Numerous methods have been tried to produce silicon directly in thicknesses suitable for cell manufacture, thereby avoiding the wasteful process of sawing wafers from ingots.[12] These methods draw ribbons or foils of silicon from the melt either vertically or horizontally and result in MC material. Some of these methods are already commercialized and others are at various stages of development. *Edge-defined film growth* is a vertical film growth technique in which a seed crystal is lowered to the melt surface and a film is pulled upwards through a graphite die by capillary action. No die is used in the *dendritic web* method. As the seed is withdrawn, two dendrites propagate from its ends into the melt and the film grows as a meniscus. The *string ribbon* technique is similar except that two filaments, passing through the bottom of the crucible, are used to define the film edges. Horizontal growth is carried out on a moving, reusable graphite or ceramic substrate from a silicon reservoir in a die in the *ribbon growth on substrate* scheme. The ribbon, 100 μm or thicker, can be separated from the substrate by thermal expansion mismatch. In the *silicon film* process, the substrate of ceramic, graphite cloth, or stainless steel is retained as part of the solar module.

Development is underway on tiny (650–750 μm) spherical solar cells.[15,16] Each cell is formed in a silicon bead rather than from a wafer. To form the beads, droplets of molten silicon fall through vacuum in a 14 m tower, solidifying into MC spheres.

Thin-Film Crystalline Silicon

Thinner cells are sought to reduce material and energy usage, reduce bulk recombination, relax material quality requirements, and potentially allow lightweight and flexible cells.[5,17] One path is to use thinner wafers but production yield then tends to drop. Alternatively, the growth of crystalline thin-films on cheap substrates, particularly glass, is a major R&D goal.[5,18–23] The usual path is to deposit amorphous silicon or nanocrystalline silicon and crystallize it. The essential problem is that crystallization into large grains requires high temperatures, which can make some substrates unsuitable. If processing is restricted to low temperatures, it is possible to form nanocrystalline silicon simply by adjusting the hydrogen content in the normal deposition process for amorphous silicon.[18]

Various methods have been tried[5] to enlarge grains, including postdeposition recrystallization and aluminum-induced crystallization. The Kaneka group uses a glass substrate with reflective coating, chemical vapor deposition (CVD)-deposited n-type microcrystalline silicon, undoped polysilicon, and a p-type polysilicon layer. CSG Solar uses solid phase crystallization of amorphous silicon on glass, deposited by plasma enhanced chemical vapor deposition (PECVD), and intends to overcome the common problems with layer uniformity, durability, and yield.[24] Other methods in the research phase include cheaper deposition by evaporation and aluminum-induced crystallization, in which amorphous silicon deposited on an aluminum layer on a borosilicate glass substrate is heated and the aluminum migrates through the silicon layer, which crystallizes.[5,23]

Amorphous Silicon

Hydrogen is usually incorporated into amorphous silicon to reduce recombination at hanging bonds, forming a-Si : H.[17,18] It requires lower film thickness (~0.4 μm) than crystalline silicon for virtually complete absorption of sunlight.

However, a serious (although self-limiting and reversible by annealing for a few hours) light-induced degradation effect has severely restricted the promise of this technology. It is a result of metastable material defects created by the light. The hydrogen that is routinely incorporated into the material to neutralize unsatisfied atomic bonds also creates unsatisfied bonds under the influence of light. Degradation has been minimized by making the cells as thin as possible and this has encouraged the use of tandem structures to achieve adequate light absorption. Tandem cells are stacks of p–n junctions, each of which may have a different bandgap, each responding to a different section

of the solar spectrum, yielding higher overall efficiency. Triple-junction tandem modules, including an amorphous germanium junction, are commercially available.

a-Si : H is usually produced by various forms of PECVD of silane[17] at about 100–300°C. The film quality depends on many deposition parameters, including the substrate temperature, which controls the incorporation of hydrogen. The low temperature deposition technology allows plastics to be used as substrates in flexible and stick-on modules.

Sanyo's HIT (*heterojunction with intrinsic thin-layer*) technology combines crystalline and amorphous silicon. n-Type crystalline silicon wafers have layers of intrinsic and doped amorphous silicon applied to the front and rear. Contacts are made via transparent conducting oxide (TCO).

Germanium, Silicon Oxides, Silicon Nitrides, Silicon Carbides

Other Group IV materials play subsidiary or relatively minor roles in photovoltaics. Most important are silicon dioxide and silicon nitride that are used to passivate silicon surfaces and to reduce reflection of light. Native dioxide has been used for this task historically but silicon nitride applied by PECVD has recently gained increasing acceptance in the manufacture of MC solar cells because of the effect that incidental hydrogen incorporation has on passivation of grain boundaries. As mentioned above, amorphous germanium is used for low-bandgap cells beneath amorphous silicon in multijunction structures, to better match the solar spectrum, but amorphous silicon carbide has not been found to be of sufficient quality for high bandgap cells.[17] Silicon nanostructures (quantum wells, quantum dots, and superlattices) have been proposed to be formed in oxides, nitrides, and carbides in preliminary research into new solar cell structures such as all-silicon multijunction cells and hot carrier cells.[25–27] The cubic phase of silicon carbide has been studied as a way to use impurities, boron in this case, to advantage.[28]

GROUP III–V PHOTOVOLTAIC MATERIALS

High efficiency solar cells are produced from crystalline binary or multinary compounds of elements from Groups III and V, almost entirely for space applications. While a wide range of materials and methods have been employed, the monolithic tandem stack of a $Ga_xIn_{1-x}P$ cell, where $x \approx 0.516$, above GaAs and Ge cells is a commercially produced, indicative example.[29] Monolithic tandem structures present several challenges. The materials used in the various junctions should have similar thermal expansion coefficients and lattice constants and the sets of bandgaps should be a good match to the spectrum.

The lowest bandgap (Ge) cell is formed by diffusion of a dopant into a Ge substrate wafer by exposure to, for example, PH_3 or AsH_3. GaAs, which is almost lattice matched, is grown on the Ge substrate by metal oxide chemical vapor deposition (MOCVD) using trimethylgallium and arsine, and forms the middle cell. The top cell is made by MOCVD of GaInP, using the above gases and phosphine. An $Al_yIn_{1-y}P$, where $y \approx 0.532$, window layer reduces carrier recombination at the front surface. Se, from decomposition of H_2Se and Si from Si_2H_6 are n-type dopants and zinc from dimethyl or diethyl zinc, magnesium from cyclopentadienyl magnesium, and carbon from CCl_4 can dope III–V compounds p-type.

GROUP II–VI PHOTOVOLTAIC MATERIALS

The basic structure of polycrystalline cadmium telluride (CdTe) thin-film cells[18,30] has a glass superstrate and a layer of TCO as front contact, a near-transparent n-type cadmium sulfide (CdS) window layer, p-type CdTe, and a metallic rear contact. The CdTe is usually deposited by three families of techniques.[30] In the first group (vapor transport deposition, close space sublimation, physical vapor deposition, and sputtering) elemental vapors of Cd and Te condense and react on the substrate. In the second (electrodeposition), Cd^{2+} and $HTeO_2^+$ ions in acidic electrolyte are galvanically reduced at the surface:

$$HTeO_2^+ + 3H+ + 4e^- \rightarrow Te + 2H_2O;$$
$$Cd^{+2} + 2e^- \rightarrow Cd; \quad Cd + Te \rightarrow CdTe$$

The third family (MOCVD, spraying, and screen printing) involves the reaction of precursors at the surface. In MOCVD, the precursors may be dimethylcadmium and diisopropyltellurium in a hydrogen carrier. The spray method uses a slurry of CdTe, $CdCl_2$ in a propylene glycol carrier. A paste of Cd, Te, $CdCl_2$, and a binder is applied through a screen in the third method in this group.

Chlorine treatments, such as heating in the presence of $CdCl_2$ vapor, dipping in solutions of $CdCl_2$: CH_3OH or $CdCl_2 : H_2O$, or exposure to HCl or Cl_2, are commonly used following chlorine-free depositions.

CHALCOPYRITE PHOTOVOLTAIC MATERIALS

Nonstoichiometric copper indium gallium diselenide [Cu(In,Ga) Se_2—abbreviated as CIGS or CIS if the gallium is absent] is another promising thin-film PV material.[18,31] Large grains can be produced on foreign

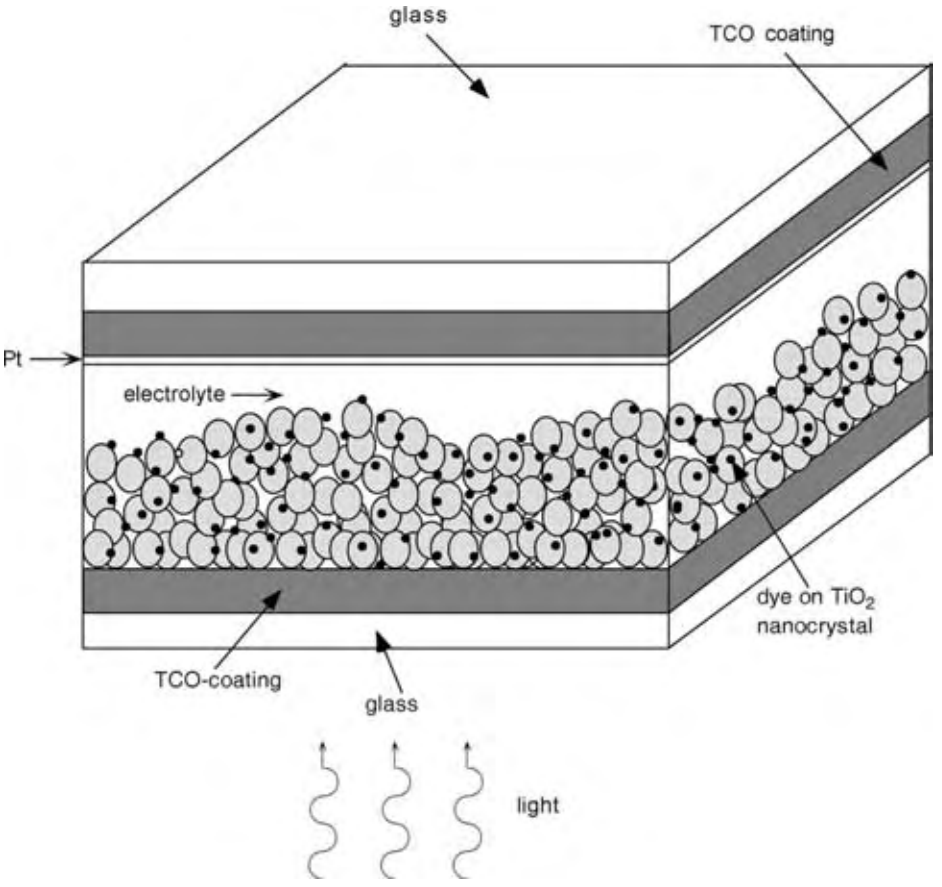

Fig. 4 Dye-sensitised nanocrystalline cell structure. (Courtesy of UNSW Centre for Photovoltaic Engineering Image Library.)

substrates, grain boundaries can be passivated, and the material is tolerant of deviations from exact ratios of the constituent elements. This material forms a heterojunction with an n-type CdS layer.

Several methods are used to deposit the films onto molybdenum-coated soda-lime glass substrates. Coevaporation of Cu, In, Se, and Ga from elemental sources onto a heated substrate, with careful control of the deposition rate of each, has achieved the highest efficiency. Another common method is selenization. A metal precursor layer of Cu, In, and Ga is deposited by, for example, sputtering and reacted in H_2Se or Se vapor. For layers without Ga, the final reaction in a series is

$$2InSe_2 + Cu_2Se + Se \rightarrow 2CuInSe_2$$

The CdS layer is grown from solution in a chemical bath of a cadmium salt, such as $CdSO_4$, $CdCl_2$, CdI_2, $Cd(CH_3COO)_2$, a ''complexing agent,'' such as ammonia and a sulfur source, commonly $SC(NH_2)_2$ (thiourea). The reaction,

$$Cd(NH)_3)_4{}^{2+} + SC(NH_2)_2 + 2OH^- \rightarrow CdS + H_2NCN + 4NH_3 + 2H_2O$$

occurs at room temperature.

A TCO layer of SnO_2, In_2O_3 : Sn (''ITO''), or ZnO interfaces to the metal electrical grid on the front of the cell. Deposition methods include dc sputtering, rf magnetron sputtering, and chemical vapor deposition.

DYE-SENSITIZED PHOTOVOLTAIC MATERIALS

Dye-sensitized nanocrystalline cells[32] are fundamentally different from the others discussed earlier in that they do not rely on semiconductor p–n junctions. Instead, they are electrochemical devices in which the optical absorption and carrier-collection processes are separated (Fig. 4).

Glass coated with TCO, normally SnO_2, has a porous film of TiO_2 (anatase phase), which is stable against photocorrosion, applied either as a colloidal solution or as a paste containing a polymer binder, such as polyethylene glycol, which is then sintered. The resulting nanoparticle film presents a large surface area of TiO_2, which is coated with a redox charge-transfer dye of ruthenium bipyridal or ruthenium terpyridine complexes.[32] The liquid electrolyte is usually an iodide/tri-iodide redox couple in a low viscosity nitrile solvent, such as acetonitrile, propionitrile, methoxyacetonitrile, or methoxypropionitrile.

A sputtered platinum counter-electrode on a TCO substrate may have its electrocatalytic activity, in the reduction of the tri-iodide ions, enhanced by creating Pt colloids from an alcoholic solution of H_2PtCl_6.

ORGANIC PHOTOVOLTAIC MATERIALS

Semiconducting polymers are in the R&D phase for several applications, including photovoltaics,[18,33,34] because they offer potential for very low cost and flexibility. Promising active materials include conjugated polymer–fullerene blends and blends of two conjugated (having conjugated carbon bonds in their backbone with alternating single and double or triple C–C bonds) polymers that form a carrier-separating heterojunction.

CONCLUSIONS

Silicon dominates the supply of material for solar cells now and for the foreseeable future for a range of practical reasons. Silicon is used in several forms, including sawn and grown wafers of single or MC material, crystalline spheres and thin-crystalline or amorphous films deposited on substrates or superstrates. The processes used to obtain MG and, subsequently, EG or solar grade silicon from raw quartz are briefly outlined, as are the fundamental processes used to make Group III–Group V, copper gallium indium diselenide, cadmium telluride, and dye-sensitized solar cells. With many competing technologies at different stages, the evolution of the industry is not clear but it is widely expected that thin-film technologies will become increasingly important relative to wafer-based methods. There is currently substantial developmental effort underway to incorporate the advantages of silicon into effective and affordable thin-film modules.

Phytoremediation

Joel G. Burken
Department of Civil, Architectural and Environmental Engineering, University of Missouri–Rolla, Rolla, Missouri, U.S.A.

INTRODUCTION

Phytoremediation is the use of plants to treat contaminated soil or groundwater. Many different plant–contaminant or plant–microbe–contaminant interactions can lead to reducing the threat posed by contaminants. To best understand how plants can reduce contaminant threat, comprehending the role of plants and their interactions with the environment overall is important. If the plant processes are recognized, then the application of plants to remedy contaminated sites is clear and logical. In this work, the ecological role of plants will be outlined, and then the ways in which plant–environment interactions can be exploited in mitigating the threat of contaminants in our environment are discussed.

PLANT BACKGROUND

In considering the potential for phytoremediation in the simplest sense, thinking ''What does a plant do?'' is very important. Plants take in water, carbon dioxide, and light to carry out photosynthesis to generate oxygen and organic carbon. Plants also carry out ''dark reactions'' utilizing molecular oxygen (O_2), organic carbon from photosynthesis, and nutrients from their surroundings to survive and thrive. On a net basis considering both photosynthesis and dark reactions, plants generate molecular oxygen and organic carbon. These two products serve as the foundation of all higher life on earth.

Overall, these reactions do not involve specific interaction with organic or inorganic contaminants other than a select few inorganics that are used as nutrients. Plants are photoautotrophs, i.e., they use light for energy and inorganic carbon (CO_2) for carbon. This is contrary to other higher life forms such as animals and microorganisms that are chemoheterotrophs, i.e., using chemical reactions (primarily with organic carbon) for energy and organic carbon for carbon.

In metabolic and physical processes, however, plants interact greatly with the surrounding environment by extracting water from the subsurface, taking inorganic nutrients from the subsurface, depositing the organic carbon both aboveground (leaf litter, fallen biomass) and belowground (root die-off and exuded organics). Through these processes plants represent the dominant interaction between the aboveground and belowground environments. The interaction with the subsurface is of greatest interest as this environment is stable for many contaminants and is therefore the target for remediation efforts.

ENVIRONMENT BACKGROUND

The subsurface environment (near surface) is relatively stable in relation to the aboveground environment. Neither does the subsurface have the energy input in the forms of sunlight, precipitation, or wind as do most surface soils, nor does it have energy input from wave, wind, or currents of surface waters. Aboveground this energy input can greatly reduce compound concentrations through mixing and the resultant dispersion and dilution, resulting in the old adage ''The solution to pollution is dilution.'' The atmosphere is also highly oxidizing, with the presence of oxygen and photolytically generated radicals. Compounds in this environment are subject to numerous chemical and biological reactions. Plants provide a connection between the two environments and have many mechanisms that can be exploited in terms of impacting subsurface contaminants, both inorganic and organic. These mechanisms are exploited to result in different phytoremediation approaches. Approaches that target contamination by metals are termed as phytoextraction and phytostabilization. For organic contaminants, approaches are termed as rhizodegradation, phytodegradation, phytovolatilization, and phytostabilization. All these approaches are covered in detail below, with examples of their uses.

METALS

Phytoextraction

Plants actively uptake selected inorganics from the environment as nutrients. Nitrogen, phosphorous, and potassium are commonly the inorganics of the greatest need, and are the basis of most fertilizers.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016194

Many others are required as micronutrients at lower levels. Elevated levels of inorganics, such as metal species, that are not needed as nutrients can act as toxicants, i.e., contaminants. Plants have adapted the ability to colonize some of the harshest environments on earth, including sites contaminated by these metals. Two types of plants generally inhabit these sites, excluders and accumulators. Excluders have adapted to be very ''tight'' with respect to uptake of the toxic metals species. These plants have highly specialized transporters in their root membranes that allow them to be efficient in the uptake of nutrient species, yet not allowing the toxic species to enter. Most plants are not as efficient and the toxic species can ''leak'' into the plant and interrupt the vital metabolic activities. Other plants have developed resistance to the toxic effects of metals following uptake as they are then dealt with to avoid toxic effects. These plants are called hyperaccumulators and are the central approach to the process of phytoextraction. The term hyperaccumulator is somewhat ambiguous. Hyperaccumulator has been consistently used to describe a plant that accumulates metals, but the term has a variety of definitions. Hyperacculator has been used for plants that accumulate greater than 1% of dry mass as a metal, concentrate metals at levels 1000 times greater than the soil concentration in which they are grown, or accumulate metals at 100 times greater concentration than nonaccumulators.[1,2] In phytoextraction, plants are used to remove the contaminant metals from the subsurface and transport the metals to aboveground tissues that can be easily harvested and treated once they are enriched. Treatments include ashing and disposing of the high-metal-content ash or reentry into a smelting process.

The initial concept of using plants to accumulate metals is found in mining. Initial efforts to look at hyperaccumulators were focused on precious metals. Attempts to locate plants that accumulate gold or silver lead to the term phytomining. Efforts to locate such plants were largely unsuccessful. From these early search efforts, however, the field of geobotany sprang forward as did numerous interesting discoveries. Perhaps, one of most spectacular documentations of hyperaccumulation is a tree from New Caledonian (*Niemeyera acuminata*) that is locally named ''sève bleue.'' The sap of the tree is blue-green because of nickel being up to 25% of its dry weight—one of the plants with the highest metal content ever discovered. The capabilities of many hyperaccumulators, over 400 taxa of terrestrial plants have been identified as hyperaccumulators, are covered in a comprehensive review by Brooks.[2]

Hyperaccumulator levels vary in the amounts of metals accumulated. For example, plants must accumulate over 10,000 mg/kg for Zn, but levels of ''hyperaccumulator status'' for Pb and Cd are less than 100 mg/kg because of lower bioavailability and the lower levels found in nonaccumulating plants. Of the many hyperaccumulators identified, only a small number are well known and have application potential in phytoremediation. Members of the *Thlaspi* family are known hyperaccumulators. Zinc, nickel, and cadmium have been found at elevated levels in *Thlaspi caerulescens* and other members of the *Thlaspi* family. In addition, members of the *Alyssum* family have been identified as hyperaccumulators. In a full-scale application in Port Colborne, Ontario, Canada, a number of *Allysum* members were evaluated and *Alyssum murale* and *Alyssum corsicum* were noted as viable candidates.[3] The full-scale application was successful, and the plants were incinerated after the growing season leading to a Ni-rich ash, enriched enough to be more valuable than the conventional crops that could have been grown on the soil. Another hyperaccumulator that has been identified and applied in full-scale applications is *Brassica juncea*, known to accumulate Zn, Pb, and Cd among other metals.

Two limiting factors in hyperaccumulators are the limited availability of the metals and the small size of many hyperaccumulators. Many times the metals at these contaminated sites have limited availability for uptake. If a metal is available, the application of hyperaccumulators without amendment is applicable, resulting in continuous uptake over the growing season. To combat low availability, chelating agents have been used to increase availability and thereby plant uptake. This has been termed ''induced phytoextraction.''[4] Chelating agents that have been applied include ethylenediamine tetra-acetic acid (EDTA) and organic acids (citric, acetic, oxalic). These efforts have not only shown an increase in uptake, but also an elevated concern that not all of the mobilized metals will be captured by the plants. Full capture is questionable in all cases, making application of mobilizing agents unfavorable. A more in-depth evaluation of phytoextraction, including a listing of full-scale applications is presented by Salt, Smith, and Raskin.[4] The future of phytoextraction includes the advancements of molecular engineering. The transport and enzyme systems are under current study, and promotion of hyperaccumulation traits in heartier, larger-biomass plants is under development.[5]

Phytostabilization

The geobotany field has also led to advanced discoveries of metal tolerant plants. These plants are not accumulators, but rather excluders. These plants are able to tolerate elevated metal contents in soils and colonize the site to stabilize possible transport. The

stabilizing mechanisms include water, wind, and soil erosion abatement and hydraulic control. Erosion control is provided by reducing kinetic energy of the water and wind, thereby reducing the capability to carry contaminated soil. Such application of plants is not novel, as vegetation has been used for millennia to stabilize soil. In the case of phytostabilization the plant selection is the novel aspect, as the metal content of such sites greatly limits the number of plants that can survive and carry out the stabilization process. Plant selection and agronomics can establish stabilizing plants within growing seasons, whereas natural colonization may not occur in contaminated sites that are distant from naturally metal-rich soils where the tolerant plants evolved and thrive. Hydraulic control is provided as plants remove water from the subsurface, reducing the potential for leaching of dissolved metals to a lower soil, groundwater profile. In addition, the plants help to stabilize soil chemistry over longer periods. Plants provide soil organic carbon, which can act to provide binding sites and increased water holding capacity. Once plants are established, ecosystems can get a toehold and remediation and restoration of a site can proceed hand in hand.

ORGANICS

Uptake

Organic contaminants have considerably different transport and fate possibilities in plant–soil systems. Organic compounds are potentially uptaken into plants with the transpiration of water from the soil profile. Once uptaken, plants can degrade certain contaminants, or contaminants can bind within the plant or volatilize from the plant. Organics can also be degraded through metabolic processes of plant-associated bacteria. Among these processes phytoremediation of organics can be classified as phytodegradation, phytovolatilization, or rhizodegradation.

Root uptake has been proven to be an important pathway for contaminants with intermediate octanol–water partitioning coefficients (K_{ow}). Variable uptake of an organic compound by different plants has been observed. Plant species such as *Daucus carota* (carrot) and *Pastinaca sativa* (parsnip) with swollen storage roots did not translocate chemicals as well as expected from barley experiments.[6] While the lipid content was considered a factor, plant structure, root types, and other properties may all play a role. The effect of the chemical itself was best illustrated by the increasing root concentration factor (RCF) and the bell-shaped transpiration stream concentration factors (TSCF) relative to $\log K_{ow}$. The physiochemical properties of compounds, including the K_{ow}, solubility, and molecular weight, all influence uptake. The dominance of compounds' K_{ow} is understandable if the entrance mechanisms of compounds to plant cells are understood on the molecular level. Two main pathways exist for chemicals to enter into the root cells, the apoplastic pathway and the symplastic pathway. To enter the symplastic path chemicals are forced to cross a cell wall to enter a cell. Chemicals can then be transported from protoplast to protoplast via plasmodesmata, which are the minute cytoplasmic threads that extend through cell walls and connect adjacent living cells. The chemicals can transport through the Casparian strip and enter tracheid or vessel cells for transport in the xylem. In the apoplastic pathway, chemicals are transported along the cell walls without passing through them. Chemicals together with water can transport apoplastically as far as the endodermis where the water impermeable Casparian strip blocks the apoplastic pathway. Compounds must cross the plasma membranes and protoplasts of the endodermal cells to gain access to the xylem tissues. In all cases, chemicals have to pass through at least two membranes. As membranes are proteins and lipid bilayers and the octanol–water partitioning coefficient is a parameter to indicate the lipophilicity, the dominance of K_{ow} can be expected even though very complicated processes were considered.[7]

The description of the entry of compounds to plant cells above also accounts for the correlations of the octanol–water partitioning coefficient with the two most commonly used factors, namely, RCF and TSCF. These relationships are based on laboratory data and are essentially empirical. Root concentration factor is defined as mass compound per mass fresh weight of roots divided by mass compound per volume ambient solution (usually in μg/mL), and TSCF is defined as mass compound per volume of water transpired divided by mass compound per volume ambient solution. Root concentration factor correlates linearly with $\log K_{ow}$ when the compound's $\log K_{ow}$ is greater than 1 and is relatively steady when $\log K_{ow}$ is smaller than 1. The linear portion of the RCF curve gives a limiting value of 0.6–1.0 for polar compounds.[6] This lower limit of RCF may be due to the transport of chemicals to the intracellular and apoplastic water in the cortex of roots via advection, dispersion, and diffusion. The second process, the sorption to the lipid, hydrophobic constituents, is likely to be the main mechanism for nonpolar compounds, leading to the linear relation to $\log K_{ow}$. Root concentration factor and TSCF are thereby interrelated as a high RCF limits the uptake of hydrophobic compounds by sorption of the compounds to the root tissues, limiting the uptake into the vascular transport system.

Compounds with intermediate $\log K_{ow,}$ ranging from 1.5 to 3.0, are translocated most efficiently.

Compounds with lower hydrophobicity appear to have resistance to pass through the lipid membrane associated with epidermal layers of the roots. Hydrophobic compounds bind to root tissues before they enter the xylem tissues as noted above.

Phytovolatilization

Following uptake, compounds have many possible fates: volatilization to the atmosphere, irreversibly binding to biomass, or plant degradation. Volatilization can occur if the compound properties allow diffusion through tissues and volatilize at the plant–atmosphere interface. Volatilization decreases the concentration in the tissues near the surface, thereby creating a concentration gradient to promote diffusion from the deeper portions.

As discussed, water enters through the roots and enters the xylem tissues. Xylem tissues are long and have a hollow, narrow, tortuous geometry. In woody plants the proportions and arrangements of these tissues vary and the anatomies are species dependent. With age, older xylem tissues become less functional. In most tree species, the outer annular rings, i.e., sapwood, dominate transport of water and nutrients, and in phytoremediation, contaminant transport as well. A good example is the viability of hollow trees. As the center of a tree rots away, it does not interrupt the tree's transport activities. Overall, xylem tissues are metabolically inactive, i.e., ''dead.'' Therefore, no metabolism of organic compounds is expected in the xylem tissues during transport. Thereby, the transport of chemicals is dominated by the chemical and hydraulic properties.

In an investigation of mass distribution and volatilization of 11 different organic compounds ranging from nonvolatile to volatile following uptake, volatilization was clearly correlated with vapor pressure.[8] Compounds with a $V_p > 0.01$ atm were volatilized, with greater V_p relating to greater volatilization. Recent findings provide new insight into the uptake of volatile organic compounds (VOCs). Investigation of tree core samples from the Savannah River site in South Carolina showed clearly that plants do uptake trichloroethylene (TCE). The work done at the Savannah River site also indicated decreasing TCE concentrations along the transpiration path (i.e., with height up the trunk).[9]

Recent research has targeted contaminated water and plant interactions. In recent work, partitioning coefficients for contaminants and plant species used in phytoremediation have been determined in the hope of better understanding the fate of compounds, particularly VOCs. Volatile organic compounds were shown to partition between plant biomass, internal water, and the vapor phase present in small vials in a laboratory study.[10] In research related to the partitioning study, diffusion from tree stems and trunks was directly measured, revealing that VOCs are taken up and can then volatilize to the atmosphere before reaching the leaves.[11] However, these studies also showed that transport to the leaves was occurring. Modeling of these mechanisms has provided an understanding of how these mechanisms interact and expectations of phytovolatilization of VOCs in remediation applications.

Phytodegradation

Plants also carry out metabolic reactions that degrade contaminants. Xenobiotics undergo detoxification processes in plants as summarized in the ''green liver'' concept.[12] This detoxification process was initially studied to consider how herbicides are degraded. Studies revealed very similar processes to mammalian liver functions and the combined processes were termed ''green liver model.'' Compounds undergo three metabolism steps, namely: transformation, conjugation, and sequestration. Xenobiotics are first transformed by ring hydroxylation of aromatics, hydrolysis, oxidation, or reduction of chemical bonds. This step often involves placing a polar, reactive group into the xenobiotics and is called ''activation'' or ''Phase I'' reaction. A major class of enzymes in the activation process is the cytochrome P-450 monooxygenases, which play key roles in a wide range of oxidative metabolic reactions in various organisms from microbes to humans. Hundreds of P-450 gene sequences have been identified, showing the important biochemical roles of P-450. Lately, complementary DNAs from three *CPR* genes from hybrid poplar (*Populus trichocarpa* × *Populus deltoides*) were isolated.[13] Many other enzymes such as peroxidases, peroxygenases, and carboxylesterases are also active in transforming organics. While oxidations comprise the majority of activation reactions, reduction processes have been identified. Of these processes, the reduction of nitro groups is of special interest as nitroaromatic compounds and explosives have been investigated extensively. The contamination by nitroaromatics and explosives is vast at former ammunition plants and ranges, and spread out over acres. In the reactions to phytodegrade these compounds, the key process involved is the conversion of a nitro group to an amino analog. Many priority pollutants can experience both oxidation and reduction process in plants. Oxidative metabolites and reductive metabolites of trinitrotoluene have been identified in cell culture studies and intact plants.[14]

In the green liver metabolism, the transformation reactions are followed by conjugation or Phase II

reaction in which sugars, amino acids/amino acid derivatives or glutathione may be transferred to the activated xenobiotics. Some compounds, however, are conjugated directly without transformation. Those compounds usually contain hydroxyl, amino, or sulphydryl moieties that are already targets for conjugation. Usually, the appearance of OH^-, SH^-, $COOH^-$, NH_2^- functional groups in transformation triggers glycosyl transfer mediated by glycosyltransferases and the presence of halogen- and nitro- functional groups triggers glutathione conjugation catalyzed by glutathione-*S*-transferases. In either case, the conjugation changes the physiochemical properties of the transformed compounds and impedes their mobility and partitioning into or diffusion through biomembranes.

The conjugation is considered to be the key step in the detoxification. Specifically, sugar conjugation has been recognized as a major detoxification reaction in plants.[12] The main process in conjugation is the glycosylation following the formation of functions, such as OH^- or NH^-, in the transformation reactions. The most common groups of sugar conjugates derive from UDP-glucose as a cosubstrate. One other consideration is that xenobiotics or their metabolites in plants are potentially bioavailable when exposed to animals. Sugar conjugates can be remobilized in the digestion process. While the sugar conjugates are generally an intermediate, they can accumulate in the cytosol or vacuole.

Another extensively encountered conjugation involves glutathione, which is highly hydrophilic. Thus, the conjugation of glutathione of hydrophobic electrophilic compounds will result in the loss of the parent compounds' lipophilicity by converting them into products possessing bulk hydrophilic regions. However, the amphiphilic metabolites have been shown to be inhibitive to other cytoplasmic enzymes, and glutathione conjugation is the dominant process in the presence of halogen- and nitro- functional groups, which may account for the low storage of TCE and metabolites in plant tissues observed in ^{14}C-labeled experiments.[15]

While the primary conjugates are more or less stable products in the cytosol, they are usually further converted to more complex or simpler products. Primary glucose conjugates are frequently converted to glucosylglucosides or 6-*O*-malonyl-glycosides, which are more stable in the vacuole.[16] Glutathione conjugates are usually metabolized within a few days to cysteinyl conjugates, believed to localize in the vacuole. However, a large part of them will leave the vacuole and reach the cytosol and be broken down there, forming xenobiotic thiol as substrate for *S*-glucosyl transferase, and methylated thiol and sulfoxidation product, both of which are volatile and inclined to escape into the atmosphere.

Plant and mammalian metabolic action showed the most difference in the third step because of the absence of the excretion system in plants. While xenobiotic metabolites after the conjugation step are readily excretable in either urine or bile in animals, they are trapped in cell walls or vacuoles in plants. Many sugar conjugates seem to be converted to different products in apoplast and sequestered into cell wall compartments with hemicellulose, cellulose, pectin, and lignin while others are stored in the plant vacuole. For most glutathione conjugates, however, the metabolism seems not to end in the vacuole. They undergo further metabolism in the cell and end up finally in the apoplast, the rhizosphere, and even the atmosphere.[17] Therefore, the vacuole may be only an intermediate storage pool for glutathione conjugates. The accumulation in the plant cell wall might be the end points of metabolism in both cases.

While the conjugates are safely trapped to the cell wall as the plant is alive, the soluble conjugates in the vacuole may become liberated quickly after the plant is dead. Research showed that polymerization of xenobiotics into lignin did not prevent the bioavailability. Sandermann[12] demonstrated that dichloroanilin in wheat straw was liberated when feeding animals. Research about the availability of residues is mainly focused on pesticides, insecticides, and drugs. A similar research on ordinary contaminants will shed light on the study of phytoremediation.

An axenic poplar cell culture experiment exhibited conclusively that poplar cells are capable of transforming and mineralizing TCE without the involvement of microbial metabolism.[15] The metabolites of TCE in cell cultures include trichloroethanol, trichloroacetic acid, and dichloroacetic acid, which was the most predominant. Chloral hydrate was also found at levels lower than the detection limit and is a product of TCE oxidation by cytochrome P-450 oxygenase and the precursor of trichloroethanol and trichloroacetic acid in mammalian systems. The same metabolites were identified in field sites where vegetation was exposed to TCE contaminated groundwater and in laboratory studies.[18,19]

Overall, the green liver metabolism of contaminants in plant cells can be substantial. Limiting factors in the metabolism are transport related. One limitation is the inability of the compound to transport to metabolically active cells, being too hydrophobic or too hydrophilic. The other limiting transport phenomenon is the volatilization prior to reaching the leaves where degradation is prevalent. All these concepts and great detail regarding the specific degradation processes and enzymes appear in a recent review chapter on the topic of plant metabolism in phytoremediation.[20]

Rhizodegradation

The rhizosphere is the area under direct influence by plant roots. The definition of the rhizosphere is vague and has different meanings for different properties. For example, if the water table is lowered and the soil profile is dewatered, the entire soil profile could be defined as ''rhizosphere.'' In the most common usage, however, rhizosphere refers to the area around the individual roots that is greatly altered by the presence of the root, perhaps the most greatly influenced in terms of biology. This alteration of the biology can lead to enhanced biodegradation by soil microbes, termed rhizodegradation.

Rhizosphere differs greatly from bulk soil, void of roots. Primary processes that lead to the changes are the removal of water and addition of organic carbon. The fact that this changes the biology greatly should be no surprise, as carbon and water are indeed the themes central to biology. When looking for life in space, the presence of organic carbon and/or water is the main requirement. Within the rhizosphere, the microbial community is generally much more active. Estimates range from 10 to 10,000 times more microbial activity in the rhizosphere. While the idea of 1000 times more microbes may seem on the extreme side, plants have been known to deposit or ''exude'' huge amounts of organic carbon. Plants have been noted to deposit as much as 50% of the photosynthetic load to the rhizosphere. In considering that plants make up over 99% of the active biomass on earth, the greatly enhanced microbial community is understandable. Once the microbial enhancement was discovered in relation to bioremediation, the development of rhizodegradation and testing was a logical step. Since that time the field of rhizodegradation has increased in activity tremendously, and many specific plant–contaminant–inoculant combinations have been investigated.

Numerous studies reveal that plants promote the degradation of certain compounds in rhizosphere. For example, biodegradation of saturated fuel oil hydrocarbons increased by 20% in the presence of maize at the early growth stage, but no obvious differences were observed between planted and bare soil when plant growth stopped after 120 days, showing the increased degradation rate rather than the extent of degradation by plants in this case.[21] Work by Siciliano and Germida investigated numerous compounds, including chlorinated aromatics, and uncovered mechanisms of plant–contaminant interactions relating to the specific organics that plants exude.[22] Plants can exude compounds with similar structure as that of contaminants, thereby enriching the microbial population for degrader organisms. Such selective enrichment was observed for mulberry trees and polynuclear aromatic hydrocarbons (PAHs).[23] Mulberry trees were shown to exude large proportions of coumarins and flavonoids, which are common and naturally occurring PAHs. Research showed that a former industrial facility had been naturally colonized by mulberry trees. Other research has shown that not only exudation, but also root turnover is vital to rhizodegradation.[24]

The rhizosphere effect does not enhance the degradation rate or the extent of chemical degradation on all occasions. In the same way that a plant can selectively promote degrader organisms if the exudates are analogs for the contaminants, plants can select nondegrader organisms. Several experiments suggest that the degradation of petroleum hydrocarbons in soil may be unaffected by the rhizosphere. Boyle and Shann observed no difference regarding the mineralization of phenol and 2,4-dichlorophenol in rhizosphere and nonrhizosphere soils. In a study of diesel fuel degradation in rhizosphere soil, diesel range organic (DRO) compounds were decomposed most rapidly in soils with NPK fertilizer, regardless of plant cover.[25,26] In unvegetated pots amended with NPK fertilizer, 92.5% of DROs were decomposed after 50 days, and all DROs were removed at 150 days. No significant difference was noted between DRO decomposition in unvegetated soil treated with NPK compared to the soil cropped to legumes, which demonstrated faster removal of DROs than grasses. The addition of readily degradable carbon to the soil was found to stimulate microbial degradation of xenobiotics. However, considering the costs of operation and maintenance, phytoremediation still holds advantages. In addition, the addition of nutrients has to be maneuvered carefully. In the same study, NPK fertilizer treatment showed the highest removal rate of DRO, with urea being the second highest. The glucose treatment under mixed grasses resulted in lower DRO removal than in amended soil, indicating that the addition of nutrients may be a more effective way to enhance the degradation ability of indigenous microorganisms than the addition of degradable carbons.[26]

Inoculating rhizosphere soil with contaminant-degrading bacteria is another way to improve rhizodegradation. Combining a TNT-transforming bacterium and a tolerant plant was observed to decrease the concentrations of TNT in soil by 30% within a 5-week period, while the plant effect was not visible and its growth was reduced in the absence of the bacteria inoculant.[27] Meadow brome (*Bromus biebersainii*) did not stimulate degradation of 2-CBA in soil when 2-CBA was present at 200 mg/kg; however, extractable 2-CBA was reduced significantly when inoculated with a mixture of two pseudomonads.[28] The inoculation of bacteria improves the rhizodegradation ability by two

main mechanisms: increasing the numbers in the microorganism community as mentioned above or increasing the capacity of rhizosphere microorganisms to degrade contaminants. Inoculating Dahurian wild rye with a mixture of strains R75 and CB35 reduced 2-CBA contaminant by the increase of the degradation capacity of rhizosphere, but had no effect on total heterotrophic populations or on plant growth variables, indicating that inoculating did not increase the rhizosphere effect, but instead the degradation capacity of rhizosphere microorganisms.

Inoculation does not always affect the rhizosphere degradation capacity of plants favorably even though the rhizosphere community is enlarged. Researchers found that bacteria inoculation protects plants from the phytotoxic effects of pentachlorophenol and other compounds. However, protecting plants from contaminant phytotoxicity with bacteria inoculants does not always lead to contaminant degradation.[29] Sometimes, the inoculation process increased contaminant phytotoxicity and resulted in other adverse effects. Inoculating bacteria into certain plants led to the death of plants. Noninoculated Altai wild rye survived in 3-CBA contaminated soil but died when inoculated with degrader strains.[28] Plant exudates were demonstrated to impact the bacteria physiology and bacteria inoculants are known to alter plant physiology. Thus, plants might change bacteria in such a way that they produce phytotoxins or phytotoxic metabolites or, alternatively, bacteria may interfere with certain plant detoxification processes.[27]

Overall rhizosphere impacts help to improve soil properties and also stimulate the organic input to a subsurface environment and act as a water sink. These processes are generally helpful for soil properties and health. There are many other details and examples of rhizodegradation than are covered in this brief summary. A recently published book provides a detailed look at rhizodegradation.[30]

ANCILLARY BENEFITS

Phytoremediation offers many advantages over more accepted and older remediation technologies like pump and treat or excavation. One advantage is public acceptance. The general public accepts and embraces trees as a sign of a good environment. Adding plants to a contaminated site not only targets the remediation in a scientific, engineered approach, but also provides confidence that the site is safe to support vegetation. Phytoremediation also offers an ecological benefit. While many technologies void the site of all life and even all organic carbon, such as thermal heating, stream injection, advanced oxidation, phytoremediation fosters additional life, working to remediate and restore the contaminated site concurrently. This aspect is unique to phytoremediation. Energy input is also not needed once the system is established. The solar powered nature of phytoremediation makes it a prime candidate for remote and vast sites, where energy input is difficult to impossible or else is prohibitively costly.

CONCLUSIONS

Phytoremediation is promising and is proving to be a useful approach to remediating contaminated soils and groundwater. The multiple mechanisms involved in phytoremediation offer many different approaches, including stabilization, phytovolatilization, rhizodegradation, phytoaccumulation, and phytodegradation. These approaches allow designers the ability to target different contaminants in different media (soil or groundwater) by understanding the approach selected and the mechanisms that are utilized. Phytoremediation also offers numerous advantages that make it an attractive option in remediating contaminated sites.

Pilot Plant and Minipilot Units

Richard P. Palluzi
ExxonMobil Research and Engineering Company, Annandale, New Jersey, U.S.A.

INTRODUCTION

Pilot plants have a distinguished and long history in supporting research in chemical process industries. Called by a variety of names—miniunits, research units, pilot units, microunits, miniplants, etc.—they all have the same basic purpose: To allow research or data gathering about actual performance of a process under real world conditions faster and cheaper than is possible in a commercial facility. A pilot plant is a tool for investigating a process or a process related problem, on a manageable scale, in a realistic and timely manner. Its size (or scale) is intended to be just large enough for all the important factors to be evaluated, yet as small and simple and economical as possible. A pilot plant is a means to an end rather than an end itself.

TYPES OF PILOT PLANTS

Pilot plants can be classified in a number of ways with the most common being by size, purpose, or degree of automation. The different classifications are summarized in Tables 1–3. Classifications are merely indications of general properties of the units; most are so unique that each one is truly ''one of a kind.''

Laboratory units typically fit on a bench top or inside a laboratory hood and are typically piped in tubing (see Figs. 1 and 2). While traditionally they are manually operated and continuously attended, most are now computer automated and often operate unattended. Integrated pilot plants range in size from several pallets or frames to a small building, and are usually piped in tubing or small pipe (see Figs. 3 and 4). Most are computer controlled and designed for unattended operation. Semiwork units are the largest type of pilot plant, and often are at the lower end of a plant scale (see Fig. 5). They are usually piped in commercial-size pipe and tend to resemble commercial units in automation and operation. Classifying pilot plants by size is useful for their relative costs and scales, but a more useful measure of a pilot plant's value is its purpose.

Process simulation pilot plants usually replicate all the major process steps in the actual order likely to exist in the plant. The pilot-plant equipment will be similar, although smaller. Because virtually all of a process is simulated, there is less chance of a critical step being missed. Any part of a process can be investigated in this type of unit; even those not identified in advance. Data are usually easier to correlate and safer to scale up than for other types of pilot plants. It is generally easier to design (assuming an existing plant exists) and useful for the life of the process. However, a process simulation pilot plant is usually more complex, expensive to build, and labor intensive to operate and support.

Problem solving pilot plants tend to be narrower in scope and limited to only the area of interest. They are usually cheaper and faster to construct. Data can often be more readily developed through a customized and focused design. Many problems are also amenable to investigation through nonprocess simulation methods, which can further reduce the cost and/or complexity. However, problem solving pilot plants often cannot be easily adapted for other purposes limiting their long-term utility. Their focused approach requires careful problem identification and does not lend itself to investigating synergistic effects or unknown causes.

Basic research pilot plants are designed for acquiring fundamental knowledge about a process; their design is set by the data required. Their size varies from small bench top units to larger integrated facilities and their complexity is usually high. A basic research pilot plant has a very narrow but deep focus. It is generally very complex and expensive.

PILOT PLANT SELECTION

Selecting the right type of pilot plant requires a clear definition of the program's goals. An optimum selection process is shown in Fig. 6. (See also Refs.[1–3].)

PILOT PLANT LOCATION

Where a pilot plant is located can have major and lasting effects on both its initial construction cost and its annual operating cost. There are four basic types of locations:

- Separate buildings.
- Containment (blast) cells.
- Open bays.
- Laboratories.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007898

Table 1 Classification by size

Class	Characteristics	Cost range
Laboratory pilot plant Microunit Laboratory unit Miniunit Pilot unit	• Fits on a bench or in a laboratory hood • Usually occupies 2 m^2 or less • Small diameter tubing, hose, or pipe used (2–12 mm OD) • May be manual operated or highly automated • Often has significant associated off-line equipment	$10,000 to $250,000
Bench top unit Pilot plant Miniplant Integrated pilot plant	• Usually constructed in a laboratory, open bay, containment cell, or large walk in hood • Typically 4–25 m^2 • Moderate diameter tubing or piping used (6–50 mm) • Usually automated • May include remote feed and product systems	$100,000 to $1,000,000
Demonstration unit Prototype unit Semiworks Large scale pilot plant	• Usually in an exterior location or a dedicated building • Typically larger than 50 m^2, often much larger • Larger size tubing and pipe used (25–100 mm) • Usually highly automated • May include laboratory and office space as part of overall unit facility	$1,000,000 and above

Separate, dedicated buildings eliminate the possibility that a pilot plant's operations will interfere with another's. It allows each building to be optimized for the pilot plant's specific purpose. Safety concerns still exist as separate buildings, and often force operating personnel to work alone, out of sight of other personnel, which can raise concerns regarding their safety and the timeliness of a response to an accident. Constructing a building each time a new pilot plant is needed is also expensive and time consuming as is service and maintenance. The trend toward smaller units has made separate buildings uneconomical.

Isolating pilot plants by means of containment cells can be via steel barricades or reinforced-concrete bunkers. Typically, the walls or roofs are designed to blow out and vent the force of an explosion to a safe area. Total-containment cells, where the entire force of the release is confined in the cell, are much more expensive and complex. Containment cells are regarded as the safest possible location when all operations are

Table 2 Classification by purpose

Classification	Process characteristics	Other characteristics
Process simulation	• Mimics process operations step by step although not all steps may be included • Uses scaled down flow rates and operating conditions • Often uses smaller scale commercial equipment	• Usually larger than bench scale • Typically fairly complex
Problem solving	• Designed to address a specific process problem or issue • May mimic a portion of the process but often designed to investigate problem in a different manner • Flow rates and operating conditions usually mimic process but may allow operation at extremes for testing	• May be of any size or complexity • Usually more focused than a process simulation
Basic research	• Laboratory style operation with no relation to process except in chemistry • Specifically designed to allow data accumulation under conditions of interest • Process conditions mimicked but flow rates usually minimal	• Size varies greatly but usually larger than bench scale • Substantial analytical equipment usually involved • Usually constructed in a laboratory environment

Table 3 Classification by extent of automation

Classification	Process characteristics	Unit characteristics
Manual	All process conditions set and monitored manually by operators	• Poor repeatability • Loose process control • High operating labor costs • Manual data gathering
Local control	Most variables monitored and/or controlled by dedicated controllers	• Better repeatability • Better process control • Lower operating labor costs • Data gathering may be manual, automatic, or a mix
Automated	Computer controlled usually through a personal computer or programmable logic controller. Less frequently by a central control computer or as part of a distributed control system	• Better repeatability • Better process control • Lower operating labor costs • Data gathering automatic although some analytical instrumentation may remain off line • Some to all routine operations may be automated
Fully automated	Computer controlled usually through a personal computer (PC), programmable logic controller (PLC), central control computer or distributed control system (DCS)	• Best repeatability • Best process control • Lowest operating labor costs • Data gathering automatic including most or all analytical instrumentation • Most routine operations automated

Older systems, which used a mixture of manual operations, local controllers and computers, are now very rare. They represented a common step in the progress of automating pilot plants but, in general, have given way to either simpler units, which remain manual, or use local controllers and more complex systems, which are automated.

remotely controlled from outside the cell. Greater risks can be accepted as equipment, not personnel, are at risk. However, containment cells are very expensive ranging from \$100,000/m^2 to \$1,000,000/m^2 depending on the degree of containment and the layout. Cell design is complex, difficult to validate, and easily voided through improper unit placement or design. Estimating the blast potential of process failures is also difficult, as it requires one to predict the specific failure mode and conditions. Hence, the safety of the cell may be less than assumed. Pilot plant installation is costly, primarily because of the extensive automation required for remote control. Operating efficiency is limited by the restricted access; some routine entry is usually accepted even with attendant increased hazard.

An open bay is a large area having few, or no, vertical partitions that permit laying out a pilot plant in almost any configuration. Open bays are the most preferred pilot-plant layout because control and interlock systems are reliable enough to reduce the risks of a major accident to acceptable levels, alleviating the need for containment cells in most cases. Open bays are the least expensive areas to construct, as an open warehouse or a prefabricated metal building can serve as the basic structure. The openness enhances safety because operators are rarely alone or even out of sight. However, interactions between pilot plants need to be evaluated carefully. A small fire on a unit handling noncombustible materials can change from a minor hazard to a major accident if the unit is located next to one handling large quantities of flammable materials.

Laboratory areas, once primarily the home of only wet chemistry operations, are now increasingly housing permanent pilot plants. This is due largely because of reductions in the pilot plant size due to improved instrumentation and analytical techniques as well as by advances in scale up allowing larger leaps between piloting processes. Many pilot plants now easily fit inside a standard or an expanded laboratory hood. The high rate of ventilation in the hood substantially reduces the hazards of dealing with hazardous materials. The climate-controlled environment of most laboratories not only enhances operator comfort and productivity but allows the use of numerous specialty equipment that cannot withstand the rigors of an un-air conditioned open bay. Laboratory buildings are, however, very expensive to construct and even more costly to operate due to their need for once-through exhaust. While newer technologies (heat recovery systems, reduced flow hoods, outside make up air, etc.) hold out the hope of reducing these operating costs, their application to date has been mostly on a trial basis. Relative costs for construction and operating different types of pilot plant space arrangements are listed in Table 4.

Fig. 1 A laboratory scale pilot installed in a knee height hood. *(View this art in color at www.dekker.com.)*

Safe unit placement enhances the overall safety of a pilot plant. A containment cell or a separate building is not, however, a guarantee of safety. Other measures include: Increased process monitoring of safety specific variables, limiting inventories of hazardous feedstocks and products, detailed hazard analysis and risk assessments, and good design practices. One essential element is to ensure that the pilot plant has adequate space to support its operation. This requires a careful evaluation of the required space before the unit is constructed. While a detailed layout and a careful evaluation of the operating requirements remains the preferred method of determining the space needed, other estimating techniques are available.[4] The space required for storing and handling feedstocks and products frequently exceeds that for the pilot plant. Typical concerns requiring additional space include:

- Storage capacity is needed for process upsets.
- Recycled material storage may be needed.
- Storage due to the lead time for ordering feedstock and the hold time for disposing of product.

Fig. 2 A small reactor unit located in a bench top hood. *(View this art in color at www.dekker.com.)*

Fig. 3 An integrated pilot plant installed in an open bay. *(View this art in color at www.dekker.com.)*

- Space for supporting chemicals such as cleaning and flushing solvents.
- Room for storing drums, cans, and other containers.
- Maintenance space.
- Spare parts and off-line equipment space.
- Associated laboratory space.

DESIGN

The unique nature of designing a pilot plant arises from the smaller size and the lower level of design information available. A pilot plant is usually the first engineered version of a laboratory process. In many cases, the full range of operating parameters would not have been fully defined before design starts. This makes detailed design more difficult and costly as either a wider range of conditions must be accommodated, or costly and time-consuming modifications may be required as the actual ranges are established after testing. In addition, industry design specific rules are often either not available for a new process or their scale is too large for the proposed smaller pilot plant or microunit. Both are problems unlikely to be encountered in the design of a commercial unit.

Pilot plant design typically follows one of two approaches: Mimic the methodology used for the

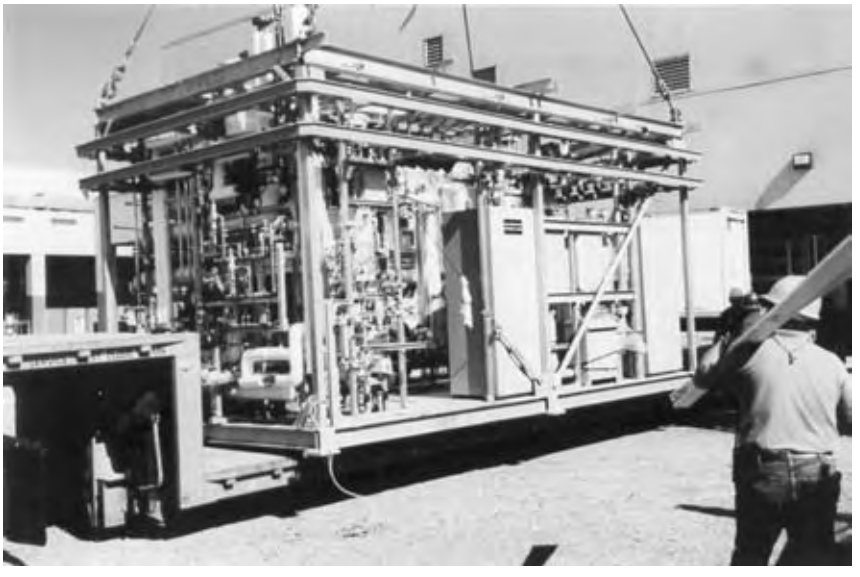

Fig. 4 A modular pilot plant in shipment from the construction shop to the field for installation. *(View this art in color at www.dekker.com.)*

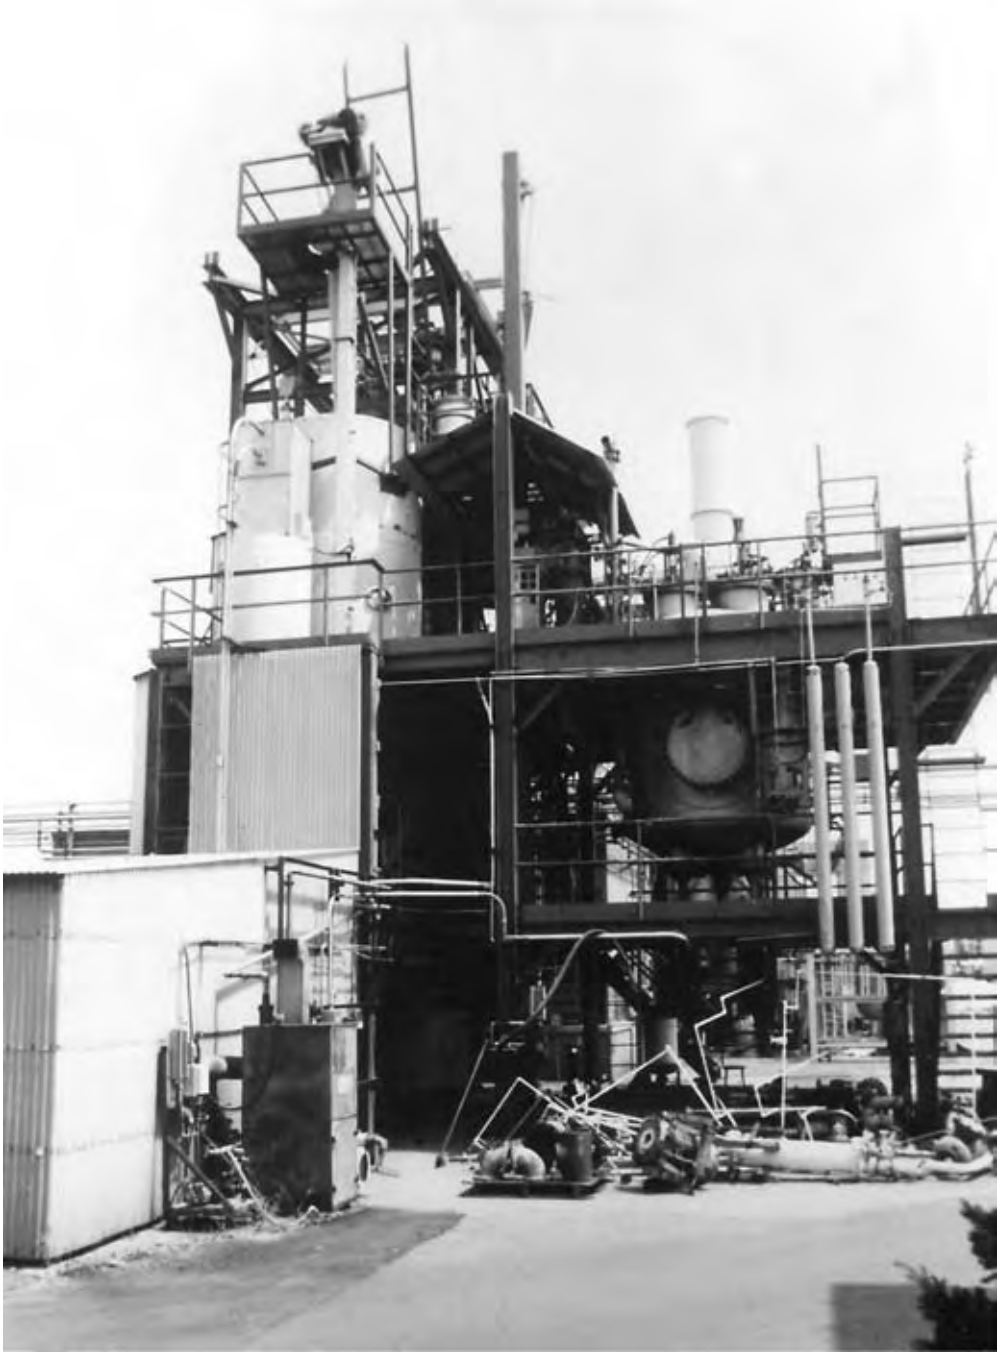

Fig. 5 A large semiworks pilot plant installed outside. *(View this art in color at www.dekker.com.)*

commercial plants or tailor the design specifically for the pilot plant. Either approach can work but the former often results in a larger and more complex design, while the latter can maximize the advantages of the pilot plant albeit at a higher level of risk in the design.

When mimicking the commercial design approach, the process steps, the basics of the process set, and the information for designing the equipment are known. Unfortunately, this approach is not always feasible particularly with new processes or novel technology. The proposed pilot scale may be outside the commercial design methodology because of the pilot plant's smaller size, different operating conditions, or novel process steps. Some full-scale operations are too expensive to reproduce on the pilot plant scale—e.g., solid handling and complex recycle systems. The commercial plant may utilize existing facilities, such as waste treating units and emission control equipment that cannot be duplicated economically in the pilot plant.

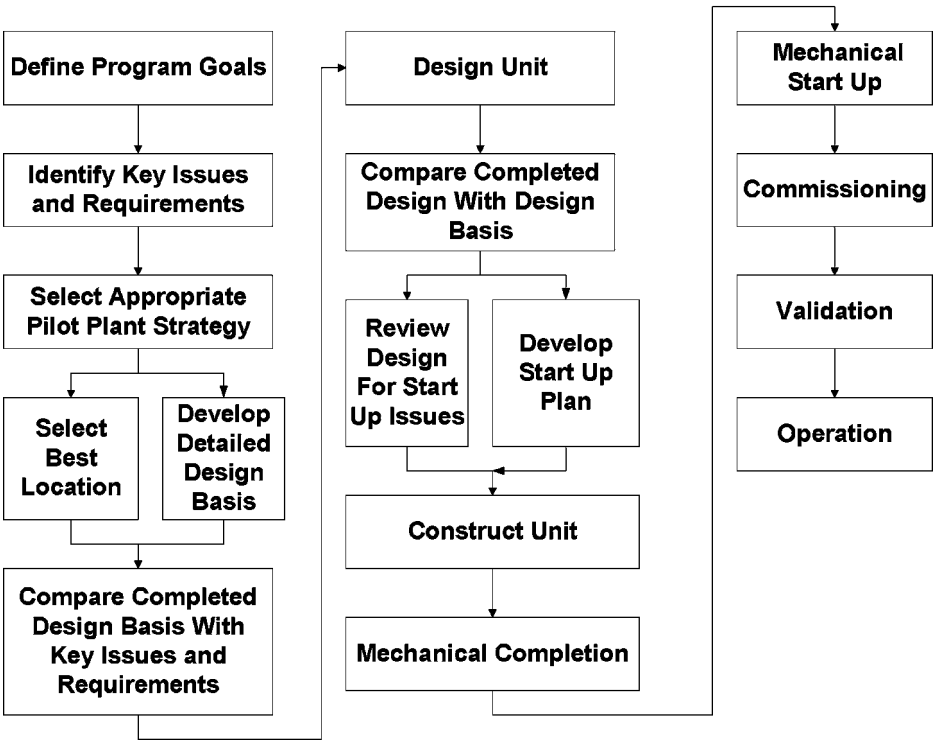

Fig. 6 A typical pilot plant selection process. *(View this art in color at www.dekker.com.)*

For a pilot plant specific design, conventional design techniques will be used whenever they can be matched to the scale and process as will commercial-scale design information. The equipment will be sized to try to maximize the advantages of the pilot plant, using the smaller scale to minimize or eliminate problem areas. This generally lowers the construction and operating costs. There are some problems with this approach as little information has been published on pilot plant design because most is considered proprietary. This makes the effectiveness of the design much more dependent on the skill level and the experience of the design engineer than in a commercial plant and increases the potential for design related problems arising later. It is still a much-pursued option as the potential construction and operating savings usually outweigh the risk. (See also Refs.[4–7].)

There are several options for those designing and building a pilot plant as summarized in Table 5. Each has advantages and disadvantages as shown. (See also Refs.[8–12].)

Two additional options exist in designing a pilot plant. The first is to rent space on an existing unit. Universities, specialty contractors, equipment manufacturers, and toll houses often have some level of existing pilot plans for rent for a test or a series of tests. This can minimize the lead time, as there is no design, construction, or start up that can give the organization access to a proven operation and reduce overall costs. Unfortunately, this option is not always viable. A suitable unit may not be

Table 4 Relative costs of constructing and operating different pilot plant space

Type of pilot plant space	Construction	Maintenance
Separate buildings	1.25–2.00	1.50–5.00
Steel cells	1.25–1.50	1.00–1.10
Barricaded concrete cells	3.00–10.00	1.10–1.25
Open bays[a]	1.00	1.00
Laboratory areas[b]	2.00–3.00	2.00–5.00

These figures are relative space costs for comparable structures in similar areas. They can vary widely across the country.
[a]All costs are relative to open bays, which for all practical purposes can be approximated by local costs to construct warehouse type space.
[b]Usually air conditioned unlike the other spaces.

Table 5 Options for design and construction

Design	Construction	Advantages	Disadvantages
In house	In house	• Most straightforward and simple • Information transfer minimized • Proprietary information protected • Reduced start up time • Improved in-house expertise developed • Reduced modification costs • Usually lowest risk option	• Requires adequate in-house resources not always available to all organizations • Requires skilled resources, design capability, construction staff, adequate resource time/availability • Often not a viable option for small organizations
In house	Contracted	• Retains most significant element affecting pilot plant success in house • Information transfer minimized • Proprietary information protected • Improved in-house expertise developed • Reduces demand on internal resources • Easier to locate a qualified construction contractor than a design contractor • Often faster to complete	• Final construction product is dependent on the skill of the contractor • Equipment and materials selection may be less than desirable unless specified • Locating qualified construction contractor is a tedious and time-consuming task • Construction supervision/follow up remains an issue • Higher cost (profit and overhead) • Some in-house follow up still required
Contracted	In house	• Reduces the need for in-house design resources • Compensates for lack of in-house design experience and/or expertise • Contractor design may be more efficient • Lump sum costs may be a viable option	• Rarely as effective as any of the other options • Locating a qualified design contractor • Lack of contractor expertise in specific area • Potential loss of proprietary information • Information transfer • Decreased operating efficiency • Higher start up costs • Higher maintenance costs • Higher cost (profit and overhead) Meeting industry and company • safety standards • Some in-house follow up still required
Contracted	Contracted	• Viable option for any size organization • Reduces the need for in-house resources to a minimum • Compensates for lack of in-house experience and/or expertise • May improve cost control • Contractor may be more efficient • Lump sum costs may be a viable option	• Locating a qualified contractor (both design and construction) • Lack of contractor expertise in specific area • Potential loss of proprietary information • Information transfer • Decreased operating efficiency • Higher start up costs • Higher maintenance costs • Higher cost (profit and overhead) • Meeting industry and company safety standards • Some in-house follow up still required

available, leading to inappropriate program compromises, expensive and/or time-consuming rework, and/or increased risk of failure. Even when a unit exists, it may not be available due to other commitments. Performing research outside the organization always raises some incremental risk of loss of proprietary information. There are also increased costs due to physical separation (travel and inefficiencies because of personnel absence), which is particularly a problem for extended programs. Safety can also be an issue if the facility owner and the organization do not share the same philosophy or concerns. Typically there is a potential disconnect as the unit owner knows the equipment safety issues but the client knows the materials concerns. Hence, an

Table 6 Types of safety reviews

Type	Purpose	Timing	Major issues
Conceptual or preliminary	• Identify potential problem areas early in design (''show stoppers'') • Ensure major safety concerns are addressed at the beginning of design • Identify problems without resolution	As early as possible in the project	• Location • Process operating conditions • Material hazards • Reactivity • Toxicity • Legal and code compliance
Preconstruction, design, or prebuild	• Review details of the proposed pilot plant • Approve final design for construction • Detailed safety review • Safety analysis or similar hazard assessment	Just before construction and materials procurement	• Detailed piping and instrumentation review • Risk assessment • Hazard analysis • Interfaces/interferences with other operations
Preoperational or prestart-up	• Review proposed operations • Examine the final construction product • Evaluate hitherto hidden concerns, interferences, or impacts • Review proposed operating procedures	Either immediately before or after start up[a]	• Operating procedures • Operating concerns • Construction deficiencies
Unit modification, control of change, or change of service	• Review the safety aspects of changes in equipment, procedures, or materials • Typically combine preconstruction and preoperational features • Prevent unauthorized, inappropriate, or poorly done modifications as they are the major cause of accidents	Whenever a change is envisioned	• Requires clear definition of what is a ''change'' • Information on existing systems and equipment must be up to date
Decommissioning, out of service, or end of service	• Ensure a unit is left in a safe condition when taken out of service • Avoid difficulties of disposing of equipmentcontaminated with unknown substances later	When a pilot plant is to be out of service for an extended period (typically 6 mo or more)	• De-energizing of equipment • Disposal of all hazardous materials • Cleaning all equipment • Identifying any long term concerns • Appropriate mothballing

[a]Before start up ensures no hazardous materials are introduced before a safety review and no operations occur before the construction product is inspected. After start up ensures start-up changes will be reviewed and accepts that actual operations are often too ill defined until this point for adequate review and many problems only appear during start-up.

independent client evaluation of all associated safety issues is critical. It is also important to reach resolution of some areas in advance such as who will handle and fund unit maintenance, who will set support priorities, who will operate the unit and ensure the accuracy, calibration, and certification of all key process and safety equipment.

Contracting the entire program, rather than just renting the equipment, reduces the in-house effort to a minimum and may result in reduced overall costs. However, it is difficult in this case to fully protect proprietary information as well as to capitalize on any fringe discoveries. The quality of the results is also highly dependent on the contractor's expertise. The distance from data can hide promising new areas and/or disguise existing problems. This approach is most viable where in-house expertise is lacking but is readily available outside. (See also Ref.[13].)

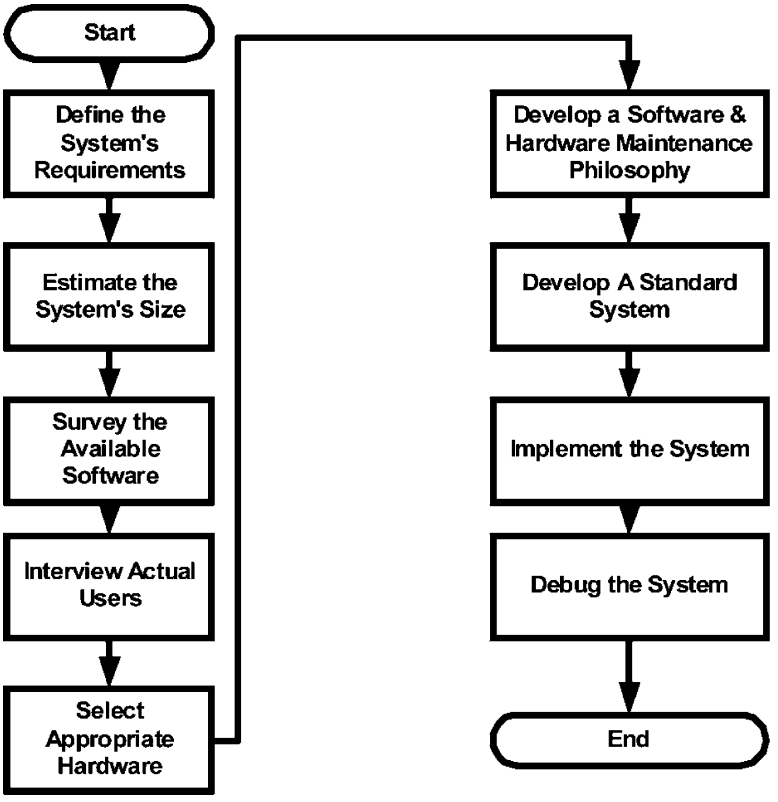

Fig. 7 Selecting a pilot plant control system. *(View this art in color at www.dekker.com.)*

SAFETY

Typically pilot plants undergo several safety reviews over the course of their conception. While names vary among organizations, the most common are shown in Table 6. (For a more detailed discussion of the numerous pilot plant and laboratory specific safety concerns, see Refs.[14–20].)

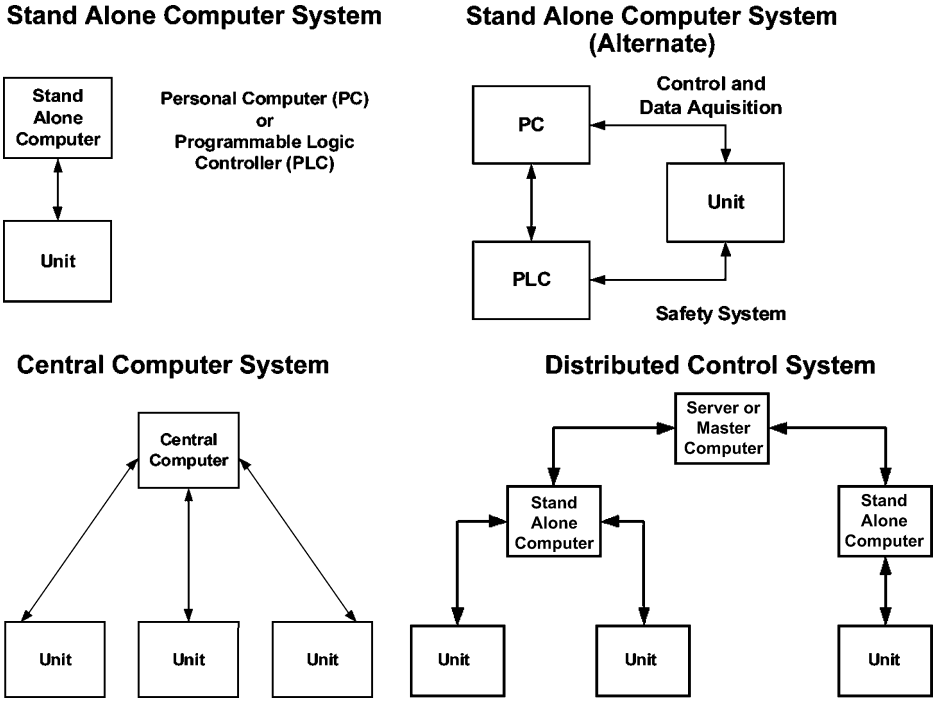

Fig. 8 Types of computer control systems. *(View this art in color at www.dekker.com.)*

Table 7 Computer control system analysis

Advantages	Disadvantages
Stand-alone computer system	
• Lowest cost per single unit • Easy and economical expansion • Separates pilot plants completely	• Standardization can become an issue • Each system's capacity can become a limiting factor • Many common components need to be reproduced • Marginal needs can be rarely satisfied • Control packages are frequently limited in size, scope, and capability • Operator access and screen displays may be limited, cumbersome, or less useful than desired • Data gathering and storage capabilities may be limited • Programming may require significant training and routine experience
Centralized computer system	
• Can be more economical for a large number of pilot plants • Usually provided with adequate programming support and maintenance services • Marginal needs are often justifiable across larger population • Usually practical to oversize all capabilities • Data gathering and control packages are more fully developed and useful • Data storage is rarely an issue	• Any failure affects everybody • Initial installation costs are much larger • Annual operating costs are very visible • Maintenance is difficult to schedule
Distributed control systems (DCS)	
• Has all the advantages of both a stand-alone and a central computer system	• Significantly more expensive to install, maintain, and support

CONTROL AND AUTOMATION

The typical process for selecting a pilot plant or a micro-unit control system is outlined in Fig. 7. This is often more difficult than immediately apparent because pilot plants are generally not operated long enough or enough are not constructed in a single location to permit side by side evaluations. The low construction rate in most organizations also leads to each new installation being treated as a unique entity. Hence most pilot plant control systems are selected from process plant experiences or literature searches rather than actual operating experience.

A key issue in selecting a pilot plant control system is to determine the degree of automation. Manual control is rarely suitable for any modern pilot plant due to the high cost of operating labor, the difficulty in ensuring consistent and quality results because of operator error and variability, and the difficulties in collecting data accurately and analyzing them later. In general, manual systems should be considered only if the control requirements are very small (one loop and less than five data points), the operation is a problem, which cannot be automated reliably or no support is available. Even then it will usually turn out to be a costly long-term choice. Automatic control systems are commonly selected because they reduce operating labor costs, increase accuracy through tighter process control, provide more rapid response and less operator bias, improve product quality, and reduce the potential for human error, which can improve both safety and operability. They also have the potential for automation with attendant savings. Automatic control systems do have some concerns. They lower operator attention, have a higher initial cost and a higher maintenance cost, and may increase support skill and staff levels. These are usually grossly outweighed by their advantages.

Automatic control systems can be based on individual stand-alone controllers or computer based systems. Individual controllers are easier to specify, readily available, and require less design and little or no programming. However, system integration is very difficult and data gathering remains a separate problem. System installation and maintenance are expensive and overall system

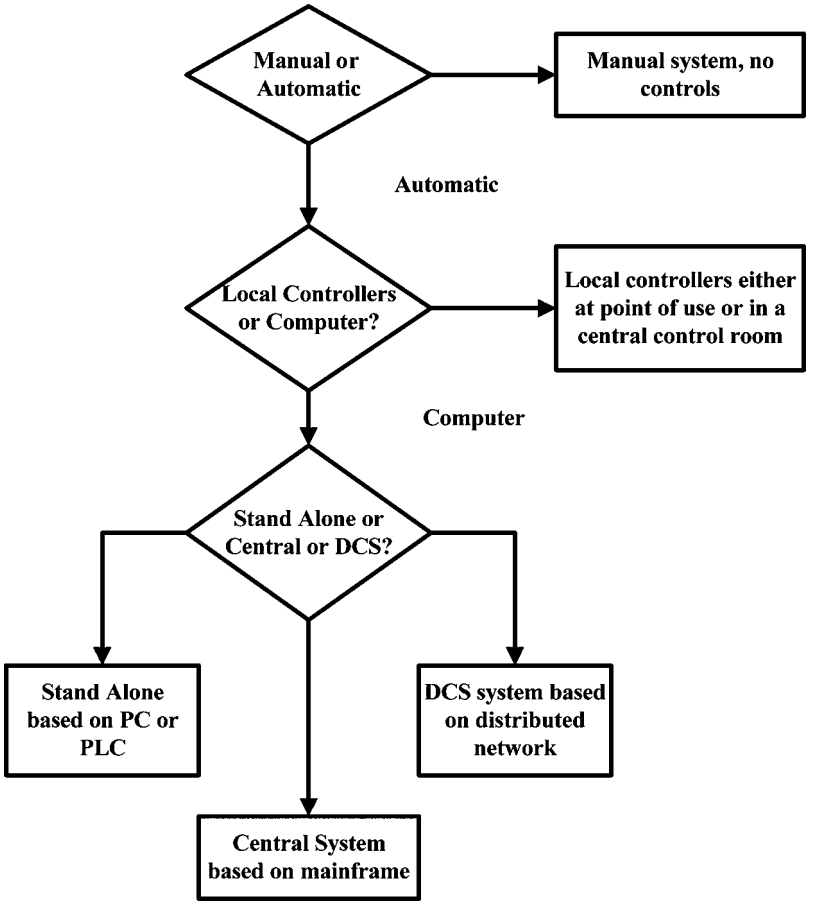

Fig. 9 Selecting the type of control system. *(View this art in color at www.dekker.com.)*

reliability is usually less than for a computer based system. Computer control systems are flexible, easier to specify and install, and simpler to modify. They inherently handle data gathering and provide the potential for easy automation. They are usually more expensive than local controllers but often not by much when the installation costs are included. Their hardware maintenance costs are less but they require programming, which can be expensive and require specialized support. Most new pilot plant control systems are computer based.

The different types of computer control systems are shown in Fig. 8, while their advantages and disadvantages listed in Table 7. Most new systems are stand-alone systems based on personal computers except for larger research organizations, which may be able to justify the more expensive distributed control systems (see Fig. 9 for a roadmap to selecting a pilot plant control system).

The first step in selecting a computer based control system is to determine the system requirements in terms of input and output signals. In most cases, this effort will have to start before the final process design is complete. Table 8 lists the common input and output requirements for typical system components.

The chosen system should have sufficient capability for the largest need envisioned. Room for expansion should be included. A typical computerized pilot plant grows by 20–50% per year during the first two years and by 10–30% thereafter. Select a control and data acquisition package first as it is the key element in obtaining a satisfactory system, then the computer hardware on which to run it. Most software control and data gathering packages can run on a wide variety of hardware platforms.

A pilot plant can be computer controlled in one of two ways: supervisory or direct digital control as shown in Fig. 10. In the first, a computer supervises another primary control element. In the second, the interfacing element is eliminated and the controller (e.g., a valve) is regulated directly. New computer-based automatic instrumentation is likely to be supervisory because it is faster and less expensive. (See also Refs.[21–23].)

COSTS

Estimating a pilot plant or a microunit's construction cost can be done in several different ways as summarized in Table 9. Pilot-plant cost estimating differs from that for full-size plants because little pilot-plant cost information has been published, the personnel

Table 8 Typical system requirements

["?" indicates either or both may be required.]

involved often less experienced in cost estimating, and every pilot plant is unique.

Similarity involves estimating the cost of a pilot plant from the cost to design and construct a similar unit. This method produces excellent results if the units are almost identical. Differences due to inflation can be accounted for reasonably through a published cost index, such as the *Chemical Engineering Plant Cost Index*. Unfortunately, few pilot plants are similar enough in all aspects to ensure an accurate estimate. Unless the cost base is large and the estimator experienced, these estimates are rarely more accurate than ± 50%. An estimate of such low accuracy is only useful for a preliminary screening.

In a cost-ratio estimate, the cost of an entire pilot plant (or a part of it) is related to a factor, such as

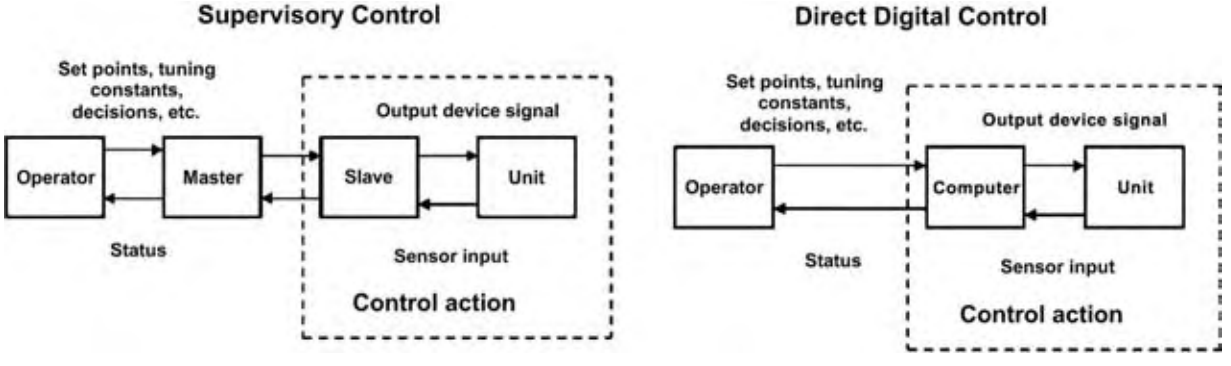

Fig. 10 Types of computer control. *(View this art in color at www.dekker.com.)*

Table 9 Pilot plant cost estimating methods

Factor	Similarity	Cost ratios	Details of time and materials required
Level of project definition	Low	Low–Medium	High
Site sensitivity	High	Low	Medium
Organization sensitivity	High	Low	Medium
Level of estimator experience	High	Medium	Medium–high
Cost accounting method sensitivity	Low	Medium	High
Ability to reconcile capabilities vs. costs	Low	Medium	High
Sensitivity to unknown factors	High	High	Medium
Sensitivity to single problem areas	High	Medium	Low
Information required	Low	Low–medium	Medium-high
Typical time required to develop (in weeks)	≤ 1	1–2	4–6
Typical cost of cost estimate as percentage of total project	≤ 1	1–3	3–5

Miscellaneous	
Control valves	2–24
Regulators	≤ 0.5
Relief valves	2–4

Note: These figures are averages over several years for reliable equipment in mild to moderate service. Older equipment, severe service, aggressive ambient conditions, and similar factors can raise these estimates significantly. These figures are based on trained and experienced personnel. New or untrained personnel typically require two to three times the maintenance-work time shown.

the cost of a major item of equipment or the number of control loops. Pilot-plant costs are rarely estimated this way because cost-ratio data for small equipment are not readily available, and most are developed by scaling down the known installed cost for the smallest item of equipment for a full-size plant. This frequently results in a highly inaccurate estimate because the cost of equipment below a certain size is often fixed. The accuracy of cost estimates based on cost ratios ranges from $\pm 25\%$ to $\pm 50\%$, depending on the nature of the ratio and the experience of the estimator.

Developing a detailed time and materials estimate requires dividing construction into a series of small tasks and estimating the labor and the materials required for each task. The narrower the scope, the higher the accuracy of the estimate. The accuracy ranges from $\pm 10\%$ to $\pm 25\%$. This is a tedious and time-consuming process but does produce the most accurate results and can serve as the framework for budgeting and controlling costs. (See also Refs.[24–27].) Operating, start up, and maintenance costs can also be estimated by a variety of methods.[1]

START UP

A pilot-plant startup typically takes longer than expected from scaling down the effort for a commercial plant because of the novelty of the process and the limited resources assigned.

The key to a successful startup is planning and organization beginning at the start of the project. The proposed design should be reviewed for start up issues such as how instrumentation will be calibrated and lines leak tested. This effort should then progress to making a detailed start up plan listing each task that must be performed in some detail and then estimating the resources and the effort required. This plan can then be used to develop a realistic start up schedule and resource list. It acts as the master plan for the entire start up and can be modified as the start up proceeds. Table 10 gives a typical generalized start up plan. An actual plan would be much more detailed. (For more details on pilot plant start up see Refs.[1,28,29].)

MAINTENANCE

Maintenance in a pilot plant often seems too insignificant or transitory to warrant organized attention. The reality is quite different. Few pilot plants operate for so short a time to require no maintenance. Annual maintenance costs are usually best expressed as a percentage of construction costs and vary widely due to differences in accounting practices and maintenance policies. In general, pilot plant maintenance costs can be estimated based on the technology and run length:

Conventional, 1–5 day runs	5–15%
Conventional, >5 day runs	10–20%
Severe service, 1–5 day runs	10–25%
Severe service, >5 day runs	20–40%

(See also Table 11.)

CONCLUSIONS

Pilot plant and microunit design and operation is a specialized area where information is often lacking. The trend is toward smaller, more heavily instrumented units that can be modified for a larger variety of programs.

Pinch Design and Analysis

Robin Smith

INTRODUCTION

Pinch analysis first emerged as an energy saving approach to the design of heat exchanger networks. The approach is soundly based in thermodynamics, but also allows economic criteria to be integrated with thermodynamics to provide practical and cost-effective solutions to energy saving problems. Since the early developments of the 1970s, pinch analysis has become established as the standard tool for the analysis and design of heat recovery systems. Many thousands of practical applications have been achieved.

Issues in the success of pinch analysis and design are:

- Pinch analysis exploits targeting before design. This allows objectives to be screened prior to detailed design. The ability to set scientifically based targets prior to design has been a key element in the success of the methodology.
- The methodology uses thermodynamic analysis and representational aids, but leaves the designer in full control of the decision making process.

The discussion here provides an introduction to the methods, but more detailed treatments are available.

DESIGN OF HEAT RECOVERY SYSTEMS

Fig. 1 shows a simple flowsheet. Some of the streams require heating (sinks for heat, or cold streams), whereas others require cooling (sources of heat, or hot streams). It is desirable to recover heat where possible from the streams requiring cooling to provide the heat for those requiring heating. Even for a simple system like the one shown in Fig. 1, the best arrangement for this heat recovery is not obvious. Streams requiring cooling need to be matched against those requiring heating, but taking account of the temperature differences available in the process. The second law of thermodynamics dictates that heat can only flow from a high-temperature source into a low-temperature sink. Moreover, there is usually a minimum acceptable temperature difference for heat transfer. Table 1 presents the details of the data from the simple example of Fig. 1. Each stream has an initial, or supply, temperature and a final, or target, temperature. In addition, there is an enthalpy change defined by the physical properties of the stream. Note that the enthalpy in Fig. 2A is a total enthalpy (i.e., the product of specific enthalpy and mass flow rate). Also, the heat capacity is a total heat capacity (i.e., the product of specific heat capacity and mass flow rate). In the simple examples in this article, it is assumed that the streams all have a constant heat capacity. With a small problem, such as the one in Fig. 1 and Table 1, trial and error might be used to try and match the hot streams and cold streams. Even for a small problem, such an approach is not guaranteed to give the best solution. A more systematic approach is required.

ENERGY TARGETS

The material and energy balance defines the heat sources (hot streams) and heat sinks (cold streams). To set energy targets, the streams are first plotted in temperature and enthalpy coordinates. Fig. 2A shows the two hot streams (sources of heat). The straight temperature–enthalpy profiles in Fig. 2A imply constant specific heat capacity. The positioning of the streams in the temperature–enthalpy plot is arbitrary on the enthalpy scale. This is because the reference enthalpy can be chosen to be any convenient value for each stream. The important specification for the stream is that the enthalpy change is fixed. Fig. 2B shows the two hot streams combined to give a composite hot curve. Where streams have a common temperature range, the enthalpies and heat capacity flow rates are combined. The hot composite curve, as shown in Fig. 2B, is the single-stream equivalent of the two separate streams in Fig. 2A in terms of temperature and enthalpy.

The corresponding cold streams (sinks for heat) are shown plotted in temperature–enthalpy coordinates in Fig. 3A. Fig. 3B shows the curves combined to give a composite cold curve. Again, where streams have a common temperature range, the enthalpies and heat capacity flow rates are combined. The cold composite curve, as shown in Fig. 3B, is the single-stream equivalent of the two streams in Fig. 3A in terms of temperature and enthalpy.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007899

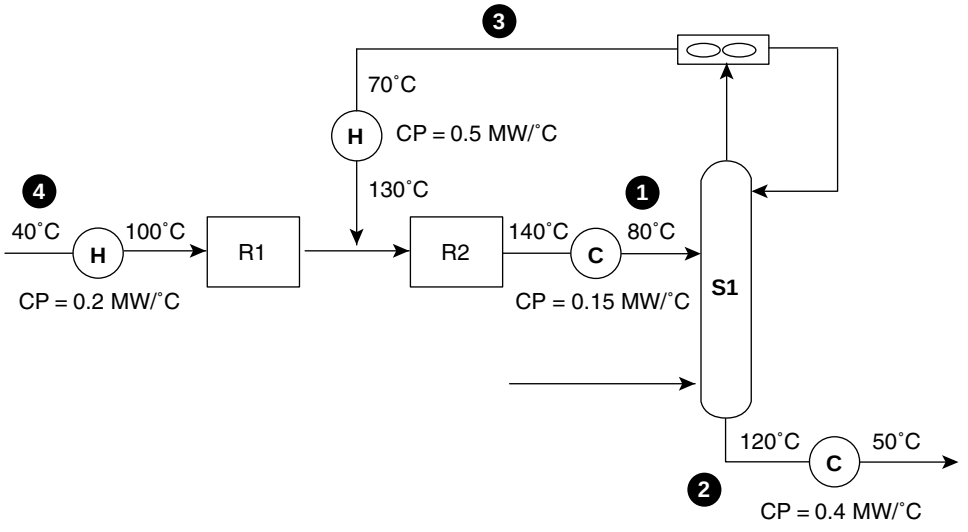

Fig. 1 A simple system with two hot streams and two cold streams.

The two curves can now be matched to determine how much heat can be recovered from the hot streams in the process to the cold streams in the process. The composite curves are shown in Fig. 4 matched such that there is a minimum temperature difference (ΔT_{min}) of 10°C. The hot composite curve must be above the cold composite curve by at least ΔT_{min} at all points for feasible heat transfer. The relative position of the two curves has been adjusted such that they are separated by a specified minimum temperature difference. In this case, $\Delta T_{min} = 10°C$. The overlap between the composite curves represents the heat recovery potential between the hot and cold streams in the process, shown in Fig. 4. The monotonic nature of the construction of the composite curves allows for maximum overlap between the curves. This in turn allows the construction to determine the maximum heat recovery potential (Q_{REC}). By maximizing the heat recovery, the residual demand for heating and cooling utilities is minimized. In Fig. 4, the part of the cold composite curve that projects beyond the start of the hot composite curve represents the external heating utilities required ($Q_{H_{min}}$). The part of the hot composite curve that projects beyond the start of the cold composite curve represents the minimum cold utility required ($Q_{C_{min}}$). The construction of the composite curves provides an energy target for the process and allows the best energy performance of the process to be determined prior to heat recovery network design.

In the case of the composite curves in Fig. 4, ΔT_{min} was chosen to be 10°C. What is the correct value of ΔT_{min}? In principle, the correct value of ΔT_{min} is determined by a capital–energy tradeoff, as illustrated in Fig. 5. The composite curves can be shifted horizontally relative to each other by adjusting the reference enthalpy of the curves. This allows ΔT_{min} to be varied. Small values of ΔT_{min} require small amounts of external heating and cooling utility. As ΔT_{min} increases, the consumption of both hot and cold utility increases to maintain the energy balance. The energy performance of the process therefore becomes poorer the larger the value of ΔT_{min}. On the other hand, the temperature differences for heat transfer between the hot and cold streams throughout the process become larger as ΔT_{min} increases. This means that the heat transfer area decreases, hence lowering the capital costs. Thus, as shown in Fig. 5, there is a capital–energy tradeoff. Combining the energy cost and capital cost allows an optimal value of ΔT_{min} to be identified. In practice, the shape of the optimization

4	Cold	40	100	12.0	0.2

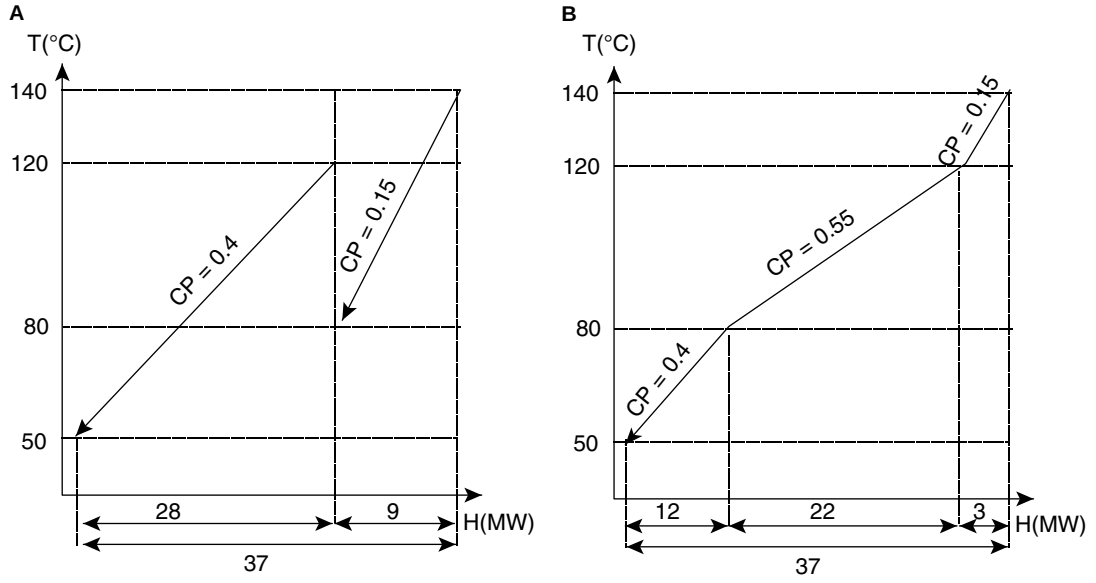

Fig. 2 Hot composite curve. (A) Individual temperature–enthalpy profiles for hot streams. (B) Combination of profiles for two hot streams.

curve tends to be quite flat, and such optimization is often not necessary. As long as the value of ΔT_{min} is somewhere in the region of the optimum point, there is little to be lost or gained in terms of the overall cost by small changes in ΔT_{min}. For chemical processes, a reasonable value of ΔT_{min} is usually around 10°C. A larger value is usually required for refinery processes (typically 20–30°C). For low-temperature processes, a reasonable value of ΔT_{min} is often lower (typically 5°C or less) because of the expense of providing cooling through refrigeration in low-temperature processes. Practical issues also restrict the choice of ΔT_{min}. For example, if shell-and-tube heat exchangers are to be used, then 10°C is, in any case, a practical minimum for equipment design. Although shell-and-tube heat exchangers can be designed with temperature differences below 10°C, special attention is required in their design, as the flow is not truly countercurrent in such devices. In contrast,

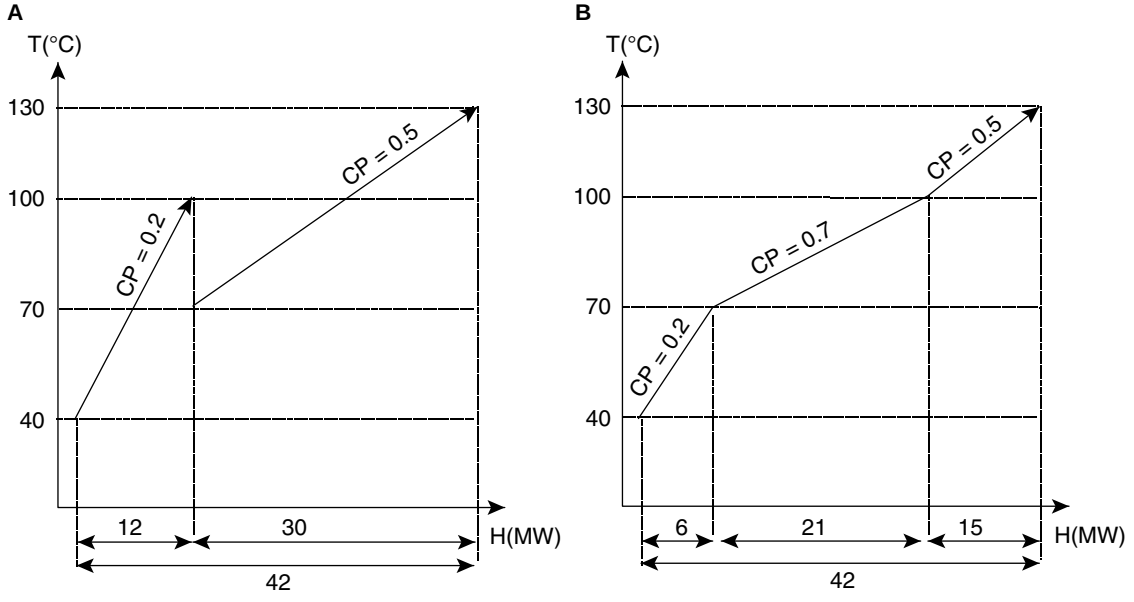

Fig. 3 Cold composite curve. (A) Individual temperature–enthalpy profiles for cold streams. (B) Combination of profiles for two cold streams.

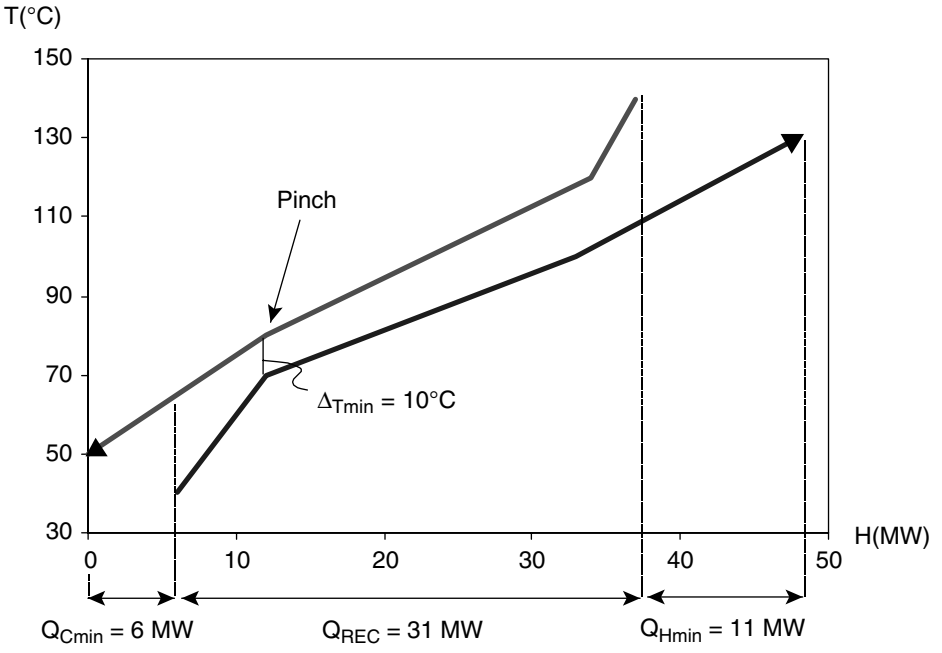

Fig. 4 Plotting the hot and cold composite curves together at $\Delta T_{\min} = 10°C$. *(View this art in color at www.dekker.com.)*

if, for example, plate heat exchangers are used, then the flow is more truly countercurrent, and a smaller temperature difference can be tolerated.

THE PINCH PRINCIPLE

The composite curves in Fig. 4 determine the target for maximum heat recovery and minimum hot and cold utility. The point of closest approach of the composite curves (where there is $\Delta T_{\min}$) limits their maximum heat recovery potential. This point of closest approach is known as the heat recovery pinch. However, not only does the pinch limit the heat recovery potential between the composite curves, it also is the key to achieving targets set by the composite curves in design.

To understand the true significance of the pinch, first divide the composite curves at the pinch, as illustrated in Fig. 6. Above the pinch (in temperature terms), the process is overall a heat sink. Heat recovery is possible from the composite hot stream to the composite cold stream above the pinch, but there is a residual amount of heat ($Q_{H_{min}}$) that is required to be imported from hot utility to satisfy the enthalpy imbalance. Below the pinch (in temperature terms), the process acts overall as a heat source. Heat recovery is possible from the composite hot curve to the cold composite curve below the pinch, but a residual amount of cooling ($Q_{C_{min}}$) is required to satisfy the enthalpy imbalance. Overall, the process above the pinch therefore acts as a heat sink, and that below the pinch acts overall as a heat source.

Now consider the possibility of transferring heat across the pinch from the overall process heat sink into the overall process heat source (Fig. 7). Temperature differences are such that it is feasible to transfer heat from hot streams above the pinch to cold streams below the pinch without violating the minimum temperature difference. On the other hand, it is not possible to transfer heat from the hot streams below the pinch to the cold streams above the pinch without either having negative temperature difference or violating the minimum temperature difference constraint. Thus, it is possible to transfer heat from above the

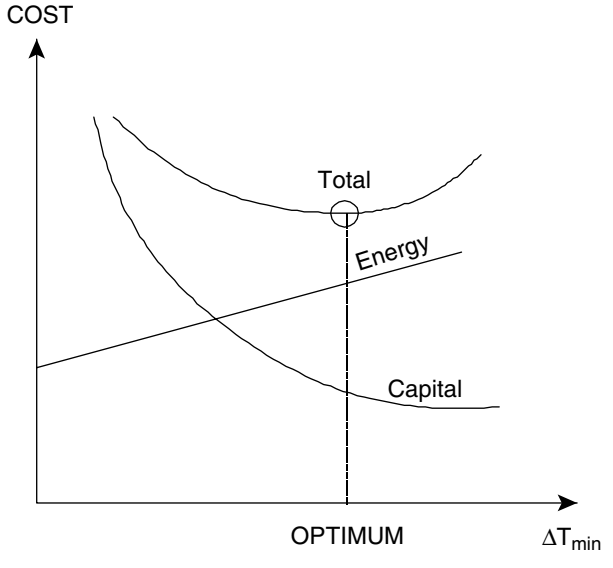

Fig. 5 Capital–energy tradeoff.

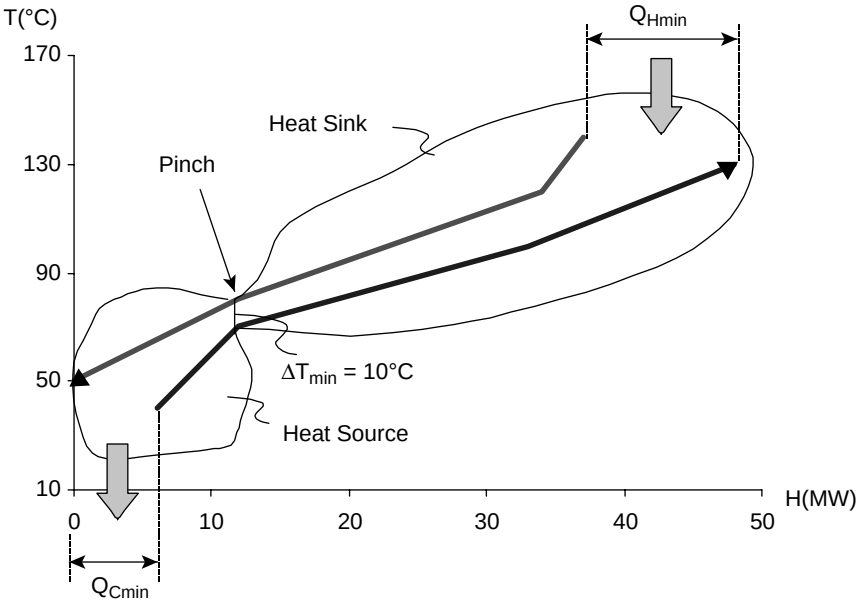

Fig. 6 The "pinch" divides the problem into a heat source and a heat sink. *(View this art in color at www.dekker.com.)*

pinch to below the pinch in process-to-process heat exchanges but not the other way around.

Having identified that it is feasible to transfer heat from above the pinch to below the pinch, suppose now that a quantity of heat XP is transferred in this way. Removal of the amount of heat XP from the system above the pinch now leads to a heat imbalance. It is not possible to correct this by transferring XP of heat from the below pinch to above the pinch, as this has been established to be infeasible. The only way to correct the enthalpy imbalance is to import an extra XP of heat from a hot utility. Having transferred XP of heat from above the pinch to below the pinch, the process below the pinch now has a surplus of even more heat than was previously the case. Thus, the result of transferring XP of heat from above the pinch to below the pinch is an increase of both the hot and the cold utility by that amount.

Process-to-process heat transfer is not the only way in which heat can be transferred across the pinch. There are basically three ways in which heat can be transferred across the pinch. The first, illustrated in Fig. 8A, is the one already discussed: transferring XP process-to-process across the pinch. Fig. 8B shows the use of hot utility below the pinch. Using hot utility to provide heat to cold streams below the pinch is feasible. However, $Q_{H_{min}}$ is still required to satisfy the enthalpy imbalance above the pinch, and the additional XP of heat transferred to the process below the pinch must ultimately be rejected to cold utility. This inappropriate use of hot utility below the pinch leads to an increase in the energy consumption. Finally, Fig. 8C shows an arrangement in which cold utility has been applied to process streams above the pinch. It is feasible to apply cold utility to the hot streams above the pinch. However, the consequence

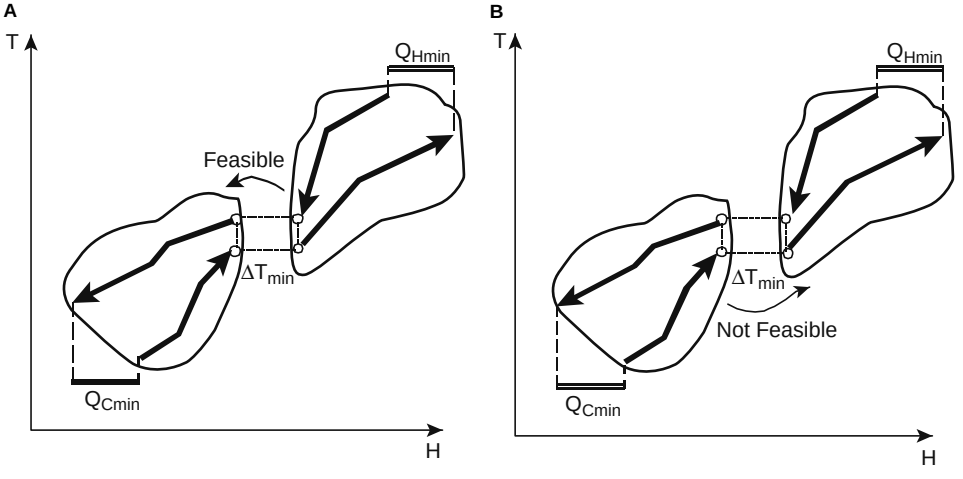

Fig. 7 Heat transfer across the pinch. (A) Heat transfer from above the pinch to below the pinch. (B) Heat transfer from below the pinch to above the pinch. *(View this art in color at www.dekker.com.)*

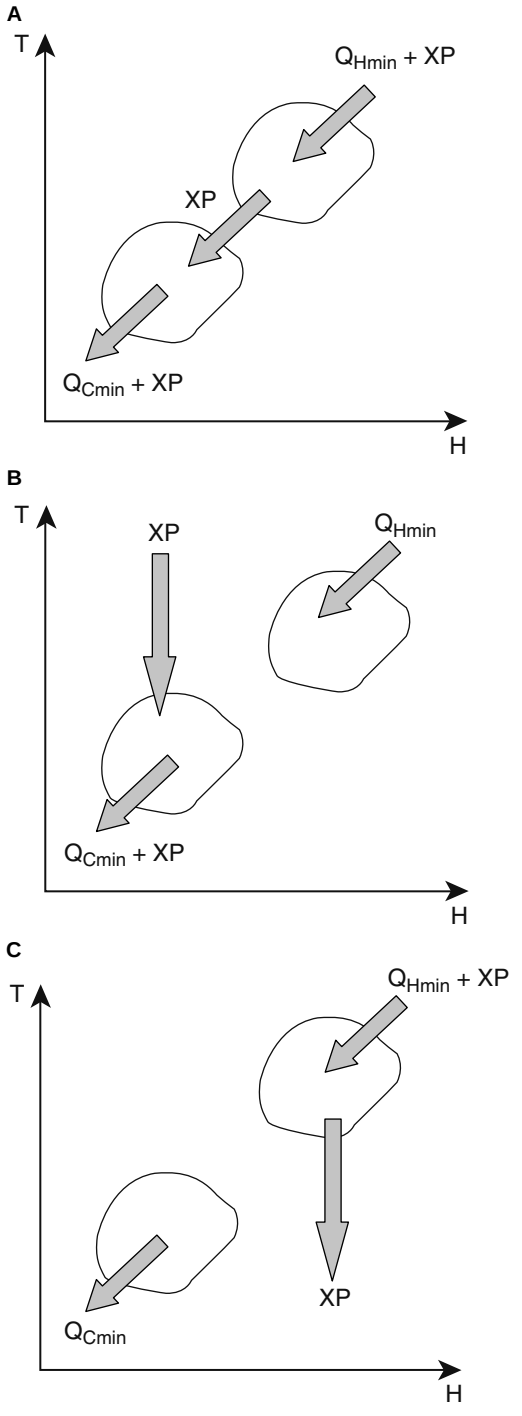

Fig. 8 Three ways of heat transfer across the pinch. (A) Process-to-process heat transfer across the pinch. (B) Use of hot utility below the pinch. (C) Use of cold utility above the pinch. *(View this art in color at www.dekker.com.)*

is now that the process above the pinch has a deficit of XP of heat that was previously being recovered from the hot streams to the cold streams above the pinch. This deficit cannot be corrected by transferring heat from below the pinch to above the pinch, for reasons already discussed. The only way this enthalpy imbalance can now be corrected is by importing an extra XP of heat from hot utility. The enthalpy balance below the pinch is maintained by $Q_{C_{min}}$ of cooling below the pinch. Thus, the inappropriate use of utilities leads to a corresponding increase in the consumption of both hot and cold utility.

If the condition of having no transfer of heat with a temperature difference smaller than ΔT_{min} is imposed, then each unit of heat transferred process-to-process from above the pinch to below the pinch or each unit of utility inappropriately used leads to a unit increase in the consumption of both hot and cold utility. Turning this argument around, to achieve the target for hot and cold utility set by the composite curves in design, the designer must not:

- Transfer heat across the pinch process-to-process
- Make use of inappropriate utility

Appropriate utilities are those required to satisfy the enthalpy imbalance in that part of the process.

THE PROBLEM TABLE

The composite curves provide a valuable tool both to set energy targets and to provide insights into the design problem. However, the composite curves are based on a graphical construction, and an alternative calculation, known as the *problem table*, can be developed to provide the energy targets. The problem table is developed here using the example from Table 1. The algorithm is in four steps.

Step 1. The first step in the problem table algorithm is to adjust the temperatures to include a finite temperature difference for heat transfer in the subsequent analysis. Hot streams are adjusted by reducing their temperature by $\Delta T_{min}/2$. Cold streams are adjusted by increasing their temperature by $\Delta T_{min}/2$. These adjusted temperatures are known as interval temperatures. They are not real temperatures, and the adjustment is made purely for the sake of the algorithm. If a hot and a cold stream have the same interval temperature, then they are in reality separated by just ΔT_{min}. Table 2 shows the supply and target temperatures of the streams from Table 1 adjusted for ΔT_{min}. In this case, the temperatures need to be adjusted by 5°C.

Step 2. In the second step, interval heat balances are created, as illustrated in Fig. 9. The interval temperatures created by adjusting the supply and target temperatures by $\Delta T_{min}/2$ are listed in descending order to create enthalpy intervals. The hot and cold streams are then superimposed on their appropriate temperature

Table 2 Shifted temperatures for the data in Table 1

Stream	Type	Supply temperature, T_S (°C)	Target temperature, T_T (°C)	Shifted supply temperature, T_S* (°C)	Shifted target temperature, T_T* (°C)
1	Hot	140	80	135	75
2	Hot	120	50	115	45
3	Cold	70	130	75	135
4	Cold	40	100	45	105

intervals. It should be noted in Fig. 9 that within each temperature interval, the hot and the cold streams are separated in temperature terms by just ΔT_{min}. This ensures that heat transfer is thermodynamically feasible within each temperature interval.

Step 3. The next stage in the algorithm is to perform a heat balance within each temperature interval. This heat balance is given by

$$\Delta H_{INTERVAL} = \Delta T_{INTERVAL}\left[\sum CP_C - \sum CP_H\right]$$

The enthalpy balance sums up the CPs of the cold streams within an enthalpy interval, sums up the CPs of the hot streams within the same interval, subtracts the latter from the former, and then multiplies the result by the temperature difference across the interval. The resulting heat balance might be a positive or a negative value. A positive value indicates that there is a net deficit of heat within a temperature interval. A negative value indicates that there is a net surplus of heat in an interval. The interval heat balances for all of the intervals are shown in Fig. 10. Such interval heat balances allow for heat recovery within each temperature interval. However, to complete the picture, the algorithm must consider heat recovery between intervals. Where an interval has a surplus of heat in Fig. 10, this should be used, where possible, to supply at least some of the deficit for those intervals that have a heat deficit. For heat transfer to be feasible, heat can only be transferred down the interval temperature scale. Fig. 11A shows heat cascaded down through the temperature intervals, assuming that there is no heat input into the highest temperature interval from utility. The heat flows between the temperature intervals show some positive and some negative values. A negative number indicates that heat needs to be transferred up the temperature scale, and this is not feasible. Thus, the cascade in Fig. 11A is not feasible, and some remedial action must be taken to correct the negative values. This can be done by increasing the heat flow through the entire system. Thus, heat should be added from hot utility to the interval with the highest temperature.

Step 4. To make the cascade in Fig. 11A feasible, enough heat must be added at the first temperature interval to make all of the flows either zero or positive. The largest negative heat flow in Fig. 11A is –11 MW. This must be added from hot utility to the first temperature interval. Fig. 11B shows the corresponding cascade. The amount of heat added in the first temperature interval corresponds to the target for minimum hot utility of 11 MW. The heat rejected from the last interval, 6 MW, corresponds to the target for cooling utility. These targets for hot and cold utility

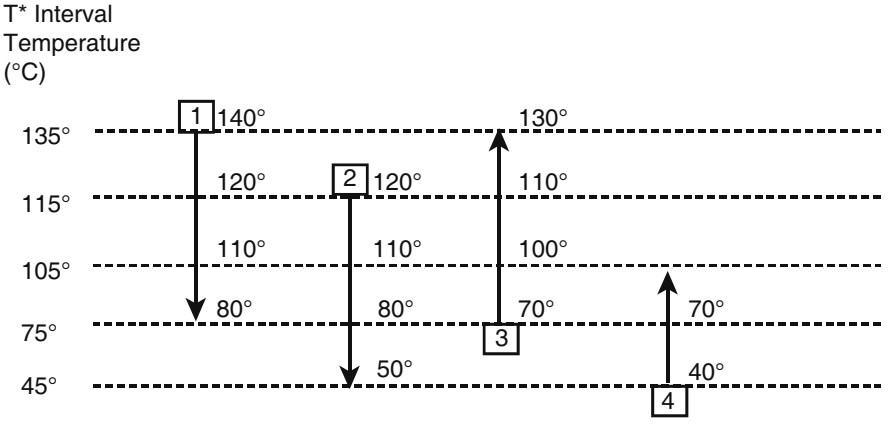

Fig. 9 The stream population for the data in Table 2. *(View this art in color at www.dekker.com.)*

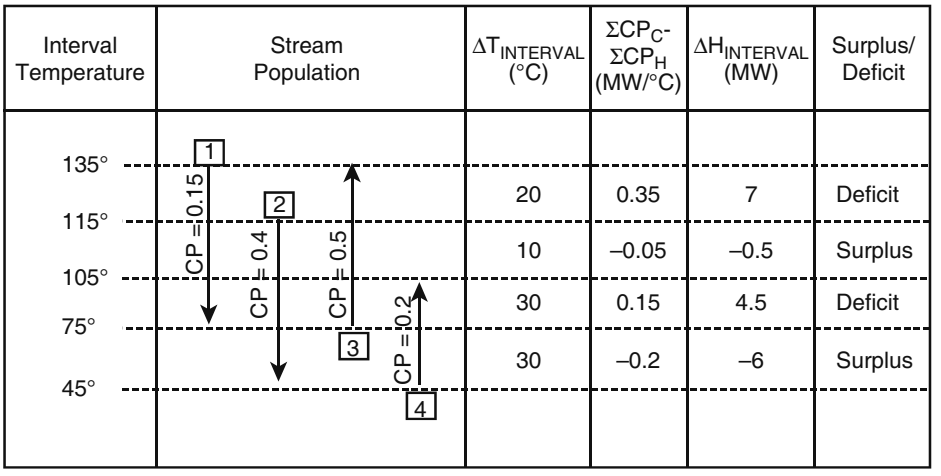

Fig. 10 Temperature interval heat balance. *(View this art in color at www.dekker.com.)*

agree with the targets generated from the composite curves.

The other feature to note regarding the cascade in Fig. 11B is the point where the heat flow becomes zero. This is at an interval temperature of 75°C. This corresponds to the location of the pinch. Given that the interval temperature for the pinch is 75°C, the hot stream pinch temperature is therefore 80°C and the cold stream pinch temperature 70°C. This agrees with the location of the pinch from the composite curves. Thus, the problem table algorithm provides the information required for minimum hot and cold utility targets and the location of the pinch that is critical in the next step, which is to design to achieve the targets.

THE PINCH DESIGN METHOD

Having established the hot and cold utility targets and the location of the pinch, the next step is to produce a design that will achieve the targets. The design procedure starts by setting up a design grid, as shown in Fig. 12. The hot streams are shown at the top of the diagram running from left to right and the cold streams at the bottom of the diagram running from right to left. A vertical line at the pinch temperature of 80°C for the hot streams and 70°C for the cold streams divides the grid into two parts. To the left is the part of the process above the pinch. To the right is the part of the process below the pinch.

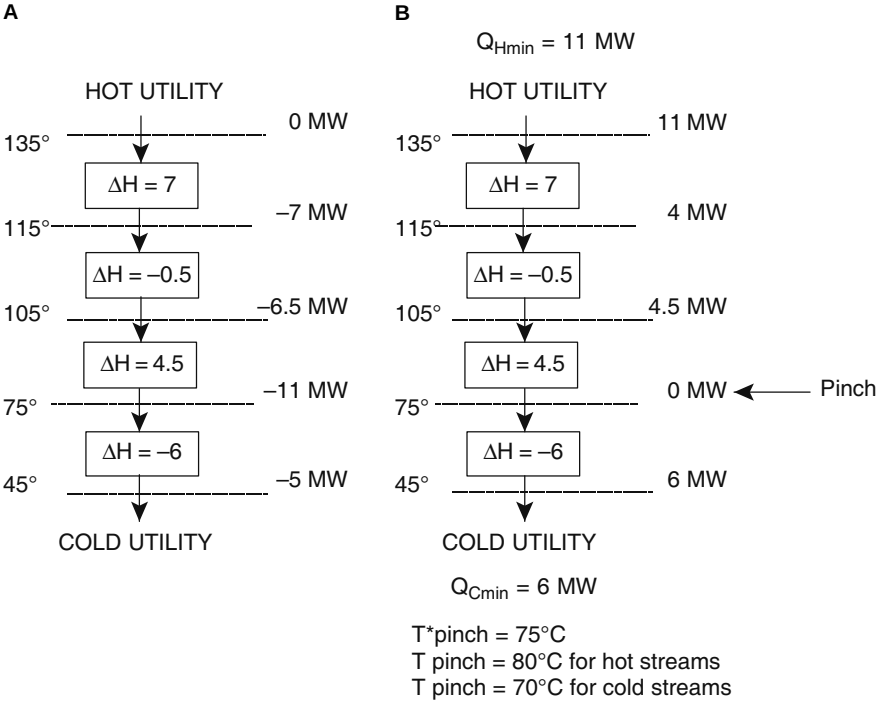

Fig. 11 The problem table cascade. (A) Cascade without heat input. (B) Cascade with heat added from hot utility. *(View this art in color at www.dekker.com.)*

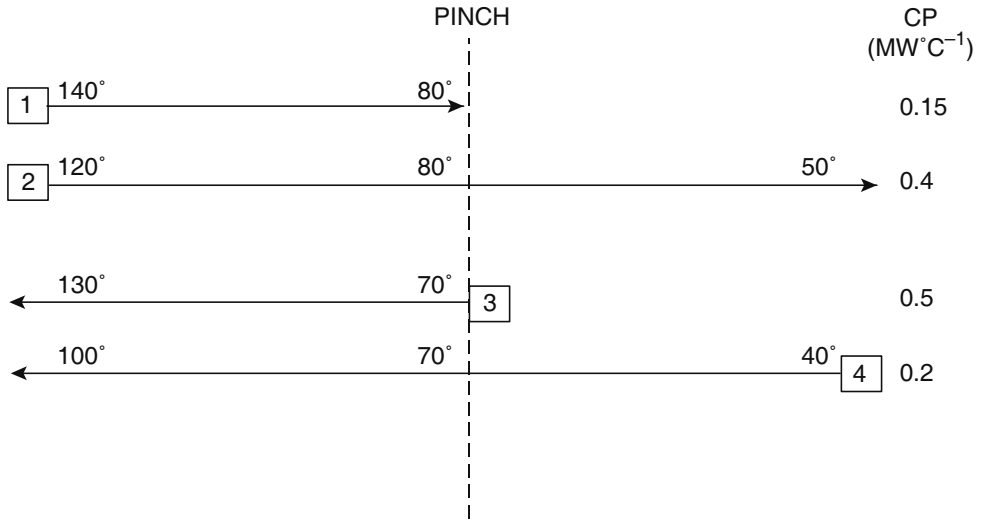

Fig. 12 Setting up a design grid. *(View this art in color at www.dekker.com.)*

To develop a design strategy, the temptation would be to start the design with the hottest hot stream and recover heat to a cold stream, gradually working from high temperatures to low temperatures. However, the composite curves in Figs. 4 and 6 show that the most constrained part of the design, where the temperature differences are the smallest, is around the heat recovery pinch. If the design was started at the highest temperatures, decisions would be made in a part of the design where there is freedom of choice, because of the large temperature differences. Working from this part of the design to the region of the pinch would mean working towards a more constrained part of the design. Decisions made away from the pinch might therefore create problems once the constrained part of the design around the pinch is approached. Thus, a sensible approach is to start the design where it is most constrained: around the pinch.

A heat exchanger in the grid diagram is represented by a vertical line joining two open circles on the streams that are being matched. Fig. 13A shows a match placed above the pinch, at the pinch. In Fig. 13A, the match is between Hot Stream 2 and Cold Stream 4. Because the match is at the pinch, the match starts with $\Delta T_{\min}$ at its cold end. The hot stream has a CP of 0.4 and the cold stream, a CP of 0.2. Because of the relative CPs of the two streams, as heat is transferred, moving away from the pinch the temperature differences become smaller and, therefore, infeasible. Fig. 13B shows an alternative arrangement whereby Hot Stream 2 is matched with Cold Stream 3. This time, the CP of the hot stream is 0.4 and that of the cold stream is 0.5. Starting with $\Delta T_{\min}$ at the pinch, because of the relative values of the CPs, now the temperature differences become wider as the heat duty increases moving away from the pinch: $CP_H \leq CP_C$. The argument only applies strictly for matches above the pinch, at the pinch.

Fig. 14 shows the part of the design below the pinch. In this particular case, because the heat exchanger network is simple, there is only one hot stream and one cold stream below the pinch. The match at the pinch shown in Fig. 14 is seen to be feasible with a hot stream CP of 0.4 matched against a cold stream CP of 0.2. By a reasoning analogous to the arguments for the CP inequality above the pinch, it can be concluded that below the pinch, at the pinch, $CP_H \geq CP_C$ for a feasible match.

To help identify suitable matches between hot and cold streams for the overall network, a CP table can be adopted, as illustrated in Fig. 15. The CP table lists the hot and cold streams in descending order of CP. This allows feasible matches between hot and cold streams at the pinch to be readily identified. Fig. 15(A) shows the hot and cold matches for the streams above and below the pinch. These satisfy the CP inequalities, and therefore the temperature differences throughout the matches are feasible.

The next question in the design is to determine how large these matches should be in terms of their duty. It would make sense for these matches to be as large as they can be to minimize the number of matches and reduce the complexity in capital costs of the design. The matches can only be made as big as the smaller of the duties on the two streams being matched. Thus, the tick-off heuristic can be used to minimize the number of matches by satisfying one of the streams in terms of its heat duty each time a match is placed. Fig. 15B shows the matches around the pinch with their duties maximized to satisfy some of the streams.

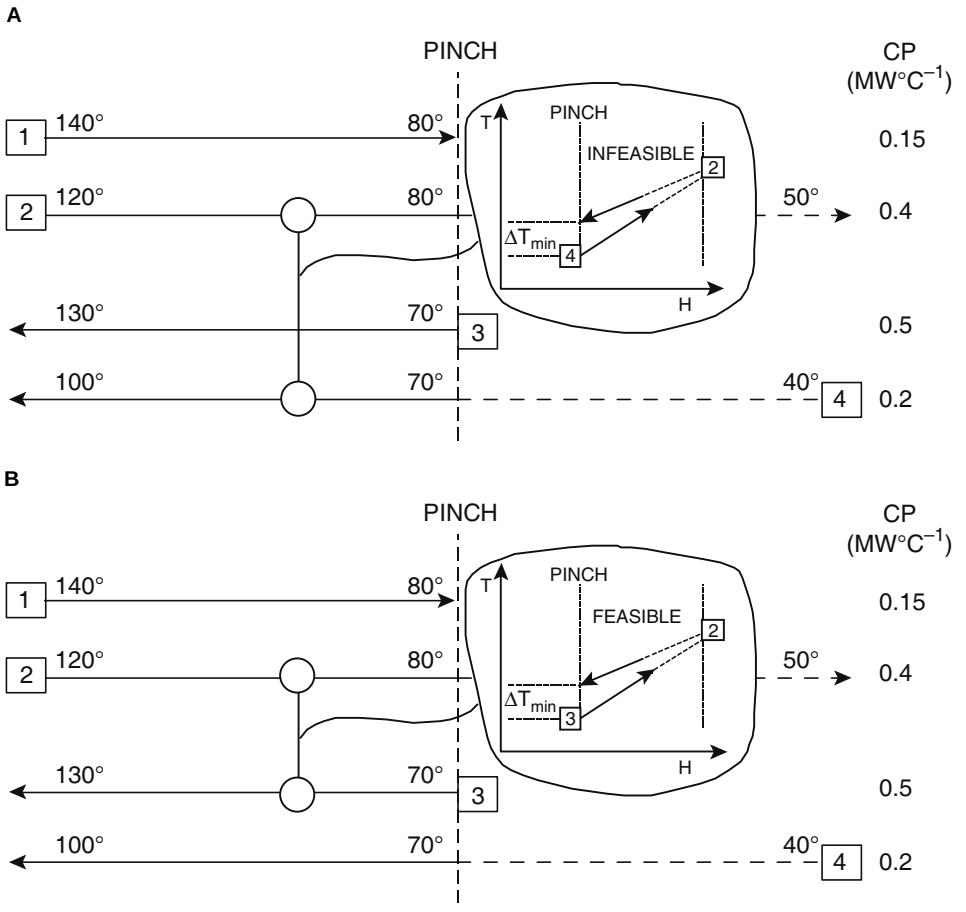

Fig. 13 Above the pinch, at the pinch, $CP_C \geq CP_H$ for a feasible match. (A) A match between hot stream 2 and cold stream 4. (B) A match between hot stream 2 and cold stream 3. *(View this art in color at www.dekker.com.)*

To complete the design, further matches are required, and also the placement of hot and cold utilities. In Fig. 15B, above the pinch, all of the hot streams must be reduced to pinch temperature by heat recovery. Thus, in Fig. 15B, a further match between a hot stream and a cold stream must be placed for the target to be achieved. This is shown in Fig. 15C, where an additional match has been placed above the pinch, maximizing its load. Once all of the hot streams above the pinch have been satisfied, it only remains to place hot utilities, as shown in Fig. 15C. Hot utilities in the grid diagram are represented by an open circle with 'H' on the stream to which the hot utility is applied.

Similar arguments apply below the pinch. In Fig. 15B, the match between Hot Stream 2 and Cold

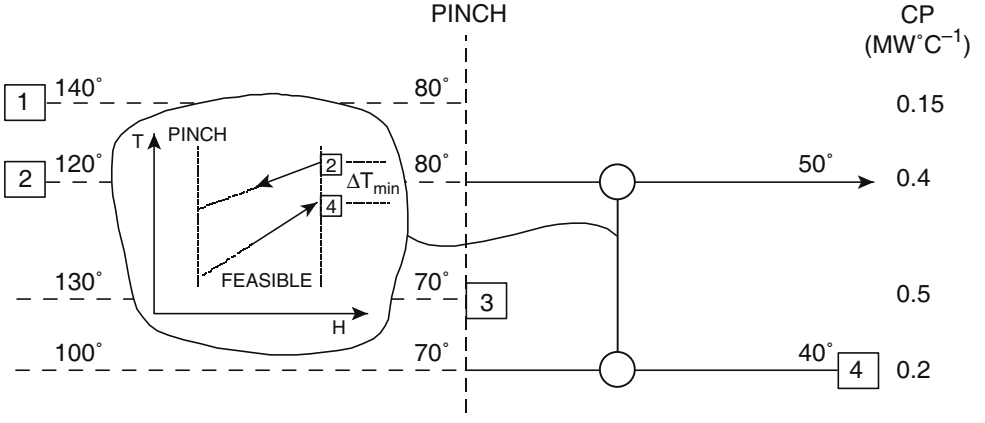

Fig. 14 Below the pinch, at the pinch, $CP_H \geq CP_C$ for a feasible match. *(View this art in color at www.dekker.com.)*

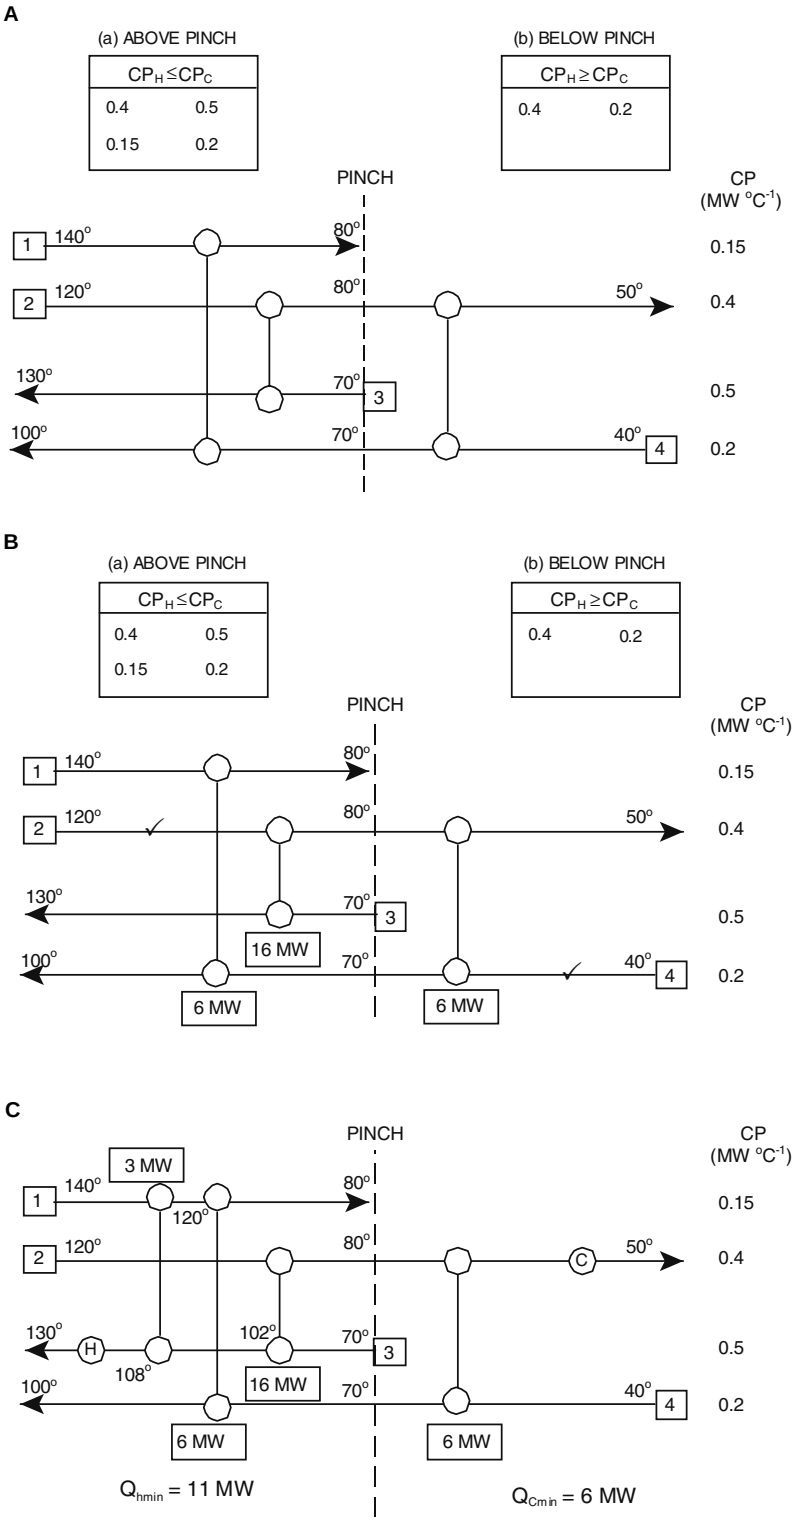

Fig. 15 The pinch design method. (A) CP tables follow feasible matches to be identified at the pinch. (B) Maximising the heat duties on the matches. (C) The completed design. *(View this art in color at www.dekker.com.)*

Stream 4 satisfies Stream 4 below the pinch once its duty has been maximized. Below the pinch, all of the cold streams must be heated to pinch temperature by heat recovery. Maximizing the duty on the match between Hot Stream 2 and Cold Stream 4 below the pinch allows Cold Stream 4 to be completely satisfied below the pinch. Thus, in this case, no further heat recovery matches are required below the pinch as all of the cold streams are satisfied. All that remains to complete the design is to apply coolers to the hot streams not satisfied by heat recovery. In the grid diagram, a cooler using cold utility is represented by

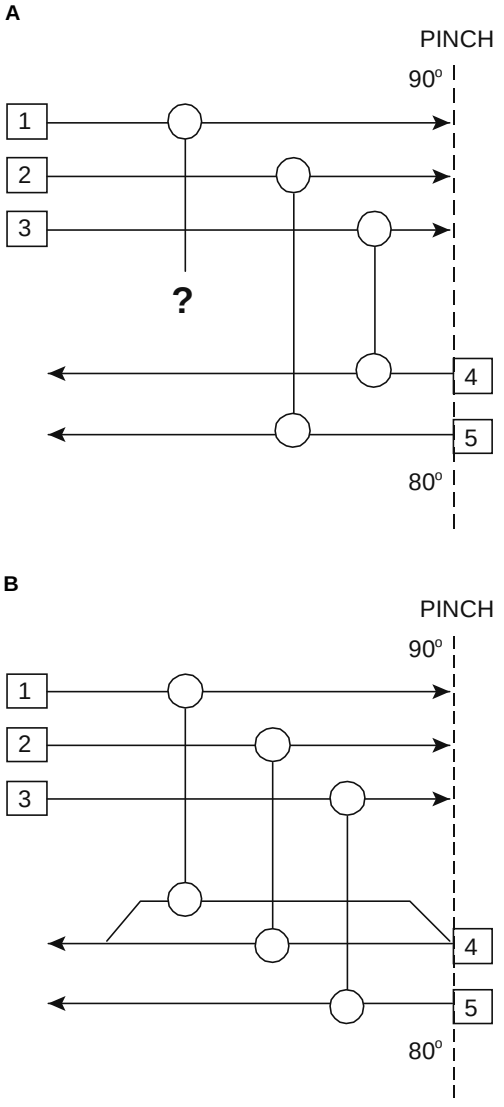

Fig. 16 Above the pinch, $N_C \geq N_H$. (A) An above-pinch part of a problem. (B) Splitting a cold stream allows all of the hot streams to be satisfied. *(View this art in color at www.dekker.com.)*

an open circle with a 'C' on the stream to which the cold utility is applied.

The completed design in Fig. 15C indicates a hot and cold utility requirement in agreement with the targets set by both the composite curves and the problem table analysis.

STREAM SPLITTING

Fig. 16A shows part of a problem above the pinch. The pinch temperature is 90°C for the hot streams and 80°C for the cold streams. The hot streams above the pinch must be cooled to a pinch temperature of 90°C by heat recovery. To reach 90°C, each of the three hot streams must be matched against a cold stream at 80°C at the pinch to have a feasible match. Unfortunately, there are three hot streams and only two cold streams. This means that one of the hot streams does not have a cold stream with the necessary 80°C to match against. This design problem can be solved by splitting a cold stream, as shown in Fig. 16B. Splitting a cold stream effectively creates another cold stream at 80°C. Now each of the hot streams can be matched against a cold stream at 80°C. The conclusion from this is that above the pinch, at the pinch, $N_H \leq N_C$.

Fig. 17A shows part of a problem below the pinch. In this case, three cold streams must be heated to the pinch temperature of 80°C without using utility. This

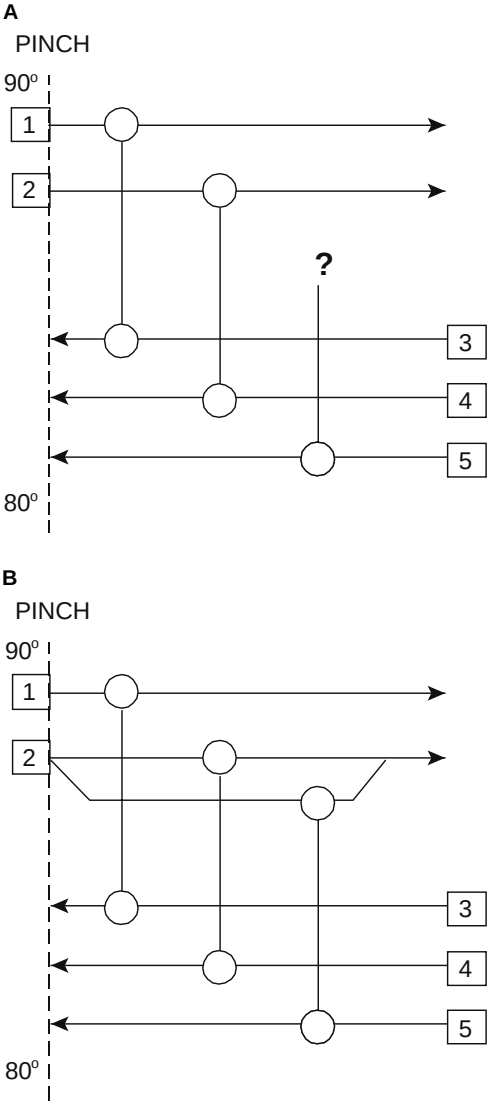

Fig. 17 Below the pinch, $N_H \geq N_C$. (A) A below-pinch part of a problem. (B) Splitting a hot stream allows all of the cold stream to be satisfied. *(View this art in color at www.dekker.com.)*

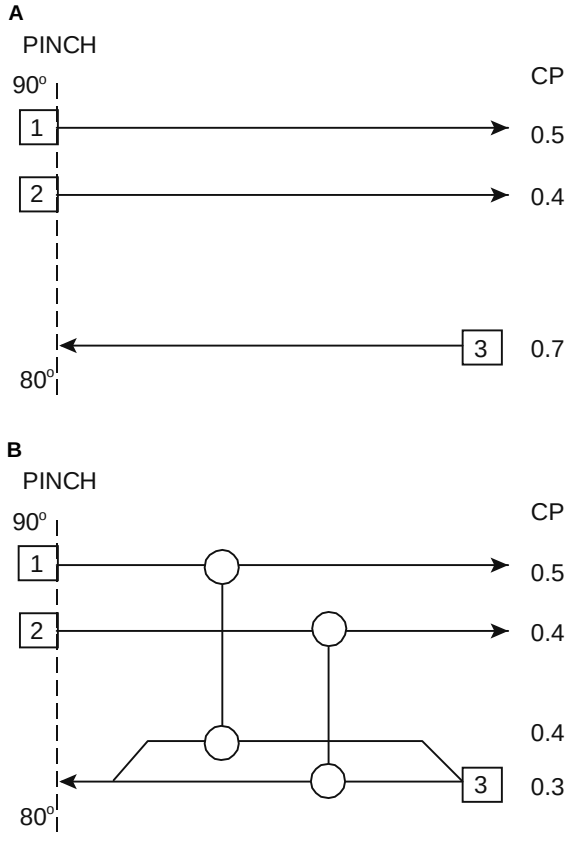

Fig. 19 Splitting a cold stream below the pinch for CP inequalities. (A) A below-pinch part of a problem in which the CP-inequalities cannot be satisfied. (B) Splitting a cold stream allow the CP-inequalities to be satisfied. *(View this art in color at www.dekker.com.)*

means that the three cold streams must be heated to 80°C by heat recovery. Two hot streams are available at 90°C. Thus, two of the cold streams can be satisfied but the third cannot. To solve this design problem requires another stream to be made available at 90°C. This can be achieved by splitting one of the hot streams, as shown in Fig. 17B. Now each of the three cold streams can be matched with a hot stream at a temperature of 90°C. The conclusion from this is that below the pinch, $N_H \geq N_C$.

Another above-pinch problem is shown in Fig. 18A. This time, there is one hot stream and there are two cold streams. Thus, as far as the number of streams is concerned, there should be no need to split a stream. However, the CP inequality also needs to be satisfied above the pinch: the hot stream, with a CP of 0.5, requires a cold stream with a greater CP. Neither of the two cold streams in Fig. 18A is large enough to satisfy the CP inequality. The design problem can be solved by splitting the hot stream into two branches, as shown in Fig. 18B. Splitting arbitrarily into two branches with a CP of 0.3 and 0.2 allows matches to be made that will satisfy the CP inequality. However, there is some freedom to change the branch flow rates.

Finally, Fig. 19A shows a below-pinch part of a problem. Cold Stream 3 has a CP of 0.7 and requires to be matched against a hot stream with a greater CP. Neither of the hot streams in Fig. 19A is large enough to satisfy the CP inequality. This time, the design problem is solved by splitting a cold stream into two branches, as shown in Fig. 19B. Now, the matches can be placed to satisfy the CP inequality required at the pinch, below the pinch.

Thus, there are two reasons why stream splitting is required at the pinch. The inequality regarding the number of streams must be satisfied; also, the CP inequality must be satisfied for each match.

THE GRAND COMPOSITE CURVE

So far, the discussion has related to problems in which there was one hot utility available and one cold utility

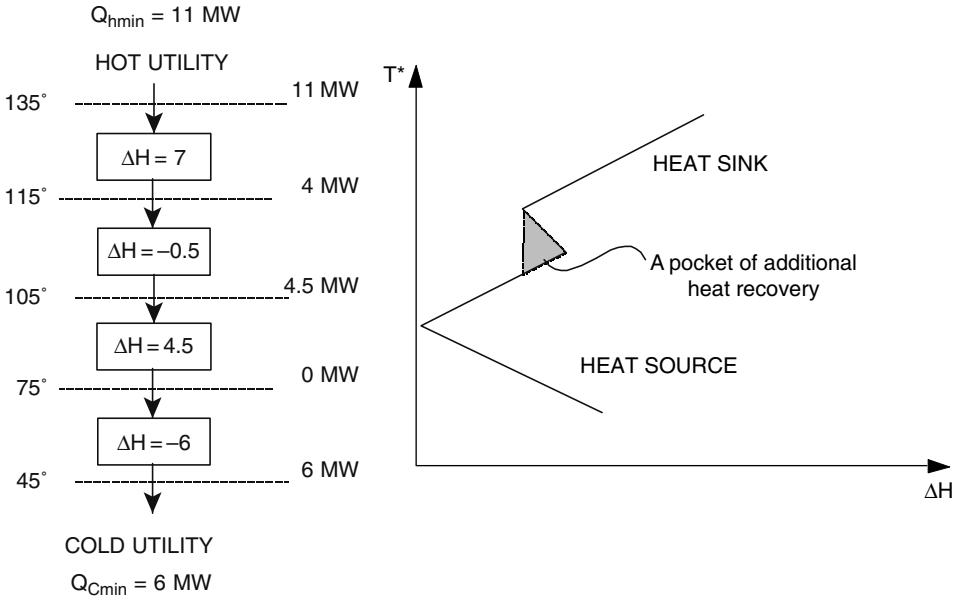

Fig. 20 The grand composite curve for the data in Table 1. *(View this art in color at www.dekker.com.)*

available. To deal with situations in which there are various utilities available, with different characteristics, another tool, known as the grand composite curve, is required. To construct the grand composite curve requires the heat flow from the problem table cascade to be plotted, as illustrated in Fig. 20. The grand composite curve represents the residual heating and cooling that are required after heat recovery has been carried

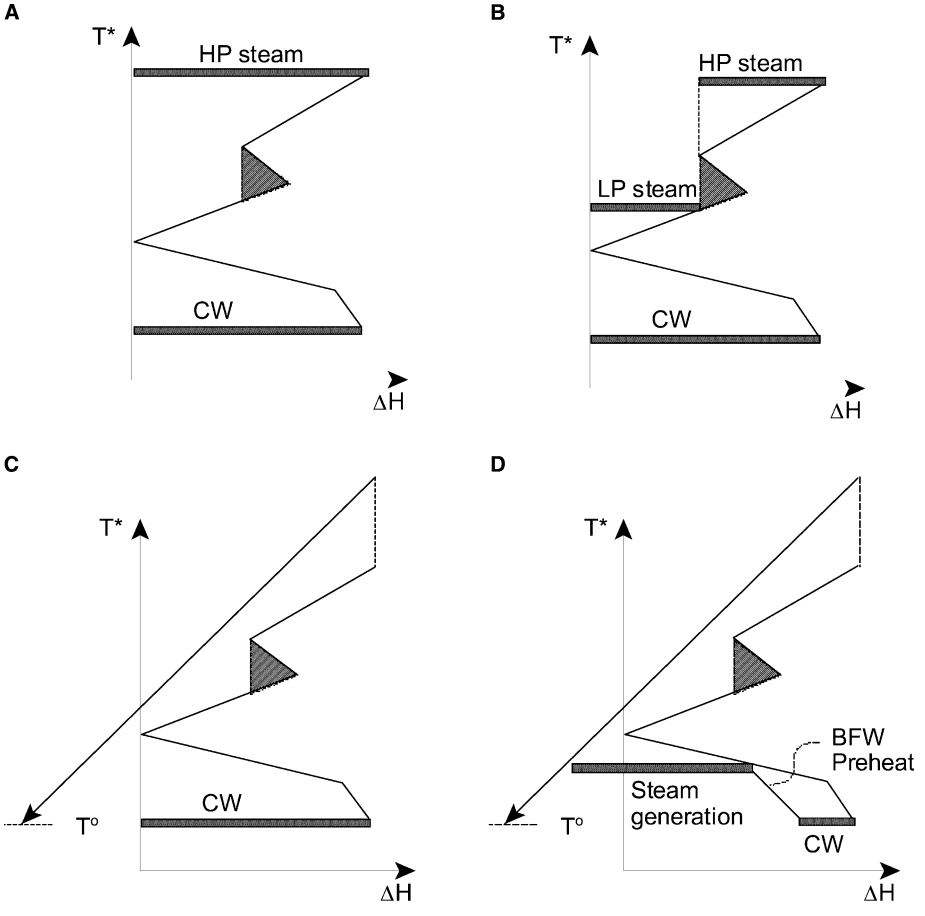

Fig. 21 Examples of the use of the grand composite curve. (A) High pressure stream and cooling water; (B) two steam levels and cooling water; (C) fuel gas and cooling water; (D) fuel gas, stream generation, and cooling water.

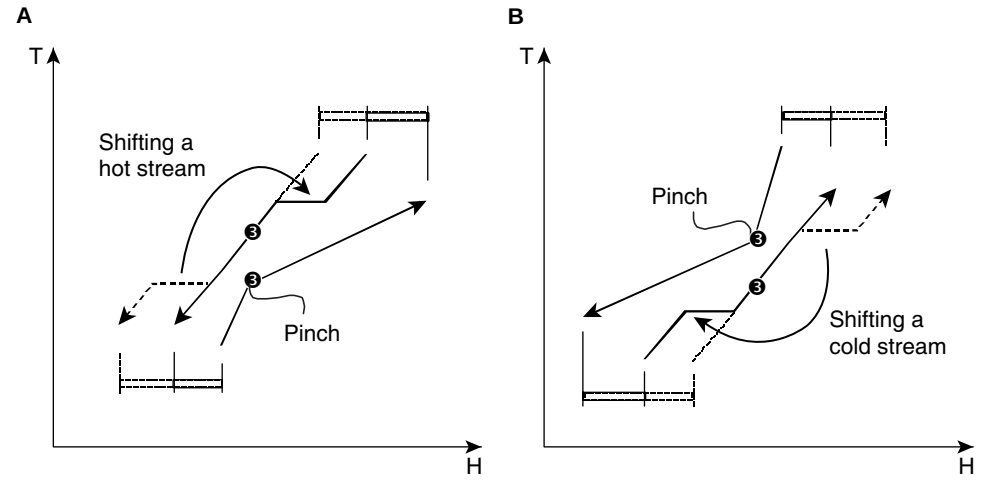

Fig. 22 Shifting streams across the pinch. (A) Shifting a hot stream from below to above the pinch reduces the utility requirements. (B) Shifting a cold stream from above to below the pinch reduces the utility requirements. *(View this art in color at www.dekker.com.)*

out. However, the heating and cooling are represented in terms of not only enthalpy, but also temperature. The grand composite curve provides a convenient tool to select the most appropriate mix of utilities for a problem.

In Fig. 20, it can be seen that there is a pocket where additional heat recovery takes place. This is in addition to the heat recovery that takes place throughout the cascade, as it is captured by the heat balance within each temperature interval. In the pocket, a local surplus of heat is used to satisfy a deficit of heat where possible.

Fig. 21 illustrates some examples of the use of the grand composite curve. Fig. 21(A) shows high-pressure (HP) steam and cooling water (CW) used to satisfy the heating and cooling requirements of a grand composite curve. In contrast, Fig. 21(B) shows the hot utility being satisfied by a mixture of HP and low-pressure (LP) steam. Fig. 21(C) shows yet another option in which a flue gas is used to provide the process hot utility. This flue gas could in principle be either that from a furnace or the exhaust from a gas turbine. The fourth option, in Fig. 21(D), shows the hot utility being satisfied by a furnace flue gas, but with cooling being taken up by LP steam generation, by a feedwater preheat and CW.

One point should be noted regarding the matching of utilities against the grand composite curve, as shown in Fig. 21. When a utility profile touches the grand composite curve, this does not imply that $\Delta T = 0$. The temperature shift included in the construction of the problem table means that the hot and cold streams are shifted by $\Delta T_{\min}/2$. This also applies to the hot and cold utilities. The result is that when a utility profile touches the grand composite curve, this implies that $\Delta T = \Delta T_{\min}$ rather than $\Delta T = 0$.

The grand composite curve is an extremely useful tool that can be used to screen and select different utilities and different utility mixes.

PROCESS CHANGES

The discussion so far has assumed that the supply and target temperatures and heat capacity flow rates of the streams in a heat exchanger network have been fixed. However, process flowsheets often feature degrees of freedom at the disposal of the designer that allow the performance of the heat exchanger network to be increased. Once the basic material and energy balance of the flowsheet have been fixed, all of the information required to carry out energy targeting is available (supply temperature, target temperature, and enthalpy as a function of temperature). There is often freedom to change the conditions within the material and energy balance within certain limits. Such changes might include, for example, changes in:

- Vaporizer and condenser pressures
- Distillation pressures
- Distillation reflux ratios
- Evaporator pressures
- Number of evaporator stages
- Reactor conversion
- Recycle flowrates

Fig. 22 illustrates how appropriate changes to the operating conditions within a flowsheet can create improvements to the targets for the process. In Fig. 22(A), a condensing stream, which is part of the hot composite curve below the pinch, has had its

pressure increased such that it is shifted from below the pinch to above the pinch. The effect is to reduce the cold utility and hot utility simultaneously. In general, shifting a hot stream from below the pinch to above the pinch causes an improvement in the targets for hot and cold utility.

The corresponding case for shifting a cold stream is shown in Fig. 22(B). This time, a vaporization stream, which is part of the cold composite curve above the pinch, has had its pressure decreased until it is below the pinch. This causes a decrease in the hot utility and the cold utility. Thus, any shift of a cold stream from above the pinch to below the pinch causes an improvement in the targets for the utilities. However, shifting streams relative to the pinch is only one way to bring about an improvement in the targets for utility consumption from process changes. In general,

- Increases in the total hot stream duty above the pinch
- Decreases in the total cold stream duty above the pinch
- Decreases in the total hot stream duty below the pinch
- Increases in the cold stream heat duty below the pinch

bring about a decrease in the utility requirements. These guidelines provide a reference for appropriate changes to improve the targets. Such process changes that improve heat recovery can be extremely important in creating cost-effective projects.

CONCLUSIONS

Pinch analysis exploits thermodynamics to allow energy systems to be targeted. These targets allow scoping and screening of different options. Composite curves can be used to provide insights into where process changes can improve targets. Process changes would mean exploiting the flexibility to change temperatures, flowrates, and pressures to alter the composite curves in a favorable way. At the same time, the grand composite curve can be used to screen different utility mixes. Once the most appropriate process conditions and mix of utilities have been chosen, the design of the heat exchanger network can proceed as described here.

Pipeline Safety

Glenn B. DeWolf
URS Corporation, Austin, Texas, U.S.A.

INTRODUCTION

Pipelines are an essential part of the energy and process industries infrastructure of modern society. They are generally viewed as a safe and economical means of transportation, but the perception of relative safety is subjective. Pipelines transport hazardous liquids and gases from their sources to customers. Transmission pipelines carry products at high pressure for relatively long distances. Gas pipeline distribution systems distribute gas in local communities, typically, at lower pressures than transmission lines. Numerous industry standards and government regulations dealing with design, construction, operations, and maintenance are the basis of managing pipeline safety. Factors affecting safety are associated with the attributes of a pipeline system and the threats that the system faces to its containment integrity. This includes factors that affect the likelihood and the severity of the consequences of failure. Technology and practices are continuing to evolve for better safety management.

THE PIPELINE INFRASTRUCTURE

Pipelines are a vital part of the energy and chemical transportation infrastructure of modern society. They are generally viewed as a safe and economical means to deliver liquid and gas fuels and chemical raw materials to customers. However, the perception of their safety varies with segments of the population. The most common pipeline with which the average person is familiar is the gas main of the local gas distribution system with service connections to homes and businesses in communities. The overall pipeline infrastructure is much more and includes long-distance transmission pipelines in addition to local distribution system pipelines. Besides natural gas, transmission pipelines transport crude oil, gasoline, petroleum products, and chemical products.

In the United States, there are approximately 160,000 mi of liquid transmission pipelines, 200,000 mi of gas transmission pipelines, and over 1,000,000 mi of distribution lines, if the mileage of individual customer connections to municipal gas mains is included.[1,2]

New pipeline design and construction projects are an ongoing part of infrastructure expansion driven by population growth and economic development. Existing pipeline modifications and repairs are also ongoing to maintain the infrastructure. Safety considerations are fundamental to all parts of the pipeline lifecycle from planning through decommissioning and removal from service.

Distribution pipelines are mostly in populated areas and transmission lines may cross through or near multiple populated areas intermittently with sparsely populated areas as they carry the product long distances. Pipelines lie within a right-of-way land corridor, usually leased from the landowners. The right-of-way provides access for ongoing maintenance and future expansion of the systems.

SAFETY CONCERNS

Safety concerns are associated with the flammability and, sometimes, toxic properties of transported products, the high pipeline pressures (hundreds of pounds to over a thousand pounds per square inch), and the proximity to population or environmentally sensitive areas at some locations along the rights-of-way.

CAUSES OF FAILURE

Failure causes have been identified and classified to varying degrees of detail. Specific causes of failure are grouped by categories. Within each of these categories, there are specific causes. Classifications differ in the published technical literature, including regulatory reporting, but the various classifications account for the same major causes. One classification of causes identifies 22 threats in five categories that lead to pipeline failure:[3]

1. External forces
    a. Earth movement
    b. Heavy rains/floods
    c. Lightning
    d. Cold weather
    e. Third party damage
    f. Previously damaged pipe
    g. Vandalism

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007900

2. Corrosion
    a. External corrosion
    b. Internal corrosion
    c. Stress corrosion cracking
3. Materials
    a. Defective pipe seam
    b. Defective fabrication weld
    c. Defective girth weld
    d. Construction damage
    e. Defective pipe
4. Equipment and operations
    a. Malfunction of control/relief equipment
    b. Threads stripped, broken coupling
    c. Gasket/O-ring failure
    d. Seal/pump packing failure
    e. Incorrect operation
5. Other
    a. Miscellaneous
    b. Unknown

Similar compilations can be found in other technical literature sources.[4]

As causes have been identified, they have been investigated for better understanding and eventual resolution. Industry and government support specific studies to examine serious problems in-depth. For example, after a number of seam failures years ago, it was found that some pipe manufactured before 1970 that was seam-welded by electric resistance welding was subject to unacceptable rates of seam failure. A specialized study focused on this single issue.[5] Results of research and other new knowledge about pipeline integrity and safety are presented at pipeline conferences that involve the regulators, industry, and other stakeholders. By these forums, the operators, regulators, and others share their knowledge about lessons learned, needs, and ways to improve pipeline integrity, reliability, and safety.

Historical experience with pipeline failures reveals that the two single most common causes for failures are outside forces and corrosion. There are variations in individual systems. Accordingly, a significant part of the effort in achieving better pipeline safety is corrosion control and damage prevention directed at outside forces. The other causes of pipeline failure, individually, contribute to a much smaller proportion of pipeline incidents, but they are still addressed because their aggregate contribution matters.

Corrosion occurs either internally or externally. External corrosion can occur on both surface and buried portions of the pipeline. Aboveground, piping is protected by painting or specialized coatings. Belowground, piping is protected by specialized coatings and cathodic protection. Coatings can be of a number of materials and can be applied at the factory and in the field. At welded joints, the coating is field-applied. An important safety aspect of coating application is that the pipe is properly cleaned before coating, and the coating properly applied. Cathodic protection (CP) applies a voltage differential between the pipe and the soil in such a way that metal loss from exposed (uncoated) metal, from a coating defect, is prevented or reduced. Maintenance of cathodic protection involves periodic checks on the CP system components and on the pipe-to-soil voltage levels at various locations along the pipeline route. Deviations from specified conditions can be an indication of external corrosion. Where such corrosion is suspected, the pipe can be dug up, examined, and repaired or replaced according to need.

Internal corrosion occurs from chemically reactive constituents in the product, including contaminants that might accumulate in the system over time and moisture. Acidic constituents are the major contributors to internal corrosion. Internal corrosion is controlled by monitoring and controlling the product composition and by periodic cleaning of the line. This is done by passing a ''cleaning pig'' through the line and removing the accumulated dirt and debris. A cleaning pig is a plug-like device pushed through the line by fluid pressure. Special devices called pig launchers and pig receivers (pig traps) are installed at each end of a piggable pipe section or segment.

For outside forces, appropriate controls must address human-caused damage and natural forces damage. Human-caused damage can be classified as first, second, or third party according to whether it is self-inflicted by the pipeline operating company, the companies contractors, or third parties. Third-party damage is a major category for human-caused outside force. Other outside forces include natural forces, such as subsidence, seismic movement, landslides, frost heave, expansion and contraction of soils, erosion, flooding, and even lightning strikes for surface equipment. Proper design and construction for environmental and location factors related to outside forces followed by operating procedures addresses these threats. Procedures include patrols along the right of way, informing persons living or working near the pipeline, contractors who may be involved in work on or near the right of way, and other public. Damage prevention programs that require a notification call to the pipeline operator by a party doing work near, on or subsurface to the right of way are also a means to reduce the chances of pipeline damage. A major study discusses damage prevention issues for pipelines.[6] Some outside force damages cause an immediate failure. However, sometimes damage occurs but a failure does not occur until later, sometimes after years.

Other causes arise from manufacturing and assembly defects in pipe and other pipeline system components. Welds and other types of joints, fittings, valves, and other system components can fail and result in a product release.

INTEGRITY ASSESSMENT

Integrity assessment is an important preventive measure that can discover pipe wall conditions, which if left unremedied could lead to pipeline failure. Integrity assessment has been defined in recent years through both industry consensus standards and government regulation as comprising inspection and testing followed by evaluation of a pipeline using internal line inspection, hydrostatic or pressure testing, and direct assessment.[4,7,8]

Internal line inspection uses instrumented in-line devices (smart pigs or intelligent pigs) that traverse the interior of a line being inspected. They are used to find anomalies in pipe wall thickness caused by corrosion or externally caused impact damage. Electronically collected data are processed to provide results interpreted by trained experts that reveal the condition of the line. It can be used for both gas and liquid lines. Technology development continues to move in the direction of developing methods for smaller line diameters and for higher resolution. More information on pigging can be found in specialized publications.[9,10]

In hydrostatic pressure testing, the pipeline is filled with water and pressurized to a specified test pressure that exceeds the operating pressure of the pipeline. If there are latent defects that are weak, a failure occurs. If failure does not occur then the line has been shown to be safe at normal operating pressure.

Direct assessment follows a prescribed process found in industry standards.[11] Direct assessment visually examines the pipeline at predetermined locations where there is a cause to believe that some corrosion or outside force damage has occurred.

TECHNICAL FACTORS AFFECTING SAFETY

The causes of failure are associated with attributes of a pipeline system that either increase or decrease the likelihood that the causes will be realized. A full comprehension of technical factors related to these attributes requires consideration of all parts of the system. The system comprises not only the line pipe, but also the pump stations for liquid lines and compressor stations for gas lines, controls, measurement, and storage facilities. After the initial compressor or pump station, at the gas or liquid supply source, periodic booster compressor or pump stations may be found along a pipeline route to repressurize the line to overcome the line's pressure drop and maintain flow.

Operating pressure is one variable affecting the potential for failure and its consequences. The pressure profile of system depends on the product, product flow rate, pipeline diameter, distance, and terrain elevation profiles. Gathering and transmission pipeline systems operate at a pressure of many hundreds and even over a thousand pounds per square inch of pressure. Gas distribution systems operate at lower pressures, even reaching a few inches of water gage pressure, at the customer end. The safety consequences of a pipeline system failure depend on the product, pressure, size of system, part of system, and location of the failure. Pipeline safety practices recognize these differences as well as features common to all systems. At the highest level, pipeline safety comprises managing the risks of failure in terms of prevention and mitigation. Prevention measures apply to reducing the likelihood of a failure and mitigation measures to reduce the severity of consequences. Regulations, industry consensus standards, and sound industry practices all target various factors that have a bearing on the likelihood or severity of a pipeline failure and product release.

LIKELIHOOD FACTORS

Likelihood factors are associated with the system attributes associated with the individual causes of failure. Likelihood factors include such considerations as pipe coating, degree of cathodic protection, soil conditions, pipe age, and maintenance history for corrosion control and depth of burial surrounding land use and activities, one-call system effectiveness, effectiveness of system marker signs, and other factors for third-party damage potential, to cite some examples.[12]

There are variations of such lists found throughout the literature, but the differences are usually at the conceptual level at which causes are defined and differences in terminology rather than fundamental differences in understanding the causes.

The causes are influenced by the specific attributes of a pipeline system. Good discussions of these be found in the technical literature. As with the causes, the system attributes can also be defined at different levels of resolution and different terms are sometimes used by different experts. Fundamentally, however, the major relationships between attributes and causes are commonly understood. Ongoing research continues to refine current knowledge about the relationships and provides a basis for ongoing improvements in pipeline safety practices, whether technical or procedural.

The safety performance of pipeline systems, as determined from an analysis of the history of pipeline

incidents, reveals that corrosion and outside force damage are the significant causes of failures for the pipeline and contribute to failures also for other parts of the overall system. The exception is for plastic piping systems, where the corrosion mechanism is absent.

Pipeline safety management is fundamentally establishing relationships between the causes of failure and pipeline system attributes, then controlling the variables associated with those attributes to within prescribed limits. By controlling the variables associated with the causes, failures are prevented and safety goals based on prevention are achieved. A second component of pipeline safety is recognizing consequences and locating systems to minimize adverse consequences in the event of failure and providing appropriate emergency preparedness and response capabilities in the event of failure. Pipeline safety regulations establish the minimum standards governing pipeline safety. Industry standards and sound industry practice will at least meet these requirements and will in some cases exceed the minimum safety standards according to specific needs on individual pipeline systems and parts of those systems.

The body of engineering and management practices that result from regulations and standards cover the entire lifecycle of a pipeline system, including design, construction, operations, and maintenance. In the United States, federal statutes and associated regulations govern gas and hazardous liquid pipelines. The federal regulations apply to all pipelines, within certain definitions, and the jurisdiction for pipeline safety through regulation rests with either the federal government or the state governments depending on whether an interstate or intrastate pipeline is involved. Federal pipeline regulations are developed and administered by the U.S. Department of Transportation, Pipeline and Hazardous Materials Safety Administration (PHMSA), Office of Pipeline Safety (OPS). The regulations are found in Title 49, Code of Federal Regulations, Parts 190 through 199.[13] Part 192 applies specifically to gas pipelines and Part 195 to hazardous liquid pipelines. There are periodic updates and some regulatory initiatives are always under way. The regulations are developed under statutory authority provided by the Congress. The statutes for pipeline safety are periodically modified. Some major new requirements were added for pipeline integrity management in the Pipeline Safety Improvement Act of 2002.[14]

Industry consensus standards are sometimes incorporated into the regulations by reference and become a regulatory requirement. Examples of some these standards incorporated by reference in the regulations for gas pipelines are listed in Table 1. The regulations and standards establish an implied level of safety based on adherence to the specified requirements. For intrastate pipelines, under the enforcement jurisdiction of the individual states, state regulations can be more stringent, but not less stringent, than the federal regulations.

Besides regulatory development and enforcement, other OPS functions include pipeline safety data analysis based on data collected by OPS through annual and incident reports from the industry and from OPS inspections of pipeline systems, sponsoring of research, and training.

Two other federal authorities, the National Transportation Safety Board (NTSB) and the General Accounting Office (GAO), also have a role. The NTSB investigates reportable pipeline incidents to determine the causes and to make recommendations to the OPS for future prevention. The GAO audits the OPS for performance against its mission and makes recommendations for improvements, if needed. A report, issued by GAO in 2000, reviewed progress on pipeline safety issues by the OPS.[15]

The remainder of this entry discusses the role of industry standards and regulations in pipeline safety, technical factors, and other issues related to pipeline safety.

As noted above, safety issues are associated with the potential for significant environmental impacts for liquid lines, as well as fire or explosion. For gas lines, the primary issue is fire and explosion. In both cases, safety depends on sound design, construction, operations, and maintenance. Standards for such practices are found in the industrial technical literature and include various designs and operating standards of organizations, such as the American Petroleum Institute (API), the American Society of Mechanical Engineers (ASME), and the American Society of Testing and Materials (ASTM), and the National Association of Corrosion Engineers (NACE), among others.[16–19] Regulations incorporate some of these and other standards by reference, as shown in Table 1, and add additional requirements targeting specific risk factors that affect safety. Similar standards are incorporated into hazardous liquid regulations.

Important topics covered by design standards are materials of construction, sizing pipe for wall thickness and operating pressure, and various design factors that provide a specific safety margin. They also deal with corrosion prevention and protection. Construction standards deal with welding, joints, field fabrication, and assembly, structural support depth of burial, and other topics. For example, one of API's standards covers pipeline welding.[20] There are also operating and maintenance standards. For example, there is a standard for determining the remaining strength of pipe when there is some corrosion, to decide on continuing service, replacement, or repair.[21]

The source of first-hand experience with the pipeline systems is the industry. There is an ongoing effort

Table 1 Examples of standards incorporated by reference under the requirements of 49 CFR part 192

Organization	Standard

between the OPS, industry, the state regulatory agencies, and outside stakeholders to better understand the causes of pipeline incident failure and modify risk control measures, that is, prevention and mitigation measures to reduce safety risks. These efforts are supported by industry organizations, which include, but are not limited to, the:

- American Gas Association (AGA)
- Association of Oil Pipelines (AOPL)
- American Petroleum Institute (API)
- American Society of Civil Engineers (ASCE)
- American Society of Mechanical Engineers (ASME)
- American National Standards Institute (ANSI)
- Interstate Natural Gas Pipeline Association of America (INGAA)
- National Association of Corrosion Engineers (NACE).

There are other specialized organizations and numerous contractors and vendors doing research to develop better materials, design methods, inspection and testing methods, and other practices to enhance the safety of pipelines. Most operators have multiple staff involved in various technical committees associated with these organizations, and various key technical people carry certifications of various types. For example, key corrosion personnel typically carry various certifications from NACE.

In the regulations, factors are addressed by specific requirements. As an example, some of the requirements for the operation and maintenance of natural gas pipelines under 49 CFR 192 Subparts L and M are shown in Table 2.

CONSEQUENCE FACTORS

The safety consequences of a pipeline failure depend on the product carried, pressure, diameter, time to shut off, distance between isolation points, and proximity to persons who could be affected. Historically, most of the harm from accidents has been to workers near the line. Some notable incidents have involved the public.

The product, conditions on the line, and conditions in the surroundings affect consequences. For example, high-pressure gas lines, which may fail by rupture, can result in a jet fire that is usually oriented vertically. The fire burns with intense heat and the primary threat is from the heat radiation within a certain distance from the fire. Flammable liquids can also burn by jet fires, but also offer the potential for a pool fire. The potential for a specific type of fire (or even a vapor explosion) varies with a number of conditions, including product properties, release conditions, and the presence of a suitable ignition source. There are releases of flammable materials for which ignition does not occur.

PIPELINE INTEGRITY MANAGEMENT FOR TRANSMISSION PIPELINES IN HIGH-CONSEQUENCE AREAS

New industry standards for pipeline integrity management began to appear in 1996.[22] New OPS regulations defining requirements for pipeline integrity management programs have been established since 2000 for both liquid and gas pipeline systems.[7,8] These standards and regulations have more explicitly defined requirements for integrity and, hence, safety management of pipelines. They define an overall process or management system, which explicitly calls for threat identification, risk-based evaluation, formal inspection, and testing referred to as pipeline integrity assessments, appropriate evaluation of the resulting data, identification and selection of prevention and mitigation measures, monitoring, and formal performance measurement based on defined performance measures. An important concept in these requirements is recognizing high-consequence areas (HCAs), based on the potential for safety and environmental impacts of a product release from a pipeline. High-consequence areas are defined in the regulations.

The purpose of formal pipeline integrity management is to better manage safety in HCAs. There are several types of HCAs and definitions differ between those designated for gas and liquid pipelines. An example for gas pipelines is:[7]

- All Class 3 and 4 locations (the definition of class locations for gas pipelines is already a part of the regulations and is based on differences in implied population density.) These are areas where there are at least 46 buildings intended for human occupancy or any buildings with four or more stories aboveground within 660 ft of the pipeline along any continuous mile of its length, respectively.
- A location not Class 3 or 4 that has an ''identified site'' within a potential impact circle of an impact radius calculated from a specified equation in the regulation.

Identified site is defined in the gas integrity management program (IMP) regulation. For liquid pipelines, HCAs include highly populated areas, other populated areas, navigable waterways, drinking water supplies, and ecologically sensitive areas.

Pipeline operators must implement an IMP, which includes periodic inspection, testing, and integration

Table 2 Example of some regulatory requirements for natural gas lines that address specific risk factors

Operation and maintenance activities	Regulatory citation
Procedural manual for operations, maintenance, and emergencies	192.605
Change in class location: required study	192.609
Change in class location: confirmation or revision of maximum allowable operating pressure	192.611
Underwater inspection and reburial of pipelines in the Gulf of Mexico and its inlets	192.612
Continuing surveillance	192.613
Damage prevention program	192.614
Emergency plans	192.615
Public education	192.616
Investigation of failures	192.617
Maximum allowable operating pressure	192.619, 192.621, 192.623
Odorization of gas	192.625
Tapping pipelines under pressure	192.627
Purging of pipelines	192.629
Replacement, repair, or removal from service of unsafe pipelines	192.703(b)
Prompt repair of hazardous leaks	192.703(c)
Patrolling	192.705, 192.721
Leak surveys	192.706, 192.723
Line markers	192.707
Record keeping	192.709
General requirements for repair procedures	192.711
Permanent field repair of imperfections and damages	192.713
Permanent field repair of welds	192.715
Permanent field repair of leaks	192.717
Testing of repairs	192.719
Test requirements for reinstating service lines	192.725
Abandonment or deactivation of facilities	192.727
Compressor stations: inspection and testing of relief devices	192.731
Compressor stations: storage of combustible materials	192.735
Compressor stations: gas detection	192.736

High-consequence areas	192.761

of information related to pipeline integrity into a risk-based process for future inspection and testing and for remedial actions of potentially unsafe conditions. The major elements of an IMP for gas pipelines, found in 49 CFR Part 192, are listed below.[7] There are similar or analogous elements for liquid lines.[8]

1. Identification of HCAs.
2. Baseline assessment plan.

3. Threats identification, which must include data integration, and risk assessment for setting priorities for integrity assessment and evaluating preventive and mitigative measures.
4. Direct assessment plan, if applicable.
5. Provision for remediating conditions found during integrity assessment.
6. Process for continual evaluation and assessment.
7. Plan for confirmatory direct assessment.
8. Provisions for adding preventive and mitigative measures to protect HCAs.
9. Performance plan as outlined in ASME/ANSI B31.8S, section 9, which includes performance measures.
10. Record keeping.

16. Process for identification and assessment of newly defined HCAs.

RISK ASSESSMENT

Safety increases as risk decreases. Risk assessment is a tool that aids in understanding and making decisions about pipeline safety. Risk assessment is used in the pipeline industry as an aid in setting priorities for integrity assessment and for the application of other prevention and mitigation measures for pipeline integrity and safety. Risk assessment recognizes both the likelihood and the severity of consequences of failure through the classic equation:

$$\text{Risk} = \text{Likelihood} \times \text{Severity of consequences}$$

Common methods of risk assessment include relative risk numerical scoring methods and numerical probabilistic methods. With relative methods, scores and weighting factors are assigned to various risk factors and grouping of factors, based on system attributes, and an overall risk score is generated. The methods determine a score for likelihood of failure, the severity of the consequences of failure, and the overall risk. A pipeline is segmented and risks for each segment are determined to identify relative risk along a line. This aids in planning prevention and mitigation measures tailored to the differing levels of risk. Commercial software is available for some of the methods but individual operators often customize these packages for their specific systems. Operators also develop their own ranking systems. These systems vary in the way specific risk factors are accounted for and in the scoring methods, but contain many of the same factors.

REMEDIAL ACTIONS

Effective remedial actions are an important element in pipeline integrity and safety. They include repair, replacement, and relocation of pipe. Standard methods are used for repair of defects due to corrosion or outside force damage on pipelines. This includes line pipe, components, and pipe coatings. If the pipe is unsuited for repair, then replacement is made of appropriate lengths, which can range from a few feet to miles. In some cases, a solution to threats and potential adverse consequences is relocation. A new pipe is installed at a new location to deliver product between two specified points.

PREVENTION AND MITIGATION MEASURES

Integrity and safety involve application of prevention and mitigation measures to address the likelihood and consequence factors of risk, respectively. They can be classified broadly as engineering controls, people controls, and management controls.

Prevention and mitigation measures address the likelihood and severity of the consequences of failures, respectively. Under the pipeline integrity programs engendered by the new regulations, prevention and mitigation applied in HCAs might be greater than in non-HCA areas. For example, patrol frequency in a specific HCA could potentially be more frequent than in a non-HCA, or another HCA, if the threat of third-party damage to the system for that particular HCA suggested that an increased frequency would be an effective option for that particular locale in the system. A variety of enhanced prevention and mitigation measures could also be applied to other threats to pipeline integrity.

PERFORMANCE MONITORING AND MODIFICATION

Performance measurement is the way improvements in pipeline safety are determined. Changes in the

frequency and severity of incidents are a direct measure of performance.

This is a lagging measure rather than a leading measure. Leading measures are preferable in giving indications of progress or problems before a failure occurs. These include both technical measures and program and management measures. The latter deal with adherence to requirements defined for carrying out various prevention and mitigation activities. The former are associated with quantitative measures associated primarily with specific technical indicators of prevention. An example is the number or frequency of potential corrosion failures averted by the discovery and remediation of corrosion defects in the pipeline.

Applying lessons learned through the periodic performance evaluation leads to safety improvements.

SECURITY

As with other sectors of our society, the operating environment of the pipeline industry has been profoundly altered by September 11, 2001. Security has been elevated to a priority that previously had not been required when the major threat was an occasional and usually minor act of vandalism. In most cases, the threat with gas pipelines may be economic disruption more than public or environmental safety for most incident locations. The lines are buried through most of their runs and there may be more attractive surface targets. However, the threat is real and is being addressed. It is beyond the scope of this entry to elaborate in detail, but enhanced security measures are being evaluated and implemented throughout the industry.

CONCLUSIONS

Pipeline safety is associated with concerns about the effects of accidental release of fuels and chemicals transported under relatively high pressures in pipelines. There are a number of causes for pipeline failure. Increased understanding is leading to measures that are more specific to control specific causes of failure. The federal government has a significant role in pipeline safety through significant regulatory authority over pipelines. Industry and government have numerous institutions and mechanisms in place for meeting the mutual interest of preventing (and mitigating) pipeline incidents and maintaining pipeline safety. Among changes in the industry and regulatory establishments are more rigorous safety regulations, such as integrity management regulations, which comprise specific elements intended to improve safety when implemented by pipeline operation.

INTRODUCTION

The advent of recombinant DNA technologies over the past 20–30 yr has resulted in an impressive emergence of metabolic engineering as a powerful complement to classical chemical synthesis for the production of specialized pharmaceuticals and industrial compounds. The simplicity and low cost of growing plants makes them ideal systems for metabolic engineering. Here, we intend to provide a perspective of the advantages of plants for metabolic engineering, highlighting the significant hurdles that still need to be overcome. This entry begins by introducing plant metabolic engineering and by providing an overview of the main systems available, whole plants or plant cells in culture. We then describe the different approaches on hand for increasing flux through existing metabolic pathways and end by providing a perspective of the future of plants as chemical factories for the production of industrial materials and pharmaceuticals, or for removing pollutants from the environment.

PLANTS: THE NATURAL FACTORIES

Plant biotechnology is rapidly gaining momentum as a serious alternative to other biotechnological approaches for the production of fine chemicals, pharmaceuticals, and industrial products, for the cleaning of the environment through bioremediation while creating novel opportunities in agriculture. Plants are very attractive for biotechnological applications in large part because of the cheap availability of the main requirements for efficient plant growth, energy (sunlight), and carbon (CO_2). Man has also known how to grow, harvest, and process plant tissues since the beginning of modern agricultural practice. Plants contain an amazing diversity of genes encoding enzymes for thousands of distinct biochemical reactions and this natural genetic diversity dwarfs growing efforts in combinatorial chemistry to increase the available space of chemical entities. As a distinct advantage over synthetic chemical transformations and in contrast with microbes, plant cells are highly compartmentalized, facilitating, for example, the separation of substrates from the products. Thus, plants provide amazing opportunities for their use as natural factories.

PLANT METABOLIC ENGINEERING

In 1991, Bailey defined metabolic engineering as ''the improvement of cellular activities by manipulation of enzymatic, transport, and regulatory functions of the cell with the use of recombinant DNA technologies.''[1] Today, the availability of the complete genome sequence for several plants, together with the development of powerful techniques for the transformation and stable or transient expression of genes in plants brings plant metabolic engineering as a strong alternative to classical chemical synthesis for the production of pharmaceuticals and other important industrial compounds. Plant metabolic engineering involves the manipulation of existing metabolic pathways by either increasing or diverting flux to desired or from undesired products, respectively, or the generation of chemical entities not normally found in the plant production system (cells or whole plants, see next section) through the introduction of genes from other organisms. Essential elements in the toolbox of the metabolic engineer are mechanisms to eliminate or overexpress gene activity.

Strategies available to eliminate the activity of specific enzymes in a pathway involve one of several possible approaches:

1. Identification of a mutant gene for the corresponding enzyme. Traditionally, plant breeding has taken advantage of natural allelic diversity to introduce mutant alleles into the genetic background of interest. Alternatively, screens have been conducted to identify mutants with desired phenotypes. Transposons have provided powerful tools, facilitating the identification of mutants in any gene of interest through what is

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039300

currently known as ''reverse genetics.'' More recently, targeting-induced local lesions in genome (TILLING) have permitted the identification of single-nucleotide mutations in any gene in a randomly mutagenized plant population.[2]

4. Knocking out gene function by targeted RNA degradation. Double-stranded RNA interference (dsRNAi) today provides probably the preferred method to knock out gene function.[3] An emerging alternative to this is the use of RNase P-mediated RNA degradation.[4] Both of these approaches are dependent on the availability of methods for introducing and expressing RNA in the host plant.
5. Interfering with protein function using specific inhibitors or antibodies. There are many protein inhibitors of metabolic enzymes that, when overexpressed, could have the potential to inhibit specific enzymatic steps (e.g., Ref.[5]). Nonprotein inhibitors of metabolic enzymes are also extensively used, resulting in some potent plant herbicides for which resistance can be easily manipulated, or in the formation of new compounds, when nonessential pathways are inhibited.[6,7]

The expression of genes in plants or plant cells is dependent on several factors that include:

1. A method to introduce genes into the plant. Such methods are available for a number of plants. While *Agrobacterium*-mediated transformation provides a facile method and usually results in a low number of integration events, minimizing problems of cosuppression of endogenous genes, introduction of genes by particle bombardment has none of the host plant limitations imposed by the host preference of *Agrobacterium* and has been used in a broad range of plants.[8]
2. Promoters to direct gene expression in the appropriate spatial and temporal landscape. A large number of plant promoters capable of directing robust gene expression in almost every plant tissue have been identified.[9,10] An emerging alternative to using natural promoters is the generation of ''artificial'' or ''synthetic'' promoters that would provide the desired expression patterns.[11]
3. A source for the gene encoding the enzyme of interest. The completion (or near completion) of the sequencing of various plant genomes together with the availability of a large number of expressed sequence tags (ESTs) for plants where complete genome sequencing is impractical provide an enormous opportunity for the selection of genes encoding plant metabolic enzymes.

CHOICE OF PLANT SYSTEM FOR METABOLIC ENGINEERING

Whole Plants

Compared to animals, cells in culture (plant or animal), or microbes, whole plants provide a cheap and simple platform for large-scale mass production. Transgenic plants can be grown, maintained, and harvested using equipment already available from classical agricultural practices. The choice of a production plant for metabolic engineering depends on the specific metabolite to be produced and whether the necessary precursors are already present. Specialized organs (e.g., leaf hairs, glands, or trichomes) can be used both to sequester compounds and to provide for an accessible source for metabolite extraction.[12] There is a growing concern in using crop species for the production of phytochemicals, particularly pharmaceuticals, in areas where those crops are grown for food consumption purposes. Thus, plant species that do not hybridize with major crops or with wild relatives are gaining importance for the purposes of genetic manipulation.

Plant Cells in Culture

Cell culture offers the advantage of growth in minimal space without requirement for greenhouses and allows for development of uniform conditions to optimize phytochemical production. While cell culture may not always mimic the biochemical profile of cells as in the growing plant, it is possible to manipulate culture conditions, such that the appropriate array of genes are expressed and metabolites are biosynthesized and accumulated (e.g., treatment with elicitors and other stress inducers).[13] Cell lines may be transformed with genes encoding biosynthetic enzymes or regulatory factors and assessed for modification of metabolite profiles. Given that conditions are established for maximizing accumulation of the desired chemical constituents, plant cell culture is a useful alternative to growing differentiated plant tissues. In addition, cell culture may provide a platform to test genes that may later be utilized for the more time-consuming production of transgenic plants. For large-scale production of metabolites, whether they represent novel drugs, or unusual metabolites needed for performing nutritional studies, cell cultures are a good alternative to harvesting metabolites from rare plant species or from those refractory to transgenic manipulation.

Using Plant Genes in Microorganisms

Microorganisms (e.g., the gram-negative bacterium *Escherichia coli*) possess a biochemical profile similar

to plant plastids, such as chloroplasts. Because of the biochemical similarity between the microorganism and the plant plastid, the results obtained by genetic modification can be applied later to testing in plants. The advantage of using the microorganism initially is the savings in time as compared to production of a transgenic plant. Examples of this approach include application to manipulation of the carotenoid and isoprenoid biosynthetic pathways. This heterologous system has been used to test the function of plant transgenes encoding putative enzymes that utilize substrates produced by the bacterium.[14,15] Alternatively, *E. coli* cells have been used to screen for genes that may positively or negatively influence pathway flux.[16] These organisms have also proven to be expedient tools for testing potential strategies for manipulating pathway flux for pathways that operate in plant plastids.[17]

STRATEGIES FOR INCREASING FLUX OF EXISTING PATHWAYS

Manipulating the Activity of "Rate Limiting" Steps

Classically, flux constraints have largely been attributed to the presence of one or a few "rate limiting" or bottleneck enzymes in a pathway. The flux theory put forward by Kacser and Burns, and supported by elegant experimentation, questions the existence of single rate limiting enzymatic steps in biochemical pathways.[18,19] These studies provided the theory behind metabolic control analysis (MCA), which furnishes a tool to interpret why experiments aimed at manipulating metabolic pathways fail, largely a consequence of the distribution of the control of flux over multiple enzymes in a pathway, instead of one as the "rate limiting step" concept would suggest.[20] Nevertheless, several examples are available in the literature in which the expression of one or a few genes results in a significant increase in flux. For example, the expression of the chalcone isomerase enzyme in tomatoes resulted in a significant increase in the accumulation of flavonols, which are important nutraceutical components of the human diet.[21] Similarly, the overexpression of phytoene synthase in canola seeds dramatically increased flux into the carotenoid pathway.[22] Increasing the metabolic flux of upstream pathways that feed precursors for the synthesis of the desired compounds provides an additional strategy for engineering metabolism, with a good example provided by the increase of isoprenoid precursor for the manipulation of carotenoids.[23]

The experimental success in increasing metabolic flux by expressing one or a few key biosynthetic enzymes contrasts with the emerging notion that enzymes in metabolic pathways are often associated in large macromolecular complexes, or metabolons.[24] The most extreme example of a metabolon is the formation of a "metabolic channel" in which pathway intermediates are directly transferred between catalytic sites without diffusion. Clearly, if channeling is a general characteristic in metabolic pathways, the perturbation of the correct stoichiometry of the enzymes in a channel, for example, by overexpression, could have results opposite to what was expected. To what extent the formation of metabolons contributes to the distribution of the overall flux in a pathway over multiple enzymes, as suggested by MCA, remains to be established.

Metabolic Flux Analysis and Modeling

Metabolic flux is the rate at which the material is processed through a specific pathway. A general misconception is that an increase in flux through a pathway will result in the increased accumulation of the pathway products. This assumption is wrong because it fails to consider that pathway products can be the substrates for other chemical reactions. A case example is provided by the biosynthesis of amino acids. While the overall accumulation of amino acids can be increased by enhancing flux through their biosynthetic pathways, the accumulation of the free amino acids (i.e., those not incorporated into proteins) may not be affected. Thus, when investigating flux with the ultimate objective of modeling metabolic pathways, one needs to take into account the ultimate fate of the metabolites. The classical mass-balance approach requires measurements of the rates of substrate uptake, rates of metabolite secretion, and rates of biomass formation. Together with the estimation of metabolic pools and with knowledge of the metabolic networks involved, a fairly accurate model of flux through a pathway can be obtained. However, many plant metabolic pathways involve reversible reactions, multiple compartments, and parallel competing pathways that significantly complicate the mass-balance approach.[25] These complications can in part be solved by stable-isotope labeling under steady-state conditions, resulting in what is known as stable-isotope metabolic flux analysis, which has been applied to modeling flux though a number of plant metabolic pathways.[25]

Expression of Multiple Genes in Plants: Progress and Limitations

One way to overcome the limitations imposed by the flux theory is to overexpress multiple genes encoding enzymes of a pathway. There are significant limitations to introducing multiple genes in a transgenic plant and ensuring that they will all be expressed at the high

desired level, as exemplified by the attempts to increase the levels of monoterpenoid alkaloid biosynthesis by coexpressing tryptophan decarboxylase and strictosidine synthase.[26] In these studies, the analysis of a large number of transgenic tobacco plants showed a dramatic variation in the levels of expression of these two genes, largely a consequence of silencing and cosuppression.[26] While part of the problems encountered could be solved by minimizing the sequence homology between the transgenes and carefully controlling transgene copy number, significant hurdles prevent the ''stacking'' of genes in transgenic plants by conventional methods. Sequential sexual crossing of transgenic plants has permitted the stacking of up to three transgenes, and significant progress has been recently made in cotransformation techniques that permit the simultaneous insertion of multiple genes.[27,28] Emerging approaches to solve the problems associated with stacking transgenes include the expression of multiple genes from a single promoter creating translational fusions of multiple enzymes, which can then be cleaved into separate enzymes by the inclusion of convenient protease cleavage sites.[29] An alternative to the use of protease sites is the synthesis of a transcript, resembling a polycistronic mRNA, encoding multiple enzymes in a pathway. By having internal ribosome entry sites between the different subunits, translation of each enzyme can be achieved.[30] However, neither of these promising approaches has yet been utilized for the successful engineering of a plant metabolic pathway.

Diverting Flux Using Loss of Function Approaches

While the overexpression of metabolic enzymes provides a powerful tool in metabolic engineering, it is often as important to minimize flux through a pathway that results in an undesired product. As described before, several approaches are currently available for the downregulation or knockout of a specific enzymatic step. RNA interference (RNAi) is indeed emerging as a powerful complement to more classic loss of function methods.[31] But often, the most impressive pathway manipulation results are obtained when gain and loss-of-function approaches are combined to increase flux through one pathway while decreasing flux through a competing pathway. This combinatorial approach has proven to be very successful in modifying multiple lignin traits in aspen trees.[32]

Targeting Entire Pathways with Transcription Factors

According to MCA, increasing the speed of a rate limiting step in a biochemical pathway is often insufficient for a significant increase in the overall flux in the pathway. Metabolic pathways are often controlled by one or a few regulatory proteins that bind to the promoters of the genes encoding the enzymes in a pathway and activate their transcription. Thus, transcription factors provide an attractive alternative to the manipulation of single or multiple enzymes for increasing flux. Because of the conspicuous pigmentation provided by anthocyanin pigments, the flavonoid pathway provides one of the best-studied cases of control of a plant metabolic pathway.[33] Anthocyanin accumulation is regulated in many plant species by the concerted action of transcription factors corresponding to the MYB and bHLH families.[34] Not surprisingly, the regulators of anthocyanin biosynthesis have been among the first ones used to demonstrate the potential of transcription factors to activate entire pathways.[35] As examples of the successful application of this approach, the maize P1 (MYB family member) and C1 and R transcription factors have been used to activate separate branches of flavonoid biosynthesis in maize cultured cells, the ORCA3 (AP2 family member) to manipulate the accumulation of alkaloids in *Catharantus roseus* cultured cells, and the maize C1 and R to increase the accumulation of flavonols in tomato.[36–38] Transcription factors provide a powerful complement to other approaches to manipulate the accumulation of desired phytochemicals. As an example, a chimeric form of the maize C1 and R regulators of anthocyanin biosynthesis was combined with the silencing of a structural gene in the flavonol/anthocyanin pathway, flavanone 3-hydroxylase, to increase the content of phytoestrogenic isoflavones in soybean seeds.[39]

The identification of novel plant repressor domains, such as the EAR motif, expands the use of transcription factors to not only activate entire metabolic pathways, but also to inhibit them.[40] In addition to using natural transcription factors, an emerging approach is to artificially create transcription factors, primarily from the Zn-finger family, with known DNA-binding specificities.[41] Thus, the use of artificial DNA-binding domains fused to either transcriptional activation or repression motifs is likely to provide a powerful future tool for altering flux through entire metabolic pathways using a single transgene.

MAKING NEW COMPOUNDS IN PLANTS

Plants as a Source of Industrial Materials

Plants continue to be the unique source of a number of very important industrial materials that include wood, cotton, cork, and rubber. However, the advent of petroleum as a source of carbon for the chemical industry

has resulted in a significant reduction in the use of plants as the feedstock for organic industrial chemicals. In 1930, 30% of the organic chemicals were derived from plants, down to 1% in 1960.[42] Is there a future for metabolic engineering to revive the role of plants as a fundamental source of industrial materials? This question can only be answered by taking into account the economics involved in growing and harvesting the plants, extracting the desired compound, and separating it from other chemicals. Previous analyses highlighted the challenges associated with this.[43] One of the best-described examples of how plants could be used to manipulate industrial products is the formation of polyhydroxyalkanoates (PHA) in plants. These polyesters of 3-hydroxyacids have unique biodegradable and elastomeric properties, which make them highly desirable in a number of applications, such as the medical industry, and for making environmental friendly plastics. Polyhydroxyalkanoates accumulate in numerous bacteria and fungi for carbon storage, and the genes from bacteria were successfully introduced into the plastids of *Arabidopsis*, resulting in a significant accumulation of polymer.[27] As of today, the accumulation of PHAs of various compositions and chain lengths has been accomplished in a number of crop plants, yet significant hurdles need to be overcome to compete in price with cheaper plastics with similar properties obtained by chemical synthesis.[44]

Another plant polymer with multiple industrial applications, which is the subject of several efforts to modify its accumulation and properties, is starch. Starch is a polymer of two glucan polymers, the mainly linear amylose and the branched amylopectin. Depending on the proportion of amylose to amylopectin, and the length and branching of the chains, starches can have very different properties. Currently, a large number of enzymes are known in maize and other starch-producing plants that influence these fundamental properties of starches.[45]

Plants as Pharmaceutical Factories

Plant parts have a widespread use in traditional medicine (such as Indian ayurvedic medicine and Chinese herbal remedies), providing clues to bioactive principles with novel health and nutritional benefits that will contribute to resources for metabolic engineering. The small fraction of plants so far surveyed (<15% of terrestrial plants) has revealed an astonishing potential for the biosynthesis of small (<1000 Da) molecules, with over 100,000 of these phytochemicals already described.[46] These phytochemicals accumulate largely as a consequence of biotic and abiotic interactions of plants with their environment, and are mainly derived from what has been classically known as secondary metabolism. In addition to the important role that these compounds play as nutraceutical components of animal diet, many of these metabolites are bioactive, providing the basis for a large fraction of all the pharmaceuticals currently available in the market. Thus, a major thrust in plant metabolic engineering continues to be to exploit their huge biochemical diversity to make new compounds from existing ones or to increase the levels of compounds with biomedical or nutraceutical significance. Future genomic investigations of medicinal plants will yield novel enzymes and genes to further expand the repertoire available for metabolic engineering of either endogenous pathways or transfer to heterologous species for enhanced accumulation of novel drugs or lead compounds for further drug development, or production of novel enzymes for bioprocessing.

The exploitation of medicinal plants for metabolic engineering of undiscovered metabolites and metabolic pathways is still at its infancy and is likely to require the initial investment of molecular markers to provide plant genotype fingerprints followed by bioactivity guided fractionation to identify the target molecule(s) and further basic studies (precursor feeding, bioinformatics approaches to identify genes) to elucidate the relevant biosynthetic pathways.

Plants as Nutraceutical Factories

Modification of plants by metabolic engineering can have a profound impact on human health. For example, the grass family (Poaceae) members are the most important food crops worldwide, and include maize, wheat, barley, sorghum, pearl millet, and rice. The endosperm tissues of these crops serve as major food staples; unfortunately, they are deficient in nutritionally essential carotenoids. Endosperms of these food crops are generally low in provitamin A (1–10%) relative to nonprovitamin A carotenoids.[47] For example, the consumption of carotenoid-poor cereal crops is associated with vitamin A deficiency affecting 250 million children in developing countries.[48] Improved vitamin A nutrition could eliminate approximately 1.3–2.5 million annual deaths.[49] Carotenoids also have important health benefits in developed countries. In humans and animals, various carotenoids derived from plant sources act as antioxidants, protect against diseases such as cancer, heart, and eye diseases, and are important in vision, while other carotenoids are precursors to vitamin A and to retinoid compounds involved in development.[50–56] An alternative approach to alleviating vitamin A deficiency worldwide is to improve levels of provitamin A carotenoids in food staples such as corn, wheat, and rice by metabolic engineering. Preliminary success with metabolic engineering of the pathway in rice, tomato, tobacco, and canola points

to the potential of this approach.[57–60] Unexpected products in these transgenic plants, however, suggest that the technology is limited by current deficiencies in understanding of endogenous gene expression. Despite the preliminary successes using laboratory-optimized experimental transgenic materials, future integration of the pathway in local varieties will also entail pyramiding of multiple traits, a challenge that can be addressed by continuing research on pathway interactions and competition for common substrates.

A similar success was recently reported in the manipulation of folates (including tetrahydrofolate) in tomato fruits. Tetrahydrofolate is an essential cofactor for several one-carbon reactions including the DNA biosynthesis cycle and the methylation cycle, and hence, folate deficiency results in anemia. Diaz de la Garza and coworkers have recently shown that increasing up to 100-fold the biosynthesis of pteridine, a precursor for folate biosynthesis, resulted in a two-fold increase in the folate content in tomato fruit.[61] In this study, the investigators utilized a mammalian GTP cyclohydrolase I to bypass the negative feedback regulation featured in regulation of the corresponding plant enzyme.

Using Plant Compartments for Chemical Sequestration

Massive accumulation of metabolites may sometimes be problematic if transgenes are expressed constitutively throughout the plant. Several strategies can be used to overcome this problem. One approach is through the use of tissue-specific promoters, allowing for accumulation in either a specific organ or tissue. Alternatively, gene expression can be controlled in such a way that biosynthetic enzymes or metabolites are directed to specific cell compartments such as the vacuole or chloroplast. For the purpose of chloroplast accumulation, either the plastid genome itself may be engineered with the desired transgene(s) or nuclear-encoded transgenes may be outfitted with chloroplast-targeting signals. Powerful new plastid transformation methods have been developed over the past few years.[62] The expression of metabolic enzymes in plastids provides several advantages over the nuclear expression. Among these advantages is the higher level of expression possible, given the large number of plastids that a plant cell can harbor, and the impact on biosafety, given that in most crops, plastids are under maternal plastid inheritance, minimizing the risks associated with gene flow from pollen derived from genetically modified plants.

In addition to targeting metabolic pathways to specific organelles, it is conceivable that pathway intermediates or final products could be sequestered in specific subcellular compartments. This could have a significant impact on metabolite production by removing toxic compounds and increasing flux through the displacement of equilibrium. However, the challenge that remains is our ignorance of the possible pathways by which phytochemicals traffic within or between cells. It is well established that many phytochemicals are sequestered in the vacuole by modifications that include glutathione conjugations followed by the action of specific transporters, particularly from the ABC family.[63–65] However, it is becoming evident that, in addition to transporters, phytochemicals can traffic between compartments using specialized vesicles, minimizing the risks of undesired chemical reactions and decreasing their toxicity.[66,67] It is evident that once we learn more on the trafficking of phytochemicals, enormous opportunities will become available to manipulate these processes as an additional tool in the toolbox of the metabolic engineer.

EMERGING TECHNOLOGIES

Plant Diversity as a Source of New Genes

In the course of plant evolution, certain plant lineages have evolved unique biosynthetic pathways that offer opportunities to use genomic approaches to capture this biochemical diversity and provide tools for manipulating plants and other organisms that do not produce the compounds or where accumulation is blocked at a particular biosynthetic step. Even in a single species, such as maize, where many diverse lines are available, allelic variation offers opportunities to use molecular tools to direct breeding efforts using molecular probes for these particular alleles. For example, using association mapping, Buckler's group has identified specific candidate genes associated with starch accumulation and these results may be applied to metabolic engineering of starch accumulation by directing breeding efforts using molecular probes representing these novel alleles.[68]

Gene Shuffling and Directed Enzyme Evolution

Directed alteration of enzyme activity and substrate specificity can broaden the repertoire of metabolites produced in plants and other organisms. Error-prone DNA polymerases can be used for PCR amplification to generate mutations in plant genes, which are then expressed in bacteria or in other organisms that can be transformed with high efficiency, which are then screened for accumulation of novel compounds.[69] Gene shuffling technologies can produce a large number of enzyme variants, by shuffling fragments

from an existing library.[70,71] While the applications of gene shuffling are multiple and include selecting for enzymes with higher stability, the recent identification of new glyphosate *N*-acetyltransferase enzymes that resulted in increased resistance of various plants to the herbicide glyphosate provides a good example of the power of the approach.[72,73]

Need for New Technology

With the growing interest in metabolomics, a field that provides the necessary data for metabolic engineering, current methodologies are limited in giving resolution of metabolic constitution in complex organisms having multiple cell types and suborganellar compartments. Therefore, advancements in the fields of metabolomics and metabolic engineering will require new types of analytical technology that provide 3-D resolution overlaid with temporal variation. The future availability of such tools will have a far-reaching impact extending from plant metabolic engineering to medical research and diagnostics. Another area in which significant improvement is needed is in the integration of chemistry and biology, for example, to better establish how small molecules bind to proteins in enzyme–substrate or ligand–receptor relationships.

CONCLUSIONS

Despite the significant advances in the field of plant metabolic engineering, many of them described here, predicting the outcome of a metabolic engineering strategy (predictive metabolic engineering) remains a significant challenge.[74] This highlights the urgent need to continue to study fundamental aspects of plant metabolism including trafficking of small molecules and how those molecules interfere with fundamental cellular processes.

ACKNOWLEDGMENTS

We apologize to the many authors whom we have not referred to in this entry. Research in plant metabolic engineering in the Wurtzel Lab is supported by NIH (grant #S06-GM08225) and New York State and in the Grotewold Lab, by grants from the National Science Foundation (MCB-0130062) and the U.S. Department of Agriculture (NRICGP 2002-01267).

Plasma Etching

David G. Retzloff
Department of Chemical Engineering, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

A gas becomes a plasma when sufficient energy results in a significant number of gas molecules losing some or all of their outer shell electrons and become positively charged. The resulting state is an assembly of ions and electrons that are not bound together and can move more or less freely. The electrically charged gas is called an ionized gas. Sir William Crookes first studied this state of matter in 1879. Irvine Langumir was the first person to use the term plasma to describe this state of matter and it is now currently viewed as a fourth state of matter distinct from the well-known gas, liquid, and solid states of matter because of its special physical and electrical properties. The most commonly known forms of plasmas are fluorescent lamps, the sun and most star systems, lightning, the solar wind, the ionosphere around earth, and the Aurora Borealis to name a few.

The importance of plasma in plasma etching is due to the ''free'' electrons that are present. These electrons can be accelerated to very high energies in the presence of electromagnetic fields provided the gas is maintained at a sufficiently low pressure (vacuum) to minimize collisions with the gas and charged molecules. These energetic electrons can ''react'' with the gas molecules to produce chemical species (frequently halides such as F or Cl) capable of etching semiconductor materials such as silicon, gallium arsenide, and aluminum in an etching reaction. Liquid acids containing halides (such as HF and HCl) have already been known to chemically etch semiconductor materials. One of the advantages in using a plasma environment was the elimination of the liquid acid waste from the etching process. The second advantage of plasma etching is the directionality that is obtained in the etching process. Etching occurs principally in the direction normal to the surface of the semiconductor wafer. This directionality is due to the applied external electric field, which is normal to the wafer surface. The directionality occurs because the electrons and ions move along the electric field lines when colliding with the wafer surface, causing the surface to be reactive while the side walls that form remain relatively nonreactive. Etch directionality is practically impossible to achieve with liquid acid etching and is the principle reason that plasma etching is used almost exclusively in defining the various active regions in semiconductor processing. Photoresist techniques are used to define the regions on the wafer that are to be etched and the photoresist itself protects the areas on the wafer that are not to be etched.

HISTORY

Acid etching traces its origins back to the times of the Pharos in Egypt. It was used in medieval times to etch glass, swords, and other metallic objects. It was also used in the early days of manufacturing semiconductor solid-state devices. At that time, silicon was the principal material etched to define regions for active devices. It was common to etch with potassium hydroxide or hydrofluoric acid. Metal contacts were etched with various acids, for example aluminum contacts were etched with an acid mixture based on phosphoric and nitric acids. To make this procedure usable in semiconductor manufacturing, the surface that was to remain unetched had to be covered with a coating to protect it from the acid etch. The surface of the material being etched had to be exposed to the etching species. In medieval times, this was accomplished by covering the protected areas with a waxy coating. Such a technique, of course, would not be viable for the small structures needed in semiconductor manufacturing, so a new procedure called photolithography was developed to provide the spatial resolutions required. Photolithography uses a combination of photography and lithography. The surface of the part that is to be etched is covered with a material called photoresist. This is an organic polymer that becomes soluble in a developer after exposure to light. A mask that contains the image of the features to be etched is made. This mask is similar in function to the negative in photography. The mask is placed in the proximity of the surface to be etched. Light of the required wavelength is then focused on the mask and the image on the mask is transferred to the photoresist. The part with the photoresist coating is then placed in a developing solution to remove the resist that was exposed to the light, resulting in a pattern on the part that has exposed features that are being etched and covered (or protected)

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120026495

features that are not etched. This part is then placed in an etching bath to remove material by etching it away. Acid etching has no preferential direction for etching; as a result the feature being etched would be larger than the feature defined on the photoresist due to lateral etching. This is termed undercut. The time of etching and the experimentally determined etch rate were used to determine the required size of the image on the mask to obtain the desired feature size and depth on the part when etching was complete. In a production environment requiring precise control of feature size, this method has many drawbacks not the least of which is that the composition and strength of the etching solution change with time resulting in a varying etch rate. This was the state of affairs until 1979 when Winters and Coburn[1,2] studied the etching of silicon with XeF_2 as a source of atomic fluorine in the presence of an argon plasma. They observed that the silicon etch rate was very small for the Ar^+ ion beam alone and XeF_2 alone. Both of these measured etch rates were less than 6 Å/min. However, when both XeF_2 and the argon plasma were present, the etch rate rose to 55 Å/min. They quickly discovered that the plasma caused XeF_2 to dissociate to form fluorine that subsequently etched the silicon. Researchers studying plasma etching[1–7] observed that the etching was directional in the sense that almost all of the etching was in the direction of the DC component of the electromagnetic field at the surface of the wafer, which was perpendicular to the surface of the wafer. This observation led to precise pattern transfers from the mask to the wafer and ultimately opened the way for the development of submicron features on the surface of the wafer that are utilized in current manufacturing of VLSI semiconductor devices such as CPUs and dynamic memory. The most common and dominant use of plasma etching is in the production of semiconductor devices.

THE PLASMA REACTOR

In almost all commercial applications and certainly in the semiconductor industry, a plasma reactor at the basic level consists of two electrodes in a parallel plate or psuedoparallel plate configuration reminiscent of a parallel plate capacitor. Currently for advanced semiconductor designs, a single wafer parallel plate plasma reactor is used to achieve the maximum uniformity across the wafer during plasma etching. A simplified representation of this type of reactor is shown in Fig. 1. It consists of two electrodes in a parallel plate configuration located in a vacuum chamber. The electrodes are connected to an RF-power supply via an impedance matching network. The purpose of this tuning network is to maximize the transmitted power (and therefore minimize the reflected power) to the electromagnetic field that exists between the electrodes. The typical frequency for the RF-power supply is 13.56 MHz, which is dictated by the Federal Communications Commission so that there will not be any interference with the FM radio stations broadcasting in the area. A DC-power source can be used but is usually unsuitable when dielectric films may form at the wafer surface, which can extinguish a DC plasma discharge. Microwave power sources can also be used but these are found in special applications where there is a need for high-energy electrons in the plasma etch process. The RF-power generator is the most common power source in use. The other common reactor configuration is a hexagonal center electrode surrounded by a second electrode, which also serves as the outer wall of the vacuum chamber. This configuration in its most elementary form is depicted in Fig. 2. In this configuration, 24 wafers are processed simultaneously. The focus of the remainder of this presentation will be on the capacitively coupled parallel plate configuration with an RF-power supply for single wafer processing, as it is a common reactor configuration. However, advanced plasma etcher design for semiconductor processing now employs a second inductively coupled powered RF electrode to obtain a more uniform plasma environment across the wafer (see for example, http://www.oxfordplasma.de/technols/rie_icp.htm, http://cfd.plasmatrancetechno.com/, http://cfdplasma.trancetechno.com/ch2.pdf). Almost all of the material presented will apply to any plasma reactor configuration used for plasma etching. A vacuum environment for the plasma etcher is required so that the electromagnetic field can interact with the electrons present and accelerate them to very high velocities between collisions so that the electrons attain large translational energies sufficient to drive the required plasma reactions. There must be adequate time between collisions for the electrons to acquire the translational energy needed.

