyzed reaction can be regioselective.[1609] Many functional groups (e.g., OH, CHO, CO_2R,[1610] CN), can be present in the molecule, although halogens usually interfere. Stereoselective syn addition has been reported,[1611] and also stereoselective anti addition.[1612]

Asymmetric hydroformylation of alkenes has been accomplished with a chiral catalyst,[1613] and in the presence of chiral additives.[1614] The choice of ligand is important in such reactions.[1615] Cyclization to prolinal derivatives has been reported with allylic amines.[1616]

When dicobalt octacarbonyl $[Co(CO)_4]_2$ is the catalyst, the species that actually adds to the double bond is tricarbonylhydrocobalt $[HCo(CO)_3]$.[1617] Carbonylation $[RCo(CO)_3 + CO \rightarrow RCo(CO)_4]$ takes place followed by a rearrangement and a reduction of the C—Co bond, similar to steps 4 and 5 of the nickel carbonyl mechanism shown in Reaction **15-35**. The reducing agent in the reduction step is tetracarbonylhydrocobalt $[HCo(CO)_4]$,[1618] or, under some conditions, H_2.[1619] When $HCo(CO)_4$ was the agent used to hydroformylate styrene, the observation of CIDNP (Sec. 5.C.i) indicated that the mechanism is different, and involves free radicals.[1620] Key intermediates have been detected in the Co catalyzed hydroformylation reaction.[1621] Alcohols can be obtained by allowing the reduction to continue after all the CO is used up. It has been shown[1622] that the formation of alcohols is a second step, occurring after the formation of aldehydes, and that $HCo(CO)_3$ is the reducing agent.

OS **VI**, 338.

15-38 Addition of HCN

Hydro-cyano-addition

Ordinary alkenes do not react with HCN, but polyhalo alkenes and alkenes of the form C=C—Z add HCN to give nitriles.[1623] The reaction is therefore a nucleophilic addition

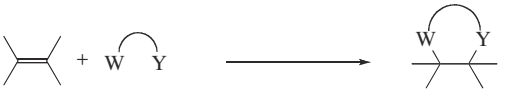
and is base catalyzed. Hydrogen cyanide can be added to ordinary alkenes in the presence of dicobalt octacarbonyl[1624] or certain other transition metal compounds.[1625] When Z is COR or, more especially, CHO, 1,2-addition (Reaction **16-53**) is an important competing reaction and may be the only reaction. An acid-catalyzed hydrocyanation is also known.[1626] Triple bonds react very well when catalyzed by an aqueous solution of CuCl, NH_4Cl, and HCl or by Ni or Pd compounds.[1627] The HCN can be generated *in situ* from acetone cyanohydrin (see Reaction **16-52**), avoiding the use of the poisonous HCN.[1628] Alkenes react with HCN via this procedure to give a nitrile in the presence of a Ni complex.[1629]

One or 2 molar equivalents of HCN can be added to a triple bond, since the initial product is a *Michael-type* substrate. Acrylonitrile is commercially prepared this way, by the addition of HCN to acetylene. Alkylaluminum cyanides (e.g., Et_2AlCN), or mixtures of HCN and trialkylalanes (R_3Al) are especially good reagents for conjugate addition of HCN[1630] to α,β-unsaturated ketones and α,β-unsaturated acyl halides. An indirect method for the addition of HCN to ordinary alkenes uses an isocyanide (RNC) and *Schwartz's reagent* (see Reaction **15-17**); this method gives anti-Markovnikov addition.[1631] *tert*-Butyl isocyanide and $TiCl_4$ have been used to add HCN to C=C—Z alkenes.[1632] Pretreatment with NaI/Me_3SiCl followed by CuCN converts alkynes to vinyl nitriles.[1633]



When an alkene is treated with Me_3SiCN and $AgClO_4$, followed by aq $NaHCO_3$, the product is the isonitrile (RNC) formed with *Markovnikov* selectivity.[1634] Enantioselective cyanation using TMSCN and HCN, and a Gd catalyst, leads to β-cyano amides.[1635]

A. Halogen on One or Both Sides

15-39 Halogenation of Double and Triple Bonds (Addition of Halogen, Halogen)

Dihalo-addition

Most double bonds are easily halogenated[1636] with bromine, chlorine, or inter-halogen compounds.[1637] Substitution can compete with addition in some cases.[1638] Iodination has also been accomplished, but the reaction is slower.[1639] Under free radical conditions, iodination proceeds more easily.[1640] However, *vic*-diiodides are generally unstable and tend to revert to iodine and the alkene.

110

The mechanism is usually electrophilic (see Sec. 15.A.i), involving formation of an halonium ion (Reaction **110**),[1641] followed by nucleophilic ring opening to give the *vic*-dihalide. Nucleophilic attack occurs with selectivity for the less substituted carbon. When free radical initiators (or UV light) are present, addition can occur by a free radical mechanism.[1642] Once $Br^{\bullet}$ or $Cl^{\bullet}$ radicals are formed, however, substitution may compete (Reactions **14-1** and **14-3**). This is especially important when the alkene has allylic or benzylic hydrogen atoms. Under free radical conditions (UV light) bromine or chlorine adds to a benzene substituent to give, respectively, hexabromo- and hexachlorocyclohexane. These are mixtures of stereoisomers (see Sec. 4.K.ii).[1643]

Under ordinary conditions fluorine itself is too reactive to give simple addition, and mixtures are obtained.[1644] However, F_2 has been successfully added to certain double bonds in an inert solvent at low temperatures (−78 °C), usually by diluting the F_2 gas with Ar or N_2.[1645] Addition of fluorine has also been accomplished with other reagents (e.g., *p*-Tol-IF_2/$Et_3N{\cdot}5$ HF),[1646] and a mixture of PbO_2 and SF_4.[1647] The Au catalyzed reaction of Et_3N—HF with alkynes gives vinyl fluorides.[1648]

The reaction with bromine is very rapid and is easily carried out at room temperature,[1649] although the reaction is reversible under some conditions.[1650] In the case of bromine, an alkene•Br_2 complex has been detected in at least one case.[1651] Bromine is often used as a qualitative or quantitative test for unsaturation[1652] because the vast majority of double bonds can be successfully brominated. Even when functions (aldehyde, ketone, amine, etc.) are present in the molecule, they do not interfere, since the reaction with double bonds is faster. Bromination has been carried out in an ionic liquid.[1653]

Several reagents other than chlorine gas add Cl_2 to double bonds, among them $Me_3SiCl^-MnO_2$,[1654] $BnNEt_3MnO_4/Me_3SiCl$,[1655] and $KMnO_4$–oxalyl chloride.[1656] A convenient reagent for the addition of Br_2 to a double bond on a small scale is the commercially available pyridinium bromide perbromide ($C_5H_5NH^+ Br_3^-$).[1657] Potassium bromide with ceric ammonium nitrate, in water/dichloromethane, gives the dibromide.[1658] A combination of KBr and Selectfluor also give the dibromide.[1659] A combination of $CuBr_2$ in aq THF and a chiral ligand led to the dibromide with good enantioselectivity.[1660] Either Br_2 or Cl_2 can also be added using $CuBr_2$ or $CuCl_2$ in the presence of acetonitrile, methanol, or triphenylphosphine.[1661] Alkenes are brominated using KBr and diacetoxyiodobenzene.[1662] Note that theoretical and experimental studies have shown that in nonpolar solvents the bromination of acetylene via a covalent tribromide adduct is strongly favored over the textbook mechanism via a bridged bromonium ion.

Mixed halogenations have also been achieved, and the order of activity for some of the reagents is $BrCl > ICl$[1663] $> Br_2 > IBr > I_2$.[1664] Mixtures of Br_2 and Cl_2 have been used to give bromochlorination,[1665] as has tetrabutylammonium dichlorobromate (Bu_4NBrCl_2).[1666] Iodochlorination has been achieved with $KICl_2$,[1667] $CuCl_2$, and either I_2, HI, or CdI_2; iodofluorination[1668] with mixtures of AgF and I_2;[1669] and mixtures of *N*-bromo amides in anhydrous HF give bromofluorination.[1670] Bromo-, iodo-, and

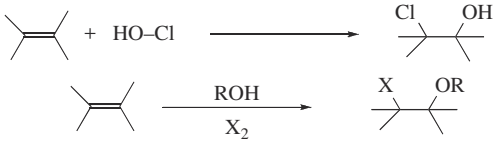
chlorofluorination have also been achieved by treatment of the substrate with a solution of Br_2, I_2, or an *N*-halo amide in polyhydrogen fluoride–pyridine;[1671] while addition of I along with Br, Cl, or F has been accomplished with the reagent bis(pyridine)iodo(I) tetrafluoroborate [$I(Py)_2BF_4$] and Br^-, Cl^-, or F^-, respectively.[1672] This reaction, which is also successful for triple bonds,[1673] can be extended to addition of I and other nucleophiles (e.g., NCO, OH, OAc, and NO_2).[1673]



Conjugated systems give both 1,2- and 1,4-addition.[1644] Triple bonds add bromine, although generally more slowly than double bonds (see Sec. 15.B.i). Molecules that contain both double and triple bonds are preferentially attacked at the double bond. Addition of 2 molar equivalents of bromine to triple bonds gives tetrabromo products. There is evidence that the addition of the first molar equivalent of bromine to a triple bond may take place by a nucleophilic mechanism.[1674] Molecular diiodine on Al_2O_3 adds to triple bonds to give good yields of 1,2-diiodoalkenes.[1675] Interestingly, 1,1-diiodo alkenes are prepared from an alkynyltin compound, via initial treatment with $Cp_2Zr(H)Cl$, and then 2.15 equiv of iodine.[1676] A mixture of $NaBO_3$ and NaBr adds two bromine atoms across a triple bond.[1677] With allenes it is easy to stop the reaction after only 1 equiv has added, to give X—C—CX=C.[1678] Addition of halogen to ketenes gives α-halo acyl halides, but the yields are not good.

15-40 Addition of Hypohalous Acids and Hypohalites (Addition of Halogen, Oxygen)

Hydroxy-chloro-addition, and so on.[1679]

Alkoxy-chloro-addition, and so on

Hypohalous acids (HOCl, HOBr, and HOI) react with alkenes[1680] to produce halohydrins.[1681] Both HOBr and HOCl can be generated *in situ* by the reaction between water and Br_2 or Cl_2, respectively. The compound HOI, generated from I_2 and H_2O, also adds to

double bonds, if the reaction is carried out in tetramethylene sulfone–$CHCl_3$[1682] or if an oxidizing agent (e.g., HIO_3) is present.[1683] Iodine and cerium sulfate in aq acetonitrile generates iodohydrins,[1684] as do iodine and ammonium acetate in acetic acid,[1685] or $NaIO_4$ with sodium bisulfite.[1686]

The HOBr can also be conveniently added by the use of a reagent consisting of an *N*-bromo amide (e.g., NBS or *N*-bromoacetamide) and a small amount of water in a solvent (e.g., DMSO or dioxane).[1687] *N*-Iodosuccinimide in aq dimethoxyethane leads to the iodohydrin.[1688] An especially powerful reagent for HOCl addition is *tert*-butyl hydroperoxide (or di-*tert*-butyl peroxide) along with $TiCl_4$.[1689] Chlorohydrins can be conveniently prepared by treatment of the alkene with Chloramine T ($TsNCl^-\ Na^+$)[1690] in acetone–water.[1691] The compound HOI can be added by treatment of alkenes with periodic acid and $NaHSO_3$.[1692] There are Se catalyzed iodohydrin forming reactions.[1693] The reaction of an alkene with polymeric $(SnO)_n$, and then HCl with $Me_3SiOOSiMe_3$, leads to the chlorohydrin.[1694] Hypervalent iodine compounds react with an alkene and iodine in aqueous media to give the iodohydrin.[1695] Halohydrins are produced in ionic liquids.[1696] *N*-Bromo and *N*-iodosaccharin have been used to prepare the corresponding halohydrins.[1697]

The compound HOF has also been added, but this reagent is difficult to prepare in a pure state and *explosions have occurred*.[1698]

The mechanism of HOX addition is electrophilic, with initial attack by the alkene on the positive halogen end of the HOX dipole. Following *Markovnikov's rule*, the positive halogen goes to the side of the double bond that has more hydrogen atoms (forming a more stable carbocation). This carbocation (or bromonium or iodonium ion in the absence of an aqueous solvent) reacts with ^-OH or H_2O to give the product. If the substrate is treated with Br_2 or Cl_2 (or another source of positive halogen, e.g., NBS) in an alcohol or a carboxylic acid solvent, it is possible to obtain, directly C—C—C—OR or X—C—C—OCOR, respectively (see also, Reaction **15-48**).[1699] Even the weak nucleophile $CF_3SO_2O^-$ can participate in the second step. The addition of Cl_2 or Br_2 to alkenes in the presence of this ion resulted in the formation of some β-haloalkyl triflates.[1700] There is evidence that the mechanism with Cl_2 and H_2O is

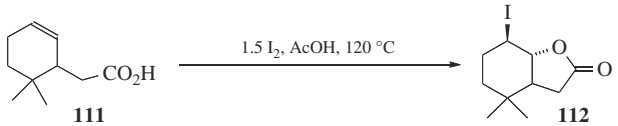
different from that with HOCl.[1701] Both HOCl and HOBr can be added to triple bonds to give dihalo carbonyl compounds (—CX_2—CO—).

Alcohols and halogens react with alkenes to form halo ethers. When a homoallylic alcohol is treated with bromine, cyclization occurs to give a 3-bromotetrahydrofuran derivative.[1702] *tert*-Butyl hypochlorite (Me_3COCl), hypobromite, and hypoiodite[1703] add to double bonds to give halogenated *tert*-butyl ethers (X—C—C—$OCMe_3$). This is a convenient method for the preparation of tertiary ethers. Iodine and ethanol convert some alkenes to iodo-ethers.[1704] Iodine, alcohol, and a $Ce(OTf)_2$ catalyst also generates the iodo-ether.[1705] When Me_3COCl or Me_3COBr is added to alkenes in the presence of excess ROH, the ether X—C—C—OR is produced.[1706] Vinylic ethers give β-halo acetals.[1707] Chlorine acetate [solutions of which are prepared by treating Cl_2 with $Hg(OAc)_2$ in an appropriate solvent] adds to alkenes to give acetoxy chlorides.[1708] Acetoxy fluorides have been obtained by treatment of alkenes with CH_3COOF.[1709]



For a method of iodoacetyl addition, see Reaction **15-48**.

15-41 Halolactonization and Halolactamization

Halo-alkoxylation

Halo esters can be formed by addition of halogen atoms and ester groups to an alkene. Alkene carboxylic acids give a tandem reaction of formation of a halonium ion followed by intramolecular displacement of the carboxylic group to give a halo lactone. This tandem addition of X and OCOR is called *halolactonization*.[1710]

111 **112**

The most common version of this reaction is known as *iodolactonization*,[1711] and a typical example is the conversion of **111** to **112**.[1712] Bromo lactones and, to a lesser extent, chloro lactones have also been prepared. In general, addition of the halogen to an alkenyl acid, as shown, leads to the halo-lactone. Other reagents include $I^+(collidine)_2PF_6^-$,[1713] KI/sodium

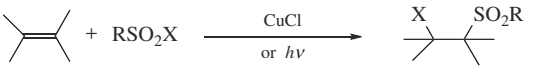
persulfate.[1714] The Tl[1715] and Y[1716] reagents, along with the halogen, have also been used. An enantioselective 5-endo-halolactonization procedure has been reported using systems, such as iodobis(collidine) hexafluorophosphate or $AgSbF_6$, followed by iodine.[1717] When done in the presence of a chiral Ti reagent, I_2, and CuO, lactones are formed with good enantioselectivity.[1718] Iodine monochloride (ICl) has been used, with formation of a quaternary center at the oxygen-bearing carbon of the lactone.[1719] Organocatalysts have also been used to mediate asymmetric halolactonization reactions.[1720] Enantioselective iodolactonization occurs with pentenoic acid derivatives in the presence of a chiral Co(salen) complex.[1721]

In the case of γ,δ-unsaturated acids, five-membered rings (γ-lactones) are predominantly formed (as shown above; note that *Markovnikov's rule* is followed), but six-membered and even four-membered lactones have also been made by this procedure. There is a *gem-dimethyl effect* that favors formation of 7–11 membered ring lactones by this procedure.[1722]



113 **114**

Formation of halo-lactams (Reaction **15-43**) by a procedure similar to halolactonization is difficult, but the problems have been overcome. Formation of a triflate from **113** followed by treatment with iodine leads to the iodolactam (**114**).[1723] A related cyclization of *N*-sulfonyl-amino alkenes and NBS gave the bromo-lactam,[1724] and a dichloro-*N,N*-bis (allylamide) was converted to a dichloro-lactam with $FeCl_2$.[1725] Note that lactone formation is possible from unsaturated amides

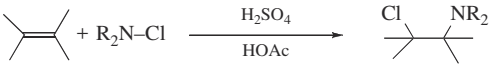
[1726] When a general group (e.g., halo) is used, its priority is that of the lowest member of its group (see Ref. 1680). Thus the general name for this transformation is halo-alkylsulfonyl addition because "halo" has the same priority as "fluoro", its lowest member.



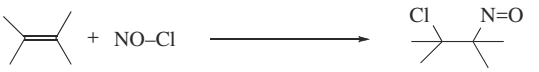
Sulfonyl halides add to double bonds to give β-halo sulfones, in the presence of free radical initiators or UV light. A particularly good catalyst is cuprous chloride.[1727] In the presence of TsCl, AIBN and a Ru catalyst, β-chloro sulfones are generated from alkenes.[1728] A combination of the anion $ArSO_2Na$, NaI, and ceric ammonium nitrate converts alkenes to vinyl sulfones.[1729] Triple bonds behave similarly, to give β-halo-α,β-unsaturated sulfones.[1730] In a similar reaction, sulfenyl chlorides, (RSCl) give β-halo thioethers.[1731] The latter may be free radical or electrophilic additions, depending on conditions. The addition of MeS and Cl has also been accomplished by treating the alkene with Me_3SiCl and Me_2SO.[1732] The use of Me_3SiBr and Me_2SO does not give this result; dibromides (Reaction **15-39**) are formed instead.

β-Iodothiocyanates can be prepared from alkenes by treatment with I_2 and isothiocyanatotributylstannane (Bu_3SnNCS).[1733] Bromothiocyanation can be accomplished with Br_2 and thallium(I) thiocyanate.[1734] Lead(II) thiocyanate reacts with terminal alkynes in the presence of $PhICl_2$ to give the bis(thiocyanato) alkene [ArC(SCN)—CHSCN].[1735] Such compounds were also prepared from alkenes using KSCN and $FeCl_3$[1736]or iodine thiocyanate.[1737] β-Halo disulfides, formed by addition of arenethiosulfenyl chlorides to double-bond compounds, are easily converted to thiiranes by treatment with sodium amide or sodium sulfide.[1738]

OS **VIII**, 212. See also, OS **VII**, 251.

15-43 Addition of Halogen and a Nitrogen Group (Addition of Halogen, Nitrogen)

Dialkylamino-chloro-addition



The groups R_2N and Cl can be added directly to alkenes, allenes, conjugated dienes, and alkynes, by treatment with dialkyl-*N*-chloroamines and acids.[1739] *N*-Halo amides (RCONHX) add RCONH and X to double bonds under the influence of UV light or chromous chloride.[1740] *N*-Bromoamides add to alkenes in the presence of a transition metal

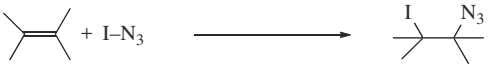
catalyst (e.g., $SnCl_4$) to give the corresponding β-bromo amide.[1741] The reaction of $TsNCl_2$ and a $ZnCl_2$ catalyst gave the chloro tosylamine.[1742] Aminochlorination of alkenes occurs in a CO_2 promoted reaction with Chloramine-T ($TolSO_2N^-$—Cl).[1743] These are free radical additions, with initial attack by the $R_2NH^{\bullet+}$ radical ion.[1744] Amines add to allenes in the presence of a Pd catalyst.[1745] A mixture of *N*-(2-nosyl)NCl_2 and sodium *N*-(2-nosyl)NH^- with a CuOTf catalyst reacted with conjugated esters to give the *vicinal* (*E*)-3-chloro-2-amino ester.[1746] A variation of this latter reaction was done in an ionic liquid.[1747]

15-44 Addition of NOX and NO_2X (Addition of Halogen, Nitrogen)

Nitroso-chloro-addition

There are three possible products when NOCl is added to alkenes, a β-halo nitroso compound, an oxime, or a β-halo nitro compound.[1748] The initial product is always the β-halo nitroso compound,[1749] but these are stable only if the carbon bearing the nitrogen has no hydrogen. If it has, the nitroso compound tautomerizes to the oxime, H—C—N=O → C=N—OH. With some alkenes, the initial β-halo nitroso compound is oxidized by the NOCl to a β-halo nitro compound.[1750] Many functional groups may be present without interference (e.g., CO_2H, CO_2R, CN, OR). The mechanism in most cases is probably simple electrophilic addition, and the addition is usually anti, although syn addition has been reported in some cases.[1751] *Markovnikov's rule* is followed, the positive NO going to the carbon that has more hydrogen atoms.



Nitryl chloride (NO_2Cl) also adds to alkenes, to give β-halo nitro compounds, but this is a free radical process. The NO_2 goes to the less-substituted carbon.[1752] Nitryl chloride also adds to triple bonds to give the expected 1-nitro-2-chloro alkenes.[1753] The compound FNO_2 can be added to alkenes[1754] by treatment with HF in HNO_3[1755] or by addition of the alkene to a solution of nitronium tetrafluoroborate ($NO_2^+ BF_4^-$; see Reaction **11-2**) in 70% polyhydrogen fluoride–pyridine solution[1756] (see also, Reaction **15-37**).

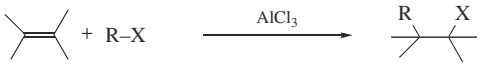
15-45 Addition of XN_3 (Addition of Halogen, Nitrogen)

Azido-iodo-addition

The addition of iodine azide to double bonds gives β-iodo azides.[1757] The reagent can be prepared *in situ* from KI—NaN_3 in the presence of Oxone–wet alumina.[1758] The addition is stereospecific and anti, suggesting that the mechanism involves a cyclic iodonium ion intermediate.[1759] The reaction has been performed on many double-bond compounds, including allenes[1760] and α,β-unsaturated ketones. Similar reactions can be performed with BrN_3[1761] and ClN_3. 1,4-Addition has been found with acyclic conjugated dienes.[1762] In the case of BrN_3, both electrophilic and free radical mechanisms are important,[1763] while with ClN_3 the additions are chiefly free radical.[1764] Iodine monoazide (IN_3) also adds to triple bonds to give β-iodo-α,β-unsaturated azides.[1765]



β-Iodo azides can be reduced to aziridines (**115**) with $LiAlH_4$[1766] or converted to *N*-alkyl- or *N*-arylaziridines (**116**) by treatment with an alkyl- or aryldichloroborane followed by a base.[1767] In both cases the azide is first reduced to the corresponding amine (primary or secondary, respectively) and ring closure (Reaction **10-31**) follows. With Chloramine T ($TsNCl^- Na^+$) and 10% of pyridinium bromide perbromide, however, the reaction with alkenes give an *N*-tosyl aziridine directly.[1768]

Alkyl halides can be added to alkenes in the presence of a *Friedel–Crafts catalyst,* most often $AlCl_3$.[1769] The yields are best for tertiary R. Secondary R can also be used, but primary R give rearrangement products (as with Reaction **11-11**). The reactive species is the carbocation formed from the alkyl halide and the catalyst (see Reaction **11-11**).[1770] The reaction with an alkene follows *Markovnikov's rule*, and generates the more stable carbocation from the alkene after reaction with the carbocation. Methyl and ethyl halides, which cannot rearrange to a more stable secondary or tertiary carbocation, give no reaction at all. Substitution is a side reaction, arising from loss of hydrogen from the carbocation (**117**). Conjugated dienes give 1,4-addition.[1771] Triple bonds also undergo the reaction, to give vinylic halides.[1772]

Simple polyhalo alkanes (e.g., CCl_4, $BrCCl_3$, ICF_3 and related molecules) add to alkenes in good yield.[1773] These are free radical additions and require initiation, for example,[1774] by peroxides, metal halides (e.g., $FeCl_2$, CuCl),[1775] Ru catalysts,[1776] or UV light. The initial reaction generates the more stable radical intermediate, as in most free radical reactions with alkenes:

Polyhalo alkanes add to halogenated alkenes in the presence of $AlCl_3$ by an electrophilic mechanism. This has been called the *Prins reaction* (not to be confused with the other *Prins Reaction*, **16-54**).[1777]

α-Iodolactones add to alkenes in the presence of BEt_3/O_2 to give the addition product.[1778] Other α-iodoesters add under similar conditions to give the lactone.[1779] Iodoesters also add to alkenes in the presence of BEt_3 to give iodo-esters that have not cyclized.[1780]

A variant of the free radical addition method has been used for ring closure (see Reaction **15-30**).