The feed gas to the reactor is composed of molecules that contain the etching species. Fluorine containing molecules such as CF_4, CF_3H, or SiF_6 are used to etch silicon. Molecules such as H_2 or O_2 may also be present in the feed gas to control the reaction pathways and will be subsequently discussed. This feed mixture is termed the recipe for the etching process. To etch aluminum or aluminum silicide, which are used to make the electrical contacts to the active device region, a chlorine containing gas such as BCl_3 is used.

THE PLASMA ETCHING PROCESS

The plasma etching process consists of two components. The first is the physics and chemistry that occur

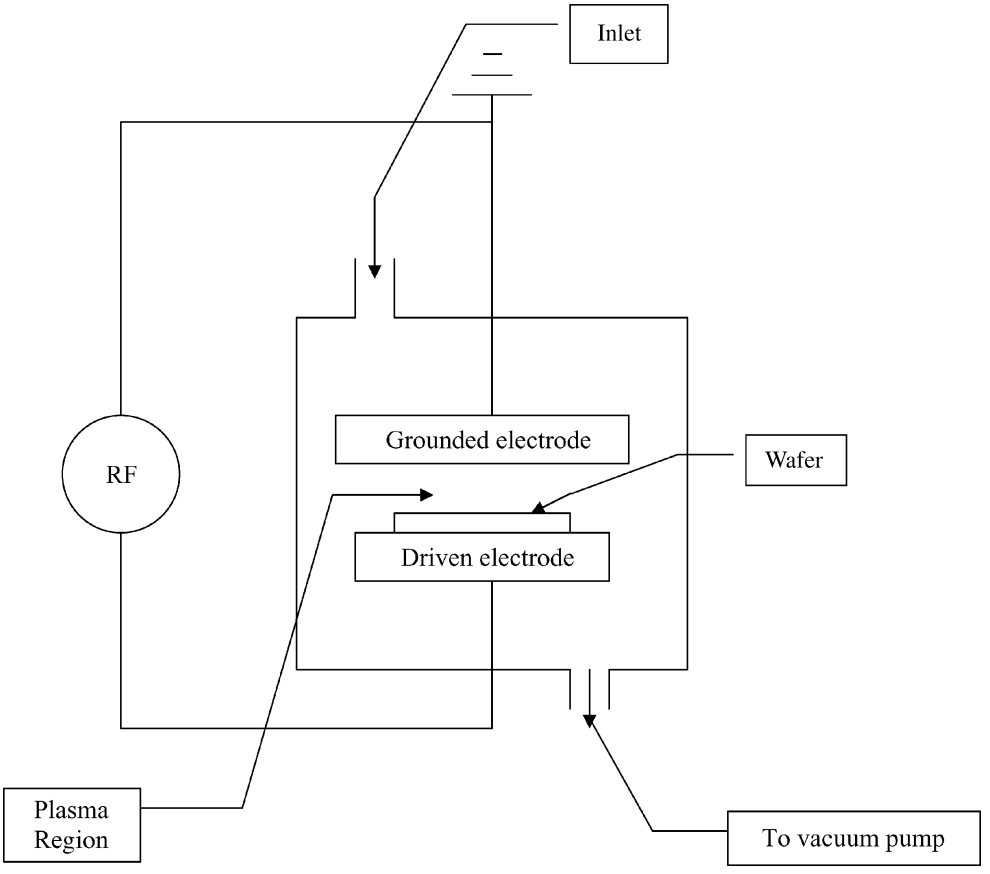

Fig. 1 Prototype single wafer parallel plate plasma etcher.

in the plasma, i.e., the physical volume between the two electrodes in the plasma reactor. The second is the physical and chemical processes that occur at the surface of the wafer (substrate). They will now be discussed in the order given above. For many commercial applications, the wafer is located on the driven electrode while the other electrode is connected to electrical ground. This configuration will be used for the purpose of discussion. The reverse configuration is also frequently found. The walls of the plasma reactor are normally grounded. To describe the etch process the space between the two electrodes is divided into three regions as depicted in Fig. 3. There is a positive space charge layer near the surface of the grounded and driven electrodes, which defines two of the three regions mentioned. There is also a positive space charge layer near the surface of any probe or wall that contacts the plasma. If one looks closely at these regions, they appear dark as the electrons in these regions have not been accelerated by the electromagnetic field to sufficiently high translational energy to achieve energy transfer to the neutral molecules by ''collision,'' which causes the outer shell electrons of the neutral molecules to make an excited state transition with an accompanying emission of radiation characteristic of that excited state as it relaxes to the ground state. The remainder of the space between the electrodes consists of a quasineutral region containing approximately equal numbers of positive and negative species and is termed the plasma. In this region there exist a large number of excited molecules, which relax back to the ground state with the emission of radiation causing the region to ''glow.'' Sometimes this region is called the glow discharge region. In this plasma region, the reaction chemistry necessary to produce the etching species occurs. A complete description of the chemistry involved is quite complex as can be seen in the work of Kushner[8] and Smolinsky and Flamm[9] for C_nF_m chemistry, which is used in the etching of silicon and silicon dioxide.

The plasma phase chemistry is most easily illustrated for a Freon 14 (CF_4) feed gas and provides the proto-type for understanding the processes in the plasma phase. The plasma chemistry must perform two tasks. First, it must generate the etching species and second, it must provide one or more additional electrons to sustain the plasma environment, as electrons are continually lost due to collisions with the walls of the reactor, recombination with positively charged ions, and flow out of the reactor towards

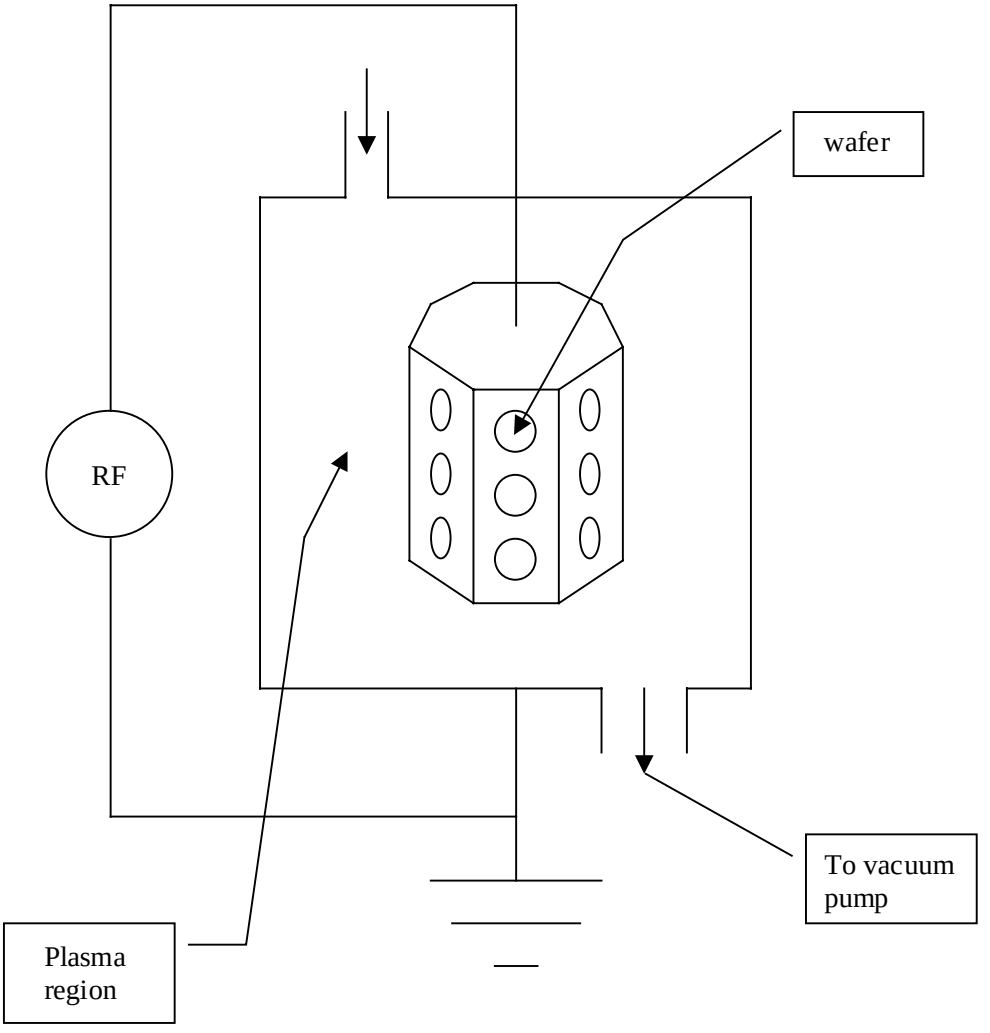

Fig. 2 Prototype hexode plasma etcher.

the vacuum pump. The following reaction occurs in the plasma:

$$CF_4 + e^- \rightarrow F + CF_3^+ + 2e^-$$

This is the simplest proto-type of the chemical processes that occur in the plasma phase. An overview of the basic plasma chemistry involved in a plasma etcher is given by Bell.[10] The characteristic glow of a plasma discharge is due to the emission or electromagnetic radiation due to the relaxation of an excited molecule to a ground or lower energy state. The glow process can be represented by a ''reaction'' of the following type:

$$CF_4 + e^- \rightarrow CF_4^* + e^-$$
$$CF_4^* \rightarrow CF_4 + hf$$

where f represents the frequency of emitted radiation and hf is the energy of the emitted radiation. This is a simplification of the processes that give rise to the glow because there are a number of molecular and atom species present in an industrial plasma that can be excited by collisions and relax back to a lower energy state by the emission of visible, higher frequency, and lower frequency radiations. The radiation field contains frequencies from all of these species as well. However, processes that result in higher frequency radiation are not significant in commercial etching.

For the plasma chemistry illustrated above, the chemistry at the surface of a silicon wafer is given by:

$$4F + Si \rightarrow SiF_4$$

This, of course, represents the overall chemical transformation that occurs and as such is a simplification of the detailed chemistry involved. A discussion

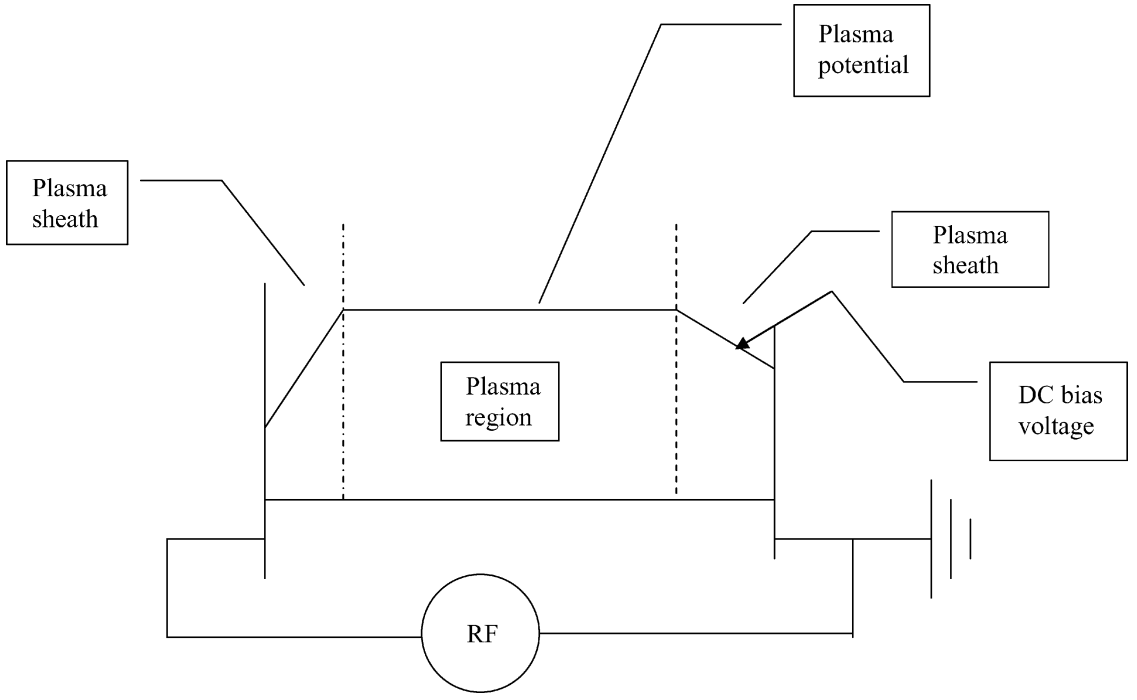

Fig. 3 DC potential, plasma, and sheath regions. The sheath region is a positive space charge region.

of the reaction mechanisms involved in the fluorine chemistry etching of silicon and silicon dioxide appears in.[2,11,12] The etch rate (reaction rate of silicon or silicon dioxide with fluorine at the surface of the wafer) for etching Si and SiO_2 has been measured and the possible chemical mechanisms that occur at the wafer surface discussed by Flamm and coworkers.[13] They report their results in terms of a standard Arrhenius form of a reaction rate with a first order dependence on the atomic fluorine concentration.

Two important observations have been made for etching SiO_2 and Si. First, the addition of O_2 to the feed increases the etch rates for both species dramatically and reaches a maximum at 12% O_2 for etching Si and 20% O_2 when etching SiO_2. However, for O_2 concentrations greater than 20% the etch rate for Si decreases much more rapidly than for SiO_2. Second, the addition of H_2 to the feed in amounts less than 40% does not effect the etch rate of SiO_2 but monotonically decreases the etch rate of Si to nearly zero at the 40% level.[14,15] Selectivities (this concept will be discussed later) for etching SiO_2 over Si of 40 : 1 are possible with CF_4/H_2. The increase in the etch rate of Si with the addition of O_2 is attributed to the following mechanism:

$$CF_4 + e^- \rightarrow F + CF_3^+ + 2e^-$$
$$CF_3^+ + O_2 + e^- \rightarrow 3F + CO_2$$
$$4F + Si \rightarrow SiF_4$$

The effects of H_2 on the Si an SiO_2 etch rates are due to the reactions:

$$CF_4 + e^- \rightarrow F + CF_3^+ + 2e^-$$
$$H_2 + 2F \rightarrow 2HF$$
$$4F + Si \rightarrow SiF_4$$

and

$$CF_4 + e^- \rightarrow F + CF_3^+ + 2e^-$$
$$4F + SiO_2 \rightarrow SiF_4 + 2O$$
$$H_2 + O \rightarrow H_2O$$

These mechanisms are grossly oversimplified and definitely not correct in detail but suggest the type of chemical competition that may occur.

A similar set of stoichiometric equations can be written for the etching of aluminum via chlorine chemistry, i.e.,

$$BCl_3 + e^- \rightarrow BCl_2^+ + Cl + 2e^-$$
$$3Cl + Al \rightarrow AlCl_3$$

See Tokunaga and Hess[16] for a discussion of aluminum etching using carbon tetrachloride.

Other materials that are normally etched in a microelectronics environment are poly-silicon, silicon nitride, doped poly-silicon, aluminum, gallium arsenide, and gold. The plasma chemistry involved is

analogous to that given previously, with the appropriate chemical species being present in the feed to provide the required etching species. A review of the chemicals and chemistry currently used in plasma etching for microelectronics applications appears in the work of Flamm and Donnelly.[17]

THEORETICAL CONSIDERATIONS IN PLASMA ETCHING

Most of the basic concepts in plasma etching are a result of the fact that the electron has an exceedingly small mass compared to atoms and molecules and the Lorentz force law for charged species in an electromagnetic field. The assumption of equilibrium or at least quasithermodynamic equilibrium plays a central role in our understanding of the plasma processes. This manifests itself in the use of the Maxwell-Boltzmann distribution to describe the energy distribution of the species in the plasma when describing particular physical phenomena at the elementary level in the plasma. This presentation begins with a review of several elementary physical principles. Charged species in an external electromagnetic field characterized by **E** and **B** fields experience a force called the Lorentz force given by $\mathbf{F} = q\mathbf{E} + q\mathbf{v} \times \mathbf{B}$ where q is the charge on the charged particle and **v** is the vector velocity of the charged particle. This causes the charged particle to accelerate. This accelerating charged particle then collides with other species present. The collisions tend to dissipate the translational energy of the charged particle and randomize the direction of motion. Thus, to accelerate the electrons to relative high translational energies to initiate plasma reactions, a vacuum environment is required to reduce the number of collisions per unit time and to allow an overall direction of motion to be established for the charged particles along the direction of the electric field. Typically, commercial plasma etching equipment operates in the high millitorr pressure range with an RF-power supply capable of up to 2 KW at a frequency of 13.56 MHz. It is an interesting aside that experimentally there clearly are sufficient electrons present to produce a plasma when the RP-power is first applied to the electrodes at low pressure as the plasma can be seen to glow. However, the two main mechanisms for producing such electrons, high field emission and thermionic emission, cannot account for the electron density necessary to produce the plasma. Thus, the true source of these initial electrons remains unknown.

Charge particles in an electromagnetic field move in a manner so as to produce an opposing induced electromagnetic field consistent with any constraints on the charged particles. This phenomenon is called shielding and also occurs in such areas as waveguides and ideal capacitors. Also, because electrons have such a small mass relative to the ions, they respond almost instantaneously to changes in the electromagnetic field while the positively charged ions to a first approximation remain stationary on the time scale of a 13.56 MHz RF-power supply. These two physical effects are responsible for the formation of an approximately equipotential region between the electrodes, which is approximately charge neutral on average, called the plasma, Debye shielding, the plasma sheath, the positive space charge, and the plasma potential. The equipotential region is a result of the shielding. Because the electrons have smaller mass, any surface at a fixed potential in contact with the plasma will initially experience a larger flux of electrons than positive ions, thus causing the surface to charge up negatively. This will continue until an opposing field builds up to oppose the motion of the electrons and results in equal fluxes of both electrons and positive ions. This is called Debye shielding and causes the potential of the surface to be lower than that of the plasma. The potential of the plasma is referred to as the plasma potential, V_p. This is true for all surfaces in contact with the plasma. Thus, the plasma potential represents the highest potential in the plasma etcher. If the surface is electrically floating with a potential V_f, the difference, $V_p - V_f$, is approximately 15 volts. The region between the plasma and any surface over which a potential difference occurs is called the plasma sheath. The width of the sheath is approximately the Debye length, which is on the order of 100 μm for typical plasmas. There is yet another feature of a plasma that occurs because of the very large mobility of the electrons relative to the ions. This is the self-bias induced in an RF-plasma. The RF generator produces a sinusoidal voltage waveform at the generator. However, the voltage waveform in the plasma etcher acquired a negative DC offset voltage. A high-voltage probe can measure this. This self-bias is on the order of half the applied RF peak-to-peak voltage. In addition, the sheath region acquires a net positive space charge. The relative sizes of the two electrodes in a plasma etcher directly influence the magnitude of the sheath voltage at these electrodes. It has been reported by Koenig[18] that the voltages at the two electrodes (labeled 1 and 2 in this formula) are given by

$$V_1/V_2 = A_2^4/A_1^4$$

This formula shows that the larger voltage sheath appears at the smaller electrode and is where the semiconductor wafer is normally located. Experimental measurements of these voltages suggest that the area ratio should be to a power smaller than 4 and greater than 1. One therefore expects sputtering to be greater

at the smaller electrode because sputtering at a surface is directly related to the magnitude of the voltage at that surface. Sputtering is the phenomenon of material ejection at a surface due to the collisions of atoms and molecules with this surface. All of these observations have been obtained by considering a simplified model that focuses on specific features of the processes that occur in a plasma.

A comprehensive model of the plasma etching environment is important for understanding how plasma etching works, improving the uniformity of the etch process, and in improving the design of a plasma etcher. Early efforts to model this process made an analogy with catalytic reactions for which a boundary layer formed at the surface due to the gas flow. The process was viewed in six steps: 1) A bulk flow of the feed gas (the etchant is produced in the bulk flow by chemical reaction) that forms a boundary layer at the wafer surface; 2) Diffusion of the etchant through the boundary layer to the wafer surface; 3) Adsorption of the etchant on the wafer surface; 4) Etchant reaction with the wafer surface; 5) Desorption of the reaction products from the wafer surface; and 6) Diffusion of the reaction products from the wafer surface to the bulk flow. This model evolved to a more fundamental description of a plasma etcher that started with kinetic theory and employed a Chapman-Enskog approach to obtain the continuum limit equations for mass, energy, and momentum. For an excellent treatment of this method, see the work of Jancel and Kahan.[19] These balance equations together with Maxwell's equations for the electromagnetic field provide a complete set of equations to describe the behavior of a plasma etcher. The Lorentz force law for charged particles contributes a term to the energy and momentum balances that is not usually present in most chemical engineering problems. There is a large literature on modeling a plasma etcher, which continues to increase every year. The general approach is illustrated in the work of several researchers.[20–29] Models of the etching process using the Boltzmann equations directly have also been proposed; however, for applications the continuum equations appear more suitable and thus a discussion of the Boltzmann equation approach to describing the etching process will not be pursued here. The interested reader may consult the work of Jensen and Graves,[20] Boeuf,[22] Tsai and Wu,[25] Kushner,[27,28] and Blaw et. al.[29] and the references therein for a discussion of these alternative models.

The models for a plasma etcher are usually one-dimensional (direction perpendicular to the electrodes in parallel plate geometry), use mobility limited description of the velocity field, use one energy equation that only involves the electron temperature, and write the electric potential in terms of Poisson's equation. This immediately eliminates spatial variations across the wafer, ignores temperature differences between the ions, neutrals, and the electrons, ignores the momentum exchange between the ions and the neutral molecules, and does not consider the fringing electromagnetic field that exists at the edge of the wafer when the wafer is approximately the same size as the electrode on which it resides. It is important to correctly predict the variation in the etch rate across the wafer as this has a direct influence on the final number of usable chips obtained from the wafer. Experimental measurements have established that in the plasma the electron temperature is on the order of 23,000 K, the ion temperature is 500 K, and the neutral temperature is 300 K. Inherent in these numbers is the assumption that the energy distribution for each species can be characterized by an equilibrium (Maxwell-Boltzmann) energy distribution, at least locally. This, of course, causes enormous fundamental problems with thermodynamic considerations. The concept of a local thermodynamic equilibrium has been advanced to address these problems but this concept has internal inconsistencies. The idea that there are species at distinctly different temperatures interacting and chemically reacting is fundamentally at odds with the concept of thermodynamic equilibrium. This also raises some interesting questions such as what does one write as an expression for the chemical rate of reaction? Specifically what is the energy dependence of the reaction rate expression? Is it Arrhenius in form? How does one treat species at different temperatures? Should one assign the concept of a phase to each species that has a characteristically different temperature, i.e., the electrons, the ions, and the neutral molecules? Of course, the phase in this context is not the same as the concept of gas, liquid, and solid. Rather, it is a conceptual way to describe the plasma by characterizing it as a collection of phases, each at a specific temperature, that interact both chemically and physically. The concept of temperature is retained, although it will require nonequilibrium thermodynamics to provide a suitable definition for temperature. The phases exchange energy and momentum and each phase moves with a characteristic vector velocity. The advantages of this approach are that it retains the usual concept of temperature and allows the energy balance for each phase to be written in terms of the temperature of that phase, the chemical reaction rates can be written down explicitly from the usual fundamental considerations, and the energy dependence of the chemical reaction rate is Arrhenius in form. The temperature that appears in this expression is a mass weight average of the temperature of the two species involved. This model reduces to models that have been previously used under appropriate assumptions. If we use the Freon-14 example and associate the electron with subscript 1, CF_3^+ with subscript 2, CF_4 with subscript 3,

and F with subscript 4, then we obtain the following model:

Mass Balance:

$$\partial n_1/\partial t + \nabla(n_1\mathbf{v}_1) = r_1$$
$$\partial n_2/\partial t + \nabla(n_2\mathbf{v}_2) = r_1$$
$$\partial n_3/\partial t + \nabla\cdot(n_3\mathbf{v}) = -r_1 + D_3\nabla^2 n_3$$
$$\partial n_4/\partial t + \nabla\cdot(n_4\mathbf{v}) = r_1 + D_4\nabla^2 n_4$$
$$\mathbf{v} = (\rho_3\mathbf{v}_3 + \rho_4\mathbf{v}_4)/(\rho_3 + \rho_4);$$
$$\rho_i = m_i n_i; \quad \rho = m_3 n_3 + m_4 n_4$$

Momentum Balance:

$$\rho_1(\partial\mathbf{v}_1/\partial t + \mathbf{v}_1\cdot\nabla\mathbf{v}_1) = \rho_1\mathbf{g} - n_1 e(\mathbf{E} + \mathbf{v}_1\times\mathbf{B}) + (\rho_1/\tau_1)(\mathbf{v}_2 - \mathbf{v}_1) + (\rho_1/\tau_1)(\mathbf{v} - \mathbf{v}_1)$$
$$\rho_2(\partial\mathbf{v}_2/\partial t + \mathbf{v}_2\cdot\nabla\mathbf{v}_2) = -\nabla p_2 + \rho_2\mathbf{g} - n_2 e(\mathbf{E} + \mathbf{v}_2\times\mathbf{B}) + (\rho_1/\tau_1)(\mathbf{v}_1 - \mathbf{v}_2) + (\rho_2/\tau_2)(\mathbf{v} - \mathbf{v}_2)$$
$$\rho(\partial\mathbf{v}/\partial t + \mathbf{v}\cdot\nabla\mathbf{v}) = -\nabla p + \rho\mathbf{g} + (\rho_1/\tau_3)(\mathbf{v}_1 - \mathbf{v}) + (\rho_2/\tau_2)(\mathbf{v}_2 - \mathbf{v}) + \nabla\cdot\tau$$
$$\nabla\cdot\tau = (\mu/3)\nabla(\nabla\cdot\mathbf{v}) + \mu\nabla^2\mathbf{v}$$

Energy Balance:

$$\rho_1(\partial U_1/\partial t + \mathbf{v}_1\cdot\nabla U_1) = -\nabla\cdot\mathbf{q}_1 + 2\rho_1(\delta_2/m_2)\nu_{12}(3k/3)(T_2 - T_1) + 2\rho_1(\delta_{34}/m_{34})\nu_{134}(3k/3)(T - T_1) - \mathbf{j}_1\cdot\mathbf{E}$$
$$\rho_2(\partial \mathrm{U}_2/\partial t + \mathbf{v}_2\cdot\nabla U_2) = -\nabla\cdot\mathbf{q}_2 - p_2\nabla\cdot\mathbf{v}_2 + 2\rho_2(\delta_2/m_2)\nu_{12}(3k/3)(T_1 - T_2) + 2\rho_2(\delta_{34}/m_{34})\nu_{134}(3k/3)(T - T_2) + \mathbf{j}_2\cdot\mathbf{E}$$
$$\rho(\partial U/\partial t + \mathbf{v}\cdot\nabla U) = -\nabla\cdot\mathbf{q} - p\nabla\cdot\mathbf{v} + 2\rho(\delta_2/m_{34})\nu_{134}(3k/3)(T_1 - T) + 2\rho(\delta_1/m_{34})\nu_{134}(3k/3)(T_2 - T)$$
$$U_i = (3/2)kT_i, \quad U = (3/2)kT_i,$$
$$\mathbf{q}_i = -k_i\nabla T_i, \quad \mathbf{q} = -\kappa\nabla T, \quad \mathbf{j}_i = en_i\mathbf{v}_i$$

Maxwell's Equations:

$$\nabla\cdot\mathbf{D} = 4\pi e(n_2 - n_1);$$
$$\nabla\times\mathbf{H} = (4\pi/c)\mathbf{j} + (1/c)\partial\mathbf{D}/\partial t;$$
$$\nabla\cdot\mathbf{B} = 0; \quad \nabla\times\mathbf{E} = (1/c)\partial\mathbf{B}/\partial t = 0;$$
$$\mathbf{j} = (\mathbf{j}_2 - \mathbf{j}_1)$$

The notation used is standard (see Ref.[19]) with the exceptions of n_i and r_1. The number density of species i is n_i and r_1 is the rate of appearance of number density for the electrons. The mass density is given by $n_i m_i$ with m_i being the mass of species i. Thus, the actual mass balance is obtained by multiplying each equation in the mass balance listed above by the mass of that species, m_i, which is constant.

These equations describe the plasma etcher. They must be supplemented by appropriate boundary conditions. Wafer etching occurs at the surface of the wafer and therefore appears as a boundary condition. Furthermore, because portions of the surface of the wafer are being removed during etching, this is a moving boundary value problem. Mathematical expressions for the reaction rate of etching can be found in the journal *Plasma Chemistry and Plasma Processing* for many materials as well as Refs.[13,30] for Si and SiO_2. It is clear that plasma etching is a difficult problem to formulate and solve. To adequately model the spatial variation in the etching at the surface of the wafer, the model must include the three spatial dimensions. One spatial dimension models will just not work.

We note that the radiation from the glow has not been considered in this model. To include this effect requires a mass balance for each excited species, a contribution in the momentum balances for each excited species, and additional terms in the energy balances that represent the energy lost via the radiation field. These effects are smaller than the terms that are retained in the model and thus represent "second order" effects. As such they are expected to change the solution to the problem slightly and have not been retained in the description.

To emphasize the complexity of the problem of modeling a plasma etcher, one more detail must be mentioned. Measurement of the temperatures of species in the plasma has been reported, which identify rotational-vibrational temperatures that are distinct from translational temperatures.[31,32] The second reference is significant in that it mentions the influence of rotational and vibrational energies (temperatures) on chemical reactivity. If one considers rotational and vibrational temperatures that are distinct from translational temperatures, then one is confronted with two questions. First, how is the reaction rate related to the rotational, vibrational, and translational temperatures? Second, how are the energy balances to be written for these distinct temperatures? It is obvious that there remain many fundamental challenges in developing a precise model of the plasma etcher. The value of such a model lies in its ability to guide the manufacturers of plasma etching equipment in the development of new designs to obtain better etching characteristics. It is also useful to the user in

identifying how to improve the current performance of a plasma etcher.

Fortunately, many improvements in plasma etcher designs and plasma etching applications can and are done through experimentation and development. This approach proceeds in concert with improvements in modeling and leads to the next generation designs for plasma etchers. Some fundamental considerations for plasma etcher performance are taken up in the next section.

PROCESS CONSIDERATIONS

The purpose of using a plasma etcher is to obtain well-defined patterns (features) on the surface of a substrate. Commercial applications of plasma etching occur almost exclusively in the microelectronics industry, in which case the substrate is a wafer. To achieve the desired resolution of the pattern being transferred to the wafer, the etching must occur in the vertical direction, i.e., perpendicular to the wafer in the areas not covered by the photoresist. There are two views of how this occurs. In the first case, both the ions and etching molecules are moving perpendicular to the wafer surface. In the case of the ions, this is due to the DC component of the electromagnetic field that exists in the sheath at the surface of the wafer and is perpendicular to the wafer surface. The etching species may be a neutral atom in which case it also is moving perpendicular to the wafer surface due to the collisions it experiences with the ions. These collisions impart the stated direction to the motion of the neutral atoms. Thus, these atoms and molecules collide only with the exposed wafer surface and not the sidewalls that develop as etching proceeds. This causes the exposed surface of the wafer to experience damage due to the collisions, which makes the area considerably more reactive than the sidewalls and results in vertical etching. The second point of view recognizes that the photoresist is also either being etched or sputtered off and reaction products form at and near the wafer surface. The products of the etch process then coat both the sidewalls and the wafer surface. However, the aforementioned sputtering action removes this coating at the surface of the wafer exposing it to further chemical etching. These are idealizations of the actual mechanism that gives rise to vertical etching. In actuality, both processes are likely to occur. The mechanisms for vertical etching have not been incorporated into a comprehensive model of the process. One obstacle is mathematically describing the relation of collisional damage to increased chemical reactivity. However, these models predict that the etch will be more vertical as the DC bias increases. To check this prediction, one has to quantify the idea of vertical etching in a way that can be experimentally measured. This is accomplished by defining the isotropy of etching and selectivity as follows. Let u denote the undercut, D the etch depth, d the thickness of the film being etched, and S denote the selectivity. The selectivity, S, is defined as the ratio of the etch rate (usually in μ/min) of the film

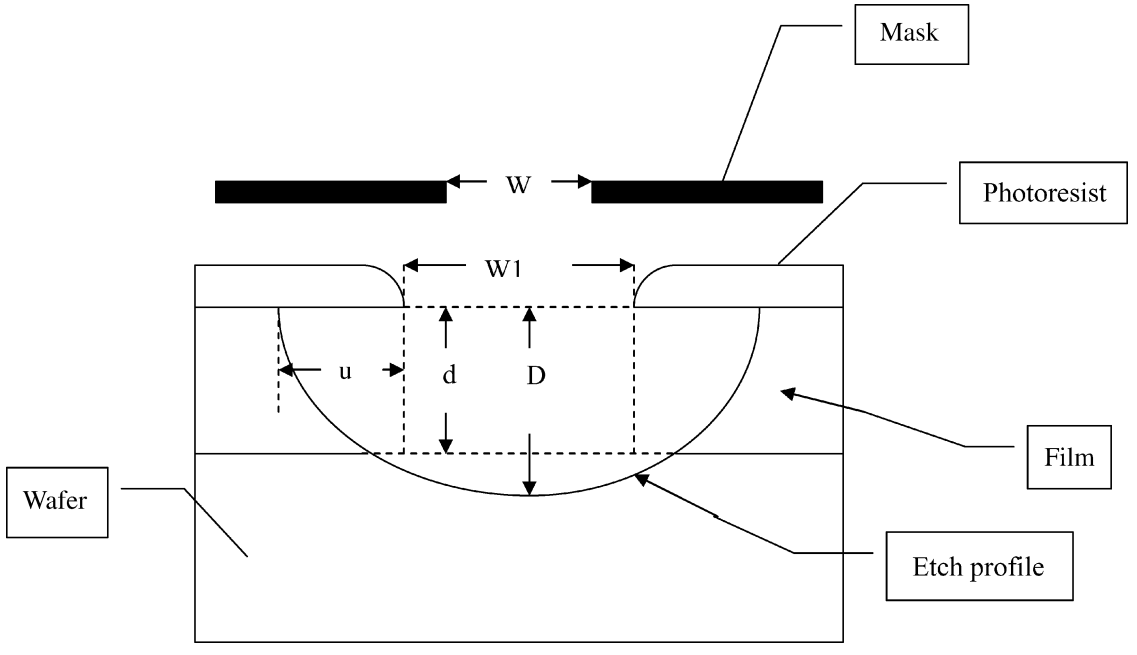

Fig. 4 Illustration of the physical quantities that determine the anisotropy and pattern fidelity. Here, u denotes the undercut, D the depth of the etch, and d denotes the thickness of the film being etched. The anisotropy, A, is defined as $A = u/D$.

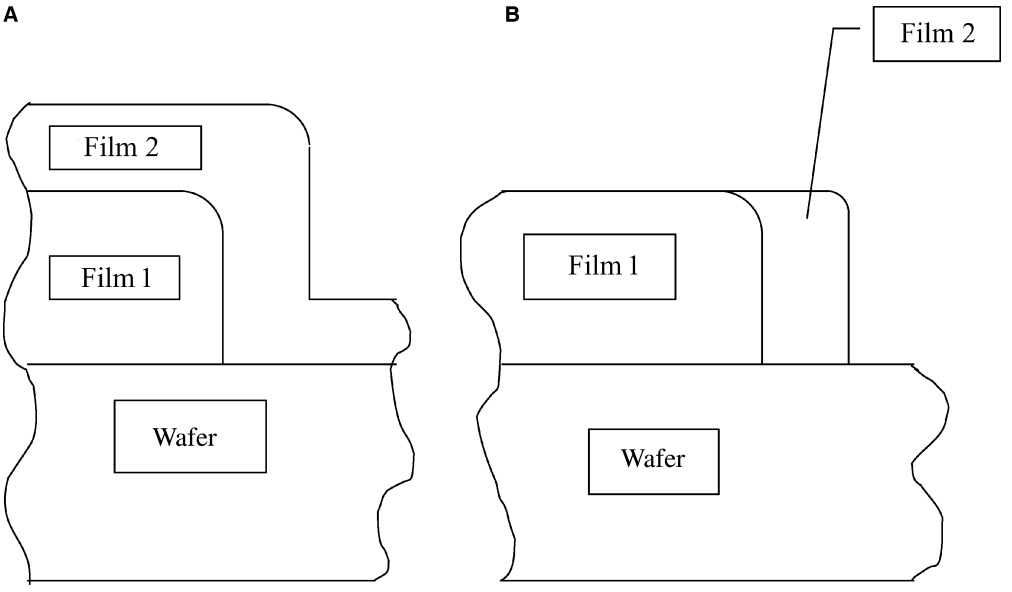

Fig. 5 (A) Depicts wafer prior to etching and (B) depicts the result of etching to endpoint. Removing the remainder of film 2 (residue) requires over-etching of both the wafer and film 1.

being etched to the etch rate of the material in the adjacent layer for the specific etching species being used. Selectivities of the order of 10 or greater are desirable because etch rates on the order of hundreds of angstroms per minute are common and selectivities of this order of magnitude are necessary to prevent excessive removal of second layer material leading to device failure. The anisotropy, A, is defined as $A = u/D$ (see Fig. 4). This is equivalent to defining the anisotropy as $A = 1 -$ (lateral etch rate/vertical etch rate). Thus, an anisotropy of zero corresponds to vertical etching only. One chooses a specific etch recipe (specific choice of feed composition to the etcher) and operating conditions to obtain anisotropy values less than 0.1 and $S \geq 10$. For $S \geq 100$, $d \approx D$ and the second layer from a practical point of view is not etched. By increasing the DC bias, smaller values of A are usually obtained; however, the selectivity frequently decreases.

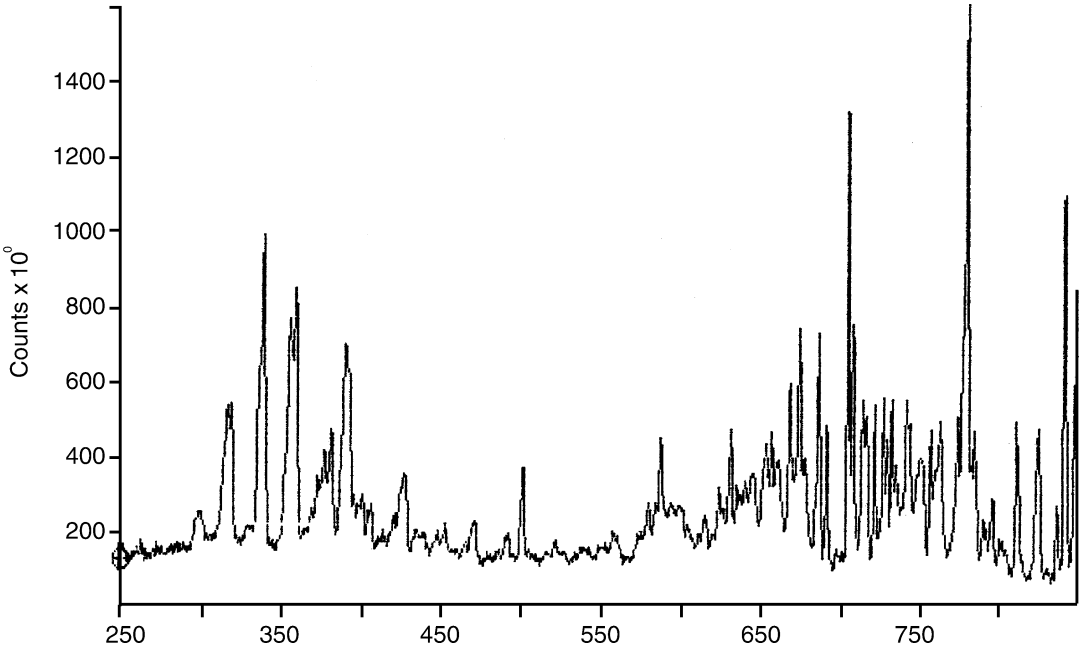

Fig. 6 A representative optical spectrum of a plasma etch process.

Thus, there is a trade-off between large S values and small A values when increasing the DC bias.

A second consideration is pattern fidelity, which is defined as the width of the feature in the photoresist before etching (which is also the width of the feature in the mask) minus the width of the feature in the photoresist after etching (which is the width of the feature etched into the surface of the wafer for a totally anisotropic etch). Pattern fidelity is controlled by both the chemistry of the process and the DC bias. Photoresists are known to undergo chemical reactions with the etching species as well as physical sputtering. Increasing the DC bias increases the sputtering effect while changing the recipe used in plasma etching can reduce photoresist etching. Pattern fidelity values must be very small for today's advanced microelectronics manufacturing with submicron geometries. The exact value is dictated by design considerations.

Over-etching is an important process consideration. The point at which a film has been etched to completion, i.e., when the film being etched is completely removed to the substrate, is called the endpoint. Over-etching occurs when etching continues beyond the endpoint. Over-etching occurs under three common circumstances. The first occurs when etching is not uniform across the wafer surface. In this case, the area of the wafer that etches the fastest will experience over-etch while the slowest etching portion of the wafer is being etched to completion. The second case occurs when there are two distinct film layers above the wafer surface as shown in Fig. 5. If one is to totally remove the top film (the ''residue'' of film 2), then both the substrate and film 1 will be over-etched. The third case occurs when the film layer is not uniform across the area being etched. The requirement that only an acceptably small amount of material may be etched away from the underlying surface during over-etching places lower limits on the values of the selectivity of material two to material one. The first two cases occur routinely in the complementary metal oxide semiconductor, [(CMOS), see Refs.[33,34]] process. The third case can also occur in CMOS fabrication.

Table 1 Emission wavelengths useful for endpoint detection

Film being etched	Wavelength (nm)
Resist	297.7, 483.5, 519.5
Si, poly-Si	704, 777
SiN, Si_3N_4	704, 674, 337
Aluminum	837, 396

The final process consideration to be discussed is endpoint detection. The objective is to determine when the material being etched has been completely removed exposing the surface of the layer beneath (endpoint) and to stop the etching at the endpoint. There are many methods to accomplish this but three in particular are in widespread use. The first method employs a spectrometer to measure the intensity of a specific spectral line. The spectral line chosen is one whose intensity will change significantly when the endpoint is reached. Thus, the etchant species or the etch products are viable candidates for the choice of spectral lines. The well-known 703.7 nm fluorine emission line is used in fluoride etching because of its strong intensity, the 337 nm N_2 line is used when etching silicon nitride, and the 837 nm line is used when etching aluminum. The endpoint is detected by observing when this change in intensity occurs. A representative spectrum for an etch process is shown in Fig. 6 and a short list of emission wavelengths useful for endpoint detection are given in Table 1.

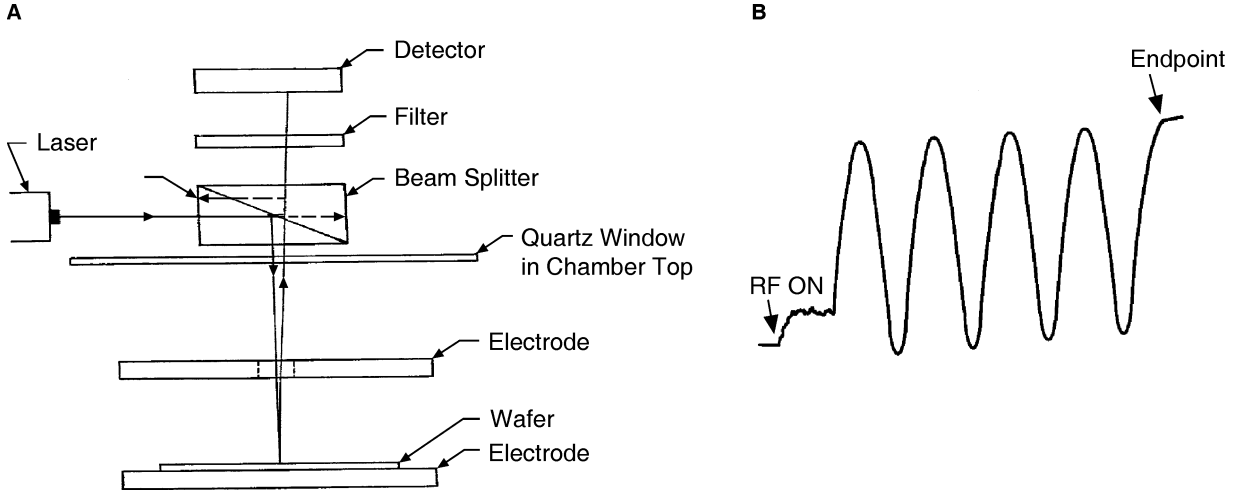

Fig. 7 (A) A common configuration for measuring the endpoint using laser interferometry and (B) a laser inteferogram depicting the point at which the RF-power is turned on as well as the endpoint for the etching process.

Table 2 Index of refraction for some common materials in semiconductor processing

Material	Index of refraction, m
SiO_2	1.46
Si_3N_4	2.05
Si	3.00
Positive resist	1.60

The second method uses laser interferometry to determine the endpoint. A laser emitting radiation at 632.8 nm is typically used. A common configuration found in plasma etching equipment is shown in Fig. 7; also shown is a typical inteferogram for the etching process. The formula for the film thickness etched is given by $t = n\lambda/2m$, where t is the thickness etched, n the number of periods (maxima or minima), λ the laser wavelength, and m is the index of refraction of the film being etched. The endpoint is usually identified as the point at which the inteferogram does not change with time. Values for the index of refraction for some common materials are given in Table 2.

The third method for endpoint detection uses a mass spectrometer that monitors a particular species whose concentration changes dramatically at the endpoint. In all three methods, the etch rate for a particular material can be determined. However, the interferometer technique has two advantages over the other methods. Changes in the etch rate with time can be detected and quantified, and significant etching of photoresist can be detected from the output of the strip chart recorder. In the next section, we take up the applications of plasma etching.

APPLICATIONS

As has already been stated previously, plasma etching is principally used in microelectronic fabrication. This is predominately due to cost considerations; the equipment for plasma etching comes with a high cost. The reason it is widely used in microelectronics manufacturing is due to the fineness of the features that can be obtained (submicron), the anisotropic nature of the etching process, and the elimination of post-treatment considerations for liquid wastes. The discussion of applications will focus on the enumeration of materials that have been etched using plasma etching and a brief presentation of etch rates that typify what occurs in plasma etching applications.

Listed in Table 3 are materials that have been plasma etched and the recipes (species in the feed gas) that have been used.

In Table 4, the etch rates and selectivities for some common materials are listed.

One should note that the actual values of the etch rates obtained are highly dependent on the composition of the feed gas, the applied RF-power, and the DC bias used. The values given in Table 4 are only indicative of what can be physically realized and have been measured in the author's laboratory. The same statement is true for the selectivities, which depend on the etch rates. There is a great deal of flexibility that can be advantageously used to obtain the desired etching conditions. Currently, the equipment manufacturers and research laboratories that focus on microelectronic manufacturing do this experimentally.

Although microelectronic applications dominate the use of plasma etching, there are many other

Table 3 Commonly etched materials and their etching recipe

Material	Plasma gas recipe
Si	CF_4, $CF_4 + O_2$, CCl_2F_2, SF_6, NF_3
SiO_2	CF_4, $CF_4 + O_2$, CCl_2F_2, $C_2F_6 + H_2$, $C_2F_6 + CF_3Cl$
Poly-Si	CF_4, $CF_4 + O_2$, $CF_3Cl + CF_4$, $C_2F_6 + CF_3Cl$
Si_3N_4	CF_4, $CF_4 + O_2$, SF_6
Al	CCl_4, BCl_3, $SiCl_4$

applications for plasma etching. Plasma etching is used for surface activation, cleaning, and modification of surface properties. It can make many surfaces hydrophilic, hydrophobic, bondable, lubricated, passivated, or abrasion resistant. These properties frequently find application in the medical equipment field. It can be used to etch plastic surfaces and act as a pretreatment in paint coatings or the gluing of plastics.

PLASMA DIAGNOSTICS

Plasma diagnostics consists of tools that can be used to characterize the plasma and thus provide information on the processes that are occurring with the plasma etcher. The main tools employed are spectroscopy, emission spectroscopy, mass spectrometry, and plasma probes. A detailed discussion on how each tool works is beyond the scope of this review. However, these tools are used to identify the species present in the plasma etcher, determine the temperature of the species, and determine the electron density.

CONCLUSIONS

Plasma etching is likely to remain a major component of microelectronic manufacturing for the future. Innovative ideas on adding additional inductively coupled electrodes and designing new feed nozzles to achieve a uniform plasma environment at the surface being etched will continue to lead to new plasma etcher designs. The driving force for these new designs will be the achievement of 100% yields for chips on a wafer as the design rules become smaller and smaller. Ultimately, the lower limit to the design rules will occur when the distance between active devices on the chip become the same order of magnitude as the molecular size of the wafer material. At the fundamental level, many questions remain to be answered before a comprehensive understanding of the plasma etching process can be achieved. There is active research on improving the description of the plasma etching process through modeling various aspects of this process. This work will continue to elucidate our understanding of this interesting and challenging process.

Plasma Polymerization Coating

Hirotsugu K. Yasuda
University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

When an organic vapor, such as methane, in low pressure (e.g., less than 1 torr) is subjected to an electromagnetic field, the electrical breakdown of the gas occurs, yielding a glow the color of which is characteristic to the gas. In the luminous gas phase, methane is activated and forms a polymeric deposition in the form of a coating on the surface of substrate placed in the glow. This process is termed ''plasma polymerization'' because the luminous gas phase or glow indicates the presence of plasma, and the process does not proceed without plasma. The strict definition of plasma is (at least partially) ionized gas, which maintains the electrical neutrality as a whole. The luminous gas phase in which plasma polymerization takes place, however, is not plasma in the strict sense.

Plasma polymerization is not a process to synthesize a polymer, but is a coating process, because the main product is in the form of a coating on the surfaces that are either in direct contact with the luminous gas phase or placed in the glow region of a reactor. Because of this, plasma polymerization is referred to as plasma polymerization coating. Plasma polymerization coating is unique in that a single process using a gas-phase monomer (starting material) achieves both the polymerization and the coating simultaneously. It is ideally suited for coating of a nanofilm (e.g., 10–100 nm), which is difficult to achieve by other conventional coating processes. Furthermore, the characteristics that could be attained by plasma polymerization coatings are unique in that they cannot be obtained by other conventional means of coating.

PLASMA, GLOW, AND PLASMA POLYMERIZATION

The glows in direct current (DC) discharge of Ar in a plasma polymerization reactor are schematically shown in Fig. 1. The size and the location of glows are dependent on the system pressure p and the distance d between the cathode and the anode. The parameter given by pd determines the glow characteristics including the breakdown voltage of discharge.

The distribution of electron temperature T_e (energy of electron) and electron density in a DC argon glow discharge in a plasma polymerization reactor is shown in Figs. 2 and 3, respectively.[1] The electron temperature rises as electrons are accelerated in the electric field. During this process, the number of electrons is relatively small. When the electron temperature reaches the maximum level as a function of the distance, T_e starts to drop significantly as the ionization of Ar atom occurs, which consumes the electron energy and creates an additional electron. The creation of excited species of Ar, which is responsible for the characteristic glow, occurs simultaneously with the ionization in the same location. The number of electrons starts to increase in this location and the density quickly increases as electrons are pulled toward the anode as depicted in Fig. 3. The true plasma state exists only in a narrow cross-sectional layer in the vicinity of the location where ionization of Ar occurs.

The main glow of Ar appears corresponding to the distance for the maximum electron temperature as observed in Fig. 2, implying that the glow recognized as the negative glow is associated with the ionization of Ar. The energy of photon-emitting species is in the vicinity of the ionization energy of Ar. Accordingly, the negative glow can be designated as ionization glow.

The ionization of organic molecules in glow discharge is not as simple as that of Ar. First of all, the ionization energy of greater than 10 eV is far above the bond energies of primary bonds involved in organic compounds. Typical bond energies are given in Table 1. Dissociation energy, metastable energy, and ionization energy for noble gases and diatomic gases are compared in Table 2. The low-energy electrons and/or off-centered collisions that cannot ionize molecules can break the bonds in organic molecules or create excited species that can trigger chemical reactions. These reactions are absent in the ionization of atoms. Furthermore, the removal of small molecules, such as H_2, HCl, HF, etc., out of an original organic molecule requires very little energy in comparison with the ionization energies.

It has been recently discovered that glow in DC glow discharge of organic compounds is significantly different from that of Ar.[2,3] In Ar discharge, the ionization glow is the primary glow and the cathode is virtually in the dark space. In strong contrast to Ar glow, the cathode in trimethylsilane (TMS) discharge is surrounded by the glow, which is weaker compared

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007902

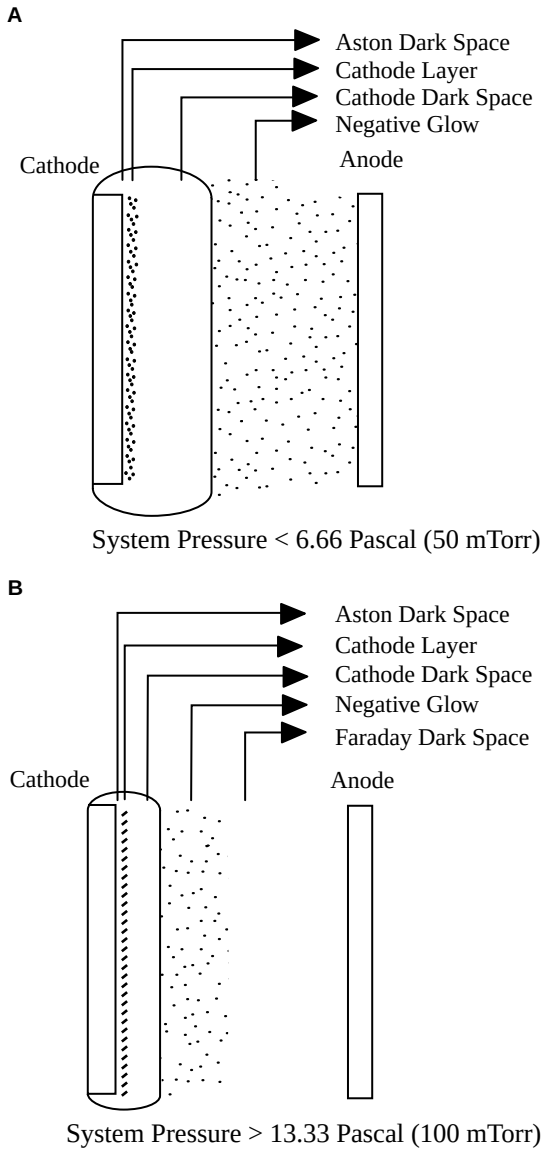

Fig. 1 Schematic view of nonmagnetron DC glow discharge of argon in the interelectrode space, interelectrode distance: 102 mm; the luminous regions are shown shaded.

to the negative glow observed in Ar discharge but is the primary glow of the system, especially at the inception of the glow discharge. The main glow adheres to the cathode surface, which means that the glow is caused by low-energy electrons and can be termed as dissociation glow in contrast to the ionization glow.

Simple molecular gases, such as O_2, N_2, CO_2, etc., do not create the dissociation glow, and photon-emitting species have energy at the level of ionization. The dissociation glow is observed only with organic gases that can be used in plasma polymerization coating, which implies that plasma polymerization proceeds by the dissociation of molecules caused by low-energy electrons but not by the ionization of molecules.

The glow discharge by alternating polarity power source up to approximately 100 kHz is essentially the same with DC discharge except that the two electrodes alternate their polarity. Accordingly, the deposition on an electrode drops to one-half of the deposition on the cathode of DC discharge.[4] As the frequency increases to radiofrequency (RF) range, an electron cannot complete the path from the cathode to the anode within the duration of one cycle, and the mode of motion changes from the linear motion to the oscillation according to the frequency of the power source. The oscillating electrons shift the dissociation glow from the electrode surface to the gas phase.

The glow in which plasma polymerization occurs is not a uniform luminous gas phase that could be viewed as multiple layers (as the onion layer structure). The location of the crucially important layer for plasma polymerization coating differs depending on the nature of gas, the frequency of electrical power source, the mode of coupling the electromagnetic energy to the gas phase, and the design factors of a reactor, that is, plasma, glow, and plasma polymerization are system dependent, and any of these terms cannot be described without specifying the details of the system. Where the substrates are placed with respect to the onion layered structure is an important factor in the processing of plasma polymerization coating.

GROWTH AND DEPOSITION MECHANISMS

As it can be recognized in the plasma polymerization coating of methane, no specific molecular structure is required to form plasma polymerization coating. The organic compounds that do not have any functional group, such as methane, can be polymerized by plasma polymerization and the normalized molar deposition rates of these nonmonomers are, by and large, the same as those for monomers that have double or triple bond, although some chemical structures influence the deposition rate in subtle manners. The growth mechanism in plasma polymerization is completely different from those of conventional polymerizations.[5]

Conventional polymerization does not occur in gas phase, particularly in vacuum, because of the limitation set by the ceiling temperature of polymerization, and there are only a few cases in which the deposition of polymeric material occurs in vacuum. Those exceptional cases are plasma polymerization and Parylene polymerization, which is also a vacuum polymerization coating process using a gaseous monomer. The common denominators for these two processes are: 1) the polymerizations yield solid-state polymer (in the form of film in most cases) from a gas phase monomer in vacuum and 2) the polymer formed by the processes

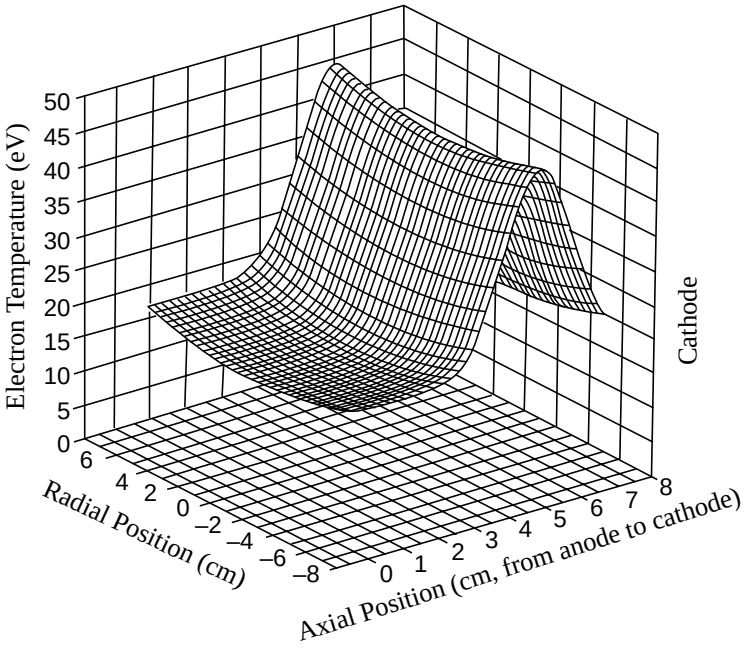

Fig. 2 Distribution profile of electron temperature in an argon DC glow discharge in a plasma polymerization reactor.

contains a large amount of dangling bonds (free radicals trapped in the solid polymer matrix).

Parylene polymerization proceeds with well-defined chemical species, whereas plasma polymerization proceeds via a variety of not well-defined chemical species, which are created in the luminous gas phase. The reactive species for Parylene polymerization is *para*-xylylene, which is bifunctional (i.e., biradicals), moderately reactive and relatively stable, and highly selective in chemical reactivity to its own structure.

Highly reactive (unstable) and nonselective species involved in plasma polymerization coating tend to react with any polymeric surface on which the species strike and form a polymer deposition with a high level of bonding or adhesion to the surface. Because of this aspect, plasma polymerization forms a thin film with a good adhesion to various kinds of substrate materials. Because of nonselective reactivity, the reactive species of plasma polymerization has poor penetration into small cavities, such as those of porous structure. Highly reactive species react with wall material at the entrance of a pore instead of penetrating into the pore.

Parylene polymer deposition has very poor adhesion to a smooth-surface substrate. A freestanding

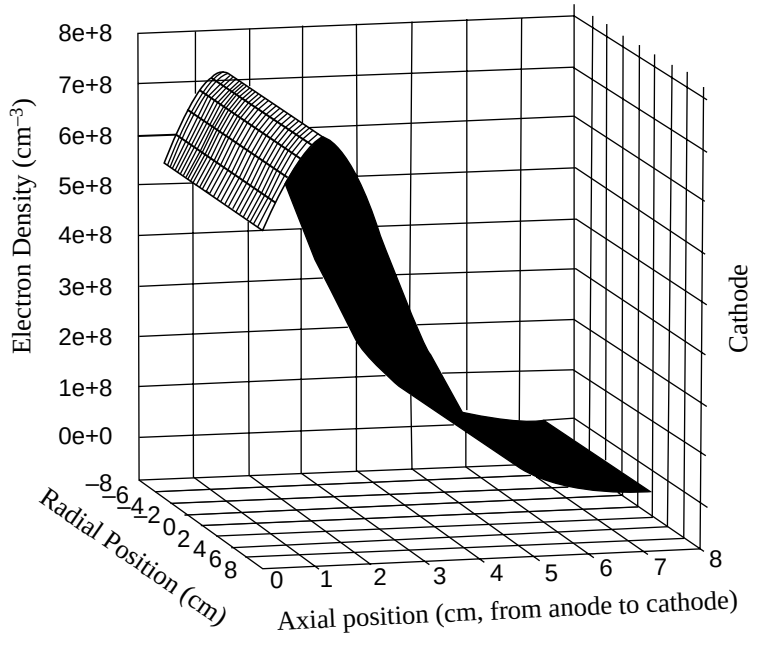

Fig. 3 Distribution profile of electron density in an argon DC glow discharge in a plasma polymerization reactor.

Table 1 Bond dissociation energy

Bond	Dissociation energy (eV)
C–C	3.61
C=C	6.35
	(2.74 for π bond)
C–H	4.30
C–N	3.17
C=N	9.26
C–O	3.74
C=O	7.78
C–F	5.35
C–Cl	3.52
N–H	4.04
C–H	4.83
O–O	1.52

ultrathin film can be obtained by peeling off the film from the substrate. On the other hand, if the substrate is porous the film adheres strongly to the substrate. Because of the high selectivity (toward the same kind of species), a *para*-xylylene molecule (in vacuum phase) can penetrate deep into the cavity without reacting with the wall material and waits for another *para*-xylylene to arrive. The second molecule reacts immediately without losing the overall reactivity because it is a bifunctional free radical. By repeating this step, Parylene deposition can penetrate deep into pores or microvoids existing on the substrate surface, yielding a very good adhesion to porous substrate by virtue of mechanical anchoring. Thus, Parylene film deposition can be characterized by 1) no adhesion to a smooth surface and 2) very good adhesion to porous substrate by forming an interpenetrating thin-layer film. These are completely opposite to the characteristics of plasma polymerization coatings.

Because of the well-defined chemical structure of the reactive intermediate, Parylene coating is semicrystalline; whereas plasma polymerization coating consists of an amorphous (noncrystalline) three-dimensional network because of the lack of well-defined chemical structure of reactive species. The amorphous nature of plasma polymerization coatings plays a crucially important role in protective coatings because there is no discernible defect or weak boundary, whereas the boundary between crystals and noncrystalline phase in a semicrystalline Parylene coating causes the intrusion of salts in a corrosive environment.[6]

In both the polymerizations, free radicals are the species that are responsible for the formation of bonds in the depositing materials. The growth mechanism, however, is not by the conventional chain-growth free-radical polymerization. In a conventional free-radical chain-growth polymerization, two free radicals and 10,000 monomer molecules yield a polymer with degree of polymerization 10,000, which does not contain free radicals. In contrast to this situation, in plasma polymerization and Parylene polymerization, 10,000 species with free radical(s) recombine to yield a polymer matrix that has an equivalent degree of polymerization, and contains numbers of unreacted free radicals (dangling bonds).

Table 2 Dissociation energy, metastable energy, and ionization energy for noble and diatomic gases

Gas	Dissociation energy (eV)	Metastable energy (eV)	Ionization energy (eV)

Kr	—	9.9	14.0
Xe	—	8.32	12.1
H_2	4.5	—	15.6
N_2	9.8	—	15.5
O_2	5.1	—	12.5

Rapid Step-Growth Polymerization Mechanism

The complex nature of plasma polymerization was explained by rapid step-growth polymerization (RSGP) in which recombination of free radicals constitutes the main mechanism to increase the size of molecules.[5] The presence of a large amount of dangling bonds, the change of the concentration of dangling bonds as a function of the duty cycle of pulsed discharge, and the dependence of the deposition rate on molecular structures of monomers, all support the RSGP mechanism. The increase of the dangling bonds because of pulsed discharge cannot be explained without RSGP mechanisms.

A schematic presentation of growth mechanisms is presented in Fig. 4. The actual growth mechanisms involve the participation of the surface or the third body in each reaction shown in the figure. To simplify the overall picture of reactions in luminous gas phase, however, the contribution of the surface is not shown in the figure. The role of ions in the growth reactions can be virtually ignored because the number of neutral species outnumber nearly 10^6 to 1.[7] How these reactions contribute to the deposition of materials is schematically illustrated in Fig. 5.

None of the reactions shown is a polymerization by itself. While repeating the steps via cycle-I or cycle-II, species with varying sizes deposit on the substrate surface. The once-deposited species increase in size by the same principle. The number of cycles repeated

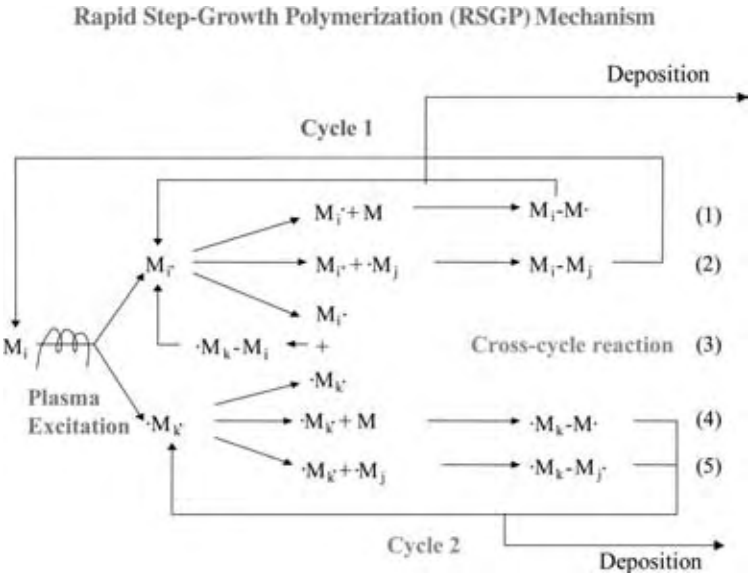

Fig. 4 Growth and deposition mechanisms in the luminous gas phase. *(View this art in color at www.dekker.com.)*

before the deposition occured can be expressed by the term kinetic path length. As the kinetic path length increases, the size of the gaseous species increases, and the saturation vapor pressure of the species decreases accordingly.

Influence of the Kinetic Path Length on Properties of Coating

An important feature of plasma polymerization is that the creation and the deactivation of reactive species (growth and deposition reactions) are not kinetically coupled. The reactive species is created irrespective of what happened to the created reactive species.

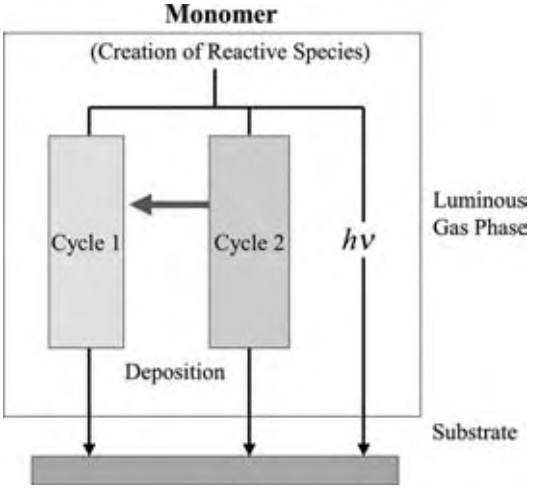

Fig. 5 Gas phase reactions and material deposition. *(View this art in color at www.dekker.com.)*

Consequently, if the temperature of a substrate is changed without changing plasma conditions, only the deposition (deactivation) process is influenced by the change. If one plots the deposition rates k at different substrate temperatures, T, as $\log k$ vs. $1/T$, it yields a negative slope indicating that the rate process cannot express the deposition rate. The change of deposition process alters the deposition rate as well as the chemical nature of plasma polymers under the identical plasma conditions, because the kinetic path length is altered.

This situation can be visualized by the analysis of plasma polymers of perfluoro-2-butyltetrahydrofuran (PFBTHF) formed at different substrate temperatures under two sets of discharge conditions.[8] Fig. 6 depicts the temperature dependence of deposition rate shown as plots of $\ln k$ vs. T. The electron spectroscopy for chemical analysis (ESCA C_{1s}) spectra of polymers deposited at different temperatures under different energy input levels are shown in Fig. 7. The details of ESCA C_{1s} spectra are shown in Table 3. The monomer is the same, and the discharge conditions are identical. Only the surface temperature of the thickness monitor is changed. Therefore, the luminous gas phase should be identical in all cases. Under such conditions, the following features of plasma polymerization coating are clearly seen: 1) the products obtained at different temperatures are not the same; 2) the temperature dependence of deposition rate is negative; and 3) a higher deposition rate at the lower temperature is obtained at the expense of the kinetic path length.

The most important factor, at a given substrate temperature, that influences the properties of plasma polymers from a monomer is the energy input level of the plasma polymerization process. The energy input level determines the extent of dissociation or

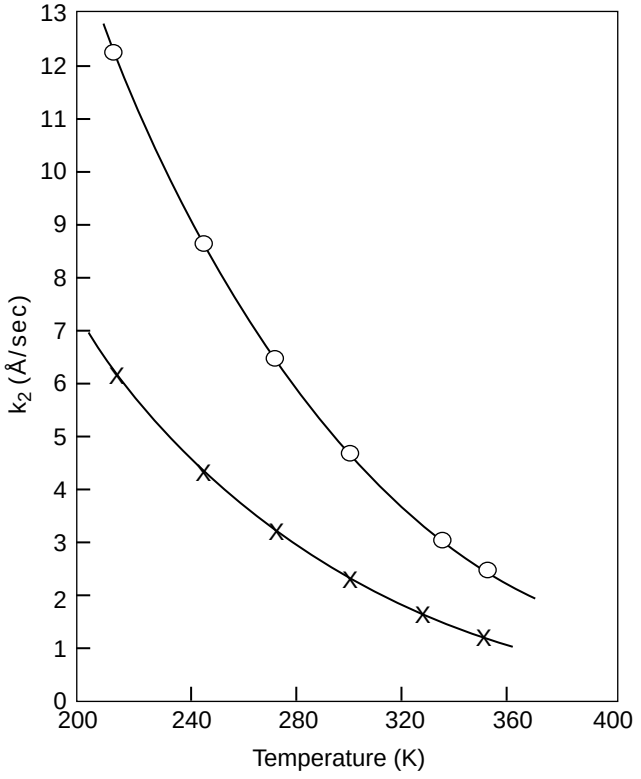

Fig. 6 Temperature dependence of the thickness growth rate k_2 for PFBTF. Flow rate [cm^3(STP)/min] and power (W): O, 1.04 (9.84 W); x, 0.54 (4–89 W). $W/FM = 12.8 \times 10^7$ J/kg.

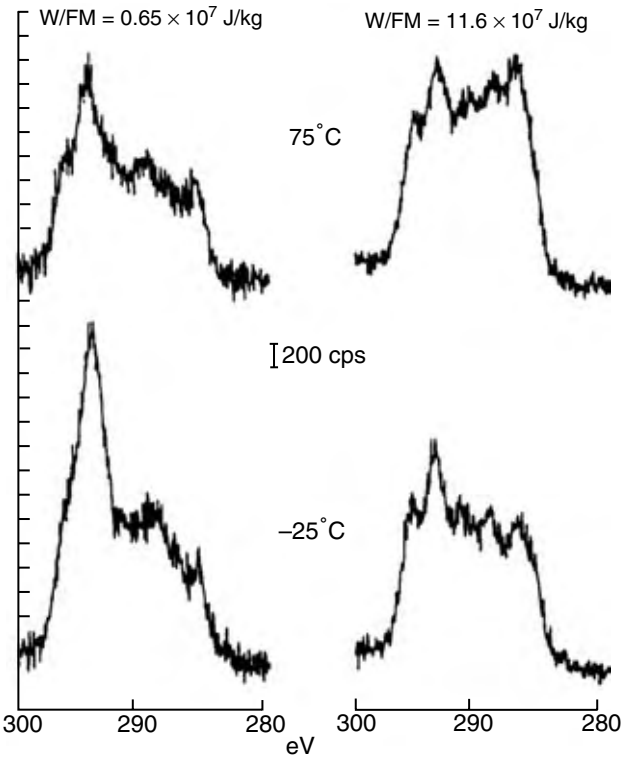

Fig. 7 The ESCA C_{1s} spectra of plasma polymers of PFBTF obtained at different W/FM and substrate temperatures.

scrambling of atoms in the monomer molecule. The retention of molecular structure of the original monomer decreases with the increasing level of energy input. The energy level in the luminous gas phase can be manifested by the parameter *W/FM*, where *W* is the discharge wattage, *F* is molar or volume flow rate, and *M* is molecular weight of the monomer.[5] The parameter has units of joules per kilogram, i.e., energy per mass (of monomer).

It is important to recognize that *W* is the energy input into the electrical discharge system, whereas *W/FM* is the energy input into the luminous gas phase in which plasma polymerization occurs. This subtle but very important difference could be visualized by the following analogy. A 10 W light bulb consumes 10 W of electrical energy. The bulb placed in a room hardly influences the temperature of the room. However, if the same bulb is placed in a small box used as an incubator, the bulb could be used as the sole heat source to control the temperature of the incubator. If the same bulb is kept in a hand it could cause burn. This means that 10 W itself does not mean anything with respect to the thermal effect of the system in which the bulb is placed. To see the effect of the light bulb on the temperature of air, it is necessary to divide the electrical energy input to the bulb by the total mass of air surrounding the bulb.

DEPENDENCE OF DEPOSITION RATE ON OPERATION PARAMETERS OF GLOW DISCHARGE

Domains of Plasma Polymerization

When the deposition rate is measured at a fixed flow rate and varying power input *W*, a line showing the dependence on *W* is obtained. However, when the same experiment is carried out at a different flow rate, another different line is obtained. Fig. 8 depicts the interrelated effect of *W* and *F* on the deposition rate plotted against *W*. At lower flow rates, the deposition rate reaches a plateau value at a very low value of *W* and becomes wattage independent. At a higher flow rate, the deposition rate reaches a plateau value at a higher value of *W*. The plateau region can be recognized as a monomer-deficient domain in which the flow rate of monomer is the rate-determining step. The domain before reaching a plateau value can be recognized as power-deficient domain in which the power input rate is the rate-determining step.

Table 3 Change in ESCA C_{1s} peaks of plasma polymers of perfluoro-2-butylterahydrofuran due to a change in substrate temperature and W/FM

W/FM [(J/kg) $\times$ 10^{-7}]	Substrate temperature (°C)	Area of component peaks (%)				
		1	**2**	**3**	**4**	**5**
0.65	75	16.0	21.1	19.4	26.6	17.0

	50	15.0	18.8	18.3	20.0	28.1
	25	16.6	20.0	17.7	18.8	27.2
	0	16.7	20.2	17.5	19.4	26.2
	−25	17.8	21.0	17.8	18.8	24.6
	−49.5	18.0	21.2	17.1	19.8	24.0

	Peak	Approximate peak position (eV)	Approximate peak width (eV)
1	$-CF_3$	295	2.0
2	$-CF_2-$	293	1.9
3		291	2.3
		288	2.3
		286	2.8

When the same experiments were carried out as a function of flow rate at various fixed input power levels, *W*, the graph is as depicted in Fig. 9. The same data can be presented as a function of *W/FM*, as shown in Fig. 10. Based on *W/FM*, the material formation in plasma polymerization can be divided into two regimes: an energy-deficient regime and a monomer-deficient regime. In the energy-deficient domain, ample monomer is available but the power input rate is not sufficient. In this domain, the deposition rate increases with the power input. In the monomer-deficient (power saturated) domain, sufficient discharge power is available but the monomer feed-in rate is the determining factor for the deposition. These two domains cannot be identified based simply on the value of operational parameters. The domain can be identified only by the dependence of the deposition rate on operational parameters as depicted in the above figures.

The value of *W/FM* necessary to bring the plasma polymerization system into the monomer-deficient region is proportional to the value of the total bond energies divided by molecular weight, which can be considered as the specific bond energy of the monomer. This dependence clearly indicates that in the monomer-deficient region nearly all bonds in a monomer are broken, and because of this fact, the additional energy input does not influence the nature of plasma polymerization. The plasma polymerization in this region is a typical ''atomic'' polymerization, because the original monomer structure is nearly totally destroyed and what accounts for the polymer formation is the atoms that comprised the original monomer molecule but that are fragmented under the plasma conditions.

Thus, the value of $(W/FM)_c$ above which the deposition rate become independent of *W/FM*, which is characteristic of a monomer, can be given by

$$(W/FM)_c = \alpha\Phi$$

where $\Phi = \sum(\text{bond energy}/M)$ is the specific bond energy of the monomer and α the proportionality

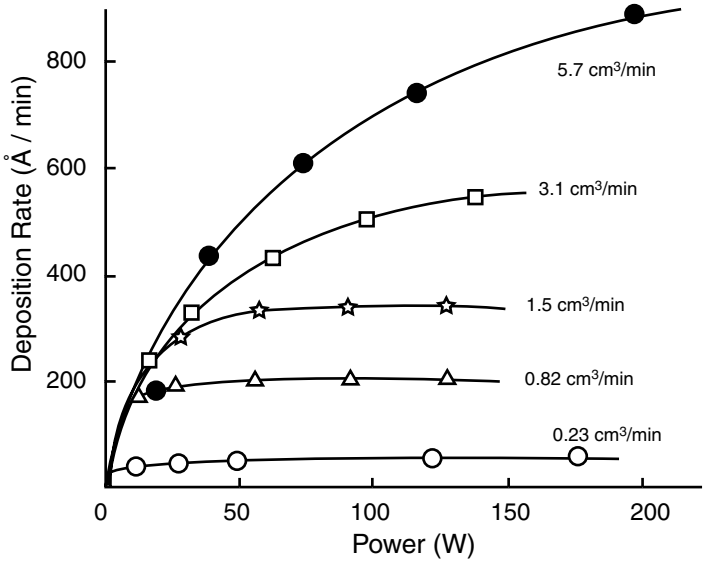

Fig. 8 Dependence of deposition rate of plasma polymer of tetramethyldisiloxane on discharge wattage at various monomer flow rates (cm^3/min).

constant for a given reactor. The value of α is roughly 20, although the value depends on the specific reactor system.[5] Thus, in the polymerization system employed, when the energy input in joules per kilogram exceeds 20 times the specific bond energy Φ (J/kg), the plasma polymerization becomes a typical atomic polymerization.

Specific Deposition Rate as a Function of *W/FM*

Most experiments start from the power-deficient domain, where the deposition of a plasma polymer can be expressed by the following expression.

$$k_1 = aW, \quad \text{where } a \text{ is a proportionality constant} \tag{1}$$

Dividing both sides of the equation by FM, one obtains

$$k_1/FM = k_0 = a(W/FM) \tag{2}$$

$$k_0 = a(W/FM) \tag{3}$$

where k_1 is the mass deposition rate and k_0 is the specific deposition rate, which is the normalized mass deposition rate.

The specific deposition rate k_0 is the only form of deposition rate that can be used to compare deposition characteristics of different monomers with different chemical structures and molecular weights under different discharge conditions (flow rate, system pressure, and discharge power). Similarly, W/FM can be considered as the normalized power input. When only one monomer is employed, k_1 can be used to establish the dependency of deposition rate on operational parameters. Even in such a simple case, k_1 cannot be expressed by a simple function of W or F, and its relationship to those parameters varies depending on the domain of plasma polymerization.

In the monomer-deficient domain, the deposition rate (asymptotic value) will increase as the flow rate is increased and shows a linear dependence on the monomer feed-in rate at a given discharge power and the system pressure (Fig. 13), i.e.,

$$k_1 = \beta(FM) \tag{4}$$

The relationship given by Eq. (4) is valid only in the monomer-deficient domain. The further increase of the

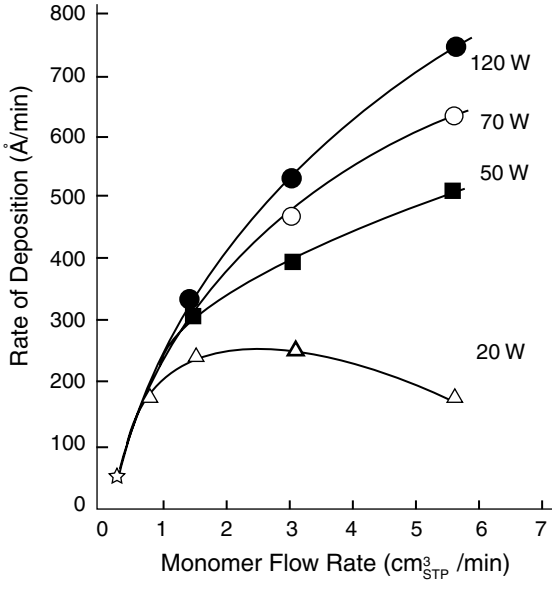

Fig. 9 Dependence of deposition rate of the plasma polymer of tetramethyldisiloxane on flow rate of the monomer.

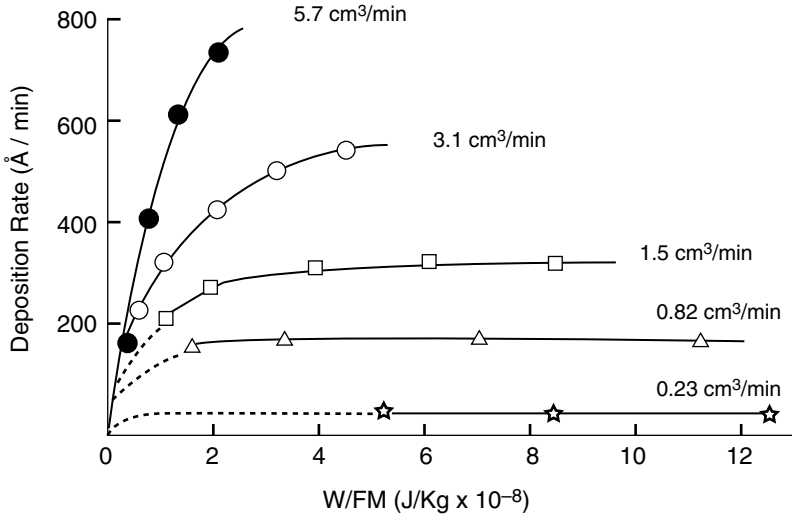

Fig. 10 Dependence of deposition rate of the plasma polymer of tetramethyldisiloxane on *W/FM* at various monomer flow rates.

flow rate (*FM*) will eventually decrease the deposition rate as the domain of plasma polymerization changes to the energy-deficient domain. Such a decrease can be expressed by Eq. (3).

The deposition rate depends on the composite parameter *W/FM*. Consequently, an increase in flow rate (at a given discharge power) has the same effect as decreasing the discharge power (at a given flow rate), and conversely, an increase of discharge power has the same effect as decreasing the flow rate. *W* and *F* cannot be regarded as independent parameters.

Fig. 11 illustrates how well the thickness growth rate, GR/*FM*, in 40 kHz and 13.5 MHz glow discharge of methane and *n*-butane, can be expressed as a function of the composite energy input parameter *W/FM*. Regardless of the mass of monomer, flow rate, and discharge wattage, a single line fits all data obtained in 40 kHz or 13.5 MHz plasma polymerization of hydrocarbons employed in which the deposition occurs on an electrically floating conductor or on a dielectric substrate placed in the glow.[9] Under the otherwise identical experimental setups, 13.5 MHz discharge yields a significantly higher deposition rate. This is due to the fact that the dissociation glow in RF discharge does not adhere to the electrode but exists in the gas phase.

The product of (deposition rate) and the deposition time *t* determine the film thickness. Hence, (*W/FM*)*t* is an important practical parameter to control the thickness of the deposition.[10] In many practical applications, in which the actual thickness of deposition is extremely difficult to measure, the overall functional character of the plasma polymerization process itself can be controlled by this parameter (*Wt/FM*).

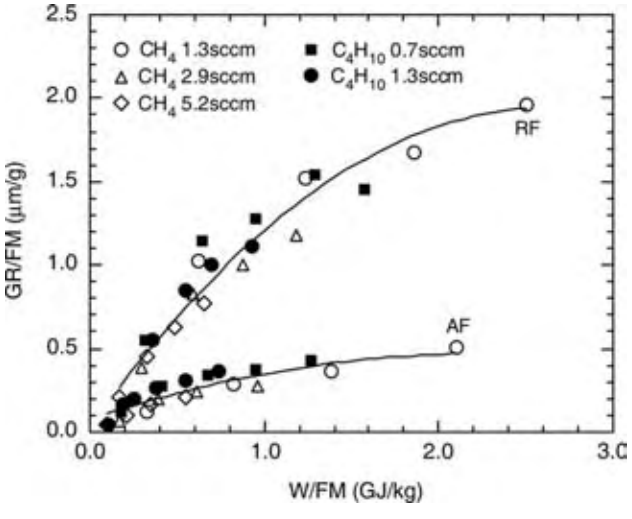

Fig. 11 Dependence of GR/*FM* on *W/FM* for 40 kHz (AF) and 13.56 MHz (RF) plasma polymerizations. Flow rate: methane, 1.3, 2.9, 5.2 sccm; *n*-butane, 0.7, 1.3 sccm.

Deposition in DC Discharge

In DC glow discharge of organic molecules, the dissociation glow adheres to the cathode surface. Consequently, the deposition onto the cathode surface is totally different from that which occurs in gas phase in most plasma polymerization coatings by HF and RF discharges. The best universal dependency for cathodic polymerization is found between k_1/M and the current density.[9] Fig. 13 depicts this relationship for all cathodic polymerization data, which were obtained in the same study, covering experimental parameters, such as flow rate, size of cathode, mass of hydrocarbon monomers, but at the same system pressure.

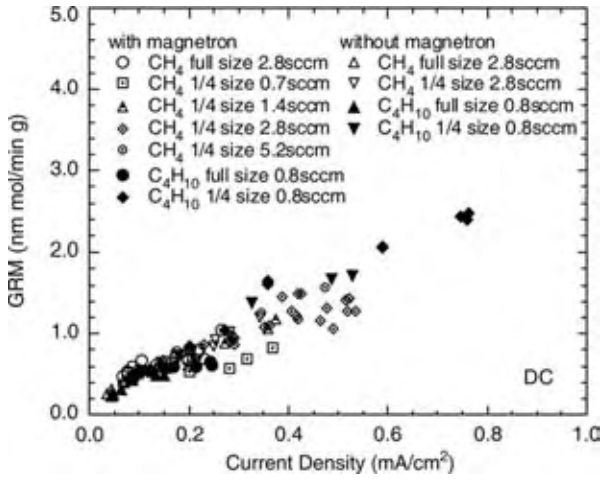

Fig. 12 A master curve for the relationship between GR/M and the current density for DC cathodic polymerization; data obtained under various conditions for methane and *n*-butane, at a fixed system pressure of 50 mtorr.

The cathodic deposition, in general cases, can be expressed by the following equation

$$k_1/[\mathrm{CM}] = \alpha_c[I] \quad (5)$$

$$k_1 = \alpha_c[I][\mathrm{CM}] \quad (6)$$

where $[I]$ is the current density, and [CM] is mass concentration of monomer in the cathode regions of a DC discharge.[4]

As the mass concentration of monomer in the cathode region depends on the system pressure, the deposition rate in the cathode region should depend on the system pressure p

$$k_1 = \alpha_c[I]p \quad (7)$$

The relationship given by Eq. (7) is a conspicuous deviation from that for the plasma polymerization (material formation in the luminous gas phase), in which the flow rate rather than the system pressure is the rate determining parameter and, hence, the deposition rate is independent of the system pressure (under a given flow rate).

MODES OF ELECTRICAL DISCHARGE PROCESS

DC Discharge

When the substrate is an electrically conducting material, DC discharge using the substrate as the cathode is a very useful and practical means to apply plasma polymerization coating on the substrate. The anode plate is a passive surface so far as plasma polymerization is concerned and is not necessary if the reactor is made of a metal.[11] The reactor wall could be used as the anode (grounded). The DC discharge has the great advantage that over 80% of plasma polymer deposits on the cathode because the dissociation glow is attached to the cathode surface, i.e., the deposition yield on substrate $Y_{p,s} > 0.8$. Depending on the size, number, and reactor design, $Y_{p,s}$ could be over 0.90. This means that the deposition on the undesirable place is minimal and could be easily controlled.

Alternating Current Discharge (Up to ~100 kHz)

An alternating current discharge, up to around 100 kHz, is essentially an alternating DC discharge and one electrode acts as the cathode in one-half of the discharge time and acts as the anode in the rest half.[4] In this mode of operation, substrates are placed in the interelectrode space. Consequently, the usable polymer deposition yield, Y_p in the interelectrode space, is less than 0.20. The deposition yield on substrates, $Y_{p,s}$, could be significantly lower than that. In DC and high-frequency discharge, the molecular dissociation glow, in which

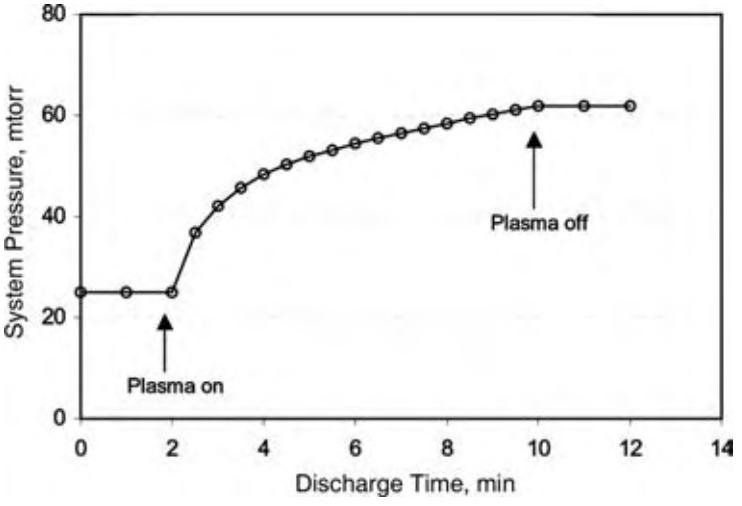

Fig. 13 Increase of system pressure during closed system plasma polymerization of TMS. Plasma conditions are: 25 mtorr, TMS, 2 panels of aluminum alloy, DC 1000 V.

the majority of chemically reactive species are created, adheres to the cathode, and consequently the interelectrode space is not a very active place unless magnetically enhanced electrode (magnetrons) is employed.

Radiofrequency Discharge

In RF discharge, the molecular dissociation glow no longer adheres to the electrode surface, and the gas phase near the electrode surface becomes the major site for the creation of chemically reactive species.[2,3] Consequently, the deposition yield on electrodes drops below 0.10, and the potential deposition yield in the interelectrode space increases to over 0.90. The deposition yield on substrate, $Y_{p,s}$, is significantly lower than the potential deposition yield because the volume of the glow expands beyond the interelectrode space as a function W/p and increases reactor wall contamination.

Because an electrode does not function as electrode in DC or alternating current high-frequency discharge, the electrode system could be kept outside a glass reactor (capacitive external electrodes) or a coil around a glass tube (inductively coupled external electrode) can be used to create plasma. These modes of coupling could be dealt as a factor in the system-dependent aspect of plasma polymerization, i.e., the basic plasma polymerization remains the same.

Pulsed RF Discharge

In pulsed RF discharge, for a certain length of time (e.g., 100 μsec) RF power is on and for another length of time (e.g., 900 μsec) power is off. During the on-period, the creation of chemically reactive species and their reactions (dissipation) occur simultaneously just as in the case of a continuous discharge. During the off-period, the creation of chemically reactive species ceases and only the dissipation reactions continues, if they could do so. The net effect is entirely dependent on the chemical structure of the monomer. If the monomer employed has the chemical structure, to which the existing free radicals can add on, the propagation via free-radical chain-growth polymerization occurs during the off-period.[5] In such a case, the pulsed discharge yields plasma coating that retains the original chemical structure of the monomer in higher degrees depending on the ratio of off-/on-period.

If the monomer contains functional groups of which one acts as an inhibitor of plasma polymerization (e.g., carboxylic acid), and another promotes the chain-growth polymerization (e.g., double bond), such as the case of acrylic acid, the net effect is seen as the greatly enhanced deposition rate because the poisoning effect that is caused by the fragmentation of the oxygen containing group in the plasma does not occur in the off-period. If the monomer does not contain these functional groups, the net effect is the reduced deposition rate more or less proportional to the fraction of on-time.

If the monomer contains a double bond or a triple bond, the concentration of dangling bonds in plasma polymerization coating increases significantly, because the cross-cycle reaction, shown as Eq. (3) in Fig. 4, ceases during the off-time and retains more bifunctional free radicals in the reaction system.[5] The increased dangling bonds could have a positive or negative effect on the coating depending on the objective of plasma polymerization coating.

While the pulsed discharge has the great advantage of retaining some monomer functional groups in the plasma polymer, in nearly all cases, it shortens the kinetic path length of plasma polymerization, which reduces the polymer characteristics of plasma polymerization coating and tends to reduce the adhesion of the coating. In other words, pulsed discharge tends to yield more or less conventional polymers at the expense of unique characteristics of plasma polymers. The advantage or disadvantage obtainable by the use of pulsed discharge entirely depends on the objective of plasma polymerization coating, particularly with respect to the types of plasma polymerization coating, which are described in a later section.

Microwave Discharge

In microwave discharge (frequency in the GHz range), the electromagnetic energy propagates on the surface, and the deposition yield on the substrate could be very high if the substrate surface could be used as the main energy propagation surface of microwave discharge. The waveguide is used externally similar to the external energy input in RF discharge. The coating of the inner surface of a plastic bottle by a microwave discharge is an example of the perfect utilization of microwave discharge in plasma polymerization coating. If numerous other substrates are placed in a bottle, however, the main energy propagation pattern is disturbed, and very uneven erratic coating occurs.

Magnetron Discharge

An electrode system equipped with a superimposed magnetic field is generally referred to as "magnetron."[12] The magnetron has been widely used in sputter deposition of metals and alloys; however, its use in plasma polymerization has been relatively uncommon.[13–15] The main use of magnetron is to

sputter the target material placed on the cathode for the subsequent physical deposition of the sputtered materials. In many applications of plasma polymerization, on the other hand, the inclusion of electrode material in the polymeric deposition has been viewed as contamination.

In certain applications of plasma polymerization, the incorporation of electrode material, particularly in a controlled and designed manner, by means of a magnetron discharge is extremely useful and becomes a great asset in plasma polymerization coating. For instance, a thin layer of plasma polymer of methane with a tailored gradient of copper has been shown to improve the adhesion of the thin layer to a copper substrate and also the adhesion of metal to a polymer film.[16,17] In general, applications of plasma polymerization coating, in which the metal contamination should be avoided, are important to select the electrode material that has low sputtering yield. Titanium has been used successfully in such cases.

The use of magnetron glow discharge for the formation of thin films by plasma polymerization has several obvious advantages over the use of glow discharges that do not have magnetic enhancement.[13] Perhaps, the most obvious advantage is the confinement of glow discharge in the lower-pressure regime of plasma polymerization, i.e., polymer deposition can be carried out at a system pressure <100 mtorr. Without a magnetic confinement of glow discharge, the glow expands as the system pressure decreases, often to the entire volume of a reactor. This expansion of glow discharge occurs even when small internal electrodes are used in a relatively large bell jar reactor. In this case, the deposition of material onto the target substrates becomes very inefficient, and the excessive deposition onto the reactor wall practically prohibits the use of such a reactor for the continuous coating of moving substrate in a large-scale operation.

Perhaps, the most important, but not so obvious, aspect of the magnetron glow discharge is that plasma polymerization coating can be performed in a low-pressure regime in which plasma polymerization by a nonmagnetron glow discharge is difficult or impossible. The magnetic enhancement lowers the overall impedance of glow discharge, and lowers the breakdown voltage.[13,18] Hence, the operation of glow discharge in the low-pressure regime becomes possible and practical. The low-pressure operation is favored in obtaining better barrier characteristics of plasma polymerization coating with larger kinetic path length.

Plasma polymerization in a low-pressure regime inevitably reduces the deposition rate of the process in the absence of the magnetic enhancement. However, the deposition rate obtainable by magnetron discharge is several folds higher than that obtained by nonmagnetron discharge, because the magnetron discharge effectively shifts the dissociation glow from the electrode surface to the toroidal glow. The reasonable deposition rates could be obtained in low-pressure regime by employing magnetron discharge. The relatively large-scale industrial applications (outside of microelectronic applications) of glow discharge polymerization employed the magnetron glow discharge.[19,20] An important advantageous factor of magnetron discharge, which is difficult to be appreciated or recognized by laboratory-scale experiments, is the minimum deposition on surfaces other than that of the substrate, i.e., the minimum reactor-wall contamination.

MODES OF OPERATION FOR PLASMA POLYMERIZATION COATING

Operational parameters that control plasma polymerization can be divided into two major categories: 1) characteristic parameters of a reactor, which can be altered but are not variable in each run, and 2) parameters that require adjustment for each run and often during a run. Size of the electrodes, distance between electrodes, and frequency of electric power are examples of parameters of the first category. Monomer flow rate, system pressure, and discharge power are examples of operational parameters of the second category. The parameters of the first category are important in designing a plasma polymerization reactor, but the parameters of the second category are critically important in executing plasma polymerization coating to produce the desired product under the restrictions set by the design of reactor.

Batch Operation

In a batch operation, substrates are placed in a reactor, and plasma polymerization coating is carried out as a unit operation. Repeating the same operation treats a large number of substrates. The batch processing is the primary mode for nearly all laboratory-scale operations. The batch processing can be done in a closed system or in a flow system. Because the number of molecules in a reactor under low pressure is small, it is often necessary to use a flow system to obtain a sufficient amount of coating.

The gas phase changes on the onset of glow discharge. The fragmentation of a molecule increases the total number of gas molecules in a system, and the polymerization or deposition of material decreases the total number of gas molecules. The balance between these two opposing reactions shows in the change of pressure of a flow system, if a throttle valve does not control the system pressure. In a batch operation,

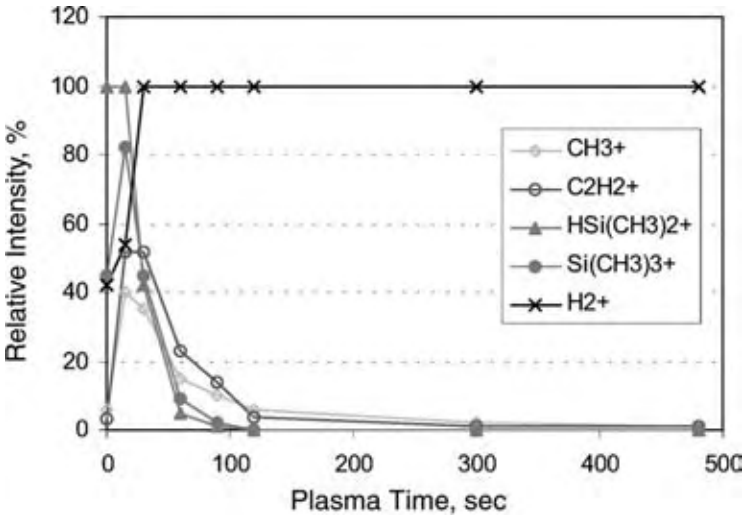

Fig. 14 Change of gas phase species in plasma of TMS with plasma time. Plasma conditions are: 25 mtorr, TMS, two panels of aluminum alloy, DC 1000 V. *(View this art in color at www.dekker.com.)*

therefore, steady-state plasma is not generally established in a relatively short operation time.

Closed System Operation

Very efficient plasma polymerization coating can be performed in a closed system reactor depending on the size of the reactor and the specificity of the deposition on the substrate. For instance, the deposition in DC discharge occurs mainly to the cathode surface and the closed system operation of DC plasma polymerization coating has a distinctive advantage that the total mass in the system is well defined and does not change by the electrical discharge, and high $Y_{p,s}$ can be achieved.

Fig. 13 depicts the change of system pressure during a closed system plasma polymerization of TMS. Fig. 14 depicts the change of gas composition during the same operation of closed system plasma polymerization coating. The easily polymerizable species disappears in the early stage of operation and after a certain time of operation the major gas phase in the reactor becomes hydrogen plasma.

The change of gas composition with the reaction time in a closed system leads to a composition-graded plasma coating, which is a great advantage in plasma polymerization coating of metals yielding excellent adhesion to the substrate as well as to the conventional coating that is applied on the plasma coating.[21] Fig. 15 depicts the comparison of X-ray photoelectron spectroscopy (XPS) cross-sectional profiles of TMS plasma polymer coatings. The coating prepared by a flow system operation shows a uniformly flat profile, whereas the coating prepared by a closed system operation shows a continuously changing profile, from Si-rich at the metal/coating interface to C-rich top surface of plasma polymerization coating.

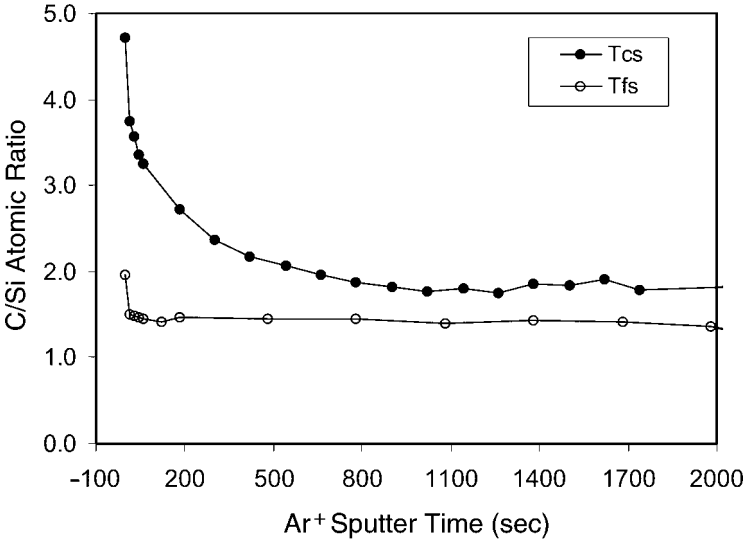

Fig. 15 C/Si ratios of plasma polymer films of TMS prepared in a flow system reactor (T_{fs}) and in a closed system reactor (T_{cs}), as generated by XPS depth profiling. *(View this art in color at www.dekker.com.)*

Continuous Operation

In the continuous processing, a steady-state flow of luminous gas is established and maintained for the duration of operation, e.g., 1 mo, without interruption. Because of the factors described above, it takes some time, e.g., 30 min, to establish a steady-state flow of luminous gas.[22] Once a steady-state is established, it is possible to maintain it for a sufficiently long period of time for a continuous processing. Substrates are fed into the steady-state flow of luminous gas in a cross-flow pattern. The rate of transport of substrate and the length of the path in the luminous gas phase determine the treatment time.

It is common that a substrate or a section of continuous substrate, such as fibers and films, passes multiple sets of luminous gas flow. Fig. 16 depicts a schematic diagram of continuous operation of plasma polymerization with two sets of luminous gas flow. A chamber that is pumped individually to avoid cross-contamination separates the two sets of luminous gas flow. Thus, multiple plasma polymerizations or treatments can be applied on a substrate according to this principle. A continuous substrate, such as fibers, tubes, and films, is fed vertically. The horizontal feeding of substrates, shown in Fig. 16, requires multiple substrates holding devices that travel through the reactor.

In a continuously operated flow system, those factors associated with a closed system or a batch-operated flow system mentioned above are virtually eliminated except at the very beginning of the operation. Therefore, the reproducibility of plasma polymerization obtained by continuous operation is superior to that obtained by the batch operation.

To achieve a continuous operation of plasma polymerization, it is necessary to consider the following factors: 1) deposition on electrodes; 2) deposition on reactor wall; and 3) flaking off of the deposition from these surfaces. Magnetron discharge confines the volume of luminous gas phase, which minimizes the deposition onto the reactor wall. It is a general practice to place removable liners on the walls of the reactor, which will be removed and replaced by new liners on each maintenance stoppage of the operation.

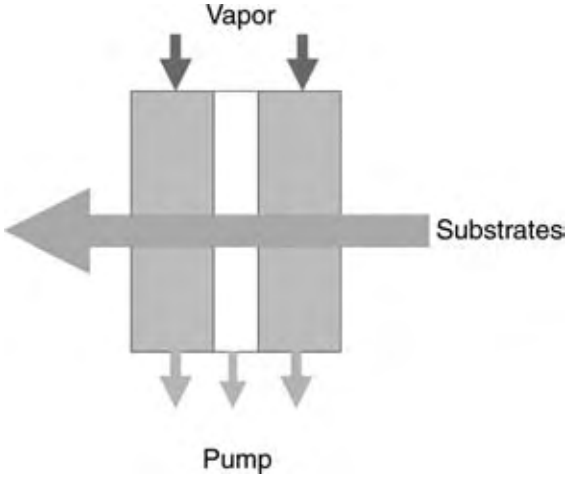

Fig. 16 Schematic representation of continuous operation of plasma polymerization coating. *(View this art in color at www.dekker.com.)*

GENERAL CHARACTERISTICS OF PLASMA POLYMERIZATION COATINGS

Plasma polymerization coating is system dependent and a monomer does not yield a well-defined polymer that can be identified by plasma polymer of the monomer. Plasma polymers formed at the high *W/FM* end of the power-deficient domain and also in the monomer-deficient domain are tight three-dimensional amorphous networks, which do not contain discernible functional groups (Type A plasma polymers). Plasma polymers formed at the low *W/FM* end of the power deficient domain could contain functional groups in the monomer, but the structure is much looser and often consists of oligomeric deposition (Type B plasma polymer). The coating that has a tight network structure with functional groups cannot be obtained by a single-step plasma polymerization of a monomer. The retention of functional groups of a monomer by some efforts, such as pulsed discharge, remote-plasma deposition, etc., can be achieved at the expense of the unique characteristics of the Type A plasma polymers, such as the good barrier characteristics and good adhesion to the substrate.

Type A plasma polymers have the characteristic internal stress built in the film, and the plasma polymerization coating acts as the tempered ultrathin layer on the substrate. The internal stress is caused by the wedging effect of the deposition process, and the total stress increases linearly with the thickness. As the thickness increases, the internal stress reaches the critical point beyond which the internal stress becomes greater than the cohesive force or the adhesive force of the plasma polymerized coating. Above the critical thickness, therefore, the coating cracks (not necessarily in macroscopic sense) or delaminates (buckles) from the substrate. Consequently, there exists a thickness limit of plasma polymerization coating. The tighter the structure, the smaller is the thickness limit.

The barrier characteristic of a thin layer is proportional to the value of (thickness)/(permeability) or (thickness) (transport resistance). Type B plasma polymers have a higher thickness limit but permeability is high. Although a thicker layer could be deposited

without creating cracks with Type B plasma polymers, the layer does not provide a good barrier because of the higher permeability due to the looser structure. Type A plasma polymers provide remarkably high barrier characteristics in spite of the small thickness limit. The barrier characteristics, however, decrease drastically as the coating thickness increases beyond the critical thickness, although the coating might visibly appear as an intact layer.[23]

A well-executed Type A plasma polymer coating is insoluble and infusible, and the surface is imperturbable to any change in the surrounding medium. Type B plasma polymer coatings, however, are often soluble in various solvents (including water) and, consequently, the surface is highly perturbable and the adhesion to the substrate is poorer than in Type A plasma polymer coatings. The frequently mentioned characteristics of plasma polymers, such as high cross-linking, insolubility and infusibility, stable network, etc., do not apply to Type B plasma polymer coatings.

CONCLUSIONS

Plasma polymerization coating is a unique nanofilm coating technology that yields a tight amorphous network structure of atoms contained in the monomer (Type A plasma polymers). Because of the unique growth mechanism of plasma polymerization, excellent adhesion of coating could be obtained in a practical manner.

Depending on the level of energy input, much loose structure with functional groups (Type B plasma polymers) could also be obtained; however, this type of coating does not share the unique characteristics of Type A coatings.

Type A plasma polymerization coatings could be the ultimate green processes that use the minimum amount of monomer and do not yield effluent. That environmental remediation processes are not required could more than offset the initial equipment cost in the overall cost of manufacturing.

INTRODUCTION

During the 1960s and the early 1970s, cleaning up wastes created as a result of industrial and social activities was the foremost concern of environmental engineers and scientists. Several strategies were implemented to help clean or treat air emissions as well as contaminated soil and water resulting from activities dating as far back as the industrial revolution. In the early 1980s, the notion of protecting the environment from the effects of pollution-causing activities gained momentum. Environmental professionals and activists in the United States and Europe realized that the traditional approach of treating the waste after it was created (or end-of-pipe treatment) and cleaning up contaminated soil or groundwater (i.e., remedial treatment) to meet government standards were less desirable from societal, technical, and financial perspectives. A shift toward an approach that favored prevention of pollution, while paving the way for process efficiency and improved process design, was realized as the need of the day. The importance of preventing pollution at source, stressing the need for reduction in waste generation and associated pollution rather than treating the waste produced at the end of the process, then became recognized as a key component of sound environmental management. This along with the methodology for more efficient use of resources allows our ecosystems to meet and sustain the growing demands of human societies.

In 1990, with the passage of the National Pollution Prevention Act (PPA), the U.S. Environmental Protection Agency (USEPA) decided to make pollution prevention or P2 a top priority. In the United States, P2 includes source reduction and other practices that reduce or eliminate the creation of pollutants through increased efficiency and conservation of natural resources. Treating wastes was considered important, but efforts to prevent wastes from being generated was the priority. This entry provides an overview of the concept of P2. It is an attempt to offer an insight into the basic P2 principles and details the P2 procedure.

POLLUTION PREVENTION (P2)

P2 over the years has evolved from a concept to a proven technology to become a stand-alone and mainstream channel for eliminating the adverse effects of industrial and manufacturing activities on the environment or the ecosystem. The U.S. P2 initiatives originated during 1976–1979 with the adoption of the Pollution Prevention pays (3P) program by the 3M Corporation. North Carolina adopted waste minimization as a statewide priority for managing emissions from industry at around the same time. Most states followed suit, and were requiring P2 programs for industry, by the mid-1980s. By 1990, the Fortune 1000 U.S. corporations had adopted P2 as a primary policy. The shift in priorities in addressing the environmental issues kindled the transition from nearly 20–50 yr of conventional pollution control to the more proactive, preventive approach. Fig. 1 is an approximate timeline of the period from 1976 to 1996 when there were distinct explosions of success in P2 activities.[1–4] For detailed information on pollution prevention, see Bishop, Higgins, and Patel and Kumar.[5–7]

Definition

P2 is a term used primarily in the United States but a host of other terms with functional similarity are used globally and represent a globally accepted movement for improving business performance and providing a vision of a profitable, cleaner, and sustainable future focusing on a strategy of continuously reducing pollution and adverse environmental impact through source reduction—that is, eliminating waste at the source rather than treating it at the end of the process (end-of-pipe treatment).

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120006820

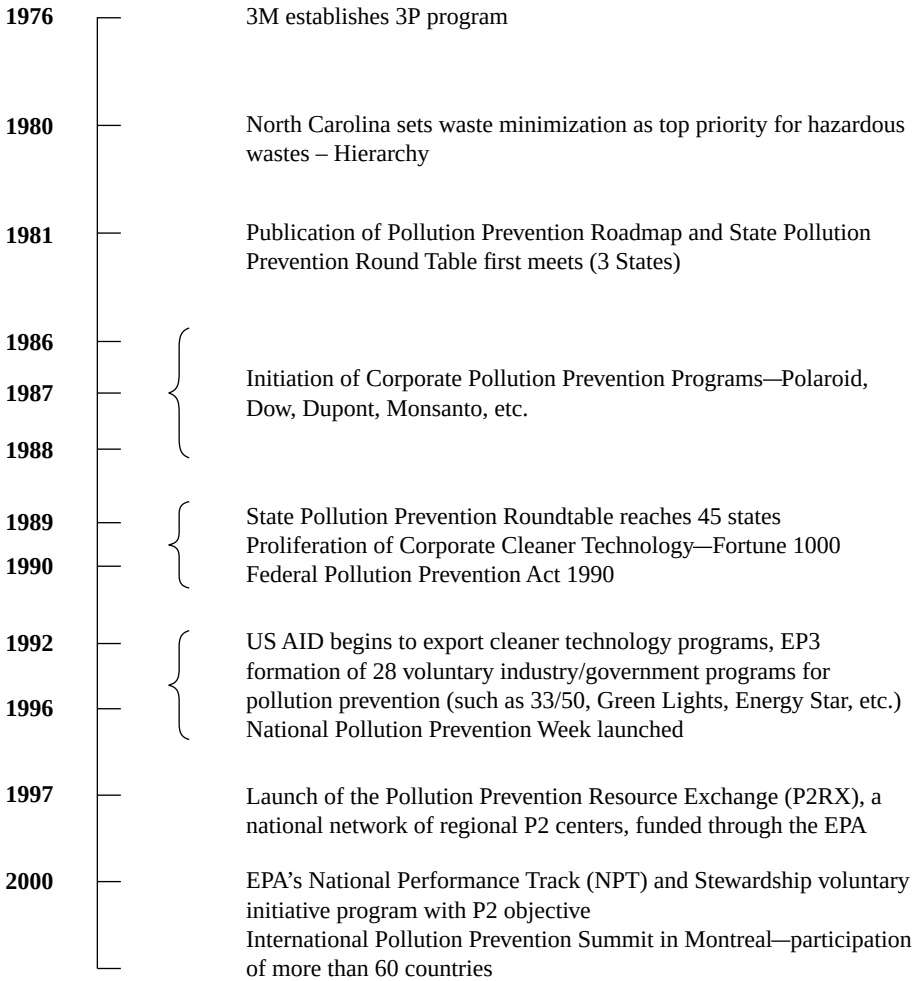

Fig. 1 Timeline of early P2 successes.

In the United States, the 1990 PPA was the first major national policy initiative aimed at promoting P2 as a fundamental component of environmental protection efforts. Under Section 6602 (b) of the 1990 PPA, Congress established a national policy that prioritized P2 over other means of reducing pollution. The policy and definitions discussed below are adapted from the USEPA's pollution prevention documents.[8–10] The policy highlighted the following aspects:

- Pollution should be prevented or reduced at the source whenever feasible.
- Pollution that cannot be prevented should be recycled in an environmentally safe manner whenever feasible.
- Pollution that cannot be prevented or recycled should be treated in an environmentally safe manner whenever feasible.
- Disposal or other release into the environment should be employed only as a last resort and should be conducted in an environmentally safe manner.

Fig. 2 is a representation of this hierarchy of priorities for managing waste.

The 1990 PPA defines ''pollution prevention'' mainly as ''source reduction,'' but it also includes other activities that reduce or eliminate the creation of pollutants through:

- Increased efficiency in the use of raw materials, energy, water, or other resources.
- Protection of natural resources by conservation.

The Act defines ''source reduction'' as any practice that

1. Reduces the amount of any hazardous substance, pollutant, or contaminant entering any waste stream or otherwise released into the environment (including fugitive emissions) prior to recycling, treatment, or disposal.
2. Reduces the hazards to public health and the environment associated with the release of such

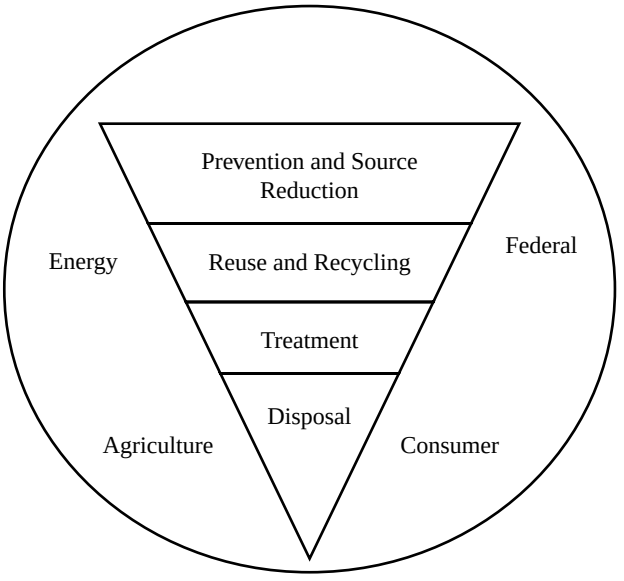

Fig. 2 Waste management structure for pollution-generating activities.

> substances, pollutants, or contaminants. Source reduction is achieved by equipment or technology modifications, process or procedure modifications, reformulation or redesign of products, substitution of raw materials, and improvements in housekeeping, maintenance, training, or inventory control. However, it does not include any practice which alters the physical, chemical, or biological characteristics or the volume of a hazardous substance, pollutant, or contaminant through a process or activity which itself is not integral to and necessary for the production of a product or the providing of a service.

Thus P2, as defined in the PPA, is a distinct approach that does not consider out-of-process recycling as a form of prevention, even though it can bring about environmental improvements and greater efficiency in resource use and conservation. This distinction is still debated between regulators and industry proponents, who assume recycling to be an equivalent of P2. In accordance with the hierarchy of preferred waste management options specified in the PPA. U.S. Environmental Protection Agency (EPA) has interpreted waste recycling is not eliminating the creation of pollution at the source, thereby posing a potentially higher hazard to workers, the environment and public health than the P2 management option and does not view recycling as synonymous with P2. However, in some cases, inprocess recycling is considered a form of P2, wherein the waste generated from a process is directly reincorporated into the same process.

As shown in Fig. 2, P2 approaches can be applied to all pollution-generating activities, including those found in the energy, agriculture, federal, consumer, as well as industrial sectors. P2 does not include practices that create new risks of concern.

Terms Synonymous with P2

P2 is a term widely known and accepted in North America, but is one of the many synonyms that are used in different parts of the world targeting environmental improvements and resource management. Some of these approaches that have functional similarity to P2 include:

Waste Minimization: Waste minimization is any effort to reduce or recycle the quantity of waste generated, and when feasible, to reduce or eliminate toxicity. It includes any source reduction or recycling activity undertaken to reduce the total volume or quantity of hazardous waste and/or the toxicity of hazardous waste, with the goal of minimizing threats to human health and the environment. Waste minimization focuses exclusively on solid wastes regulated under the Resource Conservation and Recovery Act (RCRA), and does not include treatment, unless the treatment is part of the recycling process. However, it is broader in scope than P2 to also include recycling and other means to reduce the amount of waste that must be treated or disposed of off- or onsite.

Sustainable Development: ''Sustainable development meets the needs of the present without compromising the ability of future generations to meet their own needs.'' P2 plays an important role in achieving the goal of sustainability as it emphasizes the efficient use of materials and resources with an environmental aspect added to it.

Best Management Practices: Best management practice is a process, technique, or innovative use of resources that has a proven record of success in providing significant improvement in cost, schedule, quality, performance, safety, environment, or other measurable factors that impact the health of an organization.

Cleaner Production: Cleaner production is the continuous application of an integrated preventive environmental strategy to processes, products, and services to increase overall efficiency and reduce risks to humans and the environment. Cleaner production can be applied to the processes used in any industry, to products themselves, and to various services provided in society.

Design for Environment: Design for environment means designing products and services with the environment in mind. It aims to minimize adverse environmental impacts throughout the entire life cycle of a product and integrates cleaner, cheaper, and smarter designs and solutions into everyday business practices.

Eco-efficiency: Delivery of competitively priced goods and services that satisfy human needs and bring quality of life, while progressively reducing ecological impacts and resource intensity throughout the life cycle, to a level at least in line with the earth's estimated carrying capacity. The World Business Council for Sustainable Development developed the concept of eco-efficiency to look at cost optimization in the context of positive environmental benefits.

Energy Conservation: Actions taken to reduce or more efficiently use energy, in an effort to preserve the environment and avoid depletion of energy resources.

Green Engineering: Green engineering is the design, commercialization, and use of processes and products that are both feasible and economical while minimizing 1) generation of pollution at the source and 2) risk to human health and the environment.

Green Chemistry: Green chemistry is the use of chemistry for pollution prevention, i.e., the design of chemical products and processes that reduce or eliminate the use and generation of hazardous substances. The EPA's Green Chemistry Program promotes the research, development, and implementation of innovative chemical technologies that prevent pollution in both a scientifically sound and a cost-effective manner.

All these concepts focus on improving the environmental condition. Use of a specific terminology is often linked to the particular forum in which the debate or discussion is occurring. Although these terms have subtle differences, they do share the major emphasis on prevention. For more detailed information on any of the concepts mentioned earlier, see Refs.[2,3,8,11–18].

Need for P2

The emphasis on pollution prevention is to deal with the present and future pollution. While pollution control is necessary to deal with contamination that has already occurred, the prevention of further contamination is more important. Environmental managers with the task of controlling pollution need an acceptable and measurable reason for exploring and eventually implementing a P2 project. The need for P2 implementation is chiefly to protect the environment while saving money and to save money while protecting the environment. The major advantages and benefits of developing and implementing a P2 project are as follows:

Reduced Compliance: Undertaking P2 projects reduces regulatory exposure and, in some cases, eliminates the need for expensive and time-consuming permits, manifesting, monitoring, and reporting. This has been a major thrust for waste reduction in industries.

Lowered Operating Cost: Pollution prevention activities often save money in the long run in terms of new material costs, waste treatment and disposal costs, and energy and operations costs. Many P2 projects have good returns on investment and short payback periods. Some P2 opportunities, such as reduction in toxic substances, can help reduce the costs of medical claims and disability leave. Costs associated with compliance and waste handling are also avoided if the waste or pollutant is prevented from being generated in the first place.

Enhanced Worker Health and Safety: Reduced use of toxic substances in the workplace is a major aspect of pollution prevention that improves air quality, water quality, and the safety of the work environment by reducing the likelihood of leaks, spills, and releases. These steps result in cost savings through preventing the loss of materials and decreased insurance rates by reducing medical claims and disability leave. Better labor relations also result from improved worker safety.

Increased Productivity: Pollution prevention improves plant productivity through more efficient use of raw materials, labor, equipment, and energy because of improved processes and operations. Small improvements to old and inefficient technologies and improved quality control of processes result in increased product yield and better quality.

Improved Environmental Quality and Reduced Future Liability: Reduction in waste discharges to the environment is the principal focus and benefit of P2 programs. However, many legal waste disposal and treatment methods often move environmental contaminants from one medium to another, thus resulting in environmental damage. This could result in future liability problems. Pollution prevention involving efficient methods and processes results in less waste, thus ensuring improved environmental protection and reduced long-term liability potential.

Improved Company Image and Community Relations: The USEPA publishes details of companies' waste and pollution prevention efforts through the Toxic Release Inventory. With a society aware of the environmental hazards associated with the all types of waste, it becomes increasingly difficult for big polluters to maintain an ongoing relationship with the community. The USEPA also publicly recognizes companies that make voluntary commitments to P2, so as to enhance their image in the community.

The section is adopted from the Ohio Pollution Prevention and Waste Minimization Planning Guidance Manual.[19]

METHODS FOR P2

Wastes could be reduced for any industry by a systematic analysis of processes to study the inputs

(materials, energy, and people) and activities creating wastes, which in turn requires the combined effort of the production, administration, and environmental specialist teams. One or more of the following methods can accomplish P2:[20–22]

- *Design changes*: Incorporation of environmental elements in the design of a product makes it more resource efficient and sustainable over the life cycle. Product redesign can involve extending the product's life span or enabling it to be completely recycled into a new product.
- *Process modification*: Process modifications involving reconfiguring the different steps in a process often help reduce production waste, cutting both pollution and waste management costs. This method of preventing pollution can involve reducing the total materials and energy used to manufacture a product. For example, a car wash company could reduce its rinse cycle by 5 sec, thereby conserving water and energy. Similarly, a car parts manufacturer could reduce one's paint use by utilizing more efficient painting techniques or machinery.
- *Materials substitution and product reformulation*: Use of alternative materials for production processes that can provide equivalent results while preventing costly hazardous waste generation, air emissions, and worker health risks is a sound approach to P2. Products containing toxic ingredients find their way into the ecosystem. Air, water, and soil pollution can be considerably reduced if the toxic substances are replaced with nontoxic ones. Product reformulation or redesigning a product may involve switching to new ingredients, but also includes a consideration of reducing packaging or reducing the amount of "ingredients" that go into a finished product. Reducing the amount of ingredients conserves not only resources but also energy.
- *Materials reuse*: Wastes generated from one process or industry can become the raw material for another. Materials reuse goes a long way in preventing pollution by: 1) reducing waste that needs to be disposed; 2) conserving resources; and 3) lessening the cost of materials.
- *Resource efficiency and conservation*: Using energy, water, raw materials, and other production inputs more efficiently conserves the resources apart from reducing pollution, improving productivity, and lowering the operational costs. Cutting down on the amount of water and energy use in day-to-day operations can result in reductions in the amount of greenhouse gases, particulate matter, and other pollutants that may be released into the atmosphere and into water discharges from a facility.
- *Good operating and work practices*: Rethinking day-to-day operations and maintenance activities can lead to P2 that can have a positive impact on the environment and uproot wasteful management practices that drive up costs and cause pollution. For example, volatile organic solvent emissions from a washer can be prevented during off hours if the washer is covered with a lid. Good operating practices such as: 1) inventory control 2) supply chain management; 3) preventive maintenance; 4) improved housekeeping; 5) employee training; 6) facility management; 7) material segregation, etc. play an important role in achieving P2. Educating staff on environmental issues is a very crucial work practice that help them practice P2 while carrying out their tasks. For example, employees can learn to prevent spills and leaks, to turn lights and equipment off when they are not being used, or to cut down on the amount of paper used in an office setting.
- *New clean technologies*: There is no real limit to the opportunities to practice P2, and scientists and engineers are constantly developing new technologies that enable humans to minimize adverse impacts on humans and the Earth's ecosystems that support all life. Switching to renewable energy sources to heat our homes or power our vehicles is an example of the use of a cleaner technology that can prevent pollution.

The four P2 case studies given below can provide ideas on how each of these methods can be used, depending on the nature of the operation and the goal of the P2 program.

These case studies were conducted during 2001–2003 for Ohio industries with the help of the National Institute of Standards and Technology Centers in Ohio, under a USEPA grant. Detailed information on these and other case studies is given in a report by Kumar et al.[23]

CASE STUDY 1: POLLUTION PREVENTION AT A METAL COATING FACILITY

P2 Goal

This study involved the pollution prevention assessment of a metal parts coating unit to bring about pollution prevention through waste reduction by making process changes, while maintaining the same costs.

Procedure

The study began with isolating sources of waste and pollution. This was followed up with suggestions to alleviate problems.

Sources of waste

Coating Various Customer Parts. Metal parts of various configurations are shipped to a metal coating facility (MCF) by customers for coating with various paints according to customer specifications. The customers of MCF have prepared the parts for painting, so no additional processing is necessary before painting is begun.

Each part is hand placed on an overhead chain conveyor that dips down into a trough with the appropriate paint. The parts are immersed for a few seconds to properly cover the part with the paint. As the time for immersion is completed, the part moves out of the paint trough, up an incline to a heated area for drying. When the part moves out of the trough, any excess paint will drip off onto a piece of plastic sheet. This paint currently dries on the plastic or accumulates into a small holding container, at the end of the incline, which is recovered. Plastic sheets are reused by color for other runs of the same color paint. Currently, paint dries on the sheets and can easily evaporate out of the small holding container.

Paint Sludge From the Dipping Tanks Paint used to coat the parts is adjusted by adding xylene to maintain proper viscosity. There is no mechanical agitation on the tank. Because of the configuration of the tank (low and long), it is difficult to provide manual agitation. The tank is stirred by hand whenever the xylene is added. This results in some settling of the paint, as mechanical agitation is more efficient than hand agitation. This settled paint ''sludge'' is placed in a drum for offsite disposal as a hazardous waste (Table 1).

Opportunities to Reduce Waste

Coating various customer parts

Careful consideration should be given to the placement of the parts on the hooks so that adequate paint coverage and rapid draining of excess paint are facilitated. This will require that each part be carefully analyzed to achieve these objectives.

The chain conveyor structure can be modified at a point where it leaves the dip tank to facilitate drainage. A sharp upward turn followed by a downward turn may increase the speed at which the excess paint drips off the part.

Paint sludge from the dipping tanks

As the paint drips off the parts in the line beyond the tank perimeter, it is directed toward an open top container. The open areas of the paint both in the painting tank and in the small holding container allow for airflow and drying. The surface area of the small holding container directly exposed to the air can be reduced by providing a lid that has a hole which is not larger than 2 in. in diameter and is tapered into the container. This will allow the paint to accumulate in the container rather than on the lid. Additionally, if the paint in the container has formed sludge in the bottom, thinner may be added along with mixing to decrease the viscosity of the sludge and, by careful adjustments of the thinner, may allow it to be reused as good raw material. Mechanical mixing is the preferred method for this activity. This should be a slow speed agitation that provides for mixing of the entire contents of the tank.

Expected Benefits and Results

It is estimated that emissions can decrease by up to 30% (from 42,774 to 29,942 lb/yr) with the implementation of these suggestions.

The hazardous waste issues will decrease with the reduction of the hazardous waste generation below 2200 lb/mo from 4527 lb/mo. By use of the previous recommendations and with the possibility that sludge may be recovered with thinner, the reduction can be significant. This will reduce the burden on the facility as well as the cost for paint and hazardous waste disposal. The cost reduction for hazardous waste disposal is estimated to be $25,550/yr. This cost reduction is affected by the reduction in evaporated paint and reduced sludge loss.

CASE STUDY 2: WASTE MINIMIZATION ASSESSMENT AT CLIENT COMPANY

P2 Goal

This project was intended to determine the best methods to help the client reduce the hazardous and

Table 1 Hazardous waste generated

Waste	Amount generated (£)	Amount reclaimed (£)	Amount disposed of (£)	% Reclaimed
Liquid pourable paint	22,200	0	22,200	0
Solid debris and liquid paint	20,300	0	20,300	0
3-yd boxes of paint sludge	11,820	0	11,820	0
Total	54,320	0	54,320	0

nonhazardous waste generated by the production operations.

Procedure

The facility waste reports, tours, and discussions helped gather data on the type and amount of generated waste associated with each manufacturing process.

Sources of Wastes

Nonhazardous waste

The client generated approximately 905.5 tons of solid nonhazardous waste in 2000. Only 49% of the generated waste was recycled, and the rest was sent to a landfill. Table 2 summarizes the solid waste generation/disposition.

Avenues for Nonhazardous Waste Minimization and Savings

1. Some of the raw material waste is from quality control problems when the mix is in the wet stage. Keeping the raw material in closed drums and by avoiding cross-contamination, it can be worked back into the manufacturing process within a 3–4 mo period, thereby avoiding generation of waste.
2. To respond to customer orders on a timely basis, the facility maintains a huge stock of raw material in bags (super sacks) for the two and one-half operational runs each year. Use of railcars to ship material during the runs would decrease the bag disposal cost and material-handling costs, and also improve quality. Quantitative analysis shows the elimination of 400 bags per year (a 46% reduction) by the use of two railcars per run.
3. An estimated 14,175 lb of raw material (unit price \$0.88/lb) is lost annually in the process of transportation and handling. This includes loss from damaged bags while loading and unloading from trucks, loss because of overflow while loading into the mixer, and loss owing to material left behind in emptied bags. Apart from the loss, transportation cost and labor cost are incurred in warehousing and delivery to the mixer. Railcar use would help avoid the loss of material and reduce cost. With a cost reduction of \$0.015/lb in shipment by railcars, \$12,000/yr can be saved in shipping 800,000 lb. Table 3 summarizes the savings from railcar use.
4. In one of the buildings, the drying equipment has a piece missing from the discharge side. This results in an estimated waste of 1050 lb/yr (\$924/yr), which can be easily saved by fixing the equipment.
5. Oil/grease used to lubricate the chain of bucket elevators has intermittently fallen on to the product rendering it a waste. By the use of a lubricant that does not drip, this waste could be eliminated.
6. Some of the feed hoppers for the mixers have an opening on one side to allow the control of flow out of the bag. A piece of removable Plexiglas in a slot on the side with the opening would cut down on what falls to the floor and still allow for control as needed.
7. The large dryer in Building 31 has part of the edge seal worn away allowing material to fall on the floor. Replacement or repair of this edge seal would stop this loss.

Table 2 Nonhazardous waste generation in 2000

Waste type	Amount generated (tons)	Amount reclaimed (tons)	Amount land filled (tons)	% Reclaimed
Cardboard	26	0	26	0
Pallets	114	114	0	100
Wood (pallet parts)	26	0	26	0
Fabric bags	77	0	77	0
Metal	222	222	0	100
Glass	7.5	0	7.5	0
Plastic	2	0	2	0
Office paper	30	0	30	0
Concrete	200	0	200	0
Raw materials	175	105	70	60
General trash	26	0	26	0
Total	905.5	441	464.5	49

Table 3 Railcar evaluation

Process	Amount saved	
	£	$
Offloading and warehousing	—	1,600
Delivering from warehouse to mixer	—	6,750
Bag damage	9,975	8,778
Bag overflow	1,000	880
Materials left in bags	3,200	2,816
Material cost savings	—	12,000
Total	14,175	32,824

8. Some of the conveyors to the bucket elevators on the furnaces do not have trays placed under them to catch any material that may fall off. An estimated loss of 15,750 lb/yr ($13,860) of material occurs as a result.
9. Approximately 44,000 lb of oats ($0.10/lb) are required annually for the cleanup of die from extruders. An estimated 40% of the oats could be reused one more time, saving $1760/yr, and resulting in 17,600 lb less of waste.

Hazardous waste

Table 4 shows the hazardous waste generated in 2001.

Avenues for Hazardous Waste Minimization and Savings

1. Material waste from furnaces 4 and 5 results in substantial hazardous waste generation because of the nature of the material. For furnace 4, there is a loss of 3500 lb/yr ($4.77/lb, $16,695/yr), and 7000 lb/yr for furnace 5 ($0.88/lb, $6,160/yr).
2. Improved housekeeping at waste generation sources could reduce the waste shipped offsite. Cross-contamination (mixing of nonhazardous waste with hazardous waste or vice versa) results in larger quantities of hazardous waste than are actually generated. Elimination of this would help achieve savings on disposal cost.
3. Fines and oversized custom products could be recycled, reducing waste. Metal loaded fines could be loaded to the wet mix, decreasing the amount of metal requiring impregnation in a future step.

Table 4 Hazardous waste generation in 2001

Waste	Amount generated (lb)
Miscellaneous dry waste	650,000
Water and sump sludge	52,070
Wastewater treatment sludge	200,000
Total	902,070

Recommendations

1. Switch to two railcars per run for raw material use to improve quality, decrease cost, and reduce labor.
2. Ensure that all offspecification drums of raw material wet mix are lined with a plastic bag, the bag is secured to prevent the wet mix from drying out, and training of all employees is continued on the importance of not mixing waste materials and proper labeling techniques.
3. Evaluate each wet mix for recycling. This material would be put back into the process at the wet mix portion. It can be used as a good intermediate or as a product substitute.
4. Use a different type of oil/grease or a different technique to lubricate bucket elevator chains.
5. For the custom product, continue with the investigations into using fines to make a product that can be used by the customer.
6. Reuse oats that are reusable when cleaning dyes.
7. Provide trays to capture any spillage under the conveyors and bucket elevators at all times.
8. Evaluate the gaskets and edge seal integrity on each machine before production begins, to minimize spills onto the floor.

Expected Benefits and Results. Table 5 summarizes the total estimated savings.

CASE STUDY 3: ENERGY SURVEY FOR A MANUFACTURING SERVICE CENTER

P2 Goal

An assessment to help reduce the spending on electricity bills and the amount of the pollutants produced was the highlight of the project.

P2 Procedure

The assessment procedure was broadly divided into the following two major components:

1. Data on the total electricity load were collected and compiled using the as-built drawings for lighting loads and the nameplate capacity of the motors for the major equipment and the air-conditioning loads. A spreadsheet was developed using the data mentioned earlier to conduct analysis of peak loads and energy loads under various scenarios.

Table 5 Potential savings

Improvements	Amount saved	
	£	$
Use of railcars	14,175	32,824
Use of trays under conveyors and bucket elevators	15,750	13,860
Reuse of oats for cleaning extruder dies	17,600	1,760
Lubrication type and method change for conveyors and bucket elevators	Included with others	Included with others
Hazardous waste reductions	75,500	27,730
Total	123,025	76,174

2. The utilization pattern of the lighting and equipment loads was studied by interviewing the various occupants of the manufacturing service center and observing the usage for a limited period. This part also involved measurement of light intensity at different locations in the manufacturing service center.

Observations

The study of the usage pattern revealed the following:

1. The employees of the manufacturing service center were not in the habit of shutting down their computers. The computer load was assessed to be the second highest contributor of electricity load.
2. The manufacturing service center had a shop floor that consisted of 54,400 W high-pressure sodium lamps. All these lights were kept on during office hours irrespective of occupancy of the shop. Ten of the lights were kept on for 24 hr/day, 7 days/week, 365 days/yr.
3. The light intensity as measured in some parts of the office was around 30–40% higher than the prescribed standards.

Recommendations

The following major recommendations were made:

1. The employees were asked to shut down the computers when leaving for the day. This alone would result in saving around 45,000 kWh on an annual basis.
2. The shop manager was asked to operate the shop lights on "as-needed" basis. This would result in an annual savings of around 20,000 kWh.

Apart from the major recommendations mentioned earlier, the employees were advised to use the lights in the conference room and other utility areas on an as-needed basis.

Results

Table 6 shows the amount of pollutants that will be reduced as a result of the recommendations.

CASE STUDY 4: ENERGY EFFICIENCY AND POLLUTION PREVENTION ASSESSMENT FOR CONCRETE BUILDING PRODUCTS MANUFACTURER

P2 Goal

An energy efficiency audit and a general pollution prevention assessment of the operations for a building industry, to determine if waste reduction and cost reduction are possible. Operations conducted at this facility include form fabrication, concrete mixing and pouring, and sand blasting and acid washing to impart the finish. These concrete slabs are formulated with a variety of sands and stone specific to the needs of the customer.

Table 6 Possible pollutant reduction

Name of the unit	CO_2 (lb/yr)	SO_2 (lb/yr)	NO_x (lb/yr)
Computers	81,000	1,033	348
Workshop	36,000	460	155
Total (for the facility)	117,000	1,493	503

P2 Procedure

An energy audit was conducted for the following systems:

- Hot water heater
- Boiler
- Compressed air
- Building lighting

A summary of the energy/water savings is provided in Table 7 for each of the systems examined during the assessment.

Domestic hot water heater

Current Status. The bathrooms and office area are supplied with hot water via a 32,000 Btu/hr residential hot water heater. The heater is at least 8 yr old and past its useful life, especially when heating hard water. During July and August of this year, gas usage averaged 9.5 ccf (100 cubic feet)/day. During this time, the only gas-using piece of equipment was the domestic hot water heater. If running at full capacity for the entire day, a properly operating heater of the same type should use only 7.7 ccf/day.

Recommendation. Replace the existing hot water heater with an instantaneous hot water heater to be installed in the men's bathroom fed from the existing piping.

Sioux boiler

Current Status. The Sioux boiler supplies hot water to the first mixing machine when needed. The burner has an output of 1,000,000 Btu/hr. The unit was built in 1986 and has an efficiency of 0.6.

Recommendation. Replace the Sioux boiler with a hot water heater similar to the one servicing the newer mixer but of a larger size because of the greater load.

Compressed air

Current Status. The compressed air systems are in the process of a major change out. General piping layout was discussed with plant personnel. Basic concepts in compressor room piping were discussed with the maintenance man doing the work. Leaks were tagged and the matching tags are presented with this report. On each, there is a location and an approximate leak rate.

Recommendation. Repair leaks that were tagged throughout the facility.

Lighting retrofit

Current Status. The production and shop floors are lit using 400 W high-intensity discharge (HID) lights. Because of overhead crane movement and the nature of production, lights must be kept at the ceiling level. There are also a few T12 task lights in the mixing and wood shop areas. In the offices and break rooms, inefficient T12 lighting technology is being used. The only lighting control is the standard on/off switches. Total lighting counts for the facility are: 400 W high pressure sodium (HPS)—76, 400 W metal halide (MH)—5, 4 ft four-lamp T-12 fixtures—65, and 4 ft two-lamp T-12 fixtures—11.

Recommendation. Replace all HID lights with more efficient 320 W fixtures throughout the plant. Change the offices and break room lighting from T12 to T8 lighting technology. To maximize efficiency, office lighting will not be a one-for-one change out. Lighting levels will be maintained at current standards after the retrofit. No controls will be added because at this time the company makes the effort to turn off lights when not in use.

BASIC STEPS TOWARD P2

The adoption of P2 as a core component of business management practice is a viable approach to both business success and environmental protection. Waste minimization or prevention can be made a routine part of daily business operations, at both small and large facilities. A little time and effort in following some P2 steps goes a long way toward success and preventing the creation of waste. The approach to P2 is compatible with the concept of environmental performance embodied in the Malcolm Baldridge model of rewarding businesses that raise awareness of the importance of quality and performance excellence as

Table 7 Potential energy savings identified by assessment

Proposed modification	Estimated annual energy savings	Estimated annual cost savings ($)	Cost to retrofit ($)	Payback (yr)
Change out hot water heater	2,738 ccf	2,382	2,850	1.2
Replace boiler with hot water heater	7,020 ccf	6,107	11,700	1.9
Fix compressed air leaks	6,200 kW/hr	486	450	0.9
Lighting retrofit	32,688 kW/hr	2,562	32,700	12.8

a competitive edge. The ideas of achieving environmental quality improvements using the traditional continuous quality improvement concept presented in the plan-do-check-act cycle is applicable to P2. Corporate policies and goals, plant policies and goals, environmental management tools, environmental auditing, information systems, employee awards, research and development, training and awareness, co-operation across plant boundaries are factors that lead to the greatest amounts of pollution prevention.[24] Fig. 3 shows a diagrammatic representation of the basic steps in the implementation of a P2 program in any industry.[6,8,19,25,26]

Each of the steps involved in the implementation of a P2 program and the potential benefits are described below:

1. Evaluate company policy and culture
   a. Establish an environmental management system with clear policies, goals, and objectives.
   b. Draft a brief written policy statement in support of a pollution prevention program.
   c. Justify changes in the process or design with cost savings potential and reasons that provide a win-win situation for all involved.
2. Identify waste and its source
   a. Characterize each waste stream—determine where the waste comes from, what processes generate it, and how much is being discarded.
   b. Examine all waste streams, including process wastes, hazardous wastes, nonhazardous wastes, solid wastes, and office waste.
   c. Study what is discarded in trashcans and dumpsters to determine what materials are being thrown away and consider what wastes are poured down the drain, such as rinse waters and process waters.
   d. Consider the costs of each stream, including the cost to purchase, dispose of, treat, or control it.
   e. Examine energy and water consumption on a facilitywise and process specific basis and look for high- and low-usage trends in your water and electric bills.
3. Set a target
   a. Set specific measurable and attainable goals to reduce specific types of wastes by some reasonable and feasible amount, for example, a reduction of process effluent by 10% or a reduction in energy consumption by 15%.
4. Identify and prioritize the opportunities
   a. Evaluate all the waste streams for possible reduction and come up with a list of measures that can be taken to reduce waste and improve process efficiency.
   b. Investigate opportunities for new products or ingredients that prevent waste generation.
   c. Prioritize the opportunities identified by considering
      i. Cost
      ii. Ease of implementation
      iii. Payback (and cost savings or cost avoidance)
      iv. Criteria deemed important by the organization, such as increased employee safety.
   d. Focus on opportunities that are easy to implement, have low capital investment, and reduce large volumes of waste.

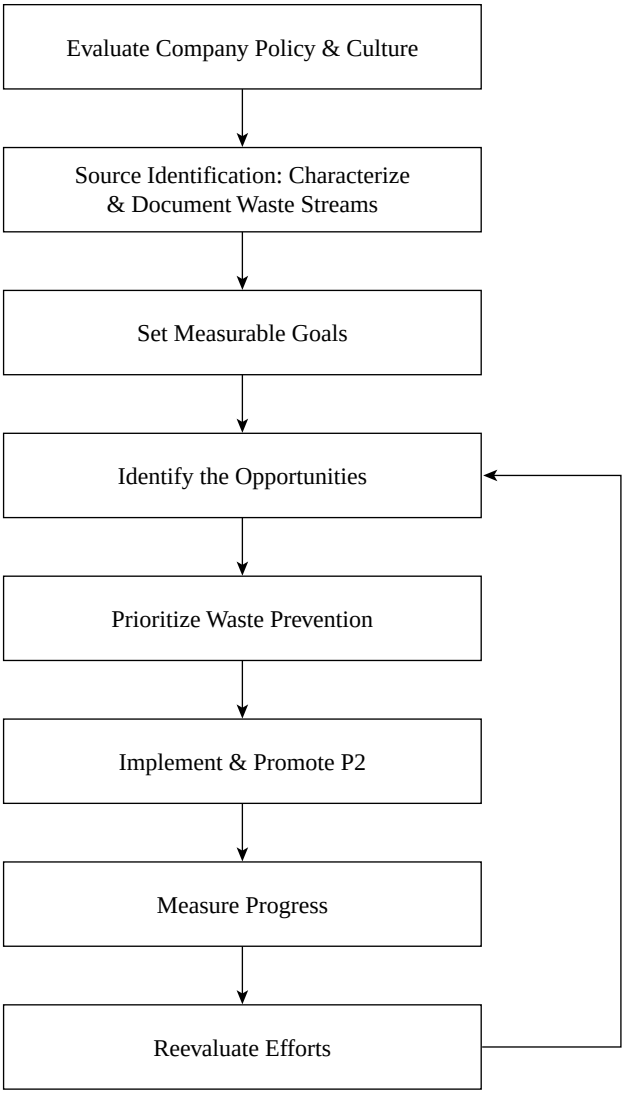

Fig. 3 Basic steps involved in a P2 program.

e. Identify the best methods or opportunities/avenues. For example, identify the practice or approach, such as process redesign, product redesign, or general operating procedures that would best enhance the efficiency and determine whether it is feasible.

5. Implement and promote P2
   a. Teach and train employees on P2 concepts on how to prevent waste from being created in the first place.
   b. Discuss the waste prevention policies and goals, and provide training to employees who must change the way they handle materials.
   c. Encourage employee involvement by asking for new suggestions and offering incentives.
6. Measure progress
   a. Quantify and track reductions and cost savings in volumes of waste produced and treated, energy and water use, raw materials consumed, toxic and greenhouse gas emissions, and other effluents.
   b. Qualitatively, claim the less tangible benefits such as improved public image, enhanced worker and workplace safety, continued community relationship, etc.
7. Re-evaluate
   a. Conduct regular assessments to identify additional waste prevention opportunities as part of a process of continual improvement. As long as wastes continue to be generated, there are opportunities to reduce it.

To derive the most benefits from the P2 program steps, various assessment tools have been developed by researchers and practitioners in the field.[27,28] Many of these tools for assessment and implementation of P2 have been developed and customized to suit a particular facility or organization. In particular, a systems approach to P2 assessment and the use of process mapping tools can be extremely useful in taking a global view of an organization's activities and how it impacts the people and the environment in which the activities are conducted.[29] The systematic approach of looking at an organization's current environmental and management systems and for deconstructing processes allows one to look at old processes in a new light. The systemwise review of processes also provides opportunities for a range of people with different functions—designers; production and operational staff, sales and marketing staff; supply chain vendors; customers and management—to come up with ideas and opportunities for actions to implement P2.

The success of P2 assessments can be evaluated in different ways. A common approach is to look at the type of assessment, the actions taken as a result of the assessment, and the P2 outcome of the actions taken. As the first step in this approach, summary information

Table 8 Company-specific P2 assessment summaries

Center	Type of assessment	Environmental impact considered	Types of pollution prevention addressed	Action by company (environmental improvement)	Reduction in the amount of pollutants released/energy consumed
Company 1	P2	Risk because of hazardous waste	Hazardous and nonhazardous wastes	Initial identification of substances of concern	Potential reduction of 75,000 lb of hazardous waste
Company 2	P2	Health risk because of chemicals	Toxic chemicals/PBT chemicals	Elimination of chemicals by their suppliers or selection of new supplies	38.2% reduction in pollutants (approx. 782 tons)
Company 3	P2	Wastewater	Reduction of blood and solids to wastewater	Began collecting blood and shipping to renderer for reuse	75,000 gal/yr blood
Company 4	Energy assessment/P2	Reduction in CO_2, SO_2, NO_x achieved by less power usage	Energy related air emissions	Installed laboratory A/C economizer, revised plant lighting layout	Reduction in energy use estimated at \$4,000 savings so far, projected \$30,000/yr total
Company 5	Lean manufacturing/P2	Reduction in time of production	Energy savings	Reduction in production time	Potential savings of \$2.5 million/yr

on various assessments may be collected from companies involved in P2 programs. A summary of assessments at five different companies is given in Table 8. The table also describes the environmental improvement as a result of the assessment and actions by the companies. The next step examines the P2 benefits derived from the assessments. The companies, where the P2 investigations were conducted, provided information as shown in Table 9 outlining which P2 benefits were derived as a result of the assessments. P2 assessments can also be evaluated by considering other metrics such as: 1) the number of recommendations implemented by the companies; 2) cost reductions after the implementation of the recommendations; and 3) risk reductions.

Potential Benefits

The potential benefits of P2 program implementation are varied and depend to a large degree on the level of effort made to systematically evaluate the policies, systems, designs, products and processes, and the commitment to take actions based on the assessment. The following major benefits may be seen as the outcome of successful P2 implementation:

- Cost savings
    - Source reduction, inprocess recycling, and improved energy efficiency reduce the amounts of raw materials and energy required.
    - Substituting hazardous chemicals with safer alternatives cuts purchasing cost and reduces pollution control costs.
    - Reduction of nonhazardous wastes reduces procurement and disposal expenses.
    - P2 activities cut down on the costs of complying with federal and state regulations and reporting requirements.
    - Undertaking P2 projects can reduce regulatory exposure and, in some cases, may eliminate the need for permits, manifesting, monitoring and reporting, and lower the cost of meeting expensive and time-consuming regulatory requirements.
- Reduced legal liability
    - Preventing the generation of wastes and emissions dangerous to the environment or human health protects a company from future liability under the Occupational Safety and Health Administration (OSHA) and federal and state environmental statutes.
    - Reducing wastes reduces long-term liability caused by improper disposal practices.
- Improved corporate image
    - P2 program can serve as an effective public relations tool. A company that demonstrates an active commitment to reducing its environmental impacts will have a more positive relationship with the local community and with its customers.
    - Improve marketing efforts by its environmental performance and its demonstrated concern for the health of people and the environment.
    - Establish itself as a responsible, reputable member of the community with a competitive advantage.
    - Be an industry leader with the ability to report on P2 activities and show measurable progress for inclusion in annual environmental reports.

Table 9 P2 benefits

Benefit	Company 1	Company 2	Company 3	Company 4	Company 5
Raw materials savings by recycling	Yes	Yes	Yes	N/A	No
Material substitution savings	Yes	Yes	N/A	Yes	N/A
Elimination of pollution control equipment	N/A	N/A	N/A	N/A	N/A
Improved process productivity	Yes	Yes	Yes	Yes	Yes
Better product quality	Yes	N/A	Yes	Yes	No
Reduced labor from pollution elimination	Yes	N/A	Yes	Yes	N/A
Reduction of permitting requirements	N/A	Yes	N/A	No	N/A
Reduction and/or elimination of offsite waste disposal	N/A	N/A	N/A	No	N/A
Reduction and/or elimination of offsite waste storage	Yes	N/A	N/A	Yes	N/A
Reduction of personal injury risks under OSHA	N/A	Yes	N/A	Yes	N/A
Permitting requirements minimized	N/A	N/A	N/A	Yes	N/A

  - Successful P2 program implementation can be used for receiving recognition from governmental and nongovernmental groups to showcase projects and be seen as a leader in environmental protection and sustainable practices.

- Improved worker safety
  - The P2 program can be used to improve worker health and safety.
  - Use of less harmful substances, reduced fugitive releases of solvents from manufacturing processes, and minimized waste to be handled and disposed of improve the occupational and environmental safety of workers and waste handlers.
  - Reducing or eliminating toxic waste emissions or discharges not only improves environmental quality, but can also reduce medical claims and disability leave requests from workers.

- Widespread use of P2
  - Success stories of the implementation of P2 in industries pave the way for more organizations to try P2 options and undertake changes and demonstrate environmental commitment and responsible stewardship.

Barriers and Challenges

Institutional, financial, and regulatory barriers to P2 adoption and full exploitation of its potential can exist in differing proportions depending on the type, size, and working culture of an industry or a facility where P2 is being considered. While a change in the attitude and behavior of the people involved with the company (i.e., the major stakeholders) helps overcome these barriers; behavioral change requires a thorough understanding of the target audience's attitudes, obstacles, and information sources.[19,30] A brief discussion of each of the major barriers follows.

Institutional barriers

1. Lack of employee participation in decision-making.
2. Employee inputs are not taken into account.
3. Organizational structure wherein the environmental management group is unaware or knows very little about the production sector's activities, i.e., no proper communication channel between different sectors in an industry or between different departments at a facility.
4. Upper management and environmental managers unaware of the cost-saving ideas and succumbing to conventional end-of-pipe solutions offered by entrenched consultants.
5. Customer demand for products resulting in toxic waste.
6. Lack of time and expertise to analyze causes of waste for small- and medium-sized industries.
7. Lack of company leadership, vision, or understanding of the company's environmental impacts and the absence of appropriate environmental policies and procedures that can benefit the business while being protective of the environment.

Financial barriers

1. Failure to understand the true costs of decisions, inclusive of the hidden costs of waste [hidden costs $= \sum$(treatment and disposal charges, permitting fees, record keeping, insurance, utility bills, and potential future environmental liability)].
2. Waste reduction proposals not able to clear the corporate internal investment hurdle threshold that a project must meet.
3. Reluctance of bankers to finance unconventional projects.

Regulatory barriers

1. Technological innovations in the current vigorously growing and competitive environment may not have been included or approved in the existing rules.
2. Companies focusing on conventional technologies geared toward compliance with single medium specific pollution control standards without being able to consider impacts on air, water, or soil media.
3. Failure of regulatory agency staff to allow innovative projects to be approved because of regulatory constraints or lack of understanding of a project's true benefits.

Integrating P2 into core business operations and understanding the full life cycle costs and benefits of decisions and increased communication among the key stakeholders are among the essential steps for overcoming these barriers.

CONCLUSIONS

The growth of P2 from its initial stages to the present stage has been a slow and steady path as with any

technical change. The progress of P2 in the United States in the last two decades has been very impressive, especially the manner in which environmental issues are being prioritized to take advantage of technological advances in the face of increased pressure to keep costs down. In addition, P2 practices that use a systems-based, quality-focused, systematic assessment approach are aiding in the creation of sustainable development practices to meet the triple bottom line—cost, environment, and social justice. The principle of a waste management hierarchy and the procedures for achieving P2 or green/cleaner production are generic across plant boundaries. Many organizational factors affect the likelihood of realizing the full potential of pollution prevention.[24] Availability of numerous case studies on P2 and a change in corporate thinking toward proactive environmental approaches show that the P2 concept has matured and is playing a major role in environmental protection without specific government regulation. The rapid development of new products using efficient processes that reduce pollution provides economic incentives for P2 propagation across a broader set of industries, which can lead to ever-faster cycles of review and implementation. P2 is a win-win opportunity as the forces of manufacturing interests and environmental responsibility come together.[4]

INTRODUCTION

Polyanhydrides are a class of bioerodible polymers that have shown excellent characteristics as drug delivery carriers. The properties of these biomaterials can be tailored to obtain desirable controlled release characteristics. Extensive research in this promising area of biomaterials is the focus of this entry. In the first part of the entry, the chemical structures and synthesis methods of various polyanhydrides are discussed. This is followed by a discussion of the physical, chemical, and thermal properties of polyanhydrides and their effect on the degradation mechanism of these materials. Finally, a description of drug release applications from polyanhydride systems is presented, highlighting their potential in biomedical applications.

BACKGROUND

The need for suitable materials for the delivery of drugs in a safe and controlled manner has led to the development of numerous biodegradable polymers. Controlled release of a variety of therapeutic agents has been achieved with the use of biodegradable polymeric devices. Research has focused on poly(α-hydroxy acids), poly(orthoesters), and poly(anhydrides). Poly(α-hydroxy acids), e.g., poly(lactic acid) (PLA) and poly(glycolic acid) (PGA), and copolymers undergo bulk erosion and the drug release kinetics from these carriers is not well defined. On the other hand, poly(orthoesters) and polyanhydrides undergo surface erosion with predictable kinetics. In the case of polyanhydrides, the degradation rates can be tailored to suit specific applications by changing the chemistry.

Polyanhydrides comprise monomer units connected by water-labile anhydride bonds. In the presence of water, the polymer is cleaved across the anhydride bond into two carboxylic acid groups (Fig. 1). It is precisely this hydrolytic instability that precluded their use in the textile industry in the 1950s and led researchers to suggest their potential as drug delivery carriers in the 1980s. Since then, polyanhydrides have been synthesized with a wide range of chemistries for a variety of biomedical applications.

The promising characteristics of polyanhydrides for biomedical applications rely on the surface erosion mechanism that translates into well-controlled release kinetics, where the drug release rate coincides with the degradation rate of the polymer. In an aqueous environment, the macromolecules at the surface break into smaller chains before water penetrates into the device. Thus, the drug is released as the polymer degrades. In contrast, bulk eroding polymers degrade slowly and water penetrates into the system much faster, having, in consequence, less predictable kinetics as the drug is released from the entire matrix. A comparison of surface and bulk erosion mechanisms is shown in Fig. 2.

Polyanhydride-based drug delivery devices (Gliadel®) have been approved by the Food and Drug Administration (FDA) for the treatment of brain tumors. This device is a polyanhydride wafer composed of sebacic acid and 1,3-bis(*p*-carboxyphenoxy) propane [1,3-bis (*p*-carboxyphenoxy) propane : poly(sebacic acid) (CPP : SA) copolymer in 20 : 80 molar ratio] loaded with the chemotherapeutic agent, carmustine, 1,3-bis[2-chloroethyl]-1-nitro-sourea (BCNU). Other potential applications of CPP : SA copolymers include the release of bethanechol for the treatment of Alzheimer's disease and the controlled release of insulin.[1] The treatment of osteomyelitis, which is a bone infection difficult to treat by conventional methods, has been carried out with 20 : 80 CPP : SA copolymer loaded with gentamicin sulfate.[1] Several chemotherapeutic drugs, local anesthetics, anticoagulants, neuroactive drugs, and vaccines have been delivered using polyanhydrides.

CLASSIFICATION

There are three major classes of polyanhydrides: aliphatic, unsaturated, and aromatic. The chemical structures are shown in Table 1.

Aliphatic Polyanhydrides

The first aliphatic polyanhydride was synthesized from the monomer adipic acid (AA), which is thermally unstable and forms cyclic dimers and polymeric rings

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039789

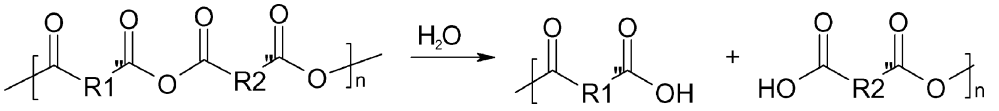

Fig. 1 Hydrolysis of polyanhydrides.

when heated at high temperatures. Poly(sebacic acid) (SA), the aliphatic polyanhydride most widely used in drug delivery applications at present, was synthesized for the first time in the 1930s.[2] Typical properties of aliphatic polyanhydrides include crystallinity, a melting temperature range of 50–90°C (increasing with monomer chain length), and solubility in chlorinated hydrocarbons. These degrade and are eliminated from the body within weeks. When copolymerized with aromatic polyanhydrides, the degradation time can be extended to several months as the aromatic composition increases. The most widely studied aliphatic–aromatic copolymer system is based on SA and 1,3-bis(*p*-carboxyphenoxy) propane (CPP).[3]

Unsaturated Polyanhydrides

The development of unsaturated polyanhydrides responded to the necessity of improving the mechanical properties of the polymers in applications such as the temporary replacement of bone.[4] Unsaturated polyanhydrides, prepared by melt or solution polymerization, include homopolymers of fumaric acid (FA), acetylenedicarboxylic acid (ACDA), and 4,4′-stilbenzenedicarboxylic acid (STDA). The chemical structures of poly(FA) and poly(ACDA) are shown in Table 1. These polymers are highly crystalline and insoluble in common organic solvents. The double bonds of these monomers make them suitable for further crosslinking to improve mechanical properties of polyanhydrides. When copolymerized with aliphatic diacids, less crystalline polymers with enhanced solubility in chlorinated solvents result.

Aromatic Polyanhydrides

The first aromatic polyanhydrides synthesized were poly(isophthalic acid) (IPA) and poly(terephthalic acid) (TA).[5] A few common aromatic polyanhydrides are shown in Table 1. Homopolymers of aromatic diacids are crystalline, insoluble in common organic solvents, and have melting points greater than 100°C. Their hydrophobicity results in a slow degradation rate that can last over a year in some cases. Thus aromatic polyanhydrides are not suitable for drug delivery when used as homopolymers. To overcome their slow degradation rates, they have been copolymerized with aliphatic diacids, i.e., CPP : SA copolymers, and with other aromatic monomers. The copolymers of the aromatic monomers TA and IPA are amorphous and soluble, with a faster degradation and a melting point below 120°C.[6]

Other Polyanhydride Chemistries

Although it is impossible to discuss in detail all the polyanhydrides that have been synthesized, some distinguishable classes are discussed here. Typical examples of novel classes of polyanhydrides include those derived from amino acids and fatty acids, and those modified by copolymerization with esters and ethers. The polyanhydrides derived from amino acids, including trimellitylimido glycine (shown in Table 1), pyromellitylimido alanine, and trimellitylimido l-tyrosine, have been copolymerized with aliphatic (SA) and aromatic (CPP and CPH) monomers to obtain enhanced degradation and improved mechanical strength because of the presence of the imide bond.[7] These polymers have been studied as vaccine carriers.[8] Some polyanhydrides have been synthesized from dimer and trimer unsaturated fatty acids, and form nonlinear hydrophobic fatty acid esters such as ricinoleic and maleic acid. Other classes of polyanhydrides include ones copolymerized with esters and ethers, which have been suggested as potential drug carriers in the last decade.[9,10] Uhrich and coworkers recently synthesized novel poly(anhydride-co-ester)s containing salicylic acid in the backbone.[11–14] The in vitro/in vivo release of salicylic acid (the active form of aspirin) was studied for the treatment of Crohn's disease and tuberculosis. Copolymers of aliphatic polyanhydrides with ε-caprolactone, trimethylene carbonate,

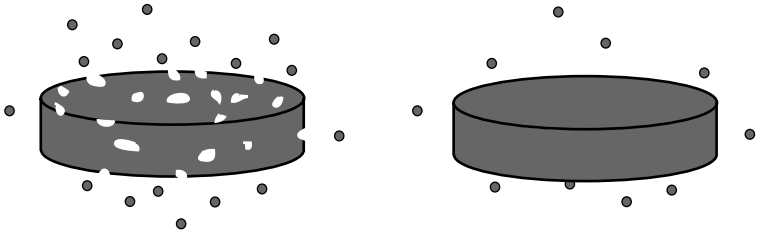

Fig. 2 Mechanisms of polymer erosion: bulk (left) and surface (right).

Table 1 Typical polyanhydrides used for drug delivery applications

Classification	R group	Examples
Aliphatic polyanhydrides		$x = 4$, Adipic anhydride (AA) $x = 8$, Sebacic anhydride (SA)
Unsaturated polyanhydrides		Fumaric anhydride (FA)
		Acetylenediacarboxylic anhydride (ACDA)
Aromatic polyanhydrides		meta: isophthalic anhydride (IPA) para: terephthalic anhydride (TA)
		$x = 1$, bis(*p*-Carboxyphenoxy)methane (CPM) $x = 3$, 1,3-bis(*p*-Carboxyphenoxy) propane (CPP) $x = 6$, 1,6-bis(*p*-Carboxyphenoxy)hexane (CPH)
Novel polyanhydrides		Trimellitylimido glycine (TMAgly)
		1,8-bis(*p*-Carboxyphenoxy)-3,6-dioxaoctane (CPTEG)

ethylene glycol,[15] and lactic acid have been synthesized. Several modifications of anhydride monomers have been carried out to obtain desired characteristics for particular applications.[16–18] An example is the incorporation of triethylene glycol (TEG) into an aromatic monomer (CPH) to enhance the hydrophilicity of the monomer, resulting in a faster degradation rate.[19] The resulting polymer (Table 1) is poly(1,8-bis(*p*-carboxyphenoxy)-3,6-dioxaoctane) (CPTEG).

SYNTHESIS

The most widely used method to synthesize polyanhydrides is melt condensation polymerization, which results in high molecular weight polymers.[20] Other methods include Schotten–Baumann condensation, dehydrative coupling, and ring opening polymerization.

Melt Polycondensation

The general process for melt polycondensation of polyanhydrides is shown in Fig. 3. It consists of reacting dicarboxylic acid monomers with an excess of acetic anhydride to form oligomers that are polymerized at high temperature under vacuum. The degree of polymerization is influenced by the monomer purity, the strength of the vacuum, the reaction temperature, and the reaction time. It has been found that for most polyanhydrides, the optimal polymerization temperature is in the range of 170–190°C.[21] In general, the condensation reaction is conducted for 2–3 hr, as significant depolymerization can occur after heating for longer periods.[22] With optimal conditions, molecular weights greater than 100,000 can be produced.

The polyanhydrides synthesized by melt condensation have fiber-forming properties in the molten state. They hydrolyze when exposed to air and this degradation is mainly controlled by the composition of the polymer. Homopolymers of aromatic monomers, such as CPH, degrade at a rate that is several orders of magnitude lower than that of homopolymers of aliphatic monomers.[22]

Several variations have been made to the melt condensation process. In the case of polymerization with propionic anhydride and butyric anhydride, harsh

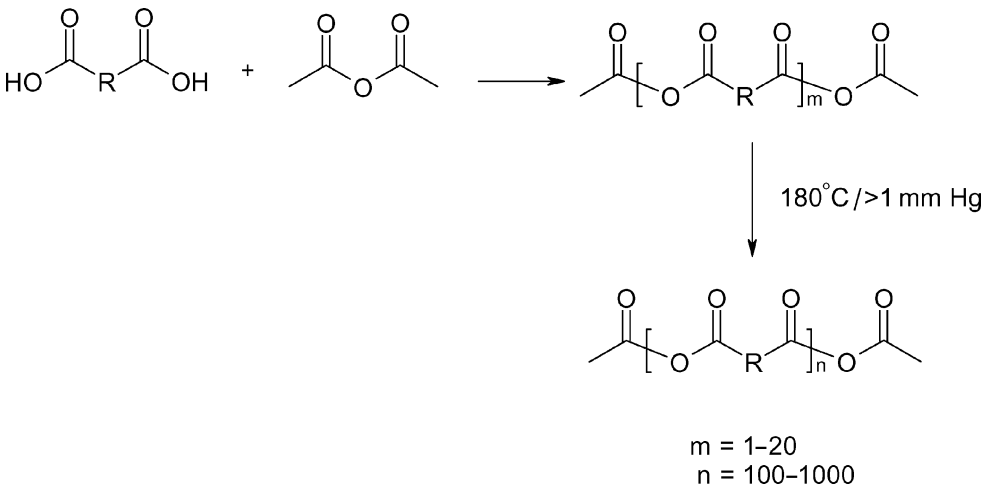

Fig. 3 Melt condensation polymerization of polyanhydrides.

conditions can be used for the removal of unreacted anhydride owing to the high boiling point of both chemicals.[6] A variety of catalysts have been used to polymerize polyanhydrides within 20–60 min; but the main disadvantage for biomedical applications is the potential toxicity from catalysts such as cadmium acetate, earth metal oxides, and $ZnEt_2$-H_2O.[6]

Schotten–Bauman Condensation

The Schotten–Bauman condensation produces polyanhydrides with moderate molecular weights by a dehydrochlorination reaction between a diacid chloride and a dicarboxylic acid.[21] The polymerization takes place by reacting the monomers for 1 hr at room temperature, and it can be conducted via solution or interfacial methods. Solvents that are used in solution polymerization include dichloromethane, chloroform, benzene, and ethyl ether. The degree of polymerization obtained with this method is approximately 20–30. Lower molecular weight products are obtained for less reactive monomers such as isophthaloyl chloride.

Polymerization conducted in aqueous interfacial systems suffers from hydrolytic decomposition. The decomposition reaction can be minimized when contact with water is avoided. In the case of polymerization in nonaqueous interfacial environments, products with number average molecular weights up to 5000 can be obtained.[22] Various aromatic polymers were prepared from the reaction of equimolar amounts of the acid dissolved in an aqueous base and the corresponding diacid chloride dissolved in an organic solvent. Reaction occurred between dibasic acid in one phase and an acid chloride in the other. Polar solvents for this reaction include dimethylformamide and 1,4-dicyanobutane.

Dehydrative Coupling

Another method to synthesize polyanhydrides is by dehydrative coupling of two carboxyl groups. Even though this method produces lower molecular weight products (mostly oligomers) compared with the methods described above, it is a single step polymerization where a dicarboxylic acid monomer can be directly converted into the polymer. Moreover, it can be conducted at low temperatures suitable for monomers that cannot resist harsh reaction conditions.

A number of dehydrative agents have been effective in coupling the carboxyl groups. The most effective agents are bis[2-oxo-3-oxazolidinyl]phosphinic chloride, *N*-phenylphosphoroamidochloridate, diphenyl chlorophosphate, diethyl phosphorobromidate, dicyclohexylcarbodiimide, chlorosulfonylisocyanate, and 1,4-phenylene diisocyanate.[22] In general, higher molecular weight polymers were obtained with polar solvents such as dichloromethane and chloroform. The major disadvantage of this method is the problematic isolation and purification of the final products while preventing hydrolytic decomposition.

Ring Opening Polymerization

Low molecular weight linear polymers undergo transformations between linear and cyclic forms. When a mixture of low and high molecular weight polymers is subjected to molecular distillation, cyclic monomers and dimers are distilled off and a high molecular weight polymer remains behind. The cyclic molecules are transformed to a polymer that contains large ring structures.[6]

Another variation of this process is the preparation of adipic acid from cyclic adipic anhydride

(oxepane-2,7-dione). The monomer is prepared by the reaction of adipic acid with acetic anhydride followed by catalytic depolymerization under vacuum. Factors that affect this reaction include temperature, reaction time, and the concentration of catalyst, if used. When catalyzed, reaction at 180°C for 30 min produced polymers with molecular weights up to 300,000. Uncatalyzed reactions that were carried out for more than 2 hr at 180°C yielded low molecular weight polymers.[6]

CHARACTERIZATION

To understand the properties that make polyanhydrides suitable drug carriers, their chemical, physical, and thermal behavior need to be characterized. This section discusses the methods to determine the chemical structure and composition, the molecular weight, the thermal properties, the phase behavior, the stability, and the erosion mechanism of polyanhydrides.

Chemical Structure and Composition

The technique most widely used for determining the chemical structure and composition of polyanhydrides is ^{1}H NMR spectroscopy. The chemical structure is assigned in accord with the chemical shifts characteristic of aliphatic and aromatic protons. The protons close to electronegative groups, i.e., aromatic groups, absorb at lower frequencies (6.5–8.5 ppm), while aliphatic protons absorb at higher frequencies (1–2 ppm).[23] ^{1}H NMR has also been used to determine the degree of randomness in polyanhydride copolymers.[24] By integration of NMR peaks it is possible to determine if a copolymer has a random or block-like structure. Other useful information obtainable from ^{1}H NMR spectra include details of the conversion of polymerization reactions, the actual composition of the polymer, the polymer molecular weight, and degradation rate.

Fourier transform infrared (FTIR) spectroscopy and Raman spectroscopy have also been used to authenticate polyanhydride structures. Aliphatic polymers absorb at 1740 and 1810 cm^{-1}, while aromatic polymers absorb at 1720 and 1780 cm^{-1}.[24] All the polyanhydrides show methylene bands because of deformation, stretching, rocking, and twisting. Aside from being used to ascertain polyanhydride structures, these techniques can be used to determine degradation progress, by monitoring the area of carboxylic acid peak (1770–1675 cm^{-1}) with respect to the characteristic anhydride peaks over time.

Molecular Weight

The molecular weight of polyanhydrides can be determined by gel permeation chromatography (GPC), viscosity measurements, and ^{1}H NMR spectra. Vapor pressure osmometry (VPO) cannot be used for molecular weight determination, as depolymerization occurs during the experiment. The weight average molecular weight (M_w) of polyanhydrides ranges from 5000 to 300,000. Typical polydispersity indexes are in the range of 2–15, which increases with molecular weight. Gel permeation chromatography determines the molecular weight relative to polystyrene standards. The intrinsic viscosity (η) is proportional to M_w, as shown by the Mark Houwink relationship for CPP : SA copolymer [Eq. (1)]. This relationship was calculated from viscosity experiments and M_w values from GPC.

$$[\eta]^{23^\circ C}_{CHCL_3} = 3.88 \times 10^{-7} \times M_w^{0.658} \quad (1)$$

An alternative way to estimate the molecular weight of polyanhydrides is by end group analysis from ^{1}H NMR spectra. The degree of polymerization can be calculated from the ratio of the area of the inner chain protons to the area of terminating groups. The number average degree of polymerization (DP) of CPP : SA copolymers is represented in Eq. (2), where (CPP) and (SA) depict the area of scaled inner chain protons, (Ac) represent the acetylated end group, and (SA^*) and (CPP^*) designate the carboxylic terminated polymer chain.[25]

$$DP = \frac{2[(CPP) + (SA)]}{[(Ac) + (SA^*) + (CPP^*)]} \quad (2)$$

Thermal Properties

The thermal transitions of polyanhydrides have been determined from differential scanning calorimetry (DSC). Differential scanning calorimetry thermal scans provide properties such as glass transition temperature (T_g), melting temperature (T_m), and heat of fusion (ΔH). It is important to know the values of T_g and T_m in the fabrication of drug delivery devices such as tablets and microspheres. While T_g determines the minimum temperature required for compression molding, T_m determines the minimum temperature necessary for injection molding or melt compression. A general decreasing trend in T_g's has been observed as methylene groups are added into the main chain of an anhydride monomer. As mentioned earlier, aliphatic polyanhydrides melt at temperatures below 100°C and aromatic polyanhydrides have melting points greater than 100°C.

It has been shown that the crystallinity of polymers affects erosion and drug release rates, because crystalline regions erode slower than amorphous ones.[26] Moreover, highly crystalline polyanhydrides affect the device morphology as it creates irregular external

surfaces. The crystallinity of polyanhydrides has been determined using x-ray diffraction, DSC, ^{1}H NMR spectroscopy, and small-angle x-ray scattering (SAXS). It has been demonstrated that homopolymers of aromatic and aliphatic diacids are crystalline. When copolymerized, polyanhydrides exhibited a decrease in crystallinity in copolymers of equimolar compositions, i.e., CPP : SA, CPH : SA, and FA : SA copolymers.[26] The ΔH from DSC thermographs exhibited a decrease as the copolymers approached equimolar compositions. This decrease in crystallinity is representative of the random behavior of the polymer chain, as determined by ^{1}H NMR spectra. In general, the copolymers rich in one monomer had higher crystallinity.

Phase Behavior

Polymer blends, which display distinct physical and chemical properties, are used for the design of materials for diverse applications. This variation in properties may lead to microphase separation, which in turn affects the drug release because of a thermodynamical partition of drugs between the phases, depending on their compatibility with the phase.[27] Research has shown that aliphatic, aromatic, and copolymers of anhydride monomers are miscible and the blends had a single melting temperature that was lower than that of the starting polymers.[6] On the other hand, polyanhydrides that are partially miscible with poly(orthoesters), poly(hydroxybutyric acids), and low molecular weight poly(esters) and have two melting temperatures are clearly indicative of the phase separation. Blends of polyanhydrides with poly(caprolactone) [poly(CL)] are completely immiscible. Degradation studies in blends of poly(CL) with poly(dodecanedioic anhydride) [poly(DD)] indicated that the anhydride component degraded rapidly and was released from the blend, without affecting the poly(CL) degradation.[24] Other studies include the characterization of microphase-separated copolymers of poly(SA) with poly(CPH) or poly(ethylene glycol).[28,29] The phase diagram for the poly(CPH)/poly(SA) blend system has been determined using SAXS, optical microscopy, and molecular simulations, while the blends of poly(SA) and PEG were characterized by DSC and infrared (IR) spectra. The poly(CPH)/poly(SA) system exhibits an upper critical solution temperature behavior.

Stability

The stability of polyanhydrides has been studied in solid state and in dry chloroform. Aromatic polyanhydrides such as poly(CPP), poly(CPH), and poly(CPM) maintained their original molecular weight for at least one year in solid state upon storage under dry argon or vacuum at 21°C. In contrast, aliphatic polyanhydrides such as poly(SA) have a high-degradation rate at the same storage conditions.[1] Studies performed with GPC revealed that M_w of polyanhydrides tends to undergo a rapid decrease initially, and later a constant stabilized decrease in molecular weight is observed. The decrease in molecular weight was explained by an internal anhydride interchange mechanism resulting in ring formation, as revealed by ^{1}H NMR. This mechanism was supported by the fact that the decrease in molecular weight was reversible and heating of the depolymerized polymer at 180°C for 20 min yielded the original high molecular weight polymer.[24] It is important to mention that polyanhydrides experienced significant weight loss when stored at ambient conditions in which water attacks the anhydride bonds.

The stability of polyanhydrides in a solution was studied using chloroform under dry nitrogen atmosphere at 37°C.[1] The aromatic polyanhydrides remained stable under these conditions during a three-day period, while copolymers with aliphatic SA had a significant molecular weight loss during the same time period. Therefore, polyanhydrides can be processed in a solution environment as long as the time is not extended more than this period.

γ-Irradiation methods have been utilized for the sterilization of polyanhydrides. In this technique, aliphatic and aromatic homo- and copolymers were irradiated at 2.5 Mrad, and the chemical structure as well as the physical properties were found to be the same before and after irradiation.[24] The studies showed that saturated polyanhydrides are stable during γ-irradiation, as a slight increase in molecular weight was observed. Electron paramagnetic resonance (EPR) spectroscopy was used to characterize free radicals in γ-sterilized polyanhydrides.[30] Polymers with high melting temperatures produced the highest yields of room temperature radicals, which in turn transform into less conjugated polyanhydrides that leads to lower molecular weight polymers.

Degradation and Erosion

Polymer erosion (i.e., mass loss) is a complex process that is determined by numerous factors, including the molecular weight loss (degradation), swelling, dissolution and diffusion of oligomers and monomers, and morphological changes.[31] Polyanhydrides undergo degradation prior to erosion, as a consequence of the chemical instability of the anhydride bond. Thus, degradation and erosion are limited to the surface, as water does not penetrate into the device.[32]

Erosion kinetics is complicated when the anhydride monomers of a copolymer system exhibit microphase separation that leads to the erosion of different phases

at different rates. The erosion of a fast eroding phase may leave the slow eroding phase intact.[33] At this point, the monomer solubility plays a major role in polyanhydride erosion kinetics, as monomers are accumulated in eroding zones of the matrix and its dissolution will depend on the pH of the microenvironment.[34] It is known that the saturation concentration of the monomers CPH, SA, and CPTEG is a function of pH and that, at a particular pH, the order of solubility of the monomers is CPTEG > SA > CPH. This provides valuable information when describing the drug release from polymers containing any of these monomers.[19,33]

POLYANHYDRIDE-BASED DRUG DELIVERY SYSTEMS

Biocompatibility

The biocompatibility of implantable polyanhydride disks was studied in the brain of rats, rabbits, monkeys, and eventually in human clinical trials.[35] Wafers of poly(CPP : SA) and poly(FAD : SA) were implanted in the frontal lobes of rats, rabbits, and monkeys. In all these studies, the animals receiving the implants showed no behavioral changes or neurological deficits, indicating that the polymers were not invoking a systemic or local toxicity. To determine how the body metabolized the poly(CPP : SA), radio-labeled copolymers were implanted in the brains of rats.[21] Seven days after the implantation, 40% of the ^{14}C SA-labeled polymer had been excreted as CO_2, 10% was excreted along with the urine, 2% with the feces, and 10% still in the implanted device. In the same period only 4% of the ^{14}C CPP-labeled polymer was excreted along with the urine and feces.

The biocompatibility of poly(CPP), poly(TA), and copolymers of CPP : SA and CPP : TA implanted in the corneas of rabbits was studied.[36,37] Six weeks after implantation, the cornea remained clear and showed no evidence of corneal edema or neovascularization, indicating biocompatibility of the polymer matrix implant.

Subcutaneous implants of 20 : 80 CPP : SA copolymer were administered in rats at doses of 40 and 120 times the size that is to be used in humans. The purpose of these experiments was to test the systemic toxicity of the polymers. Eight weeks after implanting the disks, the rats were sacrificed and their organs underwent histopathological evaluations. In general, there was little to no difference between the organs of the experimental group (receiving the implant) and those of the control group. Again, in all the cases the polymers underwent degradation and were found to cause minimal inflammation at the site of implantation. Thus, polyanhydrides are inert and suitable for in vivo drug delivery.[38]

Drug/Polymer Interactions

When selecting polymers as drug delivery carriers, it is necessary to establish whether the polymer will react with the incorporated or the released drug. Three factors need to be considered: the reactivity of the drug, the hydrophobicity of the drug, and the fabrication method. The reactivity of CPP : SA copolymer with the para substituted anilines: *p*-nitroaniline (PNA), *p*-bromoaniline, *p*-anisidine, and *p*-phenylenediamine was examined.[37] The model drugs were incorporated into the polymer matrix using injection and compression molding. When injection molding was used to encapsulate the drugs at 120°C, the more reactive drugs (*p*-bromoaniline, *p*-anisidine, and *p*-phenylenediamine) reacted with the polymer forming amides. However, when the drugs were incorporated into the polymer matrix using compression molding at room temperature, the drugs did not react with the polymer during the fabrication process.

The hydrophobicity of the drug can also influence the interactions between the drug and the polymer. When hydrophilic dyes (acid orange and brilliant blue) were encapsulated in polyanhydrides, the T_m's of the polymers were unchanged. When hydrophobic dyes (PNA and methyl red) were encapsulated, the T_m's of the polymers changed thereby indicating an interaction between the polymer and the drug.[39]

Device Fabrication

Polyanhydride drug delivery devices have been fabricated as implantable[40] and injectable devices. Implantable devices are fabricated by compression molding, melt compression, or solvent casting. The first step of compression molding is to obtain a fine powder of the drug and the polymer. The powders are physically mixed and placed in a piston mold. The wafer is formed by applying a pressure (typically 30 kpsi) and by heating the sample to a temperature 5–10°C above the T_g of the polymer.[1,41] One drawback of this method is the uneven distribution of the drug in the polymer, leading to poor reproducibility. The Gliadel system is a compression-molded wafer. To overcome the problem of uneven drug distribution, the drug and polymer are spray dried together to form microspheres. The microspheres are then compression molded to form the wafer.

An alternative to compression molding is melt compression. This procedure requires the polymer and drug to be heated 10°C above the T_m of the polymer, forming a viscous solution.[1,41] The solution can then be either placed in a conventional mold under low pressure or injection molded. This fabrication method results in an even drug distribution. However, the

elevated temperatures needed to melt the polymer could cause adverse reactions in temperature sensitive drugs such as proteins.

Solvent casting is done by codissolving or suspending the drug in the polymer solution. The solution is then poured into a flat open mold and cooled on dry ice. The resulting film is often fragile. If the drug is not soluble in the polymer, it will settle on the bottom of the film, leading to an uneven drug distribution.[27,30]

To form an injectable drug delivery device, the drug is loaded into polymer microspheres. Drug-loaded polyanhydride microspheres have been fabricated using different methods. The most common method is the solvent extraction method, which includes water/oil/water (w/o/w), water/oil/oil (w/o/o), or solid/oil/oil (s/o/o) (dependent on whether the drug is soluble in the polymer solvent). In the w/o/w method, the drug (typically proteins) is dissolved in an aqueous phase and then emulsified with a larger volume of polymer that is dissolved in an organic solvent, typically methylene chloride. The inner emulsion is then added to a larger volume of water that contains a surfactant, usually PVA, and allowed to stir for several hours to extract the solvents. In the case of w/o/o or s/o/o the outer aqueous PVA phase is replaced with an immiscible organic solvent, i.e., silicon oil. The spheres are typically collected by either centrifugation or filtration.

Microspheres can also be fabricated by the hot-melt procedure; however, this method is not ideal for encapsulating temperature sensitive drugs such as proteins.[1] Spray drying or atomizing the polymer and drug together can also be used to fabricate microspheres. This method requires the use of either a spray dryer or atomization.[1,42] In the case of a spray dryer, the polymer/drug suspension is pumped into the spray drier. As the suspension is sprayed, a stream of air causes the polymer spheres to harden. Microspheres are fabricated by atomization by passing the drug/polymer suspension through an atomizing nozzle. As the polymer/drug spheres leave the nozzle, they are collected in a bath of liquid nitrogen sitting on top of a frozen layer of ethanol.[42] The liquid nitrogen/ethanol bath is then stored at $-80^{\circ}C$ for three days. During this time the ethanol slowly thaws and the frozen microspheres fall into it. As the microspheres sit in the ethanol, the organic solvent (methylene chloride) slowly diffuses out, leaving solid spheres that could be collected by filtration.

In Vitro Release

The rate at which an encapsulated drug will be released from a polyanhydride device, either a wafer or a microsphere, is strongly dependent on polymer composition and drug distribution. Other factors that contribute to the release rate of drugs includes: fabrication technique, size/shape of the device, and pH of the surrounding media.

The hydrophobicity of a drug influences its distribution within the polymeric device.[27] *p*-Nitroaniline and disperse yellow have higher affinities for poly(CPH) and poly(SA), respectively. The two drugs were encapsulated in tablets of poly(CPH), poly(SA), and copolymers of the two to determine if the drugs would partition into the more favorable polymer microdomain. When the dominant polymer had a low affinity for the drug, a burst effect was seen. In the case of 50 : 50 CPH : SA copolymer, each drug followed the release of the monomers, indicating that the drug was partitioning into the more favorable domain.

The size of the device may also influence drug distribution and release rate.[43] Monodisperse microspheres of differing average diameters were studied to determine the influence of size of the device on the delivery. Smaller diameter microspheres showed a more prolonged release rate of drug than did microspheres that had a large diameter. As the diameter increased, the time it took for the microsphere to form by precipitation increased; thus, increasing the time for the drug to segregate toward the surface of the microspheres.

As the anhydride bonds in the polymer backbone are hydrolyzed, carboxylic acid is formed. The formation of the acidic degradation products reduces the local pH of the eroding device. The diffusion of the acidic degradation products away from the device is expedited when the device is in a basic solution. However, when the device is in an acidic solution, the erosion process is slowed significantly.[1,44]

Polyanhydrides have also been investigated as protein carriers.[45] Poly(SA) and 20 : 80 CPH : SA copolymer microspheres were found to conserve both the primary structure of the released protein [bovine serum albumin (BSA)] and the secondary structure of the encapsulated and released protein, and showed a sustained delivery for approximately 15 and 30 days, respectively. As the CPH content in the copolymer increased, the secondary structure of BSA was not conserved, as indicated by the steep decrease in the α-helix content.

In Vivo Delivery

The 20 : 80 CPP : SA copolymer was the first polyanhydride to be clinically tested in humans. The copolymer was used to encapsulate BCNU, a chemotherapeutic drug used to treat a fatal form of brain cancer known as glioblastoma multiforme. Along with the polymer, BCNU was codissolved, and the disks were fabricated by compression molding. The preclinical trials in rat, rabbit, dog, and monkey brains demonstrated the

effectiveness of the polymer in delivering an active drug that remained localized, minimizing systemic reaction to the drug.[46] The wafer, once implanted into the brain of the glioblastoma patients, releases the BCNU for approximately three weeks.[47] Scanning electron microscopy was used to monitor the erosion of the wafer both in vitro and in vivo.[48] It was found that the erosion of the wafer was controlled by diffusion of BCNU and erosion of the polymer. The delivery device was approved in 1996 by the USFDA for use in conjunction with surgery for patients suffering from recurrent glioblastoma. In 2003, the USFDA approved the use of the device in newly diagnosed advanced cases of malignant gliomas, in conjunction with surgery and radiation.

The use of 20 : 80 CPP : SA and 18 : 82 FAD : SA copolymers disks as drug delivery devices for carboplatin, a treatment for glioma, was also investigated in rodents.[49] The majority of the drug was released in seven days from the CPP : SA copolymer disk, and 65% of the drug was released from the FAD : SA copolymer disk in seven days. This method of delivery was more effective than systemic therapy and did not cause systemic toxicity.

A separate polyanhydride system has also been investigated for the treatment of osteomyelitis, a bone infection typically caused by bacteria.[50–52] Copolymer implants (50 : 50 FAD : SA) containing gentamicin were tested in the backs of rats, in the infected tarsocrural joints of horses, and in humans with infected prosthetic hips or knees.[51] In all the cases, the local delivery of gentamicin was successful and the systemic exposure to the drug was avoided.

CONCLUSIONS

Polyanhydrides are promising as biomaterials because they possess a unique combination of properties that include hydrolytically labile backbone, hydrophobic bulk, and chemistry that can be easily combined with other functional groups to design novel materials. These materials are primarily surface-erodible and offer the potential to stabilize protein drugs and sustain release from days to months. The microstructure characteristics of copolymer systems can be exploited to tailor drug release profiles. The versatility of polyanhydride chemistry promises a new class of drug release systems for specific applications.

INTRODUCTION

As background for the preparation of this article, a Google™ search of ''polybutadiene'' (PB) was made and 24,700 hits were generated. The addition of other terms to the quoted search reduced the number of hits to 1668 for structural features, 660 for modifications, 525 for uses of blends, and 52 for polymerization variations. This still is an impressive and formidable number of potential references that show the significant activity and utilization of PB. This does not include styrene/butadiene (BD)/styrene triblock and random copolymers (SBR), that are separate subjects and will not be considered. The reason for the plethora of literature available on PB is derived from a combination of factors. Primarily the base monomer BD is abundant, inexpensive, and can be converted readily to a variety of different reactive polymeric structures.

OVERVIEW

The polymerization can be accomplished by the use of free-radicals and anionic or transition metal-mediated cationic systems. Gaseous, bulk, aqueous suspension, or a solution in organic solvents has been used for the processes mentioned. These processes are simplified by the ease of purification of the low-boiling BD monomer. Another factor that contributes to interest in the PBs is the tremendous range of microstructure composition and molecular weight that can be obtained in the homopolymerization to PB. With the multitude of conditions that have already been mentioned, further refinements in the catalyst or initiators used allow the obtainment of *cis*-1,4-, *trans*-1,4-, and 1,2-(vinyl) placement of BD in PB to vary in all proportions from 0% to nearly 100% of the microstructure placement desired. These variations are not insignificant in that the polymers can vary from low-temperature elastomers to high-melting thermoplastics.

The composition and distribution of the repeat structures within the polymer chain define the flexibility of the polymer chain.[1] Because many properties depend on this chain mobility, polymer composition is carefully controlled. In addition to chain mobility, polymer composition also defines the solubility parameter of the polymer, which is a critical property relative to the type of solvents in which the polymer is soluble, the ability of the polymer to accept and hold oil, and the relative compatibility of the polymer with other polymers.[2] Basically, these properties all involve polymer–solvent interaction with differences associated with both the structure and the molecular weight of the polymer and the solvent.

End-group functionalization of the above polymers with the presence of reactive double bonds along the backbone allows a tremendous variety of chemistry to be utilized, such that a myriad of PBs can be produced. A more manageable breakdown of the current significant activity for the use of PB is presented in the entry. In deference to a concise summary, emphasis is placed on the scientific literature over the past 5 yr and the published worldwide patent activity from 1981.

Molecular Weight

Typically, a polymer is composed of a mixture of many molecules of different lengths, each of which can contain a different distribution of incorporation of the possible repeat units. Most conveniently, an average is used to characterize these features. Reaction conditions and catalyst levels are varied to form everything from low-molecular weight oil to extremely viscous materials. Thus, polymers will range in the number of average molecular weight (M_n) from about 1 to >540 kg/mol, or an average degree of polymerization (DP), from about 18 to >10,000 monomer units per molecule. The bulk polymer viscosity increases to extremely high values as the chain length is increased. At very low chain length, this increase is linear with molecular weight until the chains are long enough to become entangled. Above the entanglement molecular weight, the viscosity increases to the 3.4–3.5th power of molecular weight.[3] In addition to viscosity, many

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007906

other physical properties increase in value proportionate to the increasing molecular weight of the polymer. The 3.5th power relationship of molecular weight to bulk viscosity rapidly causes a decreased ability to compound, extrude, and mold the polymer into potentially useful material.[4] As a result, some compromise must be reached or some creative new avenues must be exploited to obtain the best possible material. Many of these approaches are apparent in this entry.

Molecular Weight Distribution

Although there are many different statistical ways to describe any population, the M_n, weight average molecular weight (M_w), and polydispersity index (M_w/M_n) have been widely used because they are readily understood in physical terms, and they can be measured directly in the laboratory by size exclusion chromatography (SEC).[5,6] The polydispersity has a lower limit of 1 (i.e., all chains of exactly the same length) and can vary to 5 or greater. Typical values for commercial polymers range from 1.2 to 5, with those under 2 considered relatively narrow and those over 2.8 considered broad in distribution. The SEC measurement sometimes has been referred to as gel permeation chromatography. These measurements of molecular weights and distributions have become commonplace, such that automatic sampling of polymerization, processing, and final product testing are routinely done and calculated to provide data for process control.[6]

Branching

The concept of a polymer chain implies two ends per chain. However, because of the nature of the process that is used to form the polymer, the chain may contain one or more branch points resulting in multiple ends per chain. These ends can have a marked influence on polymer performance. Branching, molecular weight, and molecular weight distribution also have been shown to affect processability.[7] The optimum macrostructure often represents a compromise between processing and ultimate performance.

Network Structure

A critical requirement for obtaining the desirable properties from a rubbery material is the generation of a network structure. Charles Goodyear's discovery of ''vulcanization'' changed natural rubber from a material that became sticky when hot and brittle when cold to a material that could be used over a wide range of conditions, when he found a way to chemically connect the individual polymer chains into a three-dimensional network. This network now allows the support of considerable stress and retracts rapidly on release of the stress. Efforts to elucidate this process are still of interest.[8,9] The terms vulcanization, ''rubber cure,'' and ''cross-linking'' all refer to the same general phenomenon. For most rubber systems, the network is formed after the polymer is mixed with additive and curatives (compounded) and molded into the desired final shape. Once cross-linked, the material can no longer be processed. If cross-linking occurs prior to compounding or molding, the material is referred to as gelled, and it cannot be used. Most rubber is used in a compounded and cured form. There is an optimum cross-link density for many failure properties, such as tensile strength and tear.

Glass Transition Temperature

Glass transition temperature (T_g) is usually measured using thermal methods, such as differential scanning calorimetry, which look at the change in heat capacity when a material goes through the glass transition. Another very useful method is to use dynamic mechanical properties where the polymer is subjected to a temperature sweep in a dynamic mechanical spectrometer from a very low temperature ($-120^\circ C$) to well above room temperature ($+100^\circ C$). If the modulus is plotted vs. temperature, there is a sharp decrease as the polymer warms to above the T_g. There is also a peak in the energy loss property known as tan δ.

For a polymer to behave as a rubbery material, it is necessary for the chain segments to have great mobility. As the temperature is lowered, this ability of chain segments to move decreases until T_g is reached where all large-scale chain segment motion is prevented. Below this temperature, the rubber becomes a hard and brittle glassy material. Above this temperature amorphous plastics polymers, such as polystyrene, can exhibit rubbery character if the molecular weight is sufficiently high. It has been shown that the wet traction and wear of a passenger tire are directly dependent on the T_g.[2,10] Control of T_g is possible in PB by controlling the microstructure of the polymer chain. Vinyl placements restrict chain mobility and thus raise the T_g. The average microstructure of a PB polymer can be readily tailored to obtain any T_g of the final product within the range of 100% *cis*-1,4- to 100% of 1,2-microstructure.

Crystallinity

Crystallinity can be measured using the same thermal and dynamic mechanical methods used for measuring T_g; however, the melting transition (T_m) is much sharper and is at a higher temperature than the T_g. The majority of the PB is used as an elastomer for which

a low T_g is required. Syndiotatic 1,2-PB and crystalline high *trans*-1, 4-PB are exceptions and have been used as a reactive ''plastic'' that has a T_m in excess of 150°C. Very little emphasis is placed on these materials as it represents an extremely small portion of the utility of PB polymers and has been described adequately.[11]

PRODUCTION

The worldwide demand for elastomers was estimated to be 19.44 million metric tons for 2008, excluding NR latex materials.[a] Of this demand, 55% are synthetic elastomers of various kinds. Depending on their use elastomers have been classified into general purpose and speciality. The major general purpose elastomers are natural rubber, SBR rubber, PB rubber, isoprene rubber, and ethylene–propylene rubber. These rubbers are used in tires, mechanical goods, and similar applications. Specialty elastomers provide unique properties such as oil resistance or extreme heat stability. Although this differentiation is rather arbitrary, it also tends to classify the polymers according to the volumes used. About 74% of the rubbers used consist of SBR, butadiene rubber (BR), and ethylene–propylene rubber.

The worldwide consumption of PB in 2003 was about 2.1 million metric tons and is forecast to increase to 2.5 million metric tons by 2008.[a] The total U.S. consumption of BR is about 0.41 million metric tons, of which over 70%, as *cis*-1,4-PB (*cis*-PB), is used in the manufacture of tires. The next largest use of ~20% is mainly anionic PB for the plastic industry. The remainder is used in a variety of applications that is seen in the following sections.

A search of the worldwide patent base since 1981 revealed 9980 distinct patents that have been issued or are published applications of the utilization of PB. Computer technology is now available that will list and generate a map indicating the similarities among these patents.[b] Such a map with this broad database is seen in Fig. 1. Here, the peaks are labeled to indicate clusters of similar patents. For instance, the four most intense collections of points are shown as white peaks. Each peak represents the location of the maximum of over 400 patents related to the labeled category, while the next contour line shows the distribution of less closely related patents that also have a lower level of similarity to the peak.

RUBBER COMPOUNDING

The vulcanization discovered by Charles Goodyear was essential for the use of rubber products, but the impetus for rubber use was supplied by compounding the rubber with a vast number of materials. Without compounding and curing, the rubber utilization would only be a small fraction of what it is today. Any particular compounded rubber application has been optimized to produce very specific properties. These include appearance, processing, mechanical, electrical, chemical, and thermal properties, as well as cost. Developing such compounds requires a broad knowledge of material science and chemistry combined with experience. The use of designed experiments can greatly facilitate selecting the optimum compound formulation. The major components used in such compounds are curatives, reinforcing agents, fillers, plasticizers, and antidegradants.

Processing

Wide ranges of processes are used to convert a bale of rubber into an elastomeric product, such as a tire. The process generally starts with the compounding of the rubber with many of the previously stated ingredients. Many elastomeric stocks require more than one rubber to be included to obtain the desired performance goal. This has resulted in PB being added to many applications to impart specific key properties.

Rubber can be considered as a highly viscous state of matter that processes both as a liquid and as an elastomer. Mixing materials into rubber requires high shear, for which the simplest method is a double-roll mill, where the rubber is shear-mixed along with the other compounding ingredients in the bite of the mill. Large-scale mixing is most commonly done with a high-shear internal mixer called a Banbury. This mixing is a batch process although continuous internal mixers are also used.

Typically, the compounded rubber stocks need to be further processed for use. The process could be an injection or transfer molding into a hot mold, where it is cured. Extrusion of the rubber stock is used to make hose or tire treads and sidewalls. Another common process is calendaring, in which a fabric is passed through rolls where rubber is squeezed into the fabric to make fabric-reinforced rubber sheets for roofing membranes, belting or body plies for tires. The actual construction of the final product can be quite complex. For example, a tire contains in excess of six different compounded elastomeric stocks. All the components must be prepared and assembled with high precision so that the final cured product can operate smoothly at high speeds and last over 50,000 mi.

Monomer Production

Butadiene monomer can be produced by a number of different processes. The dominant method of production is as a by-product from the steam cracking of naphtha to produce ethylene. The BD is recovered from the C_4 fractions by extractive distillation.[12] Butadiene is generally produced by dehydrogenation or oxidative dehydrogenation of C_4 hydrocarbons.[13,14]

Polymer Production

Polybutadiene is usually produced by alkali metal or transition metal coordination solution processes, which allow the production of a variety of the desired DPs and microstructures. Alkali metal-based polymerization (usually alkyllithium) produces a product with about 36% *cis*-1,4-, 54% *trans*-1,4-, and 10% 1,2-PB. The polymerization process is conducted in an aliphatic hydrocarbon under an inert atmosphere in either a batch or a continuous mode. Because of the characteristics of this polymerization system, polymers of extremely narrow molecular weight distribution and low gel can be produced.[15] The narrowest distribution is produced via batch polymerization. The largest commercial use of anionic PB is in plastics modification. The PB is commonly characterized with a Mooney viscosity (ML_4) of about 52 with a 5.43% toluene solution viscosity at 25°C of about 160 cPs. Generally, other commercial PBs has an ML_4 range of 35–70 with a solution viscosity of 40–250 cPs.

Coupled (star branched) and end-functional PBs are possible using alkyllithium technology because of the presence of a living anion on the chain end. This anion is available for further reactions, which is discussed later. Upon the addition of polar agents (modifiers), such as ethers or amines, the alkyllithium initiators can produce PBs with vinyl contents up to 100%.[16] The vinyl content can be controlled by the ratio of

modifier to initiator and the polymerization temperature, with lower temperatures favoring increased vinyl formation. Even with high vinyl contents such polymers do not crystallize, because of the atactic nature of the vinyl units.

Both free-radical and anionic polymerization produce PBs that have mixed microstructures. Neither of these routes produces a rubber that can replace the high tack, green strength, or gum tensile of natural rubber. However, these PBs have been useful in many applications.

Emulsion polymerization

The formula developed to provide emulsion SBR (GR-S) during World War II was standardized with all rubber plants owned by the U.S. government.[17] Initiation occurs by the formation of a mercaptyl radical through reaction of the persulfate with the mercaptan, followed by chain propagation and growth of the polymer by the free-radical attack of the emulsified BD and styrene monomers. The molecular weight of the chain can be controlled by the concentration of mercaptan via a chain transfer mechanism. The growing polymeric radical chain can be terminated by reaction with mercaptan to form a new mercaptyl radical, which then can initiate an additional polymeric chain.[18] The terminated polymer produced above also can react with new growing chains, to lead to branching, which if the conversion of the monomer is too high can result in gel. Thus, above about 70% conversion the polymer becomes highly branched for use. Termination by the addition of free-radical scavengers, such as hydroquinone, is commonly used to stop polymerization before this point. The excess monomer is flashed off by steam stripping. Most of the emulsion-polymerized latex made today is SBR latex. However, PB latex is also made for specialized applications.

Solution Process

In 1955 investigators from the Firestone Tire and Rubber Company and the B. F. Goodrich Company announced the synthesis of polyisoprene with over 90% *cis*-1,4- structure. The work at Firestone was based on lithium metal catalysts, whereas the work at Goodrich was the result of using Ziegler–Natta-type coordination catalysts.[19,20]

The discovery of the ability of lithium-based catalysts to polymerize isoprene to give a high *cis*-1,4-polyisoprene was rapidly followed by the development of alkyllithium-based PB. The Firestone Tire and Rubber Company built the first commercial plant in 1960.

In addition to these engineering approaches to produce uniformly random SBR copolymer, the kinetics may be changed by the addition of polar modifiers. This action results in bringing the reactivity rates of the comonomers much closer together, but changes the microstructure of the PB portion. Whereas in the nonpolar system the vinyl content of the PB is around 10%, with polar additives vinyl contents of 20% and even higher are readily obtained. Care must be taken when polar modifiers are used as they can react with the growing chain, resulting in an undesired termination.[21,22]

High *cis*-PB is produced via solution processes using Ziegler–Natta-type transition metal catalysts. The major commercial catalysts of this type are based on titanium, cobalt, nickel, and neodymium.[23] Typically, transition metal is used in the form of a soluble metal salt, which can react with alkylaluminum or an alkylaluminum halide to reduce the metal to give the active species.[24–26] Because of the active nature of the catalyst mixture, the polymer solutions must be treated to deactivate or remove these materials from the final product. Many of these catalysts produce products with 90% or higher *cis*-1,4- content. The neodymium system is reported to produce the highest *cis*-(98–99%) with the most linear chain structure.[27] The highest branched *cis*-PB is produced with the Co system with Ni giving intermediate branching.[28–30]

All of the solution processes require high efficiency in recovering the solvent. The schematic in Fig. 2 shows how a typical solution polymerization plant is arranged. The most widely used process consists of termination of the polymerization and the addition of antioxidant to the polymer solution. The solution may be treated to remove initiator or catalyst residue and then transferred into an agitated steam-stripping vessel in which unreacted monomer and solvent are flashed off, leaving the rubber as particles (crumb) in water. The water/crumb slurry then is dewatered and dried. The recovered monomer/solvent is recirculated to a series of distillation columns to recover monomer and purify the solvent. As both the anionic and the coordination catalyst systems are highly sensitive to impurities such as water, the purification system is very critical for satisfactory process control.

The mapping shown in Fig. 1 includes references to SBR and styrene block copolymers in the PB search. Removing these citations from the database reduced the number to 4297, which can be seen mapped in Fig. 3. the area of high activity is centered on hydroxy terminated PB (HTPB). Low-M_n HTPB can be prepared by a variety of polymerization processes such as radical, anionic, or even using acyclic diene metathesis (ADMET).[31–33] The HTPB has a variety of uses as a propellant.[34–39] Other uses include reaction with epoxy resins, nylon, urethane, or even in the formulation of adhesives.[40–45] The use of HTPB as an oxygen scavenger in polyamide, polyvinyl alcohol, and multilayer

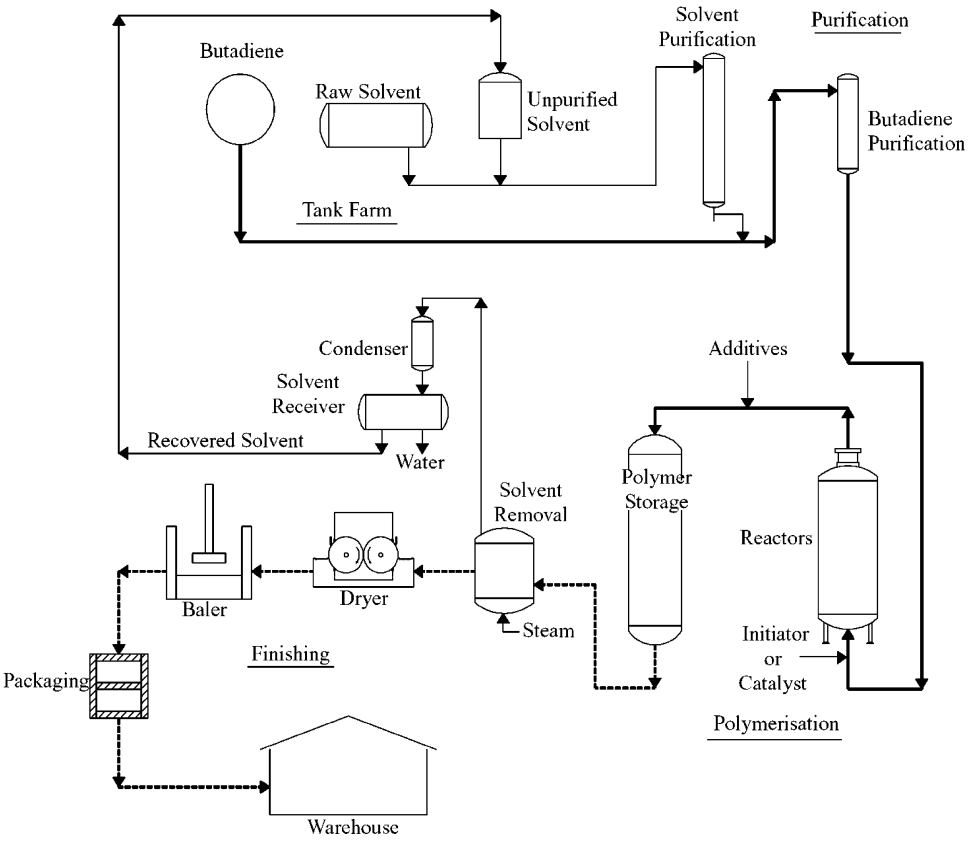

Fig. 2 Flow diagram for a typical solution process for the manufacture of PB. (Courtesy of Firestone Polymers, Akron, Ohio, U.S.A.)

composites or as a reactive component in plastic sheeting appears to be a growing market.[46–49] Another area of significant activity was in the production of syndiotatic PB with different metallic catalysts and additives.[50–53]

Now a closer look at the mapping of vinyl PB can be considered. A further refinement of the total PB citations revealed 926 references for vinyl PB, which are mapped in Fig. 4. Here, the aqueous preparation of syndiotatic 1,2-PB is seen along with the use of both syndiotatic and atactic PB in tire beads, silica containing treads, and even medical applications after cross-linking with peroxide or radiation.[54–62] Mixtures of catalysts have been used to allow amorphous 1,2-PB to be coproduced with syndiotatic PB in the same reactor.[63,64] Epoxidized vinyl PB can be used to reduce tire rolling resistance, toughen resin, and stabilize PVC.[65–67]

Further focusing of the mapping can be seen in Fig. 5, where 148 citations for high *cis*-PB are shown. The preparation of high *cis*-PB with Co, Nd, and Co with nitrogen ligands was revealed.[68–70] A significant use includes *cis*-PB as golf ball cores and covers with polyurethanes and unsaturated metal salts.[71–73] The market for high *cis*-PB in solid-core golf balls continues to grow and is very active. For this application, the polymer is compounded with zinc acrylate and the mixture is cured with peroxide.[74] The ionically cross-linked compound produced has outstanding resilience. In the last few years, the golf ball market has been shifting away from the traditional wound ball to these new solid-core balls, which use PB.

The more traditional application of the *cis*-PB continues in silica containing tire–tread applications with the majority of the polymer produced being used by the tire industry.[75–77] Cured PB has excellent low-temperature properties, high resiliency, and good abrasion resistance because of its low T_g. However, this same fundamental property also leads to very poor wet skid resistance. For this reason, PB is blended with other polymers such as natural rubber and SBR for use in tread compounds. In general, PB is a poorer-processing polymer than SBR, but this is not a problem when blended with other polymers. The very high *cis* polymers have the potential for strain-induced crystallization that can lead to improved green strength and increased cut growth resistance in the cured product. High *cis* PB is reported to have a melting point of 6°C.[78]

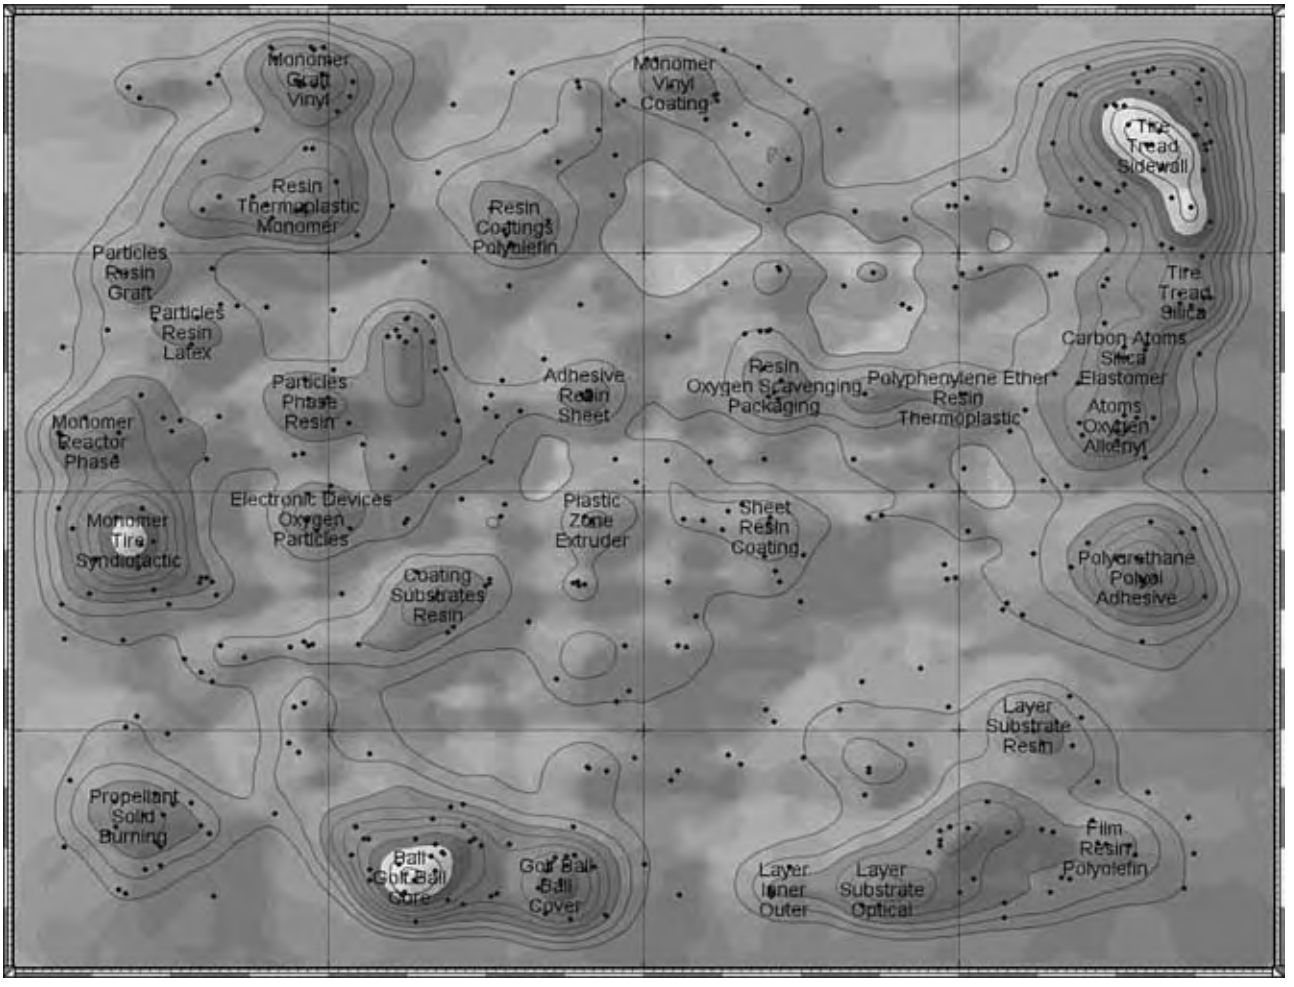

Fig. 3 Mapping of 4297 nonduplicated patent references since 1981 for the areas of use of BR without concern of SBR and block copolymer activity. *(View this art in color at www.dekker.com.)*

Fig. 6 shows the map from 109 references that cover grafting onto 1,4-PBs. The major use is as an impact modifier in plastics, in particular, high-impact polystyrene (HIPS) and acrylonitrile–BD–styrene resin (ABS).[79–83] In the HIPS application the rubber is dissolved in the styrene monomer, which is then polymerized via a free-radical mechanism. A complex series of phase changes occurs, resulting in small rubber particles containing even smaller polystyrene particles being incorporated into a polystyrene matrix. Because of the unique morphology that is formed, low levels of rubber (typically around 7%) provide rubbery particles having a volume fraction of 30–40%. This morphology leads to a high impact at very low rubber levels, providing good stiffness and hardness.[84] Major use of PB can be seen in the radical grafting to make HIPS and in the formation of ABS resins and adhesives.[83–86] Grafts of unsaturated carboxylic acids are used for high-modulus elastomers, reduction in air permeability, golf balls, and run flat tires.[87–92]

CHEMICAL ''PROMOTERS''

The promoter effect is the ability of a chemical additive to attach itself both to the polymer backbone and to the surface of the carbon black (CB) filler without causing polymer–polymer cross-linking. The best way to determine if a promoter has done its job is to look at the low-strain region of dynamic mechanical strain sweeps for decreased ''Payne Effect'' (Fig. 7). The degree of network structure can be measured from a plot of the elastic storage modulus (G') vs. strain where strain is varied from about 0.01% to 15% at 65°C. The dramatic drop in G' with strain as a result of the destruction of the CB network is known as the Payne Effect.[93] Reinforcing CBs at high loadings (>20 phr) set up a three-dimensional, chain-like network within the rubber matrix that increases the stiffness of the black-loaded compound and vulcanizes at strains <5%. This CB ''network structure'' is a major source of hysteresis in tire treads. The network is much more pronounced in the reactive super abrasion furnace

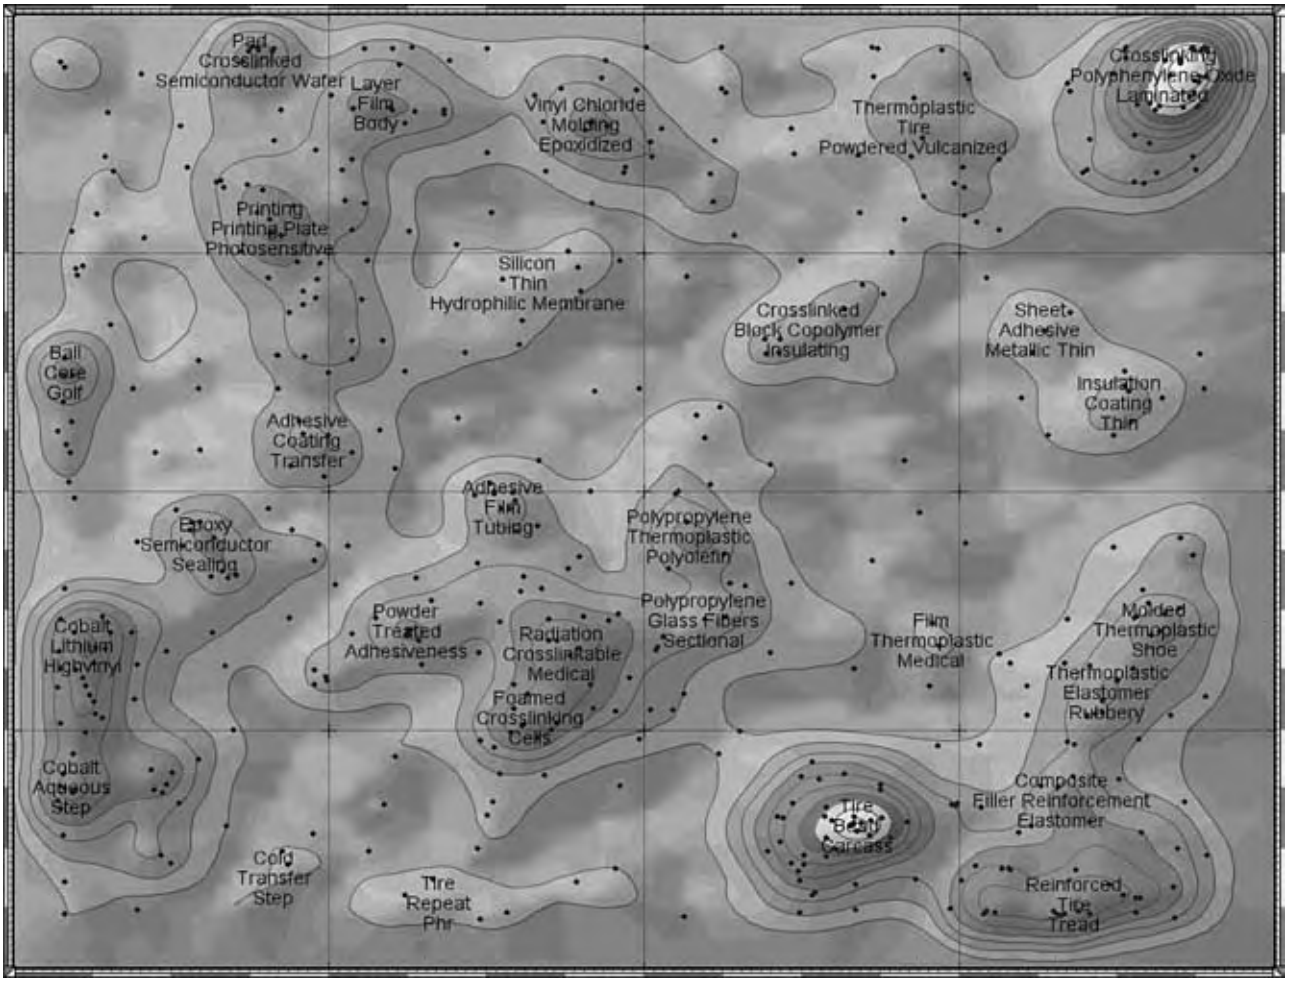

Fig. 4 A total of 926 citations for 1,2-(vinyl) BR are mapped. *(View this art in color at www.dekker.com.)*

(SAF) and high abrasion furnace (HAF) blacks and almost nonexistent with medium thermal (MT) black.

The hysteresis as measured by tan δ at about 65°C is used as a predictor of rolling resistance. As tan δ is the loss modulus (G'') divided by the elastic G', any additive that increases cross-link density would also reduce tan δ. This is why it is important to note the change in cross-link density, as predicted by G' or rheometer maximum torque when trying to determine whether a chemical additive really has a promoter effect or is just another cross-linking agent. Simply increasing cross-link density, without decreased Payne Effect, will always result in a significant drop in tear strength and may be an undesired increase in hardness. Compounds that have been successfully used include Nitrol, *N*-methyl-*p*-nitrosoaniline, benzofuroxan, and the heterocyclic di-*N*-oxides.[94–97] Despite the sharp decrease in tan δ and rolling resistance, these additives were only used briefly because their reactivity required special handling in production.

From a review of the promoter literature over the last 20 yr, it is clear that nitrogen compounds play a key role in achieving interaction with CB. The most active compounds seemed to involve some kind of nitrogen oxide chemistry that provide for the addition of the unsaturated rubber and a strong affinity for CB through a nitroxyl radical.[96,98]

Functional Solution BR

The driving force toward functional diene rubbers is to improve hysteresis properties for passenger tire treads. Historically, a classic trade-off of having to sacrifice one property to reduce another property was encountered. For instance, the reduction in hysteresis by lowering the T_g of the polymer resulted in a decrease in wet traction. As a result, another hysteresis-lowering mechanism was sought. The first promising approach was the attempt to chemically bond the elastomer to the filler, thereby reducing the agglomeration of the filler, which is a major source of hysteresis in highly filled rubber stocks. Initial efforts were directed toward the addition of reactive compounds during mixing that would show a promoter effect.

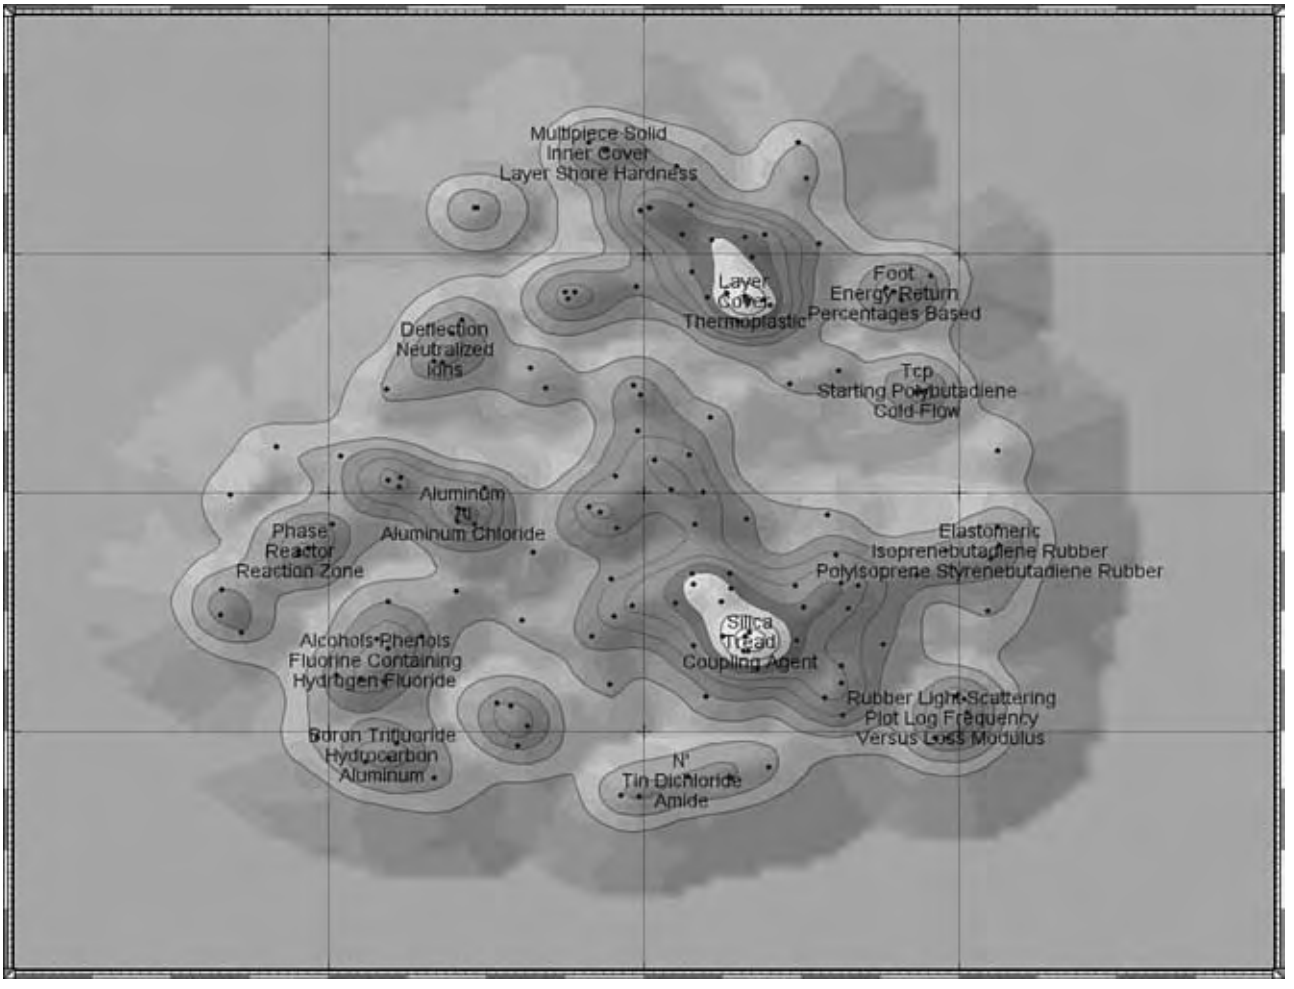

Fig. 5 Mapping of 148 citations for high *cis*-1,4-BR. *(View this art in color at www.dekker.com.)*

Anionic PB has a much narrower molecular weight distribution than an emulsion PB and gives lower hysteresis. However, the big advantage of anionic polymerization is the relatively stable growing chain ends, which can be chemically modified to improve interaction with CB and silica in tire compounds.[99] This modification can lead to a dramatic reduction in rolling resistance, which is critical for automotive manufacturers who must meet government-mandated fuel economy targets. The most active functional end groups contain either organotin or certain amines. Termination with tin tetrachloride is the easiest and the most popular method, which generates a four-armed star polymer. The polymer–tin bonds break down during mixing of the compound and both lower the compound viscosity and create active sites for reaction with CB surfaces. The creation of this ''carbon-bound rubber'' (Fig. 8) effectively prevents the formation of CB agglomerates, on a microscale, which is the source of a hysteretic three-dimensional network. The breaking of this network (Payne Effect) during the deformation of a tire tread is a major source of rolling resistance. Polymers with amine end-groups also show good activity with CB. Termination with silane esters is usually used to obtain interaction with silica fillers and provide a decrease in hysteresis. Recently, there have been efforts to make functional anionic initiators, some of which could be used to make low-hysteresis rubber.[100] Comparing an emulsion polymer to its solution counterpart and a chemically modified version of the solution polymer showed a 23% hysteresis reduction in going from emulsion to solution and an additional 15% reduction for the chemically modified polymer (representing an overall reduction of 38% of hysteresis).[101] To date, this type of chemical modification is best accomplished using anionic techniques.

UTILIZATION

The 101 citations covering functionalized PB are mapped in Fig. 9. These include epoxy, imide, and

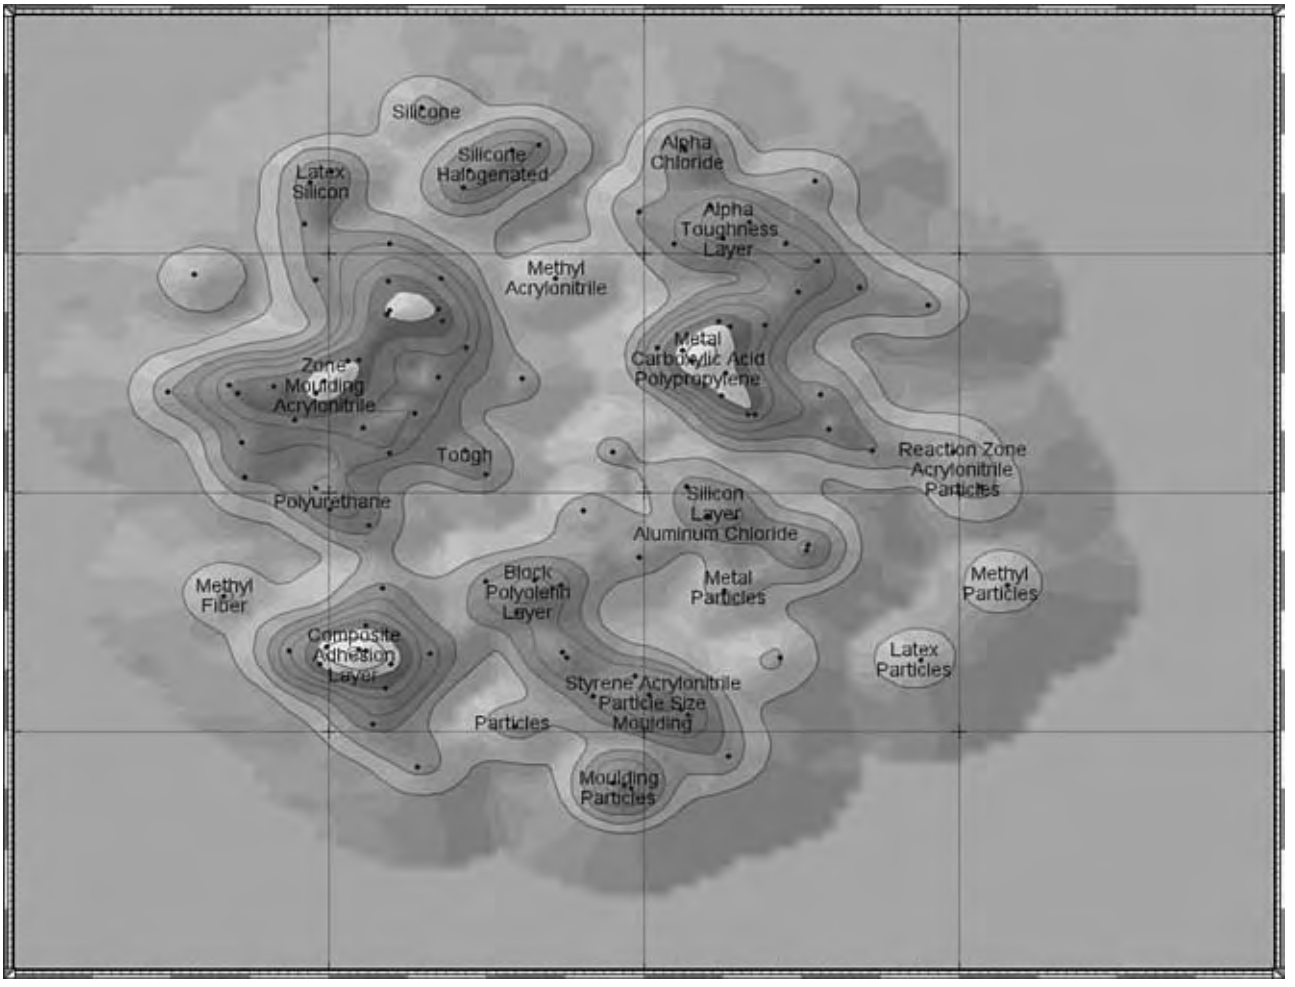

Fig. 6 Mapping of 109 references for grafted 1,4-BR. *(View this art in color at www.dekker.com.)*

modified HTPB to give toughened resins and the previously mentioned oxygen acceptors for bottles and barrier resins.[102,103] A number of citations were excluded by the searching protocol that eliminated any mention of SBR. As the functionalization chemistry is the same for SBR as for PB these citations must be included. Of particular interest is the use of functional lithium initiators containing tin, cyclic amines, *tert*-amino phenyl, or dithiane.[104–107] Termination of the lithium polymer with oxazoline, cyclic amines, and sulfur compounds, or by using high-T_g vinyl polymers also reduced hysteresis.[108–115]

Backbone functionalization with epoxide groups gave the modified PB that was discussed above. Additionally, the epoxidized PB has been used in sulfur- and amine-cured rubbers to give oil resistance.[116,117] The addition of hydrogen and chlorine or combination of alcohol and chlorine has been used as a roofing membrane.[118–120] Hydrogenated medium vinyl PB has also been reacted with maleic anhydride to give a sizing coating for glass fibers, and elastomeric impact modifier for molding resins.[121–124]

Tin-Coupled Solution PB

After the discovery that a simple tin-coupled PB showed a pronounced promoter effect, the work shifted from developing chemical additives to end-functionalizing anionic polymers. A group at Philips Petroleum Co., back in 1970, was producing tin-coupled PB using anionic techniques because the polymer–tin bonds would break down easily during mixing, yielding a better processing PB.[125] The living anionic PB was simply terminated with tin tetrachloride producing lithium chloride and a four-arm star polymer with tin at the center (Fig. 8). They noted that the improvement in heat buildup long before rolling resistance was an issue, but never related it to Payne Effect or CB–polymer interaction. They were simply trying to make an easy-processing PB. It was not until 1985 that a group at Bridgestone reported that tin-coupled polymers dramatically reduced the Payne Effect and increased carbon-bound rubber.[126] They concluded that reactive polymer chain ends, from the tin-terminated polymer, attached to the surface of CB. No mechanism was proposed for the attachment.

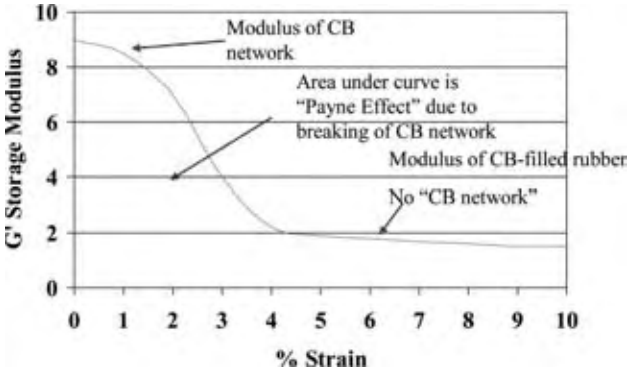

Fig. 7 The Payne Effect measured on a rheometrics dynamic analyzer (RDA II), using a 10 Hz strain sweep from 0.05% to 10% strain, 65°C, on a typical tire tread containing 50 phr HAF black. *(View this art in color at www.dekker.com.)*

Later, some Japanese synthetic rubber scientists believed the attachment involved quinone groups that are on the surface of highly reinforcing blacks blocks. This was based on the work done with allyltin compounds, and was later shown to involve a concerted reaction of the allyltin end with an *ortho*-quinone structure that is present on the reactive CB.[127,128] Tin-coupled diene elastomers are produced commercially by a number of polymer companies, including Firestone Polymers, and are still widely used today for low-rolling resistance treads, usually in a blend with natural rubber for improved tear strength. The structure for tin-coupled PB is shown in Fig. 8, along with a proposed reaction scheme for the polymer with the surface of a highly reinforcing CB.

Other Functional End-Groups for Improved Hysteresis

Since the discovery of the use of tin-coupled diene polymers for low-rolling resistance in about 1985, there is a significant effort to discover other end-grouping agents for anionic polymerization of PB and SBR, which would attach to CB. Although a myriad of terminating agents for anionic polymerization are possible only a few produce a functional group on the chain end that would reduce hysteresis in cured filled rubbers. The reaction of lithium PB with *N*-methyl pyrrolidinone, Michler's ketone (4,4′-*bis*-(diethylamino) benzophenone), or the Schiff Base from 4-dimethylamino benzaldehyde and 4-butyl aniline has given outstanding promoter effects in CB tread stocks.[129] The reduction of the 65°C tan δ by at least 20% was obtained with these compounds, indicating that significant reductions in rolling resistance would be observed in actual treads. Note that just as with the additives or chemical promoters, the most effective end groups contained either nitrogen or tin. It is shown repeatedly in studies on the promoter effect that CB seems to have a particular affinity toward compounds of tin or nitrogen (and their oxides).

Another important advantage of the above terminators is that the reaction with the polymeric live end proceeds cleanly with no coupling or side reactions producing a highly functional polymer. Many other potential terminators, like carbon dioxide, ketones, and aldehydes produce undesirable by-products and coupling of the polymer chains. To be cost-effective, the potential terminator must also survive the high temperature of the polymer cement at the peak of the

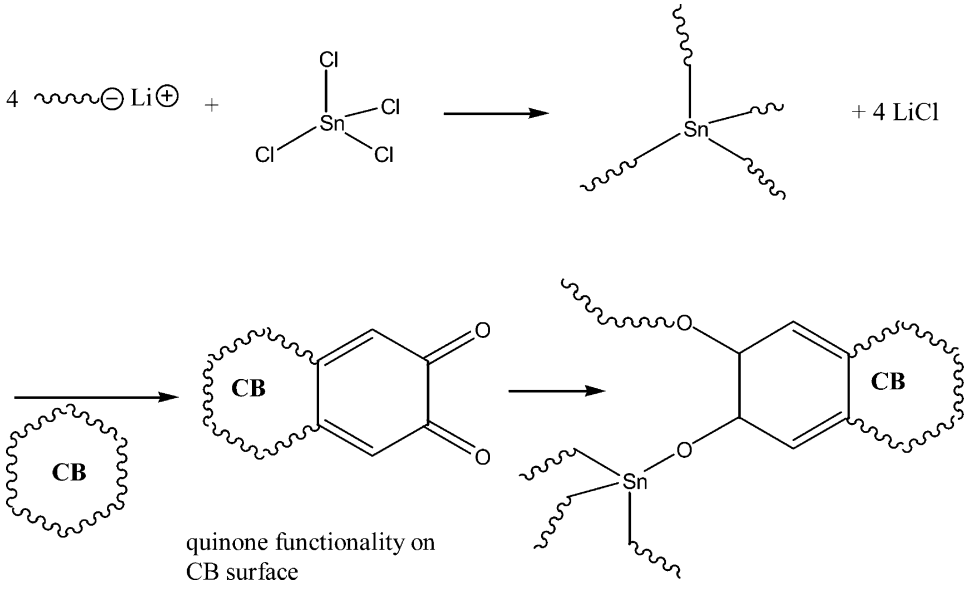

Fig. 8 Coupling of a living anionic polymer with tin tetrachloride followed by reaction with quinone functionality on CB.

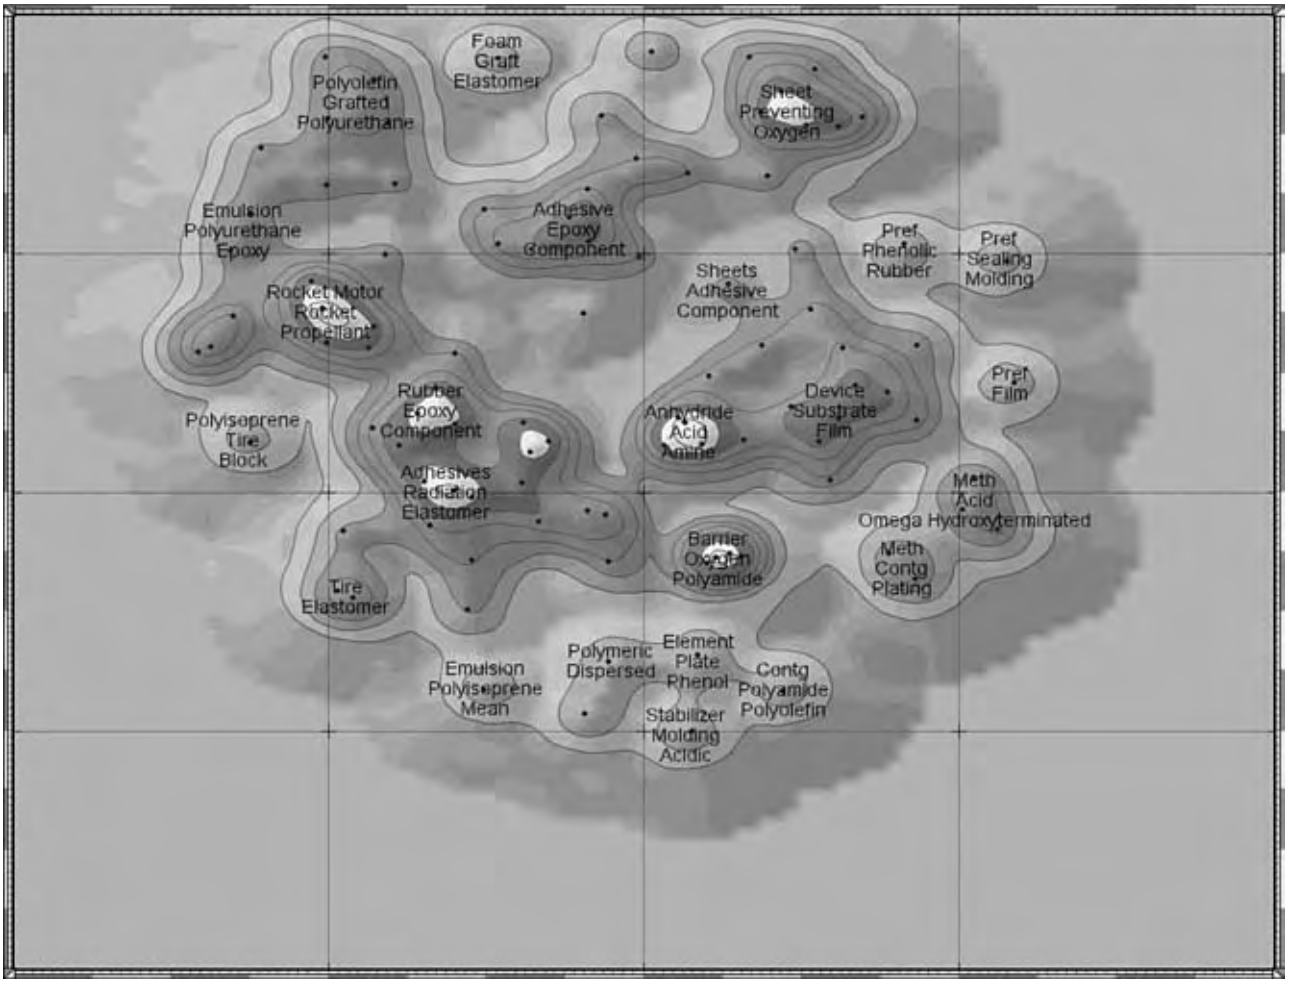

Fig. 9 Mapping of 101 patent citations for functionalized PB. *(View this art in color at www.dekker.com.)*

reaction (>100°C) and the steam desolventization process in the plant. If the polymer cement has to be cooled to low temperature prior to termination, or if the terminator is not hydrolytically stable, then the process will not be economically feasible. Tributyltin chloride has been shown to be another extremely effective promoter when used as an anionic terminator.[127] Usually, partial termination with tin tetrachloride, or other coupling agents is used to prevent cold flow problems when the above terminators are used.

Functional Anionic Initiators for Improved CB Interaction

Besides termination reactions to generate a promoter functionality on the tail of the polymer there have been a few initiators, which that have been used to attach a promoter group to the head of the polymer chain. Once again, the two most active groups were found to be certain amines and tin compounds. An even greater reduction of $\tan\delta$ and Payne Effect can be obtained with functional initiation probably owing to the fact that each polymer chain must have all of the head groups attached to a promoter. These initiators present the opportunity to also functionalize both chain ends by either coupling with tin tetrachloride or using some other active promoter-type terminator. The resulting difunctional polymer usually presents some processing challenges because of very high compound viscosities that can be controlled by slowing down the reaction of a portion of these functionalities during mixing. The amine head group could act like a macroaccelerator during sulfur curing, which results in reduced scorch time and higher cross-link density. This effect is not seen with the organotin initiator even though a pronounced decrease in Payne Effect is noted.

Tin–lithium initiator, also discovered by Bridgestone/Firestone, was found to be one of the most effective promoters for CB interaction.[104] The initiator was made from the reaction of TBT chloride with lithium metal producing tributyltinlithium. The polymerizations of SBR or PB proceeded identically to that with

butyllithium and the resultant polymer contained TBT groups on the head of every chain. When terminated with TBT chloride, the polymer had highly active TBT groups on both chain ends that produced very low tan δ and Payne Effect in black-filled stocks. The resulting low-rolling resistance and increased wear resistance were confirmed in actual tire tests.[130]

One interesting type of end-group attachment involves the addition of a free-radical generating chemical structure, which can be attached to the living anionic polymer through an epoxy group on one end of the functional chemical. This end-group then allows the functional PB to be added to a free-radical polymerization process to give HIPS or ABS with a modified structure. Under normal conditions of HIPS or ABS production, nonfunctional PB is dissolved in styrene monomer and the solution is then polymerized through a free-radical mechanism (with the additional of acrylonitrile, in the case of ABS). With a free-radical functionalized PB, block polymers are formed during the HIPS or ABS polymerization process. The formation of block polymers can lead to enhanced properties in the modified plastic compound. In some cases, the plastic compound can become clear. In other cases, the impact/gloss relationship can be improved.[131]

Promoters for Silica Stocks

In the 1990s a continuing push for lower rolling resistance led to using more silica to replace CB in passenger treads. Tread stocks for passenger tires can now contain from about 20% to almost 100% of the total filler as silica in a blend with CB to achieve low-rolling resistance. Obviously, the functional polymers developed for CB interaction would not necessarily be good with silica. For that reason, polymers were developed with organosilane end groups.[132]

Polycarbonate (PC)

Sarah E. Morgan
Jun Li
Department of Polymer Science, University of Southern Mississippi, Hattiesburg, Mississippi, U.S.A.

INTRODUCTION

Polycarbonate (PC), with its unique combination of toughness, transparency, processability, and temperature resistance, is one of the most important engineering thermoplastics in the world today. It is found in a wide range of products, from CDs and DVDs to greenhouses and optical lenses to automotive lighting and instrument panels. Polycarbonate forms a number of useful blends and composites and can be produced in a wide range of transparent and opaque colors, making it the material of choice for many products with special visual effects, like specially colored computer housings and personal communication devices. Bisphenol A polycarbonate (BPA-PC) is the most important commercial PC and is the primary subject of this review. Until recently, BPA-PC was produced via an interfacial polymerization process. Recently commercialized melt processes provide solvent- and phosgene-free production routes. This article provides a brief summary of the historical development of BPA-PC, an overview of commercial products and producers, a review of PC physical and mechanical properties, a description of current commercial production processes for PC as well as new process developments, an overview of processing and fabrication processes employed with PC, a summary of PC blends, copolymers, and applications, and a summary of PC literature.

BACKGROUND AND HISTORY

Interest in PC continues to grow, with over 44,000 current publications and patents, of which some 55% are patents.[1] Before 1960, there were fewer than 100 total publications and patents on PC. Annual new publications increased from around 200 per year in the 1960s to 2000 per year in the 1990s, with continued growth of approximately 1400 new patents published per year since 2000. Similarly, global production and consumption of PC continue to grow, with an estimated 1.5 million metric tons of global consumption in 2000[2] and a projected annual growth rate of 7% per year.[3] GE has the largest global market share of PC resin (sold under the trademark LEXAN® resin),[4,5] with Bayer (Makrolon®)[6] holding second place. Other major global producers of PC resin include Dow Chemical Company (CALIBRE®),[7] Teijin (Panlite®),[8] and Mitsubishi Engineering Plastics Corporation (Iupilon®).[9] There are frequent announcements of expansions, licenses, and plans for new production sites to serve emerging markets around the world.[10–12]

Polycarbonate based on 2,2-bis(4-hydroxyphenyl) propane (bisphenol A, BPA) is the PC of primary commercial interest (Fig. 1), but commercial production of BPA-PC did not begin until the 1960s.[13] The earliest reports of aromatic PC preparation, by Einhorn, appeared in the late 1800s and involved reaction of hydroquinone or resorcinol with phosgene in pyridine solution.[14] In 1902, Bischoff and Hedenstroem[15] reported a melt synthesis of these polymers via transesterification with diphenyl carbonate. Carothers and Van Natta[16] reported aliphatic PC synthesis in the 1930s. Aliphatic PCs display low melting points, strength, and durability and are generally of little commercial interest. The first commercial PC material, a cross-linkable allyl diglycol carbonate (CR-39®), was introduced by Pittsburgh Plate Glass Company (PPG) in the 1940s.[17]

Researchers at GE and Bayer independently developed commercially feasible synthetic processes for BPA-PC in the 1950s[18,19] and began commercial production in the early 1960s. Bayer was awarded the U.S. patent for PC produced via the interfacial polymerization process[20] and GE the U.S. patent for the melt transesterification process.[21] However, until recently, the major part of BPA-PC was produced via the interfacial process. Further information on the history of PC development can be found in previously published reviews.[22–28]

POLYCARBONATE STRUCTURE AND PROPERTIES

Aromatic PC based on BPA (Fig. 1) is the most important commercial PC. BPA-PC is amorphous and transparent, with a glass transition temperature (T_g) of approximately 150°C. The high T_g of BPA-PC is attributable to the bulky structure of the polymer,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007908

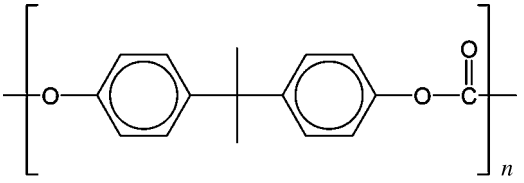

Fig. 1 Structure of BPA-PC.

which hinders segmental motion of the polymer chain. Unlike most amorphous polymers at temperatures below T_g, BPA-PC exhibits extraordinary impact strength and toughness. Its unusual low-temperature impact strength has been attributed by some authors to the presence of a low-temperature gamma transition that represents local scale motions of the polymer chain in the glassy state, which are thought to provide a mechanism for energy dissipation.[29–32] Alternative theories incorporate the importance of free volume and residual stresses on PC impact behavior (recently reviewed in Ref.[33]).[33–35] As shown in Fig. 2, a low-temperature gamma transition temperature is observed at around –100°C. Additional transitions observed are the β transition at around 60°C and the α transition (T_g) at around 150°C. The β transition temperature is dependent on the thermal and mechanical history of the test sample and is attributed to residual stresses in the polymer sample as well as to the state of aging of the sample.[36]

The mechanical, thermal, and processing parameters of PC depend on the molecular weight of the polymer. Typical commercial BPA-PCs for injection molding and extrusion applications have weight-average molecular weight (M_w) in the range of 17,000–36,000 as determined by light scattering. Molecular weight is often approximated from the intrinsic viscosity using the Mark–Houwink–Sakurada relationship:

$$[\eta] = KM_v^a$$

where $[\eta]$ is the intrinsic viscosity, M_v is the viscosity-average molecular weight, and K and a are constants for a given polymer/solvent combination at a given temperature. Molecular weight, polydispersity index, intrinsic viscosity, and melt viscosity data have been correlated for a range of PCs of differing molecular weights.[37] K and a values are reported for BPA-PC in a number of solvents.[22,38–40] In general, mechanical and thermal properties such as impact resistance and softening point increase with increasing molecular weight, as does melt viscosity (and thus resistance to flow). Mechanical properties increase rapidly with increasing molecular weight at low molecular weights, but at molecular weights higher than around 22,000 (intrinsic viscosity approximately 0.45 dl/g), only slight changes are observed. Melt viscosities, however, continue to increase, making melt processing increasingly difficult. To optimize the balance of processability with mechanical properties, the PC of lowest molecular weight that meets minimum mechanical property requirements should be chosen for a given application. Higher-viscosity resins are typically used for extrusion applications, where high melt viscosities are tolerated and high strengths are required. Very low viscosity resins are used in applications such as injection molding of CDs, where high flow is necessary but impact strength is of secondary importance. Melt flow rates, intrinsic viscosities, and molecular weights for typical commercial BPA-PCs are given in Table 1.

Typical thermal and mechanical properties for commercial BPA-PCs of differing molecular weights are given in Table 2. Softening temperature increases with molecular weight for the high-flow (low molecular weight) polymers but is virtually constant for higher molecular weight materials. Similar trends are observed for mechanical properties such as notched izod impact and tensile strength.

Polycarbonate demonstrates excellent ductility below T_g, in contrast to most glassy polymers. The ductile/brittle transition in BPA-PC is a function of molecular weight, temperature, notch radius, sample thickness, rate of deformation, annealing, physical aging, and residual stresses.[33,41–44] Whereas standard-molecular-weight BPA-PCs are ductile to approximately –10°C, low molecular weight PCs are brittle at room temperature. Incorporation of bulky end caps, such as *p*-cumyl phenol, enhances ductility for low molecular weight PCs and improves physical aging performance.[45,46] Blends and copolymers of BPA-PC can be prepared with enhanced low-temperature ductility (Fig. 3).

Stress–strain curves measured over a range of temperatures for a typical BPA-PC are given in Fig. 4, illustrating the tough and ductile behavior of the polymer. The area under the stress–strain curve represents the energy per unit volume or toughness of the material. Typical values for standard BPA-PC samples measured at room temperature are approximately 65 J/m^3 for energy per unit volume, 62 MPa for yield stress, and elongation at break around 120% (Table 2). These relatively high values make PC a useful material for many engineering applications and have allowed PC and PC blends to replace metal in applications requiring high strength-to-weight ratios, for example in many automotive parts. Fillers such as chopped glass fiber are used in BPA-PC to provide enhanced strength and stiffness and dimensional stability for engineering applications.

BPA-PC is soluble in a number of chlorinated solvents, including methylene chloride (high solubility, 350 g/L at 25°C), chloroform, *cis*-1,2-dichloroethylene, and *sym*-tetrachloroethane, and is soluble in warm chlorobenzene and *o*-dichlorobenzene. Non-halogenated solvents for BPA-PC include tetrahydrofuran, dioxane, pyridine, and cresols. Polycarbonate is not soluble in aliphatic alcohols, esters, or ketones and exhibits very low water solubility or swellability (see Table 2) and excellent resistance to hydrolysis.[47,48] BPA-PCs are generally resistant to aqueous acids and bases, though exposure to base may lead to chemical etching, and prolonged exposure to strong acids or bases results in molecular weight degradation. Crazing and cracking occur in stressed PC samples on exposure to amines, strong base, aliphatic and aromatic hydrocarbons, and certain plasticizers.[49–51] Acetone induces rapid crystallization and cracking of molded PC parts. Copolymers and blends of BPA-PC may be prepared with enhanced chemical resistance. A silicone or acrylic hard coat is often used to coat PC sheet and film products (often with added UV stabilizer) to improve chemical, UV, and scratch resistance.

BPA-PCs exhibit plastic deformation at temperatures above 200°C. Polycarbonates are processed at temperatures ranging from 270°C to 345°C, depending on the molecular weight of the polymer.[52] At these processing temperatures, linear BPA-PCs exhibit largely Newtonian flow behavior over a wide range of shear rates. Fig. 5 shows the rheological performance of a medium-flow PC at three different temperatures. Branched PCs, prepared by incorporation of small amounts of polyfunctional phenolic groups,[53–60] demonstrate pseudoplastic behavior, as shown in Fig. 6. Thus, high molecular weight branched PCs are more easily melt-processed, making them ideal for extrusion and blow-molding applications. Copolymers and blends of BPA-PC may be prepared that provide enhanced flow behavior. Polycarbonate melt rheology has recently been reviewed.[61]

Polycarbonate displays excellent optical properties, with high transparency (transmission ~90%), low haze

(<2%), high refractive index (1.588), low color, and the ability to be molded into articles with low birefringence. These properties, combined with its low density in comparison to glass, make PC ideal as a replacement for glass in applications such as optical lenses and windows. High-flow, high-purity PC grades are used in optical media applications, like CDs and DVDs. Additionally, PC is easily colored with dyes, pigments, and/or specialty additives (e.g., phosphorescent dyes, metallic particles) to provide a wide range of transparent, translucent, or opaque materials with desired visual effects.

BPA-PC absorbs in the UV region with a maximum at approximately 255 nm. On exposure to UV or sunlight, PC becomes yellow and exhibits surface degradation,[62] so for applications involving sun exposure, UV stabilizers are added.[63] Outdoor sheet applications generally employ a silicone or acrylate hard coat to provide improved weathering and scratch resistance.[64]

Pure BPA-PC shows excellent thermal stability at temperatures of up to 350°C. It is important to thoroughly dry the polymer before processing, and to ensure that impurities that might promote thermal oxidative degradation of the polymer, such as residual catalyst or metals, are removed. Generally, thermal oxidative stabilizers such as phosphites or phosphonites are added to prevent degradation and yellowing of the polymer during melt processing.[65]

Polycarbonate exhibits a relatively high oxygen index of 26. It may be further flame retarded by the addition of flame-retardant additives, including tetrabromo-BPA polymer, oligomer, or other brominated additives,[66,67] alkali metal salts,[68] polytetrafluoroethylene, phosphorus-containing additives, or silicones.[69] Glass fillers or other inert fillers may also provide improved performance in Underwriters Laboratories (UL) flame testing.

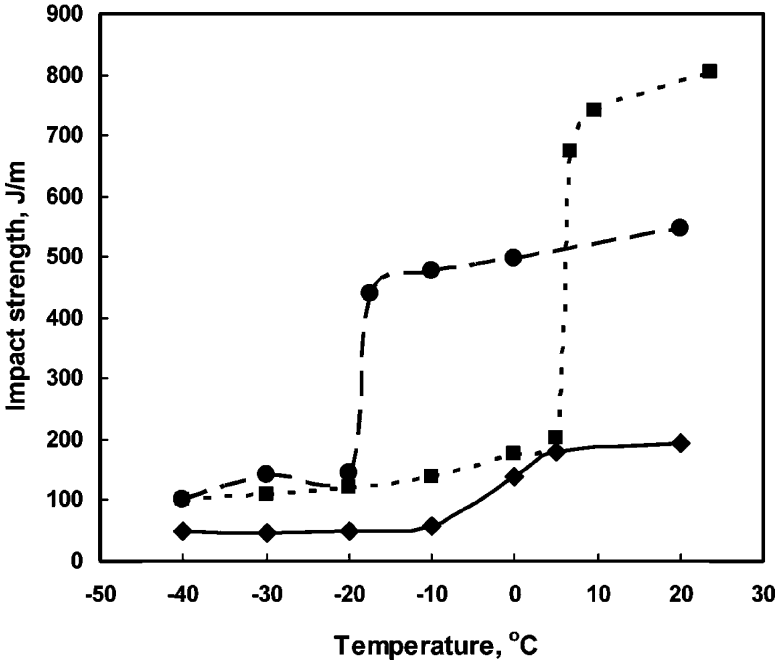

Fig. 3 Izod impact strength of PC (■), PC/ABS blend (●), and ABS (◆). (From Ref.[25]. Courtesy of GE.)

PRODUCTION PROCESSES

Interfacial Process

Until recently, virtually all commercial BPA-PC was prepared via the interfacial process (Fig. 7),[70–72] initially patented by Bayer.[18] This process involves polymerization of BPA monomer with phosgene in the presence of a catalyst at the interface of a water/organic solvent (typically methylene chloride) mixture. A monophenolic species, such as phenol or *p*-cumyl phenol, is added to control molecular weight. NaOH is added to neutralize the HCl formed and to maintain pH at reaction optimum (pH of 10–12). In a typical

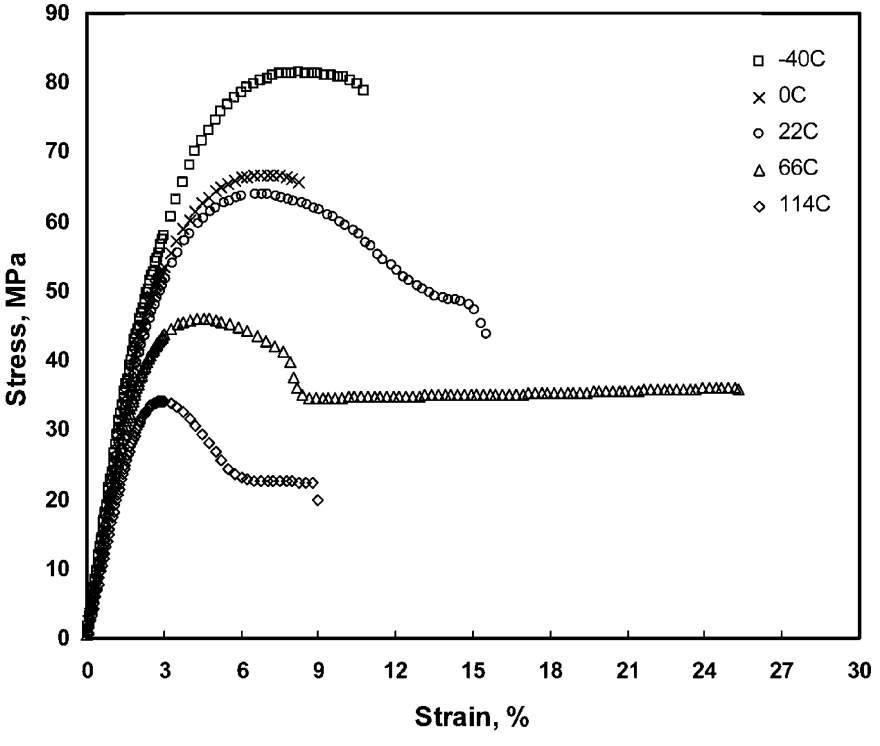

Fig. 4 Stress–strain curve for a typical commercial PC, LEXAN 141, measured at a strain rate of 0.0833%/sec. (Courtesy of GE.)

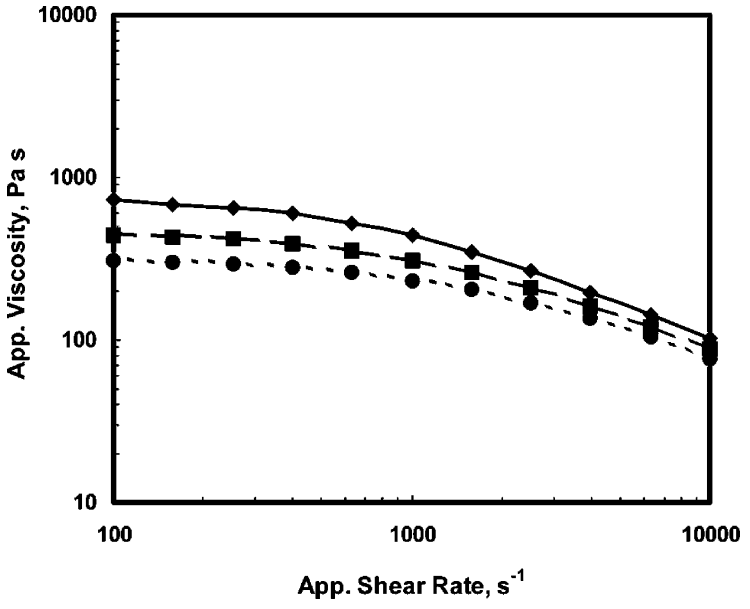

Fig. 5 Rheological performance of a medium-flow PC (LEXAN 141 resin) at three different temperatures (◆, 290°C; ■, 305°C; ●, 320°C). (Courtesy of GE.)

reaction, BPA is slurried in water with a monophenolic chain stopper (1–5%) and sodium hydroxide. Methylene chloride and a small amount of a tertiary amine catalyst are added and the mixture is stirred rapidly. Gaseous phosgene is added continuously to the stirred mixture until all phenolic groups are reacted, and NaOH is added as necessary to maintain pH. The reaction may be over-phosgenated to ensure complete reaction of all phenolic species. When the reaction is completed, the organic phase is separated from the brine phase, washed with acid to remove residual base and amine, and then washed with water to bring pH to neutral. The polymer may then be isolated via various methods, including melt devolatilization, anti-solvent precipitation, and spray-drying.[73–75]

The interfacial reaction proceeds in a complex, four-phase mixture (solid BPA, gaseous phosgene, organic phase in which polymer is soluble, and aqueous phase in which NaCl dissolves), making study and understanding of precise mechanisms difficult, although a number of models have been proposed.[71,76–82] Efficient mixing and control of pH are extremely important in controlling the reaction. A number of modifications to the basic process have appeared in the patent literature, including controlled addition of chain stoppers to control formation of oligomers[83,84] and processes to improve productivity and/or the quality[85–87] of the final product. Polycarbonate is produced industrially via both batch and continuous reactions.[24]

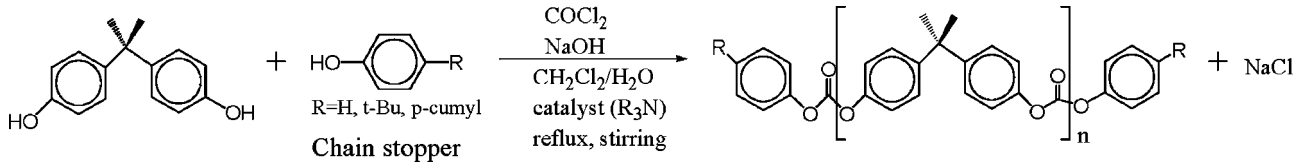

Fig. 7 Interfacial polymerization scheme for BPA-PC.

Melt or Transesterification Process

A melt process was originally developed by GE for the production of BPA-PC.[21] It was abandoned for commercial production in favor of the interfacial process because of production costs and because of the difficulty in obtaining polymer with high purity, high clarity, and low color. Work on improving the melt process continued, however, and the push to develop more ''environmentally friendly'' procedures (e.g., reduction of use of volatile organic solvents and phosgene) supplied further incentive for perfecting the process. Improvements have been achieved that allow production of BPA-PC with color and transparency of the same level as those of PC produced by the interfacial method.[25] GE currently operates a 150,000 ton per year melt production plant in Cartagena, Spain, and has announced plans to expand capacity to 300,000 metric tons per year at this site.[4,12] Additionally, GE operates a 35,000 ton per year plant in Chiba, Japan, originally built to test and validate the melt process technology.[25]

The melt polymerization process involves the base-catalyzed transesterification reaction of BPA with diphenyl carbonate (Fig. 8). A small amount (less than 0.01% molar) of basic catalyst such as Na, Li, K, or tetralkylammonium hydroxide or carbonate is used during the initial stages of the reaction. The reaction is performed under vacuum at 180–300°C. At later stages of the reaction, the temperature and the vacuum are increased (less than 1 mmHg) to remove phenol and drive the product to high molecular weight. Subsequently, the polymer becomes very viscous, and special devices, such as devolatilizing extruders, are required to ensure complete removal of phenol.

Because of the high temperatures experienced by the polymer in the melt process, initial attempts at producing melt BPA-PC resulted in highly colored product due to thermal oxidative reactions occurring during the process. Process improvements, including the use of highly pure starting materials, modified catalysts, and more reactive carbonates, have been developed that allow production of BPA-PC of high purity and transparency via the melt process.[88–96] Unlike the interfacial product, the melt product is an equilibrium product and does not undergo further transesterification reactions during subsequent melt processing. Thus, polydispersity and the amount of low molecular weight species (such as oligomers, cyclics, and diaryl carbonates) are lower for melt-produced BPA-PC than for interfacial PC. Another difference between interfacial and melt PC is that the melt product is not fully end-capped, so OH terminal groups are present in some amount in the melt product.

Initially, the melt process utilized diphenylcarbonate produced from phosgene.[97] Multiple processes are now available for entirely phosgene-free production.[98–102]

Asahi Kasei Corporation has developed a solventless, phosgene-free melt production process that uses CO_2 as a starting material and employs a reactor that uses gravity, rather than melt mixing equipment, to transfer molten polymer.[103–105] Chimei-Asahi has implemented the technology in a 50,000 ton per year commercial demonstration plant and has announced plans to expand production at their own plant and with other partners.[106]

Other Processes

There are a number of other processes for PC production that are under development or have limited current commercial application. Redistribution involves reaction of high molecular weight PC in an extruder with a catalyst that promotes transesterification.[107] The polymer undergoes ''redistribution'' to yield an equilibrium product similar to that obtained by the melt process, with reduced oligomer levels and low

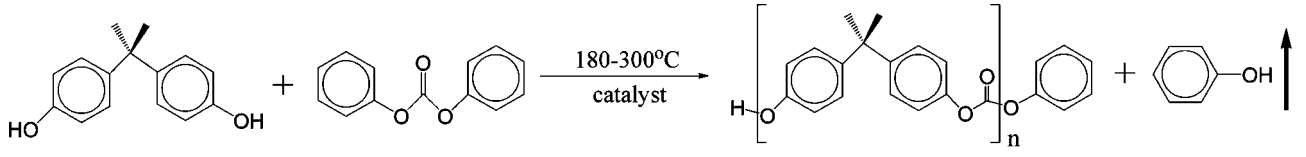

Fig. 8 Melt polymerization scheme for BPA-PC.

polydispersity index. Other monomers may also be added to the melt mixture to form copolymers or branched materials.

Ring opening polymerization of cyclic oligomers of BPA can be performed in the melt (200–300°C) or in solution at ambient temperatures.[108,109] This process can be used to obtain unique copolymers and ultra-high molecular weight polymers and enables processing techniques such as resin-transfer molding for production of composites.

Solid-state polymerization involves first-step production of low molecular weight polymer or oligomer via melt or interfacial process. The low molecular weight material is then crystallized in acetone. Basic catalyst is added and the material is heated above T_g but below crystalline melting temperature (T_m) to polymerize, and phenol is removed. The resulting polymer is melt-processed to remove crystallinity and form amorphous PC.[110,111]

Aliphatic PCs have traditionally been of low interest commercially because of their low strength and durability. There is increasing interest in the production of aliphatic PCs and their copolymers with cyclic esters for potential biomedical applications, due to their biocompatibility, low toxicity, and biodegradability, and the less acidic degradation product compared with conventional biodegradable polyesters such as poly(lactic acid). One example is poly(trimethylenecarbonate).[112–119] Recently, increasing attention has been paid to synthetic aliphatic PCs bearing functional groups to regulate hydrophilicity/hydrophobicity, permeability, bioresorption, and mechanical properties.[120–126] Preparation of functional aliphatic PCs via biocatalysis has been recently reviewed.[127,128]

POLYMER PROCESSING AND FABRICATION

Polycarbonate is readily processed by all major thermoplastic processing techniques, including injection molding, extrusion, blow molding, thermoforming, and solution casting. Polycarbonate should be thoroughly dried before melt processing, and generally a small amount of thermal oxidative stabilizer such as phosphite or phosphonite is added to prevent degradation and yellowing of the polymer.[65] Melt processing can be performed using single- or twin-screw extruders, with twin-screw generally preferred for highly filled products or blends. Polycarbonates are processed at temperatures ranging from 270°C to 345°C, depending on the molecular weight of the polymer and the specific application/processing technique. Recommended processing parameters for specific commercial grades are provided by PC producers.[5–7,52] Special processing techniques are required for high optical purity applications such as lenses and CDs, and it is important to prevent any contamination during the processing steps. Polycarbonate can be extruded into sheet, film, or tubing, and PC sheet can be thermoformed into complex shapes. Additionally, PC can be cold-formed, and rods or slabs can be machined into desired shapes. Secondary operations and part assembly for PC products have recently been reviewed.[129,130]

BLENDS AND COPOLYMERS

The most important commercial blends of BPA-PC are poly(acrylonitrile–butadiene–styrene) (PC/ABS) and polybutylene terephthalate (PC/PBT) or polyethylene terephthalate (PET). Commercial grades of PC/ABS include CYCOLOY® (GE), Bayblend® (Bayer), and PULSE® (Dow). PC/ABS blends exhibit improved flow and processability and enhanced low-temperature impact strength in comparison to PC (Fig. 3). These blends are widely used in applications requiring enhanced impact resistance, such as interior automotive parts and computer and electronics applications such as computer housings and cell phones. Non-halogenated flame-retardant PC/ABS blends are widely available. Poly(acrylic–styrene–acrylonitrile) (PC/ASA) blends (GELOY®, GE; Luran®, BASF) provide improved weatherability for outdoor applications such as exterior automotive parts, but exhibit reduced impact performance at low temperatures in comparison to PC/ABS. PC/PBT or PET blends (XENOY®, GE; Makroblend®, Bayer) provide enhanced chemical resistance and weatherability for applications such as lawn and garden equipment and automotive bumpers and fascias.

A number of commercially significant PC copolymers are produced. In addition to the previously discussed branched PCs (for extrusion and blow-molding applications) and copolymers of BPA with tetrabromo-BPA for enhanced flame retardancy, high-T_g polyester carbonate copolymers have been produced for a number of years (Bayer Apec®, GE LEXAN PPC; T_g approximately 190°C). Polyester carbonate copolymers can be produced via copolymerization of BPA with diacyl chlorides. Aromatic diacids produce high-T_g copolymers, while aliphatic diacids yield lower-T_g copolymers. A lower-T_g PC aliphatic polyester copolymer (GE LEXAN SP resin) exhibits enhanced flow and ductility in comparison to standard PC[131] and is useful for thin-wall injection molding applications requiring ductility and ease of melt processability, such as personal communication devices. GE has recently introduced two new PC copolymers, a PC–siloxane copolymer (LEXAN EXL) [132,133] and a copolymer of isophthalate terephthalate resorcinol with BPA (LEXAN SLX).[134] The PC–siloxane copolymers (LEXAN EXL resins) exhibit ultra-low temperature impact resistance (–60°C ductility), flame retardancy, and weatherability

for applications such as telecommunications and outdoor electrical equipment. Highly weatherable isophthalate terephthalate resorcinol copolymers (LEXAN SLX resins) undergo chemical rearrangement on exposure to UV light, yielding a protective weatherable surface layer for molded or extruded parts, and can replace paint in applications like exterior automotive body parts.

APPLICATIONS

Polycarbonate and its blends are used in a wide range of applications. Polycarbonate's clarity and optical properties combined with its toughness and impact resistance make it ideal for a large number of transparent products. Injection-molded transparent products include CDs and DVDs, optical lenses, sunglasses, protective eyeware, camera components, automotive lenses, and lighting. Extruded and thermoformed transparent PC products, including multilayer products with protective UV- and scratch-resistant surface layers, can be found in unbreakable windows for airplanes, trains, and schools, bullet-proof glass laminates, stadium roofs, skylights, and greenhouse roofs. Bayer and GE have established a joint venture to develop PC automotive glazing products.[135] Blow-molded applications for PC include refillable water bottles. Polycarbonate grades are increasingly used in medical applications, including blood reservoirs, membrane cartridges, filters, tubing connectors, syringes, and dental and surgical devices.[136] Medical-grade PC products can be sterilized via autoclaving, gamma sterilization, and radiation sterilization techniques. Transparent and translucent PCs with special colors and visual effects (e.g., metallic look or speckles, phosphorescence, light diffusion) are popular in applications such as computer housings and personal communication devices. Polycarbonate blends and filled products are used in opaque engineering thermoplastic applications. Key markets for PC/ABS blends include automotive applications such as instrument panels and interior components, and computer and business equipment including computer housing, printers, fax machines, personal pagers, and communication devices. PC/PBT blends are used in applications requiring chemical resistance, such as outdoor recreation equipment, lawn equipment, large structural parts, and automotive bumpers and fascias. Special grades of PC and PC blends are produced that meet global and U.S. agency standards for specific applications, including ECO-label products, UL requirements (for flame-retardant and electrical applications), FDA requirements (for food contact applications), automotive engineering requirements, and medical sterilization requirements. Continued developments in new copolymers, blends, and processes drive continued expansion of PC materials into new applications.

CONCLUSIONS

Polycarbonate is a unique and important engineering thermoplastic, with sustained growth in production, product and process development, publications, and patents. Its global consumption is projected to grow at a rate of 7% per year, with announced production expansions throughout the world. Polycarbonate's transparency, toughness, and temperature resistance, combined with its ability to form a large number of useful copolymers, blends, and filled and colored products, make it the polymer of choice for a wide range of applications. Continued research and development in PC production processes will ensure the continued growth of this important material.

ACKNOWLEDGMENTS

The authors gratefully acknowledge GE Advanced Materials and GE Global Research, especially Dr. Jim Scobbo and Dr. Andy Poslinski, for providing polycarbonate data and assistance in preparing this article.

Polycyclic Aromatic Hydrocarbons (PAHs)

Teresa J. Cutright

Sangchul Hwang
Department of Civil Engineering and Surveying, University of Puerto Rico, Mayagüez, Puerto Rico

INTRODUCTION

Polycyclic aromatic hydrocarbons (PAHs) are a class of organic compounds consisting of two or more benzene rings fused in a linear, angular, or clustered arrangement. They are formed predominantly as products of incomplete combustion. At high temperatures (e.g., in coking operations), low molecular weight PAHs are formed. Complex, multiringed PAHs occur at moderate temperatures. PAHs can also be formed over time even at low temperatures. Thus, it is not surprising that over 10,000 different PAH compounds have been identified. Due to the number of PAHs that can be formed, knowing how the ring structures are numbered and named can be critical. Fig. 1 illustrates three representative PAHs: pyrene, anthracene, and dibenz(*a*,*h*)anthracene. Typically, the PAH is shown oriented so that the greatest number of rings are in a horizontal row, with the majority being located in the top right-hand corner. As shown in Fig. 1(A), numbering starts with the first carbon position in the top-rightmost benzene ring and continues in a clockwise manner, skipping the carbons ''fused'' between rings.[1,2] The lowercase letters on the base components are used to distinguish different isomers as well as to designate where ring fusion occurs. For instance, the 3a notation in Fig. 1(A) designates a fused face after the third carbon. Using this approach, it is easy to see how the parent structure of anthracene [Fig. 1(C)] is the origin of dibenz(*a*,*h*)anthracene [Fig. 1(D)]. If there is only one ring in the top portion of the compound, numbering starts at what is typically considered the sixth carbon in a normal benzene ring [Fig. 1(E)]. Although there are a multitude of PAH structures, currently only 16 are on the U.S. Environmental Protection Agency's (USEPA) Priority Pollutants List. The specific PAHs on this list are shown in Fig. 2.

The increasing concern over PAHs stems from several of their characteristics that impact human health and the environment. The primary concerns are that PAHs: 1) are highly carcinogenic and toxic; 2) have a high potential for bioaccumulation; 3) have high occurrence of contamination; and 4) are recalcitrant to biodegradation.[3] This chapter provides an overview of the physical–chemical characteristics, sources, commercial uses, environmental regulations, fate and transport, and current remediation techniques of PAHs.

PHYSICOCHEMICAL CHARACTERISTICS

Table 1 lists the physicochemical characteristics of the 16 PAHs on the USEPA Priority Pollutants List. The extent to which a particular PAH exists in the gas or solid phase is dependent upon the compound's vapor pressure (i.e., Henry's constant) and boiling point as well as the ambient temperature. In general, an increase in molecular weight and number of ring structures leads to decreased PAH solubility and volatility, as well as increased hydrophobicity. The octanol–water partition coefficient (K_{ow}), a parameter used to describe the tendency of a compound to partition in octanol vs. water, can be used to estimate hydrophobicity. As the compound becomes more hydrophobic, K_{ow} increases, indicating that the compound preferentially sorbs to solid material vs. remaining in water. Thus, PAHs with higher molecular weights and multiple substitutions are more difficult to remediate. It is important to note that some of the physicochemical characteristics, particularly Henry's constant and solubility values, can vary depending on the estimation method used. Regardless of the source, the magnitude of the value should be similar.

SOURCES

Natural Sources

The first report on natural sources of PAHs was published in 1961 by Blumer,[4] who suggested that soil PAHs found in rural, remote areas were endogenous to the soil and not attributable to anthropogenic sources. Fifteen years later, it was found that PAHs were formed during thermal reactions associated with fossil-fuel and mineral production, natural burning of vegetation

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007910

(i.e., forest fires), and volcanic eruptions.[5] PAHs can also by synthesized by algae[6] and terrestrial plants.[7]

Anthropogenic Sources

Although PAHs can occur naturally, their presence, particularly at high concentrations, is commonly associated with anthropogenic practices. As shown in Table 2, these processes include industrial petroleum processing (cracking, coking, gasification, etc.), accidental spills and leaks, and incomplete fuel combustion. One of the primary sources of PAH contamination is abandoned manufactured gas plant (MGP) sites. From the mid-1850s to 1950s, the primary source of heating and electricity was gas from fossil fuels.[8] To increase the BTU value of the ''manufactured'' town gas, light petroleum oils were cracked with coal (Fig. 3). During the cracking process, many of the heavier organic contaminants were condensed from the raw gas to form coal tars rich in PAHs. Like most of the unwanted byproducts of that era, the coal tar was typically disposed of onsite in unlined pits.[9] As the efficiency of electricity surpassed that of coal gasification, the MGP sites were abandoned, and their exact number and location were lost. Since early disposal pits were unlined, the PAHs sorbed to the soil, providing a long-term contamination source. Although PAHs are hydrophobic, the combination of quantity released and time since disposal has resulted in extensive contaminant migration in some areas.[10,11]

Present-day PAH contamination is also associated with wood-treatment industries, since PAHs are major components of creosote and anthracene oil—commonly used in wood-preserving pesticides. Other current industrial units that generate PAH contaminants are steel and carbon manufacturers, plasticizer and dye facilities, and some explosives generators. Generally, soil PAH concentration increases with increasing impact of industry, traffic, and domestic heating. For example, PAH concentration ranges from 5 mg/kg soil in an undeveloped area to 1.79×10^6 mg/kg at an oil refinery. In urban estuaries, PAH concentration can exceed 10^2 mg/kg.[12]

COMMERCIAL APPLICATIONS

Tar (i.e., pitch) is formed during combustion and contains a vast assortment of PAHs. The exact distribution depends on the variability of the feedstock and processing temperature. In the past, tar was used an asphalt additive and even as a roof sealer due to its viscosity. However, this and other PAH uses have diminished with time. The purification and distribution of most of the 16 PAHs on the EPA Priority

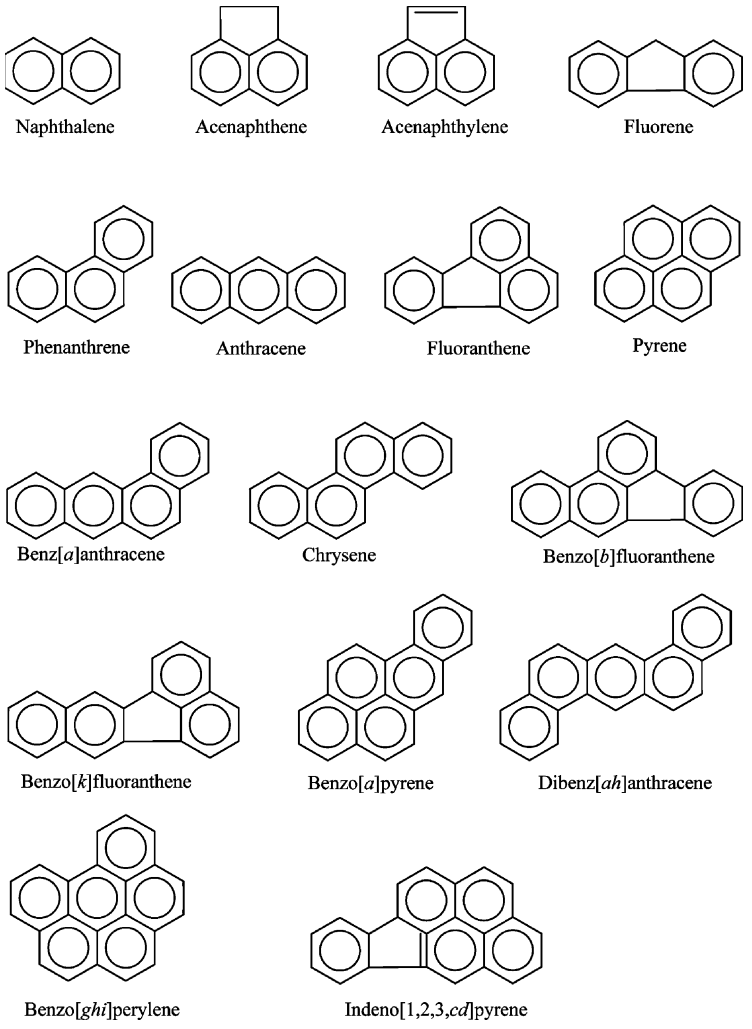

Fig. 2 Structures of PAHs on the EPA Priority Pollutants List.

Pollutants List is solely for research purposes. Currently, only a few of the PAHs generated during petroleum processing are used as raw material for other commercial applications. These include naphthalene, anthracene, phenanthrene, acenaphthene, fluorene, fluoranthene, and pyrene, with naphthalene and anthracene being the only two with large-scale commercial applications.

Naphthalene

Commercial uses

Naphthalene comprises two benzene rings and is the smallest PAH. The white, crystalline solid is also called mothballs, white tar, tar camphor, albocarbon, naphthaline, and naphthene. The most well-known commercial use of naphthalene in its pure form is as a household fumigant against moths. In 1989, naphthalene consumption as a moth repellent peaked at 12 million pounds. Since then, naphthalene has also been used as a solid block deodorizer for diaper pails and toilets, and as an antiseptic, expectorant, and anthelminthic. Approximately 65% of naphthalene is converted into phthalic anhydride.[13] Phthalic anhydride is used as an intermediate in the production of phthalate plasticizers, resins, phthaleins, dyes, pharmaceuticals, and insect repellents. It is also used in the production of the insecticide carbaryl, synthetic leather tanning agents, and surfactants. The consumption of naphthalene for the production of phthalic anhydride is expected to increase due to continued increase in demand. Another 10–15% of naphthalene is utilized for the manufacture of celluloid and hydronaphthalenes (for lubricants).[14–16] Naphthalene has had documented use as an additive in motor fuels, aluminum smelting, and soil fumigants as well. Recently, naphthalene has also been a commercial ingredient for the production of plasticizers, sulfonic acid, surfactants, and aromatic polyesters, and in the synthesis of salicylic acid and anthraquinone.[17,18]

Table 1 Physicochemical properties of PAHs on the EPA Priority Pollutants List

PAH	Structural formula	MW	Sol. (μg/L)	MP (°C)	BP (°C)	VP (Torr)	H (atm m^3/mol)	Density (g/cm^3)	log K_{ow}
Naphthalene	$C_{10}H_8$	128	31,700	80	218	4.92×10^{-2}	4.27×10^{-4}	1.03	3.37
Acenaphthylene	$C_{12}H_8$	152	3,470	92	265	2.0×10^{-2}	1.9×10^{-4}	0.899	4.07

Benzo[*g*,*h*,*i*]perylene	$C_{22}H_{12}$	276	0.26	222	—	1.0×10^{-10}	1.44×10^{-7}	—	7.23
Indeno[1,2,3,*c*,*d*]pyrene	$C_{22}H_{12}$	276	6.2	162	—	1.0×10^{-10}	2.96×10^{-20}	2.09	7.66

MW, molecular weight; Sol., solubility at 25°C; MP, melting point; BP boiling point; VP, vapor pressure at 20°C; H, Henry's constant; log K_{ow}, logarithm (to base 10) of partitioning coefficient.

Table 2 Anthropogenic activities associated with PAH production

Gasification/liquefaction of fossil fuels
Combustion of fossil fuels
Coke production
Catalytic cracking
Carbon black production and use
Asphalt production and use
Coal tar/coal tar pitch production and disposal
Refining/distillation of crude oil and crude-oil-derived products
Wood treatment processes
Wood preservative (e.g., creosote/anthracene oil) production
Fuel/oil storage, transportation, processing, use, and disposal
Landfills/waste dumps
Open burning of tires, refuse, coal, etc.
Incineration processes

Current production

Naphthalene is typically formed as a byproduct during coal gasification and liquefaction operations. By definition, coal gasification is the moderate- to high-temperature reaction of coal, air, steam, carbon dioxide, hydrogen, or a mixture of the components to generate a gaseous product.[19] The gaseous product is then used as either an energy source or a raw material for the subsequent production of industrial chemical or other liquid fuels. Depending on the coal source and temperature used, the resulting gaseous product can have a low, medium, or high BTU value. As such, the general schematic of an MGP is an example of an early coal gasification system. Additional information regarding gasification and liquefaction can be found in Speight's[10] and Perry and Green's[19] handbooks, as well as in the corresponding encyclopedia entries.

Petroleum gasification, liquefaction, and cracking processes generate byproducts that contain a large quantity of alkylnaphthalenes. These gaseous byproducts can be thermally or catalytically dealkylated to form naphthalene.[13,14] One approach is dealkylation of the gaseous stream in the presence of hydrogen. The bottoms of the dealkylator are sent to a series of four fractionators. Concentrated naphthalene is recovered from the bottom (400–450°F) of the second fractionator. The remaining two fractionators are used in conjunction with crystallizers to obtain purified fluorene and acenaphthene.

Acenaphthene and Acenaphthylene

Acenaphthene is produced by passing ethylene and benzene or naphthalene through a red-hot tube or by heating tetrahydroacenaphthene with sulfur to 180°C. Acenaphthene can also be obtained by high-temperature recovery of the distillate from concentrated tar. Once purified, acenaphthene is used as a dye intermediate, in the production of pharmaceuticals and plastics, and as a fungicide and insecticide. Acenaphthylene is typically manufactured by catalytic degradation of acenaphthene.

Fluorene and Fluoranthene

Fluorene is used in the formation of polyradicals for resins. It is also used as a raw material in the manufacture of dyes. In addition, it is used as a lining material to protect the interior of steel and ductile-iron drinking water pipes and storage tanks.

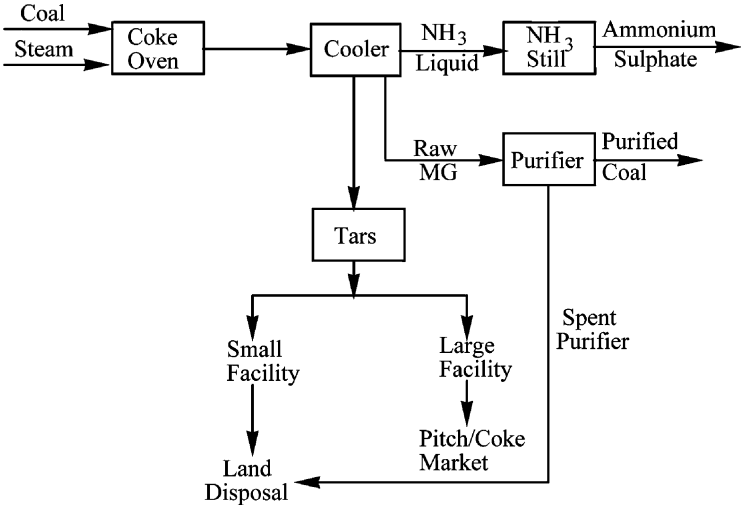

Fig. 3 Schematic of a generic MGP.

Anthracene and Phenanthrene

Anthracene and phenanthrene are stereoisomers that are crystals in pure form. Anthracene is a pale yellow crystal, while phenanthrene exhibits a yellow to brown hue. Besides its common name, anthracene is referred to as anthracin, green oil, or paranaphthalene. The compound is commercially produced by recovery from the coal tar distillation fraction known as anthracene oil or green oil. Anthracene is the key ingredient in the production of anthraquinone. However, it and phenanthrene are also used for the manufacture of dyes, fibers, plastics, and wood preservatives.[16,20] Phenanthrene, also known as phenanthrin, can be produced by high-temperature fractional distillation of coal tar oil. It is additionally used for the oxidation of diphenic acid for use in polymers,[13] as well as the production of chemical softeners, explosives, and some pharmaceuticals.[14,21,22] Recent research has extended the application of both isomers to scintillation counters, semiconductors, and photoconductors.[13,23]

REGULATIONS

As with most xenobiotics, PAHs are subject to a wide variety of environmental and occupational safety regulations. Due to space constraints, only a brief listing of the key regulations/codes is provided. A complete listing of these and other regulations can be found in the Code of Federal Regulations (CFR), standard regulation textbooks, and state and federal EPA homepages.

Current advances in epidemiological and toxicology studies have documented the potential harm that PAHs pose to human health. Therefore, the National Institute for Occupational Safety and Health (NIOSH) and the Occupational Safety and Health Administration (OSHA) have published exposure standards for individuals working in facilities that use or handle PAHs. For example:

- NIOSH: Recommends a workplace standard for coal tar products of $0.1\,mg/m^3$ as a 10-hr time-weighted average (TWA). Naphthalene has an exposure standard of 10 ppm or $50\,mg/m^3$ TWA.
- OSHA: Limits occupational exposure to coal tar pitch volatiles to $\leq 0.2\,mg/m^3$ as an 8-hr TWA. Coke oven emissions have a permissible exposure limit of less than $0.15\,mg/m^3$ as an 8-hr TWA.

Both NIOSH and OSHA have stricter exposure levels for individuals who conduct risk assessment studies at hazardous waste sites or work at incinerators. The exact exposure levels are PAH and site specific, and can be found in NIOSH and OSHA guides.

The Resource Conservation and Recovery Act (RCRA), Clean Water Act (CWA), and Clean Air Acts (CAAs) promulgate regulations to prevent future contamination by hazardous chemicals. Conversely, the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) and the Superfund Amendments and Reauthorization Act (SARA) are federal statutes that outline how existing/old contamination will be dealt with.

- RCRA: Hazardous waste disposal rules enable the EPA to regulate the manufacture, distribution, and final disposal of PAHs. It tracks each compound from cradle to grave.
- CWA: Contains guidelines of acceptable PAH levels in ground and drinking water.
- CAA amendment of 1990: Regulates air emissions containing PAHs. Specific industries impacted by this regulation include power plants, petroleum processing facilities, and steel manufacturing plants.
- CERCLA: Provides authority to enforce liabilities for the release of PAHs; established a fund for the clean up of existing sites; authorized EPA to initiate remedial actions; sets threshold constraints; and provides guidelines for acceptable remediation technologies.
- SARA: EPA includes 16 PAHs on a list of priority hazardous chemicals.

Drinking Water Standards and Health Advisories

The USEPA has established maximum contaminant levels (MCLs) for public water supplies to reduce the chance of adverse health effects from contaminated drinking water. Maximum contaminant levels are enforceable limits that public water supplies must meet and are lower than concentrations at which health effects have been observed. The only PAH with an established MCL is benz(a) pyrene, which is regulated at 0.2 parts per billion.

The USEPA[24] has, however, established health advisories (HAs) for several PAHs. An HA is defined as an estimate of acceptable drinking water levels for a chemical substance based on health effects information. An HA is not a legally enforceable federal standard but serves as technical guidance to assist federal, state, and local officials. Table 3 contains a partial listing of PAH HAs.

FATE AND TRANSPORT

This section includes an overview of the fate and transport of PAHs in air, water, and subsurface environments. Additional, more detailed information regarding PAH fate and transport can be found in publications by Hemond and Fechner-Levy,[25] Wilcke,[26] and Suess.[27]

Table 3 U.S. EPA health advisories for 16 PAHs (amounts for 10-kg child)

PAH	One-day (mg/L)[a]	10-day (mg/L)[b]	RfD (mg/kg day)[c]	DWEL (mg/L)[d]	Lifetime (mg/L)[e]	10^{-4} Cancer risk (mg/L)[f]

[a]The concentration of a chemical in drinking water that is not expected to cause any adverse noncarcinogenic effects for up to one day of exposure.
[b]The concentration of a chemical in drinking water that is not expected to cause any adverse noncarcinogenic effects for up to 10 days of exposure.
[c]Reference dose. An estimate of a daily oral exposure to the human population that is likely to be without an appreciable risk of deleterious effects during a lifetime.
[d]Drinking water equivalent level. A lifetime exposure concentration protective of adverse, noncarcinogenic health effects that assumes that all of the exposure to a contaminant is from drinking water.
[e]The concentration of a chemical in drinking water that is not expected to cause any adverse noncarcinogenic effects for a lifetime of exposure.
[f]The concentration of a chemical in drinking water corresponding to an estimated lifetime cancer risk of 1 in 10,000.

Air

PAHs are present in the air as vapors and adsorbed to airborne particulate matters. In general, high molecular weight PAHs with at least five rings are present in airborne particulate matter, whereas low molecular weight PAHs with two to three rings are more abundant in the gas phase. This trend is dependent on each compound's specific gas-to-particle partition coefficients. The physical mechanism of PAH loss from atmosphere is dry and wet deposition, i.e., gravitational settling and scavenging by precipitation/water vapor. Conversely, photochemical transformations are considered the most dominant fate mechanism. For instance, PAHs have been found to react in the presence of light with atmospheric ozone, NO_x, SO_x, and OH radicals.

Seawater and Freshwater

PAHs are transported to aquatic environments via direct atmospheric deposition, runoff from PAH-contaminated land, and direct release into water. Approximately 70% of total benz(*a*) pyrene input contributes to atmospheric deposition to the marine environment, whereas over 75% of total river PAH is from runoffs from highways. The fate of PAHs in the aquatic environment is highly dependent on sorptive/desorptive phenomena as well as the suspended matter load. Low molecular weight PAHs can be removed from open waters by volatilization. Physicochemical interactions (i.e., sorption, desorption, biodegradation, etc.) with bottom sediments are a major pathway by which PAHs are removed from waters.

Sediments

Sediments act as a sink for PAHs entering aquatic ecosystems. However, they can also serve as a source of PAHs to aquatic organisms. In general, transport of PAHs to and within sediments is controlled by their hydrophobicity and particle sedimentation. In shallow waters and estuaries, PAHs present in surface sediments are subjected to biodegradation and photo-oxidation, whereas PAH degradation in buried sediments happens at a very slow rate, if at all it occurs.

Terrestrial Environments

The key factors controlling the fate and transport of PAHs in subsurface environments are sorption and desorption phenomena. The extent of these phenomena is known to depend on the type of the PAH, the sorbent characteristics, PAH aging period, and the presence of cosolute.[28] In general, as the PAH molecular weight and the amount of soil organic matter and clay minerals increase, sorption becomes stronger. Longer contact times (i.e., aging) between PAHs and sorbents result in further diffusion into soil components, physical entrapment in soil micropores, and the formation of strong bonds between PAHs and soil constituents.

REMEDIATION OF PAH-CONTAMINATED MEDIA

This section provides a brief overview of the PAH remediation technologies available. For additional information on each process mentioned in this section, readers are encouraged to refer to other encyclopedia entries as well as established texts.[10,29]

Thermal Decomposition

Incineration is technically the most effective technique in PAH remediation. However, it is cost prohibitive due to associated high excavation, transportation, and heating costs. Dealing with NIMBYs (Not In My Back Yard) and BANANAs (Build Absolutely Nothing Anywhere Near Anything) are major constraints to the use of this technology. Furthermore, future amendments to the Clean Air Act are expected to limit incineration applications to ''last resort'' technology.

Physicochemical Treatment

Volatile and soluble PAHs can be easily extracted with air or water from the soil phase, whereas resistant, high molecular weight PAHs are extracted with the help of media that enhance their extractability. Once PAHs are extracted, they are then treated with chemical processes such as oxidation and activated carbon adsorption.

Bioremediation

Both indigenous and exogenous micro-organisms have been involved in the success of microbial remediation of PAHs. Landfarming and composting are common ex situ methods of PAH bioremediation. The former uses a top layer of agricultural soil with some nutrient amendment to stimulate microbial activity. The latter is achieved by the addition of bulking agents (e.g., sawdust or woodcuttings) and regular mixing of compost piles.

Bioreactors are another ex situ method by which indigenous or exogenous, sometimes genetically modified, micro-organisms are inoculated. In general, high molecular weight PAHs persist because of: 1) low bioavailability (i.e., strong sorption affinity); 2) lack of the proper enzyme for indigenous micro-organisms to degrade them; 3) steric hindrance to enzyme attack; and 4) toxicity to micro-organisms.[30]

Phytoremediation can be placed in the bioremediation category as either an in situ or ex situ remediation technology, depending on the approach used. It uses plants and associated micro-organisms to extract, degrade, and stabilize PAHs. If the plants are used in place, the method is in situ. If the soil is excavated and taken to a greenhouse, then the method is classified as ex situ.

CONCLUSIONS

As outlined above, the formation of PAHs as a product of incomplete combustion has occurred since humans first used combustible material for cooking and heating. Production peaked during the mid- to late 1800s. At that time, PAHs were improperly disposed of, leaving society with a vast number of contaminated sites. Current advances in remediation technologies are making great strides in cleaning up these sites. The advent of environmental regulations and implementation of waste minimization practices has led to further decrease in PAH releases during manufacturing operations. Currently, only a few PAHs, predominantly naphthalene and anthracene, are used as raw materials in manufacturing processes.

Due to the adverse effects of PAHs on humans and other natural recipients, the fate and transport of PAHs have been increasingly investigated. Photochemical degradation, wet/dry deposition, sorption and desorption, and biodegradation are known to be the governing mechanisms for the fate and transport of PAHs. The dominant mechanism depends on the specific PAH–medium combination present. Strategies for PAH remediation depend on a large numbers of factors, including, but not limited to, the extent of contamination, long- and short-term effectiveness and performance, compliance with applicable requirements, implementability, cost, and acceptance by federal, state, and local communities.

INTRODUCTION

Material properties can be tuned systematically, by various methods such as blending and mixing, to control the synergy among pure materials, and thereby achieve desirable properties for engineering applications. Hence, particles, powders, and fibers are dispersed in pristine matrix materials to form ''composite'' or ''hybrid'' materials. Over the years, research on composite materials has spanned a broad range of scientific and technological areas, including polymer matrix composites, glass–ceramics, metal matrix composites, carbon–carbon composites, ceramic matrix composites, and intermetallic matrix composites. In composites, the major component controls the primary properties, although a minor component could significantly modify or enhance the composite's properties as well. Recently, a number of engineering fields have begun to adopt the new paradigm of nanoscience and technology for a variety of applications. This paradigm shift to ''nanocomposites'' has promoted the development of extraordinary properties by overcoming the inherent limitations of pure materials. Polymer composites, especially using the layered silicate clays, have recently attracted the attention of researchers, and are the focus of this review.

HISTORY

The term ''polymer clay nanocomposite (PCN)'' refers to a material composed of two-phase materials, where one phase (clay) is dispersed in the second phase (polymer matrix) at a nanometer level.[1,2] Composites exhibiting structural and compositional changes at the molecular scale have demonstrated several physical property enhancements that are otherwise unavailable in conventional composites. Of these, layered silicates have proven themselves vital as a reinforcing agent when dispersed into engineering plastics.[3] Nanolayers, however, are extremely difficult to disperse in polymer matrices because of their tendency for face-to-face stacking and inherent hydrophilic properties. Understanding the nature of the clay itself is important for being able to control the polymer–clay surface interactions. Organoclays dispersed in polymer matrices have shown profound effects, such as improved dimensionality, barrier properties, as well as flame retardation. Such benefits have led to the use of these composites in a broad range of applications, including the automotive and package industries,[4] as well as for commodity polymers: epoxies, polyurethane, polyimide, nitrile rubber, polyester, polypropylene, polystyrene, and polysiloxanes.[5] Polymer clay nanocomposites are categorized into three groups, according to the dispersion state of the clay in the polymer matrices, as shown in Fig. 1. Notice that Ray and Okamoto[1] recently classified the different state of PCN; e.g., intercalated, intercalated-and-flocculated, and flocculated.

PCNs' advantage over pristine systems is that they are lighter than conventional polymer/inorganic blends (because of a lower amount of heavy materials, i.e., clay), yet exhibits similar mechanical strengths. Further, PCNs demonstrate outstanding gas permeability resistances, without the special molecular design of polymeric multilayers. The advantages of PCNs extend to a broad range of applications (beyond conventional usages) including optics for electronic materials, high flammability resistance, and electroactive materials, as well as environmental recycling.[6] Polymer clay nanocomposites are also used as a ''model system'' for investigating the nanoscale confined polymer structures and dynamics.[7] The high molecular weight polymer dynamics in nanoscale restricted spaces have been extensively studied via conventional wisdoms, i.e., polymer dynamics confined to a highly entangled network, as well as static and dynamic conformation via computer simulations. Intercalation and exfoliation structures result in drastically different physicochemical responses than the conventional blends.

First, the history and definition for nanomaterials, the clay materials, and the preparation methods are introduced. Second, the characterization tools including the

X-ray diffraction (XRD), transmission electron microscope (TEM), and rheological measurements are discussed. Third, the static and dynamic structures of confined polymer in the gallery are examined. Finally, the commercial applications for the PCNs are given.

Preparation Methods

Polymer clay nanocomposite preparation methods are typically categorized as either solution or solution free (''melt''). The rule of thumb in preparation is: regardless of what is inserted into the clay layer, the layer space must be expanded first. While there are no significant differences in the preparation of different PCNs, concerns arise from the use of a solvent or interaction modification between the clay and polymer (or monomer).

The very first method used to synthesize PCNs was ''in situ polymerization'' [Table 1(I)], and it still remains as the most popular process for synthesizing thermoset PCNs. As usual, the organoclay is swollen first. The surface treatment of the organoclay and the swelling temperature are determined, depending on the polarity of the monomers. The polymerization location is a key control factor after the reaction is initiated. If the curing kinetics between the layers is dominant than outside the layers (i.e., intragallery polymerization is favored over extragallery one), the delamination of the clay is occurred. The driving force behind in situ polymerization is the polarity of the monomers. During the swelling stage, the high surface energy of the clay attracts polar monomers, so that they diffuse between the clay layers [see Table 1(I)]. At thermodynamic equilibrium, the diffusion terminates and the clay is swollen in the orientation, perpendicular to the alkylammonium ions.[8] When the polymerization is initiated, the monomers start to react with the curing agent. This reaction lowers the overall polarity of the intercalated molecules and additional polar molecules are forced into the clay layers. As a result, the organic molecules will eventually delaminate the clay.

The solution technique [Table 1(II)] is similar to that of the in situ process. Here, the organoclay is dispersed first in a toluene or *N*,*N*-dimethylformamide. The alkylammonium ions treated clays will then considerably swell to form gel structures. Later, polymer is added into the solution, which intercalates between the clay layers. Finally, the solvent is removed via evaporation (usually under a vacuum).

On the other hand, the solution free (or melt) intercalation process [Table 1(III)] was first introduced

Table 1 Advantages and disadvantages of synthesis methods for PCNs

Processes	Schematics	Advantages	Disadvantages	References
Solution				
(I) In situ		Polarity of the monomers		Epoxy and polyurethane[26,27]
(II) Solution		Low or no polarity	Require large quantity of solvent	Rubber and polypeptide[29,30]
(III) Solution free (or melt)		No solvent, mass production	Limited systems	Nylon-6, lactide, and polystyrene[3,25,28]

by Vaia, Ishii, and Giannelis.[3] This process consists of blending a molten thermoplastic with an organoclay to control the polymer–clay interactions. The mixture is then annealed above the glass transition temperature of the polymer to form a nanocomposite. One may notice that the entire polymer chains transporting between the clay layers is somewhat unexpected, as the radius of gyration of the polymer is an order of a magnitude larger than the interlamellar spacing.[9] As shown in Table 1(III), the polymer chains experience a drastic loss in configurational entropy during the intercalation process. The impetus behind this mechanism is the significant enthalpic contribution of the polymer/organoclay during the blending and annealing steps. This process has become increasingly popular because of its mass production capability. Creating plasticity without a solvent is difficult, and therefore, a limitation exists for the melt intercalation process.

Emulsion polymerization intercalation[10] is an alternative method of PCN synthesis. This method is similar to in situ polymerization, but has several differences and limitations. In the emulsion polymerization method, micelle helps the polymer to be monodisperse, yet the micelles are limited in their ability to penetrate into the layer. Nonetheless, this method is attractive because of its use of a micelle as a targeted material, which helps the monomer or prepolymer to penetrate into the silicate layers.

Clay Materials

While both polymer and clay are primary PCN components, we focus mainly on clay as it plays a subtle role in the formation of PCN.

The term ''layered silicates'' refers to natural clays or altered silicates, such as mica, laponite, and fluorohectorite. Because of its desirable layer charge density, montmorillonite (MMT), which was discovered by Damour and Salvetat (in 1847 in Montmorillon),[11] has become a widely used nanofiller clay nowadays. The ideal crystallographic MMT structure derived from the pyrophyllite consists of two fused silica (Si) tetrahedral sheets sandwiching an edge-shared octahedral sheet of either aluminum (Al) or magnesium (Mg) hydroxide. The sum of the single layer thickness and the interlayer spacing (the ''*d*-spacing'' or ''basal spacing'') of 9.6 Å represent the repeated unit of the multilayer material. Typical crystalline structures are characterized by XRD (refer to the following section). The layers can be considered as large aspect ratio lamellae (100–200 nm in length and 1 μm in diameter). Large and irregular aggregates (0.1–10 μm in diameter) are formed with five to ten lamellae associated by the interlayer ions in the primary particles (8–10 nm in transverse direction). These aggregates provide the structural basis for the clay. Depending on the silicates, the lateral dimensions of the layers vary from 30 nm to several microns. The van der Waals gaps, called ''interlayers'' or ''galleries,'' result from layer stacking.

The replacement of inorganic exchange cations mirror surfaces and polymer polarities expand the clay galleries. Depending on the clay charge density and the alkyl ion chains, different arrangements of the alkyl ion chains become possible. The alkyl ion chain is a surfactant, which could modify the surface property of clay layer. In general, the clay layers will be further apart, as the surfactant chain length becomes longer and the clay charge density becomes higher. This is expected as both these parameters modify the volume occupied by the intragallery surfactant. Depending on the clay charge density, the alkyl ion chains may lie parallel to the clay surface as a monolayer, a lateral bilayer, a pseudo-trilayer, or as an inclined paraffin structure (Fig. 2).

Large surfactant ions may adopt lipid bilayer orientations in the galleries at very high charge densities. The orientations of alkyl ion chains are observed from the XRD measurements. Molecular dynamics (MD) simulation also provide further insight into these orientations by observing a nano/macroscopic properties, including density, normal forces, chain configurations, and trans-gauche ratios. It has been found that a disordered liquid-like arrangement of chains is preferable for a monolayer, a lateral bilayer, and a pseudo-trilayer, with respective *d*-spacings of 1.32, 1.80, and 2.27 nm.[5] As expected, the alkyl ion chain head group, relative to the aliphatic portion, resides near the silicate surface. For the fully extended surfactant chain, the expected conformation is the trans (over gauche) just prior to the system progressing to the next highest layering pattern. This is expected, as the alkyl ion chains must be optimally packed under such dense surfactant concentrations.[5]

CHARACTERIZATION OF POLYMER/CLAY NANOCOMPOSITES

X-Ray Diffraction

Many standard methods exist for characterizing PCN structure. One method is XRD because of its ability to accurately evaluate the spacing between layers. Further, sample preparation is relatively easy and the X-ray analysis can be performed within a few hours. However, interpretation must be done carefully, as the lack of sensitivity in the analysis itself and equipment limitations can quickly lead to incorrect findings.

Due to experimental set-up errors (e.g., misalignments, counting limitations), the XRD analysis is complicated by the factors that the XRD analysis must

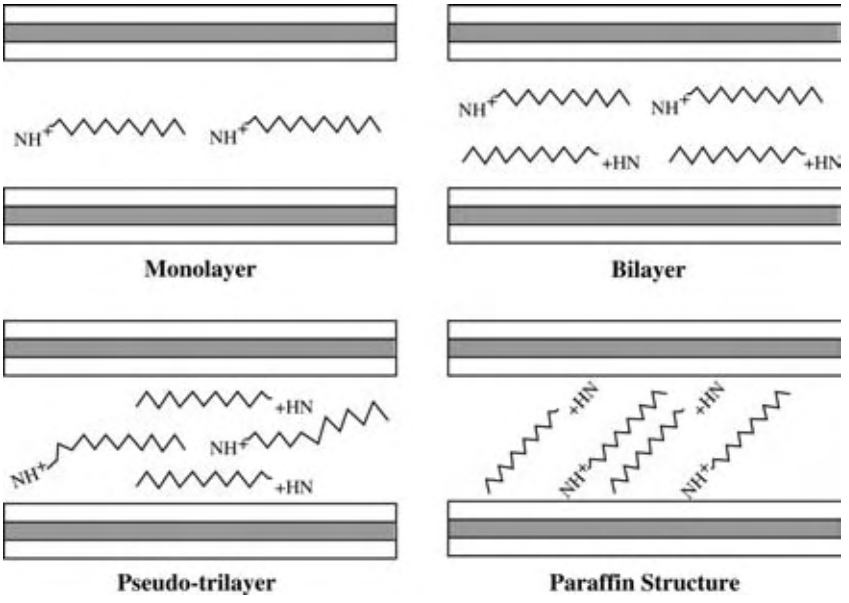

Fig. 2 Orientations of alkyl ion chains in the galleries of layered silicates with different clay charge densities.

be sensitive enough to detect the crystalline structure of the sample containing a small amount of clay, typically less than 10 wt%, otherwise, peaks in the diffraction pattern may not be observed, leading to the false diagnosis that a delaminated structure exists. Therefore, it is important to determine whether the crystallographic planes belonging to the clay layers are detectable by the XRD analysis, which is sensitive enough to detect (0 0 1) reflections. The XRD analysis should be performed at a low angle (diffraction angle $2\theta < 9^\circ$, i.e., $d > 9.8$ Å) to detect the (0 0 1) reflection to evaluate the d-spacing. Thus, the radiated surface may include the sample, as well as the sample holder, creating a large amount of noise and, in turn, complicate the interpretation of the XRD patterns. The X-ray penetration depth is inversely proportional to 2θ, implying that an analysis at a small θ will only reveal the structure presented in a thin layer near the surface (typically 0.1 μm for polymers). As a result, thin samples with large surface areas are recommended. The typical change in the (0 0 1) peak position for increased clay ratio in biodegradable polymer (BDP) matrices is shown in Fig. 3A.[12] Although a difference exists between pure polymer and PCNs, the change in the (0 0 1) peak position is not significant. Traditionally, the molecular structure of the PCNs has been elucidated using XRD and TEM in conjunction. Because of the periodic arrangement of the silicate layers, both in the pristine and intercalated structures, with periodicity of 1–4 nm and the presence of high atomic number species in the layers, the XRD method for determining the interlayer spacing becomes sufficient. However, in the absence of layer bundles, as for exfoliated or delaminated nanocomposites (as well as for disordered nanocomposites), XRD alone is not sufficient to provide definitive structural information.

TEM Analysis

The TEM is a complementary characterization tool to XRD. TEM produces a direct measurement of the spatial distribution of the layers, yet requires substantial skill in specimen preparation and analysis. TEM is a powerful technique for studying structures at the nanometer length scale, and is useful for verifying data obtained by XRD. TEM enables the precise observation of nanostructures at an extremely high spatial resolution (~0.2 nm). Specimen preparation, however, constitutes a major difficulty in TEM analysis. The specimens must be sufficiently thin to optimize the so-called mass–thickness contrast, which requires thicknesses to be on the order of 100 nm. One way to prepare specimens from polymer samples is through ultramicrotoming with either a glass or diamond knife. The ultra thin specimens, floating on the water surface, are collected on grids and dried. The grids are then transferred directly to the TEM column for observation. If the objective aperture is centered near the optical axis, then a bright background is visible (in the absence of a specimen), which is known as bright field imaging. Regions of the specimen that are thicker, or of higher density, will scatter the electron beam more and, therefore, appear darker in the image. As the clay has a higher density than the polymer, the clay layers become darker than the polymer. If the specimen is too thick, the polymer appears to be darker, which reduces the contrast with the clay. In addition to describing the spatial correlations of the layered silicates, TEM has been an extremely powerful technique for examining the homogeneity of the mixing process. A bright field TEM image of an organically modified layered silicate, intercalated with BDP is

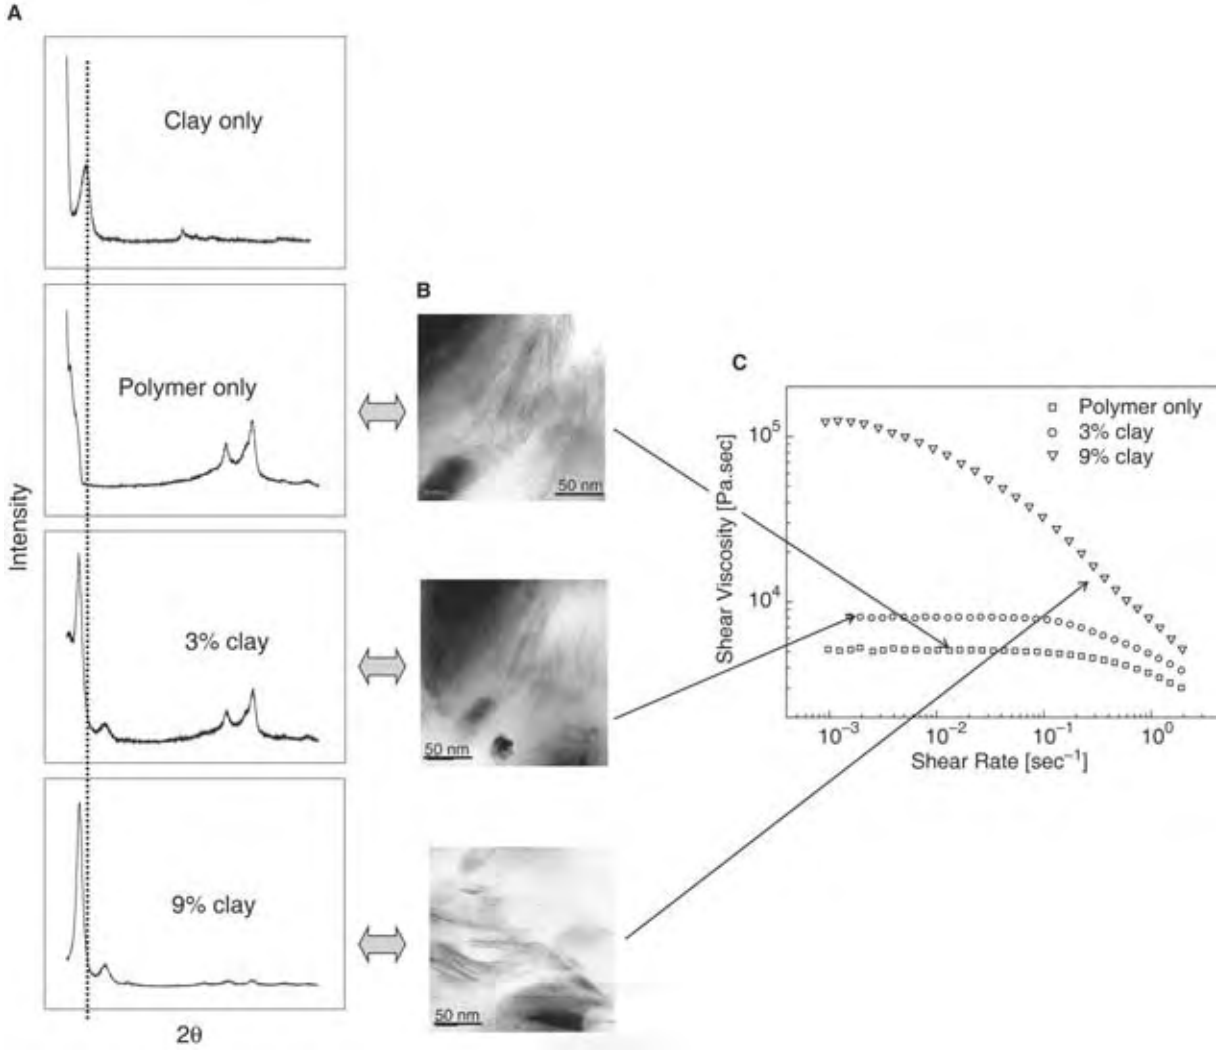

Fig. 3 Typical XRD patterns: (A) TEM images; (B) shear viscosity–shear rate relationship; and (C) BDP/clay nanocomposites. *(View this art in color at www.dekker.com.)*

shown in Fig. 3B. The periodically alternating dark and light bands, with a spacing of approximately 3 nm, represent the layers of silicate and the interlayers, respectively. The TEM also reveals the presence of individual crystallites consisting of several silicate layers, with bulk polymer filling the space between crystallites. Similar micrographs have also been obtained by the Toyota group[13] using monomer intercalation, followed by polymerization.

Rheological Measurement

Rheological measurement is another potential characterization method although an interpretation tool for the nanostructural information must be developed, before this becomes a viable characterization tool. Polymer clay nanocomposites are composed of two or more components; researchers studied their miscibility and dispersion. They investigated the rheological property change as a function of blend ratio between clay and polymer matrices. However, no significant impact from the PCN structure on the physical properties has been found. Despite this inconclusive observation, many attractions for the rheological characterization of PCNs, including processibility criteria, still exist.

The steady-shear rheological behaviors of a series of BDP/clay nanocomposites are shown in Fig. 3C.[12,14] The viscosity of the nanocomposites is enhanced considerably at low shear rates and increases monotonically with silicate loading (at a given shear rate). Furthermore, the intercalated nanocomposites display a shear-thinning behavior at low shear rates, whereas

the pure polymer exhibits Newtonian plateau in viscosity for a broad range of shear rates. At high shear rates (where the polymer displays a shear-thinning behavior), the nanocomposites also show shear-thinning characteristics. Similar trends are observed in Fig. 4 for the dynamic oscillatory measurements of BDP/clay nanocomposites,[12] where the slopes' transition to a flattened behavior is observed with an increase in the clay loading. The low-frequency response is indicative of solid-like behavior at high clay content. The slope and the absolute values of the modulus imply a supermolecular structural formation in the nanocomposites. In explanation of viscoelastic property of polymer, storage modulus G' represents the elasticity, and loss modulus G'' represent the fluidity, i.e., G' and G'' are able to represent the phase behavior of the PCN, such as solidlike and liquidlike. The melt behavior of BDP/clay nanocomposites is liquid-like at low frequencies ($G' < G''$), whereas solid-like behavior is found at high frequencies ($G' > G''$). Furthermore, the crossover frequency (ω_c) [defined as $G'(\omega_c) = G''(\omega_c)$] get smaller with the clay content. However, there exist a critical volume fraction of clay in the BDP/clay nanocomposites, where G' is always higher than G'', that is, the nanocomposites always behave like solid.

There are many other characterization methods (e.g., small-angle X-ray scattering, solid-state nuclear magnetic resonance, and Fourier-transformed infrared analysis) for investigating nanocomposite structure. These techniques are extensively reviewed in Ray and Okamoto.[1]

STATIC AND DYNAMIC POLYMER STRUCTURES

Organoclay–Polymer Interactions

If the polarity of the organoclay matches with the monomer or prepolymer, it intercalates into the galleries and pushes the clay layers out. Such behaviors have been observed for ε-caprolactam, epoxides, and polyethyleneoxide (PEO) that intercalate organoclay galleries as unreacted precursors. For long alkyl chain-exchanged organoclays, the swollen galleries show a d-spacing similar to a paraffin structure (Fig. 2). Even these ideally matched cases, however, do not necessarily form nanocomposites. The clay layers are only forced apart and no longer interacting through the alkyl ion chains. An ideal nanocomposite is formed upon polymerization (see Fig. 1A). The complete dispersion (or exfoliation) of the clay nanolayers yields composites with the highest degree of property enhancement. If the layers persist with a repeated stacking pattern with a gallery height less than two times the alkyl ion chains, then the final product will be an intercalated composite with regions of very high and low reinforced concentration (Fig. 1B). This nonuniform dispersion of nanolayers limits stress transfer throughout the composite, producing relatively less than optimal reinforcement. Although still poorer, conventionally scaled composites are formed if the clay and polymer are partially miscible (Fig. 1C). Here, the clay persists as tactoids of face-to-face stacking agglomerates throughout the polymer matrix. The poor dispersion of the reinforcing phase inhibits surface

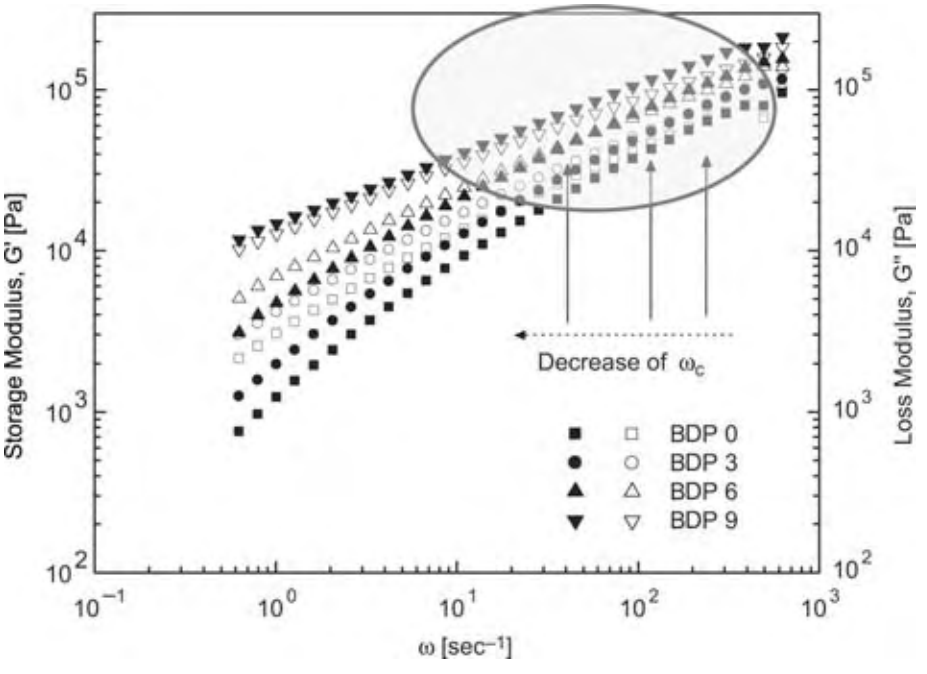

Fig. 4 Dynamic oscillatory test for BDP/clay nanocomposites (BDP series) [G' (filled), G' (open)]. The BDP 0, BDP 3, BDP 6, and BDP 9 indicate clay contents of 0, 3, 6, and 9%, respectively, in PCN. *(View this art in color at www.dekker.com.)*

contact between the polymers and clays, creating large regions of pure polymer. Therefore, it is imperative that the surface polarities of polymer and clay be matched, for the polymer to wet and intercalate the clay tactoids.

Nanoscopically Confined Polymer Dynamics

Polymer melts can intercalate as layered inorganic compounds without being assisted by shear or solvents. This is somewhat surprising, as the distances between the confined surfaces are comparable to the monomer size and are significantly smaller than the radius of gyration of the polymer. The reduction in free energy by the concentration gradient, during the intercalation, provides an ''enthalpic driving force'' for the polymer coils into the interlayer galleries. On the other hand, the configurational entropic force with chain stretching, in addition to other topological constrains and the adsorption on the surfaces, severely restricts the chains diffusion into pseudo-two dimensional slit. Using in situ XRD, Vaia et al.[15] studied the intercalation kinetics for a model polymer (monodisperse polystyrene, molecular weight = 30,000) in octadecylammonium modified fluorohectorite mixture annealed in situ at 160°C in a vacuum oven and observed that the intercalation kinetics is quite rapid, even under quiescent flow. Initially, the basal reflection was observed at $2\theta = 4.15^\circ$ (i.e., $d = 2.13$ nm). During annealing, the linearity of reflection is reduced progressively, whereas a new basal reflection develops at $2\theta = 2.82^\circ$ (i.e., $d = 3.13$ nm), which corresponds to the intercalated hybrid. The width of the original and final intercalated peaks appear to be similar, suggesting that the polystyrene melt intercalation does not drastically alter the coherence length, or disrupt the layering structure of the silicate crystallites.[15] The structure of PCN, in particular with organically modified layered silicates, is strongly dependent on the polymeric property, the charge carrying capacity of the layered silicate, as well as the chain length and structure of the cationic surfactant. However, both compatibility and hybrid structure for these nanocomposites are independent of the polymer molecular weight. The experimental results and a lattice based mean field theory are given in Vaia and Giannelis.[16]

The intercalation of polymer or prepolymer from the solution is described via minimum free energy principle. The driving force of polymer intercalation is the entropy from the solvent desorption. Several researchers investigated the thermodynamics properties of PCN with homo polymeric systems in a confined geometry. However, Lim et al.[17] investigated ternary systems, and explained that the intercalation distance of poly(methyl methacrylate) (PMMA)/organic-modified clay (OMMT) nanocomposite is larger than that for the PEO/OMMT mixture. Based on Flory–Huggins interaction parameters between polymers and silicate layers in a PEO/PMMA/OMMT mixture, the PMMA molecules have a larger affinity for the hydrophobic surfaces of OMMT than hydrophilic PEO.[17] The larger layer thickness and broadness of the peak in the PMMA/OMMT mixture are indicative of an improved intercalation for PMMA matrix over the OMMT surfaces. The relatively weak interaction between PEO and OMMT is because of the hydrophobic modification of the clay surface.

Furthermore, it is also noted that the interlayer distance of the PCN is related to the intrinsic polymer structure, such that the PEO molecule exhibits a straight chain structure and has high backbone flexibility because of the backbone oxygen atom. Also, the minimum thickness required to accommodate this polymer is much smaller than the minimum layer-thickness required for accommodating bulky PMMA molecules.

Computer Simulation in Confined Polymeric System

Giannelis, Krishnamoorti, and Manias have authored an excellent article on this subject.[14] A major challenge in developing nanocomposites for systems ranging from high-performance to commodity polymers is the lack of understanding in nanostructure-physical property relationship. Without this, progress in the nanocomposites area will largely depend on empirical rules, i.e., a cookbook approach. The large internal interfacial area between the polymer and the silicates, as well as the nanoscopic dimensions between the layered silicates differentiates PCNs from conventional blends and filled plastics. Researchers typically adopt thermodynamic and rheological analysis in bulk and extend their findings to the confined systems; however, it remains difficult to accurately implement confinement effects. Computer simulations will provide the structure and dynamics of the intercalated surfactant molecules, which will eventually assist the design of polymer-silicate nanocomposite systems. The dynamics of confined polymer is significantly different from the molecules in the local relaxation, the mobility, and the rheological properties. As a result, molecular simulation is desirable for modeling PCN, yet it requires tremendous computational effort.

The Monte Carlo (MC) and MD simulation, although still in their infantile stages, will provide in depth insight into the structure of nanocomposites at a nanoscopic level. For bulk polymeric systems, however, numerous mathematical modeling and simulation tools already exist. Manias et al.[2] examined polystyrene based nanocomposite via MD simulations,

and found the nonhomogeneity in density profile resulting from the confinement effect. For confined nanoscale systems, such as applications of PCN, only a limited body of literature exists. On the other hand, the static and dynamic behavior of a polymeric liquid film confined in a single wall case was studied extensively by our group,[18] using MC and MD (by systematically tuning polymer-wall interaction energy). In equilibrium case, we calculated the density profile and surface roughness (uniformity of the film) by MC simulation. MD simulation was used to calculate the transport coefficient and the diffusion coefficient, in particular. Relaxation process was also investigated via a correlation function. Here, the Kohlausch–Williams–Watts stretched exponential model was used, instead of single relaxation time model, to fit the time dependent correlation function. These findings can be generalized easily to the two-wall situation (as sketched in Fig. 5) and provide a fundamental understanding of nanoscopic structures and the molecular design for PCN.

APPLICATIONS

Improved Properties

In one example, the tensile strength of polyamide 6 was increased by 55% and the moduli by 90%, with the addition of only 4 wt% of delaminated clay. The enhanced tensile property of PCN suggests that nanocomposite performance is related to the degree of clay delamination, which increases the interaction between the clay layers and the polymers. Several explanations, based on the interfacial properties and the mobility of the polymer chains, have been given for this reinforcement. Kojima et al.[19] reported that the tensile modulus improvement for polyamide 6-clay hybrid originated from a constrained region, where the polymer chains have reduced mobility. The dispersion and delamination of the clay were the key factors for the reinforcement. The delaminated nanocomposite structure produces a substantial increase in modulus, yet it lowers the fracture toughness. A study on nylon 6-clay nanocomposite revealed that the fracture energy is ten times lower than the 4 wt% delaminated clay. It is thought that the reduction of plastic deformation for the constrained polymer matrix increases the brittleness of the nanocomposite. In the presence of microscale aggregates, significant plastic deformation and improvement in toughness was observed.[20] The results of tensile strength and elongation at break for PEO/clay nanocomposites vs. clay content are provided in Fig. 6A and 6B. A considerable improvement in tensile strength and a drastic decrease in elongation at break are observed as the clay content increase. The enhancement in tensile strength is directly affected by the reinforcement of PEO/clay naocomposite. The addition of clay in cross-linked matrices also triggers an increase in the elongation at break.

As described in the section ''Nanoscopically Confined Polymer Dynamics,'' an enthalpic force enables the polymer to penetrate into the clay layer (as shown in Fig. 7A), while the clay acts as a blockade to this penetration.

Another advantage of PCNs is the substantial decrease in permeability. The drastic decrease in permeability is attributed to the large aspect ratio of the clay layers, which increase the tortuous path of the gas as it diffuses into the nanocomposites.

As described in Fig. 7B(i) and 7B(ii), the relative tortuous path $\tau(\equiv d/d')$ increases with the aspect ratio of the clay layers. Measurements of the permeability of polyimide–clay hybrids, using clays with various aspect ratios, tend to verify this conjecture. However, in the case of water permeability, recent studies with the PCNs show a reduction by a factor of 40, when compared with the pristine polymer, contradicting this conjecture. Indeed, the aspect ratio of the clay layers in this material is smaller than that of the clay used in nylon 6-clay hybrids, causing a decrease in water permeability. From this, we conclude that the constraint resulting from the polymer chains structure in PCN may be the critical factor in determining the permeability. Low gas permeability for CO_2 and O_2 has advantage for food packaging (beverage or fatty food containers). These properties were examined in

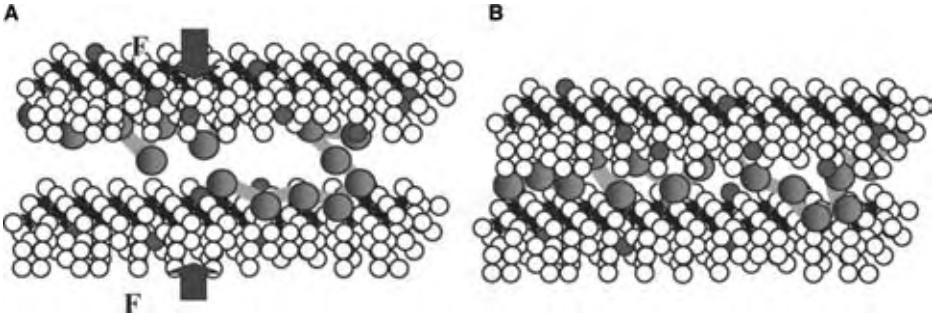

Fig. 5 Schematic diagram of reactive bead-spring model confined by two-site wall slit. Red spheres indicate polymer beads. Blue spheres in the slit wall represent the polar sites and white spheres represent the organically modified surface region: (A) before and (B) after compression.

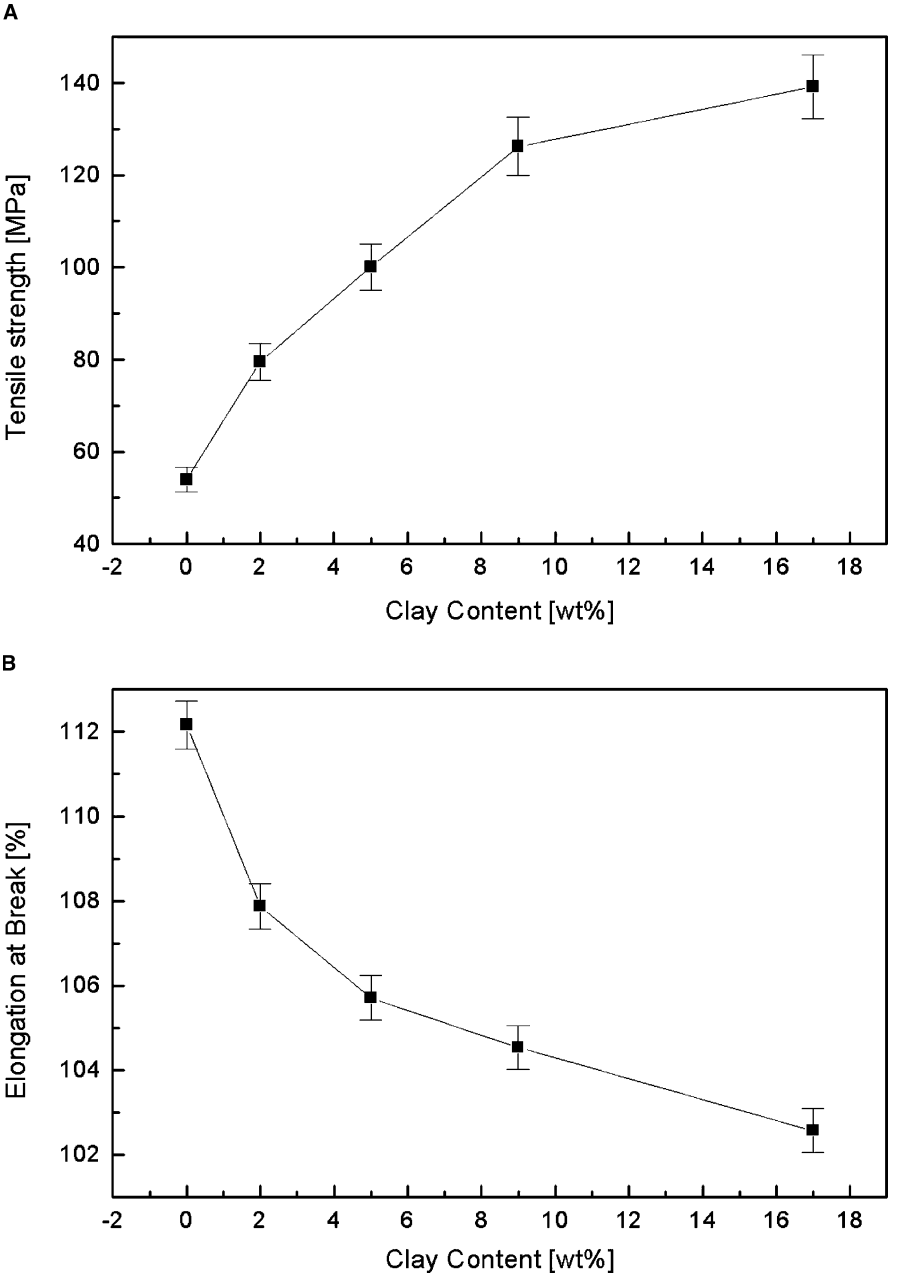

Fig. 6 (A) Tensile strength and elongation at break and (B) for PEO/clay nanocomposites.

comparison with the conventional filler type composites, and several companies have projected a market for PCNs as a packing material. The relationship between the rheological properties and microstructure of PCNs has been also examined, the results of which could complement the standard characterization methods for PCNs. Two delaminated hybrid systems prepared by in situ polymerization, poly(ε-caprolactone)/MMT and nylon 6/MMT, wherein the polymer chains are end-tethered to the silicate surface via cationic surfactants, are examined.[21] The large amplitude oscillatory shear measurements for the viscoelastic properties of the oriented nanocomposites were examined. Various molecular weights of the polymer chains, originating from the synthetic scheme used in the preparation of the nanocomposites, poses some concern for interpreting moduli variation with increasing silicate content. The average molecular weight decreased sharply at low silicate loading, and remained almost the same for nanocomposites, with 2 wt% or greater silicate loading. Despite the efforts made so far, state-of-the-art rheological measurements are insufficient to analyze the nanostructural information.

In the area of dispersion, it is believed that the shear force revokes the rearrangement of the silicate layers. This behavior increased the mechanical properties, but the rheological response is different from the

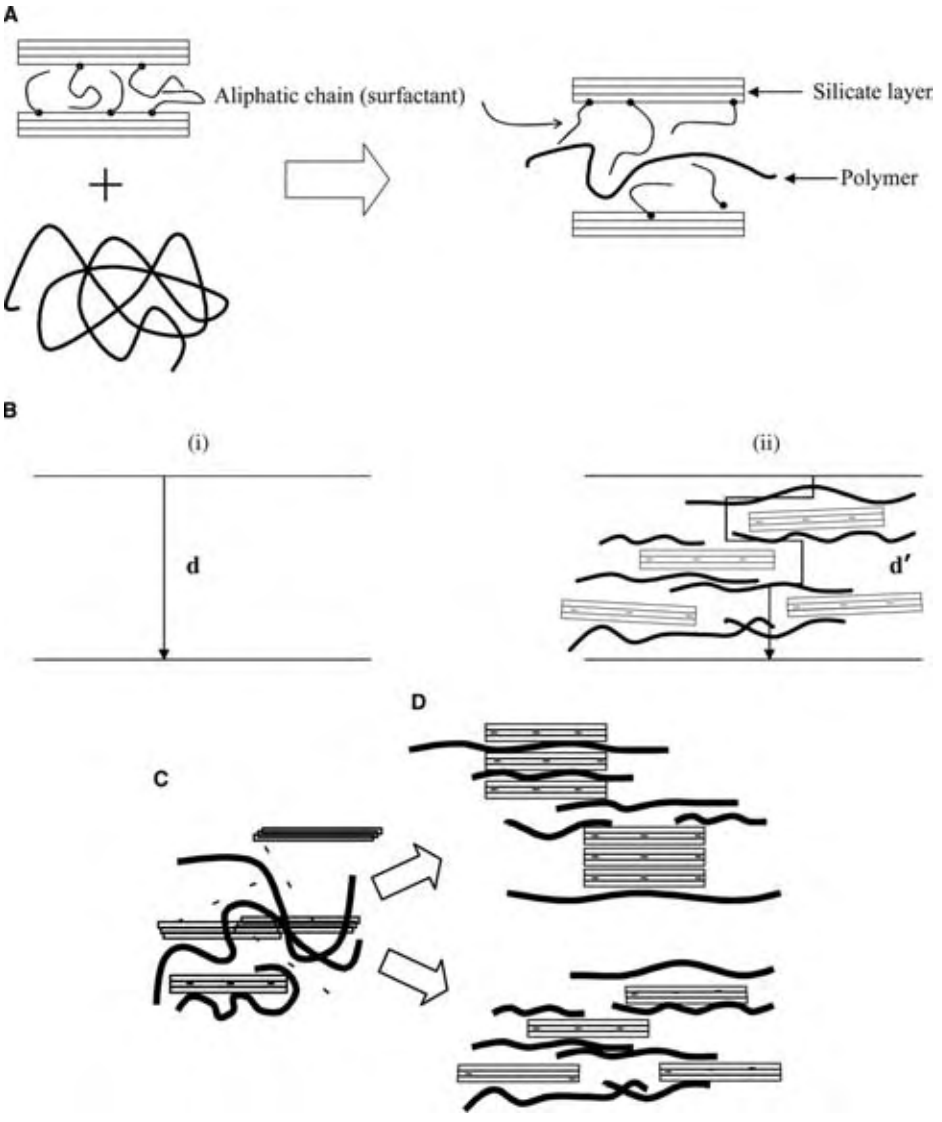

Fig. 7 (A) Polymer penetrates into the clay layer with enthalpic force; (B) (i) path without and (ii) with layered silicate clays. (C) A schematic of the PCN microstructure at equilibrium (D) and after shear.

dispersion characteristics of silicate layer in the polymer matrix. Further, the bundle of silicate layers was sheared differently (Fig. 7C and 7D). At present, it is difficult to measure the nanoscopic properties of PCN from the conventional rheological measurements alone.

An increase of thermal stability has also been observed for PEO/clay nanocomposites (Fig. 8). The nanocomposites with increasing clay content show substantially higher degradation temperatures than pure PEO. The start of the shift in the degradation temperature indicates a decrease in the oxygen permeability or a volatile degradation product, resulting from the homogeneously distributed clay sheets.

Polymer clay nanocomposites exhibit very low flammability.[22] For instance, the heat release rate during the combustion of polyamide 6-clay nanocomposite is reduced by 63% with a clay content of 5 wt%. The nanocomposite structure also enhances the property of the char through reinforcement of the char layer, indicating that nanocomposite parts preserve their shape during combustion. After 2 hr of ignition at 1000°C, it still is possible to distinguish the shape of the epoxy–clay nanocomposites samples prior to ignition. A study on polyetherimide nanocomposites demonstrated that intercalated nanocomposites showed the highest char yield and self-extinguishing behaviors. Thus, PCN has been recommended as a novel and environmentally friendly material for improving fire resistance.

Future Applications

Since the advent of PCNs, many researchers have attempted to commercialize them for a variety of engineering applications. The first commercialized nanocomposite product, developed by Toyota Central R&D,[4] was based on in-reactor processing of

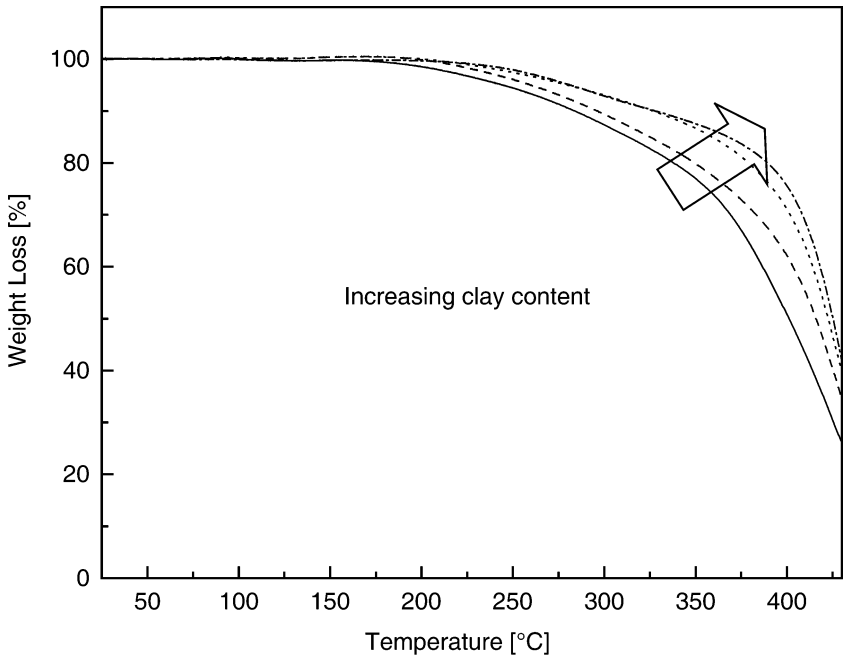

Fig. 8 Thermogravimetric analysis curves for PEO/clay nanocomposites.

caprolactam and MMT after an ion exchange with the hydrochloride salt in the aminolauric acid. While containing a minimal MMT, its properties (especially mechanical and thermal properties) were significantly improved as compared to conventional filler reinforced composites.

Technology for preparing nanocomposites directly via compounding has been investigated by Vaia, Ishii, and Giannelis.[3] Industrial R&D efforts have focused on process technology (e.g., melt or monomer exfoliation processes), as there are a number of polymers (e.g., polyolefins) that do not lend themselves to a monomer process. Nanocomposites with a variety of polymers, including polyacrylates or methacrylates, polystyrene, styrene-butadiene rubber, epoxy, polyester, and polyurethane, are amenable to the monomer process. The enhancement of mechanical properties, gas permeability resistance, and heat endurance are the primary objectives for the application of PCN, and their success will establish PCNs as a major commercial product.

Commercialization of PCN requires close consideration of potential environmental impacts, an improved understanding of synthesis mechanisms, and the PCN designs demanded by end-users.[23,24]

CONCLUSIONS

In this review, we examined the topics on PCNs in three categories: preparation, characterization, and application. Distinct from the previous review papers,[1,2] we introduced a spectrum of properties and characteristic methods, as well as our own research topics including rheology, MD in confined geometries, and applications. The preparation methods from the mass production view point were examined and the emerging role of rheology was also recognized. Although conventional rheological methods are important in processing, they may not give sufficient information for analyzing the nanocomposite structure of PCNs. The desirable properties, including improvement of mechanical properties, gas barriers, fire flammability, make commercialization and processing of PCN products viable. Future research should focus on better understanding and predicting environmental issues and must address these issues and specialized applications of PCNs, as well as their commercialization and marketability.

INTRODUCTION

Polymer composites are mixtures of a polymer, which is the major or continuous phase, and a filler, which can be either metal, ceramic, or even another polymer. Both thermosetting and thermoplastic resins can be used as the polymer phase; the former has the advantage of low viscosity while the latter has the advantage of the possibility of recycling and reuse. Essentially, all commercially important polymers have applications where the polymer is filled, although certainly some materials are more commonly filled than others. Typically, the reason that a particular polymer is a good or a bad candidate for use as the continuous phase of a composite is its ability to form strong interactions with a particular filler. Composites are a fast growing segment of the polymer industry; composites filled with materials having at least one dimension in the nanometer-size range such as nanoclays or nanotubes represent a step change in technology in the composites area. The purpose of this entry is to introduce the reader to this rather diverse field, with an emphasis on processing. For more information the reader is referred to one of the excellent monographs on the subject.[1–3]

MATERIALS

Thermoplastics

Global worldwide production of thermoplastics is approximately 100 billion kg/yr, or approximately 12 kg for every person on the planet. Only a small fraction of this amount is filled and used as a composite, but a small fraction of this large number is still a significant amount of material. By far the most important thermoplastic composites are made from flexible thermoplastics, i.e., semicrystalline materials with a glass transition temperature below room temperature. One significant exception to this generalization is polycarbonate; however, these glassy materials are, for a glass, flexible at room temperature. The reason for the use of fillers in flexible materials is to add stiffness, while the cost is typically a reduction in flexibility. Glassy polymers typically do not need more stiffness, while many applications require more stiffness from a flexible material. High-density polyethylene and polypropylene are used very commonly in polymer composites (see Fig. 1). These materials are commonly filled with a low-cost filler such as wood, clay, or glass. The decrease in flexibility and toughness caused by the introduction of filler is large in these materials because the adhesion between these materials and the filler is typically poor. The filler can be coated with a thin layer to improve the interaction between the filler and the polymer; however, this coating involves a significant cost. The cost of the composite, in the absence of a coating, can be significantly lower than the cost of the neat resin, which explains the popularity of these polymer composites. Good adhesion between relatively polar polymers and polar fillers yields higher performance composites. The most common polar filler is glass; while both polyamides (various types) and polycarbonate are commonly used as polar thermoplastic resins (see Fig. 1).

Thermosets

Unlike thermoplastics, which are simply melted, thermoset resins chemically react from low-viscosity liquids to solid materials during processing, a process termed curing. Structurally, thermosets differ from thermoplastics because of the presence of cross-links in the former, which means that thermosets cannot be reshaped or recycled once the chemical reaction occurs. One advantage of thermosets vs. thermoplastics is that wetting the filler becomes much easier with a low-viscosity material. By far the most common thermoset composite is automobile tires, which consist of a polymer made from styrene and butadiene monomers and carbon-black filler. The actual recipe used is much more complicated, and can include other monomers or polymers, as well as other fillers. In the absence of filler, the cured resin is rubbery at room temperature, which makes tires a

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039238

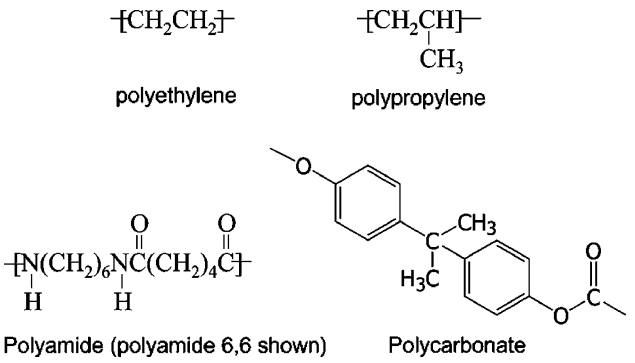

Fig. 1 Common thermoplastic resins used as the matrix phase in polymer composites.

unique thermosetting composite because most thermosetting composites are made with resins that are stiff at room temperature. Other types of resins commonly used as thermosets include epoxies, polyesters, and vinyl esters. Unlike thermoplastics, these categories are a bit misleading in the sense that various structures are classified under one heading. For example, approximately 10 different molecules with the epoxy functionality are important commercial products, and each has slightly different mechanical properties and/or environmental stability. The two monomers that typically combine to form an epoxy resin are an epoxide and an amine. Polyesters are made with polyester resins possessing unsaturation, and styrene. The structure of the polyester and the styrene (or other comonomer content) is varied in these systems. Finally, vinyl ester is a term used to describe bifunctional monomers with long organic structures between acrylic end groups.

Manufacturing Methods

The performance of a composite part depends not only on the materials selected but also on the process parameters used during manufacturing. Properties of the polymer matrix, quality of fiber–matrix adhesion, as well as composite microstructure and defects are functions of manufacturing. Various processes for manufacturing of commercial composite parts have been developed during the last 50 yr. While the aerospace, marine, and defense industries usually require manufacturing methods yielding high-performance composites, automotive and consumer goods industries focus on cost-effective, high-volume production methods. The type of manufacturing method also depends largely on whether the starting material is a low-viscosity uncured thermoset or a high-viscosity thermoplastic. This section briefly outlines the different composite manufacturing methods currently used in the composites industry.

Wet Layup

Wet layup consists of placing a layer of dry reinforcement inside a mold and then applying an uncured, low-viscosity thermoset resin as shown in Fig. 2. Woven glass fibers are the prevalent reinforcing preform utilized in layup processes, although carbon and aramid fibers are also used to a lesser extent.[3–5] Typical fiber volume fraction of composites manufactured via wet layup range between 30% and 50%. The resin can be poured, sprayed, or brushed on top of the preform layer either by hand or by machine. The fiber preform layer is rolled on or pressed after the application of resin to evenly distribute the resin and remove air pockets. Resin is applied on top after each layer of fiber mats is properly placed. This process is repeated until the desired thickness is reached. To provide a smooth surface finish on the mold side, a thin layer of mold release is often applied prior to starting the layup. Thereafter, pressure and heat are applied to allow the composite to cure. Pressure can be applied

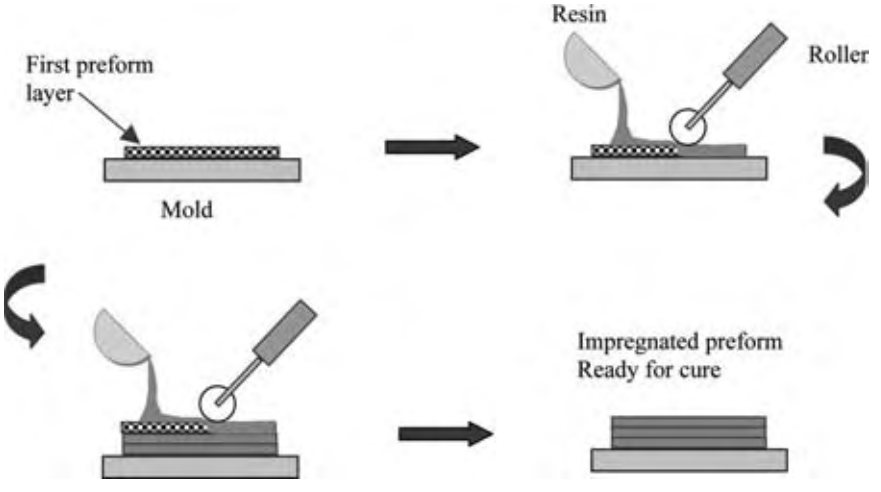

Fig. 2 Typical wet layup operation. *(View this art in color at www.dekker.com.)*

either mechanically or pneumatically; for more details see the section Molding Process. The material may not be cured to a final product; in some cases the material is partially cured to yield a product that is still soft but the resin has enough viscosity not to drip out of the material. This material is termed prepreg, and the prepreg can be shipped from one location to another where it is then formed and made into a final product.

Filament Winding

In the filament winding process, a continuous tape of polymer-impregnated fibers is wrapped over a rotating mandrel to form a composite part. Preform tapes can be either in preimpregnated or impregnated in a thermoset resin bath right before or right after winding. Successive layers are added at the same or different winding angles until the desired thickness is reached. The schematic of a typical filament winding process is shown in Fig. 3. Most winding machines operate similar to a lathe; the mandrel is mounted horizontally and rotates at a constant speed while the carriage delivering the fibers moves along the length of the composite part. Typical winding speeds range between 50 and 100 m/min. After the winding is complete, the composite part is allowed to cure either at room temperature, in an oven, or inside an autoclave. Steel and aluminum mandrels are usually used to facilitate the removal of the fabricated composite part after cure. However, inflatable and collapsible metal mandrels are also used in closed-end products.

Parts with diameters as small as 25 mm and as large as 6 m are being made by filament winding. In addition, a variety of fiber orientations can be achieved, leading to more control of design properties of the fabricated composites. Continuous fibers of glass, carbon, and aramid are used in filament winding while glass/polyester systems are more widely used because of their lower cost. The filament winding process can be automated yielding cost-effective, high-volume production. Most shapes fabricated by this technique are axisymmetric and include glass-fiber pipes, pressure vessels, rocket motor cases, sailboard masts, and other similar products.

Pultrusion

Pultrusion is a low-cost, high-volume process used to manufacture long, constant cross-section shapes from thermoset resins, and consists of pulling continuous dry fibers through a resin bath as shown in Fig. 4. Thereafter, impregnated fibers are pulled through a heated die for cure. The cross section of the die dictates the final shape of the product. The length and temperature of the die are determined by the pulling speed, the dimensions of the part, and the curing characteristics of the resin. At the exit of the heated die, the composite cools rapidly and 2–3% shrinkage is observed. The composite is continuously produced and a moving saw can be used to cut the part at the desired length without stopping the production.

Glass, carbon, and aramid fibers are used as unidirectional or fabric mat reinforcements, with E-glass/polyester being the most commonly used system.[3,6] The limitation of pultrusion is that only constant cross-section parts can be fabricated. However, a variety of hollow and solid profiles of any length can be manufactured.

Molding Processes

Compression molding

Compression molding consists of placing a predetermined amount of composite inside matching male

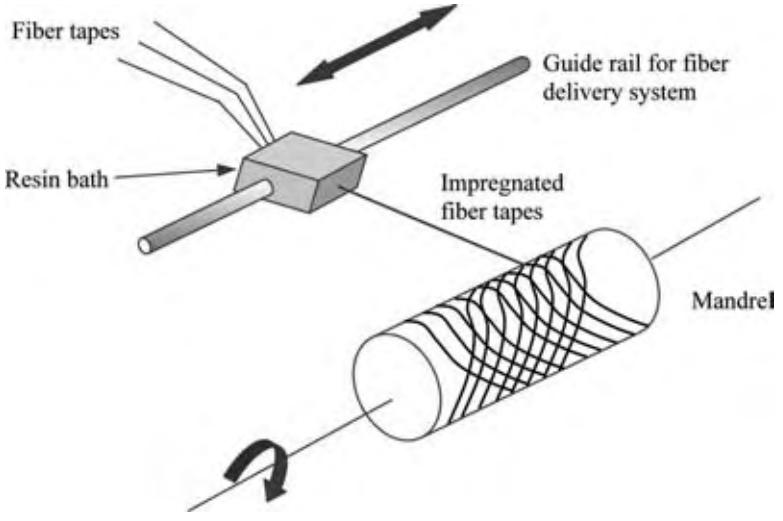

Fig. 3 Typical filament winding process schematic.

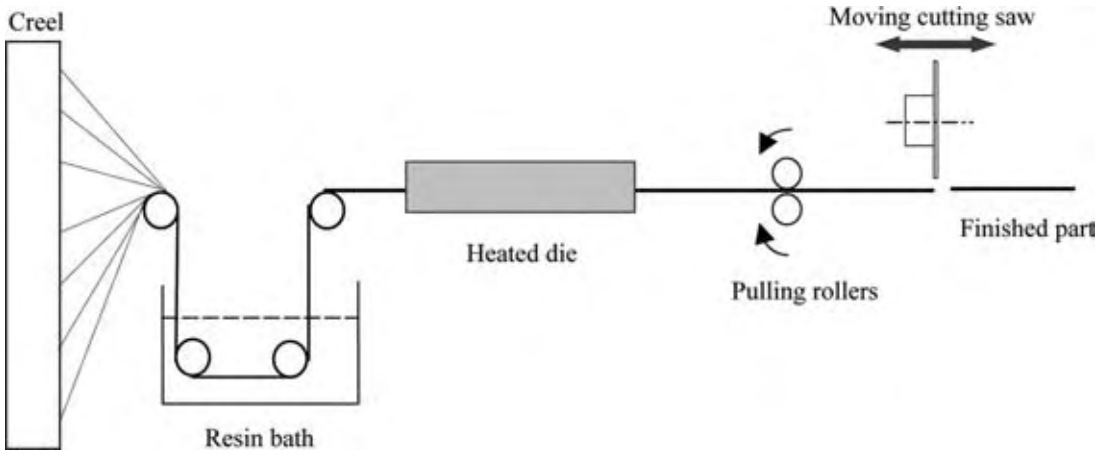

Fig. 4 Schematic of the pultrusion process.

and female metal molds. The mold walls are then heated, closed, and pressurized mechanically until the composite deforms into the desired shape. After the charge fills the mold cavity, the pressure is released and the molded part is ejected from the mold. A schematic of this process is presented in Fig. 5.

Discontinuous fibers are commonly used in compression molding with fiber contents often limited at 30% to maximize the surface quality of the final product while achieving complete filling of the mold cavity.[6,7] Sheet molding compound (SMC) and bulk molding compound (BMC) are the most commonly used materials in compression molding. Sheet molding compound is obtained by mixing chopped fibers, liquid resin, and fillers into a 2–5 mm-thick sheet product. A typical SMC compound contains glass fibers, polyester resin, and calcium carbonate.[3,6] Compression molding is also used for thermoplastics; however, injection molding is preferred unless mats are used. Compression molding usually requires a large initial investment and produces semistructural parts. The simplicity of the process minimizes part setup time, reduces secondary finishing, and allows high-volume production with a low scrap rate.

Autoclave molding

Instead of using mechanical force to pressurize a composite and force consolidation/shape, air pressure can be used if a low-viscosity thermoset is the resin. An autoclave is a large pressure vessel that allows the simultaneous application of heat and pressure during the manufacture of thermosetting composite laminates. Internal work space of commercial autoclaves can be as large as 10 m in diameter and 30 m in length. Fig. 6 depicts a small autoclave with a 90-cm diameter internal work space.

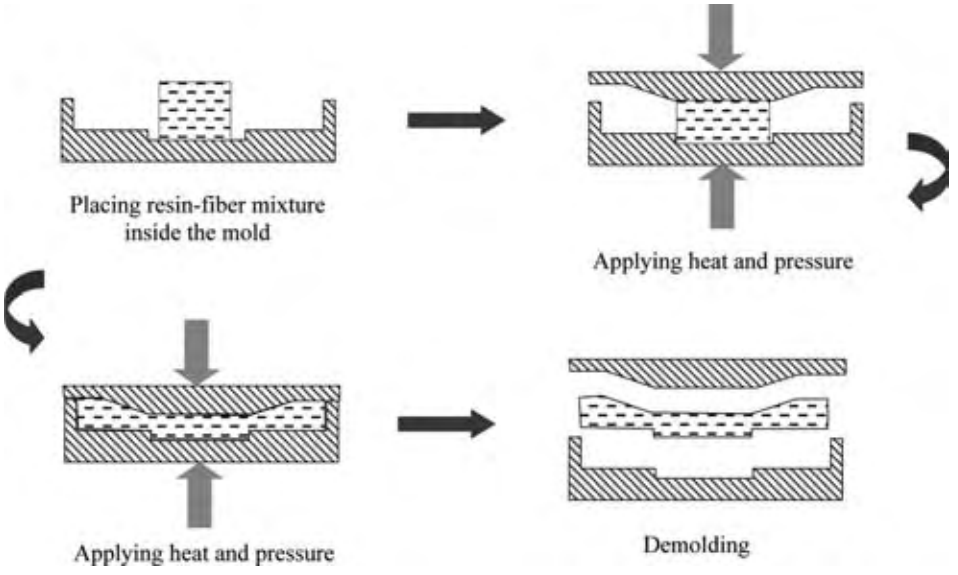

Fig. 5 Schematic of compression molding.

Fig. 6 Example of a small autoclave. *(View this art in color at www.dekker.com.)*

Typically, prepreg layers are cut to the desired shape and stacked in predefined orientations. Thereafter, the stacked prepregs are placed on a mold die and covered with a vacuum bag sealed at the edges. A vacuum is usually drawn before an external pressure of the order of 0.1–0.7 MPa is applied to the vacuum bag inside the autoclave. Simultaneously, the desired temperature profile is applied to ensure the complete cure of the composite part. An example of a temperature profile applied for 24 plies of AS4/3501-6 graphite/epoxy prepregs is depicted in Fig. 7. During most curing processes, an internal autoclave fan circulates the air inside ensuring uniform temperatures aided by convective heating. The external pressure and vacuum inside the bag create sufficient pressure differential to facilitate consolidation of the laminate and ensure good bonding between layers. During cure, the excess resin is absorbed by a bleeder placed above the prepregs within the vacuum bag. The application of vacuum also helps remove volatiles and excess air. Although autoclave processing requires high initial and operating costs, high-performance composites suitable for aerospace and similar structural applications are typically produced using this technique.

Injection molding

Injection molding is a high-volume, low-cost manufacturing process for thermoplastics, including thermoplastic composites, and is shown schematically in Fig. 8. Mixing of discontinuous fillers with a thermoplastic is the first step; this mixing typically occurs in a twin-screw extruder and the material is extruded and chopped into pellets. These pellets of thermoplastic resin mixed with chopped fibers or particles are then melted in a single-screw extruder, and the molten mixture is injected into a closed mold cavity. The injection pressure must be quite high to ensure complete filling and compensate for shrinkage due to cooling. After filling, the mold is then cooled down for solidification before the composite part is removed. Common volume fractions of particles range between 18% and 35%. Typical cycle times are on the order of 30 sec with the largest fraction of the time being spent during the cooling down step. Composites of complex geometries are conveniently fabricated to, essentially, their final shape. However, the required operating pressures (i.e., 50–100 MPa) limit injection molding to small- to medium-sized composite parts.[8]

Liquid composite molding

Liquid composite molding (LCM) processes such as resin transfer molding (RTM) have been long established in the automotive and aerospace industries as versatile technologies for manufacturing medium to large composite parts with complex geometries at low cost.[9–11] All LCM processes involve the injection of a liquid resin into a dry fiber perform, and are

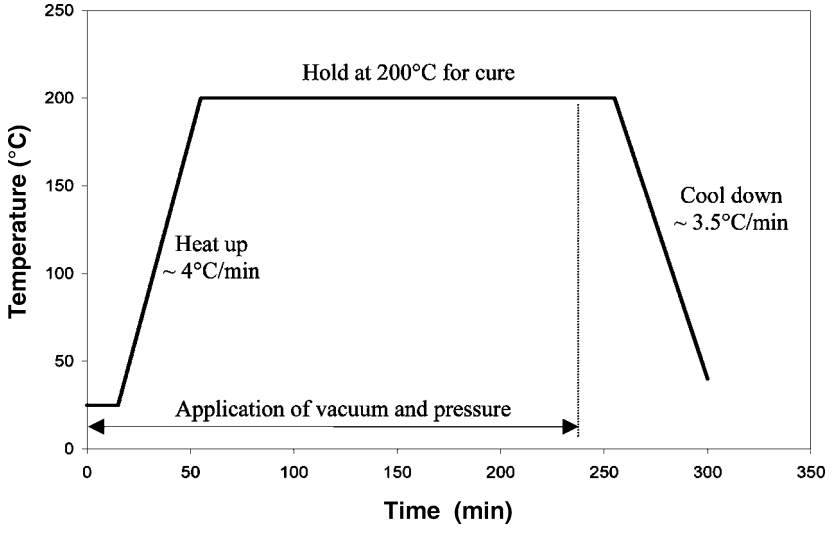

Fig. 7 Temperature profile utilized during an autoclave process for 24 plies of AS4/3501-6 graphite/epoxy prepegs.

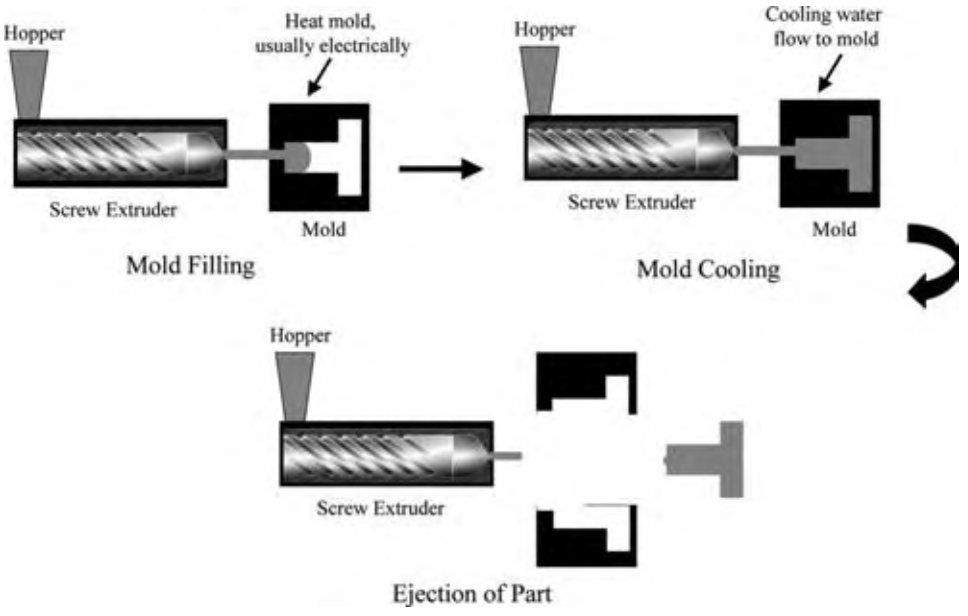

Fig. 8 Schematic of injection molding. *(View this art in color at www.dekker.com.)*

essentially the thermosetting equivalent to injection molding; except that a perform is typically placed in the mold prior to injection of the resin. Because of the lower viscosities of thermosets, the high pressures required for injection molding are not required for LCM. However, the cycle times are typically much longer because of the much longer time required for the part to harden, which in turn is due to the much slower kinetics of a chemical reaction in LCM vs. cooling in injection molding. Resin transfer molding, for instance, consists of injecting a reactive thermosetting resin into a closed mold cavity preloaded with a fibrous preform as shown in Fig. 9. Preforms used in LCM may consist of a 3D braided structure or multiple layers of 2D fabrics and mats. Glass, carbon, and aramid fibers are used as reinforcement, E-glass fibers being the most common.[3,11] High-performance carbon/epoxy systems are particularly used more often in the aerospace industry.[3,8,11] Resin transfer molding, can produce composite parts with volume fractions reaching 60%; however, typical applications may contain 25–35% fibers by volume. After the cure reaction is complete, the solidified composite part is removed from the mold. In other variants such as vacuum assisted resin transfer molding (VARTM), the impregnation is vacuum-driven, and thus half of the mold is often replaced with a vacuum bag. Because the pressure differential is much lower in VARTM, the cost of the mold can be reduced substantially, especially when fabricating larger parts.

PROPERTIES AND APPLICATIONS OF POLYMER COMPOSITES

Mechanical Properties

An increase in stiffness is probably the single most important reason that fillers are added to polymers. Stiffness is quantified using the modulus, which is the slope of a stress vs. strain curve at strain equals zero. The modulus, and other mechanical properties such as tensile strength and toughness, can be measured using different geometries; the two most common for composites are tensile and bending as shown in Fig. 10. Bending studies are typically more informative for fiber-reinforced composites because this geometry provides a better test of adhesion between the polymer and the filler, while tensile studies are more commonly used for particulate composites, if the matrix is flexible enough to allow tensile tests. For most systems, an increase in stiffness is typically accompanied by an unwanted decrease in flexibility and/or tensile

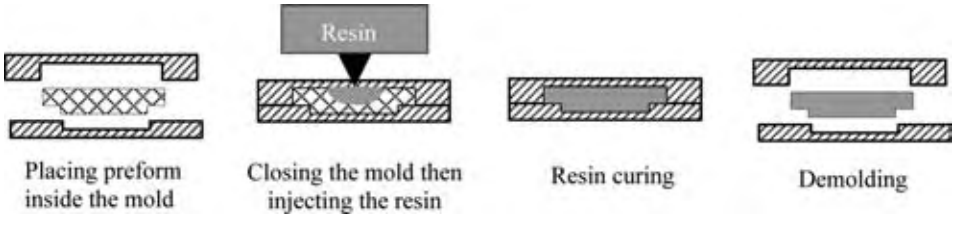

Fig. 9 Typical resin transfer molding process.

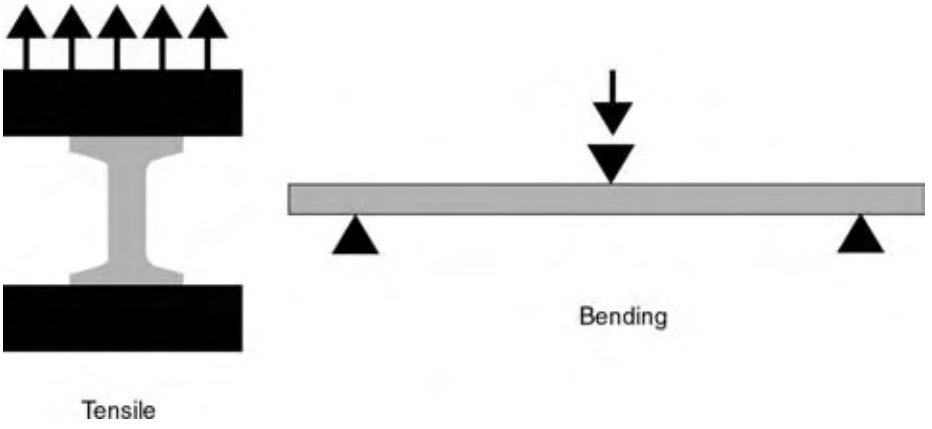

Fig. 10 Geometries for testing stress–strain of composites.

strength; and most important commercial fillers for a particular polymer have a lower reduction in these properties at a given volume fraction than other fillers. The applications of composites that depend primarily on mechanical property specifications are too numerous to list; some examples are airplane and automotive components. Other important mechanical properties that often justify the use of a filled system vs. one without a filler are abrasion resistance, for instance, automobile tires and resistance to creep, e.g., weight-bearing structural components.

Electrical and Thermal Conductivity

Another common reason to add a filler to a polymer is to increase either electrical conductivity or thermal conductivity. Polymers typically have electrical conductivity from 10^{-17} to 10^{-18} S/cm; though the addition of a moderately conductive filler such as carbon black conductivities of 10^{-2}–10^{0} S/cm are possible; highly conductive fillers such as silver can raise this value to 10^{1}–10^{2} S/cm. Applications include static dissipative devices and surge protectors. The impact of adding a highly thermally conductive filler to a polymer is much smaller at low-volume fractions vs. the impact of an electrically conductive filler on electrical conductivity. However, if a highly loaded stiff product is acceptable, polymer composites are capable of dissipating substantial amounts of heat.

Gas Diffusion and Fire Retardance

Nanotechnology has been identified as one of the key technologies that will lead to important advances in the quality of life, and important advances have been made using nanotechnology in the polymer composite area. The use of nanoclays; which have nanometer size thickness if exfoliated (i.e., separated apart), has enabled the manufacture of polymer-filled materials with vastly improved resistance to burning as well as vastly improved resistance to the diffusion of various gases. Applications that make use of the unique properties of composites filled with exfoliated clays are just beginning to appear. Manufacture of nanocomposites has proven to be quite difficult because agglomerates of clay platelets must be separated for the improved resistance to diffusion and flame to occur. Thermoplastic resins with specific clay–polymer interactions, e.g., nylon, have proven to be the most effective matrix for nanocomposites.

DEFECTS IN POLYMER COMPOSITES

The presence of defects in polymer composites adversely affects their mechanical properties and environmental resistance.[12–14] Conversely, environmental factors can lead to the worsening of already present defects. Defects in composites originate either during the manufacturing process as a result of incomplete wetting, improper process pressure, inadequate heating, or excessive temperature overshoot or during the service life of the composite because of external factors including cyclic loading, low-energy impact, moisture, and elevated temperatures. Poor choice of process parameters leads to voids, inclusions, resin burnout, and dry spots whereas external factors lead to defects such as subsurface damages, ply cracking, and delamination.

Defects Induced During Fabrication of Composites

Microvoids and dry spots

Depending on the manufacturing method, fiber type and content, and properties of the impregnating polymer, various mechanisms lead to the formation of large dry areas, called dry spots, and air inclusions or microvoids in the final composite part made with thermosetting resins. Common causes for void formation in polymer composites include volatilization of

dissolved gases or moisture in the resin during impregnation or curing, partial evaporation of mold releasing agent into the preform, and initial air bubble content in the resin mixture. In wet layup and pultrusion, uneven application of the resin is the primary cause of void and dry spot formation, whereas in autoclave curing of composite laminates, voids are mainly caused by entrapped air between layers in prepregs. In LCM processes, on the other hand, voids form during mold filling primarily because of mechanical entrapment of air at the advancing flow front.[15–19]

Void presence in composites, even in small amounts, is detrimental to their mechanical performance (Fig. 11). Judd and Wright reported that regardless of the manufacturing process, void presence induces reduction in interlaminar shear strength, tensile and flexural strength and modulus, torsional shear, fatigue resistance, and impact properties of a composite part.[12] Ghiorse indicated, for carbon/epoxy laminates, that each 1% increase in void content induced a 10% reduction in flexural and interlaminar shear strength, and a 5% reduction in flexural modulus.[13] Voidage is also known to affect both the rate and the equilibrium level of moisture absorption in composites.[14] Harper et al. reported that an increase from 1% to 5% in void volume fraction induces an increase of around 280% in the initial absorption rate, and 50% in the equilibrium mass gain for an AS4/3502 graphite/epoxy composite.[14]

Although it is not practically possible to manufacture void-free composites, different techniques have been successfully utilized for most manufacturing processes to fabricate composite parts with acceptable void content. Some of the void reduction techniques include: 1) degassing the resin mixture prior to impregnation; 2) utilization of vacuum to remove the air entrapped between prepreg layers; 3) proper selection of fiber/resin systems to lower gas emission during impregnation and cure; and 4) utilization of lower-viscosity resins at higher temperatures to facilitate the impregnation. Most industrial applications consider 1% void content as a threshold for acceptance of composite parts.[16,17] However, in highly structural applications, an acceptance threshold of 0.5% in void content is often applied.[20]

Wrinkling

A number of mechanisms are known to induce wrinkling in continuous-fiber polymer composites. These mechanisms include mismatch in thermal expansion between the fiber, matrix, and tool plate materials; the temperature changes experienced by the part during processing; and volumetric shrinkage of the matrix.[21–24] The difference between thermal expansion coefficients of fiber, matrix, and tool plate can be several orders of magnitude. Thus, residual stresses often develop during the cooling down of the part. The elevated cooling rates can lead to compressive stresses in the laminate surface, while slower cooling rates allow time for stresses to relax and avoid significant temperature gradients through the thickness of the part.[21]

Defects in injection molding

Incomplete filling and weld lines are the most common defects in injection-molded composites. High fiber contents and low heating temperatures often lead to highly viscous fiber–resin mixtures that require elevated injection pressures. If adequate pressure is not supplied or the solidified composite blocks parts of the injection gate or runners, only a fraction of the needed volume is injected into the mold cavity. This problem can usually be solved by using higher melting temperatures to reduce the mixture viscosity, and also by enlarging the injection gates. Another defect encountered in most injection-molded parts is the formation of weld lines.[25] When a weld line is formed by the merging of separate fluid fronts, fibers at both sides do not penetrate across the neighboring front, thus forming an unreinforced, structurally weak plane. This problem is often accentuated for parts containing longer fibers and higher fiber contents.[4] Fiber breakage is another defect affecting the performance of injection-molded parts. The mixing and shearing of the extruder screw often reduces the fiber length, yielding a composite part molded with reduced mechanical properties. Low screw speeds and injection pressure can be utilized to avoid excessive fiber breakage.[4]

Defects Induced During Service Life of Composites

Matrix cracks and fiber fractures

Although matrix cracks can be induced by residual stresses developed during curing, most matrix cracks are initiated during the service life of the composites.[23] Given that the matrix usually sustains a lower stress before failure compared to the fiber reinforcements, microcracks are often generated in the matrix after the application of high loads. Depending on the fiber orientation, content, and the direction of the applied load, multiple matrix cracks with different orientations can form inside the composite. If the matrix cracks propagate above a certain limit, fibers start supporting most of the applied load before they fail under different mechanisms. Short fibers frequently fail under pullout, i.e., extraction of the fiber from the matrix, while continuous fibers tend to fracture under excessive loads. Depending on the strength of the matrix–fiber adhesion, a combination of both mechanisms is usually present in fractured composites.[26] Environmental effects, such as the infusion of water, can lead to a reduction in matrix–fiber adhesion, which in turn leads to premature failure. Fig. 12 shows scanning electron micrographs of failed surfaces of an E-glass/epoxy composite.[27] Fibers failing under both pullout and fracture can be seen in Fig. 12.

Delamination

Delamination is the debonding of adjacent composite layers and is one of the most prevalent life-limiting defects in thermosetting composite laminates. Delamination is usually induced during service life of the composite from a low-energy impact or fatigue loading. However, delamination can also originate from other preexisting defects such as matrix cracks and voids. In addition to reducing the structural integrity of the material, delamination also results in deterioration of long-term performances.[28,29] Nondestructive evaluation methods have been commonly used to detect delaminations to prevent their excessive propagation leading to the final failure of the laminate.[30] Techniques such as x-ray and ultrasonic inspections are widely used, particularly in the aircraft industry where structural composite laminates are often used. Nondestructive evaluation tests usually help define regular inspection intervals and determine the need for repair.

Polymeric Membranes

Takeshi Matsuura
Mehrdad Rafat
Department of Chemical Engineering, University of Ottawa, Ottawa, Ontario, Canada

INTRODUCTION

Membrane science can be divided into the following categories: material selection, material characterization and modification, membrane preparation, membrane characterization, membrane testing for applications, membrane transport, membrane module, and system design. This entry deals with the first three of the above-mentioned subjects, exclusively for polymeric materials. Polymeric properties that have to be considered in selecting polymeric materials for membrane preparation are identified. Together with the synthesis cost of polymeric materials, which is often prohibitively high, polymers are narrowed down in the selection procedure to a handful of technical polymers for practical applications. In the section for membrane preparation, a major portion is devoted to describe the methods to prepare asymmetric membranes, because most of the membranes that are currently used in industrial separation processes possess asymmetric structures. Methods for membrane surface modification are also described in recognition of the fact that the membrane performance is governed primarily by the surface of the membrane. Membrane characterization, membrane transport and membrane module, and system design are out of the scope of this entry. Examples of polymers that are currently used to manufacture industrial membranes are reviewed. They are mostly technical polymers that are mass-produced for purposes other than membrane manufacturing. The objective of this entry is, therefore, to review knowledge on polymeric properties that are relevant to membrane manufacturing, current technologies to prepare asymmetric membranes, and applications of polymeric membranes.

POLYMERS FOR MEMBRANES

Although membranes can be prepared from both ceramic and polymeric materials, ceramic materials have several advantages over polymeric materials, such as higher chemical and thermal stability. The market share of polymeric membranes is far greater than that of ceramic membranes because polymeric materials are easier to process and less expensive. A handful of technical polymers are currently used as membrane materials for 95% of all practical applications.[1] Polymeric materials that are used to prepare separation membranes are mostly organic compounds except for silicone rubbers that contain no carbon atoms.

Among others, chain flexibility/rigidity, crystallinity, hydrophilicity/hydrophobicity, molecular weight, chemical property, biodegradability, thermal property, mechanical property, and electrochemical property of polymers are considered to affect the performance of membranes most strongly. Moreover, these properties are often mutually interrelated.

Chain Flexibility/Rigidity

The presence of bulky pendant groups hinders the rotational motion around the main chain, while increasing the distance between them. Because of the increase in the interchain void space, small molecules tend to diffuse through the space more readily. On the other hand, the diffusion of large molecules through the interchain void space becomes more restricted because of the increase in chain rigidity. As a result, the selectivity of the polymeric membrane will increase, while the permeability of small molecules will also increase with an increase in the bulkiness of the pendant groups.[2,3] This is an important design criterion for gas separation membranes.

Crystallinity

Some polymers have a regular and symmetric nature in their molecular structures and tend to crystallize partially. Because the diffusion of permeant molecules through the crystalline region is far slower than in the surrounding noncrystalline region, increase in the degree of crystallinity leads to low permeability.

Hydrophilicity/Hydrophobicity

A measure for hydrophilicity/hydrophobicity of a polymer is given by the solubility parameter.[4]

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030631

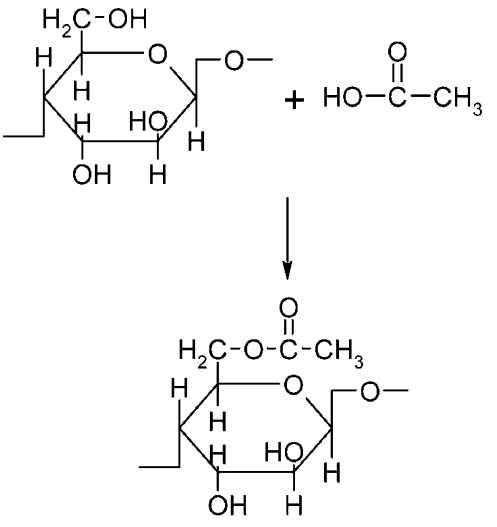
The solubility parameter is a parameter by which the nature and the magnitude of interaction forces working between molecules can be expressed. It is defined as the square root of cohesive energy density, $\Delta E/V$, where ΔE is the heat of vaporization (J/mol) and V is the molar volume (m^3/mol). Solubility parameters for some polymers are given in Table 1. Usually, a polymer of higher-solubility parameter is more hydrophilic. The interaction force working between two organic compounds, including polymers, becomes stronger when their solubility parameters are close to each other.

Molecular Weight

While the above three properties of polymers affect the permeation properties of the membrane directly, the effect of the molecular weight on permeation properties is still controversial, although there are some evidences that an increase in molecular weight enhances the permeation rate owing to an increase in chain stiffness.[5]

Chemical Property

Cellulose acetate is an ester of cellulose and acetic acid. Hence, hydrolysis takes place when the pH of the solution with which a cellulose acetate membrane is in contact is too high or too low, lowering the degree of acetylation, defined as the number of hydroxyl groups (total of three in one D-glucopyranose unit) that can be acetylated. Because a degree of acetylation above 2.5 is required for satisfactory salt rejection in seawater desalination, excessive hydrolysis results in poor membrane performance. The pH values between 5 and 7 should be maintained when cellulose acetate membranes are used.[6]



Formation of monosubstituted cellulose acetate

Aromatic polyamide, another polymeric material used for seawater desalination, can tolerate a wider pH range from 5 to 9. However, aromatic polyamide membranes are known to be susceptible to chlorination in the presence of chlorine in water.[3]

Another important chemical property of polymers is their ability to interact with organic solvents. Polymers should be dissolved in a solvent or a solvent blend when a membrane is prepared by the phase inversion technique or a thin polymer layer is coated on top of a substrate porous membrane. On the other hand, polymeric membranes are swollen by organic vapors or by organic solutes, if interaction between the polymer and the organic compounds is too strong, resulting in poor membrane performance. The strength of interaction between polymer and organic solvent is given by the Flory–Huggins (F–H) interaction

Table 1 Solubility parameters of polymers relevant for membrane preparation ($1\,cal^{1/2}/cm^{3/2} = 2.05\,J^{1/2}/cm^{3/2}$)

Polymer	Solubility parameter ($cal^{1/2}/cm^{3/2}$)	Polymer	Solubility parameter ($cal^{1/2}/cm^{3/2}$)
TFE	6.7	PEEK	12.8
PVDF	7.5	PES	13.9
PP	8.0	SPS	14.1
PE	8.6	PAN	14.4
PC	11.6	PEI	14.5
CTA	12.0	PA-300	15.0

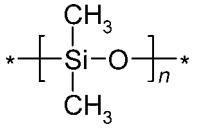
PS (Udel)	12.6	PI	19.0
SPPO	12.6	PVA	19.1
CA-398	12.7	CE	24.1

coefficient.[7] The lower the coefficient, the stronger becomes the interaction. A relationship between solubility parameter and F–H interaction coefficient has been proposed.[8]

Thermal Property

Two states are distinguished for a polymeric material, the rubbery state and the glassy state. When a polymer is in a rubbery state, the polymer chain is very mobile because the segment can rotate freely along the segment bond. On the other hand, when a polymer is in a glassy state, the rotation is restricted by the presence of bulky pendant groups or by the strong interaction between chains. The transition from a glassy state to a rubbery state occurs at the glass transition temperature T_g, at which a sufficient amount of thermal energy is supplied to make the macromolecules more mobile. Many physical properties, such as density, tensile modulus, and permeability, show an abrupt change at T_g when the temperature is gradually changed. When T_g of a polymer is lower than room temperature, the polymer is in a rubbery state at room temperature and it is called rubbery polymer. On the other hand, when T_g of a polymer is higher than room temperature, the polymer is called glassy polymer. A typical rubbery polymer that is used for gas separation membranes is polydimethyl siloxane (PDMS). Gas permeability of PDMS is very high because of its high chain mobility. However, the selectivity is low.



Polydimethyl siloxane

Many polymers are used in their glassy states because of their enhanced selectivities in the glassy state. T_g should be sufficiently high for these polymers to be durable at a high operating temperature. Otherwise, the temperature may go beyond T_g and the selectivity of the membrane will dramatically decrease. Hence, T_g is one of the important criteria for glassy polymers. Some pertinent T_g values are listed in Table 2.[7,9]

Mechanical Property

The ratio of strain (deformation per unit length) caused by a stress (force per unit cross-sectional area) applied to a polymeric material is called Young's modulus. A sufficiently high Young's modulus is desired for a polymer when it is spun to hollow fibers.

Table 2 Glass transition temperatures of some polymers

Polymer	T_g(°C)	Polymer	T_g(°C)
PDMS	−125	PEEK	145
PE	−120	PC	150
Natural rubber	−72	PS	195
PVDF	−40	PEI	210
PP	−10	PPO	218
CA	80	PES	230
PVA	85	PAI[a]	295
PAN	120	PI	300
PTFE	126		

[a]PAI, polyamideimide.

Electrochemical Property

Membranes for electrodialysis and polymer electrolyte membrane fuel cell (PEMFC) have electric charges. Most of the nanofiltration membranes also carry negative charges. The content of electric charge in a polymer is given by ion-exchange capacity (meq (milliequivalent)/g of dry polymer).

PREPARATION OF POLYMERIC MEMBRANES

Membranes Without Asymmetric Structures

Track etching

A sheet of polycarbonate film moves underneath a radiation source and is irradiated by high-energy particles. The spots that are subjected to bombardment of the particles are degraded or chemically altered during this process. Then, the film undergoes an etching process in an alkaline or H_2O_2 bath, where the polymer is etched along the path of high-energy particles. Cylindrical pores of very uniform sizes are obtained by this method. The pore sizes are in the range of microfiltration (MF) membranes and the porosity is relatively small.[10]

Precipitation from the vapor phase

This method was developed by Zsigmondy in the early part of the last century. A cast polymer solution that consists of polymer and solvent is brought into nonsolvent vapor environment saturated with solvent vapor. While saturated solvent vapor suppresses the evaporation of solvent from the film, nonsolvent vapor diffuses into the film causing polymer coagulation. The formation of the dense skin layer does not occur. Pore sizes are uniform, perpendicular to the membrane surface.[11]

Asymmetric Structure of the Membrane

Most of the membranes that are used in industrial separation processes have an asymmetric structure. Membranes with asymmetric structures are called asymmetric membranes. Fig. 1 shows schematically a typical cross-sectional view of an asymmetric membrane.[12] As shown in the figure, an asymmetric membrane consists of two layers, i.e., one is a very thin dense layer at the top of the membrane and the other is a porous sublayer underneath the top dense layer (also called top skin layer). While the top dense layer governs the permeation properties of the membrane, the porous sublayer only provides the membrane with mechanical strength. When the material of the top skin layer and the porous sublayer are the same, the membrane is called integrally skinned asymmetric membrane. This type of membrane is made by the dry–wet phase inversion technique. When the polymer for the top skin layer is different from the polymer for the porous sublayer, the membrane is called composite membrane. The advantage of the composite membrane over the integrally skinned asymmetric membrane is that the material for the top skin layer and for the porous sublayer can be chosen separately to optimize the overall performance. This type of membrane is made by coating a thin layer on top of the surface of a porous substrate. Various coating techniques are available but the interfacial in situ polymerization method has been proven to be commercially the most successful.

Phase inversion technique—Preparation of integrally skinned asymmetric membranes

Phase inversion is a process in which a polymer is transformed from a liquid to a solid state. There are a number of methods to achieve phase inversion. Among others, the dry–wet phase inversion technique and the temperature induced phase separation (TIPS) are most commonly used in the industrial membrane manufacturing. The dry–wet phase inversion technique was applied by Loeb and Sourirajan in their development of the first cellulose acetate membrane for seawater desalination.[13] Therefore, this method is often called the Loeb–Sourirajan method. According to the Loeb–Sourirajan method, a polymer solution is prepared by mixing polymer, solvent, and sometimes even nonsolvent. The solution is then cast on a suitable surface by a doctor blade to a thickness of about 250 μm. After partial evaporation of the solvent, the cast film is immersed in a bath of nonsolvent medium, often called gelation medium. Because of a sequence of two desolvation steps, i.e., evaporation of solvent and solvent–nonsolvent exchange in the gelation bath, solidification of polymer film takes place. It is desirable to choose a solvent of strong dissolving power with high volatility. During the first step of desolvation by solvent evaporation, a thin skin layer of solid polymer is formed instantly at the top of the cast film owing to the loss of solvent. In the solvent–nonsolvent exchange process that follows, nonsolvent diffuses into, while solvent diffuses out of, the polymer solution film through the thin solid layer. The change in the composition of the polymer solution film during the solvent–nonsolvent exchange process, often called a composition path, is illustrated schematically in a triangular diagram that involves polymer–solvent–nonsolvent (Fig. 2).

At some moment, the content of solvent in the solution film becomes so low that the solvent no longer

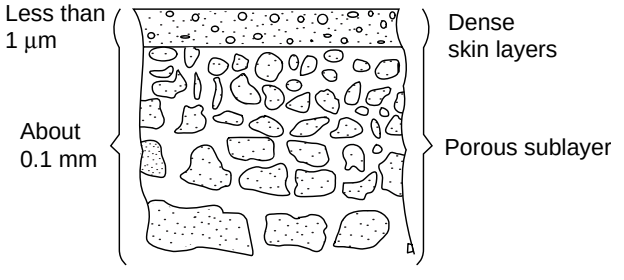


Fig. 1 Schematic representation of the cross section of an asymmetric membrane. (From Ref.[12].)

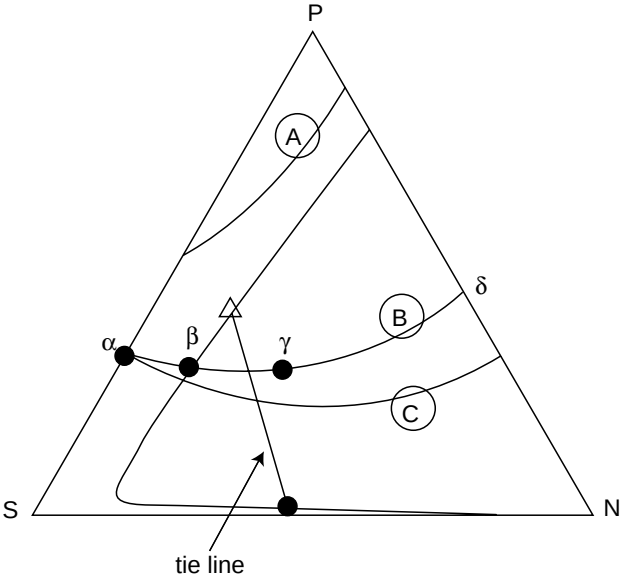

Fig. 2 Examples of the composition path on a triangular diagram. P = polymer, S = solvent, N = nonsolvent; composition paths A, B, and C depend on the ratio of solvent/nonsolvent flux rate during the solvent exchange. α, composition at the beginning of solvent exchange; β, composition at the point of crossing the phase boundary; γ, composition at the point of gelation; δ, composition at the end of solvent exchange. (From Ref.[12].)

is able to hold the polymer in one phase. Phase separation takes place at this moment, forming droplets of one liquid phase dispersed in the other continuous liquid phase. The moment of phase separation and the size and the number of the dispersed droplets depend on the nature of solvent and nonsolvent and the polymer solution composition. The control of the number and the size of the droplets will eventually control the structure of the porous substrate.[14]

The thin layer of solid polymer that forms during the first evaporation step becomes the top skin layer that will govern the selectivity and the flux of the membrane, while the porous structure that forms during the solvent–nonsolvent extraction step becomes the porous sublayer, providing the mechanical strength. Hence, the membrane obtained by the dry–wet phase inversion process is an integrally skinned asymmetric membrane. The top skin layer can also be made porous by lowering the polymer concentration in the casting solution and the solvent evaporation period. This is called, hereafter, porous skin layer. Ultrafiltration (UF) membranes have a porous skin layer. The asymmetric membranes can also be made in tubular form using a casting bob assembly and hollow fibers can be spun using a hollow fiber spinneret.[15]

Thermally induced phase separation

In this process phase inversion is introduced by lowering the temperature of the polymer solution. A polymer is mixed with a substance that acts as a solvent at a high temperature and the polymer solution is cast into a film. When the solution is cooled, it enters into an immiscible region due to the loss of solvent power. Liquid–liquid demixing occurs and the solution is separated into two phases, i.e., the polymer-lean phase is dispersed as droplets in the polymer-rich phase. Further, cooling causes gelation of polymer. Because the solvent is usually nonvolatile, it must be removed with a liquid that is miscible with the solvent but not miscible with the polymer. The membranes made by the TIPS method have pore sizes in the range of 0.1 and 1 μm and the pore structure is uniform in the depth direction.[16]

Membrane Surface Coating for Composite Membranes

Dip coating

An integrally skinned asymmetric membrane with a porous skin layer (hereafter called substrate membrane) is prepared from a polymer solution by applying the dry–wet phase inversion method and dried according to the method described later, before being dipped into a bath containing a dilute solution of another polymer. When the membrane is taken out of the bath, a thin layer of coating solution is deposited on top of the substrate membrane. The solvent is then removed by evaporation, leaving a thin layer of the latter polymer on top of the substrate membrane.

Interfacial in situ polymerization

This method, developed by Cadotte and coworkers of Film Tech in the 1970s, is currently most widely used to prepare high-performance reverse osmosis and nanofiltration membranes.[17] A thin selective layer is deposited on top of a porous substrate membrane by interfacial in situ polycondensation. There are a number of modifications of this method primarily based on the choice of the monomers.[18] However, for the sake of simplicity, the polycondensation procedure is described by a pair of diamine and diacid chloride monomers.

A diamine solution in water and a diacid chloride solution in hexane are prepared. A porous substrate membrane is then dipped into the aqueous solution of diamine. The pores at the top of the porous substrate membrane are filled with the aqueous solution in this process. The membrane is then immersed in the diacid chloride solution in hexane. Because water and hexane are not miscible, an interface is formed at the boundary of the two phases. Polycondensation of diamine and diacid chloride will take place at the interface, resulting in a very thin layer of polyamide. The preparation of composite membranes by the interfacial in situ polycondensation is schematically presented in Fig. 3.

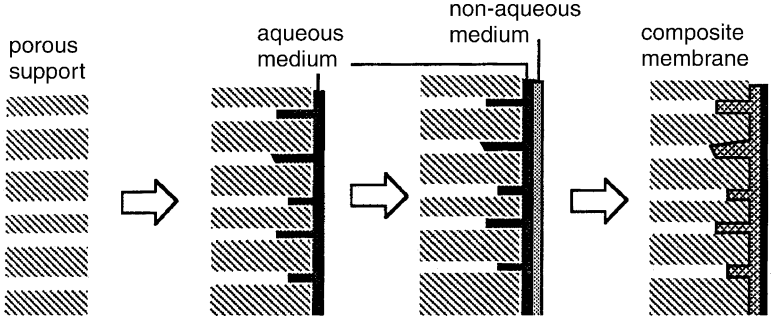

Fig. 3 Schematic representation of interfacial polycondensation to form a composite membrane. (From Ref.[3].)

There are a number of combinations for the choice of diamine and acid chloride monomers. For example, if trimesoyl chloride, which has three –COCl groups in an aromatic ring, is mixed with phthaloyl chloride, which has two –COCl groups, crosslinking will form between two main chains. Unreacted –COCl will become –COOH upon contact with water and the membrane will become negatively charged. Monomers with reactive groups other than amine and acid chloride can also be used.

Other Methods of Membrane Surface Modification

As mentioned above, the top skin layer governs the performance of a separation membrane. The surface deposition of contaminants from solutions or from gas mixtures is also affected by the surface properties of the membrane. This is particularly important when decline in the membrane flux with a prolonged operating period is observed, because it is often caused by the contaminant deposition. Hence, many attempts have been made to modify the membrane surface, aiming at prevention of contaminant deposition and maintenance of high flux. Several methods of surface modification are described below.

Chemical modification

The surface of a membrane can be modified by chemical reactions. For example, when the surface of a polyamide composite membrane is brought into contact with a strong hydrofluoric acid solution, the top polyamide layer becomes slightly thinner by a chemical reaction with hydrofluoric acid. As a result the flux increases considerably while the rejection of sodium chloride is unchanged or slightly increased.[19]

Plasma polymerization

When a vacuum is maintained inside a tubular reactor and a high-frequency field is applied outside, a glow discharge is generated inside the reactor (see Fig. 4). A plasma that consists of various ions, radicals, electrons, and molecules is formed in the glow discharge. When a porous substrate membrane is placed into the plasma, the surface of the membrane is subject to various changes corresponding to the property of plasma. The substrate surface can be etched and/or chemically active sites are introduced to the surface, and, upon contact with organic compounds, an irregular polymerization may occur at the substrate surface. This is called plasma polymerization.[20]

Graft polymerization

The surface of a porous substrate membrane is irradiated with γ-ray, which causes generation of radicals on the membrane surface. Then, the membrane is immersed into a monomer solution. The graft polymerization of the monomers is initiated at the membrane surface. By choosing a very hydrophilic monomer, the hydrophilicity of the surface is increased considerably.

Surface modification by surface modifying macromolecules

It is known that, in a polymer blend, thermodynamic incompatibility between polymers usually causes demixing of polymers. If the polymer is equilibrated in air, the polymer with the lowest surface energy (hydrophobic polymer) will concentrate at the air interface and reduce the system's interfacial tension as a consequence. The preferential adsorption of a polymer of lower surface tension at the surface was confirmed by a number of researchers for a miscible blend of two different polymers. Based on this concept, surface modifying macromolecules (SMMs) as surface-active additives were synthesized and blended into polymer solutions of polyethersulfone (PES). Depending on the hydrophobic or hydrophilic nature of the SMM, the membrane surface becomes either more hydrophobic or more hydrophilic than the base polymeric material.[21–23]

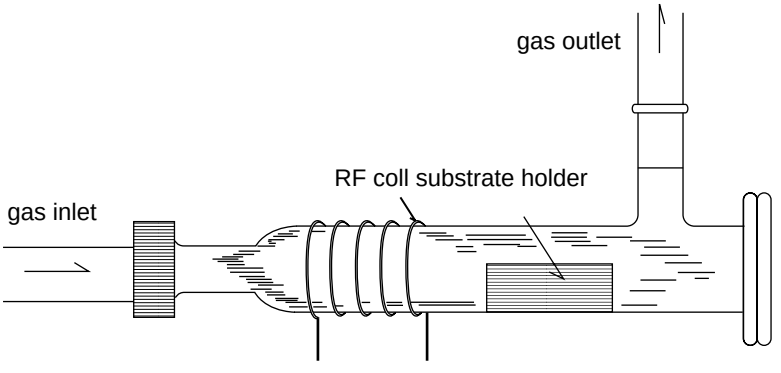

Fig. 4 Tubular reactor for plasma polymerization. (From Ref.[12].)

Membrane Drying

The wet cellulose acetate membranes prepared for reverse osmosis purposes can be used for gas separation when they are dried. The water in the cellulose acetate membrane cannot be evaporated in air, however, because the asymmetric structure of the membrane will collapse. Instead, the multistage solvent exchange and the evaporation method is applied. In this method, the water in the membrane is first replaced by a water-miscible solvent such as ethanol. Then, the first solvent is replaced by a second volatile solvent such as hexane. The second solvent is subsequently air-evaporated to obtain a dry membrane.[24,25] The reason for replacing water to hexane is to reduce the capillary force inside the pore so that the pore will not collapse during the drying process.

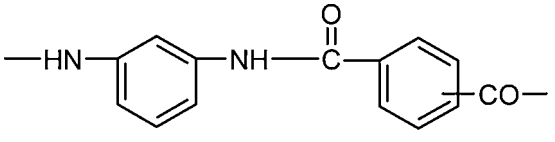
POLYMERIC MEMBRANES FOR MEMBRANE SEPARATION PROCESSES

Reverse Osmosis/Nanofiltration/ Ultrafiltration/Microfiltration

Reverse osmosis membranes

Cellulose acetate is the material for the first-generation reverse osmosis (RO) membranes. The announcement of cellulose acetate membranes for seawater desalination by Loeb and Sourirajan in 1960 triggered the applications of membrane separation processes in many industrial sectors. Cellulose acetate membranes are prepared by the dry–wet phase inversion technique.

Another polymeric material for RO is aromatic polyamide.[26]



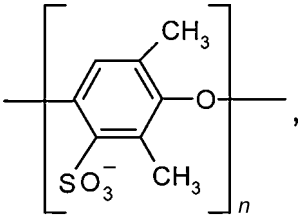
Aromatic polyamide polymer

As shown above, aromatic rings are connected by an amide linkage, –CONH–. While the aromatic ring attached to –NH– is *meta*-substituted, the ring attached to –CO– is the mixture of *meta*- and *para*-substitutions, which gives more flexibility to the polymeric material. Aromatic polyamide remains one of the most important materials for RO membranes because the thin selective layer of composite membranes is aromatic polyamide synthesized by interfacial in situ polymerization.

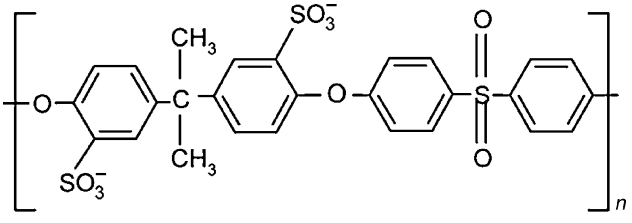
Nanofiltration membrane

Most of the nanofiltation (NF) membranes are negatively charged. As shown in interfacial polycondensation, trimesoyl (triacid) chloride is mixed with phthaloyl (diacid) chloride in the acidic component of polycondensation reaction. Although most of the carboxylic groups are consumed to form cross-linking, a small portion of carboxylic groups does not participate in the cross-linking reaction, becoming the source of the electric charge. Because –COOH becomes $–COO^-$ upon dissociation, the membranes are negatively charged. Because of the negative charge, anions are preferentially rejected by NF membranes.

Another method of preparing NF membranes is to dip-coat a thin layer of sulfonated polyphenylene oxide (SPPO), sulfonated polysulfone (SPS), or carboxylated polysulfone on a porous substrate membrane.[27–29]



SPPO



SPS

Sulfonic acid groups in SPPO and SPS also become negatively charged with $–SO_3^-$ groups upon dissociation. Sulfonic acid is a stronger acid than carboxylic acid.

Ultrafiltration membrane

In contrast to the polymeric materials for RO and NF membranes, for which the macromolecular structures have much to do with their permeation properties such as salt rejection characteristics, the choice of membrane material for UF does not depend on the material's influence on the permeation properties. Membrane permeation properties are largely governed by the pore sizes and the pore size distributions of UF membranes. Rather, the thermal, chemical, mechanical, and biological stability is considered of greater importance.

Typical UF membrane materials are polysulfone (PS), polyethersulfone (PES), polyetheretherketone (PEEK), cellulose acetate (CA), polyacrylonitrile (PAN), polyvinylidene fluoride (PVDF), polyimide (PI), and polyetherimide (PEI):

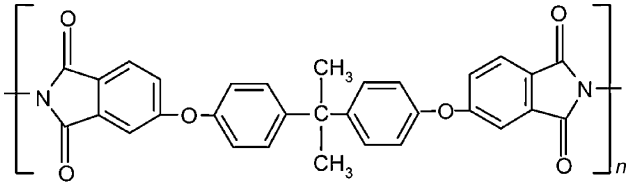
PI, Kapton

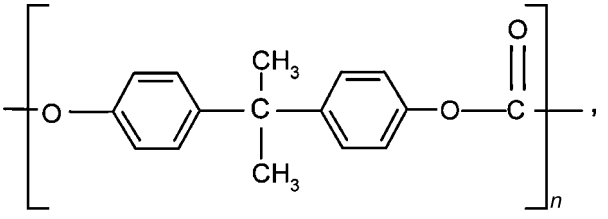


PEI, Ultem

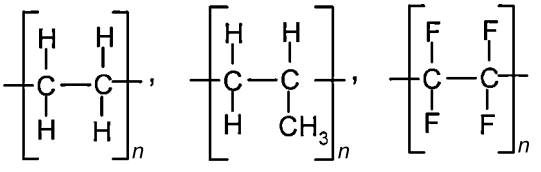
All of the above polymers have T_gs higher than 145°C except for cellulose acetate. They are also stable chemically and mechanically. Also, their biodegradability is low. The membranes are made by the dry–wet phase inversion technique.

Microfiltration membranes

Polymeric materials for MF membranes cover a very wide range from relatively hydrophilic to very hydrophobic materials. Typical hydrophilic materials are polysulfone (PS), polyethersulfone (PES), cellulose (CE) and cellulose acetate (CA), polyamide (PA), polyimide (PI), polyetherimide (PEI), and polycarbonate (PC). Typical hydrophobic materials are polyethylene (PE), polypropylene (PP), polytetrafluoroethylene (PTFE, Teflon), and polyvinylidene fluoride (PVDF).



PC

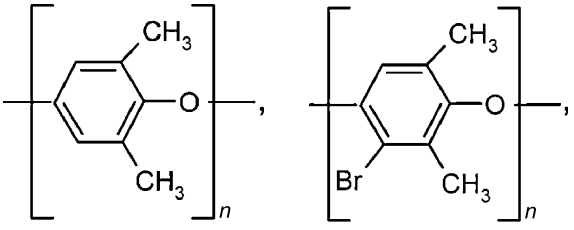


PE PP PTFE

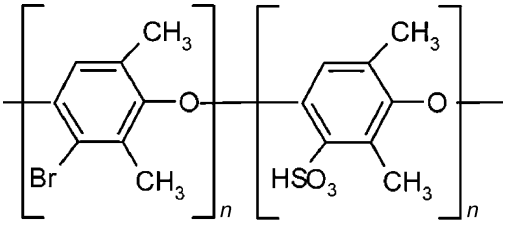
Hydrophilic MF membranes can be made by the dry–wet phase inversion technique. The latter technique is also applicable in making PVDF membranes. On the other hand, other hydrophobic MF membranes are made by the TIPS technique. In particular, semicrystalline PE, PP, and PTFE are stretched parallel to the direction of film extrusion so that the crystalline regions are aligned to the direction of stretch, while the noncrystalline region is ruptured, forming long and narrow pores. Hydrophobic membranes do not allow penetration of water into the pore until the transmembrane pressure drop reaches a threshold pressure called liquid entry pressure of water. These membranes can therefore be used for membrane distillation. Track-etching method is applied to make MF membranes from PC.

Gas and Vapor Separation

Gas and vapor separation membranes are classified into two categories. In the first one, rubbery polymers such as silicone rubber are used to take advantage of their high permeabilities, even though selectivities are rather moderate. Production of enriched oxygen for medical purposes is performed by this type of membrane with an oxygen/nitrogen selectivity of about 2. Asymmetric membranes made from glassy polymers such as cellulose acetate (CA), aromatic polyamide (PA), aromatic polyimides (PI), and polyphenylene oxide (PPO) and its derivatives belong to the second category.



PPO PPOBr



SPPOBr

These asymmetric membranes are made by the dry–wet phase inversion technique. Membranes must be dried before being used. Solvent exchange is necessary to dry cellulose acetate membranes. These membranes take advantage of the high selectivity of glassy polymers. The selective dense layer at the top of the membrane must be very thin so that a high flux can be achieved. They are used in a wide range of industrial gas separation processes such as hydrogen recovery from various chemical syntheses, sour gas removal from natural gas, and production of nitrogen-enriched air. For the asymmetric membranes to be effective in gas separation, the thin selective layer at the top of the membrane should be perfect and defect-free. This requirement is more stringent in gas separation membranes than in liquid separation membranes because defective pores cannot be automatically closed when the surface is in contact with dry gas. In contrast, the defective pores of RO and PV membranes can be closed by the swelling of the top skin layer when it is brought into contact with the feed liquid.

Because it is difficult to make a selective skin layer perfectly defect-free, a method was proposed by Henis and Tripodi to seal defective pores. Their method was applied to asymmetric PS membranes, which led to the production of commercial prism membranes.[30]

According to the method, a relatively thick silicone rubber layer is coated on a thin selective layer of an asymmetric PS membrane. The thickness of silicone rubber is about 1 μm while the effective thickness of the selective PS layer is 1/10 of 1 μm. While being coated, silicone rubber penetrates into the pores to plug them (Fig. 5). Thus, the feed gas is not allowed to leak through the defective pores. The selectivity of the membrane approaches that of the defect-free PS layer. Moreover, because the permeabilities of silicone rubber for gases are orders of magnitude higher than those of PS, the permeation rate is not affected very much even when a relatively thick silicone rubber layer is coated.

Membranes for vapor removal from air have a structure similar to the prism membrane, but they are prepared on a different principle.[31] Aromatic PEI is used to produce a porous substrate membrane by the dry–wet phase inversion method. This polymer was chosen over PS/PES because of the higher durability of PEI to organic vapors. Unlike an asymmetric PS substrate for the prism membrane, the top layer of asymmetric PEI membrane has a large number of pores, the size of which is equivalent to those of UF membranes. When a layer of silicone rubber is coated on the top layer of the porous substrate membrane, the silicone rubber layer will govern the selectivity and the porous support will provide only mechanical strength to the composite membrane. Because the permeabilities of water and organic vapors through the silicone

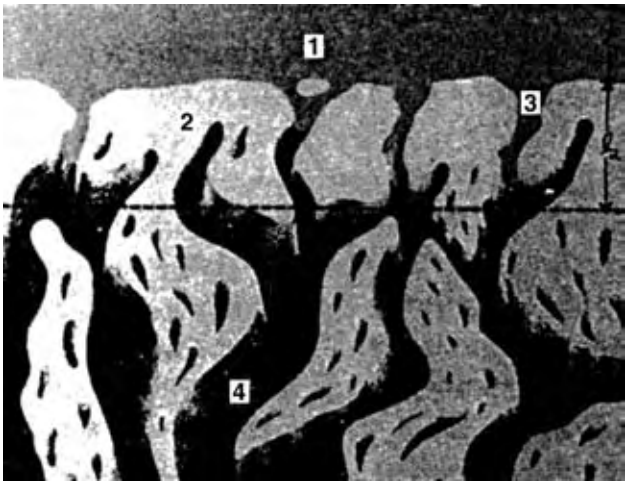


Fig. 5 Cross-sectional view of prism membrane. 1: silicone rubber layer; 2: skin layer of polysulfone; 3: pores filled with silicone rubber; 4: pores in the porous substrate membrane. (From Ref.[12].)