For another method of adding R and I to a triple bond, see Reaction **15-23**.

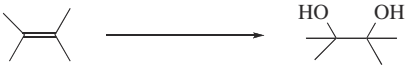
15-47 Addition of Acyl Halides (Addition of Halogen, Carbon)

Acyl-halo-addition



Acyl halides add to many alkenes using *Friedel–Crafts* catalysts, although polymerization is a problem. The reaction has been applied to straight-chain, branched, and cyclic alkenes, but to very few containing functional groups, other than halogen.[1781] The mechanism is similar to that of Reaction **15-46**, and, as in that case, substitution competes (Reaction **12-16**). Increasing temperature favors substitution,[1782] but good yields of addition products can be achieved if the temperature is kept under 0°C. The reaction usually fails with conjugated dienes, since polymerization predominates.[1783] Iodo acetates have been formed from alkenes using iodine and $Pb(OAc)_2$ in acetic acid.[1784] Rhodium-catalyzed variations are known.[1785] The reaction can be performed on triple-bond compounds, producing compounds of the form RCO—C=C—Cl.[1786] A *formyl* group and a halogen can be added to triple bonds by treatment with *N,N*-disubstituted formamides and $POCl_3$ (*Vilsmeier conditions*, Reaction **11-18**).[1787] Chloroformates add to allenes in the presence of a Rh catalyst to give a β-chloro, β,γ-unsaturated ester.[1788]

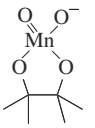
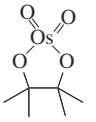
B. Oxygen, Nitrogen, or Sulfur on One or Both Sides

15-48 Dihydroxylation and Dialkoxylation (Addition of Oxygen, Oxygen)



Dihydroxy-addition, Dialkoxy-addition



There are many reagents that add two OH groups to a double bond (dihydroxylation).[1789] The most common are OsO_4,[1790] first used by Criegee in 1936,[1791] and alkaline $KMnO_4$.[1792] Both give syn addition from the less-hindered side of the double bond. Less

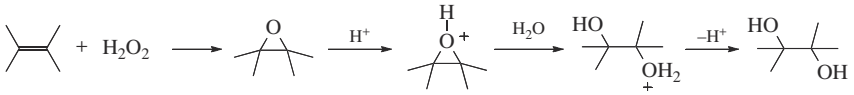
substituted double bonds are oxidized more rapidly than more substituted alkenes.[1793] Permanganate adds to alkenes to form an intermediate manganate ester (Reaction **118**), which is decomposed under alkaline conditions. Transition state structures and the energetics of the permanganate oxidation of alkenes has been studied using molecular mechanics.[1794] Bases catalyze the decomposition of **118** by coordinating with the ester. Note that there are alternative Mn complexes that may be used for cis-dihydroxylation of alkenes.[1795] Osmium tetroxide adds rather slowly but almost quantitatively to form a cyclic osmate ester (e.g., **119**) as an intermediate,[1796] which may be isolated in some cases, but is usually decomposed in solution with sodium sulfite (Na_2SO_3) in ethanol or other reagents.[1797]

118



119

The chief drawbacks to the use of OsO_4 are the facts that it is expensive and toxic, but the reaction is made catalytic in OsO_4 by using *N*-methylmorpholine-*N*-oxide (NMO),[1798] *tert*-butyl hydroperoxide in alkaline solution,[1799] H_2O_2,[1800] peroxyacid,[1801] $K_3Fe(CN)_6$,[1802] and non-heme iron catalysts.[1803] Polymer-bound OsO_4,[1804] and encapsulated OsO_4 have been shown to give the diol in the presence of NMO,[1805] as well as OsO_4^{2-} on an ion exchange resin.[1806] Dihydroxylation has also been reported in ionic liquids.[1807] Other metals have been used to catalyze dihydroxylation, including Fe[1808] or Ru catalyzed[1809] reactions with H_2O_2. A catalytic amount of K_2OsO_4 with a Cinchona alkaloid on a ordered inorganic support, in the presence of $K_3Fe(CN)_6$, gives the *cis*-diol.[1810]

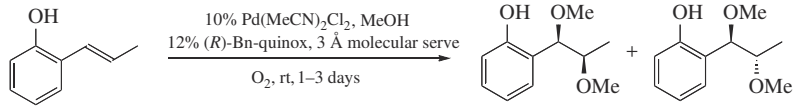
The end product of the reaction is a 1,2-diol. Potassium permanganate is a strong oxidizing agent and can oxidize the glycol product[1811] (see Reaction **19-7** and **19-10**). In acidic and neutral solution, it always does so; hence glycols must be prepared with alkaline[1812] permanganate, but the conditions must be mild. Even so, yields are seldom >50%, although they can be improved with phase-transfer catalysis[1813] or increased stirring.[1814] The use of ultrasound with permanganate has resulted in good yields of the diol.[1815] This reaction is the basis of the *Baeyer test* for the presence of double bonds. The oxidation is compatible with a number of functional groups, including trichloroacetamides.[1816]

Anti-hydroxylation can be achieved by treatment with H_2O_2 and formic acid. In this case, epoxidation (Reaction **15-50**) occurs first, followed by an S_N2 reaction, which results in overall anti addition:



The same result can be achieved in one step with *m*-chloroperoxybenzoic acid and water.[1817] Overall anti addition can also be achieved by the method of Prévost (the *Prévost reaction*). In this method, the alkene is treated with iodine and silver benzoate in a 1:2 molar ratio. The initial addition is anti and results in a β-halo benzoate, as shown. These can be isolated, and this represents a method of addition of IOCOPh. However, under normal reaction conditions, the iodine is replaced by a second PhCOO group. This is a nucleophilic substitution reaction via the neighboring-group mechanism (Sec. 10.C), so the groups are still anti:

Hydrolysis of the ester does not change the configuration. The *Woodward modification* of the Prévost reaction is similar, but results in overall syn hydroxylation.[1818] In this procedure, the alkene is treated with iodine and silver acetate in a 1:1 molar ratio in acetic acid containing water. Here again, the initial product is a β-halo ester; the addition is anti and a nucleophilic replacement of the iodine occurs. However, in the presence of water, neighboring-group participation is prevented or greatly decreased by solvation of the ester function, and the mechanism is the normal S_N2 process,[1819] so the monoacetate is syn and

hydrolysis gives the diol as the product, with overall syn addition. Although the *Woodward* method results in overall syn addition, the product may be different from that with OsO_4 or $KMnO_4$, since the overall syn process is from the *more hindered side* of the alkene.[1820] Both the *Prévost* and the *Woodward* methods[1821] have been carried out in high yields with thallium(I) acetate and thallium(I) benzoate instead of the silver carboxylates.[1822] Note that cyclic sulfates can be prepared from alkenes by reaction with PhIO and $SO_3 \cdot DMF$.[1823] Diacetates have been prepared from alkenes using a Cu catalyzed reaction with $PhI(OAc)_2$ as the oxidizing agent.[1824] A similar Pd/Cu catalyzed reaction is known using O_2 as the oxidant.[1825]

120 (5 : 1) (63%)

Dialkoxylation reactions are possible. The reaction of an aryl alkene with CH_3OH, O_2, and a Pd catalyst leads to the dimethoxy compound (see Reaction **120**), with moderate enantioselectivity if a chiral ligand is used.[1826] Dihydroxylation to alkenes of the form $RCH{=}CH_2$ has been made enantioselective, and addition to $RCH{=}CHR'$ both diastereoselective[1827] and enantioselective,[1828] using chiral additives or chiral catalysts[1829] (e.g., **121** or **122**, derivatives of the naturally occurring quinine and quinuclidine),[1830] along with OsO_4, in what is called

Sharpless asymmetric dihydroxylation.[1831] Other chiral ligands[1832] have also been used, as well as polymer[1833] and silica-bound[1834] *Cinchona* alkaloids. These amines bind to the OsO_4 *in situ* as chiral ligands, causing it to add asymmetrically.[1835] This has been done both with the stoichiometric and with the catalytic method.[1836] The catalytic method has been extended to conjugated ketones[1837] and to conjugated dienes, which give tetrahydroxy products diastereoselectively.[1838] Asymmetric dihydroxylation has also been reported with chiral alkenes.[1839] Ligands **121** and **122** not only cause enantioselective addition, but also accelerate the reaction, so that they may be useful even where enantioselective addition is not required.[1840] Although **121** and **122** are not enantiomers, they give enantioselective addition to a given alkene in the opposite sense; for example, styrene predominantly gave the (*R*) diol with **121**, and the (*S*) diol with **122**.[1841] Note that ionic liquids have been used in asymmetric dihydroxylation.[1842]

123

124

Two phthalazine derivatives,[1843] $(DHQD)_2PHAL$ (**123**) and $(DHQ)_2PHAL$ (**124**) are used in conjunction with an Os reagent to improve the efficiency and ease of use, and are commercial available as AD-mix-β (using **123**) and AD-mix-α (using **124**). Catalyst **123** is prepared from dihydroquinidine (DHQD) and 1,4-dichlorophthalazine (PHAL), and **124** is prepared from dihydroquinine (DHQ) and PHAL. The actual oxidation using AD-mix α or β- uses **124** or **123**, respectively, mixed with potassium osmate $[K_2OsO_2(OH)_6]$, powdered $K_3Fe(CN)_6$, and powdered K_2CO_3 in an aqueous solvent mixture.[1843] One study

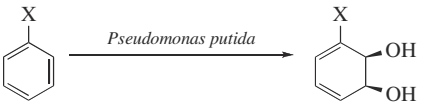
showed that osymylation does not always occur preferentially on the most electron-rich double bond. There are examples of the less-rich double bond reacting preferentially, and such preferences may be amplified using AD type reagents, which adds significant steric hindrance to the overall system.[1844]

These additives have been used in conjunction with microencapsulated OsO_4,[1845] and polymer bound **123** has been used.[1846] An asymmetric dihydroxylation was reported catalyzed by ionic polymer-supported OsO_4.[1847] A catalytic amount of flavin has been used.[1848] Both **123**[1849] and **124**[1850] have been used to generate diols with high enantioselectivity. Oxidation of a terminal alkene with AD-mix and then oxidation with TEMPO/NaOCl/$NaOCl_2$ leads to α-hydroxyl carboxylic acids with high enantioselectivity.[1851]

Enantioselective and diastereoselective addition have also been achieved by using preformed derivatives of OsO_4, already containing chiral ligands,[1852] and by the use of OsO_4 on alkenes that have a chiral group elsewhere in the molecule.[1853] A Rh catalyzed diboration of alkenes in the presence of a chiral ligand, leads to the corresponding diol with good enantioselectivity after oxidation.[1854]

Alkenes can also be oxidized with metallic acetates [e.g., lead tetraacetate[1855] or thallium(III) acetate][1856] to give bis(acetates) of glycols.[1857] Oxidizing agents (e.g., benzoquinone, MnO_2, or O_2), along with palladium acetate, have been used to convert conjugated dienes to 1,4-diacetoxy-2-alkenes (1,4-addition).[1858]



1,2-Diols are also generated from terminal alkynes by two sequential reactions with a Pt catalyst and then a Pd catalyst, both with $HSiCl_3$, and a final oxidation with H_2O_2—KF.[1859] The dihydroxylation of a vinyl ether, derived from an alkyne, leads to α-hydroxy aldehydes.[1860] Dihydroxylation of alkenes has been reported using a lipase and hydrogen peroxide, under microwave irradiation.[1861] A Pd catalyzed diacetoxylation is also known.[1862]

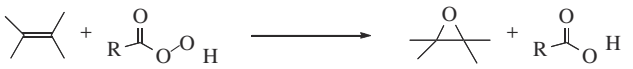
1,2-Dithiols can be prepared from alkenes by largely indirect methods.[1863]
OS **II**, 307; **III**, 217; **IV**, 317; **V**, 647; **VI**, 196, 342, 348; **IX**, 251, 383.

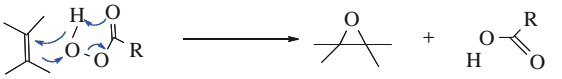
15-49 Dihydroxylation of Aromatic Rings



Dihydroxy-addition

One π bond of an aromatic ring can be converted to a cyclohexadiene 1,2-diol by reaction with enzymes associated with *P. putida*.[1864] A variety of substituted aromatic compounds can be oxidized, including bromobenzene, chlorobenzene,[1865] and toluene.[1866] In these latter cases, introduction of the hydroxyl groups generates a chiral molecule that can be used as a template for asymmetric syntheses.[1867]
OS **X**, 217.

15-50 Epoxidation (Addition of Oxygen, Oxygen)



epi-Oxy-addition

Alkenes are converted to epoxides (oxiranes) by reaction with many peroxyacids.[1868] The reaction, called the *Prilezhaev reaction*, has wide utility.[1869] The most common is probably *m*-chloroperoxybenzoic acid, but peroxyacetic and peroxybenzoic are available, and trifluoroperoxyacetic acid[1870] and 3,5-dinitroperoxybenzoic acid[1871] are particularly reactive. The limiting factor concerning choice of the peroxyacid is usually whether or not it is commercially available because an in-lab preparation is potentially rather dangerous. Magnesium monoperoxyphthalate (MMPP)[1872] is commercially available, and has been shown to be a good substitute for *m*-chloroperoxybenzoic acid in a number of reactions.

Alkyl, aryl, hydroxyl, ester, and other groups may be present, but not amino groups since they are oxidized by the reagent. The presence of electron-donating groups increases the rate, and the reaction is particularly rapid with tetraalkyl alkenes. Conditions are mild and yields are high. Transition metal catalysts can facilitate epoxidation of alkenes at low temperatures or with alkenes that may otherwise react sluggishly.[1873]

125

The one-step mechanism involving a transition state (e.g., **125**)[1874] was proposed by Bartlett.[1875] Evidence for this concerted mechanism is as follows[1876]: (1) The reaction is second order. If ionization were the rate-determining step, it would be first order in peroxyacid. (2) The reaction readily takes place in nonpolar solvents, where formation of ions is inhibited.[1877] (3) Measurements of the effect on the reaction rate of changes in the substrate structure show that there is no carbocation character in the transition state.[1878] (4) The addition is stereospecific (i.e., a *trans*-alkene gives a *trans*-epoxide and a *cis*-alkene gives a *cis*-epoxide) even in cases where electron-donating substituents would stabilize a hypothetical carbocation intermediate.[1879] However, where there is an OH group in the allylic or homoallylic position, the stereospecificity diminishes or disappears, with both cis and trans isomers giving predominantly and exclusively the product where the incoming oxygen is syn to the OH group. This probably indicates a transition state in which there is hydrogen bonding between the OH group and the peroxyacid.[1880]

In general, peroxides (HOOH[1881] and ROOH) are poor reagents for epoxidation of simple alkenes since OH and OR are poor leaving groups in the concerted mechanism shown above.[1882] Transition metal catalysts[1883] have been used with alkyl hydroperoxides,[1884]

however. Epoxidation occurs with Fe,[1885] and with Ti[1886] or V catalysts.[1887] In the presence of some other reagents,[1888] peroxides give good yields of the epoxide. These coreagents include DCC,[1889] magnesium aluminates,[1890] metalloporphyrins,[1891] hydrotalcite[1892] with microwave irradiation,[1893] and arsines in fluorous solvents.[1894] The catalyst $MeReO_3$[1895] has been used for epoxidation using sodium percarbonate and pyrazole,[1896] or hydrogen peroxide,[1897] or urea–H_2O_2.[1898]

Epoxidation has been done in ionic liquids using 10% H_2O_2 with $MnSO_4$[1899] or an Fe catalyst.[1900] Hypervalent iodine compounds [e.g., $PhI(OAc)_2$], in conjunction with a Ru catalyst in aqueous media, converts alkenes to epoxides.[1901] This reagent has been used in an ionic liquid with a Mn catalyst.[1902] Sodium chlorite ($NaClO_2$) in water gives epoxidation from alkenes.[1903] Microwave assisted epoxidations are known using H_2O_2.[1904] Epoxidation of vinyl ethers has been studied.[1905]

Several homogeneous and heterogeneous asymmetric epoxidation protocols have been developed.[1906] Enzymatic epoxidation[1907] and epoxidation with catalytic antibodies[1908] have been reported. Organocatalysts (e.g., chiral iminium salts) have been used.[1909] Asymmetric *Weitz–Scheffer epoxidation*[1910] (epoxidation of electron-deficient alkenes

using H_2O_2 in a strong alkaline solution) is common. Cinchona-derived phase-transfer catalysts, initially used by Wynberg, are now common.[1911] Enantioselectivities can be significantly improved by changes of the catalyst structure, as well as the type of oxidant.[1912] A Yb—BINOL complex, with *t*-BuOOH led to epoxidation of conjugated ketones with high asymmetric induction,[1913] as did a mixture of NaOCl and a *Cinchona* alkaloid.[1914] Treatment with aq NaOCl[1915] or with an alkyl hydroperoxide[1916] and a chiral phase-transfer agent leads to chiral nonracemic epoxy-ketones. Epoxides can also be prepared by treating alkenes with oxygen or with an alkyl peroxide[1917] catalyzed by a complex of a transition metal (e.g., V, Mo, Ti, La,[1918] Y,[1919] or Co).[1920] The use of chiral additive leads to enantioselective epoxidation,[1921] and organocatalysts have been used as well.[1922] Chiral hydroperoxides have been used for enantioselective epoxidation.[1923]

Other epoxidation methods are available. Dioxiranes,[1924] (e.g., dimethyl dioxirane, **126**),[1925] either isolated or generated *in situ*,[1926] are important epoxidation reagents. With dimethyloxirane, C—H insertion reactions can occur preferentially.[1927] The reaction with alkenes is rapid, mild, safe, and a variety of methods have been developed using an oxidant as a coreagent. Substituent effects in such reactions have been studied[1928] and also substrate variations.[1929] The most commonly used coreagent is probably potassium peroxomonosulfate ($KHSO_5$). Oxone ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$) is a common source of $KHSO_5$. Oxone reacts with ketones[1930] and sodium bicarbonate to convert an alkene to

an epoxide. Oxone converts alkenes to epoxides in the presence of certain additives (e.g., *N,N*-dialkylalloxans).[1931] Oxone, with hydrogen peroxide or a similar oxidant, can be used with chiral ketones[1932] or aldehydes to convert alkenes to chiral, nonracemic epoxides.[1933] This reaction probably converts alkenes to epoxides with good enantioselectivity by *in situ* generation of dioxirane.[1934] Chiral dioxiranes have reportedly given nonracemic epoxides.[1935] This transformation with chiral carbohydrates is sometimes called *Shi epoxidation*.[1936] Epoxidation does not occur in good yields with these reagents in most other solvents, and it is suggested that the active agent that generates dioxirane is peroxyimidic acid [MeC(=NH)OOH].[1937] Note that benzaldehyde with Chloramine-M[1938] will convert alkenes to epoxides.[1939]

Oxone oxidizes iminium salts to an oxaziridinium intermediate (**127**), which can transfer oxygen to an alkene to form an epoxide and regenerate the iminium salt.[1940] This variation has been applied to asymmetric[1941] epoxidations using chiral iminium salt precursors.[1942] Other asymmetric epoxidation reactions of alkenes use chiral ketones and iminium salts with an organocatalyst.[1943] Direct epoxidation of alkenes has been done using oxaziridinium salts.[1944]

Although cis–trans isomerization of epoxides is not formally associated with this section, it is a potential issue in the conversion of an alkene to an epoxide. There are several catalysts for this process.[1945]

It would be useful if triple bonds could be similarly epoxidized to give oxirenes (see oxirene, above), but they are not stable compounds.[1946] Two oxirenes have been trapped in solid argon matrices at very low temperatures, but they decayed upon warming to 35 K.[1947] Oxirenes probably form in the reaction,[1948] but react further before they can be isolated. Note that oxirenes bear the same relationship to cyclobutadiene that furan does to benzene and may therefore be expected to be antiaromatic (Sec. 2.B and 2.K.ii).

Conjugated dienes can be epoxidized (1,2-addition), although the reaction is slower than for corresponding alkenes, but α,β-unsaturated ketones do not generally give epoxides when treated with peroxyacids.[1949] The epoxidation of α,β-unsaturated ketones with H_2O_2 under basic conditions is known as the *Waits–Scheffer epoxidation*, discovered in 1921.[1950] This fundamental reaction has been extended to α,β-unsaturated ketones (including quinones), aldehydes, and sulfones.[1951] This is a nucleophilic addition by a *Michael-type* mechanism, involving attack by HO_2^-[1952]: This reaction is another example of 1,4-addition of a heteroatom-containing species, as discussed in Reaction **15-31**.

α,β-Unsaturated compounds can be epoxidized alkyl hydroperoxides and a base,[1953] or with H_2O_2 and a base[1954]or heteropoly acids.[1955] The reaction has been done with LiOH and polymer-bound quaternary ammonium salts.[1956]

Another important asymmetric epoxidation of a conjugated system is the reaction of alkenes with polyleucine,[1957] DBU, and urea–H_2O_2, giving an epoxy–carbonyl compound with good enantioselectivity.[1958] The hydroperoxide anion epoxidation of conjugated

carbonyl compounds with a polyamino acid (e.g., poly-L-alanine or poly-L-leucine is known as the *Juliá–Colonna epoxidation*.[1959] Epoxidation of conjugated ketones to give nonracemic epoxy-ketones was done with aq NaOCl and a Cinchona alkaloid derivative as catalyst.[1960] A triphasic phase-transfer catalysis protocol has also been developed.[1961] β-Peptides have been used as catalysts in this reaction.[1962]

When a carbonyl group is elsewhere in the molecule, but not conjugated with the double bond, the *Baeyer–Villiger Reaction* (**18-19**) may compete. Allenes[1963] are converted by peroxyacids to allene oxides[1964] or spiro dioxides, both of which species can in certain cases be isolated,[1965] but more often are unstable under the reaction conditions and react further to give other products.[1966]

Allylic alcohols can be converted to epoxy-alcohols with *tert*-butylhydroperoxide on molecular sieves,[1967] or with peroxyacids.[1968] The addition of an appropriate chiral ligand to the metal-catalyzed hydroperoxide epoxidation of allylic alcohols leads to high enantioselectivity. This important modification is known as the *Sharpless asymmetric epoxidation*,[1969] where allylic alcohols are converted to optically active epoxides with excellent enantioselectivity by treatment with *t*-BuOOH, titanium tetraisopropoxide, and optically active diethyl tartrate.[1970] The $Ti(OCHMe_2)_4$ and diethyl tartrate can be present in catalytic amounts (15–10 mol%) if molecular sieves are present.[1971] Polymer-supported catalysts have also been reported.[1972] The use of a tartrate–PEG reagent (PEG_{350} or PEG_{750}) allows generation of both enantiomers.[1973] Both (+) and (−) diethyl tartrate are readily available, so either enantiomer of the product can be prepared. The method has been successful for a wide range of primary allylic alcohols, including substrates where the double bond is mono-, di, tri-, and tetrasubstituted,[1974] and is highly useful in natural product synthesis. The mechanism of the Sharpless epoxidation is believed to involve attack on the substrate by a compound[1975] formed from the titanium

alkoxide and the diethyl tartrate to produce a complex that also contains the substrate and the *t*-BuOOH.[1976]

Ordinary alkenes (without an allylic OH group) do not give optically active alcohols by the Sharpless protocol because binding to the catalyst is necessary for enantioselectivity. Homoallylic alcohols have been converted to the epoxide, however, using a V catalyst in the presence of a chiral bis(hydroxyamide).[1977] Simple alkenes can be epoxidized enantioselectively with sodium hypochlorite (NaOCl, commercial bleach) and an optically active manganese complex catalyst.[1978] Apart from the commonly used NaOCl, urea–H_2O_2 has been used.[1979]

The use of a manganese–salen complex[1980] with various oxidizing agents, in what is called the *Jacobsen–Katsuki reaction*.[1981] Simple alkenes can be epoxidized with high enantioselectivity.[1982] In addition to Mn, Cr–salen,[1983] Ti–salen,[1984] and Ru–salen complexes[1985] have been used for epoxidation.[1986] Note that salen ligands are based on salen. The mechanism of this reaction has been examined.[1987] Radical intermediates have been suggested for this reaction,[1988] A polymer-bound Mn(III)–salen complex, in conjunction with NaOCl, has been used for asymmetric epoxidation,[1989] and manganese porphyrin complexes have also been used.[1990] Cobalt complexes give similar results.[1991] A related epoxidation reaction used an iron complex with molecular oxygen and isopropanal.[1992] Nonracemic epoxides can be prepared from racemic epoxides with (salen) cobalt(II) catalysts following a modified procedure for kinetic resolution.[1993]

In a different type of reaction, alkenes are photooxygenated (with singlet O_2, see Reaction **14-7**) in the presence of a Ti, V, or Mo complex to give epoxy alcohols (e.g., **128**), formally derived from allylic hydroxylation followed by epoxidation.[1994] In other cases, modification of the procedure gives simple epoxidation.[1995] Alkenes react with aldehydes and oxygen, with Pd-on-silica[1996] or a Ru catalyst,[1997] to give the epoxide.