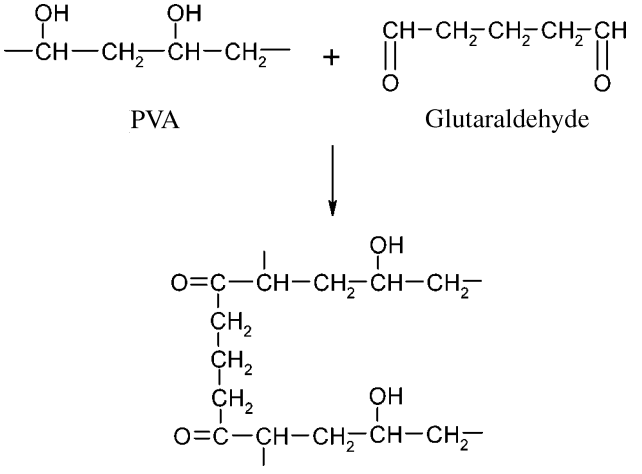
rubber layer are much greater than those of oxygen and nitrogen, these membranes are effective in dehumidification of air and removal of organic vapors from air.

Membranes for Pervaporation

Pervaporation (PV) membranes were developed for the dehydration of ethanol and other organic solvents. Therefore, the dense selective layer is made of polyvinyl alcohol, which is one of the most hydrophilic materials (see Table 2). Water is preferentially sorbed to polyvinyl alcohol and also preferentially transported. To suppress the excessive swelling of polymer in water, polyvinyl alcohol is partially cross-linked by dialdehydes such as glutaraldehyde.[32]



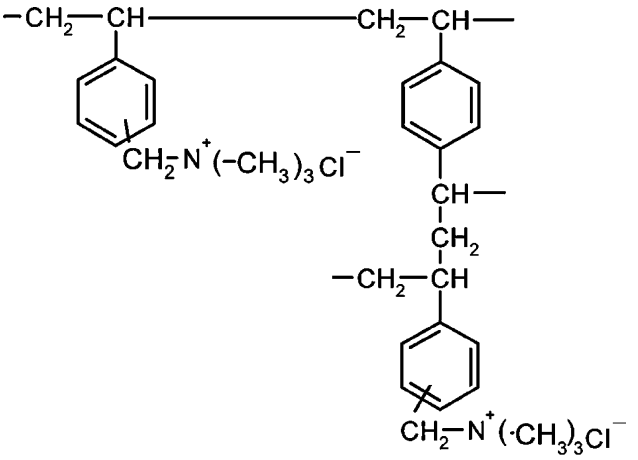
PVA Glutaraldehyde

Cross-linked PVA

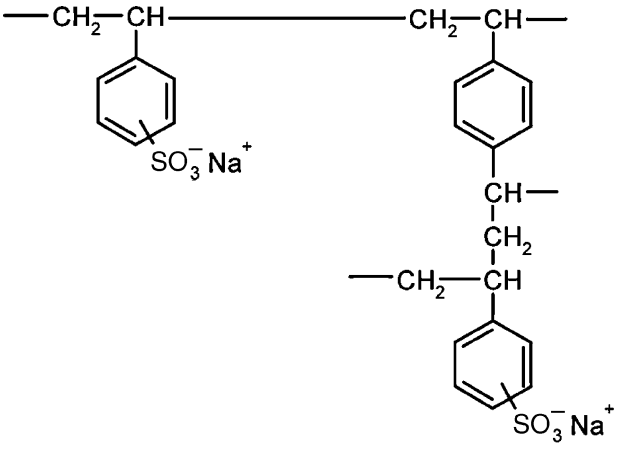
The dense polyvinyl alcohol layer is supported by a porous PAN substrate membrane. Polyelectrolyte material and chitosan, a natural product, are also potentially useful for dehydration by PV.[33,34] Silicone rubber membrane developed for the removal of organic vapors from air can also be used for the removal of volatile organic compounds (VOCs) from water by PV.[32] Because of the high hydrophobic nature of silicone rubber (see Table 2), VOCs are preferentially sorbed and transported through the membrane.

Electrodialysis

Membranes for electrodialysis (ED) are either positively or negatively charged. When a membrane is positively charged, it is called anion exchange membrane because only anions are allowed to permeate through the membrane, while a negatively charged membrane is called cationic membrane because only cations are allowed to permeate through the membrane. The base polymeric material is polystyrene cross-linked by divinylbenzene. Quarternary ammonium cations are attached to some aromatic rings of anionic membranes, while sulfonic groups or carboxylic groups are attached to some aromatic rings of cationic membranes.[35]



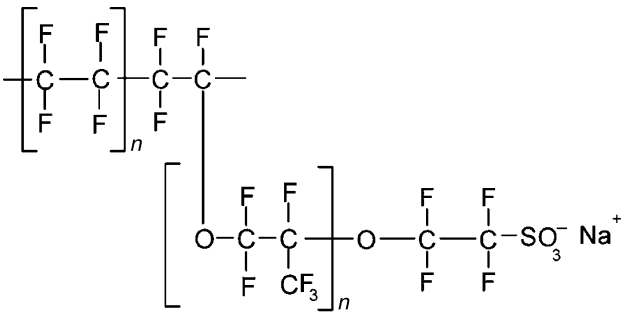
Anion selective membrane



Cation selective membrane

Fuel Cells

The development of new polymeric materials for polymer electrolyte fuel cell is one of the most active research areas, aiming at the new energy sources for electric cars and other devices. The mainstream of the material research for fuel cell is perfluoroalkyl sulfonic acid membranes such as Nafion, Acipex, and Flemion. The most well-known one is Nafion of Du Pont, which is derived from copolymers of tetrafluoroethylene and perfluorovinyl ether terminated by a sulfonic acid group.[35] Protons, when dissociated from the sulfonic acid groups in aqueous environment, become mobile and the membrane becomes a proton conducting electrolyte membrane.



Nafion

CONCLUSIONS

Many new polymers have been synthesized and tested for their permeation properties aiming at improvement in membrane performance for various applications. These efforts seem to continue in the future. However, only a handful of polymers, as shown in this entry, are currently being used as the materials for commercial membranes and they are not necessarily the polymers of the best permeation properties. This is mainly due to the cost factor that governs the membrane market. Transport properties of membranes are, on the other hand, known to be primarily governed by the membrane surface. Surface contamination, which may lead to deterioration in membrane performance, is also known to be governed by the membrane surface properties. Considering that only a small amount of polymer is required for surface coating, the future direction of R and D efforts will be focused on the development of new methods of surface coating and surface modification. This will allow us to utilize fully the potential of polymers for membrane materials.

Polymerization Reactions: Modeling, Design, and Control

Kyu Yong Choi
Department of Chemical Engineering, University of Maryland, College Park, Maryland, U.S.A.

INTRODUCTION

Synthetic polymers are of enormous industrial importance, and we can hardly think of modern life without polymers. Although many of the commercially important polymers have been around for more than 50 years [e.g., poly(vinyl chloride), nylons, polyesters, polystyrene, polyethylene, etc.], their manufacturing processes are not completely free of technical problems or new challenges because of the rapidly changing and diversifying market environment, and the pressure for cost reductions and new product developments. Polymer manufacturers always face the problem of supplying polymer products that meet the customer specifications at the lowest possible production cost. There is also a continuing need for new polymeric materials and new applications in electronics, biotechnology, energy, and environmental industries. To meet such challenges, the role of polymer science and engineering will continue to be important.

Polymerization reactors are known to be difficult to design and control because of inherent complexities in polymerization kinetic and mechanisms, physical transport effects, and strong nonlinear reactor behaviors in industrial polymerization processes. Moreover, many of the process variables that affect important product quality indices cannot be measured online or can be measured only at low sampling frequencies with time delays, making the reactor control difficult. Many polymer manufacturers find that a better understanding of their existing polymerization reactions and processes would enable them to design more efficient polymerization technology and to develop improved or new products. In this regard, one of the important tools that would allow the polymerization manufacturers to advance polymerization technology is a quantitative process model. Indeed, there is a growing consensus in the polymer industry that a mathematical modeling of a polymerization process offers an invaluable opportunity to improve product quality and productivity, thereby enhancing the overall competitiveness. Several commercial process simulation packages utilizing computer-aided design tools are available for a variety of industrial polymerization processes.

BACKGROUND

Unlike other chemical reaction processes, polymerization reaction processes offer some unique problems or issues that must be considered in process design and control. They include:

1. Complex reaction kinetics and phase behavior: In many polymerization processes, the reaction mixture undergoes a significant phase change that affects the polymerization rate, polymer properties, and reactor operations (e.g., viscosity increase, particle formation, precipitation, etc.).
2. Material mixing and conveying: Serious nonidealities in micromixing and macromixing may occur at high conversions and high viscosities. Often, a large amount of mechanical energy is required for uniform mixing and product conveying. Fluid or particle sticking, or fouling of the reactor surfaces can severely affect the reactor operations.
3. Heat removal: Removal of reaction heat from a highly viscous polymeric fluid or a heterogeneous reaction mixture is often a critical reactor design and operational problem. In many industrial exothermic polymerization processes, reactor thermal runaway is the most serious potential hazard.
4. Polymer product quality control: The molecular architecture of a polymer is very sensitive to reaction environment. The actual customer specifications are often represented by nonmolecular parameters (e.g., tensile strength, impact strength, color, crack resistance, thermal stability, etc.) that must be somehow related to fundamental polymer properties such as molecular weight distribution, composition, composition distribution, branching, crosslinking, etc. Many of these properties are influenced by more than one reaction or process variable and hence, one needs to understand complex and nonlinear relations between reaction variables and fundamental polymer properties. The lack of online

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018072

sensors to measure polymer properties makes the monitoring and control of polymerization reactors a special challenge.

A comprehensive review of the broad aspects of polymerization process modeling and its applications is not the objective here. In this entry, some critical issues related to the modeling, design, and control of polymerization reactors are discussed with some examples to illustrate modeling techniques and their applications to polymerization process optimization and control.

MODELING OF POLYMERIZATION REACTIONS

A modeling of a polymerization reactor process is needed for many reasons. Most of all, there is a need to develop a better understanding of the polymerization kinetics, chemical and physical transitions, and reactor behaviors under a given set of polymerization conditions and to use such an understanding to design improved reactor or process operations. For example, one can examine through process modeling how operating conditions of the reactor affect the polymerization rate and polymer properties. A reaction model is also useful in optimizing the process or reactor operations, and in designing advanced reactor control systems. For example, a model can be used to develop a model-based reactor control system or to evaluate various process control options even before a commercial plant is built. In modern polymerization plants, detailed polymerization process models are often used in conjunction with stochastic state estimation techniques (e.g., Kalman filter, extended Kalman filter, observer, etc.) to provide online estimates of process variables or polymer properties. Polymerization process models can also be used for training and education of production personnel. The research on modern mathematical modeling of polymerization reactions and polymerization processes was pioneered by two research groups: Ray and his coworkers at the University of Wisconsin-Madison, and Hamielec and his coworkers at the McMaster University in Canada. For a variety of industrially important polymerization systems, they developed solid frameworks for the modeling and analysis of polymerization kinetics and reactor dynamics.[1]

The mathematical modeling of polymerization reactions can be classified into three levels: microscale, mesoscale, and macroscale. In microscale modeling, polymerization kinetics and mechanisms are modeled on a molecular scale. The microscale model is represented by component population balances or rate equations and molecular weight moment equations. In mesoscale modeling, interfacial mass and heat transfer effects, micromixing, polymer particle size distribution, etc. are modeled on top of the microscale chemical kinetic model. Finally, in macroscale modeling, a reactor-scale system is modeled and the steady state and dynamic reactor behaviors are modeled and analyzed. For the simulation of a polymerization process, both microscale and mesoscale models must be incorporated into a macroscopic model.

Classification of Polymerization Systems

Polymerization reactions are classified broadly into chain-growth polymerization and step-growth polymerization by the way monomer linkages are formed. In chain-growth or addition polymerization, monomer molecules are incorporated successively into growing polymer chains bearing active propagating centers. The chain growth is terminated by termination or chain transfer reactions. If the chain termination rate is very low or controlled, a living or pseudoliving polymerization occurs (e.g., living anionic polymerization). Chain-growth polymerizations include: free radical polymerization, anionic and cationic polymerizations, group transfer polymerization, and coordination polymerization. In polycondensation or step-growth polymerization, polymer linkage occurs between the two polymers containing reactive end groups such as carboxylic acid group and hydroxyl group. It is interesting to note that a molecular weight–monomer conversion relation depends upon the type of polymerization mechanism. In free radical and coordination polymerizations, high polymer molecular weight is established at very low monomer conversions, whereas in step-growth polymerizations polymer molecular weight increases with an increase in monomer conversion (e.g., $\overline{X}_n = 1/(1 - p)$: $\overline{X}_n$ = degree of polymerization, p = conversion). Polymer molecular weight increases linearly with monomer conversion in a perfectly living polymerization system. Polymerization processes can also be classified by the types of reaction medium and kinetic mechanism as illustrated in Table 1.

Also, polymerization reactions are carried out in a variety of reactors including agitated batch reactors, continuous stirred tank reactors (CSTR), multizone autoclaves, loop reactors, tubular reactors, fluidized bed reactors, and a combination of these reactors.

Modeling Objectives

The main objectives in modeling polymerization reactions are to compute polymerization rate and polymer properties for various reaction conditions. These two types of model outputs are not separate but they are usually very closely related. For example, an increase in reaction temperature raises polymerization rate

Table 1 Classification of polymerization processes

	Kinetic mechanism			
Reaction medium	**Free radical**	**Ionic**	**Coordination**	**Condensation**
Homogeneous				
Solution bulk	Vinyl polymers (styrene, MMA, LDPE)	Polyethers (ethylene oxide), SBR	Polyolefins	Polyesters, polyamides
Heterogeneous				
Emulsion dispersion	Vinyl polymers (styrene, MMA, PVC)			
Suspension	Vinyl polymers (styrene, MMA, PVC)			
Precipitation	Vinyl polymers (PVC, PAN, PVDC)	Polyacetals, vinyls		Polyamides, solid state polymerization
Solid catalyzed			Polyolefins, syndiotactic polystyrene	

but decreases polymer molecular weight; an increase in catalyst concentration raises polymerization rate but decreases polymer molecular weight. From an industrial viewpoint, increasing polymer yield with a sacrifice in polymer quality is as unacceptable as improving the product quality with a sacrifice in polymer yield. Therefore, there is a need for a detailed understanding of the polymerization kinetics to devise a scheme to simultaneously achieve high productivity and desired polymer properties. Here, for process modeling purposes, we define the polymer properties as those that represent the polymer architecture: e.g., molecular weight distribution (MWD), molecular weight averages, copolymer composition, copolymer composition distribution (CCD), monomer sequence length distribution, short-chain and long-chain branching, crosslinking, stereoregularity, polymer particle size, particle size distribution (PSD), polymer morphology, etc. These ''fundamental'' polymer properties influence a polymer's physical, chemical, thermal, mechanical, and rheological properties.

Correlating the polymer molecular properties to end-use properties in a quantitative manner is still difficult. It is partly because most of the synthetic polymers are polydisperse and it is difficult to quantify the behaviors of a mixture of polymer molecules of different chain lengths in a processing environment.

Parameter Estimation

One important aspect of polymerization process modeling is that a modeling is never complete until all the relevant model parameters are determined or estimated. In fact, determining the model parameters using laboratory, pilot plant, or plant data is perhaps the most critical step for the successful development of a process model and at the same time it is the most time consuming, costly, and difficult process. The difficulty of parameter estimation comes from the multitude of reactions that affect each other and relevant kinetic parameters that are often masked by physical transport phenomena (e.g., diffusion, mass, and heat transfer effects). Quite often, a polymerization process model validated solely on the laboratory data fails to provide accurate predictions of the behavior of a large-scale plant reactor because reaction environments can be quite different (e.g., impurities, efficiency of mixing, etc.). It is also important to realize that extracting process data from plant operations for process modeling purpose is not as easy as one may expect. It is because few plant managers or plant engineers are willing to disturb normal commercial operations to generate some data for ''academic'' research and development. It would be important to develop a consensus between modelers and plant engineers: any efforts put into the development of a plant-scale polymerization reactor model will eventually benefit everyone involved because the model can help in improving the plant operations and product quality. In this regard, there is a need to develop some techniques of parameter estimation using plant data without disturbing normal commercial production, particularly in a large-scale continuous reactor process. Another point to be made in modeling an industrial polymerization process is that one must decide the level of sophistication of the model. Unlike academic polymerization kinetic models, industrial process models should be developed with clear objectives or purposes for a given set of constraints (e.g., personnel, cost, time). There is absolutely no reason for an industry to develop the most sophisticated and comprehensive process model in the world. For example, the goals of the

reactor/process modeling project must be clearly defined with specific applications laid down before the commencement of the modeling project. Sensible assumptions and/or simplifications are the keys to a successful modeling of an industrial polymerization process.

Modeling Procedure

In general, a polymerization process model consists of material balances (component rate equations), energy balances, and additional set of equations to calculate polymer properties (e.g., molecular weight moment equations). The kinetic equations for a typical linear addition polymerization process include initiation or catalytic site activation, chain propagation, chain termination, and chain transfer reactions. The typical reactions that occur in a homogeneous free radical polymerization of vinyl monomers and coordination polymerization of olefins are illustrated in Table 2.

The molecular weight distribution can be calculated by solving the mass balance equations for monomer(s), initiator (catalytic sites), and polymeric species with different chain lengths. When quasisteady state assumption is applied to live polymers or propagating active centers, the molecular weight distribution of live polymers is often represented by the Schultz–Flory most probable distribution. However, the calculation of the chain length distribution of dead polymers is in general quite complicated. For some special cases such as olefin polymerization with single site catalysts, the polymer molecular weight distribution follows the most probable distribution:

$$w(r) = \tau^2 r \exp(-\tau r) \tag{1}$$

where $w(r)$ is the weight fraction of polymers with chain length and τ is the ratio of chain transfer rates to propagation rate. The chain length distribution function is often combined with a reactor residence time distribution function to calculate the overall molecular weight distribution.

Instead of using a complete polymer chain length distribution, molecular weight averages are frequently used as a measure of molecular weight properties. The molecular weight averages can be relatively easily calculated by solving molecular weight moment equations derived from the polymer population balance equations. The polymer molecular weight moments are defined for live and dead polymers as follows:[2]

For homopolymerization:

$$\lambda_k \equiv \sum_{n=1}^{\infty} n^k M_n \tag{2}$$

where λ_k is the kth moment, n the number of monomer units in the polymer chain, and M_n the concentration of polymers with n repeat units (monomer units). Notice that the zeroth moment represents the total number of polymer molecules and the first moment represents the total polymer concentration. To calculate the polymer molecular weight averages, the differential equations for the first three leading moments should be derived and solved together with the rate equations for monomer, initiator (catalyst), and polymers. A detailed procedure of deriving the moment equations can be found elsewhere.[2] The variances of number average and weight average molecular weights can be calculated as follows:

$$\begin{aligned}\sigma_n^2 &= \frac{\sum_{i=1}^{\infty}\left(M_i - \overline{M}_n\right)^2 n_i}{\sum_{i=1}^{\infty} n_i} \\ &= \left[\frac{\lambda_2}{\lambda_0} - \left(\frac{\lambda_1}{\lambda_0}\right)^2\right] M_0^2\end{aligned} \tag{3}$$

$$\begin{aligned}\sigma_w^2 &= \frac{\sum_{i=1}^{\infty}\left(M_i - \overline{M}_w\right)^2 n_i M_i}{\sum_{i=1}^{\infty} n_i M_i} \\ &= \left[\frac{\lambda_3}{\lambda_1} - \left(\frac{\lambda_2}{\lambda_1}\right)^2\right] M_0^2\end{aligned} \tag{4}$$

where M_0 is the molecular weight of a repeating unit. $\overline{M}_n$ and $\overline{M}_w$ are the number average and weight average molecular weights, respectively. For a copolymer, unless it is an alternating copolymer, the degree of

Table 2 Reaction schemes for addition polymerizations

Free radical polymerization	Coordination polymerization
Initiation	Site activation
$I \xrightarrow{k_d} 2R$	$C_0^* + A \xrightarrow{k_a} C^*$
$R + M \xrightarrow{k_i} P_1$	
Propagation	Initiation
$P_1 + M \xrightarrow{k_p} P_2$	$C^* + M \xrightarrow{k_i} P_1$
$P_n + M \xrightarrow{k_p} P_{n+1} (n \geq 2)$	
Chain transfer	Propagation
$P_n + M \xrightarrow{k_{fm}} M_n + P_1$	$P_1 + M \xrightarrow{k_p} P_2$
$P_n + X \xrightarrow{k_{fx}} M_n + X$	$P_n + M \xrightarrow{k_p} P_{n+1} (n \geq 2)$
Chain termination	Chain transfer
$P_n + P_m \xrightarrow{k_{tc}} M_{n+m}$	$P_n + M \xrightarrow{k_{fm}} M_n + P_1$
$P_n + P_m \xrightarrow{k_{td}} M_n + M_m$	$P_n + X \xrightarrow{k_{fx}} M_n + C^*$
	$P_n \xrightarrow{k_{fs}} M_n + C^*$

I = initiator, R = primary radical, M = monomer, P_n = live polymer with chain length n, X = chain transfer agent, M_n = dead dead polymer with chain length n, C_0^* = active catalyst site, A = catalyst activator.

polymerization is not defined and the kth molecular weight moment of the copolymer is defined as

$$\lambda_k = \sum_{n=1}^{\infty}\sum_{m=1}^{\infty}(nw_1 + mw_2)^k \quad (5)$$

where w_1 is the molecular weight of monomer 1 (M_1) and w_2 is the molecular weight of monomer 2 (M_2). The number average and weight average molecular weights are calculated as: $\overline{M}_n = \frac{\lambda_1}{\lambda_0}$, $\overline{M}_w = \frac{\lambda_2}{\lambda_1}$. The ratio $\overline{M}_w/\overline{M}_n$ is a measure of MWD broadening and it is called the polydispersity. The mathematical techniques to derive the molecular weight moment equations can be found elsewhere.[2–4] For a linear and binary copolymerization system, the instantaneous chain length and composition distribution can be calculated using the modified Stockmayer bivariate distribution function given by:[5]

$$w(r,y) = (1 + y\delta)\tau^2 r\exp(-\tau r)\mathrm{d}r\frac{1}{\sqrt{2\pi\beta/r}}\exp\left(-\frac{y^2 r}{2\beta}\right)\mathrm{d}y \quad (6)$$

where $\beta = \overline{F}_1(1-\overline{F}_1)[1+4\overline{F}_1(1-\overline{F}_1)(r_1r_2-1)]^{1/2}$; $\delta = \frac{1-M_2/M_1}{M_2/M_1+\overline{F}_1(1-M_2/M_1)}$; $\overline{F}_1 =$ average mole fraction of monomer 1; M_1, M_2 = molecular weights of monomers 1 and 2; r = chain length; y = deviation from average copolymer composition ($=\overline{F}_1 - F_1$); and r_1, r_2 = reactivity ratios.

It should be pointed out that molecular weight averages do not necessarily represent the exact nature of polymer MWD. For example, it is possible that two polymer samples of different chain length distribution can have identical number and weight average molecular weights. In polymer industry, melt index (MI) is frequently used as a measure of polymer molecular weight or rheological properties. The melt index is the measurement of the flow rate in g/10 min of polymer flowing through a die at a given temperature under the action of a weight loaded onto a piston. Typical MI test conditions are 190/2.16, i.e., 190°C in temperature and 2.16 kg in weight. However, it is important to understand that MI is a viscosity at the particular shear rate and temperature employed in the test. Also, MI does not give any information about the elasticity of the polymer. Quite often in the polymer industry, MI is correlated with molecular weight averages (e.g., MI $= a\overline{M}_w^b$, where a and b are empirical parameters).

To illustrate the calculation of molecular weight averages using moment equations, let us consider a free radical polymerization of vinyl monomers. Table 3 shows the kinetic equations based on the kinetic scheme in Table 1 for initiator, monomer, and live and dead polymers; and the molecular weight moment equations for live and dead polymers. The molecular weight moment equations for other addition polymerization processes such as transition metal-catalyzed olefin polymerization can also be derived using the same method illustrated in Table 3.

By using the molecular weight moment equations, we can avoid the necessity of solving the infinite number of polymer population equations separately. A quasisteady state approximation is usually applied to live polymers and live molecular weight moments. Polymer molecular weight can also be calculated using the moment generating functions. If P_i denotes the discrete fraction of polymer of chain length i, the moment generating function is defined as $F_z \equiv \sum_{i=1}^{\infty} P_i z^i$. Then the kth moment is expressed as:

$$\lambda_k = \left[z\frac{\mathrm{d}^{(k)}}{\mathrm{d}z}F_z\right]_{z=1}$$

Heterogeneous Polymerization Systems

The modeling of heterogeneous polymerization systems is generally more complicated than that of the homogenous systems because mass and heat transfer effects between two or more immiscible phases must be considered. Industrially important heterogeneous polymerization reactions include emulsion polymerization, suspension polymerization, precipitation polymerization, and solid-catalyzed olefin polymerization. The general polymerization rate equation is represented simply as

$$R_\mathrm{p} = k_\mathrm{p} f([M],[A^*]) \quad (7)$$

where k_p is the polymerization rate constant, $[M]$ the monomer concentration, and $[A^*]$ the concentration of propagating centers. Both propagation rate constant and monomer concentration at active sites can be influenced by the presence of interfacial mass transfer effects. For example, in emulsion polymerization, the above general equation takes the following form:

$$R_\mathrm{p} = k_\mathrm{p} N_\mathrm{p} \overline{n} [M]_\mathrm{s} \quad (8)$$

where N_p is the number of polymer (latex) particles, $\overline{n}$ the average number of radicals per latex particle, and $[M]_\mathrm{s}$ the monomer concentration in polymer particles. Then, the question is how we can calculate these variables using the understanding of thermodynamics and the kinetics and mechanism of emulsion polymerization.[3,4,6] For example, to calculate the average number of radicals per polymer latex particle, we need

Table 3 Kinetic model equations for free radical polymerization

Kinetic equations	MW moment equations
$\frac{dI}{dt} = -k_d I$	$\frac{d\lambda_1^\ell}{dt} = k_i RM + (k_{fm}M + k_{fs}S)(P - \lambda_1^\ell) + k_p MP - (k_{tc} + k_{td})P\lambda_1^\ell$
$\frac{dR}{dt} = 2f_i k_d I - k_i RM$	$\frac{d\lambda_2^\ell}{dt} = k_i RM + (k_{fm}M + k_{fs}S)(P - \lambda_2^\ell) + k_p M(2\lambda_1^\ell + P) - (k_{tc} + k_{td})P\lambda_2^\ell$
$\frac{dM}{dt} = -k_i RM - k_p M\sum_{n=1}^{\infty} P_n - k_{fm}M\sum_{n=1}^{\infty} P_n$	$\frac{d\lambda_0^d}{dt} = \frac{1}{2}k_{tc}P^2 + k_{td}P(P - P_1) + (k_{fm}M + k_{fs}S)(P - P_1) = \frac{1}{2}k_{tc}P^2 + (k_{fm}M + k_{fs}S + k_{td}P)\alpha P$
$\frac{dP_1}{dt} = k_i RM - k_p MP_1 + (k_{fm}M + k_{fs}S)\sum_{n=2}^{\infty} P_n - (k_{tc} + k_{td})P_1\sum_{n=2}^{\infty} P_n$	$\frac{d\lambda_1^d}{dt} = \frac{1}{2}k_{tc}P^2(1-\alpha)^2\sum_{n=2}^{\infty} n(n-1)\alpha^{n-2} + k_{td}P^2(1-\alpha) \times \sum_{n=2}^{\infty} n\alpha^{n-1} + (k_{fm}M + k_{fs}S)P(1-\alpha)\sum_{n=2}^{\infty} n\alpha^{n-1} = \frac{1}{1-\alpha}\left[k_{tc}P^2 + (k_{fm}M + k_{fs}S + k_{td}P)P(2\alpha - \alpha^2)\right]$
$\frac{dP_n}{dt} = k_p M(P_{n-1} - P_n) - (k_{fm}M + k_{fs}S)P_n - (k_{tc} + k_{td})P_n\sum_{n=1}^{\infty} P_n (n \geq 2)$	$\frac{d\lambda_2^d}{dt} = \frac{P}{(1-\alpha)^2}[(k_{fm}M + k_{fs}S + k_{td}P)(\alpha^3 - 3\alpha^2 + 4\alpha) + k_{tc}P(\alpha + 2)]$
$\frac{dM_n}{dt} = (k_{fm}M + k_{fs}S)P_n + k_{td}P_n\sum_{n=1}^{\infty} P_n + \frac{1}{2}k_{tc}\sum_{m=1}^{n-1} P_m P_{n-m} (n \geq 2)$	where $\alpha \equiv \frac{k_p M}{k_p M + k_{fm}M + k_{fs}S + (k_{tc} + k_{td})P}$

(From Ref.[2])

to consider various physical transport processes such as radical transfer to and from a particle and radical termination inside and outside (aqueous phase) of a particle. To calculate the total number of latex particles, micellar nucleation as well as homogeneous nucleation kinetics needs to be understood. In emulsion polymerization, controlling the latex particle size distribution is one of the most important objectives because the particle size distribution can have a significant impact on the quality of coatings in final applications. Therefore, understanding the polymerization kinetics and complex thermodynamic and physical transport phenomena is more than a necessity in designing and operating emulsion polymerization processes. The kinetics of solid-catalyzed olefin polymerization is also quite complicated because of some physical effects such as catalyst fragmentation, monomer diffusion and sorption, and interfacial transfer resistances. In solid-catalyzed olefin polymerization, the rate equation is expressed as

$$R_p = k_p[M]_s[C^*] \tag{9}$$

where $[C^*]$ is the active catalytic site concentration and $[M]_s$ is the effective concentration of monomer at the catalytic site. Again, the question is how the reaction environment influences the rate constant, the monomer concentration at catalytic sites, and the active site concentration in the presence of intraparticle and interfacial mass transfer resistances, monomer sorption, disintegration of crystalline catalytic components, and heat transfer resistance.[7–10]

PARAMETER ESTIMATION IN POLYMERIZATION REACTION MODELING

One of the key tasks in polymerization reaction modeling is to determine or estimate the model parameters

including rate constants and relevant physical and thermodynamic parameters such as mass and heat transfer coefficients, diffusivity, density, heat capacity, active site concentrations, etc. Some kinetic parameters may change with a changing reaction environment. In transition metal-catalyzed olefin polymerizations, the kinetic parameters are catalyst dependent. Therefore, whenever a new catalyst is employed, a new set of kinetic parameters must be determined. Considering the fact that the properties of polyolefins are mostly dictated by the nature of the catalyst being used and that a large number of different types of catalysts are used for different polymer grades, we can easily understand the importance of having a well-established parameter estimation procedure that can be applied to any catalyst system. Quite often, a kinetic model validated on a small-scale laboratory reaction data provides poor predictions of a large-scale polymerization reactor. There are many reasons for such discrepancies but some notable reasons are differences in mixing performance (compositional and thermal heterogeneity), impurity levels, and mass and heat transfer resistances. In practice, the model parameters obtained from the laboratory data are used as a reference, and actual plant data are used to adjust the model parameters. To estimate the kinetic parameters, statistical experimental design techniques are highly recommended.

In some polymerization processes, developing a first principles model can be practically infeasible. For example, when several vinyl monomers are copolymerized using several free radical initiators, it is extremely difficult, if not impossible, to develop model equations to calculate the rate of polymerization and polymer properties such as molecular weight averages. Estimating the relevant kinetic parameters will be even more difficult than deriving the rate equations. In such cases, building a statistical model would be a more pragmatic approach. Of course, the statistical model should be used with some caution because it does not contain any physical or chemical information about the process in itself and the applicable process range can be quite narrow. Nevertheless, statistical models are frequently used in the polymer industry for quality control purposes.

CONTROL OF POLYMERIZATION REACTORS

Control of industrial polymerization reactors is a challenging task because, in general, control engineers lack rigorous polymerization process knowledge, process model, and rapid online or inline sensors to measure polymer properties. Exothermic polymerization processes often exhibit strongly nonlinear dynamic behaviors (e.g., multiple steady states, autonomous oscillations, limit cycles, parametric sensitivity, and thermal runaway), particularly when continuous stirred tank reactors are used.[11–15] Some polymerization processes are open loop unstable and susceptible to unmeasured disturbances or upsets even with a feedback controller in place. For example, in a transition metal-catalyzed olefin polymerization process, an unmeasured small amount of catalyst poisons can change the polymerization kinetics and hence the polymer yield and polymer properties. In worst cases, process disturbances may lead the reactor to instability.[16,17]

In polymerization processes, the primary goals of reactor control are to maintain stable reactor operations and main product quality indices at their target values. For an existing plant, improved reactor controls are needed to increase the polymer yield and to reduce production cost. As many of the polymer properties are hard to monitor online, first-level process variables are controlled. Typical reactor variables subject to control include polymerization temperature, pressure, feed rates of monomer(s), catalysts or initiators, chain transfer agents, solvents, etc. Both polymerization production rate and polymer properties are nonlinearly correlated and hence a polymerization process control system is inherently a multivariable control system. The primary control objective is to control temperature, pressure, and flow rates that can be readily measured online. The set points of these variables are often called the process recipe. In principle, as long as these variables are tightly controlled, consistent product quality can be warranted. However, in the presence of unexpected process disturbances or upsets, little can be done to correct the damages made on the product properties. The second-level control objectives include the direct control of polymer properties using online measurements or estimates of polymer quality indices. Any variations in the product quality can be corrected, in principle, if such quality indices are readily available during the polymerization. The reactor control objectives and control strategies may vary depending on the type of reactors. Table 4 illustrates typical control design issues for three different types of reactors.

Batch polymerization reactors are ideal to manufacture small volume polymers, specialty polymers, and polymers that are difficult to make in continuous reactors. Emulsion polymers, suspension polymers, and precipitation polymers are mostly made by batch polymerization processes. One of the disadvantages of a batch reactor is that the ratio of heat transfer surface area to reactor volume decreases as the reactor size is increased. For many polymer products made in batch reactors, the process economy improves with an increase in reactor size. Therefore, effective heat removal becomes a critical factor in designing and controlling a large-scale batch polymerization reactor.

In batch polymerization processes, examples of typical control objectives are 1) to maintain reactor

Table 4 Issues in reactor control designs

	Batch process	Semibatch process	Continuous process
Product type	Small volume specialty polymers; heterogeneous polymerization system (e.g., emulsion, suspension, precipitation)	Small volume specialty polymers; copolymers	Large volume commodity polymers; engineering polymers
Reaction phase	Liquid; liquid–solid	Liquid; liquid–solid	Liquid; gas phase; slurry phase
Typical reactor type	Mechanically agitated reactor with a heating jacket or condenser	Mechanically agitated reactor with a heating jacket or condenser	CSTR, tubular reactor, multiple CSTRs, fluidized bed reactor, loop reactor
Typical operations	Nonstationary dynamic process	Nonstationary dynamic process	Steady state
Control objectives	Design control trajectories; feedback tracking of control trajectories; time optimal control; temperature control	Design control trajectories; feedback tracking of control trajectories; time optimal control; optimal initial conditions	Design steady state operating conditions; maintaining steady state stability; grade transition controls; online property controls
Constraints	Batch time can be short; online property monitoring or product sampling can be difficult; reactor heat removal can be difficult for large reactors (small heat transfer area/reactor volume ratio); insufficient time for product quality analysis and corrective control	Batch time can be short; online property monitoring or product sampling can be difficult; reactor heat removal can be difficult for large reactors	Control failure leads to a large loss of product; online monitoring or direct properties control can be achieved; strong process nonlinearity; parametric sensitivity; oscillations; runaway reactions

stability (e.g., to avoid thermal runaway); 2) to obtain maximum polymer yield in minimal reaction time; and 3) to bring the product properties to their target values as closely as possible. In general, direct online control of polymer properties is not feasible in many batch polymerization processes. Even taking a sample can be quite a challenge in some high pressure batch reactor systems. A batch polymerization reactor should also be operated to maintain consistent batch-to-batch product quality and to maximize the product yield by increasing monomer conversion and/or reducing batch reaction time. The design of a batch polymerization reactor control consists of two stages: 1) offline design of a control trajectory (recipe); and 2) implementation and execution of the control trajectory. The control trajectory can be developed through experimentation, plant experience, or by using a process model.[18,19] A batch polymerization process is a multivariate and nonstationary or dynamic process. Quite often there may exist some conflicting control objectives (e.g., polymer yield, molecular weight, composition, batch reaction time) that require special treatments. For example, multiobjective dynamic optimization techniques can be used to develop optimal reactor operating policies or target control trajectories in the presence of conflicting control objectives.[20,21] Quite obviously, an accurate dynamic polymerization reactor model is a prerequisite for such advanced control designs. Many excellent dynamic optimization techniques have been developed and they are readily available to control engineers. A typical objective function (F) for reactor optimization takes the following form:

$$F = w_1 t_f + \sum_{i=1}^{N} w_i \left(\frac{Y_i}{Y_i^{\mathrm{d}}} \right)^2 \tag{10}$$

where w_i is the weighting factor, t_f the batch time, Y_i the product quality parameter (e.g., M_w, average copolymer composition, etc.), and Y_i^{d} the desired quality parameter value. The objective function is minimized

subject to process model and constraints:

$$\frac{d\mathbf{x}}{dt} = f(\mathbf{x}(t), \mathbf{u}(t), t); \quad \mathbf{c}(\mathbf{x}(t), \mathbf{u}(t), t) \leq 0 \tag{11}$$

where $\mathbf{x}$ is the state variable (e.g., concentration, temperature, molecular weight moments, etc.) and $\mathbf{u}$ the control variable. Fig. 1 illustrates the design of optimal reactor temperature trajectories to obtain a desired molecular weight distribution in a batch methyl methacrylate polymerization process.[18] Here, the feasible sequential quadratic programming (FSQP) technique is used to find the sequence of optimal reactor temperature set points that will yield the best match between target and actual polymer chain length distributions at the end of the batch. The graphs on the left in Fig. 1 represent the computed sequence of reactor temperature set points at selected iterations, and the graphs on the right show the resulting chain length distribution compared with the target distribution. The final temperature set point program can be implemented and executed, or the trajectory can be updated online if timely measurements or estimates of polymer molecular weight distribution are available during the batch operation. Once the reactor control trajectory is designed, the next goal is to execute the trajectory as

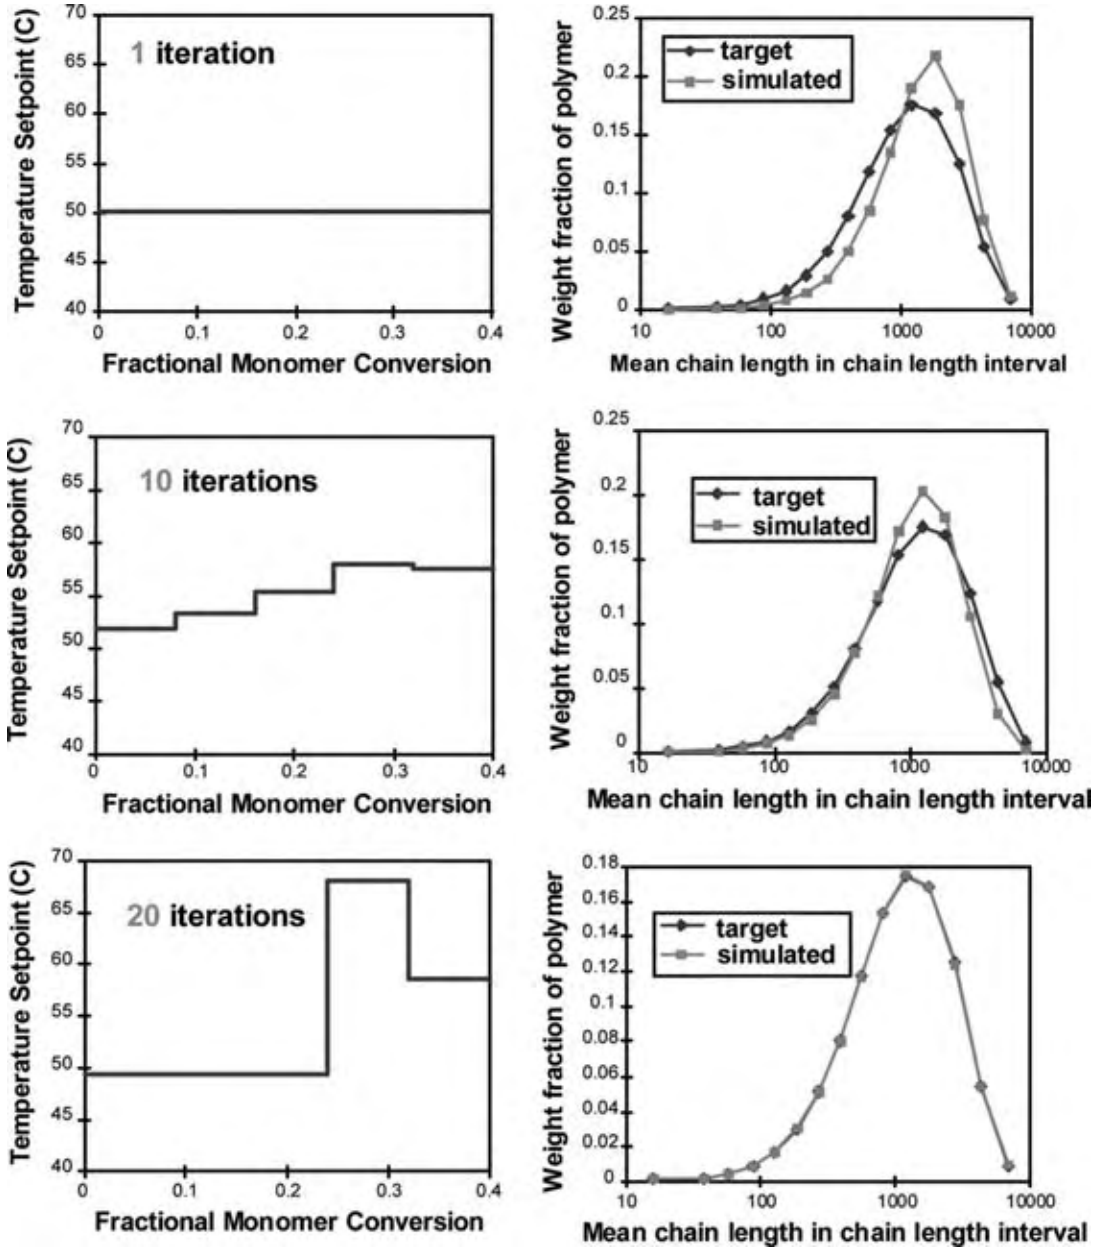

Fig. 1 Design of optimal batch polymerization reactor controls. *(View this art in color at www.dekker.com.)*

close to the design as possible. Traditional PID controllers are still widely used, but model predictive controllers (MPC) are also used in some polymerization processes where the use of advanced reactor control can be economically justified. In MPC, a process model is utilized to predict the output into the future and minimize the difference between the predicted model output and the desired output using some open loop objective function. The measurement is used to update the optimization problem for the next time step. The MPC algorithms are reasonably well developed and utilized in many chemical processes including polymerization processes.[22–27] As industrial polymerization processes exhibit strong nonlinearity, the application of linear model predictive control (LMPC) is often limited, particularly for grade transition control and for regulatory control. In nonlinear model predictive control (NMPC) algorithms, a nonlinear programming problem has to be solved online and hence computational load is generally quite heavy. To reduce the computational burden, a successive linearization of the original nonlinear process model can be used to approximate the nonlinear process behaviors.[23,25] As batch reactors are widely used to make specialty polymers of various grades, designing optimal batch scheduling is also an important issue.

Continuous reactors are operated at steady state, and hence the key objective in controlling a continuous polymerization reactor system is to maintain reactor stability in the presence of any process upsets and during normal steady state operations and grade transition operations. In some continuous polymerization processes such as liquid slurry olefin polymerizations, reactor fouling may develop over a period of time, gradually decreasing the control performance. In such a case, one may adjust the control variables to compensate for the changes in process characteristics. Then, some polymer property indices that are not directly measured or controlled online may drift from their specifications to result in poor product quality. Therefore, the development of online estimation techniques for polymer property indices that cannot be measured online or can be only measured offline with significant time delays becomes necessary.

In continuous polymerization processes, polymers of different properties are manufactured in a single product line. Therefore, the design of efficient grade transition controls and optimal production scheduling becomes another important control design objective. In some sense, the grade transition control problem is similar to the optimal design of a batch polymerization reactor control. Input–output models or transfer functional models are widely used to develop a multivariable control system. As such linear models are the approximations of highly nonlinear polymerization processes, the linear controllers have some limitations. Polymerization processes are multivariable systems in nature, and thus significant control loop interactions are expected in conventional feedback control systems. One of the most instructive examples that illustrate the value of a process model is the work by Congalidis et al. on the design of feedforward and feedback control of a continuous solution copolymerization reactor using a multivariable transfer function model.[28] They analyzed control structure/loop pairings using singular value decomposition and relative gain array. Then, loop pairings are determined and a combined feedforward/feedback strategy is developed for servo- and regulatory control problems. For a continuous terpolymerization process, Ogunnaike[27] illustrates an interesting control scheme that involves a two-tier system. In the first tier level, the flow rates of monomer, catalyst, solvent, and chain transfer agent are used to regulate reactant composition in the reactor. Then, at the second tier level, set points for the composition of the reactor contents are used at a less frequent update rate to regulate final product properties. In the second tier, an online, dynamic kinetic model running in parallel with the process supplies estimates of product properties. The model predictions are updated using delayed laboratory measurements and online stochastic filter.

Polymerization process control can benefit significantly from using online state estimation techniques. In general, online control of polymer properties such as molecular weight, MWD, copolymer composition, MI, density, etc. is difficult, mainly because of the lack of adequate online or in-process sensors.[29] Therefore, many of these polymer property parameters are controlled indirectly by controlling first-level process variables such as temperature, pressure, and the flow rates of various reactants, solvents, and catalysts. When some deviations in polymer properties are detected through laboratory sample analysis, certain reactor variables need to be adjusted. Extensive plant experience might be required to make such process adjustments, or model-based online state estimator can be used.

One alternative to the direct online measurement of polymer properties is to use a process model in conjunction with optimal state estimation techniques to predict the polymer properties. Indeed, several online state estimation techniques such as Kalman filters, nonlinear extended Kalman filters (EKF), and observers have been developed and applied to polymerization process systems.[30,31] In implementing the online state estimator, several issues arise. For example, the standard filtering algorithm needs to be modified to accommodate time-delayed offline measurements (e.g., MWD, composition, conversion). The estimation update frequency needs to be optimally selected to compensate for the model inaccuracy. Table 5 shows the extended Kalman filter algorithm with delayed offline measurements. Fig. 2 illustrates the use of online state estimator

Table 5 Extended Kalman filter algorithm with online and offline measurements

Process model	$\frac{dx}{dt} = f(x,u) + w(t), \quad w(t) \sim N[0, Q(t)]$ $x(0) \sim N[\tilde{x}_0, P_0]$
Online measurements	$y_{o,k} = h_0(x_k) + v_{0,k}; \quad v_{0,k} \sim N[0, R_{0,k}]$
Delayed measurements	$y_{d,k-\tau} = h_0(x_{k-\tau}) + v_{d,k-\tau}; \quad v_{d,k-\tau} \sim N[0, R_{d,k-\tau}]$
State estimation propagation	$\frac{d\hat{x}}{dt} = f[\hat{x}(t), u(t)]$
Error covariance propagation	$\frac{dP}{dt} = F(t)P(t) + P(t)F^T(t) + Q(t)$
State estimate update with online measurements	$\tilde{x}_k(+) = \tilde{x}_k(-) + K_k[y_{0,k} - h_0[\tilde{x}_k(-)]]$
Error covariance update with online measurements	$P_k(+) = [I - K_k H_{0,k}]P_k(-)$
Filter gain matrix with online measurements	$K_k = P_k H_{0,k}^T \left[H_{0,k} P_k(-) H_{0,k}^T + R_{0,k}\right]^{-1}$ where $F(t) = \left.\frac{\partial f[x(t), u(t)]}{\partial x(t)}\right\|_{x(t)=\tilde{x}(t)}$ $H_{0,k} = \left.\frac{\partial h_0(x_k)}{\partial x_k}\right\|_{x_k=\tilde{x}(-)}$

(i.e., EKF) with delayed molecular weight measurements in a continuous stirred tank styrene polymerization reactor.[30] In this particular simulation, the minimum offline measurement time is set as 30 min and irregular sampling intervals are assumed. Two models with different parameters are used for plant simulation (dotted lines) state estimation (solid lines). Fig. 2 clearly shows that polymer molecular weight can be estimated online with EKF and delayed offline measurements as long as a reasonably good process model is available. In general, frequent sample analysis is necessary when a relatively inaccurate process model is used for state estimation and less frequent sample analysis is necessary when a relatively accurate process model is used.

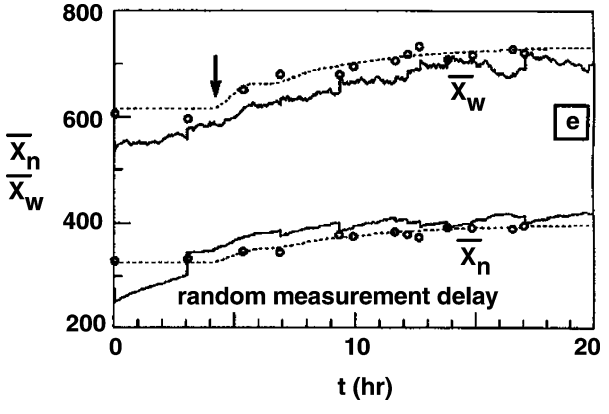

Fig. 2 Online state estimation simulations for a continuous stirred tank styrene polymerization reactor with extended Kalman filter.

The state estimation technique can also be incorporated into the design of optimal batch polymerization control system.[18,19] For example, a batch reaction time is divided into several control intervals, and the optimal control trajectory is updated online using the molecular weight estimates generated by a model/state state estimator. Of course, if batch reaction time is short, such feedback control of polymer properties would be practically difficult to implement. Nevertheless, the online stochastic estimation techniques and the model predictive control techniques offer promising new directions for the improved control of batch polymerization reactors.

CONCLUSIONS

Mathematical modeling is a powerful tool not only for the development of process understanding but also for that of the advanced reactor controls in polymerization processes. The modeling techniques for polymerization processes are reasonably well developed and several commercial simulation packages are available. The modeling of heterogeneous polymerizations such as precipitation polymerization and emulsion polymerization remains a challenge. In the past decade, excellent

design tools have also been developed for multiobjective optimization, online state estimation, and model predictive control. These techniques are gaining favorable acceptance in the polymer industry. One of the outstanding issues is to develop more efficient parameter estimation techniques, particularly in a plant environment without disturbing normal process operations.[31] Almost all the computational and modeling tools are available: the question is how one can use them wisely and creatively to produce the polymers of the highest quality at the lowest possible cost.

It is also instructive to understand that advancing the industrial polymerization process technology is often hampered because of the lack of fundamental research activities in academic and industrial laboratories. For example, in the manufacturing of poly(vinyl chloride), which is still an important and huge industry, controlling the polymer particle morphology and designing new properties are strongly needed. However, our understanding of polymerization kinetics and mechanisms remains little changed since 1980s because little research has been carried out on the polymerization of vinyl chloride in recent years. Many people believe that there should be nothing that is not understood about the polymers that are more than 50 years old, which is not quite true. With a tight economy, many companies can no longer afford advanced research and development on such old but profitable commercial polymers.

Polysaccharides

Anton Huber
PolySaccharide Initiative, Institut für Chemie, Karl-Franzens, Universität Graz, Graz, Austria

INTRODUCTION

The major part of annually assimilated biomass/renewable resources comprises polysaccharides/carbohydrates. These materials are produced, transformed, and utilized by all organisms in biosphere Earth. Although the most important producers with respect to quantities produced are green plants, polysaccharides are made by living organisms at all levels of organization by enzymatically catalyzed biochemical mechanisms in a complex aqueous environment. Estimations of global annually formed polysaccharides are in the range 100–300 Gt dry matter, which is approximately two magnitudes more than the estimated annual crude oil production of approximately 2 Gt.

Polysaccharides have no outstanding or obviously spectacular property, such as is the case with nucleic acids (genetic code) and many proteins (biocatalysts), but they have a wide range of functionalities in practically all biological transformation processes. They are involved in functionally structuring cell compartments by forming the following: matrices with varying resistance towards chemical, mechanical, or thermal stress; dynamic supermolecular soft gel structures and mucilages; rigid protective construction elements such as fibers and crystalline structures; decorative structures on surfaces; and interfaces with selective permeability.

In terms of material properties, polysaccharides are ''high-performance'' materials with superior features:

- High flexibility at the molecular level.
- Sufficient sensor and amplification quality.
- Appropriate ''smart'' response capability.
- Assembly and transformation at the molecular level.

The diversity of polysaccharides at the molecular level is due to the simple basic elements from which they are built. Abundant and ubiquitously available carbon (dioxide), oxygen, hydrogen, and H_2O, with contributions from phosphorus (P), sulfur (S), and nitrogen (N) at different states of oxidation (global distribution of C: 9.5%, H: 63%, O: 25.5%, N: 1.4%), are the building blocks for ''on-demand'' formation and transformation of natural carbohydrates, primarily by green plants and algae. The polysaccharides constituting carbohydrates contain simple functional groups: hemiacetal/hemiketal and alcoholic hydroxyl groups that can be oxidized or reduced. A chiral center at the hemiacetal/hemiketal position provides two anomeric forms (α, β) of each glycosyl residue. These have no noteworthy differences as regards usual laboratory chemistry; however, the chirality is of great significance during polymerization of the residues. The variety of polysaccharides additionally becomes practically unlimited when one considers, in combination, the heterogeneities in the degree of polymerization, branching characteristics, substitution patterns, and variations in the distribution of redox states along polysaccharide-constituting glycosyl residues.

The efficient sensor and amplification qualities of polysaccharides in different conditions in the aqueous environment are established by their pronounced and varied interactions with H_2O. This results in dynamic formation and disintegration of soft gel structures and extremely long-range interactions. In highly organized biological systems, specific glycosyl patterns on interfaces and surfaces of protein and lipid domains, such as on membranes and cell walls, can act as triggers for immune reactions. The formation and disintegration of polar and apolar glycosyl domains enable preferred docking to polar and apolar sites, respectively.

The ''smart'' response capability of polysaccharides upon application of stress allows polar and apolar domains to easily form or disintegrate due to variation of the order/disorder ratio at the molecular level. This finally results in variation of specific crystallinity index or crystalline/amorphous ratio at the macroscopic level. Significant variation of interactive properties may even be achieved by minor variation of branching characteristics, which changes surface/volume ratio and, hence, preferences for inter- or intramolecular stabilization. Additionally, a rather effective response option is variation of relative percentages of molar and mass fractions by limited degradation/reorganization or precipitation/dissolution transition.

Assembly and transformation of polysaccharides by molecular-scale tools is triggered by principles of self-organizing complex systems and include enzymatically catalyzed nonlinear formation/transformation and degradation based on molecular-level library command sequences (genetic code).

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039773

CONSTRUCTION AND NOMENCLATURE

Polysaccharides are formed by glycosidically linked carbohydrate (glycosyl) residues. As expected, the nomenclature of polysaccharides is based on the nomenclature of carbohydrates. The recommendations of the International Union of Pure and Applied Chemistry–International Union of Biochemistry and Molecular Biology Joint Commission on Biochemical Nomenclature (IUPAC–IUB JCBN) have been published[1–4] and are open to the public at http://www.chem.qmul.ac.uk/iupac/2carb/39.html.

The major basic building blocks for oligo- and polysaccharides (glycans) are D-glucopyranose (α-D-Glc*p*, β-D-Glc*p*) and D-fructofuranose (β-D-Fru*f*), either α- or β-glycosidically linked (Fig. 1). Any of the hydroxyl groups at each glycosyl residue (for the case of two (1→4)-linked glucosyl units: C2, C3, and C6 (Fig. 2A) in an oligo-/polysaccharide may be subject to oxidation/reduction, activation, substitution, or the formation of additional glycosidic linkages. In the formation of "second-order" glycosyl glycosides, branching is an important option; however, this is just one out of many possibilities, such as:

- Oxidation at the terminal secondary alcoholic hydroxyl group (C6-OH) to uronic acid (Fig. 2B).
- Substitution to increase charge density (polarity) with acetate groups [–O–C(=O)–CH_3] (Fig. 2C).
- Introduction of an amino (–NH_2) (Fig. 2D) or *N*-acetyl (Nac) (Fig. 2E) group at the C2-OH, compatible to peptide linkages.
- Substitution to reduce polarity/increase hydrophobicity by reducing –OH groups to the deoxy form (–H) or substitution with methyl groups (–CH_3).
- Activation by formation of sulfates [–O–(O=)S(=O)–O′] (Fig. 2F), phosphates [–O–(OH–)–P(=O)–O′] (Fig. 2G), or nucleosides.

There is no strict transition from oligo- to polysaccharides. However, oligosaccharides are typically

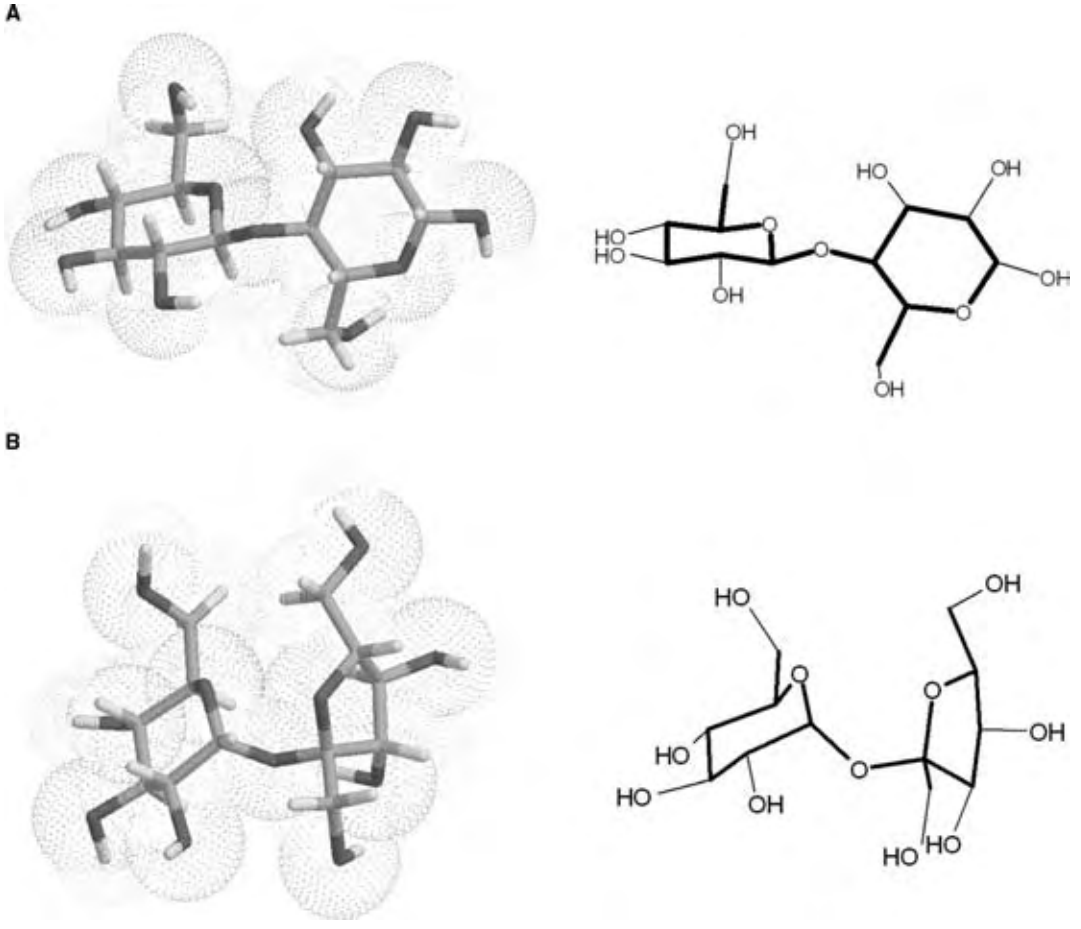

Fig. 1 Basic glycosyl residues and common glycosidic linkages: (A) β-D-Glc*p*-(1→4)-β-D-Glc*p*→β-D-glucopyranosyl-(1→4)-β-D-glucopyranose (cellobiose); (B) α-D-Glc*p*-(1→2)-β-D-Fru*f*→α-D-glucopyranosyl-(1→2)-β-D-fructofuranosid (sucrose). well-defined chemical compounds, whereas "polysaccharide" indicates multiple and superimposed heterogeneity, in particular, distributions in degree of polymerization, branching characteristics, and/or distribution of substituents and more or less oxidized glycosyl residues. Oligosaccharides and polysaccharides formed by sequences of identical or varying glycosyl residues are termed homo-oligomers/polymers and hetero-oligomers/polymers, respectively. The number of glycosyl residues is considered the degree of polymerization (dp) of a polysaccharide. However, if there is a repeating sequence consisting of several (different) glycosyl residues, this block is the reference for the degree of polymerization. The label for polysaccharides is obtained by replacing the terminal "-ose" of the glycosyl-residue parent compound with "-an." So, for instance, xylans are the homopolysaccharides formed from xylosyl residues. The terminal "-an" also indicates nonsubstituted polysaccharides. If, as for xylans, non-acetylated as well as partially acetylated forms occur, xylan refers to the non-acetylated material, and xylan acetate the acetylated derivatives. The major linkage in a polysaccharide may be indicated in the label, such as β-(1→4)-D-glycan for the glucosyl residues in cellulose. Polysaccharides entirely composed of uronic acid residues are labeled "-uronic acids." Hence, the generic name for a polysaccharide formed by glucuronyl residues is "glucuronan." However, well-established names such as cellulose, starch, inulin, chitin, amylose, and amylopectin are still used.

Although the basic qualities of polysaccharides are determined by the chemical functionality of the glycosyl residues constituting the polymers, there is another specifically polymer-related dominating property: a non-negligible excluded volume effect. Polysaccharides occupy volume; in particular, in aqueous environment, they transform rather large compartments into functional phase spaces. At the molecular level, this performance is controlled by many parameters, in particular, the following:

- Molecule geometry (they are present as regular helices and β-sheets or as irregular packed coils of varying density).
- The capacity to form polar/apolar domains.
- The optional presence of compatibility groups such as Nac.
- Pronounced and well-differentiated interactions with H_2O at different layers.
- Simple variation of local molar and mass concentrations and solubility status.

The kind of glycosyl residues and the anomeric type of glycosidic linkage in particular lead to the formation

of three basic polysaccharide conformations:

- Helical domains.
- Elongated β-sheet domains.
- Irregular, rather compact, structures of varying packing density.

The helical domains are typically stabilized by the association of several helices, internal H bonds, and strongly bound (immobilized) water. In aqueous medium, these polysaccharides tend to form dynamic supermolecular structures, in particular (soft) gels (Fig. 3A).

The elongated β-sheet domains are typically stabilized in supermolecular structures by a large number of intermolecular H bonds. Such polysaccharides are typically insoluble and form highly ordered compact structures with a rather high crystallinity index; solubility is increased if branches break the basic β-sheet symmetry (Fig. 3B).

The irregular, rather compact, structures of varying packing density are formed by more or less pronounced branching: Branches are symmetry breakers for both helical and β-sheet domains (Fig. 3C). Branching perturbs hydrophilic or hydrophobic domains and may shift material quality from ''crystalline'' to increasingly ''amorphous.'' This corresponds to a change in the preferences to stabilize their conformation: intermolecular for highly ordered helices and β-sheets; intramolecular for irregular branched structures. Whereas branching, in particular short-chain branching (scb), boosts the solubility of polysaccharides in aqueous medium, minor or no branching results in bad solubility and pronounced tendency to form supermolecular structures.

Polysaccharides may be classified in different ways. A reasonable classification refers to occurrence and dominant functionality:

- Surface/interface and bodywork structuring plant polysaccharides.
- Protective skeleton-forming chitin/chitosan of invertebrates such as arthropods.
- Extended energy repositories in eucaryotic cells, in particular those of green plants.
- Plant gums: ''response compounds'' for immediate protection upon damage or attacks and for regeneration.
- Microbial exopolysaccharides (EPSs) with cation-sequestering capabilities and protection and recognition activities.
- Functional glycosaminoglycans (GAGs), in particular, glycolipids, peptidoglycans, and proteoglycans participating in the modulation of biological process in eucaryotic cells.

POLYSACCHARIDES IN AQUEOUS ENVIRONMENT

Due to their high content of oxygen, polysaccharides are basically expected to be well soluble in polar solvents, in particular in aqueous medium. Indeed, polar groups, such as hydroxyl, uronyl, and phosphate groups, are potential partners for solvent H_2O molecules; they are also involved in the formation of inter- and intramolecular H bonds by –OH groups. An H bond is established by an H atom in a polar compound that is rather strongly attracted by two other atoms. The hydrogens in H_2O, for instance, are basically bound covalently to an oxygen atom (approximately $500\,kJ\,mol^{-1}$) but additionally may be attracted by oxygen atoms of neighboring water molecules or by similar polar attractor atoms in their environment. Such an attraction establishes a ''link,'' for instance, between two water molecules, via the H atom and is dominated by electrostatic forces (approximately 90%) with minor covalent contributions (approximately 10%). The approximately $23\,kJ\,mol^{-1}$ significantly exceeds van der Waals forces (approximately $1.3\,kJ\,mol^{-1}$). However, the electrostatic/covalent ratio is permanently fluctuating as, for instance, any influence that decreases the primary O–H bond length increases the covalent character. The de facto strength of each H bond is primarily controlled by the distance between H atom and attractor atom and decays exponentially, with minor angular dependence. Bonds exceeding 0.31 nm may be considered ''broken'' or ''not established.''[5–13]

In the natural environment, water is an integral component of polysaccharides and occurs in many forms:

- Strongly bound dense water, associated with ''amorphous,'' strongly hydrogen-bonding groups, in particular, charged groups such as uronyl, sulfate, phosphate, acetyl, or pyruvic.
- Weakly bound low-density water, associated with the dense water layers.
- Strongly bound low-density water, associated with oriented, strongly hydrogen-bonding groups, in particular, charged groups.
- Weakly bound low-density water, associated with hydrophobic groups or domains.
- Nonstabilized mobile water in hydration boundary conditions, limited to compartments within and in the vicinity of polysaccharides.

Due to these interactions, even for low polysaccharide concentrations, the aqueous medium becomes a functional phase space with stabilizing consequences for the affected compartment. This results in significantly reduced diffusion or even immobilization of

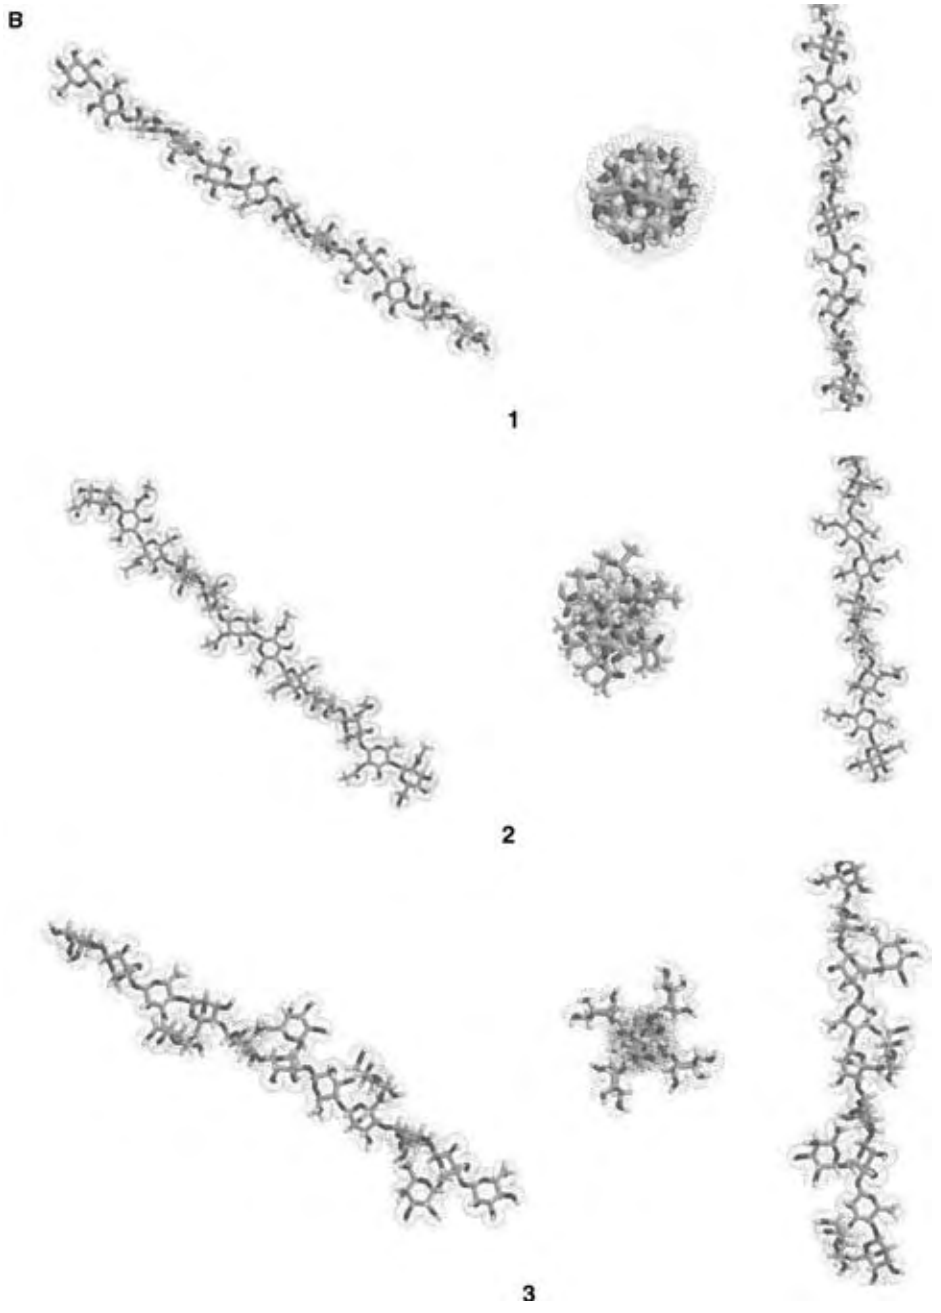

Fig. 3B *(Continued next page.)*

compounds. Phenomenologically, the formation of (soft) gels is observed. In particular, strongly bound water interacting with hydrophobic surfaces/interfaces forms junction zones and compartments of ''captured'' water clusters and increases the capability of polysaccharides to form supermolecular structures. Interaction of polar or charged groups located near hydrophobic domains with water results in isolation of these hydrophobic partitions by a zone of low-density water next to them, incapable of forming junction zones. Such structuring hydration makes polysaccharides more or less impenetrable to neighboring polymers. However, similarly hydrated polysaccharides tend to ''combine'' their hydration layers and may form rather huge supermolecular structures. If such aggregation is prevented, the alternative is phase separation and, hence, more (crystalline) or less (amorphous) ordered precipitation of polysaccharides. Hydration is controlled by equilibrium distances between polysaccharide molecules. Each equilibrium distance is the result of two antagonistic classes of forces: attractive short-range ($1/r^6$ decay) van der Waals forces and repulsive long-range ($1/r$ decay) electrostatic Coulomb forces (Fig. 4). Hence, the solubility

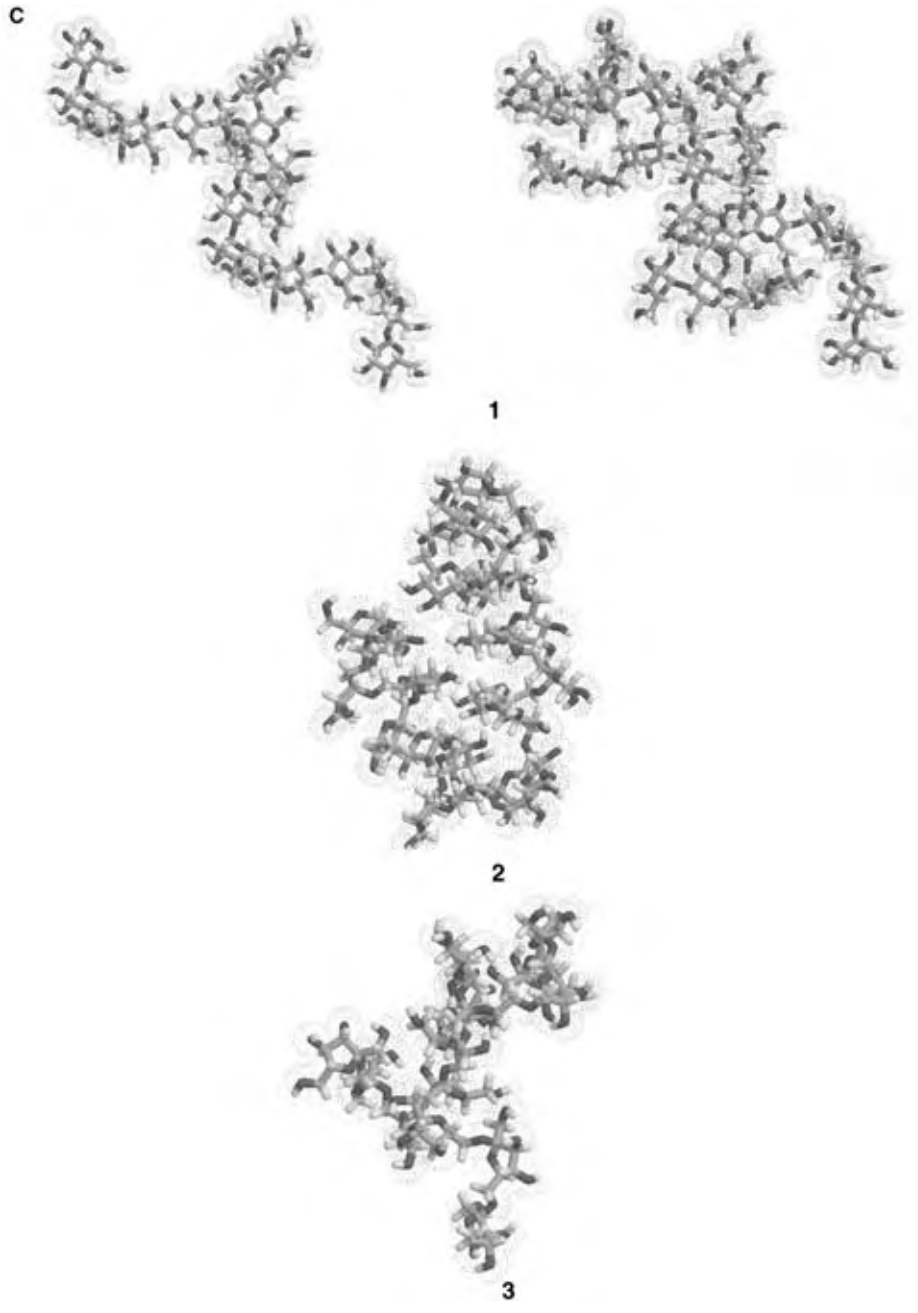

Fig. 3C *(Continued.)*

of polysaccharides in aqueous medium may be controlled by manipulation of electrostatic and van der Waals forces.

MATERIAL CHARACTERISTICS AND POLYSACCHARIDE CONCENTRATION

In particular with respect to the fact that H_2O is an integral component of the morphology and functionality of polysaccharide-containing compartments, the dependence of material characteristics on the de facto concentration or volume fraction of polysaccharides needs to be distinguished. Eq. (1) provides a scheme for a power law of controlling influences of de facto occupied/functionalized compartments (V_e):

$$V_e \propto \frac{ip}{c} md^{mc} \quad (1)$$

where V_e is the sphere-equivalent excluded volume (occupied/functionalized compartment), ip the interactive potential, c the concentration/volume fraction, md the molecular dimension (e.g., degree of polymerization), and mc the molecular conformation (e.g., helix, β-sheet, irregular).

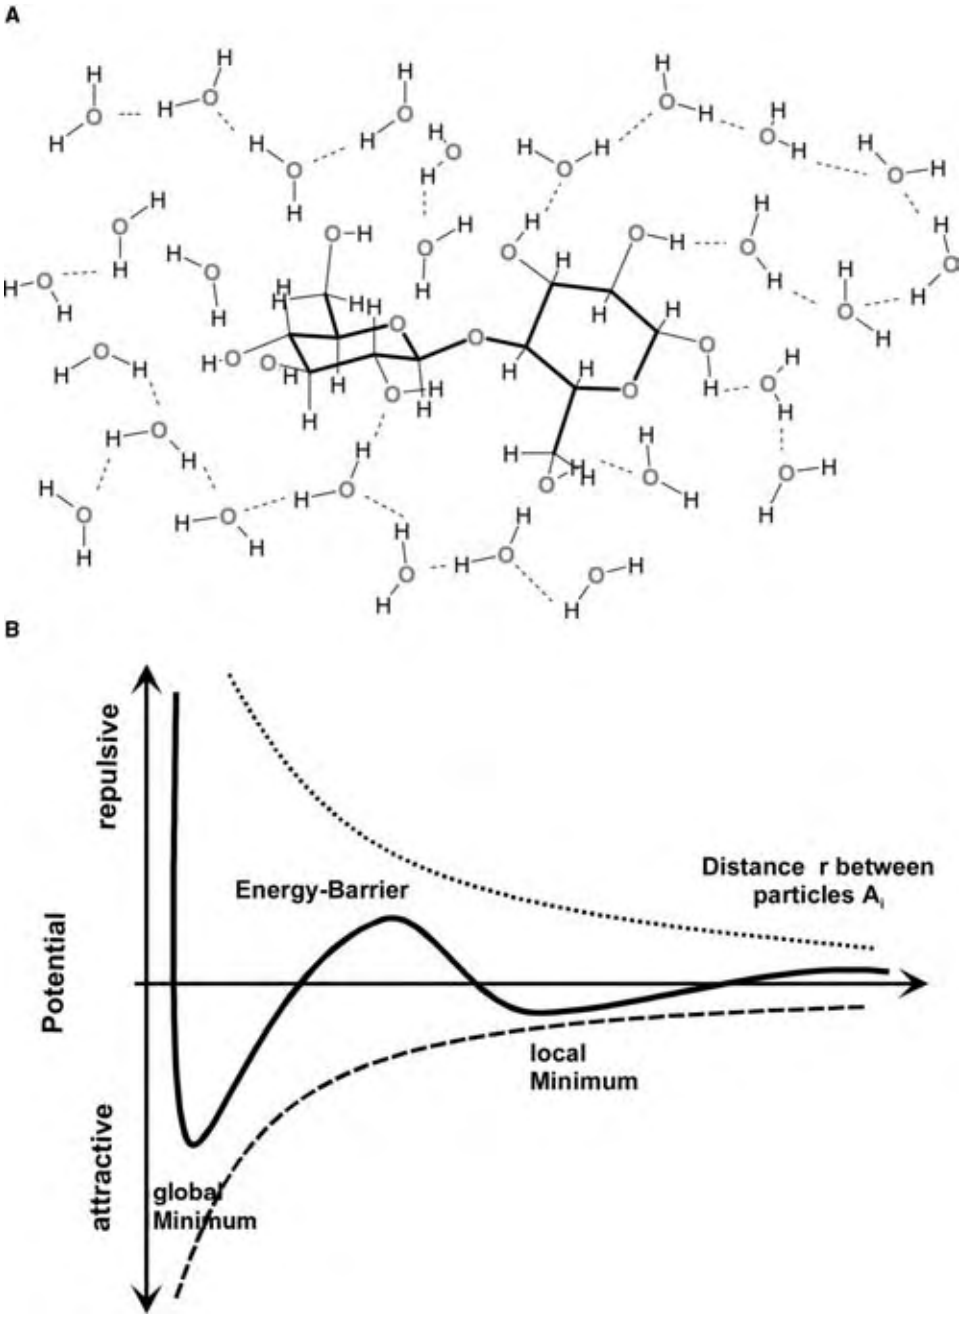

Fig. 4 Solubility of polysaccharides in aqueous medium. (A) Hydration/possible H bonds for a sequence of D-Glc*p* β(1→4)-D-Glc*p* (cellobiose). (B) Scheme for calibration of equilibrium distances due to repulsive electrostatic and attractive van der Waals forces. (Chemistry: MDL ISIS/draw. Graphics: Macromedia Fireworks.) *(View this art in color at www.dekker.com.)*

The correlation of material characteristics with de facto concentration of polysaccharides is best discussed for three regimes and limiting concentrations (Fig. 5).

In the limiting case of very dilute concentration (c_0), close to ideal conditions, interaction between polysaccharide molecules may be considered negligible, and material qualities are primarily correlated with isolated and independent conformations and dimensions of individual polysaccharide molecules.

In the range up to overlapping concentration ($c_0 - c^*$), macroscopic material qualities become increasingly influenced by polysaccharide–polysaccharide interaction phenomena. However, individual polysaccharide molecules typically do not overlap. Experimentally observed molecular and supermolecular characteristics shift away from values obtained at very dilute concentrations and become apparent values. Extrapolation with serial expansion coefficients with respect to polysaccharide concentration is an appropriate approach to obtain "ideal" ($c \rightarrow 0$) information from apparent values, and linear extrapolation works rather well, at least as a first-order approximation.

In the regime exceeding c^* ($c^* - \phi = 1$), concentration (c) is typically replaced by volume fraction (ϕ), and the polysaccharide fraction becomes equivalent

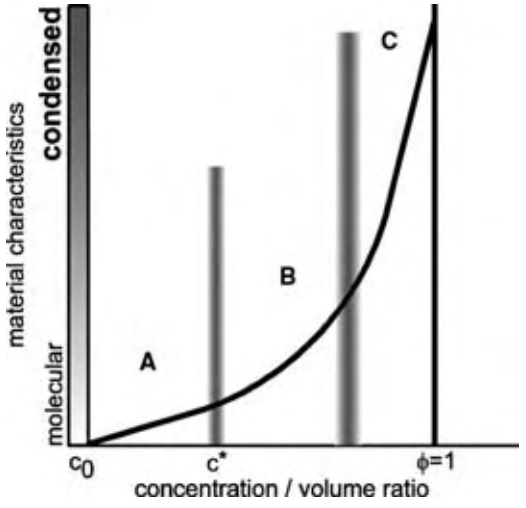

Fig. 5 Correlation of material characteristics with polysaccharide concentration. Concentration regimes [c_0: very dilute, close-to-ideal solutions; A: dilute; B: beyond overlapping concentration; C: dense systems (condensed/solid phase); volume ratio $\phi = 1$] and the consequences on observed material qualities: dependence on isolated molecule properties at close-to-ideal conditions (c_0) and increasing dominance of effects of supermolecular structures with increasing concentration. (Graphics: Macromedia Fireworks.) *(View this art in color at www.dekker.com.)*

in magnitude or even dominant with respect to total mass. Performance of such dense systems is dominated by long-range correlations, lifetime of correlations, formation and disintegration of domains, interfaces and surfaces, order of domains in terms of crystalline/amorphous ratio, and an increasing number of optional critical states with highly nonlinear response. In contrast to many other polymers, polysaccharides do not form melts at high volume ratio, but turn into interpenetrating H_2O-containing phases with complex dynamics.

Finally, for volume fractions of ϕ close to 1.0, polysaccharides typically form coexisting amorphous and crystalline phases, always containing several percent H_2O. Hence, $\phi = 1$ is practically never observed under natural conditions, and if H_2O content is reduced too much by technological processes, the system collapses and becomes ''insoluble'' forever.

HETEROGENEITY OF POLYSACCHARIDES: DISTRIBUTIONS AND MEAN VALUES

A polysaccharide is never a distinct compound, but typically consists of many similar fractions with respect to more or less any molecular characteristic. Hence, polysaccharide characteristics are characteristics of (superimposed) distributions and cannot be reduced to clearly defined, distinct values. So, for instance, polysaccharides do not have a single ''true'' molecular weight but consist of a molar mass distribution. As communication of distributions is rather tedious, mean values are often used instead, but these values must not be misunderstood as distinct ''true'' values. There are several ways to compute or determine mean values, but usually they are correlated with different moments of a distribution and indicated by either ''n'' (referring to number fractions of distributed components) or ''w'' (referring to mass fractions of distributed components). Additionally, each distribution of mass fractions may be transformed into distribution of molar fractions and vice versa if the molar mass of the fractions is known.

Hence, molecular weight, which is handled as molar mass distribution (MWD) or degree of polymerization distribution (dpD), is an important characteristic of polysaccharides (Fig. 6A). For practical purposes, molar mass distributions are expressed in either differential form (_d), with mass fractions [Eq. (2a)] or molar fractions [Eq. (2b)] represented by the normalized area (1.0), or integral form (_i), with accumulated percentages represented by the normalized height (maximum height = 1.0).

$$\int_0^\infty m(M)\mathrm{d}M = m\text{–MWD–d} = 1.0 \tag{2a}$$

$$\int_0^\infty n(M)\mathrm{d}M = n\text{–MWD–d} = 1.0 \tag{2b}$$

where MWD represents molecular weight distribution, m_ the mass fraction, n_ the molar (number) fraction, and _d the differential fraction.

Computation of the moments provides mean molar mass values, in particular, number-average molecular weight [M_n; Eq. (2c)] and weight-average molecular weight [M_w; Eq. (2d)]:

$$\text{number} - \text{average molecular weight} : \overline{M}_n = \frac{\sum n_i M_i}{\sum n_i} \tag{2c}$$

$$\text{weight} - \text{average molecular weight} : \overline{M}_w = \frac{\sum n_i M_i^2}{\sum n_i M_i} \tag{2d}$$

Additionally, molecular weight at the maximum of the differential form of distribution of mass fractions is often designated the peak molecular weight (M_p), and fraction percentages may indicate critical fractions of low- or high-molecular contributions.

Appropriate information about conformational aspects of dissolved polysaccharides may be obtained by means of a double logarithmic graph of molar mass

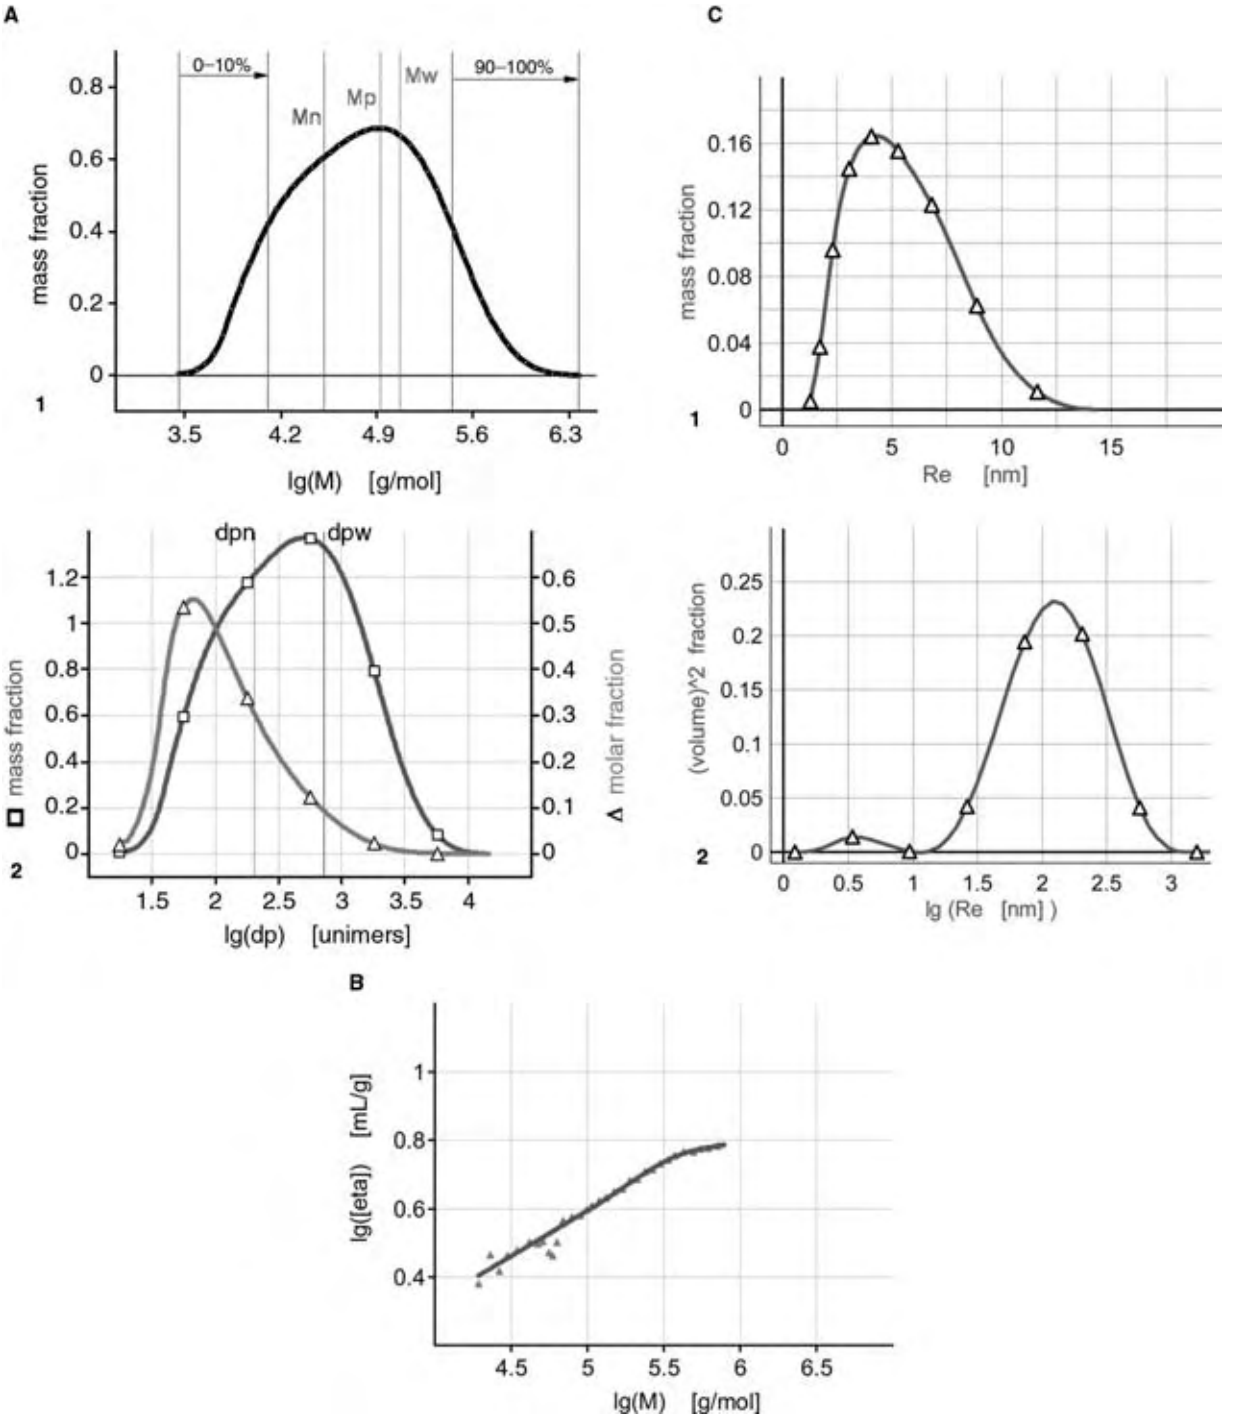

Fig. 6 (A) (**1**) Distributions, mean values, and fractions: normalized differential molar mass distribution of mass fractions (m_MWD_d); number-average molecular weight (M_n), weight-average molecular weight (M_w), molecular weight at maximum of differential molar mass distribution (M_p); 10% fraction of low molar mass components; 10% fraction of high molar mass components. (**2**) Degree of polymerization distribution derived from molar mass distribution: distribution of mass fractions (m_dpD_d), distribution of molar fraction (n_dpD_d); mean values: weight-average degree of polymerization; number-average degree of polymerization. (B) Conformation plot for aqueous, dissolved, highly short-chain, branched starch glucan: experimental data of corresponding lg(M) and lg([η]) values and least-squares fit to the data provide slope ($\equiv$ Staudinger–Mark–Houwink exponent $a = 0.29$) and intercept [$\equiv$ Staudinger–Mark–Houwink factor $K = 0.16$ (ml mol g^{-2})], indicating a rather compact, intramolecular-stabilized packing of the glucan coils. (C) (**1**) Dimensions of aqueous, dissolved, highly short-chain, branched starch glucan: sphere-equivalent radius distribution of occupied volume by constituting glucan molecules (geometric dimension) in the range of several nanometers and dimensions of coherent dynamics with contributions up to two magnitudes larger. (**2**) Transition from mass fraction to square of occupied volume and from normal to logarithmic scaling of dimensions zooms present supermolecular structures. (Data processing/graphics: a.h group CPCwin32.) *(View this art in color at www.dekker.com.)*

[lg(M)] and the corresponding intrinsic viscosity [lg([η])] (Fig. 6B). A strictly linear correlation is expected for a series of homologous polysaccharides, with the slope indicating the packing characteristics of the polymer coils: values close to 0.0 for hard/compact, spherical forms and values close to 2.0 for stiff, rodlike shapes. For irregular-shaped, uncharged, and branched polysaccharides, high packing density and, hence, small values for the slope of the conformation plot is expected; for polysaccharides with highly ordered structures established by either helices or β-sheets, or for polysaccharides with high charge density, high values for the slope are expected.

As polysaccharides tend to ''functionalize'' environmental phase space, for specification of polysaccharide dimensions, geometry and dynamics must be distinguished, although the transition is diffuse: Whereas the dimensions of polysaccharide molecules in terms of sphere equivalent radii of mean excluded volume for macroscopic periods are up to maybe 100 nm only, dynamics of coherent supermolecular structures provide sphere equivalent radii that are more than one magnitude larger and enter the micrometer range. However, these structures are ''hidden'' if mass fractions are taken for illustration. Their identification typically needs sophisticated detection and specific scaling, for instance, photon correlation spectroscopy and representation of detected populations with respect to the square of coherent (occupied) volumes (Fig. 6C).

For the case of branched polysaccharides, appropriate branching analysis is required to acquire information about general characteristics of the branching pattern (chemistry of branches, short-chain/long-chain branching, homogeneity of branching, secondary branching), percentage of branching, and mean distance between branching positions.

Controlled application of different kinds of stress, in particular, thermal, mechanical, and (bio)chemical impacts, supplies information about the response capabilities of solvent/polysaccharide systems and provides data on phase transitions, disintegration or reorganization phenomena, gel qualities, and degree of resistance or stability. But even there, any of the obtained characteristics may occur as distributions, illustrating that heterogeneity is a generic quality of polysaccharides.

SELECTED POLYSACCHARIDE SYSTEMS

Structuring Polysaccharides

Most structuring polysaccharides of higher plants are β-glycans,[14] in particular, the glycans in wood and cereals. The most abundant is a system consisting of cellulose, callose, arabinogalactans, hemicelluloses, and lignin, occurring, for instance, in wood.

Cellulose

Cellulose is a strictly nonbranched β(1→4)-linked glucan formed by the repeating dimer cellobiose (Fig. 7A). It forms microfibrils with a length of 100–x0 000 nm and a diameter between 2 and 20 nm. Cellulose fibers contain highly ordered (crystalline) and minor regular (amorphous) domains and, hence, form stiff construction material with limited flexibility.

Callose

The nonbranched β(1→3)-linked glucan callose (Fig. 7B) forms helices and is a transient cell wall component with high flexibility. It is found in growing zones; synthesis of callose is also an important response mechanism to applied physical or chemical stresses and pathogens.

Hemicelluloses

Hemicelluloses are a mix of β-linked heteroglycans with compositions that are strongly dependent on plant variety and species. They primarily consist of fucogalactoxyloglucans (XyG), glucuronoarabinoxylan (GAX), xylan (Xyl), mannan (Man), glucomannan, and galactomannan. Although not typical hemicelluloses, arabinogalactans, consisting of β(1→3)-D-galactopyranosyl residues with a high number of galactosyl and arabinosyl branches, are rather similar in functionality. Hemicellulose and arabinogalactans are closely associated with cellulose, callose, and lignin in primary and secondary layers of cell walls and are a kind of connective filling material (Fig. 7C).

Lignin/lignocellulose

Lignin primarily is formed by irreversible elimination of H_2O from carbohydrates and glycans. The actual chemical composition of lignin depends on the carbohydrate source. However, the constituting units are phenolic compounds containing alkyl residues, phenolic hydroxyl groups, carbonyl groups (aldehyde/ketone), and/or alcoholic hydroxyl groups. A three-dimensional skeleton is formed by irregular crosslinking of phenolic fragments and compounds via ether between alcoholic hydroxyl groups and by hemiacetal/hemiketal linkages of hydroxyl groups with carbonyl groups (Fig. 7D).

Pectin

Another structuring, ''compartment-connecting'' polysaccharide, in particular of fruit and vegetables, is

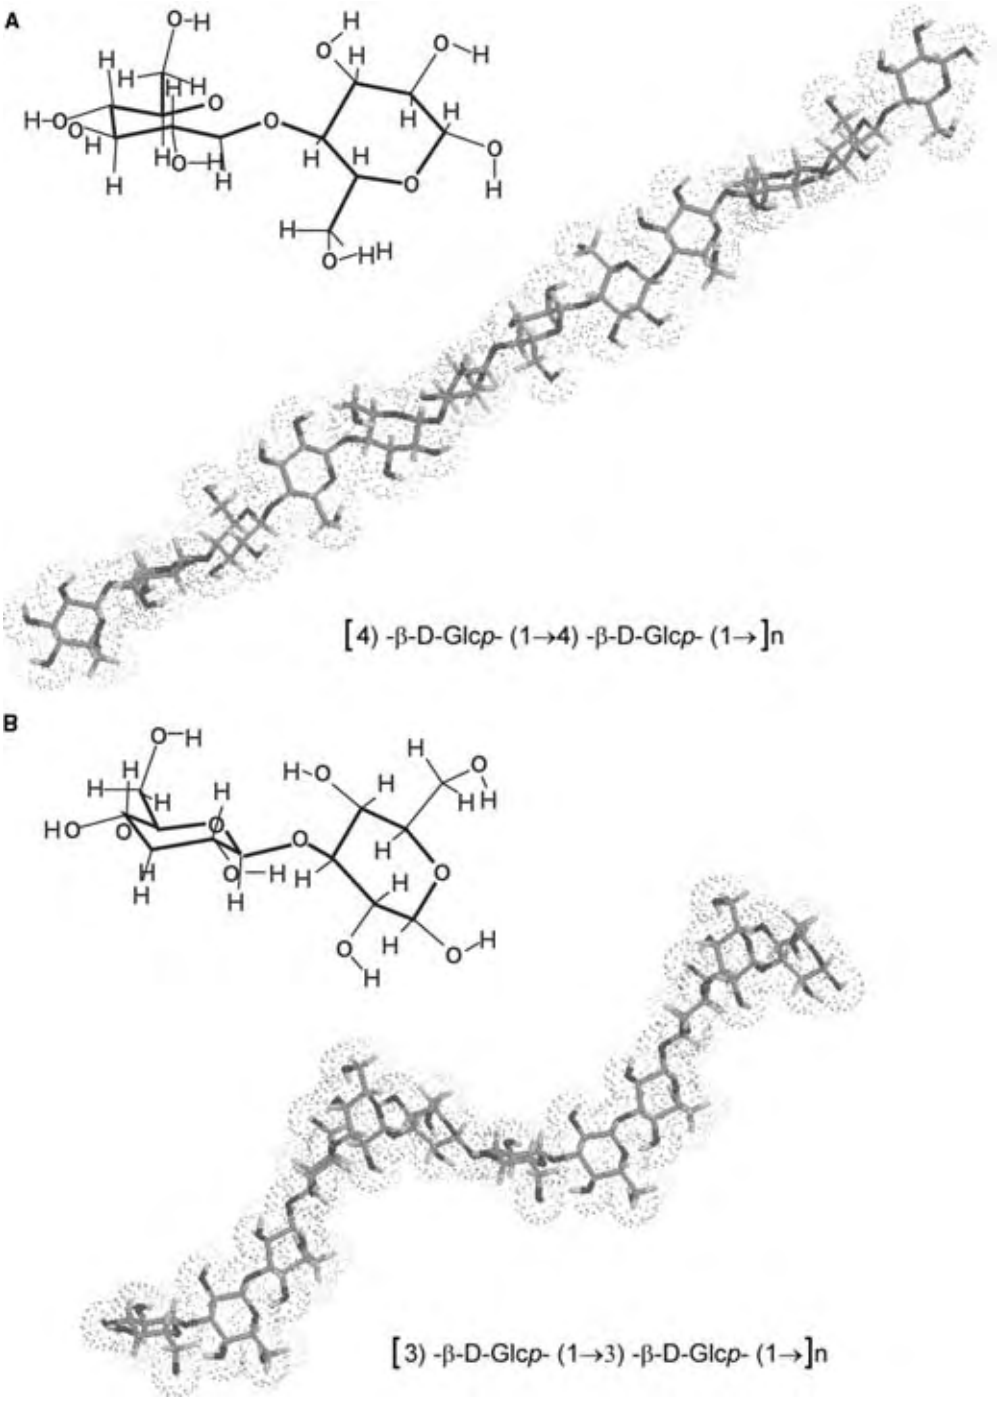

Fig. 7A, B Structuring polysaccharide system, particularly in wood (cellulose, callose, galactomannan, xylan, arabinogalactan, lignin). pectin, which consists of partially methylated α-(1→4)-D-galacturonyl (''smooth'') residues and alternating α-(1→2)-l-rhamnosyl-α-(1→4)-D-galacturonosyl (''hairy'') sections with dp 1–20 branches of neutral (primarily l-arabinose, D-galactose, D-xylose, and l-fucose) and charged [D-glucuronic acid, D-apiose, 3-deoxy-D-manno-2-octulosonic acid (Kdo), and 3-deoxy-D-lyxo-2-heptulosonic acid] glycosyl residues. Pectins are soluble in aqueous medium, but form sticky gels in the presence of divalent cations.

Fig. 7D *(Continued.)*

Chitin/chitosan

The major structuring polysaccharides of fungal cell walls and the exoskeletons of invertebrates, such as insects and crustaceans, are chitin/chitosan (Fig. 3B): (1→4)-β-D-Glc*p* 2-Nac/(1→4)-β-D-Glc*p* 2-NH_2. Chitin and chitosan differ in their degree of acetylation, and samples are typically specified by the ratio of glucosamine residues and the sum of glucosamine and *N*-acetyl-glucosamine residues.

Algae form and contain a high percentage of structuring polysaccharides that constitute cell wall layers and mucilage.

Agar

Most species of red algae (Rhodophyta) have a cell wall with an inner cellulose layer embedded in a matrix of agarose and agaropectin mucilage. This embedded

matrix causes the slippery texture of red seaweed and is commonly known as agar-agar or, simply, agar. Agarose is a virtually neutral polysaccharide, whereas agaropectin contains acidic components. Agarose is a galactan formed by the agarobiose repeating disaccharide [→3)-βD-Gal*p*-(1→4)-3,6-anhydro-αL-Gal*p*-(1→]. Agaropectin consists of an identical backbone and considerable amounts of acid groups such as sulfate, pyruvate, and uronyl residues. The composition of agar additionally varies with the source of the red algae.[15]

Alginate

In spite of the general low level of organization of algae, cellulose is the dominant structural element of their cell walls. However, in brown algae (Phaeophyta), alginic acid/alginates are important cell-wall components. Alginates are constructed from blocks of mannuronyl residues [→4)-β-D-Man*p*A-(1→] and guluronyl residues [→4)-α-L-Gul*p*A-(1→]. The β(1→4)-linked D-mannuronyl blocks form left-handed triple helices, whereas the α(1→4)-linked L-guluronyl blocks form double helices. The guluronate block has specific binding sites for divalent cations, which results in egg-box-like complexation and, hence, gel formation of alginates. Gel-forming capacity, however, strongly depends on block lengths and the kind of divalent cations present ($Mg^{2+} \ll Ca^{2+} < Sr^{2+} < Ba^{2+}$).[16]

Carrageenan

Carrageenan (Fig. 3A) is found in red seaweed (Rhodophyta), primarily in species *Chondrus*, *Gigartina*, *Eucheuma*, and *Phyllophora*. Carrageenan can be split into three major fractions: κ-carrageenan [→3)-β-D-Gal*p*-4-SO_4-(1→4)-α-D-3,6-anhydro-Gal*p*-(1→], which is insoluble and forms gel in the presence of aqueous KCl, ι-carrageenan [→3)-β-D-Gal*p*-4-SO_4-(1→4)-α-D-3,6-anhydro-Gal*p*-2-SO_4-(1→], which is soluble in aqueous K^+ solutions but forms gel in the presence of Ca^{2+}, and λ-carrageenan [→3)-β-D-Gal*p*-2-SO_4-(1→4)-α-D-Gal*p*-2,6-SO_4-(1→], which is soluble in the presence of both mono- and divalent cations. Carrageenans are flexible molecules that tend to form double-helical structures.[17]

Polysaccharides as Energy Repository

Energy-storage polysaccharides are formed by eucaryotic organisms during their growing and maturation periods as long external input is provided. If energy input is terminated (e.g., by harvesting or during starvation), the storage polysaccharides are degraded and provide energy to maintain metabolism. The most important storage polysaccharides of higher plants are the following.

Starch glucans

Starch glucans consist of nonbranched (nb) (Fig. 3A), long-chain branched (lcb), and short-chain branched (scb) (Fig. 3C) components in varying compositions. They are organized in granules with minor amounts of lipids, varying amounts of protein, and immobilized water and, depending on the source, might even be phosphorylated. In aqueous medium, starches, in particular, nb and lcb components, have a pronounced tendency to form supermolecular structures. Depending on the kind of branching pattern and degree of branching, starch glucans form highly ordered helices and multiple hexagonal (crystalline) supermolecular structures or transition structures from helices to irregular-shaped, increasingly densely packed amorphous coils.

Fructans

Fructans are oligomers and polymers formed by polymerizing fructose from transport metabolite sucrose on one out of three possible starter trioses: 1-kestose yields inulin-type (2→1)-β-D-fructans, 6-kestose yields levan-type (2→6)-β-D-fructans (Fig. 3A), and neo-kestose yields mixed-type and/or branched (2→1), (2→6)-β-D-fructans (Fig. 3C). Pronounced fructan metabolism is found in composites (chicory, Jerusalem artichoke), Liliaceae (onion, chives, garlic), cereals (wheat, barley, rye, oat), Asparagaceae (asparagus), Amaryllidaceae (banana), and Agavaceae (agave).

Plant Gum Polysaccharides

Plant gums are acidic polysaccharides in the aqueous environment that can form highly viscous gels in the presence of cations, in particular divalent Ca^{2+} and Mg^{2+}. The formation of plant gums is typically a response to damage or pathogen attack. The best-known gums are the following.

Gum arabic (gum acacia)

Gum arabic (gum acacia) is primarily formed by the gumnosis process by the species *Acacia senegal* (Mimosaceae) and consists of neutral glycosyl residues (L-rhamnose, L-arabinose, D-galactose) and glucuronyl residues (D-glucuronic acid, 4-methoxy-D-glucuronic acid). Gum arabic occurs as a hydroxyproline-rich glycoprotein (~2% protein) containing a motif of 19

amino acid residues (-ser-hyp[a]-hyp[a]-hyp[a]-thr-leu-ser-hyp[b]-ser-hyp[b]-thr-hyp-thr-hyp[a]-hyp[a]-hyp[a]-gly-pro-his-) with contiguous hydroxyprolines ([a]) attached to oligo-α-(1→3)-L-Ara*f* and noncontiguous hydroxyprolines ([b]) attached to a backbone of (1→3)-β-D-Gal*p* residues that is heavily branched with l-Rha*p*-D-Glc*p*A-L-Ara*f*-D-Gal*p* pentasaccharide.[18]

Traganth

Traganth is formed by leguminous species *Astragalus gummifer* primarily in the Near East consists of two fractions: water-soluble tragacanthin, constituted by D-Gal*p*A, D-Gal*p*, L-Fuc*p*, D-Xyl*p*, and L-Ara*f*, and water-insoluble bassorin, with predominantly D-galacturonyl methylesters.[19]

Guar/locust bean gum

Guar and locust bean gum (Fig. 3B) are galactomannans, formed by legume species *Cyamopsis tetragonolobus* (guar) primarily in Pakistan and India and *Ceratonia siliqua* (locust bean) primarily in the Mediterranean region. Guar and locust bean gum consist of a (1→4)-β-D-Man*p* backbone and statistically distributed short branches of (6→1)-α-D-Gal*p* (every 1.5–2 Man*p* residues) in case of guaran and branching at each fourth to fifth Man*p* residue in case of locust bean polysaccharide. Whereas the branches of guar are alternately disposed along the D-mannan backbone, those of locust bean gum are arranged in uniform blocks.[20]

Microbial Polysaccharides

More or less all micro-organisms form polysaccharides, either as cell wall (capsular polysaccharides, CPSs) and/or as metabolic products that are secreted into the extracellular medium (exopolysaccharides, EPSs). Capsular polysaccharides contribute to the morphology and stability of cell walls and also establish communication with adjacent cells and controlled interactions with (bio)chemical agents in the medium. Exopolysaccharides are involved in cell protection against toxic or limiting environments, sequestering of essential cations, colonization, and cellular recognition. The typically excellent water-binding capability of EPSs protects bacteria in low-moisture environments and inhibits amebic attack or phagocytosis.[21,22] In a laboratory environment, many microbial polysaccharides may be obtained rather pure and even in large, industrial-scale amounts by controlled biotechnological processing and optional prior genetic modification of microbes.

Xanthan

Xanthan is a (1→4)-β-D-Glc*p* backbone with oxidized trisaccharide branches (Man-Glc*p*A-Man) at each cellobiose residue industrially produced in large scales by *Xanthomonas campestris* from glucose, sucrose, starch, lactose, or whey feedstock. Particular due to its pronounced viscoelastic properties, xanthan is widely used as a thickener and stabilizer in food [it is listed as ''generally recognized as safe'' (GRAS) by the U.S. Food and Drug Administration (FDA) and non-food applications.[23] Under natural conditions, however, *Xanthomonas* species are plant pathogens, in particular for cultivated rutaceous species (including citrus), rice, beans, grape, and cotton, causing citrus canker.

β-Glucans

β-Glucans[24–27] are a group of basically β(1→3)-linked glucans from microbial sources, particularly of interest as they attach to specific iC3b receptors (CR3, CD11b/CD18) of phagocytic cells, stimulating phagocytosis and/or cytotoxic degranulation. Curdlan, produced by *Agrobacterium* spp. and *Alcaligenes* spp., is a strictly nonbranched β(1→3) glucan. Grifolan (GRN), made by *Grifola frondosa*, is a β(1→3)-glucan with (1→6)-β-D-Glc*p*-branches at approximately each third residue. Lentinan, made by *Lentinus edodes*, is a β(1→3)-glucan with two out of five glucosyl residues containing (1→6)-β-D-Glc*p*-branches. Schizophyllan, also known as SPG, sonifilan, or sizofilan, made by *Schizophyllum commune*, *Sclerotinia sclerotiorum glycan* (SSG), are β(1→3)-glucans with (1→6)-β-D-Glc*p*-branches at approximately each third residue. Scleroglucan, made by *Sclerotium glucanicum* from a mixed glucose/nitrate/mineral feedstock, is a β(1→3) glucan with β(1→6)-linked glucopyranosyl branches at approximately each third glycosyl residue. Beside its attractiveness as a pharmaceutical compound, scleroglucan is industrially produced on a large scale and used as drilling mud, asphalt emulsifier, adhesive, printing ink, and a component of cosmetics.

Dextran

Dextran (Fig. 3C) is a (1→6)-α-D-glucan with dominantly (1→3)-α-D-glucan branches and minor (1→4)- and (1→2)-α-D-glucan branches, industrially produced from sucrose feedstocks, primarily by *Leuconostoc mesenteroides* but also by *Streptococcus* and *Lactobacillus* spp. Crude dextran and dextran fractions are soluble in aqueous medium and have been applied in a wide range of pharmaceutical/clinical and food applications for decades.

Pullulan

Pullulan is a glucan of (1→6)-α-D-linked maltotriose residues produced by *Aureobasidium pullulans* from starch or sucrose feedstock.[28] It is well soluble in aqueous medium and forms films that possess thermal stability and are antistatic and elastic. Pullulan has adhesive properties and is directly compressible under heat with moisture. The polysaccharide is produced on an industrial scale and is used for multiple applications, including food, pharmaceuticals, and cosmetics. It has recently been classified as GRAS by the U.S. FDA.

Functional Glycosaminoglycans of Eucaryotic Cells

Together with proteins, nucleic acids, lipids, and water, glycans are basic constituents of eucaryotic cells. The short-term reserve compound glycogen, primarily in liver and muscle cells, is a pure form. Most functional glycosaminoglycans (GAGs), however, are linked to lipids (glycolipids) and proteins (peptidoglycans, proteoglycans) in the secretory pathway, where they participate in the modulation of biological processes and in the development and functioning of many physiologic systems. Approximately 1% of the genes in the mammalian genome are involved in the formation, transformation, and degradation of glycans. Many of these genes encode glycosyltransferases and glycosidases for the Golgi apparatus, where most of the surface/interface glycans and glycans of extracellular compartments are formed.[29]

Glycogen

Glycogen is an extremely α-(1→6)-short-chain branched α-(1→4)-D-glucan made by branching enzyme from prior-formed (1→4)-α-D-glucans. The major difference between glycogen of vertebrates and short-chain branched amylopectin of plants is the higher percentage of branching and statistical distribution of branching positions in vertebrates compared to clustering of fewer branches in plants. Glycogen is stored preferentially in liver and muscle cells as an immediately available short-time energy resource.

Glycosaminoglycans/proteoglycans

Glycosaminoglycans and proteoglycans[30–36] are part of mammalian core proteins with sulfated glycosaminoglycans. The core proteins direct biosynthesis, and, hence, the specific morphology and functionality of GAGs. The glycan moiety of GAGs is formed by disaccharides consisting of uronic acid or galactose and hexosamines. Chondroitin sulfate/dermatan sulfate consists of glucuronic acid/iduronic acid-β(1→3)-*N*-acetylgalactosamine sulfate and may be classified as chondroitin A [→4)-β-D-Glc*p*A-(1→3)-β-D-Gal*p*Nac-6-O-SO_3-(1→], chondroitin B, also known as dermatan sulfate [→4)-β-D-Ido*p*A-(1→3)-β-D-Gal*p*Nac-4-O-SO_3-(1→], and chondroitin C [→4)-β-D-Glc*p*A-(1→3)-β-D-Gal*p*Nac-4-O-SO_3-(1→]. Chondroitin sulfate is attached to proteoglycan's core protein via a Xyl-Gal-Gal trisaccharide; sulfate of type C additionally shows pronounced interaction with collagen and other extracellular molecules. The repeating unit of heparan sulfate/heparin heparin is [→4)-β-D-Glc*p*A-2-SO_3-(1–3)-β-D-Gal*p*-2NH-SO_3,6-SO_3-(1–4)-β-D-Ido*p*A-2-SO_3-(1–3)-β-D-Gal*p*-2NH-SO_3,6-SO_3-(1→]. As there is no structural difference between heparin and heparan sulfate, typically the amount of *N*-sulfatation is taken as the criterion for classification: heparan sulfate $<$ 50% N-O-SO_3 $>$ heparin. Keratan sulfate consists of the repeating disaccharide galactose-*N*-acetylglucosamine [→4)-β-D-Gal*p*-(1→4)-β-D-Gal*p*Nac-6-O-SO_3-(1→] and occurs in mammalian tissue in two forms, distinguished by molecular dimension and protein linkage (type I: small; *O*-glycosidically linked to Ser and Thr; type II: huge; *N*-glycosidically linked to Asp). Hyaluronan/hyaluronic acid is a GAG formed by the repeating disaccharide [→4)-β-D-Glc*p*A-(1→3)-β-D-Glc*p*Nac-(1→]. Although the biological function of hyaluronan is not completely clear, there are many tasks correlated with this most simple GAG. These comprise, for instance, the ability to immobilize different molecules/compounds at certain biological locations, support activities in cell morphogenesis and cell differentiation, inhibit cell activities on inflammation combined with simultaneous activation of phagocytosis, and protect cells against lymphocytes and viruses.

CONCLUSIONS

Polysaccharides are major renewable resources with a wide field of functional applications. They are made of glycosidically linked basic or redox-modified glycosyl residues by organisms at any level of organization on Earth. From an economic point of view, polysaccharides are abundantly available globally and, hence, are cheap raw materials. However, industrial processing is still limited to a few compounds such as cellulose and starch. From a biological point of view, polysaccharides are high-performance materials with enormous variability at molecular level, efficient sensor and amplification quality under varying conditions in an aqueous environment, smart response capability to applied stress, and assembly and transformation at the molecular level by molecular-scale tools triggered by the principles of self-organizing complex systems. This statement contains the potential explanation for

the problems faced during industrial handling of polysaccharides, as the huge variety of these materials, the unpredictable raw material qualities, and the high amount of ''impurities'' makes them an expensive raw material, because appropriate handling requires high-technology and variable processes.

The basic chemistry of polysaccharides is rather simple; however, drastically enhanced understanding of correlations between functional performance and molecular and supermolecular properties in natural systems is required, in particular information about:

- The capacity of plant polysaccharides to structure flexible and functional surfaces, interfaces, and biological compartments.
- Construction details of protective skeletons of invertebrates such as insects and crustaceans.
- The management of energy repositories in eucaryotic cells.
- Control mechanisms to establish protective gels and support regeneration upon damage or attack.
- Specific sequestration mechanisms from media and the capability to establish protection and recognition structures for microbial organisms.
- Mechanisms to modulate biological processes of eucaryotic cells.

In essence, the key to a better understanding of polysaccharide performance is understanding their interaction with water. Polysaccharides are capable of integrating water and forming functional phase spaces, and characterization of such systems requires consideration of geometric molecular-level dimensions as well as supermolecular distances of coherent dynamics.

Heterogeneity is a generic quality of polysaccharides: All characteristics occur as distributions and may be handled as distributions of molar fractions, referring to the number of distributed components, or distributions of mass fractions, referring to mass contributions of distributed components. In particular, for broad distributions, the difference between mass and molar distribution becomes significant and sometimes crucial. Molar mass distribution is a central piece in this puzzle of correlating molecular characteristics with polysaccharide performance. Additionally, optional branching characteristics, substitution patterns, and responses of aqueous polysaccharide systems to different kinds of applied stress need to be determined.

Polyurethanes

Joanna D. Fromstein
Kimberly A. Woodhouse
Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada

INTRODUCTION

A polyurethane (PU) is a polymer containing recurring urethane linkages, formed through the reaction of a di- or polyisocyanate with a compound containing active hydrogen groups, usually a polyol.[1] The PU family of polymeric materials possesses a broad range of physical and chemical properties that are useful in varied applications such as insulating foam, stretchy synthetic leathers and textiles, paints, coatings, and adhesives.[2,3] This wide variety of applications is attributable to the vast array of chemicals that can be used as reactants in the PU synthesis. Polyurethanes play an important role in the plastics industry, representing roughly 6% of plastic products synthesized worldwide.[2] Polyurethanes have relatively low cost of manufacture and processing and are traditionally stable, resilient materials.[2] This, combined with the wide range of chemical and physical properties available, makes polyurethanes a good choice for many synthetic applications.

BACKGROUND

Polyurethanes represent approximately 6% of global plastic consumption, and 50% of the entire PU consumption occurs in North America and Europe.[2] Roughly 30% of PUs are used for furniture and mattresses, 15% for vehicles, and 13% for construction.[2] In all of these applications, PU foams are used. In fact, over 80% of polyurethane applications use foam materials.[2] Other forms of PU available include solid blocks, fibers, paints, adhesives, and coatings.

Polyurethane is a term used to represent the group of polymers that contain the urethane linkage, sometimes called an ''ester of carbamic acid'' (Fig. 1).[2] Polyurethanes are block copolymers of the form $(AB)_n$ that is formed by a polyisocyanate addition reaction. Some PUs are thermoplastics, while others are thermosets. The properties of the PU can be changed substantially by changing the chemical composition of the polymer's constituents, and thus the PU backbone itself. Polyurethanes can be made in a wide variety of grades, densities, and stiffnesses.[3]

Professor Otto Bayer discovered PUs in Germany in 1937,[2,4] during the development of a rival product for nylon (polyamide) fibers.[4] In this process, he discovered the diisocyanate addition polymerization reaction that is the basis of synthesizing PUs.[4] Bayer's first polymers were polyureas, prepared by reacting hexamethylene diisocyanate with hexamethylene diamine. However, the resulting product was infusible, and it did not form fibers or films very well. Shortly after, in 1938, a German patent was issued, covering linear PU preparation from glycols and diisocyanates.[4] Since then, significant advances have been made in the PU field, enabling the use of PUs for paints, adhesives, structural foams, rigid foams, flexible foams, and medical and thermoplastic elastomers.[2,3,5]

CHEMISTRY

Polyurethanes are formed when a diisocyanate (or polyisocyanate) is reacted with hydroxyl groups at a molar ratio of 2 or higher (isocyanate : hydroxyl).[3] When the polyol and polyisocyanate are combined in the presence of a suitable catalyst, the exothermic polymerization reaction begins spontaneously. This type of synthesis is an addition polymerization. Most polyols and polyisocyanates used for manufacturing PUs are liquid at standard room temperature.[3] Industrially, the PU synthesis reaction is rapid, and the product is a solid polymer. The reaction rate can be varied significantly by changing the catalyst type and concentration, facilitating the use of PUs in a variety of applications.[3]

Reactions of Isocyanates

Isocyanate (NCO) groups are energy-rich and highly reactive; they react exothermically with hydrogen-active compounds, epoxides, and other isocyanates.[2] Isocyanate groups will react most strongly with alcohol

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007921

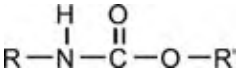

Fig. 1 The urethane linkage.

(hydroxyl) and amine groups. The reaction of an isocyanate with alcohol results in the formation of a urethane linkage with the rate depending on the chemical structure of both the isocyanate and the polyol (Fig. 2).[1] Aliphatic polyols are the most reactive, with primary hydroxyl groups having higher reactivity than secondary groups.[3] Phenol groups react significantly more slowly than aliphatic compounds. The resulting urethane groups are more susceptible to degradation upon heating.[3] This reversible reaction is used to advantage in the manufacture of ''blocked'' isocyanates.[3]

When isocyanates come into contact with water, gaseous carbon dioxide and a substituted urea are formed (Fig. 3). During foam production, this CO_2 is often used as the primary blowing agent.[2] When synthesizing PU products that are not intended to be foams, water contamination should be avoided at all costs.[2,3]

Isocyanates also react with primary and secondary amine compounds. Tertiary amines cannot react with isocyanates because they do not contain active hydrogen atoms, but they are powerful catalysts for many other isocyanate reactions.[3] Diamines are frequently used as chain extenders and curing agents in PU manufacture.[6] The addition of a diamine to the reaction mixture increases the overall reactivity during polymerization. The reaction between an isocyanate group and an amine results in the formation of a urea bond. The polyurea segments present in the finished PU serve to increase the potential for both covalent and hydrogen bond crosslinks within the polymer.

The reactivity of unhindered isocyanates with primary amines is considerably higher than that with primary alcohols. The reactivity of amines increases with the basicity of the amine, and aliphatic amines are much faster than aromatic amines.[3] Polar solvents can increase the reactivity of isocyanates through the stabilization and polarization of the isocyanate group.[3]

Isocyanate groups can react, under select conditions, with the active hydrogen atoms of urethane and urea linkages.[3] When an isocyanate reacts with a urea, it forms a biuret, whereas reaction with a urethane linkage results in an allophanate. These reactions are reversible, crosslinking reactions, and the kinetics are much faster for biuret formation.[3] Isocyanates can also react with compounds that do not contain active hydrogen, such as epoxides.[2] The products formed following the reaction of epoxides with isocyanates are used as embedding compounds and casting resins.[2]

Isocyanates can also react with other isocyanate molecules to form oligomers (Fig. 4).[3] This polymerization is more likely to occur in the presence of basic catalysts.[3] Isocyanate dimers, also called ''uretidinediones,'' can only be formed by aromatic isocyanates, and uretidinedione formation is inhibited by ortho substituents. Hence, only 4,4-diphenylmethanediisocyanate (MDI) dimerizes at room temperature, and its rate of formation is quite low.[3] At higher temperatures, MDI would form an insoluble polymeric material.[3] Trimers of isocyanates are also possible; these structures are called ''isocyanurates.''[3] Isocyanurates are formed by both aliphatic and aromatic isocyanates, and the resulting structure is highly stable to a temperature of approximately 270°C.[3] Isocyanurates give very stable branch points for crosslinking, unlike the reversible uretidinedione, biuret, and allophanate linkages.[3] Isocyanurate groups have been shown to decrease the flammability of rigid foams used for construction applications.[2,3] These isocyanurate groups are formed by polymerizing most of the isocyanate groups together to form isocyanurate ring structures.[3]

Polyurethane Synthesis

Polyurethanes can be synthesized using either a one-shot process or a two-stage, prepolymerization technique.[2] For the one-shot process, all chemicals are combined together at once and allowed to react. Although this method is faster and less labor-intensive, the final product tends to have a less organized structure than that achieved using the two-stage method.[2] In the

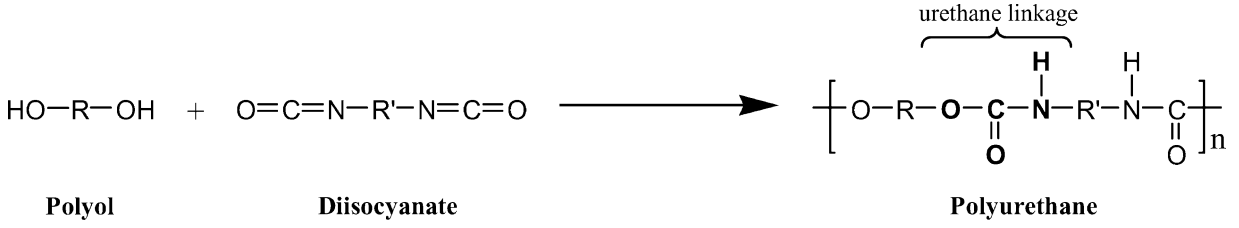

Fig. 2 The polyurethane addition reaction between a polyol and a diisocyanate.

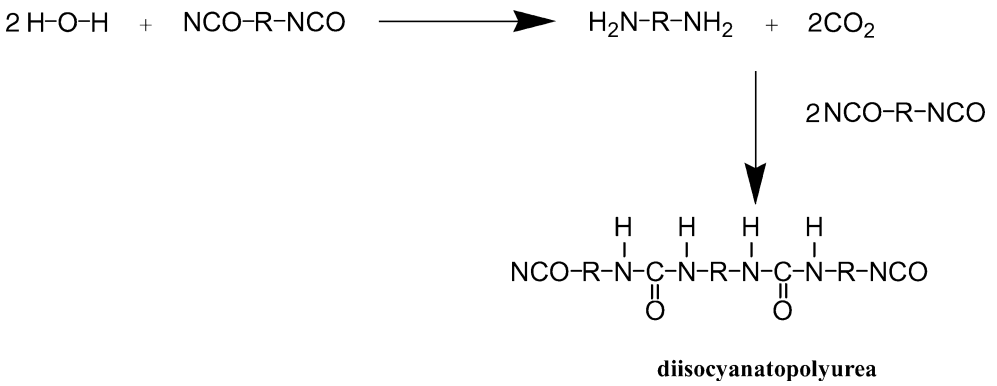

Fig. 3 The reaction between isocyanates and water, resulting in the formation of carbon dioxide gas and a substituted polyurea.

prepolymer method (Fig. 5), a diisocyanate is first allowed to react with a polyester or polyether diol at a 2 : 1 molar ratio. This results in a urethane-linked prepolymer that comprises the diol, flanked on either side by the isocyanate. In the second step of polymerization, the polymer is lengthened through the addition of a chain extender, which links up with remaining isocyanate groups. Diol chain extenders form PUs while diamine chain extenders result in the formation of PU ureas. The PUs synthesized using the two-step process are usually segmented PUs that possess a phase-segregated morphology consisting of long flexible polyester or polyether chains linked by rigid blocks.[2,3]

The isocyanate and chain extender form rigid blocks (hard segments), whereas the polyols give rise to flexible regions (soft segments).[2] By modifying the chemistry of the three reactants, segmented PUs with properties ranging from soft, jelly-like substances to hard rigid plastics can be made. Hard-segment blocks are in the order of 20 Å × 55 Å in size.[2,7]

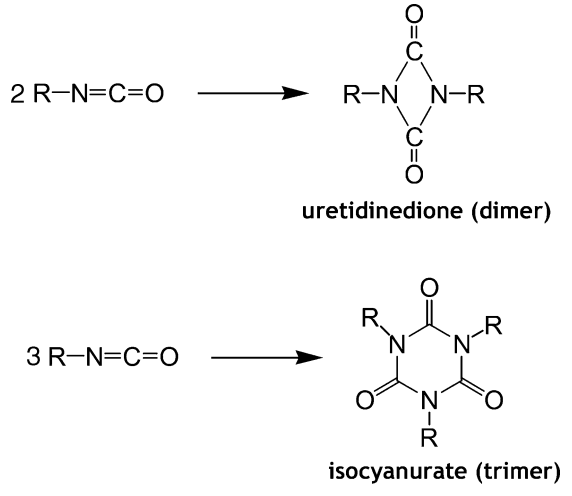

Fig. 4 Dimeric and trimeric structures formed by isocyanates when they react with other isocyanate groups.

The degree of hard-segment aggregation or separation is dependant upon the choice of polyether or polyester polyol, the weight ratio of the hard segment to that of the chosen polyol, the isocyanate, the processing parameters, and the synthesis reaction conditions.[3] Highly crosslinked rigid PUs are too tightly packed to allow for phase segregation to occur.

The Reactants

Polyisocyanates

Roughly 95% of all PUs are synthesized using either toluene diisocyanate (TDI) or MDI.[2,3] Both of these aromatic isocyanates result in the formation of strong materials with stiff polymeric chains. Of the two, MDI is more reactive and less volatile. Most TDI that are used commercially are composed of an 80 : 20 or 65 : 35 mixture of 2,4-TDI to 2,6-TDI. Both a monomer form and a polymerized form of MDI can be purchased.[3] Polymeric MDI can be reverted to monomeric diisocyanates by elevating the temperature.[3] Some specialty applications, particularly paints and coatings, use aliphatic polyisocyanates during synthesis.[2] These isocyanates are used to impart resistance to light, hydrolysis, and thermal degradation.

Polyols

There are two classes of polyols used in PU synthesis: polyesters and polyethers.[3] Approximately 90% of all PUs are manufactured using polyether polyols. Many polyols can be modified to have a higher degree of primary hydroxyl groups, or to contain one of polyurea or PU dispersions.[3] The primary polyols are more reactive and the dispersed polyurea and PU segments serve to increase the crosslinking of the finished PU.[3] Most of the polyether polyols

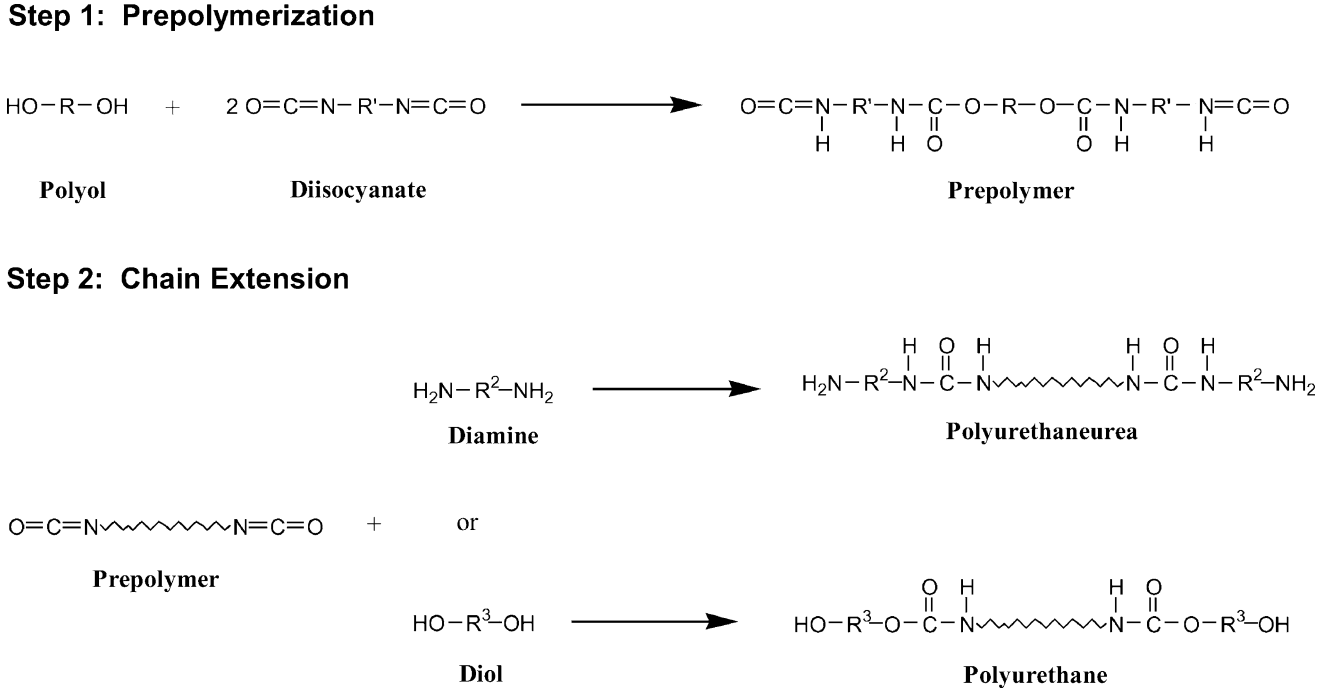

Fig. 5 The two-step PU synthesis method.

used in PU manufacture are made by the addition polymerization of alkylene oxides onto alcohol or amine initiators.[3]

Polyester polyols are more expensive to produce, more viscous, and form polymers that are more susceptible to hydrolysis. They do, however, impart high tensile strength and good resistance to flexing, abrasion, and photooxidation.[3] Hence, these polyester polyols, especially adipates, polycaprolactones, and polycarbonates, are commonly used for elastomers, coatings, and adhesives, where these properties are desirable.[3,4] Polyester polyols also form polymers that are resistant to dry cleaning solvents and high temperatures, making them attractive for use in textiles for the fashion industry.[4]

Chain Extenders and Crosslinkers

Chain extenders are low molecular weight polyols or polyamines that are used in flexible PUs to elongate the PU chain. They are difunctional glycols, diamines, or hydroxy amines.[3] Flexible polyurethanes such as flexible foams, elastomers, and reaction injection molding (RIM) processed PUs are made using chain extenders.[3] The chain extender's presence permits hard-segment segregation, resulting in an increase in both the modulus and the thermal stability.[3] Crosslinking agents are simply chain extenders with a functionality of 3 or more, providing extra crosslink sites. Some chain extenders, particularly diamines, will also behave as curing agents.[3]

Additives and Modifiers

A wide variety of catalysts have been used in PU production. Most catalysts are either tertiary amines or organo-metallic compounds.[3,8] The most commonly used catalysts in PU foam production are the tertiary amines, which catalyze the reaction between water and isocyanates.[3] The catalytic effect can be altered, depending on the chemical structure of the amine and on its basicity.[3] In addition, some tertiary amines catalyze chain branching through biuret linkages. This chain branching within the polyurea segments inhibits the formation of well-ordered secondary bonded domains, producing softer forms with higher resiliences. A similar effect can be achieved by using a catalyst that specifically encourages polymerization of the isocyanates, such as symmetrical triazine derivatives and alkali metal salts of carboxylic acids and phenols.[3] Organo-tin and other similar catalysts are used to encourage the reaction between hydroxyl groups and isocyanate groups. Usually, organo-metallic catalysts are used with aliphatic isocyanates, whereas tertiary amines are used in systems using aromatic isocyanates.[8] In the manufacture of some PU foams, a mixture of organo-metallic and tertiary amine catalysts is sometimes required to maintain a balance between the PU polymerization reaction and the reaction of water and isocyanate to form CO_2.[3,8]

Surfactants are often added to PU reactants to serve as emulsifiers; these polyether siloxanes improve the miscibilities of the reactants (polyisocyanate, polyol,

water, etc.) prior to synthesis.[2] Organo-silicon compounds are also used during foam production as ''foam stabilizers'' or ''cell regulators.''[2] These additives help to control the size and nature of the pores and stabilize the rising foam until it has cured.[2]

Other additives that may be used by PU manufacturers include curing agents, flame retardants, fillers, antiaging agents, colorants, antistatics, biocides, and release agents.[2]

MANUFACTURING AND PROCESSING

Commonly, polymerization coincides with the shaping of the PU product. In general, the polymerization process begins with the polyisocyanate and polyol being conveyed from their storage tanks to a working container. The ingredients are heated to the desired temperature and fed by metering units to the mixing head. Once mixed, the reactants are discharged into a mold or onto a substrate and allowed to react fully.[2]

There are two primary methods of PU production: continuous and discontinuous (batch). In the continuous process, the polyisocyanate and polyol are transferred from storage tanks into working containers, adjusted to the desired temperature, and then metered into the mixing head. From the mixing unit, the reaction mixture is ejected onto a substrate or into a mold, where it is allowed to react fully.

Cavity foaming and molding production are batch operations.[2] The minimum demold time depends on the reactivity of the foam system, the density of the foam, the temperature reached inside the block of foam, the size of the block, and the degree of overpack in the mold.[3]

Continuous manufacture is the most economical method of making large quantities of slabstock foam. The results also tend to be of better quality as it is easier to ensure uniformity of cell size and structure in this sort of operation. In this method, the foam reaction mixture is metered into a trough on a moving conveyer belt.[3] The sidewalls in this process must be rigid enough to withstand the pressure that occurs just after the foam has risen completely. Conveyer belts that move synchronously with the base belt are commonly used. Another conveyer that is height adjustable is used as a lid to ensure that a flat-topped foam block is formed.[2]

RIM

Reaction injection molding produces flexible foams of highly reactive PU systems using very short molding times (less than 1 sec in some cases).[2] This process uses high-pressure machines to distribute the individual reactants into the molds using closed circuit pipelines.[9] Each mold has a rigidly mounted self-cleaning mixing head attached to the clamping unit. Ground short glass fibers (140–240 μm) can be added to one of the components (commonly the polyol) to produce reinforced reaction injection molded PU.[2,9] Alternately, a glass mat can be placed in the mold and then surrounded by the reaction mix in a second step. This technique is called structural-RIM.[2] A more recent technique, long fiber injection, has been developed in which fibers that are 5–10 cm long are introduced directly into the mold with the reaction mix, all in one stage.[2]

Reaction injection molding differs from thermoplastic injection molding in numerous ways. First, the internal pressures in the molds and locking forces are one order of magnitude lower than those required for thermoplastic injection molding. In addition, the flow paths achieved with RIM are at least one order of magnitude higher.[2] Reaction injection molding is most commonly used for the production of parts with large area such as spoilers, fenders, and bumpers for motor vehicles.[9]

FOAMS

Approximately 80% of PU are manufactured as foams.[2] Polyurethane foams are lightweight materials, consisting predominantly (>98%) of air (and gases in the case of closed-cell foams).[2] Both the chemistry and the processing will have major effects on the final properties of the foam.[3] Polyurethane foams can be used to form composites with almost all flexible or rigid facings.[2] As the density of the foam increases, the suitability for demanding dynamic applications is improved.[3]

A number of higher functionality and viscosity MDIs are available for use in rigid foam manufacture.[3] Their higher viscosity improves the uniformity of the reaction mixture, resulting in a better pore structure.[2] The cells in these foams are less elongated, resulting in a final product that has a greater strength and higher dimensional stability.[2] These foams are also more fire resistant than those made using pure polymeric MDI.[3]

Glass-fiber incorporation increases the fire resistance of polyisocyanurate foam laminates. The glass fibers embedded in the foam prevent the development of deep fissures in the protective carbonaceous char that is formed when polyisocyanurate foam is exposed to high temperature flames.[3]

Flexible Foams

Flexible foams are used in mattresses, car seats, and ''comfy chairs.''[3] They are open-celled materials that

have a relatively low resistance to deformation under pressure.[2] Flexible foams can be classified as either polyether or polyester foams, depending on the chemical composition of the PU.[2] Approximately 95% of all foams manufactured are polyether foams.[2] Polyester-based PU foams are used for high load bearing applications because they have higher compressive and tensile strengths than their polyether counterparts.[2] Special polyester foams include highly elastic foams, also called ''high resilience'' (HR) or ''cold slabstock'' foams.[2] High resilience foams can be produced with flame retardants as well. These materials are called ''combustion-modified HR'' foams.[2] Other modified foams include supersoft, flame-laminated, and high-frequency welded foams.[2]

Flexible PU foams are synthesized by the reaction of a diisocyanate with a hydroxyl-terminated polyether or polyester and water, simultaneously.[1,3] When the water and the isocyanate come into contact, they react and produce heat and carbon dioxide. This CO_2 is trapped within the polymerizing material. As the gas bubbles expand, cells or pores are formed within the polymer, making a foam. This foaming process is also called chemical blowing, where the carbon dioxide created by the reaction behaves as the ''blowing agent.''[1] In addition to forming CO_2, reacting an isocyanate with water results in the formation of a substituted polyurea, which becomes the hard segment in the final PU foam.[3] The heat evolved by the reaction affects the rate of polymerization, helps the gases to expand, and aids in the curing of the finished product.[1,3] Chemical blowing also stiffens the PU by increasing the polyurea content of the polymer structure, and thus the secondary bonding between polymer chains.[3] The rates of polymerization and carbon dioxide formation are maintained in balance by selecting polyols and isocyanates of appropriate reactivities.[3] In addition, catalysts, foam stabilizers, and temperature control can also be used to help achieve the desired physical properties.[3] Some flexible foams even use additional ''physical'' blowing agents to help achieve the desired cellularity. Physical blowing agents are chemically inert liquids that have a low boiling point and will vaporize under the heat evolved by the reaction.[3] Unlike the chemical blowing agents, physical blowing agents tend to reduce the stiffness of the polymer by reducing the polymerization reaction temperature and the final curing temperature of the PU.[3]

More than half of the PUs produced worldwide are formed as low-density flexible foam.[3] In Europe, this material is made at a rate of 1 kg per person each year.[3] The bulk of this material is used in the furniture, bedding, and automotive industries.[3] These foams have high tensile strength and elongation to break values, and a HR.[3] The majority of flexible foam is fabricated as slabstock, with the remainder being molded or used as padding.[2]

There are two main types of flexible foam slabstock: polyester-based foams, used for technical and high elongation grade laminates or textiles; and polyether-based foams used for upholstery, HR, and flame retardance.[3] By varying the type of polyester or polyether, the length of the polyol chain, the structure and size of the hard segment, and the amount of blowing, the foam can be tailored to meet the required specifications.[2]

Over 90% of all flexible PU foam production is now based on polyether polyols and 80 : 20 TDI.[3] Some specialty foams have been developed recently using MDI, either alone or in combination with TDI. These new materials have been produced primarily for furniture and vehicle seating.[3]

Flexible foam slabstock is normally produced continuously.[1,2] To obtain reproducible materials, all ingredients must be conditioned to within 2°C of the manufacturer's requirements.[2] First, the reactants are metered from their working containers and conditioned to the appropriate temperature. Next, they are quickly mixed together in a mixing head. The mixer nucleates the reaction mixture, providing growth points for the bubbles.[2] This control of bubble formation is necessary to control the size, shape, and distribution of the cells within the foam. Nucleation is achieved by placing a fine dispersion of gas (usually air or nitrogen) in the reaction mixture.[2] The nucleation can be controlled by the agitator speed and by the pressure in the mixer. The mixed, nucleated reaction mixture is usually deposited in the mold or continuous trough within 1 sec after mixing begins. Next comes an induction, or ''cream'' time, that enables the bubbles to grow in size.[2] The reaction mixture is then extruded from the mixing head onto a rolling conveyor belt (up to 10 m/min), where the PU will react and form the final slabstock product. Outputs of 50–600 L/min of the reaction mix can be obtained; these materials have densities ranging from 15 to 60 kg/m^3.[2]

Once the slabstock has been made, the conveyor belts carry the foam to storage for 12–24 hr, to allow the materials to cool and cure.[2] Finally, the foams are transported via conveyor belt past cutters and trimmers that cut the foam to size. High speed water jet are used to cut a variety of shapes from the flexible foam.[2]

Flexible foams can be modified after production using post-treatments such as reticulation and impregnation.[3] Impregnation of low-density flexible foam can include a coloration of the foam by coating the material with a binder or surface coating that contains pigment.[3] The most common impregnation treatments are flame retardants such as aluminum hydroxide, which are applied by impregnating the foam with up

to 300 wt.% aluminum hydroxide in a synthetic latex binder. Other frequently impregnated coatings include antifungal, water-resistant, and ion-exchange resin coatings.[3]

Reticulation is an after-treatment that removes residual cell membranes to produce a foam with a skeletal rib structure. Reticulated foams are very effective filters for the removal of dust and fibers from air and other gases. They allow high flow rates and low pressure gradients (i.e., minimal energy consumption). Methods of reticulation include chemical hydrolysis and the use of an explosion flame front to melt the membranes.[2]

All low-density foams tend to be anisotropic. Although the nucleation bubbles start spherical, they have a tendency to elongate in the direction in which they rise. The fewer and larger the bubbles, the greater the elongation of the pores. Surface active agents can be used to prevent cells from rupturing prematurely under pressure.

Semirigid Foams

Semirigid foams are often used as padding.[2] They have a significantly higher density and compression strength and possess excellent mechanical damping capabilities. As a result, semirigid foams are frequently used as protective cushions in cars. A special, high-performance semirigid foam is known as energy absorbing foam, and it is used not only in the seats but also in car bumpers.[2] The manufacture of semirigid foams is very similar to that of flexible foams, but different reactant chemistries will be selected to create materials with more crosslinks.

Rigid Foams

Rigid PU foam is a highly effective thermal insulator, used frequently in refrigerators and as building insulation.[3] While flexible foams are slightly crosslinked materials, rigid foams are highly crosslinked.[2] Rigid foams have a relatively high resistance to deformation under pressure and particularly low heat conduction owing to the insulating gases trapped in the closed cells.[2] These materials can be used at temperatures ranging from -200 to $+150^{\circ}C$ and can even withstand short-term exposures of up to $250^{\circ}C$.[2] These properties enable special PU rigid foams to be thermoformable, despite their crosslinked nature.[2] Polyurethane rigid foams are rot proof and odor proof, and resistant to plasticizers, fuels, oils, and dilute acids and alkalis.[2] Moldings made of rigid foams are light and robust while remaining convenient and attractive. Rigid foams can also be used to fill cavities and form pipes and panels.[2]

Rigid foam slabstock is manufactured using both continuous and discontinuous processes.[3] The discontinuous method is restricted to systems in which a long cream time is needed at ordinary temperatures. In this process, a slow reacting foam mixture is stirred. The mixture is then poured into a mold, and a floating lid is placed over top of the material. The reaction mixture expands as the slabstock forms until the lid's preset height is reached. As a safety measure, if too much reaction mixture is added to the mold, the floating lid assembly has enough give to allow for overflow, thereby preventing damaging the mold with excessive pressure.[3]

Disadvantages of using batch (or discontinuous) manufacture include limited choice of chemical systems, high cost of labor, increased hazards because of frequent chemical handling, and loss of reaction mixture to the mixer and mixing bowl.[3] Many of these weaknesses can be reduced significantly by the use of machines for dispensing and mixing.[3] The cream time will be reduced compared to batch production, because of the energy input by the mixer into the system.[3] To manufacture a large, uniform block of foam using a highly reactive system, a high capacity/throughput dispensing machine is needed.[3]

Structural Foams

A special group of PU foams is structural foams that are made directly in their molds as either flexible or rigid foams.[2] Structural foams are PU moldings that have a porous core and a nonporous outer layer of the same material and have been made in a single pass.[2] These sandwich-style panels are used in construction applications.[2]

PU Elastomers

Polyurethane elastomers are used in shoe soles, sports equipment, bumpers, underwear, and other stretchy clothing.[3] A urethane elastomer is a linear block copolymer synthesized from a di- or polyisocyanate, a polyol, and (frequently) a chain extender. Traditionally, PU elastomers have been synthesized using the prepolymerization process. Solid PU elastomers have high elasticity and high resistance to wear under different stresses.[2] The high modulus of these materials is attributable to the phase segregation within the polymer. The hard segments serve to reinforce the strength of the material by forming hydrogen bond crosslinks with the surrounding soft segment matrix.[3,6] Polyurethane elastomers are resistant to light, oxygen, and UV radiation. Sometimes, additives are incorporated to protect the PU elastomer from hydrolysis.[2] Polyurethane elastomers can be made into porous foams as

well. These cellular elastomers are high-performance, elastically deformable flexible molded foams.[2]

Polyurethane elastomers are available as thermoplastic elastomers suitable for conventional thermoplastic processing, cast elastomers, elastomeric fibers, and coatings on textiles and other flexible substrates. Almost all of PU elastomers are based on the standard $(AB)_n$ block copolymer structure with alternating hard and soft segments.[6,7] The soft segments are composed of the polyester or polyether groups, while the hard segments are the reaction products of a polyfunctional (usually difunctional) isocyanate and a low molecular weight chain extender, either a diol or a diamine. Polyurethane elastomers can possess hardnesses ranging from 10° Shore A to over 60° Shore D.[3] As a group, fully cured PU elastomers are tough, resilient, abrasion-resistant, of high mechanical strength, and resistant to many solvents and chemicals.[3] However, PU elastomers are not particularly stable in the presence of strong acids or bases, oxidizing agents, and some highly polar solvents.[3]

Originally PU elastomers were synthesized using one of the aromatic isocyanates (MDI, TDI, etc.).[3] Recently, however, more focus has been placed on the use of distilled MDI and modified MDI products. HMDI and IPDI are used to make coatings for applications when high resistance to weathering and discoloration by light is important.[3]

The raw materials used for PU elastomer synthesis are often solids that first have to be melted, desiccated, and then degassed in the working container prior to use. Polyurethane elastomer synthesis usually involves the use of a chain extender as well. Diamine chain extenders increase the mechanical integrity of the PU by increasing the degree of phase segregation and physical physical crosslinking within the material.[3]

Polyurethane elastomers are often sold by the chemical companies as granules or pellets that can be used by manufacturers to create products.[3] These pellets and granules are processed using traditional methods like extrusion, injection molding, etc.

Polyurethane fibers (elastanes) can be made via either of the following two ways. In the first technique, the PU is first synthesized using the prepolymer method, and then the PU is spun from solution (approximately 30% PU) to form a filament or yarn.[2] The yarn can either be collected as one long strand or be cut as it is collected. The second method, called ''reactive spinning,'' involves synthesizing the polyurethane and forming the filament all at the same time using a reactive bath to spin the fibers.[2]

Thermoplastic PU elastomers (TPU) are a special group of PU elastomers that can be processed using the traditional economical techniques available for thermoplastic polymers.[2] These materials are designed to meet a wide variety of industrial needs, including injection molding, blow-molded parts, films, coverings, tubing, etc.[2] Polyether-based TPUs are usually composed of polytetramethyleneoxide diols and polytetrahydrofurans.[3] Thermoplastic PU elastomers synthesized using MDI appear to have a higher degree of phase separation than those made with TDI. Thermoplastic PU elastomers are frequently chain extended with a low molecular weight diol such as 1,4-butanediol. In cases where resistance to hydrolysis is required, 6-hydroxycaproic acid polyesters are used as the polyol.

Thermoplastic PU elastomers are produced both continuously and discontinuously using the one-shot process.[2] Once the components have been mixed in a reactor, they are dispensed onto a conveyor belt.[2] The TPU reacts fully and solidifies in the form of sheets which are chopped in a granulator and then processed into uniform pellets in an extruder. If the sheets are processed immediately, no drying time is needed before granulation. Otherwise, a drying step at approximately 100°C is incorporated for anywhere from 30 min to 2 hr. The production of TPU granules can also be carried out entirely in a twin-screw extruder (compression ratio 1 : 2) or in a single-screw extruder (compression ratio of 1 : 3).[2] Temperatures in the order of 180–250°C are commonly used for this method, with mold temperatures kept steady at 20–40°C using a water jacket. Finished products attain their optimal properties following a 15–20 hr curing step at 80–120°C, or 4–6 wk after storage if not treated following fabrication.[2]

Medical PUs are another subset of PU elastomers. Segmented PUs were first suggested for use in a biomedical application in 1967.[10] Early work with PU elastomers showed that these materials could be used for implants without causing a large, unwanted inflammatory response. The first medical devices made of PUs, however, were found to be susceptible to hydrolysis and degraded faster than desired.[6,10] From that time, new biostable materials have been developed for use as pacemaker leads, catheters, vascular grafts, stents, etc.[6,10–12] In addition to these stable materials, many researchers have developed intentionally biodegradable PU elastomers for use in tissue engineering.[6,13,14] These degradable materials are formed into highly interconnected three-dimensional scaffolds using new processing techniques, such as electrospinning or laser boring, and then used as the base to make replacement soft tissues.[12,14]

Specialty PUs

Polyurethane electrical embedding compounds exist in both flexible and rigid variations. These specialty PUs

have a long-term thermal stability. Another unique PU group is the PU sealants, which compete with commercially available silicone and polysulfide sealants.

Polyurethane rubbers are a special type of PU elastomer. The PU rubbers are highly resistant to oil and fuel and have high abrasion resistance and tensile strength similar to PU elastomers. Polyurethane rubbers maintain their flexibility even at a temperature as low as -40°C and are thermally stable up to 125°C. Polyurethane rubbers have better mechanical strength and resist abrasion, ozone, and oil better than other specialty rubbers such as acrylates and nitrile butadiene.[2]

Polyurethanes are also used to make paints, available as water-thinnable paints and powder coatings. Items painted with PU paints benefit not only from a lacquer film, but also from an improved chemical resistance.[2] Polyurethane paints are scratch, abrasion, and impact resistant, and they adhere well to a variety of surfaces.[2] Polyurethane adhesives are similarly good choices as they resist heat, water, solvents, grease, and oils.[2]

Polyurethanes have also been invaluable as coatings for textiles, paper, and leather. The ability of these lacquers to adhere to a wide variety of substrates, combined with the flexibility across a wide range of temperatures and high tensile strength and tear propagation resistance, makes PU coated materials attractive substitutes for PVC, nitrocellulose, and acrylates.[2]

Polyurethane fibers are another niche application. These ''elastanes,'' the basis of Lycra™, have nearly taken over the textile industry, displacing rubber threads (elastodienes) in the process.[2,15] The high popularity of PU fibers is attributable to the good tensile strength and elasticity of highly segmented polyurethanes. In addition, elastanes can be processed in a variety of sizes, either as continuous filaments (yarns) or as shorter fibers. Rubber threads, on the other hand, are available solely as monofilaments.[2]

Polyurethanes can be processed into microcapsules and gels. Polyurethane gels swell in water, absorbing up to 90% water, which then becomes trapped within the gel and cannot be squeezed back out.[2] Polyurethane microcapsules are fabricated by producing a very fine oil in water emulsion (droplet size approximately 3–10 μm) and by applying high shearing forces using ultrasonic dispersers.[2]

CONCLUSIONS

The development of PUs has had a monumental impact on our society. It is the ability to tailor-make a PU for each given application that accounts for their widespread use.[5] Since the discovery of PUs in the late 1930s, their flexible chemistry and diverse physical properties have led to the use of PUs in an astounding variety of applications. Future directions include degradable PUs for use in tissue engineering, designer polymers based on PU chemistry that combine proteins with synthetic polymers, and light weight composites for various applications.

Polyvinylidene Fluoride

Jeffrey H. Yen
Ramin Amin-Sanayei
Arkema Inc., King of Prussia, Pennsylvania, U.S.A.

INTRODUCTION

Polyvinylidene fluoride (PVDF) is produced by free radical polymerization of vinylidene fluoride ($CH_2{=}CF_2$). The demand for PVDF has been growing remarkably because of its outstanding properties such as:

- Mechanical strength and toughness.
- High abrasion resistance, enabling it to be used with slurries.
- High thermal stability under operating and processing application; PVDF does not degrade (discolor) when subjected to heat.
- High dielectric strength.
- High purity.
- Readily melt processable.
- Resistant to most chemicals and solvents.
- Resistant to ultraviolet and nuclear radiation.
- Resistant to weathering, because of its transparency and inertness to ultraviolet (UV) rays.
- Resistant to fungi.
- Low permeability to most gases and liquids.
- Low flame and smoke characteristics.

PVDF is a semicrystalline polymer: the crystalline fraction results in very low permeability to gases and fluids as well as low swelling in certain solvents, whilst retaining a high impact resistance, a good stress cracking resistance, and a very high dimensional stability. It offers a relatively wide application temperature, ranging from $-40^{\circ}C$ up to $+150^{\circ}C$. It is nonflammable and nontoxic; so it can be used in food industry.

PVDF is the third most widely used fluoropolymer, after polytetrafluoroethylene (PTFE) and fluorinated ethylene-propylene (FEP). The worldwide consumption of PVDF was approximately 15,000 metric tons in 2001 and is growing at an annual rate of ~6–8%. PVDF applications have been expanded over the past 40 years because of its unique physical properties, and have over 30 years of proven and field performance data on thermal, chemical, radiation, and weathering applications. PVDF applications include, but are not limited to, chemical processing of pipes and components, semiconductor, architectural finishes and coatings, electrical plenum, cable jacketing, offshore/petrochemical flexible piping, binders for lithium ion batteries, fuel cell membrane, polymer processing additives, decorative films and sheets, etc.

VINYLIDENE FLUORIDE: MONOMER

Chemical and Physical Properties

Vinylidene fluoride (VDF), also known as refrigerant 1132a, 1,1-difluoroethylene, 1,1-difluoroethene, vinylidene difluoride, etc., is a colorless, nearly odorless gas. Unlike the other fluoromonomers, VDF has long shelf life stability and does not self-initiate unwanted polymerization. Therefore, VDF can be stored, and shipped pure or with polymerization inhibitors. Its properties are summarized in Table 1.[1]

Manufacturing of Vinylidene Fluoride

Arkema (formerly Pennwalt or Atofina), Dow, DuPont, ICI, Kureha, etc. have developed a number of processes based on C_1 and C_2 feedstocks.

VDF from C_1 routes

Yields and product selectivity for the C_1 routes are inferior to C_2 routes, thus, are less attractive.

$$CH_3OH + CHClF_2 \rightarrow CH_2CF_2 + HCl + H_2O$$

$$CH_4 + CCl_2F_2 \rightarrow CH_2CF_2 + 2HCl$$

$$CH_4 + CHF_3 \rightarrow CH_2CF_2 + HF + H_2$$

$$CH_4 + CCLF_3 \rightarrow CH_2CF_2 + HCl + HF$$

$$CH_3Cl + CHClF_2 \rightarrow CH_2CF_2 + 2HCl$$

VDF from C_2 routes

Most commercial VDF processes are based on C_2 routes because of their superior yield to C_1 routes. Among the C_2 routes, VDF will be relatively purer

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007923

when the feedstock is methylchloroform:

$$CH_3CCl_3 + 2HF \rightarrow CH_3CClF_2 + 2HCl$$

$$CH_3CClF_2 \rightarrow CH_2CF_2 + HCl$$

Other routes commercially practiced to produce VDF are :

$$CH{=}CH + 2HF \rightarrow CH_3CHF_2$$

$$CH_3CHF_2 + Cl_2 \rightarrow CH_3CClF_2 + HCl$$

$$CH_3CClF_2 \rightarrow CH_2CF_2 + HCl$$

or

$$CH_2CCl_2 + 2HF \rightarrow CH_3CClF_2 + HCl$$

$$CH_3CClF_2 \rightarrow CH_2CF_2 + HCl$$

or

$$CH_3CF_3 \rightarrow CH_2CF_2 + HF$$

or

$$CClF_2CCl_3 + 3H_2 \rightarrow CH_2CF_2 + 4HCl$$

In the reaction path from chloro-difluoro-ethane (CDFE) to VDF, a small amount of chlorine works as a catalyst. The mixture is preheated and then fed into a metal nickel tubular reactor, which is housed in a high temperature fired furnace at 550°C–600°C. The reactor effluent is then cooled and enters HCl adsorption tower for the removal of HCl. The gaseous effluent from the HCl adsorption tower is scrubbed with dilute caustic soda and is dried in a packed molecular sieve column. It then enters a distillation column for further purification and recycling of CDFE back to the pyrolysis reactor.

Health, Environment, and Safety

VDF is a flammable gas. When inhaled, potential health effects include nausea, difficulty in breathing, vomiting, dizziness, tingling sensation, suffocation, convulsions, coma, etc. Short-term skin contact may cause blisters and frostbite. The effects on short-term eye contact include frostbite and blurred vision. Other health, environmental, and safety related ratings are given in Table 2.[1]

POLYVINYLIDENE FLUORIDE

Chemical and Physical Properties

PVDF is a linear partially fluorinate polymer containing 59.4 wt% fluorine and 3 wt% hydrogen. The high level of intrinsic crystallinity, typically near 60%, provides stiffness, toughness, and creep resistant properties. Incorporation of various fluorinated comonomers at low levels, typically about 5–20 wt%, enhances flexibility and clarity of PVDF by reducing the crystallinity, which in turn reduces the end use temperature rating. PVDF is commercially produced via free radical polymerization either with emulsion or suspension processes.

The spatial arrangement of the alternating CH_2 and CF_2 groups along the polymer backbone creates a high dipole moment that accounts for the unique polarity, unusually high dielectric constant, complex polymorphism, and high piezoelectric and pyroelectric activity of the polymer.[2] Because of its polar nature, PVDF is permeation resistant to chlorine and bromine. Both chlorine and bromine are known to permeate most commonly available commercial polymers.

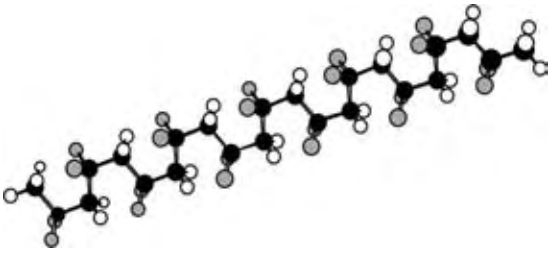
Typically, PVDF has four chain conformations:[3]

1. Alpha: The alpha form is the most common form of PVDF and is the most thermodynamically

Table 2 Environmental and safety related ratings

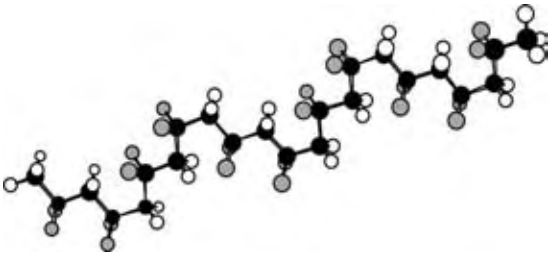
Lower flammable limit	5.5%
Upper flammable limit	21.3%
Autoignition temperature	640°C
ACGIH TWA	500 ppm
NIOSH recommended TWA 10 hr	1 ppm
NIOSH recommended ceiling	5 ppm
Octanol/water partition coefficient as log Pow	1.24

stable. It prevails on coating and normal melt processing of structural parts.



2. Beta: The beta form develops under mechanical deformation of melt-processed materials, typically at temperatures close to its melting transition. This structure provides some unique properties for PVDF: piezo- and pyro-electric activity.

3. Gamma: The gamma form arises infrequently.



4. Delta: The delta form develops through a distortion of one of the other forms under high electric fields.

(*Note*: In the above structures: grey = fluorine; white = hydrogen; and black = carbon.)

Resistance of PVDF to harsh acids, heat, ultraviolet rays, weathering, and oxidizing or high energy ionizing radiation environments, is the same as perfluoropolymers while its chemical resistance is not as broad. This is because the somewhat acidic hydrogen atoms along the chain are vulnerable to strong base attack.[4] This chemical susceptibility has, in fact, been turned into an advantage in preparing PVDF samples for adherence to a variety of substrates as well as introducing new chemical grafts to backbone. PVDF exhibits an unusual compatibility with other polymers having strong polar groups or carbonyl groups such as acrylics, and is particularly, miscible with short esters of methacrylic acid. This miscibility aspect led to the development of many alloys and mixed systems for coatings, membranes, and extruded parts.

Unlike conventional PTFE, PVDF can be molded through compression and injection processing and extruded into various shapes and configurations with conventional extruders. As a matter of fact, PVDF has been routinely processed on equipment that are also used for PVC and polyolefins.

PVDF Production

Polymerization chemistry

Free radical polymerization is the most widely used process in PVDF synthesis. It involves the reaction of VDF and other comonomers with active center followed by successive addition of monomer(s) under the condition in which monomers cannot react with each other without intervention of the active center. Active centers are generated by thermal decomposition of initiator and in some cases by photoinitiation of the catalyst. The average lifetime of each active center (free radical) is approximately few seconds depending on the degree of polymerization and the initiator concentration. For successful polymerization, the sequence of reaction must take place.

a. *Initiation Step*. VDF polymerization can be initiated with many different free radical initiators such as peroxides, peroxycarbonates, diacyl-peroxides, peroxyesters, and so on.

$$\mathrm{I} \rightarrow 2R^{\bullet}$$

b. *Propagation Step.* Successive monomer additions after the initiation step account for VDF consumption during polymerization and can be represented by

$$R_n^{\bullet} + \mathrm{VDF} \rightarrow R_{n+1}^{\bullet}$$

where n is the number of VDF units in the growing chain. The growing chain can undergo transfer reaction by abstracting hydrogen or halogen atom from a chain transfer agent(s) and that can be demonstrated by

$$R_n^{\bullet} + R' - X \rightarrow R_n - X + R'^{\bullet}$$

where $R_n - X$ is a dead chain and $R'^{\bullet}$ is a new radical that may or may not initiate new growing chain.

c. *Termination Step.* Termination can take place by the mutual annihilation of radical center to produce dead polymers.

$$R_n^{\bullet} + R_m^{\bullet} \rightarrow \text{dead polymer}$$

There are two possible points of addition on VDF for a propagating chain, either on carbon 1 (CF_2) or carbon 2 (CH_2). If each successive addition occurs in the same manner, the final polymer will have alternate carbon atoms. This type of addition will lead to head-to-tail arrangement. An inversion of in monomer addition will cause the formation of head-to-head and tail-to-tail addition. PVDF contains some head-to-head linkages because the F atoms are relatively small and their contribution to resonance stabilization of the growing polymer chain is not great. The head-to-tail placement, however, is the predominant successive propagation that favors both on steric and resonance grounds. Commercial grades exhibit a wide range of 3–7 mol% defect structures as determined usually by ^{19}F-NMR. The level increases with increasing polymerization temperature. The defect linkages affect significantly the crystallization processes and ultimate morphology.

Manufacturing process

The interesting and useful mechanical properties that are associated with PVDF depend on its molecular weight. The degree of polymerization of most commercial PVDF ranges from 1000 to 20,000 VDF repeating units. The heat of polymerization associated with propagation step is about 33 kcal/mol, which is much higher than that of a common vinyl monomer. This is because VDF is in a gaseous state and the resultant PVDF is solid. The common commercial polymerization reaction systems are emulsion and suspension polymerizations where the thermal and the viscosity problems can be managed. Use of nonaqueous media, such as CO_2, is also an active research area. Polymerization procedures, including temperature, pressure, recipe ingredients, monomer feeding strategy, and postpolymerization processing, are variables that influence product characteristics and quality.

Emulsion Polymerization. The temperature of the polymerization can vary depending on the characteristics of the initiator used, but it is typically between 30°C and 125°C. The pressure of the polymerization is typically between 1380 and 8275 kPa, but it can be higher if the equipment permits operation at higher pressure.

Surfactants used in the polymerization are water-soluble, halogenated surfactants. They are in particular fluorinated surfactant such as ammonium, substituted ammonium, quarternary ammonium, or alkali metal salts of perfluorinated or partially fluorinated alkyl carboxylates, monoalkyl phosphate esters, alkyl ether or polyether carboxylates, alkyl sulfonates, and alkyl sulfates.

A paraffin antifoulant may be employed, if desired, although it is not preferred, and any long-chain, saturated, hydrocarbon wax or oil may be used.

After the reactor has been charged with water, surfactant, and any optional paraffin antifoulant, it is brought to temperature and then pressurized with VDF and optional comonomer(s). The reaction pressure is maintained during polymerization course by adding monomer(s) to the reactor.

Chain-transfer agents range from alcohols, carbonate esters, ketones, carboxylate esters, to ethers compounds. Other classes of compounds, which serve as chain-transfer agents in the polymerization of VDF, are halocarbons and hydrohalocarbons such as chlorocarbons, hydrochlorocarbons, chlorofluorocarbons, and hydrochlorofluorocarbons.

The reaction can be started and maintained by the addition of any suitable initiator known for the polymerization of fluorinated monomers, including inorganic peroxides, ''redox'' combinations of oxidizing and reducing agents, and organic peroxides. Examples of typical inorganic peroxides are the ammonium or alkali metal salts of persulfates, which have useful activity in the 65°C–105°C temperature range. ''Redox'' systems can operate at even lower temperatures. Among the organic peroxides that can be used for the polymerization are the classes of dialkyl peroxides (di-*t*-butyl peroxide), peroxyesters (*t*-butyl peroxypivalate, *t*-butyl peroxyacetate), and peroxydicarbonates (di-*n*-propyl-peroxydicarbonate, diisopropyl-peroxydicarbonate).

Suspension Polymerization. Suspension polymerization of VDF can be carried out using an oil-soluble radical initiator such as peroxides, peroxycarbonates, diacyl-peroxides, or peroxyesters. Various dispersant agents such as cellulose derivatives or vinyl alcohol are used to prevent agglomeration during polymerization course. Coagulation of the polymer particle may occur at high comonomer loading when the polymer Tg is lower than the polymerization temperature. Suspension polymerization can be carried out using an oil-soluble initiator such as preoxy-dicarbonates or proxy. A suspension polymerization can also be conducted using a radical photoinitiator with UV–visible light. The polymerization temperature can be lowered because of photogeneration of radicals. Lowering the polymerization temperature reduces the number of defect structures in PVDF.

Other polymerization systems

VDF polymerization technology based on supercritical or liquid carbon dioxide as polymerization media has been reported.[5–8] This technology offers an advantage in the polymer isolation step where a clean dry polymer is produced simply by depressurization. The residual monomer(s) and CO_2 can be recycled back to the reactor. The PVDF having a multimodal molecular weight distribution is produced in CO_2. Adequate CO_2 density

for polymerization requires a pressure significantly higher (typically >100 bar) than a conventional emulsion polymerization. Fluorocarbons and partially fluorinated hydrocarbons with no significant chain-transfer activities are reported to be a suitable medium for VDF polymerization.[9]

A multistage emulsion polymerization of VDF and acrylics monomer facilitates production of alloys of PVDF and PVDF copolymers with acrylic polymers. The fluoropolymer portion is produced in the first stage having small particle size somewhere between 50 and 150 nm. Acrylic monomers with specific functionalities are generally added in the later stage under atmospheric pressure in the presence of an initiator.[10,11] The final morphology of the alloy depends upon the composition of the fluoropolymer particles, the acrylic monomer type, and the feed schedule. The structure of alloys can range from a core-shell, an interpenetrated structure, to an intimate blend morphology.[12–14]

Hydroxyl terminated telomers of VDF are prepared in methanol using *tert*-butyl peroxide as the initiator. Less than 10 mm thick film has been produce using microwave-stimulated, low-pressure plasma polymerization of VDF. An isoregic PVDF polymer with minimized head-to-head placement has been synthesized and reported.[15] Properties and synthesis of perdeuterated PVDF have also been pointed out.[16]

Polymer Properties

As mentioned previously, PVDF provides a number of outstanding chemical and physical properties, such as

mechanical strength and toughness, abrasion resistance, thermal stability, dielectric strength, melt processable, UV and radiation resistance, low gas permeability, flame resistance, etc. The design properties for PVDF homopolymers are summarized in Table 3.[17,18]

COMMERCIAL PVDF PRODUCERS AND MARKET

The process for PVDF polymerization was first patented by DuPont in the 1940s and acquired by Pennwalt in the 1950s. In 1961, Pennwalt introduced Kynar® PVDF into the market for several applications, including coatings, resins, etc. In 1965, Pennwalt's Calvert City plant came on stream producing a series of homopolymers with varying molecular weight. In the 1970s, Pennwalt introduced Kynar PVDF SL and ADS as low bake and air-dry touch-up paints, and Kynar PVDF 700 series for melt processing. Pennwalt was acquired by Elf Atochem in 1989. In 2002, TotalFina acquired Elf Aquitaine, and Elf Atochem was renamed as Atofina Chemicals. In 2004, Atofina was reorganized into Arkema Inc.

The production of VDF and PVDF is capital intensive as it requires R-142b as a monomer precursor, corrosion-resistant pyrolysis reactors, and low temperature distillation columns for the vinylidene fluoride monomer, high-pressure polymerization reactors, and finishing process. So far, mass production of PVDF has been limited to the United States, Europe, and Japan. Major PVDF producers are shown in Table 4.

The PVDF production in Thorofare, NJ, was originally built by Pennwalt and was diversified to Ausimont in 1999. In late 2001, Solvay started up its Decater, Alabama, plant with a capacity of 5000 MT. In 2002, Ausimont sold its Thorofare plant to Solvay and Solvay diversified its Decater plant to Dyneon (a 3M subsidiary). In 2003, Arkema expanded its PVDF production in Pierre-Benite, France.

The production capacity and market demand for PVDF in major producing and consuming regions are summarized in Table 5. [19]

Table 4 Major PVDF producers

Region	Producer	Location
North America	Arkema	Calvert City, Kentucky
	Solvay	Thorofare, New Jersey
	Dyneon	Decater, Alabama
Europe	Arkema	Pierre-Benite, France
	Solvay	Belgium
Asia	Kureha	Iwaka, Japan

APPLICATIONS OF PVDF

Both homo- and copolymers of vinylidene fluoride are melt processable with a broad operating window. Typical processing temperatures are 180–240°C for extrusion and for injection. At temperatures well above 300°C and approaching 350°C, thermal decomposition will start, and at about 400°C hydrogen fluoride evolution becomes a significant by-product, leading to dangerously high pressure build-up in the equipment. The onset of a thermal degradation will be evident as a darkening, or a discoloration of resin takes place, which in turn is a sign of forming the conjugated double bonds at the expense of dehydrofluorination of PVDF.

All the ordinary extrusion and molding equipment and techniques can be used to process PVDF into different shapes ranging from pipes, fitting, parts, solid rods and sheets, to thin films. Longevity of equipment can be extended using special alloys on the surface that is in contact with molten PVDF, but usually it is not necessary. PVDF based polymers are available commercially in a wide range of melt flow index and with additives to enhance processing or end use properties. However, both homopolymers and copolymers may be shaped from the molten state without extrusion aids or thermal stabilizers.

Industrial Applications

PVDF components are used extensively in the high purity semiconductor market (low extractible values), pulp and paper industry (chemically resistant to halogens and acids), nuclear waste processing (radiation and hot acid applications), and the general chemical processing industry (chemical and temperature applications). Fluoropolymers have also met specifications for food and pharmaceutical processing industries.

There are VF_2/HFP copolymers that are similar to PVDF resins in purity and chemical resistance, but possess unique qualities of additional chemical compatibility in high pH solutions, increased impact strength at ambient and colder temperatures, and increased clarity. The chemical usage guidelines for PVDF and PVDF FLEX can be found from PVDF manufacturers.[20]

PVDF can be fabricated into a wide range of components including:

- Pipes, fittings, and valves
- Pump assemblies
- Sheets and stock shapes
- Films
- Tubing

Table 5 PVDF production capacity and demand in major markets

	Year 2000		Year 2001	
Region	**Capacity (MT)**	**Demand (MT)**	**Capacity (MT)**	**Demand (MT)**
North America	16,300	9700	16,300	8700
Western Europe	7200	3900	7200	4100
Japan	1600	1520	1600	1400

- Tower packing
- Powder-coated metal
- Membranes
- Foam insulation

Offshore and Petrochemical Handling

Because of its exceptionally wide temperature tolerance (up to ~160°C), excellent UV and aging resistance, resistance to a wide range of hydrocarbon solvents and aggressive chemicals, high dielectric strength, flexural response, buoyancy and thermal insulation properties, PVDF is used in a broad spectrum of applications, ranging from sealing and thermal insulation in aggressive environments to pipeline pigs.

Architectural

PVDF resin has been used as the base resin in liquid coatings formulated by leading paint manufacturers. When formulated into a coating composition, which according to the license agreement contains a minimum of 70% by weight of PVDF resin, the resultant coatings exhibit superior

- Color retention
- Chalk resistance
- Gloss retention
- Chemical resistance
- Corrosion resistance
- Flexibility
- Stain resistance
- Overall exterior durability

Substrates

Liquid coatings containing PVDF resin are factory applied to properly cleaned, pretreated, and primed metal substrates, and then oven baked. Metal substrates most commonly coated with PVDF resin based finishes are aluminum, galvanized steel, and aluminum/zinc alloy plated steel. PVDF resin based coatings are typically applied to building components such as metal siding and roofing, storefront extrusions, curtain walls, louvers, skylights, and other miscellaneous metal trim and extrusions. Components can be either postformed from precoated coil stock, or spray coated after fabrication.

Color

Each of the PVDF brand licensees has established its own standard colors. Special colors, including metallics and exotics, are subject to approval by the licensees; however, a broad range of brighter colors are now available.

Composition and materials

Finishes based on PVDF resin are formulated by licensed formulators and contain, in addition to PVDF resin, solvents and high quality pigments. These high quality coating systems have a proven history of performance when exposed to severe ultraviolet radiation for extended periods (over 30 yr) of time.

Fig. 1 compares the performance of PVDF resin-based coating systems with competitive coatings for their weather resistance.[21,22] Panels coated with Kynar 500® and other coating systems were exposed on a South Florida test fence for 10–17 yr. The top of the panels was unexposed while the lower part was exposed to sunlight for 10–17 yr. It was concluded that Kynar 500 PVDF offers superior color retention, greater gloss retention, and better resistance to chalking than other systems tested.

Waterborne PVDF-based coatings

Recently, waterborne and environmentally favorable coatings have been developed based on fluoropolymer resin technology. Arkema is developing novel latex dispersions, using vinyl fluoride fluoropolymers and acrylic polymers similar to those used in PVDF architectural coatings. This new acrylic-modified fluoropolymer (AMF) technology can be used to make air-dry latex coatings with an inertness to photochemical attacklike traditional baked PVDF coatings.[23] In addition, compared to conventional PVDF paint formulations, such waterborne latex dispersions offer

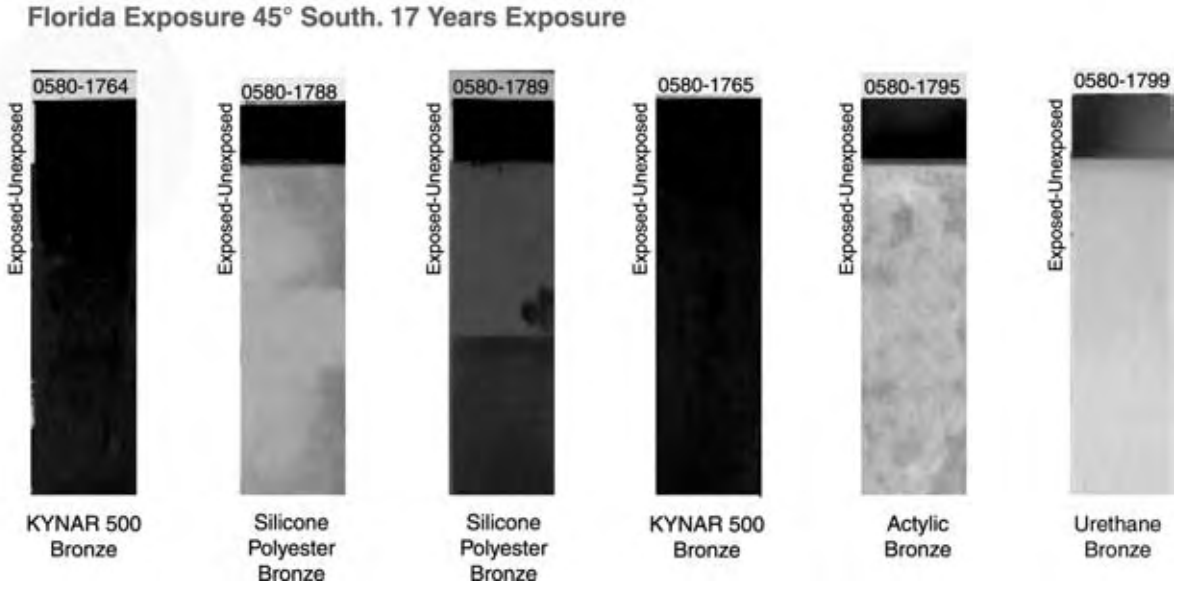

Fig. 1 Comparison of weather resistance of competitive coating systems. *(View this art in color at www.dekker.com.)*

a lower VOC emission while maintaining a comparable long term weathering performance.

Electrical Applications

PVDF/HFP fluoropolymer resin is the premium jacketing material for use on data, voice signal, alarm, and video low-voltage cable. Because the PVDF/HFP fluoropolymer exhibits minimal flame spread and smoke generation, cable jacketing with this fluoropolymer meets National Electrical Code (NFPA-70A) requirements for installation in building plenum areas without the need for conduit casing. In fact, to increase the safety factor, many insurance carriers recommend that their clients install plenum cable throughout in plenum and nonplenum building areas. VF_2/HFP fluoropolymer resin is extremely durable, and resistant to abrasion and mechanical damage during and after cable installation. The flexibility makes cable installation faster and easier. VF_2/HFP fluoropolymer is also a jacketing material for nonplenum cable applications where its flexibility; toughness; light weight; and resistance to chemical, thermal, corrosive, and ultraviolet attack are important. VF_2/HFP fluoropolymer resin is particularly well suited for use in hostile environments where corrosive atmospheres, thermal cycling, or mechanical stress to the cable are possible.

Lithium Ion Batteries and Fuel Cells

PVDF homopolymers and copolymers have gained success in the battery and fuel cell industry as binders for cathodes and anodes in lithium ion technology, and as battery separators in lithium-ion and fuel cell polymer technology. Their high electrochemical, thermal, and chemical stability, as well as ease of processing yields unmatched performance compared to other polymeric binders in lithium ion systems. The development of polymers for such challenging applications takes into account the adhesion properties of the polymer, crystallinity, solvent effects, solution behavior, and slurry preparation and processing.

Lithium ion batteries

Both the anode and the cathode are composed of a coating of the electrochemically active material onto a current collector (copper or aluminum). Another key component of the battery is the separator that physically separates the two electrodes and prevents contact between them. In the case of a liquid technology battery, a polyolefin separator is typically used and a liquid electrolyte is used to transport the Li ions from one side of the porous separator to the other. In the case of a polymer Li ion battery, a polymer, such as PVDF, is used to form a porous structure, which is then swollen with a Li^+ conducting liquid electrolyte.[24] This results in a gel-type electrolyte, which plays the dual role of electrolyte and separator, with no free liquid present.

Fuel cells

PVDF/graphite composites can lend themselves as the best materials for both molded and coated plates. A key component of a fuel cell stack is the bipolar plate. Also referred to as a water transport plate or a separator

plate, this plate functions to channel air (oxygen) to the cathode and hydrogen to the anode, while providing a method to carry away the heat of reaction and water formed in the process. The plates are the backbone of the fuel cell representing significant cost and weight. Operational fuel cells with bipolar plates produced from exotic materials such as titanium, niobium, tantalum, vanadium, etc. have proven useful for the testing of concepts but can never be used in a commercial operation. Machined graphite is also used. Viable processes for bipolar plate manufacture have explored a variety of low cost materials to replace the expensive metals or machined graphite.

Polymer Processing Additives

PVDF-based resins offer a range of fluorinated processing aids specifically designed to improve LLDPE and PP film extrusion, when used at 100–1000 ppm addition levels. Special grades of PVDF are effective in eliminating melt fracture (shark skin) and die build-up while allowing for higher outputs and reduced extruder pressure. This results in improved film quality and strength even when utilizing antiblock agents.[25]

PVDF-based processing aids can eliminate or minimize many of the melt instabilities that occur in high shear extrusion, mainly melt fracture. This allows a wider operating window for process parameters. This coating acts as a lubricant to reduce apparent viscosity, lower die pressure, and melt temperature, and increase film production rates.

Films and Foams

With the flexibility of the blown film extrusion process, one-step production of wide multilayer films is possible. Incorporating a built-in adhesive layer, PVDF films can be laminated directly onto various thermo and thermoset plastics or primed metal substrates. PVDF films can protect the esthetics of UV sensitive substrates while also providing a thermal, chemical, and abrasion-resistant barrier. Recently, white PVDF films have been commercialized that are of full opacity in the UV range of 290–400 μm.[26] Most recently, PVDF has been used in foams. The potential applications include flame-resistant insulation; filtration materials; exterior decorative, acoustical, or insulation materials, etc.[27]

USE, FABRICATION, PROCESSING, AND DISPERSION

PVDF is available commercially in a wide range of physical properties (e.g., melt flow rates, melting point, comonomer content, etc.) and a variety of forms, such as pellets, granulars, latex, fine powders, sheets, films, etc.

Extrusion

All the common extrusion techniques can be used to process PVDF into various products, such as rod, sheet, film, pipe, tubing, monofilament, wire insulation, etc.[28] No extrusion additives, lubricants, or heat stabilizers are needed. Equipment with materials of construction similar to those used for extruding PVC and polyolefins is applicable for PVDF. Extrusion temperatures vary from 210°C to 270°C depending on the type of PVDF resin and the shape being extruded. Extruders with L/D ratios of at least 20 are recommended. For very thin products, the temperature at the dietip can be as high as 320°C as required for heat polishing.

Water quenching can be used for wire insulation, tubing, and pipe. Sheet and film extruded from slit dies are frequently crystallized on polished steel rolls operating at 65°C–145°C. Extruded, blown, or flat film can be uniaxially or biaxially oriented to submil thickness. Monofilament is extrusion spun into a water bath, and then oriented and heat set at an elevated temperature.

Molding

PVDF resins are readily molded in conventional compression, transfer and injection molding equipment. Typical molding temperatures in the cylinder and nozzle are 180–240°C for injection types and 50–90°C for molds. As a crystalline polymer, PVDF typically shows relatively high mold shrinkage of about 2–3%, reflecting the high degree of crystallization and the difference between the solid and the molten densities.

Fusion Welding

PVDF components, such as pipe and tubing, may be joined by various fusion welding methods.[28] Compared to the solvent jointing method, fusion methods are preferred as the joints are stronger and processing itself is easier. Among the most common and efficient fusion welding methods are heat contact welding and hot gas/air using a welding rod. Contact welding is performed by holding two sections that have each been heated to create a molten layer of resin, in position with adequate pressure until the polymer has congealed and cooled. Hot as-welding using a welding road is a common way to construct PVDF lined components such as metals and fiber-reinforced plastics.

Temperatures required to adequately produce a molten layer of the surfaces vary from 210°C–290°C. Welds may be particularly susceptible to stress cracking in strongly alkali solutions where discoloration develops as a result of dehydrofluorination. VF_2/HFP fluoropolymers exhibit improved resistance to a high pH environment, where PVDF homopolymers have been known to become brittle over time.

Dispersion for Coating and Paint

Powder-grade PVDF is the key ingredient in the formulation of premium architectural coatings. The primary components of a PVDF-based coating system are: 1) PVDF resin (typically 15–30%); 2) acrylic resin (typically 6–15%); 3) pigment (typically 10–20%); 4) organic solvent (typically 40–65%); and 5) other additives (typically 2–5%), such as UV absorbers, antisettling additives, surfactants, etc.[3]

The coating formulation includes other ingredients, such as a pigment for color and opacity, modifiers and additives for performance enhancement, etc. Because the coating will be baked at elevated temperatures, the pigment must also be resistant to heat and chemicals. Nonorganic color pigments, such as ceramic compounds, are preferred.

In most cases, the substrates are metals, such as copper, aluminum, etc. The pretreatment of the metal substrate is critical to its performance. In some cases, a primer is applied to impart adhesion, corrosion, and delamination resistance.

Application is usually done through coil coating, spray coating, or powder coating. The coated material then undergoes a baking process, which evaporates the solvent, coalesces the PVDF particles, and fuses them together. The baking process is typically carried out at elevated temperatures above 165°C.

HEALTH AND SAFETY FACTORS

PVDF resins are relatively stable, nontoxic, odorless, and nonhazardous under typical handling conditions. Incidents, mechanical malfunctions, or human error may lead to thermal decomposition with evaluation of toxic hydrogen fluoride (HF) at high temperatures. Precautions must be taken to prevent excess inhalation and physical contact with hydrogen fluoride should decomposition take place. Unlike PVC, PVDF resins will stop decomposing when the heat source is removed and the temperature of the melt is allowed to fall to normal processing temperature. Generally speaking, PVDF has a limiting oxygen index (LOI) of ~44, i.e., an ~44% oxygen environment is needed for PVDF to continue to burn.

PVDF resins are stable when processed as recommended at temperatures between 190°C and 300°C.[19,28] Thermogravimetric analysis has shown that the initial thermal decomposition starts at approximately 375°C. At temperatures approaching 300°C, the onset of a thermal degradation will be evident as a darkening of the resin.

Additives, such as mica, glass fibers, titanium dioxide, and very finely divided metals, may catalyze thermal decomposition rates during processing and should be used with caution.

When handling PVDF powders, personal protective equipment should be used. The powder is not removed readily by dry cleaning; it should be brushed from clothing.

Similar to other fluoropolymers and fluoroelastomers, such as PTFE, FEP, PFA, etc., low-level perfluorinated surfactants or chemicals, such as ammonium perfluoro-octanoate (APFO), etc. may be used in some fluoropolymer production as an emulsifier. These perfluorinated compounds are mostly extremely stable, degrade slowly, and therefore persist in the environment. These surfactants have varying ecotoxicity profiles, and users should contact their supplier for a more detailed ecotox information for their particular product.[29] Industrial efforts are being made to reduce or even eliminate the use of such perfluorinated surfactants in their products and/or manufacturing processes.

CONCLUSIONS

PVDF is a high performance, melt-processible fluoropolymer with good mechanical strength and toughness, high thermal stability, high dielectric strength, excellent resistance to most chemicals, solvents, radiation and weathering, and low flame and smoke characters. Because of its excellent weatherability, PVDF-based architectural coatings have been used widely in high rise buildings as well as industrial and residential applications. Flexible VDF-based copolymers have been used in a wide spectrum of applications, such as plenum wire and cable, film, membrane for lithium batteries and fuel cells, etc. Owing to its outstanding mechanical, physical, chemical, electrical, weathering, and other properties, PVDF is among the cost-effective materials of choice when used in compatible applications.

Porous Media

Karsten E. Thompson
Gordon A. and Mary Cain Department of Chemical Engineering, Louisiana State University, Baton Rouge, Louisiana, U.S.A.

INTRODUCTION

Porous media are a part of many chemical processing applications, including reaction engineering, chromatography, filtration, separations, catalysis, and more. They also impact related processes: the production of raw materials (hydrocarbons) from porous rock and the transport of chemical contaminants spilled into the environment.

The purpose of this entry is to provide an introduction to the morphology of porous media, the behavior of fluids in porous media, and modeling techniques. While selected equations are presented, the emphasis is on phenomenological behavior, the aim being to give the reader a basic foundation in the physics of transport before a more detailed study might be undertaken. Many important topics have been omitted due to space constraints; see the ''Conclusions'' section for recommended texts on these topics.

CONCEPTS AND DEFINITIONS

A porous medium is a material that is composed partly of solid phase, partly of void phase. In most porous media of interest, the void space is interconnected, which allows for fluid transport through the material. The term ''pore-scale'' implies behavior or analysis performed at a resolution where the void phase and solid phase can be distinguished. At this scale, the void phase is conceptually divided into pores (the larger voids, which provide its volume) and pore throats (constrictions that connect the pores), though the distinction is rarely black and white. In contrast, the continuum-scale approach is usually adopted in engineering practice. Continuum techniques treat the bulk porous medium as a single phase, which in turn requires spatially averaged parameters to be introduced that are intended to capture relevant characteristics of the pore-scale structure.

Unconsolidated porous media are loose packings. Examples include packed columns, sand, and loose fibrous materials. Conversely, consolidated media have a fixed, interconnected solid phase. Examples include sintered materials, reservoir rocks, and certain catalyst supports. The terms fibrous vs. granular media denote the aspect ratio of the particles (long and slender in fibrous materials). A medium's wettability indicates the preference of the solid phase for contact with one fluid as opposed to another. Clean quartz sand is water wet, while sand with adsorbed organic material can become oil wet. Most liquids behave as the wetting fluid relative to air, though mercury is an important exception. Wettability is quantified by the contact angle, which, in this entry, is defined as the angle between the fluid–solid boundary and the fluid–fluid interface at the three-phase contact point, measured through the wetting phase. This definition is not universal, however.

Porosity is one of the most important continuum-scale parameters. It is defined as the fraction of the total volume that comprises void space: $\varepsilon = V_{\text{void}}/V_{\text{total}}$. Equivalently, the solid volume fraction ($\phi = 1 - \varepsilon$) is generally used for fibrous materials or other open structures. The term microporosity implies that the particles in a porous medium are themselves porous, usually at a much smaller scale. A common example is porous catalyst in a packed-bed reactor.

Single-phase flow means that only one fluid phase is present in the void space (implying, most importantly, that no fluid–fluid interface exists). The superficial velocity v is a volume flux based on the *total* cross section of the material. (For flow in a packed column, $v = Q/A$, where Q is the volumetric flow rate and A is the column cross-sectional area.) The interstitial velocity, $v_{\text{int}} = v/\varepsilon$, better characterizes the average fluid velocity actually present in the voids.

MORPHOLOGY

The term ''morphology'' is used in a general sense to include any parameter that quantifies pore-scale structure: pore geometry, pore coordination number, grain shape, porosity, spatial correlations in pore size, etc. Pore morphology varies dramatically from one material to another and has a very strong influence on continuum-scale behavior.

Packed Beds

In industrial packed beds, particle shapes vary widely. Irregular shapes are often used to minimize frictional

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008116

losses, improve contacting or heat transfer, increase surface area, etc. However, spheres are also common (and are more amenable to mathematical analysis than other shapes); consequently, random sphere packings are the most carefully characterized of any specific porous medium. Random packings of uniform spheres exhibit a tight porosity range that falls between 0.36 and 0.42, independent of sphere diameter. Values of $\varepsilon = 0.37 - 0.38$ are most typical in practice, provided the particle-size distribution is tight. However, as polydispersity increases, porosity generally decreases.

The random close-packed (RCP) limit is the lowest porosity achievable without ordering, and has long been a subject of theoretical interest.[1] It is thought to be very close to 0.36, though an exact value has never been proved. Experimental determination of the limit is difficult due to edge effects (which increase the average porosity), local ordering, and the inability to obtain uniform-sized exact spheres. A classic study undertaken by Scott and Kilgour[2] involved packing spheres into a series of dimpled containers and then extrapolating the porosity results to an infinite radius to remove edge effects. Their results give $\varepsilon_{\min} = 0.3634 \pm 0.0005$. Much research has been performed using computer-generated packings, and limiting porosities have been achieved that are slightly lower than the experimental values.[3]

The packing structure near a wall differs from the bulk structure. This phenomenon has important implications with regard to fluid channeling and heat transfer near reactor walls. Fig. 1 is a graphic from a numerical simulation of flow in a chemical reactor.[4] The velocity quivers indicate preferential fluid flow near the walls. This particular simulation contains only a few particles across the reactor diameter. For larger ratios ($d_{\text{bed}}/d_{\text{particles}} > 30$), wall effects decay quite rapidly, penetrating approximately two sphere diameters in from the wall.[5]

In cases where the locations of individual spheres are known, detailed analyses of void structure can be carried out. This situation is restricted mainly to computer-generated packings, though one significant exception is the Finney packing,[1] which is an experimental mapping of ~8000 sphere locations in the interior of a random packing. Mellor[6] provides extensive statistical analysis of the Finney packing based on Delaunay and Voronoi discretizations.

The Delaunay tessellation is particularly important because it provides a tool to decompose the continuum void space into discrete pores, which is essential for pore-scale modeling.[7] An important drawback to using the Delaunay tessellation for extracting pore structure is that it leads to a fixed pore coordination number of 4, which is a geometric artifact; in a real packing, not all voids conform to the tessellation's tetrahedral structure. Experimentally, the average coordination number for a sphere packing has been measured to be $z = 4.3$.[8] A numerical analysis has been performed that constructs irregular polyhedral pores based on local geometry, as shown in Fig. 2. It suggests that this number should be higher, of the order of $z = 5.2$ for $\varepsilon = 0.38$.[9]

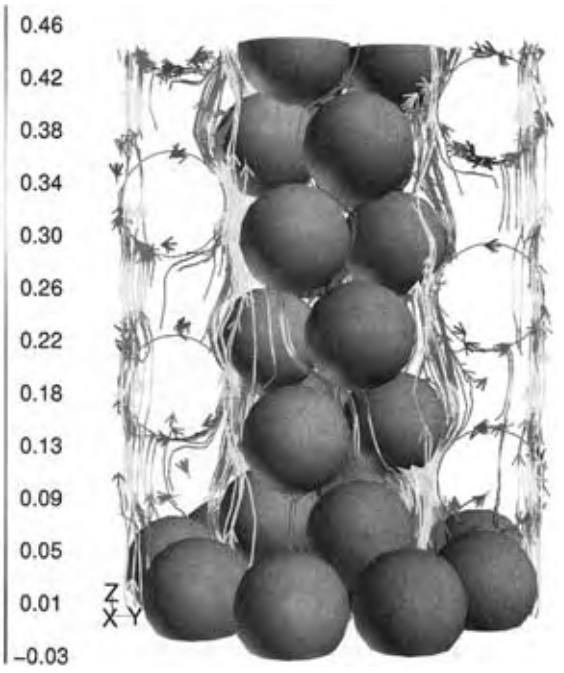

Fig. 1 Numerical simulation of flow in a packed-bed reactor. Velocity quivers illustrate near-wall channeling, which affects residence time distributions, heat transfer, etc. (From Ref.[4].)

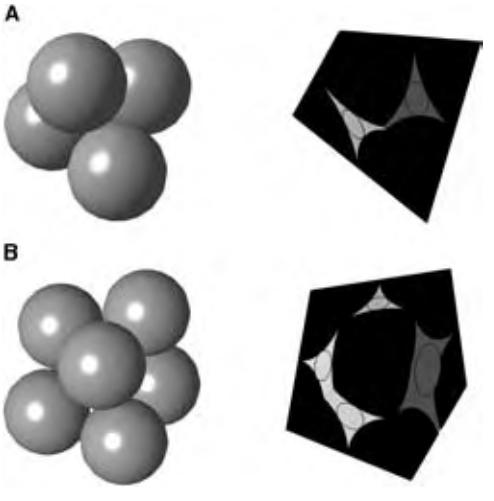

Fig. 2 Three-dimensional visualizations of pore structures in a random packing; sphere clusters on left; polyhedral discretizations of the same on right: (A) $N_s = 4$; $z = 4$ (tightest cluster possible); (B) $N_s = 6$; $z = 7$.

Consolidated Materials

Sandstones originate from loose packings and then become consolidated over time due to compaction, radial grain growth, and cementation at grain contacts. Despite these diagenetic processes, the original granular structure is evident in many sandstones. The final permeability depends primarily on the original grain size and the final porosity, and varies from the millidarcy range to the 1000-darcy range.

Carbonates are formed from irregular particles, and diagenesis has a more pronounced effect on the resulting structure. As such, they are more difficult to characterize using simple parameters such as grain- or pore-size distributions. Factors such as vugs, fractures, and other heterogeneities tend to have an adverse effect on their permeability.

Fibrous Materials

The defining feature of fibrous materials is their high-aspect-ratio particles, which in turn are responsible for significant differences from granular packings: The solid volume fraction can span nearly three orders of magnitude; anisotropy is the norm rather than the exception; and ordered fibrous materials are commonplace (e.g., woven fabrics and materials composed of aligned bundles, both of which are precursors for composite materials manufacturing).

Characterizing Morphology

Because mercury is nonwetting, mercury porosimetry is used to obtain capillary pressure curves during injection (see section on ''Immiscible Displacement''). This technique allows estimates of pore-size distribution to be made.

Thin-section analysis is an important (though destructive) tool. The void space is filled with epoxy or an equivalent compound, and the sample is sectioned and viewed by microscopy. The main advantage is the excellent resolution of detailed pore structure. However, sample preparation and image analysis are labor intensive. Additionally, three-dimensional structure can be obtained only by reconstruction from consecutive thin slices.

Though it is still an evolving technique, tomography is perhaps the most powerful tool for nondestructive analysis. Initial research in this area was performed using medical-grade equipment and gave only continuum-scale resolution. More recently, high-resolution microtomography has been developed, which can resolve detailed pore structure in many types of media.[10,11] Microtomography systems employ synchrotron beamlines or new-generation conventional X-ray sources and can achieve resolutions down to approximately 1 μm. Contrast in the images is derived from density difference (to resolve basic pore structure) or doping agents (to study fluid-phase distributions), both of which affect the absorptivity of the beam.

Raw data from microtomography consist of pixelized values of absorptivity. Depending on the contrast in the data, the pixelized mapping can often be used to generate images directly, as shown in Fig. 3. Otherwise, segmentation must be performed to map the continuous distribution of absorptivity values to discrete phases in the system. Even more challenging is extracting statistical information or reconstructing topology from the pixelized map. The most promising computational tool appears to be medial-axis analysis or a close variant.[10] It creates a skeleton of the void space, upon which the complete void structure or a fluid-phase distribution can be built.

SINGLE-PHASE FLOW

Equations for Fluid Motion

The Reynolds number for porous media is defined using an appropriate characteristic length, usually an average particle or pore diameter, so that $Re = \rho v D_p/\mu$. For single-phase flow at low Reynolds numbers ($Re < \sim 1$), the superficial velocity is linearly proportional to the applied force(s) driving the fluid flow. The most common equation for this linear relationship is Darcy's law:

$$\mathbf{v} = -\frac{1}{\mu}\mathbf{K} \cdot \nabla \mathscr{P} \tag{1}$$

where $\mathbf{v}$ is the superficial velocity, $\mathbf{K}$ is the permeability tensor, and $\mathscr{P}$ is the dynamic pressure. Eq. (1) is the

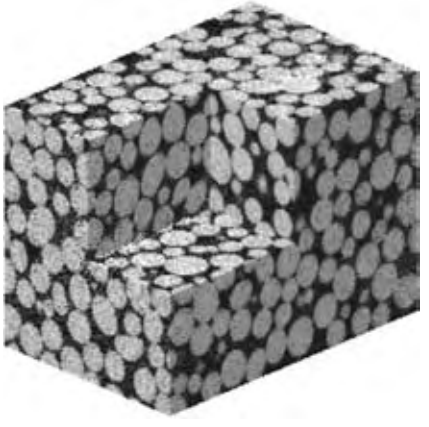

Fig. 3 Three-dimensional image of a packed bed of glass spheres obtained by synchrotron microtomography. (Courtesy of Clinton S. Willson.)

most general form of Darcy's law, valid for three-dimensional anisotropic porous media. In isotropic materials, the velocity and pressure gradient are collinear; hence, permeability can be assigned a scalar value. Additionally, in many practical situations (e.g., flow through a packed-bed reactor), the flow is macroscopically one-dimensional, and a convenient form of Darcy's law becomes

$$\frac{Q}{A} = \frac{K}{\mu}\frac{\Delta\mathscr{P}}{L} \tag{2}$$

The role of permeability in Darcy's law is to quantify the hydraulic conductivity of the medium. Permeability has dimensions $(\text{length})^2$, and is typically assigned units such as cm^2 or μm^2 in hydrology or materials science literature. The unit ''darcy,'' which has retained prominence in petroleum engineering, is based on an inconsistent set of traditional engineering units, and thus requires the awkward conversion $1\,\text{darcy} = 1\,\text{cm}^2\,\text{cp}/(\text{atm s}) = 9.8692 \times 10^{-9}\,\text{cm}^2$.

Beginning at approximately $Re = 1$, inertial forces become significant, and the linear relationship is no longer valid. The Forchheimer equation addresses this limitation by including a quadratic velocity term:

$$\frac{\Delta\mathscr{P}}{L} = a_1 v + a_2 v^2 \tag{3}$$

The Ergun equation (described subsequently) assumes this functionality and incorporates explicit expressions for the two coefficients. For $Re >> 1$, turbulent flow is observed. However, due to the distribution of length scales and velocities, and the large surface area for viscous dissipation, the onset of turbulence is gradual as Re is increased, rather than sudden.

In addition to the Reynolds-number limitations discussed above, a shortcoming of Darcy's law is that it does not allow boundary conditions to be imposed at porous media interfaces (e.g., a no-slip condition at a reactor wall). This problem is addressed by Brinkman's equation, which is a combination of the Stokes equation and Darcy's equation:

$$\nabla\mathscr{P} = \mu\nabla^2 v - \frac{\mu}{K}v \tag{4}$$

Brinkman's equation is restricted to higher-porosity materials: It is invalid for $\varepsilon < 1/3$,[12] and is best used for $\varepsilon > \sim 2/3$.[13]

Predicting Permeability, Pressure Drop, and Flow Rate

For porous media with unknown or complex pore structure, permeability must be determined experimentally. It can be measured by injecting fluid through a cylindrical packed bed or a cylindrical core sample and measuring the required pressure drop. Flow must be single phase (to avoid the very strong effects of multiphase flow on permeability). Additionally, edge effects must be avoided: Flow tends to channel near the edge of packed beds and around consolidated samples unless they are well contained. Methods for containment include cementing a sample into a flow cell with epoxy or placing it in a flexible sleeve and applying a very high overburden pressure to the sleeve.

Experimental measurements are time intensive and require special equipment, so empirical equations for permeability are of great value. Unfortunately, because the structures of porous media are so complex and varied, empirical techniques are quite specialized. A few important relationships are summarized below.

Flow in packed beds—The Ergun equation

For packed beds, a number of semi-empirical equations have been developed by approximating the packed bed as a bundle of tubes. Notably, this approach neglects heterogeneity, interconnectivity, and the converging–diverging nature of the pore space, but nonetheless it has proved effective for single-phase flow in packed beds because friction drag is the dominant effect.

The general approach is to define the traditional hydraulic radius, but for a more complex cross section for flow. For a porous medium, it is equivalent to the ratio of void volume to surface area, which is known for certain geometries, such as a packing of spheres:

$$\text{HR} = \frac{\varepsilon}{1-\varepsilon}\frac{D_\text{p}}{6} \tag{5}$$

The equivalent diameter ($D_\text{eq} = 4\text{HR}$) is used to define the Reynolds number and the frictional loss term in the mechanical energy balance:

$$Re = \frac{2}{3}\frac{\rho v D_\text{p}}{\mu}\frac{\varepsilon}{1-\varepsilon} \tag{6}$$

$$\mathscr{F} = 3f\frac{L}{D_\text{p}}\frac{(1-\varepsilon)}{\varepsilon}v^2 \tag{7}$$

At low Reynolds numbers, the friction factor for flow in tubes is $f = 16/\text{Re}$. For packed beds, both f and v are adjusted by a tortuosity factor to account for the fact that a fluid element travels a longer distance (winding through the pore space) than bed length L. Empiricism has led to adjustments in either the tortuosity or the final equation or both (depending on the derivation) to yield a well-accepted result for

low-Reynolds-number flow:

$$\mathscr{F} = 150\frac{v\mu L}{\rho D_p^2}\frac{(1-\varepsilon)^2}{\varepsilon^3} \quad (8)$$

At higher Reynolds numbers, the friction factor becomes roughly constant, and $\mathscr{F}$ is expected to take on a v^2 dependence. These arguments, and an empirical friction factor of $f = 7/12$, lead to

$$\mathscr{F} = 1.75\frac{v^2 L}{D_p}\frac{(1-\varepsilon)}{\varepsilon^3} \quad (9)$$

These two frictional loss terms can be used in the mechanical energy balance, leading to the Blake–Kozeny equation (for low Re) and the Burke–Plummer equation (for higher Re). Ergun combined the two to give the most well-known equation for flow through packed beds:

$$\frac{\Delta\mathscr{P}}{L} = 150\frac{v\mu}{D_p^2}\frac{(1-\varepsilon)^2}{\varepsilon^3} + 1.75\frac{\rho v^2}{D_p}\frac{(1-\varepsilon)}{\varepsilon^3} \quad (10)$$

(see Ref.[14] and the references therein). Because of its importance in chemical engineering, the Ergun equation has been studied extensively, and various adaptations can be found in the literature to improve predictions for specific media or flow conditions.

Single-phase flow—The Carman–Kozeny equation

The Carman–Kozeny equation is also a bundle-of-tubes model,[15] but is usually written in terms of permeability and, more importantly, retains specific surface area as an adjustable parameter. The latter difference makes it somewhat more general than the Ergun equation, and it has found widespread application in areas such as soil science and materials science.

Carman's approach begins with a general expression for laminar flow in a duct: $v = (\mathrm{HR})^2\Delta\mathscr{P}/(C\mu L)$. The constant C equals 2 for a cylindrical tube and varies between 1.78 and 3 for other regular cross sections.[15] Carman proposed $C = 2.5$ for the generally complex shapes in porous media and incorporated a tortuosity factor $L_{\mathrm{equiv}}/L = \sqrt{2}$, leading to the often-quoted Carman–Kozeny constant, $k_{\mathrm{CK}} \equiv C(L_{\mathrm{equiv}}/L)^2 = 5$. Retaining the specific surface S_0 (instead of assuming spherical particles) and substituting the duct velocity into Darcy's law gives the Carman–Kozeny equation:

$$K = \frac{1}{k_{\mathrm{CK}}S_0^2}\frac{\varepsilon^3}{(1-\varepsilon)^2} \quad (11)$$

Other values of k_{CK} have been measured for various porous media (e.g., see Ref.[16]). The fact that both k_{CK} and S_0 can be adjusted from one material to another makes this equation more flexible than the Ergun equation, though the tradeoff for this flexibility is the need to provide the two constants for a given porous medium.

Fibrous materials—The Jackson and James approach

Empirical permeability predictions are not as effective in fibrous materials as in packed beds due to wider variations in pore morphology. The Carman–Kozeny equation is used at times, in which case k_{CK} and S_0 must be inferred from what is known about the particular fiber structure or from available experimental data.

A more general approach was proposed by Jackson and James,[17] who derived a simple equation for the permeability of fibrous materials based on asymptotic expansions for flow perpendicular to and parallel to cylinders. Their equation for nondimensional permeability is

$$\frac{K}{R^2} = \frac{3}{20\phi}[-\ln\phi - 0.931 + \mathrm{O}(\ln\phi)^{-1}] \quad (12)$$

where R is the fiber radius. The same authors collected a large set of experimental permeabilities that span nearly three orders of magnitude in solid volume fraction, as shown in Fig. 4. These data indicate that order-of-magnitude nondimensional-permeability predictions can made by using ϕ as the sole parameter.

MULTIPHASE FLOW

Multiphase flow theory is very well developed because of applications such as interfacial separations, petroleum production, and vadose-zone hydrology; yet, it remains a mostly empirical science. This is a consequence of the complex physics of flow and because the parameters describing multiphase flow are highly sensitive to pore structure and interfacial configurations. Though three-phase flow is important in applications such as oil production and contaminant transport in the subsurface, we limit the following discussion to two-phase flow for simplicity.

Phase Distributions

At the macroscale, only the *average* fractional saturation of a phase, S_{w} or S_{nw}, is usually known (where, for instance, wetting-phase saturation $S_{\mathrm{w}} \equiv V_{\mathrm{wetting\ phase}}/V_{\mathrm{void}}$). However, the spatial distribution of phases at the microscale is important because of its strong effect on macroscopic behavior. A generic rule of thumb is

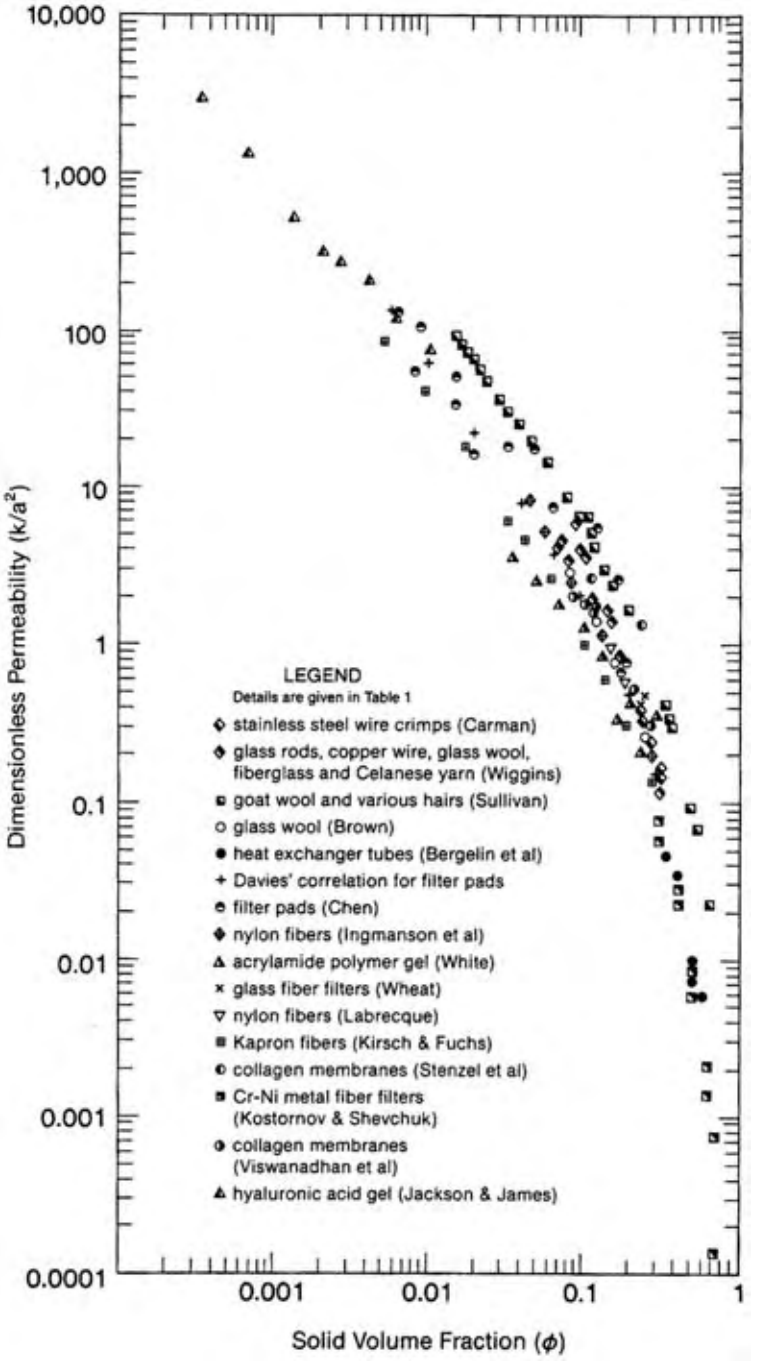

Fig. 4 Nondimensional permeability vs. solid volume fraction for a variety of fibrous porous media. (From Ref.[17].)

that nonwetting phase can be found in larger pores, while wetting phase fills the smaller pores and corners of the larger pores. Furthermore, in strongly wetting materials (i.e., contact angle $\approx 0^\circ$), a very thin film of wetting fluid coats all surfaces. While these generalizations oversimplify the real situation, they provide valuable insight into fundamental behavior.

Consider a nonspherical pore (any shape with angles, corners, cervices, etc.) that contains two immiscible fluids. The nonwetting fluid tends to reside in the center of the pore, reducing its contact area with the solid surface. The wetting fluid occupies the corners and crevices, where the specific surface area is larger. This configuration leads to a pressure difference between the two phases, which is called the capillary pressure. Under equilibrium conditions, it is related to the curvature of the interface according to

$$\Delta P_c = \sigma\left(\frac{1}{r_1} + \frac{1}{r_2}\right) \tag{13}$$

where σ is the interfacial tension. Note that the interface can have opposing radii of curvature r_1

and r_2—see the subsequent discussion of pendular rings. In general, a change in the fraction of wetting phase in the pore changes the interfacial curvature, and therefore must be accompanied by a capillary-pressure change. These simple arguments illustrate a fundamental relationship that exists between phase saturation and capillary pressure. In individual pores, the functionality is complex and of interest only in theory. However, when averaged over the entire medium, this functionality is called the capillary pressure curve and is a key component of multiphase flow modeling.

Because the natural wetting-phase configuration includes occupation of the tighter pore spaces, wetting phase can be drawn into pore throats and cause a disconnection in the nonwetting phase. This behavior leads to arguably the most significant difference between the two fluid phases: the tendency of fractions of the nonwetting phase to become disconnected. The resulting blobs or ganglia can occupy single pores or many pores. In percolation terminology, a ganglion is disconnected from its backbone fraction, meaning that there is no continuous path from the ganglion to the boundary of the porous medium through the nonwetting phase.

The consequences of this behavior are important: Without a connection to the porous-medium boundary, fluid from a ganglion can no longer be evacuated from the pore space by simple pressure-driven flow. Though disconnected ganglia can be mobilized, this is rare in applications where interfacial forces tend to overwhelm viscous or gravitational forces. Hence, formation of a disconnected fraction of nonwetting phase is often viewed as being synonymous with trapping of the nonwetting phase. This behavior is responsible for immobilizing organic-phase contaminants in groundwater and for the formation of trapped voids (defects) during injection molding of composite materials.

The implication of the foregoing discussion is that the wetting phase does *not* become isolated or trapped, which is a difficult statement to assess. Consider a packing of perfect glass spheres. At sphere–sphere contacts, wetting phase collects in pendular rings, which have opposing radii of curvature, as shown in Fig. 5.[18] By increasing the capillary pressure, the pendular ring can be forced to shrink in size, constricting toward its axis. Hence, *in a geometrical sense*, the wetting phase can become disconnected (i.e., it becomes so small that it touches no other pendular ring).

Two issues cloud this picture, however. First, for strongly wetting materials, thin wetting films cover all surfaces. These films provide connectivity in the strictest sense, but do not allow for measurable flow. Second, Dullien et al.[19] showed that if sphere surfaces are roughened, wetting fluid continues to drain even after the rings become geometrically disconnected.

Obviously, the issue of phase connectivity is complex, but as before, it can be summarized by certain useful rules of thumb. In real materials, the wetting phase generally remains interconnected (via a combination of crevice geometry and surface roughness). However, even when connected, it may be very slow to drain at low wetting-phase saturations, giving the appearance of a trapped phase over short time scales. Finally, true trapping of the wetting phase can occur under certain conditions. Factors conducive to this behavior include high-porosity media, smooth surfaces (e.g., synthetic fibers), and nonzero contact angles.

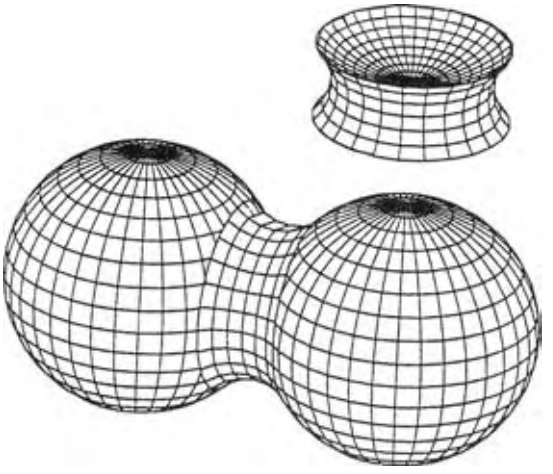

Fig. 5 Schematic of a pendular ring of wetting phase formed at a sphere–sphere contact (inset shows wetting phase only). (From Ref.[18].)

Immiscible Displacement

One phase displacing another from a porous medium is termed ''immiscible displacement.'' The process is usually inefficient from the standpoint of how much of the original phase can be displaced, which is the reason that large amounts of crude oil remain unrecovered in abandoned reservoirs.

Consider, first, displacement of a wetting phase by a nonwetting phase, which is termed drainage. A qualitative understanding of the process can be gained by considering invasion into a single pore, as shown schematically in Fig. 6. Frame B in this figure depicts a nonwetting phase poised at the constriction into an uninvaded pore. As the capillary pressure is increased, the interface deforms until its radius of curvature is small enough to pass through the constriction. At this point, the interface quickly moves across the downstream pore in a non-equilibrium process that has been termed a Haines jump. The dynamics of this jump are very rapid, even if the overall immiscible displacement is carried out very slowly so as to ensure equilibrium interface configurations otherwise.

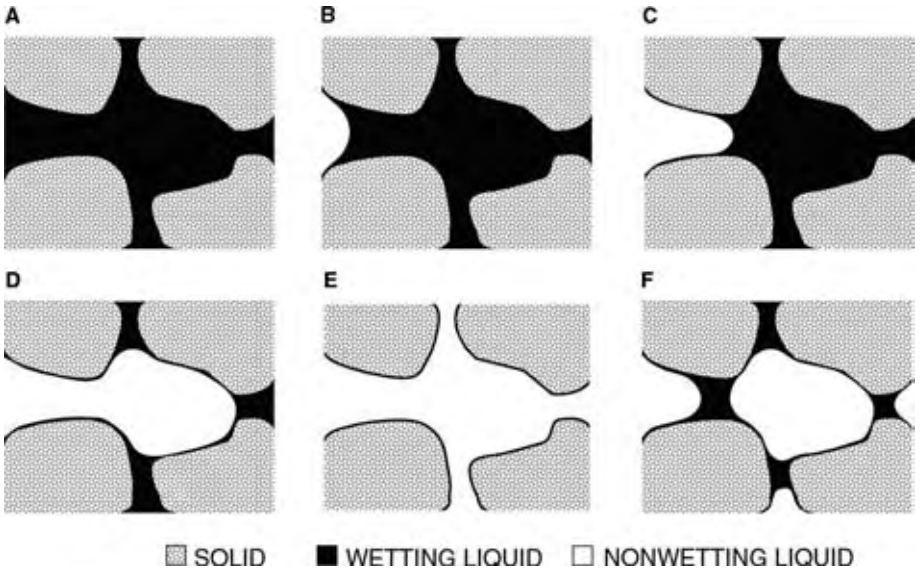

Fig. 6 Schematic of nonwetting phase invasion into a pore: (A) schematic representation of a pore formed by four grains; (B) low capillary pressure; (C) critical capillary pressure for invasion; (D) phase distributions after Haines jump; (E) high capillary pressure; (F) disconnection of the nonwetting phase after snap-off.

Despite the suddenness of these pore-scale events, the displacement process appears smooth at the macroscopic scale: As the capillary pressure is increased, the nonwetting phase flows into increasingly smaller pore spaces, and S_w is thereby reduced. The macroscopic functionality (capillary pressure vs. saturation) is the capillary pressure curve mentioned previously. Fig. 7 is an example capillary pressure curve obtained by injecting mercury into a dry packing of glass spheres.[20] (For the following discussion, view Fig. 7 rotated 90° counterclockwise, which is the more common method of presentation.) The upper curve is the primary drainage branch. It should be followed from right to left beginning at $S_w = 1$ (or $V_{free}/V_{sphere} \approx 0.58$). The initially steep ascent represents the invasion of a small fraction of larger pores that happen to be near the inlet face. The long plateau is characteristic of homogeneous porous media and represents invasion of the bulk of the pore space at an essentially constant capillary pressure. The steep rise at low wetting-phase saturations can be indicative of two different phenomena. In a material with distributed throat sizes, it can represent the fraction of void space composed of small pores (inaccessible except at high capillary pressures). In relatively uniform media, it corresponds to the wetting phase retreating into the tightest corners and crevices of the void space.

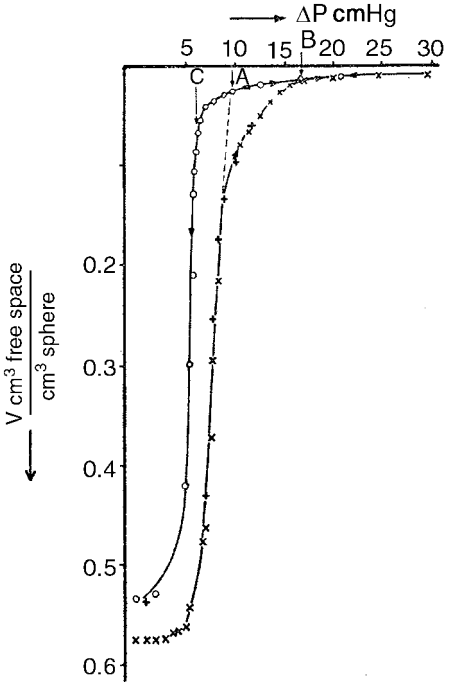

Fig. 7 Capillary pressure curve for mercury (nonwetting phase) intrusion into a packing of glass spheres. (From Ref.[20].)

The reverse process, displacement of the nonwetting phase by the wetting phase, is called imbibition. It is a dramatically different process than drainage. Consider the end of the drainage curve in Fig. 7 as the staring point for secondary imbibition. This point is represented by the Fig. 6E schematic, in which a large capillary pressure must be applied simply to keep the wetting films (black) squeezed into the corners of the pore space. If the capillary pressure is then decreased slowly, the radii of curvature must increase to maintain equilibrium [provided that an interconnected path exists to deliver wetting phase fluid into the pore! (See the discussion in the previous section.)] At some critical capillary pressure, the radii of curvature can no longer increase to maintain equilibrium (because of geometric constraints), the interface becomes unstable, and the nonwetting phase quickly retracts into a connected pore.

As with drainage, these sudden non-equilibrium retractions are masked at the continuum scale, and the process is simply exhibited by the steep descent (increasing S_w) on the imbibition capillary pressure curve. The plateau is lower than the drainage plateau because the instability that causes nonwetting-phase retraction from a pore usually occurs at a lower capillary pressure than that required to invade the same pore during drainage. Thus is derived the generalization that *pore* size controls imbibition, while *pore-throat* size controls drainage.

In reality, other factors complicate the imbibition process. First, retraction of the nonwetting phase can occur only if the nonwetting phase is connected to the backbone fraction. Second, the capillary pressure at which retraction occurs depends on the current configuration of the interface in the pore. This latter effect has been observed in simple geometries[21] but is nearly impossible to quantify in real media because of the complex, saddle-shaped configurations that interfaces adopt. Third, the entire process is rate dependent because of the need to deliver wetting fluid (sometimes through thin films) and evacuate nonwetting phase.

A final distinction worth noting is the occurrence of spontaneous imbibition, which is commonplace: for instance, water absorbing into a dry porous material such as cloth or wood. The physics of this process stem from the interfacial tension: When the wetting fluid contacts the dry material, the tension (in an average sense) is oriented into the porous medium because of the contact angle. When this tension is integrated over the perimeter of the three-phase contact line, a net force results that draws the wetting phase into the medium. Though spontaneous imbibition is rapid when a dry material first contacts a wetting phase, it slows as the net force from interfacial tension is counteracted by viscous forces behind the invading front. If the spontaneous imbibition is upward, it comes to equilibrium when the static head of wetting fluid equals the capillary pressure difference.

Stability of Displacement Phenomena

Immiscible displacements rarely proceed as uniform fronts. The most well-documented instability is viscous fingering, which occurs due to an unfavorable mobility ratio, meaning

$$M \equiv \frac{(k_r/\mu)_{\text{injected}}}{(k_r/\mu)_{\text{displaced}}} > 1 \tag{14}$$

where k_r are relative permeabilities (see the following section). Under these conditions, spatial disturbances in the injection front grow rather than being damped out. The result is that fingers of the injected fluid move well ahead of average front position $v\,\Delta t$. The onset of viscous fingering has been characterized using linear stability analysis (e.g., see Ref.[22]). The nonlinear regime, which is of the most practical importance, is characterized by tip splitting (which produces new fingers), shielding (which stunts the growth of smaller fingers), and stabilizing phenomena. Additionally, there is a strong coupling between viscous instabilities and permeability heterogeneity,[23] though this effect is difficult to generalize because it depends on the specific permeability field and the wavelength of the instability.

Other instabilities include gravity fingering (which is analogous to viscous fingering) and capillary fingering (which is unrelated phenomenologically but also leads to highly nonuniform displacement fronts).

Channeling is the tendency for fluid to respond to continuum-scale variations in permeability. It is sometimes confused with viscous fingering, in part because the two often occur simultaneously in real applications. However, channeling is observed over much larger scales than viscous fingering.

Equations for Multiphase Flow

During multiphase flow, the presence of a second phase in the pore space considerably reduces the apparent permeability of a medium. Mathematically, this behavior is quantified by the relative permeability k_r, which is used in a multiphase version of Darcy's law:

$$\mathbf{v}_w = -\frac{k_{r,w}K}{\mu_w}\nabla\mathscr{P}_w \tag{15}$$

$$\mathbf{v}_{nw} = -\frac{k_{r,nw}K}{\mu_{nw}}\nabla\mathscr{P}_{nw} \tag{16}$$

(Isotropic permeability is assumed for simplicity.) Relative permeability is dimensionless. It is simply a scaling factor that quantifies the reduction in permeability to a given phase due to the fact that it must share the void space.

Intuitively, a strong dependence on phase saturation should be expected: For example, if the nonwetting phase occupies a large fraction of the pore space, then the apparent conductivity to the wetting phase is low. What may be surprising is how strong this dependence is. For the wetting phase, in particular, k_r decreases over orders of magnitude as its saturation decreases. The reason is that wetting phase is relegated to smaller pores, corners, thin films, etc., which are poor conductors of fluid due to their large specific surface areas (and therefore high drag). Hence, as S_w decreases, there is a disproportionate loss of hydraulic conductivity.

For nonwetting-phase fluids, a converse argument could be made: that the relative permeability should

decrease slowly because the fluid occupies larger pores. While this effect is underlying, it is usually offset by other factors: more tortuous flow paths and larger dead-end and disconnected fractions of nonwetting phase. In general, both branches of a relative permeability curve are nonlinear and can exhibit strong hysteresis, as shown by the schematic in Fig. 8. (The data are often presented on a semi-log plot because of the large range of k_r values.) Examples of relative permeability curves for simple porous media can be found in Ref.[24].

Experimental measurement of relative permeability is problematic. Rigorously, experiments should be performed during steady-state multiphase flow: Two fluids are simultaneously injected into a porous medium, and the pressure drop over an interior section (to avoid large capillary-pressure gradients) is measured. However, there are drawbacks to this approach: First, obtaining steady-state multiphase flow is an exceptionally slow process because of subtle shifts in phase distributions en route to the final steady state. Second, determining the phase saturation is a significant challenge. Overall mass balances can be used, but exhibit poor precision. Tomography techniques (preferred) require specialized equipment. For these reasons, other techniques have been developed that allow relative permeability to be measured during a transient immiscible displacement.[25] These techniques require a priori assumptions about the multiphase behavior, but the tests are widely accepted because of the lack of good alternatives.

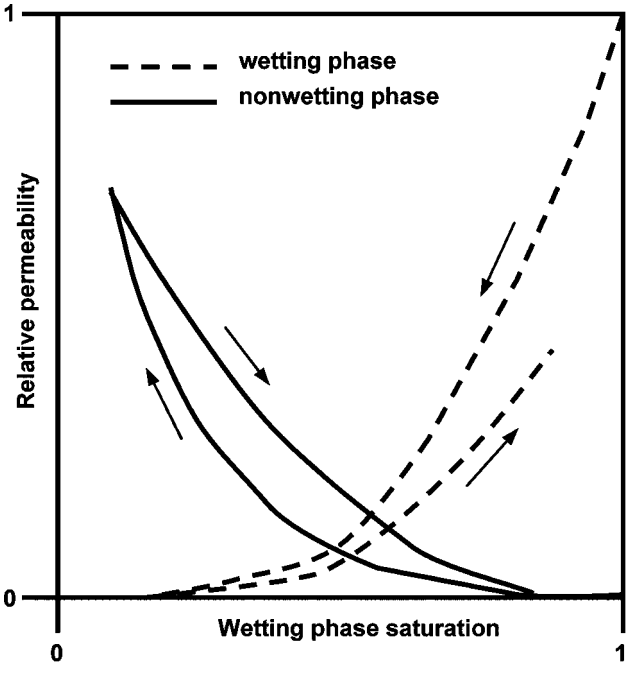

Fig. 8 Schematic of typical relative permeability curves for strongly wetting materials. Curves with positive slope are for the wetting phase. Arrows indicate the direction of change of phase saturation.

In the foregoing discussion, the assumption is that each phase is transported in its own percolating network by a pressure-driven flow mechanism. This is the generally accepted view of multiphase flow in subsurface applications, and is certainly true at low values of the capillary number ($Ca \equiv v\mu/\sigma$). However, blob mobilization is a dominant form of transport in many unit operations in chemical engineering, where the capillary number and Reynolds number are higher. In these cases, specialized correlations for multiphase flow should be used.

MISCIBLE DISPLACEMENT

Examples of miscible displacement are the intrusion of saltwater into fresh groundwater or a step change in feed composition in a chemical reactor. In one sense, miscible displacements are simpler processes than immiscible displacements because issues such as interfacial behavior and phase trapping are not relevant. However, they are complicated by hydrodynamic dispersion (which tends to smear the displacement front), and they are subject to similar viscous instabilities as those described earlier.

Phenomenologically, dispersion occurs because different solute molecules take different times to move from point A to point B in a convective flow. The difference in transit times is attributed to a combination of kinematic and dynamic effects.[26] Kinematic effects stem from tortuosity and the splitting and joining of stream tubes during flow, so that different particles traverse paths of different length. Dynamic effects stem from the distribution of velocities that a particle encounters on its path. Mechanical dispersion consists of the combined effects associated purely with convection (i.e., velocity variations due to hydrodynamics). Nonmechanical effects are associated with the diffusion of solutes from one streamline to another and into stagnant regions.[27]

Dispersion is most commonly modeled as a diffusive process. For flow in a packed column, dispersion is captured by the $D\nabla^2 C$ term in the one-dimensional convection–diffusion equation. The longitudinal dispersion coefficient, D, is a function of the Peclet number, $Pe = vR/D_m$ (where D_m is the molecular diffusion coefficient). At very low Peclet numbers, dispersion stems simply from molecular diffusion and is quantified by $D = D_m/(F\varepsilon)$, where F is the formation factor. At $Pe > \sim 10$, mechanical effects begin to dominate. In practice, D can be considered nearly proportional to Pe over a large range, though theoretical analysis has identified phenomena responsible for nonlinear scaling in this regime.[27] The actual value of the

dispersion coefficient depends on the structure of the material. Numerous tabular and empirical relationships have been developed that allow for its estimation. A summary can be found in Section 6.3.4 of Ref.[12].

A problem with the approach mentioned is that Fickian dispersion (i.e., dispersion that behaves in a diffusive manner) requires solutes to have sufficient time during their transit to be exposed to a representative sample of the velocity field. This requirement is not always satisfied, particularly in situations such as short packed beds, very high Peclet numbers, or media with severe heterogeneities. The latter case is common in fractured materials, where non-Fickian dispersion is nearly always observed. The issue has raised interesting research questions during recent years, and alternative mathematical techniques are only now emerging.[28]

MODELING FLOW IN POROUS MATERIALS

Continuum-Scale Modeling

For calculating one-dimensional flow behavior in a packed bed, the Ergun equation is generally sufficient. For single-phase, constant-density flow in two or three dimensions, Darcy's law can be substituted into the continuity equation ($\nabla \cdot \mathbf{v} = 0$) and simplified to obtain the Laplace equation:

$$\nabla^2 \mathscr{P} = 0 \tag{17}$$

After solving this boundary-value problem for pressure, the velocity field can easily be obtained in conjunction with Eq. (1).

Modeling solute transport requires the convection–dispersion–reaction equation to be used, written as

$$\frac{\partial C_A}{\partial t} = \nabla \cdot (\mathbf{D} \cdot \nabla C_A) + \mathbf{v} \cdot \nabla C_A + R_A \tag{18}$$

for the general case, or

$$\frac{\partial C_A}{\partial t} = D \frac{\mathrm{d}^2 C_A}{\mathrm{d}z^2} + v \frac{\mathrm{d}C_A}{\mathrm{d}z} + R_A \tag{19}$$

for axial flow in a reactor. C_A is the concentration of a reacting species and R_A is its reaction rate (generation). Except for the simplest cases (e.g., steady flow with a first order chemical reaction), a numerical solution is required.

Research on numerical modeling of large-scale flows has been driven by hydrologists and the oil industry. In the latter application, the main focus is on simulating multiphase displacements at the reservoir scale, and physical dispersion is generally unimportant. Hence, the mathematical approach is to write the unsteady continuity equation for each phase and substitute multiphase Darcy's law into the velocity terms. For two-phase flow, this approach gives two equations, with the following four unknowns: S_w, S_{nw}, P_w, and P_{nw}. Two auxiliary equations complete the system of equations: $S_w + S_{nw} = 1$, and $P_{nw} = P_w + P_c(S_w)$. The capillary pressure functionality in the second equation is obtained from the macroscopic capillary pressure curve. The equations also contain relative permeabilities that require explicit evaluation.

In practice, the resulting partial differential equations are usually solved using a finite-difference or finite-volume method. A general approach is to combine the equations so that one can solve implicitly for the pressure field P_w. The phase saturations are then updated implicitly or explicitly, depending on accuracy and stability issues. These ideas are described in a number of general texts (e.g., Ref.[29]). Recent advances in numerical reservoir simulation, including important issues related to upscaling, can be found in the Society of Petroleum Engineers conference proceedings and journals.

Pore-Scale Simulation

The advantage of continuum-scale simulation is the ability to capture large-scale behavior. Its disadvantage is that it is an empirical approach at heart: The fundamental details are wrapped into spatially averaged parameters such as permeabilities, mass-transfer coefficients, etc.

At the pore scale, the basic equations for fluid flow are the fundamental equations of motion. (And, once velocity is obtained it can be used in the convection terms of the energy- and mass-conservation equations.) Two significant hurdles exist when working with these equations. The first is the complexity of the boundary conditions. The second is the very small length scales over which numerical solutions can be obtained.

Volume averaging is a technique in which the fundamental equations are spatially averaged over a representative elementary volume (REV) of porous media.[30] This approach has provided insight into the relationship between fundamental physics and larger-scale behavior but is rarely used for studying transport in specific media in a deterministic sense.

Direct numerical solution using finite-difference, finite-element, and boundary-element methods have played important roles in porous-media research. During the last decade, the lattice-Boltzmann method[13] has emerged as a preferred method for many applications, particularly in the hydrology literature. Significant advantages include relatively simple

coding, the ability to simulate moderate-Reynolds-number flows, and the use of regular grids (which alleviates complex meshing problems). However, the method has certain drawbacks: Its ability to model interfacial phenomena quantitatively remains in question, and it is not amenable to local grid refinement.

Finally, pore-scale network modeling is a specialized technique that has evolved over the past half-century. It is an approximate technique, where the pore space is discretized into pores and pore throats, and local flow is approximated using Poiseuille flow equations. It retains many advantages of other pore-scale techniques: The physics of flow are incorporated using first principles, and it captures factors such as pore-size distribution, interconnectivity, and small-scale heterogeneity.[26] At the same time, significant gains in efficiency are realized by the approximations, so that much larger characteristic lengths can be modeled than with other numerical techniques. Modern network models are built upon physically representative networks of complex three-dimensional porous media and can be used for quantitative modeling in certain applications.[7,9]

CONCLUSIONS

Porous media pose interesting scientific challenges because of the interplay between a series of factors: heterogeneity, complex structure, and multiscale behavior. This entry provides only a brief introduction to important phenomenological behavior, with the expectation that this background will be of value during more in-depth reading.

Excellent texts are available that describe fundamental behavior, including Refs.[12,26,31]. Current research is often published in *Transport in Porous Media* (which tends to have a mathematical focus), *Water Resources Research*, *Journal of Fluid Mechanics*, and the traditional chemical engineering journals.

Powder Coating Application Processes

Harry J. Lader
Harry Lader and Associates, Inc., Cleveland, Ohio, U.S.A.

INTRODUCTION

Powder coating originated in the 1950s as a method to coat parts by immersing preheated parts in a fluidized bed. This method was used primarily for corrosion resistance or electrical insulation since only thick films were possible. These powder coatings were dry-blended mixtures of pigmented epoxy resins, flow agents, and curing agents. Over time, electrostatic fluidized beds were developed that provided better control over film thickness and are now used mostly for coating small parts. Powder coatings were compounded using extruders in the 1960s. This development meant that powder coatings could now be applied as an electrostatic spray, instead of using fluidized beds. The resin of choice was epoxy due to its good storage stability, good flow properties, and reasonable appearance. Epoxy powders had the ability to retain an electrostatic charge that allowed the powder to be attracted to and adhere to a grounded part during the application process. The charged powder remained on the part until the powder was cured. The ability to formulate a powder coating as compounded particles spurred tremendous growth for the powder coating industry.

While compounded epoxy powders stimulated the development of the powder coating industry, epoxies were prone to chalking and gloss reduction because of poor stability to ultraviolet (UV) radiation for exterior applications. This property deficiency encouraged research on other resin systems and eventually led to a range of powder coatings that now include epoxy/polyester hybrids, TGIC (triglycidyl isocyanurate)–polyesters, polyurethanes, acrylics, in addition to epoxies. These powders are known as ''thermosetting powders'' as they crosslink on heating and comprise a majority of the powder coatings in use today. On the other hand, thermoplastic powders, which can also be used in electrostatic powder coating applications, do not crosslink on heating and therefore can be remelted. Examples of these types of powders include polyolefins, polyvinyl chloride, polyamides, and polyvinylidene fluoride.

In this entry, we review basic charging concepts, corona charging, internal charging, tribocharging, and electrostatic fluidized beds. Along with these methods, some of the properties of powders needed for their application are also discussed.

BACKGROUND

Advantages

The major advantage of powder coatings is that there are no solvents with which to contend; hence, compliance with environmental regulations is much easier. The problems and costs associated with them, such as toxicity, mixing, thinning, and labor, are eliminated while reducing time and material variability. Another major benefit is the high material utilization through recycling. While a primer is generally not required, the part must be properly cleaned to ensure a good quality coating.

After powder has been applied, a convection oven, infrared heating, or a combination of infrared followed by UV curing is used to cure the part. In some cases, induction heating of metals parts is used. Powder coated parts are fully cured when they leave the oven; hence the total processing time tends to be shorter as compared with wet coatings. This results in a reduction of rejects due to damage that can occur after painting. Powder coating allows the parts to be racked closer together on a conveyor allowing more parts to be processed in a shorter time. Powder coated parts are cured at elevated temperatures, usually between 160°C and 220°C (320–430°F), which generally results in a tougher, more chip-resistant coating.

Disadvantages

While there are many advantages to using powder coatings, there are also some disadvantages. Some of the challenges include the ability to quickly change colors, especially to take advantage of the benefits of recycling; color matching and uniformity; particle size variation during recycling that could lead to color variation, especially with regard to metallic powders; high cure temperatures; film thickness nonuniformities, especially at edges, corners, or in recessed areas; thin films; and good surface appearance with high transfer efficiency. Advances in equipment technology are addressing some of these challenges, while others are being improved through material technology.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007927

Powder Coating Markets

Powder coatings are used in a wide range of markets. Epoxy powders are typically used for functional applications such as steel pipelines and rebar that is used in concrete construction. These functional coatings typically have film thicknesses of over 250 μ (10 mil) and are usually applied onto preheated substrates. Many decorative coatings also serve a protective function, but have to be visually appealing as well. These coatings are typically applied between 25 and 100 μ (1–4 mil). The choice of powder depends on the environment in which the part is to be used. Today, polyester/epoxy hybrids comprise almost half of all the powders used worldwide. Their improved weatherability over epoxies and lower cost have allowed them to capture the largest percentage of the powder market. Polyesters have captured almost 40% of the world market, while epoxies have diminished to only about 10%. Polyurethane and acrylic powders are in low single digits.[1] Typical applications for powder coatings include metal furniture and fixtures, machinery, major and small appliances, automotive, electrical components and equipment, building and architectural, farm, and garden equipment.

The types of powder coatings available are gradually evolving with the advent of new powder chemistries that allow for numerous formulation variations. For example, powder coatings have been developed to replace porcelain in laundry applications, heat-resistant polymers for range door trim, and flexible powder coatings for refrigerator doors. This wide latitude in formulation capabilities means that there may be more than one resin chemistry used in a particular powder formulation.

OVERVIEW OF THE POWDER COATING APPLICATION PROCESS

Powder charging can use either a corona gun or a tribocharging gun. Other types of application devices are discussed later. Corona charging uses a gun applicator with an electrode at the tip, usually at a negative high voltage, while a tribogun does not need an external power supply as the powder is charged by friction. A fluidized bed or a box feeder is used to feed the powder to the gun. The powder in the fluidized hopper is mixed with dry compressed air through a porous fluidizing plate so that the powder acts like a liquid. A pump transports the powder through a delivery tube into a corona- or tribogun applicator. The charged powder is sprayed through the gun onto a part. Nozzles are used to shape the spray pattern to the part so that most of the powder attaches itself to the grounded part. The booth contains the powder. This powder can be recovered and transported back to the feed hopper, if necessary. Virgin powder is added to the system to maintain powder levels. (See Ref.[2] for an excellent practical guide on powder coating.)

Recently, the adoption of lean manufacturing practices, which focuses on meeting customers' needs to quickly deliver any quantity of any parts in specified colors, has resulted in many color changes daily. This need has encouraged equipment manufacturers to provide the ability to change powder color quickly. In addition, equipment improvements have increased transfer efficiency and have reduced the need to recover powder. By increasing first pass transfer efficiency, spray-to-waste is gradually becoming accepted.

POWDER CHARGING AND APPLICATION

Corona Charging

A basic knowledge of corona charging is important for understanding how powders charge, the limitations of charging efficiency, and how this impacts transfer efficiency and surface appearance. A corona discharge occurs when a high voltage is applied to an electrode in the presence of a ground. When the electric field at the electrode is very high and exceeds the breakdown of air, negative ions, present naturally in air, are split into both an electron and a neutral atom when they enter the high field region. The electron is driven away from the high electric field and gains enough energy to ionize an air molecule, creating a cascading effect. At the same time, naturally occurring positive ions are attracted to the negative point electrode, where they attain sufficient energy from the high electric field and release secondary electrons that add to the discharge. This process is self-sustaining above the threshold voltage. Light emitted during ionization creates a glow around the sharp electrode causing a "corona."[3]

Numerous negative ions are created when the electrode goes into corona. These ions will follow the field lines toward the grounded part. Fig. 1 is a schematic of a corona gun spraying powder and shows the electric field lines between the electrode and a flat part. The powder dispersed from the nozzle will enter the region between the electrode and the grounded part. Most of the air-diffused powder particles will attract ions and become charged. The electric field lines will accelerate the charged particles toward the grounded part and the free ions will also continue along the same path.

Fig. 1 also shows that the electric field lines concentrate on the sharp edges of the part. Some of the electric field lines actually wrap around the back of the target. In addition to the electric field lines, aerodynamics will also contribute to this "wrap" effect. Increased film thickness at the edge is usually referred

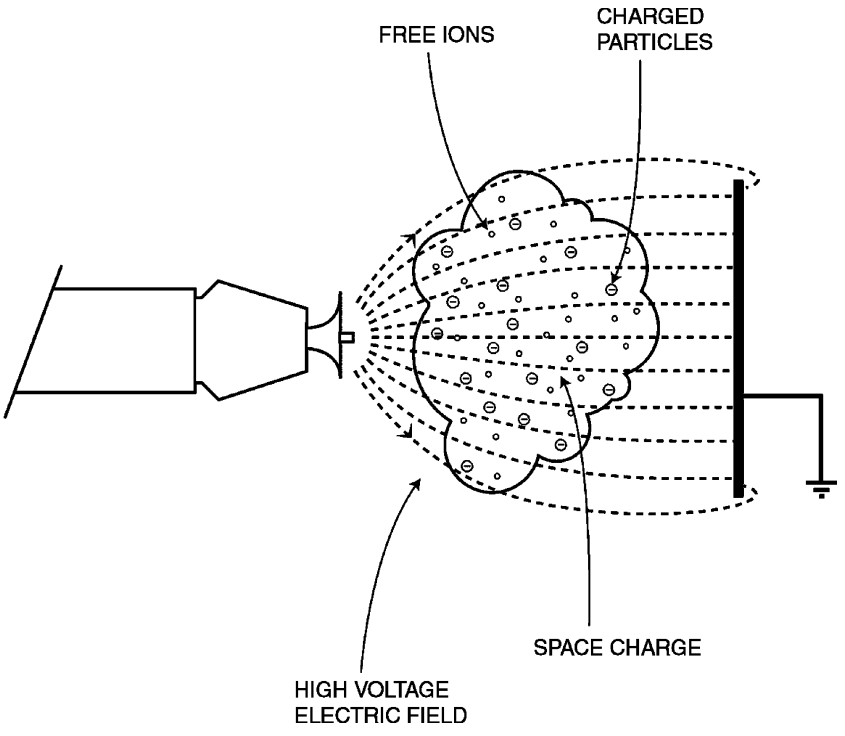

Fig. 1 Schematic of a corona gun with an electrode at high negative voltage with charged powder and ions in the presence of a grounded flat part.

to as the ''picture frame'' effect. The charged powder and free ions between the gun and ground comprise a charged cloud known as the ''space charge.'' This space charge creates its own electric field lines to the ground.

Fig. 2 is a schematic representation of the electric field lines from the gun to a part that has a protrusion at its center. In this case, the electric field lines will concentrate at the protrusion. The charged powder and free ions will build up faster here and contribute to back-ionization. Because the powder particles are strong dielectrics, their charge will be retained for many hours, depending on a number of factors such as powder resistivity, as well as the ambient relative humidity.

The maximum charge that can be acquired by a spherical, nonconducting particle in a uniform electric field was determined by Pauthenier[4] and is shown in Eq. (1):

$$q_{\max} = 4\pi\varepsilon_0 a^2 E p, \quad \text{where } p = \frac{3\varepsilon_r}{(\varepsilon_r + 2)} \tag{1}$$

In Eq. (1), ε_0 is the permittivity of free space (8.8×10^{-12} F/m), E is the maximum electric field before breakdown of air occurs (3×10^6 V/m), a is the particle radius in m, and ε_r is the relative dielectric constant of a powder particle. This equation shows that the maximum charge that can be acquired is proportional to the electric field and the square of the particle radius. It is also weakly dependent on the relative dielectric constant of the particle. The charge-to-mass ratio takes into account the mass of the particle and is determined by dividing Eq. (1) by the mass of a spherical particle, $(4/3)\ \pi a^3 \rho$, where ρ is the density of the

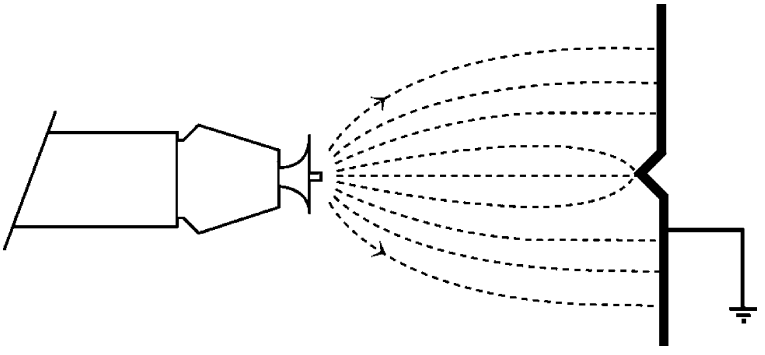

Fig. 2 Schematic of a corona gun with an electrode at high voltage in the presence of a part containing a protrusion at its center.

powder (kg/m^3), as shown in Eq. (2):

$$\frac{q_{max}}{m} = \frac{3\varepsilon_0 Ep}{a\rho} \quad (2)$$

Eq. (2) shows that the maximum charge-to-mass ratio is inversely proportional to the size of the particle. This equation shows that the maximum charge-to-mass ratio of a 100 μ particle will be 10 times lower than a 10 μ particle. It is also important to note that because the mass of a spherical particle is proportional to the third power of a particle's radius, the mass of one 100 μ spherical particle is the same as that of a thousand 10 μ particles.

The actual charge-to-mass ratio of a charged particle will depend on the mechanism of charging used, such as the electrical characteristics of the charging gun, as well as the surface chemistry and electrical resistivity of the particle, particle shape, ambient relative humidity, and the charging time. Powder particles are not perfectly spherical. Rather, they have a gravel-like shape and, as they have a high electrical resistivity, they will not be uniformly charged. Also, the particles spend only a finite amount of time in the charging zone. Therefore, the theoretical maximum charge-to-mass ratio cannot be achieved. Under ideal conditions, smaller particles can have a larger charge-to-mass ratio. However, when they are mixed with larger particles, the field lines will interact more strongly with the larger particles, making it more difficult for the smaller particles to become charged.

Aerodynamics and gravity also come into play. Smaller particles will tend to follow the airflow lines across the part while the larger particles, having a greater inertia, will generally move in the direction toward the part. Gravity will tend to act more strongly on larger particles, pulling them downward. While some of the coarser particles will bounce or fall off the target and be pulled downward by gravity, the finer particles will tend to overspray the target.

Eq. (3) shows how long it will take a particle to reach its maximum charge.

$$q(t) = \frac{q_{max}}{1 + \tau/t} \quad (3)$$

Here, τ is the time for a particle to reach half of its maximum charge and was calculated to be about 0.1 sec for a typical corona discharge.[5] After 1 sec, 90% of the maximum theoretical charge will be realized. Particles having a lower velocity will spend more time in the charging zone and will have a higher charge-to-mass ratio. Reducing the powder feed rate and its velocity will allow the powder cloud to be more diffuse and spend more time in the charging zone, improving powder charging that will result in more powder being deposited onto the target.

Corona charging is very widely used due to its ability to charge a wide range of powders at fairly high throughput. This charging method is relatively insensitive to ambient humidity, plus the equipment is robust for a wide variety of manufacturing processes.

Back-Ionization

Increasing the voltage on the electrode tends to increase transfer efficiency, up to a point. As voltage is increased, back-ionization also increases until powder deposition is reduced. This is due to the fact that less than 1% of the total number of ions generated contributes to charging the powder and more than 99% of the ions are deposited on the surface of the part and any other nearby grounds.[6] Ions are much smaller and have a much faster mobility than powder particles. As powder is sprayed onto the part, the particles adhere where little or no powder has previously been deposited. Back-ionization begins with as little as a single monolayer of powder.[7] As powder is deposited onto a surface, electrical discharges in the layer can be observed by using an image intensifier. Air that is trapped in the powder layer is highly stressed, which causes it to break down into both positive and negative ions at these discharge points. The positive ions move away from the part and "back" toward the negative electrode, reducing the efficiency of powder deposition onto the part by neutralizing the oncoming negatively charged powder. The effects of back-ionization can usually be seen in the uncured powder as "starring" or "orange peel" in the finished coating. In severe cases, back-ionization can cause craters and pinholes down to the substrate.

Equipment manufacturers have found ways to deal with this problem. One method simply uses a grounded metal rod or ring, known as an "ion collector," positioned behind the electrode but at a distance closer to the electrode than the distance between the electrode and the part. The idea is to create a stronger electric field between the electrode and the ion collector than between the electrode and grounded part, so that fewer ions will be attracted to the grounded part.[8] Internal charging is another way to reduce the effects of back-ionization. In this case, the ground electrode is located inside the powder applicator, instead of outside, which neutralizes a significant portion of free ions during the charging process.

A recent study was done to examine the effectiveness of ion collectors in reducing ion current and its effect on surface appearance.[9] A smooth ring and a ring with 11 sharp points for concentrating the electric field were investigated. The authors found that both

the charge-to-mass ratio and transfer efficiency correlate directly with an increase in ion current on the target. That is, a reduction in ion current responsible for back-ionization occurs at the expense of transfer efficiency. Interestingly, they also found an improvement in surface appearance with the smooth ring that collected fewer ions. Therefore, care needs to be taken when using ion collectors to reduce back-ionization while optimizing transfer efficiency and surface appearance.

Another technique to reduce back-ionization is to control the gun current. Controlling gun current helps reduce excessive free ions by automatically reducing the electrode voltage when the gun-to-part distance decreases. This method reduces back-ionization and the Faraday Cage effect (see below).

Free ions also affect the ability to apply a second layer of powder on top of a coating that has already been cured. This application is known as ''recoating.'' When charged powder and ions are applied to this surface, the charge builds rapidly as charge cannot bleed off. Therefore, minimizing the amount of free ions makes recoating easier to achieve.

The Faraday Cage Effect

As discussed earlier, electric field lines concentrate on sharp points or edges. Fig. 3 shows what happens to the electric field lines when the part has a recessed area or a channel. Here, the electric field lines concentrate on the edge of the corner. This means that the powder and ions will deposit more rapidly on these areas and will tend to go into back-ionization. Furthermore, as there are very few field lines inside the channel, the powder has difficulty penetrating there. Back-ionization at the edge of the recess will also neutralize incoming charged particles and prevent them from depositing inside the corners. The use of ion traps, controlling gun current, or an internal charging gun can be used to overcome the Faraday Cage effect.

In addition to the Faraday Cage effect, aerodynamic effects do not favor spraying inside a corner. Airflow considerations based on part geometry must also be taken into account to deliver the highly charged powder inside a corner or a channel, while not using so much air that the powder is prevented from depositing.

Internal Charging

Corona guns have the disadvantage of the Faraday Cage effect from strong electric fields and back-ionization due to excess ions. As seen later, tribocharging largely overcomes the problem of the Faraday Cage effect and back-ionization, but is sensitive to the chemistry of the powder and the extreme ambient relative humidity conditions. Internal charging guns can minimize these disadvantages by putting both the high-voltage electrode and the ground inside the gun.[8] Fig. 4 is a schematic of an internal charging gun. As both the charging electrode and the ground are inside the gun, few electric field lines will escape outside the gun minimizing back-ionization resulting in a smoother finish, similar to a tribogun. Furthermore, the powder does not have to be specially formulated as it does for the tribogun. External electrodes are used to improve transfer efficiency. Powder flow rates are similar to a conventional corona gun.[10] A patent on an internal charging gun[11] refers to a chamber used to slow down and swirl the powder to increase the time of the particles in the charging zone.

Tribocharging

This method charges powder as a result of frictional contact with the inside surfaces of a tribogun. No source of high voltage is required. Transfer of charge occurs when two materials that differ in their ability to accept electrons are brought into close contact with one another. Materials that have the ability to accept

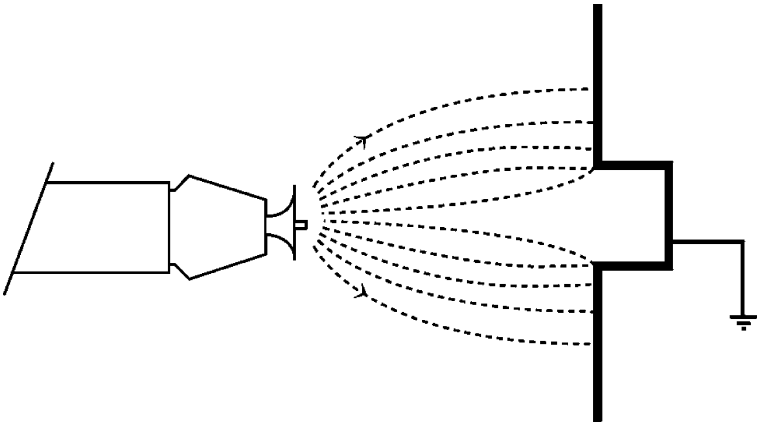

Fig. 3 Schematic of a corona gun with an electrode at high voltage in the presence of a part containing a recess.

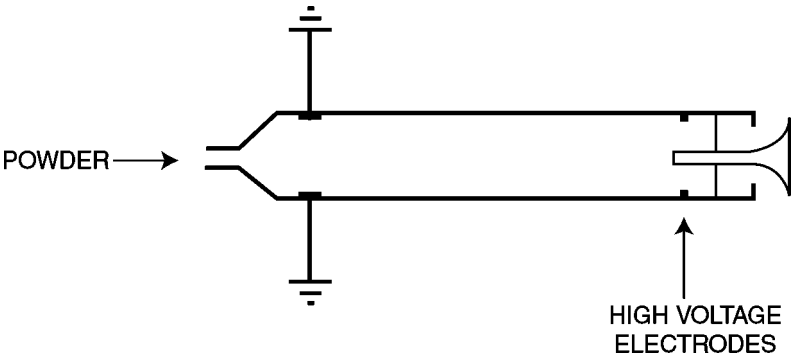

Fig. 4 Schematic of an internal charging gun.

electrons are called electronegative, while those that can donate electrons are called electropositive. The internal surfaces of a tribocharging gun are usually made of a material that is very electronegative, such as polytetrafluoroethylene or Teflon®.[12] This material accepts electrons from powder particles, causing the powder to charge positively. A tribogun typically uses additional air to help charge the powder. The path inside the gun is designed to ensure multiple contacts between the powder and the internal walls.

Fig. 5 shows a schematic of a tribocharging gun. As negative charge builds up inside the gun, a means is needed to bleed off this excess charge. This is accomplished by grounding the gun, sometimes through a microammeter to monitor or record the current. The current-to-ground is an indication of the amount of charging that occurs inside the gun. If the powder flow rate is constant, the charge-to-mass ratio can be determined by dividing the current (in μA) by the powder flow rate (in g/sec) to obtain μC/g.

Because triboguns have no charging electrode, the Faraday Cage effect is greatly reduced. This allows the powder to penetrate recesses, corners, and deep channels. In addition, as triboguns do not generate free ions, as corona guns do, they can coat parts that are not highly conductive more easily than a corona gun. This means that triboguns are better at recoating parts, as they do not build up charge as fast as corona guns. The resulting surface appearance is usually smoother and has considerably less back-ionization at a given film thickness. Triboguns, therefore, can build thicker films than corona guns before back-ionization becomes a problem.

The amount of charge on powder is determined by many factors including the composition of the powder, particle size, velocity of the powder on contact, and ambient relative humidity. Some powder formulations will tribocharge better than the others depending on their ability of being charged positive. Most polyamide and epoxy powders will tribocharge well. Some epoxy/polyesters, polyurethanes, and TGIC–polyester powders can also be tribocharged. Powder formulators can adjust the tribocharging properties of the powder through selection of the resin and the use of additives.

Another factor that controls charging efficiency is particle size distribution, which is discussed in more detail later. Larger particles will impact the tribosurface with greater energy, resulting in better charging. If the level of fine particles is too high, they will tend to build up in the reclaim system as they would not charge as effectively as larger particles. Typically, tribocharging powders have a median particle size between 30 and 45 μ, slightly greater than corona or internal charging guns. The level of fine particles (under 10 μ) should be minimized to enhance the charging process and also to minimize problems associated with fluidization.

Recently, a new tribocharging method has been developed that charges the powder negatively[13] instead of positively, as conventional tribocharging. This method relies on air jets to force the powder particles to contact the internal walls. In this case, the tribocharging surface gives up an electron to the powder. This method has the same advantages as conventional tribocharging. In addition, this charging gun can be

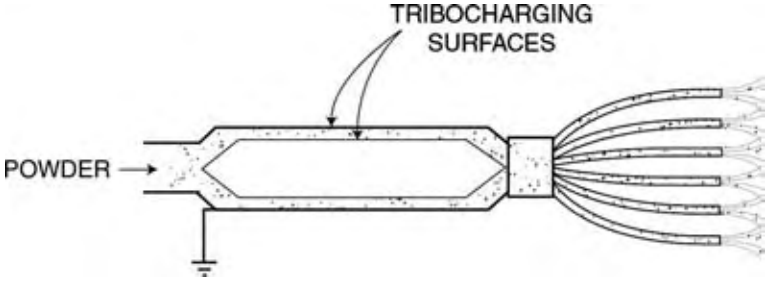

Fig. 5 Schematic of a tribocharging gun.

used together with a conventional corona gun for touch-up of difficult-to-coat areas, because the charged powder has the same negative polarity as a corona gun. However, it also suffers from the same disadvantages as conventional tribocharging in that the charging is sensitive to the type of powders that can be used. As with conventional tribocharging, most powder suppliers have learned how to optimize the powder formulation for negative tribocharging.

Nozzles

After the powder becomes charged, whether by corona, internal charging, or tribocharging, the mixture of air and powder particles is shaped into a spray pattern. The air velocity and the nozzle influence the spray pattern. Because corona charging uses a high voltage electrode, an electric field between the gun and the grounded part causes the charged powder and ions to follow the field lines to the part. If the part geometry is complex, electric field lines will not penetrate inside recesses and corners making it difficult for powder to penetrate these areas due to the Faraday Cage effect described earlier.

Flat spray (also called fan spray) nozzles can partially overcome this effect by forcing powder into recesses. However, if the velocity is too high, it can also blow powder off the part. Fig. 6 shows a perspective of a flat spray nozzle. The electrode is slightly recessed inside the nozzle and the powder emerging from the slot somewhat shields the electrode from the grounded workpiece. These factors combine to reduce the electric field between the gun and the part. This nozzle generates a directed fan spray pattern that has a pattern width of approximately 15 cm (6 in.) to more than 30 cm (12 in.). The flat spray nozzle is ideal for large flat areas. This nozzle is not recommended for wire goods because of its high powder velocity.

Conical nozzles use deflectors to generate a cone-shaped pattern as shown in the schematic in Fig. 7. Pattern widths can vary from as small as about 2.5 cm (1 in.) to approximately 60 cm (2 ft) in diameter, depending on the size and the radius of the deflector. The size of the pattern also depends on the powder flow rate. Conical nozzles generate a ''softer'' spray pattern because the deflector creates a partial vacuum that ''pulls'' the inner part of the cone pattern toward itself. This reduces the forward velocity of the powder. Conical nozzles are usually used in manual coating operations, where they are used for large flat parts and complex shapes.

Electrostatic forces dominate when the charged powder comes within about 10 mm (<0.5 in.) of the grounded part. As the conical nozzle has a lower forward velocity, the powder cloud tends to hover in front of the target, allowing the charged powder particles to be attracted to the grounded surface. In addition, the powder from a conical nozzle has a longer residence time in the charging zone allowing it to pick up more charge. In contrast, the flat spray nozzle is more directional, allowing aerodynamic forces to dominate making it easier for the powder to penetrate recessed areas. For both nozzles, the best transfer efficiency is achieved by good dispersion of the powder in air, reducing the velocity and the powder flow rate as low as possible for the specific application. Some powder guns swirl the air to control the velocity of powder, which improves particle charging.

Nozzles used for tribocharging can be very flexible, as tribocharging does not depend on a high voltage electrode at the front of the gun. The powder exiting the gun can be split into different streams and shaped in a multitude of ways allowing the powder to conform to the part geometry. The velocity of the powder from each ''finger'' of the nozzle is relatively low, allowing the gun to be closer to the part resulting in uniform

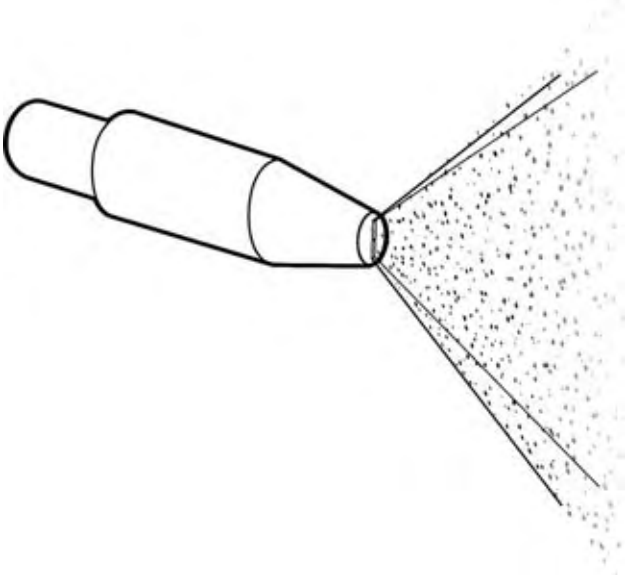

Fig. 6 Schematic of a flat spray (fan spray) nozzle.

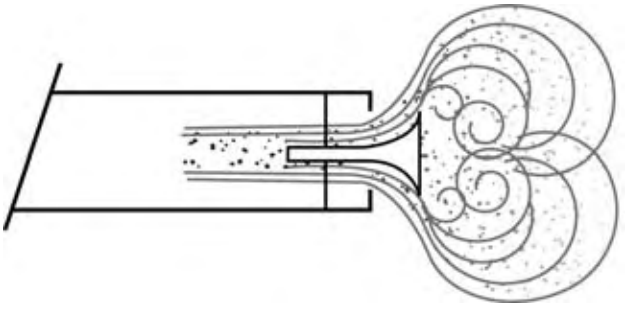

Fig. 7 Schematic of a conical nozzle.

powder deposition. Parts that can be coated using this technique are, for example, radiators, transformers, bicycles frames, or wire goods.

Bells and Discs

Powder can also be applied by bells or discs, similar to that used in the liquid paint industry. A powder bell uses a rotating turbine that rotates an enclosed bell head. The powder is delivered to the head where centrifugal forces disperse and atomize the powder. The particles are charged by corona either from the high voltage at the edge of the bell or from the external electrodes. Shaping air around the head controls the spray pattern and the forward velocity of the particles. The powder bell delivers high powder output uniformly over a wide flat area, making it ideal for the automotive industry.

Discs use large conical-type deflectors usually mounted in the vertical downward position so that powder is deflected in a horizontal position in a 360° radius. An omega (Ω) loop conveyor system normally surrounds the powder disc that is usually mounted on an oscillator or reciprocator for vertical up-and-down motion. The powder can be charged by a corona edge or by tribocharging guns. Typical applications for the powder disc are vertical extrusions or wire goods.

Electrostatic Fluidized Bed Technology

Powder application technology began with fluidized beds and evolved to electrostatic fluidized beds that are still in use today. Electrostatic fluidized beds are a method of powder application that does not use guns to apply the powder. Dry, compressed air passes through the charging media that has electrodes at a high voltage as shown in Fig. 8. This causes the air to become ionized. The ionized air is used to fluidize the powder and causes the powder to become charged. An electric field is created between the grounded part above and the charged powder cloud resulting in the powder being attracted to the part. As the grounded part becomes coated, additional charged powder will have difficulty in adhering to the coated surface due to back-ionization discussed earlier. The film thickness is controlled by voltage and exposure time.

POWDER RECYCLING

Particle Size

Any discussion of recycling powder must include information about particle size. As powders are similar to

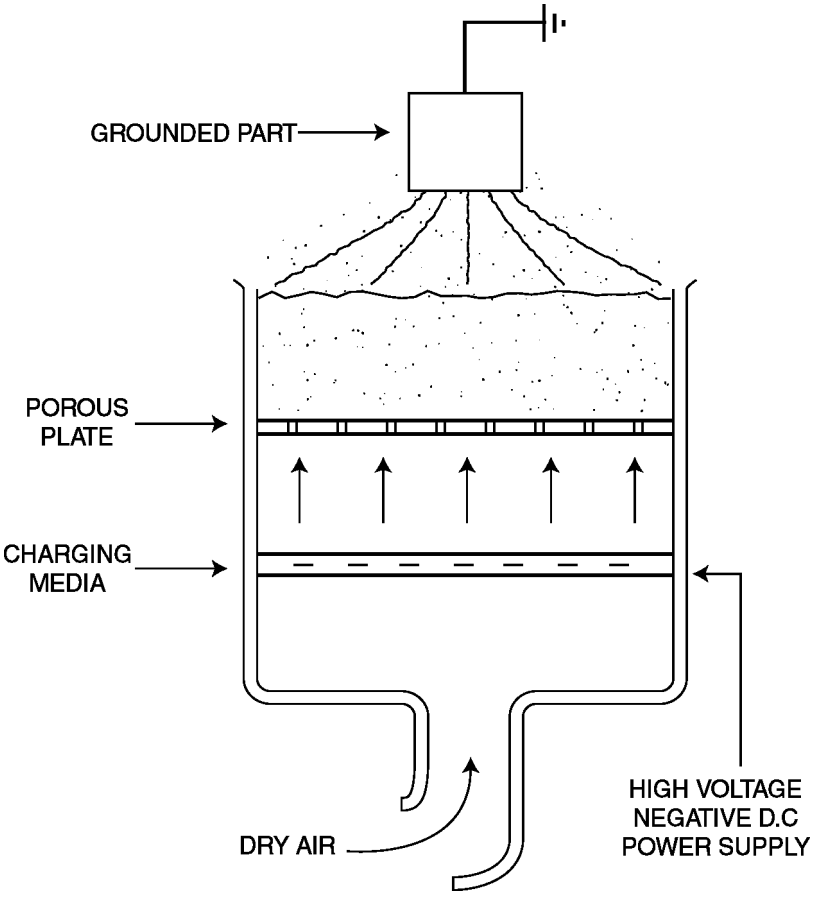

Fig. 8 Schematic of an electrostatic fluidized bed.

gravel-shaped particles, their size is not easily defined. There are many ways to define particle size, as well as different techniques that can give different results. An excellent review of this subject is presented by Rawle.[14] Low angle laser light scattering or commonly referred to as "light scattering" or "laser diffraction" is used extensively in the powder coating industry. Assumptions used in the older instruments that use the Fraunhofer approximation can make it difficult to compare the results between different instruments; the algorithms used to calculate particle size can vary depending on the type and model instrument that is used. Recently, particle size instruments have been developed that are based on Mie scattering theory, which gives more accurate results, as long as the refractive index of the powder and medium are known.

Laser diffraction methods generate a volume mean distribution. For laser light scattering techniques, the median particle size, commonly referred to as $D(v, 0.5)$, is defined as the value that divides half of the volume distribution, i.e., 50% of the distribution by volume is above this value and 50% is below this value. It is also common to define the volume percentage that is either above or below certain particle sizes. For example, particles below 10 μ agglomerate due to van der Waals forces causing fluidization and pumping problems. Therefore, it would be important to know the volume percentage of particles less than 10 μ. Coarse particles can also be a problem, especially when trying to obtain film uniformity; so it would be prudent to know the volume percentage of particles greater than, for example, 100 μ. Knowledge of these percentages helps to define the particle size distribution used.

Powder Recovery

Fig. 9 shows a simplified schematic of how powder is recycled in a system. After the powder is charged, the mixture of air and powder particles is sprayed onto a part. The powder that does not adhere to the part is contained in the spray booth and can be recycled. The oversprayed powder and the air mixture are drawn into the collector, where either a cartridge filter system or a cyclone (not shown) is used to separate the powder from the air. The collected powder is then transferred to the feed hopper where it is sieved (not shown) and remixed with virgin powder and pumped to the guns. Sieving the powder removes foreign particulates and conditions the powder prior to spraying. The particle size distribution in a cartridge filter system usually shifts toward finer particles. In a cyclone system the fines are scalped off, shifting the particle size distribution to the coarser side.

A model was developed that accurately predicts how particle size changes in a recovery system.[15] The basis of the model is that each particle size in a distribution has a certain probability of depositing onto the part. Probability factors for each particle size can be determined by comparing the particle size distribution of virgin powder to the powder that has been oversprayed one time. Factors calculated for one cycle are used to calculate the particle size distribution of subsequent cycles. In addition to these factors, a transfer efficiency value is needed to determine how much virgin powder needs to be added to maintain a constant level in the system. The particle size results calculated using this model were in good agreement with those measured from a production run of primer surfacer for exterior vehicle application. The model also showed

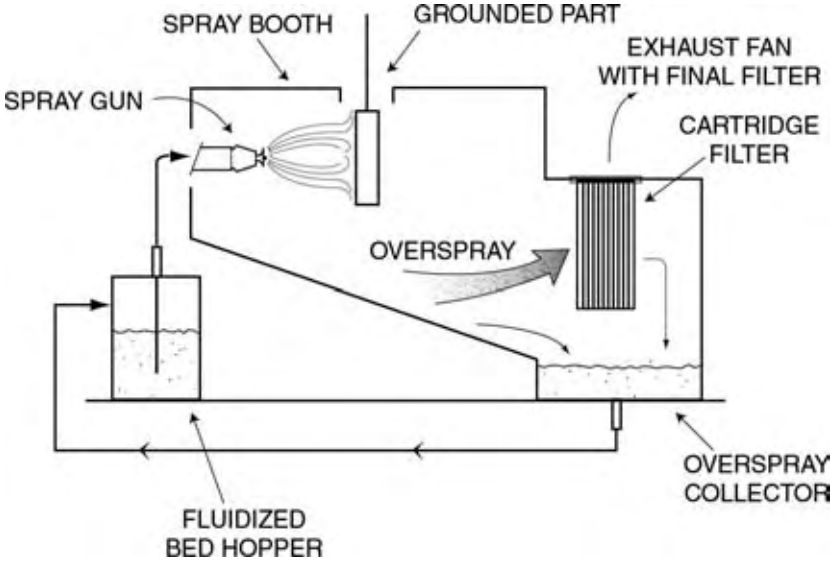

Fig. 9 Schematic of a powder recycling system.

that the median particle size in that system achieved steady state after only four complete cycles.

MEETING NEW CHALLENGES

New Equipment Technology

Recent developments in equipment technology are addressing some of the challenges of powder coatings such as fast color change and improved transfer efficiency. New powder feed technology has been developed[16,17] that allows greater powder loading at slower powder velocity to the spray guns using much less compressed air than a standard venturi pump. The advantages of this new technology are reduced powder consumption for better transfer efficiency using less energy, gentler transport of powder with less wear on the powder and the equipment, constant high delivery of powder over longer distances, and faster color change.

Fast color change developments have recently been made that utilize a two-canister system to apply color-specific powders for automotive applications.[18] While one canister is used for powder coating, the other one is getting ready for the next job. This allows a continuous operation with 8 sec claimed between jobs. Another recent development[19] consists of a color-changing manifold that uses automated valves to control color change. Powders from the different feed hoppers are attached to the manifold. The powder of choice is fed into the manifold that consists of a central channel. Air is used to purge the hose and block between colors, which allows for a color change of usually less than 8 sec.[10]

New Powder Technology

Much development work has produced powder coatings for decorative niche markets. They are now available in a wide range of gloss levels, colors, and specialized surface effects such as metallics, pearlescent, fluorescent, antique, hammertone, textured, wrinkled, and clearcoats. Metallic powder coatings have presented an application challenge, because some types of metallics are dry blended. Application equipment manufacturers have learnt how to apply these challenging materials.[20]

A major disadvantage of powder coatings has been their high cure temperature requirement. A great deal of progress has been accomplished over the past several years to reduce the cure temperature of powder. Conventional powders typically have cure temperatures between 160°C and 220°C (320–430°F) for about 20–30 min. These high cure temperatures and long cure times have prevented powder coatings from being used for plastics, wood, and medium-density fiberboard products, or metals with heat-sensitive parts such as low melting solder joints. Recent developments in curing technology have produced powders that can be melted at much lower temperatures of 100–140°C (212–285°F) for powder flow-out followed by curing with UV light.[21] Recent advances also include antimicrobial and high-temperature resistant coatings, improvements in weatherability, resistance to loss of gloss, improved mar- and scratch-resistance, and superdurable coatings. Nanotechnology will gradually play an increasing role as new powder coating compositions are developed having improved properties.[22]

CONCLUSIONS

An overview of powder coating application technology that includes the basics of powder charging has been described. From early developments, powder coating and powder application equipment technology have also been examined. Application methods have made great strides from its early beginnings using fluidized bed technology to provide thick coatings for corrosion protection and insulation. Today, the emphasis is on faster color change, higher transfer efficiency, and in some cases spray-to-waste. Powder coatings have evolved into the decorative markets that include specialty surface textures and appearances, antimicrobial powders, scratch-resistant, heat-resistant and low-cure temperature coatings. Application equipment has kept pace with new powder introductions. Improvements in powder coatings and application technology have steadily eliminated many of the drawbacks of using powder coatings. It is clear that equipment technology, as well as powder coating technology will continue to evolve in new directions creating new opportunities.

ACKNOWLEDGMENT

My sincere appreciation to Leah Lader for beautifully creating all the line drawings for the figures.

Power Factor

Peter R. Pujadó
UOP LLC, Des Plaines, Illinois, U.S.A.

INTRODUCTION

In an alternating current (AC) circuit, the power factor is the ratio of the real power delivered to the apparent power supplied, with the apparent power supplied being defined as the product of intensity times voltage. Therefore, the apparent power supplied is measured in ''volt-amps,'' while the real power delivered is measured in ''watts.''

The power factor arises from the dephasing of the electromotive force or voltage, in volts, and the current, in amperes. This dephasing results from the interaction of inductances and/or capacitances together with the resistance of the circuit. Because direct current is unaffected by inductances or capacitances, the power factor, cos φ, for direct current is always one, provided that the direct current is free of fluctuations. Similarly, if the circuit consists of resistance only, and is free of both inductances and capacitances, the power factor for AC is also one—this would be the case, for example, in the tungsten (wolfram, W) filament of a light bulb that has negligible inductance characteristics

DISCUSSION

The power factor, cos φ, is defined as

$$\cos\varphi = \frac{\text{watts}}{E^{*}I} = \frac{\text{watts}}{\text{volts}^{*}\text{amperes}} \quad (1)$$

This number can never be greater than one. Usually, it is given as a percentage, with 100% being the maximum theoretical power deliverable.

To some extent, the power factor is of more importance to the electric supply company than to the consumer. The consumer pays for the watts actually consumed, not the volt-amps supplied. A low power factor of, say, 50% is almost tantamount to saying that 50% of the energy supplied is returned to the supplier, thus increasing the supply and distribution costs. Because of this, consumers with low power factors may be required to raise them or to incur additional charges from the suppliers.

In the U.S.A., the Energy Policy Act (EPAct) of 1992 became effective on October 24, 1997, with some provisions delayed until October 24, 1999. The intent of the law was to reduce the rate of energy consumption in the U.S.A. by requiring the use of energy-efficient products. In order to accomplish this goal, the EPAct mandates that most industrial AC motors used in the U.S.A., whether imported or manufactured locally, must meet some minimum energy efficiency standards as defined in Table 12-10 of the National Electrical Manufacturers' Association (NEMA) Standard MG 1. The overall energy efficiency of a motor is the combination of its electrical and mechanical efficiencies.

In general, the EPAct regulations apply to all general-purpose motors that meet the following specifications (http://www.nema.org):

- single speed, polyphase T frame
- 1–200 horsepower (HP)
- 3600, 1800, and 1200 rpm
- foot mounted
- squirrel-cage induction motors, NEMA design A and B
- continuous rated
- operating at 230/460 V, constant 60 Hz line power (see NEMA Standard MG1)

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007925

Other motors do not fall under the EPAct regulations. for example, footless designs, other horsepower ranges, 900 rpm and slower speeds, two-speed versions, 50 Hz, 200/400 and 500 V, NEMA design C and D types, U frame, single-phase motors, frame sizes 56 and smaller, and motors designed for inverter use only; covered motors may be used with inverters and still fall under the provisions of the EPAct. Underwriters' Laboratory listed motors may be handled on a case-by-case basis.

While motors are available that have significantly higher efficiencies than those specified by the EP Act, many existing industrial motors have much lower efficiencies than required.

In addition to the above, NEMA designates a special class of Premium Efficiency Electric Motors (2003) for three-phase induction motors applied to municipal or industrial applications for operation on voltages of 600 V or less, rated 500 HP or less, operating more than 2000 hr/yr at more than 75% of full load. For details, please refer to NEMA MG 1-1998 Table 12-12. For each HP rating, that table defines nominal and minimum efficiencies for 2-, 4-, and 6-pole open motors.

PURE RESISTANCE

The general term for the combined effect of resistance, inductance, and capacitance is impedance. Briefly, we shall describe each of the contributions and their net effect.

Resistance is the obstacle that a direct electric current has to overcome to circulate through a conductor under the driving force of the voltage or electromagnetic force. In its simple form, it can be defined as:

$$\text{Resistance} = R = \frac{E}{I} = \frac{\text{volts}}{\text{amperes}} = \text{ohms} \qquad (2)$$

RESISTANCE AND INDUCTANCE IN SERIES

Any changes or oscillations in an electric current generate a counterforce that opposes such changes. By definition, an AC changes continuously, with both the intensity and the voltage varying according to sinusoidal functions

$$\begin{aligned} I &= I_o \sin\theta \\ V &= V_o \sin\theta \end{aligned} \qquad (3)$$

If the AC flows through a short straight wire, any such counterforces are negligible. However, if the AC flows through a coil, the effects can be very significant. A coil, or any similar device, is said to generate "self-induction" or, in brief, it creates a circuit with inductance. Electric motors, for example, are wired through numerous coils with high inductance. Thus, electric motors, if not corrected, can have very low power factors.

In the presence of inductance we can still think of a reactance similar to the resistance, but now defined as:

$$\text{Reactance} = X_L = \frac{E}{I} = \frac{\text{volts}}{\text{amperes}} = \text{ohms} \qquad (4)$$

where

$$X_L = 2\pi f L \qquad (5)$$

with f being the frequency of the AC in hertz or cycles per second (typically 60 in the U.S.A. and 50 in Europe) and L being the inductance in henrys. L is a property of the circuit and depends on the coil (diameter and number of turns) and on the core material inside the coil. A circuit has an inductance of 1 henry when a variation of 1 ampere per second generates an electromotive force of 1 V. Correctly speaking, X_L is the "inductive reactance."

If the coil consists of a wire with negligible resistance, $R \sim 0$, the intensity I is delayed 90° with respect to the voltage V. This can be explained in terms of an induced counterforce proportional to the rate of variation in intensity.

$$E = L\frac{dI}{dt} + I^*R \qquad (6)$$

such that, if $R = 0$ and I varies according to $I = I_o \sin(2\pi ft)$, then

$$\begin{aligned} E &= L(dI/dt) = 2\pi f L I_o \cos(2\pi ft) \\ &= 2\pi f L\ I_o \sin(2\pi ft + \pi/2) \end{aligned} \qquad (7)$$

namely, E is advanced 90° with respect to the intensity, I.

$$E = 2\pi f L I = X_L I \quad \text{with} \quad X_L = 2\pi f L \qquad (8)$$

In such a circuit with pure inductance, $\cos\varphi = \cos 90° = 0$, such that the power supplied to the coil is stored in the electromagnetic field and is returned when the field disappears, with no net power delivery.

If the resistance, R, is not negligible, the wire can be regarded as consisting of a resistance and an inductance in series, and a more general impedance can be defined as follows:

$$\text{Impedance} = Z = \frac{E}{I} = \frac{\text{volts}}{\text{amperes}} = \text{ohms} \qquad (9)$$

where $Z = [R^2 + X_L{}^2]^{1/2}$, or the square root of the sum of the squares of resistance and inductive reactance, respectively.

In this case, the intensity I is delayed an angle φ with respect to the voltage, such that

$$\varphi = arc\tan(X_L/R) \tag{10}$$

The effective power delivered is $EI\cos\varphi$, with $\cos\varphi$ being the power factor.

If $R \sim 0$, $\varphi \sim 90^\circ$ as before, and the effective power delivered is zero.

If $X_L \sim 0$, $\varphi = 0^\circ$, and the effective power delivered is $E \times I$.

RESISTANCE AND CAPACITANCE IN SERIES

If a circuit in which AC flows was to consist of a pure capacitance, the intensity would be advanced with respect to the voltage by an angle of 90°, or the opposite of the effect of the inductance seen above.

The capacity of a circuit is defined as $C = Q/E$, with C in farads, Q being the electrical charge in coulombs, and E the voltage. One farad is the capacity of a capacitor or a circuit in which one coulomb of electrical charge creates a voltage difference of 1 V.

In the presence of capacitance we can define a capacitive reactance as follows:

$$\text{Reactance} = X_c = \frac{E}{I} = \frac{\text{volts}}{\text{amperes}} = \text{ohms} \tag{11}$$

where

$$X_c = \frac{1}{2\pi f C} \tag{12}$$

with f being the frequency of the AC and C the capacity of circuit measured in farads.

Following the same reasoning we used for inductance, if $E = E_o \sin(2\pi ft)$, we obtain:

$$\begin{aligned} I &= \frac{dQ}{dt} = C\frac{dE}{dt} = 2\pi f C E_o \cos(2\pi ft) \\ &= 2\pi f C E_o \sin(2\pi ft + \pi/2) \end{aligned} \tag{13}$$

With pure capacitance, the intensity is advanced by $\varphi = 90^\circ$ with respect to the voltage. Therefore, the net power delivered is zero. In this circuit,

$$E = X_c I \quad \text{with} \quad X_c = \frac{1}{2\pi f C} \tag{14}$$

If the circuit can be regarded as consisting of resistance and capacitance in series, then:

$$\text{Impedance} = Z = \frac{E}{I} = \frac{\text{volts}}{\text{amperes}} = \text{ohms} \tag{15}$$

where $Z = [R^2 + X_c{}^2]^{1/2}$, or the square root of the sum of the squares of resistance and capacitive reactance, respectively.

In this case,

$$\varphi = arc\tan(X_C/R) \tag{16}$$

RESISTANCE, INDUCTANCE, AND CAPACITANCE IN SERIES

We can equally define

$$\text{impedance} = Z = \frac{E}{I} = \frac{\text{volts}}{\text{amperes}} = \text{ohms} \tag{17}$$

where $Z = [R^2 + (X_L - X_C)^2]^{1/2}$, and $\varphi = arc\tan[(X_L - X_C)/R]$

In the resulting configuration, the intensity may be advanced or delayed with respect to the voltage depending on whether X_C is greater than or less than X_L.

If $X_C = X_L$, the intensity is at its maximum E/R, and the circuit is in resonance. Note that $X_C = X_L$ implies that

$$2\pi f L = \frac{1}{2\pi f C} \tag{18}$$

so that

$$f = \frac{1}{2\pi(L C)^{1/2}} \tag{19}$$

is the resonant frequency or the natural frequency of the circuit. If R is low, resonant circuits can lead to dangerously high internal voltages across the coils and capacitors, much higher than the externally applied voltage. A circuit with resistance, impedance, and capacitance in series can lead to hazardous situations if it is not properly monitored to avoid the onset of resonance.

OTHER CIRCUITS

Using the same analogy as resistance, any other impedance configurations can be structured with, for example, resistance, inductance, and capacitance all in parallel; or various combinations of impedances in series and in parallel. The analysis is analogous to that of resistances with direct current. For impedances in series, we start with the vector of intensity and locate the voltage vectors advanced or delayed depending on the type of impedance. For impedances in parallel,

we start with the voltage vector and advance or delay the intensity vectors as required.

Note that, although we indicated above that a short straight wire can be regarded as consisting solely of resistance, this is no longer true for long power lines. Apart from the power factor at the generating station, the magnetic field produced by each conductor will affect the other conductors and, in effect, create an inductance. The analysis is different for monophase or triphase transport systems but, in general, the inductive reactance will be a function of the distance between cables, the frequency of the AC, and the gauge and resistance of the cables. Significant power losses can arise in long AC power lines.

HOW TO IMPROVE THE POWER FACTOR

We have seen above that the dephasing angle φ between intensity and voltage can be modified by using various combinations of inductive and capacitive reactance.

The most usual situation that leads to low power factors is the use of inductive motors that, as the name implies, can introduce very large inductive reactance in the line. The electric load introduced by an inductive motor can be represented as a resistance and an inductance in series. This combination will have an intensity vector that will be delayed with respect to the voltage.

If we add a capacitor in parallel to the motor, we are imposing an intensity vector that will be advanced 90° with respect to the voltage. By using the right size capacitor we can decrease the angle by which the overall intensity is delayed with respect to the voltage and, therefore, increase $\cos\varphi$. A capacitor with only a few micro-farads (μF) usually suffices to increase the power factor from, say, 75% to approximately 85% or higher.

For example, let us assume that we wish to improve the power factor from $\cos\varphi_1$ to $\cos\varphi_2$, where $\cos\varphi_2 > \cos\varphi_1$ in a circuit that delivers W W, at E V, and at a frequency of f Hz (cycles/second)

In Fig. 1, I is the initial current in amperes, equivalent to the vector length $\underline{oa}$. Addition of a capacitor in parallel will create an intensity vector I_C advanced 90° with respect to the voltage, E. In order to calculate the new angle φ_2, all we need to do is set the distance $\underline{ab} = I_C$.

$$I = \frac{W}{E^* \cos\varphi_1} \tag{20}$$

$$\underline{ac} = I\sin\varphi_1$$
$$\underline{oc} = I\cos\varphi_1$$
$$\underline{bc} = \underline{oc}\tan\varphi_2$$

$$I_C = \underline{ab} = \underline{ac} - \underline{bc} = E/X_c = 2\pi f C E \tag{21}$$

$$\begin{aligned} C &= \frac{I_C}{2\pi f E} = I\frac{\sin\varphi_1 - \cos\varphi_1\tan\varphi_2}{2\pi f E} \\ &= W\frac{\tan\varphi_1 - \tan\varphi_2}{2\pi f E^2} \end{aligned} \tag{22}$$

The corrected line intensity will now be

$$I_L = \frac{W}{E^*\cos\varphi_2} = I\frac{\cos\varphi_1}{\cos\varphi_2} < I \tag{23}$$

As an example, if $W = 10$ kW, $E = 480$ V, $f = 60$ Hz, and $\cos\varphi_1 = 0.70$, and we wish to improve the power factor to $\cos\varphi_2 = 0.90$, we should add a capacitor in parallel to the load with a capacity $C = 61.7$ μF (micro-farads). The line current will decrease from 29.8 A to 23.1 A.

It should be remembered that both the efficiency and the power factor of a typical motor are a function of the load. Motors should be sized for optimum operation at 100% load on a continuous operation basis. At 100% load, the efficiency of a good motor in the 10–30 HP range will typically be somewhere between 89% and 92% (up to 93–94% for a NEMA premium motor). If the load is decreased to, say, 50%, the efficiency of the same motor may easily drop to 85% or lower.

If the load with low power factor were capacitive, we can achieve a similar correction of the power factor by adding an inductance in parallel to the load.

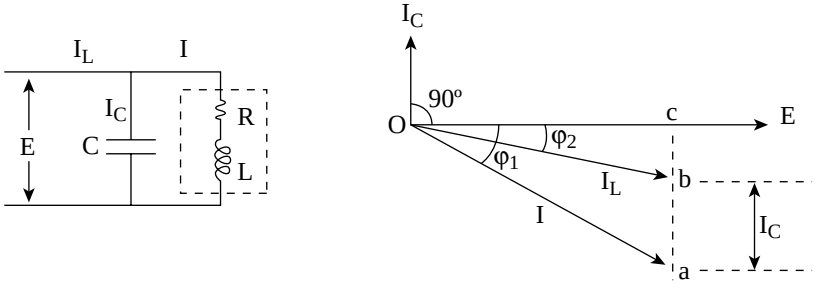

Fig. 1 Correction of the power factor.

CONCLUSIONS

The power factor, or potency factor, is a natural result of the intrinsic nature of AC and its interaction with self-induced magnetic fields. It can be corrected and minimized but it cannot be eliminated altogether, principally when subject to varying loads. Use of direct current may be a preferred solution when the dissipative losses from AC may become prohibitive.

Pressure-Relief Valve Design

Jonathan Francis
University of Central Lancashire, Preston, U.K.

INTRODUCTION

Protection against overpressure is essential for the safe operation of fluid power and process plant. Automatic pressure-relief valves are commonly used for this purpose. They work on the principle of a force balance. When the valve is shut the hydrostatic force tending to open it varies linearly with system gauge pressure, and the return force tending to keep the valve closed is (very nearly) a constant. If system pressure is too high then the hydrostatic force will surmount the return force opening the valve and venting the system.

This entry describes the design of relief valves. Engineering design of these protection devices is dominated by function, but is also influenced by manufacturing cost and assisted by consideration of scale and shape. The main aim of this entry is to describe the function, performance requirements, and control dynamics of spring-loaded automatic pressure-relief valves. A secondary aim is to discuss modern engineering design solutions and some relatively recent theoretical and practical developments affecting relief valve design.

TYPES OF RELIEF VALVE

Early Relief Valves

Fuller describes four types of automatic relief valve. Each differs by means of the return force applied, as illustrated in Fig. 1. The four types are:[1]

1. Mass lever
2. Tension spring lever
3. Deadweight direct load
4. Compression spring direct load.

The first valves were of the mass–lever type. Tension spring lever and deadweight direct load valves were later developed to overcome weaknesses inherent in the mass lever design: a calibrated tension spring provides evidence of set pressure; the deadweight direct load valve improved stability and reseating because of reduced tilt. However, an appropriate valve size was not easily determined until James Joule provided evidence of the energic nature of heat in the mid-19th century, to dispel the myth of ''phlogiston'' (a supposedly weightless fluid previously blamed for boiler explosions).

Emergence of the Direct-Acting Spring-Loaded Relief Valve

Also in the mid-19th century, the basic Cornish boiler was replaced as state-of-the-art by the Lancashire boiler. A design feature of the latter allowed subsequent passage of combustion products beneath and around the water drum, after leaving the fire tube (passing through the drum). Thermal efficiency of boilers was further improved by a number of later designs, such as the Cochrane vertical boiler, the economic boiler, and the package boiler. However, the greatest leap forward in terms of steam pressure and steaming rate came with the introduction of the water-tube boiler. With their small-diameter water tubes, these could operate at higher fluid pressures and provide a large heating surface to water volume ratio.

Deadweight and mass lever valves are impractical for use on high-pressure systems, being too heavy and cumbersome. Tension spring valves tilt more easily and for an equivalent lift of the valve disk, spring movement in a tension spring lever valve must be greater than that in a compression spring direct-load valve. The benefits of being lightweight and compact are reflected in the low cost of a compression spring direct-loaded valve, making it the most common for protection of pressurized systems.

Terminology

A primary aspect of relief valve design is to provide an increase of fluid force on the disk to raise it against the spring. When this is achieved without an increase of reservoir pressure, but as a result solely of the changing flow structure in a lifting valve, it is known as ''lift-assistance.'' Without lift-assistance, valves will open smoothly and linearly with overpressure. It is the lift-assistance that causes the classic popping action of valves used with compressible fluids (i.e., sudden and rapid opening).

Design for lift-assistance is associated with pressure recovery downstream of the valve seal. Generally, two approaches are adopted: 1) a valve arrangement with huddling chamber as shown in Fig. 2(A) and 2) a valve arrangement with a deflector plate as shown in Fig. 2(B). Both approaches require extra disk area outside the sealing area on which the recovered pressure may

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007929

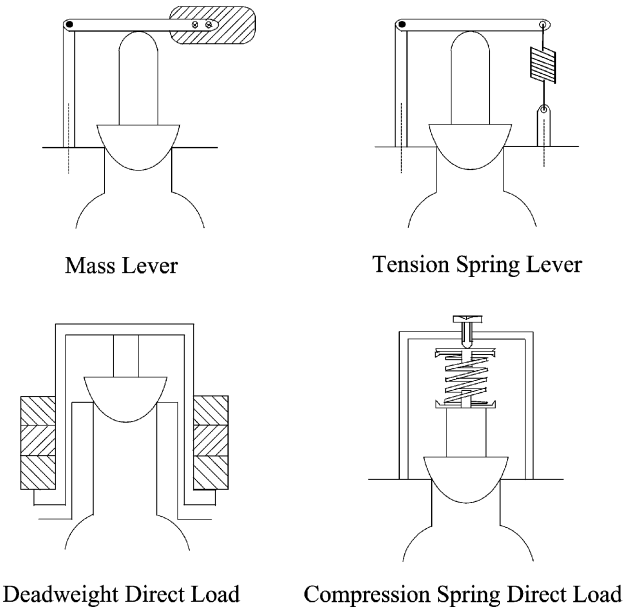

Fig. 1 Schematic illustrating four early types of automatic pressure-relief valve.

act to drive the disk upward. With the disk extended beyond the seal radius, a huddling chamber forms a gradually enlarging flow area immediately downstream of the seal to assist in pressure recovery. The addition of a deflector plate causes a dynamic pressure on the outer portion of the disk because of a change of momentum beneath it, but the volume between the deflector plate, body base, and seat support can also be considered a huddling chamber.

In the United Kingdom, relief valves were traditionally categorized by the degree of lift necessary to achieve the rated discharge. The division into ordinary-lift, high-lift, and full-lift categories is a throwback to BS 759 (obsolescent).[2] The subsequent standard BS 6759 and the recently introduced harmonized European standard BS EN ISO 4126-1 do not make any such distinction.[3,4] Ordinary-lift valves achieved their maximum disk lift at less than 1/12 the bore diameter and were generally used on liquid service. High-lift valves would attain lifts up to one-fourth the bore diameter and full-lift valves over one-fourth, making them suitable for gas or vapor service.

Modern terminology is derived from the United States, where valves lacking appreciable lift assistance, but which open smoothly to rated discharge at a low disk elevation (i.e., ordinary-lift valves), are referred to as "relief valves" or sometimes "pressure-relief valves." Valves with lift-assistance may be termed "safety valves" or "safety-relief valves," where the former might be used to describe a valve lifting to less than one-fourth the bore diameter (i.e., a high-lift valve) and the latter to describe valves achieving higher lifts (i.e., full-lift valves). A consistent use of terminology is no longer prevalent throughout either North America or Europe. In the International Standard, the phrase "safety valve" is used as a generic term to describe all types and classes of valves that open automatically to relieve excessive pressure.[4]

DOMINANT DESIGN CONSIDERATIONS

This entry focuses on the design of the product itself. The phenomenon of explosion (that it is meant to prevent) and the selection, sizing, or application of

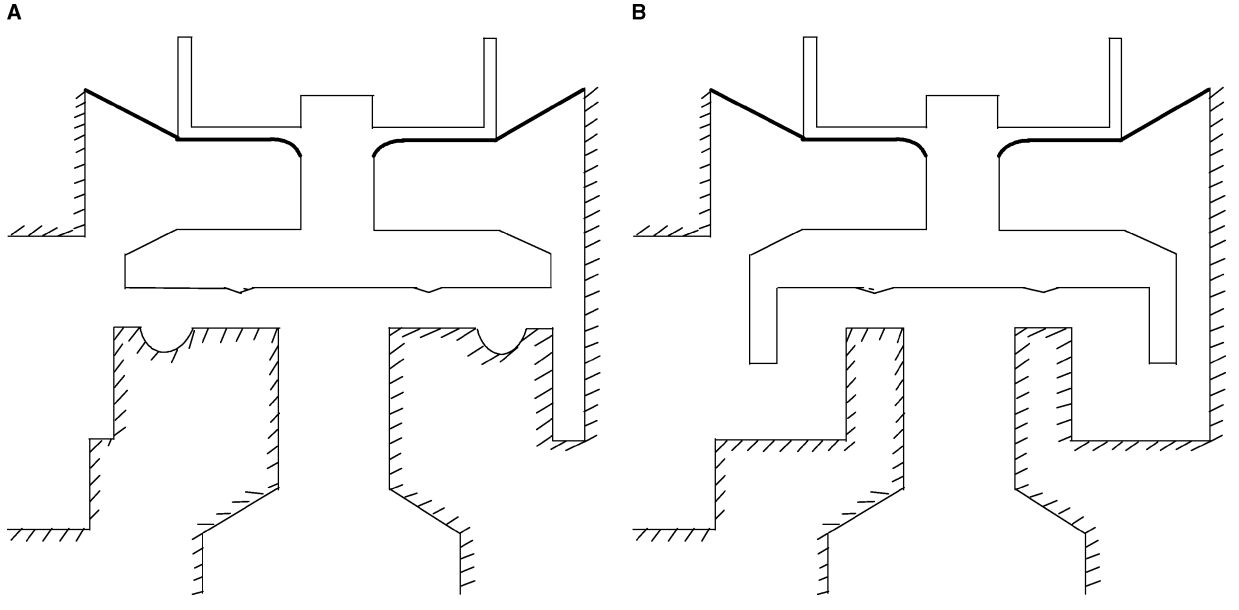

Fig. 2 (A) Illustrative valve arrangement with huddling chamber. (B) Illustrative valve arrangement with deflector plate/skirt.

the device are worthy of entire books in their own right. Readers are directed to alternative sources for information concerning the dynamics of reacting flows, design for fire safety, pressure vessel design, and bursting disk design.[5–12] They are also advised to study relevant standards and manufacturer's literature for information concerning sizing, type testing of relief valves, independent witness approval, statutory requirements, and application to potable water and flammable atmospheres.[4,13–15]

Valve Shape and Manufacture

Valve shape is constrained by its function. An entrance and an exit port are needed to pass fluid from an overpressurized system to a place of safe discharge. Between the two ports, a barrier is needed to prevent discharge under normal operating conditions (i.e., a disk and a seat) and a means to ensure that the barrier remains leakproof (i.e., a seal and hence a spring to provide a clamping force). There must be facility for the barrier/disk to move to allow passage of fluid in an emergency; and this movement must be initiated by system pressure.

The aim is to achieve functionality with minimum product cost. Generally, product cost can be maintained as low as possible by minimizing both material volume and machining of parts. Fig. 3 shows a sectional sketch of a prototype high-lift valve. The main body, moving parts, and flow passages are shown in full. The thick black line is a diaphragm that prevents fluid entering the spring chamber. This chamber is foreshortened at the top of the figure and its actual height significantly affects material and production cost. The shorter is the spring chamber, the less is the material needed and the cheaper is the bonnet casting. The height of the bonnet is controlled by spring wire thickness and pitch, as design lift must not be compromised by prior achievement of full coil compression. Spring design is beyond the scope of this entry, but note that the piston into which the spring would fit (spring not shown) is not wholly within the bonnet. The piston sits on the spindle collar and disk within the main body of the valve to reduce the necessary bonnet height; and body height cannot be reduced without compromising escape of fluid from the backpressure space above the disk.

Valve bodies are generally cast. The thickness of a valve wall for use on medium pressure systems (1–10 bar) is generally well in excess of that needed to meet pressure test standards. However, reduction in material volume for thinner walls would be more than offset by the additional difficulties of casting thin walls with thicker seat supports or screwed fixings. Ease of assembly also reduces cost.

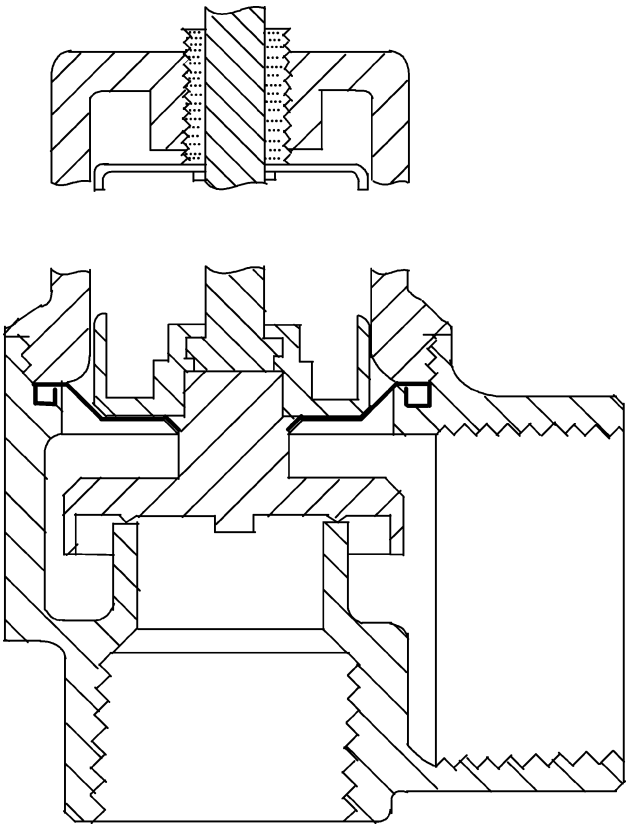

Fig. 3 Sectional sketch of a spring-loaded pressure-relief valve (spring not shown).

Careful examination of Fig. 3 reveals that the disk and its spindle connector would need to be made in two parts to enable the assembly of this prototype. A slightly larger access where the bonnet connects would enable a composite disk and spindle to be inserted from above. However, the spindle needs to be able to pivot within the disk mounting to enable the three-dimensional fluid forces to tilt the disk without causing excessive friction in the spindle-lift guides. Nevertheless, assembly would be simpler where the disk is inserted from above, and any reduction in diameter (and hence material) confined to the spring chamber.

Valves should be installed vertically as shown in Fig. 3. Care must be taken that the internal diameter of the pipe fixing is equal to or greater than the valve bore and the connector is short enough to limit pressure loss between the reservoir and bore to 3% of set pressure.[16] If the pipe-fixing diameter is too small then the valve may not discharge at full capacity. Moreover, instability may be induced because of excessive pressure drop in the pipe connector. Rapid and repetitive rise and fall of a valve disk is referred to as valve "chatter." It can also be induced by misapplication of a valve intended for gas service on liquid service.

Good design can be compromised by poor application or size selection. If a valve passes too little fluid

then the system will not be adequately protected. Conversely, if a valve is oversized then its disk may lift only a short distance and continually pass fluid. This is known as ''simmering.''

Sometimes the valve disk does not reseat properly, but continues to discharge a small quantity of fluid. This is known as ''feathering'' of the valve, and it can be caused by damage to the seal from particulate matter suspended in the relieving fluid. It can also be due to balance of those forces that control the functioning of the valve, which can be checked using the techniques described in the next section.

RELIEF VALVE FUNCTION

Valve Operation

The operating cycle

Fig. 4 illustrates an operating cycle. When system pressure is raised above working pressure, the seal relaxes under the influence of a gradually reduced clamping force. At a preset pressure, leakage past the seal is initiated; this is denoted by point ''a'' in Fig. 4. Further increase in pressure will cause the disk and seal to be lifted clear of the seat (e.g., point ''b''). In an ordinary-lift valve the initially smooth opening is sufficient to relieve excess pressure, so that once the system fault is rectified the relief valve will ideally shut by retracing the line to point a. In practice, friction in the spindle-lift guides will cause the valve to close at a lower pressure. In a high-lift or full-lift valve, the initial opening is not sufficient to relieve the overpressure, so that the valve continues to lift beyond point b. If the pressure is raised sufficiently then the disk–spring force system will become unstable (point ''c''), and the valve will open rapidly to point ''d.''

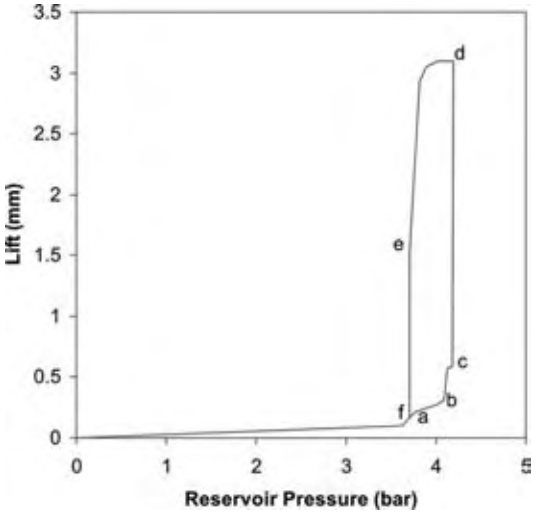

Fig. 4 Example of the operating cycle of a pressure-relief valve. *(View this art in color at www.dekker.com.)*

With pressure relief from point d, a gradual reduction in pressure and lift is seen until at point ''e'' the disk–spring force system once again becomes unstable, and the valve rapidly closes (point ''f''). Soft seals (such as neoprene) are desirable at low pressures because they distort more easily to form a seal. Hard seals (such as ptfe or viton) are needed to withstand the reaction forces at the seat on high-pressure systems, but do not so easily distort to prevent flow when slightly damaged. On some high-pressure applications, metal to metal seating is used because even hard sealing materials are prone to damage (either from the reaction forces or from the fluids in the system).

The pressure at which the valve begins to pass fluid is termed the ''set pressure'' and the pressure at which it opens rapidly to its highest lift is called the ''popping pressure.'' The difference between them is called the ''accumulation'' and the difference between set pressure and reseating pressure is called ''blowdown.'' Technical standards provide limitations for accumulation and blowdown and for most of the 20th century the designer's aim was to meet these standards, but recently focus has shifted so that more valves are being developed with the intention of minimizing fluid loss (or waste, see later).

Cycle synthesis

The foregoing operating cycle is controlled by the balance of forces acting on the valve disk. The force due to the fluid surrounding the disk and the force due to the spring compression are the main components in the force balance. As a first approximation, all other forces can be ignored. Fig. 5 is typical of the way in which the opposing forces of the fluid and spring vary with lift when the disk is artificially raised from its seat at constant pressure. Curves of fluid force can be identified for notable pressures in the operating cycle and compared with spring forces. Neglecting the mass of moving parts, the spring force on the point of lifting is equal to the product of sealing area and gauge reservoir pressure.

The cycle of Fig. 4 can be deduced from the graph of Fig. 5. Intersections a–f on Fig. 4 correspond to points a–f in Fig. 5.

The valve begins to leak at some pressure ($P1$), which is set by precompression of the spring. However, the spring force remains greater than the fluid force (at $P1$) for an initial lift, which explains why the valve does not pop open immediately on leaking. A gradual lift can be observed (say $L2$) for further small increases in

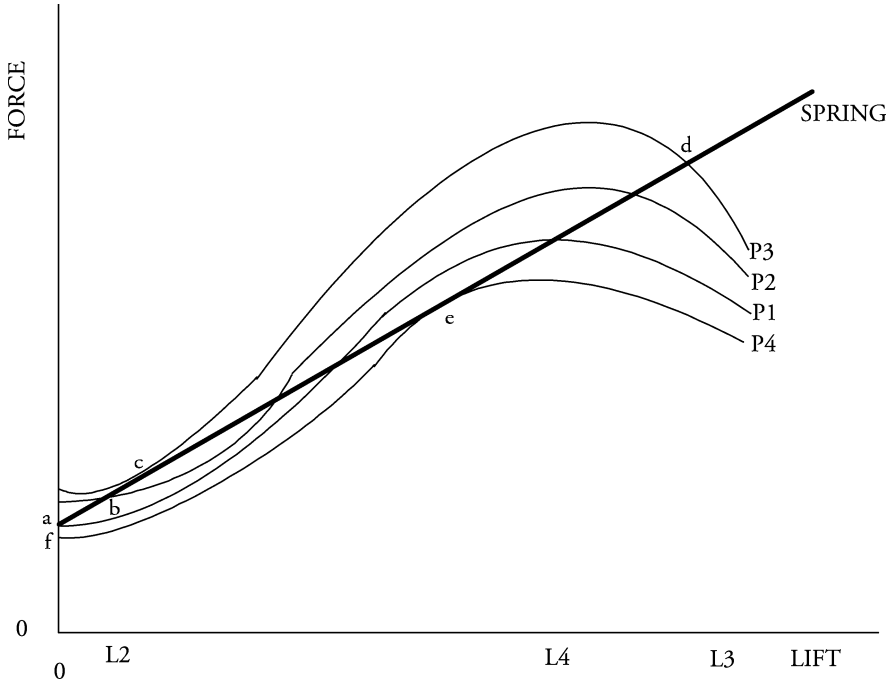

Fig. 5 Variation of spring and fluid forces with lift.

reservoir pressure (e.g., $P2$). However, when a particular pressure is reached ($P3$) the rate at which the fluid force increases with disk lift becomes greater than the spring rate, and the system becomes unstable. A further infinitesimal increase in pressure causes the valve to open quickly until the forces are once again in balance at a new position ($L3$).

With pressure relief, the disk elevation gradually reduces until another point of instability ($L4$) is reached, at which the valve suddenly closes.

A typical lifting transient has been found to be in the order of 50 msec. [17,18] In this time, the disk of a 20 mm nominal bore full-lift valve will move approximately 5 mm, while a particle of air travelling at sonic velocity would move in excess of 15 m. Even at a Mach number of 0.1 these rough figures indicate that a quasi-steady assumption is reasonable, as Bicen, Vafidis, and Whitelaw also discovered for internal combustion engine valves.[19]

It is known that the opening part of the operating cycle can be synthesized in the manner just described. The maximum lift position and popping pressure can be reliably predicted from force analysis or experimentally derived force plots.[20–22]

Force Characteristics

Force plots like those of Fig. 5 can be generated from steady forces measured in the absence of a spring. The spring is removed from the valve so that the (fluid induced) upward thrust can be measured with a cantilever load cell. The load cell is used as a lift stop, initially set at a low lift but then adjusted to gradually higher positions. Prestressed mild steel spindles should also be substituted for soft metal spindles, and designed so that the upward force on the piston reacts on a collar of the new spindle. This helps to reduce buckling and direct compression errors on supposed lift position during testing.

Individual plots need not be generated for all possible set pressures and valve sizes that a valve series is intended to cover. Instead, a force characteristic can be defined in which dimensionless force (or force factor) is plotted against dimensionless lift.

The moving parts of a valve are the disk, piston, and spindle. Fig. 6A shows a cutaway section of a general purpose relief valve when closed and Fig. 6B shows the forces experienced by the moving parts during the lifting transient.

$F1$ is the vertical component of the combined hydrostatic and hydrodynamic (fluid) force acting on the moving parts arising from the absolute pressure distribution and denoted by the shading on the wetted surfaces in Fig. 6B. $F2$ is the weight of the moving parts, $F3$ is the spring compression force, and $F4$ is the weight of the spring. $F5$ is the atmospheric pressure acting over the top of the piston. Neglecting friction in the guides, $F6$ is the viscous damping due to movement of fluid into and out of the space above the disk (and for a few valves, though not the one illustrated here, also due to an additional dashpot). $F7$ is due to the accelerating mass of moving parts and $F8$ is the clamping force or reaction at the seat in a closed valve.

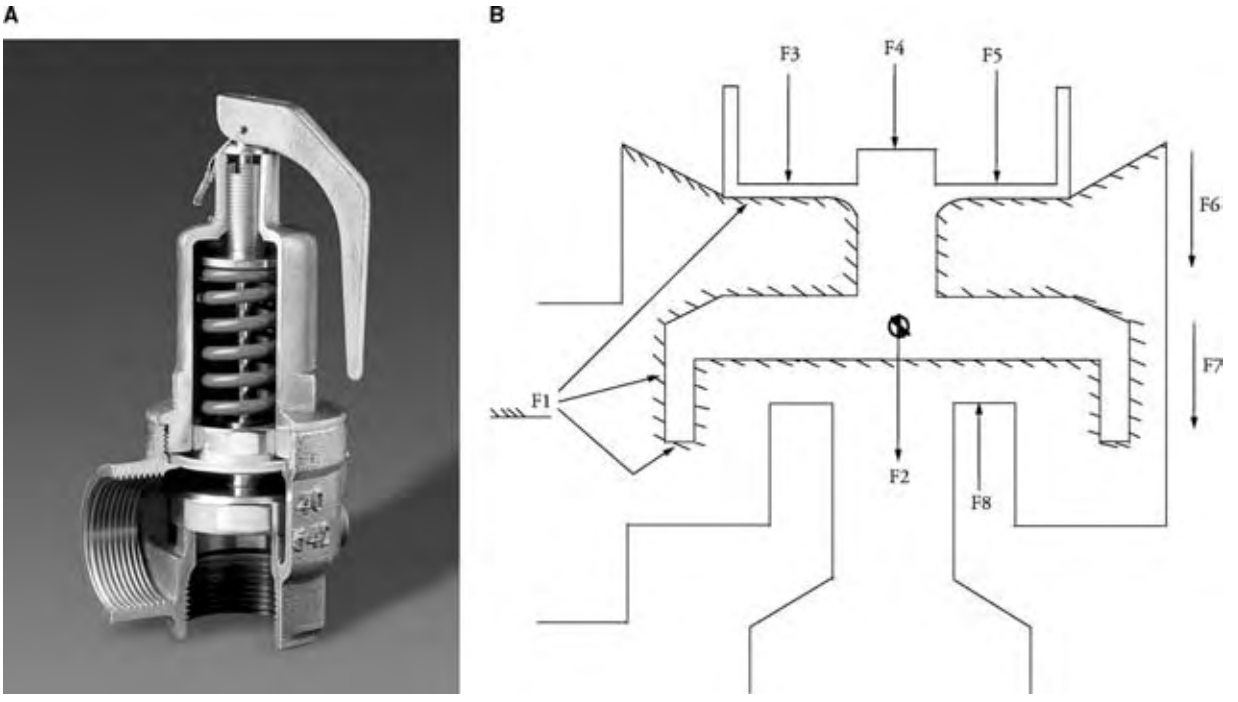

Fig. 6 (A) Cutaway view of a general-purpose relief valve. (Reproduced by kind permission of Delta Fluid Products Ltd.) (B) Forces acting on the disk, piston, and diaphragm assembly. *(View this art in color at www.dekker.com.)*

Under steady conditions in an open valve, $F6$, $F7$, and $F8$ all have a zero value, and

$$F1 = F2 + F3 + F4 + F5 \tag{1}$$

The valve spring is removed when testing with the load cell, which then bears the upward thrust ($F0$), and

$$F0 = F3 + F4 \tag{2}$$

and as F4 $\ll$ F3, it can be neglected. Thus, load cell thrust $F0$ is virtually the equal of spring compression force in a complete valve.

Spring compression cannot be easily measured, but if a touch-tight seal is assumed, then just prior to the disk rising clear of the seat, the spring compression force will be equal to the hydrostatic resultant on the disk, i.e.,

$$F3_{(X=0)} = (P_o - P_a)\frac{\pi}{4}D_s^2 \tag{3}$$

where $P_o - P_a$ is the gauge reservoir pressure and D_s is the diameter (not of the bore, but of the seal) and $X = 0$ represents a nil dimensionless lift.

At the point of lifting, the load cell force $F0$ will vary linearly with the reservoir gauge pressure. It will also vary linearly with the square of the sealing diameter (D_s), but bore diameter (D) is usually chosen as a nominal measure of valve size. The force factor can be defined as:

$$K_F = \frac{4xF0}{\pi(P_o - P_a)D^2} \tag{4}$$

A graph of the force factor (K_F) plotted against dimensionless lift (L/D) can be referred to as a "force characteristic." An example is shown in Fig. 7 for a particular valve tested at various pressure ratios on air service. For ideal flow, at pressure ratios below 0.528, the valve would be subject to choked flow and the pressure distribution on the moving parts, and hence the dimensionless force factor, would vary according to the position and strength of the shock wave downstream of the throat (see later), and hence according to the built-up backpressure value in any particular application. The design lift for the valve shown in Fig. 7 is $X = 0.167$, and within that range the results tend to collapse toward a single curve for lower pressure ratios. At excessive lifts, the diaphragm (protecting the spring chamber) can become trapped and impart inconsistent retarding forces on the disk.

The spring compression force can also be normalized by the hydrostatic resultant at $X = 0$, and the resulting line superimposed on the force characteristics, as shown in Fig. 8. Maximum lift occurs at the intersection of the force and spring characteristics. It is by this means that lift and popping pressure can be predicted across a range of valves and springs selected to achieve design lift. However, accuracy of these

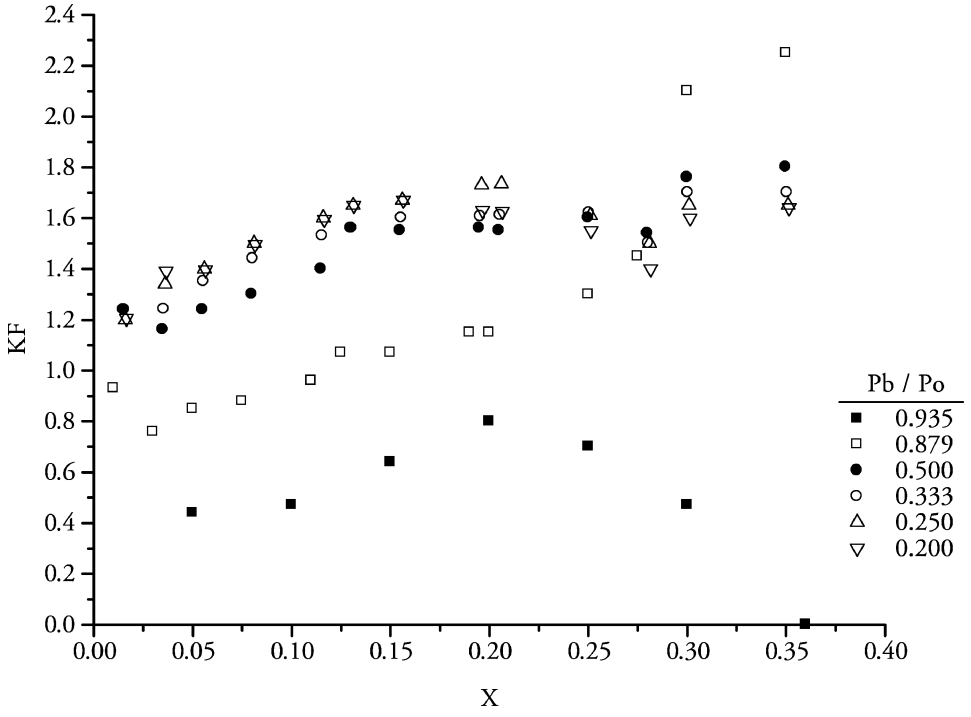

Fig. 7 Effect of pressure ratio on force characteristics of a high-lift relief valve.

predictions is limited by the degree of dynamic similarity that can be achieved, which is mainly dependent on geometrical similarity across the valve range.

Prediction of Blowdown

The compression spring direct loaded valve is reminiscent of a classic mass–spring–damper arrangement. As a result, there have been many publications purporting to simulate the dynamic response of spring-loaded relief valves using a linear second-order system, but few are compared with real valve activations.[23–25] Unfortunately, such simulations are prone to omitting important variables, especially when coupled with momentum models of fluid dynamics intended to predict the forcing function. In practice, the valve exhibits hysteresis, which enables it to open and close at different pressures. This is partly a result of Coulomb damping due to sliding friction and stiction in the valve guides, but may also be due to different flow structures beneath an opening and closing valve disk (i.e., a Coanda effect).

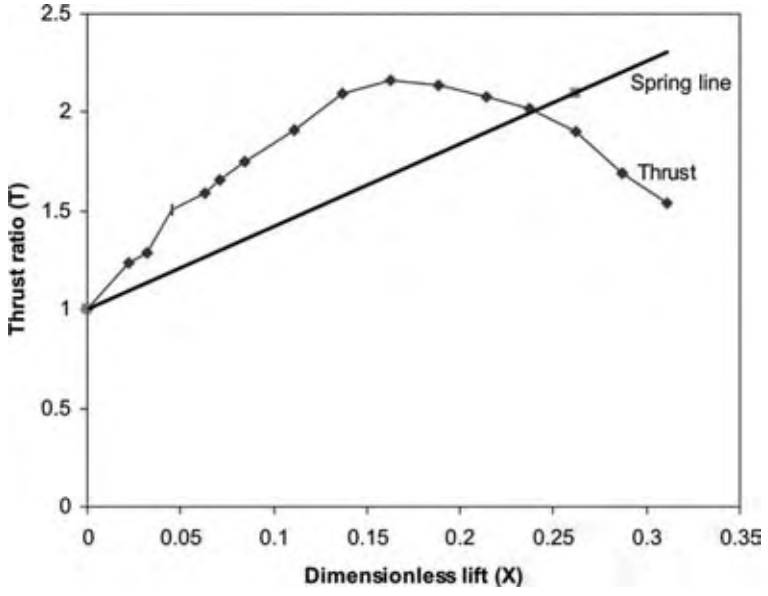

Fig. 8 Example of spring characteristic intersecting the force characteristic. *(View this art in color at www.dekker.com.)*

It is difficult to account for hysteresis in a second-order model because of its nonlinearity with viscous damping (disk movement in the relieving fluid), its lack of repeatability, and its dependence on built-up backpressure (and hence the particular application). However, where additional viscous damping is deliberately added, a linearized analysis will yield useful results.[26–28]

Hysteresis also prevents force plots generated for a gradually lifting valve from being used to synthesize the closing action of a valve; and so predict blowdown. Nevertheless, the shape of the force curve generated for a gradually closing valve is clearly related to blowdown (from Fig. 5); and the two force plots will be of similar shape where any Coanda effect is minor. It has been demonstrated that the shallower is the rise of the force curve above the spring line, the more difficult is lift prediction, but the smaller is the blowdown; a shape factor can then be used to empirically predict blowdown.[18]

VALVE FLOW

Dimensional Analysis

Flow-through relief valves have traditionally been analyzed by treating the valve as a convergent nozzle.[17,29,30] A discharge coefficient (k_d or k_m) is defined as the ratio of actual mass flow rate to the theoretical ideal mass flow rate through a one-dimensional convergent nozzle of exit area equal to the nominal bore of the tested valve. Measured discharge coefficients are derated by 10% (K_{dr}) to specify valve capacity.

According to Ref.[4] where the bore is treated as a nozzle of area (A) (mm^2), reservoir and backpressures (P_o and P_b, respectively) (bar) (abs.), and density of fluid (ρ) (kg/m^3), then valve capacity (Q_m) (kg/hr) can be found for liquids:

$$Q_m = 1.61 K_{dr} K_v A[\rho(P_o - P_a)] \tag{5}$$

where K_v is a correction factor for viscosity, usually assumed to be unity.

For compressible flows, two conditions exist: critical and subcritical flow. Neglecting friction, subcritical flow occurs when:

$$P_b/P_o > [2/(\gamma + 1)]^{\gamma/(\gamma - 1)} \tag{6}$$

where γ is the isentropic index at the reservoir conditions, or ratio of specific heats. Critical or choked compressible flow occurs when Eq. (6) is untrue. In the latter condition, the valve capacity can be found:[4]

$$Q_m = 0.2883 K_{dr} C A[\rho P_o]^{0.5} \tag{7}$$

where C is a complex function of the isentropic index. If flow is subcritical then the equation becomes:

$$Q_m = 0.2883 K_{dr} C A K_b[\rho P_o]^{0.5} \tag{8}$$

where K_b is a different complex function of the isentropic index. These complex functions can be found in Ref.[4] and their development can be traced from gas dynamics texts.[4,31,32]

However, the end of the inlet bore is not the minimum section of a valve flow passage. Even in the full-lift condition, separation of a shear layer at the leading edge of the seat will often make the mainstream flow contract further as it passes over the seat. Flow through the bore and that across the seat have also been modeled as a convergent nozzle followed by one-dimensional frictional adiabatic ''Fanno'' flow between parallel plates with successful prediction of the lifting transient (from forces) as the result.[33] However, from Fig. 3 it can be seen that the flow path generally converges toward the seal, and diverges at greater radii downstream of the seal. Where the seat has any degree of thickness, or where a deflector skirt or a huddling chamber exist then the transition from the bore to the main body appears as a convergent–divergent passage.

A convergent–divergent nozzle is a useful analogy by which is developed the scientific basis of relief valve flow for compressible fluids.[22] For liquid service, a convergent nozzle is sometimes considered a more appropriate analogy, but pressures measured beneath the disk of a valve subject to both incompressible air flow and choked compressible air flow are in keeping with those expected from a converging–diverging geometry.[34–36]

Compressible mass flow rate (m) through a valve can be affected by the following variables:

1. Component shape and finish (λ)
2. Disk lift (L)
3. Valve nominal bore (D)
4. Absolute reservoir pressure (P_o)
5. Absolute exhaust pressure (P_b)
6. Atmospheric pressure (P_a)
7. Reservoir viscosity (μ)
8. Isentropic index (γ)
9. Reservoir density (ρ_o).

Use of the Buckingham pi theory leads to a functional relationship, such as:

$$\frac{m}{D^2\sqrt{P_o \rho_o}} = \Phi(\Theta) \tag{9a}$$

The independent groups (Θ) include dimensionless lift (L/D), backpressure ratio (P_b/P_o), Reynolds number

(Re), and the isentropic index or ratio of specific heats (γ). The dependent group relates the mass of discharge to the valve size and to the reservoir conditions. It is suitable for assessing dynamical similarity under conditions of choked compressible flow. Substitution of P_o/RT_o for ρ_o in the dependent group produces a more conventional representation:

$$\frac{m\sqrt{R\,T_o}}{D^2 P_o} = \Phi(\Theta) \tag{9b}$$

where R is the characteristic gas constant and T_o is the absolute reservoir temperature.

An ideal gas is completely defined by the gas constant (R) and isentropic index (γ). For any such gas a critical flow factor (ψ) can be found assuming one-dimensional isentropic mass flow (m^*) through a minimum section or "throat" (A^*):

$$m^* \frac{\sqrt{T_o}}{A^* P_o} = \psi \tag{10}$$

For air entering a valve at room temperature $R = 284\,\text{kJ/kg/K}$, $\gamma = 1.4$, and $\psi = 0.04042$. However, real relief valves suffer from area contraction due to separated flow patterns, and the flow is neither one-dimensional nor isentropic. Consequently, the flow rate (m) will differ from that in an ideal duct having the same minimum section. A general form of discharge coefficient can then be defined by

$$\frac{m}{m^*} = m\frac{\sqrt{T_o}}{\psi P_o A^*} \tag{11}$$

If the bore is assumed to be the minimum area then the discharge coefficient may be designated K_M, where

$$K_M = \frac{m\sqrt{T_o}}{\psi P_o(\pi/4) D^2} \tag{12}$$

The derated coefficient (K_{dr}) is then 90% of K_M.

Flow Characteristics

A graph of discharge coefficient (K_M) plotted against dimensionless lift (L/D) is known as a "flow characteristic." Fig. 9 shows an example of flow characteristics plotted for various pressure ratios relieving from an air receiver, where P_b is the total backpressure at the valve exit port and P_o the reservoir total pressure.[22] According to ideal one-dimensional compressible flow theory, choked flow should occur at pressure ratios below 0.528. In practice, choked flow will occur at lower pressure ratios because of friction losses upstream of the curtain area. Nevertheless, the curves in Fig. 9 are close-together at pressure ratios below 0.333, and have collapsed to almost a single curve for ratios less than 0.25. Other work shows a similar effect.[29,37,38] One curve can therefore be used to represent many pressures.

In the medium pressure range (1–10 bar) the Re is almost always above 4000 and below 400,000, so its effect on flow pattern is almost nonexistent, and consequently, it has a minor effect on dimensionless flow characteristics. If the valve range is truly geometrically similar, then the discharge coefficient will be unaffected

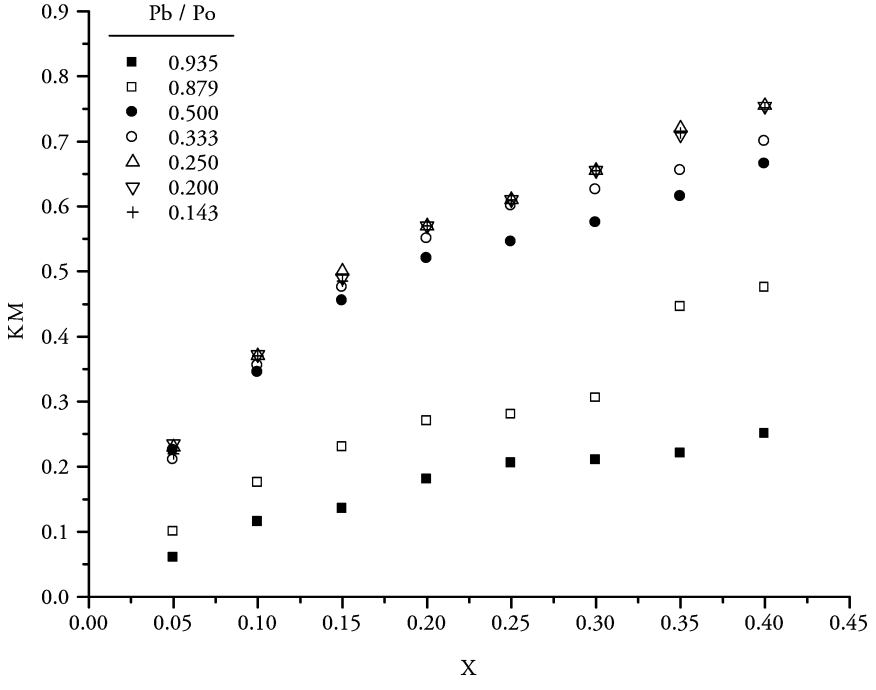

Fig. 9 Effect of pressure ratio on flow characteristics of a high-lift relief valve.

by changes in scale and in exhaust, atmospheric, or reservoir pressures. For a selected design (Θ) there remains only the one major variable: dimensionless lift (L/D).

Passage Shape

It has been known for many years that changes in slope and sudden discontinuities in flow characteristics of disk valves coincide with sudden alterations in separated flow patterns.[39] In relief valves, flow separates from the leading edge of the inlet bore and from the tip of the seal. As lift of a relief valve disk increases, the separated shear layer issuing from the leading edge of the seat reattaches further along the seat; and that from the seal tip reattaches to the disk closer to the skirt. By use of both computational fluid dynamics (CFD) software and oil-paint technique for incompressible flow at pressure ratio $P_b/P_o = 0.935$, Francis and Betts have shown that the apparent reduction of slope at midlift in relief valve flow characteristics (appearing in Fig. 9 between 0.10 and 0.15) coincides with the point at which reattachment to the rear edge of the seat ceases, so that at higher lifts the separated shear layer misses the rear edge by a considerable margin.[35] It was also found that reattachment to the disk ceased at a slightly lower lift.

A shock wave will exist downstream of the throat and is typically located where flow enters the huddling chamber. A sketched example is shown in Fig. 10. Evidence of shock wave location has been found from pressures measured on the disk surface.[36] Between the throat (usually close to the seal) and the shock wave is a supersonic region of low pressure that detracts from the general upward thrust. If the shock wave can be induced soon after the mainstream flow passes the seal then pressure recovery downstream of the shock wave can act on a greater area (and low pressure immediately upstream of the shock on a smaller area) to assist lifting. However, to avoid instability, the exit from the huddling chamber should not be so restricted as to form a second throat.

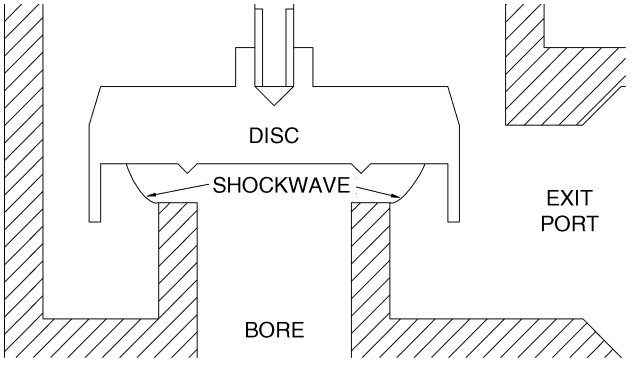

Fig. 10 Schematic showing likely position of shock wave downstream of the minimum section.

In fact, the gap at exit from the huddling chamber (or at the bottom of the skirt) is quite critical, as the pressure established in the huddling chamber significantly affects blowdown. This is why some valves have adjustable rings that can be moved up/down the outer surface of the seat support to adjust the size of gap at exit from the huddling chamber/skirt bottom edge (and so optimize performance). It is a balance between the desire to establish a high pressure to assist lifting and avoid too high a pressure that exacerbates blowdown.

MODERN DESIGN SOLUTIONS

Modern valve development is incremental. The techniques described in this entry are used to a greater or lesser extent by various designers, together with reliance on ''black art'' career expertise and prototyping by trial and error.

Theoretical Developments

Zonal models are not new in relief valve development. They are prone to oversimplification, but have been used successfully to approximate fluid forces on a disk and approximate the lifting transient.[30,40,41]

Fig. 11 reproduces the flow passage geometry of a relief valve. Note that the seal is modeled as a knife-edge. The fluid regions are split into three zones. Zone ''A'' is that region beneath the disk within the compass of the seal. Zone ''B'' is the remaining passage beneath the disk encompassed by the deflector skirt. Zone ''C'' is the backpressure region that affects both the piston and the disk top surface. In this model the skirt is presumed to be thin and thus the thrust from pressure acting on the lower surface of the skirt is lumped together with that from Zone B. Assuming that each zone can be represented by a pressure homogenous throughout the zone, then by analyzing the fluid mechanics and particularly the pressure losses through a valve, it is possible to provide a reasonable representation of upward thrust. A recent model has shown that despite lift and popping pressure being adequately predicted, the shape of the force characteristic (and hence blowdown) is not so well predicted.[41] Greater sophistication is required and this is now offered by field models.

Two areas of research that are ripe for making incremental improvements to knowledge of spring-loaded valves are: 1) use of CFD to identify beneficial changes to geometry and 2) CFD studies and theoretical or empirical modeling of two-phase flows to enable

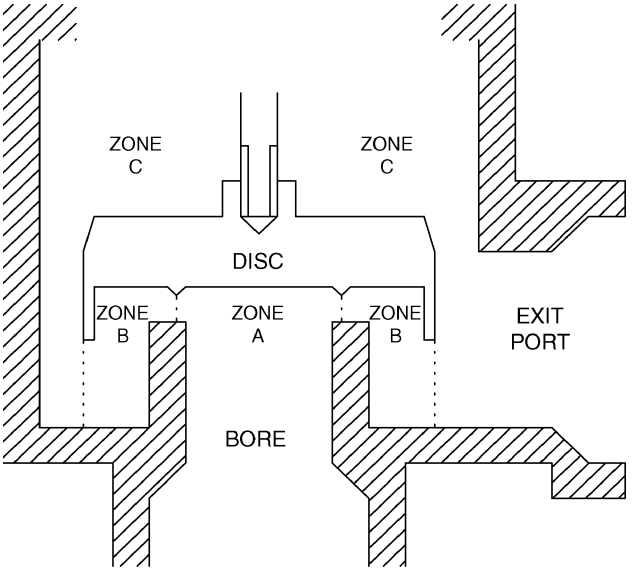

Fig. 11 Zones of homogenous pressure assumed in zone model of a high-lift valve.

appropriate sizing methods to be developed and applications skill to become more widespread. In the latter case, manufacturers often quote discharge capacities for single-phase flows but rarely for applications where two-phase flows can be expected.

Published use of CFD to analyze flow structure in relief valves is sparse and its potential for prototype simulation has not been realized.[35,42,43] However, the last 5–8 yr have seen improvements in meshing and processing capability of commercial solvers, as well as the turbulence models that can be selected, so that CFD is expected to be used more frequently in the development of engineering components. Some current (and early stage) work is aimed at improving the accumulation and blowdown characteristics (without blowdown rings or pilot operation), and investigating the potential for fluidic design within this context.[44]

Procedures for sizing relief valves for two-phase flows are still in the developmental stage but the potential safety advantages of promulgating sizing methods among suppliers make it a worthwhile pursuit.[45,46]

Practical Developments

Temperature relief valves for use on unvented hot-water systems are beyond the scope of this entry. Combined pressure and temperature relief valves became popular in the United Kingdom in the early 1990s, but these devices are merely pressure-relief valves with additional facility for actuation by a temperature-sensitive element. As the bore of a combined valve is not required to choke, the addition of a temperature-sensitive actuator passing through the bore does not meaningfully affect the valve operation or flow characteristic.

In the last 15 yr there has also been an increase in the use of full-bore valves with dual outlets. Full-bore valves are intended to ensure that the bore is subject to choked flow, maximizing the discharge capacity. Despite the outlet pipe connection usually being one nominal size up from the inlet connection, the flow passages within older designs of valve encouraged a buildup of backpressure above the disk by restricting flow toward the exit port. This tended to limit the valve lift during discharge. Bellows, used to protect the disk and spindle connector, also had the advantage of limiting the area of the disk top surface subjected to built-up backpressure. Moreover, a piston arrangement is still sometimes introduced to balance out the backpressure forces, as shown in Fig. 3, where any excess pressure acting on the upper surface of the disk also acts on the underside of the piston to further compress the spring that fits snugly into the piston. However, prevention of built-up backpressure is preferred to these methods of compensation. For example, by altering the shape of the disk top surface to increase the chamfer size, an improved flow and better k_{dr} were achieved by one manufacturer (S. Cooper, private communication). See Fig. 12 and compare with Fig. 6A.

Dual outlets are used to minimize built-up backpressure. They are usually used in high-pressure protection and where the maximum use of the bore is

Fig. 12 Cutaway view of a high-lift safety valve. (Reproduced by kind permission of Delta Fluid Products Ltd.) *(View this art in color at www.dekker.com.)*

desired without excessive restrictions downstream or where long discharge piping is needed to carry the fluid some distance to a safe collection point. Some dual outlet valves have opposing outlets to minimize the reaction forces that the valve mount needs to withstand. Others are actually twin valves mounted alongside each other on the same valve body (see Fig. 13).

An aspect of valve design that is now of growing importance is waste minimization. This is achieved through a combination of good sealing, closely controlled operating pressures, and correct sizing of valves. Good sealing is promoted by pilot operation.

Fig. 14 shows an example of a closed pilot-operated valve. Operation of the main valve is subject to operation of the pilot, which is itself a spring-loaded direct-acting relief valve, except that the valve is held open by the spring to allow system pressure to be bled to a chamber above the main valve disk. As the system pressure rises, so too does the pressure in the chamber above the main valve disk (and as this acts downward on a larger area than the main valve bore, it keeps the valve firmly clamped shut). The pilot valve is set to commence lifting at (say) 97% of the intended main valve set pressure. With a short travel, it reaches the seat and hence seals off the bleed line to the chamber above the main valve disk at (say) 98% of the set pressure. Further, increase in system pressure causes the pilot valve spindle to lift clear off its disk, opening a central drain to relieve pressure in the chamber above the main valve disk (see Fig. 15). Hence, the main valve lifts, and fully.

Fig. 13 Example of a twin valve mounted on the same bore supply. (Reproduced by kind permission of Delta Fluid Products Ltd.) *(View this art in color at www.dekker.com.)*

The advantages of this type of valve are considerable. Because the clamping force keeping the main valve shut is itself linearly dependent on system pressure, an increase in system pressure does not cause the seal to

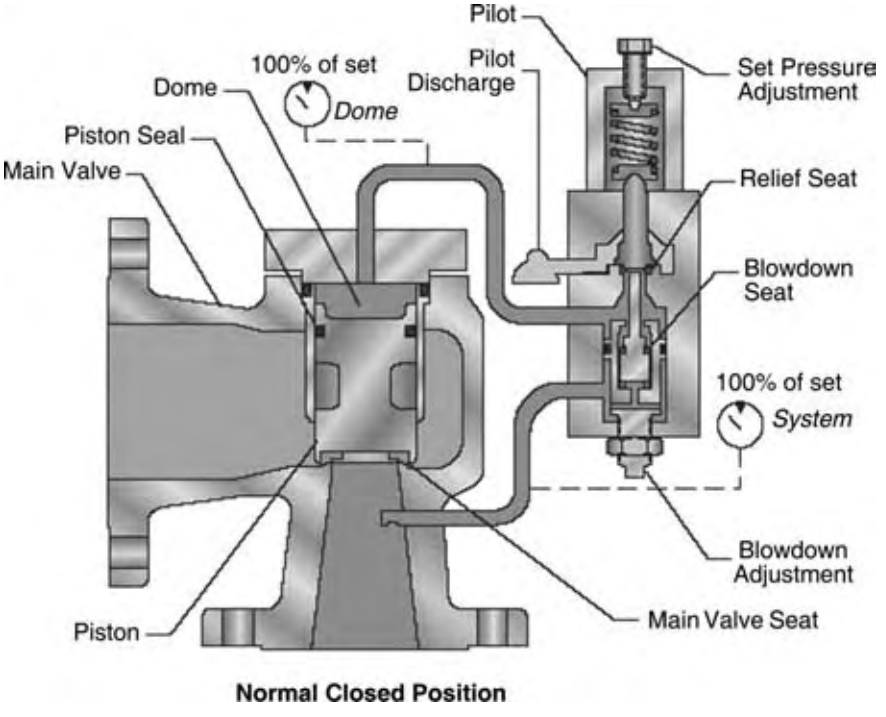

Fig. 14 Schematic of a pilot-operated valve in the closed position. (Reproduced by kind permission of Tyco Valves & Controls.) *(View this art in color at www.dekker.com.)*

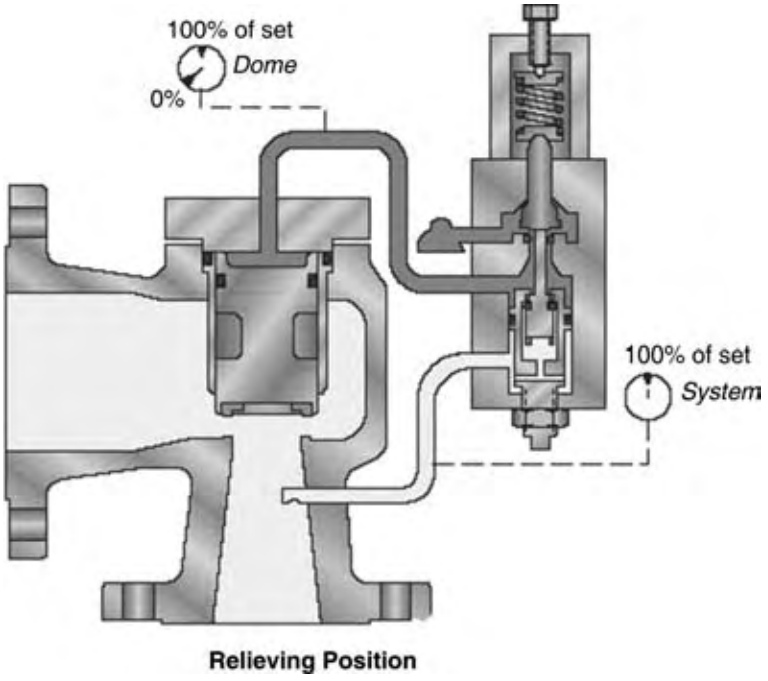

Fig. 15 Schematic of a pilot-operated valve when draining fluid from the upper chamber. (Reproduced by kind permission of Tyco Valves & Controls Ltd.) *(View this art in color at www.dekker.com.)*

relax. Hence, leakage is minimized until the set pressure is achieved. Moreover, when the main valve reaches set pressure it opens to full lift without an appreciable pressure accumulation, whereas a spring-loaded valve needs some accumulation above set pressure to raise the disk against its spring, to generate sufficient change of momentum beneath the disk to cause rapid opening. Pilot-operated valves are also thought to incur less hysteresis from friction and stiction in the moving part guides, partly owing to piston rings on the main valve disk sealing the upper chamber from the bore and partly because the pilot valve's travel and tilt are reduced compared to an equivalent-sized spring-loaded valve. As a result, the blowdown can be reduced.

Reduced accumulation, reduced blowdown, and improved sealing have given pilot-operated valves a reputation for minimizing the loss of system fluid when called on to operate. They require less overall mass than an equivalent-sized spring-loaded valve, and the pilot valve could potentially be sited remote from the main valve (but limited by lag in the bleed lines). However, they have more moving parts and more and narrower flow passages, making them more prone to failure through damage or blockages.

Finally, in the United Kingdom increasing regulation over the last 15 yr has driven the relief valve industry, but has led to few design improvements. Products sold 15 yr ago have proven suitable for meeting new statutory requirements for potable water and national regulations introduced to meet the European Union Pressure Equipment Directive (97/23/EC) and "ATEX" Directive (94/9/EC). Together with harmonization of Technical Standards across the European Union, these laws have led to more robust methods of independent witnessing of type tests and approval of products. However, the focus has been on providing documentary evidence of design and performance and not on improving already well-established and successful designs.

CONCLUSIONS

Design of spring-loaded pressure-relief valves is supported by a well-established mechanical engineering science base. With the use of established techniques, together with modern developments in zone and field modeling, there is potential for incremental improvements to be made to flow structure and stability or modulation of relief valves. However, for leading manufacturers supplying the mass market, the performance vs. cost balance must surely be close to its optimum.

Pilot-operated valves, and to a lesser extent spring-loaded valves offer opportunities for waste minimization. Advances in sealing technology and reductions in friction/stiction may continue to be made to reduce accumulation and blowdown. The potential advantages of fluidic design to this goal are as yet unclear.

Process Optimization

Ralph W. Pike
Department of Chemical Engineering, Louisiana State University, Baton Rouge, Louisiana, U.S.A.

INTRODUCTION

The objective of optimization is to select the best possible decision for a given set of circumstances without having to enumerate all the possibilities. For an operating plant, the objective is to determine operating conditions that give the maximum profit or the minimum cost. For plant design, the corresponding objective is to determine the process equipment size and minimum cost as measured by the net present value (NPV) and the rate of return. For operating plant and plant design optimization, a quantitative description is required in the form of a model or simulation that accurately predicts the performance of the actual plant. An economic model is required that gives the profit or the cost that can be maximized or minimized. The optimal design and operating conditions for the plant are determined using an optimization algorithm.[1]

There are mathematical programming languages that have the user enter the process and the economic model and then specify a solver (optimization algorithm). The resulting program is run, and the results are presented to the user in a readable form. Examples of these languages are General Algebraic Modeling System (GAMS), A Mathematical Programming Language (AMPL), LINDO/LINGO, and the Solver option in Excel.

The following sections describe the theoretical basis for mathematical programming and applications in linear programming (LP), nonlinear programming (NLP), mixed-integer programming (MIP), and multicriteria programming. Also, formulating economic and process models required for process optimization is summarized. Optimization methods take advantage of the mathematical structure of the economic and the process models to locate the optimum, possibly a global optimum. Models should be developed to use these capabilities to locate optima. For example, if linear equations can provide satisfactory representations of the economics and processes of the plant, then LP can be used to locate the global optimum. However, if the models are nonlinear, optimization methods can only guarantee a better point than the starting point, possibly a local optimum.

PROCESS MODELS

A process model or simulation of a plant is a set of equations that describe the operations of the plant and predict its performances. This set of equations includes material and energy balances, rate equations, and equilibrium relations. The material balances describe the conservation of mass in the individual units of the process, and the energy balance equations describe the conservation of energy in these units. In the material balances, there are terms that describe the rate of conversion of components by chemical reactions. These terms are given by the rate equations from chemical kinetics. In energy balances, there are terms that describe the exchange in energy with the surroundings and the work done by the unit. The energy exchange is described by rate equations for heat transfer, and the work performed is described by the method used for fluid movement, e.g., compressor.

A chemical plant includes tens to hundreds of process units, such as chemical reactors, heat exchangers, distillation columns, absorption towers, etc. For each unit, material and energy balances are used to relate input and output streams. Rate equations and equilibrium relations help describe the conversion of species, mass, and energy in the units. Collectively, these equations provide the equality constraints for the plant model.

The model or simulation of an operating plant requires a detailed model of the process units and their integration. This simulation is developed following the well-known onionskin approach. First, the chemical reactor is described; this is followed by developing the separation and recycle models that model the feed preparation and product purification unit operations. Then, pinch analysis is used to configure the heat exchanger network for minimum utility requirements. The simulation must predict the performance of the actual plant with sufficient accuracy that changes predicted by the model match the changes in the plant, called plant-model matching.

In the design of a new plant, the simulation requirements vary depending on the economic analysis. An order of magnitude economic analysis would use a block flow diagram with complete material and energy

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP–120018026

balances. A study estimate uses a process flow diagram (PFD), and the major equipment is sized. PFD is a major step up from a block flow diagram, and it represents all the equations (process model) necessary for the design of the process. All the major units are represented on the diagram with a unique number and a descriptive name. Also process streams are shown and identified with a number, along with a description of the process conditions and chemical composition included. In addition, all utility streams supplied to the major units are shown along with basic control loops illustrating the control strategy to operate the plant during normal operations. This diagram represents the material and energy balance equations, rate equations, and equilibrium relations.

PROCESS ECONOMICS

New plants, products, and technology require new capital, and most firms have limited resources. Consequently, investment decisions require capital budgeting. This plant profitability analysis is the evaluation and the selection of the best investments from a set of alternatives. Methods for evaluating investments include NPV and rate of return, among others, for private companies and benefit-cost ratio for public works projects. All these come under the purview of plant profitability analysis.

Risk is a part of the decision process also. The analysis of projects must incorporate the level of risk to be able to judge projects with high returns and high risks with those having lower returns and more certain outcomes.

A company typically has several projects competing for funds to be invested. The projects are ranked based on their NPV and risk. This is an economic decision problem. However, each project is an optimization problem by itself. For a valid comparison among projects, the optimum design is required for each project to have the maximum NPV.

Some terms used in economic decision analysis are given in Table 1,[2] and using an annual basis is

Table 1 Terms used in economic decision analysis on an annual basis

Sales (sales price S_p × product flow rate − mass per yr, m)	$S = S_p m$
Manufacturing costs	C_M
General expenses	C_G
Total product cost or total annual expenses	$C_T = C_M + C_G$
Purchased equipment cost	$C_{purchase}$
Installed equipment cost or fixed capital investment, FCI	$C_{installed} \sim (2.5–6.8)C_{purchase}$
Total plant cost or total capital investment, TCI	$C_{total\ plant} \sim 2.4C_{installed}$
Capital expenditure annually	C_{cap}
Depreciation and allowance for tax purposes	$D \sim C_{installed}$/economic life
Gross profit	$P_G = S - C_M - D$
Net annual income before taxes	$I_{net} = S - C_T$
Net annual profit before taxes	$P_{net} = P_G - C_G$
Net annual cash flow before taxes	$CF = I_{net} - C_{cap}$
Taxable income	$I_{net} - D$
Taxes (tax rate $t \sim 35\%$ of taxable income in United States)	$T = t(I_{net} - D)$
Net annual income after taxes	$I_{xt} = I_{net} - T$
Net annual profit after taxes	$P_{xt} = I_{xt} - D$
Net annual cash flow after taxes	$CF_{xt} = I_{xt} - C_{cap}$
Value added (sales − raw materials cost)	$P_{value\ added} = S - C_{raw\ matls}$
Earnings—net annual income after taxes from continuous operations excluding significant extraordinary and nonrecurring items	E
Profit margin − after tax earnings as a percentage of sales	P_{margin}

(From Ref.[2].)

standard. Sales (S), the income or revenues received from customers who will purchase the plant's products and by-products, is estimated using market research. Total product costs or total annual expenses of a plant (C_T), the sum of manufacturing costs (C_M), and general expenses (C_G) are estimated by cost engineering using a flowsheeting program and related information. Capital expenditure annually (C_{cap}) includes funds for working capital and plant additions and modifications.

The annual gross profit (P_G) is the sales less manufacturing costs and depreciation. Depreciation is a business expense. The annual net profit (P_{net}) is the gross profit less the general expenses. The annual net profit after taxes (P_{xt}) is the net income after taxes less depreciation.

Table 1 shows the net or cash annual income before taxes (I_{net}), which is the income from sales less total product costs. Plant equipment can be depreciated, and the taxable income is the net income less depreciation. Taxes (t) are paid on a sliding scale, and a corporate rate of 35% is used for estimation in the United States and approximately 50% in developed countries. Then the net income after taxes (I_{xt}) can be determined.

In profitability assessments, annual cash flows are more meaningful than net profit. The net annual cash flow after taxes (CF_{xt}) is the net profit after taxes less the annual expenditure of capital for additions and modifications. Net annual cash flows are used in discounted cash flow calculations to determine the NPV and the rate of return, which are two key measures used in economic decision analysis.

The following example illustrates the development of an economic model for the NPV, rate of return, and economic price using a preliminary design of a process to produce 100 million pounds per year of aniline from the reaction of phenol and ammonia. The following information has been developed.

Plant capacity	100 million pounds/yr
Plant installed cost	\$6.0 million
Total plant cost	\$11.9 million
Total product cost	\$46.3 million/yr
Annual capital expenditures for worn out equipment	\$0.5 million/yr
Estimated annual sales	\$53.2 million/yr
Economic life	10 yr
Tax rate	35%
Minimum attractive rate of return	15%
Depreciation	Straight-line method with no salvage value

Performing the following economic analysis determines:

Net annual income before taxes
= sales − total product cost
= \$53.2 − \$46.3 = \$6.9 million

Net annual cash flow before taxes
= net annual income before taxes
− annual capital expenditures for worn out equipment
= \$6.9 − \$0.5 = \$6.4 million/yr

Depreciation = plant installed cost/economic life
= \$6.0/10 yr = \$0.6/yr

Taxes = tax rate* taxable income
= tax rate*(net annual income before taxes − depreciation)
= 0.35(6.9 − 0.6) = \$2.2 million

Net annual income after taxes
= net annual income before taxes − taxes
= 6.9 − \$2.2 = \$4.7 million

Net annual cash flow after taxes
= net annual income after taxes
− annual capital expenditures for worn out equipment
= \$4.7 − \$0.5 = \$4.2 million

NPV based on the net annual cash flow after taxes and minimum attractive rate of return:

$$\begin{aligned} NPV &= -CF_0 + A\{[1 - (1 + i)^{-n}]/i\} \\ &= -\$11.9 + \$4.2\{[1 - (1.15)^{-10}]/0.15\} \\ &= \$9.2 \text{ million} \end{aligned}$$

Rate of return where the NPV is zero:

$$\begin{aligned} NPV &= -CF_0 + A\{[1 - (1 + i)^{-n}]/i\} = 0, \\ &\quad -\$11.9 + \$4.2\{[1 - (1 + i)^{-10}]/i\}, \\ i &= 33.3\% \end{aligned}$$

$$\begin{aligned} \text{Annual cost of capital} &= EUAC = P^*(A/P) \\ &= P^*\{i/[1 - (1 + i)^{-n}]\} \\ &= \$11.9\{0.15[1 - (1.15)^{-10}]\} \\ &= \$2.37 \text{ million/yr} \end{aligned}$$

Economic price
= (total product cost
+ annual cost of capital)/product rate
= ($46.3 million/yr + $2.37 million/yr)/
100 million pounds/yr = $0.49/lb

Total Cost Assessment

The business focus of chemical companies has moved from a regional to a global basis, and this has redefined how companies organize and view their activities. Tools such as total (full) cost assessment (accounting) (TCA), life cycle assessment, sustainable development, and eco-efficiency (economic and ecological) are being used. Total or full cost accounting identifies the real costs associated with a product or a process. It organizes different levels of costs and includes direct, indirect, associated, and societal. Direct and indirect costs include those associated with manufacturing. Associated costs include those associated with compliance, fines, penalties, and future liabilities. Societal costs are difficult to evaluate as there are no standard, agreed-upon methods to estimate them, and they can include consumer response and employee relations. The AIChE/CWRT TCA program[3] uses five types of costs. Type 1 costs are direct costs for the manufacturing site, type 2 are potentially hidden corporate and manufacturing site overhead costs, type 3 are future and contingent liability costs, type 4 are internal intangible costs, and type 5 are external or sustainable costs that the company does not pay directly including those borne by society and from deterioration of the environment by pollution within compliance regulations. Sustainable development is the concept that development should meet the needs of the present without sacrificing the ability of the future to meet its needs. External or sustainable costs are very difficult to quantify, and the TCA report gives some estimates for these costs from a study of environmental cost from pollutant discharge to air from electricity generation, e.g., $0.22–2.38/ton for CO, $0–3.25/ton for carbon dioxide.

OPTIMIZATION METHODS

In this section, the important aspects of the mathematical basis for optimization methods are described. This will provide the necessary background to understand the most widely used method, LP. Then descriptions of two more effective NLP methods are outlined: the generalized reduced gradient method and the successive LP method. Then methods for mixed-integer and multicriteria optimization problems are summarized.

Analytical Methods (Theory of Maxima and Minima)

The classical theory of maxima and minima (analytical methods) is concerned with finding the maxima or minima, i.e., extreme points of a function and it provides the theoretical basis for optimization methods and computer programs. This theory determines the values of the n independent variables $x_1, x_2, \ldots, x_n$ of a function, where it reaches maxima and minima points.

The necessary conditions have been developed by Kuhn and Tucker for a general nonlinear optimization problem with equality and inequality constraints.[1] This optimization problem written in terms of minimizing $y(\mathbf{x})$ is:

$$\text{minimize: } y(\mathbf{x}) \tag{1}$$

$$\text{subject to: } f_i(\mathbf{x}) \leq 0 \quad \text{for } i = 1, 2, \ldots, h \tag{2}$$

$$f_i(\mathbf{x}) = 0 \quad \text{for } i = h + 1, \ldots, m \tag{3}$$

where $y(\mathbf{x})$ and $f_i(\mathbf{x})$ are twice continuously differentiable real valued functions.

Any value of $\mathbf{x}$ that satisfies the constraint equations (2) and (3) is called a feasible solution to the problem. Then to locate points that can potentially be local minima of equation and satisfy the constraint equations (2) and (3), the Kuhn–Tucker necessary conditions are used. These conditions are written in terms of the Lagrangian function for the problem, which is:

$$L(\mathbf{x}, \lambda) = y(\mathbf{x}) + \sum_{i=1}^{h} \lambda_i \left[f_i(\mathbf{x}) + x_{n+i}^2 \right] + \sum_{i=h+1}^{m} \lambda_i f_i(\mathbf{x}) \tag{4}$$

where the x_{n+i}s are the surplus variables used to convert the inequality constraints to equalities.

The necessary conditions for a constrained minimum are given by the following theorem:

In order to minimize $y(\mathbf{x})$ subject to $f_i(\mathbf{x}) \leq 0$, $i = 1, 2, \ldots, h$ and $f_i(\mathbf{x}) = 0$, $i = h + 1, \ldots, m$, the necessary conditions for the existence of a relative minimum at $\mathbf{x}^*$ are:

1. $\dfrac{\delta y(\mathbf{x}^*)}{\delta x_j} + \sum_{i=1}^{h} \lambda_i \dfrac{\delta f_i(\mathbf{x}^*)}{\delta x_j} + \sum_{i=h+1}^{m} \lambda_i \dfrac{\delta f_i(\mathbf{x}^*)}{\delta x_j} = 0$
   for $j = 1, 2, \ldots, n$
2. $f_i(\mathbf{x}^*) \leq 0$ for $i = 1, 2, \ldots, h$
3. $f_i(\mathbf{x}^*) = 0$ for $i = h + 1, \ldots, m$
4. $\lambda_i f_i(\mathbf{x}^*) = 0$ for $i = 1, 2, \ldots, h$
5. $\lambda_i > 0$ for $i = 1, 2, \ldots, h$
6. λ_i is unrestricted in sign for $i = h + 1, \ldots, m$ (5)

Examining these conditions, the first one is setting the first partial derivatives of the Lagrangian function with respect to the independent variables $x_1, x_2, \ldots, x_n$ equal to zero to locate the Kuhn–Tucker point, $\mathbf{x}^*$. The second and third conditions repeat the inequality and the equality constraint equations that must be satisfied at the minimum of the constrained problem. The fourth condition is another way of expressing $\lambda_i x_{n+i} = 0$, $i = 1, 2, \ldots, h$ from setting the partial derivatives of the Lagrangian function with respect to the surplus variables equal to zero. Either $\lambda_i = 0$ and $x_{n+i} = 0$ (constraint is active) or $\lambda_i = 0$ and $x_{n+i} \neq 0$ (constraint is inactive). Thus, the product of the Lagrange multiplier and the constraint equation set equal to zero is an equivalent statement, and this is called the complementary slackness condition. The fifth condition comes from examining the equation $\partial y(\mathbf{x}^*)/\partial b_i = -\lambda_i$. The argument is that as b_i is increased the constraint region is enlarged; this cannot result in a higher value for $y(\mathbf{x}^*)$, the minimum in the region. However, it could result in a lower value of $y(\mathbf{x}^*)$, and correspondingly $\partial y(\mathbf{x}^*)/\partial b_i$ would be negative; as b_i increases, $y(\mathbf{x}^*)$ could decrease. Therefore, if $\partial y(\mathbf{x}^*)/\partial b_i$ is negative, then the Lagrange multiplier λ_i must be positive, for the equation to be satisfied. This condition is called a constraint qualification, as is discussed subsequently. For the sixth condition, it has been shown that the Lagrange multipliers associated with the equality constraints are unrestricted in sign; there is no argument comparable to the one given above for the Lagrange multipliers associated with the inequality constraints.

In summary, condition 1 gives a set of n algebraic equations, and conditions 2 and 3 give a set of m constraint equations. The inequality constraints are converted to equalities using h slack variables. A total of $n + m$ constraint equations are solved for n variables and m Lagrange multipliers that must satisfy the constraint qualification. Condition 4 determines the value of the h slack variables. This theorem gives an indirect problem in which a set of algebraic equations is solved for the optimum of a constrained optimization problem.

The Kuhn–Tucker point located using the necessary conditions described above requires sufficiency conditions to determine if it is a maximum, a minimum, or a saddle point. Tests for sufficiency conditions are determined by expanding the Lagrangian function in a Taylor series and neglecting third and higher order terms to give a function that contains only terms involving second partial derivatives evaluated at the Kuhn–Tucker point. This gives a differential quadratic form, and a test similar to the one for the unconstrained problem is obtained to determine if the Kuhn–Tucker point is a maximum, a minimum, or a saddle point. The sufficient conditions for the case of both inequality and equality constraints are more elaborate than if only equality constraints are involved. Further details are given in standard texts.[1,2,4]

Linear Programming

Of all the optimization methods, LP is the one that is most widely applied. The technique has been used for optimizing many diverse applications, including refineries and chemical plants, livestock feed blending, routing of aircraft, and scheduling their crews. Many industrial allocation and transportation problems can be optimized with this method. The application of LP has been successful, particularly in the cases of selecting the best set of values of the variables when a large number of inter-related choices exist. Often such problems involve a small improvement per unit of material flow times large production rates to have as the net result be a significant increase in the profit of the plant. A typical example is a large oil refinery where the stream flow rates are very large, and a small improvement per unit of product is multiplied by a very large flow rate to obtain a significant increase in profit for the refinery.

The term ''programming'' of LP does not refer to computer programming but to scheduling. Linear programming was developed about 1947, before the advent of the computer, when Dantzig recognized a generalization in the mathematics of scheduling and planning problems. Developments in LP have followed advances in digital computing, and now problems can be solved involving several hundred thousand independent variables and constraint equations.

As the name indicates, all the equations that are used in LP must be linear. Although this appears to be a severe restriction, there are many problems that can be cast in this context. In an LP formulation, the equation that determines the profit or the cost of operation is referred to as the objective function. It must have the form of the sum of linear terms. The equations that describe the limitations under which the system must operate are called the constraints. The variables must be nonnegative, i.e., positive or zero only.

Fig. 1 gives some geometric intuition about the mathematical structure of the problem and the way this structure can be used to find an optimal solution. The profit function is a plane and the highest point is the vertex $A = 10$, $B = 20$ with a profit of $P = 110$. The intersection of the profit function and planes of $P =$ constant gives a line on the profit function plane as shown for $P = 96$. This diagram emphasizes the fact that the profit function is a plane, and the maximum profit will be at the highest point on the plane and located on the boundary at the intersection of constraint equations, a vertex.

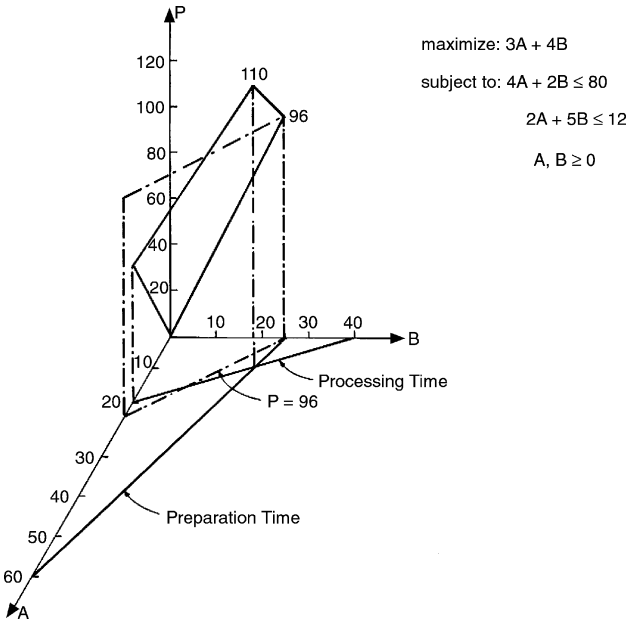

Fig. 1 Geometric representation of objective function and constraints of a LP problem (From Ref.[1].)

The general formulation of the LP problem can be written as:

$$\text{optimize:} \quad \sum_{j=1}^{n} c_j x_j$$

$$\text{subject to:} \quad \sum_{j=1}^{n} a_{ij} x_j \leq b_i \quad \text{for } i = 1,2,\ldots,h$$

$$\sum_{j=1}^{n} a_{ij} x_j = b_i \quad \text{for } i = h+1,\ldots,m \qquad (6)$$

The computational method to determine the optimum, the simplex method, requires equality constraints. The inequalities are converted to equalities by introducing slack and surplus variables. This is illustrated by converting the inequality equation given here to an equality by adding a slack variable x_3.

$$x_1 + x_2 \leq b \qquad (7)$$

$$x_1 + x_2 + x_3 = b \qquad (8)$$

If the inequality had been of greater than or equal to type, then a surplus variable would have been subtracted from the left-hand side of the equation to convert it to an equality.

A basic solution of the constraint equations is a solution obtained by adding slack and surplus variables to the inequality constraints, then by setting $(n - m)$ the variables equal to zero, and solving the constraint set for the remaining m variables. From this set of basic solutions, the groups of solutions where the values of the variables are all nonnegative are called basic feasible solutions; all the m variables are positive. There are several theorems that establish global optimality and relate the maximum or the minimum of the objective function to the basic feasible solutions of the constraint equations. An important result is:[1]

> If the objective function possesses a finite minimum, then at least one optimal solution is a basic feasible solution.

The standard procedure to solve an LP problem is the simplex algorithm.

The steps in this algorithm for maximizing the profit (objective) function are as follows:[1]

1. Place the problem in an LP format with linear constraint equations and linear objective function.
2. Introduce slack and surplus variables to convert inequalities to equalities and adjust the constraint equations to have positive right-hand sides.
3. Select an initial basic feasible solution. If all the constraint equations were inequalities of the "less than or equal to" form, the slack variables can be used as the initially feasible basis.
4. Perform algebraic manipulations to express the objective function in terms of variables that are not in the basis, i.e., are equal to zero. This determines the value of the objective function for the variables in the basis.
5. Inspect the objective function and select the variable with the largest positive coefficient to bring into the basis, i.e., make nonzero. If there are no positive coefficients, the maximum has been reached (automatic stopping feature of the algorithm).
6. Inspect the constraint equations to select the one to be used for algebraic manipulations to change the variable in the basis. The selection is made to have positive right-hand sides from the Gaussian elimination. This is necessary to guarantee that all the variables in the new basis will be positive. Use this equation to eliminate the variable selected in step 5 from all the other constraint equations.
7. Use the constraint equation selected in step 6 to eliminate the variable selected in step 5 from the objective function. This moves one of the variables previously in the basis to the objective function, and it is dropped from the basis, i.e., set equal to zero. Also this determines the new value of the objective function.
8. Repeat the procedure of steps 5–7 until all coefficients in the objective function are negative

and stop. If the procedure is continued past this point, then the value of the objective function would decrease. This is the automatic stopping feature of the algorithm.

The simplex method is called a direct method because it moves from one basic feasible solution to another until the optimum is reached. Examples are given to illustrate this method in standard texts,[1,5,6] and the algorithm can be modified to minimize rather than maximize. Also, artificial variables are added in computer programs to have an initially feasible basis, and these are removed using the big M method or the two-phase method. The revised simplex method is more efficient computationally, and it uses the same logic but works with the coefficients in the original problem. In addition, there is a dual problem that can be constructed from the primal (original) problem that may be easier to solve if it has fewer constraint equations than the original problem. Also, standard texts[1,5,6] discuss degeneracy and infeasible and unbounded solutions.

The procedure for formulating the LP problem for a plant or a process includes developing the objective function from the cost or the profit of the process or the plant and the constraint equations. The equality constraints are the material and energy balances, rate equations, and thermodynamic relations. The inequality constraints are the availability of raw materials, the demand for products, and equipment capacity limitations and conversion capabilities. A simple petroleum refinery has been used to demonstrate the development of the LP problem, and the optimal solution has been obtained using GAMS and Excel for comparison.[1] Linear Programming models of chemical plants and refineries have the form of very large and sparse matrices. These problems can have several hundred thousand constraint equations, and programs such as Aspen Technology's PIMS program are designed for obtaining solutions to these problems.

Sensitivity analysis or postoptimal analysis determines the range of values for a_{ij}, b_i, and c_j for the optimal solution to remain optimal. Changes in the right-hand side of the constraint equations, b_i, correspond to changes in the maximum capacity of a process unit or the availability of a raw material, for example. Changes in the coefficients of the objective function, c_j, correspond to changes of the cost or the sale price of the products. Changes in the coefficients of the constraint equations, a_{ij}, correspond to changes in mass or volumetric yields of a process. Knowing that these various coefficients and parameters can vary with-out changing the optimal solution reduces the number of times the LP problem must be solved.

Sensitivity analysis requires evaluating Lagrange multipliers using the following equation obtained from the classical theory of maxima and minima.

$$\lambda_i = -\sum_{k=1}^{m} \beta_{ki} c_c \quad \text{for } i = 1, 2, \ldots, m \tag{9}$$

where β_{ik} are the elements of the inverse of the matrix of the coefficients of the variables that are the basis from the original problem.[1]

The following Eqs. (10) and (11) give the changes of the variables in the basis and profit for changes Δb_i. Referring to Eq. (11), the units on the Lagrange multiplier are dollars per unit mass or volume, hence the name "shadow prices." For the optimal solution to remain optimal, $\mathbf{x}^*_{j,\text{new}} \geq 0$.

$$\mathbf{x}^*_{j,\text{new}} = \mathbf{x}^*_j + \sum_{i=1}^{m} \beta_{ji} \Delta b_i \quad \text{for } j = 1, 2, \ldots, m \tag{10}$$

$$p^*_{\text{new}} = p^* - \sum_{i=1}^{m} \lambda_i \Delta b_i \tag{11}$$

The following equation gives the new value of the reduced cost, $c'_{j,\text{new}}$, the coefficient of the variables not in the basis at the last step in the simplex algorithm.

$$c'_{j,\text{new}} = c'_j + \Delta c_j - \sum_{k=1}^{m} \Delta c_k \sum_{k=1}^{m} \Delta a_{ij} \beta_{ki} \quad \text{for } j = m + 1, \ldots, n \tag{12}$$

where Δc_j, is the change in nonbasic variable cost coefficients c_j, and Δc_k, is the change in the basic variables cost coefficients c_k. When maximizing, the new coefficients must remain negative for the variables not in the basis to have the optimal solution remain optimal, i.e., $c'_{j,\text{new}} < 0$.

Examples illustrating these procedures are given in standard texts.[1,5,6] Also, equations for changes in a_{ij} are given in these texts.

Nonlinear Programming

There are essentially six types of procedures to solve constrained nonlinear optimization problems. The three methods considered more successful are the successive LP, the successive quadratic programming, and the generalized reduced gradient method. These methods use different strategies but the same information to move from a starting point to the optimum, the first partial derivatives of the economic model, and constraints evaluated at the current point. Successive LP is used in a number of solvers including MINOS. Successive quadratic programming is the method of

choice for flowsheeting optimization, for example in Aspen Plus. The generalized reduced gradient method is the optimization program used in Excel's Solver. The other three have not proved as useful as these three, especially in problems with a large number of variables. These are penalty and barrier function methods, augmented Lagrangian functions, and the methods of feasible directions (or projections), which are sometimes called methods of restricted movement.

Successive LP solves a sequence of LP problems to move from a starting point to the optimum. Successive quadratic programming solves a sequence of quadratic programming problems to move from a starting point to the optimum. The generalized reduced gradient method performs a series of line searches in space in the direction of the reduced gradient to move from a starting point to the optimum. These methods require a feasible starting point and a stopping criterion.

Successive LP expands Eqs. (1–3) in a Taylor series about a feasible point $\mathbf{x}_k$ and retains the linear terms. This formulation gives an LP problem in Δx_j, which has to be modified using $\Delta x_j^+ = \Delta x_j - \Delta x_j^-$ where $\Delta x_j^+ = \Delta x_j$ if $\Delta x_j > 0$ and 0 if not, and $\Delta x_j^- = -\Delta x_j$ if $\Delta x_j < 0$ and 0 if not. This permits the algorithm, Eq. (13), to move in all directions from $\mathbf{x}_k$ to locate an optimum.

$$\begin{aligned}
\text{optimize:} \quad & \sum_{j=1}^{n} c_j \Delta x_j^+ - \sum_{j=1}^{n} c_j \Delta x_j^- = y - y(\mathbf{x}_k) \\
\text{subject to:} \quad & \sum_{j=1}^{n} a_{ij} \Delta x_j^+ - \sum_{j=1}^{n} a_{ij} \Delta x_j^- \le b_i - f_i(\mathbf{x}_k) \\
& \qquad \text{for } i = 1, 2, \ldots, m \\
& \Delta x_j^+ - \Delta x_j^- \le (u_j - x_{jk}) \\
& \qquad \text{for } i = 1, 2, \ldots, n \\
& \Delta x_j^+ - \Delta x_j^- \ge (l_j - x_{jk})
\end{aligned} \tag{13}$$

The bounds on the upper and lower limits on the variables are specified by $(u_j - x_{jk})$ and $(l_j - x_{jk})$. The value of the next point for linearizing is given by $x_{jk+1} = x_{jk} + \Delta x_j^+ - \Delta x_j^-$, and the procedure is started by specifying a feasible starting point $\mathbf{x}_0$ $(k = 0)$.

In the generalized reduced gradient method, the independent variables are separated into basic and nonbasic ones. There are m basic variables $\mathbf{x}_\mathrm{b}$, and $(n - m)$ nonbasic variables $\mathbf{x}_\mathrm{nb}$ from Eqs. (2) and (3) with the inequalities converted to equalities using slack and surplus variables. In theory, the m constraint equations could be solved for the m basic variables in terms of the $(n - m)$ nonbasic variables, i.e.,

$$f_i(\mathbf{x}) = f_i(\mathbf{x}_\mathrm{b}, \mathbf{x}_\mathrm{nb}) = 0 \quad \text{for } i = 1, 2, \ldots, m \tag{14}$$

Indicating the solution of $\mathbf{x}_\mathrm{b}$ in terms of $\mathbf{x}_\mathrm{nb}$ from Eq. (14) gives:

$$x_{i,\mathrm{b}} = f_i(\mathbf{x}_\mathrm{nb}) \quad \text{for } i = 1, 2, \ldots, m \tag{15}$$

Then, the economic model can be thought as a function of the nonbasic variables only, i.e., if the constraint Eq. (15) is used to eliminate the basic variables in Eq. (1), i.e.,

$$y(\mathbf{x}) = y(\mathbf{x}_\mathrm{b}, \mathbf{x}_\mathrm{nb}) = y(f(\mathbf{x}_\mathrm{nb}), \mathbf{x}_\mathrm{nb}) = Y(\mathbf{x}_\mathrm{nb}) \tag{16}$$

Expanding the above equation in a Taylor series about $\mathbf{x}_k$ and including only the first order terms gives:

$$\nabla^T Y(\mathbf{x}_k) \mathrm{d}\mathbf{x}_\mathrm{nb} = \nabla^T y_\mathrm{b}(\mathbf{x}_k) \mathrm{d}\mathbf{x}_\mathrm{b} + \nabla^T y_\mathrm{nb}(\mathbf{x}_k) \mathrm{d}\mathbf{x}_\mathrm{nb} \tag{17}$$

A Taylor series expansion of the constraint equations gives an equation that can be substituted into Eq. (17) to eliminate the basic variables.

$$\begin{aligned}
& \sum_{j=1}^{m} \frac{\partial f_i}{\partial x_j}(\mathbf{x}_k) \mathrm{d}x_{j,\mathrm{b}} + \sum_{j=m+1}^{n} \frac{\partial f_i}{\partial x_j}(\mathbf{x}_k) \mathrm{d}x_{j,\mathrm{nb}} = 0 \\
& \quad \text{for } i = 1, 2, \ldots, m
\end{aligned} \tag{18}$$

and Eq. (18) can be written in the matrix form as:

$$\mathbf{B}_\mathrm{b} \, \mathrm{d}\mathbf{x}_\mathrm{b} + \mathbf{B}_\mathrm{nb} \mathrm{d}\mathbf{x}_\mathrm{nb} = 0 \tag{19}$$

where $\mathbf{B}_\mathrm{b}$ as the matrix of the first partial derivatives of f_i associated with the basic variables and $\mathbf{B}_\mathrm{nb}$ as the matrix associated with the nonbasic variables.

Eq. (19) can be solved for $\mathrm{d}\mathbf{x}_\mathrm{b}$ and substituted into Eq. (17) to obtain the equation for the reduced gradient given below.

$$\nabla^T Y(\mathbf{x}_k) = \nabla^T y_\mathrm{nb}(\mathbf{x}_k) - \nabla^T y_b(\mathbf{x}_k) \mathbf{B}_\mathrm{b}^{-1} \mathbf{B}_\mathrm{nb} \tag{20}$$

Knowing the values of the first partial derivatives of the economic model and constraint equations at a feasible point, the reduced gradient can be computed by Eq. (20). Then the reduced gradient line is used to locate the optimum by a single variable search on α, the parameter of the reduced gradient line in Eq. (21).

$$\mathbf{x}_\mathrm{nb} = \mathbf{x}_{k,\mathrm{nb}} + \alpha \nabla^T Y(\mathbf{x}_k) \tag{21}$$

In taking trial steps as α is varied along the generalized reduced gradient line, the matrices $\mathbf{B}_\mathrm{b}$ and $\mathbf{B}_\mathrm{nb}$ must be evaluated along with the gradients $\nabla y_\mathrm{b}(\mathbf{x}_\mathrm{b})$ and $\nabla y_\mathrm{nb}(\mathbf{x}_\mathrm{k})$. This requires knowing both $\mathbf{x}_\mathrm{nb}$ and $\mathbf{x}_\mathrm{b}$ at each step. The values of $\mathbf{x}_\mathrm{nb}$ are obtained from Eq. (21). However, Eq. (15) must be solved for $\mathbf{x}_\mathrm{b}$; frequently, this must be done numerically using the

Newton–Raphson method, which gives Eq. (22).

$$\mathbf{x}_{i+1,\mathrm{b}} = \mathbf{x}_{i,\mathrm{b}} - \mathbf{B}_{\mathrm{b}}^{-1} f\left(\mathbf{x}_{i,\mathrm{b}}, \mathbf{x}_{\mathrm{nb}}\right) \tag{22}$$

where the values of the roots of the constraint equations (2) and (3) are sought for $\mathbf{x}_{\mathrm{b}}$, having computed $\mathbf{x}_{\mathrm{nb}}$ from Eq. (21). Thus, the derivatives computed for the generalized reduced gradient's $\mathbf{B}_{\mathrm{b}}$ matrix can be used in the Newton–Raphson root seeking procedure also.

Successive quadratic programming solves a sequence of quadratic programming problems. A quadratic programming problem has a quadratic economic model and linear constraints. To solve this problem, the Lagrangian function is formed from the quadratic economic model and linear constraints. Then, the Kuhn–Tucker conditions are applied to the Lagrangian function to obtain a set of linear equations. This set of linear equations can then be solved by the simplex method for the optimum of the quadratic programming problem.

Successive quadratic programming solves a NLP problem iteratively by constructing a quadratic approximation to the economic model and a linear approximation to the constraint equations. Then a sequence of quadratic programming problems are solved, and these intermediate solutions generate a series of points that must remain in the feasible region or sufficiently close to this region to converge to the optimum. The logic used with this method is to search along the line between the new and the previous point to maintain a feasible or a near feasible solution. An exact penalty function is used with the line search to adjust the step from one feasible point to the next feasible point.

The computational effort in evaluating the Hessian matrix is significant, and quasi-Newton approximations have been used to reduce this effort. The Wilson–Han–Powell method is an enhancement to successive quadratic programming where the Hessian matrix, $(\mathbf{q}_{jk})$, is replaced by a quasi-Newton update formula such as the BFGS algorithm. Consequently, only first partial derivative information is required, and this is obtained from finite difference approximations of the Lagrangian function.

The methods described in this section locate local optima, and different starting points are used frequently to determine if other local optima are found. Also, the methods can stall before reaching an optimum. Consequently, code testing is an ongoing effort to improve these algorithms. The Optimization Technology Center of the Argonne National Laboratory of the Department of Energy maintains a website that provides recent results.

Methods are being developed that can locate the global optimum of a NLP problem from industrial plants. One approach, αBB,[4] uses an upper bound and a lower bound that is a convex NLP with a global optimum. An iterative procedure is used to have the upper and the lower bounds converge to the global optimum. Another approach, interval analysis,[7] eliminates intervals on the independent variables to locate an increasingly smaller region that contains the global optimum. A third approach uses convexification.[8]

Mixed-Integer Programming

There are linear and NLP problems that require integer values for some or all the decision variables. For example, integer quantities are necessary for activities associated with machines, vehicles, or people. These problems with some of the variables having integer values are known as MIP problems.

Mixed-integer linear programming (MILP) problems require maximizing or minimizing a linear function subject to linear equality or inequality constraints with integer restrictions on some or all the variables. The mathematical statement of MILP can be expressed as:

$$\text{(MILP)} \quad \max\left\{cx + hy : \mathbf{A}x + \mathbf{G}y \leq b, \; x \in Z_+^n, y \in R_+^p\right\} \tag{23}$$

where Z^n is a set of n-dimensional vector of positive integers and R^p is a set of p-dimensional positive real vectors. The variables or unknowns are $x = (x_1, \ldots, x_n)$ and $y = (y_1, \ldots, y_p)$. $\mathbf{A}$ and $\mathbf{G}$ are $m \times n$ and $m \times p$ matrices, respectively. The objective function is $z = cx + hy$ with c and h being n and p ordered vectors, respectively.

The MILP has two special cases: LP that has all continuous variables and integer programming that has only integer variables. The mathematical statement of an integer LP problem is the same as the LP model, but with an additional restriction that the variables must take on integer values.

The two primary determinants of computational difficulty for an MILP problem are the number of integer variables and the structure of the problem. The number of integer variables is important, because the computational time increases tremendously as the number of integer variables increases.

The most widely used method for solving both integer and MIP problems is the branch-and-bound algorithm. Most commercial computer codes for solving integer programming problems use this approach. The method performs an efficient enumeration of a small fraction of the possible feasible integer solutions to locate the optimum.

The basic idea of the branch-and-bound technique is to divide and conquer. If the original problem is very

large, then it would be difficult to solve it directly; and hence it is divided into increasingly smaller subproblems until they can be solved easily or conquered. To divide (branch) the original problem into smaller subproblems, the entire set of feasible solutions is partitioned into increasingly smaller subsets; and for each one, an upper bound for the value of the objective function is obtained from the solutions within that subset (when maximizing). The conquering (fathoming) is done in two parts. Firstly, the bounds for the best solution in the subset are found; and then the subset is discarded if its bound indicates that it cannot possibly contain an optimal solution for the original problem. The subset with the highest upper bound is partitioned further into subsets. Their upper bounds are obtained in turn and used as before to exclude some of these subsets from further consideration. From all the remaining subsets, another one is selected for further partitioning and so forth. This process is repeated until a feasible solution is located such that the corresponding value of the objective function is greater than the upper bound for any of the other subsets. Such a feasible solution must be optimal because none of the subsets can contain a better solution. A detailed description of this algorithm is available in Refs.[2,4]

Design optimization problems frequently involve both continuous and binary variables, and have the form of mixed-integer nonlinear programming (MINLP) problems. The continuous variables represent the flow rates, temperature, pressures, etc., and binary variables represent the configuration of process units. These problems have been difficult to solve, and a significant amount of research has been spent developing algorithms that are effective in solving MINLP problems. The results have been improved algorithms implemented in relatively reliable computer programs. The mathematical form of a MINLP problem can be expressed as:

$$\begin{aligned} \text{minimize:} \quad & c^T y + f(x) \\ \text{subject to:} \quad & \mathbf{A}y + h(x) = 0 \\ & \mathbf{B}y + g(x) \leq 0 \\ & x \in X = \left\{x | x \in R^n, x^L \leq \mathbf{x} \leq x^U\right\} \\ & y \in Y = \{y | y \in \{0,1\}^m, \mathbf{A}y \leq \mathrm{a}\} \end{aligned} \quad (24)$$

where $\mathbf{x}$ is a vector of continuous variables and y is a set of binary variables that can be used to define the topology of the system representing the existence or nonexistence of different processing units. The nonlinearities in the economic and process models appear in the terms $f(x)$, $g(x)$, and $h(x)$.

MINLP problems can be solved using several algorithms including branch-and-bound, generalized Benders decomposition (GBD), and the Outer Approximation/Equality–Relaxation (OA/ER). These and other methods have advantages and disadvantages.[2] Floudas[4] described the GMIN-αBB algorithm that uses a branch-and-bound strategy to locate the global optimum of nonconvex MINLP problems, while Tawarmalani and Sahinidis[8] described the BARON algorithm that uses a branch-and-bound and convexification strategy. General Algebraic Modeling System includes the following solvers for MINLP problems, DICOPT, SBB, BARON (global optimizer), and solver manuals can be downloaded from the website, www.gams.com.

CONCLUSIONS

Multicriteria optimization adds the complication that there is more than one economic model to be optimized. One approach is to convert the multicriteria into a single criterion using weighting factors and then apply previously described methods. Another approach is to convert the economic criteria into constraints. The objective is to locate an optimal solution to one economic model that cannot be improved without deteriorating other economic models, called Pareto optimal solutions. The most difficult optimization problem to solve is a multicriteria, MINLP. Other important topics that are worth pursuing for process optimization include online optimization where data are obtained from the distributed control system of the plant, gross errors are removed, and the data are reconciled to satisfy material and energy balances. These reconciled data are used to update parameters to have plant-model matching, and then optimal set points are determined using economic optimization.[2] Dynamic programming converts a large, complicated optimization problem into a series of simpler, related problems that can be solved with the dynamic programming algorithm. Dynamic programming is very effective for optimization over time and optimal allocation problems.[1] A statistical approach divides the feasible region into a set of grid points. Then the economic model is evaluated at a number of these grid points selected randomly. Depending on the total number of grid points and the number of evaluations of the economic model, a statement can be made that the largest value found is in the top x percent with a probability of y.[1] These methods are called random search, genetic algorithms, and simulated annealing. Sensitivity analysis for NLP comparable to LP is not available, and Monte Carlo simulation is used to determine the sensitivity of the optimal solution to parameters in the process and economic model. Variational methods determine an optimal function rather than an optimal point and are based on the calculus of variations. Variational methods are the basis

for optimal control and are effective methods for approximated solutions to the second order partial differential equations arising from the conservation equations in momentum, energy, and mass transfer (transport phenomena).[1]

INTRODUCTION

Particle size and polymorphism are key characteristics of pharmaceutical compounds. They determine not just the ''processing behavior'' but also the therapeutic effects of active pharmaceutical ingredients and their formulation with excipients. Particle size and polymorphism determine the dissolution rate of poorly water soluble drugs, which, in turn, is related to bioavailability. Dimensional properties can determine the practicability of specific administration routes. Efficient lung delivery, for instance, is heavily dependent on the production of particulates with suitable fluid dynamic properties to ensure the efficient deposition of the active in the target site as well as consistency and uniformity of the active dose. It is widely recognized that the ideal aerodynamic particle size for lung delivery is between 1 and 5 μm. Nanosized particles are amenable to parenteral delivery in suspension, a mode of delivery particularly advantageous for actives with very low solubility in biological fluids since particles in this size range can cross the cellular membranes so that a preliminary dissolution stage is not required.

Particle design applied to pharmaceutical processing has the potential to improve the efficacy of current medications as well as to open the way to the use of alternative delivery routes. An example is the administration of drugs, such as insulin, that are subject to extensive gastrointestinal breakdown and thus cannot be administered orally. The alternative is parenteral administration, which has major side effects, especially in long-term or chronic conditions.

Conventional micronization techniques are not always adequately responsive to the demands of the pharmaceutical industry. Processing limitations can be related to high shear forces, high temperature, electrostatic charges, and difficulties of solvent removal that are the main disadvantages of jet milling, spray drying and ball milling, and liquid–liquid antisolvent processes, respectively. An emerging technology that has demonstrated the capability of generating micrometer- and nanoparticles of active pharmaceutical compounds utilizes the properties of dense gases (DGs).

Dense gases are fluids that are near or above their critical points, generally with reduced temperature and pressure between 0.9 and 1.2. Near-critical fluids exhibit distinctive properties such as low viscosity, high diffusivity, low surface tension, and solvation power. Because the properties of DGs are dependent on pressure and temperature, they offer a unique environment with tunable properties that is ideal for the formulation of pharmaceuticals.

PARTICLE FORMATION

Rapid Expansion of a Supercritical Solution

The rapid expansion of a supercritical solution (RESS) is a crystallization process that relies on the ability of DGs to dissolve the compound to be processed. Conceptually, the process comprises two stages: initially, the DG dissolves the solute and subsequently, the DG solution is depressurized through an expanding device. The abrupt pressure reduction dramatically reduces the dissolving power of the dense phase. The pressure wave propagates through the dense phase at the speed of sound inducing a fast nucleation of the solute and promoting the formation of micrometer size particles with narrow particle size distribution. The process generates uncontaminated particles. Pharmaceutical compounds exhibiting a significant solubility in the dense phase are amenable to RESS processing. The dissolution rate of the poorly water soluble anti-inflammatory drug ibuprofen was improved by micronizing the drug with the RESS process. The improvement was related to particle size reduction and the formation of amorphous fractions.[1] The enhancement of dissolution rate achieved by the RESS process can be higher than that obtained with other methods such as milling as indicated by the micronization of the antifungal griseofulvin.[2] Other examples of drugs micronized with the RESS process include

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120040350

β-sitosterol, theophylline, progesterone, medroxyprogesterone acetate, and stigmasterol.[2–5]

The RESS process has also been used to generate composite materials including pharmaceutical agents. Examples of drug–polymer formulations generated by the RESS process are the antiinflammatory naproxen and the cholesterol lowering drug, lovastatin, each processed with the biodegradable polymer poly(lactic acid) producing composite microparticles.[6–8]

To extend the applicability of the RESS process to compounds with low solubility in DG cosolvents have been used. The addition of small amounts of organic solvents can significantly increase the solvation power of carbon dioxide for many solutes. Commonly used modifiers are acetone and low molecular weight alcohols. The addition of 1 wt% acetone improves the solubility of poly-lactic acid in carbon dioxide by 500%.[9] The acetone-modified carbon dioxide was used to process poly-lactic acid by the RESS process. The product morphology varied greatly with the operating conditions, from irregular particles within 10 and 25 μm to microspheres of about 10 μm.[9] Commonly used modifiers are completely miscible with the DG under a wide range of conditions. However, a phase separation should be avoided during the depressurization stage, otherwise the liquid solvent may dissolve the particulate or induce coalescence with substantial loss of the product morphological characteristics.

Alternatively, modifiers that are not solvents for the products can be introduced in the system. Dense gas–modifier mixtures can exhibit higher solvent power than each of the components.[10,11] In such instances phase separation during the depressurization stage does not affect the particle morphology because the liquid phase present is a nonsolvent for the product. The process is known as RESS-N and has been applied to the processing of various polymers. Mishima et al. reported the formation of micrometer-sized composite particles including the proteins lysozyme and lipase and other compounds of pharmaceutical interest such as the active ingredients *p*-acetamidophenol, acetylsalicylic acid, 1,3-dimethylxanthine, flavone, and 3-hydroxyflavone. The coating agent—poly(ethylene glycol) (PEG) with different molecular weights—was dissolved in carbon dioxide modified with ethanol. Ethanol was preferred over other modifiers, such as methanol, propanol, acetone, and toluene, because of its significant cosolvency effect and low toxicity. The solubility of PEG with different molecular weights in carbon dioxide rose from below 1 wt% to about 13 wt% when 35 wt% ethanol was added to carbon dioxide at 35°C and 160 bar. The process was performed by using modified carbon dioxide to solubilize the polymer and the DG solution was used to suspend micrometer-sized protein. The suspension was depressurized through a capillary nozzle causing the precipitation of the polymer on the protein particles. Discrete microparticles were produced in all cases with a coating thickness that could be controlled through variation of the polymer concentration in the dense phase. The process was extended to the use of other coating agents: poly(methyl methacrylate), poly(lactic acid), poly(DL-lactide-*co*-glycolide), poly(DL-lactide-*co*-glycolide), poly(ethylene glycol)–poly(propylene glycol)–poly(ethylene glycol) triblock copolymer, and ethylcellulose;[10,11] however, such polymers exhibit higher solubility in liquid ethanol rather than in ethanol–carbon dioxide mixtures, therefore its definition as a nonsolvent in the process may not be proper.

The potential of the RESS process for the manufacture of pharmaceutical formulations with superior characteristics has been demonstrated. The implementation of the process on the production scale presents challenges related to the high gas/product ratios that are usually required, high operating pressures, complexity of particle recovery, and intense cooling effect during the expansion stage, which can result in nozzle blockage.[12] Batch mode RESS plants for the production of tens of kilograms per day are currently in operation.[13]

Particles from Gas Saturated Solutions

Particles from gas saturated solutions (PGSS) is a technique applicable to compounds that melt under exposure to DGs. Melting point depression by exposure to high-pressure fluids is a well-known phenomenon that has been observed in various systems. In the PGSS process the DG dissolves in the product and can induce a phase transition, from solid to fluid, and reduce melt viscosity. The melt is rapidly expanded through a nozzle. Associated with the rapid expansion is a sharp drop in temperature and the release of the gas that induces the crystallization of the product. The process can be extended to the processing of multiphase systems such as emulsions and suspensions. The PGSS process is particularly suitable for the processing of systems containing polymers that are often able to absorb large amounts of DGs.[14] The PGSS process can generate micrometer-sized particles and is suitable also for the processing of highly viscous and adhesive material.[15] By controlling the operating conditions, it is possible to produce highly differentiated products from microparticles to films.

Composite particles for controlled release of pharmaceutical compounds have been generated by the PGSS process. An example is the formation of 2–3 μm theophylline/hydrogenated palm oil (HPO) particles.[14] The process produced fine and dry powders operating at 60°C and at pressures between 120 and 180 bar. The morphology of the particulates varied with the

operating pressure and included spherical and needle-like particles.[14] Dissolution studies showed the burst release of 22–45% of the drug content followed by an almost complete release over 10 hr. The results indicated that a significant amount of theophylline was on the surface of the microparticles.[14]

It has to be noted that the drug concentration in the dissolution medium approximated its equilibrium solubility values,[14] thus a reduction of the dissolution rate vs. time cannot be conclusively related to the coformulation with HPO.

The PGSS process has also been successfully applied to the production of drug/polymer composites with the intent of enhancing the solubility and the dissolution rate of the active ingredient. Nifedipine and felodipine are antihypertensive drugs with very low solubility in water. The coprecipitation of each compound with the hydrophilic polymer PEG (MW 4000) was achieved by the PGSS process using carbon dioxide between 50°C and 70°C and at pressures below 200 bar. Both DG processed drug formulations exhibited dramatic dissolution rate improvements compared with untreated samples.[16]

The PGSS process is quite versatile and does not generally involve the use of liquid solvents. Compared with the RESS process it requires much lower DG consumption and operates at lower pressures. Particle recovery is easier than in the RESS process because bigger particles are formed from smaller volumes of DG. The reduced amount of DG required and the lower operating pressure substantially affect the installation and operation costs related to the size of the high-pressure vessels required and the recycling of the DG. The process has been used on the pilot scale for various compounds and has also been applied on a large scale for coating.[15,17] Knez and Weidner have estimated the processing costs to be between 0.15 and 0.60 Euro/kg. The operating cost of the PGSS process will obviously depend on the substrate as well as on the size of the plant. However, the cost estimate indicates that the process may also be suitable for the production of formulations that are not highly valuable.[15]

Gas AntiSolvent Precipitation

Most pharmaceutical compounds have low solubility in DGs and can be processed by DG antisolvent techniques. Dense gases can expand solutions, thereby lowering the solvent power of the solvent and triggering the precipitation of the solute thus acting as antisolvents. Various processes have been developed utilizing DGs as antisolvents. A major distinction is made between batch and semicontinuous processes. In the first case, a liquid solution is introduced into a high-pressure vessel. Subsequently, the system is pressurized with a DG that expands the solution to an extent that is dependent on the operating conditions. Stirring devices can eventually be used to improve mass transfer in the system. Once the final pressure is reached and the precipitate is formed the expanded solvent is purged from the system and the residual solvent is removed from the product by a flux of DG antisolvent. The system is then depressurized and the product collected. The process is commonly referred to as gas antisolvent precipitation (GAS).

Gas antisolvent processes can be performed in a semicontinuous mode. In this case the solution and the antisolvent are continuously introduced in the system until the desired amount of the product is formed. The introduction of the solution is then stopped and the DG flux extracts the residual solvent from the system. The system is then depressurized to enable collection of the product. The solution is generally introduced through an atomization nozzle that favors the prompt expansion of the solution and the formation of small particles. Different process configurations have been utilized, i.e., co- and countercurrent introduction of the solution and antisolvent fluxes and various nozzles have been designed. The process is referred to by different acronyms such as ASES (aerosol solvent extraction system), SAS (supercritical antisolvent), SEDS (solution enhanced dispersion by supercritical fluids), PCA (precipitation with a compressed fluid antisolvent), GASR (gas antisolvent recrystallization), GASP (gas antisolvent precipitation).

Dense gas antisolvent processes have been widely used for pharmaceutical applications because of the possibility of operating under mild conditions, thus preserving the properties of labile compounds, and because of their ability to generate micronsized particles with optimum morphology for various drug applications. Crystallization by DG antisolvent processing has a very broad applicability because many organic solvents, including low molecular weight alcohols, dimethyl formamide, acetonitrile, and methylene chloride, can be expanded by DGs.[18]

Processing Proteins from Aqueous Solutions

The range of applications of peptide drugs is very broad, and includes analgesia, cancer therapy, and infection treatment.[19]The processing and delivery of proteins are often challenging, as many protein molecules are physically and chemically unstable.[20,21] Once administered, proteins can be subject to enzymatic degradation, and present unfavorable permeation through cellular membranes.

Inhalation delivery of therapeutic peptides is a promising administration route to avoid the degradation pathways in the gastrointestinal tract and in the liver.

An optimum aerodynamic particle diameter for lung delivery is considered to be ~3 μm. Particles having aerodynamic size above 5 μm typically deposit in the upper part of the lung, which is not an efficient site for drug adsorption. Particles with aerodynamic diameter smaller than 1 μm can be expelled during exhalation. To deliver powders efficiently via inhalation, particles with defined size must be obtained and delivered.[22–24]

Conventional micronization techniques generally have drawbacks such as interbatch inconsistency, low yield, and broad particle size distribution.[25] Proteins micronized through these techniques can be thermally and chemically degraded.[25] For example, proteins can be unstable to lyophilization while spray drying and milling (capable of producing protein particles in the size range of 5–50 μm) can easily denature the product from the heat and shear forces involved.[26] Grinding with the use of high-velocity compressed air can generate particles in the range 1–10 μm, but there are difficulties in the product collection due to electrostatic charges.[26] Another limit of some conventional techniques is the considerable use of organic solvents, which results in high environmental impact and the presence of solvent residues in the final product.[25]

Dense gas antisolvent techniques are amenable to the precipitation of proteins because of the low solubility of these compounds in DGs such as carbon dioxide. Lysozyme, trypsin, myoglobin, and insulin are examples of peptides that have been precipitated from organic solutions using CO_2 as an antisolvent.[26–30] Both batch and semicontinuous DG antisolvent techniques have been used to precipitate proteins from organic solvents such as methanol, ethanol, and dimethyl sulfoxide.[31,32]

The use of organic solvents, however, can be detrimental to the integrity of the protein. Furthermore, the solubility of proteins is generally low in such solvents so that only low yields can be obtained.[25,33] Aqueous solutions provide a more favorable medium for protein stability and good solvating power so that the precipitation of proteins from aqueous solutions can be preferable to organic solvent systems.[25,33,34]

The precipitation of different proteins from water solutions using modified CO_2 has been described in various works. Lysozyme, trypsin, albumin, and recombinant human deoxyribonuclease (RHO) are examples of proteins that have been precipitated from water using carbon dioxide, modified with ethanol, as an antisolvent.[25,34] Because proteins are typically labile molecules, the ability of DG processing to maintain protein integrity is an important issue. The biochemical integrity of lysozyme, albumin, and insulin has been retained after DG processing, while trypsin and RHO were partially degraded.[25,34] The proteins were precipitated as microspheres in the inhalable size range. The percentage of respirable fraction (RF) suitable for respiratory delivery was protein dependent. Lysozyme could be precipitated as a powder with an RF of 63%, while the maximum RF for albumin was 45%.[25]

The effect of processing technique on the aerosol performance of insulin formulations prepared by DG antisolvent precipitation and spray drying has been investigated. Two types of insulin formulations were produced. They were 1 : 20 insulin–mannitol (IM) and 1 : 20 : 8 insulin–mannitol–citric acid (IMC). Mannitol is an excipient commonly used to improve aerodynamic performance of powders for inhalation delivery. Citric acid has been found effective in improving insulin absorption in the lungs.[35]

Dense gas IM samples were precipitated from dimethylsulfoxide solutions using carbon dioxide as an antisolvent, while spray dried products were generated from insulin suspensions in mannitol aqueous solutions. Dense gas and spray dried IMC samples were produced from aqueous solutions; in the DG antisolvent process carbon dioxide modified with ethanol was used as an antisolvent. The particle size of DG processed formulations was substantially larger than the corresponding spray dried material for both IM and IMC samples: 21.8 vs. 5.71 μm and 11.9 vs. 7.24 μm, respectively, as measured by laser diffraction of the dry powders. The aerosol performance of DG processed IMC formulations, however, was superior to the spray dried counterpart, as measured by impactor studies. In fact, the RF of the DG processed IMC was 47.6%, while spray dried IMC had an RF of 30.0%. The aerosol performance of IM samples followed an opposite trend with the DG product exhibiting an RF of 26.6% and the spray dried of 30.6%.[35]

Insulin bioavailability by intratracheal administration of the different formulations to rats was studied. The absorption of formulations containing citric acid was not influenced by the preparation technique. The DG processed IM samples had a marked improvement of insulin absorption compared with the spray dried material. The difference may have been ascribed to the faster dissolution rate presented by the DG processed material or by reversible changes in the secondary structure of the protein.[35] The reasons for the improved performance of DG processed IM samples were not ascertained. It has to be noted that the in vivo test did not rely on the aerodynamic properties of the powders for their delivery to the absorption site. An overall evaluation of the different formulations that combined aerodynamic properties and in vivo absorption results indicated that the DG processed formulations had the potential to be more effective than the corresponding spray dried products. Particularly interesting is the improvement of lung absorption registered for IM samples upon DG processing. The results indicate that improving the RF of DG

processed insulin is an achievable way to improve insulin absorption in the lungs without resorting to the use of absorption enhancers.[35]

Dense gas antisolvent precipitation processes have been put into operation on pilot and commercial scale for the production of various materials including pharmaceuticals.[13] Pilot scale micronization of the antibiotic amoxicillin from *N*-methylpyrrolidone (NMP) solution was conducted by DG antisolvent precipitation using carbon dioxide as an antisolvent.[36] Amoxicillin is used in the therapy of respiratory tract conditions. The pilot scale process was performed at 40°C and 150 bar processing 0.6 kg/hr of solution and delivering 20 kg/hr of antisolvent to the precipitation chamber. The process yield was about 90%. The large-scale process was able to reproduce the particle morphology obtained on the laboratory scale with high consistency. The effect of operating parameters observed on the bench scale, specifically solution concentration, was accurately replicated on the larger scale. Amorphous spherical particles were produced with average particle size within 0.3 and 1.2 μm, depending on the concentration of solute in the NMP.[36]

Highly consistent results were also obtained in the scale-up of the precipitation of nicotinic acid from methanol from a laboratory rig to a pilot plant. The process, performed at 90 bar and 90°C, produced rectangular prism particles between 4 and 5 μm on both manufacturing scales.[12,37]

The analgesic paracetamol has been processed in a pilot plant from dimethylformamide (DMF), ethanol, and acetone. The plant used had the capacity of 30 kg/hr of CO_2 and 0.6 m^3/hr solution and included an 8 L precipitation vessel. The operating temperature was fixed at 45°C while the pressure was varied between 100 and 200 bar. Particle size and morphology varied mostly with the nature of the solvent. Spherical particles were obtained from DMF and acetone, while needle-shaped particles could be produced from ethanol and acetone. Rhombic particles were produced only from ethanol. Particle size varied between 1 and 10 μm depending on the operating pressure.[38]

The cost of a semicontinuous antisolvent precipitation process on a large scale has been estimated between 47 and 97 Euros/Kg, based on a production of 1–8 tons/yr from a feed containing 5–10 wt% product. The authors concluded that a production in excess of 4 tons/yr would be necessary for the process to be economically viable.[39] The cost of the process has been estimated to be comparable to the cost of spray drying.[12] Overall, large-scale semicontinuous antisolvent precipitation processes appear to be an economically viable alternative for the micronization of high-value-added products.[39]

POLYMORPHISM IN DENSE GAS PROCESSING

Dense gas antisolvent processes are capable of producing pure polymorphic forms of compounds. The significance of this property is that crystal polymorphism is a critical factor in determining the biological activity of pharmaceuticals as well as their performance in delivery devices and the shelf life of drug formulations.[40] Additionally, different polymorphic forms of currently marketed drugs can be considered as new entities and may be patented, thus providing significant financial advantage to the assignee. Polymorphism is a common phenomenon in the pharmaceutical industry and affects the manufacturing of various classes of drugs including barbiturates and steroids.[41]

To overlook the importance of polymorphism for the properties of therapeutic compounds before commercialization can have considerable repercussions. In 1998, the Abbott company was brought into a market crisis because the anti-HIV drug ritonavir—commercialized since 1996 under the name Norvir—failed a dissolution specification.[42] Investigations led to the discovery that an unknown, thermodynamically more stable, and much less soluble, polymorphic form of ritonavir (RII) was crystallized upon storage. It was discovered that traces of RII during processing led to the production of unstable formulations in which the desired polymorph converted to RII. The composition of the drug formulation was adapted to the properties of RII to compensate for its lower solubility; however, the original polymorph was still preferable owing to production issues and, eventually, a selective crystallization technique that produced only the desired polymorph was developed.[42] In this case, the active ingredient in the final formulation was in solution, thus the polymorphic form from which the solution was generated did not impact the efficacy of the preparation. Thus modification of the formulation composition to ensure complete dissolution of both ritonavir polymorphic forms was an acceptable procedure.[42]

In cases where drug formulations containing more than one polymorph are marketed it is required that the composition is fixed in relation to each polymorphic form. The issue is complicated by the conversions between polymorphs in the solid state. It is clear that the conversion of a crystal structure in a more stable polymorph has to be inhibited, to preserve the composition of the drug formulation. In terms of morphological stability, the production of the more stable polymorph of an active pharmaceutical ingredient is the more convenient option; however, other issues may play critical roles.