128
(67%)

Thiiranes can be prepared directly from alkenes using specialized reagents.[1998] Thiourea with a tin catalyst gives the thiirane, for example.[1999] Interestingly, internal alkynes were converted to 1,2-dichorothiiranes by reaction with S_2Cl_2 (sulfur monochloride).[2000] Note that epoxides are converted to thiiranes with ammonium thiocyanate and a cerium complex.[2001] A trans-thiiration reaction occurs with a Mo catalyst, in which an alkene reacts with styrene thiirane to give the new thiirane.[2002]

15-51 Hydroxysulfenylation (Addition of Oxygen, Sulfur)

Hydroxy-arylthio-addition (overall transformation)

Both hydroxy and an arylthio group are added to a double bond by treatment with an aryl disulfide and lead tetraacetate in the presence of trifluoroacetic acid.[2003] Manganese and copper acetates have been used instead of $Pb(OAc)_4$.[2004] Addition of the groups OH and RSO has been achieved by treatment of alkenes with O_2 and a thiol (RSH).[2005] Addition to RS groups to give *vic*-dithiols was observed by treatment of the alkene

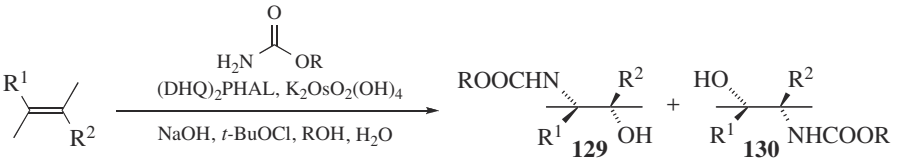
with a disulfide (RSSR) and BF_3–etherate.[2006] This reaction has been carried out intramolecularly.[2007] In a similar manner, the reaction of alkenes with ceric ammonium nitrate and diphenyl diselenide in methanol leads to vicinally substituted phenylselenyl methyl ethers.[2008] Dimethyl diselenide adds to alkenes to form vicinal bis(methylselenyl) compounds, in the presence of tin tetrachloride.[2009]

Halo-ethers can be formed by the reaction of alkenyl alcohols with various reagents. Hept-6-en-1-ol reacts with $(collidine)_2I^+PF_6^-$, for example, to form 2-iodomethyl-1-oxacycloheptane.[2010]

15-52 Oxyamination (Addition of Oxygen, Nitrogen)



Tosylamino-hydroxy-addition

N-Tosylated β-hydroxy alkylamines, which can be easily hydrolyzed to β-hydroxyamines[2011], can be prepared[2012] by treatment of alkenes with the trihydrate of Chloramine-T (*N*-chloro-*p*-toluenesulfonamide sodium salt)[1690] and a catalytic amount of OsO_4.[2013] In some cases, yields can be improved by the use of phase-transfer catalysis.[2014] The reaction has been carried out enantioselectively.[2015] Alkenes can be converted to amido alcohols enantioselectivity by modification of this basic scheme. The *Sharpless asymmetric aminohydroxylation* employs a catalyst consisting of *Cinchona* alkaloid derived ligands and an osmium species in combination with a stoichiometric nitrogen source that also functions as the oxidant.[2016] The Cu catalyzed reaction of an alkene with a *N*-sulfone oxaziridine leads to an oxazolidine.[2017] *N*-Chlorosulfonyl isocyanate has been used to prepare 1,2-amino alcohols.[2018] The Cu catalyzed hydroxyamination of alkenes was reported using Boc-hydroxylamine.[2019]

The reaction of a carbamate with $(DHQ)_2PHAL$ (**124**) and the osmium compound, with NaOH and *tert*-butyl hypochlorite, leads to a diastereomeric mixture of amido alcohols **129** and **130**, each formed with high enantioselectivity.[2020] An enantioselective aminohydroxylation of acrylamides has been reported.[2021]

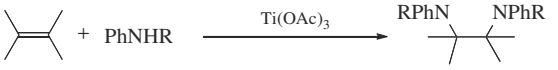
In general, the nitrogen adds to the less sterically hindered carbon of the alkene to give the major product. *N*-Bromoamides, in the presence of a catalytic amount of $(DHQ)_2PHAL$ and LiOH converts conjugated esters to β-amido-α-hydroxy esters with good enantioselectivity.[2022] Another oxyamination reaction involves treatment of a Pd complex of the alkene with a secondary or primary amine, followed by lead tetraacetate or another oxidant.[2023]



The organolanthanide-catalyzed alkene hydroamination has been reported.[2024] With this approach, amino alkenes (not enamines) can be cyclized to form cyclic amines,[2025] and amino alkynes lead to cyclic imine.[2026] The use of synthesized C-1[2027] and C-2 symmetric[2028] chiral organolanthanide complexes give the amino alcohol with good enantioselectivity.

β-Amino alcohols can be prepared by treatment of an alkene with a reagent prepared from HgO and HBF_4 along with aniline to give an aminomercurial compound (PhHN—C—C—$HgBF_4$, aminomercuration; see Reaction **15-7**), which is hydrolyzed to PhHN—C—C—OH.[2029] The use of an alcohol instead of water gives the corresponding amino ether. β-Azido alcohols are prepared by the reaction of an alkene with $Me_3SiOOSiMe_3$, Me_3SiN_3, and 20% $(Cl_2SnO)_n$, followed by treatment with aqueous acetic acid.[2030]

OS **VII**, 223, 375.

15-53 Diamination (Addition of Nitrogen, Nitrogen)

Di(alkylarylamino)-addition

Primary (R = H) and secondary aromatic amines react with alkenes in the presence of thallium(III) acetate to give *vic*-diamines in good yields.[2031] The reaction is not successful for primary aliphatic amines. In another procedure, alkenes can be diaminated by treatment

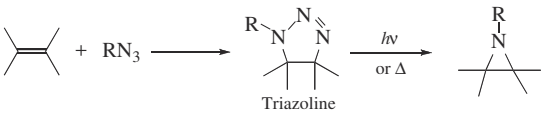
with the Os compounds R_3NOsO (R = *t*-Bu) and R_2NOsO_2,[2032] analogous to the Os compound mentioned at Reaction **15-52**.[2033] The Pd promoted method of Reaction **15-52** has also been extended to diamination.[2034] Alkenes can also be diaminated[2035] indirectly by treatment of the aminomercurial compound mentioned in Reaction **15-52** with a primary or secondary aromatic amine.[2036] The reaction of an alkene with *N*-arylsulfonyl dichloroamines ($ArSO_2NCl_2$) followed by reaction with aq Na_2SO_3, gives the *anti-vic*-diacetamde.[2037] The Pd catalyzed addition of saccharin and $H(NTs)_2$ with an alkene, in the presence of a hypervalent iodine oxidant leads to a precursor that can be converted to a 1,2-diamine.[2038]



Two azido groups can be added to double bonds by treatment with sodium azide and iodosobenzene in acetic acid, $C{=}C + NaN_3 + PhIO \rightarrow N_3{-}C{-}C{-}N_3$.[2039]

Dienes react with ureas in the presence of a Pd catalyst, to give an oxazolidinone.[2040] A Pd catalyzed reaction of dienes with di-*tert*-butyldiaziridinone also leads to an oxazolidinone.[2041]

Alkynes react with the bis(tosylate) of ethylenediamine, in the presence of a CuI catalyst, to give a dihydropiperazine.[2042]

15-54 Formation of Aziridines (Addition of Nitrogen, Nitrogen)

***epi*-Arylimino-addition**, and so on

Triazoline

Aziridines can be prepared directly from double-bond compounds by photolysis or thermolysis of a mixture of the substrate and an azide.[2043] The reaction has been carried out with R = aryl, cyano, EtOOC, and RSO_2, as well as other groups. The reaction can take place by at least two pathways.

In one pathway, a 1,3-dipolar addition (Reaction **15-58**) takes place to give a triazoline, which can be isolated, followed thermal by extrusion of nitrogen (Reaction **17-34**). Evidence for the nitrene pathway is most compelling for R = acyl groups. In the other, the azide is converted to a nitrene, which adds to the double bond in a manner analogous to

that of carbene addition (Reaction **15-64**). Sulfonyloxy amines (e.g., $ArSO_2ONHCO_2Et$) form an aziridine when treated with CaO in the presence of a conjugated carbonyl compound.[2044] In the presence of Cu,[2045] Co,[2046] or Rh complexes,[2047] ethyl diazoacetate adds to imines to give aziridines. Diazirenes (Sec. 5.D.ii) with *n*-butyllithium converted conjugated amides to the α,β-aziridino amide.[2048] Calcium oxide has also been used to generate the nitrene,[2049] including nitrene precursors that have an attached chiral ester.[2050] Other specialized reagents have also been used.[2051] As discussed in Section 5.E, singlet nitrenes add stereospecifically while triplet nitrenes do not. Aminonitrenes (R_2NN:) have been shown to add to alkenes[2052] to give N-substituted aziridines and to triple bonds to give 1-azirines, which arise from rearrangement of the initially formed 2-azirines.[2053] *N*-Aminophthalimide generates a nitrene in the presence of a Pd catalyst, giving an *N*-phthalimido aziridine upon reaction with electron-deficient alkenes.[2054] Alkyl azides add to conjugated alkenes in the presence of an acid.[2055] Intramolecular aziridination reactions are known (e.g., the Pd catalyzed addition of *N*-tosyloxycarbamates to alkenes to form the bicyclic oxaziridinone).[2056] Tosylamines react with alkenes in the presence of a Rh catalyst[2057] or with iodine/$PhI(OAc)_2$.[2058] Trichloroethylsulfamate esters react with $PhI(OAc)_2$ and a Rh catalyst to give the corresponding *N*-sulfonyl aziridine.[2059]

Like oxirenes (see Reaction **15-50**), 2-azirines are unstable. 1-Azirines can be reduced to give chiral aziridines.[2060]

An alternative preparation of aziridines reacts an alkene with iodine and Chloramine-T, generating the corresponding *N*-tosyl aziridine.[2061] Chloramine T and NBS also give the *N*-tosyl aziridine,[2062] and Bromamine-T ($TsNBr^-Na^+$) or TsNIK and have also been used in a similar manner,[2063,2064] Diazoalkanes react with imines to give aziridines.[2065] Another useful reagent is NsN=IPh, which reacts with alkenes in the presence of Rh compounds[2066] or Cu complexes[2067] to give *N*-Ns aziridines. Other sulfonamide reagents can be used,[2068] including PhI=NTs.[2069] Enantioselective aziridination is possible using this reaction with chiral ligands.[2070] This reagent has been used in ionic liquids with a Cu catalyst.[2071] Palladium catalyzes such reactions[2072] and we can also use methyl trioxorhenium ($MeReO_3$).[2073] Manganese(salen) catalysts have also been used with this reagent.[2074] A nitrido Mn(salen) complex was used with ditosyl anhydride, converting a conjugated diene to an allylic *N*-tosylaziridine.[2075] Arylsulfonamides react with alkenes via the nitrene using an Au[2076] or a Cu catalyst.[2077]

Organocatalysts have been used for the enantioselective aziridination of the C=C unit in conjugated aldehydes.[2078]

Nitrenes can add to aromatic rings to give ring-expansion products analogous to those mentioned in Reaction **15-62**.[2079]

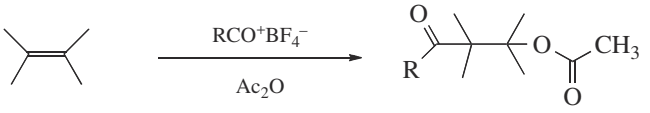
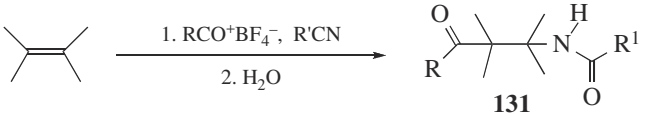
15-55 Aminosulfenylation (Addition of Nitrogen, Sulfur)



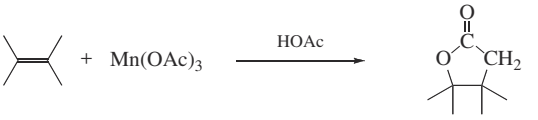
Arylamino-arylthio-addition



An amino and an arylthio group can be added to a double bond by treatment with a sulfenanilide (PhSNHAr) in the presence of BF_3–etherate.[2080] The addition is anti, and the mechanism probably involves a thiiranium ion.[2081] In another aminosulfenylation procedure, the substrate is treated with dimethyl(methylthio)sulfonium fluoroborate ($MeSSMe_2$ BF_4^-) and ammonia or an amine,[2082] the latter acting as a nucleophile. This reaction was extended to other nucleophiles:[2083] N_3^-,[2084] NO_2^-, CN^-, ^-OH, and ^-OAc to give MeS—C—C—A, where A = N_3, NO_2, CN, OH, and OAc, respectively. An RS (R = alkyl or aryl) and an NHCOMe group have been added in an electrochemical procedure.[2085]

15-56 Acylacyloxylation and Acylamidation (Addition of Oxygen, Carbon, or Nitrogen, Carbon)

Acyl-acyloxy-addition



An acyl and an acyloxy group can be added to a double bond by treatment with an acyl fluoroborate and acetic anhydride.[2086] As expected, the addition follows Markovnikov's rule, with the electrophile Ac^+ going to the carbon with more hydrogen atoms. In an analogous reaction, an acyl and an amido group can be added to give **131**, if a nitrile is used in place of the anhydride. Similarly, halo-acetoxylation is known.[2087] This reaction has also been carried out on triple bonds, to give the unsaturated analogues of **131** (syn addition).[2088]

15-57 The Conversion of Alkenes or Alkynes to Lactones (Addition of Oxygen, Carbon)

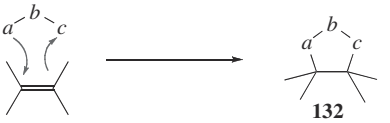
This reaction is clearly related to forming esters and lactones by reaction of carboxylic acids with alkenes (Reaction **15-6**), but the Mn reagent leads to differences. Alkenes react with manganese(III) acetate to give γ-lactones.[2089] The mechanism is probably free radical, involving addition of $^{\bullet}CH_2COOH$ to the double bond. Ultrasound improves the efficiency of the reaction.[2090] In a related reaction, cyclohexene reacted with $MeO_2CCH_2CO_2K$ and $Mn(OAc)_3$ to give an α-carbomethoxy bicyclic lactone.[2091] The use of dimethyl malonate and ultrasound in this reaction gave the same type of product.[2092] Lactone formation has also been accomplished by treatment of alkenes with α-bromo carboxylic acids in the presence of benzoyl peroxide as catalyst,[2093] and with alkylidene $Cr(CO)_5$ complexes.[2094] Alkenes can also be converted to γ-lactones by indirect routes.[2095] Chromium carbene complexes add to alkenes to give β-lactones using ultrasound.[2096]

Cyclic dienes react with β-keto esters, in the presence of a Ga[2097] catalyst and water, to give an α-acyl bicyclic lactone.

Alkenyl acids cyclize to the corresponding lactone upon treatment with sodium hypochlorite and a Lewis acid.[2098] Alkynyl acids cyclize upon treatment with PIFA [phenyliodine(III)-bis(trifluoroacetate)] to give ω-acyl lactones.[2099] A variation of this reaction also employs a diselenide.[2100] Treatment of alkynyl acids with a Au catalyst[2101] leads to an alkylidene lactone.

An intramolecular variation of this reaction is known, involving amides, which generate a lactam.[2102]

OS **VII**, 400.



Note that the related halolacctonization reaction, including iodolactonization, is discussed in Reaction **15-41**.

For addition of aldehydes and ketones, see the *Prins reaction* (**16-54**), and Reactions **16-95** and **16-96**.

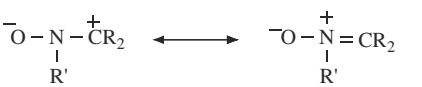
15.C.iv. Cycloaddition Reactions

15-58 1,3-Dipolar Addition (Addition of Oxygen, Nitrogen, Carbon)

132

There are a large group of reactions ([3 + 2]-cycloadditions) in which five-membered heterocyclic compounds are prepared by addition of 1,3-dipolar compounds to double bonds. This reaction is quite useful in the synthesis of alkaloids,[2103] including asymmetric syntheses.[2104] These dipolar compounds have a sequence of three atoms *a*—*b*—*c*, of which a has a sextet of electrons in the outer shell and *c* has an octet with at least one unshared pair (see Table 15.3).[2105] The reaction can then be formulated as shown to generate **132**. Note that the initial reaction of potassium permanganate (Reaction **15-48**) occurs by [3 + 2]-cycloaddition to give a manganate ester (**119**).[2106] [3 + 2]-Cycloaddition occurs with other metal oxides.[2107] Hydrazones have also been reported to give [3 + 2]-cycloadditions.[2108]



1,3-Dipoles of the type shown in Table 15.3 have an atom with six electrons in the outer shell, which is usually unstable. Such compounds will delocalize the change to alleviate this electronic arrangement (they are resonance stabilized). 1,3-Dipolar compounds can be divided into two main types:

1. Those in which the dipolar canonical form has a double bond on the sextet atom and the other canonical form has a triple bond on that atom:

$$^{-}\mathrm{a} - \mathrm{b}{=}\mathrm{c}^{\pm} \longleftrightarrow {}^{-}\mathrm{a} - \mathrm{b}{\equiv}\mathrm{c}^{\pm}$$

If the discussion is limited to the first row of the periodic table, b can only be nitrogen, c can be carbon or nitrogen, and a can be carbon, oxygen, or nitrogen; hence there are six types. Among these are azides (a = b = c = N) and diazoalkanes.

2. Those in which the dipolar canonical form has a single bond on the sextet atom and the other form has a double bond:

$$^{-}a - b^{\pm} c— \longleftrightarrow {}^{-}a - b^{+}{=}c—$$

Here b can be nitrogen or oxygen, and a and c can be nitrogen, oxygen, or carbon, but there are only 12 types, since, for example, N—N—C is only another form of C—N—N. Examples are shown in Table 15.3.

Of the 18 systems, some of which are unstable and must be generated *in situ*,[2117] the reaction has been accomplished for at least 15, but not in all cases with a carbon–carbon double bond (the reaction also can be carried out with other double bonds[2118]). Not all alkenes undergo 1,3-dipolar addition equally well. The reaction is most successful for those that are good dienophiles in the *Diels–Alder Reaction* (**15-60**).

The addition is stereospecific and syn, and the mechanism is probably a one-step concerted process,[2119] as illustrated above,[2120] largely controlled by Frontier Molecular Orbital considerations.[2121] Reactivity has been shown to correlate with the energy required to distort 1,3-dipole and dipolarophiles to the transition state.[2122] In-plane aromaticity has been invoked for these dipolar cycloadditions.[2123] As expected for this type of mechanism, the rates do not vary much with changes in solvent,[2124] although rate acceleration has been observed in ionic liquids.[2125] Nitrile oxide cycloadditions have also been done in supercritical carbon dioxide.[2126] There are no simple rules covering orientation in 1,3-dipolar additions. The regioselectivity has been explained by MO treatments,[2127] where overlap of the largest orbital coefficients of the atoms forming the new bonds leads to the major regioisomer. When the 1,3-dipolar compound is a thiocarbonyl ylid ($R_2C{=}S^{+}{-}CH_2^{-}$) the addition has been shown to be nonstereospecific with certain

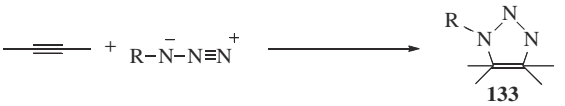
substrates, but stereospecific with others, indicating a nonsynchronous mechanism in these cases, and in fact, a diionic intermediate (see mechanism *c* in Reaction **15-63**, category 4) has been trapped in one such case.[2128] In a theoretical study of the 1,3-dipolar cycloadditions (diazomethane and ethene; fulminic acid [H—C≡N—O] and ethyne),[2129] calculations based on valence bond descriptions suggest that many concerted 1,3-dipolar cycloaddition reactions follow an electronic heterolytic mechanism where the movement of well-identifiable orbital pairs is retained along the entire reaction path from reactants to product.[2130]

An antibody-catalyzed [3 + 2]-cycloaddition has been reported.[2131] Metal-assisted dipolar additions are also known.[2132] In a different metal-mediated reaction, alkenyl *Fischer carbene complexes* react with alkynes, in the presence of a Ni catalyst, to give cyclopentenones.[2133] Fischer carbene complexes take the form $R_2C{=}M(CO)_x$,[2134] and the metals include those of low oxidation state, and Fe, Mo, Cr, or W. Ligands include π-electron acceptors and π-donor substituents on methylene groups (e.g., alkoxy and amino groups).



Many of the cycloadducts formed from the dipoles in Table 15.3 are unstable, which lead to other products. The reaction of alkyl azides with alkenes generates triazolines (Reaction **15-54**), which extrude nitrogen (N≡N) upon heating or photolysis to give an aziridine.[2135] With a transition metal catalyst, alkyl azides add to alkynes to give triazoles.[2136] Retro [3 + 2]-cycloaddition reactions are also known.[2137] Cycloaddition of azides to allenes leads to pyrrolidines.[2138]

[3 + 2]-Cycloaddition reactions occur intramolecularly to generate bicyclic and polycyclic compounds.[2139] The intramolecular cycloaddition of azomethine imines give bicyclic pyrazolidines, for example.[2140] When diazoalkanes (including diazo acetates, e.g., ethyl diazoacetate, N_2CHCO_2Et) react with an alkene and a Cr catalyst the initially formed product is a five-membered ring, a pyrazoline.[2141] Pyrazolines are generally unstable and extrusion of nitrogen leads to a cyclopropane.[2142] Rhodium-catalyzed cycloaddition using chiral ligands leads to formation of cyclopropanes with good enantioselectivity.[2143]

There are many cases where the [3 + 2]-cycloaddition leads to cycloadducts with high enantioselectivity.[2144] Cycloaddition of diazo esters with a Co catalyst having a chiral ligand leads to cyclopropane derivatives with good enantioselectivity.[2145] Cycloaddition of nitrones and pyrazolinones with a Cu catalyst and a chiral ligand leads to pyrrolidine derivatives with good enantioselectivity.[2146] In the presence of a Ni catalyst and a chiral ligand, nitrones react with activated cyclopropanes to give a tetrahydro-1,2-oxazine, with high enantioselectivity.[2147] Nitrones react with conjugated carbonyl compounds, with a transition metal catalyst (e.g., a Ti complex) to give an 1,2-oxazoline.[2148]

Conjugated dienes generally give exclusive 1,2-addition, although 1,4-addition (a 3 + 4 cycloaddition) has been reported.[2149] Carbon–carbon triple bonds can also undergo 1,3-dipolar addition.[2150] For example, azides react to give triazoles, (**133**).

133

The 1,3-dipolar reagent can in some cases be generated by the *in situ* opening of a suitable three-membered ring system. For example, aziridines open to give a zwitterion (e.g., **134**), which can add to activated double bonds to give pyrrolidines.[2151]

134

Aziridines also add to C≡C triple bonds, as well as to other unsaturated linkages, including C=O, C=N, and C≡N.[2152] In some of these reactions, it is a C—N bond of the aziridine that opens rather than the C—C bond.

For other [3 + 2]-cycloadditions, see Reaction **15-59**.

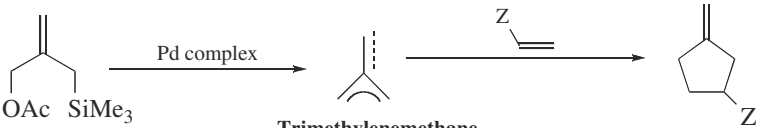
C. Carbon on Both Sides

Reactions 15-58–15-64 are cycloaddition reactions.[2153]

15-59 All-Carbon [3 + 2]-Cycloadditions[2154]



Several methods have been reported for the formation of cyclopentanes by [3 + 2]-cycloadditions.[2155] Heating conjugated ketones with trialkylphosphines generates an intermediate that adds to conjugated alkynes.[2156] One type involves reagents that produce intermediates **135** or **136**.[2157] A synthetically useful example[2158] uses 2-[(trimethylsilyl)methyl]-2-propen-1-yl acetate (**139**), which is commercially available, and a Pd or other transition metal catalyst to generate **135** or **136**, which adds to double bonds to give cyclopentanes

135 **136** **137** **138**

with an exocyclic double bond. The reaction occurs with **139** to generate trimethylenemethane *in situ*, which reacts with alkenes to give methylenecyclopentane derivatives.[2159] A similar reaction occurs with imines to give methylene pyrrolidines.[2160] The Pd catalyzed reaction with CO_2 leads to butenolides.[2161]

Note that **136** also reacts with *N*-tosyl aziridines, with 20% *n*-butyllithium and 10% of $Pd(OAc)_2$, to give a vinylidene piperidine derivative.[2162] Similar or identical intermediates generated from bicyclic azo compounds **137** (see Reaction **17-34**) or methylenecyclopropane (**138**)[2163] also add to activated double bonds. With suitable substrates the addition can be enantioselective.[2164]

139 **Trimethylenemethane**

In a different type of procedure, [3 + 2]-cycloadditions are performed with allylic anions. Such reactions are called 1,3-anionic cycloadditions.[2165] For example, α-methylstyrene adds to stilbene on treatment with the strong base LDA.[2166]

The mechanism can be outlined as:

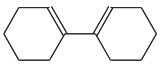
140

In the case above, **140** is protonated in the last step by the acid HA, but if the acid is omitted and a suitable nucleofuge is present, it may leave, resulting in a cyclopentene.[2167] In these cases, the reagent is an allylic anion, but similar [3 + 2]-cycloadditions involving allylic cations have also been reported.[2168]

OS **VIII**,173, 347.

15-60 The Diels–Alder Reaction

(4 + 2) *cyclo*- Ethylene-1/4/addition or **(4 + 2) *cyclo*-[Bu *t*-2-ene-1,4-diyl]-1/2/addition**, and so on



In the prototype *Diels–Alder reaction*, the double bond of an alkene adds 1,4- to a conjugated diene (a [4 + 2]-cycloaddition),[2169] so the product is always a cyclohexene. The cycloaddition is not limited to alkenes or to dienes (see Reaction **15-61**), but the substrate that reacts with the diene is called a *dienophile*. The reaction is of very broad scope[2170] and reactivity of dienes and dienophiles can be predicted based on analysis of *the* HOMOs[2171] and LUMOs of these species (FMO theory).[2172] Ethylene and simple alkenes make poor dienophiles, unless high temperatures and/or pressures are used. Most dienophiles are of the form —C=C—Z or Z—C=C—Z′, where Z and Z′ are

electron-withdrawing groups[2173] (e.g., CHO, COR,[2174] CO_2H, CO_2R, COCl, COAr, CN,[2175] NO_2,[2176] Ar, CH_2OH, CH_2Cl, CH_2NH_2, CH_2CN, CH_2CO_2H, halogen, $PO(OEt)_2$,[2177] or C=C). In the last case, the dienophile is itself a diene.[2178]

The low reactivity of simple alkenes can be overcome by incorporating an electron-withdrawing group to facilitate the cycloaddition, as indicated above. Electron-withdrawing groups may be incorporated to facilitate the *Diels–Alder reaction* and then removed after cycloaddition. An example is phenyl vinyl sulfone ($PhSO_2CH=CH_2$),[2179] and the $PhSO_2$ group can be easily removed with Na—Hg after the ring-closure reaction. Similarly, phenyl vinyl sulfoxide ($PhSOCH=CH_2$) can be used as a synthon for acetylene.[2180] In this case, PhSOH is lost from the sulfoxide product (Reaction **17-12**).

141

142

143

Electron-donating substituents in the diene accelerate the reaction; electron-withdrawing groups retard it.[2181] For the dienophile, it is just the reverse: donating groups decrease the rate, and withdrawing groups increase it. The s-cis (cisoid) conformation is required for the cycloaddition,[2182] and acyclic dienes are conformationally mobile so the s-cis conformation will be available.[2183] Cyclic dienes, in which the s-cis conformation is built in, usually react faster than the corresponding open-chain compounds, which have to achieve the s-cis conformation by rotation.[2184] Dienes can be open-chain, inner-ring (e.g., **141**), outer-ring[2185] (e.g., **142**), across rings (e.g., **143**), or inner–outer (e.g., **145**), except that they may not be frozen into a s-trans (transoid) conformation (see category 3). They need no special activating groups, and nearly all conjugated dienes undergo the reaction with suitable dienophiles.[2186]

While *Diels–Alder reactions* generally require no catalyst, Lewis acids are effective catalysts,[2187] particularly those in which Z in the dienophile is a C=O or C=N group.[2188] Chemoselectivity is related to the choice of Lewis acid or Brønsted–Lowry acid catalyst.[2189] A Lewis acid catalyst usually increases both the regioselectivity of the reaction (in the sense given above) and the extent of endo addition,[2190] and, in the case of enantioselective reactions, the extent of enantioselectivity. Copper catalysts have been used.[2191] Brønsted acids have also been used to accelerate the rate of the *Diels–Alder reaction*.[2192] *Diels–Alder reactions* have been done in ionic liquids (see Sec. 9.D.iii).[2193] Lanthanum triflate [$La(OTf)_3$] has been reported as a reusable catalyst[2194] and Me_3SiNTf_2 has been used as a green Lewis acid catalyst.[2195] Cationic *Diels–Alder* catalysts have been developed (e.g., oxazaborolidine catalysts).[2196] Some *Diels–Alder reactions* can also be catalyzed by the addition of a stable cation radical,[2197] for example, tris(4-bromophenyl)aminium hexachloroantimonate ($Ar_3N^{\bullet+}$ $SbCl_6^-$).[2198] Zirconocene-catalyzed cationic *Diels–Alder reactions* are known.[2199] Certain antibodies have been developed that catalyze *Diels–Alder reactions*.[2200] Photochemically induced *Diels–Alder reactions* are also known.[2201]

A number of other methods have been reported for the acceleration of *Diels–Alder reactions*,[2202] including the use of microwave irradiation,[2203] ultrasound,[2204] absorption of the reactants on chromatographic absorbents,[2205] via encapsulation techniques,[2206] and the

use of an ultracentrifuge[2207] (one of several ways to achieve reaction at high pressures).[2208] Solid-state *Diels–Alder reactions* are known.[2209] One of the most common methods is to use water as a solvent or a cosolvent (a hydrophobic effect).[2210] Catalysts have been developed for aq *Diels–Alder reactions*[2211] that are suitable for ionic *Diels–Alder reactions*.[2212] There are cases of hydrogen-bonding acceleration.[2213] The influence of the hydrophobicity of reactants on the reaction has been examined,[2214] as has micellular effects.[2215] Another alternative reaction medium is the use of 5M $LiClO_4$ in Et_2O as solvent.[2216] An alternative to lithium perchlorate in ether is lithium triflate in acetonitrile.[2217] The addition of HPO_4^- to an aq ethanol solution has also been shown to give a small rate enhancement.[2218] This appears to be the only case where an anion is responsible for a rate enhancement. The *retro-Diels–Alder reaction* has also been done in water.[2219]

Note that *Diels–Alder reactions* have been done with supercritical carbon monoxide[2220] and with supercritical water[2221] as solvents. *Diels–Alder reactions* on solid supports also have been reported,[2222] and zeolites have been used in conjunction with catalytic agents.[2223] Alumina has been used to promote *Diels–Alder reactions*.[2224] *Diels–Alder reactions* can be done in ionic liquids,[2225] including asymmetric *Diels–Alder reactions*.[2226] Note that the rate of *Diels–Alder reactions* is faster in water than in ionic liquids.[2227]

When an unsymmetrical diene adds to an unsymmetrical dienophile, regioisomeric products (not counting stereoisomers) are possible. Rearrangements have been encountered in some cases.[2228] In simple cases, 1-substituted dienes give cyclohexenes with a 1,2-

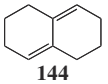
and a 1,3- substitution pattern. 2-Substituted dienes lead to 1,4- and 1,3-disubstituted products.



Although mixtures are often obtained, one usually predominates (the one shown lowed major above), but selectivity depends on the nature of the substituents on both diene and alkene. This regioselectivity, in which the "ortho" or "para" product is favored over the "meta", has been explained by molecular orbital considerations.[2229] When $X = NO_2$, regioselectivity to give the "ortho" or "para" product was very high at room temperature. This method, combined with subsequent removal of the NO_2 (see Reaction **19-67**), has been used to perform regioselective *Diels–Alder reactions*.[2230] Competing reactions are polymerization of the diene or dienophile, or both, and [1,2]-cycloaddition (**15-63**).

The stereochemistry of the *Diels–Alder reaction* can be considered from several aspects:[2231]

1. With respect to the dienophile, the addition is stereospecifically syn, with very few exceptions.[2232] This means that groups that are cis in the alkene will be cis in the cyclohexene ring (A—B and C—D) and groups that are trans in the alkene will be trans in the cyclohexene ring (A—D and C—B).

2. With respect to 1,4-disubstituted dienes, fewer cases have been investigated, but here too the reaction is stereospecific and syn. Thus, *trans*,*trans*-1,4-diphenylbutadiene gives *cis*-1,4-diphenylcyclohexene derivatives. This selectivity is predicted by disrotatory motion of the substituent in the transition state[2233] of the reaction (see **18-27**).
3. The diene must be in the s-cis conformation. If it is frozen into the s-trans conformation, as in **144**, the reaction does not take place. The diene either must be frozen into the s-cis conformation or must be able to achieve it during the reaction.

4. There are two possible ways in which addition can occur to a cyclic diene, if the dienophile is not symmetrical: say a monosubstituted alkene. The substituent on the dienophile (usually an electron-withdrawing substituent) may approach under the ring (*endo addition*), or away from the ring (*exo addition*):

Most of the time, the addition is predominantly endo; that is, the more bulky side of the alkene is under the ring, and this is probably true for open-chain dienes also.[2234] However, exceptions are known, and in many cases mixtures of exo and endo addition products are found.[2235] An imidazolidone catalyst was used to give a 1:1.3 mixture favoring the exo isomer in a reaction of conjugated aldehydes and cyclopentadiene.[2236] Secondary orbital interactions.[2237] have been invoked, but this approach has been called into question.[2238] There has been a direct evaluation of such interactions, however.[2239] It has been argued that facial selectivity is not due to torsional angle decompression.[2240] The endo/exo ratio can be influenced by the nature of the solvent.[2241]

5. As seen previously, the *Diels–Alder reaction* can be both stereoselective and regioselective.[2242] In some cases, the *Diels–Alder reaction* can be made enantioselective,[2243] as described above. Solvent effects are important in such reactions.[2244] The role of reactant polarity on the course of the reaction has been examined.[2245] Most enantioselective *Diels–Alder reactions* have used a chiral dienophile (e.g., **145**) and an achiral diene,[2246] along with a Lewis acid catalyst (see below). In such cases, addition of the diene to the two

146 **145** **147**

faces[2247] of **145** takes place at different rates, and **146** and **147** are formed in different amounts.[2248] An achiral compound can be converted to a chiral compound by a chemical reaction with a compound that is enantiopure. After the reaction, the resulting diastereomers can be separated, providing enantiopure compounds, each with a bond between the molecule of interest and chiral compound (a chiral auxiliary). Common chiral auxiliaries include chiral carboxylic acids, alcohols, or sultams. In the case illustrated, hydrolysis of the product removes the chiral R group, making it a chiral auxiliary in this reaction. Asymmetric *Diels–Alder reactions* have also been carried out with achiral dienes and dienophiles, but with an optically active catalyst.[2249] Many chiral catalysts have been developed.[2250] In many cases, asymmetric Lewis acids form a chiral complex with the dienophile.[2251] Chiral organocatalysts are increasingly important.[2252]

Triple bond compounds (—C≡C—Z or Z—C≡C—Z′) may be dienophiles,[2253] generating nonconjugated cyclohexadienes (**148**). This reaction can be catalyzed by transition metal compounds.[2254] Aromatic rings can be generated by cycloaddition of aryl alkynes.[2255] Allenes react as dienophiles, but without activating groups are

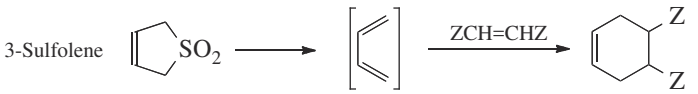
very poor dienophiles.[2256] Ketenes, however, do not undergo *Diels–Alder reactions*.[2257]

148 **149**

Many interesting compounds can be prepared by the *Diels–Alder reaction*,[2258] some of which would be hard to make in any other way. Some aromatic compounds can behave as dienes,[2259] but benzene is very unreactive toward dienophiles,[2260] and very few dienophiles (one of them is benzyne) have been reported to give *Diels–Alder* adducts with it.[2261] Benzynes (e.g., **149**), although not isolable, act as dienophiles and can be trapped with dienes.[2262] The interesting compound triptycene can be prepared by a *Diels–Alder reaction* between benzyne and anthracene.[2263] Naphthalene and phenanthrene are poor reaction partners, although naphthalene has given *Diels–Alder addition* at high pressures.[2264] Anthracene and other compounds with at least three linear benzene rings give *Diels–Alder reactions* readily.

For both all-carbon and hetero systems, the "diene" can be a conjugated enyne. If the geometry of the molecule is suitable, the diene can even be nonconjugated, for example,[2265]



This last reaction is known as the *homo-Diels–Alder reaction*. A similar reaction has been reported with alkynes, using a mixture of a Co complex, ZnI_2, and tetrabutylammonium borohydride.[2266]

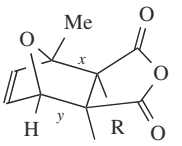
Intramolecular versions of the *Diels–Alder reaction* are well known,[2267] and this is a powerful method for the synthesis of mono- and polycyclic compounds.[2268] There are many examples and variations, including Lewis acid catalysis.[2269] The origin of cis/trans stereoselectivity has been examined using density functional theory.[2270]

Internal *Diels–Alder reactions* can be viewed as linking the diene and alkene by a tether, usually of carbon atoms. Dienophile twisting and substituent effects influence the rate of cycloaddition.[2271] If the tether is replaced by functional groups that allow the selectivity inherent to the intramolecular cycloaddition, but can be cleaved afterward, a powerful modification is available. Indeed, such tethered cycloaddition reactions are increasingly common. After cycloaddition, the tether can be cleaved to give a functionalized cyclohexene derivative. Such tethered reactions allow enhancement of stereoselectivity[2272] and sometimes reactivity, relative to an untethered reaction, giving an indirect method for enhancing those parameters. Tethers or linkages include C—O—SiR_2—C[2273] or a C—O—SiR_2—O—C,[2274] or hydroxamides.[2275] The nature of the tether plays a role in cis/trans selectivity for the intramolecular reaction.[2276] Transient tethers can be used, as in the reaction of a diene having an allylic alcohol unit in a reaction with allyl alcohol, with $AlMe_3$ to give the cycloadduct with good selectivity.[2277]



The *Diels–Alder reaction* is usually reversible, although the retro reaction typically occurs at significantly higher temperatures than the forward reaction. However, the reaction is reversible[2278] and this fact has been used. A convenient substitute for butadiene in the *Diels–Alder reaction* is the compound 3-sulfolene, since the latter is a solid, which is easy to handle while the former is a gas.[2279] Butadiene is generated *in situ* by a reverse *Diels–Alder reaction* (see **17-20**).

There are, broadly speaking, three possible mechanisms that have been considered for the uncatalyzed *Diels–Alder reaction*.[2280] In mechanism *a*, there is a cyclic six-centered transition state and no intermediate. The reaction is concerted and occurs in one step. In mechanism *b*, one end of the diene fastens to one end of the dienophile first to give a diradical, and then, in a second step, the other ends become fastened.[2281] A diradical formed in this manner must be a singlet; that is, the two unpaired electrons must have opposite spins, by an argument similar to that outlined in Section 5.C.i. The third mechanism (*c*, not shown) is similar to mechanism *b*, but the initial bond and the subsequent bond are formed by movements of electron pairs and the intermediate is a diion. Electrophilicity–nucleophilicity indices have been analyzed to understand the mechanism of polar *Diels–Alder reactions*.[2282] There have been many mechanistic investigations of the *Diels–Alder reaction*. The bulk of the evidence suggests that most *Diels–Alder reactions* take place by the one-step cyclic mechanism *a*,[2283] although it is possible that a diradical[2284] or even a diion[2285] mechanism may be taking place in some cases. Radical cation *Diels–Alder reactions* have been considered.[2286] The main evidence in support of mechanism *a* is as follows: (1) the reaction is stereospecific in both the diene and dienophile. A completely free diradical or diion probably would not be able to retain its configuration. (2) In general, the rates of *Diels–Alder reactions* depend very little on the nature of the solvent. This would rule out a diion intermediate because polar solvents increase the rates of reactions that develop charges in the transition state. (3) It was shown that, in the decomposition of **150**, the isotope effect k_I/k_{II} was equal to 1.00 within experimental error.[2287] If bond *x* were

150

I: R = H, R' = D

II: R = D, R' = H

to break before bond *y*, there should surely be a secondary isotope effect. This result strongly indicates that the bond breaking of *x* and *y* is simultaneous. This is the reverse of a *Diels–Alder reaction*, and by the principle of microscopic reversibility, the mechanism of the forward reaction should involve simultaneous formation of bonds *x* and *y*.

Subsequently, a similar experiment was carried out on the forward reaction[2288] and the result was the same. There is other evidence for mechanism *a*.[2289] However, the fact that the mechanism is concerted does not necessarily mean that it is synchronous.[2290] In the transition state of a synchronous reaction both new σ bonds would be formed to the same extent, but a *Diels–Alder reaction* with nonsymmetrical components might very well be nonsynchronous;[2291] that is, it could have a transition state in which one bond has been formed to a greater degree than the other.[2291,2292] A biradical mechanism has been proposed for some *Diels–Alder reactions*.[2293]

In another aspect of the mechanism, the effects of electron-donating and electron-withdrawing substituents (see above) indicate that the diene behaves as a nucleophile and the dienophile as an electrophile. However, this can be reversed. Perchlorocyclopentadiene reacts better with cyclopentene than with maleic anhydride and not at all with tetracyanoethylene, although the latter is normally the most reactive dienophile known. This diene is said to be the electrophile in its *Diels–Alder reactions*.[2294] Reactions of this type are said to proceed with *inverse electron demand*.[2295] It is known that alkynylboronates participate in inverse electron demand cyclization.[2296]

The *Diels–Alder reaction* generally takes place rapidly and conveniently. In sharp contrast, the apparently similar dimerization of alkenes to cyclobutanes (Reaction **15-63**) gives very poor results in most cases, except when photochemically induced. Woodward and Hoffmann[2297] showed that these contrasting results can be explained by the *principle of conservation of orbital symmetry*, which predicts that certain reactions are allowed and others are forbidden. The orbital-symmetry rules (also called the *Woodward–Hoffmann rules*)[2298] apply *only to concerted reactions* (e.g., mechanism *a*) and are based on the principle that reactions take place in such a way as to maintain maximum bonding throughout the course of the reaction. In a separate work, Fukui used MO arguments to

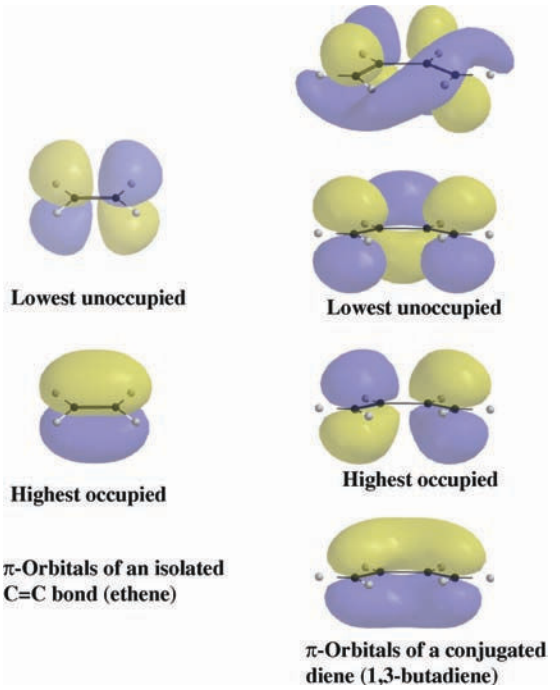

FIG. 15.2. Schematic drawings of the π orbitals of an isolated C=C bond and a conjugated diene

explain these reactions. There are several ways of applying the orbital-symmetry principle to cycloaddition reactions, three of which are used more frequently than others.[2299] Of these three, two will be discussed: the FMO and the Möbius–Hückel method. The third, called the correlation-diagram method,[2300] is less convenient to apply than the other two.

The Frontier-Orbital Method[2301]

As applied to cycloaddition reactions, the rule is that *reactions are allowed only when all overlaps between the HOMO of one reactant and the LUMO of the other are such that a positive lobe overlaps only with another positive lobe and a negative lobe only with another negative lobe*.[2302] Recall that monoalkenes have two π molecular orbitals (Sec. 1.D) and that conjugated dienes have four (Sec. 2.C), as shown in Fig. 15.2. A concerted cyclization of two monoalkenes (a [2 + 2] reaction) is not allowed because it would require that a positive lobe overlap with a negative lobe (Fig. 15.3). On the other

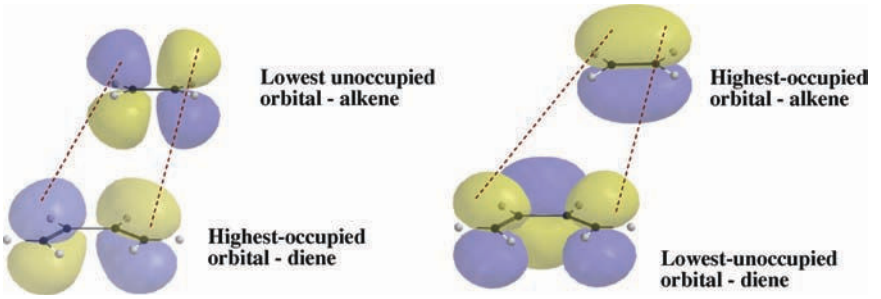

FIG. 15.4. Two ways for orbitals to overlap in a thermal [4 + 2]-cycloaddition

hand, the *Diels–Alder reaction* (a [4 + 2] reaction) is allowed, when considered from either direction (Fig. 15.4).

These considerations are reversed when the ring closures are photochemically induced, since in such cases an electron is promoted to a vacant orbital before the reaction occurs. Obviously, the [2 + 2] reaction is now allowed (Fig. 15.5) and the [4 + 2]-reaction is disallowed. The reverse reactions follow the same rules, by the principle of microscopic reversibility. In fact, *Diels–Alder* adducts are usually cleaved quite readily, while cyclobutanes, despite the additional strain, require more strenuous conditions.