The manufacturing of amorphous products may be considered because they usually present solubility and

dissolution rates significantly higher than the corresponding crystalline forms. Examples of amorphous drugs that have been accepted in the market are the antihypertensive quinapril HCl (Accupril®), the antiasthma zafirlukast (Accolate®), and the anti-AIDS nelfinavir masylate (Viracept®).[43] However, drug formulations containing amorphous fractions of products generally exhibit very low stability toward various degradation processes such as chemical degradation, particle aggregation, and crystallization so that the production of crystalline material is generally pursued when possible.[41]

Conventional processing usually requires two separate steps to produce a specific polymorph with controlled particle size. They are the crystallization of the polymorph and subsequent particle size reduction. The first step may include a purification stage (i.e., when liquid–liquid antisolvent crystallization is applied and the second step (i.e., milling) may generate amorphous fractions.[44] Crystallization techniques that may be used to produce particulates with high surface area, such as spray drying and freeze-drying, also can generate defective crystals and amorphous fractions.[41]

The RESS process has been used to produce a single polymorphic form of carbamazepine—an anticonvulsant drug—that is accepted by the Food and Drug Administration. Carbamazepine has four polymorphic forms of which only one is approved for commercial formulations. The RESS process generates micrometer particles with mean diameter smaller than 3 μm and a quite narrow particle size. The crystal structure of the product could be controlled by modification of operating pressure and temperature, which were varied between 170 and 200 bar and 35 and 75°C, respectively. All the RESS processed samples contained a higher fraction of amorphous material than raw carbamazepine.[45]

Dense gas antisolvent crystallization has been used to control the ratio of the polymorphic forms generated. The ability of DG processes to produce microparticles of pure polymorphs holds significant advantages compared with conventional processing. Beach et al. reported the precipitation of the antiasthma drug salmeterol xinafoate from acetone and ethanol solutions.[46] Sameterol xinafoate exists in two polymorphic forms (PI and PII). Conventional crystallization techniques generate PI with a small fraction of PII. By modifying the operating temperature and pressure, the authors could control the ratio between PI and PII in the product. Single polymorphic forms were produced by operating at pressures above 250 bar. The material produced was suitable for lung delivery, having a particle size between 2 and 5 μm, and exhibited notable stability.[46]

The antibacterial sulfathiazole presents five polymorphic structures. The modification of the operating conditions in a DG antisolvent process allowed control over product composition so that it was possible to produce three of the polymorphic forms separately. By DG antisolvent precipitation from saturated acetone solutions it was possible to produce amorphous material and two of the polymorphs. The effect of operating temperature was not significant. The formation of the different forms was determined by kinetic factors modified through changes of the solution flow rate. Sulfathiazole was also processed by the same DG antisolvent process from saturated methanol solutions. In methanol systems, the crystal structure of the precipitate was thermodynamically controlled and three of the polymorphic forms were individually produced by changing the operating temperature. The operating temperature (between 0°C and 120°C) was found to be the most important parameter in determining the formation of a certain polymorphic form from methanol solutions while changes in the solution flow rate had a minor effect and could be manipulated to vary the particle morphology. The flow rate of the antisolvent (carbon dioxide) and the operating pressure were 10 ml/min and 200 bar in all the experiments.[47]

Three polymorphic forms of the antiepileptic drug carbamazepine could be produced individually and as mixtures by the DG antisolvent precipitation by using carbon dioxide as an antisolvent. The parameters controlling the polymorphism of carbamazepine were the solvent (dichloromethane or methanol), temperature (within 45°C and 85°C), pressure (within 80 and 250 bar), and the level of supersaturation reached in the precipitation chamber (modified through changes of experimental pressure, temperature, solvent flow rate). In all experiments solution concentration and antisolvent flow rate were kept constant. Particle size and morphology were highly dependent on the polymorph form, which varied between needle-like particles over 60 μm long and plate-like particles about 10 μm wide.[48]

A modification of DG antisolvent precipitation, involving introducing water with the DG antisolvent, was developed to promote the formation of crystalline rather than amorphous products. The water and the antisolvent should be miscible and the mixture is used to expand the primary solvent to trigger particle precipitation. The same antisolvent/water stream can be used to condition the already formed particles after the flow of solution in the precipitation chamber is terminated. The process has been applied to the production of crystalline formoterol fumarate, an antiasthma drug. Dense gas antisolvent precipitation of formoterol fumarate from methanol solutions using carbon dioxide as an antisolvent generated totally amorphous particles. By introducing water to the carbon dioxide stream and further exposing the particles thus formed to the carbon dioxide–water flux, it was possible to generate the dihydrated formoterol fumarate polymorph. It has been claimed that the technique is suitable for processing a wide range of pharmacologically active ingredients,

excipients, and their combinations.[49] The process has been extended to the control of the polymorphic structure of preformed compounds, particularly to convert amorphous forms to crystalline. Application to the conditioning of amorphous lactose (120 bar and either 40°C or 70°C) resulted in substantial conversion to crystalline material as observed by thermal activity monitoring. The particle size before and after the process was monitored through Coulter counter analysis and was found to be preserved.[50] However, due to the hygroscopic nature of many amorphous compounds, resulting in substantial particle agglomeration upon exposure to humidity, the process is unlikely to generally preserve the original particle morphology. In particular, particle size measurements based on aerodynamic performance are likely to produce substantially different results before and after powder processing.

CONCLUSIONS

The unique properties of DGs, including tuneable solvation power and excellent mass transfer properties, are advantages that are beneficial in a wide range of processes applied to pharmaceutical compounds. Dense gas technology commonly utilizes carbon dioxide, which is nonflammable, nontoxic, and inert, and has moderate critical conditions. The properties of carbon dioxide are particularly suited to the processing of labile compounds such as many active pharmaceuticals.

The potential of DG technology for the engineering of micronized particles, with control over critical physical properties such as particle size and morphology and polymorphism, has been demonstrated. However, the widespread application of DG technology on the commercial scale is complicated by an incomplete understanding of the particle formation mechanisms and the consequent limited predictive ability. Additional issues are related to the relatively high implementation costs. Nevertheless, various DG processes have been successfully applied to the manufacture of compounds on the commercial scale. Further developments are expected from the improving knowledge of current DG techniques and fundamental studies in the area.

Propylene Production

Abdullah M. Aitani
King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia

INTRODUCTION

Propylene is one of the main building blocks for petrochemicals and for clean fuel alkylate blends. It is used in the production of a wide variety of petrochemical products such as polypropylene, acrylonitrile, cumene, oxo-alcohols, propylene oxide, acrylic acid, isopropyl alcohol, and polygas chemicals. Polypropylene accounts for about half of the world propylene consumption, which consequently drives the demand. Other uses of propylene within a refinery include alkylation, catalytic polymerization, and dimerization for the production of high-octane gasoline blends. In general, propylene is supplied in three separate quality grades: refinery (~70%), chemical (~92 to 96%), and polymer (99.6%).

The two major commercial sources of propylene are ethylene steam cracker plants and refinery fluid catalytic cracking (FCC). Other routes include olefin metathesis and propane dehydrogenation. About 68% of world propylene is produced as coproduct to ethylene by the steam cracking of hydrocarbons and about 29% is produced as coproduct to gasoline in the FCC of gas oils. The remaining 3% is produced via propane dehydrogenation and olefin metathesis.[1,2]. Other emerging technologies include catalytic cracking of higher hydrocarbons, olefin interconversion, and methanol conversion. Table 1 presents a summary of world propylene sources and production data.

Current global production of propylene stands at about 54 million metric tons per year (tpy) and is valued roughly at $17 billion.[2] The bulk of propylene production and consumption is concentrated in North America, Western Europe, and Japan. These areas represent about 68% of world capacity and 70% of demand. Propylene demand is expected to grow fast and to nearly double in the next 10 yr, reaching more than 91 million tons by 2010 at a growth rate of 4.7%/yr.[2] Because world consumption is forecast to grow faster than production capacity, propylene has been termed as "olefin of the future."[1] This increase is driven by the demand for derivatives, especially polypropylene.

STEAM CRACKING OF HYDROCARBONS

The main route for producing light olefins, especially ethylene and propylene, is the steam cracking of hydrocarbons, which was commercialized in the 1950s. Currently, world capacity of ethylene steam crackers stands at about 112 million tpy and the amount of propylene coproduced in these steam crackers is about 36 million tpy. The capacity and the throughput of steam crackers are continuously growing due to the ever-increasing world demand for polymers (polyethylene and polypropylene in particular) and other olefin-based derivatives. Ethane, LPG, and naphtha are the dominant steam cracker feedstocks. Natural gas condensate is abundant in North America and the Middle East, while naphtha is commonly used in Asia and Europe.

Steam cracking reactions are principally bond breaking and a substantial amount of energy is needed to drive the reaction toward olefin production. The reaction is highly endothermic; so it is favored at higher temperatures and lower pressures. Superheated steam is used to reduce the partial pressure of the reacting hydrocarbons. It also reduces carbon deposits that are formed by the pyrolysis of hydrocarbons at high temperatures. Long chain hydrocarbons crack more easily than shorter chain compounds and require lower cracking temperatures.

A typical steam cracker consists of several identical pyrolysis furnaces in which the feed is cracked in the presence of steam as a diluent.[3] The cracked gases are quenched and then sent to the demethanizer to remove hydrogen and methane. The effluent is then treated to remove acetylene, and ethylene is separated in the ethylene fractionator. The bottom fraction is separated in the de-ethanizer into ethane and C_3^+, which is sent for further treatment to recover propylene and other olefins. Typical operating conditions of ethane steam cracker are 750–800°C, 1–1.2 atm, and steam/ethane ratio of 0.5. Liquid feeds are usually cracked at lower residence time and higher steam dilution ratios compared to gaseous feeds. Typical conditions for naphtha cracking are 800°C, 1 atm, steam/hydrocarbon ratio of 0.6–0.8, and a residence time of 0.35 sec. Liquid feedstocks produce a wide spectrum of coproducts including BTX aromatics that can be used in the production of variety of chemical derivatives.

In the cracking furnaces, the achievable propylene to ethylene ratio (P/E) is limited to a value of about 0.65, because at higher ratios the total olefin yield

Table 1 Sources of propylene and world production data

Propylene source	World production in 2002 (million tpy)	Share (%)	Annual growth for 2002–2015 (%)
Steam crackers	35.9	68.0	4.3
Refinery FCC units	15.3	29.0	5.0
Metathesis/dehydrogenation	1.6	3.0	6.5
Total	52.8	100.0	4.7

(From Refs.[1,2].)

(i.e., the sum of ethylene and propylene) drops to an uneconomically low level. Due to the higher annual growth rates of propylene compared to ethylene, the highest possible P/E in steam crackers is very desirable. Table 2 shows typical propylene yields from steam cracking of different hydrocarbon feedstocks, and how the C_5^+ liquid byproducts increase dramatically with heavier feeds.[4]

FLUID CATALYTIC CRACKING

Fluid catalytic cracking units account for about 97% of propylene produced at the refineries as a coproduct to gasoline. Delayed cokers and visbreakers produce the remaining 3%. In some refineries, a fraction of the propylene and all light gases are normally diverted into sweet fuel gas. About 60% of FCC propylene is used in chemical production and the remaining is used in the production of high-octane gasoline blends. Fluid catalytic cracking is the largest refining process for the production of gasoline with a global capacity of more than 14.2 million bbl/d or 715 million tpy; about 50% of this capacity is in North America alone. Fluid catalytic cracking converts heavy oil feedstocks such as vacuum gas oil, residues, deasphalted oil into lighter products that are largely olefinic for light fractions and strongly aromatic for heavy fractions.[5]

A schematic flow diagram of a conventional FCC unit is shown in Fig. 1. The main FCC sections comprise feed injection system, reactor (riser), stripper, fractionator, and regenerator. A fluidized catalyst system is used to facilitate catalyst and heat transfer between the reactor and the regenerator. Cracking reactions are endothermic; the heat balance is obtained by the combustion of catalyst-deposited coke in the regenerator. In general, all cracking reactions are characterized by the production of appreciable amounts of corresponding olefins. The propylene yield from FCC unit is a function of the following parameters:

- Processing capacity of the FCC unit;
- Type of feedstock;
- Riser reactor outlet temperature (severity); and
- Fluid catalytic cracking catalyst type and additives.

To achieve higher outputs of light olefins, particularly propylene, the hydrogen content of the feedstock must be increased and the sulfur content reduced. This can be achieved by the utilization of low sulfur crude oils or using a higher performance feed hydrotreater upstream of the FCC unit. There are several commercial FCC processes currently employed with major differences in the method of catalyst handling.

Currently, it is not economical to build an FCC for on-purpose propylene production because of low

Table 2 Product yields from steam cracking of various hydrocarbons

	Gaseous feeds			Liquid feeds	
Product yield (wt% on unit)	Ethane	Propane	Butanes	Naphtha	Gas oil
H_2 and methane	13	28	24	26	23
Ethylene	80	45	37	30	25

propylene yield; however, it is economical to recover propylene from an FCC unit for chemical uses. Deep catalytic cracking, licensed by Stone & Webster/Shaw Shaw and RIPP/Sinopec, is the only high-olefin FCC process that reached the commercialization stage.[5] Recent catalyst developments have helped increase the propylene yield of conventional FCC from 4.5% to 10% or greater. In particular, the use of ZSM-5 catalyst additive is increasing to boost propylene production. Processes in various stages of development include PetroFCC (UOP), High Severity-FCC (KFUPM, JCCP, Saudi Aramco), Maxofin (KBR, ExxonMobil), Selective Component Cracking (Lummus), and IndMax (Indian Oil). Table 3 presents a comparison of the yield structure of conventional FCC and selected high-olefin technologies.[5–7]

Table 3 Product yields of conventional and emerging FCC processes

Parameter	FCC	DCC	PetroFCC	HS-FCC
Reaction temperature (°C)	500	530	590	600
Product yield (wt%)				
Ethylene	1.5	5.4	6.0	2.3
Propylene	4.8	14.3	22.0	15.9
Mixed butanes	6.9	14.7	14.0	17.4

Table 4 Typical properties of commercial propane dehydrogenation processes

Process	Licensor	Reactor type	Catalyst	Reaction conditions
Catofin	Lummus-Houdry	Fixed bed	Cr_2O_3/Al_2O_3	560–620°C, > 0.5 atm
FBD-3	Snamprogetti-Yarsintez	Fluidized bed	Cr_2O_3/Al_2O_3	540–590°C, 1 atm
Oleflex	UOP	Moving bed	Pt/Al_2O_3	550–650°C, > 1 atm
PDH	Linde-BASF-Statoil	Fixed bed	Cr_2O_3/Al_2O_3	590°C, > 1 atm
STAR	Krupp Uhde	Fixed bed	$Pt/Sn/Zn/Al_2O_3$	500°C, 3.5 atm

(From Ref.[8].)

PROPANE DEHYDROGENATION

Propane dehydrogenation is a highly endothermic process. High temperatures and relatively low pressures are used to get a reasonable conversion of propane. The reaction is equilibrium limited. The amount of olefin in the reactor effluent is dependent on the reactor outlet conditions. Thermal cracking reactions limit the maximum practical temperature, and pressure, therefore, becomes the dominant variable.

$$C_3H_8 \Rightarrow C_3H_6 + H_2 \quad \Delta H_{r,298\,K} = 129.4\,kJ/mol$$

Side reactions that occur simultaneously with the main reaction cause the formation of some light and heavy hydrocarbons that result in the deposition of a small amount of coke on the catalyst. Two different catalyst systems based on chromium and platinum are used within a temperature range of 500–650°C. Because of the fast deactivation by coke formation, different concepts have been used to enable regeneration of the catalyst.

Several commercial processes have been developed for the catalytic dehydrogenation of propane to propylene as presented in Table 4.[8] Of the seven commercial propane dehydrogenation plants in operation, six use UOP's Oleflex continuous moving-bed process. The other uses ABB Lummus' Catofin cyclic multiple-reactor system. Other processes include Krupp Uhde's STAR process, as well as technologies from Linde and Snamprogetti.[9]

Fig. 2 presents a typical schematic flow diagram for propane dehydrogenation. In a process with fixed-bed reactors, at least two reactors must be used so that the catalyst in one reactor can be regenerated without stopping the process. The advantage with a moving bed or a fluidized bed is that the catalyst can be continuously removed from the reactor and be regenerated. The disadvantage is that a separate regeneration unit is needed.

METATHESIS

Olefin metathesis is a useful reaction for the production of propylene from ethylene and butenes using certain transition-metal compound catalysts. The two main equilibrium reactions that take place simultaneously are metathesis and isomerization. Metathesis transforms the carbon–carbon double bond, a functional group that is unreactive toward many reagents that react with many other functional groups. New carbon–carbon double bonds are formed at or near room temperature even in aqueous media from starting materials. Because olefin metathesis is a reversible reaction, propylene can be produced from ethylene and butene-2. Metathesis can be added to steam crackers to enhance the production of propylene by the transformation of ethylene and the cracking of mixed butenes. Fig. 3 shows a schematic flow diagram of a typical metathesis process. Examples of metathesis

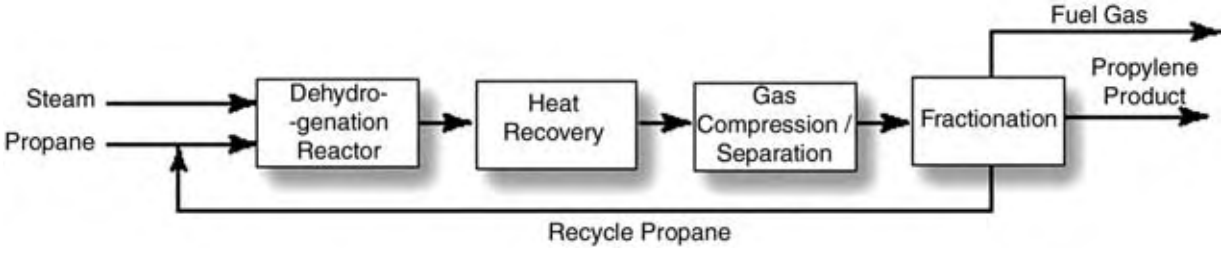

Fig. 2 Flow diagram of catalytic dehydrogenation of propane to propylene.

processes include the low temperature Meta-4 by Axens and the Olefins Conversion Technology (OCT) by ABB Lummus (acquired from Phillips).

EMERGING TECHNOLOGIES

Catalytic Cracking of Higher Hydrocarbons

A number of nonconventional technologies such as the catalytic cracking of naphtha are being explored as an alternative conventional steam cracking of hydrocarbons. The main objective is to achieve higher yields of light olefins and to lower capital and operating costs. Vniios has developed a conceptually new technology for the catalytic cracking (pyrolysis) of petroleum fractions using heterogeneous catalysts. The process key element is a potassium–vanadium catalyst doped with boron oxide and supported on a robust mullite–corundum carrier. Despite numerous patents and demonstration plant trials, none of these processes have been used in commercial olefin production. However, it is unlikely that these processes will replace steam cracking for ethylene production in the foreseeable future.

Olefin Interconversion

Several on-purpose propylene production technologies are based on the catalytic interconversion of C_4–C_8 olefins in a fixed- or fluidized-bed reactor configuration. The process can be added to conventional steam cracking plants or FCC units. All developed processes use shape-selective medium-pore zeolitic catalysts that crack olefin-rich streams to predominately ethylene and propylene. The fluidized-bed technologies are based on a reactor/regenerator design similar to conventional FCC. Reaction thermodynamics determine the product slate and the selectivity independent of feedstock sources. Lurgi developed a low-pressure catalytic process known as Propylur that uses adiabatic fixed-bed technology for converting higher olefins to propylene and ethylene in the presence of steam. Other technologies include Atofina/UOP's olefin cracking process (OCP), Lyondell/Kellogg's fluidized-bed Superflex process, Linde's fixed-bed catalytic cracking (FBCC), and ExxonMobil's olefin interconversion (MOI) and fluidized-bed propylene catalytic cracking (PCC).

Propylene from Methanol

Because the market for olefins currently greatly exceeds that for methanol production, olefin production could become an important new outlet for the potentially vast quantities of low-cost methanol. Methanol conversion produces a mixture of ethylene and propylene of various ratios or primarily propylene depending on the process. Currently, there are two processes for the production of propylene from methanol: the first process is methanol to olefin (MTO) process, developed by UOP and Hydro,

Table 5 Selection criteria for on-purpose propylene production processes

Selection criteria	Refinery DCC	Dehydrogenation	Metathesis	Olefin cracking	MTO/MTP
Feedstock	Gas oils	Propane	C_2–C_4 Olefins	C_4–C_8 Olefins	Methanol
Steam cracker integration	No	No	Yes	Yes	No
Investment	Moderate	High	Moderate	Moderate	Very high
Commercial units	Several	Several	One	None	None

(From Ref.[1].)

and the second process is methanol to propylene (MTP) process, developed by Lurgi. Both processes start from converting natural gas into methanol, which is then converted to light olefins. The processes are attractive as part of a complex for the utilization of stranded natural gas reserves.

CONCLUSIONS

Propylene is conventionally produced as a coproduct in steam cracking of naphtha or FCC of gas oil in refineries and to a lesser extent via propane dehydrogenation and olefin metathesis. To meet strong demand for propylene derivatives, research is ongoing to develop new on-purpose technologies such as catalytic cracking of hydrocarbons, olefin interconversion, and methanol conversion. The selection criteria for on-purpose propylene production processes are summarized in Table 5. These processes uncouple propylene production from steam crackers and refineries allowing higher production flexibility. However, they will remain more expensive than the coproduct routes and will continue to provide only marginal production volumes in niche circumstances. Much of the increase in propylene demand is expected to come from steam crackers, followed by refineries and dehydrogenation plants.

INTRODUCTION

Protein design refers to the ability to alter protein structure to achieve the desired protein function. Of the two classes of proteins (binding proteins and catalytic proteins), catalytic proteins, or so-called enzymes, are of particular importance to chemical processing because they can be used as chemical catalysts. Enzymes are able to catalyze a broad range of chemical reactions with exquisite specificity and selectivity (stereo-, regio-, and chemo-). In addition, most enzymes are quite efficient catalysts and operate at mild conditions, resulting in less energy consumption. In the past several decades, enzymes have been increasingly employed to synthesize chemicals and materials in the pharmaceutical, chemical, food and agriculture industries. However, the number and diversity of the applications are modest compared to the total number of enzymes identified so far (~4000 enzymes). One main reason for this discrepancy is that naturally occurring enzymes are often not functionally optimal under process conditions in terms of their activity, stability, specificity, and selectivity. To overcome this limitation, tailor-made biocatalysts must be developed by protein design. This entry discusses the molecular tools of protein design and their applications in engineering naturally occurring enzymes into commercially viable biocatalysts for chemical processing. However, their applications in the development of therapeutic proteins and monoclonal antibodies are not discussed.

PROTEIN DESIGNER'S TOOLBOX

Prior to the advent of recombinant DNA technology, the ability to design proteins was limited to chemical modification methods in which specific residues in a protein are modified at the protein level by chemical agents. Different strategies such as atom replacement and segment reassembly have been used to alter enzyme substrate specificity, activity, cofactor requirement, and stability.[1] These methods can introduce a diverse range of functionality that does not occur in natural proteins. However, because only a few protein residues can be selectively modified chemically and the modifying process is rather tedious and time-consuming, these tools have not been widely used for the development of commercial enzymes.

The advent of recombinant DNA technology and polymerase chain reaction (PCR) technology has greatly changed the landscape of protein design. Numerous powerful protein design techniques have been developed in the past two decades, all of which target the modifications at the DNA level. Consequently, these protein design methods have been classified as genetic methods to distinguish them from the above chemical methods. Apart from this classification, all current protein design methods can be categorized into two general strategies: rational design and directed evolution. Rational design involves rational alterations of selected residues in a protein to cause predicted changes in function. It usually requires detailed knowledge of enzyme structure, function, and catalytic mechanism, which represents a bottom-up approach. In comparison, directed evolution, sometimes called irrational design, mimics the natural evolution process in the laboratory and involves repeated cycles of generating a library of different protein variants and selecting the variants with desired functions. Due to its combinatorial nature, it does not require any detailed structural and functional understanding of the target enzymes. Nonetheless, further characterization of the isolated variants may provide insights into protein structure and function. Thus, directed evolution represents a top-down approach. It should be noted that both rational design and directed evolution have been widely used in protein design.

Rational Design

With the aid of site-directed mutagenesis and the availability of enzyme structures solved by x-ray crystallography, many attempts involving rationally designing proteins were made in the 1980s. Early successful

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018030

examples such as rational design of tyrosyl-transfer RNA synthetase and β-lactamase demonstrated the power of this approach in understanding enzyme catalysis and engineering enzyme activity and specificity.[2,3] The numerous studies that followed these early examples have led to the formation of a new field–protein engineering.[4] Notable examples include the design of a T4 lysozyme with increased stability by engineering disulfide bonds into the protein, the redesign of a lactate dehydrogenase into a malate dehydrogenase by introducing a single point mutation, and the design of subtilisin enzymes with increased activity and altered pH profiles by engineering surface charge.[5–7] However, owing to the sieving effect of publication (only the successful cases are published), rational design may look more "rational" than it actually is. The truth is that our current ability of rationally designing protein is still rather limited. It became apparent that, owing to the intricate and complex relationship between protein structure and function, rationally introduced mutations often have unexpected disastrous effects on enzyme stability and activity. Thus, to circumvent the unpredictable effects of individual residues, methods that are able to assess mutations at single sites or multiple sites in a large-scale format were developed in the early 1990s. This new trend ultimately led to the establishment of directed evolution as a powerful approach for protein design. The past 10 yr have witnessed many more publications on directed evolution than those on rational design. Nonetheless, with recent advances in genomics, bioinformatics and structural proteomics, our knowledge about proteins is rapidly expanding. Computational techniques are also playing an increasingly important role in protein rational design, especially with the availability of faster and cheaper computers. Thus, it is foreseeable that the ability to rationally design proteins will be significantly improved.

Site-directed mutagenesis

Site-directed mutagenesis is the most powerful and widely used rational design approach, which entails the precise modification of specific residue(s) in a given protein at the DNA level. These residue(s) are typically identified from the three-dimensional protein structure obtained by x-ray crystallography or NMR methods. In the absence of structure, a structural model of the target protein can be built from the three-dimensional structure of a related protein sharing high sequence homology with the target protein using homology-modeling programs such as Insight II (Accelrys Inc., San Diego, CA) and SYBYL®/Base (Tripos, Inc., St. Louis, MO). If these options are not available, sequence analysis programs such as BLAST and CLUSTALW (http://workbench.sdsc.edu/) can be used to identify the residues that are conserved among a family of homologous proteins, and are therefore presumed to be functionally important.

A large number of experimental methods have been devised for site-directed mutagenesis. The methods developed in the early 1980s all involve the use of single-stranded bacteriopbage DNA molecules carrying a target gene and chemically synthesized complementary oligonucleotides containing the desired nucleotide substitutions. After DNA annealing and synthesis, the newly synthesized DNA strand contains the target gene with the desired mutations. Although these methods are conceptually simple, the generation of single-stranded DNA is time-consuming and the mutagenesis efficiency (the frequency of the target genes with mutations) is relatively low (less than 50%). Thus, a few PCR-based mutagenesis methods have been developed to overcome these limitations. One of the most widely used methods is the overlap extension PCR mutagenesis method.[8] As illustrated in Fig. 1, four primers, A-F, A-R, M-F and M-R, are used. A-F and A-R correspond to the beginning and the end of the target gene sequence, respectively. M-F and M-R cover the region where a point mutation is desired. First, two independent rounds of PCRs are performed using the target gene as a template.

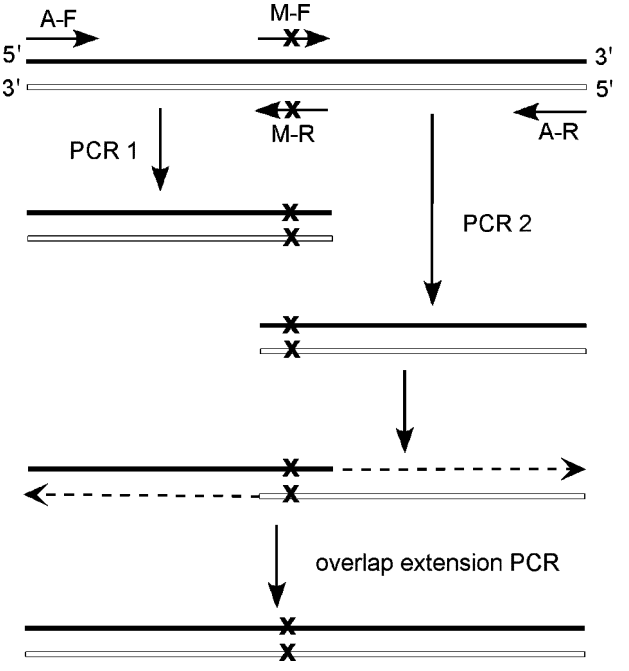

Fig. 1 Site-directed mutagenesis by splicing overlap extension (SOEing). Both the target gene and the PCR products are shown in double strands. Primers are shown as arrows and mutations in primers and products as ×. Dashed arrows indicate the directions of DNA extension by DNA polymerases.

Primers A-F and M-R are used as a pair to amplify the 5′ end of the target gene, and this amplified product will contain a point mutation near the 3′ end. Primers M-F and A-R are used together to amplify the 3′ end of the target gene, leaving a point mutation near the 5′ end of the product. Polymerane chain reaction products from both the reactions are purified and combined for another round of PCR without additional primers. This reaction is called overlap extension because the 3′ end of the first PCR product is complimentary to the 5′ end of the second PCR product, resulting in these two DNA ends priming each other. The resulting target gene with a point mutation will be further amplified by primers A-F and A-R and subcloned into a vector for protein expression.

Domain swapping

Novel protein functions are needed for many applications. Although site-directed mutagenesis is effective in altering protein functions, it often results in incremental improvement of protein functions rather than dramatically improved or novel protein functions because it can only modify protein sequences at single or multiple sites. It is expected that the creation of novel protein functions may require dramatic changes in protein structures. To address this limitation, one simple genetic method to introduce novel protein functions is to combine protein domains from different proteins, or so-called domain swapping. A protein domain is typically defined as a folding and/or functional unit of a protein. Because many large proteins contain several functional domains and domains tend to fold independently, the fusion of domains with different functions may result in a multifunctional protein with unique features.

One recent example of domain swapping is the design of a ligand-regulated DNA recombinase in which the ligand binding domain of human estrogen receptor was linked to the Cre recombinase.[9] The Cre recombinase can integrate a foreign gene into the *LoxP* site on the host genome while the human estrogen receptor is a nuclear hormone receptor that regulates the action of estrogen in different tissues and organs. The human estrogen receptor contains at least three distinct domains: a DNA-binding domain, a transactivation domain, and a ligand binding domain. The binding of estrogenic compounds to the ligand binding domain of the estrogen receptor will cause conformational changes in the estrogen receptor. The Cre recombinase and the estrogen receptor are two completely different proteins, yet the fusion protein created by domain swapping exhibits a protein function different from either parental protein: the recombinase activity is dependent on the ligand binding of the estrogen receptor. Such a fusion protein was used to reduce the toxicity to the proliferating *Drosophila* cells caused by the chronic expression of the Cre recombinase. It should be noted that for a domain swapping experiment to be successful, it is very important to define the exact domain boundaries within a protein. Two main methods have been developed: one is through sequence alignment of a pool of homologous proteins, and the other is through deletion experiments. These two methods usually give a similar but not identical definition of domain boundary. In many cases, because of the lack of complete understanding of protein functions, these slightly different definitions may lead to different results.

Directed Evolution

Although rational design has been demonstrated to be an effective protein design strategy, its success rate is not very high because of our limited understanding of protein folding, structure, function, and dynamics. Moreover, it is rather time-consuming owing to the need of a high-quality three-dimensional protein structure for experimental guidance. In contrast, directed evolution does not use any preconceived ideas about what is important and only relies on a very simple algorithm that nature has successfully been using for eons: diversification coupled with selection. In essence, directed evolution mimics natural Darwinian evolution in a laboratory environment. As shown in Fig. 2, genetic diversity is first introduced into a target gene through random mutagenesis and/or recombination. The library of mutant genes is then transformed into host cells in which the mutant genes are converted into their corresponding proteins. Functionally improved mutant proteins are identified through an appropriate selection or screening strategy. The same process will be repeated until the goal is achieved or no further improvement is possible. It should be noted that the host cells used for protein expression in a directed evolution experiment are laboratory microorganisms such as *Escherichia coli* and *Saccharomyces cerevisiae.* Expression of foreign proteins in these host organisms is enabled by recombinant DNA technology. These microorganisms are favored because of their rapid growth rates, the availability of many genetic engineering tools, and their well-known genetics.

It should also be noted that both screening methods and selection methods have their own advantages and disadvantages. Screening involves physically or chemically interrogating every mutant protein in a library individually, and is often implemented in a 96-well plate format using plate readers. As a result, its throughput is relatively low (the size of the library that can be screened is limited to $\sim 10^4$). However, because the screens are done in vitro with whole cells, cell

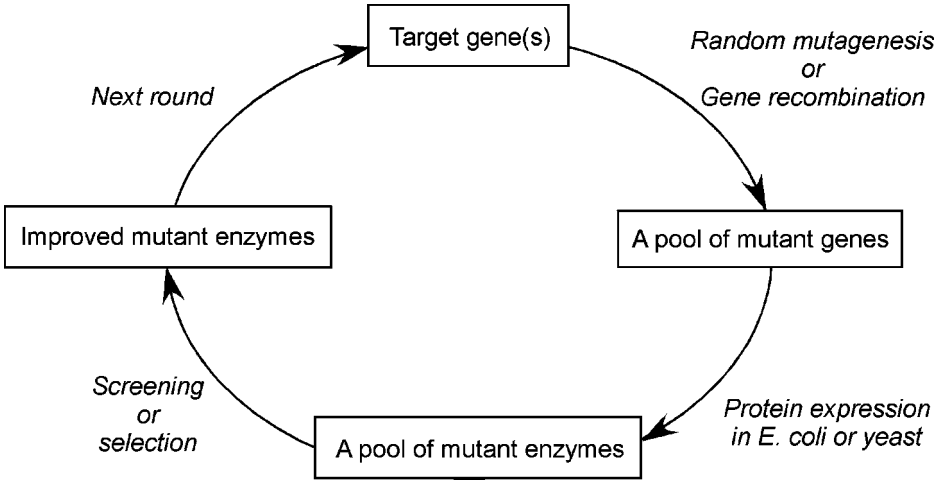

Fig. 2 The general scheme of directed evolution.

lysates, or partially purified enzymes, and often in much the same way the enzymes are traditionally assayed, the experimental conditions can be easily tailored to meet the reaction constraints such as non-natural environment or substrates, and the screens can be implemented very quickly. Moreover, multiple measurements can be made on each sample to check several key enzyme properties. Thus, screening is the most flexible sorting method in directed evolution. In comparison, selection involves linking the survival or growth of the microorganism to the target protein so that only the microorganisms possessing the desired enzyme function can grow. Consequently, a much larger library of enzyme mutants ($>10^6$) can be assessed by selection, and the size of the library is limited only by the cell transformation efficiency. Unfortunately, it is not an easy task to devise a selection method for a given protein in most cases because the desired enzyme function is often nonnatural and cannot be coupled to the growth and survival of the host organism. Even when a selection is available, because of the redundancy and complexity of genetic regulatory networks, host organisms can often create solutions that are not related to the targeted enzyme function. Thus, extra care must be taken to ensure that the positives are indeed the result of the mutations in the targeted enzyme. It is often advised to combine selection and screening if both methods are available.

A successful directed evolution experiment involves two key components: creating genetic diversity and developing a screening or selection method. In the past several years, many experimental methods have been developed to introduce genetic diversity into the target gene, all of which can be grouped into two categories: methods of random mutagenesis and methods of gene recombination. As shown in Fig. 3, random mutagenesis starts from a single parent gene and introduces new nucleotide substitutions randomly in the progeny genes, or inserts or deletes one or more nucleotides at random positions in the progeny genes. In contrast, gene recombination usually starts from a pool of mutants from a single gene or a pool of closely related parental genes of different origin and creates blockwise exchange of sequence information among the parent

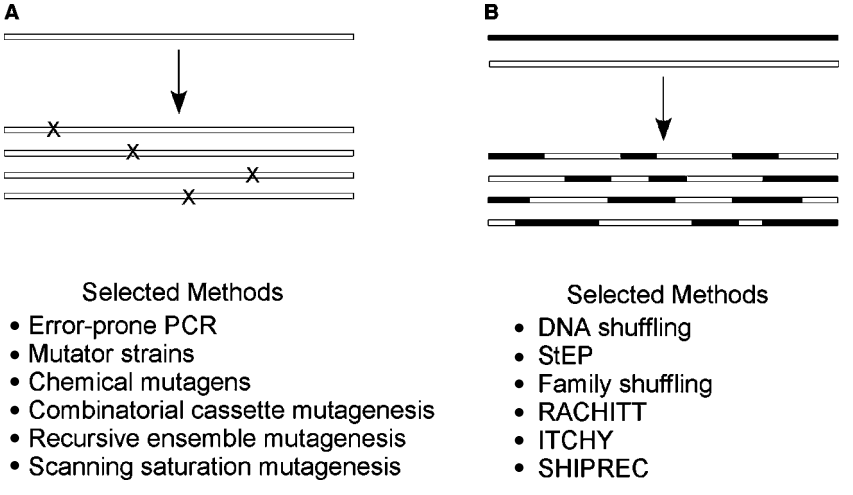

Fig. 3 The comparison between random mutagenesis methods and gene recombination methods. Random mutagenesis methods create a library of variants containing point mutations or insertions/deletions (represented by $\times$) from a single parental gene, whereas gene recombination methods create a library of chimeric variants via blockwise exchange of sequence information among the parental genes. A few representative methods that have been developed so far are listed.

genes. Recombination in a genetic sense means the breaking and rejoining of DNA fragments in new combinations. Both random mutagenesis and gene recombination are important natural evolutionary processes. A few of the most commonly used techniques for generation of diversity will be discussed below. For additional and more detailed discussions on various evolutionary methods, interested readers are referred to a recent review contributed by Zhao and Zha.[10]

Error-prone PCR

Because of its simplicity and efficiency, error-prone PCR is the most widely used random mutagenesis method. It is essentially a variation of the standard PCR with slightly modified reaction conditions. The reaction buffer used for standard PCR contains an equal molar amount of each dNTP and a certain concentration of Mg^{2+} (typically 1.5 mM). Mg^{2+} is very important for the activity of *Taq* DNA polymerase because it is directly involved in catalysis. During the DNA amplification process in a standard PCR, the chance of incorporating wrong nucleotides into the progeny genes by the *Taq* DNA polymerase is very low. However, this very small error rate can be dramatically increased by modifying the reaction buffer so as to force the *Taq* DNA polymerase to incorporate more incorrect nucleotides during amplification. These changes include: 1) use of unbalanced concentrations of dNTPs; 2) addition of $MnCl_2$ in addition to $MgCl_2$; and 3) use of a high concentration of Mg^{2+} (typically 7 mM). Owing to the limitations on library sorting imposed by screening or selection and the observation that most of the mutations are deleterious and beneficial mutations are rare, the mutation rate must be tuned to the power of the sorting method. Thus, only one or two amino acid substitutions are usually introduced to the target protein to increase the possibility of finding mutant proteins with the desired function. Fortunately, it was found that the error rate of error-prone PCR can be easily and precisely controlled by the Mn^{2+} concentration, which makes this method even more appealing.[11] The main disadvantage of error-prone PCR is that it can only access about six amino acid substitutions at a given residue position because of the degeneracy of the genetic code, thus reducing the potential diversity significantly. Moreover, the mutations are not truly random. For example, a common bias of error-prone PCR is the high occurrence of AG substitutions.

DNA shuffling and family shuffling

The method of DNA shuffling, also known as ''sexual PCR,'' is the first and most widely used gene recombination method, developed in 1994 by Stemmer.[12] As shown in Fig. 4, a pool of selected closely related genes containing point mutations are randomly digested with enzyme DNase I to obtain small double-stranded DNA fragments (20–50 bp). These DNA fragments are purified and reassembled into a full-length gene in a PCR-like reaction (without primers). Recombinogenic events occur when fragments derived from different parental genes prime one another. This reassembly mixture is then used as a template for a standard PCR reaction with primers flanking the gene of interest. The final amplified product will consist of a library of full-length genes containing recombined mutations from different parental genes.

It is noteworthy that these closely related genes are often mutants derived from a single parental gene. However, naturally occurring homologous genes sharing relatively high sequence identity (>70%) can also be recombined using DNA shuffling under modified reaction conditions, which is called ''family shuffling.''[13] It has been demonstrated that family shuffling can significantly accelerate the rate of functional enzyme improvement in comparison with

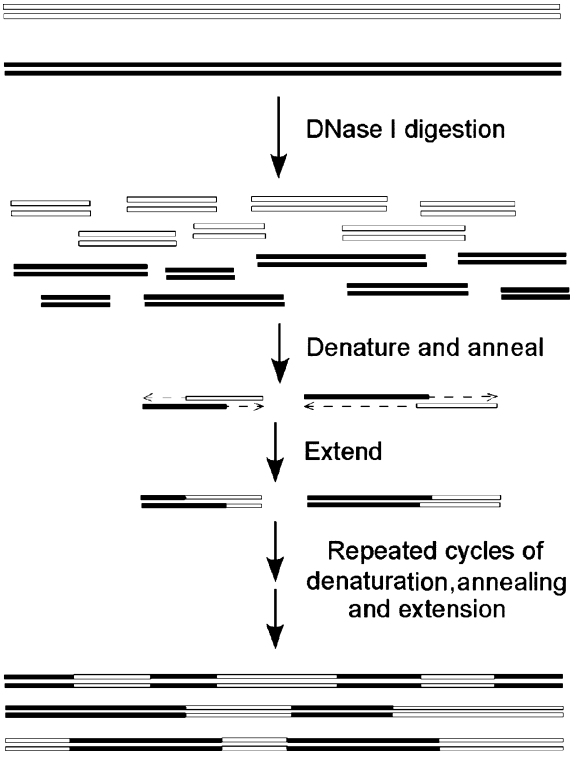

Fig. 4 DNA shuffling. For simplicity, only two homologous genes are shown. These two double-stranded genes are mixed in equal molar ratio followed by random fragmentation with DNase I. These short fragments are reassembled into full-length chimerical genes in a PCR-like process. The full-length genes may be amplified by a standard PCR and subcloned to an appropriate vector.

DNA shuffling or error-prone PCR. The power of family shuffling may arise from its ability to sparsely sample a larger portion of sequence space that is functionally rich because the parental genes have been preselected in nature to be functional and useful. Generally speaking, compared to error-prone PCR, the main advantages of DNA shuffling or family shuffling include its ability to rapidly accumulate beneficial mutations and remove deleterious mutations, and its ability to explore a larger portion of protein sequence space.

Nonhomologous DNA recombination

DNA shuffling or family shuffling relies on relatively high levels of sequence identity (more than 70%) to recombine genes in vitro. DNA shuffling also tends to generate crossovers only in regions of the highest sequence identity. In general, if the sequence identity is less than 70%, most of the shuffled progeny genes will be the same as parental genes. Given that many proteins having similar three-dimensional structures share low or no discernible sequence homology, homology-dependent methods for recombining genes may potentially limit the solutions to protein design problems. In fact, many lines of evidence from rational design and computational studies have indicated that functional proteins can be obtained by recombining genes with low sequence homology.[12]

Recently, several methods have been developed to recombine nonhomologous genes. One of them is the so-called sequence homology-independent protein recombination (SHIPREC) method.[14] As illustrated in Fig. 5, two parental nonhomologous genes of similar size are fused together through a DNA linker containing multiple restriction sites. This dimer gene is digested with DNase I to produce a pool of random-length fragments. Fragments of a length corresponding to either of the parental genes are isolated and treated with nuclease S1 to form blunt ends. These blunt-ended fragments will then be circularized by blunt-end ligation, followed by linearization with restriction digestion in the linker region to create a library of chimerical genes. The chimerical genes are subsequently cloned into an appropriate expression vector and transformed into a suitable host for further screening or selection. This method was used to recombine a membrane-associated human cytochrome P450 (1A2) and the heme domain of a soluble bacterial P450 (BM3), which resulted in variants of 1A2 enzymes that are properly folded and more soluble in the bacterial cytoplasm than the wild-type 1A2 enzymes.[14] One limitation of this method is that only two parental genes are shuffled and there is only one crossover in every chimerical gene.

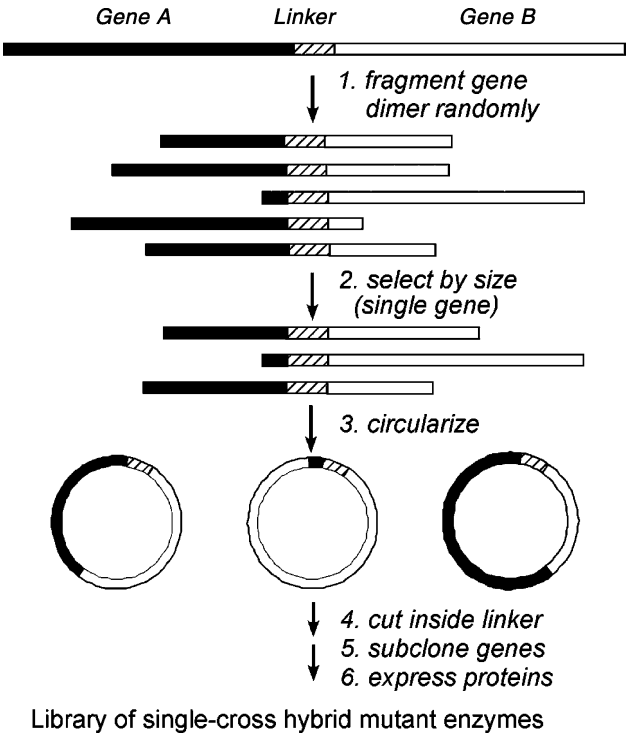

Fig. 5 Schematic representation of the SHIPREC method.

Hybrid Approaches Combining Rational Design and Directed Evolution

Although directed evolution is a powerful tool for protein design, it is limited by the number of protein variants that can be screened experimentally. As shown in Table 1, for a protein of typical size (300 amino acids), the library size of protein variants with each variant containing three mutations is over 3×10^{10}, which is too large to be examined experimentally. However, it is possible that even more simultaneous mutations are needed in a protein to achieve novel protein activity or drastic improvement of protein functions. On the other hand, although rational design has been used for more than two decades, our

Table 1 The potential mutant library size of a protein with 300 amino acids

Mutations	Potential library size[a]
1	5700
2	16, 190, 850
3	30, 557, 530, 900
4	43, 109, 036, 717, 175
5	48, 489, 044, 499, 478, 440

[a]The number of enzyme mutants can be calculated by the simple algorithm $N = 19^M \times 300!/[(300 - M)!M!]$ where M is the number of simultaneous mutations in a protein.

current understanding of protein structure and function still cannot guarantee the success of rational design approaches. Nonetheless, rational design may enable large jumps in the fitness landscape and create protein variants with novel but poor functions, which can then be optimized by directed evolution (Fig. 6). In particular, owing to their high speed, computational techniques may be used to perform in silico screening of protein variants with a library size of $\sim 10^{80}$ or to search vast regions of sequence space to identify the protein sites for more efficient directed evolution.[15,16] Thus, a hybrid approach combining the best of rational design and directed evolution may represent the most powerful approach for protein design.

One such hybrid approach has been recently used to create TEM-1 β-lactamase mutants with increased resistance to the antibiotic cefotaxime.[15] This approach involves a computational protein optimization algorithm called protein design automation (PDA) to reduce the sequence space by many orders of magnitude followed by experimental screening of these selected sequences. The algorithm starts with the structure of a target protein, selects all or a specified set of residues responsible for a specific protein function and predicts the optimal sequences consistent with the proper fold. In this study, 19 residues near the active site of TEM-1 β-lactamase were selected for optimization, which corresponds to a theoretical library of 20^{19} ($\sim 7 \times 10^{23}$) sequences. After computational prescreen by PDA, this library was reduced to 200,000 sequences, which were then constructed and experimentally screened. In a single round, several variants showing a 1280-fold increase in cefotaxime resistance were obtained. These variants contained multiple mutations that have not been discovered before.

EXAMPLES

The applications of enzymes as biocatalysts for industrial chemical processes are rapidly expanding. Like chemical catalysts, the ideal biocatalysts are those enzymes with high stability, activity, specificity, and/or enantioselectivity under process conditions. Unfortunately, naturally occurring enzymes are often deficient in one or more of these important aspects, and therefore cannot meet the stringent requirements of process conditions. In addition, because not all the chemical reactions can be catalyzed by enzymes, owing to either the use of unnatural substrates or the limitations in the chemistry of catalysis, the creation of novel enzyme functions is highly desired. Protein design has been used to address these limitations with great success. Some of these examples will be highlighted below.

Increasing Enzyme Activity and Stability

Both enzyme stability and activity are major concerns in all biocatalytic processes. Poor enzyme stability requires frequent replacement of catalysts while poor enzyme activity requires the use of large amounts of catalysts, both of them resulting in low productivity and unfavorable process economics. Moreover, a high reaction temperature is usually desired in a chemical process because it can result in high reaction rates, favorable equilibrium, and increased substrate solubility, but it also requires high enzyme stability. As naturally occurring enzymes have been evolved for specific biological functions under biological conditions (i.e., aqueous solutions, neutral pH and mild temperatures for most of the organisms), their intrinsic activity and stability are often not high enough for practical applications that may require enzymes to function at extreme pHs, high temperatures, or in organic cosolvents. Thus, further improvement of enzyme activity and stability may be required.

Many successful examples using rational design to engineer enzyme stability or activity have been reported. One of them is the above-mentioned redesign of a T4 lysozyme with increased stability by engineering disulfide bonds into the protein.[5] Another notable example is the design of a subtilisin BPN' mutant containing six site-directed mutations, which was 100-fold more stable than the wild-type enzyme in an aqueous environment and 50-fold more stable than the wild-type in anhydrous dimethylformamide.[17] Subtilisin enzymes have been used as additives in laundry detergents for stain hydrolysis and solubilization, and catalysts for the synthesis of peptides and enantioselective transformation of chiral alcohols, acids, and amines.

Directed evolution is also very effective in engineering enzyme stability and activity. Unlike rational design, which tends to improve one enzyme property at a time (in fact, attempts to rationally alter one enzyme property often disrupt other existing important characteristics), directed evolution may improve multiple enzyme properties simultaneously. For example, five rounds of directed evolution consisting of alternate cycles of error-prone PCR and in vitro gene recombination coupled with screening led to the isolation of a highly stable and active subtilisin E mutant.[11] This mutant contained eight thermo-stabilizing mutations, which were located all over the protein structure. It showed a >200-fold longer thermal inactivation half-life at 65°C, an 18°C higher temperature optima, and a >5-fold higher activity than the wild-type enzyme. Another impressive example is the simultaneous improvement of four distinct enzyme properties of subtilisin, including thermostability, activity in organic solvents, activity at pH 10, and activity at pH 5.5 by

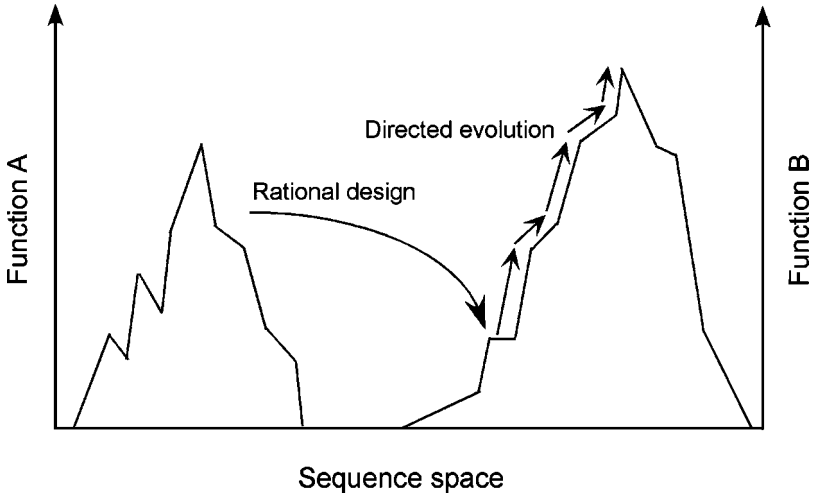

Fig. 6 Schematic representation of hybrid approaches combining rational design and directed evolution. Rational design may allow a large jump in sequence space from high fitness for function A to a low fitness for novel function B. The low fitness for function B might be readily optimized by directed evolution.

directed evolution.[18] Family shuffling was used to recombine 26 homologous subtilisin genes to create a library of chimerical subtilisin genes. Out of 654 active subtilisins, a few mutants showed significant improvement over any of the parental enzymes for each individual enzyme property.

Changing Substrate Specificity

Natural enzymes are optimized for their intended substrates, and often cannot accept nonnatural substrates that are required for a desired chemical process. In the past two decades, both rational design and directed evolution have been successfully used to alter substrate specificity of a large number of common classes of enzymes such as oxidoreductases, hydrolases, and transferases. One exemplary enzyme of particular interest is aspartate aminotransferase which catalyzes the interconversion of aspartate with its corresponding α-keto acid using pyridoxal phosphate as a cofactor. *E. coli* aspartate aminotransferase shares 43% sequence identity with *E. coli* tyrosine aminotransferase. Onuffer and Kirsch [19] used homology modeling to build a structural model of *E. coli* tyrosine aminotransferase based on the solved crystal structure of *E. coli* aspartate aminotransferase.[19] Structural comparison of the active sites of these two enzymes revealed six different positions between them. Mutagenesis of all six residues in aspartate aminotransferase by site-directed mutagenesis of those found in tyrosine aminotransferase successfully altered the substrate specificity of aspartate aminotransferase. The reactivity of the aspartate aminotransferase with phenylalanine was increased by over three orders of magnitude without sacrificing the high transamination activity with aspartate observed for both enzymes. In another case, directed evolution was used to convert *E. coli* aspartate aminotransferase into a valine aminotransferase.[20] A mutant enzyme with 17 amino acid substitutions was generated that shows a 2.1×10^6-fold increase in the catalytic efficiency for a nonnative substrate, valine. The crystal structure of the mutant enzyme indicated a remodeled active site and altered subunit interface caused by the cumulative effects of mutations. Most amazingly, only one of the mutations directly contacts the substrate, which underscores our limited understanding of enzyme substrate specificity. These mutations would be difficult, if not impossible, to be identified and introduced to the mutant enzyme by a rational design approach.

Improving Enantioselectivity

The production of enantiomerically pure compounds is of great importance to the chemical and pharmaceutical industries. Enzymes are chiral catalysts by nature and they have incredible potential for creating enantiomerically pure products. However, many existing natural enzymes show low degrees of enantioselectivity, which requires further improvement by protein design.

Because the molecular basis of enantioselectivity is poorly understood, directed evolution seems to be an excellent choice for engineering enantioselective biocatalysts. Several impressive examples have been documented. In a classical study, Reetz and coworkers[21] used error-prone PCR coupled with a 96-well plate based colorimetric screening method to increase the enantioselectivity of a *Pseudomonas aeruginosa* lipase toward 2-methyldecanoate.[21] After several rounds of directed evolution, the enantioselectivity of the lipase increased from $E = 1.04$ (2% enantiomeric excess) to $E = 25$ (90–93% enantiomeric excess, ee) (E is the enantioselectivity factor). Using a similar approach,

Arnold and coworkers even inverted the enantioselectivity of hydantoinase from D-selectivity (40% ee) to moderate L-preference (20% ee at 30% conversiton).[22] This evolved mutant is now being evaluated in an industrial chemical process at Degussa.

With the increasing knowledge of the molecular basis of enzyme enantioselectivity, rational design has also achieved some success. In one case, Rotticci et al. used molecular modeling to study the different binding modes for alcohol enantiomers in the active site of *Candida antarctica* lipase B and proposed a model for its enantioselectivity.[23] Site-directed mutagenesis was used to alter the active site residues causing unfavorable interactions between the substrate and the enzyme. A single mutation, Ser47Ala, resulted in improvement of the lipase-catalyzed resolution of l-chloro-2-octanol from $E = 14$ to $E = 28$. In another case, van Den Heuvel, Fraaije, and Van Berkel[24] studied the crystal structure of vanillyl-alcohol oxidase and identified a few important residues within the active site that might contribute to the (*R*)-selective formation of (*R*)-l-(4′-hydroxyphenyl) ethanol from 4-ethylphenol. A double mutant was constructed by site-directed mutagenesis, which shows inverted enantioselectivity [(*S*)-selective with 80% ee].

Creating de novo Catalytic Activity

Although natural enzymes can catalyze numerous chemical transformations such as oxidation, reduction, hydrolytic reactions, and carbon–carbon bond formation reactions, enzymes with novel catalytic activities are still needed for the application of enzymes in many industrial biocatalytic processes. The ultimate goal of protein design is to design de novo catalytic activity such that a biocatalyst can be readily obtained for any given chemical transformation. While most protein design so far has really been protein redesign in which the existing protein functions have been adapted under different regimes, a few successful attempts have been made toward this ultimate goal.

An impressive example is the creation of novel enzyme substrate specificity and activity by the DNA shuffling of two highly homologous triazine hydrolases, AtzA and TriA.[25] These two enzymes catalyze the dechlorination and deamination reaction of atrazine and aminoatrazine, respectively. Although they share limited overlap in substrate preference, they only differ by 9 out of 475 amino acids. After one round of DNA shuffling, several variants were found to hydrolyze substrates that were not substrates for either of the parental enzymes.

Another impressive example is the directed evolution of novel ampicillin-resistant activity from a functionally unrelated DNA fragment.[26] A DNA fragment from the genomic DNA library of *Pyrococcus furiosus* was shown to confer very low ampicillin resistance activity (β-lactamase activity) on *E. coli,* while *P. furiosus* itself does not have any β-lactamase activity. This ampicillin resistance activity was significantly enhanced after 50 rounds of DNA shuffling and screening at increasing ampicillin concentrations. The evolved DNA fragments also confer resistance to other drugs that inhibit bacterial cell-wall synthesis.

By taking advantage of the ever-increasing computing power, various computational techniques have been attempted to create de novo protein activity. A particularly impressive example is the creation of catalytic activity in a binding (catalytically inert) protein.[27] Mainly owing to its favorable protein expression properties and thermodynamic stability, rather than any structural similarity to a natural enzyme, *E. coli* thioredoxin was used as a protein scaffold to create enzyme activity concerning histidine-mediated nucleophilic hydrolysis of *p*-nitrophenyl acetate. The design strategy is based on the physical and chemical principles governing protein stability and catalytic mechanism. A protein design software ORBIT was used to perform an active site scan and identified two promising catalytic positions and the surrounding active-site mutations required for substrate binding. Two candidate mutants were constructed by site-directed mutagenesis and both of them showed catalytic activity significantly above the background. Although they are not particularly impressive catalysts, such mutants should be adequate starting points for directed evolution.

CONCLUSIONS

Protein design or engineering is a rapidly growing field of academic research and industrial practice. Its goals include not only addressing fundamental relationships among protein folding, structure, function, and dynamics, but also designing proteins with desired features for applications in pharmaceutical, chemical, agricultural, and food industries. Of particular interest to chemical processing is the application of protein engineering tools to the development of enzyme biocatalysts. Two distinct and yet complementary protein design approaches, rational design and directed evolution, have been successfully developed to engineer biocatalysts with altered or novel stability, activity, substrate specificity, selectivity, cofactor specificity, reaction chemistry, and pH optima. Recently, a third approach combining the best of rational design and directed evolution has also shown great promise in protein engineering, which will attract increasing attention in the near future. With recent advances in

structural genomics and proteomics, and the development of miniaturized and automated high throughput screening technologies, protein engineers will be equipped with more powerful tools to tackle the ever-challenging protein design problems, which will certainly accelerate the widespread adoption of biocatalysts in chemical processing.

INTRODUCTION

The correct folding of proteins from the inactive folded form to the native (active) folded form has implications in the biotechnology industry, as well as in medical science. In both cases, improper folding results in aggregation that has deleterious results. In the biotechnology industry, the aggregates often lead to a substantial decrease in the yield of the desired active protein form. This can be critical in the economics of the process, especially when the final product is required in a very pure form and is expensive. Novel methods have been explored to unfold the aggregates and then fold them back to the desired and active form. The procedures involved are often expensive and substantially increase the bioprocessing cost and reduce the yield of the desired product. The cost of the downstream processing train can often be as high as 90% of the entire cost of the process, due to the increasing number of steps required.[1] A way to minimize the cost of the downstream process is to minimize the formation of aggregates. The formation of such protein aggregates in the human body leads to pathogenic diseases, some of which are fatal. Proteins misfold to form aggregates at various parts in the human body. Aggregate deposition in the brain lead to Alzheimer's disease, deposition in the knee or elbow joints lead to arthritis, etc. If the causes can be determined for the deposition of such aggregates, then perhaps their deposition could be eliminated, or at least minimized. For this, detailed structural and biochemical information about the protein is required.

Immunoglobulin (Ig) light chains are responsible for quite a few protein deposition diseases. Some immunoglobulin chains form amyloid deposits, whereas others do not. A protein conformational change in the partially folded protein is involved that subsequently leads to association and fibril formation. During the folding pathway of especially larger proteins, hydrophobic patches may be exposed.[2] These hydrophobic patches, especially in the restricted and constrained environments of the cell, may lead to misfolding and aggregate formation. Molecular chaperones minimize the off-pathway events that decrease the yield of the stable and native form of the protein,[3] and assist the unfolded conformation to fold correctly to the native form.

The entry reviews the kinetic approach used to analyze the formation of protein aggregates. The kinetic approach analyzes different folding kinetic mechanisms of proteins that misfold to form pathological aggregates. This would include simple series, series-parallel, and complex mechanisms. The thermodynamics approach describes the search for the structure with the low energy, low entropy, and most stable conformation. This approach facilitates an easy comparison of different mechanisms involved during the slow transition of the normal (healthy) state to pathological state. A few examples are discussed with respect to each mechanism. A unified model for folding is proposed and the kinetics is critically analyzed. A complete understanding of protein folding from the kinetic perspective can help prevent aggregate formation. This can then outline some general principles involved in designing therapeutic strategies to cure such intractable diseases.

PROTEIN FOLDING MECHANISMS

Protein folding mechanisms can be classified into three different categories: series, series-parallel, and complex mechanisms. In general, it is the series pathway that leads to the formation of the native and functional form of the protein. Series-parallel and complex mechanisms often contain ''off-pathway'' steps that generally yield aggregates, which lead to deposition. Such mechanisms that result in the deposition of pathological aggregates and in the elimination of such aggregates are our primary focus.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120022533

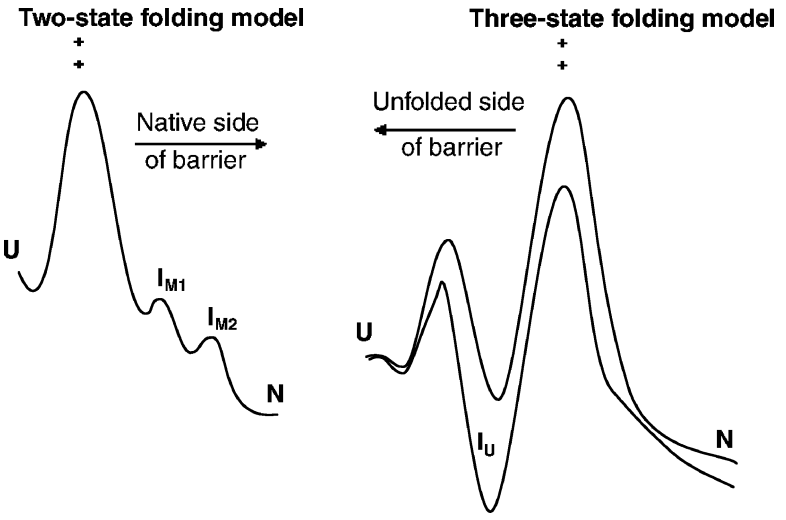

Fig. 1 Comparison of free-energy diagrams of two-state (left) and three-state (right) folding mechanisms. (From Ref.[4].)

Series Mechanisms

The series mechanism of protein folding may or may not involve the presence of stable and detectable intermediates. The following two-state mechanism is involved during the folding of small proteins:

$$U \rightleftharpoons N \tag{1}$$

Here U is the unfolded protein. N is the native form of the protein that exhibits a three-dimensional structure and a specific biological function. This mechanism exhibits the potential to provide the highest yield, and there is minimal possibility of aggregate formation because of the absence of off-pathway steps. An attempt was made to distinguish whether a two-state (no intermediate) or a three-state (defined kinetic intermediate) kinetic process is involved during ubiquitin folding.[4] The results indicate that a two-state folding model is adequate to describe the folding pathway. Free-energy diagrams were used to distinguish between a two-state and a three-state model.

Fig. 1 shows that in two-state folding, intermediates are formed on the native side of the barrier, indicating that the conversion from intermediates to the native states is a fast reaction and that conversion from the unfolded to the first intermediate is the rate-limiting step. Two-state folding behavior requires that any intermediate formed during the folding process, be more stable than the denatured state, as seen in the two-state folding model in Fig. 1 and that the intermediates be located on the native side of the rate-limiting barrier.[4]

In three-state folding, Fig. 1 indicates that the intermediates are formed on the unfolded side of the barrier indicating that the conversion from the intermediate to the native state is the rate-limiting step. The three-state mechanism was used when a detectable intermediate was present. Here "I" is the intermediate form.

$$U \rightleftharpoons I \rightleftharpoons N \tag{2}$$

This mechanism has been observed during the folding kinetics of phage 434 Cro protein.[5] The mechanism provides an insight into the links between the structures, stability, and folding mechanisms involved when small, completely helical proteins fold.

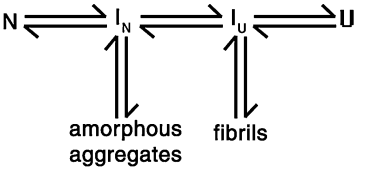
In general, the series pathway may be extended to involve "*n*" stable and detectable intermediates. Here $I_1, I_2, I_3, \ldots, I_n$ are the intermediate states:

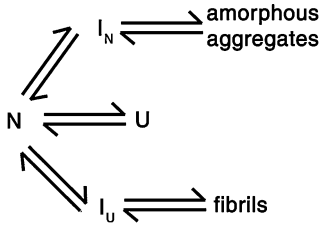
$$U \rightleftharpoons I_1 \rightleftharpoons I_2 \rightleftharpoons I_n \rightleftharpoons N \tag{3}$$

Series-Parallel Mechanisms

Series-parallel mechanisms often include off-pathway steps from the intermediates that sometimes deposit to form aggregates. In some proteins such aggregates are pathological. The biophysical properties and amyloidogenicity of the variable domain of a recombinant amyloidogenic light chain (spinal muscular atrophy, SMA) were analyzed.[6] The mechanistic schemes were proposed in Scheme 1 and Scheme 2.

In both the schemes, the intermediates lead to the formation of amorphous and fibrillar aggregates that causes light chain deposition disease and light chain





(or) AL amyloidosis (amyloid fibrils characterized by the presence of immunoglobulin light chains), respectively. Hence different forms of aggregates formed due to misfolding of the same protein may lead to different diseases.

Light chain or AL amyloidosis is a pathological condition arising from systemic extracellular deposition of monoclonal immunoglobulin light chain variable domains in the form of insoluble amyloid fibrils, especially in kidneys. Amyloid fibril formation from native proteins occurs via a conformational change leading to a partially folded intermediate conformation, whose subsequent association is a key step in fibrilization. Hence, partially folded intermediates are critical precursors for both light chain amyloid fibrils and amorphous aggregates.

Amyloid Aggregates

Major classes of amyloid diseases, e.g., Alzheimer's disease, Type II diabetes, and Parkinson's, are characterized by deposition of ordered protein aggregates termed amyloidosis.[7] Type II diabetes is an autoimmune disease. As the protein misfolds, it forms insoluble aggregates. The mechanism of amyloid fibril formation, an insoluble aggregate, is shown in Fig. 2.

Native state (N) is formed from the unfolded state through intermediate(s) (I). The intermediate(s) acts as a template and propagates to form ordered oligomeric intermediates or protofibrils (PF), which builds up to form stable, insoluble fibrils (F) as shown in Fig. 2. The reaction mechanism involved in this sequence is similar to initiation, propagation, and termination steps in a polymerization reaction. Amorphous aggregates, formed are in equilibrium with the intermediates. In other words, this process is reversible. However, amyloid fibrils are the byproducts of irreversible protein aggregation.

In vivo, the correct assembly of proteins is guided by a family of cellular proteins termed molecular chaperones, e.g., heat shock protein (HSP), nuleoplasmins, and chaperonins. Chaperones bind to the intermediate that tends to aggregate, and either assembles the intermediate to the native state or renders the intermediate void of further reaction to form an aggregate.[8] Normally, all proteins should fold without molecular chaperones. Proteins that tend to form aggregates, like those shown in the above mechanisms, bind to a chaperone to yield the native state.

Prion as Pathological Aggregates

Prion represents a distinct class of infectious agents that are proteinacious and devoid of nucleic acid.[9] The proposed mechanism for prion aggregation is shown in Fig. 3.[10]

Normal protease sensitive form (PrP^c) is formed from the unfolded protein via a prionogenic intermediate.

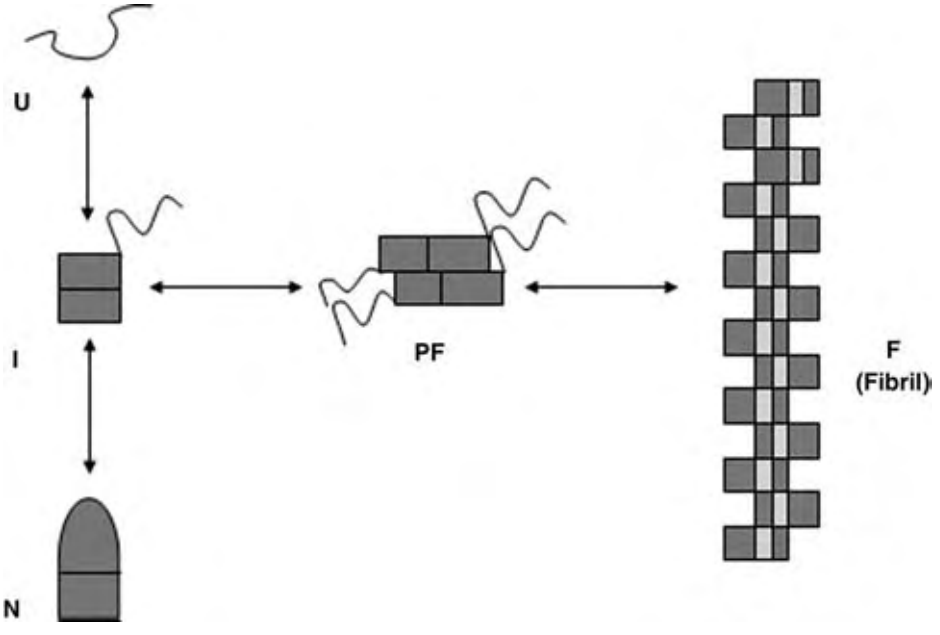


Fig. 2 Mechanism of amyloid fibril formation. (From Ref.[7].)

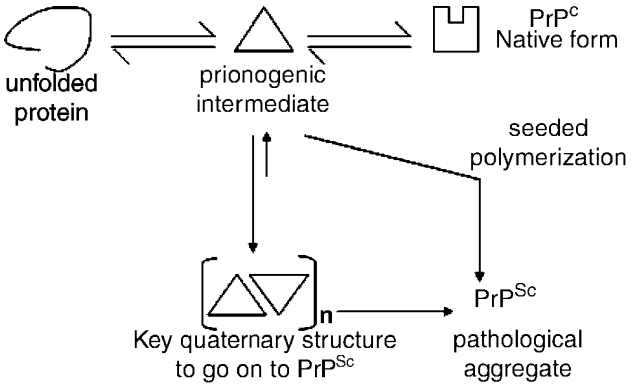

Fig. 3 Folding pathway of prion protein to form scrapie. (From Ref.[9].)

This misfolded form protease-resistant form (PrP^{Sc}) or scrapie may form by

i. Propagation of the prionogenic intermediate to form a template that terminates to form the PrP^{Sc} fibril.
ii. The PrP^{Sc} formed catalyzes the conversion of prionogenic intermediate, as well as the normal form of PrP^{C}. Since scrapie acts as a ''seed'' that catalyzes the conversion to the misfolded form, the conversion is termed as seeded polymerization.

PrP^{C}, which is the native form, acts as a self-chaperone to form PrP^{C}, termed autochaperone, which is similar to autocatalysis in chemical reactions.[11] Since PrP^{Sc} also converts the normal form of the PrP^{C} to the misfolded form, there exists a kinetic competition between these reactions. The model shown in Fig. 4 illustrates such kinetic competition representing the normal folding mechanism, misfolding via prionogenic intermediate, autochaperone folding, and seeded polymerization misfolding. Hence, the key step to prevent aggregate formation is to block the formation of PrP^{Sc} via the prionogenic intermediate step. The model is termed as autochaperone misfolding invasion.

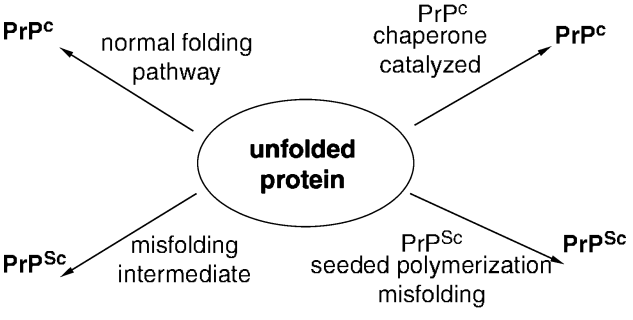

Fig. 4 Kinetic competition in prion folding–autochaperone invasion model. (From Ref.[11].)

The misfolded form, scrapie, results in a class of disease called spongiform encephalopathies, e.g., mad cow disease. Unlike other diseases caused due to protein misfolding, prion diseases are infectious. The infecting agent is the misfolded protein. Prionogenic diseases are transmitted across the species barriers, from cow to sheep to human beings, and are fatal.

Protein Triage Model: Repair Mechanism

The refolding and degradation of proteins and the role of chaperones and proteases in protein folding are analyzed.[12] The ''triage model'' describes the quality control mechanism within the human body. The mechanism describes the fate of an unfolded protein, which may fold either to the native state or form the aggregate. The protein that tends to misfold may bind with the chaperone. This undergoes protein remodeling and is mixed with the pool of unfolded and misfolded proteins as shown in Fig. 5.

A unique repair mechanism is involved. The misfolded protein gets bound to ubiquitin and ATP; a proteasome. A part of the protein-bound proteasome undergoes degradation releasing ATP, while the other part releases the remodeled protein and ubiquitin. This recirculates back to the pool of unfolded and misfolded proteins. Hence, the misfolded protein gets a chance to fold to its native functional form. The mechanism is termed post-translational quality control. The onset of pathological diseases occurs when protein escapes such quality control mechanisms and deposits into extracellular space. Protein aggregation associated with prion and amyloid diseases can be considered biologically relevant failures of post-translational quality control.

Complex Mechanisms

Mechanisms other than series and series-parallel mechanisms are classified under complex mechanisms. The following mechanism was proposed for β(25–35) amyloid-protein interaction:[13]

Amyloid fibrils of the β(25–35) peptide are a cytotoxic fragment of Alzheimer's β-peptide at position 25 and 35. The native, soluble, and folded state that is soluble interacts with the β(25–35) amyloid (step 1 in Fig. 6). The amyloid–protein complex forms aggregates and deposits (step 2). In some cases, the amyloid exerts a force to unfold the protein on the surface of the amyloid fibril (step 3). The unfolded or partially unfolded state has a stronger propensity to aggregate resulting in amorphous aggregates, which adhere strongly to the surface of the amyloid fibril and undergoes irreversible deposition.

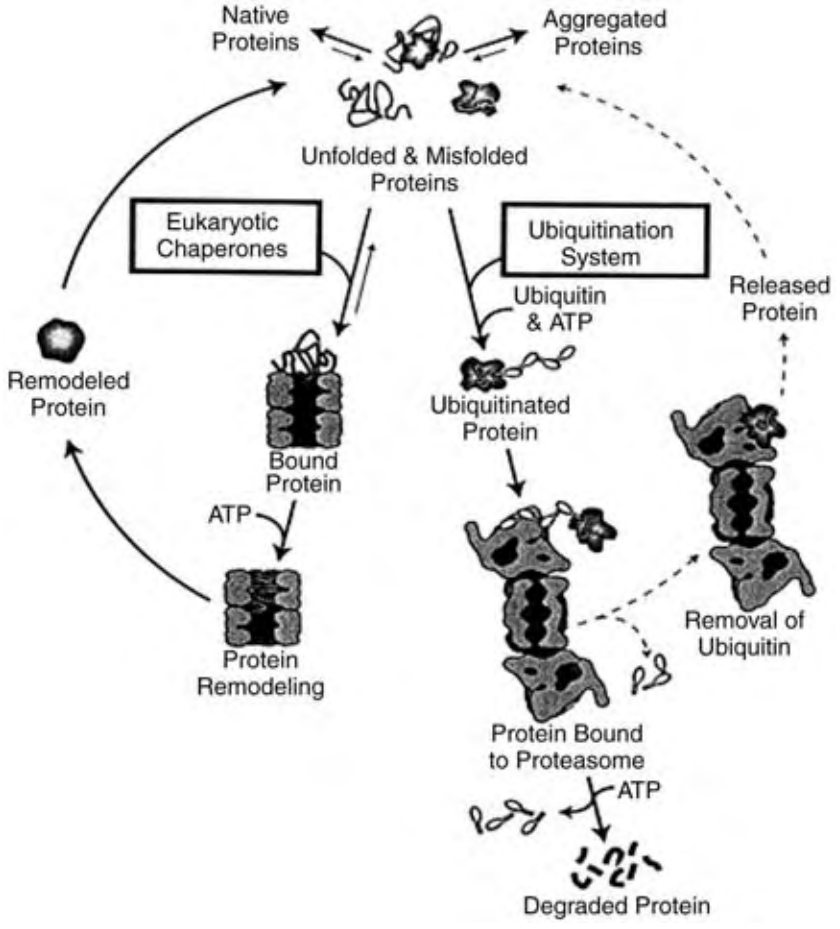

Fig. 5 Protein triage model–repair mechanism. (From Ref.[12].)

The β(25–35) interacts with the native protein, destroys its native conformation, and forms pathological aggregates. Its action is exactly opposite to that of a chaperone, which helps proteins fold correctly. Hence, β(25–35) is termed as an antichaperone. protein disulphide isomerase (PDI), a folding catalyst and chaperone, under certain conditions, can facilitate the misfolding and aggregation of its substrates during lysozyme folding. However, there is not enough evidence to prove that the aggregates are amyloidal in nature.[14] Although aggregation has been viewed as arising from nonspecific interactions, it is clear that specific interactions between the folding intermediates and/or misfolded proteins may be responsible for the

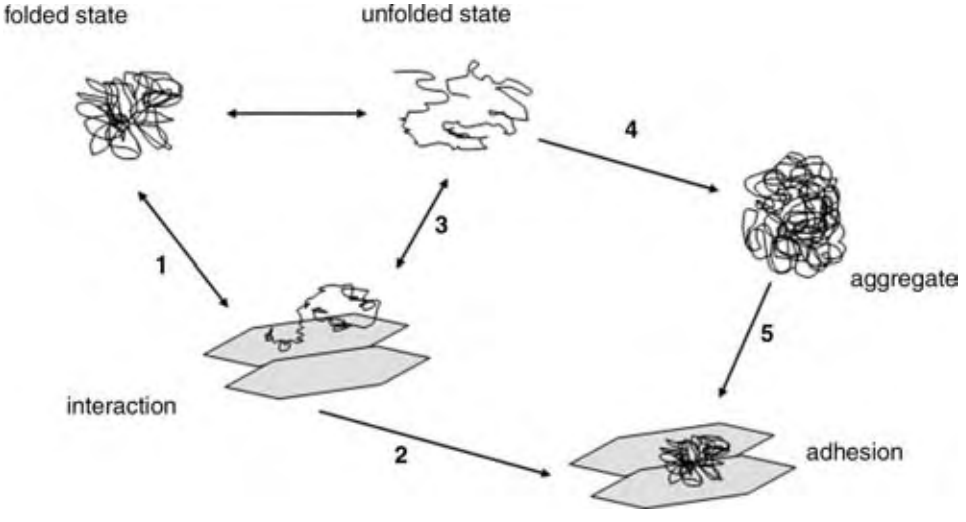

Fig. 6 Complex mechanism–β amyloid–protein interaction. (From Ref.[13].)

multiple interactions leading to the formation of large, insoluble aggregates.

UNIFIED MECHANISM FOR FOLDING

The unified mechanism for folding was presented in view of all the different categories of mechanisms. In most cases of aggregation, there is a kinetic competition between aggregation and other processes such as folding. The environmental conditions and the protein concentration(s) significantly affect the degree and rate of intermolecular association.[15] The mechanism is shown in Fig. 7.

In many cases, when aggregation occurs from a solution of the native protein, it is the partially folded intermediates in equilibrium with the native state that are the immediate precursors of the aggregates.

Longer-lived intermediates are more likely to lead to aggregation, because there is a greater chance of interaction with another such partially folded intermediates. In vivo, the molecular chaperones involved in preventing aggregation may become saturated, and thus there will not be enough free chaperones to bind to the newly synthesized protein, to help it fold to the native state.

Aggregation occurs when hydrophobic surfaces on proteins interact in an intermolecular manner. Three-dimensional propagation of such interaction leads to larger aggregates and deposits when the solubility limit is exceeded. In the unfolded state, the hydrophobic side chains are scattered around, whereas in intermediates there exists large patches of contiguous surface hydrophobicity. Hence, there is greater propensity for the partially folded intermediates to aggregate.

Two basic models have been proposed for amyloid fibril formation from the intermediates.[16] In the nucleation model, the intermediates cluster to form nuclei. Fibril is formed from the nucleus after the nucleus has reached a critical size. Such fibrils add on to its ends to form aggregates. In the polymerization model, intermediate peptide–PF complexes are formed and associate end to end or laterally to form fibrils. The amyloid fibrils also add to the existing PF and deposits, once the solubility limit is reached.

KINETICS OF AGGREGATION

Amyloid Fibrils

The origin of the essentially irreversible formation of fibril is that the peptide adds to the existing fibril, and then it is buried as other peptide(s) is added and the fibril continues to grow. Therefore, while the peptide at the reaction interface shows a reversible reorganization and deorganization with rate constants k_r and k_d, respectively, once the peptide is buried within the fibril, the rate of deorganization k_d is effectively zero.

Amorphous Aggregates

In amorphous deposits, the initial adsorption and desorption steps with associated rate constants k_a and k_d, respectively, are reversible. However, a peptide with the β-peptide deposit is essentially trapped making k_d effectively zero for those molecules that are not at the interface with the solution. Finally, within the amorphous deposit, the "β'' peptide that is not at the reaction interface in contact with the existing fibril has a rate of reorganization k_r, to the β-peptide that is effectively zero.

THERAPEUTIC STRATEGIES

In principle, masking the hydrophobic surfaces on intermediates and monomers can prevent aggregation. This would reduce the rate of aggregate deposition. A system of artificial chaperones (detergents and cyclodextrin), have been successfully used to minimize aggregation.[15] Increasing the stability of the native state prevents the backward reaction and does not favor the formation of the intermediates that lead to aggregate formation. Subsequently, this prevents

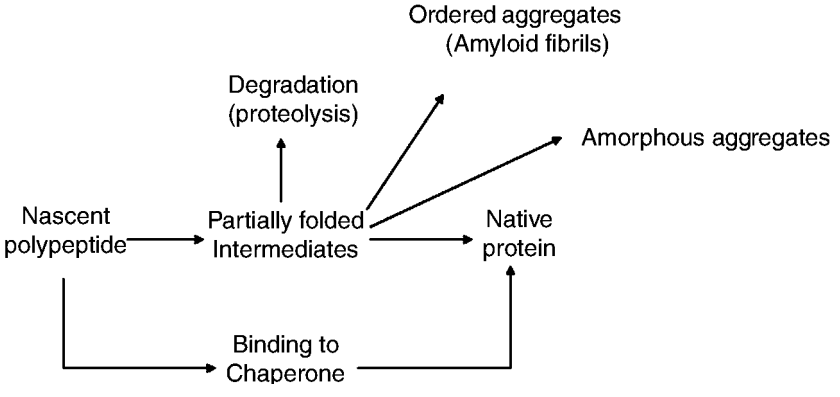

Fig. 7 Unified mechanism of protein folding. (From Ref.[15].)

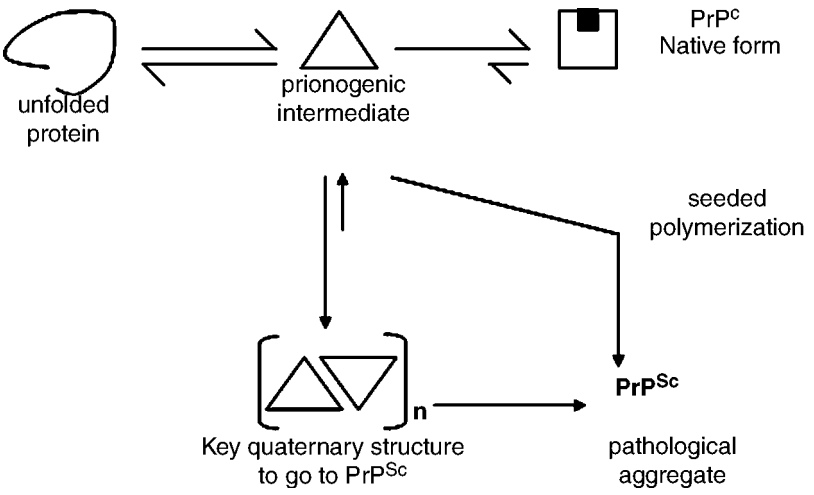

Fig. 8 Ligand binding to prion protein–a possible therapeutic strategy to prevent scrapie formation. (From Ref.[9].)

pathological deposits. Osmolytes and other stabilizing ligands (kosmotropes) may decrease the amount of aggregation. This presumably reflects differential stabilization of the native state. Osmolytes have been shown to inhibit prion formation in the scrapie system. This is consistent with the formation of prions.[15]

The stability of the native protein PrP^C is increased by ligand binding to the specific site on the protein molecule. This reduces the rate of conversion (backward reaction) of native protein to prionogenic intermediate that aggregates to form pathological PrP^{Sc}. The rate of amyloid formation is usually greatly enhanced by seeding. Hence, prevention of amyloid seeds will delay the onset of amyloid formation.

Therapeutic methods have been developed that are designed either to inhibit amyloid formation by blocking fibril growth. Diclofenac analogues that belong to the class of nonsteroidal anti-inflammatory drugs are transthyretin amyloid formation inhibitors[17] (refer to Fig. 8). Apart from these therapeutic strategies, surgical gene therapy and organ transplantation are the other methods of curing such diseases.[15]

THERMODYNAMIC PERSPECTIVE OF PROTEIN FOLDING

Kinetics and thermodynamics are always complementary for process study. While kinetics describes the rate of the process, thermodynamics analyzes its feasibility. As kinetic mechanisms describe the sequential search with the end state being a single protein having a particular function, a thermodynamic study involves

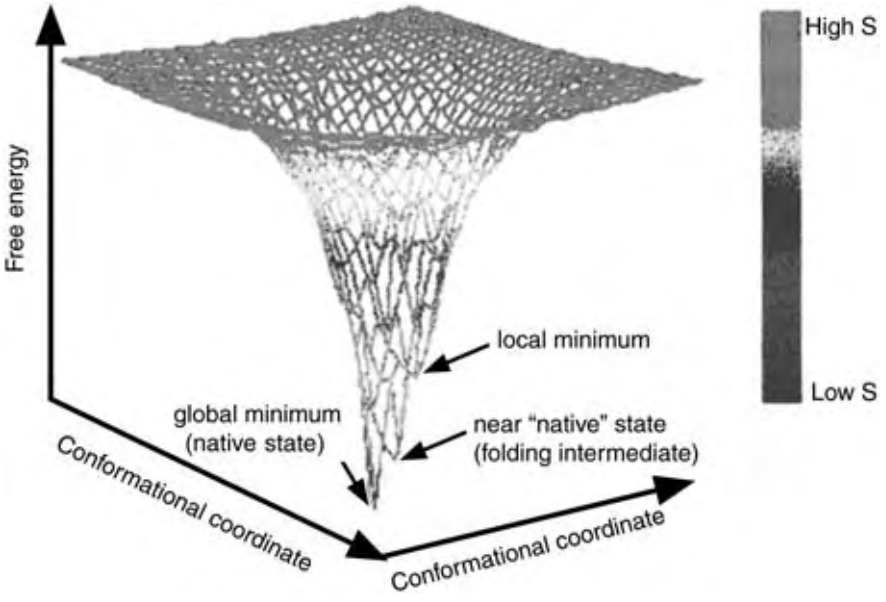

Fig. 9 Energy landscape diagram. (From Ref.[18].) *(View this art in color at www.dekker.com.)*

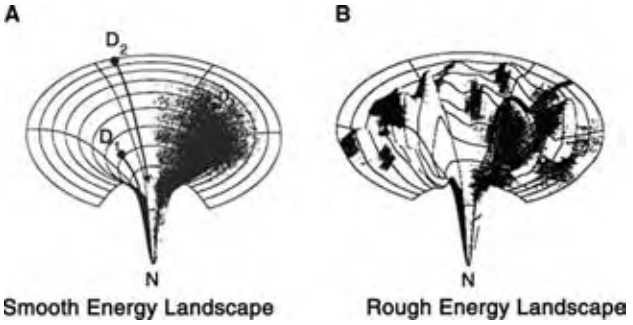

Fig. 10 (**A**,**B**) Comparison of smooth and rough energy landscape. (From Ref.[18].)

a conformational search with the end state being the single native structure of a given protein.

The thermodynamics of protein folding can be viewed as a ball rolling down a cone trying to reach a stable stationary position, which is the lowest point in the cone. In this case, the ball is the protein and the path traced by it, to reach the final position or the folded state, is the folding sequence. The cone represents the energy coordinates. Thus, protein folds to attain the least free-energy state. The plot is represented three dimensionally with the free-energy (z-axis) and conformational coordinates (x- and y-axis). Such plots or cones are referred to as energy landscapes.[18]

As we move down an energy landscape, many conformations have high energy and a few have a low energy. Conformations having high energy have high conformational entropy (high S), and states having low energy (native state and other deep minima) have low conformational entropy (low S) (refer to Fig. 9). Also, smoother funnel topography (surface) has implications about dynamics and time dependence, because the energy barriers are so small that the process happens quickly. For the smooth funnel, folding, kinetics should be fast and two-state, and for the rugged landscape folding, kinetics will be slower and more complex.

A protein can fold to only one native functional form. In the landscape, there should exist a point of least energy that corresponds to the native state. Such a point of least energy is called the global minima. However, there exist several local minima on the conformational coordinates on the energy landscape. Such points of local minima are ''kinetic traps,'' where folding might sometimes stop after attaining that minima. ''Kinetic traps'' refer to ''off-pathway'' proteins that may aggregate to form pathological aggregates. All such points of local minima can be joined together to form a parabolic curve called convex global underestimator (CGU).[18] Several CGU's can be constructed for a single landscape. The apex of the CGU corresponds to the lowest energy, and gives the global minimum. This is the ultimate native and functional state of the protein.

Figs. 10A and 10B show a section of a smooth energy landscape with three different proteins trying to attain a native state via different conformational pathways, and a section of another energy landscape with a rough topology, energy barriers, and local minima.

The transition of short protein from the unfolded to the folded state is accompanied by a drastic reduction of entropy. In this scenario, there is competition between the two minima of the free energy: the folded state with low energy and entropy, and the unfolded state corresponding to high energy and entropy. The folding mechanism can be viewed as multiple conformations racing down the funnel slopes in multiple paths, with some paths more heavily traveled than others.[19]

Fig. 11 represents the two-dimensional section of the energy landscape with the free energy plotted against the conformational coordinate. The CGU can

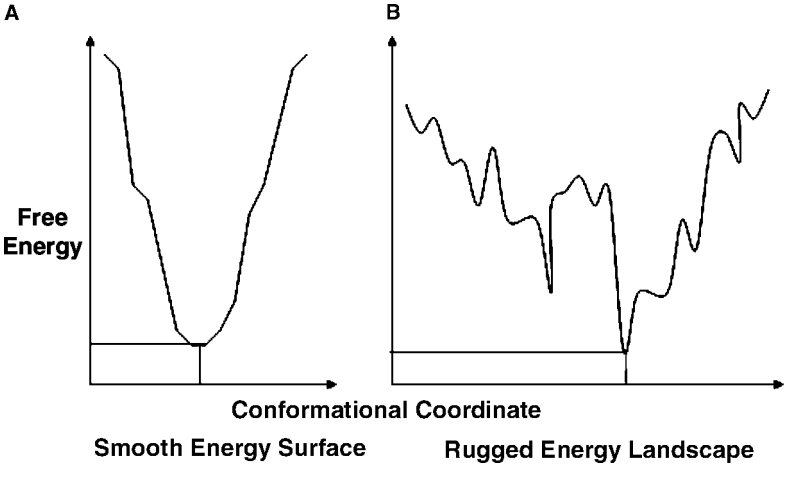

Fig. 11 Smooth and rough energy landscape fluctuations on a two dimensional coordinate. (From Ref.[18].)

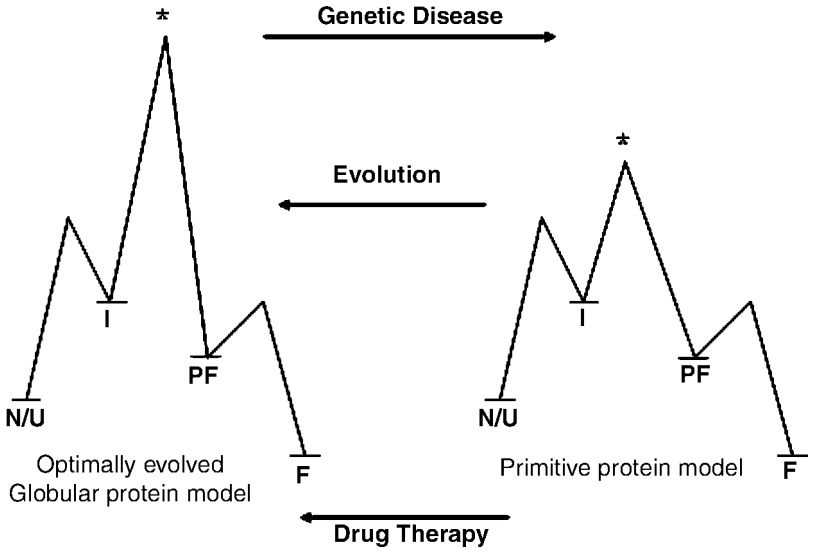

Fig. 12 Primitive vs. optimally evolved protein folding model. (From Ref.[7].)

be constructed for the rugged surface by joining all the points of local minima.[18] This would serve to find the global minima in the case of complex landscape and to convert the rugged surface to a smoother surface. Thus, the CGU removes all the local minima and the energy barrier. This also provides an easier and a correct route to reach the native state with the least free energy and entropy. This is a possible solution to complex landscapes.

KINETICS VS. THERMODYNAMICS

Pathological aggregates may be formed when a protein encounters local minima and fails to recover from it and folds further to a native state. A protein that folds through a complex mechanism must overcome all the energy barriers (up hills) and local minima (kinetic traps) to attain global minima (native state). The surface of the energy landscape would have more corrugations for a complex mechanism than either a series or a series-parallel mechanism. A series mechanism has a smoother surface where the local minima and the energy barriers are the minimum. Kinetically, the off-pathway steps have to be minimized to prevent aggregate formation. This implies a reduction in the number of local minima and the energy barrier towards the formation of the native state. In some cases, the native protein is unstable, and reverses to form aggregates via the intermediates. This could probably be because of the presence of a small energy barrier that the native protein can overcome to deposit into a ''deep'' local minima some where near the global minima. The role of chaperones would be similar to catalysts, where the activation energy to overcome the energy barrier and to rise out of the local minima is provided by the chaperone.

THERMODYNAMIC INERPRETATION OF THERAPEUTIC STRATEGY

Evolution has designed proteins to fold in a pathway that leads to their native form. However, proteins that tend to escape such pathways result in the deposition of aggregates. The free-energy diagram or thermodynamic diagrams for an optimally evolved protein-folding scheme vs. a primitive protein-folding scheme, which tends to form aggregates is shown in Fig. 12.[7]

Ribosomal production of the unfolded state leads to amyloid fibril formation in the primitive situation. In the optimally evolved globular protein, the model native state can be formed and fibril formation can be overcome by one of the three cases.[7]

Energy barrier to ordered aggregation that results from stabilization of the folded state.

Destabilization of the intermediate to prevent its build up.

An increase in the activation energy (*) for ordered oligomerization (I to PF), or the conversion of the intermediate to Protofilament (precursor to fibrils).

All therapeutic strategies are designed based on one of the three cases outlined above.

CONCLUSIONS

Protein-folding mechanisms are reviewed with the purpose of providing physical insights into the formation of fibrils and aggregates that deposit in different parts of the body and gradually lead to intractable diseases. The folding mechanisms were classified into three types. Examples in each category were given, and a unified mechanism for folding was proposed. The mechanism discussed in each category is related to a specific disease. Models and mechanisms of

aggregation and the kinetics of aggregate formation were presented. The focus was also on different therapeutic strategies, which prevent the β-peptide from precipitating and becoming toxic to nerve cells. The unified mechanism of protein folding was represented thermodynamically using energy landscapes. The regions relating to the formation of the native state and misfolded proteins were represented on the energy landscape. The entry describes the relation between the different kinetic mechanisms and its relation to the thermodynamic landscapes. The basic principle in the treatment of such intractable diseases caused due to misfolding lies in blocking or inhibiting the fibril formation. Thermodynamically, it refers to smoothening the surface of the energy landscape by reducing the kinetic traps or local minimas that lead to misfolding. Therapeutic strategies to cure diseases caused due to misfolded protein deposition can be designed and developed based on fundamental kinetic and thermodynamic principles. This entry is an effort to present mechanisms and methods that can be designed to block or prevent pathological aggregates deposition. This could be used to develop effective therapeutic strategies to cure diseases caused due to misfolding.

Protein Production in Transgenic Plants: Development and Commercialization

Wayne R. Curtis
Department of Chemical Engineering, The Pennsylvania State University, University Park, Pennsylvania, U.S.A.

INTRODUCTION

The potential for producing commercially important proteins in plants has been obvious since the first reports of successful integration of foreign genes in plants over three decades ago. However, to date, only Prodigene has produced a commercial recombinant protein product in transgenic plants.[1] The motivations include reduced production cost, scalability, avoidance of human pathogens, and eukaryotic post-translational modification; however, numerous problems have slowed down the progress. The range of application of this technology is quite large, from industrial enzymes to injectable or diagnostic monoclonal antibodies. Although in this entry the emphasis is on therapeutic proteins, the basic concepts and associated citations are equally applicable to any protein of commercial interest.

The use of genetic engineering to improve food production is ongoing throughout the world. While many of these companies are predominantly in the field of agriculture biotechnology (Monsanto, Syngenta), virtually every, other chemical company has significant agricultural chemicals divisions and plant biotechnology efforts (Dow AgroSciences, Bayer CropScience, BASF Plant Science GmbH, and DuPont Agriculture & Nutrition). The efforts of these companies are (presumed to be) largely focused on issues such as crop improvement (e.g., nutrition, food processing, cultivar development, etc.) and productivity enhancement (e.g., insect resistance and herbicide tolerance). The focus of this entry is specifically on the use of plants for protein production with an emphasis on pharmaceuticals. Because of lack of information, any efforts within—and collaborations between—large pharmaceutical and agrichemical companies are omitted. It must be kept in mind that the efforts of these companies have not only created the enabling technologies associated with transgenic plants, but are pushing the boundaries of genetic modification in plants as well. If ''molecular farming'' becomes profitable, these companies can and will likely become the major players.

TRANSGENIC PLANTS FOR AGRONOMIC PRODUCTION

The introduction of DNA into plant cells to facilitate expression of heterologous proteins such as human therapeutics has become routine. Strategies for DNA delivery are improving and evolving, but the use of *Agrobacterium tumafaciens* remains the dominant technique. Agrobacterium is a natural pathogen of plants that has the ability to transfer DNA from a specialized tumor-inducing plasmid. Genetic engineering involves replacing a portion of the transfer DNA (T-DNA) with the heterologous gene of interest (which is carried out in *Escherichia coli* by standard molecular biology techniques). Exposure of the plant tissue to Agrobacterium containing the modified plasmid results in integration of the T-DNA into the plant chromosome.[2,3] Other techniques including the introduction of modified plant viruses or chloroplast transformation will also be discussed in this section because they similarly represent approaches for genetically engineering plants to produce proteins. These three approaches are shown schematically in Fig. 1.

Much of the work with transgenic plants has focused on species that are ''easy'' to transform such as the Solonaceous family that includes tobacco, tomato, and potato. Commercial targets include more difficult species including corn and soybeans. An important aspect of understanding the technological development of transgenic plants is that ease of transformation does not imply speed. Regeneration of fertile plants from a transformation event that is often a single cell takes months to complete. In addition, the size of transgenic plants and the space needed for subsequent maintenance and genetic crosses invariably result in the academic screening of relatively small populations of plants (10–20 plants). The variation among these transformants is often quite large (order of magnitude) and it is not unusual to have plants that do not express the transgene at all. Not surprisingly, more intensive efforts that screen larger populations of plants are able to identify higher levels of expression; nonetheless, the levels of heterologous protein

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030629

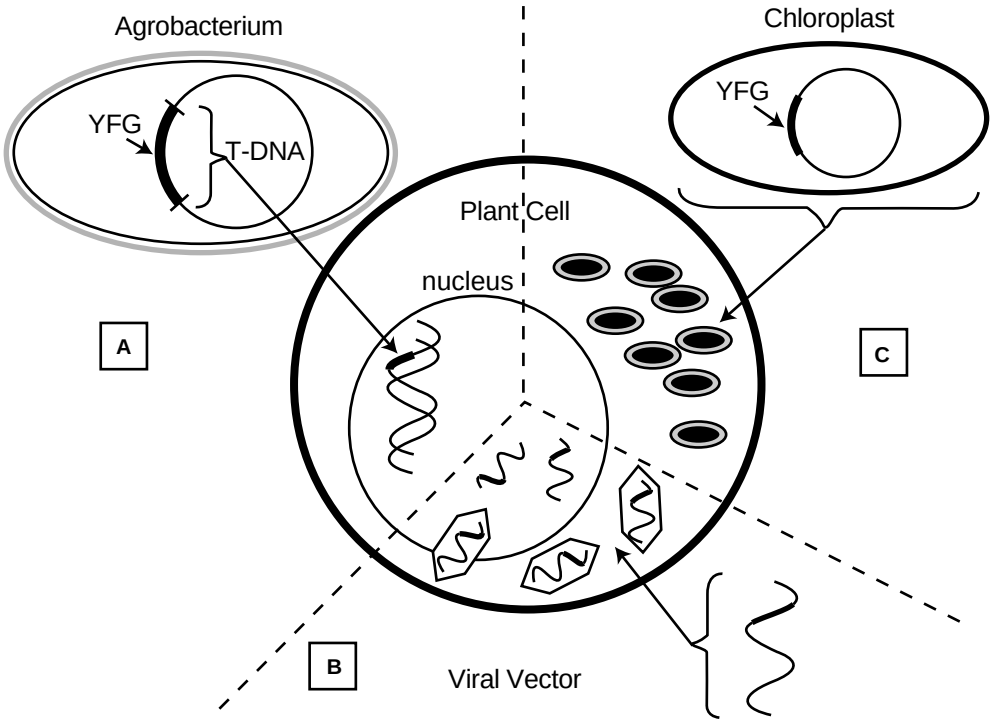

Fig. 1 Schematic of gene delivery strategies for producing protein in plants. (A) Agrobacterium where ''your favorite gene'' (YFG) is inserted into the bacterial T-DNA and infection results in transfer of the T-DNA to the plant chromosome; (B) DNA is inserted into the viral genome and the protein is produced as the virus amplifies inside the plant cell; (C) DNA is inserted into the chloroplast DNA resulting in protein expression inside the chloroplast

expression in plants are limited to relatively low levels (a few percent of soluble protein). One of the most important mechanisms limiting the expression is gene silencing. Technology is being developed using virus proteins, which inhibit this phenomenon as a strategy to overcome current limitations in expression levels.[4,5]

Stable Chromosomal Transformation

In the plant chromosome, each gene is driven by its own promoter. The most straightforward approach to transformation is the use of a constitutive promoter that expresses the heterologous gene ''all the time'' and in ''all'' tissues. The promoter of the cauliflower mosaic virus CaMV 35s protein is the most commonly used constitutive promoter.[6] Other promoters are gaining popularity for expression.[7] particularly for monocots (grasses). Use of specialized promoters opens up opportunities for controlling expression to specific organs or at specific times.[8] These different approaches to control gene expression are reflected in Table 2 among the technologies that have spawned companies. Wound-induced promoters were the strategy used by CropTech, Inc., where the protein was expressed only after the plant (tobacco) tissue was harvested and macerated. This provided a means of obtaining ''containment'' as the protein would be minimally expressed in the field. This strategy also exemplifies the advantage of an inducible promoter where toxic effects associated with expression can be minimized. Expression of proteins from genes integrated into the chromosome generates a protein extract that usually contains 99% plant proteins (Table 1).

The strategy of SemBioSys, Inc. is based on expression associated with oil bodies in seeds.[30] The premise of this approach is that the protein can be recovered from the majority of the contaminating proteins by partitioning with the oil fraction of the seed.[31] Seed specific expression is very attractive for commercial production because it is amenable to agronomic practices for harvest. Expression in seeds has also been shown to provide for long-term stable storage (years without refrigeration), and seeds are typically characterized by only a few ''contaminating'' seed storage proteins rather than the complex mixture found in other plant parts. Prodigene, Monsanto, and invariably many Agriscience groups have developed efficient strategies for corn and soy seed expression. The acquisition/affiliation of major seed companies by agrichemical companies (DeKalb and Asgrow by Monsanto, Northrup King and Ciba Seed by Novartis, and

Mycogen with Dow and Pioneer by Dupont) makes the perspective of plants as a chemical production platform a logical extension of these agrichemical businesses. However, seeds are also the dominant source of human nutrition.

Concerns for gene containment and public perception of genetically modified foods (and potential cross contamination) have placed a major roadblock in the path of these commercialization efforts. Examples of alternatives that achieve better-contained expression (e.g., potato tubers[12]) are given in Table 1. Transformed plant tissues in culture are also a contained system, where expression levels are comparable to those of other transgenic systems. As shown in Table 1, Monsanto developed and patented secreted antibody levels of 25–200 mg/L,[23] and reports for antibodies in tobacco cell suspension achieved 6.5% TSP.[22] More recent specialized production systems that can achieve containment include secretion from roots in hydroponics (Phytomedics, Inc.) and secretion from duckweed (BioLex). Phytomedics is based on a specialized promoter and secretion sequence that is induced by phosphate deprivation.[38] BioLex has reported prepurified protein titers of over 600 mg/L for α-interferon (www.biolex.com). According to news releases, these companies have each secured multimillion dollars of venture and government funding in 2003–2004, reflecting both progress and optimism for use of plants for protein production. It is improbable that any such containable plant production could compete with field-based production. Therefore, the continued development of these processes also reflects concern for the future of production of human therapeutics in the field. Growth of large quantities of transgenic plants in containment greenhouses and the use of underground mines for contained growth of plants expressing human cytomegalovirus glycoprotein[10] illustrate how containment concerns are impacting the development of this technology.

Viral Vectors

Genetic elements of viruses are ubiquitously used in genetic engineering to achieve supranatural expression in organisms. For viral vectors, the production system involves the use of a ''functional'' virus. The expression levels achieved by these systems are typically several percent of soluble protein—consistently higher than achieved by chromosomal integration (Table 2).

Viral vector technology launched a company called ''Large Scale Biology Corporation'' (LSBC^{TM}). Part of the commercialization plan is to grow tobacco plants and introduce the genetically engineered tobacco mosaic virus (TMV) into plants by high-pressure spraying. For field application, this system would require approval for ''release'' of a genetically modified organism (GMO) virus. There have also been concerns on the size of the protein that can be expressed efficiently without disrupting the virus as well as on the genetic integrity for an RNA virus. The extent to which these issues have been resolved is not clear; the role of virus-based expression of proteins has been significantly downplayed in current company literature.

The use of viral vectors has been impressively successful in expressing small proteins and epitopes as fusions with the viral coat protein. This approach also displays the protein on the surface of the viral capsid which has been utilized very effectively for achieving an immunization response in animal studies.[33,39] The initial use of this system appears to be as a development platform for protein production—much like baculavirus for mammalian protein production. The future of viral vectors beyond this stage depends upon issues of containment similar to field-grown transgenic plants. The cost-advantage of plant-based expression is severely reduced if plants must be produced in containment greenhouse conditions. Although studies have shown that genetically modified viruses have limited survival relative to their wild-type counterpart,

rational arguments of virus containment are subject to the same—sometimes nonscientific—scrutiny of the public (in this case it would include tobacco farmers whose crops could be a host). Viral vectors are discussed further under transient gene expression.

Chloroplast Transformation

Although chloroplast transformation is relatively new, it represents a significant breakthrough in plant transformation that has achieved expression levels that is several orders of magnitude higher than chromosomal integration.[40] In Table 1, reported expression levels of 7–46% of TSP are shown. Functional human growth hormone has been produced.[20] The highest expression level of 46% of leaf protein for the 65 kDa insecticidal ''Bt protein'' was associated with the precipitation of protein into ''inclusion bodies'' within the chloroplast. High levels of expression result from both the presence of many gene copies (200–10,000 plastids/cell) and the lack of gene regulation characteristic of the prokaryotic-like gene expression of the chloroplast. The prokaryotic nature of the chloroplast also confers limitations in desirable post-translational modification. Nonetheless, formation of disulfides and protein folding has been accomplished, and, because of its polycistronic nature, the chloroplast gene expression lends itself to introduction of multiple genes to facilitate modifications of gene expression that might be needed. At this time, technical information on gene expression from chloroplast transformation is very limited, as there is intense activity in development and patenting.

Patents and Politics/Start-Ups and Shut Downs

Successful genetic transformation in plants started with a flourish of patent applications in 1983 from Washington University, Max Planck Institute, and Monsanto. The application of Washington University took 17 years to be issued (U.S. 6,051,757, 4/18/2000). Max Planck Institute received its European patent September 5,1996 (EP 116,718). Ironically, Monsanto did not receive a U.S. patent based on these initial filings (though technically their initial approach to transformation could be considered superior). Attempting to understand the significance of these patents, or the dozens of related patents granted for plant transformation is outside the scope of this entry. The intellectual property landscape has become increasingly complex and includes a combination of techniques, genes, and genetic elements (promoters, terminators) so that understanding legal issues in genetic engineering of plants has become more difficult than understanding the technical aspects of generating transgenic plants.

In contrast to the general area of plant transformation, Monsanto has clearly had the dominant patent position in the niche area of pharmaceutical production in plants. In its acquisition of Calgene, Monsanto acquired the dominant patent in this field of human therapeutic protein expression in plants. Although the patent of Goodman et al. (U.S. 4,956,282, 9/11/1990) demonstrated and claimed expression of interferons in dicot plants, it became the pivotal enabling technology for mammalian gene expression in plants. Monsanto chose to exercise this patent (in conjunction with acquired Agracetus expertise) to pursue ''third party'' development of therapeutic molecules. However, on October 15, 2003, Monsanto announced dissolution of its Protein Technology business unit. In exiting this business, it stated that the decision was ''not a reflection on the performance of the business or the viability of the technology.'' It would appear that the obstacles that have slowed down the commercialization of this technology have diminished the useful patent life of their dominant patent (impending expiration 9/11/2007). Nonetheless, for the next few years, any company that intends to commercialize mammalian gene in transgenic plants will have to consider this patent as part of the ''freedom to operate'' (FTO). It is not clear how Monsanto plans to manage this lingering IP. It could either try to recover some value by licensing to a company that might want to get a ''headstart'' in this field or leverage this in public relations associated with GMO by sharing a more favorable ''limelight'' associated with the use of genetically engineered plants to improve human health. Either way, public opinion and liability will invariably play a large part in what happens in the next few years. The interesting consequence of an early dominant patent position for the area of mammalian genes in plants is that, postexpiration, there is equally broad FTO for commercialization. If issues associated with containment and public perception can be resolved, there are huge business opportunities. Commercialization of these technologies in non-U.S./EU countries such as India seems inevitable.

The fate of ''molecular farming'' is intrinsically linked to public perception associated with GMO and more specifically genetically modified food crops. ''Incidents'' associated with GM-plants have become familiar to the public: the contamination of tacos with Avantis' Starlink corn,[41] public outcry over the ''terminator gene'' to prevent seed replanting is often associated with Monsanto, who did not develop or ever own the technology,[42] and finally, the killing of monarch butterflies with B.t. *(Bacillus thuringiensis)* corn pollen in laboratories at Cornell,[43] all fuel concerns of the public and politicians. Reviews specifically discussing the details of safety are a better place to become acquainted with the technical details behind

these often misunderstood news stories.[44] These concerns became more tangible for Prodigene Inc., arguably the leader in technology to produce proteins in plants, because of their commercialization of several (non-mammalian) proteins from transgenic plants. While neither β-glucuronidase nor avidin appears to be current commercial products, these products provided much needed case studies on the processes associated with expression and purification of protein from transgenic corn.[17,45] These early successes were offset by a nearly disastrous USDA/FDA December 6, 2002, sanction for reported violation of the Plant Protection Act, where transgenic corn containing a protein being studied under an FDA-IND permit became mixed into a soybean crop as a result of ''volunteer'' growth the next year (FDA, release T02-46, 11/19/2002). In addition to a $250,000 fine, the company agreed to purchase half a million bushels of soybeans and pay for disposal as well as cleaning of the contaminated storage facility in Nebraska.[46] Besides the $3 MM price tag, this incident demonstrated the financial risk associated with ''molecular farming'' and validated concerns for containment of therapeutic molecules in food-crop species. Prodigene has survived this incident. In April 2004, Prodigene announced another commercial product (TrypZean™) a plant-produced recombinant bovine serine protease trypsin, and others are in development.[47] A final twist of irony is that Prodigene is one fourth owned by a publicly financed Iowa investment fund; therefore, Iowa taxpayers are indirectly gambling on the success of molecular farming. For field-based production (the basis of favorable economics), the strategies for gene containment must be incorporated in the initial stages of genetic engineering. There are many transgenic plant materials containing mammalian and human genes developed for commercialization that may remain indefinitely in laboratory seed collections. If issues of containment are dealt with to permit field-based production of therapeutic proteins in plants, Prodigene may benefit because its near demise has clearly refocused other efforts on more contained (and more expensive) production systems. Discoveries and associated patent rights have been a very important driving force for continued efforts in commercialization of pharmaceuticals in plants for ''startup'' ventures. A summary of some key patents and associated companies is provided in Table 3.

Many of the new companies have leveraged novelty of an expression platform (e.g., containment) as the competitiveness of the protein production platform. Epicyte, Inc. appears to have been an exception that developed proprietary expertise in antibody expression in plants without a discernable novel patent position (whether Epicyte obtained a license to operate from Monsanto is not clear; Epicyte was acquired by another ''startup,'' BioLex, Inc. in 2004). Because expression of mammalian genes in plants has been covered by the Calgene-Monsanto patent since 1990, much of the academic research in this area is not protected by intellectual property. This includes a wide variety of therapeutic proteins that have been expressed in plants. Several organizations at the academic–commercial boundary have made considerable advances toward commercialization: Fraunhofer IME, Aachen, or Schmallenberg Branches, Germany (and associated Research Center for Molecular Biotechnology in Newark, Delaware, U.S.A.) falls on the commercial boundary, while the Biotechnology Foundation Laboratories at Thomas Jefferson University, Philadelphia, Pennsylvania, U.S.A. and Boyce Thompson Institute for Plant Research (BTI), Cornell University Campus, Ithaca, New York, U.S.A. have more academic orientations. These groups have made tremendous public domain contributions to issues of glycosylation and pharmacokinetics of plant-expressed proteins (antibodies in particular) as reflected in the various tables and references of this entry.

There are numerous additional companies which have either faltered or altered their mission as the field of ''molecular farming'' continues to germinate. CropTech filed for bankruptcy in April 2003, while in the middle of a planned move from Blackburg Virginia to Charleston, South Carolina. Large Scale Biology Corporation has extensively diversified into providing a wide range of diagnostic and proteomic services to the applied plant biotechnology community. Both of these companies sought to utilize tobacco as the production platform; this alternative use of tobacco has had potential connections to Tobacco Settlement Funds to help spur their development. These funds can have continued impact on commercialization in the U.S.A. if they are managed as development funds by states looking to attract biotechnology industry.

The preceding brief summary of the current status of commercialization of protein production in plants is heavily focused on U.S. industry—owing to the knowledge of the author. It emphasizes the role of safety and public perception in addition to technical and economic feasibility as the factors dictating commercialization. Another very important influence on commercialization is the slow development time-scales for transgenic plants which is a motivation behind rapid expression systems as described in the next section.

RAPID PROTEIN EXPRESSION SYSTEMS FOR DEVELOPMENT

Developing a transgenic plant takes several months as a minimum—much longer for transformation that involves plant regeneration from embryogenic tissue.

Table 3 Key patents for protein expression in transgenic plant production systems (Note: The associated company relates to the company associated with commercialization of the patent)

Inventor(s)	Patent #	Filed: issued	Assignee	Company	Area
Goodman et al.	4,956,282	7/29/85 9/11/90	Calgene, Inc.	Monsanto	Mammalian proteins in plant cells
Moloney	5,650,554	12/30/94 7/22/97	SemBioSys, Inc.	SemBioSys	Protein on seed oil bodies to facilitate separation.
Cramer and Weissenborn	5,670,349	7/29/94 9/23/97	Virgina Tech Intellectual Properties, Inc.	CropTech	Post-harvest promoter (achieve containment)
Wesley et al.	5,804,694	11/6/95 9/8/98	Prodigene, Inc.	Prodigene	β-Glucuronidase production; first commercial product
Artnzen and Lam	5,914,123	6/7/95 6/22/99	Prodigene, Inc.	Prodigene	Edible vaccines in plants
Fitchen and Beachy	5,955,647	9/21/99 1/7/03	The Scripps Research Institute	Large Scale Biology Corp.	Proteins expressed in plants from tobacco mosaic virus (TMV)
Stomp	6,040,498	8/11/99 3/21/00	North Carolina State University	BioLex (+Epicyte)	Genetic engineered Lemna (duck weed) for protein production.
Raskin and Haran	6,544,789	3/13/00 4/8/03		Phytomedics, Inc.	Phosphate-starvation-induced promoter/hydroponic secretion.
Daniell and McFadden	6,680,426	9/19/02 1/20/04	Auburn University	—	Gene expression from plant chloroplasts

Techniques for expedited transformation of meristems and embryos risk chimeric tissues, but increase speed of obtaining tissue to examine stability and expression levels of the introduced gene. It can take several years to obtain sufficiently characterized seeds to permit production of milligram quantities of product for testing. This extended development time-frame tends to place plant-based production as a second generation production platform for established drugs rather than a primary development platform. This is unfortunate, as plant-based production should expand commercialization of new drugs because of lower production costs. Recently there have been several strategies to rapidly provide proteins expressed in plant tissues (Table 4) to speed up the development time-frame.

Laboratory techniques such as biolistics (gene gun) and DNA delivery to protoplasts are not discussed in this section, as they are inadequate for producing quantitative amounts of purified protein. The speed of the viral vectors does provide material in the time-frame of several weeks; therefore, this production system can provide both rapid and scaleable production. This system is described in the previous sections; it is still not clear how well the viral expression system can tolerate large proteins. Most of the reports concern epitopes or small proteins. In addition, the potential need for fusions with coat protein for efficient expression might also limit this system. The lack of reports to refute these concerns after many years suggests that there are serious limitations to using viral vectors for expressing some proteins.

Agrobacterium can facilitate transient expression in both intact and tissue cultured plants. Leaf infiltration involves introducing the Agrobacterium suspension into the intracellular spaces of the leaf, using pressure or vacuum.[52,53] This approach has been scaled to a level of a kilogram of leaves, sequentially vacuum infiltrated to permit recovery of 20 mg of purified full chimeric antibody used in pregnancy testing after only three days of coculture.[50] This system has also been successfully used to express single-chain antibodies and diabodies in tobacco leaves as well (Table 4). While this technique is scalable, it does require the production of tobacco leaf tissue as the substrate. Thus far, all reports have used either in vitro or greenhouse grown tobacco leaves; it would be interesting to see if field-grown material could also be used, as it would be less expensive.

Suspension cultured cells have also been used for transient expression.[54] This approach has been used to show that by combining two different Agrobacterium strains, the T-DNA from both (Fig. 1) can enter the cell and be expressed.[55] This approach is carried out in static culture where the cells are mixed with Agrobacterium and coculture takes place on an agar-solidified medium. This approach has been ''rediscovered'' recently in a slightly larger format,[45] where Agrobacterium are introduced into a lawn of plant cells created by growmg filtered plant cell suspension on solid media. Although this approach can provide small amounts of protein for functional testing, it is limited in terms of scaleup. This is particularly important because the levels of expression in transient culture are toward the lower end of what is observed in stable transformed lines (Tables 1 and 4). To alleviate this limitation, our laboratory has developed a liquid culture based transient expression system that can be scaled up in bioreactor systems.[56] This was accomplished by developing Agrobacterium auxotrophs[48] that were selected specifically for their inability to grow in liquid culture medium. Using this system, the Agrobacterium growth can be controlled and permit

Table 4 Transient expression of heterologous genes in plant tissues using Agrobacterium-delivered T-DNA (no viral vector)

Protein/peptide	Titer	Host: approach	Ref.
β-Glucuronidase	0.03% TSP	*Nicotiana glutinosa* cell suspensions; liquid co-culture w/Agro	Collens et al.[48]
β-Glucuronidase	Qualitative	Tobacco cell suspension, static co-culture 5 days with Agro; ~150 mg FW tissue/treatment	Fuentes et al.[49]
CryIAbl (insecticidal protein)	0.25 μg/ml extract		
Antibody, hepititus B surfice antigen	0.62 μg/ml extract		
HCG antibody, pregnancy test, scFv, 33 kDa	32 μ/g FW (purified)	Tobacco leaves, vacuum infiltrated Agro; cocultured for 3 days; ~1kg leaf tissue	Kathuria et al.[50]
Diabody, 66 kDa	40 μg/g FW		
full antibody, 170 kDa	20 μg/g FW		
Diabody, carcinoembryogenic antigen	12 μg/g FW	Tobacco leaves, vacuum infiltrated Agro; cocultured 3 days; ~1 kg leaf tissue	Vaquero et al.[51]

expression in liquid grown plant cell suspensions, germinating seeds or other plant tissues in a time-frame of several days. Scalability can be accomplished based on standard bioreactor technology, and biomass production can come from many different formats.

These rapid expression technologies have developed to try to reduce the time-frame for protein expression in plants. Protein is expressed in plant tissues in a small fraction of the time and effort it takes to generate transgenic plants and should prove valuable for rapidly producing quantitative amounts of protein for early stage testing of therapeutic proteins. The recent concerns for containment and potential advantages of non-animal-based production of proteins for safety reasons may also make these approaches a potential alternative to other contained production systems. This is particularly true if the expression levels can be enhanced. The potential is particularly high for quantities of protein that are quite small (e.g., diagnostics) where there is no real advantage to the scale of production that would be represented by field-based production. Because transient systems include both plant and bacterial proteins, they are inherently ''messier'' than transgenic plants. Purification becomes particularly important as described briefly in the next section.

PROTEIN PURIFICATION FROM PLANTS

The predominant focus of this entry is on the production of proteins, and specific details on protein purification can be found in references which deal more specifically with this topic.[57,58] Only general comments will be provided here as the separation strategy is invariably linked to the production system. Specific details of protein purification will be dependent on the molecule of interest and intended purpose.[59,60] In the case of edible vaccines, the hope is to eliminate purification. In this case, the protein being expressed contains the antigenic epitope with the intent of obtaining a mucosal antibody response. As noted above, the use of viral vectors with coat-protein fusions has particular advantages by presenting the antigen on the surface of the virus particle. Virus particles can also be the purified product, as it has been shown that injection of the chimeric plant virus can produce IgG response. Reviews on plant-based vaccines can provide the details of this very broad and complicated area of research. Industrial or commercial enzymes can be used at a minimum level of purification, while injectable therapeutics require absolutely meticulous purification and process validation with the FDA. If agronomic production of proteins becomes a reality, the great reduction in production costs will offset the costs of development and implementation of new process schemes for protein purification from plants. However, if requirements for containment impose cost restrictions on production (transgenic greenhouses, GMP process tanks, etc.), then the ability to tolerate more difficult separations will be reduced. Transgenic expression in leaf extracts provides a ''messy'' starting point for purification. This is particularly true for expression senescing tissue (e.g., CropTech) or plant tissues that have high content of phenolics or other compounds that can react with the proteins. Transgenic production in seeds permits separation from a subset of storage proteins. In corn, seed storage proteins (zeins) should be relatively easy to separate from many therapeutic protein candidates. The strategy of SemBioSys is a novel means of reducing ''hydraulic load'' by partitioning protein with oil bodies; however, this introduces a predominantly hydrophobic phase that is an atypical starting point for downstream purification. While the production of chloroplast ''protein crystals'' may facilitate high levels of production and initial separation, the ability to utilize this will depend on the characteristics of the protein and ability to recover functional protein. The secretion approach of Biomedics and BioLex produces dilute initial concentrations—but with the advantage of avoiding contamination with intracellular proteins.

CONCLUSIONS

Use of plants as a production platform for proteins is rapidly advancing. This is being driven by discoveries in control of gene expression in plants, perceived future needs of the pharmaceutical industry and maturing patent positions. Safety, gene containment and public acceptance are equally important inertial forces shaping the industry. In the next decade, commercialization of nontherapeutic (lower value) proteins in plants is inevitable as expression levels increase and the industry gains experience. Commercialization of biologically active (high value) human therapeutics is more problematic because of issues other than technical and economic feasibility.

INTRODUCTION

This article provides a basic explanation of fuel cells, especially the fundamentals of proton-exchange membrane fuel cell (PEMFC). Starting with an introduction to fuel cells, it addresses principles, materials, fuel generation processes, and future technological challenges of PEMFC.

DEFINITION

A fuel cell is defined as an electrochemical device in which the chemical energy of a fuel is converted directly into electrical energy. The fuel is typically a conventional fuel, such as an alcohol or a hydrocarbon, or a substance derivable from it, e.g., hydrogen, which can be supplied continuously. The term directly implies that the device has an anode at which the fuel is electrocatalytically oxidized with the concomitant production of electrons, and a cathode at which a continuously supplied oxidant, typically oxygen, is reduced. The electrodes sandwich an electrolyte layer through which ions produced at the anode (e.g., H^+) or at the cathode (e.g., OH^-, O^{2-}, CO_3^{2-}) diffuse, but not electrons, which proceed through the external circuit where useful electrical work may be extracted. Fuel cells are distinct from batteries, wherein the fuel is typically a metal sealed into the device.

BRIEF HISTORY

The ''fuel cell effect'' was first discovered in 1838 (published in 1989) by C.F. Schoenbein who found the ''inverse electrolysis'' principle in his experiment using platinum electrodes immersed in dilute sulfuric acid solution.[1] However, the invention of the ''fuel cell'' is credited to W.R. Grove who demonstrated Schoenbein's discovery on a practical scale by inventing the ''gas battery'' during 1839–1845.[2–4] Fig. 1 shows an early experiment in which hydrogen and oxygen gases were produced by applied electric current and collected in the small tubes holding the electrode. When the electric current was stopped, a current in the reverse direction was observed, which was generated by the recombination of the gases on the platinum electrodes. The electrochemical reactions took place at gas–liquid–solid interface and the platinum electrodes acted as catalysts, as well as current collectors. W.R. Grove realized the importance of the ''surface of action'' and designed platinum electrodes with deposited platinum particles to increase the surface area of the reaction.[3] In 1889, the term ''fuel cell'' was coined by L. Mond and C. Langer, who utilized a three-dimensional porous electrode structure.[5] In 1894, the utilization of coal as a fuel for fuel cell was designed and coal-based fuel cell employing molten carbonate was developed in early 1900s, and solid oxide fuel cell, molten carbonate fuel cell, alkaline fuel cell were developed later, and phosphoric acid fuel cell was the last fuel cell invented in 1967.[6–8] In 1965, United Technologies Corporation (UTC) produced alkaline fuel cell for the Apollo Lunar Mission. In the late 1950s and early 1960s, General Electric (GE) started to work on fuel cells and developed the first fuel cell, based on a proton-exchange membrane (PEM) as the electrolyte.[9–11] The PEMs used were blends of inert polymer with a highly cross-linked polystyrene-based ionomer, sulfonated phenol-formaldehyde, and heterogeneous sulfonated divinylbenzene cross-linked polystyrene. However, these materials were found to be chemically degraded during the operation of the fuel cells. A solution came in mid-1960s through the collaborative efforts of GE and DuPont, resulting in the development of the Nafion® membrane. In August 1965, the Gemini 5 spacecraft used GE's PEMFC as a source of electrical power. In 1986, Los Alamos National Laboratory (LANL) demonstrated a high surface area electrocatalyst layer that included ionomer gel to increase the three-phase interface and, thus, reduced the amount of catalyst loading significantly without a loss in the cell performance.[12] In 1991, Ballard designed the ''serpentine'' flow field in bipolar plates

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007780

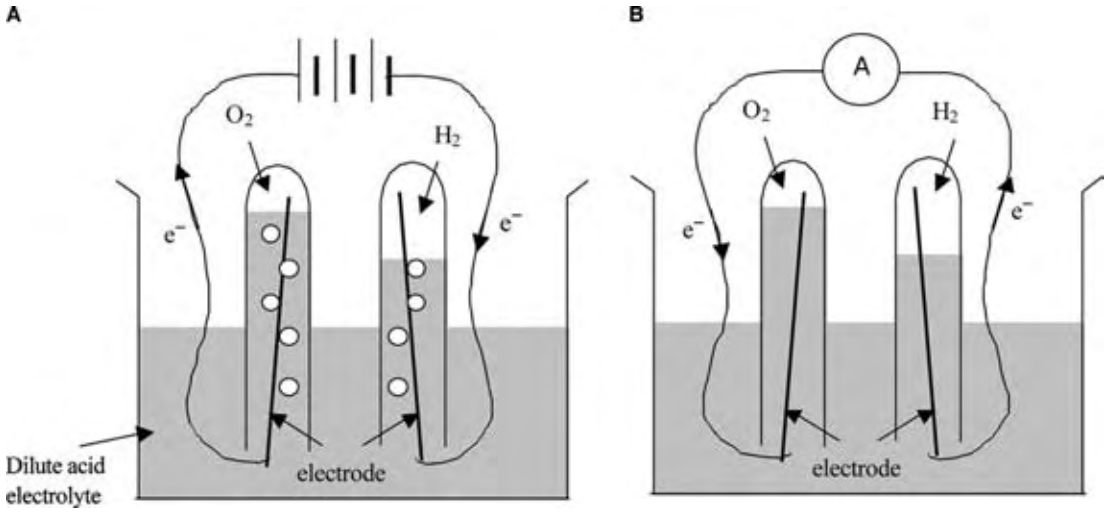

Fig. 1 Comparison of electrolysis (A) and fuel cell (B).

to facilitate water removal from the cathode, thereby improving performance through enhanced oxygen distribution to the cathode.[13] Since the middle of 1990s, a significant number of fuel cell programs have evolved. In recent years, almost all of the major auto-makers, e.g., General Motors (GM), Toyota, Daimler-Benz, Honda, Nissan, and Ford, have made substantial investment into the development of fuel cell technology for use in fuel cell vehicles (FCV), which would provide higher efficiency and require less maintenance than conventional engines. Fuel cells are also of interest for stationary energy generation because they can provide power directly at the site of use and avoid energy distribution losses. Recent progress in reducing the costs and improving the performance and durability of fuel cells promises that, in the near future, this revolutionary technology will be an important power generation system that is reliable, clean, and environment friendly.[14–19]

TYPES

Fuel cells are usually classified by the electrolyte employed in the system, which determines the operating temperature and, hence, the fuel that could be utilized. Table 1 summarizes the characteristics of different types of fuel cells.[20–22]

Alkaline Fuel Cell

Alkaline fuel cell (AFC) was used for Apollo and Space Shuttle program. Alkaline fuel cell employs liquid alkaline, e.g., KOH, as an electrolyte so that fuel, as well as air or oxygen, should be free of CO_2 because the strong alkaline electrolyte reacts with CO_2 to form carbonates, which reduces the ionic conductivity. Electrodes, e.g., Ni, Ag, and metal oxides, are relatively inexpensive compared to that of other fuel cells.

Table 1 Comparison of different types of fuel cells

Type	Fuel	Electrolyte	T (°C)	Charge carrier	Anode reaction	Cathode reaction
AFC	H_2	KOH	65–220	OH^-	$H_2 + 2OH^- \leftrightarrows 2H_2O + 2e^-$	$\frac{1}{2}O_2 + H_2O + 2e^- \leftrightarrows 2OH^-$
PEMFC	H_2	PEM	80	H^+	$H_2 \leftrightarrows 2H^+ + 2e^-$	$\frac{1}{2}O_2 + 2H^+ + 2e^- \leftrightarrows H_2O$
PAFC	H_2	H_3PO_4	205	H^+	$H_2 \leftrightarrows 2H^+ + 2e^-$	$\frac{1}{2}O_2 + 2H^+ + 2e^- \leftrightarrows H_2O$
MCFC	H_2, CO, CH_4	$LiCO_3$–K_2CO_3	650	CO_3^{2-}	$H_2 + CO_3^{2-} \leftrightarrows H_2O + CO_2 + 2e^-$	$\frac{1}{2}O_2 + CO_2 + 2e^- \leftrightarrows CO_3^{2-}$
SOFC	H_2, CO, CH_4	YSZ	600–1000	O^{2-}	$H_2 + O^{2-} \leftrightarrows H_2O + 2e^-$	$\frac{1}{2}O_2 + 2e^- \leftrightarrows O^{2-}$

Phosphoric Acid Fuel Cell

Phosphoric acid fuel cell (PAFC) was the first fuel cell to be commercialized. PAFC uses liquid phosphoric acid as an electrolyte, which is soaked in silicon carbide particle matrix using capillary action. PAFC is tolerant to CO_2 feed stream because the electrolyte is an acid. However, carbon monoxide poisons the Pt electrodes so that its concentration should be below 3–5 volume % in the feed stocks.

Proton-Exchange Membrane Fuel Cell

Proton-exchange membrane fuel cell (PEMFC) is receiving the main attention today. Proton-exchange membrane fuel cell employs a solid polymer with acid sites as an electrolyte so that the cell can easily be stacked. In the presence of water, the acid sites dissociate to provide the protons for conduction. Thus, the feed gases must be humidified to provide good proton conductivity. The management of water is one of the important issues in PEMFC. The operating temperature of PEMFC is below 100°C, typically around 80°C, which is set by the thermal stability and conductivity of polymeric PEMs. Some increase in operating temperature may be possible under pressurized conditions or with electrolytes that perform adequately at low relative humidity.

Direct Methanol Fuel Cell

Direct methanol fuel cell (DMFC) was developed in 1950s–1960s, based on the liquid alkaline or aqueous acid solution as the electrolyte. It converts the methanol directly into electricity, instead of using ''indirectly'' produced hydrogen from methanol through the reforming process. Today, DMFC commonly refers to as the one that employs PEM as the electrolyte. Fuel for DMFC is a dilute solution of methanol, usually 3–5 wt% in water. The size of DMFC can be considerably smaller than PEMFC because of the elimination of fuel processor, and complex humidification and heat management systems. The performance of DMFC is relatively low compared to that of PEMFC.

Molten Carbonate Fuel Cell

Molten carbonate fuel cell (MCFC) uses an electrolyte composed of a molten mixture of carbonate salts, e.g., lithium carbonate, potassium carbonate, and sodium carbonate, usually retained in a ceramic matrix, e.g., $LiAlO_2$. When heated to a temperature of around 650°C, these salts melt and become conductive to carbonate ions (CO_3^{2-}). Natural gas can be used directly without a fuel processor because of the high operating temperature (~650°C). Nickel (or Ni–Cr) and NiO have been used for anode and cathode materials for MCFC, respectively.

Solid Oxide Fuel Cell

Solid oxide fuel cell (SOFC) uses solid ceramic material, such as Y_2O_3 stabilized ZrO_2 (YSZ), as an electrolyte. As SOFC operates at high temperature (600–1000°C), a variety of fuels, e.g., hydrogen, methane, and carbon monoxide, can directly be utilized. The high temperature places severe constraints on material selection and results in difficult fabrication process. Co–ZrO (or Ni–ZrO) and SrO doped $LaMnO_3$ have often been used for anode and cathode materials, respectively.

PRINCIPLES OF PEMFC

Working Principle

A schematic diagram showing the nanostructure of the PEMFC is shown in Fig. 2.[23] PEMFC has received tremendous attention lately because of its potential in transportation and other applications, and is the focus of this review. The fuel, typically H_2, is fed continuously to the anode and the oxidant, usually O_2 from air, is fed continuously to the cathode. At the surface of the anode, the fuel is converted into protons (H^+) and electrons (e^-). The protons travel through a PEM, which prohibits the flow of electrons to the cathode. The electrons (e^-) are, thus, forced to travel through an external wire and deliver part of their energy to a ''load'' on their way to the cathode. At the cathode, the transferred protons and the energy depleted electrons combine with oxygen to produce water. Hydrogen and methanol are the common choices as fuels because of their relatively high activity at low temperatures (<100°C). Gaseous oxygen, or air, is the most common choice for the oxidant because it is readily and economically available. In principle, other fuels and oxidants can also be utilized. The electrochemical reactions take place at the surface of the electrode that is in contact with both the PEM as well as the backing of carbon paper or carbon cloth, which provides a conductive and porous medium that simultaneously allows the flow of reactant gases, liquid water produced, and electrons. The catalyst layer is usually 5–50 μm in thickness and consists of platinum nanoparticles, e.g., 2–4 nm in diameter, supported on the carbon black particle, e.g., 30 nm in diameter. The amount of the Pt on the carbon support is 10–40 wt%

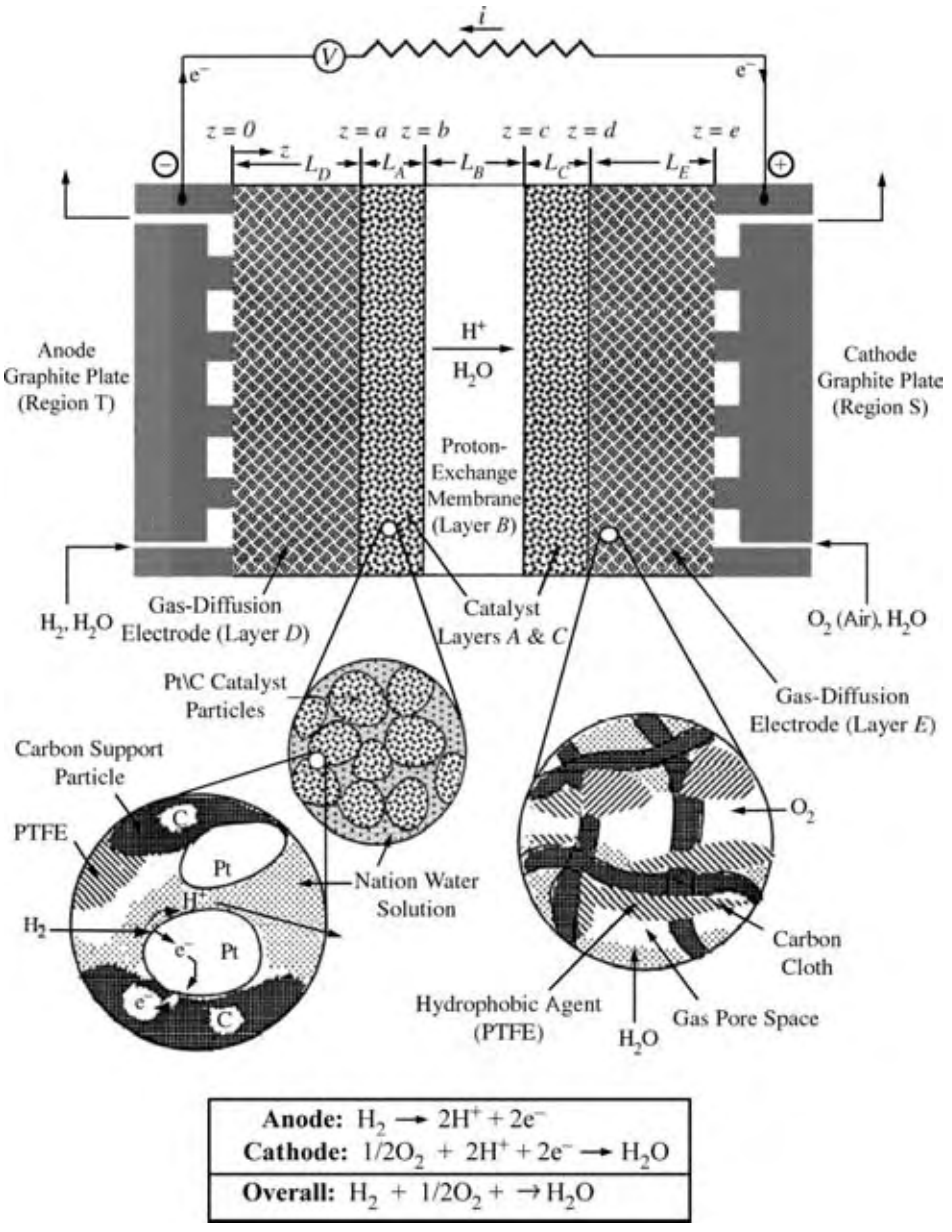

Fig. 2 A schematic representation of H_2/O_2 PEMFC.

and the loading of Pt is in the range of 0.1–0.4 mg/cm^2 MEA and 1–4 mg/cm^2 MEA for PEMFC and DMFC, respectively, where MEA (Membrane-Electrode-Assembly) refers to a proton exchange membrane, anode and cathode, and gas diffusion layers (GDLs). The electrode is mixed with an ionomer solution, e.g., Nafion, a common PEM, to provide a conduction medium for protons within the electrode layer. To bind the electrode particles together and facilitate the water management within MEA, the hydrophobic poly-tetrafluoroethylene (PTFE) solution may be added to the electrode. The protons produced at the anode travel through the membrane by virtue of the electric field created across the membrane between the anode and cathode.

Essential Concepts

Potential

An electrical potential exists across the interface between an electrode and an electrolyte, when partitioning of electrons and charged species occurs between the electrode and the electrolyte.[24–26] Consider the immersion of platinum electrode in acid electrolyte containing hydrogen ions as an example. Equilibrium would soon be established between the hydrogen ions in solution near the electrode, the electrons on the surface of the electrode, and the dissociated hydrogen atoms on the Pt surface

$$Pt + H^+ + e^- \leftrightarrows Pt - H \quad (1)$$

The H^+ represents a hydrated proton in the form of hydronium ion H_3O^+, which itself is hydrated. As a result, the electrons build up on the electrode surface in a layer, while the hydrated protons form an adjacent layer in the electrolyte, setting up a double layer of charges. Fig. 3 shows an example of the double layer formed near the negative electrode. The separation of charges leads to a potential difference between the electrode and electrolyte. The potential difference across the double layer at equilibrium would be the ideal potential of the electrode. However, the absolute potential between the electrode and electrolyte cannot readily be measured experimentally. Thus, the potential is typically given with reference to a reference electrode, where the potential corresponding to the reversible equilibrium between hydrogen gas at one atmosphere and hydrogen ion at unit activity is taken as zero at all temperatures. This defines the standard hydrogen potential (SHP) scale on which all other potentials are quoted.

Current

At equilibrium, Eq. (1) is in its dynamic condition, i.e., the rate of forward reaction equals the rate of the reverse reaction. If Eq. (1) departs from equilibrium, i.e., one of the directions of the reaction is faster than the other, then the net flow of protons and electrons, or current, develops. The anode is defined as the electrode at which the de-electronation reaction occurs and the cathode as the electrode at which the electronation reaction occurs. The rate of the electron transfer reaction can be written in terms of current, which is defined by the movement of electrical charges carried by electrons in an electronic conductor and by ions in an ionic conductor. The more the system is away from equilibrium, the higher the current. As the current is a measure of the rate of the reaction, the current is a function of the concentration of the species participating in the electrochemical reaction. The direction of conventional current is defined by the direction of flow for a positively-charged particle and, therefore, electron flow is opposite in direction to conventional current flow. Fig. 4 shows a schematic representation of the anode, the cathode, corresponding electron flows, net electron flow, current flows, and net current flow.

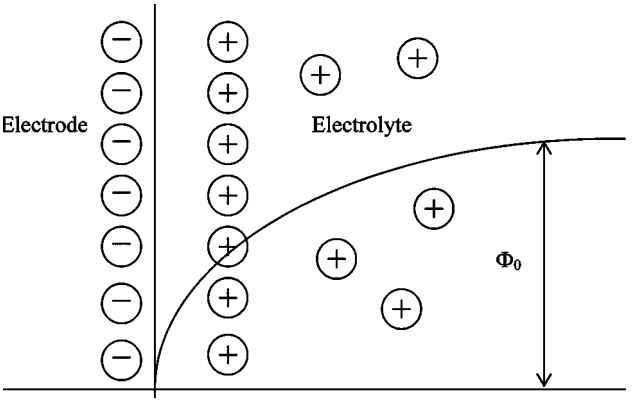

Fig. 3 A schematic of double layer at the surface of an electrode and potential gradient established between the layers of charges.

Overpotential

The overpotential η is defined as the difference in the potential of an electrode between its equilibrium and operating potentials when a current is flowing. Thus, higher overpotential leads to a higher current, the direction of which depends on the sign of the overpotential. The overpotential represents the extra potential energy needed to force the electrode reaction to proceed at a desired rate and in a desired direction. Charging the potential of metal electrode changes the energy of the surface electrons for the charge transfer by changing the position of Fermi level.[26,27] Fig. 5 illustrates the electron transfer by the applied potential, which alters the electron energy level of the metal electrode and, thus, facilitates the reduction or oxidation reaction. For a desired current density, the value of the overpotential also depends upon the inherent rate of the electrode reaction, i.e., a fast reaction will need a smaller overpotential than a slow reaction. The rate of an electrode reaction, of course, depends upon the temperature, potential, and activities of reacting species at the interface.

Electrochemical interface

Electrochemical reactions in a PEMFC occur at the ''three-phase interface,'' where the three necessary components for the reaction, i.e., reactant (e.g., gas), electron conductor (e.g., metal electrode), and ionic conductor (e.g., solid polymer electrolyte), meet. Fig. 6 schematically illustrates this in the PEMFC situation. The three components can actually meet, not only on the line defining the three-phase contact, but also in an area of two-phase contact, where gas molecules dissolve and diffuse through the electrolyte onto the electrode surface. As the electrochemical reaction depends on the concentrations of reacting species at the interface, the diffusion and solubility of the reactants and products in the electrolyte are important parameters in determining the overall rate of the electrochemical reactions. In practice, the polymer electrolyte, which is dissolved in solution, is mixed with electrode

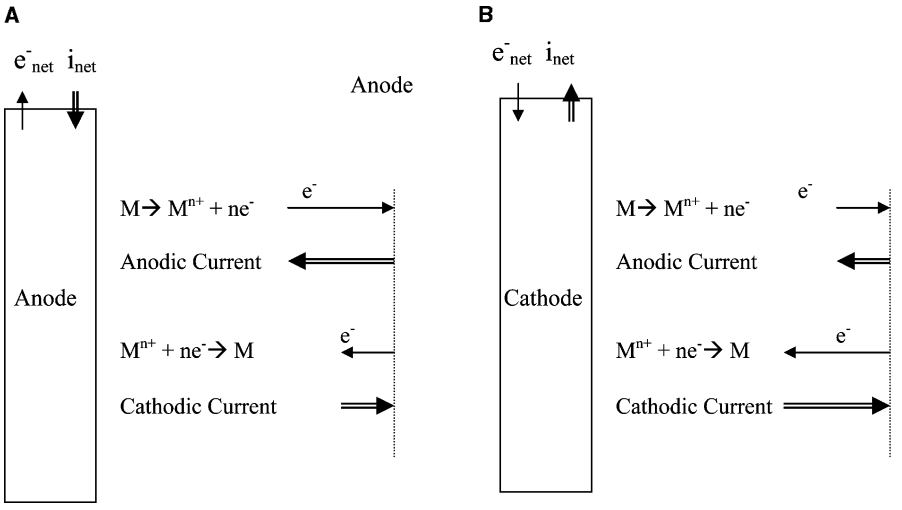

Fig. 4 A schematic representation of an anode (A) and a cathode (B) with their corresponding electron and current flows.

particles (Pt black or Pt/C) to increase the electrochemical interface to improve the overall rate of the reaction and thus, the performance of PEMFC. A thin layer (~1 nm thickness) of electrolyte is often envisioned to cover the electrode particle. However, the entire surface of electrode particle should not be covered by the electrolyte because this would preclude the electronic continuity. The electrode and the electrolyte phases need to maintain their continuity as conductors of charged reaction products, namely, electrons and protons, respectively.

Thermodynamics

A PEMFC converts the chemical energy of reactants into electrical energy by electrochemical reactions, which involve the transfer of electrons across the interface. Thermodynamic analysis describes fundamental aspects of the relationship between the thermodynamic and electric energies. An electrochemical reaction may be written in the generic form[23]

$$\sum_{\substack{i=1 \\ i \neq e^-}}^{n} \nu_{\rho i} A_i^{z_i} + \nu_{\rho e^-} e^- = 0 \tag{2}$$

where $\nu_{\rho i}$ is the stoichiometric coefficient of species i in reaction ρ, A_i is the chemical species i, z_i is the charge number of species i, $\nu_{\rho e^-}$ is stoichiometric coefficient of electrons in reaction ρ, and e^- represents the electrons participating in the reaction ρ. The electrochemical reactions should satisfy the charge balance, i.e.,

$$\sum_{\substack{i=1 \\ i \neq e^-}}^{n} \nu_{\rho i} Z_i = \nu_{\rho e^-} \tag{3}$$

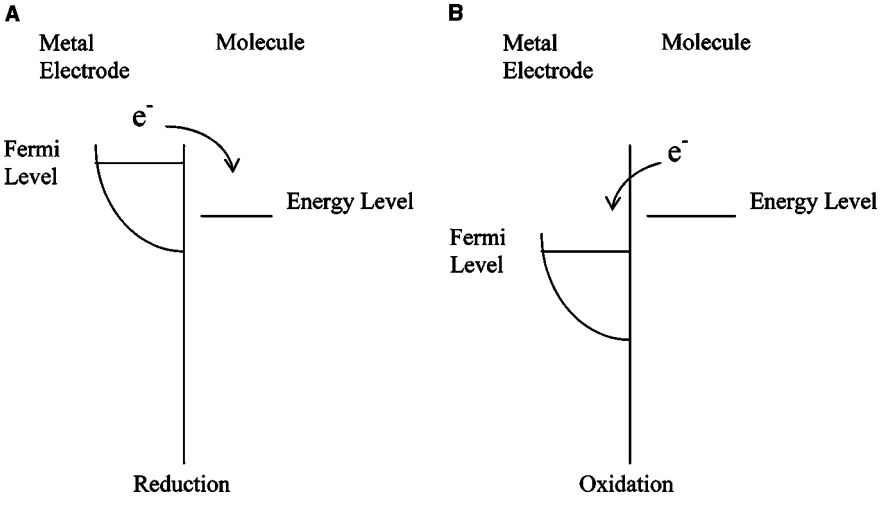

Fig. 5 Electron transfer at an inert metal electrode. The Fermi level of electrons in metal is altered by the applied potential so that the electron can move from the electrode to the molecule (A) or from the molecule to electrode (B).

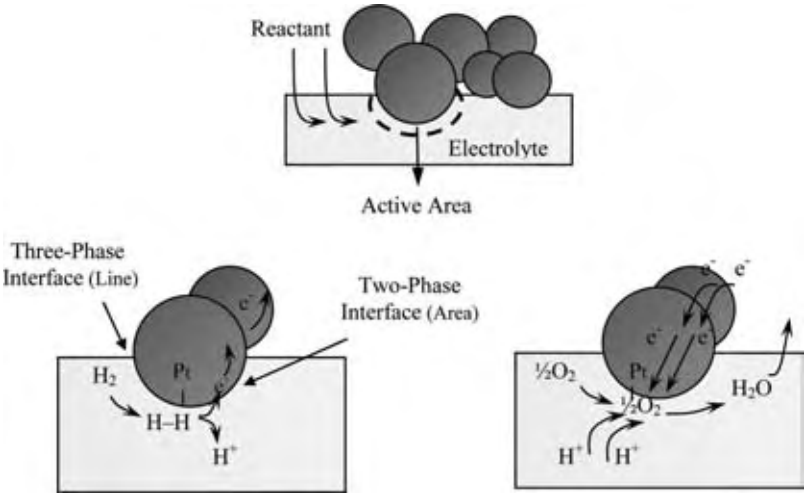

Fig. 6 A schematic illustration of the electrochemical interface and reactions at the anode and cathode in PEMFC. *(View this art in color at www.dekker.com.)*

The electrochemical reaction equilibrium condition in phase α can be written by separating the electrons from other reacting species as

$$\sum_{\substack{i=1 \\ i\neq e^-}}^{n} \nu_{\rho i}\mu_i^{e,\alpha} + \nu_{\rho e^-}\mu_{e^-}^{e,\alpha} = 0 \tag{4}$$

where $\mu_i^{e,\alpha}$ denotes the electrochemical potential of component i in phase α. When a metal (M) electrode and electrolyte solution (S) is in electrochemical reaction equilibrium, the electrochemical potential of a component i should be the same for both phases

$$\mu_i^{e,M} = \mu_i^{e,S} \tag{5}$$

Substitution of Eq. (5) into (4) gives

$$\sum_{\substack{i=1 \\ i\neq e^-}}^{n} \nu_{\rho i}\mu_i^{e,S} + \nu_{\rho e^-}\mu_{e^-}^{e,M} = 0 \tag{6}$$

The electrochemical potential of species i in phase α is the sum of its chemical potential and electrical potential

$$\mu_i^{e,\alpha} = \mu_i^{\alpha} + z_i F\phi^{\alpha} \tag{7}$$

where F is Faraday's constant (=96,485 C/equiv.) and ϕ^{α} is the electrical potential in phase α. Substitution of Eq. (7) into (6) gives

$$\sum_{\substack{i=1 \\ i\neq e^-}}^{n} \nu_{\rho i}\mu_i^{S} + \sum_{\substack{i=1 \\ i\neq e^-}}^{n} \nu_{\rho i}z_i(F\phi^{S}) + \nu_{\rho e^-}\mu_{e^-}^{M} + \nu_{\rho e^-}(-1)(F\phi^{M}) = 0 \tag{8}$$

Using the charge balance [Eq. (3)], Eq. (8) can be rearranged as

$$\Phi_0 = \frac{1}{\nu_{\rho e^-}F}\left(\sum_{\substack{i=1 \\ i\neq e^-}}^{n} \nu_{\rho i}\mu_i^{S} + \nu_{\rho e^-}\mu_{e^-}^{M}\right) \tag{9}$$

where the electrode potential Φ_0 is

$$\Phi_0 = \phi^{M} - \phi^{S} \tag{10}$$

Next, using the chemical potential of species i

$$\mu_i^{\alpha} = \mu_i^{0,\alpha} + RT\ln a_i^{\alpha} \tag{11}$$

where $\mu_i^{0,\alpha}$ is the chemical potential of species i when the activity a_i^{α} of i is 1, R is the gas constant, and T is the temperature. Substitution of this into Eq. (9) provides

$$\Phi_0 = \frac{1}{\nu_{\rho e^-}F}\left(\sum_{i=1}^{n} \nu_{\rho i}\mu_i^{0} + RT\sum_{\substack{i=1 \\ i\neq e^-}}^{n} \nu_{\rho i}\ln a_i^{S}\right) \tag{12}$$

where $a_{e^-}^{M} = 1$ is adopted. Defining the standard Gibbs free energy change for reaction ρ

$$\sum_{i=1}^{n} \nu_{\rho i}\mu_i^{0} = \Delta G_{\rho,\Phi=0}^{0} \tag{13}$$

Combining Eqs. (12) and (13) provides

$$\Phi_0 = \frac{1}{\nu_{\rho e^-} F}\left(\Delta G^0_{\rho,\Phi=0} + RT \ln \prod_{\substack{i=1 \\ i\neq e^-}}^{n} a_i^{\nu_{\rho i}}\right) \quad (14)$$

This reflects a relationship between the chemical energy ($\Delta G^0_{\rho,\Phi=0}$) and electrical potential (Φ_0) at equilibrium. For unit activities, Eq. (14) provides the standard equilibrium potential

$$\Phi^0_0 = \frac{\Delta G^0_{\rho,\Phi=0}}{\nu_{\rho e^-} F} \quad (15)$$

Thus, Eq. (14) may be expressed alternatively as

$$\Phi_0 = \Phi^0_0 + \frac{RT}{\nu_{\rho e^-} F} \ln \prod_{\substack{i=1 \\ i\neq e^-}}^{n} a_i^{\nu_{\rho i}} \quad (16)$$

Eq. (16) is commonly referred to as Nernst equation that provides a relationship between the standard potential at standard conditions (1 M, 1 atmosphere, and 298 K) and actual potential, which is the sum of the standard electrode potential and a correction term for the deviation from unit activities of the reactant and product species.

The electrochemical reactions and thermo dynamic relations are provided below for PEMFC and DMFC.

	$\Delta G^0_{\rho,\Phi=0}$ (kJ/mol)	Φ^0_0 (Volts)	
PEMFC			
Anode: $H_2(g) \leftrightarrows 2H^+ + 2e^-$	0.00	0.00	(17)
Cathode: $\frac{1}{2}O_2(g) + 2H^+ + 2e^- \leftrightarrows H_2O(l)$	−237.1	1.229	(18)
Overall: $H_2(g) + \frac{1}{2}O_2(g) \leftrightarrows H_2O(l)$	−237.1	1.229	(19)
DMFC:			
Anode: $CH_3OH(l) + H_2O(l) \leftrightarrows CO_2(g) + 6H^+ + 6e^-$	9.3	0.016	(20)
Cathode: $\frac{3}{2}O_2(g) + 6H^+ + 6e^- \leftrightarrows 3H_2O(l)$	−237.1	1.229	(21)
Overall: $CH_3OH(l) + \frac{3}{2}O_2(g) \leftrightarrows 2H_2O(l) + CO_2(g)$	−702	1.213	(22)

Nernst equations for the anode and cathode reaction of PEMFC, thus, are

$$\Phi_{0,A} = 0 + \frac{RT}{2F} \ln\left(\frac{a^2_{H^+}}{a_{H_2}}\right) \quad (23)$$

$$\Phi_{0,C} = 1.229 - \frac{RT}{2F} \ln\left(\frac{a_{H_2O}}{a^{1/2}_{O_2} a^2_{H^+}}\right) \quad (24)$$

For the overall reactions, the relation between the potential and activity is

$$V_0 = 1.229 + \frac{RT}{2F} \ln\left(\frac{a_{H_2} a^{1/2}_{O_2}}{a_{H_2O}}\right) \quad (25)$$

It is clear that the activity at the interface influences the potentials of both electrodes as well as terminal cell potential of PEMFC. Table 2 provides a list of standard potentials for electrode reactions and the overall reactions for the system of interest based on standard thermodynamic data.[28]

Kinetics

The rate of an electrochemical reaction ρ, r^*_ρ (mole/cm^2 catalyst surface area/s), as that of a chemical reaction, depends upon the temperature and activities of reacting species. In addition, in the case of the electrochemical reaction, the electric energy at the electrode–electrolyte interface also strongly influences the rate of the reaction. Thus, the rate of an electrochemical reaction is commonly written as the product of a reaction rate constant k^*_ρ and a function of activities of various species, a_A, a_B, ..., involved in the reaction

$$r^*_\rho = k^*_\rho(T,\Phi) \cdot f(a_i) \quad (26)$$

From the thermodynamic formulation of transition state theory (TTST),[29] the net rate for an elementary electrochemical reaction may be written as

$$r^*_\rho = \overrightarrow{r}^*_\rho - \overleftarrow{r}^*_\rho = \overrightarrow{k}^*_\rho \prod_{i=1}^{r} a_i^{-\nu_{\rho i}} - \overleftarrow{k}^*_\rho \prod_{i=r+1}^{n} a_i^{\nu_{\rho i}} \quad (27)$$

where $\overrightarrow{k}^*_\rho$ and $\overleftarrow{k}^*_\rho$ represent the rate constants for the forward and reverse reactions, respectively. It is assumed that the first r species are reactants and the remaining are products. The rate constant for the

Table 2 Thermodynamic values of H_2, O_2, and some hydrocarbon fuels of PEMFC interest

electrochemical reaction from TTST can be written as

$$k_\rho^* = \left(\kappa \frac{k_B T}{h\gamma^{\pm}}\right) \exp\left(\frac{-\Delta \overline{G}_\rho^{\neq,e}}{RT}\right) \tag{28}$$

where κ is the transmission coefficient, k_B is the Boltzmann constant, h is the Planck constant, $\gamma^{\pm}$ is the activity coefficient of transition state complex, and $\Delta \overline{G}_\rho^{\neq,e}$ is the Gibbs free energy of activation for electrochemical reaction. The Gibbs free energy can be divided into the chemical component and electrical component as

$$\Delta \overline{G}_\rho^{\neq,e} = \Delta \overline{G}_{\rho,\Phi=0}^{\neq} - \nu_{\rho e^-} \alpha_\rho \Phi \tag{29}$$

where $\Delta \overline{G}_{\rho,\Phi=0}^{\neq}$ represents the contribution of chemical part to the electrochemical activation energy, α_ρ is the transfer coefficient, i.e., the fraction of potential contributing to the electrical part of the activation energy of the forward reaction, and Φ represents the potential difference between the electrolyte and electrode. The Gibbs free energy of charged species is influenced by the electric potential formed between the electrode and the electrolyte through which the electrochemical charge transfer occurs. The transfer coefficient describes the position of maximum, or transition, in the diagram of the potential energy to distance along the reaction coordinates.[25] For oxidation reactions, the reaction rate constant can now be written as

$$\overrightarrow{k}_\rho^* = \left(\kappa \frac{k_B T}{h\gamma^{\pm}}\right) \exp\left(\frac{-\Delta \overrightarrow{G}_{\rho,\Phi=0}^{\neq} + \alpha_\rho \nu_{\rho e^-} F\Phi}{RT}\right) \tag{30}$$

$$\overleftarrow{k}_\rho^* = \left(\kappa \frac{k_B T}{h\gamma^{\pm}}\right) \times \exp\left(\frac{-\Delta \overleftarrow{G}_{\rho,\Phi=0}^{\neq} + (\alpha_\rho - 1)\nu_{\rho e^-} F\Phi}{RT}\right) \tag{31}$$

The rate of the electrochemical reactions is frequently expressed in terms of current density (A/cm^2) as

$$i^* = F\nu_{\rho e^-} r_\rho^* \tag{32}$$

This indicates that the anodic current is positive, while the cathodic current is negative. Using Eqs. (27) and (32) the net current density, or the measured current density, is

$$i^* = \overrightarrow{i^*} - \overleftarrow{i^*} \tag{33}$$

where $\overrightarrow{i^*}$ is the forward current density and $\overleftarrow{i^*}$ is the reverse current density for the electrochemical reaction ρ. When the potential of an electrode deviates from

equilibrium conditions, the overpotential η is given by

$$\eta = \Phi - \Phi_0 \tag{34}$$

Applying the rate constants [Eqs. (30) and (31)] to Eqs. (27), (32), and (33) gives the rate of forward and reverse reactions in terms of current densities $\overrightarrow{i^*}$ and $\overleftarrow{i^*}$

$$\overrightarrow{i^*} = F\nu_{\rho e^-}\left(\kappa\frac{k_B T}{h\gamma^{\pm}}\right)\exp\left(\frac{-\Delta\overrightarrow{G}^{\neq}_{\rho,\Phi=0}}{RT}\right) \times \exp\left(\frac{\alpha_\rho \nu_{\rho e^-} F\Phi_0}{RT}\right)\exp\left(\frac{\alpha_\rho \nu_{\rho e^-} F\eta}{RT}\right)\prod_{i=1}^{r} a_i^{-\nu_{\rho i}} \tag{35}$$

$$\overleftarrow{i^*} = F\nu_{\rho e^-}\left(\kappa\frac{k_B T}{h\gamma^{\pm}}\right)\exp\left(\frac{-\Delta\overleftarrow{G}^{\neq}_{\rho,\Phi=0}}{RT}\right) \times \exp\left(\frac{(\alpha_\rho - 1)\nu_{\rho e^-} F\Phi_0}{RT}\right) \times \exp\left(\frac{(\alpha_\rho - 1)\nu_{\rho e^-} F\eta}{RT}\right)\prod_{i=r+1}^{n} a_i^{\nu_{\rho i}} \tag{36}$$

Use of Eq. (33) and consolidating terms on the right hand side of Eqs. (35) and (36) except the overpotential part give

$$i^* = i_0^*\left[\exp\left(\frac{\alpha_\rho \nu_{\rho e^-} F\eta}{RT}\right) - \exp\left(\frac{(\alpha_\rho - 1)\nu_{\rho e^-} F\eta}{RT}\right)\right] \tag{37}$$

where i_0^* is the current density at equilibrium and commonly referred to as exchange current density, i.e.,

$$i_0^* = F\nu_{\rho e^-}\left(\kappa\frac{k_B T}{h\gamma^{\pm}}\right)\exp\left(\frac{-\Delta\overrightarrow{G}^{\neq}_{\rho,\Phi=0}}{RT}\right) \times \exp\left(\frac{\alpha_\rho \nu_{\rho e^-} F\Phi_0}{RT}\right)\prod_{i=1}^{r} a_i^{-\nu_{\rho i}} = F\nu_{\rho e^-}\left(\kappa\frac{k_B T}{h\gamma^{\pm}}\right)\exp\left(\frac{-\Delta\overleftarrow{G}^{\neq}_{\rho,\Phi=0}}{RT}\right) \times \exp\left(\frac{(\alpha_\rho - 1)\nu_{\rho e^-} F\Phi_0}{RT}\right)\prod_{i=r+1}^{n} a_i^{\nu_{\rho i}} \tag{38}$$

At electrochemical dynamic equilibrium, the net current is zero, i.e., the electron transfer process occurs at equal rates, both in the forward and in the reverse direction because of the formation of excess charges on both sides of electrode and electrolyte. The exchange current density is large when the chemical components of Gibbs free energies for forward and backward reactions are small [Eq. (38)]. Eq. (37), known as Butler-Volmer equation, is the most general expression describing the relation between the current and overpotential at a particular electrode.[24–27]

In PEMFC, the current density based on geometric area of MEA is frequently used for its convenience. The net current density i (A/cm^2 MEA) can be described as $i = \gamma_M i^*$ and $i_0 = \gamma_M i_0^*$, where γ_M is the roughness factor, i.e., the ratio of electrochemically active area per geometric MEA area. Thus, the current density based on geometric MEA area is given by

$$i = i_0\left\{\exp\left[\frac{\alpha_\rho \nu_{\rho e^-} F\eta}{RT}\right] - \exp\left[\frac{(\alpha_\rho - 1)\nu_{\rho e^-} F\eta}{RT}\right]\right\} \tag{39}$$

Therefore, the current density depends on the exchange current density (i_0), transfer coefficient (α_ρ), overpotential (η), and temperature (T). Fig. 7 represents typical current-overpotential curves based on Eq. (39). The net current is the result of the combined effects of the forward (anodic) and reverse (cathodic) currents. Although the Butler-Volmer equation for an electrochemical reaction in PEMFC is valid over the full potential range, simpler approximate equations may often be used for limited conditions. Thus, for the common value $\alpha_\rho = 1/2$, Eq. (39) becomes

$$i = 2i_0 \sinh\left(\frac{\nu_{\rho e^-} F\eta}{2RT}\right) \tag{40}$$

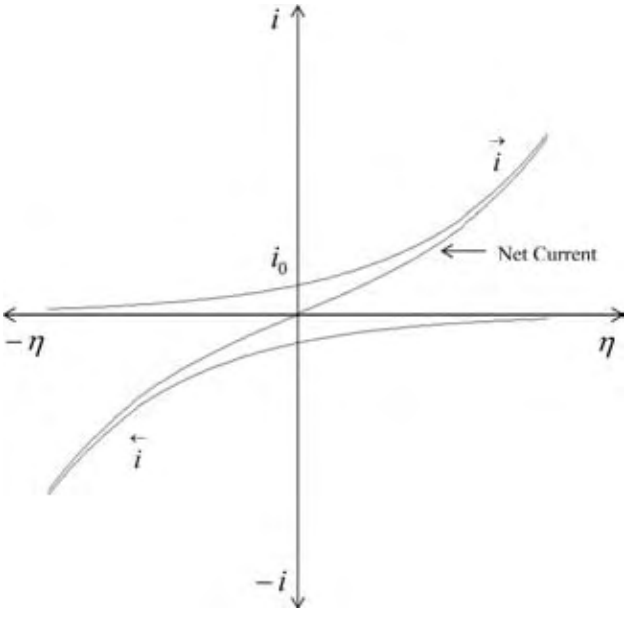

Fig. 7 A typical over-potential and current curve for electrochemical reactions. *(View this art in color at www.dekker.com.)*

For large overpotential η, i.e., $|\eta| \gg RT/F$, the second exponential term on the right hand side of Eq. (39) can be neglected compared with the first and gives

$$i \approx i_0 \exp\left(\frac{\alpha_\rho \nu_{\rho e^-} F\eta}{RT}\right) \tag{41}$$

Solving for η, Eq. (41) reduces to

$$\eta \approx \left(\frac{2.3RT}{\alpha_\rho \nu_{\rho e^-} F}\right) \log i - \left(\frac{2.3RT}{\alpha_\rho \nu_{\rho e^-} F}\right) \log i_0 = a + b \log i \tag{42}$$

Thus, the overpotential is logarithmically dependent on the current density. The parameter a and b are characteristics of electrochemical reactions and are readily obtained from a plot of η vs. $\log i$. The intercept of the straight line at $\eta = 0$ gives the exchange current density and the slope can provide α_ρ, the transfer coefficient. Eq. (42) is commonly referred to as the Tafel equation.

For very low overpotential, i.e., $|\eta| \ll RT/F$, the exponential term may be expanded in a series in Eq. (39) and approximated by a linear form

$$\eta \approx \left(\frac{RT}{\nu_{\rho e^-} F}\right) \frac{i}{i_0} \tag{43}$$

At very low overpotential region, the exchange current density can be readily obtained from the slope of the η versus i plot, which gives a line passing through the origin. It can be perceived from Eqs. (42) and (43) that electrochemical reaction with a large exchange current density needs low overpotential for a required current density, and vice versa.

Reaction Mechanisms

Hydrogen oxidation reaction

The hydrogen oxidation reaction (HOR) at the anode proceeds on Pt-based catalysts and is one of the simplest reaction systems.[30–36] Nonetheless, fundamental information of the mechanism and kinetics of HOR is still lacking. The most common mechanisms are the so-called Heyrovsky-Volmer and Tafel-Volmer mechanisms involving the following steps:

Tafel step:

$$S_T: \quad 2Pt_{(S)} + H_2 \leftrightarrows Pt\text{-}H_{ads} + Pt\text{-}H_{ads} \tag{44}$$

Heyrovsky step:

$$S_H: \quad Pt_{(S)} + H_2 \leftrightarrows Pt\text{-}H_{ads} + Pt + H^+ + e^- \tag{45}$$

Volmer step:

$$S_V: \quad Pt\text{-}H_{ads} \leftrightarrows Pt + H^+ + e^- \tag{46}$$

where $Pt_{(S)}$ is a free surface site on Pt and $Pt\text{-}H_{ads}$ is an adsorbed H-atom on the Pt active site. The Tafel-Volmer pathway involves S_T and S_V, i.e., the overall reaction (OR) is given by $OR = S_T + 2S_V$, while in the Heyrovsky-Volmer pathway, $OR = S_H + S_V$. The dissociative adsorption of H_2 is considered to be a rate-determining step. The overpotential for the HOR is relatively small at most practical current densities for a pure hydrogen feed. However, for reformed hydrocarbons, the anode feed may contain roughly 100 ppm CO, even after gas clean up in the fuel reforming section of a fuel cell power plant. Even at this low level, CO adsorbs very strongly on Pt surface, occupying the vast majority of the sites and, thus, increasing the anode overpotential substantially.[33,34] The CO coverage on the Pt surface depends on the temperature and CO concentration. In the presence of CO, a possible mechanism is[33]

$$Pt_{(S)} + CO \leftrightarrows Pt\text{-}CO_{ads} \text{ (high CO coverage)} \tag{47}$$

$$Pt_{(S)} + \frac{1}{2}H_2 \leftrightarrows (Pt\text{-}H_{ads}) \text{ (low H coverage)} \tag{48}$$

$$Pt_{(S)} + H_2O \leftrightarrows Pt\text{-}OH_{ads} + H^+ + e^- \tag{49}$$

$$Pt\text{-}(CO)_{ads} + Pt\text{-}OH_{ads} \leftrightarrows Pt_{(S)} + CO_2 + H^+ + e^- \tag{50}$$

Carbon monoxide preferably adsorbs on the Pt surface and inhibits the dissociative adsorption of H_2, which may be explained by the strong bond strength of Pt-CO compared to that of Pt-H. The last two reactions explain CO removal from the surface via electro-oxidation at high anode overpotentials. Alloying Pt with Ru improves CO tolerance through the facile removal of $Pt\text{-}(CO)_{ads}$ as[33,35,36]

$$Ru + H_2O \leftrightarrows Ru\text{-}OH_{ads} + H^+ + e^- \tag{51}$$

$$Ru\text{-}(OH)_{ads} + Pt\text{-}CO_{ads} \leftrightarrows Ru + Pt + CO_2 + H^+ + e^- \tag{52}$$

This enhancement is ascribed to both the activation of H_2O to OH_{ads} on Ru and a decrease in CO binding energy when Ru is added to the surface due to electronic effects of alloying (bifunctional mechanism). Raising the fuel cell temperature above 160°C can decrease the CO coverage remarkably. For a reformate gas containing CO, Pt–Ru electrodes are commonly used,[37,38] and a number of other Pt-alloys such as Pt–Mo,[39] Pt–Sn,[40] Pt–Rh,[41] and Pt–Re[42] have been studied for the HOR reaction.

Methanol oxidation reaction

The anode reaction mechanisms suggested for methanol oxidation reaction (MOR) in DMFC include:[43–46]

1. Absorption of methanol on the electrode;
2. Stepwise electro-dehydrogenation to eventually form adsorbed CO; and
3. Surface reaction of OH (resulting from water) with adsorbed CO to generate CO_2.

The electro-oxidation on Pt is, thus, considered to take place through the following steps:[43]

$$Pt_{(S)} + CH_3OH \leftrightarrows Pt\text{-}(CH_3OH)_{ads} \quad (53)$$

$$Pt\text{-}(CH_3OH)_{ads} \leftrightarrows Pt\text{-}(CH_2OH)_{ads} + H^+ + e^- \quad (54)$$

$$Pt\text{-}(CH_2OH)_{ads} \leftrightarrows Pt\text{-}(CHOH)_{ads} + H^+ + e^- \quad (55)$$

$$Pt\text{-}(CHOH)_{ads} \leftrightarrows Pt\text{-}(CHO)_{ads} + H^+ + e^- \quad (56)$$

$$Pt\text{-}(CHO)_{ads} \leftrightarrows Pt\text{-}(CO)_{ads} + H^+ + e^- \quad (57)$$

$$Pt_{(S)} + H_2O \leftrightarrows Pt\text{-}(OH)_{ads} + H^+ + e^- \quad (58)$$

$$Pt\text{-}(CO)_{ads} + Pt\text{-}(OH)_{ads} \leftrightarrows Pt\text{-}(COOH)_{ads} \quad (59)$$

$$Pt\text{-}(COOH)_{ads} \leftrightarrows Pt_{(S)} + CO_2 + H^+ + e^- \quad (60)$$

Thus, the reaction is poisoned by the formation of $Pt\text{-}(CO)_{ads}$ after complete methanol dehydrogenation. There have been intensive searches for other active materials, which can provide oxygen in its active form from water at low overpotentials, to increase the oxidation rate of chemisorbed CO. Pt–Ru alloys are reported as having excellent promotional effects,[47,48] and PtSn,[49] PtMo,[50] PtRuCo,[51] and PtRuIrOs[52] have also been studied for the MOR reaction of DMFC.

Oxygen reduction reaction

The oxygen reduction reaction (ORR) at the cathode

$$O_2 + 4H^+ + 4e^- \leftrightarrows 2H_2O \quad (61)$$

has also been studied extensively and a number of mechanisms have been proposed.[53–60] However, there is still considerable uncertainty in the ORR. A simple mechanism may be written for ORR in an acid electrolyte

$$Pt_{(S)} + O_2 \leftrightarrows Pt\text{-}(O_2)_{ads} \quad (62)$$

$$Pt\text{-}(O_2)_{ads} + H^+ + e^- \leftrightarrows Pt\text{-}(OOH)_{ads} \quad (63)$$

$$Pt\text{-}(OOH)_{ads} + H^+ + e^- \leftrightarrows Pt\text{-}(OHOH)_{ads} \quad (64)$$

$$Pt\text{-}(OHOH)_{ads} + H^+ + e^- \leftrightarrows Pt\text{-}(OH)_{ads} + H_2O \quad (65)$$

$$Pt\text{-}(OH)_{ads} + H^+ + e^- \leftrightarrows Pt_{(S)} + H_2O \quad (66)$$

The dissociative adsorption of the oxygen molecule is unlikely and the first electron transfer to the oxygen molecule [Eq. (63)] is considered to be the rate determining step.[59,60] The formation of H_2O_2 and various forms of platinum oxides on the surface reduces the theoretical potential obtainable by ORR. In fact, potential losses in PEMFC arise predominantly because of the sluggishness of the ORR. The structural sensitivity of ORR has been discussed[61–64] over the Pt-based electrodes. Pt/C is commonly used for the cathode material, and Pt-based alloys, such as PtCr[65] and PtNi,[66] have also been investigated.

Overall PEMFC Performance

The performance of PEMFC is often presented by the polarization curve that shows the voltage output as a function of current density. Fig. 8 shows a typical polarization curve of PEMFC. As the PEMFC processes charge-transfer reactions and the diffusion of the reactants to and products from the electrochemical interface, the transport and kinetics within the cell determine the polarization characteristics of PEMFC. In the practical PEMFC, the terminal cell potential V

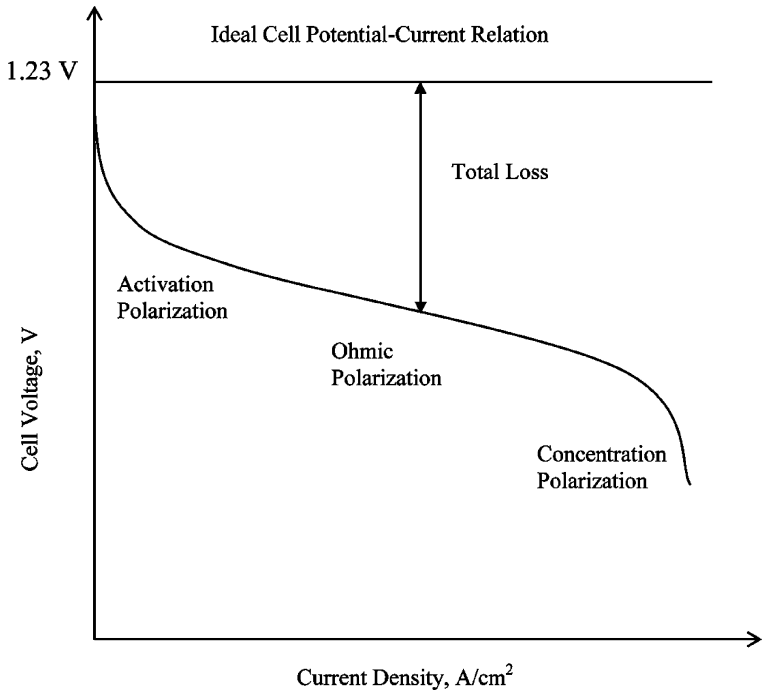

Fig. 8 A typical polarization curve of PEMFC.

(the output voltage) is a function of current density i, i.e., it decreases with increasing current density drawn from the cell because of the losses encountered in the various reactions and transport processes. Three major reasons of the potential loss are termed: concentration, activation, and ohmic overpotentials. First, the concentration overpotential is caused by the resistance of mass transport of reacting species. For example, the concentration of a reactant (e.g., O_2) in the vicinity of the interface may be lower than that in the bulk phase because of the hindrance to the transport of reactants, or the fact the products may not leave the surface instantaneously, e.g., H_2O in PEMFC. Second, the activation overpotential is caused by the finite rate of the electrochemical reactions, e.g., the reaction may proceed via several steps, one or more of which may be slow and irreversible. Third, ohmic overpotential is caused by the internal resistance of the phases to the transport of charged species. In most cases, the resistance of electrode to electronic conduction is relatively small compared to that of the electrolyte to ionic conduction because the electronic conductivity is much higher than the ionic conductivity in the electrolyte. A thin electrolyte layer having high proton conductivity, therefore, reduces the ohmic overpotential. In PEMFC, the transport of reactants across the electrolyte, i.e., hydrogen to cathode or oxygen to anode, may cause mixed potential at the electrodes, which may result in the departure from the ideal behavior expected at the electrodes. Under the conditions where all three types of overpotentials are considered, the terminal cell potential may be written as

$$V = V_0 - \sum_i^n |\eta_i| \tag{67}$$

where the second term on the right hand side includes all the three major types of overpotentials. The absolute symbol is used to prevent any confusion in the sign because the cathode side gives negative overpotentials due to negative currents by the electronation reactions. The overpotentials for PEMFC can, thus, be written as

$$\sum_i^n |\eta_i| = |\eta_{C,A}| + |\eta_{C,C}| + |\eta_{K,A}| + |\eta_{K,C}| + |\eta_M| + |\eta_I| \tag{68}$$

where the terms on the right hand side represent the concentration overpotential at the anode, concentration overpotential at the cathode, kinetic overpotential for an anode reaction, kinetic overpotential for a cathode reaction, membrane overpotential, and any interface contact overpotential, respectively. Fig. 9 schematically illustrates a PEMFC as an electrical network having an internal ideal voltage source coupled with the internal losses because of the resistances.

The overpotential increases with the current density and the potential–current relation of the cell can be obtained by solving transport and kinetic equations in the cell. Fig. 10 shows a schematic of

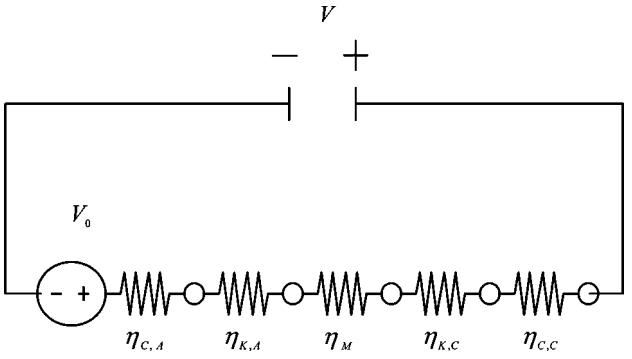

Fig. 9 A schematic representation of electrochemical reactions as an electrical network having an internal ideal potential source coupled with the losses because of the resistances. *(View this art in color at www.dekker.com.)*

the concentration distribution of reacting species across the MEA during PEMFC operation. A simple analytical model, based on Figs. 2 and 10, has been reported.[23] The basic conservation equations are presented as follows:

Anode chamber (Region *T*):

$$F_{\mathrm{T}}(c_{\mathrm{H}_2,T0} - c_{\mathrm{H}_2,T}) = N_{\mathrm{H}_2,z} \cdot A \tag{69}$$

where F_{T} (cm^3/sec) is the volumetric flow rate of the reactant (e.g., hydrogen) in the anode, $c_{\mathrm{H}_2,T0}$ and $c_{\mathrm{H}_2,T}$ are the concentration of H_2 entering and exiting the region *T*, respectively, $N_{\mathrm{H}_2,z}$ ($\mathrm{mol/cm}^2$/sec) is the flux of *i* in z-direction, and *A* (cm^2) is the geometric area of the MEA.

Gas diffusion layers (Layers *D* and *E*):

$$\frac{dN_{i,z}}{dz} = 0 \tag{70}$$

$$N_{i,z} = -D_i^{e,\alpha}\frac{dc_i}{dz} \tag{71}$$

where $D_i^{e,\alpha}$ denotes the effective diffusivity of species *i* in phase α. Fick's law is simply used for the diffusion of species *i* (e.g., hydrogen or oxygen) with an effective diffusion coefficient for the constant flux condition.

Electrodes (Layers *A* and *C*):

$$\frac{dN_{i,z}}{dz} = \nu_{\rho i} r'_{\rho} \tag{72}$$

$$N_{i,z} = -D_i^{e,\alpha}\left(\frac{dc_{i\alpha}}{dz} + \frac{z_i c_i F}{RT}\frac{d\phi^{\alpha}}{dz}\right) \tag{73}$$

where r'_{ρ} represent the rate per volume of electrode layer (rate/cm^3 catalyst layer). For electrochemical systems, the driving forces for diffusion are approximated as chemical potential gradients and electrostatic forces.

PEM electrolyte (Layer *B*):

$$\frac{di}{dz} = 0 \tag{74}$$

$$i = -\sigma_B \frac{d\phi^S}{dz} \tag{75}$$

where σ_B is the specific ionic (proton) conductivity of the electrolyte (layer *B*) and ϕ^S represents the potential of the solid electrolyte. If it is assumed that the specific proton conductivity remains constant, Eq. (75) becomes

$$\phi^{S,B}(b) - \phi^{S,B}(c) = \left(\frac{L_B}{\sigma_B}\right) \cdot i \tag{76}$$

where L_B is the thickness of the electrolyte. Hence, the overpotential increases with the current drawn and the thickness of electrolyte, and decreases with the specific proton conductivity.

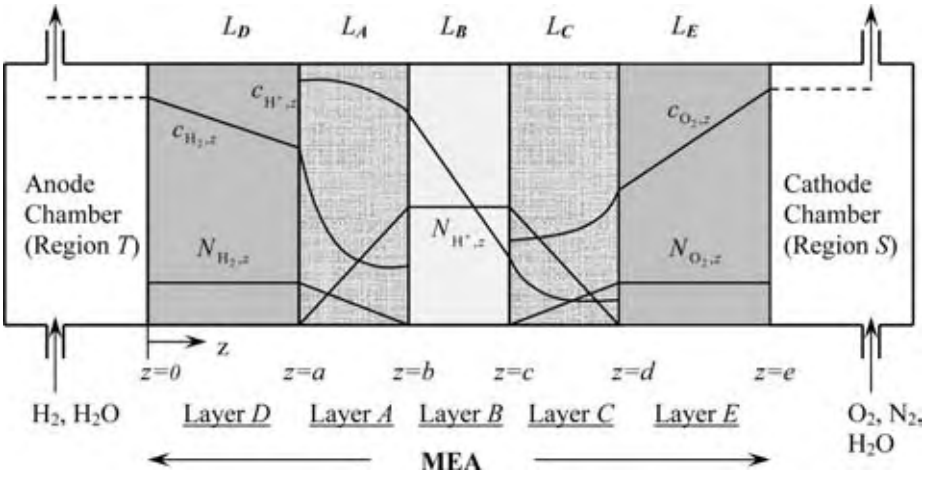

Fig. 10 A simplified one-dimensional picture of the concentration distribution of reacting species across MEA in the operating conditions of PEMFC. *(View this art in color at www.dekker.com.)*

Cathode chamber (Region S):

$$F_S(c_{O_2,S0} - c_{O_2,s}) = N_{O_2,z} \cdot A \tag{77}$$

where F_S is the volumetric flow rate of the oxidant (oxygen or air), and $c_{O_2,S0}$ and $c_{O_2,S}$ represent the concentration of oxygen at the inlet and outlet of the cathode chamber (region S), respectively. These equations can be solved for the case of no transport limitations in the catalyst layers, providing the overpotentials related to the current densities as

$$\eta_A = \eta_{C,A} + \eta_{K.A} = \frac{RT}{\alpha_A F}\sinh^{-1}\left\{\frac{1}{2}\left[\frac{i_A/i_{A,0}}{1 - i_A/i_{A,L}}\right]\right\} \tag{78}$$

$$-\eta_C = -(\eta_{C,C} + \eta_{K.C}) = \frac{RT}{\alpha_C F}\sinh^{-1}\left\{\frac{1}{2}\left[\frac{i_C/i_{C,0}}{1 - i_C/i_{C,L}}\right]\right\} \tag{79}$$

$$\eta_M = i\left(\frac{L_B}{\sigma_B}\right) \tag{80}$$

$$\eta_I = iR_I \tag{81}$$

where $i_{A,0}$ (or $i_{C,0}$) is the exchange current density at the anode (or cathode), $i_{A,L}$ (or $i_{C,L}$) is the limiting current density at the anode (or cathode), $\eta_{C,A}$ (or $\eta_{C,C}$) is the concentration overpotential because of the diffusion of hydrogen at the anode (or oxygen at the cathode), and $\eta_{K,A}$ (or $\eta_{K,C}$) is the overpotential because of the kinetics at the anode (or cathode) surface. Usually, $\eta_{K,C}$ is the dominant overpotential in PEMFC. The limiting current density is the maximum current density that can be achieved for an electrode reaction at a given concentration of the reactant. As the current density is increased, the surface concentration of the reactant is decreased by virtue of diffusional limitations. Finally, a limiting current situation is reached, when the further change of the electrode potential cannot increase the reactant flux because of diffusional limitations, i.e., no more reactant can be supplied to the electrode to sustain the desired current.

The terminal potential, or potential difference at terminals, can be obtained as

$$V = \frac{1}{F}(\mu^e_{e^-,A} - \mu^e_{e^-,C}) = \frac{1}{F}\left((\mu_{e^-,A} + (-1)F\phi^{M,A}) - (\mu_{e^-,C} + (-1)F\phi^{M,C})\right) \tag{82}$$

where $\mu^e_{e^-,A}$ and $\mu^e_{e^-,C}$ denote the electrochemical potential of electrons at the anode and cathode, respectively. If it is assumed that the chemical potential of electrons at the anode and cathode are equal, the terminal potential is given by

$$V = \phi^{M,C} - \phi^{M,A} \tag{83}$$

where $\phi^{M,C}$ and $\phi^{M,A}$ represent the potential of the metal (M) electrode at the cathode (C) and anode (A), respectively. It is shown that the electrode potential is given by

$$\Phi_M = \phi^M - \phi^S = \Phi_{0,M} + \eta_M \tag{84}$$

By the substitution of Eq. (84) into (83) and followed by the arrangement of terms, the terminal cell potential can be obtained as

$$V = (\Phi_{0,C} - \Phi_{0,A}) + \eta_C - \eta_A - (\phi^{S,A} - \phi^{S,C}) \tag{85}$$

where $(\Phi_{0,C} - \Phi_{0,A})$ is the open circuit potential V_0 and the last term on the right hand side can be written as

$$\phi^{S,A} - \phi^{S,C} = (\phi^{S,A} - \phi^{S,B}(b)) + (\phi^{S,B}(b) - \phi^{S,B}(c)) + (\phi^{S,B}(c) - \phi^{S,C}) \tag{86}$$

The first and third parentheses on the right hand side of Eq. (86) represent the electrodes and electrolyte contact resistances and the second term represent the bulk resistance of the electrolyte. Substitution of Eqs. (78–86) into (85) gives the following current–voltage relation, or polarization equation, for PEMFC

$$V = V_0 - \frac{RT}{\alpha_A F}\sinh^{-1}\left\{\frac{1}{2}\left[\frac{i/i_{A,0}}{1 - i/i_{A,L}}\right]\right\} - \frac{RT}{\alpha_C F}\sinh^{-1}\left\{\frac{1}{2}\left[\frac{i/i_{C,0}}{1 - i/i_{C,L}}\right]\right\} - i\left(\frac{L_B}{\sigma_B}\right) - iR_I \tag{87}$$

The anode overpotential for hydrogen oxidation reaction is low, i.e., $\eta_A \approx 0.05\,\text{V}$, so that Eq. (78) may be linearized, while the cathode overpotential is very high, i.e., $\eta_C \approx -0.4\,\text{V}$ in normal hydrogen fuel cells, and η_C vs. i is highly nonlinear, often approximated by the Tafel expression.

Fig. 11 shows a typical polarization curve for PEMFC along with potential losses for different regions of current densities. The corresponding power density can be obtained by multiplying i in Eq. (87), i.e., $P = V \cdot i$, where P is power density (W/cm^2). To produce a high power density, the polarization curve needs to be flattened by reducing the various types of the overpotentials. In the practical PEMFC, the operating terminal voltage is in the vicinity of 0.5–0.7 depending on the shape, e.g., flatness, of the

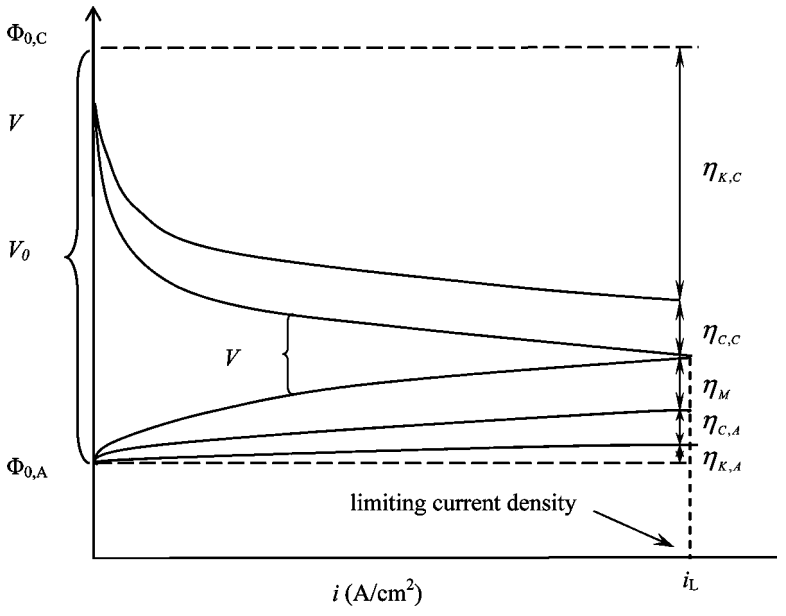

Fig. 11 A typical polarization curve for PEMFC along with potential losses because of the overpotentials with current densities.

polarization curve. This is discussed in more detail below.

In analogy to the linear Ohm's law, it may useful to define a *differential* specific resistance

$$R \equiv \frac{d(V_0 - V)}{di} \tag{88}$$

Use of Eqs. (67), (68), (78), and (79) gives

$$R = \frac{d}{di}(|\eta_C| + |\eta_A| + |\eta_M| + |\eta_I|) \tag{89}$$

Differentiation of overpotentials given in Eqs. (78)–(80) with respect to i provides the differential specific resistances at the anode and cathode as

$$R_A = \frac{RT}{(2\alpha_A F i_{A,0})(1 - i/i_{A,L})^2\left[1 + \frac{1}{4}\left(\frac{i/i_{A,0}}{1 - i/i_{A,L}}\right)^2\right]^{1/2}} \tag{90}$$

$$R_C = \frac{RT}{(2\alpha_C F i_{C,0})(1 - i/i_{C,L})^2\left[1 + \frac{1}{4}\left(\frac{i/i_{C,0}}{1 - i/i_{C,L}}\right)^2\right]^{1/2}} \tag{91}$$

and, of course, $R_M = L_M/\sigma_M$. It can be shown from a current versus differential resistance plot that the kinetic resistance at the cathode, the membrane resistance, and the diffusional resistance dominate at low, intermediate, and high current density regions, respectively.

Overall PEMFC Efficiency

The application of the first law of thermodynamics to a PEMFC provides the relation between enthalpy change and heat added to the system, as well as the electric work done by the system, in the absence of kinetic and potential energy changes

$$\Delta H = Q - W_E \tag{92}$$

where the electric work done by the PEMFC, $W_E = nFV$, where n is the number of electrons transferred. To determine the maximum useful electric work possible, Eq. (92) is applied to a reversible process

$$-W_{E,rev} = \Delta H - Q_{rev} \tag{93}$$

For a reversible change at constant temperature and pressure, the second law of thermodynamics provides the heat transferred to the system as

$$Q_{rev} = T\Delta S \tag{94}$$

Another relevant thermodynamic relation between the state functions is

$$\Delta G = \Delta H - T\Delta S \tag{95}$$

Combining Eqs. (93–95) gives

$$W_{E,rev} = -\Delta G = nFV_0 \tag{96}$$

Therefore, the changes in Gibbs free energy is equal to the maximum electrical work (or energy) attainable at the given temperature and pressure.

The efficiency of energy conversion devices is given by

$$\varepsilon = \frac{\text{useful energy output}}{\text{energy input}} = \frac{W_E}{-\Delta H} \quad (97)$$

If the PEMFC works ideally, the change of Gibbs free energy of the reaction can be completely converted to electrical energy. Thus, the ideal or thermodynamic efficiency of PEMFC can be given as

$$\varepsilon_0 = \frac{W_{E,rev}}{-\Delta H} = \frac{\Delta G}{\Delta H} = 1 - \frac{T\Delta S}{\Delta H} \quad (98)$$

If the change in the Gibbs free energy ΔG is greater than the changes in the enthalpy ΔH, the thermodynamic efficiency can exceed 1 (or 100%). Table 2 also lists the thermodynamic efficiencies for fuel cell reactions of interest under standard conditions.

From the data provided in the Table 2, the reversible heat generated in PEMFC

$$Q_{rev} = T\Delta S = \Delta H - \Delta G \quad (99)$$

is $-48.7\,\text{kJ/mol}$ for liquid water product at standard state PEMFC reactions, indicating that heat is released from the system. If the potentials of the anode and cathode are at their equilibrium values, i.e., $\Phi_{0,A}$ and $\Phi_{0,C}$, and also the terminal voltage V is independent of current, then the actual voltage would be the same as the ideal voltage, i.e., $V = V_0$. In practice, however, the operating potential V deviates significantly from the equilibrium value V_0 because of the reasons discussed above. The voltage efficiency is usually defined as

$$\varepsilon_V = \frac{V}{V_0} \quad (100)$$

The potential loss, i.e., the deviation of the overall potential V from V_0, is described in the previous section.

In addition to the potential losses, the current loss from the theoretical conversion of reactants could be significant. The current (or Faradic) efficiency is defined as

$$\varepsilon_C = \frac{I}{I_T} \quad (101)$$

where I_T and I represent the theoretical current calculated based on the consumed reactants and the actual current, respectively. This loss may be caused by side reactions, loss or accumulation of reaction intermediates, chemical decompositions of reactants, and chemical (non-Faradic) reactions between reactants because of dissolution and diffusion through electrolyte layer to the opposite electrode. The PEMFC efficiency is then the product of the efficiencies described above, i.e.,

$$\varepsilon = \varepsilon_0\varepsilon_V\varepsilon_C \quad (102)$$

Frequently, ε_C is close to 1.0 for PEMFC, while the thermodynamic efficiency ε_0 is fixed. Therefore, ε directly varies with the operating voltage. This indicates the great importance of operating at as high a potential as feasible. Thus, even though a smaller fuel cell would result if it is operated at around 0.5 V corresponding to the maximum in power density, it is common to operate it in the range of 0.6–0.7 V, where the efficiency is higher, even though the fuel cell is bigger for a given power density. Assuming $\varepsilon_C = 1.0$, the efficiency of PEMFC is given by

$$\varepsilon = \frac{nFV}{-\Delta H} = \frac{nF}{-\Delta H}(V_0 + \eta_C - \eta_A - \eta_{PEM} - \eta_I) \quad (103)$$

Using Eq. (87), the efficiency can be obtained, i.e., for $n = 2$, by

$$\varepsilon = \frac{2F}{-\Delta H}\left[V_0 - \frac{RT}{\alpha_A F}\sinh^{-1}\left\{\frac{1}{2}\left[\frac{i/i_{A,0}}{1 - i/i_{A,L}}\right]\right\} - \frac{RT}{\alpha_C F}\sinh^{-1}\left\{\frac{1}{2}\left[\frac{i/i_{C,0}}{1 - i/i_{C,L}}\right]\right\} - i\left(\frac{L_B}{\sigma_B}\right) - iR_I\right] \quad (104)$$

The heat generated by a fuel cell per kW electricity produced can be obtained by

$$\overline{Q} = \frac{1}{\varepsilon} - 1 \quad (105)$$

Also, the amount of hydrogen required to produce 1 kW electricity can be given by

$$\bar{n}_{H_2} = \frac{1}{-\Delta H}\left(\frac{1}{\varepsilon}\right) \quad (106)$$

Thus, the higher the operating voltage and efficiency, the lower the heat loss and hence, the smaller the heat exchanger, and the lower the amount of H_2 needed, and the smaller the balance of plant.

MATERIALS FOR PEMFC

Electrode

The materials for PEMFC electrodes should have good electrical conductivities and be stable in contact with electrolyte. Platinum-based electrodes have shown excellent electrochemical activities for PEMFC.

To reduce the cost of precious Pt metal as well as improve the electrochemical activity, nano-sized Pt particles are dispersed on supports, e.g., Vulcan XC-72 (30 nm), by various techniques.[67–70] The carbon-based support has sufficient electron conductivity and inhibits agglomeration of Pt particles. However, the growth of particles during the PEMFC operation may occur due to crystallite migration and local heat generated by the electrochemical reactions. Nanomaterials such as carbon nanotubes have recently been used as supports for platinum nanoparticles.[71] Fig. 12 shows TEM (transmission electron microscope) images of Pt nanoparticles supported on carbon black. There have been continuous efforts to reduce the amount of expensive platinum loadings for PEMFC electrodes.[72–75] As the electrochemical reactions occur only on the interface between the electrode and electrolyte, the electrodes should be designed to contact the electrolyte to provide high interface area with high rates of transport of the reacting species. It is estimated that even in state-of-the art designs, only roughly 20% of available platinum surface is utilized.[69] Thus, the development of new methodologies for producing a large interface area as well as the highly active electrode materials for electrochemical reactions one of the most challenging tasks in PEMFC. For a reformate containing CO, as mentioned previously, the platinum is usually alloyed with other metals, e.g., ruthenium, to tolerate to the CO-poisoning on the surface of the electrode. PtRu/C (Pt : Ru = 1 : 1 atomic ratio) electrode has shown an excellent performance for PEMFC containing 10–100 ppm CO, when compared with pure Pt.[32] For the DMFC, which has virtually the same problem of strongly adsorbed CO on the surface of the electrode, a number of the ratios of PtRu alloy have been studied to find an optimum composition for DMFC.[46]

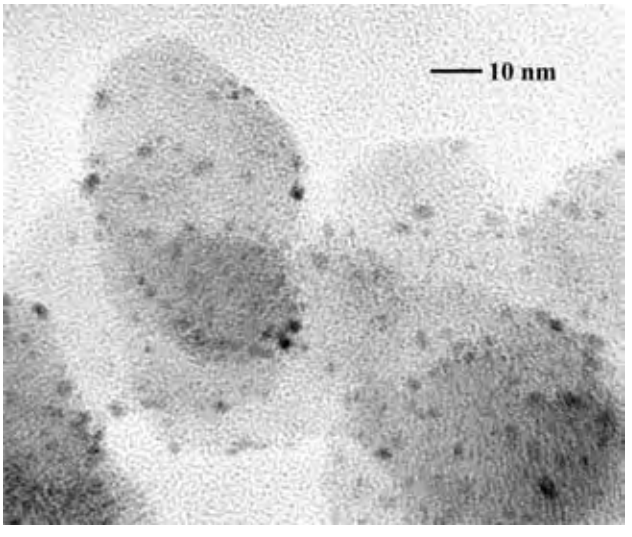

Fig. 12 A TEM image of 20% Pt/C nanoparticles taken at the author's laboratory.

Electrolyte

A solid polymer electrolyte, i.e., a PEM, conducts protons from anode to cathode and keeps the reactant gases from mixing directly. Suitable materials for electrolytes, thus, need to meet certain requirements such as stability (chemical, thermal, and mechanical) and low gas permeability over fuel cell operating conditions, in addition to excellent proton conductivity, low cost, and mechanical strength. The PEM electrolytes developed so far can be classified into three categories:[76–80] i) perfluorinated polymers, e.g., Nafion®; ii) partially fluorinated polymers, e.g., poly-α, β, β-trifluorostyrene; and iii) hydrocarbon polymers, e.g., poly(benzimidazole) or PBI. In addition, composite membranes, which can be obtained via modification of polymer (host membrane) by the incorporation of inorganic solid acids, may be identified as a new family of PEM.[80,81] Hydrocarbon membranes are relatively cost effective and the composite membranes are developed for high temperature PEMFC operation, which can provide improved kinetics at the electrodes, as well as higher tolerance to contaminant gases.[82,83]

Nafion and its other perfluorosulfonic acid (PFSA) relatives have so far demonstrated that they meet the key requirements, and hence have been widely used as PEM materials. However, they are expensive, effective at low temperature (100°C), highly permeable to liquid, and degraded during the operation. The properties and structure of Nafion have been extensively studied.[84,85] Fig. 13A shows a chemical structure of Nafion in which the backbone structure is similar to that of Teflon (PTFE). The backbone provides mechanical strength and is strongly hydrophobic, while the proton conducting sulfonic acid group is hydrophilic and, thus, nanoseparation is obtained when water is introduced into the Nafion. There have been a number of models for the nanostructures of Nafion including a cluster-network model, an elastic model, a three-phase model, and a variety of recent models based on a wide range of experimental techniques.[85] Nafion is classified by the equivalent weight (EW), defined by the weight of dry Nafion per mole of sulfonic acid groups, and an EW of 1100 is widely utilized. Nafion is commonly labeled with numbers such as Nafion 117 (or 115, or 112), referring that its EW is 1100 and thickness is 0.007 inch (or 0.005, or 0.002 inch). Nafion is usually pretreated prior to use in PEMFC and the pretreatment can also provide different forms, namely, N, S, and E forms. The N (normal) and S (shrunken) forms are the membranes

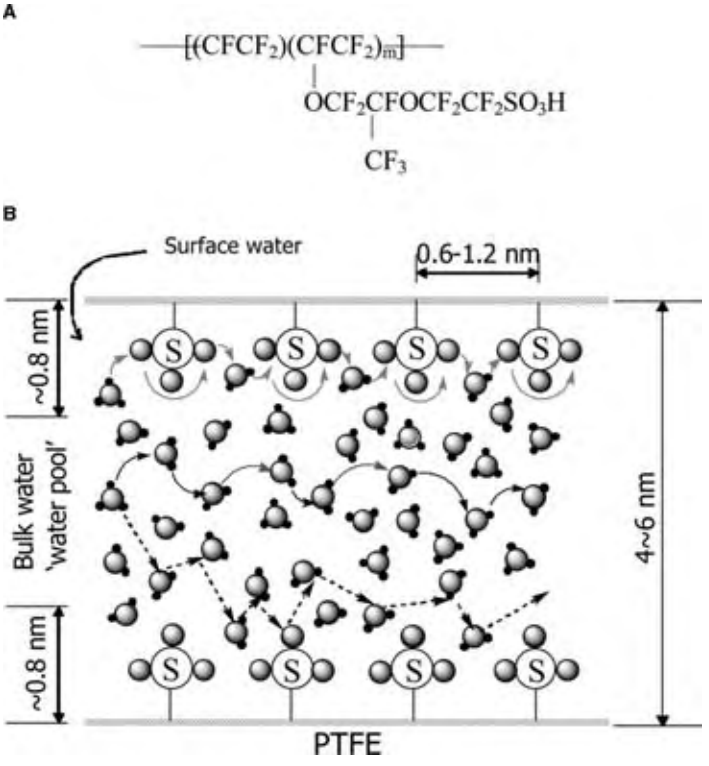

Fig. 13 A chemical structure (A) in which the relationship between EW and m is given by EW = 100 m + 446, and a simplified physical picture (B) showing proton transport, in a pore of Nafion. *(View this art in color at www.dekker.com.)*

dried at 80°C and 105°C, respectively. The E form is the one treated by increasing the temperature to around the glass transition temperature of Nafion (111°C) to allow the polymer chains to reorient themselves in the presence of water and then cleaned in a boiling 3% H_2O_2 solution, followed by boiling in 0.5 M H_2SO_4 to ensure full protonation, and finally in deionized water. The proton conductivity of Nafion is highly dependent upon the hydration level.[86,87] Thus, an understanding of water uptake in Nafion is very important to design electrolytes as well as to operate PEMFC at its optimum conditions. A thermodynamic model for water sorption has been developed in which the water uptake was determined by a balance between the internal pressure of water within the pores and the elasticity of the polymer matrix.[88] The state of water molecules in Nafion could be divided into two types, i.e., the strongly or chemically bound molecule to the sulfonic acid site and physically equilibrated water molecules. As the water generated at the cathode is not enough to humidify the membrane, water is usually supplied with the feed gases to provide proper proton conductivity. However, it is not desirable to keep too much water in the cell because of flooding that prohibits the transport of reactant gases to the active site for the electrochemical reaction. Thus, the management of water in the cell is one of the key issues to address to achieve enhanced fuel cell performance.[89–91] The distribution of water within the cell depends on the sorption characteristics of the polymer membrane, the drag coefficient of water molecule that accompany protons that transfer from anode to cathode, the diffusion of water because of concentration gradient within the cell, and the current density that affects the rate of generation of water at the cathode side by ORR, etc. The formation of water at the cathode and the drag of water molecules, i.e., 1–2.5 H_2O/H^+, may induce a back diffusion of water from the cathode to the anode.[92] There are some theoretical treatments of water transport in PEMFC.[93–95]

PEM separates the reactant gases and prohibits the transport of gases from the anode to the cathode, and vice versa. However, the gases dissolve and permeate through the PEM. The permeation of gases through the electrolyte is not favorable in a sense that it leads a loss of fuels and causes mixed potentials at both electrodes. However, it can provide appreciable concentration of reactants on the electrochemical interface by two phase contacts as explained previously. The solubility of hydrogen and oxygen gases in Nafion depends upon the humidification level and temperature.[96–98]

The mechanism of proton conduction in Nafion has been studied.[99–102] The proton transport can proceed via Grotthuss or structural diffusion mechanism that requires structural orientation of water molecules, and *en masse* or vehicle mechanism by which hydrated proton, e.g., H_3O^+, migrates by an ordinary diffusion process.[100,101] The interaction of protons with the membrane and water would determine the dynamics of proton environment, and thus, the proton conduction

through the membrane. Although there have been various proton transport mechanisms suggested,[103–106] a development of a complete mechanism of proton transport in PEM is still a challenging task because of the complex nanostructure and the inhomogeneous nature of PEM when hydrated. Fig. 13(B) shows a simplified physical picture of Nafion showing a possible proton transport mechanism in its fully hydrated state.[100]

The chemical stability of PEMs is an important matter for its long-term use in PEMFC. Unfortunately, PEMs are degraded during the course of PEMFC operation, which can be determined by the detection of the decomposition products, e.g., fluorine from Nafion, in the product water.[107–109] The crossover of oxygen gas from the cathode to anode may form H_2O_2 at the anode, which can decompose to give $^{\bullet}OH$ or $^{\bullet}OOH$ radicals.[107] The attack of these radicals may initiate the polymer degradation at the anode side, which is evidenced by the observation of the increase of the degradation rate, when operating at the open circuit, or very low current density conditions, which facilitate the diffusion of oxygen gas.[109] The radicals can attack any H-containing bonds in the polymer, e.g., for the end group of CF_2COOH[107,110]

$$R_f - CF_2COOH + {}^{\bullet}OH \rightarrow R_f - CF_2^{\bullet} + CO_2 + H_2O \quad (107)$$

$$R_f - CF_2^{\bullet} + {}^{\bullet}OH \rightarrow R_f - CF_2OH \rightarrow R_f - COF + HF \quad (108)$$

$$R_f - COF + H_2O \rightarrow R_f - COOH + HF \quad (109)$$

As the peroxide radical is considered as the main reason for the polymer degradation, a diluted solution of hydrogen peroxide (3% H_2O_2) was used to investigate the degradation process.[111] A more severe degradation at the cathode side, rather than anode side, of the membrane has been reported.[112] The radicals, such as $^{\bullet}OH$ or $^{\bullet}OOH$, which could be formed during ORR, may cause the degradation process at the cathode side of the membrane. The durability of PEM depends on the mechanical stability (swelling, thickness change), operating conditions, such as temperature, pressure, water management, hydration level, and impurities of reactant gases, and materials contacting the membrane, such as gasket and bipolar plates.