The Möbius–Hückel Method[2303]

In this method, the orbital symmetry rules are related to the *Hückel aromaticity* rule discussed in Chapter 2.[2304] *Hückel's rule*, which states that a cyclic system of electrons is aromatic (hence, stable) when it consists of $4n + 2$ electrons, applies of course to molecules in their ground states. In applying the orbital symmetry principle, we are not concerned with ground states, but with transition states. In the present method, do not examine the molecular orbitals themselves, but rather the *p* orbitals before they overlap to form the molecular orbitals. Such a set of *p* orbitals is called a *basis set* (Fig. 15.6). In investigating the possibility of a concerted reaction, the basis sets are put into the position they would occupy in the transition state. Figure 15.7 shows this for both the [2 + 2] and the [4 + 2] ring closures, looking for *sign inversions*. In Fig. 15.7, there are no sign inversions in either case. That is, the dashed line connects only lobes with a minus sign. Systems with *zero or*

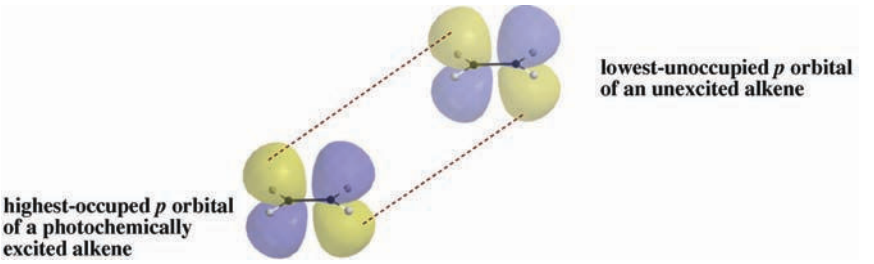

FIG. 15.5. Overlap of orbitals in a photochemical [2 + 2]-cycloaddition

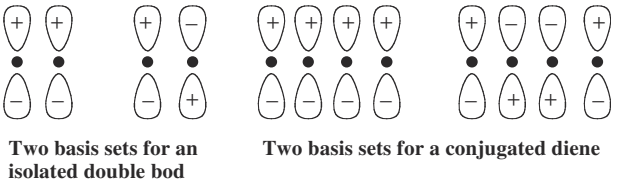

FIG. 15.6. Some basis sets

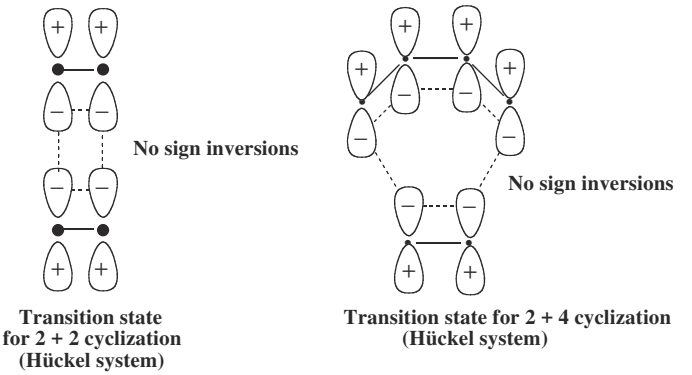

FIG. 15.7. Transition states illustrating Hückel–Möbius rules for cycloaddition reactions

an even number of sign inversions are called *Hückel systems*. Because they have no sign inversions, both of these systems are Hückel systems. Systems with *an odd number* of sign inversions are called *Möbius systems* (because of the similarity to the Möbius strip, which is a mathematical surface, shown in Fig. 15.8).[2305] Möbius systems do not enter into either of these reactions, but an example of such a system is shown in Reaction **18.-28, B**. Double-twist *Möbius* aromaticity has been invoked in the *Diels–Alder* transition state for the reaction of a 5,6-di-*tert*-butyl substituted decapentaene.[2306]

The rule may then be stated: *A thermal pericyclic reaction involving a Hückel system is allowed only if the total number of electrons is 4n + 2. A thermal pericyclic reaction involving a Möbius system is allowed only if the total number of electrons is 4n*. For photochemical reactions, these rules are reversed. Since both the [4 + 2]- and [2 + 2]-cycloadditions are *Hückel* systems, the *Möbius–Hückel method* predicts that the [4 + 2]-reaction, with

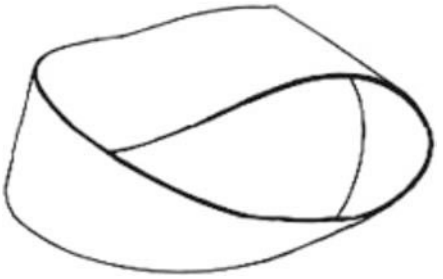

FIG. 15.8. A Möbius strip. Such a strip is easily constructed by twisting a thin strip of paper 180° and fastening the ends together

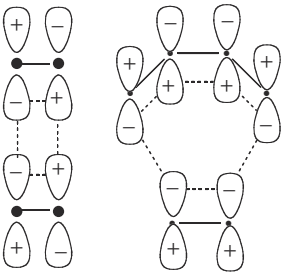

FIG. 15.9. Transition states of $\{2+2]$ - and $[4+2]$-cyclizations involving other basis sets

6 electrons, is thermally allowed, but the $[2+2]$-reaction is not. One the other hand, the $[2+2]$ -reaction is allowed photochemically, while the $[4+2]$-reaction is forbidden.

Note that both the $[2+2]$ and $[4+2]$ transition states are *Hückel* systems no matter what basis sets were chosen. For example, Fig. 15.9 shows other basis sets we might have chosen. In every case there will be zero or an even number of sign inversions.

Thus, the FMO and *Hückel–Möbius* methods (and the correlation-diagram method as well) lead to the same conclusions: Thermal $[4+2]$-cycloadditions and photochemical $[2+2]$-cycloadditions (and the reverse ring openings) are allowed, while photochemical $[4+2]$- and thermal $[2+2]$-ring closings (and openings) are forbidden.

Application of the same procedures to other ring closures shows that $[4+4]$- and $[2+6]$-ring closures and openings require photochemical induction while the $[4+6]$- and $[2+8]$-reactions can take place only thermally (see Reaction **15-53**). In general, cycloaddition reactions allowed thermally are those with $4n+2$ electrons, while those allowed photochemically have $4n$ electrons.

It must be emphasized once again that the rules apply only to cycloaddition reactions that take place by cyclic mechanisms, which is where two σ bonds are formed (or broken) at about the same time.[2307] The rule does not apply to cases where one bond is clearly formed (or broken) before the other. It must further be emphasized that the fact that the thermal *Diels–Alder reaction* (mechanism *a*) is allowed by the principle of conservation of orbital symmetry does not constitute proof that any given *Diels–Alder reaction* proceeds by this mechanism. The principle merely says the mechanism is allowed, not that it must go by this pathway. However, the principle does say that thermal $[2+2]$-cycloadditions in

[2307] See Lehr, R.E.; Marchand, A.P. in Marchand, A.P.; Lehr, R.E. *Pericyclic Reactions*, Vol. 1, Academic Press, NY, ***1977***, pp. 1–51.

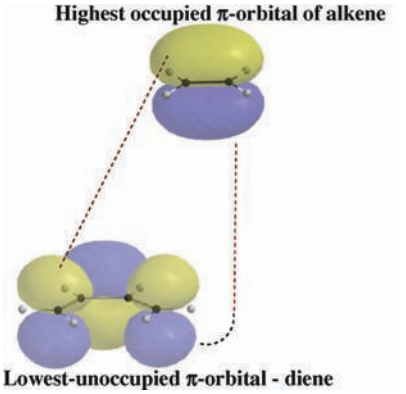

FIG. 15.10. Overlap of orbitals in an antarafacial thermal [4 + 2]-cycloaddition

which the molecules assume a face-to-face geometry cannot[2308] take place by a cyclic mechanism because their activation energies would be too high (however, see below). In Reaction **15-62** it will be seen that such reactions largely occur by two-step mechanisms. Similarly, [4 + 2]-photochemical cycloadditions are also known, but the fact that they are not stereospecific indicates that they also take place by the two-step diradical mechanism (mechanism *b*).[2309]

In all of the above discussions, it has been assumed that a given molecule forms both the new σ bonds from the same face of the π system. This manner of bond formation, called *suprafacial*, is certainly most reasonable and almost always takes place. The subscript *s* is used to designate this geometry, and a normal *Diels–Alder reaction* would be called a $[_{\pi}2_s + {}_{\pi}4_s]$-cycloaddition (the subscript π indicates that π electrons are involved in the cycloaddition). However, there is another approach in which the newly forming bonds of the diene lie on *opposite* faces of the π system, that is, they point in opposite directions. This type of orientation of the newly formed bonds is called *antarafacial*, and the reaction would be a $[_{\pi}2_s + {}_{\pi}4_s]$-cycloaddition (*a* stands for antarafacial). The FMO method shows that this reaction (and consequently the reverse ring-opening reactions) are thermally forbidden and photochemically allowed. Thus in order for a $[_{\pi}2_s + {}_{\pi}4_a]$ reaction to proceed, overlap between the highest-occupied π orbital of the alkene and the lowest-unoccupied π orbital of the diene would have to occur as shown in Fig. 15.10 , with a + lobe overlapping a −lobe. Since like signs are no

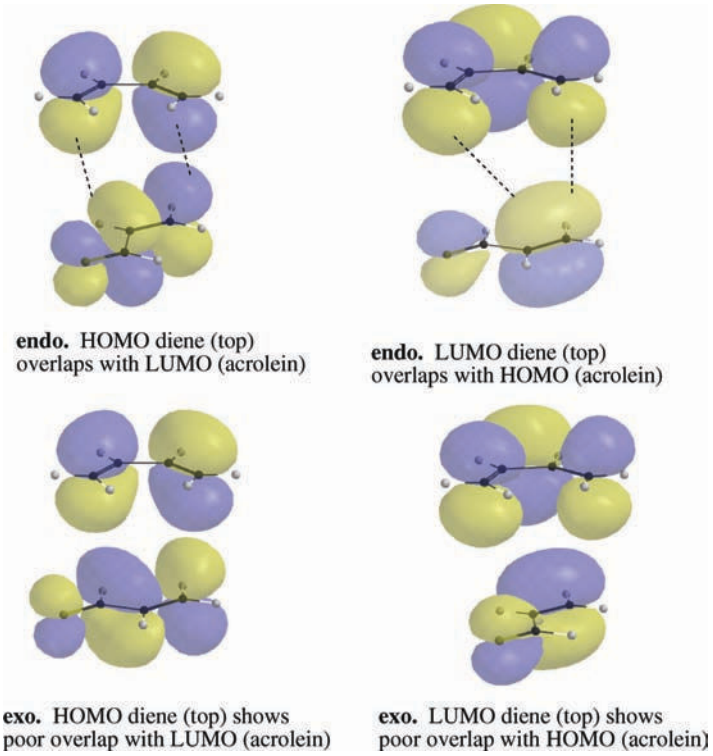

FIG. 15.11. Overlap of orbitals in [4 + 2]-cycloaddition of 1,3-butadiene with acrolein

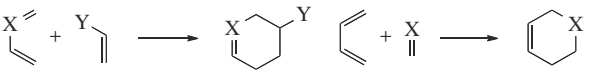
longer overlapping, the thermal reaction is now forbidden. Similarly, thermal [$[_\pi 4_s + {}_\pi 2_a]$ and $[_\pi 2_s + {}_\pi 4_a]$-cyclizations are forbidden, while thermal [$\pi 4a + \pi 2a$]- and $[_\pi 2_s + {}_\pi 2_a]$-cyclizations are allowed. These considerations are reversed for the corresponding photochemical processes. Of course, an antarafacial approach is highly unlikely in a [4 + 2]-cyclization,[2310] but larger ring closures could take place by such a pathway, and [2 + 2] -thermal cyclizations, where the $[[_\pi 2_s + {}_\pi 2_s]$-pathway is forbidden, can also do so in certain cases (see Reaction **15-63**). Whether a given cycloaddition is allowed or forbidden depends on the geometry of approach of the two molecules involved.



Symmetry considerations have also been advanced to explain predominant endo addition.[2311] In the case of [4 + 2]-addition of butadiene to acrolein, the approach can be exo or endo. It can be seen (Fig. 15.11) that whether the HOMO of the diene overlaps with the LUMO of acrolein or vice versa, the endo orientation is stabilized by additional secondary overlap of orbitals[2312] of like sign (dashed lines between heavy dots). Addition from the exo direction has no such stabilization since the sign of the orbitals do not match. Evidence for secondary orbital overlap as the cause of predominant endo orientation, at least in some cases, is that [4 + 6]-cycloaddition is predicted by similar considerations to

[2310] A possible photochemical [2 + 4] cycloaddition has been reported: Hart, H.; Miyashi, T.; Buchanan, D.N.; Sasson, S. *J. Am. Chem. Soc.* ***1974****, 96*, 4857.

proceed with predominant exo orientation, and that is what is found.[2313] However, this explanation does not account for endo orientation in cases where the dienophile does not possess additional π orbitals, and a number of alternative explanations have been offered.[2314]

15-61 Heteroatom Diels–Alder Reactions

Alkenes, alkynes, and dienes are not the only units that can participate in *Diels–Alder reactions*. Other double- and triple-bond compounds can be dienophiles and they give rise to heterocyclic compounds.[2315] Among these are N≡C—, —N=C—,[2316] iminium salts,[2317] —N=N—, O=N—,[2318] and —C=O compounds,[2319] and even molecular oxygen (Reaction **15-62**). Several catalysts can be used, depending on the nature of the heteroatoms incorporated into the alkene or diene.[2320] Intramolecular cycloaddition with a diene–imine substrate leads to pyrrolidines.[2321]

151

Aldehydes react with suitably functionalized dienes (e.g., **151**), known as *Danishefsky's diene*,[2322] and the reaction usually requires a Lewis acid catalyst (e.g., lanthanide compounds).[2323] The *Diels–Alder reaction* of aldehydes with dienes can be catalyzed by many transition metal compounds, including Co[2324] and In[2325] catalysts. Aldehydes react using a chiral Ti[2326] or a Zr[2327] catalyst to give the dihydropyran with good

enantioselectivity. Copper(I) catalysts have been used as well.[2328] Note that the reaction of *Danishefsky's diene* with an imine,[2329] formed *in situ* by reaction of an aryl aldehyde and an aniline derivative, proceeds without a Lewis acid.[2330] Ketones also react with suitably functionalized dienes.[2331] Indium trichloride ($InCl_3$) is a good catalyst for imino-*Diels–Alder reactions*.[2332] Hetero-*Diels–Alder reactions* involving carbonyls have been done in water.[2333] Ultrasound has been used to promote the *Diels–Alder reactions* of 1-azadienes.[2334] Polymer-supported dienes have been used.[2335]

Hetero-*Diels–Alder reactions* that proceed with good-to-excellent asymmetric induction are well known.[2336] Asymmetric *Diels–Alder reactions* of carbonyl compounds are well known.[2337] Chiral 1-aza-dienes have been developed as substrates, for example.[2338] Azadienes also react with chiral dienophiles.[2339] Chiral catalysts have been developed.[2340]

Dienes related to **151** are known, and their reactivity has been examined. Amino-substituted dienes undergo what is known as hydrogen-bonding catalyzed reactions.[2341] Imines react with other substrates (e.g., allenes), to give tetrahydropyridine derivatives, with good enantioselectivity in the presence of a chiral ligand.[2342] Azo compounds (—N=N—) react as dienophiles in the presence of an Ag catalyst.[2343] Iminium ions undergo *Diels–Alder cycloaddition*.[2344]

Azadienes undergo *Diels–Alder reactions* to form pyridine, dihydro- and tetrahydropyridine derivatives.[2345] *Aza-Diels–Alder reactions* have been done in ionic liquids.[2346] Similarly, acyl iminium salts (C=N(R)—C=O) react with alkenes via cycloaddition.[2347] *N*-Vinyl lactim ethers undergo *Diels–Alder reactions* with a limited set of dienophiles.[2348] Brønsted acids can catalyze inverse electron demand aza-*Diels–Alder reactions*.[2349]

Thioketones react with dienes to give *Diels–Alder cycloadducts*.[2350] The carbonyl group of lactams has also been shown to be a dienophile.[2351] Certain heterocyclic aromatic

rings (among them furans)[2352] can also behave as dienes in the Diels–Alder reaction. Some hetero dienes that give the reaction are —C=C—C=O, O=C—C=O, and N=C—C=N.[2352] Nitroso compounds of the type *t*-BuO_2C-N=O react with dienes to give the corresponding 2-azadihydropyran.[2353] Conjugated aldehydes react with vinyl ethers, with a chiral Cr catalyst, in an inverse electron demand cycloaddition that give a dihydropyran with good enantioselectivity.[2354] Vinyl sulfilimines have been used in chiral *Diels–Alder reactions*.[2355]

15-62 Photooxidation of Dienes (Addition of Oxygen, Oxygen)

[4 + 2] *OC*,*OC-cyclo*-Peroxy-1/4/addition

152

Conjugated dienes react with oxygen under the influence of light to give cyclic peroxides (**152**).[2356] The reaction has mostly[2357] been applied to cyclic dienes.[2358] Cycloaddition of furan has been reported using singlet oxygen.[2359] The scope extends to certain aromatic compounds (e.g., phenanthrene).[2360] Besides those dienes and aromatic rings that can be photooxidized directly, there is a larger group that gives the reaction in the presence of a photosensitizer (see Sec. 7.A.vi, category 5; e.g., eosin, a red xanthene dye). Among these is α-terpinene, which is converted to ascaridole:

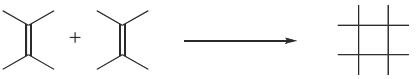
As in Reaction **14-7**, it is not the ground-state oxygen (the triplet), that reacts, but the excited singlet state,[2361,2362] so the reaction is actually a *Diels–Alder reaction* (see Reaction **15-60**) with singlet oxygen as dienophile:[2363]

Like Reaction **15-60**, this reaction is reversible.



153

As previously discussed, the reaction of singlet oxygen with double-bond compounds gives hydroperoxides (Reaction **14-7**), but singlet oxygen can also react with double bonds in another way to give a dioxetane intermediate[2364] (Reaction **153**), which usually cleaves to aldehydes or ketones,[2365] but has been isolated.[2366] Both the six-membered cyclic peroxides[2367] and the four-membered **205**[2368] have been formed from oxygenation reactions that do not involve singlet oxygen. If cyclic peroxides (e.g., **205**) are desired, better reagents[2369] are triphenyl phosphite ozonide [$(PhO)_3PO_3$] and triethylsilyl hydrotrioxide [$(Et_3SiOOOH)$], but yields are not high.[2370]

Two alkene molecules react under thermal conditions to give cyclobutane derivatives in what is known as a *[2 + 2]-cycloaddition*. The cycloaddition occurs when the alkenes are the same or different, but the reaction is not general for all alkenes.[2371] Certain transition metal complexes can catalyze the cycloaddition.[2372] Benzynes undergo cycloaddition to give biphenylene derivatives (**154**),[2373] activated alkenes (e.g., styrene, acrylonitrile, butadiene), and certain methylenecyclopropanes.[2374] Alkenes react with alkynes[2375] or with activated alkynes, with a Ru catalyst, to give cyclobutenes.[2376] Dimerization of allenes leads to bis(alkylidene) cyclobutanes.[2377] Substituted ketenes can dimerize to give cyclobutenone derivatives, although ketene itself dimerizes in a different manner, to give an unsaturated β-lactone (Reaction **16-95**).[2378]

Biphenylene

154

Intramolecular [2 + 2]-cycloadditions are common in which a diene is converted to a bicyclic compound with a four-membered ring fused to another ring. Transition metal catalyzed reactions have been reported, including the use of Fe complexes.[2379] Heating *N*-vinyl imines, where the vinyl moiety is a silyl enol, gives β-lactams.[2380] Apart from photochemical initiation of such reactions (see below), intramolecular cycloaddition of two conjugated ketone units, in the presence of $PhMeSiH_2$ and catalyzed by Co compounds, leads to the bicyclic compound with two ketone substituents.[2381] In a variation of this reaction, a diyne was treated with $Ti(OiPr)_4$/2 *i*PrMgCl to generate a bicyclic cyclobutene with two vinylidene units.[2382]

Ketenes react with many alkenes to give cyclobutanone derivatives[2383] and intermolecular cycloadditions are well known.[2384] A typical reaction of dimethylketene and ethene gives 2,2-dimethylcyclobutanone, as shown.[2385] Ketenes react with imines via

[2 + 2]-cycloaddition to produce β-lactams.[2386] Cycloaddition of an imine with a conjugated ester in the presence of Et_3MeSiH and an Ir catalyst also gives a β-lactam.[2387] See Reaction **19-66** for a discussion of reactions that give β-lactams.

Different alkenes combine as follows:

1. $F_2C{=}CX_2$ (X = F or Cl), especially $F_2C{=}CF_2$, form cyclobutanes with many alkenes. Compounds of this type even react with conjugated dienes to give four-membered rings rather than undergoing normal *Diels–Alder reactions*.[2388]
2. Allenes[2389] and ketenes[2390] react with activated alkenes and alkynes. Ketenes give 1,2-addition, even with conjugated dienes.[2391] Ketenes also add to unactivated alkenes if sufficiently long reaction times are used.[2392] Allenes and ketenes also add to each other.[2393]
3. Enamines[2394] form four-membered rings with *Michael-type* alkenes[2395] and ketenes.[2396] In both cases, only enamines from aldehydes give stable four-membered rings:

Generating the ketene *in situ* from an acyl halide and a tertiary amine is a convenient way to carry out the reaction of enamines with ketenes.

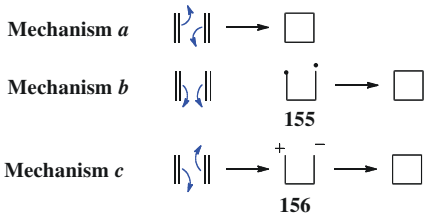
4. Alkenes with electron-withdrawing groups may form cyclobutanes with alkenes containing electron-donating groups.[2397] The enamine reactions, mentioned above, are examples of this, but it has also been accomplished with tetracyanoethylene and similar molecules, which give substituted cyclobutanes when treated with alkenes of the form C=C—A, where A may be OR,[2398] SR (enol and thioenol ethers),[2399] cyclopropyl,[2400] or certain aryl groups.[2401]

Enantioselective [2 + 2]-cycloaddition reactions are known. Chiral organocatalysts lead to chiral cyclobutane derivatives.[2402]

Solvents are not necessary for [2 + 2]-cycloadditions. They can be carried out at 100–225 °C under pressure, although the reactions in Group 4 occur under milder conditions. However, the choice of solvent can control the distribution of products in photochemical [2 + 2]-cycloaddition.[2403]



It has been found that certain [2 + 2]-cycloadditions that do not occur thermally can be made to take place without photochemical initiation using certain catalysts, usually transition metal compounds.[2404] Among the catalysts used are Lewis acids[2405] and phosphine–Ni complexes.[2406] The role of the catalyst is not certain and may be different in each case. One possibility is that the presence of the catalyst causes a forbidden reaction to become allowed, through coordination of the catalyst to the π or *s* bonds of the substrate.[2407] In such a case, the reaction would of course be a concerted $[2_s + 2_s]$ process.[2408] However, the available evidence is more consistent with nonconcerted mechanisms involving metal–carbon σ-bonded intermediates, at least in most cases.[2409] For example, such an intermediate was isolated in the dimerization of norbornadiene, catalyzed by Ir complexes.[2410] Photochemical[2411] $[_\pi 2 + _s 2]$-cycloadditions have also been reported. Visible light mediates cycloaddition in the presence of a Rh catalyst.[2412] Some reverse cyclobutane ring openings can also be catalytically induced (Reaction **18-38**).

Thermal cycloadditions leading to four-membered rings can also take place between a cyclopropane ring and an alkene or alkyne[2413] bearing electron-withdrawing groups.[2414]

These reactions are $[_{\pi}2 + {}_{s}2]$-cycloadditions. Ordinary cyclopropanes do not undergo the reaction, but it has been accomplished with strained systems (e.g., bicyclo[1.1.0] butanes[2415] and bicyclo[2.1.0]pentanes). For example, bicyclo[2.1.0]pentane reacts with maleonitrile (or fumaronitrile) to give all three isomers of 2,3-dicyanonorbornane, as well as four other products.[2416] The lack of stereospecificity and the negligible effect of solvent on the rate indicate a diradical mechanism.

If dienes are involved in the reaction, the *Diels–Alder reaction* may compete, although most alkenes react with a diene either entirely by 1,2- or entirely by 1,4-addition. Three mechanisms have been proposed for [2 + 2]-cycloaddition.[2417]

Mechanism *a* is a concerted pericyclic process, and mechanisms *b* and *c* are two-step reactions involving, respectively, a diradical (**155**) and a diion (**156**) intermediate. As in Reaction **15-60**, a diradical intermediate must be a singlet. In searching for ways to tell which mechanism is operating in a given case, mechanism *c* is expected to be sensitive to changes in solvent polarity, while mechanisms *a* and *b* should be insensitive. Mechanism *a* is expected to be stereospecific, while mechanisms *b* and *c* probably would not be stereospecific. However, if the second step of these processes takes place very rapidly, before **155** or **156** have a chance to rotate about the newly formed single bond, stereospecificity might be observed. Because of entropy considerations, such rapid ring closure might be more likely here than in a [4 + 2]-cycloaddition.

There is evidence that the reactions can take place by all three mechanisms, depending on the structure of the reactants. A thermal $[_{\pi}2_s + {}_{\pi}2_s]$ mechanism is ruled out for most of these substrates by the orbital symmetry rules, but a $[_{\pi}2_s + {}_{\pi}2_a]$ mechanism is allowed (see above), and there is much evidence that ketenes and certain other linear molecules[2418] in which the steric hindrance to such an approach is minimal can and often do react by this mechanism. In a $[_{\pi}2_s + {}_{\pi}2_a]$ cycloaddition, the molecules must approach each other in such a way (Fig. 15.12*a*) that the HOMO–LUMO overlap requires that the groups of one molecule project *into* the plane of the other. This does not happen with ordinary alkenes,[2419] but if one molecule is a ketene (Fig. 15.12*b*), a group on the carbon of the C=C unit is missing (relative to an alkene) and the $[_{\pi}2_s + {}_{\pi}2_a]$-reaction can take place.

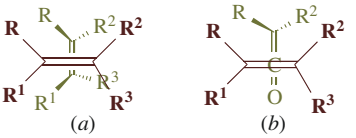

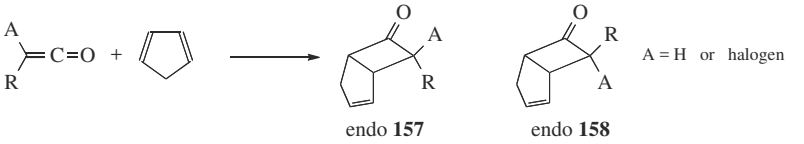

FIG. 15.12. Steric interactions in $[\pi 2_s + \pi 2_s]$-cycloaddition between (*a*) two alkene molecules and (*b*) a ketene and an alkene

Among the evidence[2420] for this mechanism[2421] is the following: (1) the reactions are stereospecific.[2422] (2) The isomer that forms is the *more hindered one*. Thus the reaction of methylketene plus cyclopentadiene gave only

endo **157** endo **158**

the endo product (**157**, A = H, R = CH_3).[2423] Even more remarkably, when haloalkyl ketenes RXC=C=O were treated with cyclopentadiene, the endo/exo ratio of the product (**157**, **158**, A = halogen) actually *increased* substantially when R was changed from Me to *i*Pr to *t*-Bu![2424] One would expect preferential formation of the exo products (**158**) from $[\pi 2_s + \pi 2_s]$-cycloadditions where the molecules approach each other face-to-face. However, a $[\pi 2_s + \pi 2_a]$-process leads to endo products because the ketene molecule (which for steric reasons would approach with its smaller group, methyl in the figure, directed toward the alkene) must twist as shown in Fig. 15.13 (*tert*-butyl = larger; methyl = smaller group) in order for the + lobes to interact. This process swings the larger group (*tert*-butyl) into the endo position.[2425] The experimental results in which the amount of endo isomer increases with the increasing size of the R group appears to be contrary to what would be expected from steric hindrance considerations (called *masochistic steric effects*), but they are just what is predicted for a $[\pi 2_s + \pi 2_a]$ reaction. (3) There is only moderate polar solvent acceleration.[2426] (4) The rate of the reaction is not very sensitive to the presence of electron-withdrawing or electron-donating substituents.[2427] Because cycloadditions involving allenes are often stereospecific, it has been suggested that these also take place

by the $[\pi 2_s + \pi 2_a]$ mechanism,[2428] but the evidence in these cases is more consistent with the diradical mechanism *b*.[2429]

The diradical mechanism *b* is most prominent in the reactions involving fluorinated alkenes.[2430] These reactions are generally not stereospecific[2431] and are insensitive to solvent effects. Further evidence that a diion is not involved is that head-to-head coupling is found when an unsymmetrical molecule is dimerized. Thus dimerization of $F_2C{=}CFCl$ gives **159**, not **160**. If one pair of electrons moved before the other, the positive end of one molecule would be expected to attack the negative end of the other.[2432]

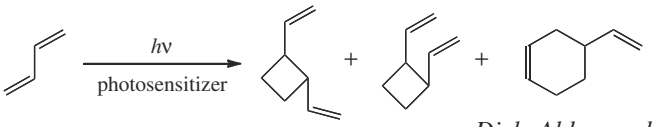
The diion mechanism[2433] *c* has been reported for at least some of the reactions[2434] in categories 3 and 4,[2435] as well as some ketene dimerizations.[2436] The rate of the reaction between 1,2-bis(trifluoromethyl)-1,2-dicyanoethene and ethyl vinyl ether, for example, was strongly influenced by changes in solvent polarity.[2437] Some of these reactions are nonstereospecific, but others are stereospecific.[2438] As previously indicated, it is likely that in the latter cases the diionic intermediate closes before rotation can take place. Such rapid ring closure is more likely for a diion than for a diradical because of the attraction between the opposite charges. Other evidence for the diion mechanism in these cases is that reaction rates are greatly dependent on the presence of electron-donating and electron-withdrawing groups and that it is possible to trap the diionic intermediates.

Whether a given alkene reacts by the diradical or diion mechanism depends, among other things, on the groups attached to it. For example, phenyl and vinyl groups at the α positions of **155** or **156** help to stabilize a diradical, while donors (e.g., oxygen and nitrogen) favor a diion (they stabilize the positively charged end).[2439] A table in Ref. 2439 (see p. 451) shows which mechanism is more likely for [2 + 2]-cycloadditions of various pairs of alkenes.



Thermal cleavage of cyclobutanes[2440] to give two alkene molecules (*cycloreversion*,[2441] the reverse of [2 + 2]-cycloaddition) operates by the diradical mechanism, and the $[_{\sigma}2_{s} + _{\sigma}2_{a}]$-pathway has not been found[2442] (the subscripts σ indicate that σ bonds are involved in this reaction).

In some cases, double bonds add to triple bonds to give cyclobutenes, apparently at about the same rate that they add to double bonds. The addition of triple bonds to triple bonds would give cyclobutadienes, and this has not been observed, except where these rearrange before they can be isolated (see Reaction **15-65**)[2443] or in the presence of a suitable coordination compound, so that the cyclobutadiene is produced in the form of a complex (Sec. 2.K.ii).[2444]

Although thermal [2 + 2]-cycloaddition reactions are essentially limited to the cases described above, many (although by no means all) double-bond compounds react *when photochemically excited* (either directly or by a photosensitizer, see Sec. 7.A.vi,

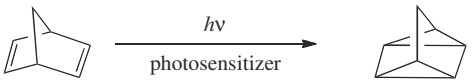
category 5), even if they are not in the above categories.[2445] Simple alkenes absorb in the far-UV (Sec. 7.A.iii), which is difficult to reach experimentally, although this problem can sometimes be overcome by the use of suitable photosensitizers. The reaction has been applied to simple alkenes[2446] (especially to strained compounds, e.g., cyclopropenes and cyclobutenes), but more often the double-bond compounds involved are conjugated dienes,[2447] α,β-unsaturated ketones,[2448] conjugated acids or acid derivatives, and quinones. Since these compounds, are conjugated, they absorb at longer wavelengths (Sec 7.A.iii). Both dimerizations and mixed additions are common. Some examples follow:



Diels-Alder product

Ref. 2449

Ref. 2450

See also, Section 7.A.vii (Reaction **7-9**). Photochemical [2 + 2]-cycloadditions can also take place intramolecularly if a molecule has two double bonds that are properly oriented.[2451] The cyclization of the quinone dimer shown above is one example. Other examples are

Carvone Carvonecamphor

Ref. 2453

It is obvious that many molecules can be constructed in this way that would be difficult to make by other procedures. However, attempted cyclizations of this kind are not always successful. In many cases, polymeric or other side products are obtained instead of the desired product.

161

The photochemical cycloaddition of a carbonyl, generally from an aldehyde or ketone and an alkene, is called the *Paternò–Büchi reaction*.[2454] This [2 + 2]-cycloaddition gives an oxetane (**161**) and the reaction is believed to proceed via a diradical intermediate. Silyl enol ethers react with aldehydes under nonphotochemical conditions using $ZnCl_2$ at 25°C or $SnCl_4$ at −78°C.[2455]

It is possible that some of these photochemical cycloadditions take place by a $[\pi 2_s + \pi 2_s]$-mechanism, which is of course allowed by orbital symmetry; when and if they do, one of the molecules must be in the excited singlet state (S_1) and the other in the ground state.[2456] The nonphotosensitized dimerizations of *cis*- and *trans*-2-butene are stereospecific,[2457] making it likely that the $[\pi 2_s + \pi 2_s]$-mechanism is operating in these reactions. However, in most cases it is a triplet excited state that reacts with the ground-state molecule; in these cases the diradical (or in certain cases, the diionic) mechanism is taking place.[2458] In one intramolecular case, the intermediate diradical has been trapped.[2459] Photosensitized $[2\pi + 2\pi]$-cycloadditions almost always involve the triplet state, and hence a diradical (or diionic) mechanism.

The photochemical diradical mechanism is not quite the same as the thermal diradical mechanism. In the thermal mechanism, the initially formed diradical must be a singlet, but in the photochemical process a triplet excited state is adding to a ground state, which is of course a singlet. Thus, in order to conserve spin,[2460] the initially formed diradical must be a triplet; that is, the two electrons must have the same spin. Consequently, the second, or ring closing, step of the mechanism cannot take place at once, because a new bond cannot form

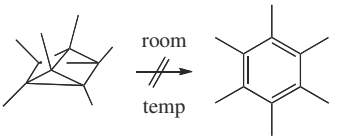
[2460] This is an example of the *Wigner spin conservation rule* (Sec. 7.A.vi, category 5). Note that spin conservation is something entirely different from symmetry conservation.



from a combination of two electrons with the same spin, and the diradical has a reasonably long lifetime before collisions with molecules in the environment allow a spin inversion to take place and the diradical to cyclize. The prediction is nonstereospecificity, and that is what is found.[2461] It has been believed that at least some [2 + 2] photocycloadditions take place by way of exciplex intermediates[2462] [an *exciplex*[2463] is an excited EDA complex (Sec. 7.A.vii) that is dissociated in the ground state; in this case one double bond is the donor and the other is the acceptor], but there is evidence against this.[2464]

In Reaction **15-60**, the principle of conservation of orbital symmetry was used to explain why certain reactions take place readily and others do not. The orbital-symmetry principle can also explain why certain molecules are stable although highly strained. Quadricyclane and hexamethylprismane[2465] are thermodynamically much less stable (because they are much more strained), for example, than their corresponding isomeric dienes, norbornadiene and

Quadricyclane — Norbornadiene — Hexamethylprismane — **162** (A Dewar benzene)

hexamethylbicyclo[2.2.0]hexadiene (**162**).[2466] Yet the former two compounds can be kept indefinitely at room temperature, although in the absence of orbital-symmetry considerations it is not easy to understand why the electrons simply do not move over to give the more stable diene isomers. The reason is that both these reactions involve the conversion of a cyclobutane ring to a pair of double bonds (a $_s2 + _s2$ process) and, as seen previously, a thermal process of this sort is forbidden by the *Woodward–Hoffmann rules*. The process is allowed photochemically, so both quadricyclane and hexamethylprismane are photochemically converted to the respective dienes at room temperature or below.[2467] It is also possible to conceive of simple bond rearrangements whereby hexamethylprismane is converted to hexamethylbenzene (as shown below), which of course is far more stable than either hexamethylprismane or **162**. It has been calculated that hexamethylbenzene is at least 90 kcal mol^{-1} (380 kJ mol^{-1}) more stable than hexamethylprismane. A correlation diagram for this reaction[2468] discloses that it too is a symmetry-forbidden process. All three of these "forbidden" reactions do take place when the compounds are heated, but the diradical mechanism is likely under these conditions.[2468]

Bicyclo[2.2.0]hexadienes and prismanes are *valence isomers* of benzenes.[2469] These compounds actually have the structures that were proposed for benzenes in the nineteenth century. Prismanes have the Ladenburg formula, and bicyclo[2.2.0]hexadienes have the *Dewar* formula. Because of this, bicyclo[2.2.0]hexadiene is often called *Dewar benzene*. In the paragraph prior to Section 2.A, it was mentioned that Dewar formulas are canonical forms (although not very important) of benzenes. Yet they also exist as separate compounds in which the positions of the nuclei are different from those of benzenes.

15-64 The Addition of Carbenes and Carbenoids to Double and Triple Bonds

***epi*-Methylene-addition**

Carbenes and substituted carbenes add to double bonds to give cyclopropane derivatives by what can be considered as a formal [1 + 2]-cycloaddition.[2470] Many carbene derivatives [e.g., PhCH, ROCH,[2471] $Me_2C{=}C$, and $C(CN)_2$] have been added to double bonds, but the reaction is often performed with CH_2 itself, with halo and dihalocarbenes,[2472] and with carbalkoxycarbenes[2473] (generated from diazoacetic esters). Alkylcarbenes (HCR) have been added to alkenes,[2474] but more often these rearrange to give alkenes (Sec. 5.D.ii, category 4). The carbene can be generated in any of the ways normally used (Sec. 5.D.ii). However, most reactions in which a cyclopropane is formed by treatment of an alkene with a carbene "precursor" do not actually involve free carbene intermediates. In some cases, it is certain that free carbenes are not involved, and in other cases there is doubt. Because of this, the term *carbene transfer* is often used to cover all reactions in which a double bond is converted to a cyclopropane, whether a carbene or a carbenoid (Sec. 5.D.ii) is actually involved.

Carbene itself ($:CH_2$) is extremely reactive and gives many side reactions, especially insertion reactions (**12-21**), which greatly reduce yields. This competition is also true with Rh catalyzed diazoalkane cyclopropanations[2475] (see below). When: CH_2 must be added for preparative purposes, a free carbene is not used, but the *Simmons–Smith procedure*

(see **167**) or some other method that does not involve free carbenes is employed instead. Halocarbenes are less active than carbenes, and this reaction proceeds quite well, since insertion reactions do not interfere.[2476] Vinyldiazolactone is a vinylcarbene precursor for a reaction with alkenes to give spirolactones.[2477]

The absolute rate constant for addition of selected alkoxychlorocarbene to butenes has been measured to range from 330 to $1 \times 10^4\ M^{-1}\ s^{-1}$.[2478] Both entropy and enthalpy play a role in addition of some carbenes.[2479] Shown are a few of the many ways[2480] in which halocarbenes or carbenoids are generated,[2481] and most involve formal elimination (for the first two steps of the S_N1cB mechanism, see Sec. 10.G.iii):

$$CH_2Cl_2 + RLi \longrightarrow CHCl$$

$$N_2CHBr \xrightarrow{h\nu} CHBr$$

$$CHCl_3 + {}^-OH \longrightarrow CCl_2$$

$$PhHgCCl_2Br \xrightarrow{\Delta} CCl_2 \qquad \text{Ref. 2482}$$

$$Me_3SnCF_3 + NaI \longrightarrow CF_2 \qquad \text{Ref. 2483}$$

$$Me_2CBr_2 \xrightarrow{\text{electrolysis}} Me_2C: \qquad \text{Ref. 2484}$$

The reaction between $CHCl_3$ and HO^- is often carried out under phase-transfer conditions.[2485] It has been shown that the reaction between $PhCHCl_2$ and *t*-BuOK produces a carbenoid, but when the reaction is run in the presence of a crown ether, the carbene [Ph(Cl)C:] is formed instead.[2486] The reaction of iodoform and $CrCl_2$ leads to iodocyclopropanes upon reaction with alkenes.[2487] Dihalocyclopropanes are very useful compounds[2488] that can be reduced to cyclopropanes, treated with Mg or Na to give allenes (Reaction **18-3**), or converted to a number of other products.

Alkenes of all types can be converted to cyclopropane derivatives by this reaction, but difficulty may be encountered with sterically hindered ones.[2489] Even tetracyanoethylene, which responds very poorly to electrophilic attack, gives cyclopropane derivatives with carbenes.[2490] Conjugated dienes give 1,2-addition to give a vinylcyclopropane.[2491] Addition of a second molar equivalent gives bicyclopropyl derivatives.[2492] 1,4-Addition is rare but has been reported in certain cases.[2493] Carbene adds to ketene to give cyclopropanone.[2494] Allenes react with carbenes to give cyclopropanes with exocyclic unsaturation:[2495]

A second equivalent gives spiropentanes. In fact, any size ring with an exocyclic double bond can be converted by a carbene to a spiro compound.[2496]

Free carbenes can also be avoided by using transition metal–carbene complexes ($L_nM{=}CRR'$, L = a ligand, M = a metal),[2497] which add the group CRR′ to double bonds.[2498] An example is the reaction of iron carbene (**163**).[2499] These complexes can be isolated in some cases; in others they are generated *in situ* from appropriate precursors, of which diazo compounds are among the most important. Chromium complexes have been used for the cyclopropanation of alkenes.[2500]

163

Diazo compounds, including CH_2N_2 and other diazoalkanes, react with metals or metal salts (Cu, Pd,[2501] Ag,[2502] La,[2503] and Rh[2504] are commonly used) to give the carbene complexes that add:CRR′ to double bonds.[2505] Polymer-supported benzenesulfonyl azides

have been developed as a safe diazo-transfer reagent.[2506] Diazoketones and diazoesters react with alkenes to give the cyclopropane derivative, usually with a transition metal catalyst (e.g., a Cu complex).[2507] The Ru catalyst reaction of diazoesters with an alkyne gives a cyclopropene.[2508] An X-ray structure of an Os catalyst intermediate has been determined.[2509] Electron-rich alkenes react faster than simple alkenes.[2510]

Asymmetric cyclopropanation reactions are a growing area of interest,[2511] and chiral complexes have been used for enantioselective cyclopropane synthesis.[2512] Decomposition of diazoalkanes in the presence of chiral Rh[2513] Cu,[2514] Ir,[2515] Co,[2516] Au,[2517] or Ru[2518] complexes leads to optically active cyclopropanes. Diazosulfonate esters have been used in asymmetric cyclopropanations.[2519] The use of chiral additives or auxiliaries with a metal complex also leads to cyclopropanes enantioselectively.[2520] An important chiral species is $Rh_2(S\text{-DOSP})_4$,[2521] which leads to cyclopropanes with excellent enantioselectivity in carbene cyclopropanation reactions.[2522] Chiral organocatalysts have been used.[2523] The Cu catalyzed diazoester cyclopropanation was reported in an ionic liquid.[2524] Phosphonate esters have been incorporated into the diazo compound.[2525] *Fischer carbene* compounds (see Reaction **15-58**) react with enolate anions to

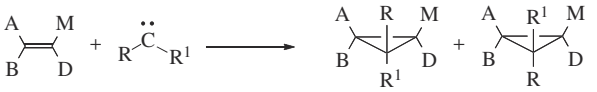
give cyclopropane derivatives.[2526] A Cr promoted cyclopropanation of conjugated amides has been reported.[2527]

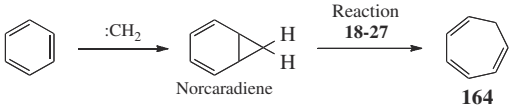
Asymmetric, intramolecular cyclopropanation reactions have been reported.[2528] Note that the reaction of a diazoester with a chiral dirhodium catalyst leads to β-lactones with modest enantioselectivity.[2529]

Triple-bond compounds[2530] react with carbenes to give cyclopropenes, except that in the case of acetylene itself, the cyclopropenes first formed cannot be isolated because they rearrange to allenes.[2531] Cyclopropenones (Sec. 2.K.i) are obtained by hydrolysis of dihalocyclopropenes.[2532]

Most carbenes are electrophilic, and, in accord with this, electron-donating substituents on the alkene increase the rate of the reaction, and electron-withdrawing groups decrease it,[2533] although the range of relative rates is not very great.[2534] As discussed in Section 5.D.i, carbenes in the singlet state, which is the most common state, react stereospecifically and syn,[2535] probably by a one-step mechanism,[2536] similar to mechanism *a* of Reactions **15-60** and **15-63**:



Infrared spectra of a carbene and the cyclopropane product have been observed in an Ar matrix at 12–45 K.[2537] Carbenes in the triplet state react nonstereospecifically,[2538] probably by a diradical mechanism, similar to mechanism *b* of Reactions **15-49** and **15-63**:



For carbenes or carbenoids of the type R—C—R′ there is another aspect of stereochemistry.[2539] When these species are added to all but symmetrical alkenes, two isomers

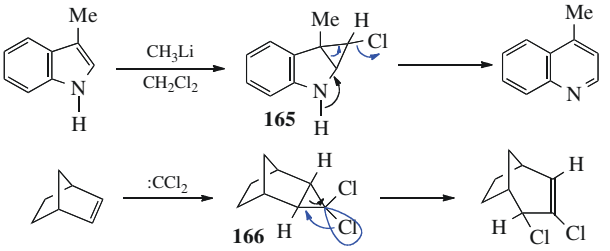
are possible, even if the four groups originally on the double-bond carbons maintain their configurations:

Which isomer is predominantly formed depends on R, R′, and on the method by which the carbene or carbenoid is generated. Most studies have been carried out on monosubstituted species (R′ = H), and in these studies it is found that aryl groups generally prefer the more substituted side (syn addition) while carbethoxy groups usually show antistereoselectivity. When R = halogen, free halocarbenes show little or no stereochemical preference, while halocarbenoids exhibit a preference for syn addition. Beyond this, it is difficult to make simple generalizations.