Gas Diffusion Layers

The gas diffusion layers, one next to the anode and the other next to the cathode, are usually made of a porous carbon paper or carbon cloth, typically 100 μm to 300 μm thick. Fig. 14 shows a porous GDL made of carbon paper, which is partially covered by catalyst layer. The porous nature of the backing layer ensures effective diffusion of feed and product components to and from the electrode on the MEA. The correct balance of hydrophobicity in the backing material, obtained by PTFE treatment, allows the appropriate amount of water vapor to reach the MEA, keeping the membrane humidified while allowing the liquid water produced at the cathode to leave the cell. The permeability of oxygen in the GDL affects the limiting current density of ORR, and thus the performance of PEMFC.[113]

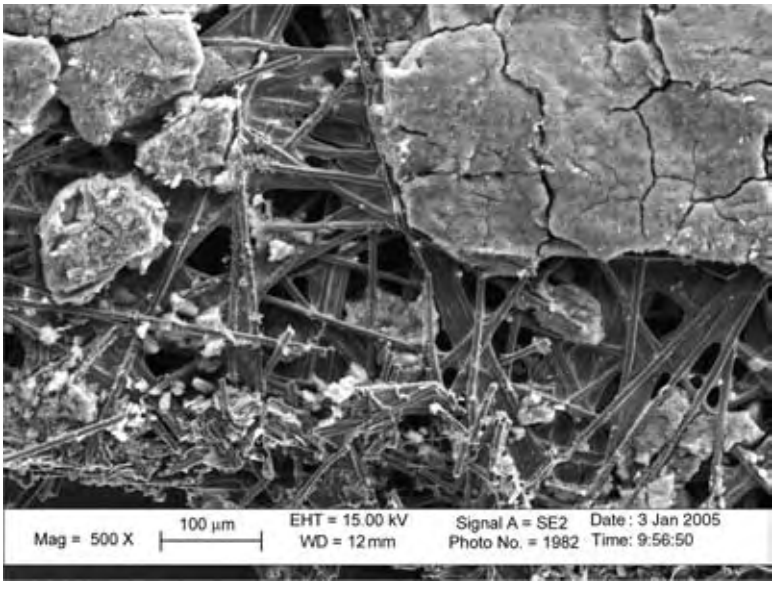

Fig. 14 A SEM (scanning electron microscopy) image of GDL made of carbon paper, which is partially covered by catalyst layer (taken at the author's laboratory).

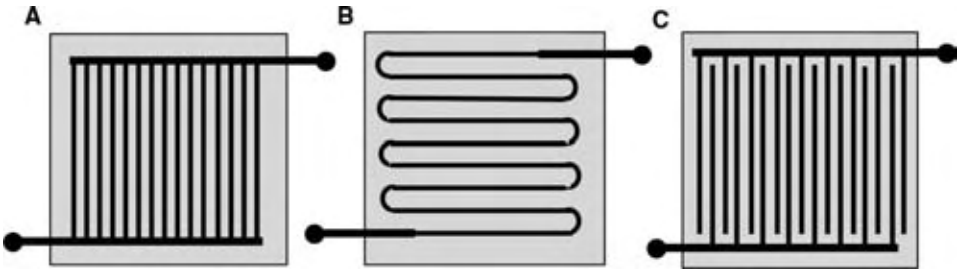

Fig. 15 Some topographies of bipolar plates: (A) parallel; (B) serpentine; and (C) interdigitated flow patterns.

Bipolar Plates

Two plates in a single cell provide a flow field for the feed stream and collect current in fuel cells. The plates should be made of lightweight, mechanically strong, chemically stable, gas impermeable, and electrically conducting materials; graphite (or metal) is commonly used.[114] The pattern of the flow field in a plate, as well as the width and depth of the channels, is very important for the efficiency of PEMFC.[115] A number of plate topologies have been developed including straight, serpentine, and interdigitated flow fields (Fig. 15). The design of the flow field also influences water supply to the membrane, water removal from the cathode, and distributions of current across the cell. In fact, several techniques have been developed to measure the distribution of current density in flow fields of an operating cell.[116,117]

Sealing Materials

Sealing in fuel cell is required to separate gases entering into the cell. The materials for sealing should withstand the acidic environment of electrolyte and be durable for long-term operation. Silicone rubber based materials are widely employed because of their elasticity and excellent heat resistance. Silicone based materials, however, are degraded during the operation due to the acidic environment and thermal stress in the cell. The decomposition product can affect the hydrophobic property of the electrode layer and transport of reacting species, and thus the performance of PEMFC.[118]

Fabrication of MEA

The efficiencies of electrochemical kinetics and transport of reaction species are determined by the effective utilization of the electrodes, membrane, and reactant gases in PEMFC systems.[119,120] The effective design and fabrication of the MEA is the heart of PEMFC technology. The porous gas diffusion layer allows the flow of reactant gases, and also acts as the electron collector while allowing liquid water transport. The electrode is often placed on one side of the GDL by a painting, spraying, or screen-printing technique. The MEA should be designed to maximize the electrode utilization through enhanced transport of protons, electrons, and feed gases and products. Nafion solution is usually added to the electrode to improve accessibility of protons and thus decreases the inactive sites for the electrochemical reaction. However, too much Nafion over electrodes decreases the porosity of the electrode and inhibits transport of reaction species and can also cause electronic insulation. Fig. 16 shows a focus ion beam (FIB) image of the electrode layer on GDL, which provides the surface and sub-surface

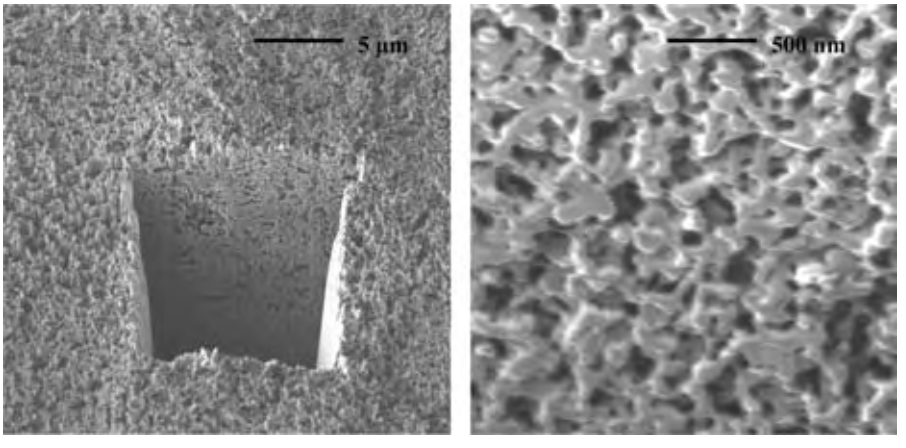

Fig. 16 A surface morphology of an electrode layer (~30 μm) and pore distribution of subsurface trenched (~10 μm) taken at the author's laboratory.

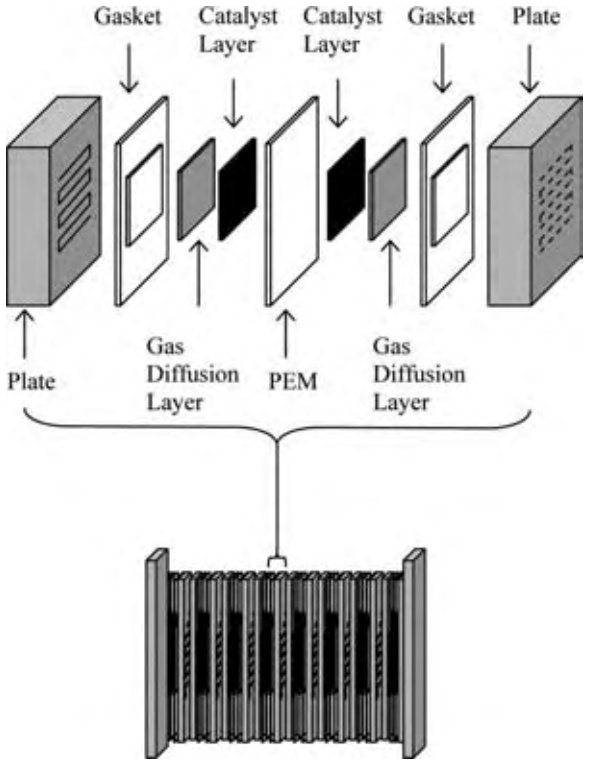

Fig. 17 A schematic diagram of a single fuel cell and a cell stack.

morphology, i.e., porosity distribution, agglomeration of any particular phase, and nanostructure. Design of nanostructure is necessary to optimize a number of properties, such as diffusivity of reactant and products, proton conductivity, electrical conductivity, and hydrophobicity. The preparation of MEA is usually completed by hot pressing the membrane at slightly above its glass transition temperature with the two electrodes in which two anode and cathode layers contact with the membrane. Fig. 17 shows the components of a single cell and a stack. The connection of single cells in a stack can be in series or parallel depending on the voltage and current requirements for specific applications. Large-scale production of MEA for PEMFC should consider a variety of material selection criteria and material processing aspects along with MEA fabrication technologies, which are optimized for the transport and electrochemical reactions.

FUELS FOR PEMFC

Fuels

Hydrogen and methanol are the common choice of fuels for PEMFC. Hydrogen is produced industrially by processing conventional hydrocarbon fuels. This process has been adopted for small-scale generation of hydrogen for use in fuel cells. Fig. 18 shows a general scheme of a hydrogen generation process for PEMFC applications. It consists of fuel reforming, water gas shift reaction, and deep cleaning of CO.[121–123] Steam reforming of methane is generally the most economic way to produce hydrogen industrially. Catalytic hydrodesulfurization and sulfur adsorption should precede the reforming reactions in the conventional plants for hydrogen generation from natural gas. Methanol, which is produced from syngas obtained by steam reforming of methane industrially,[124] can be used directly in DMFC or reformed to hydrogen for PEMFC. The choice of fuel in PEMFC is based on a number of factors, such as safety of fuel, fuel economy, cost for fuel storage, performance, infrastructure, lifecycle cost of transportation, emission, etc.[125]

Fuel Reforming

Fuel reforming can be performed by steam reforming,[126–128] partial oxidation,[128–130] and autothermal reforming.[131–133] The steam reforming reactions for hydrocarbons and alcohols are given below:

$$CH_4 + H_2O(g) = CO + 3H_2 \quad \Delta H = 205.9\,\text{kJ/mol} \tag{110}$$

$$C_mH_n + mH_2O = mCO + \left(m + \frac{n}{2}\right)H_2 \tag{111}$$

$$CH_3OH(g) + H_2O(g) = CO_2 + 3H_2 \quad \Delta H = 49.3\,\text{kJ/mol} \tag{112}$$

$$C_nH_{2n+1}OH + (2n - 1)H_2O = nCO_2 + 3nH_2 \tag{113}$$

Steam reforming reactions are highly endothermic ($\Delta H > 0$), and thus, heat needs to be supplied by the appropriate design of a reactor and a heat exchanger. Industrial methane steam reforming operates at high temperatures (~800°C) over Ni-based catalysts. However, the Ni-based catalysts have several drawbacks, including their high exothermicity for the reaction with air, high tendency for coke formation, and extremely low tolerance of sulfur. Steam reforming of methanol [Eq. (112)] operates at relatively low temperatures (200–400°C) with low steam-to-carbon ratios to produce a reformate with a high H_2 concentration. Cu-based catalysts are highly active for methanol steam reforming. However, the deactivation of Cu-based catalysts, when exposed to liquid water during shutdown, is a concern for PEMFC applications.

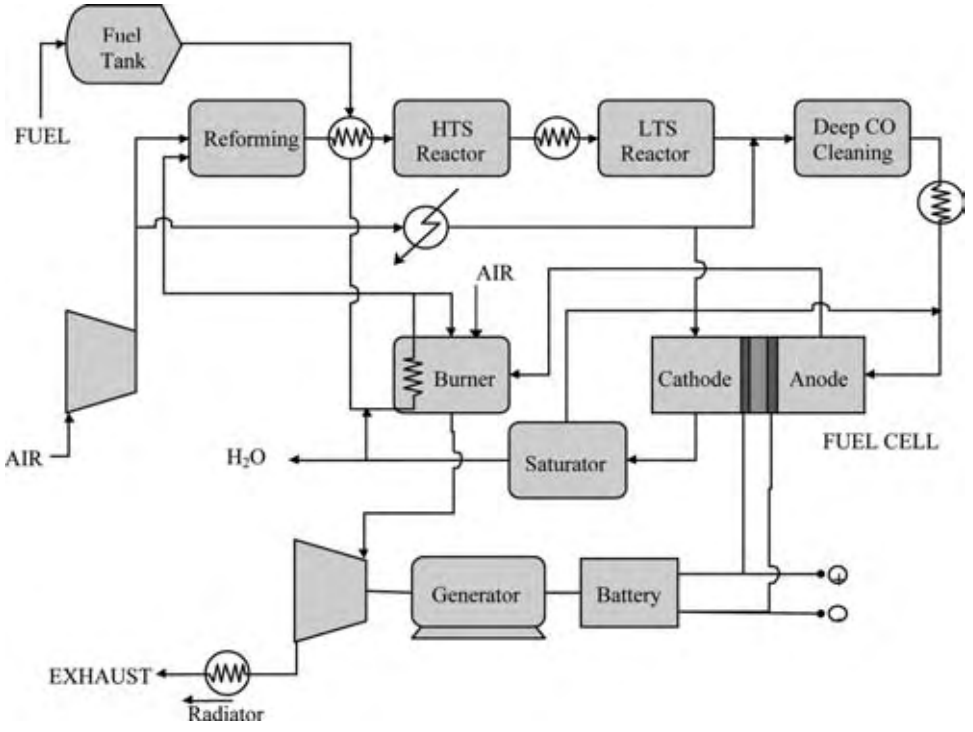

Fig. 18 A general scheme of hydrogen production for PEMFC application. *(View this art in color at www.dekker.com.)*

Partial oxidations of hydrocarbons and alcohols are given by the following:

$$CH_4 + \frac{1}{2}O_2 = CO + 2H_2 \quad \Delta H = -35.9\,\text{kJ/mol} \tag{114}$$

$$C_mH_n + \frac{m}{2}O_2 = mCO + \frac{n}{2}H_2 \tag{115}$$

$$CH_3OH(g) + \frac{1}{2}O_2 = CO_2 + 2H_2 \quad \Delta H = -192.5\,\text{kJ/mol} \tag{116}$$

$$C_nH_{2n+1}OH + \left(n - \frac{1}{2}\right)O_2 = nCO_2 + (n+1)H_2 \tag{117}$$

These partial oxidation reactions are exothermic and, thus, reformers are expected to be energy efficient and compact compared to the steam reforming. The partial oxidation of methane can be carried out by Ni, Co, Rh, and Pt group metals for the temperature range of 700–1000°C, while that of methanol has been studied over Cu-based catalysts in the temperature range of 200–300°C. Autothermal reforming of hydrocarbons and alcohols may be represented by the following:

$$CH_4 + aH_2O + bO_2 = cCO + dCO_2 + eH_2 \quad \Delta H = \sim 0\,\text{kJ/mol} \tag{118}$$

$$C_mH_n + \frac{m}{2}H_2O + \frac{m}{4}O_2 = mCO + \frac{1}{2}(m+n)H_2 \tag{119}$$

$$CH_3OH + a'H_2O + b'O_2 = c'CO + d'CO_2 + e'H_2 \quad \Delta H = \sim 0\,\text{kJ/mol} \tag{120}$$

$$C_nH_{2n+1}OH + \left(n - \frac{1}{2}\right)H_2O + \left(\frac{n}{2} - \frac{1}{4}\right)O_2 = nCO_2 + \left(2n + \frac{1}{2}\right)H_2 \tag{121}$$

Partial oxidation provides quick start-up and compactness, while steam reforming produces relatively high concentration of hydrogen in the product gas. The steam reforming is endothermic and the partial oxidation is exothermic so that the combination of these two reactions in appropriate proportion allows close to thermal neutrality, or adiabatic conditions at the desired temperature. HotSpot™ reactor systems have been developed for the autothermal reforming of methanol.[133]

Water Gas Shift Reaction (CO Cleanup)

The products from the reformer usually contain up to 12% CO depending upon the choice of fuels, catalysts, and operating temperatures. The concentration of CO is reduced further by the water gas shift reaction,[134–136] which is industrially performed in two stages in different temperature regions. First one is the high temperature (320–450°C) shift (HTS) reactor that reduces CO to the equilibrium value for a given set of reaction conditions over Fe_2O_3–Cr_2O_3 catalysts, and the second is low temperature (~200°C) shift (LTS) reactor that provides further reduction of CO over Cu/ZnO catalysts

$$\begin{aligned} CO + H_2O\,(g) &= H_2 + CO_2 \\ \Delta H &= -41.2\,\text{kJ/mol} \end{aligned} \tag{122}$$

The concentration of CO leaving the low temperature shift reactor can be reduced to the range of 0.1–1%, depending on operating conditions. However, it is still too high to be used directly for PEMFC applications.

Deep Cleaning of CO

For the long-term durability of PEMFC, the acceptable CO concentration appears to be 10–100 ppm. To meet the requirement, three possible reactions can be considered: preferential (or selective) oxidation,[137] methanation,[138] and Pd (or Pd alloy) membrane processes.[139–141] Preferential oxidation (PrOx) of CO can convert CO to CO_2, without excessive hydrogen oxidation (to water), to acceptable levels of CO using multi-stage reactors

$$\begin{aligned} CO + \frac{1}{2}O_2 &= CO_2 \\ \Delta H &= -283.0\,\text{kJ/mol} \end{aligned} \tag{123}$$

$$\begin{aligned} H_2 + \frac{1}{2}O_2 &= H_2O\,(g) \\ \Delta H &= -241.8\,\text{kJ/mol (undesirable)} \end{aligned} \tag{124}$$

Methanation can also be used for deep CO cleaning process

$$\begin{aligned} CO + 3H_2 &= CH_4 + H_2O\,(g) \\ \Delta H &= -205.9\,\text{kJ/mol} \end{aligned} \tag{125}$$

However, it requires three molecules of hydrogen for the removal of a CO molecule. Furthermore, the control of the reaction is difficult because of the presence of CO_2 created by the following undesirable reactions

$$\begin{aligned} CO + H_2O\,(g) &= CO_2 + H_2 \\ \Delta H &= -41.2\,\text{kJ/mol (undesirable)} \end{aligned} \tag{126}$$

$$\begin{aligned} CH_4 + 2H_2O\,(g) &= CO_2 + 4H_2 \\ \Delta H &= 164.7\,\text{kJ/mol (undesirable)} \end{aligned} \tag{127}$$

Thus, the methanation reaction appears to be impractical in conjunction with PEMFC, especially for on-board use in vehicles.

Palladium (or Pd alloy) membranes can be effectively used for CO removal or hydrogen separation because hydrogen diffuses through dense palladium membranes extremely selectively. Thin layers of Pd can be prepared over the steam reforming or water gas shift reactor so that only hydrogen can diffuse through the membrane. In principle, this combined system can represent the integration of reforming, water gas shift, and deep cleanup of CO in a compact way suitable for transportation applications. However, the need for a high pressure difference, relatively high temperature (300–400°C), and high cost are drawbacks of this process.

Hydrogen Storage

Hydrogen can be stored in the form of compressed gas[142] or as a liquid.[143] It is also stored in solids using adsorbents[144–146] and metal hydrides.[147,148] Hydrogen storage as a compressed gas in a high-pressure cylinder (200–300 bar) can be widely used because of its simplicity and low cost for storage. However, it requires a relatively large vessel volume compared to the other techniques because of the low density of hydrogen in its gas state. Hydrogen can also be stored as a liquid at the boiling point of hydrogen (−252.67°C) in highly insulated vacuum containers. This technique has higher volumetric hydrogen density. However, a large amount of energy is needed to liquefy hydrogen gas and a special vessel is also required to reduce evaporation of liquid hydrogen over a long period of time. Hydrogen can be stored in solid adsorbents, such as activated carbon[144] and nanostructured materials.[145,146] Some metals can absorb hydrogen under moderate pressures, forming reversible hydrogen compounds called hydrides, e.g., $NaBH_4$, $LiBH_4$, and $LaNi_5H_6$.[147,148] As hydrogen is stored in its atomic form in the metal alloy state, storing hydrogen in metal hydrides is volumetrically effective, but the weight of metal alloy along with vessel for the alloy is quite high compared to other techniques. The challenging issues in complex metal hydrides are the dense packing hydrogen atoms and scientific understanding

of the mechanisms and kinetics of the absorption and desorption.

FUTURE CHALLENGES OF PEMFC

Although there have been significant technological advancements in PEMFC, there are still some fundamental issues that need to be addressed before its anticipated commercialization. Some significant challenges in obtaining the performance enhancement of PEMFC include the development of: i) anodes tolerant to CO ($\sim$100 ppm) with noble metal loading lower than 0.1 mg/cm^2 MEA; ii) cathodes which reduce overpotentials with noble metal loading lower than 0.1mg /cm^2 MEA; iii) electrolytes which are relatively inexpensive, highly conductive, stable at high temperature (150–200°C), and/or impermeable to methanol; iv) electrolytes working without water so that the cumbersome hydration equipment is not required; v) efficient storage materials for hydrogen; vi) hydrogen generation processes optimized and reduced in size and complexity; and vii) low cost fuel cell stacks by increasing the effectiveness of all the components of fuel cells. Other concerns include the durability of PEMFC components and the ability to withstand temperature extremes common in North America, including well below freezing.

CONCLUSIONS

This article reviews fundamental knowledge and understanding of PEMFC. It is hoped that this review has provided useful information for PEMFC researchers and others who are interested in fuel cell systems. It is possible that power generation via fuel cells will become as common as that at present via heat engine that could provide substantial economic and environmental benefits.

Reactive Extrusion

Gerard T. Caneba
Department of Chemical Engineering, Michigan Technological University, Houghton, Michigan, U.S.A.

INTRODUCTION

In the last quarter of the 20th century, there has been a tremendous spurt in the manufacture and application of polymers. The rapid growth of the polymer industry since the 1970s has led to the development of new methods of polymer synthesis and processing. An operation where simultaneous polymer synthesis and processing occurs is called reactive processing. Reactive extrusion (REX) and reaction injection molding (RIM) are particular examples of reactive processing. In REX, polymerization and other reactions and formulations associated with polymers are carried out inside the extruder, while processing is underway.

In the 1960s, practical processes for several types of chemical reactions run in extruder reactors were developed in a number of industrial laboratories. Landmark examples of reactive processing include controlled rheology of polyolefins by controlled molecular weight degradation, halogenation of polyolefins, and grafting of acrylic acid and vinylsilanes. Various commercial products are being manufactured through reactive processing and more are being produced every year. Compounding is being done more effectively through reactive processing because of the added dimension of chemical reaction in using a processing type of equipment. Such an approach has resulted in better performing products and/or lower cost.

CHEMICAL REACTIONS WITHIN REX SYSTEMS

REX, also called reactive compounding, refers to performance of chemical reactions during the extrusion processing of polymers.[1] In this case, an extrusion device is used as a chemical reactor instead of being used only as a processing equipment. Fig. 1 shows a schematic of a typical REX operation.

An early published example of reactive processing was a description of bulk polymerization of caprolactam in an extruder to give nylon-6.[2] Intense activity in recent years, mostly in industrial laboratories and at extruder companies, has produced more than 600 patents and 60 published papers on the subject of reactive processing or REX.[3] Various types of polymer reactions that have been implemented through REX include:[4]

1. Bulk polymerizations, such as addition (free-radical- and ionic-based) and step-growth types.
2. Grafting polymerization by small molecules.
3. Interchain copolymer formation, based on chain cleavage, graft copolymerization, and end-group block copolymerization.
4. Coupling and branching.
5. Controlled degradation.
6. Polymer functionalization and functional group modification.

Bulk Polymerization

In this type of polymerization, an undiluted monomer or mixture of monomers is converted to a high molecular weight homopolymer or copolymer. The progress of the reaction is characterized by a large increase in the viscosity of the reacting mixture (from less than 50 Pa-s to greater than 1,000 Pa-s). Two reaction mechanisms of bulk polymerization have been implemented in REX: free-radical addition and condensation reaction chemistries.

Addition, also known as chain polymerization, occurs when the monomer units are added singly to a growing chain. The reaction takes place in three steps. The first is initiation, wherein a catalyst or initiator molecule (I) is broken down to give free radicals ($R^{\bullet}$ or $RO^{\bullet}$). A free radical activates a single monomer unit to produce the primary radical ($R'\text{-}M^{\bullet}$). The next step is propagation, wherein new monomer units are singly added to the radical ends. As the propagation reaction proceeds, these polymer radicals grow in length, and the molecular weight of the polymer increases. The third and final step is termination, in which two polymer radicals either combine or undergo a charge transfer to form dead polymer molecules. The former type of termination is called coupling or recombination, while the latter case is called disproportionation. An outline of the basic free-radical addition polymerization is shown below.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120027022

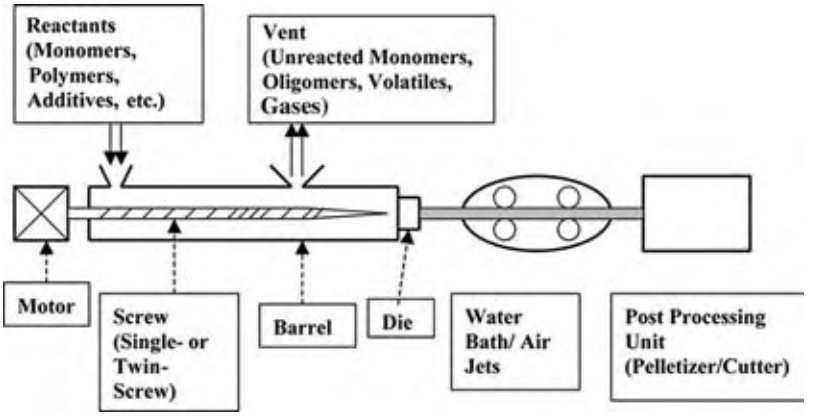

Fig. 1 Schematic of a reactive extrusion (REX) system.

Initiation:

$$I \Longrightarrow 2R^{\bullet} \text{ or } 2RO^{\bullet} + \text{Gas}$$

$$R^{\bullet} \text{ or } RO^{\bullet} + M \Longrightarrow R' - M^{\bullet}$$

Propagation:

$$R' - M^{\bullet} \Longrightarrow R' - M - M^{\bullet}$$

$$\vdots$$

$$R' - M_n^{\bullet} + M \Longrightarrow R' - M_{n+1}^{\bullet}$$

Termination:

$$R' - M_x^{\bullet} + R' - M_y^{\bullet} \Longrightarrow R' - M_{x+y} - R'$$

(Coupling or Recombination)

$$\Longrightarrow R' - M_{x+1} + R' - M_y - 1$$

(Disproportionation)

Chain Transfer:

$$R' - M_x^{\bullet} + C_T \Longrightarrow R' - M_x + C_T$$

The species C_T is the chain transfer agent, which can be monomer, solvent, initiator, and/or polymer molecules. The new radical site $C_T\bullet$ can in turn undergo further propagation, termination, and chain transfer reactions.

Bulk addition multipolymerization kinetics occurs when two monomers are employed. Bulk free-radical homopolymerizations and copolymerizations that are implemented in REX include:[4] a) styrene-acrylonitrile, styrene-methyl methacrylate, styrene-acrylamide; b) methyl methacrylate-acrylonitrile, ABS; c) acrylate ester mixtures; d) ethyl acrylate-methacrylic acid and mixtures with other monomers; e) methyl methacrylate; f) ε-caprolactone;[5,6] and, *n*-isopropylacrylamide-acrylic acid-alkyl acrylates.[7–11] To implement REX for bulk free-radical polymerizations, the highest possible operating temperature is used for maximum reaction rate. Both single (1.2 m diameter, 15.2 m long, at production rate in the order of 900 kg/h) and twin screws have been used, although better heat removal was obtained using twin intermeshing self-wiping screws. Sometimes, a low-viscosity prepolymer is produced using a CSTR leading to a REX reactor.

Step-growth polymerization occurs when two individual molecules react to form the monomer. Two monomers react to form a dimer. These dimers react to form tetramers, etc. If at each step a byproduct small molecule is excluded, such as water or an alcohol, then we have the so-called condensation polymerization. A scheme describing a polyesterification reaction involving the manufacture of poly ethylene terephthalate (PET), which is used to produce plastic beverage bottles, is shown below.

$$n\text{HOOC-}(C_6H_6)\text{-COOH} + n\text{HO-}(CH_2)_2\text{-OH} \Longrightarrow \text{^^^[-(CO)-}(C_6H_6)\text{-(CO)-O-}(CH_2)_2\text{-O-]}_n\text{^^^} + nH_2O$$

Terephphthalic Acid — Ethylene Glycol — PET — Water

Polyesters, polyetherimide, melamine-formaldehyde, polyurethanes, polyurethane-ureas and polyamides (nylons)[12,13] are examples of condensation polymers prepared by REX.[4] Because a small molecule is produced in condensation reactions, vent ports are employed. Between the ports are melt sealing screw sections, to prevent back mixing of volatilizing melt. Sealing screw sections are constructed by a right handed–left handed sequence of screw elements. Another chemistry feature of step-growth reactions is their sensitivity to errors in stoichiometric feed proportions. This poses problems with solid feed materials, which are normally converted to liquid form for more

accurate metering. In a representative process for the production of a polyurethane from 9 parts butane-1,4-diol chain extender, and 91 parts low molecular weight polyester (OH number = 51.7, prepared from adipic acid and butane-1,4-diol), and 35 parts 4,4′-diisocyanatodiphenylmethane, the reactants are fed as liquids into the 53-mm-diameter 1855-mm-long twin-screw extruder with corotating self-wiping screws. The extruder entry zone is at 90–120°C, the middle section at 180–260°C, and the last section at 100–180°C. The extruder has two to three kneading zones that are 240-mm long, to prevent the formation of gel inhomogeneities at 0.8–2.5 min residence times with throughputs of 10–100 kg/h and screw speeds of 70–130 rpm.

Polyureas have been produced in an extruder from where it comes out as a shaped product inside a mold.[14] This special type of REX is called RIM. Polyurea is formed (a) directly from a complex or (b) from the reaction of the complex with a second amine:

$$\text{Amine} + \text{Isocyanate} \Longleftrightarrow \text{Complex} \longrightarrow \text{Polyurea(a)}$$

or

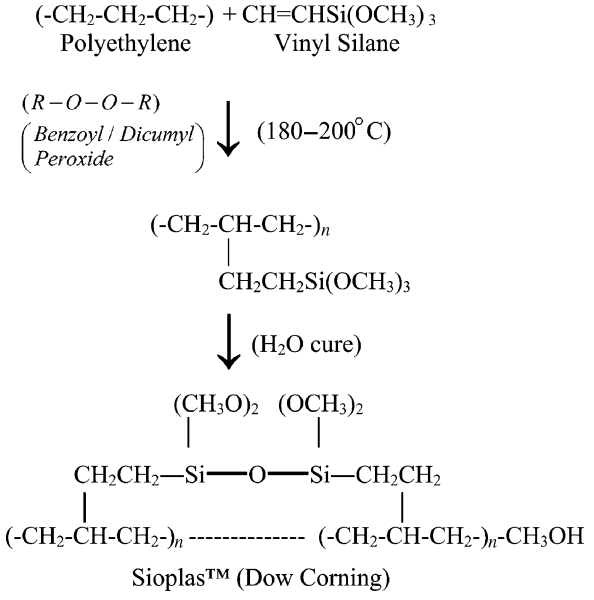
$$\text{Amine} + \text{Isocyanate} \Longleftrightarrow \text{Complex} + \text{Amine} \longrightarrow \text{Polyurea(b)}$$

Usually, methylene diisocyanate (MDI) is used with m-phenyl diamine (m-PDA) with hard (aromatic amine) or- soft (amine terminated polyether with MW of 500–5400 Daltons) chain extenders. With optimized formulations and extruder-mold conditions, cycle times of 3 to over 5 min can be obtained. With the use of internal mold release agents, the cycle time can be reduced to less than 2 min. Typical RIM operations for the production of automotive parts can run down to 1-min cycle time. These products range from the softer bumper covers to stiffer vertical body panels, such as fenders, doors, and quarter panels.

Bulk polymerizations are also implemented in REX systems in the presence of pre-existing polymers, to produce interpenetrating polymer networks (IPNs) (Refer discussion of IPNs in a later section).

Grafting Polymerization by Reactive Small Molecules

This involves the formation of graft copolymers from a reaction between polymers and monomers.[4] Monomer units can be propagated onto the polymer backbone to form a graft structure. Free radicals, air, or ionizing radiations are used to initiate the reaction. A schematic representation is shown below. A more specific case, the manufacture of vinyl silane (Sioplas™), is also been presented. Sioplas™ has been developed by Dow Corning and is used in wire coating and pipe insulation processes.



The REX process is normally carried out in two steps, with the first step occurring at 180–200°C. The mixture is passed through another REX reactor for mixing, and then through a final shaping REX reactor to complete the water curing reaction. The final cross-linked product (Sioplas™) is used as a wire or cable coating.

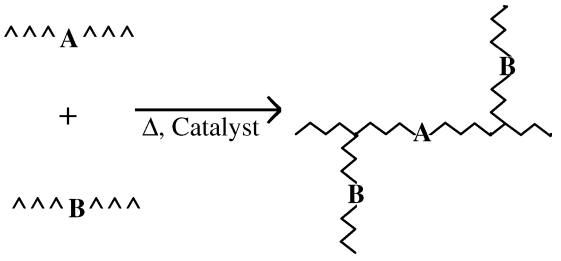
Grafting onto polyolefins (especially branched polyolefins) using free-radical sources is feasible because of the relative stability of these radical sites.[15] Moreover, propagation of certain monomers from radical sites is favored. Thus, it has been reported that acrylic acid, its derivatives and analogs (acrylic acid, methacrylic acid, glycidyl acrylate, butyl acrylate, methyl methacrylate, lauryl methacrylate, butyl methacrylate, polyethylene glycol methacrylates, 2-hydroxyethyl methacrylate, styrene, styrene-acrylonitrile, other styrene derivatives, and trialkoxysilane-containing monomers) have been grafted onto various polyolefins and copolymers (PE, PP, EP, EVA, ethylene-butyl acrylate, natural rubber, EPDM, PB, poly(ethylene oxide)) using REX operations.[4,16–19]

Interchain Copolymer Formation

This involves the reaction between two or more polymers to form a copolymer.[4] Interchain copolymer

formation is further subdivided into the following types:

i. Graft copolymerization:



A popular example involves the grafting of maleic anhydride (MA) onto polypropylene (PP) using peroxide initiators. MA grafts become reactive sites along the PP chains resulting in the first polymer substrate. A second polymer substrate (Nylon 6) is intensely mixed with it to produce rubber-toughened nylon.[20] Other graft copolymers produced in this scheme involve ethylene-vinyl acetate-g-glycidyl methacrylate/styrene-maleic anhydride, and ethyl acrylate-vinylbenzyl chloride copolymer/Nylon 6,6 first substrate/second substrate combinations. Another system developed by Dow Chemical Co. involves a reactive polystyrene, RPS, as the first substrate, which is a polystyrene with approximately 1% reactive oxazoline groups distributed randomly along the chain. The oxazoline ring, which is reactive to both weak and strong nucleophiles, can react with the polymers that are terminated with amine, mercaptan, hydroxyl, epoxy, anhydride, and carboxylic acid groups.[4]

ii. Block copolymerization by end-group reaction:

For example, Nylon 6,6 can be reacted with PET in a reactive extruder to produce a block copolymer. However, as the concentration of A and B groups is relatively low, long residence times are required. Thus, it is more economical to form the block copolymer by other methods.[3]

Coupling/Branching

This type of reaction is one in which a homopolymer interacts with a polyfunctional agent to build molecular weight by chain extension or branching.[4] In Table 1, some examples of these reactions are tabulated.

For the Nylon 6,6 chain extension reaction,[21] a 5-cm single-screw extruder was used with a 5-min residence time. As the coupling agent is multifunctional, some branching can occur. Stoichiometric control is important to produce the required exact amount of branching. If no branching is required, a slight excess of the coupling agent has been used.

Controlled degradation

Controlled degradation is a reaction in which a reduction in polymer molecular weight is effected to meet the specific performance criteria.[4] One such application of controlled degradation is in the preparation

Table 1 Examples of coupling/branching reactions implemented with REX

Polymer(s)	Agent(s)	Temperature (°C)	Result
Nylon -6, -66[21]	Triphenyl phosphite (1% by weight)	250–300	Increase in molecular wt
PET[22]	Triphenyl phosphite (0.5–2.5% by weight)	265–285	A 40% increase in molecular wt
Linear PC[23]	1,1,1-tri(4-hydroxy-phenyl) ethane, 2,2′5,5′-tetra(4-hydroxyphenyl) hexane, trimellitic anhydride, trimellitic acid, trimellitoyl trichloride, 4-chloroformyl phthalic anhydride, pyromellitic acid, pyromellitic dianhydride, mellitic acid, mellitic anhydride, trimesic acid, benzophenonetetracarboxylic acid and benzophenonetetracarboxylic anhydride (0.1–10 % by weight)	100–400	Increased branching and crosslinking
Linear PC[24]	Triacrylate and peroxide	100–350	Increased branching

of lower-viscosity resins for injection molding.

$$\text{Polypropylene} \xrightarrow[Air,290^{\circ}C]{} \text{Decrease in molecular weight, viscosity, and elasticity (BASF, Exxon)}$$

$$\text{Polypropylene} \xrightarrow[(220-240^{\circ}C,Dialkyl-Peroxide)]{} \text{Increase in molecular weight, viscosity, and elasticity.}$$

$$\text{Poly(ethylene terphthalate)} \xrightarrow[(265-275^{\circ}C,0.19\%\ Ethylene-Glycol)]{} \text{20\% decrease in viscosity (Eastman Kodak).}$$

Controlled degradation of PP (BASF, Exxon) was done using a single-screw extruder with an air and polymer feed. The Eastman Kodak PET degradation process involves the coextrusion of PET and ethylene glycol.

In a more recent work, REX was used to produce levulinic acid by controlled degradation of Starch.[25]

Polymer Functionalization and Functional Group Modification

This application area involves the introduction of functional groups onto polymer backbone, end group, side chain, or modification of existing functional groups.[4] Thus, it is an intermediate result of some of the above-mentioned REX reactions, such as grafting and coupling. Chlorinated PVC (CPVC) is an end product from this type of reaction, wherein chlorine gas is reacted with PVC or LDPE. Other polyolefins, such as butyl rubber, high density or linear low density polyethylene, EP rubber, EPDM, EVA, or polyisobutylene, have been used as feedstocks for the formation of various chlorinated products. Challenges of this type of operation include widely varying viscosities, corrosion, and removal of hydrogen and hydrogen chloride gases. The reaction is conducted in a 5-cm extruder with nonintermeshing counter-rotating twin screw made from Hastelloy. Gas removal zones are isolated by melt seals from reverse-flight screw elements. Chlorine incorporations of 0.38–3.64% have been realized from these other polyolefin materials at 90–300 rpm, maximum temperatures of 140–220°C, and yields of 25–83 kg/h.

Other examples of functionalization/functional group modifications systems implemented in REX include:

1. Saponification of EVA with sodium methoxide in methanol using a twin-screw extruder.
2. Capping of carboxylic acid end groups, such as PET, with 1 wt% phenyl glycidyl ether at 255°C by coextrusion in a twin-screw extruder.
3. Hydrolysis of acyl fluoride end groups on hexafluoropropylene-tetrafluoroethylene copolymer with 1% water in a corrosion-resistant 28-mm intermeshing twin-screw extruder at 360°C.
4. Cyclicization of pendant carboxylic acid groups, such as the ammonia treatment of poly(methyl methacrylate) at 310°C to give ring closure of adjacent carboxylic acid unite to produce 2,6-piperidinedione (glutarimide) units in the chain.
5. Introduction of hydroperoxide groups into polyethylene by coextrusion with air under pressure at 190°C in a 20-mm extruder with 3-min residence time.
6. Grafting of muconic acid onto polyolefins.[26]
7. Conversion of polyketones to polyesters with organic acid.[27]
8. Conversion of poly(acrylic acid) to poly(*n*-isopropylacrylamide).[7–11]

Reactive compounding using REX[28,29] could involve the above-mentioned reactions. In a number of instances, the reactions involved are not well defined and/or is a complicated combination of the above-mentioned chemistries.[30–34] Most recently, REX has been used to make nanosilicates (nanoclay) compatible,[35] which signals a new emerging area of nanocomposite (nanometer-scale particles in polymers) manufacture using REX methods.

ADVANTAGES AND DISADVANTAGES OF REX

REX has certain advantages over other types of reactors, although it has its own set of limitations.[36,37] It involves higher surface-to-volume ratio compared to a stirred-tank reactor, resulting in better mixing, homogenization, and even temperature control. Consequently, there is better distribution of reactants, resulting in faster conversion rates. Also, REX involves easier venting of volatiles and unreacted monomer, and less chance of stagnation and thermal degradation. Because of the capability to impart relatively high mixing power per fluid volume, REX has the ability to handle highly viscous fluids, such as high polymers. Sections of screw elements can be constructed in series in REX operations, which results in operational flexibility and versatility, cleanliness, and ability to create specific reaction zones. If the operation is possible at all, the normal result is a lower process investment cost.

A disadvantage of REX operation is its difficulty with low-viscosity fluids (<10 Pa-s) and temperature control especially for highly exothermic reactions. Usually, a critical design criterion is that REX is not feasible beyond the residence times greater than

1000 s. Finally, there is no such thing as a multipurpose REX system, as their designs are specific to the chemistry and material properties of materials being handled.

Equipment

Reactive processing is limited to polymerization or chemical reactions of polymers in conventional single-screw or twin-screw extruders, excluding processes in oscillatory kneaders, Banbury-type continuous mixers, or Diskpack equipment. Emphasis is placed on continuous processes that have been implemented commercially or that can serve as models for commercial purposes.

A reactive extruder may be considered to be a horizontal reactor with one or two internal screws for conveying reactant polymer or monomer in the form of a solid or slurry, melt, or liquid. The most common reactants are polymer or prepolymer melts and gaseous, liquid, or molten low molecular weight compounds.

A particular advantage of the extruder as a chemical reactor in this context is the absence of a solvent as the reaction medium. No solvent stripping or recovery process is required, and the product contamination by solvent impurities is avoided. However it should be noted that minor amounts of small molecule species can be used in REX operations. In this case, REX also allows stripping of these components in isolated sections of the extruder.

Because of their versatility, most extruder reactors are twin-screw extruders that possess a segmented barrel, each segment of which can be individually heated or cooled externally. In addition to external heating, a molten material may be shear heated by the resistance of the viscous material to the conveying motion of the screw; these processes provide energy for the chemical reaction. Extruder screws often have specialized sections or configurations, e.g., high shear mixing sections. Twin-screw extruder screws may be equipped with interchangeable screw elements that provide different degrees of mixing and surface area exposure by varying the depth between screw flights, the individual flight thickness, and the direction and degree of flight pitch. Kneading blocks may be included as screw elements to provide intensive mixing. By varying the external heating, the screw element configuration, the clearance between screw and barrel wall in individual barrel segments, the total energy and the degree of mixing of material in each barrel segment may be varied. In this way, an extruder may be transformed into a chemical reactor with controlled reaction zones made up of individual barrel segments. In each of these segments sequential chemical processes can occur.

PROCESS PROCEDURE AND CONDITIONS

In a typical REX process, the reactants are fed into the extruder feed throat, where the material is usually heated to initiate reaction or increase the reaction rate. The reactant mixture is conveyed through sequential barrel segments, where the degree of mixing and specific energy input bring the reaction to the desired degree of completion, within the limits of residence time in the extruder. At this stage, the reaction may be quenched by cooling or addition of a catalyst quencher where applicable, and volatile by-products or excess reactants may be removed. Molten polymer is forced from the extruder through a die with one or more openings. The geometry of the die openings is one factor determining the pressure against which the extruder has to pump by the conveying motion of the internal screw. Polymer melt issuing from the die is usually rapidly cooled by contact with a fluid medium such as water. Cooling and solidification quench any chemical reaction that still occurs but may not have been particularly quenched in the extruder.

An advantage of an extrusion device as a reactor is the combination of several chemical process operations into one piece of equipment with accompanying high space-time yields of product. An extruder reactor is ideally suited for continuous production of material after equilibrium is established in the extruder barrel for the desired chemical processes.

For extruder reactors typical operating conditions are 70–500°C. Although this entire range of temperatures may extend over the length of an extruder, the temperature differential between adjacent barrel segments is often greater than 100°C because of slow heat transfer to and from reactant material. Typical extruder residence times are 10–600s. Residence time and, hence, the time available for chemical reaction is determined by extruder length, rate of introduction of reactants, and screw speed. Often greater versatility may be achieved by running a chemical reaction in two or more extruders connected in series.

By providing individual barrel segments with external openings, it is possible to introduce solid, liquid, or gaseous reactants at specified points in the chemical process. Their residence time in the reactor is controlled by the distance between the injection point and the die. For example, a heat-sensitive reactant may be introduced at a barrel segment near the die to minimize residence time. Similarly, an inert gas may be introduced at the extruder feed throat to protect a process from atmospheric oxygen. Volatile by-products from chemical reactions or excess reactants may be easily removed by applying a vacuum to the appropriate barrel segment and providing the appropriate screw segment with proper flight depth and geometry to ensure efficient surface renewal and exposure of the reaction

mixture to low pressure. The individual reaction zones at different pressures may be segregated from one and another by melt seals formed by restricting the flow of material both before and after the zone. Melt seals are commonly formed by using reverse flight and/or shallow screw flight segments that prevent back mixing of material in adjacent zones. Typical pressures encountered in REX processes are 0–50 MPa (7250 psi).

With the highly efficient mixing provided by an extruder, it is possible for two materials with great differences in viscosity to react. In the extreme case, molten polyolefins have been chlorinated using chlorine gas in a commercial extrusion process developed at Exxon.[20] A key to the success of this process is the design of the screw element geometry to give highly efficient surface renewal of polyolefin in contact with chlorine gas in a pressurized reaction zone segregated from the remainder of the extruder by formation of melt seals.

INTERPENETRATING POLYMER NETWORK SYSTEMS

A very convenient use of reactive processing equipment systems is the formation of IPNs. Traditionally, IPNs are synthesized by swelling a crosslinked polymer (Polymer I) with a second monomer together with crosslinking and activating agents, and then polymerizing the monomer in situ[38,39] to form Polymer II. An IPN can be distinguished from simple polymer blends, blocks, and grafts in two ways: 1) An IPN swells, but does not dissolve in solvents and 2) creep and flow are suppressed. Due to the wide range of possibilities covered by the working definition of IPN and its extensions, it is obvious that polymer scientists and engineers have barely scratched the surface of what is rapidly becoming one of the major areas of technological learning. In terms of mechanical properties, desirable characteristics of the two polymeric materials making up the IPN seem to have been preserved.

A number of variations of the above-mentioned full IPNs have also been stated in the literature.[40] One of them involves having either Polymer I or II as linear (not crosslinked) polymer, in which case it is called semi-IPN. The other variation involves the formation of Polymer I and II simultaneously through two noninterfering polymerization processes (such as stepwise and chain polymerizations); in which case it is called simultaneous IPN (SIN). If a linear polymer is formed simultaneously with a crosslinked polymer, then we have a semisimultaneous IPN (semi-SINS). Still another type is taking a mixture of two linear polymers, and crosslinking both components simultaneously, in which case it is called interpenetrating elastomeric network (IEN). The common feature of all these types of IPNs is that a monomer system is being polymerized in the presence of another polymer.

If physical crosslinks are used in an IPN system, then we would have a thermoplastic IPN.[41] Up to this time, few IPNs or SINs have been made where both components are elastomeric. One of these rare works involves the crosslinking of cis-1,4-polyisoprene (Elastollan) in thermoplastic polyurethanes (Morthane).[42]

Examples of IPN systems in which the pre-existing polymer was usually an elastomer include: a) ethyl acrylate, methyl methacrylate, or styrene and tetraethylene glycol dimethacrylate (TEGDM) as crosslinking agent was polymerized with dissolved benzoin or dicumyl peroxide by exposure to ultraviolet (UV) light or application of heat, respectively;[43] (b) butadiene crosslinked with peroxides using potassium persulfate as initiator in an emulsion;[44] (c) castor oil crosslinked by tolylene diisocyanate (TDI);[45] (d) styrene polymerized in SBR by thermal polymerization techniques;[44] (e) simultaneous IPN of castor oil crosslinked with TDI and styrene crosslinked with divinylbenzene (DVB) using benzoin and UV light.[45]

A work in IPN systems involving a Hytrel^{TM} copolyester includes crosslinking of methyl methacrylate (20%) with ethylene glycol dimethacrylate (1%) and an initiator in Hytrel 7246 fibers (3.1%) and alumina filler (61.9%),[46] wherein the product exhibited good impact and crack resistance. Another work involves the vulcanizing of acetal resins (Delrin 100F, 80%) with 0.01–5 phr isocyanates or isothiocyanates (Desmodur TT) in Hytrel 4056 (20%)[47] to produce high impact strength mixtures. The work in which chloroprene rubbers (Denka Chloroprene DCR-35, 50 parts) is vulcanized with diglycidyl phthalate (5 parts) in Hytrel HTC2551 (50 parts) resulted in tensile strength of 1.88 MPa, elongation of 390%, and Shore D hardness of 35 compared with 0.45 MPa, 40%, and 31, respectively, for a similar test piece without Hytrel.[48] An interesting type of IPN work with Hytrel involves the radiocuring (1.5 MeV of electron beam, Mrad) of poly(vinylidene fluoride) (30 parts) with triallyl isocyanurate (3 parts) in Hytrel (70 parts), which gave good flexibility, transparency, and flame resistance.[49]

PROCESS DESIGN CONSIDERATIONS

It is usually not possible to employ a simple commercial single- or twin-screw extruder for a given chemical reaction without considerable modification. For optimum operation, an extruder reactor must be custom designed with specific knowledge of the type of chemical reaction desired. Numerous parameters must be considered, such as the number of barrel segments and barrel diameter; length of the conveying screw; screw element design in

the individual barrel segments; venting locations; control of by-products and excess reactants; heat transfer; feed injection points; feed-rate control; feed quality, metallurgy, and corrosion; product quenching, cooling, and forming; and online analyzers.

The limited residence time available for reaction in an extruder is often a disadvantage. Although about 30 min is the maximum, less than 5-min residence time is usually observed in commercial extruders with realistic barrel lengths. Thus, the kinetics of the desired chemical reaction must be such that about 1–5 min would be the sufficient time for complete reaction, although when applicable, catalysis frequently shortens the time required for reaction.

Despite the advantages of operating without a solvent, there are disadvantages as well. The beneficial effects on the rate and outcome of reaction often observed in inorganic and polymer reactions by changing solvent polarity, hydrogen bonding ability, boiling point, and other parameters are not easily duplicated in a melt process. The absence of a liquid phase in most REX processes may make heat transfer inefficient and difficult to control in exothermic chemical reactions. Liquids may be highly effective heat-transfer agents, whereas most polymer melts have only low thermal conductivity. However, as a common characteristic of extruder reactors is the very high surface to volume ratio of reactant mixture, problems involving heat transfer are easily overcome. When liquid reactants are used, a certain minimum viscosity is required for efficient conveyance through an extruder. Variation in screw geometry and sequential extruders may be used to overcome problems with low-viscosity bulk reactants.

Small commercial continuous extruders require a minimum of 100–1000 g of material for a typical experiment. Such extruder reactions may not be convenient for running a large matrix of screening experiments to optimize processing conditions, especially when limited amounts of valuable starting materials are involved. Most commercial REX processes are simple one-step chemical reactions between inexpensive and readily available starting materials. REX is particularly suited for ''just-in-time'' inventory control of a commercial polymer product because the total time involved in reaction and product finishing is often much shorter than in conventional continuous processes.

CONCLUSIONS

The process REX involves chemical reactions within an extruder equipment and has several advantages over conventional manufacturing methods. Not only does it mean a reduction in equipment cost, but also unique advantages have been realized in cases wherein relatively fast chemical reactions occur in viscous fluids. However, limitations have been observed, such as limited residence times and inability to handle thin fluids. In general, if possible, REX is a method that should always be given serious consideration.

Reactive Separation

Vincent G. Gomes
University of Sydney, Sydney, New South Wales, Australia

INTRODUCTION

Many industrially important chemical reactions are limited by the equilibrium conversion of reactants within a feed and product mix. An important recent innovation in process design and operation is to combine the reaction and separation steps in a single unit operation known as reactive separation or integrated reactive separation and the process unit is called a multifunctional reactor. This combination has been recognized by the process industries as having favorable economics and as an important means for implementing process intensification for certain classes of reacting systems. This entry primarily provides an overview of reactive separation processes in use or under development and describes the design, operation, optimization, and control issues associated with selected classes of reactive separations. Particular emphasis is placed on reactions involving gas/liquid and gas/liquid/solid systems, both mediated by catalysts. The entry includes recent results and important on-going innovations in this fast-developing field.

PROCESS DESCRIPTION

A new class of unit operation, known as reactive separation or integrated reactive separation using a multifunctional reactor, is currently under various stages of development and implementation.[1–8] Process intensification presents one of the most important trends in today's process technology. It consists of the development of innovative processes that offer drastic improvements in chemical manufacturing and processing, substantially decreasing equipment volume, energy consumption, or waste formation, and ultimately leading to cheaper, safer, sustainable technologies.

Reactive separation processes are of significant industrial importance owing to the potential opportunities in generating novel products and their substantial technical and commercial advantages. Some of the advantages of conducting reaction and separation simultaneously include:

- *Improved conversion*: High conversion (close to 100% and beyond equilibrium) can be achieved because the removal of one or more products from the reaction phase could force the equilibrium to move to a higher level of conversion.
- *Improved selectivity*: Owing to the removal of products and establishment of favorable conditions for the main reaction, there is often reduction in the rates of side reactions.
- *Catalyst requirement*: Significantly reduced catalyst is required for the same degree of conversion.
- *Achieving difficult separations*: The process can help separate products that otherwise could not be separated, e.g., avoidance of azeotropes in multiple product streams in multicomponent systems or mixtures.
- *Heat transfer integration*: If the reaction is exothermic, the heat of the reaction can be used to reduce the overall heat duty required for separation. Some processes can be run at less severe conditions, resulting in longer catalyst life.
- *Multifunctional reactor*: Novel reactive separation design enables carrying out of several reactions in distinct dedicated zones.
- *Hot spots and runaways*: Avoidance of hot spots and runaways can be achieved by using milder conditions and thermal integration.
- *Cost*: Significant reduction in capital and operating costs can be achieved through simplification, reduction, or elimination of the usually expensive separation systems.

An important step is to decide on the separation methods that can be used to improve the performance of the reaction. The selection of a suitable separation method may be an iterative process and requires satisfaction of several factors, such as:

- Nature of the reaction
- Phases present
- Type of catalyst
- Operating conditions
- Residence time requirement
- Scaling up to large flows
- Removing of desired components and effect on other components
- Aspects such as fouling or foaming
- Process optimal condition mismatch for separation and reaction
- Process flexibility and control despite reduction in degrees of freedom.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120041308

Nominally, integration of reaction and separation may take place only at the equipment level, without introducing new functional interrelations between the operations. In that case, neither does the reaction have any influence on the separation, nor has the separation process any effect upon the reaction. The desired outcomes of such a combination are a smaller inventory, compact plant layout, and improved energy management. The Urea 2000+ technology represents a typical example of such a noninteracting integration.[7] In this process, the carbamate condenser, the urea reactor, and the inert scrubber have been successfully combined in a single vessel, the pool reactor. The integration resulted in a considerably smaller, less energy intensive, and relatively low-cost plant (height of equipment decreased 2.5 times). However, interrelations between the reaction and the other operations remained as in the conventional technology. In most cases, however, the reaction and separation are integrated to benefit from the interactions between the two, for instance, a shift of the product composition beyond the equilibrium via in situ separation, or enhancement of separation efficiency via chemical reaction.

Studies on combined reactive processes with separations have been carried out primarily for the following interacting configurations:

- Reaction with distillation
- Reaction with adsorption
- Reaction with permeation
- Reaction with absorption
- Reaction with leaching
- Reaction with extraction
- Reaction with crystallization.

A sample of the integrated processes is shown in Fig. 1.

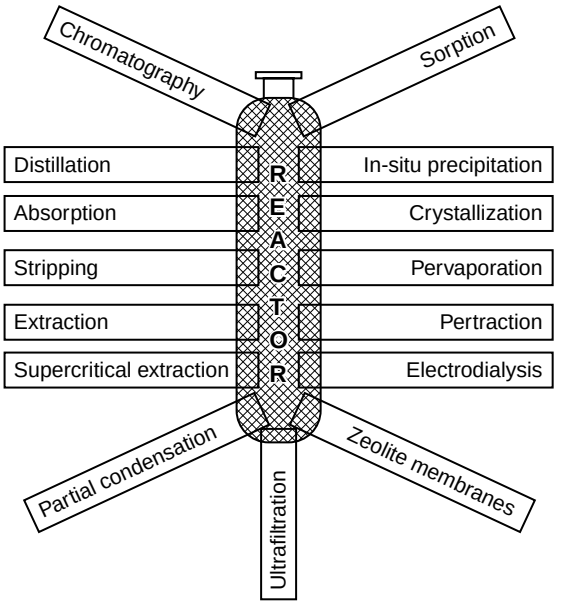

Fig. 1 In situ separation functions integrated into the reactor. (From Ref.[4].)

REACTIVE DISTILLATION

Overview

Distillation is a process of physically separating a mixture of liquids into two or more products that have different boiling points by preferentially boiling the more volatile components out of the mixture. Conversely, if a vapor is cooled, the less volatile (i.e., higher boiling point) material has a greater tendency to condense in a greater proportion than the more volatile material. Despite its antiquity, distillation is still a major unit operation in chemical plants due to certain fundamental kinetic and thermodynamic reasons:

- From a kinetic view, in distillation, mass transfer is limited only by the diffusional resistances on either side of the vapor–liquid interface because no inerts are present. Distillation, therefore, has the potential to deliver high mass transfer rates.
- From a thermodynamic view, typical efficiency is about 10% for distillation (can be improved with intercondensers). Most other separation processes are not more efficient.
- Distillation is cost-effective for separating liquid mixtures, except when:

  (a) The difference in volatility between components is small
  (b) A small quantity of feed is to be vaporized to recover small quantities of products
  (c) A component is thermally unstable even under vacuum
  (d) The mixture has highly corrosive or fouling tendencies.

The term reactive distillation (RD) refers to both catalyzed and uncatalyzed reaction systems. Catalytic distillation systems may use a homogenous or heterogenous catalyst to accelerate the reaction. Reactive distillation is a well-known example of reactive separation process, and is used commercially. The first patent and early journal articles deal mainly with homogenously catalyzed reactions such as esterifications, transesterifications, and hydrolysis.[9] Heterogenous catalysis with RD is a more recent development. The key advantages for a properly designed RD column are complete conversion of reactants and attainment of high selectivity. An example of the benefits of RD is the acid catalyzed production of methyl acetate by

Eastman Chemical, regarded as a classic illustration of the process intensification.[10,11] The reaction was traditionally carried out using the processing scheme shown in Fig. 2(A), which consists of one reactor and a train of nine distillation columns. In the RD implementation, only one column is required and nearly 100% conversion is achieved with significantly reduced capital and operating costs (Fig. 2B).

A substantial number of studies have been carried out with RD because of the significant benefits of the distillation process and its widespread use.[12–23] Other known applications of RD include:

- Manufacture of ethers (MTBE, ETBE, TAME).
- Hydration of ethylene oxide to monoethylene glycol.
- Selective hydrogenations of dienes and aromatics.

Processes in which RD may become potentially useful include:

- Decomposition of ethers to high-purity olefins
- Dimerization
- Alkylation of aromatics and aliphatics, e.g., ethylbenzene from ethylene and benzene, cumene from propylene and benzene, alkylation of isobutane with normal butenes
- Esterifications, e.g., ethyl acetate from ethanol and acetic acid
- Hydroisomerizations
- Hydrolyses
- Dehydrations of ethers to alcohols
- Oxidative dehydrogenations
- Carbonylations, e.g., *n*-butanol from propylene and syngas
- C1 chemistry reactions, e.g., methylal from formaldehyde and methanol

Design and Operational Considerations

A pilot scale RD column is shown in Fig. 3. Some of the constraints and difficulties in RD implementation are:[19]

- *Volatility constraints*: The reagents and products must have suitable volatility to maintain high concentrations of reactants and low concentrations of products in the reaction zone.
- *Residence time requirement*: If the residence time for the reaction is long, a large column size and large tray holdups will be needed.
- *Scale-up to large flows*: For large flow rates, liquid distribution problems arise.
- *Process condition mismatch*: Optimum conditions of temperature and pressure for distillation may be distant to optimal conditions for reaction and vice versa.
- *Construction*: Ease of installation, containment, and removal of the RD equipment and the catalyst are important.
- *Catalyst/liquid contact*: Good liquid distribution (avoidance of channeling and good radial dispersion

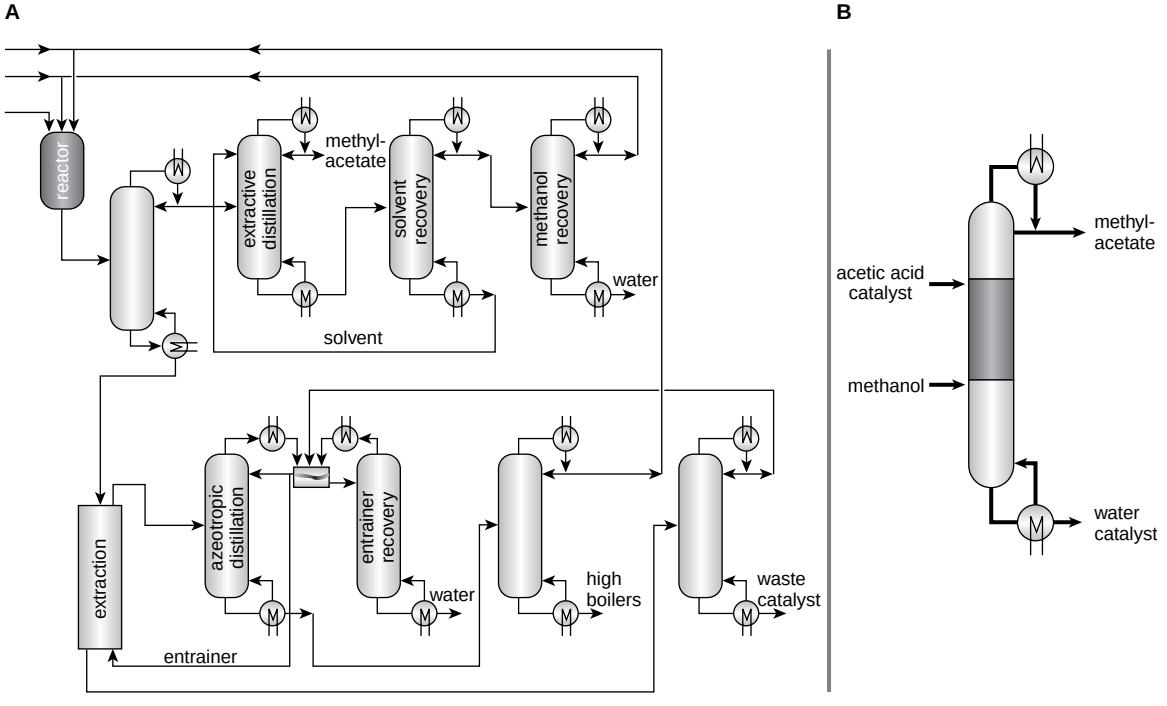

Fig. 2 Plant integration in methyl acetate separative reactor process by Eastman Chemical. (From Ref.[11].)

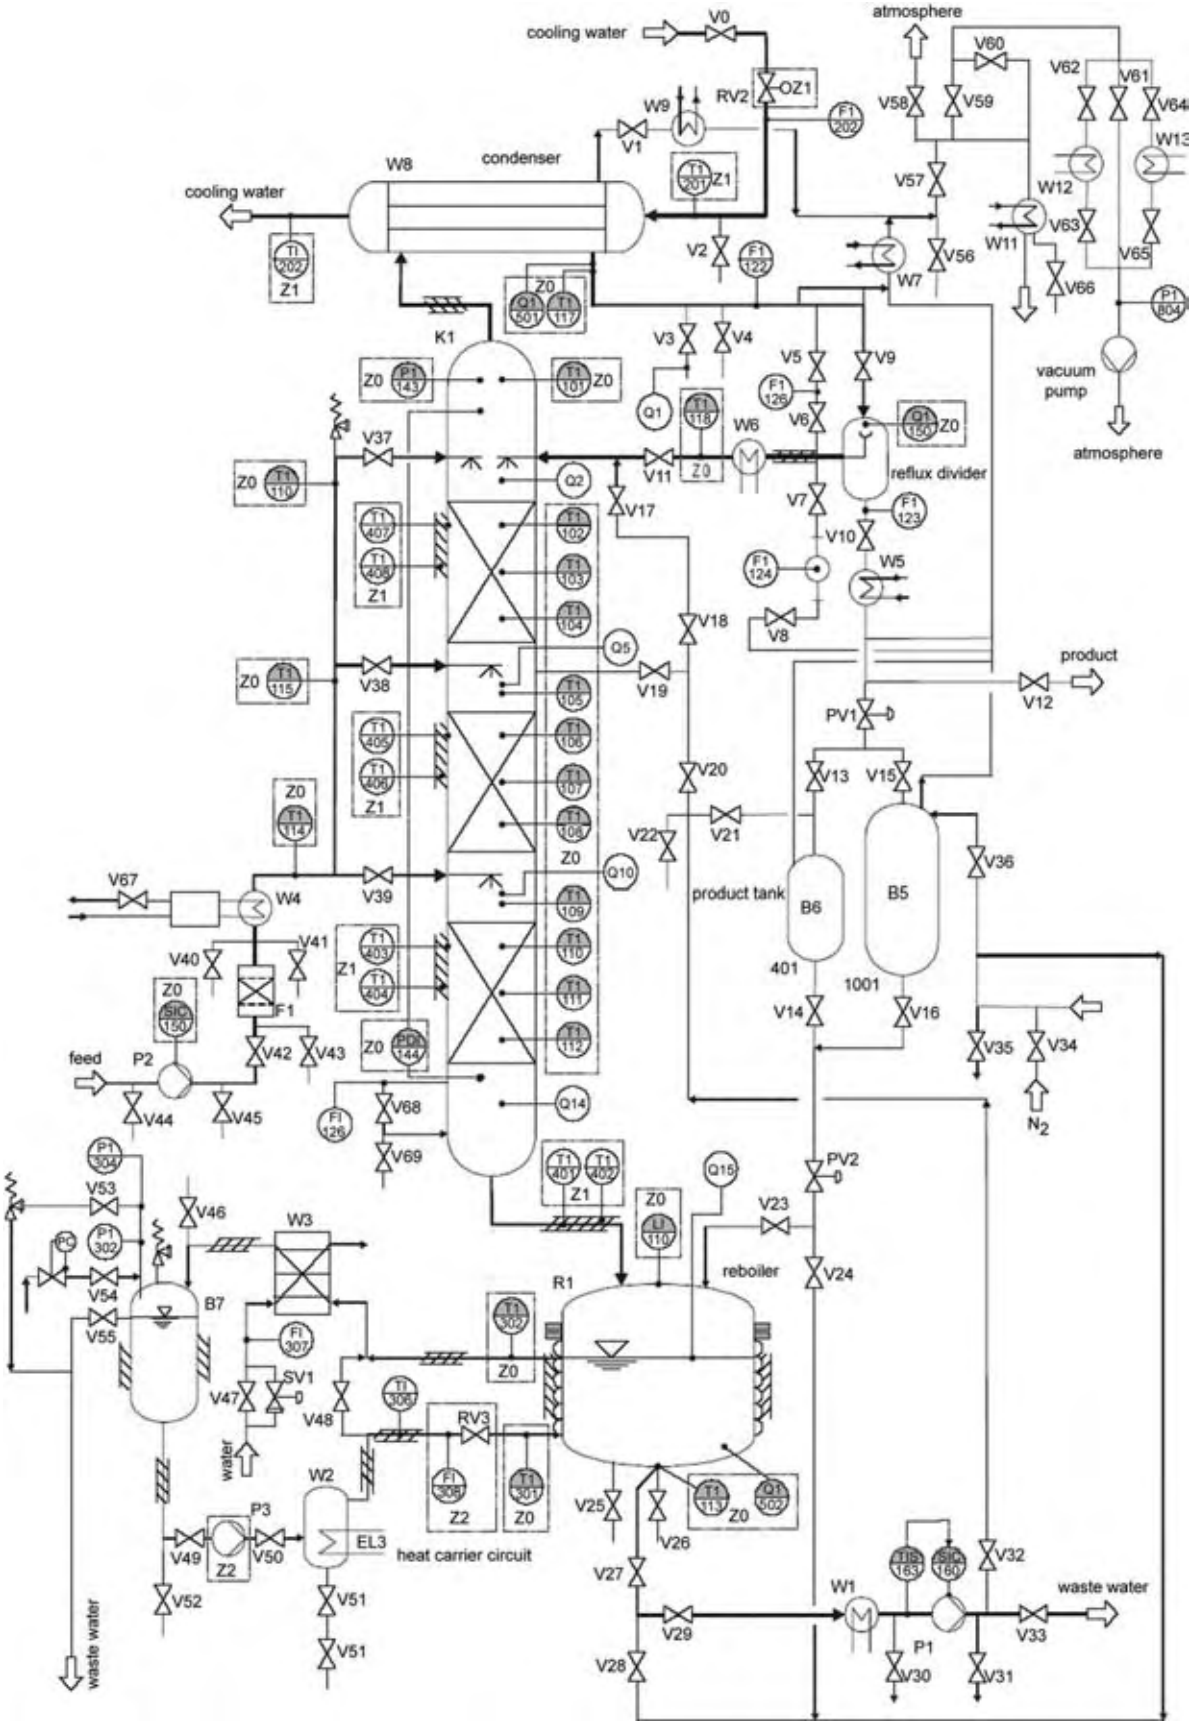

Fig. 3 Flowsheet of RD pilot plant. (From Ref.[22].)

of liquid) through the catalyst bed is required to ensure efficient mass transfer and to avoid reactor hot spots and runaways with even catalyst aging.
- *Vapor/liquid contact*: For fast reaction rates and equilibrium-limited reactions, the required size of the reactive zone is strongly influenced by vapor–liquid contact efficiency.
- *Column pressure drop*: This problem arises because of the need to use small catalyst particles (1–3 mm) through the catalytically packed reactive section to avoid intraparticle diffusional limitations.
- *Liquid holdup*: Liquid holdup, mean residence time, and liquid residence time distribution are important in determining conversion and selectivity.
- *Catalyst deactivation*: Catalyst deactivation is often accounted for during design by use of excess catalyst, and increase in reaction severity by increasing reflux (for increased residence time) or by increasing reaction temperature.
- Process flexibility and control aspects due to reduction in the degrees of freedom.

Hardware Considerations

The hardware issues regarding RD columns focus on the column internals such as the packings (random or structured packing, Fig. 4), distillation trays, and downcomers. Typical hardware design information is given in the standard sources as for conventional distillation.[24] Some of the important issues on hardware design aspects are discussed below.[19]

Catalytically packed columns

The catalyst particle sizes used in RD are usually of 1–3 mm range to avoid intraparticle diffusion limitations. To overcome the flooding limitations, the catalyst particles are contained within wire gauze envelopes. Most commonly, the catalyst envelopes are packed inside the column. Various shapes of catalyst envelopes have been patented. Some of these structures include:[18]

- Porous spheres filled with catalysts.
- Cylindrical envelopes with catalyst inside them.
- Wire gauze envelopes with various shapes: spheres, tablets, or doughnuts.
- Horizontally disposed wire mesh gutters filled with catalyst.
- Horizontally disposed wire mesh tubes containing catalyst.
- *Catalyst particles enclosed in bales*: Catalysts are loaded in pockets sewn into a fiberglass cloth. The resulting belt or catalyst quilt is rolled with layers of steel mesh to form a cylinder of catalyst bales, which are piled up to the required height. After the catalyst is spent, the column is shut down and the bales are replaced with the ones containing fresh catalyst.
- *Catalyst particles sandwiched between sheets of wire gauze*: These structures [licensed by Sulzer (KATAPAK-S) and Koch–Glitsch (KATAMAX)] consist of two pieces of crimped wire gauze sealed around the edge, forming a pocket 1–5 cm wide between the two screens. The catalyst sandwiches or wafers are bound in cubes, which are installed as monoliths inside the column to the required height. When the catalyst is spent, the packing is replaced with the ones containing fresh catalysts. An advantage of these structures over the catalyst bales is that the radial dispersion is about an order of magnitude higher.

Trays and downcomers

The catalyst envelopes placed in a trayed RD column are designed with various configurations:[18]

- Vertical envelopes, placed along the direction of the liquid flow path across a tray, are almost

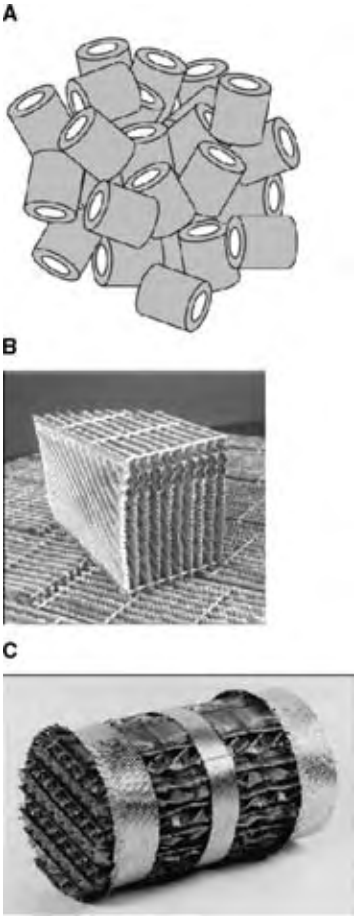

Fig. 4 (A) Random packings (Raschig rings). (B) Structured packings, KATAPAK (Sulzer). (C) Structured packings, MULTIPAK (Sulzer).

completely immersed in the froth on the tray, ensuring good contact between liquid and catalyst.
- Catalyst envelopes are placed within the downcomers. The primary drawback with installing the catalyst within downcomers is the limited volume available for catalyst inventory. Each stage is regarded as a reaction device (downcomer) followed by a separation section (froth on the tray).
- Catalyst envelopes are placed near the exit of the downcomer. Catalyst inventory is limited as the vapor does not pass through the catalyst envelopes.
- Trays and packed catalyst sections are used on alternate stages. The vapor flows through the packed section through a central chimney without contacting the catalyst. The liquid from the separation trays is distributed evenly into the packed reactive section below by a distribution device.
- Designs proposed for tray columns with catalyst containing pockets or regions that are fluidized by the liquid. Catalyst attrition is a concern in a fluidized bed and is taken care of by filtration of the liquid and by makeup of the catalyst.

Modeling and Control

The rate-based model often employed is based on the two-film theory and comprises the material and energy balances of a differential element of the vapor and of the liquid phase. The dynamic component balances for the liquid and the vapor are given by:[22]

$$\frac{\partial U_{\mathrm{L}i}}{\partial t} = \frac{D_{\mathrm{ax,L}}}{u_{\mathrm{L}}}\frac{\partial^2\left(Lx_i^{\mathrm{B}}\right)}{\partial z^2} - \frac{\partial\left(Lx_i^{\mathrm{B}}\right)}{\partial z} + \left(N_{\mathrm{L}i}a^i + N_{\mathrm{S}i}a^{\mathrm{cat}}\right)A_{\mathrm{c}} \quad i = 1,\ldots,\mathrm{nc}$$

$$\frac{\partial\left(Vy_i^{\mathrm{B}}\right)}{\partial z} - N_{\mathrm{L}i}a^iA_{\mathrm{c}} = 0$$

The dynamic energy balances are:

$$\frac{\partial E_{\mathrm{L}}}{\partial t} = \frac{\alpha_{\mathrm{ax,L}}}{u_{\mathrm{L}}}\frac{\partial^2(Lh_{\mathrm{L}})}{\partial z^2} + \frac{\partial(Lh_{\mathrm{L}})}{\partial z} + \left(Q_{\mathrm{L}}a^i + Q_{\mathrm{S}}a^{\mathrm{cat}}\right)A_{\mathrm{c}} - Q_{\mathrm{L}}^{\mathrm{HL}} \quad i = 1,\ldots,\mathrm{nc}$$

$$\frac{\partial(Vh_v)}{\partial z} - Q_{\mathrm{L}}a^iA_{\mathrm{c}} - Q_{\mathrm{V}}^{\mathrm{HL}} = 0$$

The symbols in the above equations denote the following: a is specific gas–liquid interfacial area (m^2/m^3); A is column cross-section (m^2); u_{L} is liquid velocity (m/sec); U is specific molar holdup (mol/m); V is vapor molar flow rate (mol/sec); L is liquid molar flow rate (mol/sec); x is liquid mole fraction; y is vapor mole fraction; Q is molar enthalpy (J/mol); N is molar flux [mol/(m^2 sec)]; Q is heat flux (W/m^2); $D_{\mathrm{ax,L}}$ is axial dispersion coefficient (m/sec^2); E is specific energy holdup (J/m); t is time (sec); z is axial coordinate (m); α is thermal dispersion coefficient (m^2/sec); nc is the number of components; subscripts i, j, k are component indices; superscript B is bulk phase.

A widely studied system is the synthesis of methyl acetate from methanol and acetic acid. This is a slightly exothermic, equilibrium limited liquid phase reaction:

$$CH_3OH + CH_3COOH \rightarrow CH_3COOCH_3 + H_2O$$

The low equilibrium constant and the strongly nonideal behavior causes the formation of the binary azeotropes: methyl acetate/methanol and methyl acetate/water, which pose challenges. As the column is operated at atmospheric pressure the vapor holdup is negligible. Moreover, reaction rates are taken into account by considering the solid catalyst phase and diffusion within the catalyst is neglected. The diffusional interactions such as osmotic or reverse diffusion that may occur are included in the Maxwell–Stefan equations. Modeling approaches for the simulation of the transient behavior of catalytic distillation columns require detailed information about the hydrodynamics of the column internals as structured packings and liquid distributors as well as the column periphery such as the top and bottom sections. A modified Langmuir–Hinshelwood–Hougen–Watson-based model was refitted and used with binary adsorption data.

Fig. 5 shows good agreement between the experimental and simulation results of dynamic liquid bulk concentrations. Because of its complexity the rate-based model is not suitable for controller design and optimization of the RD process. Therefore, an extended equilibrium stage model, which includes a reaction kinetic, is used for these tasks. Fig. 6 shows comparisons of simulation results of the rate-based model (RBA) and the equilibrium stage model for a typical trajectory of input variables. The dynamic behavior is covered well by the simplified model and the deviations between the absolute values are acceptable for control purposes. The advantage of substantially reduced computing time motivates the use of the simplified model for control and optimization purposes.

REACTIVE ADSORPTION

Overview

Adsorption separation combined with reaction has advantages similar to those described earlier for reactive separations. The primary advantages are, again,

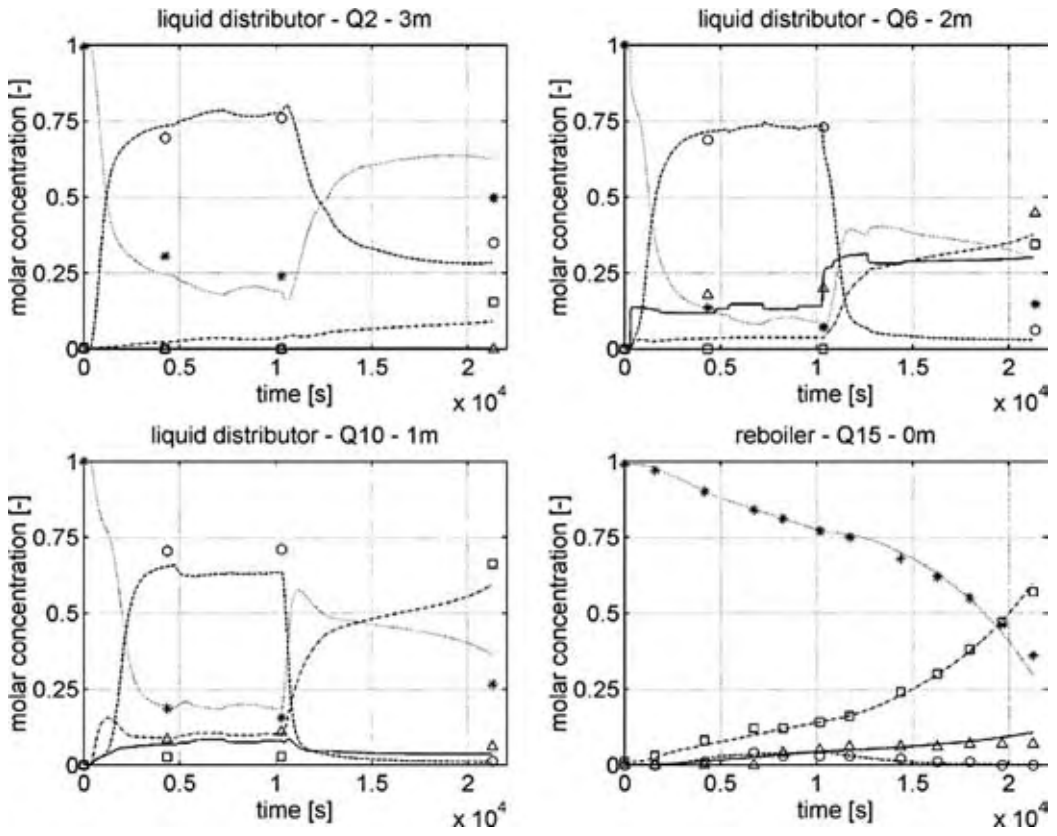

Fig. 5 Dynamic liquid bulk concentrations: experimental and simulation results. (Δ, acetic acid; ∗, methanol; ○, methyl acetate; □, water.) (From Ref.[22].)

significantly high conversion and selectivity and lower costs overall. Some suitable applications are as follows:

- Equilibrium- or selectivity-limited reactions.
- Reactions in which products can be separated by adsorption.
- Conditions for reaction and adsorption are compatible.
- Reaction with adsorption may be preferable when azeotropes or close-boiling products are obtained.
- Rapid mass transfer and low dispersion are desirable characteristics.
- *Heterogenous or homogenous*: The catalyst can be either a solid or a fluid. If a solid, the catalyst or adsorbent could be on the same particle or on discrete particles.

Specific applications include:

- Equilibrium-limited reactions

  Hydrogenation of 1,3,5-trimethylbenzene
  Methanol synthesis
  Ethyl acetate synthesis
  Methyl acetate synthesis
  Propene metathesis.

- Selectivity-limited reactions

  Isomerization of light paraffins
  Methane oxidative coupling.

Reactors

The types of reactors often used for integrated sorption with reaction are:

- Pressure swing reactors (PSR) or sorption enhanced reaction process (SERP)
- Chromatographic reactors
- Moving-bed reactors (MBR)
- Simulated moving-bed reactors (SMBR)
- Trickle bed reactors (TBR)

Currently, the application of adsorption-based processes to reaction systems are of considerable interest.[26–41] Hydrogen production from hydrocarbons and dehydrogenation are important industrial reactions, for example, the catalytic steam-methane reactor (SMR):

$$CH_4 + H_2O \rightarrow CO + 3H_2$$

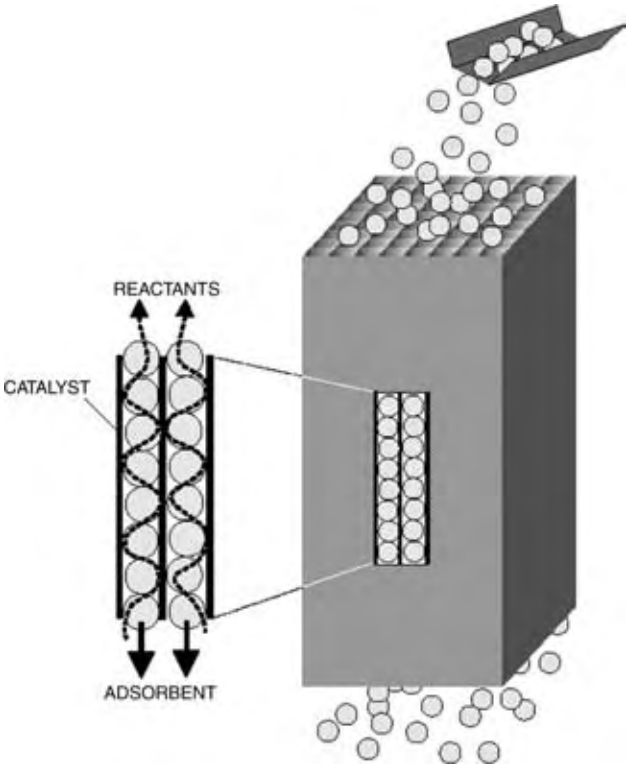

Fig. 6 Monolithic catalyst in moving-bed reactive adsorption system. (From Ref.[25].)

Steam–methane reaction is usually carried out at 50–600 psig and 750–900°C. The reactor effluent (70–72% H_2, 6–8% CH_4, 8–10% CO, 10–14% CO_2, and dry basis) is cooled and fed to another catalytic reactor for the water-gas shift reaction. The SERP concept for H_2 production by SMR has been experimentally demonstrated at a temperature of 450°C and a pressure of 55 psig (480 kPa). The reactor directly produced a 95 mol% pure H_2 stream containing 5 mol% CH_4 and less than 50 ppm of carbon oxide impurities using a feed gas containing steam and methane in the ratio of 6 : 1. The CH_4 to H_2 conversion was 82%. A conventional SMR reactor operated at 450°C under equivalent feed gas conditions would produce a product stream containing 53% H_2, 34% CH_4, and 13% carbon oxides with a CH_4 to H_2 conversion of only 28%. A temperature of 650°C would be necessary for a conventional SMR reactor to match the conversion of the SERP concept operated at 450°C using the same feed gas conditions. The SMR reactor effluent in that case would be 75.5% H_2, 4.4% CH_4, and 20.1% carbon oxides. Thus, the SERP operation provides substantial advantages.

The usual PSR or SERP reactors combine pressure swing adsorber with a periodic flow-forced fixed-bed reactor, and involve feeding reactants in a reactor having a mixture of catalysts and sorbents. The sorbents selectively remove some of the reaction products via physical and/or chemical sorption. Processes involving heterogenous catalysis reactions are by far the most dominant (>90%) in the chemical industry. Thus, considerable techno-economic incentives exist in combining chemical reaction and separation of products in a single unit operation. However, some of the challenges include a lack of validated tools for design and scaling of these reactors, a lack of knowledge about materials to mediate separation, and major gaps in techno-economic evaluation.

The simulated moving-bed reactor integrates continuous countercurrent chromatographic separation with chemical reaction. Such a combination allows higher conversions and better yield to be achieved by separating educts and products of an equilibrium reaction from each other. The movement of the bed with regard to the reactants inlets/outlets is usually realized in a rotating system. Another variant of the rotating cylindrical annulus chromatographic reactor is having the inlets of the mobile phase uniformly distributed along the annular bed entrance, while the feed stream is stationary. Because of the rotation of the reactor, the selectively adsorbed species traverse different helical paths through the bed and are collected at fixed locations. Alternatively, the reactor can be held stationary and the feed rotated. The hydrolysis of aqueous methyl formate and dehydrogenation of cyclohexane to benzene have been investigated using this technique.[26]

Another variant of adsorptive reactor is the gas–solid–solid trickle flow reactor, in which fine adsorbents trickle through the fixed bed of the catalyst, removing selectively one or more products from the reaction zone.[42] In case of methanol synthesis this leads to conversions significantly exceeding the equilibrium conversions under given conditions. The economics of methanol process based on this reactor was compared with a conventional low-pressure Lurgi process. For a 1000 tons/day production, the new technology offered considerable reductions in cooling water use (50%), recirculation energy (70%), raw materials (12%), and catalyst amount (70%). A further improvement of the concept has been in applying a moving bed of adsorbent through parallel channels of a monolithic catalyst, as shown in Fig. 6.[25]

Modeling of PSR

A fundamental understanding of sorption processes requires a detailed mechanistic knowledge of the equilibria, kinetics, and dynamics of the sorption process. The PSR is a cyclic batch process for which adsorption is carried out at a relatively higher pressure and desorption (regeneration) is accomplished at a lower pressure, generally using part of the product from the adsorption

step. During the high-pressure adsorption step, the preferentially adsorbed species are retained in the column, leaving the purified raffinate product in the gas phase. During desorption (regeneration), the adsorbed species are removed from the adsorbent, thus regenerating the column for use in the next cycle. The two-bed PSR (Fig. 7) involves four main steps:[39]

- *Pressurization* (*step 1*): One column is pressurized to the operating pressure of the adsorption step with feed gas entering one end, while keeping the other end closed. During this stage, the species with the lower sorption affinity is pushed toward, and hence is enriched, at the closed end.
- *Adsorption* (*step 2*): The concentration wave front developed at the pressurization step travels along the column during this stage such that the raffinate mainly contains the less strongly adsorbed species. A portion of it is used as a feed into the other column for desorption, while the remainder is delivered as a product.
- *Blowdown* (*step 3*): The pressure of the bed is lowered to atmospheric or subatmospheric pressure. The countercurrent direction of the flow reverses the direction of the traveling concentration wave front of the less sorbed species. As a result, the product end of the bed is not contaminated with the more strongly adsorbed species.
- *Countercurrent purge* (*step 4*): The raffinate gas from the adsorption step of the other bed is used to desorb the adsorbate and to remove it from the voids so that its amount within the bed is reduced at the start of the next cycle. Similar to blowdown, this step ensures that most of the strongly adsorbed species is removed from the product end.

The mathematical model for this process was derived based on the assumptions that the effect of thermal excursions is negligible, the total pressure remains constant during the high- or low-pressure steps, the fluid velocity variation along the bed is determined by the mass balance, the flow is governed by the axially dispersed plug flow model, the equilibrium relations are given by the extended Langmuir isotherm, the mass transfer rates are represented by the linear driving force (LDF) equations, and the rate coefficients are the same for both the high- and the low-pressure steps. The dynamic behavior of flow and species concentrations in the two columns is given below.

Component mass balance for reactants in the gas phase:

$$\frac{\partial c_{ij}}{\partial t} - D_Z \frac{\partial^2 c_{ij}}{\partial z^2} \pm v_j \frac{\partial c_{ij}}{\partial z} \pm c_{ij} \frac{\partial v_j}{\partial z} + \frac{1 - \varepsilon}{\varepsilon} \frac{\partial \overline{q}_{ij}}{\partial t} - v_i \rho_s R_i = 0 \tag{1}$$

Component mass balance for products in the gas phase:

$$\frac{\partial c_{ij}}{\partial t} - D_Z \frac{\partial^2 c_{ij}}{\partial z^2} \pm v_j \frac{\partial c_{ij}}{\partial z} \pm c_{ij} \frac{\partial v_j}{\partial z} + \frac{1 - \varepsilon}{\varepsilon} \frac{\partial \overline{q}_{ij}}{\partial t} + v_i \rho_s R_i = 0 \tag{2}$$

Overall mass balance:

$$\pm C_j \frac{\partial v_j}{\partial z} + \frac{\partial C_j}{\partial t} + \frac{(1 - \varepsilon)}{\varepsilon} \sum_i \frac{\partial \overline{q}_{ij}}{\partial t} = 0 \tag{3}$$

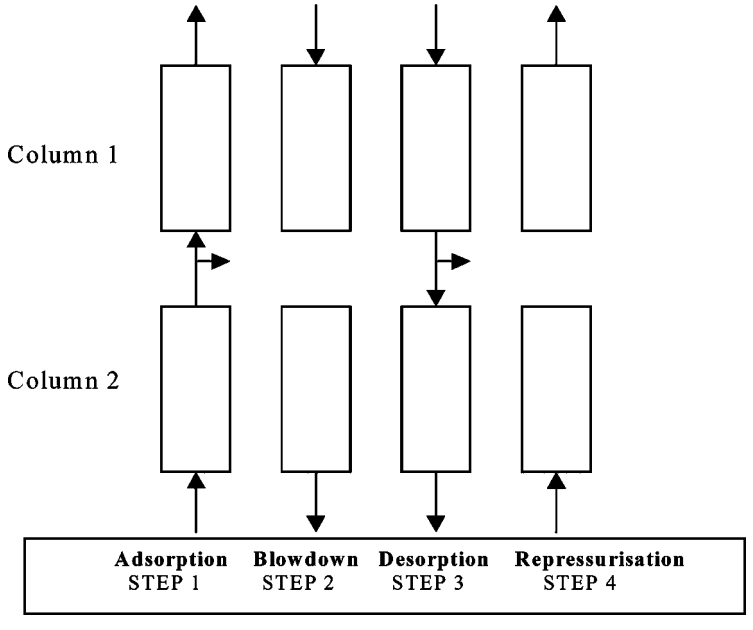

Fig. 7 Schematic diagram of a two-bed PSA cycle.

The mass transfer rate (from LDF or LDF model) across the external film is given by:

$$\frac{\partial \bar{q}_{ij}}{\partial t} = k_i(q^*_{ij} - q_{ij}) \quad (4)$$

$$q^*_{ij} = q_{is}\frac{b_i c_{ij}}{1 + \sum_i b_i c_{ij}} \quad (5)$$

Continuity condition:

$$C_j = \sum c_{ij} \quad (6)$$

Initial conditions:

$$c_{ij}(z = 0) = 0; \quad \bar{q}_{ij}(z = 0) = 0 \quad (7)$$

Boundary conditions for fluid concentration:

$$D_Z\left[\frac{\partial c_{ij}}{\partial z}\right]_{z=0} = -v_j|_{z=0}(c_{ij}|_{z=0^-} - c_{ij}|_{z=0^+})$$

$$\frac{\partial c_{ij}}{\partial z}_{(z=L)} = 0 \quad (j = 1 \text{ and } 2) \quad (8)$$

$$\frac{\partial c_{ij}}{\partial z}_{z=0} = 0; \quad \frac{\partial c_{ij}}{\partial z}_{(z=L)} = 0 \qquad (j = 3) \quad (9)$$

$$D_Z\left[\frac{\partial c_{ij}}{\partial z}\right]_{z=L} = -v_j|_{z=L}(c_{ij}|_{z=L^-} - c_{ij}|_{z-L^+})$$

$$\frac{\partial c_{ij}}{\partial z}_{(z=0)} = 0 \quad (j = 4) \quad (10)$$

Boundary conditions for fluid velocity:

$$v_j(z = L) = 0 \quad (j = 1 \text{ and } 3) \quad (11)$$

$$v_j(z = 0) = v_{0j} \quad (j = 2) \quad (12)$$

$$v_j(z = L) = v_{0j} \quad (j = 4) \quad (13)$$

$$\frac{\partial c_{ij}}{\partial z}_{(z=L)} = 0 \quad (j = 2) \quad (14)$$

In the equations above, subscript "i" denotes a gas species, subscript "j" represents a specific step; t denotes time; z is bed axial distance; c is gas phase mole fraction; q denotes adsorbed phase mole fraction; v is reaction stoichiometry for the species; R_i is the rate of reaction; v is interstitial fluid velocity; v_0 is inlet gas velocity; D_Z is dispersion coefficient; k is LDF coefficient; b is sorption coefficient; ε is bed voidage. For both the pressurization ($j = 1$) and the adsorption ($j = 2$) steps, the ($\pm$) signs are replaced by ($+$), while for the blowdown ($j = 3$) and purge ($j = 3$) steps, the ($\pm$) signs are replaced by the ($-$) sign. The ($+$) sign denotes flow from $z = 0$ to L, while the ($-$) sign denotes flow from $z = L$ to 0. The expressions containing $\bar{b}$ denote adsorbed phase concentration averaged over the adsorbent particle; $c_{|z=0^-}$ appearing in the boundary condition represents the concentration of the species just prior to feeding into the column inlet, while $c_{|z=0^+}$ denotes the concentration just inside the column.

Reactor Operation with and without Periodic Separation

The enhancement of conversion through the use of PSR was tested for a metathesis reaction, which is industrially relevant in producing ethene from propene and vice versa.[41]

$$2CH_2 = CH - CH_3 \leftrightarrow CH_2 = CH_2 + CH_3 - CH = CH - CH_3$$

The importance of this reaction is in maximizing the production of ethene (via forward reaction) or that of propene (via reverse reaction), depending on whether the demand for poly(ethylene) exceeds that for poly(propylene) or vice versa.

Initially, a fixed-bed reactor with no separation was tested. The reactor was packed only with the catalyst and inert filler material with no adsorbent. Further, the feed gas propene (9% by volume) was mixed with helium as a carrier. No separation via PSR operation was imposed on the reactor contents. Fig. 8 shows that the steady-state conversion of propene is significantly less than 1% (about 0.03%) and the product recovery is almost negligible. The slight time lead in simulation is due to nonaccounting of the dead time in experiments. The estimated equilibrium conversion from thermodynamics is about 24% based on pure propene feed. Thus, the conversion in a fixed-bed reactor is far below the equilibrium conversion.

The conversion could be enhanced for the forward reaction if the reverse reaction involving ethene and 2-butene is minimized. Further, since 2-butene desorption is a controlling factor due to its strong sorptive properties, 2-butene removal, in particular, will allow improved rate of reaction and product separation with the use of a sorbent such as γ-Al_2O_3. The effect of the PSR operation (cycle time = 40 sec) on the reactor performance was tested through simulations and by conducting experiments. Step inputs in inlet feed composition containing propene with helium carrier were conducted with clean sorbent beds and constant total gas flow rates. The results, compared with theoretical predictions, are shown in Fig. 9. Because ethene has

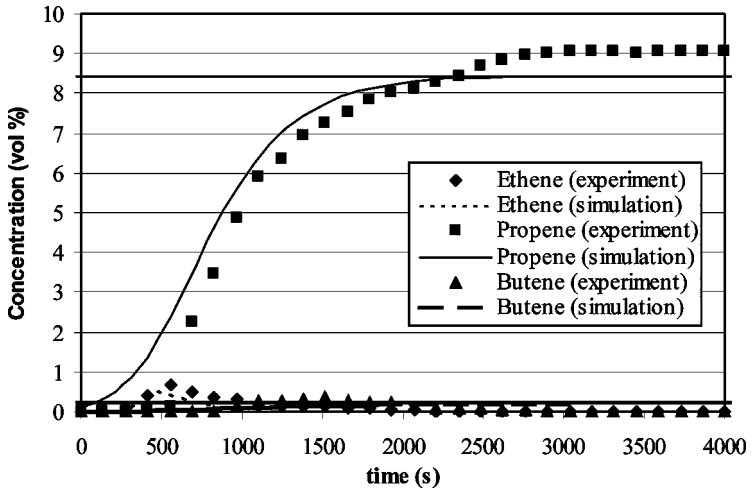

Fig. 8 Simulations and experimental results: gas phase exit composition for propene metathesis in fixed-bed catalytic reactor without pressure swing effect. (From Ref.[41].)

the lowest affinity toward γ-alumina, it is the first species to elute, followed by propene.

Both the simulation and the experimental results show that ethene is enriched to around 25% before stabilizing to a value of 6%. Simulation results are also close to those obtained from experiments. Simulation results, as a function of bed length and time, show that ethene, owing to its low sorption affinity is substantially affected by the sorption–desorption behavior of propene and 2-butene. Initially, the small amounts of ethene formed are obtained at the exit with no other component. As the reaction proceeds, additional 2-butene and propene are preferentially adsorbed and ethene is largely displaced from the adsorbent.

However, as 2-butene and propene concentration increases, re-equilibration of gases occurs in the sorbed phase with the result that ethene exit gas concentration decreases to attain a cyclic steady state (CSS) value of about 0.1 in about cycle 10. It may be noted that the steady-state exit concentrations of the desired product, ethene, is enhanced substantially over the case with no PSR, as described earlier. Further, the output of coproduct, 2-butene, though greater than the case without PSR, makes up a much smaller proportion of the total product mix at the column outlet. Thus, both the total yield of the product and the proportion of the desirable product have been increased by using PSR.

Performance Indicators

Ethene fraction in product stream at column exit (C_E):

$$C_{\mathrm{E}} = \frac{\text{Amount of ethene in product}}{\text{Amount of (ethene + propene + butene) in product}}$$

Recovery of ethene (RE_E):

$$\mathrm{RE_E} = \frac{\text{Amount of ethene in product}}{\text{Total ethene produced by the catalyst}}$$

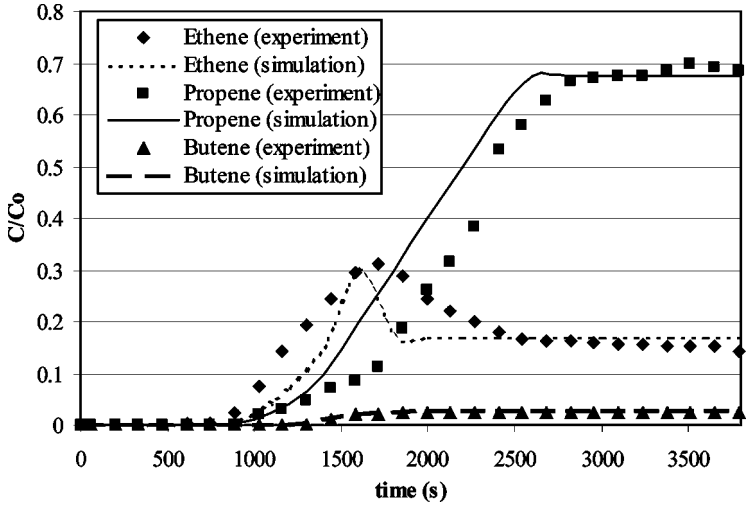

Fig. 9 Simulations and experimental results: gas phase exit composition for propene metathesis in fixed-bed catalytic reactor with PSR (cycle time = 240 sec, Co = 1.2×10^{-4} mol/cm^3, $C_{He} = 8 \times 10^{-5}$ mol/cm^3). (From Ref.[41] with permission.)

Butene–ethene ratio (B/E): It measures the extent of separation of the two products within the adsorption columns. If butene is considered as a by-product, this ratio also relates to product impurity.

Yield of ethene (Y_E): Owing to the adsorption of both the reactants and the products, the yield of ethene, rather than propene conversion, is used:

$$Y_{\mathrm{E}} = \frac{\text{Amount of ethene at column exit}}{\text{Ethene generated via metathesis with no physical adsorption effects}}$$

Catalyst/adsorbent productivity (Pd): It is the molar amount of ethene collected per unit amount of catalyst and adsorbent per unit time.

The performance indicators for the three cases of reaction are shown in Table 1. The analysis shows that the use of pressure swing reaction in propene metathesis has several advantages. First, a higher proportion of ethene is obtained in the product stream with pressure swing reaction. Based on a cycle time of 240 sec, ethene constitutes about 20% of the product stream, while it is about 7% without pressure swing and 4% in the absence of the 13× adsorbent. Further, the separation between ethene and 2-butene in the product stream for pressure swing reaction produces four times as much ethene as that of 2-butene. In contrast, the ethene and 2-butene gases are obtained in almost equal amounts from the other alternative methods investigated. If 2-butene is regarded as a by-product, the percentage of impurity of the product stream will be reduced with the use of pressure swing reaction. Further, the total productivity of the catalyst and the adsorbent system is increased significantly by PSR. Propene metathesis is favored by the use of pressure swing, with an increase in ethene yield by a factor of 3. The adsorbent is regenerated in situ by pressure swing to increase the total adsorption capacity. Hence, the product species, 2-butene in particular, is continuously adsorbed and removed from the gas stream, resulting in an increase in reaction rate.

The effects of changes in total cycle time and in propene feed rate were also investigated with the help of simulations. For enhanced product purity, PSR with a relatively short cycle time is favored, because the reaction is enhanced by the increased frequency of adsorbent regeneration, even though the adsorption is equilibrium controlled. This is demonstrated in Table 1, where ethene fraction, ethene yield, and adsorbent productivity are almost doubled as the total cycle time is decreased from 440 to 120 sec. However, the differences between these indicators are marginal for cycle times of 120 and 240 sec. The recovery increases on increasing the cycle time with decrease in product purity. Further, the separation of 2-butene from the product stream becomes less efficient, as B/E ratio is increased from 0.11 to 0.37.

OTHER REACTIVE SEPARATIONS

Membranes

The use of perm-selective membranes for separation in conjunction with reactors is gaining substantial attention.[43–46] An example of the various functions a membrane may have is shown in Fig. 10.[45] The area of membrane reactors is replete with interesting ideas, for example, heat- and mass-integrated combination of hydrogenation and dehydrogenation processes in a single membrane unit. However, no large-scale industrial applications of catalytic membrane reactors have been reported so far, the main reason being the relatively high price of membrane units, in addition to low permeability, sealing difficulty, as well as mechanical and thermal fragility of membranes. Potential areas for applications of catalytic membrane reactors are:

- Methane steam reforming
- Dehydrogenation, e.g., ethane to ethene, ethylbenzene to styrene
- Water-gas shift reaction

Table 1 Reaction/separation performance with variable process conditions

	Reactor without adsorbent and without PSR	Reactor with adsorbent and without PSR	Reactor operation with PSR (cycle time: 240 sec)
C_{E} (%)	4.0	7.4	19.7
$\mathrm{RE_E}$(%)			55.5
B/E	1	1	0.25
Y_{E} (%)	7.9	10.4	30.7
Pd $\times$ 10^4 (mol/kg/sec)	2.4	2.4	5.8

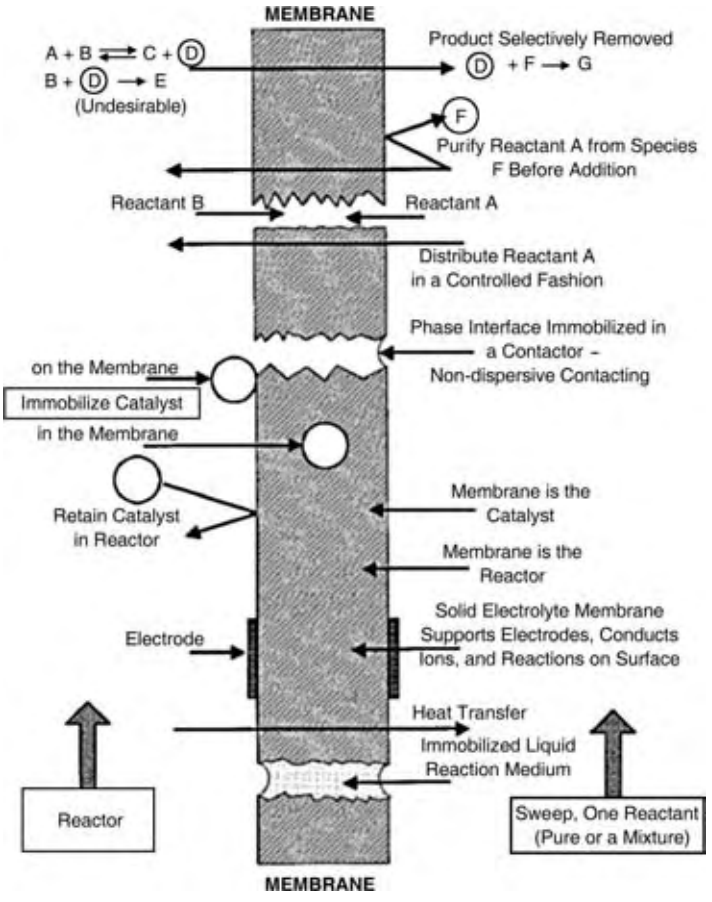

Fig. 10 Membrane functions in chemical reactor. (From Ref.[45].)

- Selective oxidations, e.g., butane to maleic anhydride, ethylene to ethylene oxide
- Oxidative dehydrogenation of hydrocarbons
- Oxidative coupling of methane.

Membranes are being frequently employed in the manufacturing of pharmaceuticals in combination with a bioreactor for enzymatic reactions. In DSM such a combination has been studied for the production of *S*-ibuprofen, via the hydrolysis of the (*R,S*)-ibuprofen methylester coupled to a racemization of the unwanted enantiomer.[46] The esterase used for the above conversion is strongly deactivated by the product. To solve this problem, an ultrafiltration membrane unit has been coupled to the reactor, to remove in situ the product formed. The application of the ultrafiltration has led to a twofold increase of the conversion/productivity, as shown in Fig. 11.

Extraction

Reactive extraction processes include simultaneous reaction and liquid phase separation. The immiscibility may occur naturally within the reactive system or is introduced deliberately by adding solvents. Reactive extraction can be used for significant improvements in selectivities or yields of desired products in multireaction systems, thereby reducing recycle flows and waste formation. The combination of reaction with liquid/liquid extraction can also be used for the separation of waste by-products that are difficult to separate using conventional techniques.[47,48]

Crystallization

Reactive crystallization or precipitation processes of industrial relevance include liquid-phase oxidation of *para*-xylene to terephthalic acid, acidic hydrolysis of sodium salicylate to salicylic acid, and the absorption of ammonia in aqueous sulfuric acid to form ammonium sulfate.[49] A special type of reactive crystallization is the diastereomeric crystallization, widely applied in the pharmaceutical industry for the resolution of the enantiomers. Here, the racemate is reacted with a specific optically active material (resolving agent), to produce two diastereomeric derivatives (usually salts), which are separated by crystallization. Diastereomeric crystallization is commonly used in

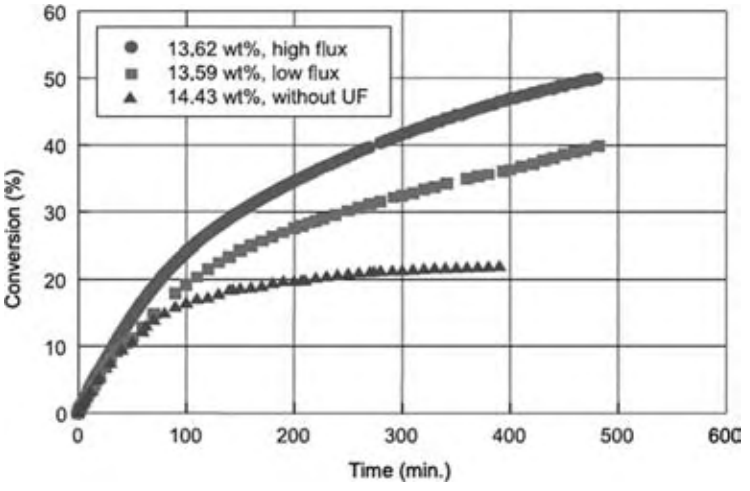

Fig. 11 Ibuprofen methylester conversion as a function of time, with and without integrated ultrafiltration unit. (From Ref.[46].)

the production of a number of pharmaceuticals, such as ampicillin, ethambutol, chloramphenicol, diltiazem, fosfomycin, and naproxen. Recently, reactive precipitation has successfully been used for the production of nanosized cubic particles of $CaCO_3$. Ultrafine particles with a mean size of 15–40 nm and a narrow size distribution were produced by the carbonation of lime suspension in a rotating packed-bed reactor.[50] The reaction times were 4–10-fold shorter than the corresponding reaction times in a conventional stirred-tank unit.

Absorption

Reactive absorption is the most widely applied type of a reactive separation process. It is used for production of a number of bulk chemicals, such as nitric and sulfuric acid. It is also often employed in gas purification, e.g., removal of carbon dioxide or hydrogen sulfide. Other areas of application include olefin/paraffin separations, where reactive absorption with reversible chemical complexation is a promising alternative to cryogenic distillation.

CONCLUSIONS

There are significant gains to be achieved through multiunctional reactor design concepts. There are major opportunities in partial or discretized multifunctionality. Rapid progress is expected in the application of RD, reactive adsorption, and membrane reactors, including bioreactors. Reactive absorption and adsorption processes may further be intensified by the use of rotating equipment, in which high-gravity fields enhance the mass transfer rates and which has almost exclusively been used for nonreactive separations. A type of rotating equipment has already been successfully applied on a large scale in deaeration of water in oil fields, by stripping it with natural gas in a rotating bed; another is offered commercially for countercurrent liquid/solid adsorption/ion exchange.[50] First commercialization of the reactive stripping in rotating equipment has also taken place.[51] Combination of Higee technology with reactive separations may lead to significant compacting of the process equipment resulting in smaller, cleaner, and more energy-efficient chemical plants.

The advantages of reactive separation are unfulfilled if design or operation is not proximate to the optimal requirements for the various integrated coprocesses. The problems often relate to incompatibility of operating conditions for separation. The studies cited demonstrate that high conversions are achievable at reduced temperatures. The problems lie in managing the requirements of the two processes, or of identifying separation compatible with the demands of the catalytic reaction. Forcing conditions for the combined process may not work economically. For example, a detailed process economic evaluation of RD for toluene disproportionation showed that the potential benefits of process simplification offered from the multifunctionality of RD are negated by the need to design the unit at conditions that are optimal for neither reaction nor distillation.[52]

Reactor Engineering

Ken K. Robinson
Mega-Carbon Company, St. Charles, Illinois, U.S.A.

INTRODUCTION

Reactor and reaction engineering play a vital role in petroleum and chemical processing. The aim of this article is to acquaint the reader with the interaction between reactor design/selection and the characteristics of the chemical reaction of interest. Reactor selection and design are the basis of economical and safe operation. Chemical reactions in petroleum refining include a huge spectrum of unique properties. This includes how the reactants are contacted, whether a catalyst is used, how much heat is evolved or absorbed, and how fast the reaction takes place. This article guides the reader in selecting and designing reactors that will best carry out the reactions of interest. The reactor types discussed focus on those in a petroleum refinery, but many can be used in chemical processing as well.

This article first describes the ideal reactor types, namely batch, plug flow, and completely mixed reactors. Then, the petroleum reactors are discussed based on whether the reaction occurs in the vapor, liquid, or mixed vapor–liquid phase. More specifically, the naphtha-processing reactors are examined first, then gradually moving to heavier hydrocarbons, like kerosene and distillate, that react partially in the liquid and gas phases, and finally ending with a discussion on reactors processing heavy hydrocarbons like petroleum residuum, which reacts completely in the liquid phase.

THE IMPORTANCE OF REACTOR ENGINEERING

Commercial refineries represent huge investments in capital. Small errors in equipment sizing or yield translate to millions of dollars in unnecessary expense. Hence, it is extremely important to do the best job possible on sizing, modeling, and specifying reaction conditions for petroleum refining reactors. We need to have a clear understanding of reactors in the three stages of development. At the earliest stage, the laboratory reactors explore new reaction conditions, catalyst formulations, or feedstock types. Reaction kinetics may also be studied at this stage and reaction rate models developed, making sure that there are no confounding factors of the experimental test that will not scale appropriately to the commercial reactor.

The second stage of development is typically aimed at mimicking commercial operations by employing recycle streams to achieve realistic simulations of the integrated process. Isothermal conditions are usually maintained in the reactor, but if heat release is a concern, such as residuum hydrotreating, then it is wise to run adiabatically so that the adiabatic reaction temperature can be established and also how much heat must be removed in the final commercial design. Defining catalyst deactivation, yield patterns, and how various feed types influence the process are typical aspects to explore.

Finally, we move to commercial scale and adiabatic operation. We need to design the commercial reactor so that it is sized properly, can be started up and shut down safely, and can be operated confidently under steady-state conditions. It is a formidable problem for reaction engineers, but if they are careful and rigorous, the end product will be a success.

The flow diagram of a gasoline-orientated refinery is shown in Fig. 1. Most important, we look at the numerous reactors, which can convert feedstocks, sometimes catalytically and at other times with thermal processing to more valuable products. The reactors are summarized in Table 1 with some of the general characteristics.

The large spectrum of reactors is shown in Fig. 2 with the vertical axis showing the progression from the simplest types such as a delayed coker (a semibatch reactor) to the highly complex fluid catalytic cracking (FCC) unit, which has both the reaction phase and the catalyst being transported through the reactor.

REACTOR TYPES/MODELS

Ideal Reactors—A Brief Review

Many types of reactors have entered the field of petroleum refining, but they can be roughly divided into three types: 1) batch; 2) continuous stirred tank reactor (CSTR); and 3) continuous plug flow. In small-scale studies, the researcher may use a simple pipe reactor, which is operated batchwise. The CSTR reactor is used in small-scale studies for kinetic studies

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120040388

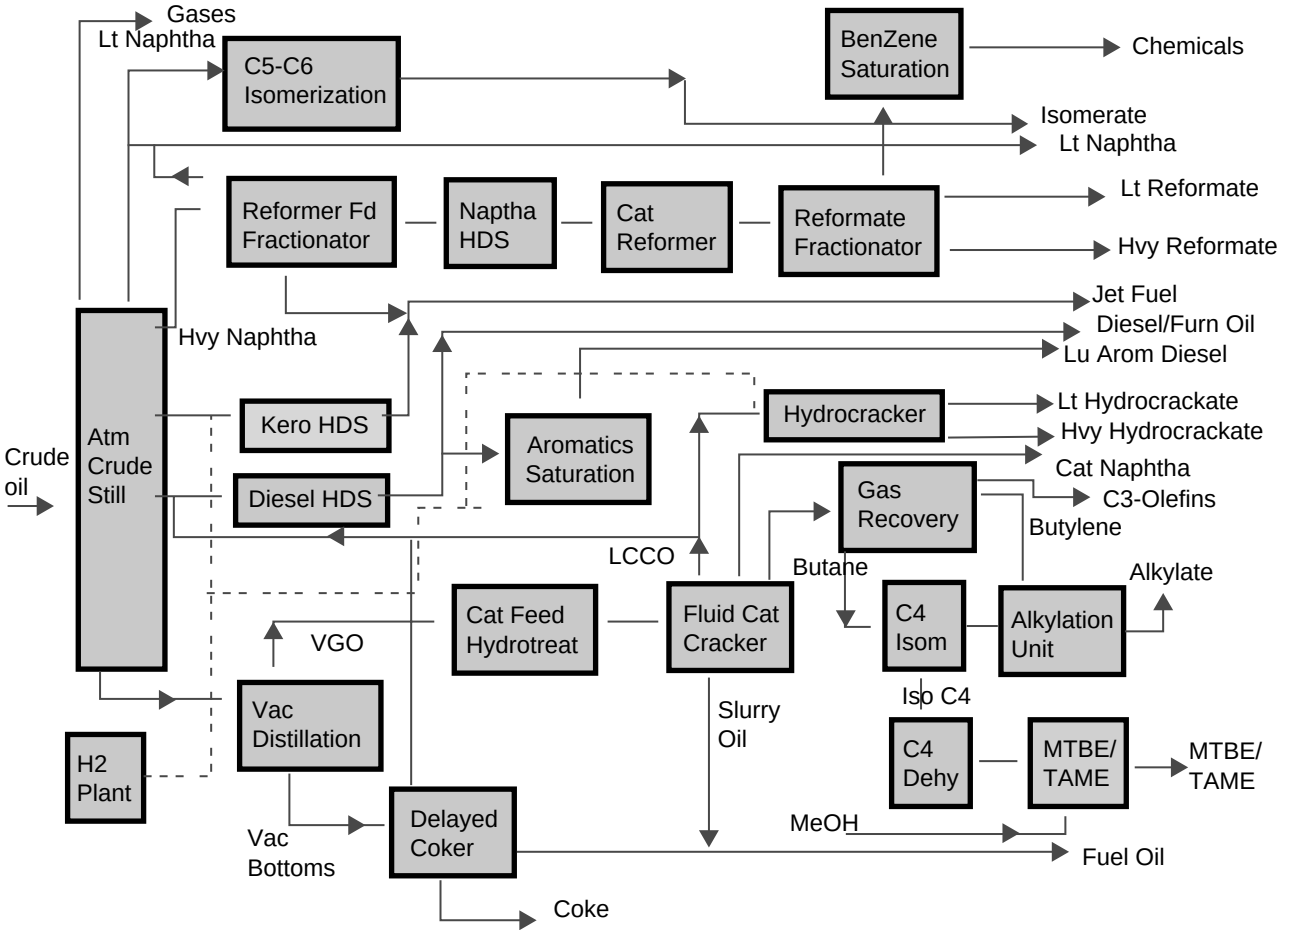

Fig. 1 Flow diagram of a gasoline-oriented refinery. *(View this art in color at www.dekker.com.)*

because the reaction rate is derived directly from the inlet and out concentrations, and it may simulate operation in a larger commercial reactor such as an ebullated bed where the high recycle rate approximates complete mixing. For continuous processing, almost any petroleum fraction may be fed over a fixed bed of catalyst in a plug flow reactor, with vapor phase operation for naphthas and trickle phase for distillates and residuum. The reactor performance equations for these three ideal reactors are given later.

A microbatch reactor (−5 ml) such as the tubing bomb reactor is a common, inexpensive device to develop data. The reactants and, optionally, the catalyst are changed in the small reactor, sealed, and then pressured. To start the reaction, the tubing bomb is typically immersed in a heated fluidized sand bath for a specified length of time with agitation. Shortly after immersion in the heated sand bath, the reactor pressure is increased to a final level, close to commercial conditions. To stop the reaction, the microreactor is pulled out of the heated bath and rapidly quenched in a cooling fluid. The defining equations are given in Eq. (1).

Batch reactor equations

$$t = C_{A_o}\int_o^x \frac{dx}{-r_A} \quad t = \frac{N_{A_o}}{W}\int_o^x \frac{dx}{-r'_A} \tag{1}$$

(thermal) (catalytic)

where

t = time

C_{A_o} = feed concentration of A

x = fractional conversion of A

r_A = reaction rate (mol/hr/volume of the reactor), $\frac{1}{V}\frac{dN_A}{dt}$

r'_A = reaction rate (mol/hr/weight of the catalyst), $\frac{1}{W}\frac{dN_A}{dt}$

W = catalyst weight

N_{A_o} = molar feed rate of A.

The CSTR operates continuously and is frequently a better tool to obtain kinetic data, if one can afford

Table 1 Types of reactors in a petroleum refinery

Reactor(s)	Type	Purpose
Naphtha hydrotreater	Vapor phase catalytic	Remove S and N from catalytic and virgin naphtha before catalytic reforming
Catalytic reformer	Vapor phase catalytic	Convert paraffins to higher-octane aromatics and isoparaffins
Alkylation unit	Catalytic liquid phase (H_2SO_4 or HF)	Combine isoparaffins with olefins to gasoline
Distillate hydrotreating cat-feed hydrotreater	Trickle phase catalytic	Remove S and N and saturate aromatics
Hydrocracker	Trickle phase catalytic	Convert gas oils, coker gas oil, and light catalytic cycle oil to lighter products
Fluid catalytic cracker unit	Vapor phase catalytic	Convert vacuum gas oil to catalytic naphtha
Coker	Semibatch thermal	Convert residuum to gas oil and coke
Residuum hydrotreater	Trickle phase catalytic/thermal	Convert heavy residuum to lighter distillates, removing metals (Ni, V), S, and N

the time and expense of setting one up. The reaction rate can be derived directly from experimental data as pointed out by Mahoney.[1] The reactor has no concentration or temperature gradients, and conversion is controlled by changes in feed rate or reactor temperature. A unique aspect of petroleum refining, relative to chemical processing, is that the streams are mixtures of thousands of compounds. Thus, it is not easy to work with moles as is common for a simple feed. We must, therefore, frequently use mass rather than moles for the reactor design equations. A common convention is to replace space time (J = reactor volume/volumetric feed rate) with reciprocal space velocity, using 1/WHSV for mass of catalyst/time/mass of feed or 1/LHSV for volume of catalyst/time/volume of feed. The reactor performance equation for a CSTR is given in Eq. (2).

CSTR reactor

$$\frac{V}{Q} = \tau = \frac{C_{A_o} X}{r_A} \quad \frac{W}{F_{A_o}} = \frac{X}{-r'_A} \quad \frac{1}{\text{WHSV}} = \frac{X}{-r'''_A} \tag{2}$$

(thermal) (catalytic)

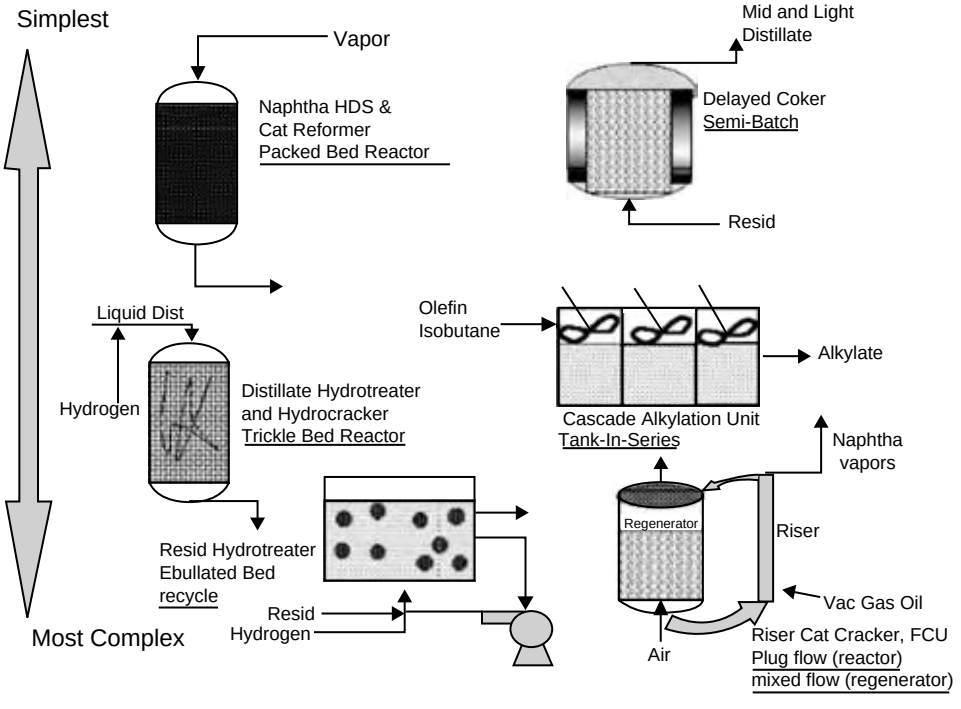

Fig. 2 Petroleum refining reactors. *(View this art in color at www.dekker.com.)*

where

τ = V/Q, volume of the reactor/volumetric flow rate
F_{A_o} = molar feed rate of A
r'''_A = $g/hr/g$ catalyst
WHSV = weight hourly space velocity (g total feed/hr/g catalyst).

The plug flow reactor is probably the most commonly used reactor in catalyst evaluation because it is simply a tube filled with catalyst that reactants are fed into. However, for catalyst evaluation, it is difficult to measure the reaction rate because concentration changes along the axis, and there are frequently temperature gradients, too. Furthermore, because the fluid velocity next to the catalyst is low, the chance for mass transfer limitations through the film around the catalyst is high. Eq. (3) is the reactor performance equation for a plug flow reactor.

Integral plug flow

$$\frac{V}{Q} = \tau = C_{A_o}\int \frac{dx}{-r_A} \quad \text{(thermal)}$$

or

$$\frac{W}{F_{A_o}} = \int \frac{dx}{-r'_A} \quad \frac{1}{\text{WHSV}} = \int \frac{dx}{-r'''_A} \quad \text{(catalyst)} \quad (3)$$

Commercial Reactor Design and Scale-up

The design of larger commercial reactors provides a significant challenge because heat effects are typically substantial and vary with the endothermic cat-cracking or reforming reactions to the highly exothermic hydrotreating and hydrocracking reactions; the flow regime deviates from the ideals of plug flow and perfect mixing. We examine commercial reactors in increasing order of complexity.

Heat Aspects

An energy balance is given below in Eq. (4) and is shown graphically in Fig. 3 for the various types of refining reactions, with the graph developed by Levenspiel.[2]

Energy balance for reactor

$$X = \frac{C_p \Delta T}{-\Delta H_r} \quad (4)$$

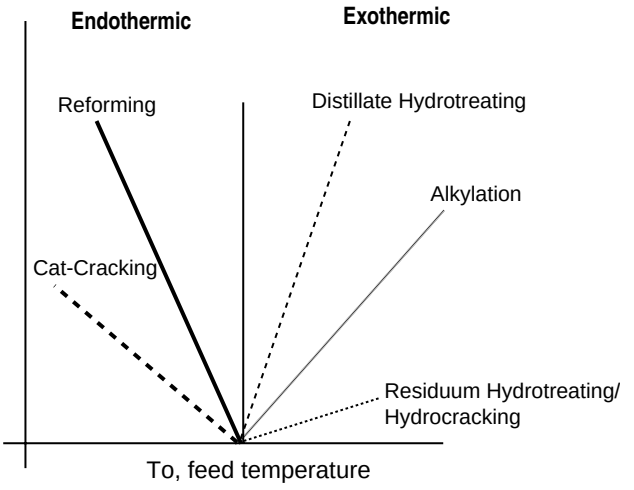

Fig. 3 Heat effects.

where

C_p = molar heat capacity of stream (BTU/lb/mol/°F)
ΔT = temperature difference, outlet minus inlet
$-\Delta H_r$ = heat of reaction (BTU/lb/mol).

Endothermic Reactions (Cat-Cracking, Reforming, Coking). In Fig. 3, we see that the fluid cracking unit (FCU) requires heat input to maintain the reaction temperature in the cracking zone and is shown on the far right in the endothermic region. Burning coke off the catalyst in the regenerator provides this heat and the recirculating catalyst transfers that energy to the cracking reaction in the riser of the FCU. Cat-cracking involves bond breakage and may be classified as endothermic. The second reaction that is highly endothermic is catalytic reforming. The dehydrogenation reaction is very endothermic and requires a reactor system of three to four reactors in series, with interstage heating between the reactors because the reaction temperature drop in each stage must be increased so that the reaction rate does not slow down too much.

Thermally Neutral (Isomerization). Isomerization, represented by the vertical line in the diagram, involves skeletal rearrangement of molecules but no change in the molecular weight. Thus, the reaction does not cause any cooling or heating of the feed stream.

Exothermic (Hydrotreating, Hydrocracking, Alkylation). Many of the petroleum refining reactions are exothermic. Hydrocracking is very exothermic

owing to aromatic saturation reactions. Although the molecular weight is reduced by the cracking reaction, this is preceded by hydrogenation (HDN) reactions, for example, aromatic ring saturation, which is necessary before the ring opening can occur. Alkylation is also quite exothermic because higher molecular weight compounds are formed from isobutane and olefins. Distillate and naphtha hydrotreating also release heat when organo-sulfur and nitrogen compounds (i.e., dibenzothiophene and pyridine) are converted to hydrogen sulfide and ammonia, respectively.

Naphtha/light hydrocarbon processing

Catalytic Reforming of Naphtha. Catalytic reformers may be differentiated as to mechanical design. Those that do not employ on-stream regeneration of the catalyst are fixed-bed processes and are called semiregenerative. The regenerative or cyclic processes include the original hydroforming process (Exxon), ultraforming (Amoco), and power forming (Exxon); they are characterized by a ''swing'' reactor in the multiple reactor train that is substituted for the reactor, which is off-line during regeneration (see Fig. 4).[3,4] The fluid hydroforming employs fluidized bed and the thermofor and hyperforming processes employ moving beds of catalyst. Universal Oil Products has developed a unique reforming process, called CCR for continuous catalyst regeneration, which integrates the reactor with the regeneration process in a stacked reactor concept. It makes use of a radial flow reactor with a moving bed of catalyst. The CCR platforming process (see Fig. 5) utilizes naphtha boiling in the range of 180–400 °F to produce high-octane gasoline or petrochemical precursors. This technology is one of the world's leading reforming processes, with many units operating currently. The platforming process provides refiners with proven, ultra-low-pressure (50 psig reactor pressure) operation and the highest reforming yields. In gasoline applications, the platforming process produces high-octane reformate for unleaded gasoline blending. In reformulated gasoline applications, the low-pressure, low-severity platforming process restores a refinery's hydrogen balance by maximizing the yield of hydrogen, even at the required low-octane severities. With appropriate prefractionation, the process produces the low-benzene, low-vapor-pressure material mandated by reformulated gasoline. The principal problem in the design of catalytic reformers is heat balance, with many of the reactions that produce aromatics being very endothermic. Cyclic mode is preferred for high aromatics production, while semiregenerative for moderate to high severity. Low-octane naphtha is converted to high-octane reformate by dehydrogenation and dehydrocyclization of paraffins to make an aromatic-rich product. Fig. 4 shows cyclic reforming where any reactor can be isolated, regenerated, and placed back on-stream. Typical yields and process conditions for these two processes are listed in Tables 2 and 3.

Catalysts

Reforming catalyst was developed essentially for the production of high-octane blending components from low-octane naphthas. Hydrogenation–dehydrogenation and acidic catalytic components are required for the various reactions that produce high-octane materials. These components are supported on a suitable base. Reforming catalyst has generally used platinum for the HDN–dehydrogenation function and chloride active sites for the acidic function, both supported on gamma alumina. The desirable reactions for octane production are listed below:

1. Dehydrogenation of cyclohexanes to aromatics.
2. Dehydroisomerization of cyclopentanes to aromatics.

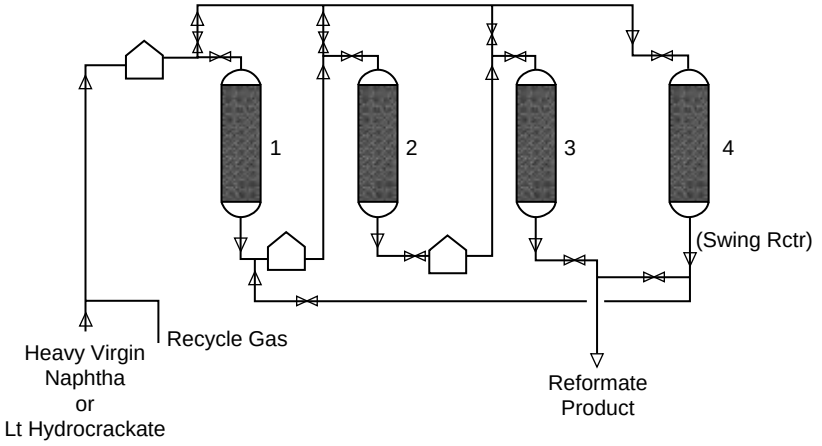

Fig. 4 Catalytic reforming unit (semiregenerative or cyclic).

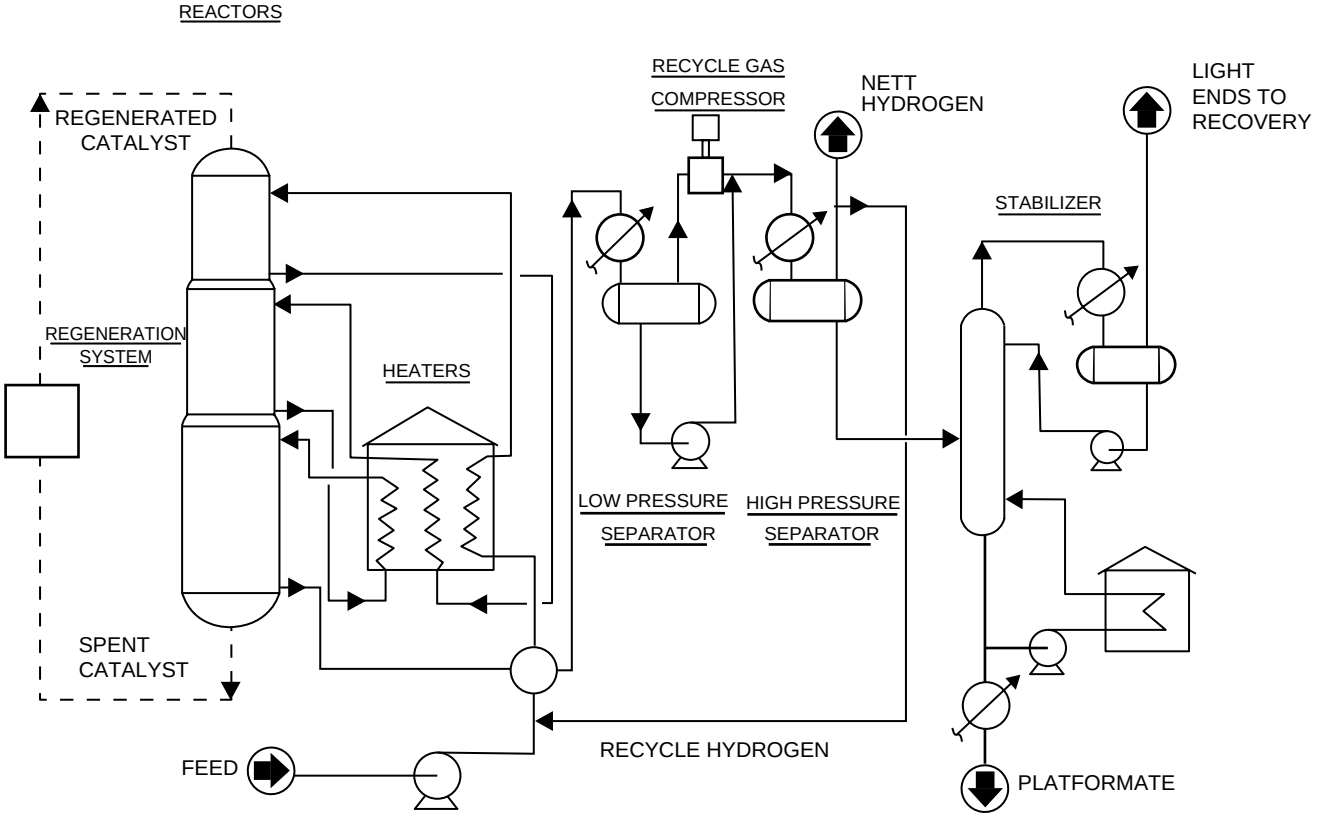

Fig. 5 CCR reforming process.

3. Dehydrocyclization of paraffins to aromatics.
4. Isomerization of *n*-paraffins to isoparaffins.
5. Hydrocracking of low-octane, long-chain paraffins.

Reformer reactor variables

Temperature. Normally, inlet temperatures range between 850 and 1000 °F. The temperature at which the catalyst beds are held is the primary variable available to the refiner to control product quality. Very high temperatures, above 1000 °F, can cause thermal reactions that will decrease reformate yields and increase catalyst deactivation from coke formation.

Space Velocity. Space velocity is defined as volume of naphtha processed per hour per volume of catalyst (or weight of naphtha per hour per weight of catalyst). It determines the limits of product quality (i.e., octane number). The greater the space velocity, the lower the limit, or maximum octane possible. For highly naphthenic feedstocks, high space velocity can be used. For more paraffinic feedstocks, lower space velocity is required to achieve the desired octane number in the product.

Pressure. Pressure affects dehydrogenation and hydrocracking reactions. Increasing the pressure will increase hydrocracking but adversely affect equilibrium aromatic

Table 2 Yields for semiregenerative and cyclic reforming

	Yield	Semiregenerative	Cyclic
57 °API naphtha 30 vol% cycloparaffins 57 vol% paraffins 53 Research octane No. (RON)	H_2 (%)	2.3	2.6
	C1–C4 (%)	13.1	11.2
	C5+ (%)	78.5	79.1
	RON	99	101

Table 3 Process conditions for semiregenerative and cyclic reforming

Process variable	Semiregenerative mode	Cyclic mode
Pressure (psig)	150 (low severity)	350
Temperature (°F)	960	960
Feed rate, WHSV	5.5	5.5
Catalyst	Pt/Re (0.4/0.4%)	Pt/Re (0.4/0.4%)
Octane, $(R + M)/2$	93	98

formation. Higher pressure reduces carbon deposition on the catalyst and slows down deactivation.

Reformer reactor design aspects

The principal problem in the design of catalytic reformers is heat balance. Reactions that produce aromatics are very endothermic, being partially offset by exothermic hydrocracking reactions. Large amounts of heat must be supplied to the reaction zone to keep the temperature high enough. In fixed-bed units the heat is supplied by reactors in series with intermediate reheating. The largest temperature drop is in the first reactor.

Reactor models

The plug flow model is frequently used to describe catalytic reformers. Referring to Eq. (5), we see that one way to calculate the amount of catalyst needed for a specified conversion level and naphtha feed rate is to graphically integrate the expression on the right-hand side of the equation. We do this by plotting 1/rate vs. the fractional conversion, and then compute the area. This area yields a value for 1/WHSV, the ratio of the catalyst charge to the oil flow rate. For a multiple-stage reactor, with an endothermic reaction, we have the plots shown in Fig. 6 for three reactors in series. As the temperature decreases in the reactor, the rate is correspondingly lowered and causes the 1/rate curves to increase as conversion, x, increases. The interstage heaters, between each reactor, bring the naphtha temperature up for the next reactor stage, so that the reaction rate is maintained high enough. The size of each stage can be computed from the area and the total area representing either W/Fao or 1/WHSV (reciprocal space velocity).

Reactor performance equations for a plug flow reactor

$$\frac{\mathrm{d}x}{\mathrm{d}(W/\mathrm{Fao})} = -r'_{\mathrm{A}} \quad \text{or} \quad \frac{\mathrm{d}x}{\mathrm{d}(1/\mathrm{WHSV})} = -r''_{\mathrm{A}}$$
$$W/\mathrm{Fao} = \int \frac{\mathrm{d}x}{-r'_{\mathrm{A}}} \quad \text{or} \quad (1/\mathrm{WHSV}) = \int \frac{\mathrm{d}x}{-r''_{\mathrm{A}}} \qquad (5)$$

where

x = fractional conversion
W = catalyst charge (lb)
Fao = molar feed rate (mol/hr)
WHSV = weight hourly space velocity (lb oil/hr/lb catalyst)
r'_{A} = reaction rate (mol/hr/lb catalyst)
r''_{A} = reaction rate (lb/hr/lb catalyst).

The energy balance equations for a plug flow reactor are given below in Eq. (6) and relate temperature change to either reactor length, z, or reciprocal space velocity, 1/WHSV.

Energy balance equations for plug flow reactor

$$\frac{\mathrm{d}T}{\mathrm{d}z} = \frac{\rho_{\mathrm{b}} \sum(-\Delta H_{\mathrm{r}})_{\mathrm{i}}\, r_i}{GC_{\mathrm{P}}}$$
$$\frac{\mathrm{d}T}{\mathrm{d}(1/\mathrm{WHSV})} = \frac{\sum \Delta H_{\mathrm{r}}\, r_{\mathrm{i}}}{C_{\mathrm{P}}} = \frac{\sum \alpha_{\mathrm{i}}\, \mathrm{d}x}{\mathrm{d}(1/\mathrm{WHSV})} \qquad (6)$$

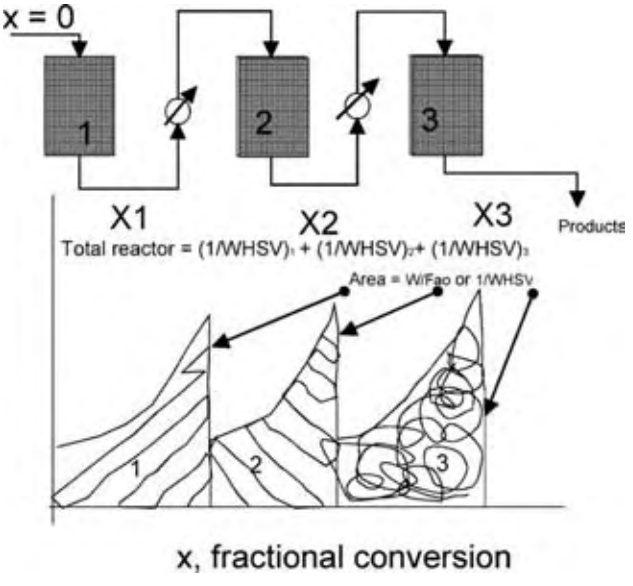

Fig. 6 Plug flow reactors in series.

where

T = temperature (F)
z = reactor length (ft)
ρ_b = bulk density of catalyst
G = mass velocity of feed (lb/hr/ft^2)
C_p = heat capacity of feed stream (BTU/lb)
ΔH_r = heat of reaction (BTU/lb/mol)
r_i = reaction rate of species i
WHSV = space velocity (lb naphtha/hr/lb catalyst)
α_i = adiabatic temperature rise for reaction i
x = fractional conversion of species i.

If the flow regime in the reactor has some mixing and/or dispersion and deviates slightly from plug flow conditions, then the mass balance can account for this with an ''axial dispersion'' model, a one-parameter model.[5] The material balance is shown below in Eq. (7).

Dispersion model for small amounts of mixing

$$\frac{D}{uL}\frac{d^2x}{dZ^2} - \frac{dx}{dZ} + \frac{\tau\rho_b r'_A}{C_{A_o}} = 0 \quad x = 0 \text{ at } Z = 0$$
$$\frac{D}{uL}\frac{d^2x}{dZ^2} - \frac{dx}{dZ} + \frac{\rho_f r'_A}{\text{WHSV } C_{A_o}} = 0 \qquad (7)$$
$$\frac{dx}{dZ} = 0 \text{ at } Z = 1$$

where

x_A = conversion
Z = axial position in reactor, z/L (dimensionless)
u = superficial velocity, Q/A
L = reactor length
(D/uL) = dispersion number, 1/Peclet (reactor)
Peclet = $Pe'(d_p/L)$
d_p = catalyst particle diameter
Pe' = particle Peclet = $20/(Re/\text{Schmidt}) + 1/2$
ρ_f = fluid density
ρ_b = bulk density of catalyst
r'_A = reaction rate of A (mol/hr/ft^{3}reactor)
τ = space time (hr)
C_{A_o} = feed concentration
z = $G/(\rho_b\text{WHSV})$(ft)
G = mass velocity, $\rho_f u$ (lb/hr/ft^2).

The second-order differential equation is solved with a numerical differential equation solver. The dispersion number is estimated by first predicting the particle Peclet number, Pe', from the equation above. Then, the value of the reactor Peclet number, Pe, is predicted from the particle Peclet number Pe' by multiplying by the ratio of the particle diameter, d_p, to the reactor length, L. Pe is the only parameter required to solve the dispersion model equation.

Alkylation

In sulfuric acid alkylation, olefins and isobutane react to form a gasoline blending component at around 45°F.[6] This reaction only occurs in the acid phase. Olefins are extremely soluble in sulfuric acid; isobutane is only slightly soluble. Olefins will polymerize in the absence of isobutane.

The polymerization reaction competes with the alkylation reaction:

Olefin + olefin = polymer
Olefin + isobutene = alkylate

A simplified sketch of an alkylation unit is given in Fig. 7. Olefin and isobutane are charged to a refrigerated stirred reactor. Acid in the reactor effluent is removed in a settler and recycled to the reactor. The most commonly used reactor in sulfuric acid alkylation is the Stratco contactor.[7] The principal advantage of the Stratco contactor is the high isobutane concentration in the reactor effluent. This is achieved by operating the contactor at a pressure sufficient to suppress vaporization of the isobutane refrigerant recycle. The heat of the alkylation reaction is removed indirectly by partially vaporizing the settler effluent through the tube bundle shown in Fig. 8.

The Kellogg cascade autorefrigeration unit, shown in Fig. 9, differs from the Stratco process in that the refrigeration is provided in situ by allowing a proportion of the reactants to vaporize within the reaction zone. In the cascade system, dilute olefin concentrations are obtained by splitting the olefin feed into a number of parallel streams, each of which is fed to a separate reaction compartment containing its own mixer. Isobutane passes through all of the compartments in series, but the olefin-containing feed is divided among the several components. The Kellogg cascade alkylation unit can be approximated by a tank-in-series reactor model.

Any olefin-containing hydrocarbon stream may be used to alkylate isobutane. Butenes are the usual alkylating agents, but propylene is also used, and ethylene and pentenes are employed to a limited extent.

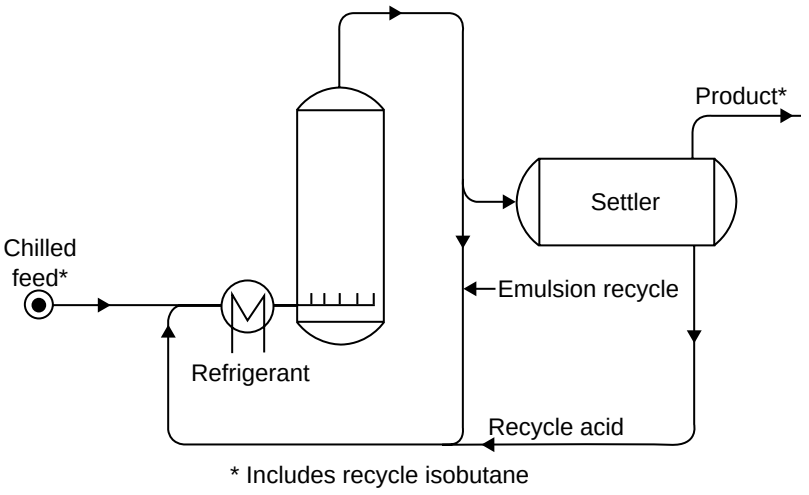

Fig. 7 Simplified sketch of an alkylation unit.

The chief sources of olefins are cracking operations, especially catalytic cracking. However, olefins can be produced by the dehydrogenation of paraffins; butanes are dehydrogenated commercially to provide feeds to alkylation. Isobutane is obtained from crude oils, cracking operations, catalytic reformers, and natural gas. To supplement these sources, *n*-butane is sometimes isomerized. Only small concentrations of diolefins are permissible in feeds to alkylation, particularly for sulfuric acid catalyst. Diolefins increase the consumption of acid.

Although the majority of early alkylation units used sulfuric acid as a catalyst, there has been a trend over recent years in favor of the hydrofluoric (HF) process. Today, the installed capacity of each process is roughly the same. The HF alkylation process is offered by two licensors, Universal Oil Products and Phillips Petroleum. The reaction is carried out at temperatures between 75 and 115 °F, which is considerably higher than the sulfuric acid process.

Rate Models for Alkylation. The rate model to describe alkylation of isobutane with olefins is complicated by the presence of two phases, sulfuric acid and hydrocarbon, and the transfer of reactants between these two phases. As mentioned earlier, the alkylation reaction takes place in the acid phase, with olefins highly soluble in the acid and isobutane only moderately soluble. The isobutane is fed in large excess to compensate for the lower solubility and the olefin concentration must be kept low or it will polymerize and form ''red oil,'' consuming the sulfuric acid catalyst. In Fig. 10, we have shown the film model, with olefins in the bulk gas phase, transferring first through the gas film, then dissolving in the acid, transferring through the liquid film, and finally entering the main body of the bulk liquid acid phase. The rate expression must account for the mass transport across both the gas and the liquid films as well as the alkylation reaction in the acid phase.

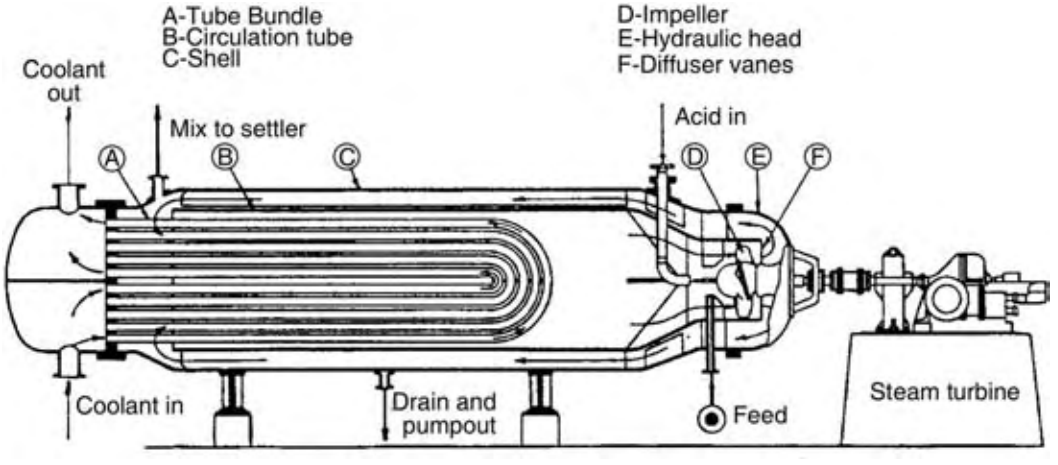

Fig. 8 Stratco contactor for alkylation.

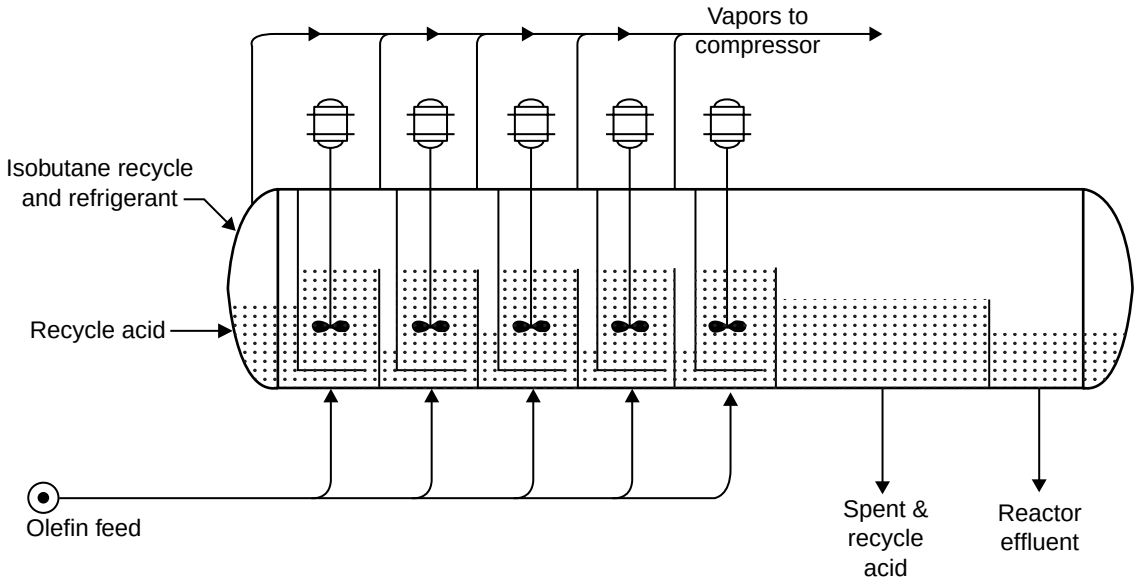

Fig. 9 The Kellogg cascade autorefrigeration unit for alkylation.

Levenspiel has presented a thorough analysis of the many situations involving multiphase kinetics and the equation that applies to alkylation is given below:[8]

$$-r_o''' = \frac{P_o}{1/(k_{og}\,a) + H_o/(k_{ol} \sim aE) + H_o/(k\,C_{iso} f_l)} \quad (8)$$

where

$-r_o'''$ = reaction rate (mol/hr/ft^3 reactor)
P_o = olefin partial pressure (atm)
k_{og} = mass transfer coefficient for gas film (mol/ft/hr/atm)
a = superficial area (ft^2/ft^3 reactor)
H_o = Henry's law constant (atm/ft^3/mol)
k_{ol} = liquid film mass transfer coefficient
E = liquid film enhancement factor,

$$\frac{\text{rate of transfer with chemical reaction}}{\text{rate for straight mass transfer}}$$

k = reaction rate constant (ft^3 liquid/mol/hr)
C_{iso} = liquid concentration (mol/ft^3)
f_l = fraction of liquid phase in the reactor.

Reactor design equations

The contacting pattern in two types of alkylation units is shown in Fig. 11. More specifically, we see that the Stratco unit with the single mixer on one end is approximated by a single mixed tank, as shown in the upper part of the figure. However, the Kellogg cascade unit has a series of compartments with mixers and olefin is sparged into each compartment to keep the concentration low so that it reacts with the isobutane rather than polymerizing. The tank-in-series model may be used to model this type of unit and this is shown in the lower part of the figure. A mass balance can be made for a stirred tank reactor readily because the composition is the same everywhere in the vessel.

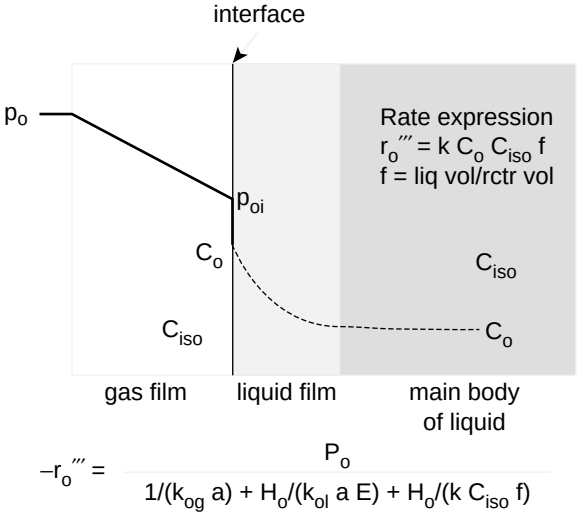

Fig. 10 Transfer of olefin into acid phase, and then reaction with I-C4. *(View this art in color at www.dekker.com.)*

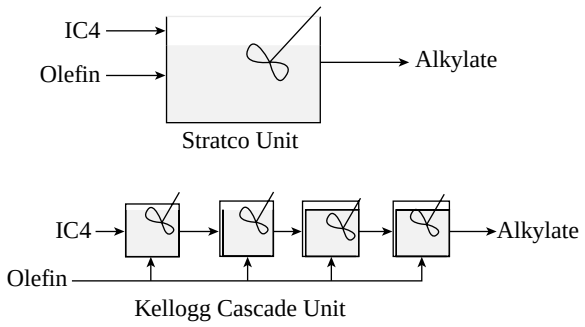

Fig. 11 Contacting patterns for alkylation. *(View this art in color at www.dekker.com.)*

For the case of mass transfer and reaction in an agitated tank contactor, the balance is simply olefin lost by gas = disappearance of olefin by reaction.

Thus, the equation below is the reactor performance equation for a single stirred tank.

Reactor performance for single stirred tank

$$\frac{F_g}{\prod}(P_{o\,in} - P_{o\,out}) = (-r_o''')|_{at\ exit}\ V_r \qquad (9)$$

where

F_g = molar flow rate of the gas
$\prod$ = total pressure
$P_{o\,in}$ = partial pressure of olefin into reactor
$P_{o\,out}$ = partial pressure of olefin leaving reactor
$-r_o'''$ = overall rate of conversion of olefinto alkylate
V_r = total volume of reactor.

To estimate the reactor volume, V_r, the solution is direct. Evaluate the overall rate, r_o''', from known stream compositions. Then, solve for the reactor volume. For several tanks in series, each tank is calculated separately and then the individual tank volumes are summed up to yield the total volume.

DISTILLATE PROCESSING

Hydrotreating

Hydrodesulfurization (HDS), HDN, and HDN of petroleum distillates (i.e., light cycle oil, kerosene, and light gas oil) can be accomplished in a down-flow trickle bed reactor, filled with cobalt–molybdenum (Co–Mo) or nickel–molybdenum (Ni–Mo) catalyst. Hydrocarbon feed and hydrogen-rich gas are mixed, heated, and contacted with the catalyst. The outlet stream is cooled and separated, with hydrogen-rich gas recycled and additional makeup hydrogen blended into the feed stream; the liquid is stripped to remove dissolved hydrogen sulfide and ammonia and then sent to storage. The process flow is shown in Fig. 12 for a distillate hydrotreating unit. In Table 4 are shown the reactor conditions for three streams varying in boiling point (i.e., naphtha, light catalytic cycle oil, and vacuum gas oil) and impurity content.

In petroleum hydrotreating, both vapor phase and trickle bed reactors are used for catalytic hydrotreating of petroleum fractions. Under normal processing conditions, naphthas are completely in the vapor phase while higher boiling fractions are hydrotreated in a mixed-phase trickle bed reactor. These two types of catalytic reactors are discussed extensively.

Fixed-bed catalytic reactors are widely applied to reaction systems in which the reactants are present in a single vapor phase. The scale-up and performance of commercial reactors can be predicted from experiments in small-scale reactors. On the other hand, the mixed-phase trickle bed reactor is considerably more complex to analyze and scale up. The performance of trickle bed reactors is influenced by many factors associated with mixed-phase (gas–liquid–solid) processing. Some of

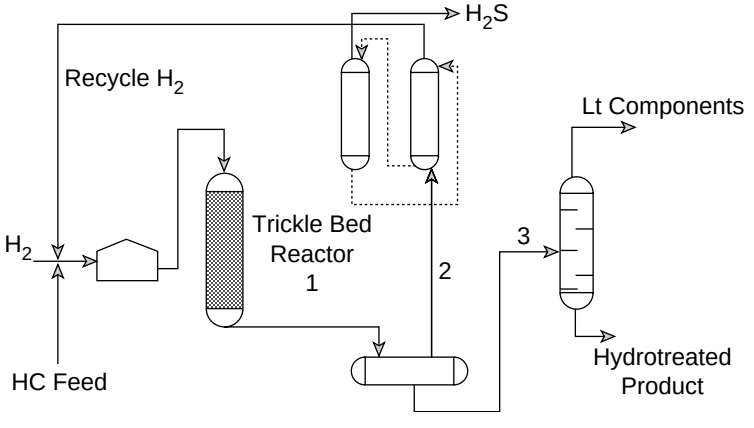

Fig. 12 Distillate hydrotreating.

Table 4 Types of hydrotreaters

	Type of reactor			
	Vapor phase	Trickle bed		
Purpose	**Reformer feed treating**	**Distillate HDS**		**Cat-feed hydrotreat**
Feed	Virgin/cracked naphtha	Light cycle oil, diesel	Kerosene	Vacuum gas oil
Gravity (°API)[a]	62	26	45	17
Boiling range (°F)	175–360	310–660	302–490	650–1000
Sulfur (%)	0.001/0.1	1.4	0.5	1.4
Nitrogen (ppm)	4	400	10	6000
Bromine (No.)	0/19	30	—	—
H_2 consumption (SCFB)[b]	80	350	150	700
Temperature (°F)	550	625	600	700
Pressure (psig)	500	400	350	1000
WHSV (lb/hr/lb catalyst)	6	4	4	1
Catalyst		Co–Mo/alumina		Ni–Mo/alumina
Recycle gas rate (SCFB)	500	700	400	1500

[a]Specific gravity = 141.5/(°API + 131.5).
[b]SCFB = Std. ft^3 per barrel

these include gas–liquid distribution, catalyst contacting, and mass transport resistances in the gas and liquid phases. To appreciate the complexity of this type of reactor, a step-by-step description of the reaction process follows:

1. *Gas–liquid distribution*: Oil and hydrogen are fed into the top of the reactor and distributed uniformly over the catalyst bed. Further, down the catalyst bed, flow maldistribution (i.e., channeling, wall flow) may take place owing to nonuniform bed properties.
2. *Catalyst contacting*: Catalyst particles must be actively contacted with fresh reactant to effectively utilize the catalyst. Stagnant regions on the catalyst particles impair overall reactor performance.
3. *Transport of reactants to catalyst*: To supply the catalyst with fresh reactant, several mass transfer steps are involved. The hydrogen must first transfer through the gas–liquid interface before it is in the bulk liquid phase. Then, dissolved hydrogen and oil reactant (sulfur, nitrogen, aromatics) in the bulk phase transfer through the liquid film around the catalyst to its outer surface. Finally, the reactants diffuse into the catalyst pores.
4. *Catalytic reaction*: The reactant molecules chemisorb on the active sites of the catalyst surface, react, and then desorb off the active site.
5. *Transport of reactants from catalyst*: Reaction products diffuse out of the catalyst pores, then through the film around the catalyst to the bulk phase, and finally the gaseous product (H_2S, NH_3, or H_2O) transfers through the gas–liquid interface into the bulk gas phase.

Heat transfer is also an important consideration in a commercial operation, because reactors are operated adiabatically. The heat release from desulfurization, polyaromatic saturation, etc., produces a temperature gradient along the catalyst bed, the magnitude directly proportional to hydrogen consumption. Temperature control in a multibed commercial reactor frequently employs ''cold-shot cooling'' between the beds with hydrogen to limit the maximum temperature rise. Other cooling means such as interreactor heat exchangers are also used. On the catalyst particle scale, heat transport considerations are usually not important. Interphase (film) and intraparticle temperature gradients are not large because the liquid phase effectively transfers heat from the particle.

General Kinetic Rate Model for Mixed-Phase Catalytic Systems

In general, the rate equation for heterogeneous reactions accounts for more than one rate process. This leads one to ask how processes involving both physical transport and reaction steps can be incorporated into one overall

rate expression. We can make an analogy with conductive heat transfer, in which a combination of different resistances is applied to chemical systems. In Fig. 13, we see that when catalyst particles are immersed in a liquid, there are two film resistances, one at the gas–liquid interface and the other on the catalyst surface, that must be accounted for plus the catalytic surface reaction, which can be influenced by pore diffusion. Thus, we can write the following equation to account for all of these physical transport and reaction steps.

$$H_2 + D \rightarrow \text{Products}$$

$$-r_{H_2} = \frac{P_{H_2}}{H/(k_l a) + H/(k' a_s) + H/(\epsilon k C_D)} \quad (10)$$

where

P_{H_2} = hydrogen pressure
H = Henry's law constant (atm/ft^3/mol)
k_l = liquid film mass transfer coefficient
a = interfacial area between gas and liquid
a_s = catalyst external area
k' = catalyst film mass transfer coefficient
ϵ = catalyst effectiveness factor for pore diffusion effects
k = rate constant for catalytic reaction
C_D = concentration of D in liquid phase.

Plug Flow Reactor Model for Mixed-Phase Reactor

The general reactor model for a trickle bed reactor was derived by Frey and Mosby and appropriately accounts for partial vaporization of the liquid hydrocarbon as it enters the reactor; a plug flow model is used.[9] Some of the hydrocarbon travels downward through the liquid phase, while the portion that is vaporized travels with the hydrogen-rich phase. The reactor model is given below in Eq. (11) and the energy balance equation follows it.

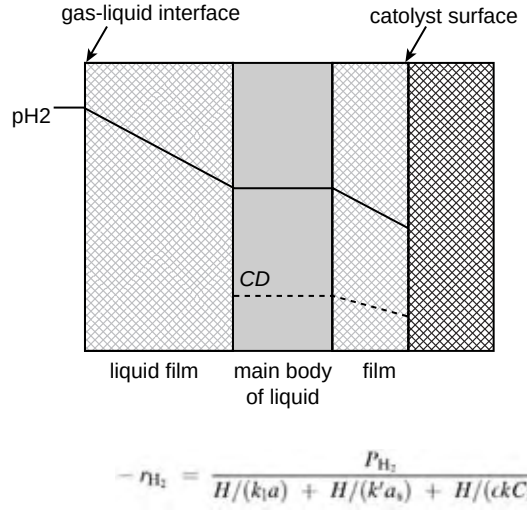

Fig. 13 Multiphase resistances in distillate hydrotreating. *(View this art in color at www.dekker.com.)*

Rate equation

$$\frac{dx_1}{d(1/WHSV)} = \frac{\text{reaction rate of species } i}{P_{io}[(a + H/O)\frac{P_v}{P} + (1 - a)]} \quad (11)$$

where

P_{io} = feed partial pressure of i (atm)
a = fractional vaporization of liquid feed
x_i = fractional conversion of i
H = mol gas/barrel of oil
O = mol oil/barrel of oil
P_v = vapor pressure of oil
P = total pressure
r_i = reaction rate of i (lb/mol/hr/lb catalyst)
WHSV = space velocity (lb oil/hr/lb catalyst).

Energy balance equation

$$\frac{dT}{d(1/WHSV)} = \frac{\sum \alpha_i \, dx_i}{d(1/WHSV)}$$

where α_i = adiabatic temperature rise per unit of conversion of i.

Hydrodesulfurization Kinetics

Reactions for removing sulfur, nitrogen, and oxygen, which are present as organic compounds, are characterized by replacement of the nonhydrocarbon component with hydrogen. The nonhydrocarbon component is hydrogenated (to H_2S, NH_3, and H_2O) and subsequently removed by stripping and fractionation. The desulfurization reaction for single compounds (i.e., benzothiophene and dibenzothiophene) can be modelled with the Frey–Mosby relationship, which has a Langmuir–Hinshelwood form and accounts for inhibition by hydrogen sulfide and aromatics.[10] This works well for single-sulfur compounds, but it should be pointed out that overall desulfurization kinetics, which includes compounds with a large range in reactivity, often behaves more like second order [see Eq. (12)]:

Rate expression

$$-r_s = \frac{k_s \, \text{Act} P_s \, P_{H_2}}{(1 + K_{HS} P_{HS} + K_{AR} P_{AR})^2} \quad (12)$$

Performance equation for plug flow reactor

$$\ln\frac{1}{1-x} = \frac{k_s\,\mathrm{Act}\,P_{H_2}}{\mathrm{WHSV}\left[1-a+(a+H/O)\left(\frac{P_s}{P}\right)\right]\times\left[1+K_{HS}P_{HS}+K_{AR}P_{AR}\right]^2}$$

where Act = catalyst activity.

Denitrogenation Rate Equation

Nitrogen removal is generally more difficult than desulfurization, for several reasons, for instance: 1) side reactions yield nitrogen compounds more difficult to remove than the original ones (indole ⇒ quinoline and carbazole derivatives) and 2) heterocyclic, nitrogen-containing rings must saturate during the hydrogenolysis, and the presence of large side groups on the ring appears to hinder the reaction sterically. Ho has a comprehensive review on hydrodenitrogenation catalysis that covers many topics.[11] The rate of denitrogenation is frequently described as being first order in nitrogen and hydrogen, as discussed by Satterfield and Yang, and the rate equation is given below as Eq. (13):[12]

$$-r_N = K_N\,\mathrm{Act}\,P_N P_{H_2} \tag{13}$$

where

r_N = rate of denitrogenation
Act = catalyst activity
P_N = partial pressure of nitrogen compounds
P_{H_2} = partial pressure of hydrogen.

Nitrogen becomes increasingly harder to remove as the number of aromatic rings increase. More specifically, as we go from single-ring heterocyclic compounds such as pyridine to multiring compounds like quinoline, nitrogen removal is significantly more difficult.

Aromatic Saturation Rate Equation (Equilibrium Limited)

The aromatic saturation rate equation is similar in form to denitrogenation with the exception that it is strongly influenced by chemical equilibrium, instead of the irreversible form. Levenspiel has developed an integrated expression for reversible reactions and this is provided in Eq. (14):[2]

$$-r_A = k_A\,\mathrm{Act}[P_A P_{H_2}^n - (1/K)P_{sat}]$$
$$K_o = \frac{k_A}{k_{sat}} = e^{-\Delta G_o/RT_o} \tag{14}$$
$$\ln(K/K_o) = \frac{-\Delta H_R}{R}\left[\frac{1}{T}-\frac{1}{T_o}\right]$$

where

ΔG_o = free energy of formation at T_o
ΔH_R = heat of reaction (− is exothermic, + is endothermic)
T_o = temperature under standard conditions
T = reaction temperature
P_{sat} = saturated aromatic pressure
P_A = aromatic pressure
k_A = rate constant of reaction
Act = catalyst activity for aromatic saturation
R = gas constant
K = equilibrium constant.

$$\ln\left(\frac{1}{1-X/X_e}\right) = \frac{k_A\mathrm{Act}(M+1)P_{H_2}^n}{\mathrm{WHSV}(M+X_e)\left[1+a+(a+H/O)\frac{P_s}{P}\right]}$$

where

M = ratio of saturates/aromatics in the feed stream and
X_e = equilibrium conversion value.

Hydrogen Consumption Estimates for Hydrotreating

The hydrogen used in hydrotreating can be predicted from the set of equations given in Table 5, which are based on stoichiometry of model reactions. The formulas correspond to 1, 3, and 5 mol of hydrogen per mole of olefin, sulfur, and nitrogen, respectively.

DISTILLATE HYDROCRACKING

Since the mid-1960s, hydrocracking has become a major refining process. It is one of the most versatile of modern petroleum processes. Flexibility of operation, with respect to both feedstock and product, has been reported. This flexibility in operation may be related to the development of specific families of the catalyst, the design of processing schemes that allow the catalysts to function efficiently, and the optimum refining relationships between hydrocracking and other refining processes. Whereas the commercial feedstocks range from naphtha to residua, there is a wide choice for the product of a hydrocracker.

Table 5 Calculation of hydrogen consumption

Reaction	Constant	Feed density (lb/gal)	Feed impurity	Conversion	Hydrogen consumed (SCFB = SCFB1 + SCFB2 + SCFB3)
Desulfurization	0.15	lb/gal	%S	% Desulfurization	SCFB1
Denitrogenation	0.57	lb/gal	%N	% Denitrogenation	SCFB2
Olefin saturation	0.10	lb/gal	Bromine number	% Saturation	SCFB3

SCFB = Std. ft^3 per barrel

The hydrocracking catalyst is dual functional: 1) cracking of high molecular weight hydrocarbons and 2) HDN of the unsaturates either formed during the cracking step or otherwise present in the feedstock. A typical cracking catalyst is silica–alumina and a base or noble metal serves as a hydrogenating catalyst. In a way, HDN helps cracking. The metal HDN sites keep the acid sites of the cracking catalyst clean and active by HDN of the coke precursors. During the past several years, interest in zeolite catalyst has been relatively high. Zeolites X and Y, and mordenite have been the center of attraction. [13] Zeolite, being a superior cracking catalyst compared to amorphous silica–alumina, permits a decrease in reaction temperature for the same level of conversion. The major HDN components are platinum, nickel, palladium, molybdenum, cobalt, etc. These may be altered by promotion with another metal. Inorganic salts, water, metals, and organic compounds of sulfur, nitrogen, or oxygen in petroleum act as poisons for the hydrocracking catalysts. Sulfur compounds inhibit the HDN component while nitrogen compounds inhibit the cracking component of the catalyst. Metal contaminants are deposited on the catalyst to deactivate it. These deposits, when in the active state, promote various dehydrogenation reactions and increase coke-producing tendency.

Types of Hydrocracking

Depending on the feedstock used, two types of hydrocracking are practiced industrially. If the feedstock is a heavy distillate obtained from a straight-run refining or cracking operation, it is called distillate hydrocracking. Residual hydrocracking is the name given to the process if the feedstock happens to be the residue of straight-run refining. The residues are usually lower in API gravity and higher in carbon residues and carbon/hydrogen ratio as compared to distillates. Galbreath and Van Driesen have shown that residual hydrocracking is clearly a different process from distillate hydrocracking; a different type of catalyst is used at a relatively high temperature.[14] We will discuss residual hydrocracking in a later section of this entry. The various distillate-hydrocracking processes include Unicracking, Isocracking, Houdry-Gulf, Isomax, Ultracracking, and BASF-IFP. They can be operated in either a single- or a two-stage process and the product slate can be adjusted by catalyst selection, reaction temperature, and staging. Most of these processes recycle the unconverted higher boiling product to extinction. Unicracking is characterized by the use of a molecular sieve catalyst but many of these other processes are converting to this sieve catalyst technology. Typical conditions for distillate hydrocracking include:

- Pressure: 1000–3000 psig
- Temperature: 575–825 °F
- Liquid space velocity: 0.3–2.0 × volume of feed/volume of catalyst/hr
- Recycle gas rate: 3000 std ft^3 per barrel.

A typical single-stage process is shown in Fig. 14 with the hydrocracking reactor in the middle and a pretreating section on the far left to convert sulfur, nitrogen, and oxygen compounds to hydrogen sulfide, ammonia, and water. The effluent then flows directly to the hydrocracking reactor. Interstage quenching of recycle gas between catalyst beds controls heat release and maintains temperature control.

A diagram of a five-bed hydrocracker is shown in Fig. 15. The dimensions of this particular commercial reactor were 10 ft diameter with 8 in.-thick walls. The design of hydrocracking reactors must be carefully considered on account of the severe operating conditions to which they are subjected, namely:

- High total pressure and hydrogen partial pressure.
- High hydrogen sulfide and ammonia partial pressure from the HDS and HDN reactions.
- High operating temperatures.
- High exothermic heat of reaction.

The heat of reaction is a function of the amount of hydrogen consumed and is normally in the range

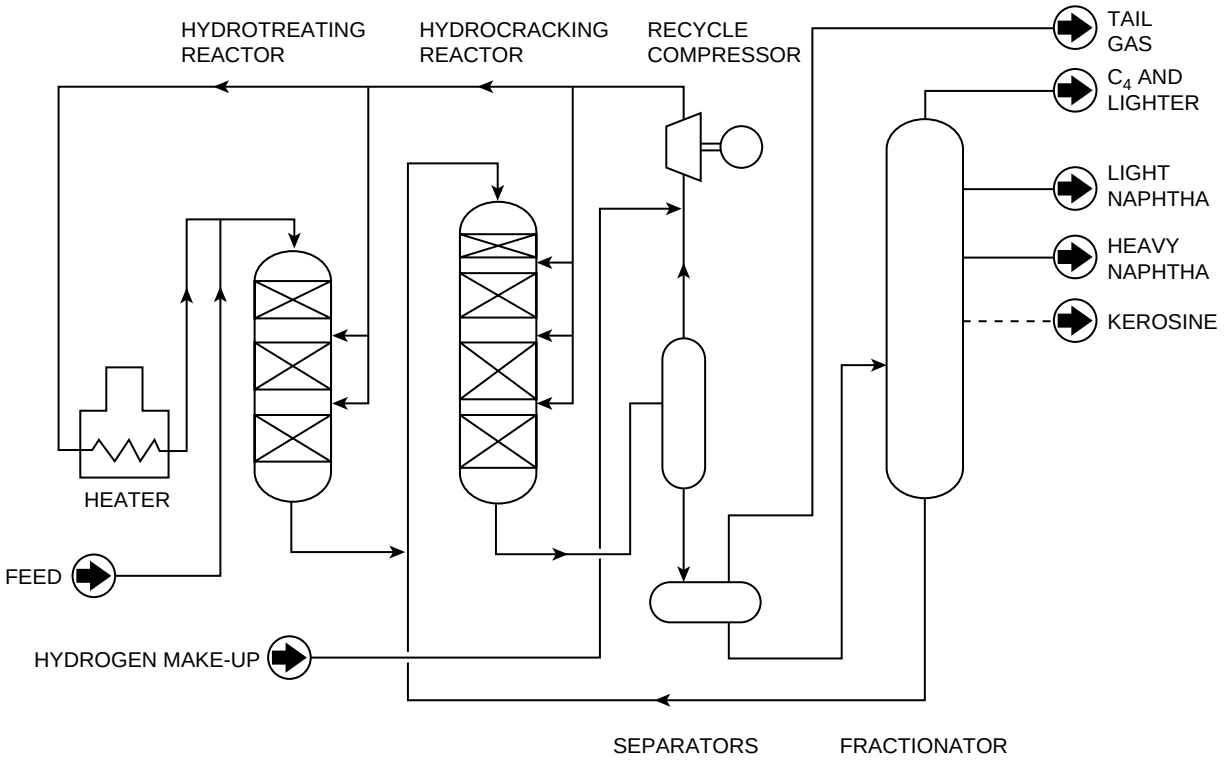

Fig. 14 Hydrocracking process with recycle.

of 490–630 kcal/m^3 of hydrogen. To control the temperature in the reactor, the catalyst charge is split into a number of separate beds with means of cooling the effluent from each bed. This is normally achieved by injection of cold recycle gas between beds or injection of cold recycle liquid between the catalyst beds. Gas injection, the first alternative, is the most favored. The reactor design equations, given for the trickle bed reactor in the previous section on hydrotreating, should be referred to for design of the hydrocracker. Unfortunately, we are not able to provide rate equations to describe the cracking reaction as this information is highly proprietary and is specific to the catalyst and feedstock used.

HEAVY GAS OIL CONVERSION

Fluid Cat Cracking

Fluid catalytic cracking is a process for the conversion of straight-run atmospheric gas oil, vacuum gas oil, and some atmospheric residues and heavy stocks into high-octane gasoline, light fuel oils, and olefin-rich light gases. Basically, the cracking reactions are carried out in a vertical reactor vessel in which vaporized oil rises and carries along with it, in intimate contact, small fluidized catalyst particles (see Fig. 16). The reactions are very rapid and only a few seconds of contact time is necessary for most applications. Simultaneously, with the desired reactions, a carbonaceous material with low H/C ratio, ''coke'' deposits on the catalyst and deactivates it. The spent catalyst and the converted oils are separated and the catalyst passed down-flow to a separate chamber, the regenerator, where the coke is combusted, reactivating the catalyst. The regenerated catalyst is then conveyed down-flow to the bottom of the reactor riser, where the cycle begins again. Control of the regenerator temperature is based on coke made in the reactor.

A major breakthrough in catalyst technology occurred in the mid-1960s with the development of zeolitic catalysts. These sieve catalysts demonstrated superior activity, gasoline selectivity, and stability characteristics compared to silica–alumina catalysts, then in use. The continuing advances in both activity and process design resulted in the advanced design concept of riser cracking in which all of the cracking reaction occurs in the dilute phase in the riser. The key to all-riser cracking is the design of a quenching system that stops the cracking reaction at the optimum yield of desired products. Operating conditions for a typical FCU are shown in Table 6 and how it might be altered is as follows.

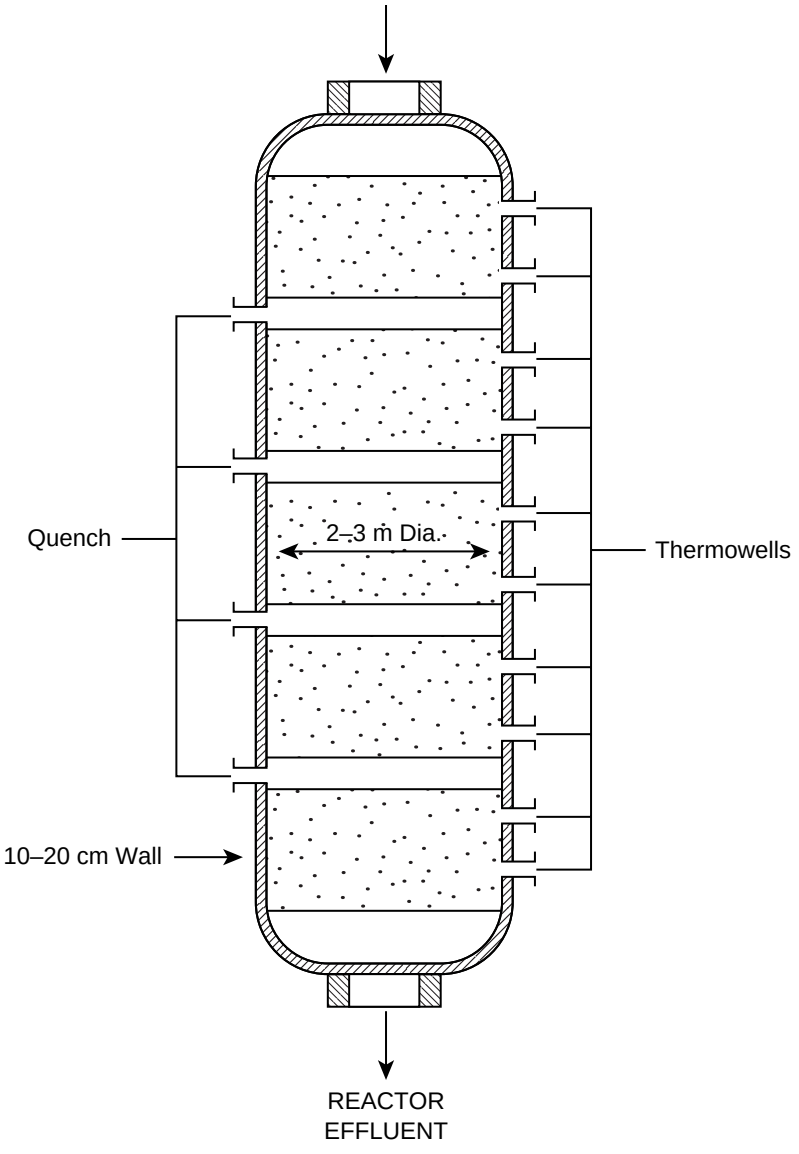

Fig. 15 Five-bed hydrocracker.

Every FCC complex contains the following sections:

1. *Reactor and regenerator*: Reactor cracks feed to light hydrocarbons, gasoline, middle distillates, coke, hydrogen, and hydrogen sulfide. In the regenerator, the circulating catalyst is reactivated by burning off the coke at high temperatures, releasing CO_2, CO, water, and SO_2.
2. *Main fractionation column*: Reactor effluent is separated into various products. The overhead includes gasoline and lighter material. The heavy liquid products, heavier naphtha, and cycle oils are separated as side cuts and slurry oil is separated as a bottom product.
3. *Gas concentration unit*: Unstable gasoline and lighter products from the main fractionation overhead are separated into fuel gas, C1–C4 for alkylation, and debutanized gasoline.

New concepts for FCC

Quick-Quench Cracking. Dilute phase cracking in the riser offers significant advantages over dense-bed cracking. As much as 90% of the feed conversion takes place in the short-contact-time condition in the riser, while the remaining 10% conversion in the dense-bed reactor is accompanied by overcracking of the desirable products. The introduction of the high-activity zeolitic catalysts demonstrated the need for short-contact-time cracking. UOP modified the design of the riser–reactor system. The rise was extended axially well into the reactor shell. The catalyst–hydrocarbon mixture exiting the reactor was directed through a simple device to disengage the hot catalyst from the products. In addition, the catalyst in the dense bed was also reduced. This quenched the cracking reactions at the riser outlet.

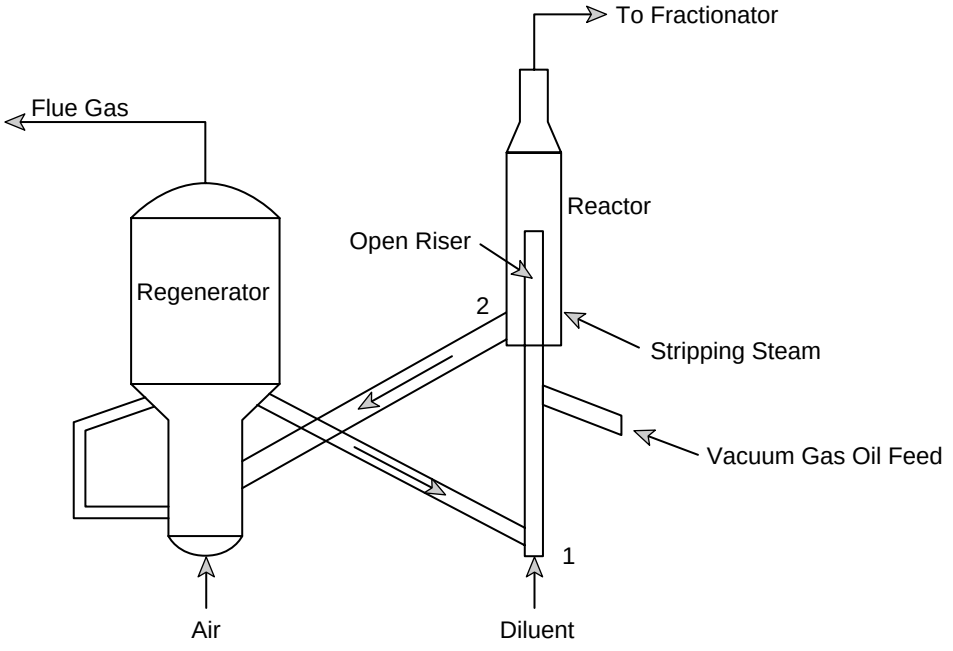

Fig. 16 Fluid cat-cracking unit.

CO Combustion. Complete or partial CO combustion will often benefit FCU operation. In conventional operation, the carbon from the spent catalyst is converted to equimolar quantities of carbon oxides. If the remaining CO is converted to carbon dioxide, the potential heat can be increased by 40–50%. This combustion can be promoted by adding very small amounts of platinum to the cracking catalyst. Complete CO combustion results in the regenerator flue gas containing less than 500 ppm CO, eliminating the need for a CO boiler. The increased heat release produces a higher regenerated catalyst temperature. Therefore, less catalyst recirculation is required to satisfy the reactor heat demand. Coke yield is also decreased and correspondingly is matched on a weight-for-weight basis with an increase in FCC products.

Types of FCU Designs

Model II "down-flow"

The Model II "down-flow" design (Fig. 17) was the first improvement to the Model I "up-flow" unit. The principal features of Model II include a reactor vessel near ground level with the catalyst regenerator offset and above it. A rather short transfer line carries both catalyst and hydrocarbon vapor to a dense-bed reactor. Double slide valves are used at various points in the unit, and the long regenerated-catalyst standpipe causes major operating problems. Commercial evidence indicated that although conversions were relatively low (40–55 vol%), a large portion of the cracking took place in the short transfer line.

Table 6 Process conditions for FCC

Operating variable	Current	Future
Pressure (psig)	20–30	20–30
Reactor temperature (°F)	925	10–25
Regenerator temperature (°F)	1200	1200
Catalyst/oil	12	14
Conversion (%)	80	85
Coke yield (%)	5	4
Catalyst makeup (lb/barrel)	0.15	0.15
Catalyst type	Ultrastable Y sieve	ZSM-5 additive for light olefins + desulfurization additive to capture S as H_2S rather than SO_2

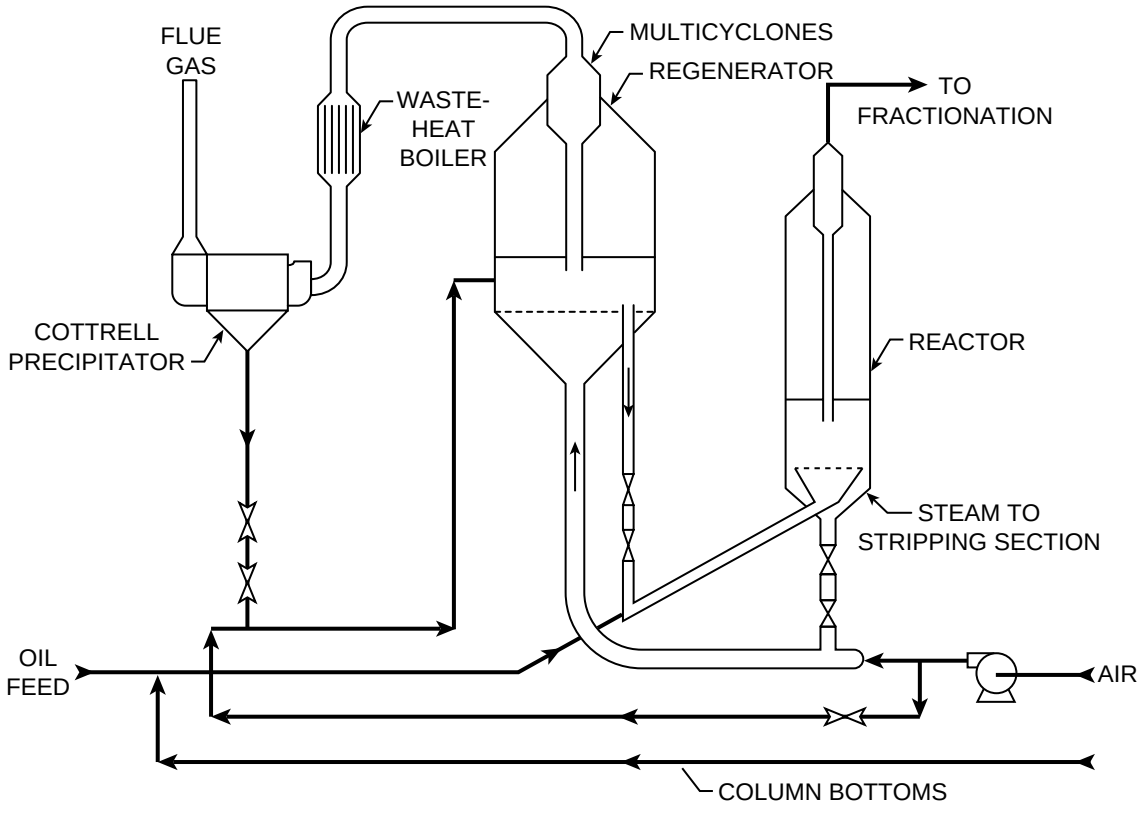

Fig. 17 Model II "down-flow" catalytic cracker.

UOP "stacked" FCU

Following the war, the "stacked" FCU design (Fig. 18), which featured a low-pressure reactor stacked directly above a high-pressure regenerator, was commercialized. The design was a major step toward shifting the cracking reaction from the dense phase of the catalyst to the dilute phase.

UOP "side-by-side" FCU

In the mid-1950s, the "straight riser" or "side-by-side" design (Fig. 19) was introduced. The regenerator was now near ground level with the reactor to the side in an elevated position. Regenerated catalyst, fresh feed, and recycle were directed to the reactor by means of a long, straight riser located directly below the reactor; product yields and selectivity were substantially improved.

Reactor Performance Equations for the "Reactor–Regenerator" System

If the catalyst deactivates rapidly, such as in the FCU, and it is circulated between a regenerator and a reactor, we need to properly account for the catalyst age in the reaction kinetic expression. Some simplifying assumptions are made regarding the catalyst deactivation rate model and the cracking conversion model. However, this allows us to clearly address the coupling of these two processing units and more elegant kinetics can be used for the cracking reactions to upgrade this model, as shown in Eq. 15:

Performance equations for the simplest kinetics reactor (plug flow)–regenerator (mixed flow)

A – R

Cracking reaction (first order):

$$-r'_{\mathrm{A}} = k'aC_{\mathrm{A}} \quad \text{and} \quad R = k'\tau' \tag{15}$$

Deactivation (first order):

$$-\frac{\mathrm{d}a}{\mathrm{d}t} = k_{\mathrm{d}}a \quad \text{and} \quad R_{\mathrm{d}} = k_{\mathrm{d}}\bar{t}_{\mathrm{s1}}$$

Catalyst regeneration:

$$\frac{\mathrm{d}a}{\mathrm{d}t} = k_{\mathrm{r}}(1 - a) \quad \text{and} \quad R_{\mathrm{r}} = k_r\bar{t}_{\mathrm{s2}}$$

Solids in reactor:

$$\overline{a}_1 = \left[R_{\mathrm{r}}\left(1 - \mathrm{e}^{-R_{\mathrm{d}}}\right)\right] / \left[R_{\mathrm{d}}\left(1 + R_{\mathrm{r}} - \mathrm{e}^{-R_{\mathrm{d}}}\right)\right]$$

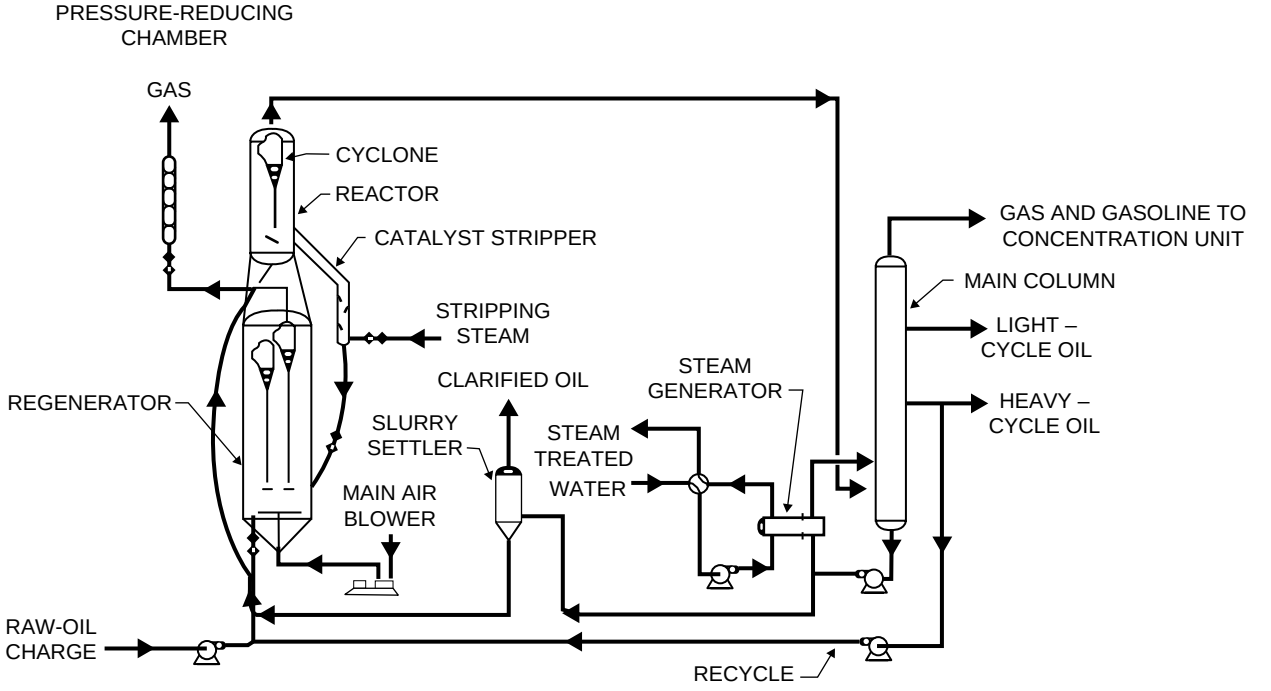

Fig. 18 The ''stacked'' FCU design.

$$\text{Solids in regenerator:} \quad a_2 = R_r/\left[1 + R_r - e^{-R_d}\right]$$

$$\ln\frac{1}{(1-X)} = \frac{RR_r(1 - e^{-R_d})}{R_d(1 + R_r - e^{-R_d})}$$

where

X = fractional conversion of A
a = catalyst activity
k' = rate constant
τ' = space time in reactor $(WC_{A_o})/F_{A_o}$
k_d = deactivation rate constant
$\bar{t}_{s1} = W_1/F_s$ and $\bar{t}_{s2} = W_2/F_s$
W_1 and W_2 = catalyst in reactor and regenerator
F_s = solids circulation rate.

The nomenclature for the above set of equations is given for the reactor–regenerator system in Fig. 20.

RESIDUUM PROCESSING

Residuum Hydroconversion

Residuum hydroconversion is a special case of hydrocracking. Compared to distillate hydrocracking, a significantly different catalyst is used, frequently low metal loading with Mo, with a special pore size distribution less subject to pore plugging by coke. More specifically, a bimodal pore size distribution is frequently used with large macrofeeder (GT. 1000 A°) pores along with smaller mesopores.[15] Because residuum frequently has high levels of vanadium and nickel in it, the catalyst activity may actually increase initially and then slowly decrease as the promotional effects of the metals adsorbed on the hydrocracking catalyst are counterbalanced by deactivation because of coking. The resid hydroconversion reactors may be either trickle bed or moving bed. Because of the high rates of catalyst coking, most moving bed residuum conversion reactors have a capability for fresh catalyst addition and spent catalyst withdrawal while the reactor is operating.

Typical conditions used for the hydroconversion of residuum include:

- Pressure: 2000–2500 psig
- Temperature: 725–800 °F
- Space velocity: 0.4–0.8 × volume of oil/hr/volume of catalyst.

Process Kinetic Models

S. J. Khang and J. F. Mosby (personal communication) have presented process models to describe the removal of sulfur, vanadium, and nickel in residuum hydroprocessing. The kinetic models are given below in Eq. (16):

Desulfurization rate, second order, 1000°F inhibited

$$-r_s = ak_s(1 - C_A/C_{A_o})^m \quad S^2$$

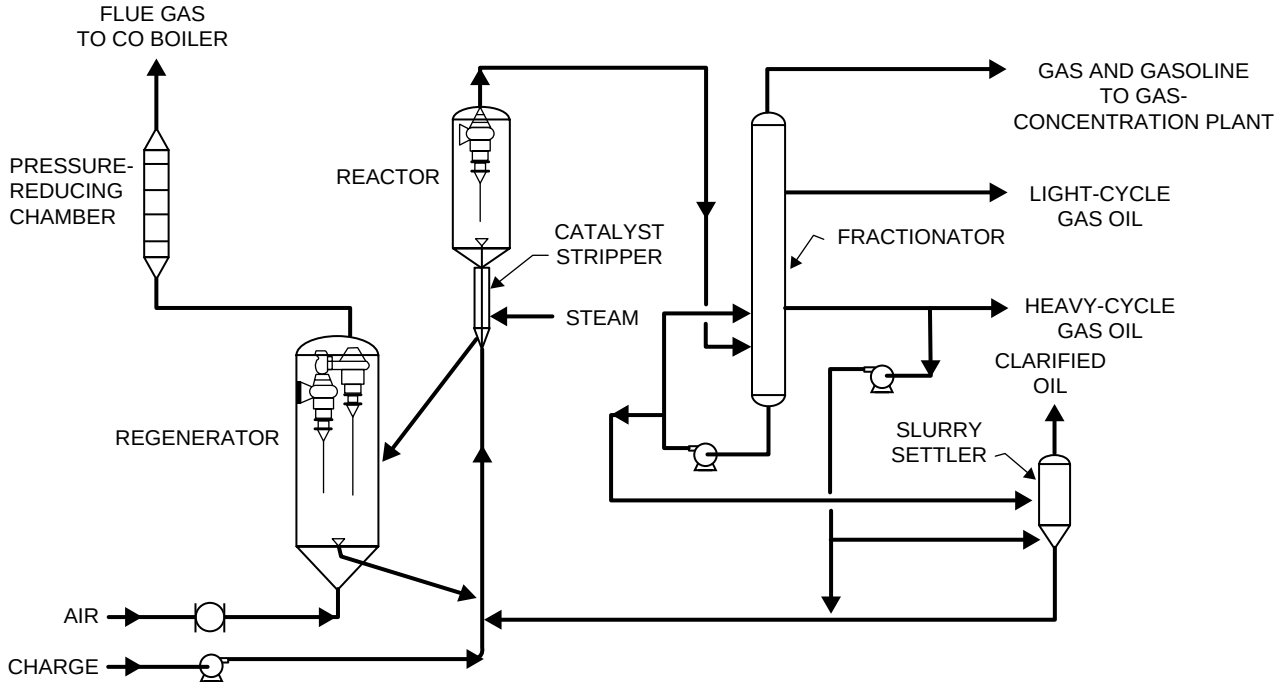

Fig. 19 The ''straight riser'' or ''side-by-side'' FCU design.

Devanadation rate, first order, 1000°F inhibited

$$-r_{\mathrm{v}} = ak_{\mathrm{v}}(1 - C_{\mathrm{A}}/C_{\mathrm{A_o}})^{n} \quad \mathrm{V}$$

Denickelation rate, first order, 1000°F inhibited

$$-r_{\mathrm{N}} = ak_{\mathrm{N}}(1 - C_{\mathrm{A}}/C_{\mathrm{A_o}})^{q} \quad \mathrm{N} \tag{16}$$

where m, n, and q are the orders indicating the degree of inhibition by 1000°F + materials.

Ebullated Bed Reactor for Resid Hydroconversion

Two moving bed processes are available for license, and include the H-Oil process developed by Hydrocarbon Research Inc. and the LC-Fining process developed by Cities Service and C-E Lummus.

The H-Oil reactor (Fig. 21) is rather unique and is called an ebullated bed catalytic reactor.[16,17] A recycle pump, located either internally or externally, circulates the reactor fluids down through a central downcomer and then upward through a distributor plate and into the ebullated catalyst bed. The reactor is usually well insulated and operated adiabatically. Frequently, the reactor-mixing pattern is defined as backmixed, but this is not strictly true. A better description of the flow pattern is ''dispersed plug flow with recycle.'' Thus, the reactor equations for the axial dispersion model are modified appropriately to account for recycle conditions.

The schematic in Fig. 22 shows the key elements of recycling a portion of the exit stream with the feed stream and how that affects the feed concentration(s). The recycle increases the superficial velocity, u, and changes the feed concentration owing to dilution with the product stream.