164

Carbenes are so reactive that they add to the "double bonds" of aromatic rings.[2540] The products are usually unstable and rearrange to give ring expansion. Carbene reacts with benzene to give cycloheptatriene (**164**),[2541] but not all carbenes are reactive enough to add to benzene. The norcaradiene intermediate cannot be isolated in this case[2542] (it undergoes an electrocyclic rearrangement, Reaction **18-27**), although certain substituted norcaradienes, [e.g., the product of addition of:$C(CN)_2$ to benzene],[2543] have been isolated.[2544] With:CH_2, insertion is a major side reaction, and, for example, benzene gives toluene as well as cycloheptatriene. A method of adding:CH_2 to benzene rings without the use of free carbene is the catalytic decomposition of diazomethane (CH_2N_2) in the aromatic compound as a solvent with CuCl or CuBr.[2545] By this method, better yields of cycloheptatrienes are obtained without insertion of side products. *Picosecond optical grating calorimetry* has been used to investigate the photochemical decomposition of diazomethane in benzene, and it appears that a transient is formed that is consistent with a weak complex between singlet methylene and benzene.[2546] Chlorocarbene (:CHCl) is active enough to add to benzene, but dihalocarbenes do not add to benzene or toluene, only to rings with greater electron density. Pyrroles and indoles can be expanded, respectively, to pyridines and quinolines by treatment with halocarbenes[2547] via the initially formed adduct **165** in the case of the indole. In such cases, a side reaction that sometimes occurs is expansion of the *six-membered* ring. Ring

expansion can occur even with nonaromatic compounds, when the driving force is supplied by relief of strain (see Reaction **166**).[2548]

As previously mentioned, free carbene is not very useful for additions to double bonds since it gives too many side products. The *Simmons–Smith procedure* accomplishes the same result without a free carbene intermediate and without insertion of side products.[2549] This is known as a *carbenoid* reaction. Intramolecular variations are known.[2550] This procedure involves treatment of the double-bond compound with CH_2I_2 and a Zn—Cu couple and leads to cyclopropane derivatives in good yields.[2551] The Zn—Cu couple can be prepared in several ways,[2552] and heating Zn dust with CuCl in ether under nitrogen[2553] is particularly convenient. The reaction has also been done with unactivated Zn and ultrasound.[2554] When $TiCl_4$ is used along with Zn and CuCl, CH_2I_2 can be replaced by the cheaper CH_2Br_2.[2555]

The actual attacking species is an organozinc intermediate, probably $(ICH_2)_2Zn \cdot ZnI_2$, which is stable enough for isolable solutions.[2556] An X-ray crystallographic investigation of the intermediate, complexed with a diether, has been reported.[2557] The addition is stereospecifically syn, and a concerted mechanism[2558] is likely, perhaps involving **167**.[2559] An iodomethylzinc phosphate has also been used for cyclopropanation reactions.[2560] Diiodomethane gives cyclopropanes in a reaction mediated by indium.[2561]

Asymmetric induction is possible when chiral additives are used.[2562] Chiral complexes also lead to enantioselectivity in the cyclopropanation reaction.[2563] Organocatalysts have been used.[2564]

With the *Simmons–Smith procedure*, as with free carbenes, conjugated dienes give 1,2-addition,[2565] and allenes give methylenecyclopropanes or spiropentanes.[2566]

An alternative way of carrying out the *Simmons–Smith reaction* is by treatment of the substrate with CH_2I_2 or another dihalomethane and Et_2Zn in ether.[2567] This method can be adapted to the introduction of RCH and ArCH by the use of $RCHI_2$ or $ArCHI_2$ instead of the dihalomethane.[2568] The reaction is compatible with other functionality in the carbenoid complex. The reaction of RCO_2CH_2I with diethyl zinc and an alkene under photolysis conditions give a cyclopropane.[2569] In another method, CH_2I_2 or $MeCHI_2$ is used along with an alane (R_3Al) to transfer CH_2 or CHMe.[2570] Titanium complexes have been used similarly.[2571] Samarium and CH_2I_2 has been used for the cyclopropanation of conjugated amides.[2572] For the conversion of enolate anions to cyclopropanols, CH_2I_2 has been used along with SmI_2.[2573] Diodomethane in the presence of isopropylmagnesium chloride has been used to cyclopropanate allyl alcohols.[2574]

The *Simmons–Smith reaction* is the basis of a method for the indirect α methylation of a ketone.[2575] The ketone (illustrated for cyclohexanone) is first converted to an enol ether, an enamine (Reaction **16-13**) or silyl enol ether[2576] (Reaction **12-17**), and cyclopropanation via the *Simmons–Smith reaction* is followed by hydrolysis to give the α methylated ketone. A related procedure using diethylzinc and diiodomethane allows ketones to be chain-extended by one carbon.[2577] In another variation, phenols can be ortho methylated in one laboratory step, by treatment with Et_2Zn and CH_2I_2.[2578]

Diazoesters react with amines with a Rh catalyst to give α-amino esters.[2579] Diazoesters also react with aldehydes and a Rh catalyst. The product is an α,β-epoxy ester.[2580]

15-65 Trimerization and Tetramerization of Alkynes

Aromatic compounds can be prepared by cyclotrimerization of alkynes[2582] or triynes. Cyclotrimerization is possible by heating to 450–600 °C with no catalyst.[2583] The *spontaneous* (no catalyst) trimerization of *t*-BuC≡CF gave 1,2,3-tri-*tert*-butyl-4,5,6-trifluorobenzene (**169**), which the first time was three adjacent *tert*-butyl groups put onto a benzene ring.[2584] The fact that this is a head-to-head joining allows formation of **169** from two alkynes. The fact that **168** (a *Dewar benzene*) was also isolated lends support to this scheme.[2585]

When acetylene is heated with nickel cyanide, other Ni(II) or Ni(0) compounds, or similar catalysts, it gives benzene and cyclooctatetraene.[2586] It is possible to get more of either product by a proper choice of catalyst. Substituted acetylenes give substituted benzenes,[2587] and this reaction has been used to prepare very crowded molecules. Dialkylalkynes were trimerized over $CO_2(CO)_8$[2588] and over $Hg[Co(CO)_4]_2$ to give hexaisopropylbenzene.[2589] The six isopropyl groups are not free to rotate, but are lined up perpendicular to the plane of the benzene ring. Highly substituted benzene derivatives have also been prepared via cyclotrimeriztion using a Rh,[2590] Ni,[2591]

Ti,[2592] Mo,[2593] Ru,[2594] Co,[2595] or a Pd[2596] catalyst. Alkynes react with allenes and a Ni catalyst to give highly substituted benzene derivatives.[2597] Conjugated ketones react with internal alkynes with Me_3Al and a Ni catalyst[2598] to give an aromatic ring fused to a cyclic ketone after reaction with DBU and air.[2599] N-Aryl chloroimines react with alkynes and a Rh catalyst to give quinolines,[2600] as do N-aryl alkynyl imines with a W complex.[2601]

Intramolecular cyclotrimerizations have been reported by condensation of a diyne[2602] with an alkyne in the presence of a Pd,[2603] Mo,[2604] Ni,[2605] Rh,[2606] Ir,[2607] Ag,[2608] Co,[2609] or Ru catalyst.[2610] Triynes have been similarly condensed with a Rh catalyst.[2611] Note that this type of cyclization has been labeled as a $[2+2+2]$-cycloaddition reaction, which is discussed in Reaction **15-66**. The internal cyclotrimerization of a triyne, utilizing a siloxy tether and a Co catalyst has been reported.[2612] Fused-ring aromatic compounds are prepared by this method. Similar results were obtained from diynes and allenes with a Ni catalyst.[2613] Solid-supported cyclotrimerizations have been reported.[2614] Endiynes are cyclized to bicyclic arenes using a Pd[2615] or Ru[2616] catalyst, as are yndienes with a Ru catalyst.[2617] Alkynyl biaryls are cyclized to phenanthrene derivatives using ICl.[2618] In the presence of $PhMe_2SiH$, CO, and a Rh catalyst, a nonconjugated triyne leads to a tricyclic compound in which a benzene ring is fused to two carbocyclic rings.[2619] Internal cyclotrimerization of an aryl alkynyl ketone where the aryl group has an *ortho*

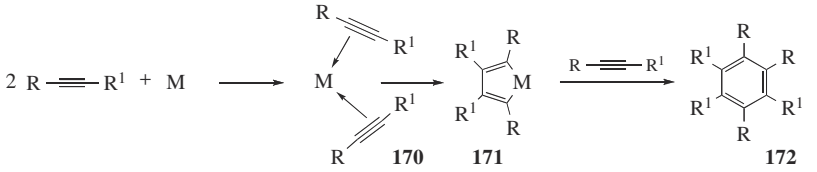
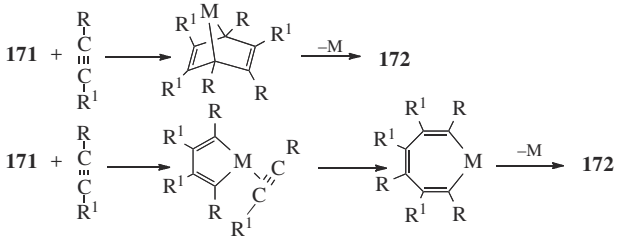
trimethylsiylalkyne substituent gives a tetracyclic naphthalene derivative with a fused cyclopentanone unit.[2620] Benzene derivatives with ortho alkyne units can be converted to naphthalene derivatives in aq NaOH with hydrazine, Te, $NaBH_4$ and sonication.[2621] Vinyl and alkyne substituents with a Ru catalyst lead to naphthalene derivatives.[2622] Cyclotrimerization occurs with alkynyl boronic esters.[2623]



Imino and iodo substituents with a silyl alkyne and a Pd catalyst leads to an isoquinoline.[2624] Benzene derivatives having ortho imine and alkyne substituents give an isoquinoline when treated with iodine[2625] or with a Pd catalyst.[2626] Diynes with nitriles and a Ru catalyst lead to isoquinolines.[2627] Pyridines fused to carboxylic rings can be prepared by similar methodology using a cyanoamine and a Co catalyst.[2628] An isocyanate (Ar—N=C=O) reacts with a diyne and a Ru catalyst to give a bicyclic pyridone.[2629] Isocyanides and alkynes also react with a phosphine catalyst to give pyrroles.[2630] Ortho alkynyl and epoxy substituents leads to β-naphthols using a Ru catalyst.[2631]

Nitriles react with 2 molar equivalents of acetylene, in the presence of a Co catalyst, to give 2-substituted pyridines.[2632] Propargyl amines react with cyclohexanone derivatives and a Au complex to give tetrahydroquinolines.[2633] Treatment of alkynes with Cp_2ZrEt_2 followed by reaction with acetonitrile and then a second alkyne with a Ni catalyst gives a highly substituted pyridine.[2634] This reaction can be done intramolecularly using a photochemically induced reaction with a Co catalyst and *p*-TolCN to give pyridines incorporated into macrocycles.[2635] Diynes react with *N*-heterocyclic carbenes in the presence of a Ni catalyst to give pyridines.[2636] Alkynyl esters react with enamino esters with a $ZnBr_2$ catalyst to give substituted pyridines.[2637] α-Halo oxime ethers react with alkynes and *Grignard reagent*s, with a mixture of Pd and Cu catalysts, to give pyrimidines.[2638] Triketones fix nitrogen gas in the presence of $TiCl_4$ and Li metal to form bicyclic pyrrole derivatives.[2639]



In contrast to the spontaneous reaction, the catalyzed process seldom gives the 1,2,3-trisubstituted benzene isomer from an acetylene (RC≡CH). The chief product is usually

the 1,2,4-isomer,[2640] with lesser amounts of the 1,3,15-isomer also generally obtained, but little if any of the 1,2,3-isomer. The mechanism of the catalyzed

reaction to form benzenes[2641] is believed to go through a species **170** in which two molecules of alkyne coordinate with the metal, and another species (**171**), a five-membered heterocyclic intermediate.[2642] Such intermediates (where M = Rh, Ir, Zr,[2643] or Ni) have been isolated and are shown to give benzenes (**172**) when treated with alkynes.[2644] Note that this pathway accounts for the predominant formation of the 1,2,4-isomer. Two possibilities for the last step are a *Diels–Alder reaction,* and a ring expansion, each followed by extrusion of the metal:[2645]

In at least one case, the mechanism is different, going through a cyclobutadiene–nickel complex (see Sec. 2.K.ii), which has been isolated.[2646] Similar results were obtained with a Ti complex.[2647] Using a mixture of $PdCl_2$ and $CuCl_2$, however, aliphatic alkynes are converted to the 1,3,5-trialkyl benzene derivative.[2648]

Alkoxy chromium carbenes (*Fischer carbene complexes*, see Reaction **15-58**) react with phenylalkynes to give naphthalene derivatives.[2649] These Cr carbenes react with

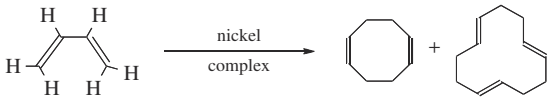
alkynyl boronates, cerium(IV) compounds, and then PhBr and a Pd catalyst to give a naphthoquinone.[2650] Diynes react to give cyclotrimerization.[2651] Note that vinyl Chromium carbenes react directly with alkynes to give spirocyclic compounds (spiro [4.4]nona-1,3,6-trienes).[2652] Benzofurans can be prepared using methoxy carbenes.[2653] Amino-substituted chromium carbenes react with alkynes and then silica to give substituted benzene derivatives that have an aminoalkyl ($—NR_2$) substituent.[2654] Imino-substituted Chromium carbenes react with alkynes to give pyrrole derivatives.[2655] Fischer carbene complexes react with alkynes to give the *Dötz benzannulation*,[2656] giving *p*-alkoxylphenol derivatives. Modification of this basic technique can lead to eight-membered ring carbocycles (see Reaction **15-66**).[2657]



When benzene, in the gas phase, was adsorbed onto a surface of 10% rhodium-on-alumina, the reverse reaction took place, and acetylene was formed.[2658]

Heating ketones in the presence of $TlCl_3OTf$ leads to 1,3,5-trisubstituted arenes.[2659] Heating acetophenone with $TiCl_4$ gives 1,3,5-triphenylbenzene.[2660]

15-66 Other Cycloaddition Reactions

***cyclo*-[But-2-en-1,4-diyl]-1/4/addition**, and so on

Cycloaddition reactions other than [4 + 2], [3 + 2], or [2 + 2] are possible, often providing synthetically useful routes to cyclic compounds. Conjugated dienes can be dimerized or trimerized at the 1,4-positions (formally, [4 + 4] and [4 + 4 + 4] cycloadditions) by treatment with certain complexes or other transition metal compounds.[2661] Thus butadiene gives 1,5-cyclooctadiene and 1,5,9-cyclododecatriene.[2662] The relative amount of each product can be controlled by use of the proper catalyst. For example, Ni:P $(OC_6H_4$-*o*-$Ph)_3$ gives predominant dimerization, while Ni(cyclooctadiene)$_2$ gives mostly trimerization. The products arise, not by direct 1,4 to 1,4 attack, but by stepwise

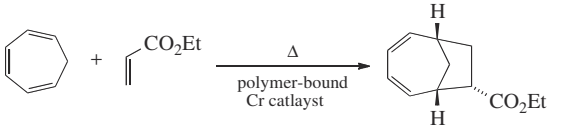
mechanisms involving metal–alkene complexes.[2663] The Rh catalyzed intramolecular cycloaddition of a furan with a conjugated diazoester gives a [3 + 4]-cycloadduct.[2664] The suprafacial thermal addition of an allylic cation to a diene (a [4 + 3] cycloaddition) is allowed by the *Woodward–Hoffmann rules* (this reaction would be expected to follow the same rules as the *Diels–Alder reaction*[2665]). Pyrroles react with allylic diazo compounds, in the presence of a Rh catalyst, to give bicyclic amines in a [4 + 3]-cycloaddition.[2666] A different [4 + 3]-cycloaddition involves the intramolecular reaction of a diene with an alkylidenecyclopropane unit, in the presence of a Pd catalyst, to give a seven-membered ring as part of a bicyclic system.[2667] A [3 + 2 + 2]-cycloaddition was reported with an alkyne and an alkene–alkylidenecyclopropane substrate, in the presence of a Rh catalyst.[2668] Reaction with a chiral Rh catalyst converts dienes and diazo compounds to cycloheptadienes.[2669] Chiral cations have been used in [4 + 3] cycloadditions.[2670] A [5 + 2]-cycloaddition of vinylcyclopropanes and alkenes, in the presence of a Rh catalyst, leads to seven-membered rings.[2671] The reaction of a conjugated carbonyl compound with a diazo ester, in the presence of a Cu catalyst, leads to a dihydropyran in what is labeled a [4 + 1]-cycloaddition.[2672] Dienes react with nitriles in a Ti mediated [4 + 1]-cycloaddition.[2673] Cycloheptatriene reacts with terminal alkynes, using a complex catalyst involves Co and Zn compounds, to give a bicyclic triene via a [6 + 2]-cycloaddition.[2674]



As seen in Reaction **15-60**, the *Woodward–Hoffmann rules* allow suprafacial concerted cycloadditions to take place thermally if the total number of electrons is $4n + 2$ and photochemically if the number is $4n$. Furthermore, forbidden reactions become allowed if one molecule reacts antarafacially. It would thus seem that syntheses of many large rings could easily be achieved. However, when the newly formed ring is eight membered or greater, concerted mechanisms, although allowed by orbital symmetry for the cases stated, become difficult to achieve. Due to the entropy factor the two ends of one system must simultaneously encounter the two ends of the other, unless one or both components are cyclic, in which case the molecule has many fewer possible conformations. There have been a number of reports of cycloaddition reactions leading to eight membered and larger rings, some thermally and some photochemically induced, but (apart from the dimerization and trimerization of butadienes mentioned above, which are known not to involve direct

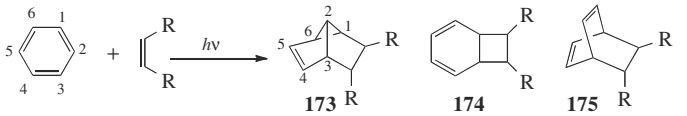
[4 + 4]- or [4 + 4 + 4]-cycloaddition) in most cases evidence is lacking to indicate whether they are concerted or stepwise processes. Some examples follows:



4 + 4 2  Ref.2675

5 + 2  Ref.2676

6 + 2  Ref.2677

8 + 2  Ref.2678

Benzene rings can undergo photochemical cycloaddition with alkenes.[2679] The major product is usually the 1,3 addition product (**173**, in which a three-membered ring has also been formed), although some of the 1,2-product (**174** Reaction **15-63**) is sometimes formed as well. Compound **174** is usually the main product where the alkene bears electron-withdrawing groups and the aromatic compound electron-donating groups, or vice versa. The 1,4-product (**175**) is rarely formed. The reaction has also been run with benzenes substituted with alkyl, halo, OR, CN, and other groups, and with acyclic and cyclic alkenes bearing various groups.[2680]

[2680] See the table in Wender, P.A.; Siggel, L.; Nuss, J.M. *Org. Photochem.* ***1989****, 10*, 357, pp. 384–415.

[2 + 2 + 2]-Cycloaddition reactions are known[2681] (also see Reaction **15-65**), usually with diynes, enynes, or intermolecular reactions of alkynes or alkenes with an alkyne, and facilitated by Ni[2682] Ru,[2683] or a Co catalyst.[2684] A mechanistic density functional study has been reported for this reaction.[2685] With a Co catalyst, an intramolecular [2 + 2 + 2]-cycloaddition of diynes with nitriles leads to bicyclic pyridines.[2686] Alkenyl isocyanates and alkynes react via [2 + 2 + 2]-cycloaddition, in the presence of a Ru catalyst, to form bicyclic conjugated lactams.[2687] Pyridines can also be prepared by metal-catalyzed [2 + 2 + 2]-cycloaddition.[2688] Alkynes and isocyanates react with CO in the presence of a Ru catalyst to give imides,[2689] and other [2 + 2 + 1]-cycloadditions are known,[2690] A Co catalyst is used for a [4 + 2 + 2]-cycloaddition of 1,3-butadiene and bicyclo[2.2.2]octa-2,5-diene.[2691] Eight-membered rings are produced by a Rh catalyzed [4 + 2 + 2] cycloaddition.[2692] Yne-dienes undergo [4 + 2 + 1]-cycloaddition in the presence of a Ni catalyst.[2693] Chromium catalysts are available for [6 + 4]-cycloadditions.[2694] Ene-diynes undergo [2 + 2 + 2 + 1]-cycloaddition to form seven-membered ring ketones, in the presence of CO and a Rh catalyst.[2695] Nickel catalyzed [2 + 2 + 2 + 2]-cycloadditions of alkynes lead to eight-membered rings.[2696]

Allenes and vinylcyclopropanes undergo [5 + 2]- and [5 + 2 + 1]-cycloadditions in the presence of a Rh catalyst.[2697] A reductive elimination step determines the selectivity for various substrates in Rh catalyzed catalyzed [5 + 2]-cycloadditions.[2698]

CHAPTER 16

Addition to Carbon–Hetero Multiple Bonds

16.A. MECHANISM AND REACTIVITY

The reactions considered in this chapter involve addition to the carbon–oxygen, carbon–nitrogen, and carbon–sulfur double bonds, as well as the carbon–nitrogen triple bond. The mechanistic study of these reactions is much simpler than that of the additions to carbon–carbon multiple bonds considered in Chapter 15.[1] Since C=O, C=N, and C≡N bonds are strongly polar, with the carbon always the positive end (except for isocyanides, see Sec. 16.B.iv), there is never any doubt about the *orientation* of unsymmetrical addition to these bonds (the regiochemical preference). Nucleophilic attacking species always go to the carbon and electrophilic species to the oxygen or nitrogen. Additions to C=S bonds are much less common,[2] but in these cases the addition is sometimes in the other direction (reaction at sulfur is called *thiophilic addition* and addition to the carbon is called *carbophilic addition*).[3] For example, the reaction of phenyllithium with thiobenzophenone ($Ph_2C{=}S$) gives, after hydrolysis, benzhydryl phenyl sulfide (Ph_2CHSPh).[4]

1

The normal acyl addition of YH to a ketone gives an alkoxide, and hydrolysis gives **1**. Note that the product has a stereogenic carbon, but unless there is chirality in R or R′, or YH is optically active, the product must be a racemic mixture because there is no facial bias for addition to the carbonyl. The same holds true for C=N and C=S bonds. The stereochemistry of addition of a single YH to the carbon–nitrogen triple bond could be investigated, since the product can exist in (*E*) and (*Z*) forms (Sec. 4.K.i), but these reactions generally give imine products that undergo further reaction. Of course, if R or R′ *is* chiral, a mixture of diastereomers

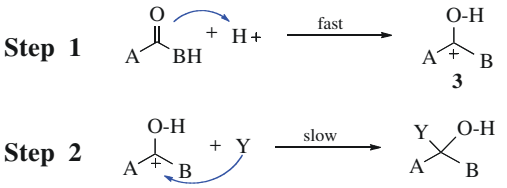
will result, and the stereochemistry of addition can be studied in such cases. *Cram's rule* or the *Felkin–Anh model* (Sec. 4.H) allows the direction of attack of Y to be predicted in many cases.[5] However, the relative directions of attack of Y and H are not determined, but only the direction of attack of Y with respect to the rest of the substrate molecule.

In Section 15.B.iii, electronic effects were shown to play a part in determining which face of a carbon–carbon double bond is attacked. The same applies to additions to carbonyl groups. For example, in 5-substituted adamantanones (**2**) electron-withdrawing (*–I*) groups W cause the attack to come from the syn face, while electron-donating groups cause it to come from the anti face.[6] In 5,6-disubstituted norborn-2-en-7-one systems, the carbonyl appears to tilt away from the π bond, with reduction occurring from the more hindered face.[7] An *ab initio* study of nucleophilic addition to 4-*tert*-butylcyclohexanones attempted to predict π-facial selectivity.[8]

2

The mechanistic picture is further simplified by the fact that free radical additions to carbon–heteroatom double bonds are not as prevalent (but see Reaction **16-31**).[9] In most cases, the nucleophile forms the first new bond to carbon, and these reactions are regarded as *nucleophilic additions*, which can be represented as:



The electrophile shown in step 2 is the proton. In almost all the reactions considered in this chapter the electrophilic atom is either hydrogen or carbon. Note that step 1 is exactly the same as step 1 of the tetrahedral mechanism of nucleophilic substitution at a carbonyl carbon (Sec. 16.A.i), but carbon groups (A, B = H, alkyl aryl, etc.) are poor leaving groups so that substitution does not compete with addition. For carboxylic acid derivatives, there are leaving groups (B = Cl, OR, NH_2, etc.) and acyl substitution predominates (Sec. 16.A.i). *The nature of A and B determines whether a nucleophilic attack at a carbon–heteroatom multiple bond will lead to substitution or addition.*

Both acids and bases can catalyze many of these reactions.[10] Bases catalyze the reaction by converting a reagent YH to the more powerful nucleophile Y^- (see Sec. 10.G.ii). Acids

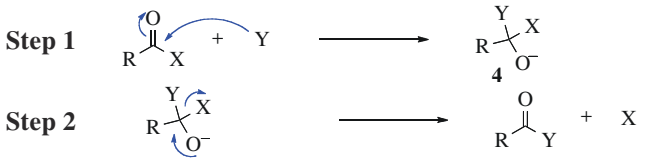
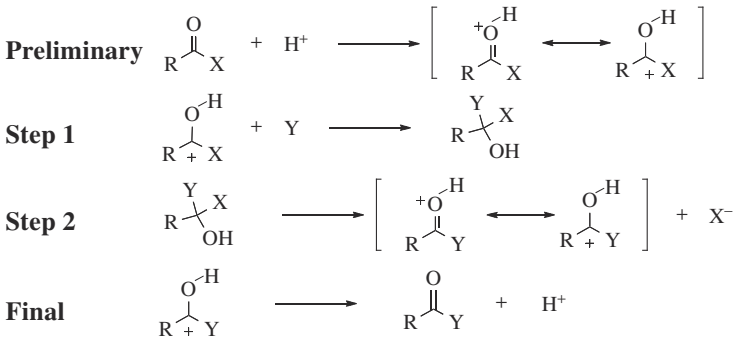
catalyze it by converting the substrate to an heteroatom-stabilized cation (oxocarbenium ion **3** from C=O) in step 1, thus making it more attractive to nucleophilic attack and making the reverse reaction somewhat less favorable. Similar catalysis can also be achieved with metallic ions (e.g., Ag^+), which act as Lewis acids.[11]

In step 1 of the acid-catalyzed mechanism, the carbonyl reacts as a base with the proton to give **3**, which is known as an *oxocarbenium ion*. In Section 5.A.ii, it was pointed out that oxocarbenium ions are comparatively stable carbocations because the positive charge is delocalized on the oxygen by resonance.[12] Intermediate **3** then reacts with the nucleophile in step 2 to give the acyl addition product. The rate-determining step is usually the one involving nucleophilic attack. If one heteroatom (e.g., oxygen) stabilizes an adjacent carbocation, as in **3**, a second heteroatom (X) will stabilize an oxocarbenium ion (—X—C^+—X—) to a greater extent.[13]



Reactivity factors for carbon–heteroatom multiple bonds are similar to those for the tetrahedral mechanism of nucleophilic substitution.[14] If A and/or B are electron-donating groups (e.g., alkyl groups), rates are decreased. Electron-attracting substituents increase rates. This means that aldehydes are more reactive than ketones. Aryl groups are somewhat deactivating compared to alkyl, because of resonance that stabilizes the substrate molecule, but is lost on going to the intermediate. Double bonds in conjugation with the carbon–heteroatom multiple bond also lower addition rates, for similar reasons but, more important, may provide competition from 1,4-addition (Sec. 15.A.ii). Steric factors are also quite important and contribute to the decreased reactivity of ketones compared with aldehydes. Highly hindered ketones like hexamethylacetone and dineopentyl ketone either do not undergo many of these reactions or require extreme conditions.

16.A.i. Nucleophilic Substitution at an Aliphatic Trigonal Carbon: The Tetrahedral Mechanism



All the mechanisms discussed in previous chapters for substitution take place at a saturated carbon atom. Nucleophilic substitution is also important at trigonal carbons, especially when the carbon is double bonded to an oxygen, a sulfur, or a nitrogen. Substitution at a carbonyl group (or the corresponding nitrogen and sulfur analogues) most often proceeds by a second-order mechanism, which in this book is called the *tetrahedral*[15]*mechanism*.[16]

Phys. Org. Chem.* ***1967***, *5*, 237.

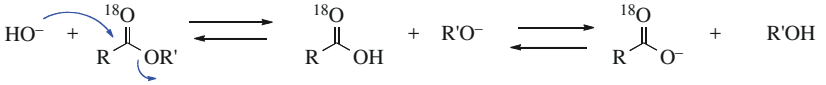
The IUPAC designation is $A_N + D_N$. The S_N1 mechanisms, involving carbocations, are sometimes found with these substrates, especially with essentially ionic substrates (e.g., $RCO^+ BF_4^-$; there is evidence that in certain cases simple S_N2 mechanisms can take place, especially with a very good leaving group (e.g., Cl^-);[17] and an SET mechanism has also been reported.[18] However, the tetrahedral mechanism is by far the most prevalent. Although this mechanism displays second-order kinetics, it is not the same as the S_N2 mechanism discussed in Section 10.A.i. In the tetrahedral mechanism, first Y attacks to give an intermediate containing both X and Y (**4**), and then X leaves. This sequence, impossible at a saturated carbon, is possible at an unsaturated one because the central carbon can release a pair of electrons to the oxygen and so preserve its octet:

When reactions are carried out in acid solution, there may also be a preliminary and a final step:

The hydrogen ion is a catalyst. The reaction rate is increased because it is easier for the nucleophile to attack the carbon when the electron density of the latter has been decreased.[19]



Evidence for the existence of the tetrahedral mechanism is as follows:[20]

1. The kinetics are first order each in the substrate and in the nucleophile, as predicted by the mechanism.
2. There is other kinetic evidence in accord with a tetrahedral intermediate. For example, the rate "constant" for the reaction between acetamide and hydroxylamine is not constant, but decreases with increasing hydroxylamine concentration.[21] This

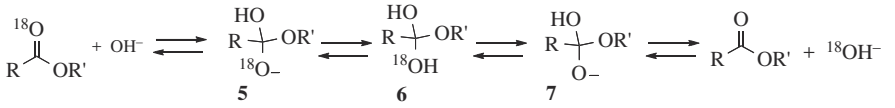
[21] Jencks, W.P.; Gilchrist, M. *J. Am. Chem. Soc.* ***1964***, *86*, 5616.

is not a smooth decrease; there is a break in the curve. A straight line is followed at low hydroxylamine concentration and another straight line at high concentration. This means that the identity of the rate-determining step is changing. Obviously, *this cannot happen if there is only one step: there must be two steps, and hence an intermediate*. Similar kinetic behavior has been found in other cases as well;[22] in particular, plots of rate against pH are often bell-shaped.



3. Basic hydrolysis has been carried out on carboxylic esters labeled with ^{18}O in the carbonyl group.[23] If this reaction proceeded by the normal S_N2 mechanism, all the ^{18}O would remain in the carbonyl group, even if, in an equilibrium process, some of the carboxylic acid formed went back to the starting material:

On the other hand, if the tetrahedral mechanism operates

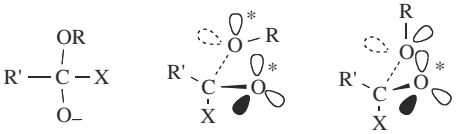
then the intermediate **5** reacts with an acid (e.g., water) and is converted to the conjugate acid, symmetrical intermediate **6**. In this intermediate, the OH groups are equivalent, and (except for the small $^{18}O/^{16}O$ isotope effect) either one can lose a proton with equal facility:

The intermediates **5** and **7** can now lose OR′ to give the carboxylic acid (not shown in the equations given), or they can lose OH to regenerate the carboxylic ester. If **5** reverts back to an ester, the ester will still be labeled, but if **7** reverts to an ester, the ^{18}O will be lost. A test of the two possible mechanisms is to stop the reaction before completion and to analyze the recovered ester for ^{18}O. Experiments by Bender[24] found that in alkaline hydrolysis of methyl, ethyl, and isopropyl benzoates, the esters had lost ^{18}O. A similar experiment carried out for acid-catalyzed hydrolysis of ethyl benzoate showed that here too the ester lost ^{18}O. However, alkaline hydrolysis of substituted benzyl benzoates showed *no* ^{18}O loss.[24] This result does not necessarily mean that no tetrahedral intermediate is involved in this case. If **5** and **7** do not revert to an ester, but go entirely to an acid, no ^{18}O loss will be found even with a tetrahedral intermediate. In the case of benzyl benzoates, this may very well be happening, because formation of the acid relieves steric strain. Another possibility is that **5** loses OR′ before it can become

[22] Kevill, D.N.; Johnson, S.L. *J. Am. Chem. Soc.* ***1965***, *87*, 928; Leinhard, G.E.; Jencks, W.P. *J. Am. Chem. Soc.* ***1965***, *87*, 3855; Schowen, R.L.; Jayaraman, H.; Kershner, L.D. *J. Am. Chem. Soc.* ***1966***, *88*, 3373.

[23] Bender, M.L.; Thomas, R.J. *J. Am. Chem. Soc.* ***1961***, *83*, 4183, 4189.

[24] Bender, M.L.; Matsui, H.; Thomas, R.J.; Tobey, S.W. *J. Am. Chem. Soc.* ***1961***, *83*, 4193. See also, Shain, S.A.; Kirsch, J.F. *J. Am. Chem. Soc.* ***1968***, *90*, 5848.

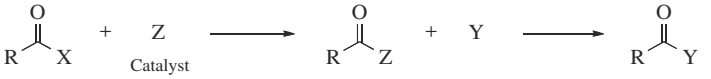


protonated to **6**.[25] Even the experiments that *do* show ^{18}O loss do not *prove* the existence of the tetrahedral intermediate, since it is possible that ^{18}O is lost by some independent process not leading to ester hydrolysis. To deal with this possibility, Bender and Heck[26] measured the rate of ^{18}O loss in the hydrolysis of ethyl trifluorothioloacetate–^{18}O:

This reaction had previously been shown[27] to involve an intermediate by the kinetic methods mentioned above. Bender and Heck[26] showed that the rate of ^{18}O loss and the value of the partitioning ratio k_2/k_3 as determined by the oxygen-exchange technique were exactly in accord with these values as previously determined by kinetic methods. Thus the original ^{18}O exchange measurements showed that there is a tetrahedral species present, but not necessarily on the reaction path, while the kinetic experiments showed that there is some intermediate present, but not necessarily tetrahedral. Bender and Heck's[26] results demonstrate that there is a tetrahedral intermediate and that it lies on the reaction pathway.

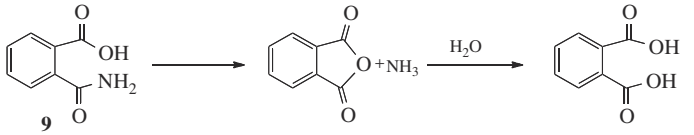
4. In some cases, tetrahedral intermediates have been isolated[28] or detected spectrally.[29]

Several studies have been made of the directionality of approach by the nucleophile.[30] Menger[30] has proposed for reactions in general, and specifically for those that proceed by the tetrahedral mechanism, that there is no single definable preferred transition state, but rather a "cone" of trajectories. All approaches within this cone lead to reaction at comparable rates; it is only when the approach comes outside of the cone that the rate falls.



8 **A** **B**

Directionality has also been studied for the second step. Once the tetrahedral intermediate (**4**) is formed, it loses Y (giving the product) or X (reverting to the starting compound). Deslongchamps has proposed that one of the factors affecting this choice is the conformation of the intermediate; more specifically, the positions of the lone pairs. In this view, a leaving group X or Y can depart only if the other two atoms on the carbon both have an orbital antiperiplanar to the C—X or C—Y bond. For example, consider an intermediate **8** formed by attack of $^{-}$OR on a substrate R′COX. Cleavage of the C—X bond with loss of X can take place from conformation **A**, because the two lone-pair orbitals



[25] For evidence for this possibility, see McClelland, R.A. *J. Am. Chem. Soc.* ***1984***, *106*, 7579.

marked ∗ are antiperiplanar to the C—X bond, but not from **B** because only the O^- has such an orbital. If the intermediate is in conformation **B**, the OR may leave (if X has a lone-pair orbital in the proper position) rather than X. This factor is called *stereoelectronic control*.[31] Free rotation in acyclic intermediates leads to many conformations, but some are preferred, and cleavage reactions may take place faster than rotation, so stereoelectronic control can be a factor in some situations. Much evidence has been presented for this concept.[32] More generally, the term *stereoelectronic* effects refers to any case in which orbital position requirements affect the course of a reaction. The backside attack in the S_N2 mechanism is an example of a stereoelectronic effect.

Some nucleophilic substitutions at a carbonyl carbon are *catalyzed* by nucleophiles.[33] There occur, in effect, two tetrahedral mechanisms:

(For an example, see Reaction **16-58**). When this happens internally, it is a neighboring-group mechanism at a carbonyl carbon.[34] For example, the hydrolysis of phthalamic acid (**9**) takes place as follows:

Evidence comes from comparative rate studies.[35] Thus **9** was hydrolyzed $\sim 10^5$ times faster than benzamide ($PhCONH_2$) at about the same concentration of hydrogen ions. That this enhancement of rate was not caused by the resonance or field effects of COOH (an electron-withdrawing group) was shown by the fact both *o*-nitrobenzamide and terephthalamic acid (the para isomer of **9**) were hydrolyzed more slowly than benzamide. Other examples of neighboring-group participation at a carbonyl carbon have been reported.[36] It is likely that nucleophilic catalysis is involved in enzyme catalysis of ester hydrolysis.

The attack of a nucleophile on a carbonyl group can result in substitution or addition, depending on the substituents, but the first step of each mechanism is the same. The main factor that determines the product is the identity of the group X in RCOX. When X is alkyl or hydrogen, addition usually takes place. When X is halogen, OCOR, NH_2, and so on, the

[31] It has also been called the "antiperiplanar lone-pair hypothesis (ALPH)". For a reinterpretation of this factor in terms of the principle of least nuclear motion (see Reaction **15-10**), see Hosie, L.; Marshall, P.J.; Sinnott, M.L. *J. Chem. Soc. usual reaction is substitution. When X = OH, protonation to generate OH_2^+ is usually required before the group can be lost.

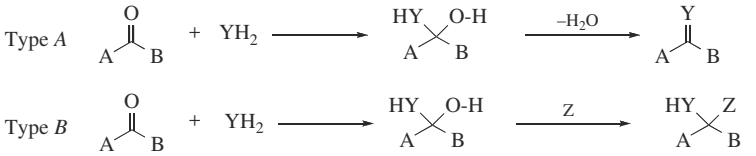
In both the S_N1 and S_N2 mechanisms, the leaving group departs during the rate-determining step and so directly affects the rate. In the tetrahedral mechanism at a carbonyl carbon, the bond between the substrate and leaving group is still intact during the slow step. Nevertheless, the nature of the leaving group still affects the reactivity in two ways: (1) By altering the electron density at the carbonyl carbon, the rate of the reaction is affected. The greater the electron-withdrawing character of X, the greater the partial positive charge on C and the more rapid the attack by a nucleophile. (2) The nature of the leaving group affects the *position of equilibrium*. In the intermediate **4**, there is competition between X and Y as to which group leaves. If X is a poorer leaving group than Y, then Y will preferentially leave and **4** will revert to the starting compounds. Thus there is a partitioning factor between **4** going on to product (loss of X) or back to starting compound (loss of Y). The sum of these two factors causes the sequence of reactivity to be $RCOCl > RCOOCOR' > RCOOAr > RCOOR' > RCONH_2 > RCONR'_2 > RCOO^-$.[37] Note that this order is approximately the order of decreasing stability of the leaving-group anion. If the leaving group is bulky, it may exert a steric effect and retard the rate for this reason.

For a list of some of the more important reactions that operate by the tetrahedral mechanism, see Table 16.1, which shows the main reactions that proceed by the tetrahedral mechanism.

TABLE 16.1 The More Important Synthetic Reactions That Take Place by the Tetrahedral Mechanism.[a]



Reaction Number	Reaction
16-57	$RCOX + H_2O \longrightarrow RCOOH$
16-58	$RCOOCOR' + H_2O \longrightarrow RCOOH + R'COOH$
16-59	$RCO_2R' + H_2O \longrightarrow RCOOH + R'OH$
16-59	$RCONR'_{2'} + H_2O \longrightarrow RCOOH + R'_2NH\ (R' = H, alkyl, aryl)$
16-61	$RCOX + R'OH \longrightarrow RCO_2R'$
16-62	$RCOOCOR + R'OH \longrightarrow RCO_2R'$
16-63	$RCOOH + R'OH \longrightarrow RCO_2R'$
16-64	$RCO_2R' + R''OH \longrightarrow RCO_2R'' + R'OH$
16-66	$RCOX + R'COO^- \longrightarrow RCOOCOR'$
10-21	$RCOX + H_2O_2 \longrightarrow RCO_3H$
16-69	$RCOX + R'SH \longrightarrow RCOSR'$

16-85	$2RCH_2CO_2R' \longrightarrow RCH_2COCHRCO_2R'$

[a]Catalysts are not shown.

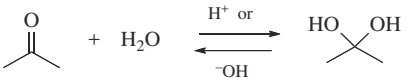
[37] The compound RCOOH would belong in this sequence just after RCOOAr, but it fails to undergo many reactions for a special reason. Many nucleophiles, instead of attacking the C=O group, are basic enough to take a proton from the acid, converting it to the unreactive $RCOO^-$.

16.B. REACTIONS

Many of the reactions in this chapter are simple additions to carbon–hetero multiple bonds, with the reaction ending when the two groups have been added. But in many other cases subsequent reactions take place. There are generally two types:

In type *A*, the initially formed adduct loses water (or, in the case of addition to C=NH, ammonia, etc.), and the net result of the reaction is the substitution of C=Y for C=O (or C=NH, etc.). In type *B* there is a rapid substitution, and the OH (or NH_2, etc.) is replaced by another group Z, which is often another YH moiety. This substitution is nucleophilic is most cases: Y usually has an unshared pair and S_N1 reactions occur very well on this type of compound (Sec. 10.G.i, category 2), even when the leaving group is as poor as OH or NH_2. In this chapter, reactions will be classified according to what is initially adding to the carbon–heteroatom multiple bond, even if subsequent reactions take place so rapidly that it is impossible to isolate the initial adduct.

Most of the reactions considered in this chapter can be reversed. In many cases, we will consider the reverse reactions with the forward ones, in the same section. The reverse of some of the other reactions are considered in other chapters. In still other cases, one of the reactions in this chapter is the reverse of another (e.g., **16-2** and **16-13**). For reactions that are reversible, the principle of microscopic reversibility (Sec. 6.H) applies.

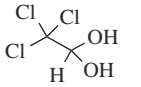


First, reactions in which hydrogen or a metallic ion (or in one case phosphorus or sulfur) adds to the heteroatom will be discussed. Second, reactions in which carbon adds to the heteroatom will be discussed. Within each group, the reactions are classified by the nature of the nucleophile. Additions to isocyanides, which are different in character, follow. Acyl substitution reactions that proceed by the tetrahedral mechanism, which mostly involve derivatives of carboxylic acids, are treated at the end.

16.B.i. Reactions in which Hydrogen or a Metallic Ion Adds to the Heteroatom

A. Attack by OH (Addition of H_2O)

16-1 The Addition of Water to Aldehydes and Ketones: Formation of Hydrates

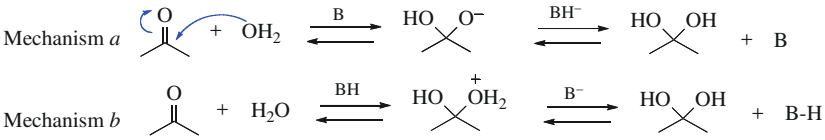


***O*-Hydro-*C*-hydroxy-addition**

The adduct formed upon addition of water to an aldehyde or ketone is called a hydrate or *gem*-diol.[38] These compounds are usually stable only in water solution and decompose on

[38] See Bell, R.P. *The Proton in Chemistry*, 2nd ed., Cornell University Press, Ithaca, NY, ***1973***, pp. 183–187; *Adv. Phys. Org. Chem.* ***1966****, 4,* 1; Le Hénaff, P. *Bull. Soc. Chim. Fr.* ***1968***, 4687.

distillation; that is, the equilibrium shifts back toward the carbonyl compound, usually via formation of an enol and tautomerization to the carbonyl. The position of the equilibrium is greatly dependent on the structure of the hydrate. Thus, formaldehyde in water at 20 °C exists 99.99% in the hydrated form, while for acetaldehyde this figure is 58%, and for acetone the hydrate concentration is negligible.[39] It has been found, by exchange with ^{18}O, that the reaction with acetone is quite rapid when catalyzed by acid or base, but the equilibrium lies on the side of acetone and water.[40] Since methyl, a $+I$ group, inhibits hydrate formation, it may be expected that electron-attracting groups would have the opposite effect, and this is indeed the case. The hydrate of chloral (trichloroacetaldehyde)[41] is a stable crystalline substance. In order for it to revert to chloral, ^-OH or H_2O must leave. This is made difficult by the electron-withdrawing character of the Cl_3C group and by the absence of a proton on the α carbon, which is required for loss of water to form an enol. Some other[42] polychlorinated and polyfluorinated aldehydes and ketones[43] and α-keto aldehydes also form stable hydrates, as do cyclopropanones.[44] In the last case,[45] formation of the hydrate relieves some of the *I* strain (Sec. 9.B) of the parent ketone.



Chloral hydrate

Hydrate of cyclopropanone

The reaction is subject to both general-acid and general-base catalysis; the following mechanisms can be written for basic (B) and acidic (BH) catalysis, respectively:[46]

In mechanism *a*, as the H_2O attacks, the base pulls off a proton, and the net result is addition of ^-OH. This can happen because the base is already hydrogen bonded to the H_2O molecule before the attack. In mechanism *b*, because HB is already hydrogen bonded to the oxygen of the carbonyl group, it gives up a proton to the oxygen as the water attacks. In this way, B and HB accelerate the reaction even beyond the extent that they form ^-OH or H_3O^+ by reaction with water. Reactions in which the catalyst donates a proton to the electrophilic reagent (in this case the aldehyde or ketone) in one direction and removes it in the other are called class e reactions. Reactions in which the catalyst does the same to the nucleophilic reagent are called class n reactions.[47] Thus the acid-catalyzed process here is a class e reaction, while the base-catalyzed process is a class n reaction.

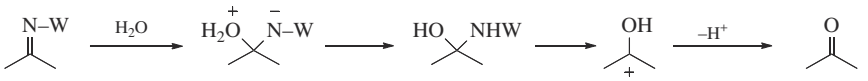
16-2 Hydrolysis of the Carbon–Nitrogen Double Bond[48]

Oxo-de-alkylimino-bisubstitution, and so on

Compounds containing carbon–nitrogen double bonds can be hydrolyzed to the corresponding aldehydes or ketones.[49] For imines (W = R or H) the hydrolysis is easy and can be carried out with water. When W = H, the imine is seldom stable enough for isolation, and in aqueous media hydrolysis usually occurs *in situ*, without isolation. The hydrolysis of *Schiff bases* (W = Ar) is more difficult and requires acid or base catalysis. Oximes (W = OH), arylhydrazones (W = NHAr), and, most easily, semicarbazones (W = $NHCONH_2$) can also be hydrolyzed. Often a reactive aldehyde (e.g., formaldehyde), is added to combine with the liberated amine.

A number of reagents[50] have been used to cleave C=N bonds, especially those not easily hydrolyzable with acidic or basic catalysts or those that contain other functional groups that are attacked under these conditions.



Oximes have been converted to the corresponding aldehyde or ketone[51] by treatment with aq phosphoric acid without an organic cosolvent,[52] periodic acid,[53] DABCO–Br_2,[54] NBS in water,[55] Chloramine-T[56] HCO_2H on SiO_2 with microwave irradiation,[57] and 20% I_2 in water containing SDS (sodium dodecyl sulfate)[58] or in an ionic liquid on SiO_2.[59] Transition metal compounds have been used, including those of Sb,[60] Co[61] Hg,[62] Bi,[63] Cu,[64] or Zn.[65] Oxidizing agents can be quite effective, including $KMnO_4$ on Al_2O_3,[66] tetraalkylammonium permanganates,[67] and quinolinium dichromate.[68] Alkaline H_2O_2[69] has also been used.

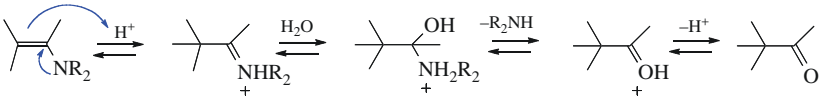
Phenylhydrazones can be converted to a ketone using Oxone and $KHCO_3$,[70] polymer-bound iodonium salts,[71] or $KMnO_4$ on wet SiO_2.[72] Dimethylhydrazones have been converted to ketones with $FeSO_4 \cdot 7\ H_2O$ in chloroform,[73] and Me_3SiCl/NaI in acetonitrile with 1% water.[74] Hydrazones (e.g., RAMP or SAMP, Reaction **10-68**, category 4) can be hydrolyzed with aq $CuCl_2$.[75] Tosylhydrazones can be hydrolyzed to the corresponding ketones with aq acetone and BF_3–etherate,[76] as well as with other reagents.[77]

Semicarbazones have been cleaved with ammonium chlorochromates on alumina[78] $(Bu_4N)_2S_2O_8$,[79] $Mg(HSO_4)_2$ on wet silica,[80] or by $SbCl_3$ with microwave irradiation.[81]

The hydrolysis of carbon–nitrogen double bonds involves initial addition of water and elimination of a nitrogen moiety:



It is thus an example of reaction type *A* (see above). The sequence shown is generalized.[82] In specific cases, there are variations in the sequence of the steps, depending on acid or basic catalysis or other conditions.[83] Which step is rate determining also depends on acidity and on the nature of W and of the groups connected to the carbonyl.[84]

10

Iminium ions (**10**)[85] would be expected to undergo hydrolysis quite readily, since there is a resonance contributor with a positive charge on the carbon. Indeed, they react with water at room temperature.[86] Acid-catalyzed hydrolysis of enamines (the last step of the *Stork enamine reaction*, **10-69**, involves conversion to iminium ions).[87]