Although the H-Oil reactor is loaded with catalyst, not all of the reactions are catalyzed; some are thermal reactions, like thermal cracking, which depend on liquid holdup and not on how much catalyst is present. Thus, the material balance equations need to be divided into two categories, one set for the noncatalytic thermal reactions and another set for the catalytic reactions. A convenient parameter to use is the thermal volume/catalytic volume ratio, T/C, which is the ratio of liquid holdup to catalyst volume. In a commercial ebullated bed, this ratio is close to 1.0 under ebullation conditions. Consequently, the material balance equations for the catalytic reactions with no recycle are given in Eq. (17):

Dispersion model with no recycling catalytic reaction—only material balance

$$\left[\frac{D}{uL}\right]\frac{\mathrm{d}^2C_{\mathrm{A}}}{\mathrm{d}z^2} - \frac{\mathrm{d}C_{\mathrm{A}}}{\mathrm{d}z} + \frac{\tau r'_{\mathrm{A}}\rho_{\mathrm{B}}}{(T/C)} = 0 \begin{cases} C_{\mathrm{A}} = C_{\mathrm{A_o}}, & z = 0 \\ C_{\mathrm{A}} = C_{\mathrm{A_f}}, & z = 1 \end{cases} \tag{17}$$

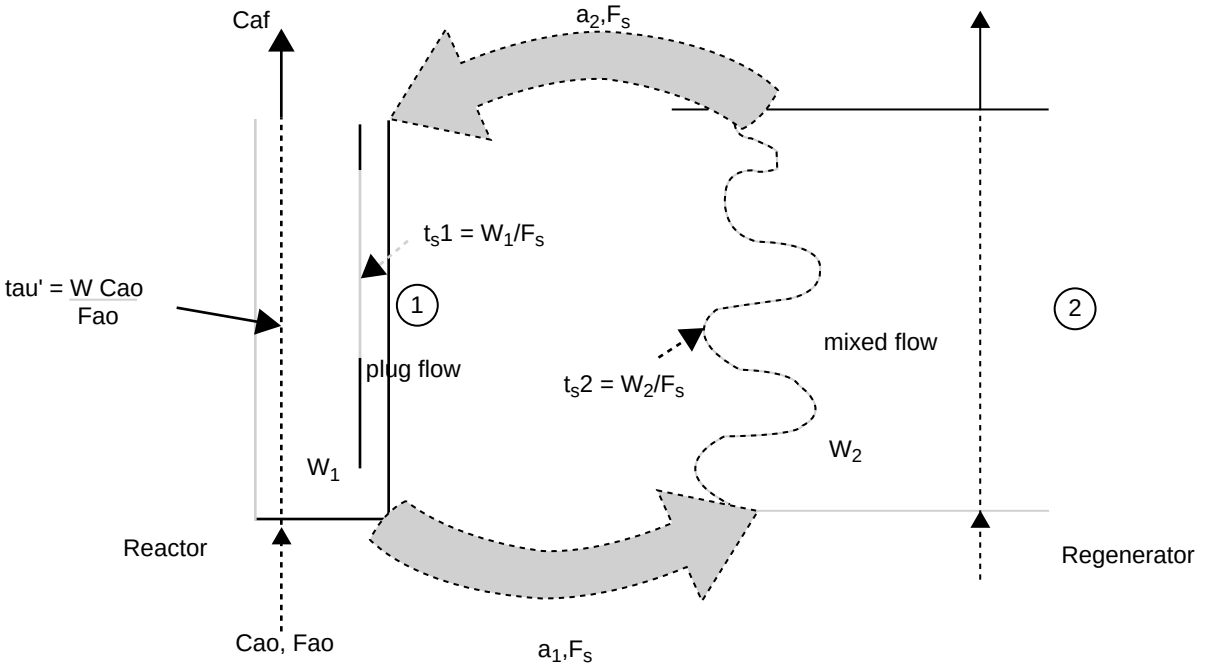

Fig. 20 Reactor–regenerator system. *(View this art in color at www.dekker.com.)*

where

T/C = thermal volume to catalytic volume
C_A = concentration
z = axial position in reactor, l/L (dimensionless)
D = diffusivity
u = superficial velocity, Q/A
L = reactor length
(D/uL) = dispersion number
r'_A = reaction rate of A (mol/hr/weight of catalyst)
τ = space time, L/u
ρ_B = bulk density of catalyst.

The final set of equations for the H-Oil reactor can now be written to account for the recycle situation, and thermal reactions in concert with catalytic reactions.

The model for the H-Oil reactor introduces two complications beyond the axial dispersion model. First, the boundary conditions are modified to account for the recycle and second, the catalyst in the reactor means that both thermal and catalytic reactions are occurring simultaneously. The set of equations given in Eq. (18) are solved numerically with a differential equation solver. This allows the reactor size to be determined by integrating along dimensionless distance z until concentration C_A equals the desired final concentration C_{A_f}.

Dispersion model with recycling catalytic and thermal reaction material balance

$$\left[\frac{D}{uL}\right]\frac{d^2C_A}{dz^2} - \frac{dC_A}{dz} + \tau\left[r_A + \frac{r'_A\rho_B}{(T/C)}\right] = 0$$

$$\begin{cases} C_{A_1} = \dfrac{(C_{A_o} + RC_{A_f})}{(1+R)}, & z = 0 \\ C_A = C_{A_f}, & z = 1 \end{cases} \tag{18}$$

Energy balance

$$\rho u C_P \frac{dT}{dz} = (r_A - \Delta H_R) + (r'_A - \Delta H'_R)$$
$$T = T_o \quad \text{at} \quad z = 0$$

Two- or More-Stage Residuum Hydroconversion

A two-stage residuum hydrocracker represents one additional level of complexity beyond the single-stage

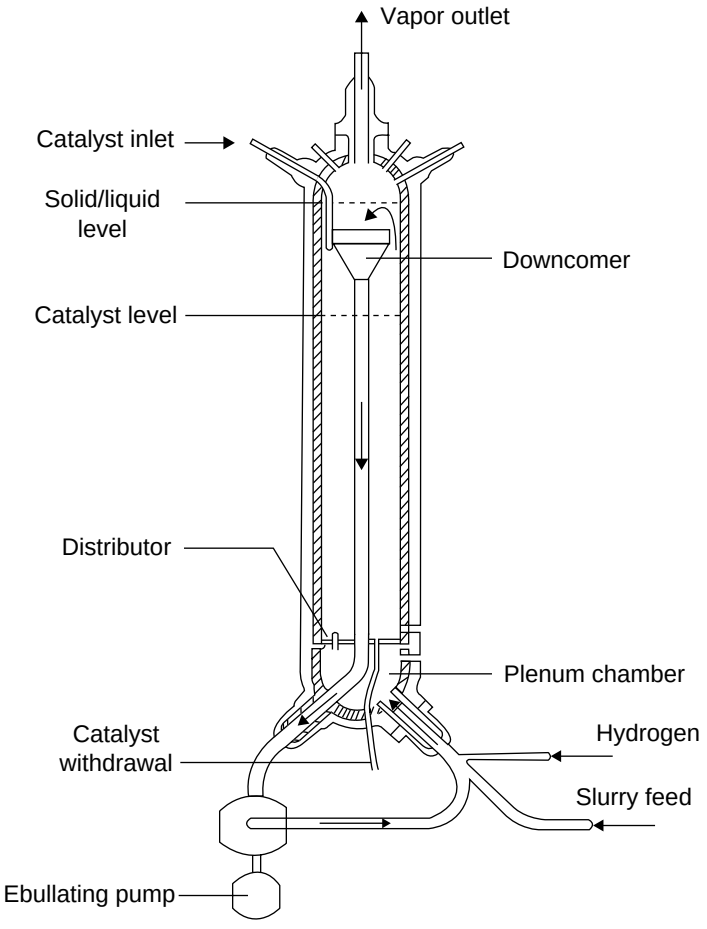

Fig. 21 Ebullated bed reactor.

H-Oil reactor. Now the exit stream from the first reactor becomes the feed stream for the second reactor. The reactor system may be visualized as shown in Fig. 23.

The approach to solving the above reactor system is to first develop the exit values for Reactor 1 and then to use these outlet variables as input for Reactor 2. The reactors will usually be operated at different temperature levels with stage 2 cooler than stage 1 so that the equilibrium for aromatic saturation reactions is favorably shifted. The interstage cooler is shown in the diagram for this reason. Furthermore, the second-stage catalyst may be different.

DELAYED COKING

Delayed coking is a semicontinuous process that is applied to the conversion of most types of residuum. Delayed coking is an endothermic process with the furnace supplying the necessary heat to complete the coking reaction in the coke drum. A diagram of the delayed coking process is given in Fig. 24, showing two coke drums, one active and the other off-line with the coke being cut out of it with high-pressure water nozzles. Hot fresh liquid feed is charged to the fractionator two to four trays from the bottom vapor zone. Any lighter material is stripped from the fresh feed

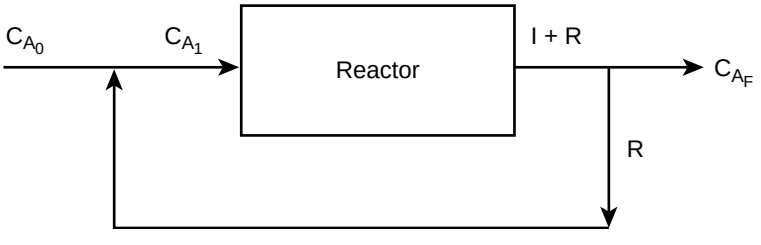

Fig. 22 Recycle reactor.

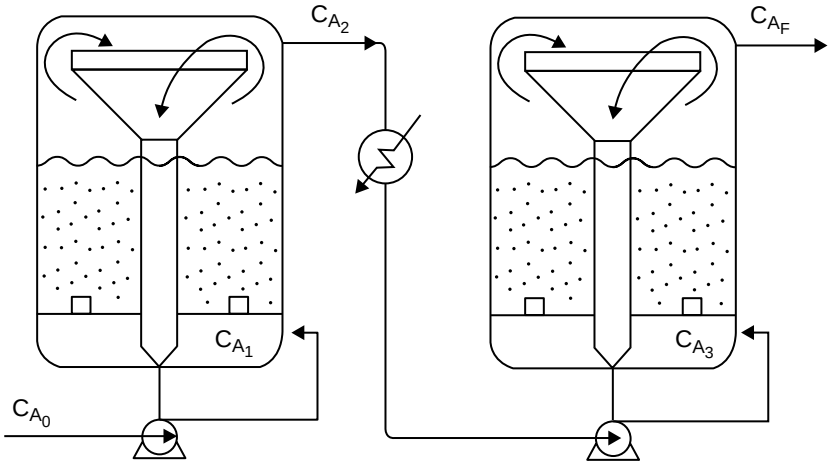

Fig. 23 Two stage residuum hydrocracker.

and then combined with the unconverted residuum to be fed through a heater and into the active coke drum. Steam is usually introduced in the heater tubes of the furnace to control velocities and prevent coke deposition in the heater tubes. The unvaporized portion of the heater outlet settles out in the coke drum where the combined effect of retention time and temperature causes the formation of coke. The exact mechanism of delayed coking is complex and it is not possible to determine the reaction steps involved; however, three distinct steps take place:

- Partial vaporization and mild cracking of the feed as it passes through the furnace.
- Cracking of the vapor as it passes through the coke drum.
- Successive cracking and polymerization of the heavy liquid trapped in the drum until it is converted to vapor and coke.

Three basic operating variables contribute to the quality and yields of delayed coking products. They are temperature, pressure, and recycle ratio:

- Heater outlet temperature: 875–975 °F
- Top coke drum pressure: 15–150 psig
- Recycle ratio, volume of recycle/volume of fresh feed: 0.05–2.

Temperature is used to control the volatile combustible material content of the coke product. The current trend is to produce coke with volatile matter between 6% and 8%. Pressure tends to retain more of the heavy hydrocarbons in the coke drum. This increases the coke yield and slightly increases the gas yield while decreasing pentane and heavier liquid product yield. Recycle ratio has the same general effect as pressure. As the recycle ratio is increased, the coke and gas yields increase and pentane, etc. decrease. The recycle ratio is primarily used to control the end point of the coker gas oil.

A typical coking cycle is as follows:

- Fill the drum with coke while it is in the ''active'' cycle—24 hr.
- Switch from active drum to inactive drum and steam out—8 hr.
- Cool with water and fill the entire coke drum—3 hr.
- Drain water from drum—2 hr.
- Unhead and decoke by drilling a 4 ft pilot hole and cutting—5 hr.
- Replace heads and test with steam—2 hr.
- Heat up by backing vapors from active drum to top of inactive drum—7 hr.
- Spare time for slippage of other steps—2 hr.
- Total—48 hr (24 hr cycle).

Yields for Delayed Coking

If the Conradson Carbon (Con Carbon) is known, the equations in Table 7 may be used.[18]

Table 7 Delayed coking yield equations

Coke (wt%)	1.6 × wt% Con Carbon
Gas (C4–) (wt%)	7.8 + 0.144 wt% Con Carbon
Gasoline (wt%)	11.29 + 0.343 wt% Con Carbon
Gas oil (wt%)	100 − wt% coke − wt% gas − wt% gasoline
Gasoline (vol%)	186.5/(131.5 + °API) × gasoline wt%
Gas oil (vol%)	155.5/(131.5 + °API) × gas oil wt%

Reaction Model for Residuum Coking

Levenspiel has developed an analysis for reactions where the phase changes from a liquid to a solid.[19] It is an adaptation of the Prout–Tompkins model and assumes that all coke nuclei are present at the start and no new ones are formed later.[20] Product grows from the nuclei along fracture places. The model is characterized by conversion first being slow because the boundaries between the reactant and product are very small. Growth then speeds up and eventually slows down as advancing product fronts meet. Please refer to Fig. 25 for the model description. This sounds strikingly similar to the situation in a delayed coker and thus it is proposed for use in the delayed coking process. Because little kinetic analysis has been done on this ''brute force'' process, it seems that some type of model is definitely needed for one to be able to predict performance and make logical judgments on process improvements. The reaction model takes the following form in Eq. (19):

$$\ln\left(\frac{X_R}{1-X_R}\right) = Mt - N \tag{19}$$

where

X_R = residuum conversion
M = characteristic slope
t = time
N = intersection point of plot where $t_i = N/M$.

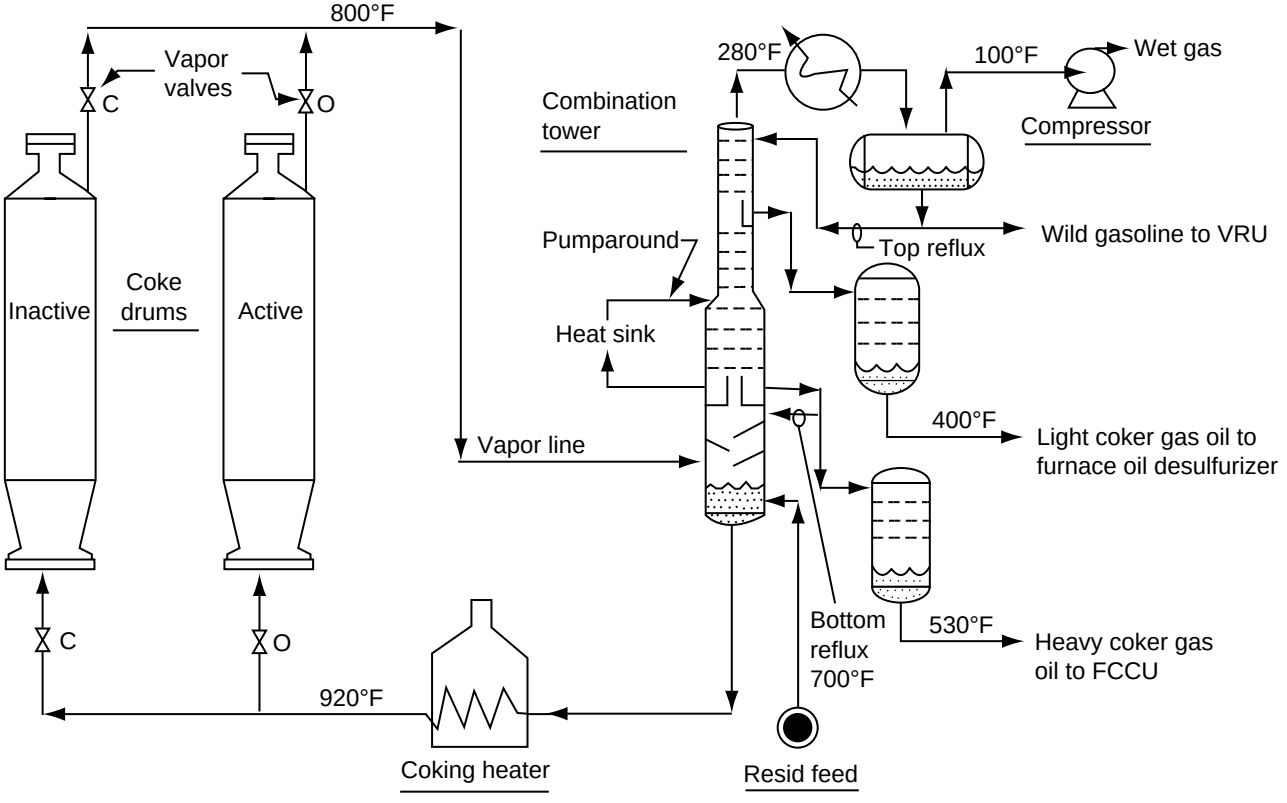

Fig. 24 Delayed coking process.

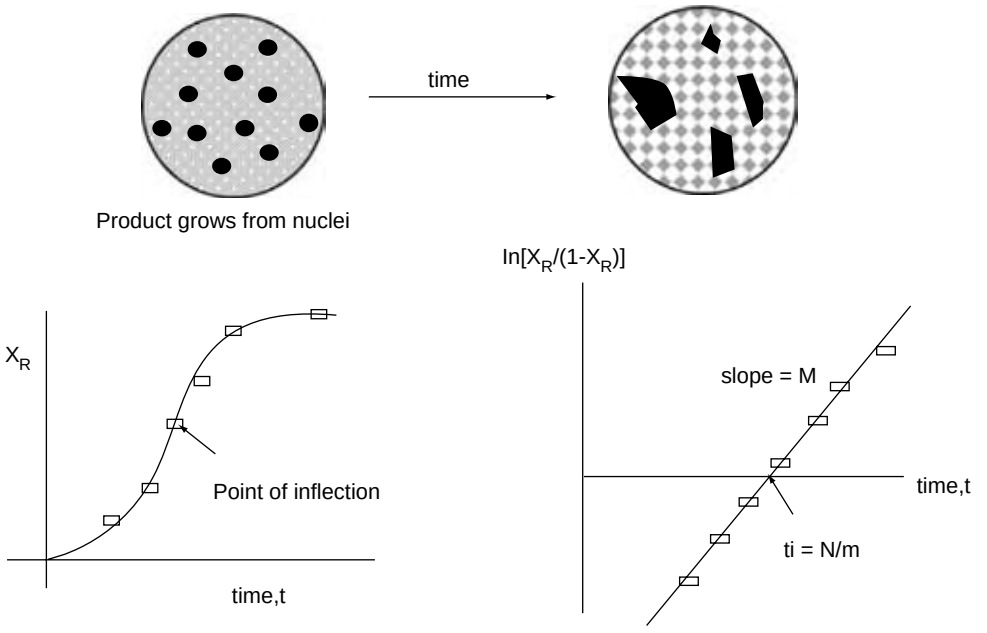

Fig. 25 Phase change model for coking. *(View this art in color at www.dekker.com.)*

In summary, a basic model can be used to interpret the coking data and establish how the coke is being formed as a function of cycle time in the coke drum.

CONCLUSIONS

The various reactors used in petroleum refining have been described along with the defining reactor performance equations and, occasionally, energy balances. The sizing of these reactors can be accomplished with these equations but, of course, for the detailed reactor design for materials of construction, process control, start-up/shut-down, we need to dig much deeper. Still, the methodology presented is the basic starting point to the final design and gives the engineer the tools to begin the design process. For catalytic reactions, this means how much catalyst is needed, and for noncatalytic reactions, it establishes the reactor size given the feed flow rate to the conversion unit. Although the focus has been on petroleum refining reactors, it should be noted that many of the reactors in chemical processing are very similar, where one has a well-defined feed composition rather than a mixture of many different hydrocarbons.

INTRODUCTION

Process control, involving both closed-loop automatic control and advisory systems, contributes to the safe and profitable production of materials with consistently high product qualities at specified production rates. In many process plants considerable opportunity exists for further improvement of plant operations by increasing profit; this increased profit is achieved through Real-time operations optimization (RTO). Real-time operations optimization is an integral element of the typical hierarchical plant automation system shown in Fig. 1. The process control level achieves safety, product quality, and production rate goals, and all closed-loop technology including multivariable control (e.g., model predictive control) is implemented at this level. The RTO level is the first level at which economics is considered explicitly in operations decisions, i.e., in control calculations. This level addresses the short-term decisions on a time scale of hours to a few days. The third level provides integration of multiple RTO systems, which would be required for very large plants that cannot be modeled in a single system. The fourth level addresses longer-term issues like material inventories and production rate targets. All levels utilize process measurements as inputs to their feedback loops. Each higher level provides guidance to the subsequent lower level; for example, the RTO outputs could be set points to the process controllers.

The structure in Fig. 1 is essentially a cascade design. This structure is appropriate because of the differences in the plant dynamics and disturbance frequencies associated with the decisions at each level. Control responds to rapid disturbances and requires execution periods on the order of 1 sec. Real time optimization typically responds to disturbances occurring every few hours or slower, and it requires tens of minutes to compute. The higher levels respond to disturbances occurring every few days. While the cascade structure provides timely responses, it introduces interactions among decision makers that can lead to suboptimal results; therefore, coordinating the levels becomes a challenge.

This entry is organized in the following manner: the first section provides a thorough overview of the process operations challenges that RTO addresses, the potential opportunities that may be realized from effective RTO and the range of applicability of RTO; the second section focuses on the architecture of a typical RTO system, provides a summary of the current state of component technologies of an RTO system and areas where further development would be beneficial; the third section provides a discussion of possible future directions for RTO research and an introduction to some emerging RTO technologies; the entry closes with some concluding remarks.

The Fundamental Challenge in RTO

Process plants have benefited from the application of process control for many decades. Therefore, one might ask, ''What is the benefit for optimization beyond successful process control?'' The answer lies in the fundamental difference between control and optimization. In process control, the goal is assumed to be known, and the challenge is to achieve the goal. For example, the set point of each controller is specified, and the control performance is measured as the deviation on the measured variables from its set point.[1] In addition, the relationship (gain) between the adjusted variable and the controlled variable has an unchanging sign.

In optimization, the goal is defined in a very general manner through the objective function, constraints, and parameter values. Changes in the adjusted variables that increase profit can depend on the scenario. Stated another way, the gain between the adjusted variables and the profit can change magnitude significantly and

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030615

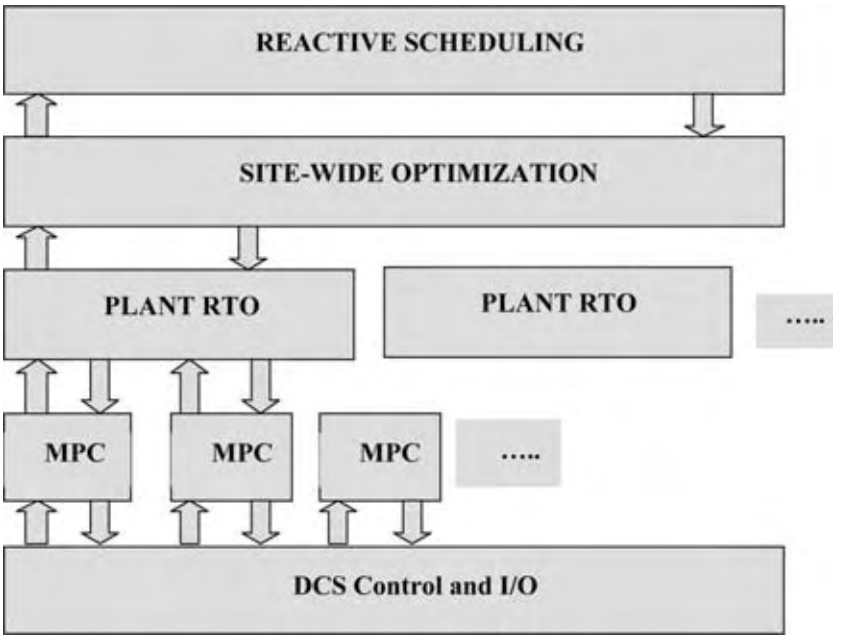

Fig. 1 Plant decision-making hierarchy.

can change sign. Thus, optimization is appropriate when the correct direction and distance for changes in adjustable variables cannot be determined through prior analysis, because they depend on the specific scenario. To achieve this demanding goal, optimization requires substantially better information about the process than does feedback control.

The RTO Opportunity

A key challenge for the engineer is to identify plants that will benefit from the application of RTO. Some key factors in selecting good candidates are given in the following with examples for an ethylene plant shown in Fig. 2. The process technology is covered in for example, Grantom, and Royer, and operation optimization for an ethylene plant is presented in Yang and Waldman.[2,3] Increased plant profit is possible via real-time optimization when the following criteria are satisfied.

1. Additional adjustable optimization variables exist after higher-priority safety, product quality, and production rate objectives have been achieved. Typically, many operating policies will achieve

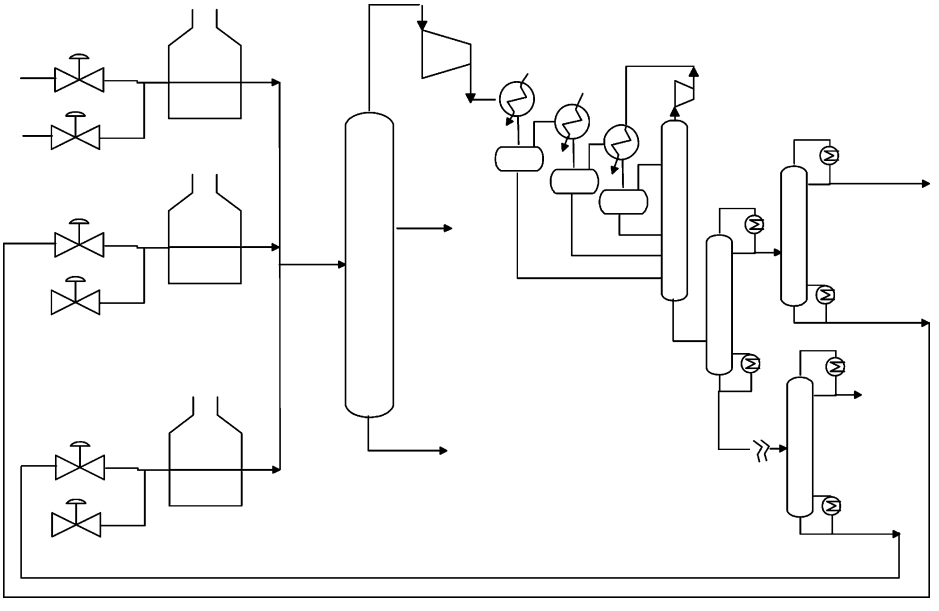

Fig. 2 Schematic of an ethylene production plant.

the same production and product quality because the plant contains more adjustable variables (final control elements) than control objectives. These final control elements are included to provide operating flexibility. For example, several boilers are installed, rather than one large boiler, which provides the ability to generate steam efficiently over a wide range of demands. In addition, one of the multiple boilers can be shut down (either for maintenance or for emergency shutdown) without interrupting the operation of the plant. As a result, optimization can reduce fuel consumption by adjusting steam production in the multiple boilers.

For an ethylene plant, each reactor has three key operating variables; outlet temperature, steam dilution, and feed flow rate. Plants have on the order of 24 parallel reactors (with several within each heater). In addition, the separation section has many variables that can be adjusted for optimization, including recycle compositions, distillation pressures, and refrigeration temperatures. Thus, a plant often has 100 variables or more for optimization.

2. The profit changes significantly as values of the optimization variables are changed. Naturally, no optimization is justified if the values of the optimization variables do not significantly influence profit. For the boiler example discussed above, similar boilers could have essentially the same efficiency relationship with the rate of steam production. If these efficiency curves were concave (as they usually are) optimum profit would be achieved at equal production by every boiler.

   For a typical ethylene plant, the cost of naphtha feed and fuel would be on the order of U.S.$ 260 million/yr. thus, a small percent decrease would yield a significant improvement in profit.
3. Disturbances occur frequently enough for real-time adjustments to be required. Real-time operations optimization improves profit by responding quickly to disturbances when compared to conventional off-line optimization, which involves a person inputting the data and analyzing the results. The importance of the disturbance frequency is represented in Fig. 3, in which the loss of profit for perfect optimization is plotted vs. disturbance frequency. (The loss of profit is used so that the figure resembles the common Bode plot used in automatic control, e.g., Ref.[4].) The dot–dash line represents the profit achieved if no optimization were performed, which is unlikely but provides a base line for the worst performance. Naturally, the profit losses would be large for most disturbance frequencies; however, the effect of all frequencies would diminish when the frequency is high, beyond the corner frequency of the process, where the process ''filters'' the disturbances.

   The dashed line represents the common situation of infrequent, off-line optimization. Performance is good and the profit losses are small for disturbances that occur at a much lower frequency (longer period) than the off-line analysis. The off-line analysis is not effective for disturbances occurring faster than the off-line analysis frequency, and as discussed, the disturbance effects decrease for a frequency beyond process corner frequency. Note that the off-line analysis performance requires the technology and software tools described here for RTO; if off-line analysis is performed using simplified technology, profit losses are likely to occur even at very low disturbance frequencies.

   Finally, the RTO system extends the range of good performance to much higher frequencies because of its much higher frequency of execution. The RTO performance is good until the frequency reaches the resonant frequency of the plant (under closed-loop control). Note that this resonant frequency is primarily determined by the plant dynamics, although it is affected by the process control design and tuning. Thus, RTO offers the potential for increased profit for disturbance frequencies between the off-line frequency and the resonance frequency.
4. Determining the proper values for the optimization variables is too complex to be achieved by selecting from standard operating procedures. Steps 2 and 3 above establish that a potential benefit exists for changing plant operations frequently. However, the optimum operating policies must be evaluated to determine if they could be achieved through process control or whether they require frequent optimization. Approaches for designing control that (approximately) maximizes profit is addressed through ''self-optimizing control.'' (e.g., Ref.[5].) Examples of self-optimizing control include maintaining the proper ratio of steam to hydrocarbon feed to the cracking furnace reactors and minimizing the pressure in a distillation tower.

The Use of Models in RTO

Optimization can be achieved using various combinations of models and plant data to represent the plant. The correct approach depends on the specific application. Some small-scale optimizations can be addressed using direct search methods. (e.g., Ref.[6–10].) These

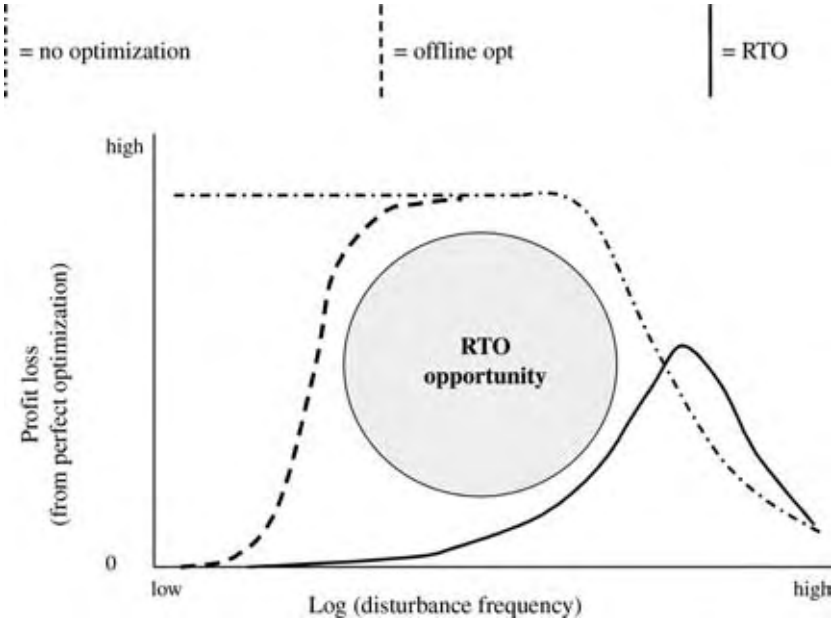

Fig. 3 The effect of disturbance frequency on optimization performance. *(View this art in color at www.dekker.com.)*

methods introduce designed experiments to determine the gradient of the profit. By the nature of this approach, the gradient estimate is only locally valid and corrupted by disturbances and measurement noise. In addition, the experiments can be time-consuming, especially when the method requires that a steady state be achieved between experiments. However, this approach can be appropriate when the following criteria are satisfied.

- Relatively few variables are adjusted by the optimizer.
- A good estimate of profit can be calculated using the values of measured variables.
- The plant achieves steady state quickly.
- Experiments of small magnitude do not seriously degrade product quality.

In contrast, plant-wide optimization involves a large number of variables throughout a slowly responding plant. For this situation, a model-based method is required to approach the best conditions within reasonable times. A fundamental process model provides information on the effects of optimization variables on the profit and potential inequality constraints over a wide range of conditions. A model-based approach is required for the following situations.

- A large number of variables are adjusted by the optimizer.
- The profit and potential inequality constraints are affected by variables that are not readily measured in real time, but can be predicted with reasonable accuracy.
- The plant responds slowly to changes in operation.
- Strong interactions occur between variables, so that sequential optimization of individual variables is not appropriate.
- Plant operations change frequently, requiring frequent re-optimization.

As an example of the importance of integrated models, the distillation column in Fig. 4 is considered. The optimizer must determine the effect on energy costs of a change in the reboiler heat transfer. In a typical process, the steam is generated in boilers that are owned by the plant and supply steam at several pressures for numerous consumers. The change in reboiler steam flow rate influences both steam levels, the steam flow through the turbine and the steam production in the boiler. Clearly, the optimizer must include models of the distillation process and the entire steam system; only with this complete model can a change in reboiler duty be related to the change in fuel purchase.

The models used in RTO are more complete than those typically used for plant design, because the equipment performance calculations are integrated with the flowsheet material and energy balances. Because the plant equipment exists, it must be modeled as it performs. One important reason for detailed performance models is the change in performance as the optimizer adjusts plant operation; for example, the shell and tube exchanger overall heat transfer coefficient depends on the flow rates. Another reason is the limitations imposed by equipment on the feasible operating window. For example, flows are limited by pumping capacities, separation by distillation tray hydraulic limits, and heat transfer by area and temperature driving force.

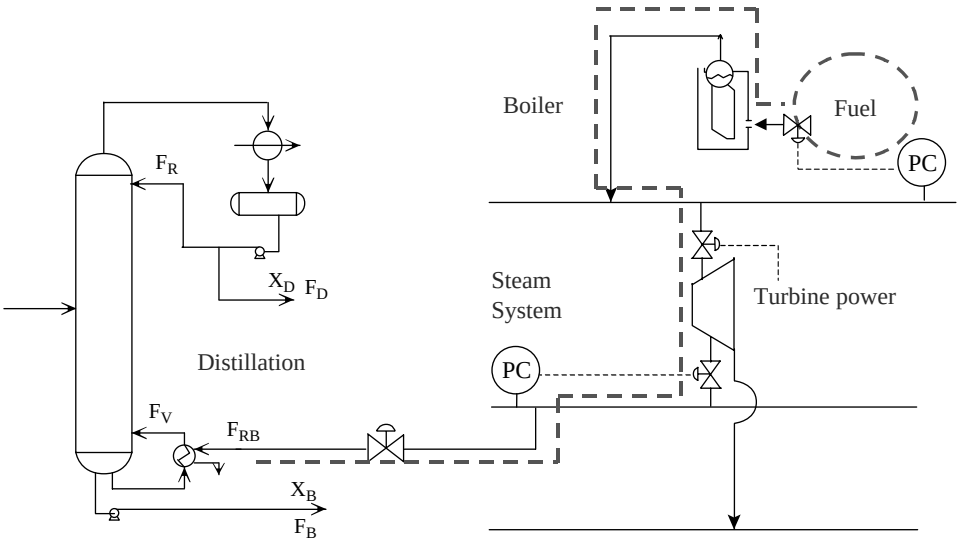

Fig. 4 The integrated effect of a process change on the plant and utility system. *(View this art in color at www.dekker.com.)*

Another important facet of RTO models is the inclusion of the effects of the lower-level process control. The controls are included because they influence the total effect of changes in optimization variables on the profit. A simple example demonstrating the importance of control is shown in Fig. 5. The fuel gas system pressure is controlled by adjusting one of the two sources of purchased fuel. Because the two sources have different prices, the selection of the manipulated fuel determines the incremental price of the fuel. The control design determines that the incremental prices is \$2/GJ. Note that this incremental price is different from the average price. Also, the price for reducing fuel consumption is lower than if the higher price fuel had been adjusted.

Naturally, even the best available fundamental models do not match the true plant behavior exactly. Therefore, RTO employs feedback to improve the approach to the true plant optimum by updating selected model parameters using current measurements. The performance of an RTO system depends strongly on the availability of key measurements, selection of updated parameters, and fidelity of the fundamental model structure and constant parameters.

RTO SYSTEMS ARCHITECTURE

A typical structure of a closed-loop RTO system is shown in Fig. 6, which consists of subsystems for data validation, model updating, model-based optimization, and command conditioning.[11] Raw measurements taken from the plant are filtered and checked for reliability in the data validation subsystem. Because, model-based RTO systems rely on model updating to correct for modeling errors and disturbances, an effective model updating system is required to ensure that the RTO system tracks the changing optimal operations closely. Model updating, most commonly effected via on-line estimation of some set of model parameters, uses the validated data. The updated process model is then used by the model-based optimization

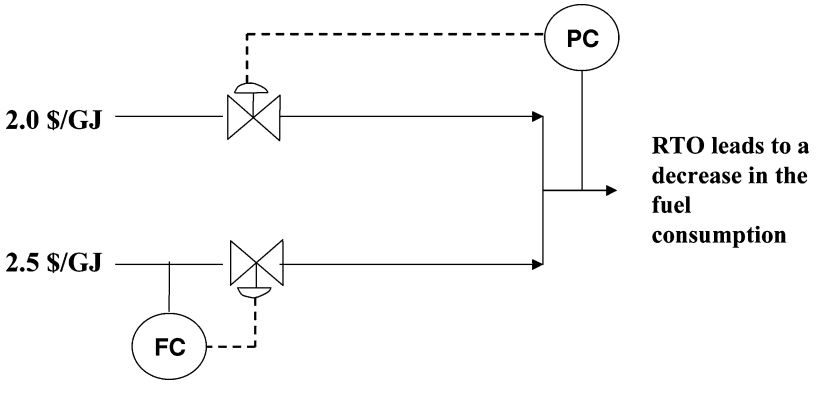

Fig. 5 Determining the incremental cost of fuel requires a model for the control system.

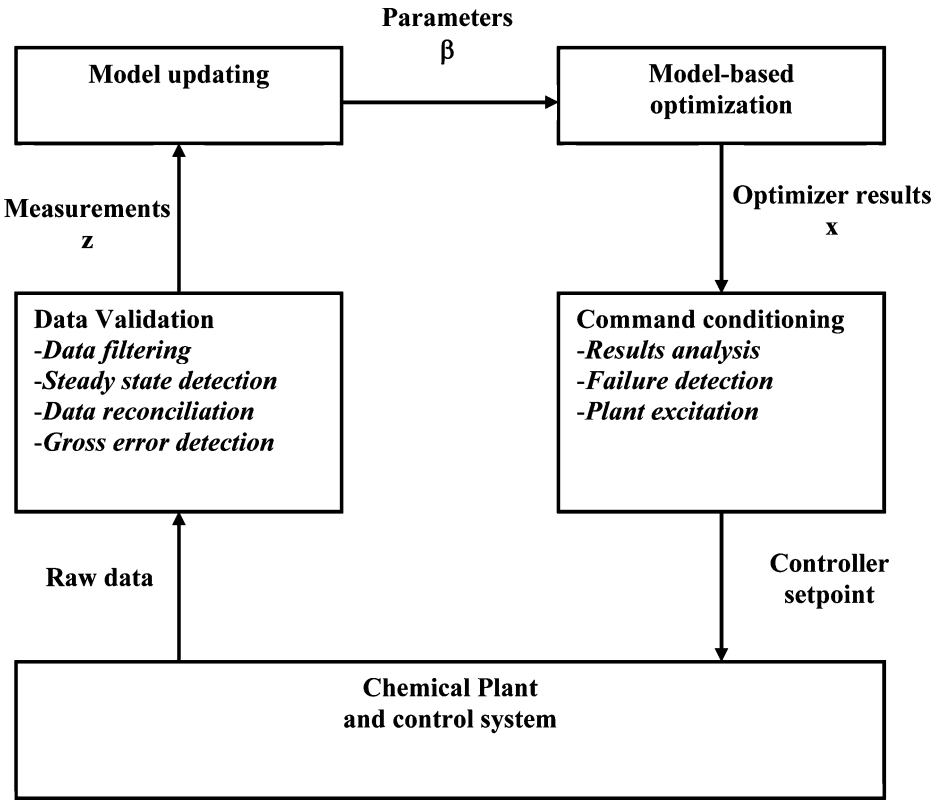

Fig. 6 Closed-loop RTO system.

subsystem to determine the optimum operating policy. The optimization results are analyzed and validated in the command conditioning subsystem before being forwarded to process controllers for implementation. In the following subsections, the details of individual subsystems, which represent the current available technologies for RTO implementation, are described.

Data Processing

The performance of an RTO system depends on the ability of the model to accurately reflect plant behavior, which is observed via process measurements that can be unreliable and subject to disturbances. Therefore, plant measurements are processed and validated in the data validation subsystem before they are used for model updating. The data validation process consists of three steps: 1) steady-state detection; 2) measurement filtering; and 3) data reconciliation and gross error detection.

Steady-state detection

Most industrial RTO applications consider steady-state optimization. Thus, measurements should represent steady-state plant behavior when used to update the RTO model. The steady-state detection module determines if a steady state has been reached based on plant measurements by one of the various statistical methods. Control charts in statistical process control, such as the Shewart chart,[12] can be used to monitor the process variables. If the variations of the process variables are within the control limits, the process is considered at steady-state. Steady state can also be detected by Hotelling T^2 test analysis of variance (ANOVA).[13–15] These techniques identify if the difference between two sample means taken in two consecutive periods is due to common cause variability or not. If the sample means are statistically equal, the process is considered at steady state.

Measurement filtering

Measurements are often corrupted by high frequency, zero-mean, random variations (i.e., measurement noise). These variations can be caused by high-frequency disturbances from the process (e.g., vortices shedding in flow measurement) or electrical interference during signal transmission. Plant measurements should be filtered to reduce the impact of high-frequency variations on the quality of the estimated parameters and as a result, the predicted optimal plant operation.

The filter should be able to attenuate spurious high-frequency variations without affecting the low-frequency variation to which the RTO system must respond. Such

low-pass filtering can be achieved by a variety of approaches, including averaging a set of sampled measurements. Commonly used averaging filters are the moving average and exponentially weighted moving average filters. In the moving average filter, a moving window with fixed size is used to keep a record of the most recent data sets. The filtered signal is calculated by averaging these equally weighted data sets. In the exponentially weighted moving average filter, weightings for the data sets are chosen so that older data sets are discounted in an exponential manner, and the filtered signal is calculated as the weighted mean of the data sets (cf. Ref.[16]).

Gross error detection and data reconciliation

After the process measurements have been initially processed, they should be analyzed for the presence of gross errors before being used in model updating. Gross errors are systematic errors, which can result in measurement bias. Gross errors can be caused by instrument miscalibration, changes in process conditions (fluid density measured by an orifice meter), inappropriate sensor technology (thermocouples for accurate temperature measurement), and so forth. Measurements that are contaminated with gross errors should be removed from the data set before further processing. Measurement data sets that have been deemed to be free of gross errors are then reconciled to ensure their consistency with respect to conservation laws, e.g., material balances.

The measurement adjustments required to satisfy the conservation law(s) are used to detect gross errors in the measurements and to ensure that the data set used for model updating is self-consistent.

Data reconciliation can be formulated as an optimization problem. The adjusted values of the measurements are determined by minimizing the weighted sum of squared measurement adjustments (i.e., the difference between measured values of the process variables and the process variable values that would satisfy the requisite conservation laws) subject to the conservation laws:[17]

$$\text{Minimize } \hat{\mathbf{z}},\ \mathbf{x} \quad (\mathbf{z} - \hat{\mathbf{z}})^{\mathrm{T}}\mathbf{Q}^{-1}(\mathbf{z} - \hat{\mathbf{z}}) \tag{1a}$$

$$\text{subject to} \quad \mathbf{B}(\hat{\mathbf{z}}, \mathbf{x}) = 0 \tag{1b}$$

where z is the vector of steady-state measurements, $\hat{\mathbf{z}}$ is the vector of reconciled process variables, Q is the measurement covariance matrix, x is the vector of unmeasured process variables, and the constraint in Eq. (1b) represents the steady-state balances. In this formulation, it is assumed that measurement errors are random errors. It is important to note that data reconciliation can be performed only when the set of process measurements contains sufficient redundancy.

Gross errors can be detected using statistical tests on the measurement adjustments. If there are no gross errors in the measurements, the measurement adjustments should be statistically indistinguishable from 0. Gross errors can be detected using a range of statistical tests on the adjustment(s) to the measurements.[17–22] For example, the sum of squared adjustments to all flow rates can be compared with a chi-squared statistic to test the hypothesis that the adjustments are all randomly distributed within their variances. Identification of gross errors via the typical statistical testing approaches requires iteration, as the underlying assumption of the available methods is that measurement data contain only random errors. Therefore, when gross errors are detected, suspect measurements are removed from the measurement data set and the procedure is repeated until no identifiable gross errors remain or there are insufficient measurements available to perform the tests.

Recently, simultaneous procedures for data reconciliation and gross error detection have been developed based on the maximum likelihood principle.[23–25] This formulation combines the univariate distributions for random errors and gross errors to account for the possible occurrence of gross errors in the measurements; however, an a priori knowledge of the gross error distributions is required for these methods. In these procedures each measurement error is tested using a combination of the assumed distributions to detect gross errors. These combined data reconciliation/gross error detection approaches have not been extended to handle highly correlated, jointly distributed gross errors.

Model Updating

Because plant–model mismatch is inevitable, process models must be updated on-line, and this is usually accomplished using validated process measurements. Most commonly, model updating is limited to a selected set of model parameters (e.g., heat transfer coefficients, reaction rate constants, and unmeasured feed compositions). The selection of parameters for updating is guided by the key insight that the optimizer uses derivatives in finding the economic optimum operation. Therefore, the updated parameters should change significantly and improve the accuracy of the important variables used in economic optimization. After the parameters have been selected, sensors can be located to ensure that the updated parameters can be calculated with sufficient accuracy. Selection of parameters and measurements for updating has been addressed by several researchers.[26–29]

Some commercial RTO systems either "back-calculate" model parameters from available process measurements or use some form of least-squares parameter estimation.[27] The back-calculation approach has been shown to be less robust to errors in the data and model than the least-squares approach and, as a result, is less desirable in RTO applications. The least-squares model updating problem can be solved by a number of nonlinear programming solvers, and the estimated parameters used for model-based optimization.

As an alternative to a sequential approach (gross error detection followed by parameter estimation), simultaneous data reconciliation and parameter estimation (DRPE) has been espoused by a number of researchers and has been tested in industrial application.[30–34] In the DRPE formulation, parameters are estimated by minimizing the difference between the measured and calculated values of process variables in a least-squares sense:

$$\text{Minimize } \beta, \hat{z}, x \quad (z - \hat{z})^{T} Q^{-1} (z - \hat{z}) \tag{2a}$$

$$\text{subject to} \quad f(\hat{z}, x, \alpha, \beta) = 0 \tag{2b}$$

where z is the vector of measured variables, $\hat{z}$ is the vector of adjusted measurements, α is the vector of fixed parameters, β is the vector of estimated parameters, x is the vector of unmeasured process variables, and the constraints in Eq. (2b) represent the process model. This model updating problem can be solved by any nonlinear programming solvers, and the estimated parameters are used for model-based optimization.

The main difference between the least-squares DRPE problem Eq. (2) and conventional least-squares parameter estimation is that in DRPE the measured variables are estimated, as well as the parameters and unmeasured process variables. Thus, the combined DRPE problem in Eq. (2) can become ill-conditioned because of missing measurements, changes in operating points, and so forth. In an ill-conditioned parameter estimation problem, measurement errors will be amplified in the model updating subsystem causing RTO performance degradation. Miletic and Marlin developed the updater diagnosis strategy to detect the ill-conditioned parameter estimation problem by checking the condition number of the covariance matrix of the estimated parameters.[35] If the ill-conditioned parameter estimation problem is identified, a recovery strategy of fixing one of the model parameters at its previous value and reestimating the other parameters is proposed by the authors. The choice of the parameter to be fixed can be made by evaluating each parameter's contribution to the ill-conditioning of the parameter estimation problem using singular value decomposition. The parameter that contributes the most to ill-conditioning should be fixed. The procedure is repeated until the parameter estimation problem becomes well conditioned.

Yip and Marlin showed that RTO performance can be improved through the use of multiple data sets for updating.[36] In this approach, a moving window of fixed size is used to keep a record of the current and most recent data sets for updating. Using multiple data sets increases the parameter observability and reduces the variability of the parameter estimates.

Economic Optimization

The updated model can be used to determine the optimum values for the optimization variables. The general formulation of the economic optimization problem is:

$$\begin{aligned} &\max_{x,y} P(\beta, x, y) \\ &s.t. \\ &f(\beta, x, y) = 0 \\ &g(\beta, x, y) \le 0 \\ &x_{\min} \le x \le x_{\max} \\ &y_{\min} \le y \le y_{\max} \end{aligned} \tag{3}$$

The symbols are P for profit, f for equality constraints, g for inequality constraints, x for optimization variables, y for dependent variables, and β (constant) for updated parameters. The objective function is a scalar measure of plant profit; it is usually the instantaneous profit (\$/hr), because the optimization variables do not involve the time value of money. Typical equality constraints include material and energy balances, heat and mass transfer relationships, and thermodynamic and kinetic models, and typical inequality constraints include equipment limitations limit compressor horsepower, and distillation tray hydraulics. The optimization variables are flow rates, pressures, temperatures, and other variables that can be manipulated directly. The dependent variables involve intermediate values required for the detailed models; for example, all distillation tray compositions, flow rates, and temperatures. Because of the fundamental models often used in RTO, the number of dependent variables can be quite large, on the order of hundreds of thousands.

Results Processing

Once the RTO system has calculated the optimal operating variables for the plant or system, these

optimal results must be analyzed to ensure that a number of critical issues are addressed, including:

1. The results are still relevant, given that RTO computations can take a substantial amount of time relative to the dominant plant dynamics.
2. The results may be corrupted by sensor noise (and other common cause sources of variation) propagating throughout the RTO loop.
3. The results may not represent a sufficiently large improvement in the operation to merit the recommended change.
4. The results may lead to a decrease in operating efficiency due to plant–model mismatch.
5. The results may not provide sufficient ''excitation'' to improve model accuracy in subsequent model updating cycles.

To address these issues, results processing must include functions for results analysis, failure detection, and information generation.

Results analysis

Of the five issues identified in the preamble to this section, results analysis addresses the first three, which focus on the relevance and validity of the calculated optimal operating targets.

Validity Checking. The main idea is to ensure that the plant has not undergone any substantive change (e.g., a change in feed conditions or process equipment being brought on- or off-line) during the time the RTO calculations took to execute. In general, it would not be appropriate to implement the results of an RTO calculation if model parameters, which were determined during RTO calculations, are no longer valid because of some set of system changes that have occurred during the course of these RTO calculations.

Determining whether the RTO results are still relevant to system operation most often involves testing to see if the steady-state operation has changed during the execution of the RTO calculations. This usually involves testing whether some set of preidentified set of process variables has significantly deviated from their measured values prior to the start of RTO calculations. No literature has developed on setting the thresholds, and as a result, practitioners rely solely on experience. If the plant is not at steady state, no variables are changed by RTO; it is especially important to recognize that outputting a partial solution could lead to suboptimal and even unfeasible plant behavior.

Significance Testing. The second issue that the results analysis subsystem must address is whether the difference between the RTO results and the current operation is due to the propagation of some ''common cause'' variability (e.g., sensor noise), which has resulted in a spurious change to the calculated optimal operation.

Miletic and Marlin proposed a statistical test to determine whether the difference between the current process operation and that predicted by the RTO system is statistically significant with respect to the common cause variability that propagates around the RTO loop.[35] In their work, Miletic and Marlin focus on the predicted values for the controller set points. When the RTO economic optimization problem is subject to limits on the amount that it will be allowed to change the process operation, this approach can fail. Zhang, Nadler and Forbes extended the approach to handle the situation where RTO changes are limited by constraints and proposed a two-step procedure for analyzing the statistical significance of RTO predictions.[29] The above statistical test is valid only when the common cause variability of the optimization results does not result in changes to the active set, so that these variations can be characterized by an ellipsoidal confidence region. Yip and Marlin developed a result analysis strategy to handle the situation where variations in the optimization results could result in active set changes.[37]

The final issue that the results analysis subsystem must address is whether the calculated change in optimal operation will produce a sufficient change in process performance that merits the change. Any RTO prediction, which is not restricted by move limits, that does not produce a significant change in the process performance should not be implemented, as it may contribute to unnecessary process variation and possibly disruptions to effective process operation. This can occur when the process performance is (locally) insensitive to changes in the RTO decision variables (i.e., process controller set points). Statistical tests similar to those used in checking the statistical significance of changes to the RTO decision variables could be employed; however, little work has been done in developing effective methods for testing the significance in predicted changes in process performance. Practitioners typically use ''common sense'' thresholds in the profit based on estimated model accuracy and meaningful profit changes.

RTO: Fault Detection and Diagnosis. Halim proposed a method that uses gradient information from the plant, which is obtained via plant experiments, and the model to both quantify plant–model mismatch and monitor RTO system performance.[38] In this work, the angle between the two profit gradients of the model-based RTO system and that obtained via plant experiments is used as an indicator of RTO

performance and the presence of faults. The source of the faults is determined by comparing input–output sensitivity matrices obtained from the plant and the model, using matrix decomposition techniques.

Current industrial technology involves monitoring the results from the DRPE updating calculation. Heuristic rules are used to determine whether measurement adjustments are ''too large'' or parameter values are ''beyond anticipated ranges.'' When results are questionable, RTO output is typically halted until the results return to acceptable values.

Information Generation. Pfaff studied the problem of ensuring that predictions in subsequent RTO intervals increase in accuracy.[39] In this work, he proposed an expansion of the command conditioning subsystem to evaluate whether the predicted RTO results generate sufficient information to increase the accuracy of parameter estimates in future RTO calculations. When the RTO predictions are not sufficiently information-rich (i.e., do not contain adequate excitation) an experimental design calculation, which uses an A-optimal criterion to reduce the uncertainty associated with decision variables, is employed to produce small adjustments to the RTO predictions. The resulting process controller set points sacrifice short-term profit for improved accuracy and greater profit in future RTO intervals. A profit-based experimental design criterion has been developed by Yip and Marlin which considers short-term profit loss during experimentation and future profit gain after experimentation to design the plant excitation.[40]

Apparently, no commercial application introduces plant changes to improve the parameter updating in model-based RTO. In some cases, the actions of the RTO system in responding to disturbances provide adequate variability.

Results analysis procedure

Any comprehensive results analysis procedure should involve five stages:

1. Relevance checking to determine whether the basis of RTO calculations has significantly changed (i.e., the process operation remains at the same steady state as before the initiation of RTO calculations).
2. Significance testing of predicted changes to the RTO decision variables (controller set points).
3. Significance testing to determine whether the RTO results will produce a meaningful change in system performance (e.g., process profitability).
4. An examination of the RTO results to determine whether the RTO system has failed and, if so, a determination of the source of the failure.
5. A determination of whether the predicted RTO results will produce sufficient excitation to ensure improving efficacy of the model updating system and, if not, an injection of an excitation signal into the RTO predictions.

If the RTO results fail any of the first four tests they should not be implemented and the RTO calculations should be reexecuted at the appropriate time.

OPTIMIZATION

At the heart of any RTO system is the optimization subsystem, which may be used to solve a number of problems including: data reconciliation, parameter estimation, and the determination of the optimal plant operating conditions or set points. Each of these optimization tasks has similar characteristics and it is these characteristics that guide the selection of appropriate solver technologies. Each of the optimization problems encountered within an RTO system is based on the process model, or at least a portion of it, and most often involves a very small number of degrees of freedom (e.g., less than 100 independent decision variables) in comparison to model size and total number of model variables. Furthermore, the optimization problems encountered within RTO systems are typically, but not always, nonlinear. For the purposes of this discussion, the prototypical optimization problem will be considered to be nonlinear with continuous variables, will be based on a model that may contain hundreds of thousands of variables and equations, will contain inequality constraints and bounds, and will have fewer than 1000 degrees of freedom.

Solution methods for optimization problems that involve only continuous variables can be divided into two broad classes: derivative-free methods (e.g., pattern search and stochastic search methods) and derivative-based methods (e.g., barrier function techniques and sequential quadratic programming). Because the optimization problems of concern in RTO are typically of reasonably large scale, must be solved on-line in relatively small amounts of time and derivative-free methods, and generally have much higher computational requirements than derivative-based methods, the solvers contained in most RTO systems use derivative-based techniques. Note that in these solvers the first derivatives are evaluated analytically and the second derivatives are approximated by various updating techniques (e.g., BFGS update).

There are a range of candidate techniques that could be used in the solution of the optimization problems that arise in RTO and comprehensive treatments of these can be found in a wide range of texts (e.g., Ref.[41–45]). Although early implementation of

RTO was based on solvers such as MINOS, which uses a reduced Lagrangian approach, most solvers used for RTO are based on sequential quadratic programming (SQP).[46]

Sequential quadratic programming is an iterative technique, wherein the optimization problem to be solved is locally approximated by a quadratic programming (QP) problem at each iteration. The solution to the local QP problem yields a search direction along which the next iterate is found. The process of local approximation, solution of the QP approximation for the search direction, and line search are repeated until a solution is found (i.e., convergence tolerances are satisfied). A thorough treatment of SQP can be found in Chapter 18 of Nocedal and Wright.[41] What makes the SQP approach particularly attractive for RTO applications is that the main computational steps (i.e., the solution of the QP approximation and the line search) occur only in the space of the degrees of freedom, which is usually orders of magnitude smaller in dimension that the full optimization problem space. This reduction in the dimension of the search space provides the opportunity to solve larger-scale RTO problems in a reasonable period of time (e.g., between 10 and 20 min) on currently available commercial computing platforms.

There are a number of variations on the basic SQP framework. These can differ in the heuristics that are used in initiating the solver, dealing with feasibility and convergence issues, and in the underlying QP solver. Some of these issues are discussed in Nocedal and Wright.[41] An extensive bibliography on the solution of the QP problems can be found in Gould and Toint.[47] Finally, there are emerging approaches that are based on interior point methods that show promise for RTO applications, (e.g., Ref.[48].) but have not yet been incorporated into commercially available RTO offerings.

FUTURE DIRECTIONS FOR RTO

A successful RTO application results from a series of judicious system design decisions (e.g., sensor system design, process model development, model updating strategy selection, and so forth). Although there has been research in most of these areas and some industrial practice has developed, a number of critical issues remain. In the current design approaches, design decisions, such as the selection of adjustable parameters or the sensor system design, are made either based on experience or using the expected RTO performance for different alternatives. Comprehensive and systematic approaches to making RTO system's design decisions are not yet available. Further, the RTO performance metrics on which such systematic approaches would be based currently use linear approximation to estimate performance and, as a result, are only valid in a small region near the test point. Incorporation of nonlinearity into RTO performance would help the designers make more informed design decisions and may decrease the design effort, because fewer nominal operating points would have to be tested.

Effective RTO design requires that a number of issues be addressed, including measurement selection and sensor system design, model fidelity and updating strategies, and so forth. Much of the available literature has tended to focus on the interdependence of parameter uncertainty and measurements availability and accuracy. A number of critical open questions remain, such as: what level of accuracy is required in the process model or parameter estimates; what is the benefit of improving the accuracy; how can the economic benefit of RTO be assessed in a systematic manner.

A well-designed RTO system will encounter performance degradation over time and therefore, on-line RTO performance monitoring and diagnosis are necessary to detect performance degradation. Although there has been some work in the detection of RTO performance degradation, it is only the beginning and further work is required. Detection of performance degradation or other RTO system faults is only the first step and effective methods to diagnose the root cause of the system failure are crucial to the success of any complex automation system. Plant operation's personnel cannot be expected to possess the skill set to effectively diagnose RTO system faults and it is unlikely operating companies will maintain a high level of RTO expertise. Thus, effective subsystems for RTO fault detection and diagnosis are essential in ensuring the widespread and effective use of the technology.

Requirements for higher performance at the plant-wide and, perhaps, the company-wide level are driving an emerging interest in plant-wide RTO. This is optimization on a very large scale. Such an ambitious undertaking cannot be handled as a simple extension of unit level RTO, as the resulting system would be extraordinarily difficult to build, implement and maintain. Rather than monolithic RTO, a decentralized approach is required. Because most continuous processing plants (e.g., oil refineries, chemical plants, etc.) are highly integrated with respect to the flow of material and energy, the operations of individual process units can influence the behavior of many other units. If a purely decentralized approach was taken where optimization problems were solved independently and the inter-dependence of the process unit operations ignored, the resulting plant-wide operation is most likely to be suboptimal and may not represent an

overall performance improvement. Plant-wide optimum operation could be achieved either by a monolithic RTO system whose scope is the entire plant or by coordinating the interacting unit-level RTO systems. The coordinator acts as a channel for the decentralized RTO systems to communicate with each other and exchange information, so that the interdependence of process unit operations is properly integrated into the decisions made by the unit-level RTO systems. Such a distributed approach to RTO will provide much higher levels of system integrity and reliability, drastically increase the ease of maintainability, while requiring little loss in system performance. A similar coordination scheme can be developed for coordinating the optimization problems vertically across the different layers of the hierarchy shown in Fig. 1.

The speed, accuracy, and reliability of an RTO system largely depend on the optimization algorithms at its heart. Most current SQP algorithms employ active set strategies to solve the optimization problems and these can be inefficient for problems with large numbers of inequality constraints. Application of interior point methods in commercial RTO offerings may hold promise for reducing the computation time in comparison to active set methods, but research is only just beginning to yield interior point algorithms that can challenge the more established approaches in terms of speed. Furthermore, because most RTO applications incorporate nonlinear process models, there is a possibility of multiple local optima. Little consideration has been given to this problem, despite the growing research in global optimization. As computer speed increases and more efficient algorithms become available, this issue should be addressed.

A recent resurgence of interest in self-optimizing or extremum-seeking control may result in the convergence of high-performance control and RTO technologies into a single application. This extremum-seeking research, has merged advanced process control techniques and RTO into a single technology.[49–51] The resulting approach has been termed economic optimizing control (EOC). This EOC approach is a fusion of nonlinear adaptive control and optimization, which achieves a high level of performance by simultaneously steering the process in a direction that maximizes the estimated profit function while continually updating the process parameters. As a result, EOC efficiently tracks optimal process operations as they change due to external driving forces. One of the powerful features of EOC is that it results in a relatively simple control law, which may drastically reduce the on-line computational requirements for RTO. Further, EOC promises to simplify the implementation and maintenance of the overall process automation system. To date, EOC has only been tested on comparatively small-scale simulations, under nearly ideal conditions. A considerable amount of further work is required to understand how this emerging technology will fare in industrial-scale application.

CONCLUSIONS

Real-time optimization or on-line optimization has proven itself to be an effective form of process optimization for delivering lasting economic benefit. The objective of this entry is to provide the reader with a concise, yet comprehensive introduction to RTO that discusses the challenges, benefits, and opportunities for RTO; the range of applicability of RTO; the current status of RTO technology and the research on which this technology is based.

Research and development of RTO technology continues and a number of the key directions were discussed in this entry; however as is pointed out, a vital area that has been largely overlooked, yet is critical for the long-term success of this model-based automation technology, is fault detection and diagnosis for RTO. Real-time optimization systems are composed of a complex, interacting set of subsystems, which are each crucial to the success of the system. The current RTO technology requires specialist skills to troubleshoot system performance problems and other forms of systems' failure. To ensure that the promise of RTO is realized and the widespread use of this automation technology, methods must be developed to aid plant personnel in quickly detecting and accurately diagnosing RTO system failures, without requiring specialty skill sets.

The performance of an RTO system is highly dependent on the effectiveness of the control system that implements RTO commands. The current approach to process optimization and control is to separate the two technologies (i.e., RTO and high performance process control) into two layers that are connected in a hierarchical structure. Some merging of the two technologies has occurred in commercial model predictive control offerings, but only to a limited extent. The emergence of extremum-seeking controllers that are specifically designed to maximize economic performance may represent the next step in the evolution of RTO by providing the framework for merger of process optimization and control.

Recent Advances in Catalytic Distillation

R

Flora T. T. Ng
Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada

INTRODUCTION

Catalytic distillation (CD) is a novel green reactor technology that combines a heterogeneous catalytic reaction and separation via distillation in a single distillation column. It is an excellent example of process intensification. There are many possible advantages in carrying out a chemical process using CD. They include enhanced product yield and selectivity, reduction of capital and operating costs, enhanced catalyst lifetime, reduction of waste treatment streams, and higher energy efficiency. Owing to the current concern of the impact of greenhouse gases such as carbon dioxide on the environment, a major benefit of CD is related to the utilization of the reaction heat for distillation, which reduces the energy consumption and hence reduces the production of greenhouse gases. This review will give an introduction to the fundamental aspects of CD and its application in different chemical processes such as etherification, hydration and dehydration, alkylation, hydrogenation, desulfurization, esterification, dimerization and oligomerization, and aldol condensation. Some examples of the recent advances and utilization of CD in the chemical and petrochemical industries are provided.

GREEN ENGINEERING AND CD

Green engineering is a new paradigm for the chemical processing industry. The principles of green engineering encompass energy efficiency, reduction of greenhouse gases and waste treatment streams.[1] Green engineering may be achieved in a number of ways including green chemistry, atom efficiency, and process intensification. Process intensification is one of the most important trends in chemical process engineering.[2,3] Integration of reaction and separation is one excellent example of process intensification. Catalytic distillation combines a heterogeneous catalytic reaction and separation via distillation in the same distillation column and is an excellent example of green engineering and process intensification.[4,5] Catalytic distillation is a novel green reactor technology, which has many potential industrial process applications.[4,6] The combination of a reaction (noncatalyzed and homogeneously catalyzed) and separation via distillation is defined as reactive distillation (RD) in this entry and will not be reviewed in detail here.

A schematic configuration for CD is shown in Fig. 1. It consists of a conventional distillation column, a condenser, reboiler, inlets, and outlets for the feed and product. A distinctive feature of the CD column is the placement of heterogeneous catalysts within the distillation column. The nature and placement of heterogeneous catalysts in the CD column is a key parameter to determine in a CD process. Besides catalyzing the reaction, the heterogeneous catalyst could also provide the interfacial area for liquid/vapor separation and distillation. Owing to the high-pressure drop in a distillation column when conventional catalyst particles were placed in it, the commercial implementation of a CD process was not feasible until a method of placing catalyst particles in a fiberglass bag was patented in 1980 by Smith in Texas, U.S.A.[7] This method of placing catalyst particles in a fiberglass bag is also known as ''Texas Tea Bags'' where the fiberglass bags are rolled in bundles and wrapped around with demister wire to provide void space for vapor flow so as to result in a low-pressure drop in the CD process. The fiberglass bags also reduce corrosion in the reactor because the acidic resins will not be in direct contact with the reactor wall. Since the invention of the Texas Tea Bags, a number of new CD packings have been patented or published.[4] There are a number of new patents on novel CD packings but this aspect will be not reviewed in this entry.

Smith also patented the CD process and its application for the production of methyl-*tert*-butyl ether (MTBE).[7–10] In 1981, Charter Oil refinery (now known as Valero Energy) in Houston, TX, U.S.A., demonstrated the first commercial application of CD for the production of MTBE. The commercial success of the application of CD for the production of MTBE led to the development of other CD processes for the refining, petrochemical, and chemical industries. In the past 6 yr, there is an exponential increase in the number of patents and papers appearing on various aspects of CD such as process development, process design and modeling, and the improvement of mass transfer characteristics of the catalyst packing. This entry will provide a review of the benefits and the most significant recent advances and industrial applications of CD.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007965

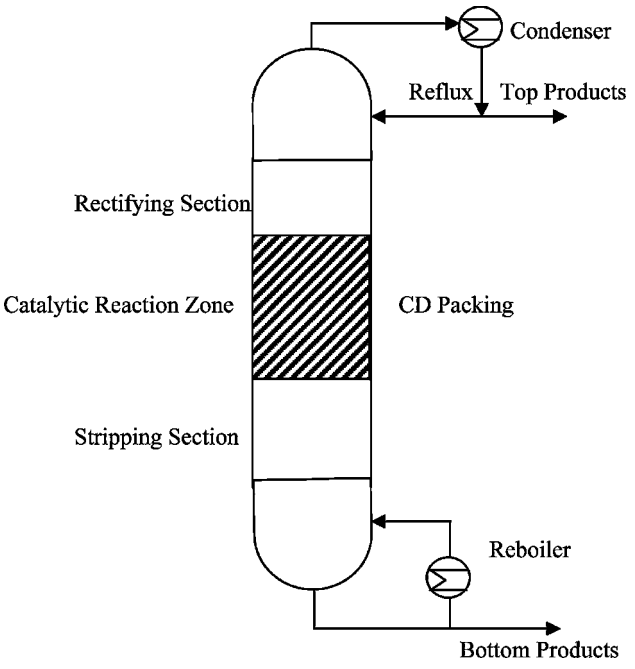

Fig. 1 A schematic for a CD process.

BENEFITS OF CD

Catalytic distillation provides the benefits of green engineering because of the inherent advantages of carrying out a heterogeneous reaction with separation via distillation in the same distillation column. It should be noted that in RD, there is the problem of separation of the homogeneous catalyst and also the corrosion problem associated particularly with the use of acidic or chloride containing homogeneous catalysts. The benefits of combining reaction with separation in CD include energy and capital savings, enhanced conversion and selectivity, longer catalyst lifetime, and reduction of waste streams.[4,6] The following describe the potential benefits in more detail:

1. In situ reaction and separation provides significant energy savings for exothermic processes. The heat generated in the reaction zone in the CD column is used to vaporize the liquid surrounding the catalyst and hence the reboiler duty in the distillation column can be reduced.
2. Process intensification reduces the number of process equipment and hence reduces the capital cost.
3. Increased conversion for equilibrium limited reactions due to the continuous removal of products via distillation as predicted by Le Chatelier's principle.
4. Improved product selectivity for consecutive and parallel reactions due to possible selective removal of the desired product via distillation.
5. Reduction of downstream waste treatment or separation stream due to the enhanced conversion and selectivity.
6. Improved catalyst lifetime due to the use of reaction heat for distillation and hence a reduction of hot spots and sintering of the catalyst. The reflux could also remove the foulant or coke precursors from the catalyst. It is also possible to eliminate the catalyst poisons or impurities by selecting a suitable feed position in the CD column.
7. Less reactor fouling for corrosive type of catalyst because the catalyst used is normally held within some structures and hence will not be in direct contact with the reactor wall.
8. Catalytic distillation could be used to break azeotropes.
9. Catalytic distillation provides a built-in safety feature for exothermic reactions because the reaction heat is used for distillation and hence reduces the risk of runaway reactions. Some CD reactions, e.g., hydrogenation, could be carried out at lower pressure than in the conventional reactor and hence it provides an added safety feature.

GUIDELINES FOR CD PROCESS SELECTION

Catalytic distillation is a multifunctional reactor, which combines a catalytic reaction and separation via distillation in a single distillation equipment. A CD reactor combines the characteristics of a countercurrent (liquid/vapor) flow reactor together with separation via distillation. Although CD has many advantages compared to conventional reactors, not all reactions could take advantage of CD. The following are some of the criteria to consider when evaluating whether a reaction could benefit from being carried out in a CD mode:

1. The reaction preferably occurs in the liquid phase at a reasonable rate because the catalyst particles are mostly wetted by the boiling liquid. The reaction temperature should be less than the critical temperature of at least one of the components because both liquid and vapor phases are required for distillation.
2. The reactants and products can be separated by distillation.
3. Very endothermic processes are not as suitable for CD because the inherent advantage of using the reaction heat for distillation cannot be achieved.
4. A catalyst with high stability and a long lifetime is required because it is normally packed in

some kind of distillation packing and it is very labor intensive and expensive to change it. Generally, the catalyst should have a lifetime of 1–2 yr to be commercially viable.

5. The temperature profile in a CD column is controlled by column pressure and is not isothermal. The kinetics of the reaction should be known prior to the CD experiments so that the CD packing could be located in the section of the column where the temperature is optimal for production of a specified product.

APPLICATIONS OF CD

The first comprehensive review of the application of CD up to the end of 1996 was published by our research group in CHEMTECH.[6] Ng and Rempel also wrote a chapter on CD in the *Encyclopedia of Catalysis*, which included literature information up to the end of December 2000.[4] A review on RD (including both homogeneous and heterogeneous catalyzed reactions) appeared recently.[11] This current review on CD will highlight the commercial CD processes and discuss the advances in CD, particularly since 2000, and includes the literature up to October 2004.

The first commercial and most well-known application of CD was in the production of MTBE. Besides etherification for the production of MTBE, CD could be applied in a number of processes such as alkylation, hydrogenation, isomerization, esterification, desulfurization, aldol condensation, oligomerization, hydration, hydrolysis, amination, and halogenation. Catalytic Distillation Technology (CDTECH), a partnership between ABB Lummus Global and Chemical Research and Licensing, is the leader in the development and commercialization of CD processes particularly related to the refining, petrochemical, and chemical industries. However, there are many more potential applications of CD that could be developed.

Etherification

Because of the reformulated gasoline program introduced by the U.S. government to amend the Clean Air Act in 1990 to reduce emissions from vehicles, oxygenates such as MTBE, ethyl-*tert*-butyl ether (ETBE), and tert-amyl methyl ether (TAME) were favored as some of the components to increase the octane number of gasoline. In 2002, there were over 60 MTBE units and 10 TAME units worldwide. Methyl-*tert*-butyl ether is now phased out in California and possibly banned in the United States nationwide because of its discovery in groundwater. Nevertheless, the experience gained from the successful application of CD for the production of MTBE is applicable to the development of other CD processes and hence will be discussed in some detail here.

Methyl-*tert*-butyl ether is produced from the acid catalyzed reaction between methanol and isobutylene:

$$CH_3OH + CH_2{=}C(CH_3)_2 \leftrightarrow CH_3OC(CH_3)_3 \qquad (1)$$

The first CD packing used in the CD process for MTBE process consisted of an acidic ion-exchange resin such as Amberlyst 15. These macroporous resin beads are packed into fiberglass bags wrapped with demister wire, which are subsequently arranged into bales of Texas Tea Bags that are inserted into a certain location in the CD column.

The advantages of this CD process include increased catalyst lifetime, higher energy efficiency, because the heat released in the adiabatic reactor also preheats the feed and vaporizes some of the feed for the CD column, and a simpler process layout.[4] Another important advantage is that isobutylene conversions up to 99.99% could be achieved in the CD process, whereas only 95–97% isobutylene conversion was achieved with a conventional process configuration (i.e., reactor followed by separation in a distillation column).[4] Although the CD process for MTBE production provides only a slight improvement in the conversion of isobutylene because the equilibrium constant for MTBE favors high isobutylene conversions, it should be emphasized that for a large volume production of fuel additives, even an increase of 2–3% conversion results in significant economic advantages.

An unusual feature of the CD process for MTBE production is that it is recovered from the bottom of the CD column even though its normal boiling point (55°C) is less than the boiling point of methanol (64.5°C). This observation is attributed to the formation of a minimum boiling azeotrope from methanol and MTBE. Apparently, if sufficient quantities of MTBE were accumulated in the CD column, it would ''lift'' the methanol into the reaction zone of the column resulting in a higher methanol conversion. This unusual behavior is believed to be responsible for the multiple steady states observed in the MTBE synthesis shown in process simulation and optimization studies and verified experimentally.[12,13]

Even though new MTBE plants are not being built in North America, CD is used currently for the production of other oxygenates such as TAME or ETBE, which being less soluble in water (i.e., less tendency to be transported in groundwater) are being considered or used as alternative octane enhancers. Ethyl-*tert*-butyl ether is produced from the etherification of ethanol and isobutylene while TAME production requires isoamylene and methanol. A simulation of the industrial production of a ''green'' octane enhancer from

etherification using bioethanol was reported recently.[14] The first commercial TAME plant came onstream at Star Enterprise at Convent, LA, U.S.A., in 1992. It was reported that a CD process for the production of TAME achieves over 90% isoamylene conversion compared to less than 70% conversion obtainable with fixed-bed reactors.[15] A recent patent disclosed an integrated process for the production of TAME from a light naphtha stream derived from a fluid catalytic cracking (FCC) unit.[16] This process involves hydrotreating and isomerization of the light naphtha fraction prior to the reaction of isoamylenes with methanol in the presence of an acidic ion-exchange resin. Recycling of the overhead from an etherification CD column containing unreacted alcohol and isoolefin to improve the conversion of an etherification process was also patented.[17] Catalytic Distillation Technology has a patented CD Taee® technology for the production of *tert*-amyl ethyl ether (TAEE) via the etherification of isoamylene with ethanol. The CD Taee process is based on a two-step reactor design, consisting of a boiling point fixed-bed reactor followed by final conversion in a CD column (Fig. 2). It is stated that the process design retains the heat of reaction as latent heat and reduces the heat input for the subsequent fractionation.

A large number of papers have been published on the process modeling and optimization of the etherification process. More details could be found in a handbook.[18] The most important aspect of process improvement is catalyst improvement because the Amberlyst ion-exchange resin used in the MTBE synthesis has an upper thermal stability limit of less than 100°C and there is a need to develop other acidic catalysts with higher thermal stability. Some of the recent papers have described the use of zeolites, particularly β-zeolites and β-zeolite membranes, as the acidic catalysts for the production of propylene glycol monoethyl ether and ETBE.[19,20]

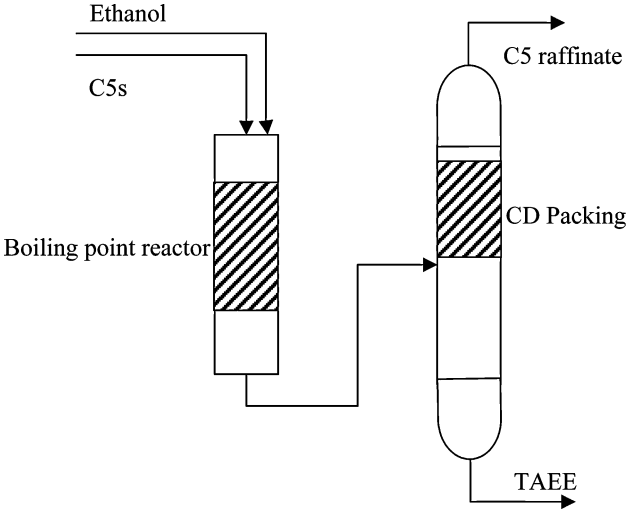

Fig. 2 A schematic of a CD Taee process.

Etherification of propylene and isopropyl alcohol to produce diisopropyl ether, an octane enhancer, has been patented as a two-stage process.[21] The first step involves the hydration of propylene to isopropyl alcohol using acidic ion-exchange resins or acidic zeolites and an optional cosolvent and the second step involves the etherification of propylene and isopropyl alcohol using an acidic catalyst such as Amberlyst 36 in a CD column.

A potential commercial development of oxygenates is related to the use of ethers to enhance the cetane number of diesel fuel. Because the solubility of ethers in water decreases with an increase in the molecular weight, there is a potential application of higher-molecular-weight oxygenates in the diesel fuel pool as their negative environmental impact on the groundwater diminishes should any leakage or spillage occur.

Hydration

Hydration of olefins to alcohols is equilibrium limited and hence CD is potentially suitable for such applications. The catalysts used for the process are acidic catalysts such as cation-exchange resins or zeolites. The hydration of isobutylene to produce *tert*-butyl alcohol via CD results in a higher conversion and there is no need to recycle the water.[22] The hydration process is catalyzed by acidic ion-exchanged resins at 85°C and about 1200 kPa. The CD process configuration involves feeding the isobutylene below the catalyst zone and the water is fed above the catalyst zone. Flooding of the reaction zone is introduced in the process to improve the contact between the catalyst and the liquid and to ensure that the water is in constant contact with the catalyst sites. Flooding of the catalyst zone apparently improves the catalyst lifetime and performance because catalyst deactivation is caused by mass transfer and liquid distribution problems. Some recent publications on the hydration of isobutylene include a patent and a study of the kinetics of the hydration process and discussions on the merits of the application of CD for hydration.[23,24]

Hydration of propylene to isopropyl alcohol or hydration of ethylene to ethanol requires much more severe reaction conditions, which are not as suitable for distillation unless a more active catalyst could be developed. A recent design of a CD process for the production of isopropyl alcohol via hydration of propylene indicates that high-purity isopropanol (99.9%) could be achieved operating at 2 MPa; however, the viability of the catalysts proposed for the process is yet to be determined.[25]

The hydration of ethylene oxide is a consecutive reaction that produces diethylene glycol from the consecutive reaction of ethylene glycol with ethylene oxide. Therefore, CD could be used to produce the desired ethylene glycol in high yield and selectivity. Recently, the hydration of ethylene oxide to produce ethylene glycol with conversion close to 100% and >98% selectivity was reported.[26] The synthesis of cyclohexanol by the selective hydration of cyclohexene in a mixture of benzene, cyclohexene, and cyclohexane with very close boiling points was reported.[27] This process configuration involves feeding a slurry containing hydrophilic H-ZSM5 zeolite particles into an RD column. The catalyst particles were recovered in the aqueous phase.

Dehydration

The production of diisopropyl ether by the dehydration of isopropyl alcohol and the simultaneous removal of the product diisopropyl ether and water at the reaction zone was reported to increase the conversion of this equilibrium limited reaction.[21] The dehydration of methanol to produce dimethyl ether was also reported.[28]

The dehydration of *tert*-butanol to produce isobutylene using β-zeolite, hydrofluorine (HF)-treated zeolite, and HF-treated montmorillonite has been reported to give a higher conversion of *tert*-butanol due to the in situ separation via CD.[29–31] It was reported that at a pressure of 80 kPa and 64–99°C using β-zeolite, conversion of 99% and selectivity of 94.5% were obtained.[31] The preparation of isobutene from a slurry CD process by feeding fine particles of acid cation-exchange resins with the *tert*-butanol was reported to give a 99.99% conversion.[32] Recently, the production of high-purity (>98%) tetrahydrofuran from the dehydration of 1,4-butanediol using cation-exchange resins was reported. Furthermore, this process was carried out using a new technique involving the use of a dual column operating at different pressures.[33,34]

Alkylation

An important industrial application of CD is the alkylation of benzene with ethylene or propylene to produce ethylbenzene or cumene, respectively, using acidic ion-exchange resins such as Amberlyst or zeolites operating at 130–5065 kPa and 80–500°C.[35] Cumene is a chemical intermediate for the production of phenol, acetone, and alpha-methyl styrene, which are used to produce resins and solvents. Ethylbenzene is an intermediate for styrene, an important monomer for polymers. Alkylation of benzene could also be used to reduce the carcinogenic benzene content of gasoline. A number of advantages of CD were obtained for the exothermic alkylation process and particularly noteworthy is the increased catalyst lifetime and enhanced selectivity to monoalkylated rather than dialkylated or trialkylated product. Catalytic Distillation Technology commercialized the production of ethylbenzene using the CD EB® technology in 1994 at the Mitsubishi Petrochemical in Yokkaichi, Japan. The CD Cumene® process was first brought onstream in 2000 at a capacity of 270,000 MTA by Formosa Chemicals and Fibre Corporation, Taiwan, and was expanded to double the capacity since 2004.

A schematic of a CD process for cumene production is shown in Fig. 3. The CDTECH process uses a zeolite catalyst in one of its patented CD structures and the product yield exceeds 99.5% purity with 99.9% selectivity to cumene. The high selectivity to cumene is achieved by controlling a low propylene concentration in the reaction section using a combination of process parameters such as system pressure, location of catalyst zone, and feedpoint. A low propylene concentration will result in a low propylene oligomerization rate and hence will reduce the amount of diisopropylbenzene and triisopropylbenzene produced by the consecutive reactions. One interesting aspect of this process is to recycle the diisopropylbenzene and triisopropyl benzene where transalkylation with benzene produces more cumene.

Recently, a novel CD process for the alkylation of benzene with propylene using suspended catalyst rather than encasing the catalyst in a rigid structure with 100% conversion for propylene with more than 90% selectivity to high-purity cumene was reported.[36] An improvement of the suspension CD by simultaneous alkylation and transalkylation for producing

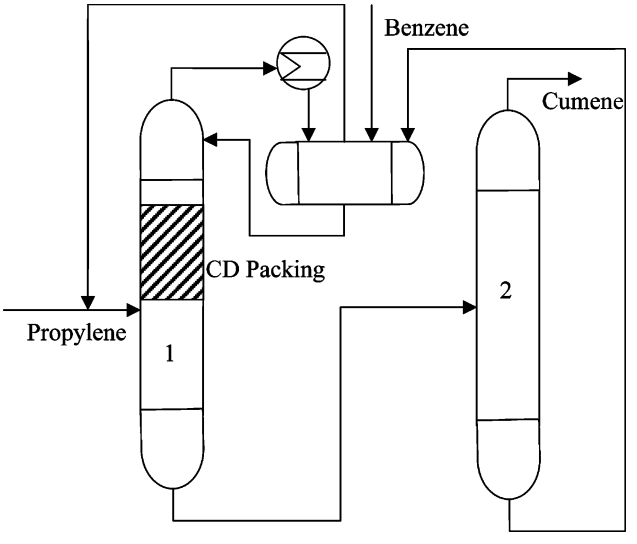

Fig. 3 A schematic of a CD process for cumene production: 1) CD column and 2) distillation column.

cumene was also reported using a modified zeolite catalyst.[37] Suspension CD involves the use of small catalyst particles inside the distillation column and the separated catalyst particles can be recycled and/or regenerated before recycling. Although suspension CD overcomes the difficulty of getting suitable CD packings, it requires the separation and recycling of the catalyst particles, which will increase the cost of the process. Currently, there is no commercial process using suspension CD.

The alkylation of benzene with C2–C4 olefins has also been patented using the acid form of the β-zeolite.[38] Selective alkylation of toluene with C2–C4 olefins using acidic zeolites such as Y-, β-, or Ω-zeolites followed by transalkylation with benzene has also been patented.[39] A recent paper reported an increased catalyst lifetime for the alkylation of benzene with ethylene at a relatively high ethylene to benzene ratio using Y-zeolite contained in high-efficiency packing.[40] This paper clearly shows that many of the advantages of CD are due to the fact that selectivity greater than 99.5% to ethylbenzene at a benzene to ethylene molar ratio of 1.5 : 2 was achieved. A recent patent on the use of enriched or pure ethylene at a benzene/ethylene ratio of 1 : 1 for the production of ethylbenzene was granted.[41]

The alkylation of FCC off-gas with benzene to produce ethylbenzene by CD was recently reported.[42] A rectified RD configuration could be used to increase the yield of monoalkylated product.[43]

Besides the production of cumene and ethylbenzene, there are a number of recent reports on the production of linear alkylbenzene, precursors to detergents, via the alkylation of benzene with C6–C18 olefins. One process uses suspension CD and essentially 100% conversion of olefin at low temperatures of 90–100°C was obtained.[44] An HF-treated mordenite used in the alkylation of benzene and C10–C14 olefins was found to give a 74–84% selectivity to linear alkylbenzene containing 80% 2-phenyl isomer.[45] A new patent on the alkylation of aromatic hydrocarbons such as benzene and cumene with straight-chain C6–C20 olefins on acidic catalyst such as zeolites or fluorine-treated zeolite catalyst packed in a Katamax-type packing was granted.[46] A patent application on the manufacture of xylenes from reformate by RD also appeared and higher than equilibrium amounts of *para*-xylene were claimed.[47]

Hydrogenation

Catalytic distillation hydrogenation is one of the more recent applications of CD that was commercialized by CDTECH for the selective hydrogenation of dienes in C4–C6 streams and the saturation of benzene in the aromatics under the trade name CD Hydro®. Commercial applications of CD Hydro include selective hydrogenation of butadiene in a mixed C4 refinery stream, selective hydrogenation of pentadiene and hexadiene, hydrogenation of benzene to cyclohexane and hydrogenation of acetylene in a C4 stream.[48] A process for the hydrogenation of benzene in a reformate stream was commercialized in Texaco's refinery at Bakersfield, TX, U.S.A., to produce gasoline with less than 10 ppm benzene in 1995. Conventional Ni or Pd catalyst supported on alumina placed in a distillation packing consisting of flexible, semirigid open-mesh tubular element was used as CD packing. The process operates at 1378–1723 kPa and 149–204°C compared to 2412–3101 kPa and 260°C for a fixed-bed hydrogenation process. The highly exothermic reaction is controlled by recycling the condensed overhead to the column and therefore safer than conventional fixed-bed hydrogenation processes, which require a high mass flow rate or efficient heat exchangers to remove the reaction heat. The heat of hydrogenation could also be used for vaporization of the feed in the catalyst zone resulting in a near-isothermal operation, which improves catalyst lifetime since the sintering of catalyst is reduced. It was reported that the CD Hydro process could be installed at about 25% less capital cost than a conventional reformate splitter followed by a fixed-bed hydrogenation unit.

It should be noted that there are a number of benefits associated with a hydrogenation process carried out in a CD column. Besides significant energy savings and hence reduction of greenhouse gases such as carbon dioxide, there is improved process safety due to the lower temperature and pressure required for a CD hydrogenation process and the near-isothermal temperature profile in the reaction zone, which reduces the possibility of runaway reactions. The lower pressure requirement also eliminates the need for a hydrogen compressor. In a recent patent on the hydrogenation of cyclopentadiene, it was shown that the pressure required for hydrogenation in a CD column was 8 psig and 175°F whereas greater than 200 psig and 200–450°F were used in a conventional hydrogenation reactor to achieve 99% conversion.[49] It was also reported that the catalyst was found to be more stable in the selective hydrogenation of methylacetylene and propadiene in a C3 fraction in a CD column than in a trickle-bed reactor.[50] An extended catalyst lifetime in the hydrogenation of C3 fraction was also reported.[51] The phenomena of lower hydrogen pressure and temperature required for hydrogenation in a CD column is particularly noteworthy. Experimental and modeling studies are being carried out by our research group to understand this distinctive feature of CD hydrogenation. This is likely related to the enhanced mass transfer of hydrogen to the catalyst in a CD process.

In 2001, a CD process for the production of 2,2,4-trimethylpentane with 100 octane rating from the dimerization of isobutene and hydrogenation of the octenes using a Pd/cation-exchange resin was disclosed, but no data were given in the patent.[52]

Hydrogenation in a CD column has been now applied to the hydrocracking and hydrotreating processes for vacuum gas oil to produce diesel and lighter distillates using different conventional hydrogenation catalysts such as Ni/Mo on alumina and Pd/alumina/zeolite.[53] Another related patent disclosed that hydrocracking together with posttreatment of the hydrocracked fraction via RD resulted in the reduction of hydrogen consumption and reduction of the overall reactor and catalyst volumes for a given level of performance.[54] It appears that the application of CD to the treatment of petroleum fractions will gain more attention in the near future.

An improvement on the catalytic hydrogenation of acetylenes and dienes in the C2–C5 fraction in a thermally cracked feed stream without significantly hydrogenating the C2 and C3 olefins was achieved using a combination of CD and fixed-bed catalytic steps.[55]

Desulfurization

With the new legislation on the reduction of S content in gasoline and diesel worldwide, production of low-S gasoline and diesel fuel is of great importance. Catalytic distillation was found to be particularly effective for the desulfurization of naphtha and gasoline produced from FCC.[4,56] In 2000, a new commercial CDTECH process for the desulfurization of FCC gasoline (CD HDS®) came onstream at Motiva in Texas, U.S.A. CD HDS takes advantage of the fact that the light olefins are fractionated to the top of the column while the benzothiophenes and substituted thiophenes are fractioned to the bottom of the column. Therefore, CD HDS minimizes the hydrogenation of light olefins and preserves the octane number of gasoline. The catalysts used are conventional hydrodesulfurization (HDS) catalysts such as Co/Mo and Ni/Mo on alumina supports, which are put inside catalyst structures composed of flexible, semirigid open-mesh tubular material such as stainless steel wire mesh.[57] A CD process, CD Hydro/CD HDS, utilizing two-distillation columns for the desulfurization of a naphtha stream with a minimum loss of olefins and octane number was disclosed.[58] The naphtha is fed to the first column containing hydrogenation catalysts such as Ni sulfide and Pd oxide to catalyze the reaction of mercaptans with some diolefins to form olefinic thioethers, which are then sent to the second distillation column together with the heavy sulfur compounds where desulfurization occurs (Fig. 4). This CD process produces gasoline with a minimal mercaptan content and eliminates the caustic treatment process used to remove mercaptans. It was reported that a combination of CD Hydro and CD HDS could reduce the FCC gasoline sulfur by 90% while the octane loss is very minimal.

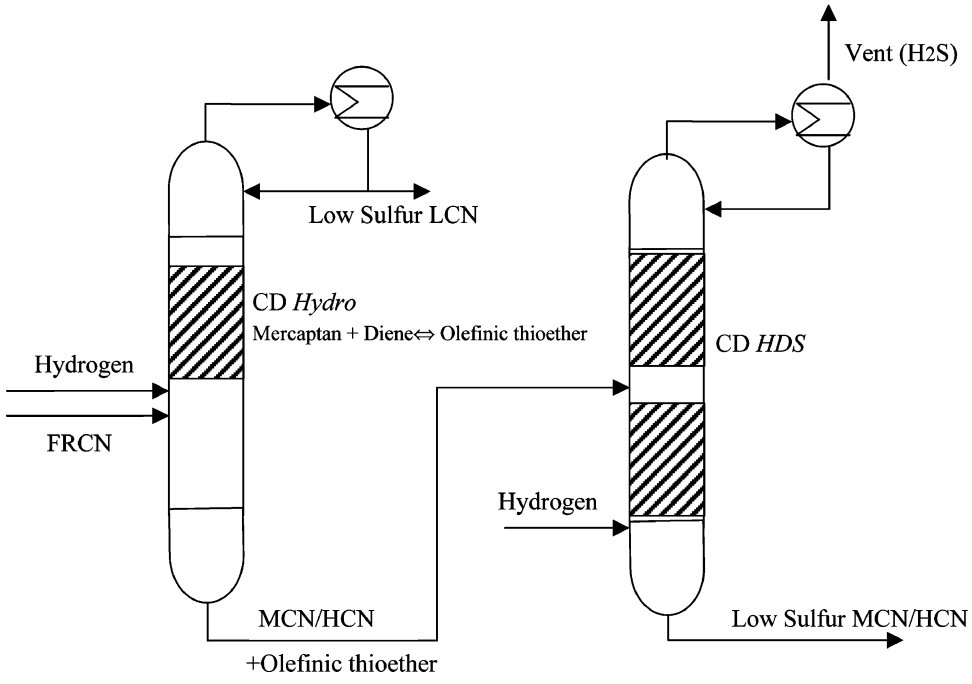

Fig. 4 A schematic of a CD Hydro/CD HDS process for production of low-sulfur gasoline. FRCN, full-range catalytic naphtha; LCN, light catalytic naphtha; MCN, medium catalytic naphtha; HCN, heavy catalytic naphtha.

This combined process could produce low-sulfur gasoline at half the current cost of desulfurization and won the Brian Davis Refining Technology award in 1999. The start-up of the first CD Hydro/CD HDS unit was at Irving Oil's St John, New Brunswick Refinery, Canada, in 1999 and produced less than 150 ppm S.[59] In 2000, Irving Oil received a U.S. Environmental Award. In 2004, the CD Hydro/CD HDS process was used to process about 1.0 million barrels per day of gasoline for mercaptans and sulfur removal in refineries all over the world.

Recently, a review of the production of ultra-low-sulfur gasoline, a patent application for the desulfurization of full-range naphtha by thioetherification and HDS, and the sulfidation of HDS catalysts utilizing CD also have appeared.[60–62] A recent paper on the comparison between the HDS in a conventional trickle-bed reactor and CD for light gas oil HDS concluded that the CD process for HDS is more efficient because the distillation process reduces the inhibitory effects of the H_2S and allows the HDS of the more refractory sulfur compounds to produce a low-sulfur diesel fuel and enhanced catalyst lifetime.[63] Application of CD for the HDS of diesel fuel is more challenging owing to the high boiling point of the diesel fraction although a design for the ultra-low-sulfur diesel production was published.[64]

A stripped RD column could be applied in the hydrocracking and hydrotreating of petroleum to avoid excessive hydrocracking or hydrotreating of lighter products.[43] If the desired products are of higher molecular weight, a rectified RD column can be used.

Esterification

There are many examples of the application of CD or RD for esterification.[4,11] Esterification of methanol or ethanol with acetic acid forms methyl acetate or ethyl acetate, respectively. Methyl acetate is important in the manufacture of polyesters and is an important solvent for cellulose while ethyl acetate is used in inks, fragrances, and pharmaceuticals. The manufacture of high-purity methyl acetate is difficult because of the equilibrium limitation and also the formation of azeotropes. The production of methyl acetate by Eastman Chemical Co. was the first commercial application of RD using a homogeneous liquid acid catalyst. Only one RD column and two smaller columns for processing sidestreams are required while in the conventional methyl acetate synthesis, two reactors and eight distillation columns are required.

Catalytic distillation was also used to produce methyl acetate. A macroporous acidic ion-exchange resin fixed in an open cross-flow structure packing was used in the CD column where the acetic acid was fed above the catalyst zone and the methanol was fed below the catalyst zone.[65] Because the acidic ion-exchange resin provides at least 20 times more protons per unit volume of reacting liquid than a homogeneous catalyst, the residence time to achieve a given level of conversion can be reduced. The process operates at atmospheric pressure with virtually complete conversion of methanol and acetic acid in equimolar proportions and only 10 theoretical plates are required. The CD process also eliminates the need for downstream treatment of liquid acid. A pilot scale production of butyl acetate in a CD process using a Katapak in combination with a CY packing from Sulzer Chemtech containing an acidic ion-exchange resin was reported.[66]

In the past few years, a large number of CD processes on esterification using Katapak packing such as Katapak-S or Multipak packing together with solid acid catalyst such as Amberlyst 15 have been reviewed in detail and hence these processes will not be reviewed here.[11] All these processes operate at mild temperature and pressure with conversions and selectivities in excess of 95% and in some cases close to 100%.

Dimerization and Oligomerization

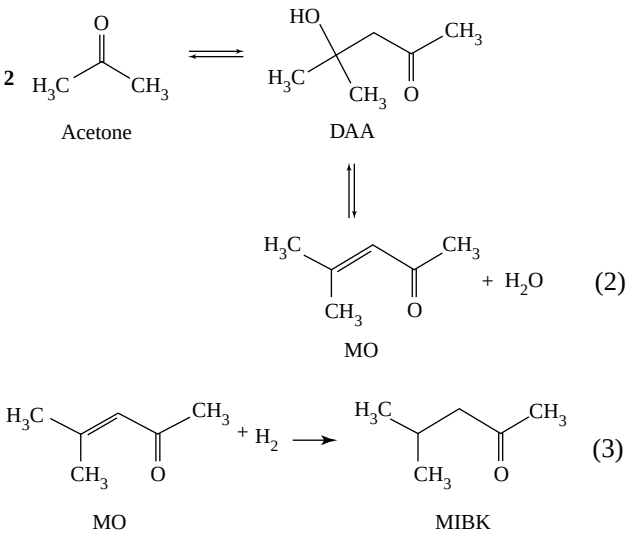
The oligomerization of olefins is an exothermic consecutive reaction, which benefits from the application of CD for enhanced selectivity to intermediate products. Catalytic distillation plays a particularly important role in enhancing the catalyst lifetime because in situ separation reduces the undesirable high-molecular-weight oligomers or polymers, which will form coke and deactivate the catalyst. The use of reaction heat for distillation also reduces the formation of hot spots and catalyst deactivation due to sintering.

Because of the phase out of MTBE, octenes will take on a more important role in the gasoline pool. The selective dimerization of C4 in a raffinate stream to octenes from the steam cracking of naphtha could be used to produce octane enhancers. In addition, there is an existing source of isobutylene due to the phase out of MTBE, which could be selectively dimerized to 2,4,4-trimethylpentene-1 and 2,4,4-trimethylpentene-2, which on hydrogenation will produce 2,2,4-trimethylpentane with an octane number of 100. Smith et al. have patented a CD process for dimerization using an acidic cation-exchange resin.[67] A patent application on the dimerization of light olefins using a combination of RD and conventional reactors was filed.[68] We have studied the oligomerization of butenes in a CD column. We found that when a Ni-zeolite was encased in a fiberglass bag as a CD packing, owing to the mass transfer resistance of the fiberglass bags, rapid catalyst deactivation due to the formation of

higher oligomers on the catalyst was observed. A novel CD packing containing Ni was found to be very effective for the selective dimerization of butenes to octenes.[69] Such CD packing containing Group VIII metals such as Pd was also very active for the hydrogenation of the C8 alkenes. We found that a combination of dimerization and hydrogenation CD packing provides a high conversion of isobutylene with high selectivity to 2,2,4 trimethylpentane and long catalyst lifetime time (Fig. 5). It was also reported that the dimerization of isobutene was more selective in the presence of *tert*-butyl alcohol.[70] A patent application on the production of oligomer from isobutane with CD that combines dehydrogenation and oligomerization was reported.[71] A process for the dimerization of isobutene and the hydrogenation in the presence of S compounds was patented.[72] Recently, the use of CD to produce a lubebase stock from lower-molecular-weight feedstock and acidic catalyst such as zeolites was disclosed.[73] A CD process for improving yields of higher-molecular-weight olefins from lower-molecular-weight olefins using isomerization and disproportionation was also patented.[74]

Aldol Condensation and the Production of Methyl Isobutyl Ketone

Aldol condensation of acetone produces diacetone alcohol (DAA), an environmentally friendlier solvent due to its low volatility and high boiling point, 165.6°C. Aldol condensation of acetone to produce DAA is strongly limited by equilibrium. At the boiling point of acetone, the equilibrium conversion of acetone is only 4.3%. Diacetone alcohol also undergoes dehydration to mesityl oxide (MO).



Experimental studies in our laboratory on the aldol condensation were carried out in a 1 in. CD column using Ambelite IRA-900 anion-exchange resin housed in fiberglass bags. The reboiler duty, which affected the flow rates, was found to play an important role in the selectivity to DAA.[75,76] A rate-based three-phase CD model was developed, which accurately predicts the yield and selectivity obtained under steady-state and transient conditions.[77–79] Model predictions and experimental data indicate that the production of DAA is external mass transfer controlled while the production of MO is kinetically controlled. The external mass transfer resistance was caused by the fiberglass bags. Recently,

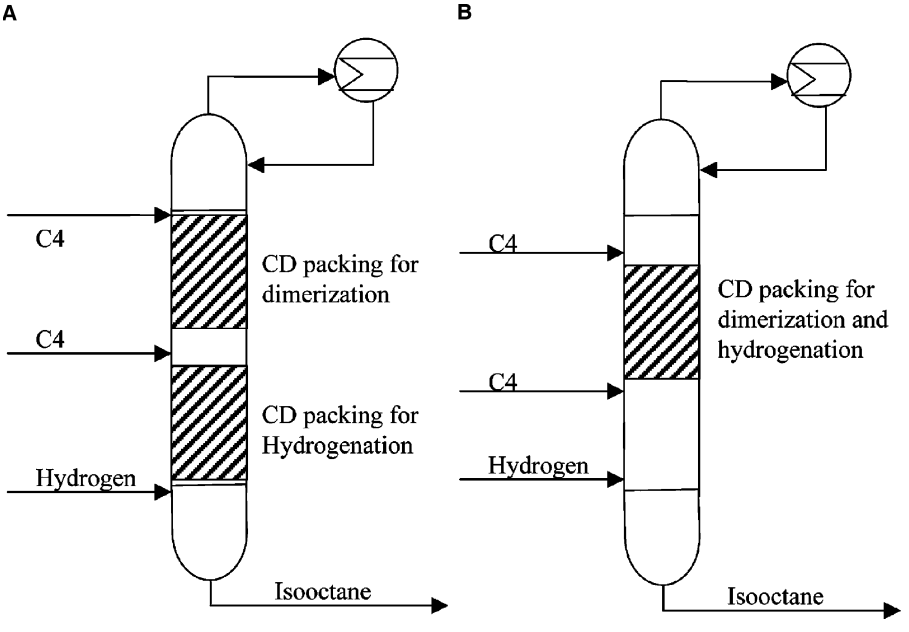


Fig. 5 A schematic of a CD process for the production of isooctane. (A) Dimerization and hydrogenation in two separate zone. (B) Dimerization and hydrogenation in the same zone.

we prepared beryl saddles coated with MgO and used it as CD packing without any fiberglass bags; a higher selectivity to DAA was obtained.

A one step synthesis of methyl isobutyl ketone (MIBK) via the aldol condensation of acetone and the in situ hydrogenation of MO was patented.[80,81] However, it is clear that a CD process for a one-step synthesis of MIBK from acetone and hydrogen is very complicated because MO can undergo a large number of reactions such as the production of higher-molecular-weight phorones besides being hydrogenated to MIBK. In addition, the presence of azeotropes and phase separations due to the production of water from the dehydration of DAA makes the one-step synthesis of MIBK from the aldol condensation of acetone very challenging.

OTHER CD APPLICATIONS

Besides the above CD processes, some of the recent novel applications of CD are outlined below. The production of amines from the hydrogenation of aniline and the selective production of diethanolamine from the reaction of monoethanolamine and ethylene oxide have been reviewed.[4] A patent on the production of phenol from cumene hydroperoxide disclosed that solid acid catalysts such as zeolites, ion-exchange resins achieved 100% conversion with about 60% selectivity to phenol at 50–90°C and 0–10 psig.[82] This process utilizes the heat of the decomposition of cumene hydroperoxide to effect the separation of the lower boiling components and hence reduces the energy cost and carbon dioxide emissions.

An interesting application of CD for the production of methanol from syngas (a mixture of CO and H_2) was patented in 1999.[83] Recently, another process on the methanol production from syngas using a CD column and multiple distillation stages, at least three, was disclosed.[84] This process utilizes CD to increase the conversion of synthesis gas to methanol beyond the equilibrium limitation using catalysts such as Cu–Zn, or Raney™ in the form of sponge.

A patent on the application of CD to produce alpha-olefins via the isomerization of internal olefins was granted.[85]

A new CD process for the production of vinyl acetate from acetic acid, ethylene, and oxygen using a Pd-type catalyst at 338–420 K, 2–5 bar was disclosed.[86] This illustrates the wide-ranging possibilities for the application of CD in a variety of processes for the chemical, petrochemical, and petroleum industry. The production of acetic acid from the carbonylation of dimethyl ether or methanol using RD and homogeneous catalyst was also patented.[87]

Applications of CD for Separations

Catalytic distillation can also be used for selective separations such as the separation of piperidine from *n*-amylamine, separation of isobutylene in a C4 stream, and removal of acetic acid from dilute aqueous streams.[4] The application of CD for separations will not be reviewed in this article. The potential use of RD for the separation of chiral compounds is very noteworthy although no corresponding CD process was reported.[88]

CONCLUSIONS

Catalytic distillation is a rapidly developing field with applications in many processes for the chemical, petrochemical, and petroleum industry. It is emerging as a tool for green process and technology innovations because it utilizes process intensification to achieve energy efficiency and the reduction of greenhouse gases.

With the advances in the fundamental understanding of the reaction engineering aspects of CD based on both experimental research and mathematical modeling, CD is becoming a valuable tool for the development of new green chemical and petrochemical processes. Some challenges for CD include the development of robust catalysts or CD packings that will have the mechanical strength to withstand high liquid/vapor flow rates in a distillation column and modeling the multiphase flow characteristics in a CD column using computational fluid dynamics. Another important aspect is to understand the behavior of noncondensable gases such as hydrogen in the CD hydrogenations. We are currently carrying out both experimental and mathematical modeling of a new CD process for the production of isooctane from isobutene.

Recycling of Spent Tires

Roger N. Beers
David A. Benko
The Goodyear Tire & Rubber Company, Akron, Ohio, U.S.A.

INTRODUCTION

Automobiles are an important part of our modern life providing mobility, status, enjoyment, and numerous other things. The tires from these cars and other vehicles are mostly discarded after their first useful life is consumed, even though a substantial amount of the original tire remains. Because tires are vulcanized under heat and pressure to form an extremely durable thermoset composite of high-molecular weight polymers, organic and inorganic fillers, steel, fabric, and rubber chemicals, it is very difficult to reverse the process and recover the original materials in the same form as when they started. Simply discarding the scrap tires is a waste of resources and causes environmental problems if landfilled or kept in tire stockpiles. Through the 1990s U.S. motor vehicle registrations have risen, greatly increasing the number of tires in use. Advancements in tire durability and treadwear have increased the tire mileage expectations, but large numbers of tires are still being removed from service. A great amount of effort is being exerted by the tire and rubber companies, government bodies, waste management companies, recyclers, and other interested parties to address this scrap tire challenge. New and innovative uses for scrap tires are being developed, and traditional uses are being expanded by improved quality products, improved processing, and changing government and consumer attitudes toward recycled products. This entry shows the major uses for scrap tires now and the amount of scrap tires disposed of by those processes. Reviews of rubber recycling, technical aspects of reprocessing vulcanized rubber, and recovery and reuse of rubber have been published previously and provide more information on this topic.[1–6]

COMPOSITION

The number of scrap tires generated annually is about 281 million.[7] Passenger tires account for 84% of the tires scrapped in a year, while light and heavy trucks contribute 15%, and the remaining 1% is generated from aircraft, heavy equipment, and off-road tires.

The approximate weight of scrap tires is 5.86 million tons.[7] The average scrap passenger tire weighs 20 lb, light truck tires weigh 30 lb, heavy truck tires weigh 100 lb, with the largest weighing up to 10,000 lb. For a typical spent passenger tire, 12–13 lb of rubber can be recovered. This rubber is composed of about 35% natural rubber and 65% synthetic polymers, while in truck tires the percentages are reversed with about 35% synthetic polymers and 65% natural rubber.[8] Rubber polymers found in tires are polyisoprene (mostly natural and some synthetic), polybutadiene, styrene–butadiene (solution and emulsion), and butyl. The other major components of scrap tires are carbon black, inorganic fillers, polyester or nylon fabric for ply, wire for belts and beads, and a variety of rubber chemicals comprising sulfur, accelerators, antidegradents, oils, and waxes. See Fig. 1 for the amounts of these materials.[9] A tire is a highly engineered and a complex composite that is difficult to physically degrade and nearly impossible to devulcanize to reclaim the original starting materials. Major emphasis has been put on using the cured rubber in some form (whole tires, cut tires, crumb) or to burn the tires to recover the energy value of all the components.

ENVIRONMENTAL CONCERNS

Scrap tires account for about 1.8% of the solid waste generated annually in the United States.[7] Besides, the tires taken out of service each year, approximately 300 million tires, are stockpiled around the country as of 2001.[7] These stockpiles are breeding grounds for mosquitoes, fire hazards, unsightly, and are liabilities. Fortunately, since the early 1990s this number has been reduced from the 1 billion tires reported stockpiled. This decline in stockpile estimates was based on three factors. Aggressive programs in some states to clean up stockpiles, improvements in estimating stockpile size, and the loss of tires in tire fires. This large number of tires provides a huge challenge for tire companies, environmentalists, government agencies, and businesses to utilize efficiently.

HISTORY

Rubber reclaiming or recycling is nearly as old as the rubber industry itself. In the early 1900s rubber was

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007939

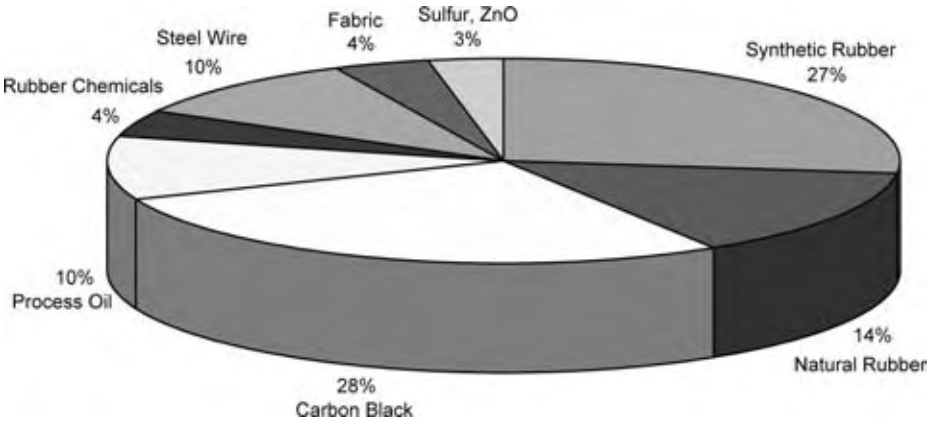

Fig. 1 Composition of average radial passenger tire by weight. *(View this art in color at www.dekker.com.)*

scarce and very expensive, so it was reused as much as was practical. The tire splitting industry dates back to about 1915.[3] Tires were split and made into shims, gaskets, mats, dock fenders, and other useful items. Before World War II all the rubber used was natural rubber, which was reclaimed with heat and chemicals and reused at levels up to 20% in new rubber compounds. Retreading of passenger tires was used extensively through the 1930s and 1940s. In the 1960s, recycling dropped to about 20%.[3] Cheap oil imports, larger uses of synthetic rubber, and the advent of steel-belted radials along with changing consumer attitudes led to a steady decline in tire recycling. In the 1970s interest in recycling spent tires increased as tire companies and others realized that discarding these high-energy containing materials was economically and environmentally unsound. Whole scrap tires were used as floating breakwaters, tire reefs, and highway crash barriers to take advantage of their energy absorbing properties and resistance to environmental degradation. Emphasis was placed on manufacturing increased quantities of shredded and ground rubber of different sizes and composition for use in engineering applications, such as road bases, erosion control, and asphalt modifiers. Finely ground crumb rubber was also used in tires and automotive applications. This was also the time when efforts began to use the high energy content of tires to generate steam and electricity. Pyrolysis of scrap tires was conducted under different processing conditions to degrade the tires to recover a mixture of gas, oil, and carbon black for sale and reuse. Although much work and investigation of the pyrolysis process was performed, it was not economically viable. Some of these recycling processes are still being used and have been enhanced by new technology, while others have declined significantly or are no longer used. The major uses for scrap tires today will be described in the remainder of this entry.

UTILIZATION OF RESOURCES

There are many new and innovative ways to utilize the resources offered by scrap tires. The reuse/recovery rate for scrap tires is about 78% with another 8% being retreaded.[7] There are five methods available to solve the problems associated with scrap tires:

Reduce: The most desirable option is to reduce the number of tires that enter the waste stream. Manufacturers have reduced the number of scrap tires by selling more durable extended mileage tires, with average tread life of 40,000–50,000 mi. Compared to the average mileage expectations of 25,000–27,000 in the 1970s, the industry has prevented millions of tires annually from becoming scrap tires.

Reuse: Reusing the tire is the next best alternative. Tire casings can be retreaded or made into various miscellaneous products. Aircraft tires can be retreaded up to 12 times and the average truck tire can be retreaded two or three times. About 16.2 million tires were retreaded in 2001 if passenger, light, medium, and heavy trucks are included. Casings can be used for products, such as muffler hangers, snow blower blades, plant holders, and other miscellaneous engineering applications. A large amount of casings are shredded, the wire and the fabric removed, and the rubber ground into various size crumbs. Larger-size tire shreds and tire chips are used in civil engineering uses. The smaller size crumb rubber is used in rubber and plastic articles and in asphalt.

Recycle: Today there is a great emphasis on devulcanization methods to recycle the rubber in tires and other rubber products. Some of these new devulcanization methods use supercritical fluid technology, ultrasonic techniques, microwave energy, and biological modification.[10–28] These methods are explained in detail in the entry, which deals primarily with devulcanization.

Recover: Much emphasis is being directed toward recovering the energy from the materials remaining

in the spent tires. The use of old tires to provide electricity and energy for cement kilns and papermaking are economically and environmentally sound solutions.

Landfill: Whole tires create problems in landfills, but shredded tires do not. They take up less space, do not readily burn, and do not provide habitat for mosquitoes. Landfilling of tires is a poor alternative to the options presented above and is simply disposal with no intent to get any value from the tires.

The major uses of scrap tires are divided into categories as shown in Table 1. About 218 million tires were reused in 2001, with the majority going to energy recovery. The next two largest usage categories were for civil engineering applications and ground rubber applications. All these uses will be described in detail.

GROUND OR CRUMB RUBBER

Tires are shredded and reduced in size for most reuse and recycle applications. The larger sizes are called tire shreds and tire chips. Tire shreds are basically flat irregularly shaped tire chunks ranging in size from 18 to 1 in. with the majority being between 4 and 8 in.[29]. These are used mainly for construction and civil engineering applications. Tire chips are more finely and uniformly sized, ranging from 3 to 0.5 in. in size. Tire chips are used extensively in civil engineering and tire-derived fuel (TDF). Ground rubber and crumb rubber are used interchangeably, but actually ground rubber particles are intermediate in size between tire chips and crumb rubber, ranging from 3/8 in. to 20 mesh. Crumb rubber particles range from 4 to about 200 mesh, with 20 to 80 mesh particles used the most.[30] Ground and crumb rubber are free of fabric, wire, and other contaminants. The smaller the particle size, the more expensive the rubber. In 2001, the average price of 10 mesh crumb rubber was about 13 cents/lb, and 80 mesh crumb rubber averaged about 31 cents/lb.[31]

There are three main methods for producing crumb rubber: dry ambient grinding, wet grinding, and cryogenic grinding.[4] Dry ambient grinding uses serrated grinders to grind various types of scrap and spent rubber articles. Normally, any wire or steel has been separated previously. The size of the rubber particles from this process usually ranges between 10 and 30 mesh. Even though this process is considered an ambient process, the rubber particles are exposed to considerable heat that is generated in the grinding process. Ambient grinding produces irregular-shaped particles with small appendages caused by the softening and tearing during grinding. Wet or solution grinding uses water and starts with 10–20 mesh rubber. These particles are ground between two wheels with the water enhancing the lubricity and cooling. Particles as fine as 200 mesh are obtained and size is related to the grinding time. This process gives fairly smooth particles. Scrap rubber can also be reduced in size by cryogenic grinding. Small pieces of rubber are placed in liquid nitrogen and ground into fine powder generally ranging from 30 to 100 mesh. Surface morphology is different from ambient grinding because the particles are fractured and surface oxidation is believed to be less.[32] Table 2 shows the amount of ground rubber used in North America in 2001.[33] This amount includes the market for the United States and Canada. The ground-rubber market consists of ground scrap

tires and tire buffings. Table 3 shows the amounts of crumb rubber used in the United States only for 1995 and 2000 and shows the growth taking place in this market.[1] Although estimates vary slightly, at least 33 million scrap tires were used in this market in 2001 and the rest was obtained from tire buffings. No attempt is made to differentiate between tire buffings and scrap tires in identifying markets.

Rubber Modified Asphalt

Ground tire rubber is used as an additive in various types of asphalt pavement constructions. There are two main processes in use: the dry and the wet process, and modifications of both exist. In the dry process, ground rubber ranging in size from 0.25 in. to 20 mesh can be used as an aggregate substitute at a loading of 3–4 wt%.[34] The wet process uses 30–100 mesh crumb rubber, which is added to modify the physical and the chemical properties of the binder. Levels of crumb rubber in the wet process can vary, but as the level rises above 5–10%, the cost increases significantly compared to conventional pavement.[35] A recent article shows that 80 mesh crumb rubber is very good for use in both wet and dry processes.[36] The small particle size reacts faster with the asphalt to form a homogenous mix and is compatible in all types of asphalt equipment.

A study conducted in Canada used three types of crumb rubber at 10% by weight with two commonly used asphalt binders.[37] The rubber-modified asphalts (RMAs) prepared were evaluated for resistance to forming ruts and low-temperature cracking. Compared to conventional asphalt, the crumb rubber modifications significantly improved the high-temperature performance and moderately improved the low-temperature cracking. Both low- and high-temperature responses revealed improvement as the particle size of the rubber was reduced from 30 to 80 mesh and lower. The wet process modified binder is commonly referred to as asphalt rubber and is also used in seal coats, stress absorbing membranes, waterproofing membranes, and hot mix binders. The level of use of ground rubber varies according to the method, but in 2001 about 290 million pounds was used for asphalt construction.[33] The rubber improves asphalt ductility and increases the temperature at which asphalt softens, thus improving durability and fatigue resistance. The rubber also improves the skid resistance of the asphalt pavement.

A review paper by Van Kirk indicated that there is sufficient field experience to show the advantages of crumb rubber in RMA.[38] The main advantages are that pavement thickness can be reduced with no loss in service life, pavement cracking is decreased, and maintenance cost is reduced. The use of RMA has demonstrated that it is quieter, smoother, reducing overall cost, and a good method of using scrap tires.

California, Arizona, Texas, and Florida promote the use of ground rubber in asphalt. Several other states are evaluating the use of RMA and may utilize this method. Growth in this area for crumb rubber depends on a number of factors: DOT support, additional performance and cost data, and a readily available supply of crumb rubber.

Molded Products

Molded products are another large market for ground and crumb rubber from scrap tires. The size-reduced rubber can be molded, extruded, or processed in various ways with other thermosets or virgin rubber. Automotive products, tires, and plastic blends are not included in this category and will be discussed as separate categories. Crumb rubber extends and modifies the molded products, in particular lowering cost, improving impact resistance, lowering shrinkage, and improving processing. This market should experience relative growth because of improved product quality, more manufacturer and consumer interest, campaigns to buy recycled materials, and state tire program incentives. In 2001, about 300 million pounds was used in this area.[33] Some typical products are floor tile, mats, water hoses, sound proofing panels, bin liners, and belt covers.

Tires and Automotive Applications

Great effort is being expended to find ways to use increasing amounts of scrap tires in the manufacture of new tires. Automotive companies are strongly encouraging tire producers to increase the recycle content in the new tires they purchase. Ford is currently trying to have the tire recycle content raised to 10% by weight with the ultimate goal being 25% recycle. Many new technologies are being investigated to enable higher use of tire-derived rubber without compromising the stringent physical properties needed in a radial tire. Currently, about 10% is the maximum amount of reprocessed rubber used in certain compounds, and the overall tire content is around 3%.[7] Recycle is used in passenger, farm, and light and heavy truck tires. Tire components that commonly contain reprocessed rubber are the innerliner, treads, sidewall, ply, and barrier compounds. Currently, only about 25% of the total reprocessed rubber used in tires comes from scrap tires. The remainder comes from curing bladders, inner tubes, and tread peels. The curing bladders and inner tubes are used almost exclusively in the tire liners because they are butyl and provide excellent

Table 4 Tread compound properties containing crumb rubber

(From Ref.[39].)

air retention properties. Also, butyl is incompatible with other tire elastomers.

Typical particle sizes used range from 20 to 80 mesh. The 80 mesh particles provide smoother compounds and possibly slightly improved properties. The effect of ground rubber recycle on most rubber compound properties is negative, which prevents higher usage. Ground rubber is used as an extender or filler to reduce costs and help processing. Properties that are impacted negatively are compound viscosity, tensile strength, modulus, elongation, scorch, abrasion resistance, cure, and hysteresis.[39] Typical effects of loading on key compound properties are shown in Table 4. The table shows how compound properties change as the amount of 40 mesh ground scrap tire rubber is added to a typical passenger tire tread.[39] The control contains no crumb rubber and 20, 30, and 40 parts of crumb rubber are added to the other tread formulations. The data are normalized with the control given a value of 100, and the other compounds compared to that value. Processing improvements generally noted are improved mold flow, better air bleed, and reduced shrinkage.

There are several reasons for the reduced properties. The hard ground rubber particles contain accelerator fragments from being cured previously and these fragments migrate into the virgin rubber and cause it to cure faster with less scorch protection.[40] Sulfur from the virgin rubber compound also migrates into the cured particles making them harder and causing the matrix to be cured to a lower amount, reducing properties. Another reason attributed to the reduced strength is poor interfacial bonding between the crumb rubber and the virgin rubber matrix.[41] Various surface treatments, both chemical and physical, additives, new processing methods, and compound modifications are being developed to improve the physical properties.[42–45] Table 5 shows the results of treated and untreated crumb when added at 20% to a natural rubber compound. In this case, the crumb is also natural rubber and the treated portion was surface activated with a two-step process developed by Vredestein rubber recycling.[44] The treated crumb compound was significantly better than the untreated crumb compound.

Automotive uses besides tires include belts, hoses, friction materials, mud flaps, air deflectors, brake pedal covers, caulks, and coatings. Like tires, the industry would like to see more recycled content in these applications. A total of about 112 million pounds of ground rubber is consumed in these applications.[33]

Sports Surfacing

This market segment has undergone a huge growth rate in the past several years. Examples are the use of

Table 5 Comparison of treated and untreated crumb rubber in NR compound

(From Ref.[44].)

rubber in running track material, in grass surfaced playing areas, in stadium playing surfaces, and as turf topdressing. The main reasons for using ground or crumb rubber for these type surfaces is to reduce injuries, improve drainage, reduce damage to fields, and improve turf viability. Crumb rubber also retards weed growth, does not attract insects or rodents, and has a higher cushioning effect than other fill materials. The Detroit Lions football team's practice field contains a rubber soil material that has allowed practice in all weather conditions and has reduced player injuries. Another use is in horse arenas, where it gives the animals better footing and reduces injuries to the horse and to the rider. One company produces a granular product $3/8 \times 1/8$ in. in size for the playground market.[46] The material is put down in a layer 6 in. thick and provides greater shock absorbing characteristics than other playground surfaces, such as sand or mulch. Approximately 140 million pounds of ground rubber was used for some type of sport surfacing in 2001.[33] The increased use was mostly because of the improved quality of the surfacing, better application techniques, and the safety benefits. These type materials are finding use in golf courses and public parks.

Plastic Blends

Thermoplastic materials are manufactured using many processes, such as injection molding, extrusion, hot stamping, and others, that use heat and pressure to form a particular product or shape. In most cases, the thermoplastic is pelletized and crumb rubber can be readily blended in the composition during processing. The crumb rubber is used to improve impact resistance, improve processing, extend the material, or provide some performance improvement to the finished product. In many cases, the crumb rubber surfaces are treated with silanes, chemicals, such as ethylene–glycidyl methacrylate, compatibilizing agents, high-energy radiation like plasma etching, or other novel techniques to increase the adhesion with the thermoplastic matrix and improve compatibility.[47–50] Plastic blends with rubber are used for a great number of products, such as body panels for golf carts and lawn tractors, sports equipment, toys, cable and wire insulation, and truck bed liners. Crumb rubber is even used to make thermoplastic elastomers (TPE) by alloying 120 mesh rubber with an olefinic matrix.[51,52] Before alloying, the rubber powder undergoes a proprietary surface devulcanization process and compatibilization technique to enhance the blending of the rubber with a polyethylene/polypropylene mix to form the TPE. These applications accounted for about 38 million pounds in 2001 and there appears to be significant market potential for this application because of increased research and development on surface treated rubber.[33]

Construction

Ground rubber finds many uses in the construction industry because of its excellent weathering, chemical resistance, and nonbiodegradable properties. Some uses are paving or tiles for driveways, shingles and roofing materials, thermal and acoustic insulation panels, plastic lumber, flooring materials, and other building materials. There has been substantial growth in the manufacture of floor tiles and sidewalk pads, where crumb rubber is used with urethane binders for cost and injury reduction. About 28 million pounds of ground rubber was used for these applications in 2001.

Surface Modification/Reclaim

This category involves processing used rubber products into a form that can be incorporated into virgin rubber compounds. Ground rubber is the starting material for the chemical process that severs the cross-links and polymer chains by chemical or steam digestion to make reclaim. Other reprocessed rubber uses crumb rubber and modifies the surface by chemical or physical means to enhance the adhesion and compatibility to improve properties when mixed with virgin rubber compounds. About 36 million pounds of ground rubber is used for these applications.[33] The major benefit of using reclaim is lower cost and the improvements in processing it can add to the compounds. Compounds containing reclaim have lower nerve, which translates into better extrusion, increased calendar speed, and improved flow and mold filling. Properties like green strength and tensile are lowered when reclaim is used. Today some whole tire reclaim is used in low performance requirements like mats and extruded rubber products. The major rubber reclaimed is butyl that comes from truck inner tubes.

Crumb rubber can be ground into small particles from 30 to 200 mesh and used in virgin rubber compounds primarily as a filler. Smaller particle sizes give optimum surface smoothness and slightly higher physicals. Mesh sizes from 30 to 80 can lower compound cost, improve mold flow, help air bleed, and reduce shrinkage. However, crumb rubber generally increases compound viscosity and reduces strength and modulus. In low performance requirements, levels from 5% to 10% are commonly used. To increase properties, the crumb rubber is treated to enable the virgin rubber to bond better. New surface treatments are gaining, particularly in the tire market.

Animal Bedding

Ground rubber is used in agriculture for animal bedding. Ground rubber is used because it does not hold moisture, is relatively cheap, is not readily biodegradable, and does not harbor insects and pests. Mats are also made with crumb rubber for use by animals. Over 35 million pounds of ground rubber is used for this application.[33]

These are the main uses for ground and crumb rubber. In addition, another half-million tires or less are used for miscellaneous applications as diverse as can be imagined. The exact numbers of tires used for each application are as up-to-date as possible and as accurate as the data available. Overlaps in category use and some estimates in the number of actual tire units consumed may be slightly different from other published figures. The source of most of the information is the Scrap Tire Management Council that was formed to monitor and promote disposal and reuse of scrap tires.

CIVIL ENGINEERING

Civil engineering includes a wide range of uses for scrap tires. The five main applications include lightweight fill for embankments, subgrade insulation for roads, backfill for walls and bridge abutments, landfill construction and operation, and septic system drain fields. In nearly all the applications, the tire chips or tire shreds typically replace currently used construction materials, such as soil, clean fill, drainage aggregates and lightweight fill materials. The benefits of using the tire chips and shreds are lower density, improved drainage properties, better thermal insulation, and lower cost. Tire stockpiles are good for these applications, as the presence of dirt on the tires is not a problem. The civil engineering area is growing and about 40 million tires were used in 2001.[7]

Lightweight Fill for Embankments

Work has been done in a number of states using tire shreds as a subgrade fill in the construction of highway embankments and other fill projects. Tire shreds weighs considerably less than conventional soil fill and this allows construction on weak compression foundation. The use of tire shreds for most projects is considerably cheaper than alternatives, such as expanded shale aggregate and polystyrene insulation blocks.[29,53] Scrap tire materials have also been used to retain forest roads, protect coastal roads from erosion, enhance the stability of steep slopes along highways, and reinforce shoulder areas. The importance of this application is illustrated by a project in Maine, which used 1.2 million tires as lightweight fill for the construction of two highway embankments on weak clay and saved about $300,000.[7]

Subgrade Insulation for Roads

In northern climates, one of the problems affecting roads is the water released when the subgrade soils thaw in the spring. To prevent this, tire shreds are used as subgrade insulation. The insulation provided by a 6–12 in. layer of tire shreds keeps the subgrade soils thawed during the winter. Tire shreds also allow excess water to drain from beneath the road.[54]

Backfill for Walls and Bridge Abutments

Several projects have been constructed using tire shreds as backfill for walls and bridge abutments. The weight of the tire shreds produces low horizontal pressure on the wall allowing thinner walls at lower cost. Another advantage is that tire shreds provide better drainage and good thermal insulation, which eliminates problems with water or frost buildup behind the wall.[55]

Landfill Construction and Operation

Many landfill operators have found that scrap tires can be used beneficially in the construction and operation of the landfill. Tire shreds are used in building leachate collection basins in new landfills and they can also be used as the drainage layer in landfill caps. Another application is mixing tire shreds with soil as daily cover material.

Septic System Drain Fields

Tire shreds and chips are used as a replacement for stone in septic system leach fields. The lower density of the tire shreds greatly reduces the expense and the labor to construct leach fields, while providing equal performance to stone and gravel. The number of states allowing scrap tires in septic systems is increasing. As in all the civil engineering applications, there is concern about the environmental impact of using scrap tires. One of the major issues is groundwater contaminants and the effect of tire shreds on water quality. Studies have shown that tire shreds placed above or below the water table pose no significant health or environmental risk.[7,56] Neutral pH groundwater does not increase the concentration of metals and no detectable organic leachates are found from the tire shreds. Under some conditions, the steel belts contained in the tire

shreds may increase the levels of iron and manganese, but these are not harmful. These concerns affect the laws related to scrap tire use, and along with other issues like cost and availability, determine the use and growth. Each potential civil engineering use brings with it a particular set of technical, environmental, and economic constraints that must be fully evaluated before the application is readily acceptable. The potential use of scrap tires in civil engineering is very substantial and this will continue to grow.

ENERGY MARKET

Tires have a tremendous market potential as fuel. Energy recovery was the largest market in 2001, representing about 115 million scrap tires annually.[7] On average, 97% of a tire's content contributes directly to energy value. The average radial passenger tire derives its energy content from the following ingredients:

- *Synthetic rubber* is produced from crude oil, a high-energy fuel much cleaner than coal.
- *Natural rubber* is a renewable energy source that is harvested from trees.
- *Carbon black* also comes from crude oil and has a high energy value.
- *Rubber chemicals*, *oils, and organic fibers* are all derived from crude oil and contribute to the energy value.
- *Steel belts and beads* oxidize at high temperatures to produce 3500 Btu/lb.

Energy from scrap tires is being recovered in the United States and many other countries worldwide with beneficial results. Burning one passenger tire produces approximately 300,000 Btu, which is roughly equivalent to 2 gal of fuel oil or 23 lb of coal. Whole scrap tires average 15,000 Btu/lb and most coal averages 12,000–12,500 Btu/lb (Table 6).[57] Tires contain less nitrogen than coal, and there is less sulfur in tires than most types of coal. Tires burned under proper conditions reduce solid waste and air emissions, and produce little or no smoke or fumes.

Table 6 Comparative energy values

Fuel	Btu/lb
Petroleum coke	13,700
Bituminous coal	12,750
Subbituminous coal	10,500
Lignite coal	7,300
TDF	14,000–15,500

(From Ref.[57].)

Cement, electricity, and paper producers burn scrap tires as a supplemental fuel, because tires have more energy value per pound than most coal and burn more evenly. Scrap tire combustion decreases the emission of particulates, oxides of nitrogen, and carbon dioxide compared to coal. Whole tires can be burned in some cases or TDF is created by shredding scrap tires and processing them into tire chips. Typically, these tire chips range in size between 2 and 4 in., but many facilities are shifting to smaller fuel chips 2 in. by 2 in. or slightly smaller. These smaller chips contain less steel and can reduce handling problems and lower ash disposal. Boiler design and the production process determine the allowable wire content level. Tire-derived fuel is easy to handle, store, and feed into combustion devices. It is also easily blended with conventional fuels. Using scrap tires as fuel totally eliminates the scrap tire, while it decreases the dependence on foreign oil supplies and conserves precious natural resources.

The total use of scrap tires for energy recovery has declined over the past several years from 1996 when approximately 135 million scrap tires were consumed.[7] The use for energy recovery seems to have stabilized with the potential for slow growth over the next several years. It must be remembered that the energy market is very complex and many other factors affect the use of scrap tires for energy recovery. Factors that impact this area are air pollution laws, states subsidies for use of scrap tires, energy deregulation, economic conditions, product quality, and costs. All of these issues plus others can affect the economics and help or hinder the use of scrap tires in these energy applications.

Cement Industry

There are 36 cement kiln locations that processed tires for fuel in 2001 with the majority burning whole tires and the rest tire chips.[7] The original reason cement kilns began using scrap tires was to reduce fuel costs. A big advantage of using scrap tires in cement kilns is that there is no solid waste disposal. The tires are completely consumed and become a part of the final product. Other advantages are less carbon dioxide, nitrogen oxides, and sulfur dioxide. The wire of the tire provides iron oxide, which is one of the raw materials required. Also, limestone, which is a raw material for the cement, neutralizes sulfur from the tires. The amount of scrap tires used as a percentage of the total fuel consumed can range from 5% to 25%. The cement industry is the largest user of scrap tires for energy and will continue to consume significant amounts. Two important issues that will affect the amount of scrap tires used are USEPA focus on nitrogen oxides and the demand for cement.

Paper and Pulp Mills

There are 18 facilities that use scrap tires for pulp and paper production.[7] Tire-derived fuel is mixed with wood waste to produce steam. The TDF improves the combustion efficiency and displaces fossil fuels. A significant portion of Oregon's scrap tires goes to this market. The volume of scrap tires used for this application has fallen from its high in 1996 much like cement industry use. It should be noted that the decrease in TDF consumption was never attributed to increased air pollution or environmental degradation.

Utility Boilers

There are 11 plants using scrap tires to produce electricity for sale and they consume the second largest amount after the cement industry.[7] Two factors that have impacted the use of TDF and will continue to impact its use are the electric industry deregulation and the implementation of Clean Air Act amendments. Until all the issues are sorted out, further expansion in this area is unlikely.

Industrial Boilers

Industrial boilers use TDF to generate steam. There are 17 facilities that use scrap tires, although it is usually in a limited degree.[7] In this market segment, the use of TDF is primarily a function of the solid wastes available and represents about 2–5% of the fuel supply. Still, tires are used because the economics and the emissions are favorable. A small increase in the use of TDF should occur in the industrial boiler market.

EXPORT OF TIRES

Tires with adequate tread and/or retreadable tires are regularly exported from the United States. Used tires are regularly sold in these markets in many other parts of the world. Routinely, slightly more than 1 million tires/mo are exported or about 15 million tires/yr by best estimate.[7]

FABRICATED PRODUCTS

The fabricated products market encompasses those products made by cutting, punching, or stamping from scrap tire carcasses. This is one of the oldest methods of reuse and is not changing. This market has a large array of products, all of which take advantage of the toughness and durability of tire carcass materials. Examples of these products are dock bumpers, muffler hangers, mat components, and snowblower blades. These entire applications generally only use bias ply tires, or tires with no steel belts. This market will remain the same and uses about 8 million scrap tires.[7]

MISCELLANEOUS USES

There are a wide variety of uses for scrap tires that do not fit neatly into any of the preceding categories. The total in this catchall category is about 7 million scrap tires. These include agricultural uses where tires are used to construct stock feeders, protect fence posts, weigh down covers, erosion control, and other uses. Usage can also include swings, planters, or other more imaginative and innovative uses.

CONCLUSIONS

Among all the methods available to manage the increasing number of scrap tires, reuse, recycle, and recovery offer the most potential to arrive at a program that consumes all the scrap tires generated each year and steadily decreases the existing tire piles. Reuse includes the civil engineering and ground rubber markets that are steadily increasing the volumes of tires they consume in highway construction projects, asphalt modifications, sports surfaces, and molded products. New technology and innovations are driving the increased use of scrap tires, but there are other factors that impact use of scrap tires. State regulations on landfills, incentive programs to use tires, establishment of an infrastructure to collect, market and distribute scrap tires, and consumer attitudes also affect the number consumed.

Reclaim or recovery of the polymers and the carbon black in the tires has great potential for providing new sources of materials to be used again to manufacture tires or other rubber products. Scientists are working on new ways to devulcanize rubber and success has been reported by using ultrasonic, microwave, supercritical fluids, and mechanical means. True devulcanization would allow much more of the recaptured polymers to be used in tires and/or other demanding applications. Recovery of energy is still the largest market for scrap tires today, even though this important market that has shown some decline in volume since 1996. New boiler technology and processing enhancements to burn scrap tires are emerging and should solve any technical problems related to this application. Again, air pollution laws, energy deregulation, and economic issues are just as important as new technology in expanding the energy recovery market.

All these forces will continue to challenge the industry for ways to consume spent tires. Currently,

about 78% of the tires removed from service each year are being reused and that number should continue to grow as new technology and greater acceptance of recycled products occurs.

Reformulated Gasoline

A. K. Dalai
D. Ferdous
Catalysis and Chemical Reaction Engineering Laboratories, Department of Chemical Engineering, University of Saskatchewan, Saskatoon, Canada

INTRODUCTION

The purpose of introducing reformulated gasoline (RFG) is to improve the air quality to reduce motor vehicle emissions of toxic and tropospheric ozone-forming compounds. The RFG regulations involve the greatest reduction in emissions of ozone-forming volatile organic compounds (VOCs) and toxic air pollutants (TAP) through the reformulation of conventional gasoline. They also take into consideration the cost of achieving such reduction.

BACKGROUND

Prior to 1995, around 85 million people (one-third U.S. population) lived in urban areas. The air quality of these areas violated federal public health standards, largely because of automotive pollutants. Gasoline and diesel-fueled cars, trucks, and buses produced half of all air pollution in the United States. This air pollution includes 66% of airborne carbon monoxide, 31% of smog-forming hydrocarbons, and 43% of lung-damaging nitrogen oxide.

On January 1, 1995, nearly one-third of the motorists in the United States found something different at the gas pump, RFG. This gasoline is designed to reduce the environmental impact of burning the fuel so that air quality meets public health standards of the national Clean Air Act amendments of 1990. The CAA was designed to address the issues related to fuel quality improving gasoline. This required that the RFG to be used in cities with the worst smog pollution should contain oxygen to reduce harmful emissions of ozone. ARCO first introduced RFG in 1989 in Southern California. In the RFG, benzene and aromatic levels were reduced, vapor pressure (or volatility) decreased, and the oxygenates were added to improve combustion and other fuel properties.

Reformulated and oxygenated fuels have been already used at different regions of the United States where the ozone level limit has been exceeded. As indicated earlier, one way to reduce air pollution from cars and trucks is to use an RFG that is designed to burn cleaner, while the CAA requires cities with the worst smog pollution to use RFG, but other cities with smog problems may choose to use RFG. The RFG program is a significant step toward cleaning the air we breathe, and a significant component of the country's smog reduction strategy. The RFG is currently used in 17 states and the District of Columbia in the United States. Nowadays, about 30% of gasoline sold in the United States is reformulated. Each oil company prepares its own formula to meet federal emission reduction standards. The RFG's air quality benefits and other industrial and transportation controls aimed at smog reduction are responsible for the long-term downward trend in U.S. smog. In North America and other countries, increasingly stringent fuel specifications for RFG are mandated.

REFORMULATED GASOLINE AND ITS GOAL

Reformulated gasoline, referred to as ''clean gasoline'' is designed to reduce both exhaust and evaporative emissions from vehicles. This fuel offers a way to reduce a variety of gasoline emissions without developing alternative fuel technologies to replace oil derived fuels and internal combustion engine. The definition of RFG includes the following key factors:[1]

- A 15% reduction in toxic chemicals, including VOCs.
- A maximum of 1% of the carcinogen benzene (a 50% reduction) and a maximum of 25% for aromatic hydrocarbons (compared with 40% previously).
- A minimum content of 2% oxygen, by weight, to promote cleaner combustion, especially to reduce carbon monoxide emission.

The sunlight driven complex reactions involving VOCs and oxides of nitrogen (NO_x) are responsible for atmospheric ozone formation. The purpose of using reformulated fuels is to reduce both ozone-forming VOC emissions and air toxic emissions from vehicles. The key constraints that are introduced by Phase I in 1995 and II in 2000 are reduction in VOCs, NO_x, and toxics. While each of theses variables has complex

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007943

interactions with other gasoline properties, each is affected by a dominating component.[2] Volatile organic compounds, NO_x, and toxics are the functions of Reid vapor pressures (RVP), nitrogen content, and benzene content, respectively.

Beginning in January 1995, Phase I RFG was intended to provide a 15–17% reduction in both ozone-forming VOC emissions and air toxic emissions from vehicles. In the beginning of January 2000, Phase II RFG intended to provide a 25–29% reduction in VOC emissions, 20–22% reduction in air toxics emissions, and 5–7% reduction in nitrogen oxide emissions from vehicles.[3] This phase-wise introduction of RFG indicated that fuel parameters reduced a vehicle's pollutant emission. Phase I of California's RFG program began in 1992 and required reduced gasoline vapor pressure during the summer ozone season, use of detergent additives to control engine deposits, and elimination of lead-based antiknock additives.[4] The current EPA summer vapor pressure maximum for most areas of the United States is 9.0 psi. A lower summer maximum of 7.8 psi has been in effect in ozone nonattainment areas in VOC Control Region 1, such as California, since 1992.[5] However, Phase 2 of the California RFG program that took effect in the first half of 1996 required more extensive changes to gasoline properties.[6]

A number of programs have assessed the effect of the use of RFG on vehicle emissions; the most comprehensive of these is the Auto/Oil Air Quality Improvement Research Program.[4] Their task of assessing the air quality benefits of RFGs was relatively difficult, compared to the other evaluations of control measures that have typically been undertaken for regulatory purposes.[7]

The tailpipe emissions of the major pollutants regulated under the CAA such as carbon monoxide, hydrocarbons, and nitrogen oxide were reduced by 10–20% using RFG in conventional automobiles compared to that with conventional gasoline. The changes in gasoline properties included an increase in oxygen content, decrease in alkenes, aromatics, benzene, and sulfur content, reduction in volatility, and decrease in distillation temperatures.[4] Evaporative VOC emissions can be reduced by limiting the vapor pressure of RFG during the summer months. The limit is lower for the southern part of states because higher ambient air temperatures increase evaporative losses. The RFG vapor pressure limits are lower than the current Environmental Protection Agency (EPA) limits. Lowering RVP increased the refiner's cost of producing gasoline because low-cost normal butane must be removed from the gasoline pool. Phase 2 required approximately a 1.3 psi reduction in RVP (from 8 to 6.7 psi) in northern control areas (Region 2) and a 0.4 psi reduction (from 7.1 to 6.7 psi) in southern areas (Region 1) from Phase 1 RFG levels during the summer months. Reid vapor pressure plays an important role in reducing VOC emissions. However, reduction in RVP alone is not enough to achieve the required Phase 2 VOC reduction. A reduction in VP to 6.7 psi will reduce VOC emissions by about 24% in Region 1 and 22% in Region 2, well below the 29% and 27.4% required in Regions 1 and 2, respectively. Reduction in sulfur from 300 to 140 ppm will yield an additional reduction of 1.9%. Lowering aromatics from 32 to 26 vol% in Phase 1 provided an additional 1.5% VOC reduction that is still not enough to meet Phase 2 VOC reduction. The final necessary emission reductions must come from increasing E200, E300, and olefins, without violating the NO_x emission reduction requirement.[6]

TOTAL OXYGEN CONTENTS AND TYPE OF OXYGENATES

Oxygenates represent a key component of RFG. This fuel is required to contain an average of 2.1% oxygen by weight. The source of this oxygen is oxygenates organic combustible liquids containing an oxygen atom in their structure. While methyl tertiary-butyl ether (MTBE) and ethyl alcohol (ethanol) have been the oxygenates most commonly used in gasoline, ethyl tertiary-butyl ether (ETBE) and tertiary-amyl methyl ether (TAME) are likely to be used in RFG as well.[5] As the different oxygenated compounds contain different amounts of oxygen, the amount of oxygenate needed to meet the RFG oxygen requirement depends on which oxygenate the refiner/blender uses. Initially, it was believed that the oxygen requirement would advance the RFG goals but lately on subsequent testing has shown that oxygen content has very little effect on VOC or toxic emissions.

Oxygenates are either alcohol or ether. The purpose of oxygenates in gasoline is to reduce CO and hydrocarbons emission by assisting fuel combustion. Since 1979, oxygenates have been added to the fuel in the form of MTBE and ethanol as octane enhancers to replace lead in limited areas of the country. During the 1980s, oxygenates were used on a large scale because of the implementation of oxygenated gasoline programs to control emissions of CO in cold weather. In 1990, the CAA Amendments required the use of a high percentage of oxygenates in gasoline. For example, seasonally 15% MTBE by volume or year-round 11% MTBE is added in parts of the United States where CO levels in the winter or ozone concentrations in the summer exceed the National Ambient Air Quality Standards. Several researchers have studied the effect of oxygenates in gasoline on pollutant emissions. Kirchstetter et al. reported no change in NO_x emissions

and decreases in CO and VOC for the oxygenated gasoline.[8] On the other hand, Keller et al. reported no significant change in exhaust emissions from advanced technology vehicles when comparing oxygenated and nonoxygenated gasolines that meet all other California Phase 2 RFG standards.[9] The emission reduction benefit of oxygenated gasolines is highest for older vehicles with open loop control. Newer vehicles with computerized closed-loop control get a lesser benefit, and there is only a small benefit for advanced technology vehicles. These vehicles have a feedback emission control system that takes away the majority of the effect of the oxygenate.[10] However, the oxygenate requirement remains because of the following reasons: 1) it is an octane booster; 2) it is helpful to older vehicles; and 3) it is domestically produced, displacing imported petroleum. The most commonly used oxygenate in the United States was MTBE because of its compatible blending properties, high octane, low vapor pressure, availability, and low cost. However, this oxygenate is being phased out because of its detection at low levels in groundwater and possible toxicity.[10] Several studies have been conducted to find an alternative to MTBE.[11,12] At this moment, ethanol is the only approved replacement.

DIFFERENT PHASES OF REFORMULATED GASOLINE PROGRAM

Phase I of RFG

Phase I of RFG was introduced on January 1, 1995. It contains both formula standards and performance standard.[13] These standards for RFG are described below.

Formula standards

The formula standards for RFG are as follows: maximum of 1 wt% benzene, maximum of 25 wt% total aromatic content, 2 wt% minimum of oxygen, no metals and detergent additives.

Performance standards

Because of the various needs for suppliers, consumers, regulators and the complexity of predicting fuel emissions, the development of performance standard involved different groups such as the EPA along with the petroleum industry, auto manufacturers, oxygenate producers, the Department of Energy, various environmental groups, and state air pollution directors, etc.[13] Two models were developed by the EPA to predict emission performance from fuel composition. The models are described below:

Simple Model. The simple model was available for use from 1995 to 1997. In the simple model it was believed that RVP, oxygen, benzene, and aromatics will have a significant effect on emissions. However, the effects of aromatics on VOC and NO_x emissions were unclear. During the ''high-ozone season'' (summertime), the performance characteristics of the RFG were estimated to reduce total car VOCs and total toxic emissions by 15% of the 1990 baseline levels, or to meet the equivalence of a formula fuel performance, whichever is more stringent.[13]

The simple model was not directly used for monitoring VOC emissions. The EPA determined that a fuel with an RVP of 8.1 psi and 2.0 wt% oxygen would be sufficient to achieve the minimum 15% VOC emission reduction. Baseline emission levels are from 1990 model year (MY) vehicles operated on a baseline gasoline (Table 1). The baseline fuel, derived from average survey data of the compositions of gasolines in the United States in 1989, is shown in Table 1. This baseline fuel was defined to indicate a performance standard and not a formula composition standard. To achieve equivalency certification, refiner and importer's gasoline must comply with the CAA requirements for emissions as shown in Table 2.[14]

The simple model allows a wide variety of gasolines to comply with the regulations without specifying or limiting any other gasoline properties. For example, the formula states that oxygen content be at least 2 wt% but it does not stipulate the form of oxygen. This leaves the choice to the refiner as long as the fuel is blended to contain 2 wt% oxygen. Also, the RFG must produce no increase in NO_x emissions because NO_x and hydrocarbons react in the lower atmosphere or troposphere to form ozone in the presence of sunlight.[13]

Table 1 Baseline gasoline properties defined by the EPA in 1989

Property	Summer	Winter
API gravity	57.4	60.4
RVP (psi)	8.7	11.7
IBP (°F)	91	87
10% (°F)	128	111
50% (°F)	218	199
90% (°F)	330	332
EBP (°F)	415	404
Aromatics (vol%)	32	26.4
Olefins (vol%)	9.2	11.9
Saturates (vol%)	58.8	61.7
Sulfur (ppm)	339	338
Benzene (vol%)	1.53	1.62
Octane $(R + M)/2$	87.3	88.1

R, rated; *M*, measured.
(From Ref.[13].)

Table 2 Simple model baseline emissions

	Summer		
	Region 1	**Region 2**	**Winter**
Exhaust VOCs (g/mL)	0.444	0.444	0.656
Nonexhaust VOCs (g/mL)	0.858	0.766	0
Total VOCs (g/mL)	1.3	1.21	0.656
Exhaust benzene (mg/mL)	30.1	30.1	40.9
Evaporated benzene	4.3	3.8	0.0
Running loss benzene	4.9	4.5	0.0
Refueling benzene	0.4	0.4	0.0
1,3-Butadiene	2.5	2.5	3.6
Formaldehyde	5.6	5.6	5.6
Acetaldehyde	4.0	4.0	4.0
POMs	1.4	1.4	1.4
TAPs (mg/mL)	53.2	52.3	55.5

Region 1 is southern areas of the United States typically covered by ASTM class B during summer. Region 2 is northern areas of the United States typically covered by ASTM class C during summer. (From Ref.[13].)

Complex Model. A complex model is a set of statistically derived equations that relate fuel properties to vehicle emissions. This model became mandatory in 1998. The simple model calculates emission based on a fuel's RVP, oxygen, aromatic, and benzene content whereas the complex model adds four more variables (sulfur, olefin, and the 200°F and 300°F distillation volume fractions) to the equation. This model is based on the data collected from programs conducted around the United States. The database was made up of over 200 test fuels, 500 automobiles, and 5000 emission testings.[15] The complex model can be divided into two portions: exhaust and nonexhaust. The nonexhaust VOC was derived directly from the simple model approach where the nonexhaust benzene was modeled as a weight fraction of nonexhaust VOC from the headspace model of General Motors. The exhaust model was based on 19 different test programs.[13]

Phase II of RFG

Phase II of the RFG program began at refineries on December 1, 1999, and at retails outlets beginning January 1, 2000. This part of the RFG requirements used the complex model with stricter standards, as follows: a 25% reduction of VOCs and toxic emissions from baseline levels, with a latitude granted to the EPA encompassing consideration of technological feasibility and cost.[13] The Phase II complex emissions model uses the same variables as the Phase I complex emissions model. However, the estimated emissions using the Phase II model are different from those predicted by the Phase I model. An approximate comparison between Phase I and Phase II is given in Table 3. The VOC, NO_x, and TAP emissions reduction performance standards under Phase I using Phase I complex emissions model and under Phase II using Phase II complex emissions model are not directly comparable because of the differences between the Phase I and Phase II complex emissions models.[6] From Table 3, it was observed that Phase I winter RFG comes very close to meeting the Phase II RFG requirement.

AIR QUALITY BENEFITS OF USING RFG

The emissions from vehicles impact our environment in three different ways. They impact our air quality by contributing toxins to the air, by interacting with other emissions and sunlight to form ground-level ozone (smog) and by staying in the atmosphere as greenhouse gases.[16] The literature of the actual emissions from oxygenated fuels is quite limited. In 1987, the EPA found that oxyfuels, especially gashols, can reduce CO emissions by 10–30% in high-altitude areas, whereas in 1988 the EPA reported that CO reductions depend on the percentage of oxygen in the gasoline along with engine and exhaust-system technology. Analysis of fuel data submitted to the EPA by industry for compliance purposes shows that emission reductions from the RFG program have been more than the program requires each year since 1995. The Auto/Oil Air Quality Improvement Research Program (Auto/Oil) study highlights changes in fuel formulations that reduce automotive pollutants, especially photochemical ozone precursors and mobile air toxic emissions. This study concluded that California Phase 2 RFG reduces fleet average hydrocarbon emissions by 10–27% compared to industry average gasoline.[17] The estimated reductions in total air toxics emissions from the use of California Phase 2 RFG relative to conventional gasoline range from 9% to 32%, largely because of the reduced benzene and aromatic content of California Phase 2 RFG.[18] This gasoline is associated with significant decreases in benzene emissions and increases in formaldehyde emissions, as well as minor decreases in 1,3-butadiane and acetaldehyde emissions.[19]

The Auto/Oil study compares the emissions from vehicles using nonoxygenated RFG to vehicles using 11 vol% RFG.[18,20] This study showed only a 13% decrease in formaldehyde tailpipe emissions with the oxygenate-free fuel. The Auto/Oil study also evaluates engine-out and tailpipe (exhaust) emissions for 157

Table 3 Reformulated gasoline averaging standards

	RFG Phase 1 (January 1995–December 1999)			RFG Phase 2 (January 2000)		
	Summer region 1	Summer region 2	Winter	Summer region 1	Summer region 2	Winter
Product quality standard						
Oxygen (wt% min)	2.1	2.1	2.1	2.1	2.1	2.1
Benzene (vol% max)	0.95	0.95	0.95	0.95	0.95	0.95
Performance standards (using Phase II complex emissions model), percent reduction required						
Toxic air pollutants (TAP) (%)	18.5	17.8	17.3	21.5	21.5	21.5

(From Refs.[6,16].)

hydrocarbons for different fuel formations such as California Phase 2 RFG with MTBE, nonoxygenated California Phase 2 RFG, and a conventional nonoxygenated gasoline.[20] This study shows that California Phase 2 RFG with MTBE is associated with large increases in MTBE emissions and a lesser increase in isobutylene emissions and smaller increases in formaldehyde, acetone, and propadiene emissions compared to nonoxygenated RFG. Kirchstetter et al. compared the on-road emissions associated with California Phase 2 RFG and a California Phase 1 RFG.[4,21] The comparison was made by measuring the tunnel emissions for two sequential years when different statewide gasoline formulation standards were in effect. On the basis of representative samples of service stations, California Phase 2 RFG contained, on an average, 10.7 vol% MTBE in the summer of 1996 compared to 1.0 vol% MTBE for the Phase 1 formulation in the summer of 1995. Kirchstetter et al. also observed an 18% reduction in CO emissions, a 22% reduction in nonmethane organic carbon emissions, and a 6% decrease in NO_x emissions from the summer of 1995 (California Phase 1 RFG) to the summer of 1996 (California Phase 2 RFG).[4,21] Gertler et al. performed a tunnel study in the Sepulveda Tunnel in Los Angeles in October 1995 (Phase 1 California RFG) and July 1996 (California Phase 2 RFG).[22] A significant decrease in CO and NO_x vehicle emission was observed for 1996 California Phase 2 RFG compared to the California Phase 1 RFG measurements in 1995. In their study, the most important change in the hydrocarbons measured from the 2 yr was a nearly 50% increase in the faction of MTBE emissions.

Case Study 1

In Mexico, 76.7% of the population lives in urban areas. It has three mega cities with a population ranging from 1.5 to 8.0 million. In particular, Metropolitan Area of Mexico City (MAMC) alone has more than 18 million people. This urban region is expected to be one of the 20 largest urban regions of the world by the year 2015.[23,24] In the year of 2001 Mexico started a program to limit the exhaust emissions on new gasoline vehicles. Schifter et al. studied the fuel reformulation on the vehicle exhaust emissions in MAMC.[24] In their work, they prepared 15 gasoline blends using the current refinery streams available in the country. The RVP, sulfur, aromatic, olefin, and oxygenated molecule (MTBE or ethanol) were the main parameters considered in their studies. The United States Federal Test Procedure and FTP were used to evaluate total hydrocarbons, nitrogen oxides, and toxic exhaust emissions. The statistical design and analysis methods similar to those employed in the Auto/Oil Air Quality Research program were used in this work. In their work, different ranges of MYs were used, which acted as a surrogate for different emission control technologies. Thirty vehicles such as GT-1 (GM: Cutlass-89; Chrysler: Spirit-90; VW: Sedan-90; Nissan: Tsuru-90), GT-2 (Chrysler: Spirit-93; Nissan: Tsuru-93; GM: Cavalier-94; VW: Jetta-98; Nissan: Sentra-98; GM: Monza-98; Ford: Pick-up-98; Ford: Escort-98; Chrysler: Stratus-98), and GT-3 (Nissan: Tsuru-90; Chrysler: Neon-99; GM: Chevy-99; Chrysler: Stratus-99; Dodge: Pick-up-99; Nissan: Pick-up-2000; VW: Pointer-2000; Nissan: Sentra-2001; GM: Monza-2001; Ford: Fiesta-2002; GM: Astra-2002; Ford: Focus-2001; VW: Jetta-2001; VW: Sedan-2001) were randomly recruited in areas of the MAMC of different socioeconomic indicators. Addition of MTBE deceased CO emissions to some extent in all cases. However, it was statistically significant in the case of the GT1 fleet. Substitution of MTBE by ethanol decreased CO emissions in the entire fleet and it was statistically significant only for GT-1 and GT-2 vehicles. Methyl

tertiary butyl ether had a statistically significant impact on total hydrocarbon emissions for the entire fleet. A similar impact on GT1 and GT2 was observed when ethanol was added, whereas its effect on GT3 was significant. Increase in RVP resulted in lower emissions, which was statistically significant on GT-2 and GT-3 fleets. Increase in olefins and aromatics did not have any significant impact. However, concerning NO_x emissions, the only statistically significant impact was that increasing olefins raises emissions on GT-1. For selected fuels (see Table 4) a comparison of calculated straight average values of VOCs, TAP, and NO_x was made using the EPA Phase 1 and Phase 2 complex model. For complex model predictions, see Table 5. From Table 5 it was observed that F-10 had the highest reduction among the tested fuels with the 1990 MY's American fleet.

Case Study 2

The effects of the use of reformulated and oxygenated gasoline fuel blends on the air quality of European city were studied by Vinuesa et al.[25] The urban region of the Strasbourg–Kehl area (GSKA) in the middle of the upper Rhine valley was chosen as the area of investigation. The part of the valley used in this work was flat, 29 km wide, and 33 km long. The chosen period of investigation was May 9–15, 1998, which corresponded to a photochemical ozone pollution episode with low synoptic wind and high temperature (3–5°C above the seasonal average). Their study focused mainly on May 11 when the maximum value of 193 $\mu g/m^3$ of ozone was measured in the center of Strasbourg. Ethyl-*t*-butyl ether was used as an oxygenated compound in their work. The daily emissions of CO, VOC, and NO_x (in milligrams or tons) for May 11, 1998, are given in Table 6. The goal of their work was to examine the differences in pollutant concentrations predicted by the model when the gasoline vehicles used different fuel blends. The wind fields were exactly the same in the reference case and in different scenarios and consequently the concentration levels were explained in a similar way. The effects of alternative fuels on the urban air quality were studied by building emission scenarios based on available emission factors. From their work they observed that the reformulation directly decreased the aromatic fraction in the composition of the fuel and the oxygenated compounds decreased this part by dilution. They also observed that the use of alternative fuels considerably reduced the direct emissions of total VOC by up to 30% and 45%, respectively. For NO and NO_2 the situation was less clear. For all the scenarios, the simulated ozone levels were slightly lowered in the range of 1–5% and the maximum effect was obtained when all the vehicles used these alternative fuel blends. When the percentage fell to 80%, the reduction of ozone became less than 3%. However, from their work they concluded that the use of reformulated and oxygenated fuel blends led to some improvement of the air quality at a local scale but it did not lead to the drastic changes even when all the fleets use various alternative fuels.

Impacts of Oxygenated Compounds on the Environment

In RFG, the most commonly used oxygenates are MTBE (methyl tertiary butyl ether) and ethanol. As a component of RFG, MTBE plays a role in reducing total hydrocarbons, air toxics, and CO.[18] However, it is also responsible for certain pollutant emissions.

Table 6 Daily emissions of CO, VOC, and NO_x for 11 May 1998

	CO emisssions		VOC emissions		NO_x emission	
Sources	**mg**	**% CO**	**mg**	**% VOC**	**mg**	**% NO_x**

Methyl tertiary butyl ether enters the environment in different ways such as auto emissions, evaporative losses from gasoline stations and vehicles, storage tank releases, pipeline leaks, and accidental spills, and refinery stock releases. When gasoline is released into air, a significant portion exists in air and a small portion enters into soil and water.[26] When it is released into water a significant portion remains dissolved in surface water, with some partitioning into air and a much smaller amount into soil.[27] Because of its high solubility, it moves through the soil and into the groundwater more rapidly than other chemicals.[26]

Time spent at the service station, driving cars, at the parking garage and in homes with attached garage are the nonoccupational sources of gasoline emission to the environment and human exposure occurs through inhalation during fueling of automobiles.[28] Also, leakage from stationary sources (under ground storage tank) to soil or groundwater can contaminate the water supply. Methyl tertiary butyl ether has a strong taste and odor. A small amount of MTBE in water can make the water supply distasteful. Dermal contact (exposure of skin to toxic materials) of gasoline may occur though accidental spills of MTBE-blended gasoline or through the use of gasoline as a solvent.[29]

The estimated arithmetic mean occupational dose via air is in the range of 0.1–1.0 mg/kg/day, whereas doses from residential exposures, communicating, and refueling are in the range of 0.0004–0.006 mg/kg/day.[30] During refueling of a car, the concentrations of MTBE range from less than 1 ppm to 4 ppm (within the breathing zone) and from 0.01 ppm to 0.1 ppm inside cars (1 ppm = 3.57 mg/m^3 at 25°C, 1 atm).[31] However, the reference dose imposed by the EPA is 42 mg/kg/day.

The data on the presence of MTBE in drinking water are very limited. The most extensive monitoring data on MTBE in drinking water are available from California. In January 2000, 1444 systems had tested 6492 sources of drinking water. Methyl tertiary butyl ether was detected in 52 (0.8%) of these sources, including 31 of 6076 groundwater sources (0.5%) and 21 of 416 surface water sources (5%). Overall, 30 (2.1%) of the 1444 public water systems reported detection of MTBE in at least one of their drinking water sources. Although the state database did not include some contaminated wells that have been closed, very few sources had MTBE concentrations exceeding the EPA taste and odor drinking water recommendation of 20–40 μg/L.[26]

ALTERNATIVES OF MTBE

Because of the adverse effects of MTBE, ethanol is now considered as a promising alternative oxygenate. Ethanol is now marketed and distributed in every state in the United States. Ethanol is safe, biodegradable, and renewable. It also does not harm drinking water resources. Currently, around 80% of gasoline in California is blended with ethanol. At this time, the total ethanol consumption in California is 950 million

gallons per year, whereas in 2002 the consumption was 100 million gallons.[32]

But other concern also arises in the case of ethanol. It raises vapor pressure of the ethanol–gasoline mixture, resulting in increased evaporative emissions.[10] Also, there are cost and supply issues if a large amount of ethanol is required.[11,12]

CONCLUSIONS

The RFG program is a significant step toward cleaning the air we breathe. Evaporative VOC emissions can be reduced by limiting the vapor pressure of RFG during the summer months. The RFG program reduces emissions of TAP such as benzene, a known human carcinogen. It is possible to reduce the tailpipe emissions of the major pollutants regulated under the CAA-carbon monoxide, hydrocarbons, and nitrogen oxide by 10–20% using RFG. Methyl tertiary butyl ether oxygenate is being phased out because of its adverse effects on the environment. Ethanol is now considered as a promising alternative to MTBE.

NOMENCLATURE

API	American Petroleum Institute
ASTM	American Standards for Testing and Materials
CAA	Clean Air Act
EBP	End boiling point
ECS	Emission control system
ETBE	Ethyl tertiary butyl ether
E200	Percentage of fuel evaporated at 200°F
E300	Percentage of fuel evaporated at 300°F
MTBE	Methyl tertiary butyl ether
IBP	Initial boiling point
POM	Particulate organic matter
RFG	Reformulated gasoline
RVP	Reid vapor pressure
TAP	Toxic air pollutants
TAME	Tertiary amyl methyl ether
VOC	Volatile organic compound

Renewable Energy

Gareth P. Harrison
Institute for Energy Systems, School of Engineering and Electronics, University of Edinburgh, Edinburgh, U.K.

INTRODUCTION

Climate change is widely regarded as one of the most significant global challenges in the 21st century. With conventional fossil fuel generation a major contributor, the expansion of renewable energy use is a critical element of the strategy to lower emissions of greenhouse gases. Many countries have set challenging targets for renewable use and deployment driven by the environmental, sustainability, and security benefits that may be attributed to renewables.

Here, these arguments are reviewed along with the renewable technologies available. The challenges for integrating these variable and often intermittent generating sources are highlighted and alternative applications in creating new energy vectors and in direct use are explored. Finally, the economics of renewables are examined with particular reference to the limitations of traditional comparisons with conventional sources and the impact of more robust techniques on the relative cost of fossil fuels and renewables.

THE DRIVE FOR RENEWABLE ENERGY

The case for promoting renewable energy revolves around the three key benefits associated with it:

1. Nonpolluting
2. Infinite reserves
3. Security of supply

Pollution

The primary argument in favor of renewable energy is that it does not entail the release of chemical pollutants to convert the energy. This is in contrast to fossil fuels, which emit a range of pollutants from carbon dioxide (CO_2) to the components of acid rain to ash. Table 1 shows the pollutants from typical 2000 MW plants.

The combustion of fossil fuels produces the majority of anthropogenic CO_2 with transport and power generation the largest sources. CO_2 is widely accepted as the major cause of climate change, which, if left unchecked, is predicted to lead to a global temperature rise of between 1.5°C and 5.8°C by the end of the century (Fig. 1).[2] This, and accompanying changes in other climate variables (precipitation, wind speed, etc), will have impacts on many sectors ranging from agriculture to human health that will be seen at local, regional, and global scales. In responding to this, many industrialized countries have signed the Kyoto Protocol requiring cuts in CO_2 and other gases by 2010, which became legally binding on participants in February 2005 following ratification by Russia. A difficulty for the Kyoto agreement is the refusal of the U.S.A. and Australia to ratify it, partly because large developing nations like China and India escape emissions limits. In July 2005, the U.S.A. and five Asia-Pacific states announced a voluntary pact to reduce emissions by developing new technology like 'clean coal;'[3] the effectiveness of this nonbinding agreement is disputed, however. These aggrements are the beginning of a longer process, with the United Kingdom Royal Commission on Environmental Pollution recommending CO_2 cuts of 60% by 2050 to limit the eventual rise of greenhouse gas concentrations to twice the preindustrial level.[4] Achieving the reductions required by Kyoto and the longer-term targets will not be straightforward. To date, modest CO_2 emissions have been achieved through switching to less carbon-intensive fuels like natural gas (albeit justified on a cost basis) but, ultimately, emission-free energy is required. While continued fossil fuel use will be possible if large-scale capture and sequestration of carbon can be achieved, the development and deployment of truly carbon-free energy sources like hydrogen, nuclear, and renewables will be critical.

Fossil-fueled power stations produce significant quantities of sulfur dioxide (SO_2) and nitrogen oxides (NO_x), which are precipitated as "acid rain" across wide areas and legislation such as the European Union Large Combustion Plant Directive has imposed emission limits in response. SO_2 emissions can be reduced by a range of techniques including the treatment of coal before ignition, combustion processes that collect sulfur in the ash, and SO_2 removal from the combustion product gases, known as flue gas desulfurization (FGD). Although effective, FGD is expensive, particularly so for retrofit, and reduces station efficiency.[5] While road transport is the major cause of NO_x emissions, power

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007945

Table 1 Typical emissions from 2000 MW fossil-fueled power stations (in ktons/yr)

Pollutant	Conventional coal (no FGD)	Conventional oil	Combined-cycle gas turbine
Carbon dioxide	11,000	9,000	6,000
Sulfur dioxide	150	170	~0
Nitrogen oxides	45	32	10
Airborne particulates	7	3	~0
Solid waste and ash	840	~0	~0
Ionizing radiation (Bq)	10^{11}	10^{9}	10^{12}

(From Ref.[1].)

stations still contribute a significant fraction. A wide variety of NO_x control technologies have been developed (e.g., flue gas scrubbing with alkalis) but again are expensive. Despite not deploying NO_x scrubbing, the United Kingdom has achieved reductions with greater use of gas-fired plant and the retrofit of low-NO_x burners to existing coal stations. Use of renewables can avoid these costly removal processes.

Radiation is emitted from nuclear and, because of the presence of trace elements, from fossil-fueled power stations. The amounts are generally small, with public exposure similar to that of background radiation levels. However, the major issues surrounding nuclear power are how to deal with radioactive waste products and how to avoid proliferation of radioactive material. Until these issues are resolved and a clear lead given by governments, new nuclear plant is unlikely to be built, particularly not by the private sector. Once again, renewables can begin to fill the gap.

Finite Resources

There is also the issue of sustainability of fuel supplies. Fossil fuels are the product of sedimentation processes over millions of years, but they will have been consumed in a matter of centuries. Table 2 shows recent estimates of global proven fossil fuel reserves and an estimate of their remaining lifetime assuming current usage rates. While there is uncertainty over the remaining reserves, particularly given that further oil and gas fields will be identified, there is little doubt that with rapidly increasing demand for oil and gas and increasing exploitation costs (in financial and energy terms) supplies will be limited to several decades.

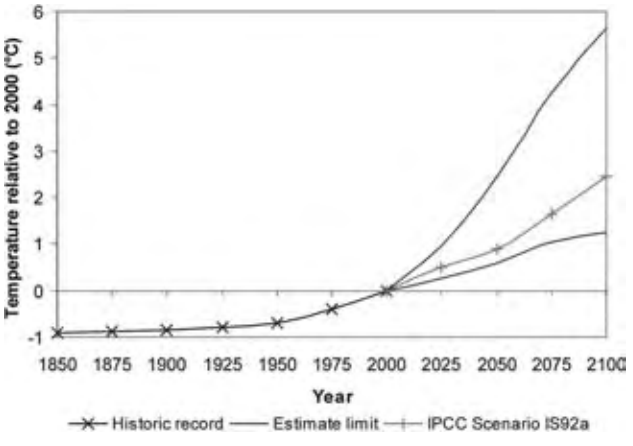

Fig. 1 History and range of future temperature rise. (From Ref.[2].) *(View this art in color at www.dekker.com.)*

Fortunately, there are sufficient renewable energy resources to meet our energy needs many times over, although in many cases the means of doing this in a technically and economically efficient manner is still under development. Table 3 shows an estimate of the power available from a range of renewables. To put these in perspective, global installed electrical capacity is currently just over 3000 GW (3 TW) and is anticipated to grow by some 120 GW/yr.

Although biomass is currently the most heavily used renewable in overall energy terms, very little is used to generate electricity. Accordingly, hydropower is the number one renewable in electricity terms and contributes around 19% of global supply. Installed capacity is currently around 650 GW with a further 100 GW under construction. In recent years wind has seen the largest growth and, with 8 GW added in 2003 alone, global installed capacity is now almost 40 GW; forecasts suggest an installed capacity of 1250 GW by 2020 meeting 12% of electrical needs.[8]

Security

An increasingly strong argument in favor of renewables is their positive effects on security by spreading risk. At the crudest level this can be interpreted as

Table 2 Proven fossil fuel reserves and reserve/production ratio

Fuel	Proven reserve	Reserve to production ratio
Oil	156 billion tonnes	41
Gas	176 trillion m^3	67
Coal	984 billion tonnes	192

(From Ref.[6].)

Table 3 Estimate of global renewable energy resource

Resource	Estimate of recoverable resource	Resource base
Solar radiation	1,000 TW	90,000 TW
Wind	10 TW	1,200 TW
Wave	0.5 TW	3 TW
Tides	0.1 TW	30 TW
Geothermal (heat flow)	—	30 TW
Biomass	1,150 TW	450 TW yr

(From Ref.[7].)

increasing energy self-sufficiency and lowering the risk of supply interruptions by accident, terrorist activity, or the actions of politically unstable fossil fuel exporting nations. In the U.K., fuel diversity is often indicated using the Shannon–Weiner index, which measures the logarithmic weighting of fuel technologies. Hence, by increasing the variety of fuel sources through new types and increasing volumes of renewables, diversity and, by implication, security increase.

Security can also be measured in terms of the economic implications of exposure to volatile fossil fuel prices. Studies suggests that fossil fuel price volatility has a range of negative effects on economic activity including impacts on employment levels and asset values; for example, a 10% oil price spike is estimated to reduce economic growth in the United States alone by as much as $200 billion over the following year.[9] This dwarfs current and future investment to commercialize renewables estimated at around $125 billion between 2001 and 2010.[10] The deployment of renewables reduces exposure to fossil price risk and this can be shown to lower overall cost.[11] This perhaps surprising result arises as the costs of renewables do not have any correlation with fossil fuel price changes. The addition of renewables creates a diversified generation portfolio that serves to lower overall generating costs for a given level of risk.

BRIEF REVIEW OF RENEWABLE ENERGY

There are a range of renewable energy sources currently in use in electricity systems or with the potential to contribute significantly in the future. The following energy sources are briefly reviewed and their merits explored:

- Hydropower
- Solar energy
- Wind energy
- Geothermal energy
- Biomass
- Tidal power
- Wave energy

Hydropower

Hydropower is the conversion of the gravitational potential energy of water into electricity. The power generated depends on the water flow rate and the height through which the water falls—the "head"—and is roughly 10 times the product of the two quantities. Global installed capacity is approximately 650 GW and produced 2700 TW hr in 2003 (around 19% of primary energy).[6] The estimated technical potential is around 14,000 TW hr/yr but the economically exploitable potential is between 40% and 65% of that, with much of the more economic plant already installed. The pattern of availability and exploitation varies significantly with countries like Norway producing 99% of their electricity from it while others little or none. The more developed regions have exploited far greater proportions of their resource while only around a small fraction of Asia's much larger potential has been tapped.

Hydropower is characterized by high initial capital costs offset by a long lifetime (civil engineering works often last more than 50 yr), high reliability, and low operational costs. Hydro is generally defined on the basis of its installed capacity as Table 4 indicates.

Large hydro is often defined as a grid-connected scheme in excess of 20 MW capacity and would normally possess a dam and a storage reservoir (Fig. 2). The largest scheme, the Three Gorges project on the Yangtze, will shortly have a capacity of 18 GW. Most large-scale schemes were developed prior to 1990 and the potential for new large schemes is now rather limited given that there are fewer commercially attractive sites still available, but perhaps more importantly, because of opposition on environmental grounds mainly as a result of the flooding of land to create the storage reservoir.

Fig. 2 Typical embankment dam in Texas, U.S.A. *(View this art in color at www.dekker.com.)*

Table 4 Hydro capacity definitions

Type	Capacity
Micro hydro	<100 kW
Mini hydro	<1 MW
Small hydro	<20 MW
Large hydro	>20 MW

Pumped storage schemes are large hydro schemes that are designed with a storage reservoir that is larger than justified by the natural flow of water into it. Alternatively, they may consist of a pair of reservoirs that are connected by appropriate penstocks. They operate such that when electricity demand is high, water is released from the upper reservoir driving the generators and exporting power to the grid; when electricity demand is low, the generators draw electricity from the grid (i.e., become motors), which are used to drive the turbines in reverse and pump water back into the reservoir. Pumped storage schemes play a major role in many countries in smoothing out imbalances between supply and demand and providing rapid response capabilities that help stabilize the grid. Their economics are based partly on these balancing and response capabilities but also on the fact that electricity at low demand is cheaper than at peak.

Schemes of less than 20 MW are relatively common and can be extremely competitive with minimal environmental impacts. While these smaller schemes currently contribute only about 3% to global hydropower capacity, they make a significant contribution in many regions of the world, especially in rural or remote regions where other conventional sources of power are less readily available. Small schemes can be associated with a dam and storage reservoir or can consist of short diversion schemes that are termed ''run-of-river.'' Small and micro hydro can also provide competitive power and while per-unit capital costs are higher than for larger schemes these can often be reduced by use of existing structures or by refurbishing existing plant and equipment. The cost of generating power from smaller hydro schemes depends on site characteristics and the hydraulic head (with economic viability decreasing as the head reduces).

Solar Energy

Most renewable energy sources are, ultimately, concentrated forms of solar energy. However, there are two distinct approaches to generating electricity directly:

- Solar thermal engines
- Photovoltaic (PV) cells

Solar thermal engines use a solar collector to create a temperature sufficient to raise steam and drive a turbine-generator. There are a wide range of prototype stations around the world that, unsurprisingly, tend to be in areas that are hot, dry, and sunny. The schemes use some form of solar collector to concentrate the sun's rays to a point or series of points. These arrangements include parabolic dishes, solar collector fields that use long lines of planar parabolic mirrors, and power towers that rely on the surrounding heliostats to reflect light into the power chamber. The devices range from a few hundred kilowatt to several hundred megawatt schemes that are cofired with gas. A different approach makes use of the smaller temperature differential at the ocean surface and at great depth. Ocean thermal energy (OTEC) pumps water from both 1000 m at low temperature and at the surface to drive a power-vapor cycle.[12]

Photovoltaic (PV) cells are semiconductor devices that convert sunlight directly into electricity. It is a well-established technology particularly for sites that are far from the distribution network. The cost of PV has dropped significantly and is a promising, low-risk technology—a fact indicated by the involvement of oil companies in their large-scale manufacture. The greatest potential for developing PV is to integrate it into buildings as PV modules can substitute for roof or façade elements, hence reducing net costs, can be operationally integrated and, being relatively unobtrusive, are unlikely to face public opposition.[13]

Wind Energy

Winds are the product of pressure differences in the atmosphere and the wind speed at a given location continuously varies. The power available from the wind is proportional to the cube of the wind speed. Accordingly, wind turbines are generally sited in areas of high mean wind speed and development of taller, larger-capacity turbines has occurred to harness the greater wind speeds at height (owing to the wind shear effect near the ground). Wind speed is quite unpredictable and at a given point fluctuates second by second and over longer periods of time; given the power law, individual wind turbine output varies significantly. Fortunately, wind turbines are commonly connected in substantial groups with aggregation having a marked smoothing effect.[13] An enormous variety of designs have been created to extract power from the wind but the three-bladed horizontal axis (HAWT) model is now the industry standard (Fig. 3).

A desire for economies of scale and the harnessing of higher wind speeds has seen turbine capacities grow significantly to the current standard of around 2 MW. The increase in blade diameter has pushed the overall

Fig. 3 Lamb Rigg wind farm, U.K. *(View this art in color at www.dekker.com.)*

height of these machines to around 130 m. Larger machines are being used for offshore wind developments of which there are several in the United Kingdom and Denmark. Offshore sites tend to benefit from higher wind speeds and lower turbulence levels, resulting in higher energy capture. There are several other advantages of offshore wind as well as a number of negative aspects as Table 5 indicates.

Despite the trend toward larger generators there are a wide range of smaller devices available, including those in the tens of kilowatt range as well as a number of microturbines for battery charging, water heating, as well as newer grid-connected versions (e.g., Ref.[14]) which are designed to be connected to domestic property.

Table 5 Advantages and disadvantages of offshore wind

Advantages	Disadvantages
Reduced visual impact	Higher capital costs
Higher mean wind speed	Access restrictions in poor weather
Reduced wind turbulence	Submarine cables required
Low towers due to low wind shear	

A number of different approaches have been taken by wind turbine manufacturers in converting the rotational motion into electricity. Some of the main differences include:

- Fixed- or variable-speed operation
- Direct drive generators or the use of a gearbox
- Stall or pitch regulation

Fixed-speed wind turbines usually use an induction generator via a gearbox and capacitors are required to improve the poor power factor.[15] Variable-speed operation increases energy capture by allowing maximum efficiency over a wide speed range. This necessitates a power electronic converter and while this increases losses the rotor acts as a flywheel smoothing the output. Power limitation in high wind speeds is achieved by shedding load either by stall control, which relies on the aerodynamics, or pitch control, which actively turns the blade away from the optimal position. Beyond the cutout speed, which is normally around 25 m/sec, the turbine shuts down to minimize damage.

Geothermal Energy

Geothermal energy is sourced from the heat flowing from the interior of the Earth to the surface. While the overall energy flow is small relative to that of solar heating, in some places the heat flow is concentrated sufficiently to allow the exploitation of the steam and hot water in the ground to drive thermal power stations and produce electricity. Strictly speaking, geothermal energy is nonrenewable on human lifetimes, but it is often grouped with renewables as it is a natural energy flow rather than the exploitation of stored chemical energy.[16]

The major advantage of geothermal energy is that it produces controllable and predictable power and the plant exhibits high availability and fairly competitive capital and operational cost. Other than site preparation, the longer-term concerns with geothermal plant include ground subsidence, induced earthquakes, and the release of pollutant gases. The pollutants include carbon dioxide, methane, as well as hydrogen sulphide, the source of the rotten eggs smell often associated with geothermal plant. In most cases these concerns tend to be related to older plant where the reinjection of cooler water is not practiced.[16]

Biomass

Biomass is the Earth's living matter and is an enormous store of energy. Historically, biomass was the sole fuel source with material burned for heat and

animal and vegetable fats used for lighting. The primary technology was the processing of wood to produce charcoal and allowed temperatures sufficient to extract metals from their ores. While such technologies have been largely superseded in the developed world, biofuels still represent around 14% of global primary energy consumption and over a third of consumption in developing nations.[17]

A whole range of materials can be used as biomass including wood, straw, and sewage. The majority decompose quickly so are not very good long-term energy stores. In addition, their low energy density (relative to fossil fuels) increases transport costs. This means that biomass power generating units are relatively small compared to conventional plant, relying on local supply chains for feedstock. A range of processes can be used to extract the energy in the biomass:[17]

- Direct combustion of raw biomass.
- Combustion following physical processing (e.g., chipping, drying).
- Thermal/chemical processing to concentrate the fuel.
- Biological processing such as anaerobic digestion or fermentation.

The direct product of each of these products is heat, which may be used locally for heating or chemical processing, to raise steam to generate electricity or a combination of the two as combined heat and power. As such, modern biomass generation will use electrical technologies common in other thermal generating plants. This is particularly true where biomass (e.g., solid processed sewage) is cofired with coal; this is becoming increasingly common in the United Kingdom.

While biomass generally involves the burning of material it differs from fossil fuels in that no more heat or carbon dioxide is produced than would be produced by natural processes. As such, it is referred to as ''carbon neutral.'' However, it still produces CO_2 and a range of other pollutants including nitrogen oxides, ash, but virtually no SO_2. A further environmental benefit is that the combustion of landfill gas avoids accidental explosions and prevents the release of methane, which is more potent as a greenhouse gas.

Tidal Power

Tidal power can use either conventional or new technology to extract energy from the tides. It is usually best deployed in areas where there is a high tidal range, which includes many areas of the United Kingdom as well as the United States, New Zealand, and parts of the west coast of India.

The conventional approach to extracting tidal energy is to construct a barrage across an estuary or a bay. As the tide rises (floods) and falls (ebbs), it creates a height differential between the inner and outer walls of the barrage. Water can then flow through turbines installed in the barrage and drive generators. Some tidal barrages operate on both the rising and the falling tide, but others, particularly estuarine barrages, are designed to operate purely on the falling tide. With basic ebb or flood generation the installed capacity is used for only short periods of 3–6 hr in each tidal cycle producing a block of power that may or may not coincide with high demand. Fortunately, a degree of smoothing of the power output can be achieved and tides can be predicted to a high degree of accuracy. Technology for tidal barrages is essentially the same for hydro schemes with the barrage and axial flow turbines of similar construction to those used in low-head dams.

Very few tidal barrages are in existence worldwide with the exception of the 240 MW La Rance scheme in France and smaller installations in Nova Scotia, Russia, and China. The United Kingdom has a number of attractive sites because of its high tidal ranges including the Severn (8 GW potential) and the Mersey (700 MW).[18] The scale of these installations and the associated high capital costs mean that the necessary investment is unlikely to be forthcoming within the current privatized electricity supply industry. Their environmental impact is also a major constraint on large-scale developments.

The construction of a large barrier across an estuary would have a major impact on the local estuary although there would be benefits as well as detrimental effects. The La Rance scheme caused the local ecosystem to collapse, although it has regenerated.[18] There would be a tendency for the water behind the barrage to become less saline as a result of lower seawater inflows, which would tend to allow freshwater flora and fauna to extend seaward. Lower tidal current velocities, particularly on the ebb tide, will tend to reduce sediment erosion or increase sedimentation. A reduction in suspended sediments allows increased sunlight penetration stimulating biological productivity and water level changes would also impact on the mud flats, home to wading sea birds.[18]

A more benign approach is to extract energy from the tidal flows that occur between headlands and islands or in and out of estuaries. The power available in these tidal streams varies with the cube of the current velocity and while sea currents are typically around 3 m/sec, much lower than the minimum velocities required for wind turbines ($\sim$7 m/sec), the density of seawater is such that the output of tidal stream devices is much higher than equivalently sized wind generators. The energy flows are significant with around 7.5 GW of accessible resource in Scotland alone.[19]

Fig. 4 Impression of a large-scale vertical-axis tidal rotor. *(View this art in color at www.dekker.com.)*

Tidal stream technology, which directly exploits these currents, is relatively new but is presently generating considerable interest. Turbine rotors can be used to extract energy from the flows, much as a wind turbine does. Alternative designs use oscillating aerofoils or rotating vertical hydrofoils (Fig. 4) to pump oil and generate power. Prototype devices currently on test in the United Kingdom include the 300 kW SeaFlow turbine possessing an 11 m-diameter rotor attached to a monopile.[20] The tidal turbines can be arranged singly or in arrays, allowing a range of power outputs that avoid the massive bursts of power associated with barrage technology. In common with barrages, the output will be variable but to a great extent predictable. In addition to monopiles, tidal devices can be moored to the seabed or perhaps more cleverly secured by an ''active'' mooring device designed to allow the easy recovery of the tidal device itself. The ''Snail'' (developed at the United Kingdom's Robert Gordon University) possesses hydrofoils that press the device onto the seabed.

Wave Energy

The worldwide wave power resource potential is huge with global power potential estimated to be up to 10 TW, which is the same order of magnitude as world electrical energy consumption. The power in the waves varies with the square of the wave height and is proportional to the period. Island countries are well placed to exploit wave energy with what is considered a huge accessible resource. However, when practical constraints such as conversion efficiency, shipping lanes, and environmental restrictions are taken into account, the resulting practicable resource is significantly reduced.

Waves are primarily driven by the wind with the best wave climates found in the temperate zones (30–60° latitude) where strong storms occur. The best locations include the United Kingdom, Ireland, Portugal, and the Canadian west coast.[21] Attractive wave climates are also found within ±30° latitude where trade winds blow as the lower power levels are compensated by the lower wave power variability.

Since the early 1970s there has been research into developing means of harnessing the power of the waves and various machines have been developed. These fall broadly into three categories:

1. Oscillating water column (OWC) devices, which channel waves into constricted chambers so that as the waves flow in and out of the chamber, they force air in and out of the chamber. These air flows are in turn channeled through a Wells turbine (which turns in the same direction irrespective of the air flow direction), which is used to drive a generator. This type of machine is generally designed to be fixed on or near the shore (or for incorporation into breakwaters) although several floating OWCs are at the prototype stage. This kind of machine is the most advanced and is particularly advantageous when incorporated into coastal protection. The U.K.-based company Wavegen built a shoreline OWC device known as the ''Limpet'' on the coast of Islay in Scotland, the first grid-connected wave device.
2. Fixed or semifixed machines that harness the hydraulic head in the water that occurs at a submerged point as the wave passes over that point. The pressure differential is used by a variety of means to cause a fluid to flow in a circuit, which is then used to drive a turbine and generator. The Archimedes Wave Swing is such a device.
3. Devices that use buoyancy to cause relative movement to indirectly drive a generator. Examples include the heaving buoy, rafts, and the original wave device, the ''Duck'' designed by Professor Stephen Salter at the University of Edinburgh (Fig. 5). An Edinburgh spin-out company, Ocean Power Delivery, has developed the ''Pelamis,'' which resembles (and indeed is named after) a sea snake in that it is a long-articulated series of tubes that flex as waves run along the length of the device.[22] This device has recently been connected to the grid at the European Marine Energy Test Centre in Orkney, Scotland.

Wave energy converters will be among the least environmentally harmful energy sources with minimal chemical and shipping hazard risk and zero visual impact for offshore devices (although there are some with shoreline-based devices).[21] There are, however, as yet unconfirmed suggestions of low-frequency effects on marine mammals.

EFFECTIVE USE OF RENEWABLES

Grid Connected

There are difficulties in absorbing the variable and often unpredictable energy of renewable energy sources into the electrical system.[23] At the root of the problem is the fact that electrical networks were designed to convey power from large, centrally dispatched thermal and hydropower plants via the high-voltage supergrids to customers at lower voltages. The capacities of many renewable sources and their geographical locations means they are being connected at lower-voltage distribution levels. The design of the networks together with geographic remoteness from load centers creates a range of technical difficulties such as changes to power flows, voltage variations, and rising fault levels among others. A significant academic and industrial research and development effort is concerned with identifying and mitigating the impact of embedded or distributed generation on the electricity network.

A further issue relates to the intermittent nature of the resources, particularly wind, and the ability of the electrical system as a whole to respond to rapidly changing power input. Studies in the United Kingdom suggest that at penetrations of 10% there is virtually no impact on network operation.[24] At 20% and above there are issues of raised reserve in the form of partly loaded conventional generators as well as the standing capacity required for periods of calm and this has economic implications. Denmark currently has well in excess of 20% although this to some extent is due to their connections with the German and Nordic networks that provide much of the response required. The introduction of other renewables is anticipated to partly mitigate the issue of wind intermittency as they are generally more predictable and less variable. Further research is under way in the United Kingdom and elsewhere, although it should be noted that other renewables will take many years to make a significant contribution.[25]

Overall, the needs of current electricity systems to maintain power balances on a second-by-second basis and the current approach of trying to get renewable generators to mimic thermal generation creates a range of technical and economic problems for renewables. These range from strict technical requirements for generator capability to network planning and protection, which conspire to make the connection of renewables appear fairly expensive. This is compounded by electricity markets that operate around "firm" power and penalize intermittent sources. An alternative approach that does not try to "shoehorn" renewables into conventional generation in embracing a more decentralized network will serve to mitigate many of these problems.[26]

Alternative Energy Vectors

One of the means of tackling the intermittency issue is to provide a degree of energy storage that accepts fluctuating inputs while providing a firm electrical output. A range of storage technologies are in development including flywheels, superconducting coils, and compressed air and oil. While these offer storage solutions on relatively short time frames, the energy density of chemical fuels provides a longer-term storage opportunity with the added benefit of creating new energy delivery vectors.

The most commonly mentioned is hydrogen in the context of a new hydrogen economy to supplant the existing carbon-based economy. Iceland has set itself the target of becoming the first all-hydrogen economy and has one of the first hydrogen refueling stations. Recently, Norsk Hydro has developed one of the Norwegian islands into an all-hydrogen system.

While it is possible to create hydrogen (H_2) by reforming natural gas this will require the release of CO_2, which will be difficult to sequester if it is performed on a decentralized basis. However, the electricity from carbon-free nuclear and renewables can be used to electrolyze water (H_2O) forming oxygen (O_2) as a by-product:

$$H_2O + \text{electricity} \rightarrow H_2 + \frac{1}{2}O_2$$

The process is appealing as H_2 is excellent for fuel cells in both electricity generation and vehicles and overall energy conversion efficiencies are over 60%.[27] The downside is that large-scale storage and transport of H_2 is difficult although research is looking into how

best to store hydrogen, e.g., in carbon nanotubes and prototype H_2-fueled vehicles are in existence.

An alternative or intermediate approach to the development of a full-scale hydrogen economy would be to convert the hydrogen into hydrogen-rich liquid fuels such as methanol, ethanol, or even longer-chain hydrocarbons.[27] These methods are proven to pilot stage or further.[28] Each approach requires a readily available source of CO_2—in the flues of fossil fuel power stations. This would not only assist in achieving high levels of renewables through chemical buffering but would allow continued use of fossil fuel plant and recycle CO_2 as a hydrogen carrier fuel. However, it would still require the capture of CO_2 from flue gases.

Direct Use

Renewables can also be used directly to provide useful work in chemical processes and elsewhere without the need to integrate with the electrical network. One approach is to use the mechanical energy from renewables such as wind to drive heat pumps to abstract thermal energy from the ambient airstream (or other low-grade heat source such as the ocean). The resulting heat may be delivered at a useful temperature for drying, steam raising, or other thermal processes.[29] Processes such as desalination that currently require significant fossil fuel usage could be achieved using renewables such as wind and wave.[30,31]

ECONOMICS OF RENEWABLE ENERGY

Probably the most controversial aspects of renewable energy are their apparent cost relative to conventional forms of generation. It is commonly stated that fossil-fueled generation has a lower cost than renewables with, for example, CCGT costing 2–3 p/kW hr while wind costs 4–5 p/kW hr and other renewables more. Fig. 6 shows such a comparison as was carried out for the United Kingdom's Royal Academy of Engineering; these suggest that it would be more economic to invest in gas and nuclear rather than wind and renewables and that the increasing use of renewables will raise electricity prices.[32] There are several critical flaws underlying such interpretations and analyses.

First, the analyses consider the direct costs associated with generation and ignore the social and environmental cost associated with them. The exclusion of these ''external'' costs means that fossil fuels appear cheaper than their true cost. Inclusion of damage costs for SO_2, NO_x, and, importantly, CO_2 makes a large difference even if they might be difficult to predict. Estimates of the ''cost'' of CO_2 vary significantly but £30/tonne—at the lower end—is often used in comparisons such as that in Fig. 6, which is seen to raise coal generating costs by almost 1 p/kW hr.[32]

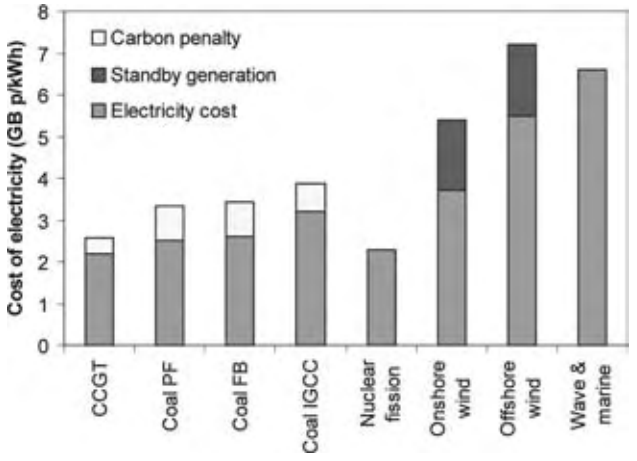

Fig. 6 Levelized electricity cost for generating technologies with/without carbon and standby generation for periods of no wind. (From Ref.[32].) *(View this art in color at www.dekker.com.)*

Second, the issue of subsidy for renewables is often used as an argument against their deployment and development and it should be removed to ''level the playing field.'' It should be remembered that fossil fuels and particularly nuclear power are mature technologies and have benefited from many decades of development and public subsidy. Although hydro is mature, wind is only just approaching maturity and newer renewables like wave and tidal stream are yet to receive significant development funding. As such, expecting these newer technologies to compete directly is not a reasonable or socially responsible approach; once developed subsidy will not be required.

Third, the standard approach of comparing technologies is inappropriate given the diversity of technologies and an increasingly market-orientated power sector. It is common practice to use the discounted cash flow methodology to calculate the levelized unit cost (p/kW hr) of a given technology. It is given by the ratio of the capital and recurring cost stream and the energy output stream, where both streams are discounted at the same rate. The International Energy Agency favors a 7% discount rate while it is common in the United Kingdom to use 8% and 15% to represent nominal state and private sector discount rates. Renewables are, in general, characterized by relatively high capital costs but compensated by low recurring operations and maintenance and zero fuel costs. The use of discounting in this manner means that the full renewable capital costs are seen while the often significant fossil fuel costs are reduced; this automatically biases the outcome in favor of the fossil technology. While nuclear also has large capital costs, discounting

Table 6 Standard and risk-adjusted leveled generation costs

Technology	Standard approach (U.S. cents/kW hr)	Risk-adjusted approach (U.S. cents/kW hr)	(%) Change
Geothermal energy	3.3	3.1	−6
Biomass	2.8	3.2	14
Wind	4	3.6	−10
Large hydro	5	4.7	−6
Nuclear	4	5.5	38
Pulverized coal	3.2	6.7	109
CCGT	3	7.2	140
Solar thermal	11.9	11.1	−6

(From Ref.[33].)

lowers the deferred decommissioning costs to a negligible level—again biasing the outcome.

Historically, the levelized cost methodology was used to compare financially similar alternatives, that of hydro with high capital cost and zero fuel costs and coal with similar capital costs and very low fuel costs. As fuel prices have risen and different technologies have become available the comparison has become less and less appropriate and is creating perverse outcomes. The problem stems from the fact that discount rate is, by definition, a reflection of risk. By applying the same discount rate to each generating technology it implies that the risks for each technology are identical. This is clearly not the case.

A more sophisticated approach is to use risk-adjusted discounted cash flow methods that properly account for the nondiversifiable risk associated with fossil fuel price volatility and the lower diversifiable risk associated with capital projects.[11] Application of this more robust financial analysis leads to a significant change in the costs of technologies. Table 6 suggests that the renewable technologies become slightly less costly while nuclear and fossil fuels, particularly gas, become significantly more expensive (in some cases the cost more than doubles). Furthermore, the cost rank order alters such that, with the exception of solar thermal, renewables become cheaper than the fossil fueled and nuclear options.

CONCLUSIONS

This entry outlines the arguments in favor of developing and deploying renewable energy technologies in terms of its environmental, sustainability, and security benefits. A range of technologies are briefly examined before the difficulties of integrating these variable and often intermittent generating sources are highlighted along with alternative uses for creating new energy vectors and in direct-use applications. Finally, the economics of renewables were explored with reference to the limitations in traditional comparisons with conventional sources.

Reprocessing of Domestic Spent Nuclear Fuel

R

Truman S. Storvick
Chemical Engineering Department, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

The story of nuclear fuel reprocessing begins with the production of weapons grade plutonium. Natural uranium strategically placed in a large block of graphite gives sustained nuclear fission of uranium 235 (^{235}U) with some excess neutrons captured by uranium 238 (^{238}U) to produce plutonium 239 (^{239}Pu). The successful chemical process to isolate nearly pure weapons grade plutonium is the first production-scale nuclear fuel reprocessing. The military program to bridle the rate fission energy is released to power submarines led to domestic nuclear power plants serving electric utilities. It is the spent fuel from these power plants that is the object of domestic spent fuel reprocessing. There are two reasons to consider reprocessing spent nuclear fuel. The mass of radiotoxic material that accumulates using the current ''once through'' nuclear fuel cycle and the thousands of years this spent fuel remains hazardous can both be significantly reduced. Second, a major fraction of the energy content of the natural uranium remains when it is a declared ''spent fuel.'' These fuel values can be recovered and with proposed advanced nuclear reactor designs the mass and burial time for the remaining radioactive waste can be significantly reduced.

BEGINNINGS OF NUCLEAR FUEL PROCESSING

The remarkable story of the development of the nuclear power industry begins when Lise Meitner and Otto Hahn interpreted the capture of neutrons by a uranium atom nucleus (the ^{235}U isotope in natural uranium) followed by spontaneous splitting of the nucleus to form smaller atom nuclei. They called this process fission in their article published in *Nature* on February 6, 1939. The huge energy release by nuclear fission suggested that as each fission produces two or more neutrons, it should be possible to bring together a critical mass of fissionable material that would produce a chain reaction. The resulting explosion would be millions of times more powerful than the energy released by an equal mass of any known chemical explosive.

The curtain of secrecy dropped during World War II and the race to produce this nuclear explosive accelerated. Progress to separate nearly pure ^{235}U from natural uranium was under way, but proving to be very difficult. In January 1941, Seaborg and coworkers reported the discovery of the new element ^{239}Pu with a fission capture cross section greater than ^{235}U, suggesting that it would be an even better explosive.[1] A continuous source of neutrons would produce the ^{239}Pu by neutron capture of the ^{238}U in natural uranium. Chemical separation of ^{239}Pu from the uranium and fission products would be easier than separating the isotopes of natural uranium to produce weapons grade ^{235}U.

The emphasis on production of pure plutonium for weapons continued throughout the Cold War period. The successful control of the chain reaction to power submarines to cruise underwater for weeks rather than hours for the diesel–electric powered substitutes opened up a new option. The contractors that built the nuclear reactors and steam turbines for submarines also served the electric power utilities. Extension of this nuclear technology to domestic electric power production was obvious. President Eisenhower's Atoms for Peace initiative in 1954 opened the way for the nuclear power plants that followed that currently supply about 20% of the electric power to the U.S. power grid.

Plutonium Production by Precipitation

The initial laboratory experiments to isolate plutonium from irradiated uranium were based on precipitation. Plutonium was discovered and first produced by irradiation of uranyl nitrate hexahydrate with neutrons.[1] The Berkeley 60 in. cyclotron provided a 12 meV beam of deuterons directed onto a beryllium target producing neutrons by the (d,n) reaction. Cunningham and Werner showed that LaF_3 precipitate was an efficient plutonium carrier for Pu^{4+} but not Pu^{6+}.[2] This produced the first 2.8 μg pure plutonium metal. A 0.5 μg sample of ^{239}Pu was used to determine the fission cross section.[3] It was about 50% greater than ^{235}U making ^{239}Pu an attractive alternative to ^{235}U as nuclear bomb material.

Microscopic samples were used to determine the half-life of the alpha decay of ^{239}Pu to be $(2.43 \pm 0.12) \times 10^4$ yr compared to the current accepted value of 24,110 yr. The isotopic sequence to plutonium, ^{238}U + neutron (immediate release of gamma energy

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120022535

equal to the binding energy of the neutron), produced ^{239}U (half-life 23 min), which decays to ^{239}Np (half-life 2.4 days), yielding ^{239}Pu (with a half-life of 24,110 yr). The oxidation states of plutonium were determined using submicrogram quantities of plutonium and α-particle counting with samples too small for chemical analysis.

Fermi's Stagg Field demonstrated in 1942 that a properly configured graphite pile fueled with natural uranium produced a sustained fission reaction necessary to produce plutonium by neutron capture by ^{238}U.[4] This nuclear reactor demonstration promoted plutonium production to the fast track. The decision to build the Hanford plutonium production facility was made using an unprecedented engineering scale factor of about 10^9 going from micrograms to kilograms of Pu and reactor thermal energy release from watts to megawatts.

The design of the production-scale reactor began before the chemical isolation of plutonium was known. Eugene Wigner, an accomplished theoretical physicist who studied engineering in Europe, led the group that designed the nuclear pile, which became the Hanford reactor.[5] It was Wigner's computational procedures that were used to fix the dimensions of the graphite moderator, the distribution of the uranium metal fuel elements, and selected water to cool the reactor. Crawford Greenewalt, the leading engineer for the Du Pont Company in charge of plutonium production, played an important role in this project when everything was new and untried with enormous pressure to speed the project to completion.

Each of the Hanford reactors was a 28 (diameter) by 36 ft long pure graphite cylinder on its side, over 1200 tons of graphite. More than 2000 holes passed though the faces of the graphite and these were lined with aluminum tubes. About 250 tons of cylindrical uranium slugs encapsulated in aluminum were placed in the tubes in the graphite pile with control rods strategically located among the uranium fuel load. The aluminum tubes were also cooling water channels that removed approximately 250,000 kW of thermal energy. The nuclear pile was run for 100 days, a time that transmuted about one out of 4000 ^{238}U atoms to plutonium. The fuel slugs were pushed out of the graphite pile by fresh fuel and dropped into a pool of water that provided shielding from the intense radiation. After 60 days, the irradiated slugs were moved to chemical separation.

The laboratory methods for recovering and purifying plutonium were not suited for large-scale production. The ether extraction used on the cyclotron-produced plutonium is a safety hazard. The lanthanum fluoride precipitation step yielded a gelatinous product that is difficult to process and the aqueous fluorides produced serious equipment corrosion. Other processes were investigated, but precipitation was selected as the best alternative for quick development when early in 1943, S.G. Thompson showed that $BiPO_4$ precipitate would strongly carry Pu^{4+}.[6] The $BiPO_4$ precipitate is crystalline and easily collected by filtration or with a centrifuge. The crystals readily dissolve in strong nitric acid. This process was selected to recover plutonium from the irradiated uranium fuel from the Hanford graphite pile reactors.[7]

The aluminum cladding was removed and the fuel elements dissolved in nitric acid and treated with $NaNO_2$ to reduce the plutonium to Pu^{4+}. Sulfuric acid was added to complex the uranyl nitrate to prevent it from precipitating with the plutonium. The $BiPO_4$ precipitate carried essentially all the plutonium while most of the fission products and the U^{6+} remained in solution in this extraction step. The centrifuged precipitate was dissolved in nitric acid and $NaBiO_3$ added as an oxidant and a source of bismuth. The oxidized plutonium, Pu^{6+}, remains soluble and the fission products carried by the $BiPO_4$ precipitate were removed.

The sequence: plutonium reduction, $BiPO_4$ plutonium precipitation, oxidation of the plutonium to dissolve the precipitate, and precipitate by-products was repeated three times.[8] The final by-product precipitation with $BiPO_4$ was followed by a by-product precipitation with LaF_3 to remove traces of fission products and uranium. The Pu^{6+} in solution was reduced and precipitated with LaF_3 for the final Pu^{4+} precipitation. This precipitate was treated with KOH to give a mixture soluble in HNO_3. Two precipitation steps with H_2O_2 separated the plutonium and lanthanum with the product plutonium dissolved in nitric acid. The overall decontamination factor for this batch process was 10^7 with 97–98% plutonium recovery. This solution was processed to obtain PuO_2, which was reduced to metal and further refined to weapons grade plutonium.

CONTINUOUS PROCESS FOR PLUTONIUM PRODUCTION

Early consideration was given to developing a continuous process to produce weapons grade plutonium. Countercurrent extraction was an advanced chemical engineering technology but the equipment is complex and remote operation and maintenance required by radiation shielding made the first choice batch precipitation process. Following World War II and moving into the Cold War period, plutonium production remained a high priority and the Purex (plutonium uranium reduction extraction) was developed for processing irradiated uranium fuel.[9,10]

The Purex process feed was the uranium slugs irradiated from the graphite pile reactors. The aluminum

cladding on the irradiated uranium slugs was removed and the uranium dissolved in nitric acid. The solution contains uranium as uranoyl nitrate, $UO_2(NO_3)_2$, and plutonyl nitrates with the plutonium in both the tetravalent and the hexavalent states. Most of the fission products go into solution, but solid fines form when solubility limits are exceeded and were removed.

Design of nuclear fuel processing equipment must avoid any possibility of fissionable material producing a chain reaction.[11] The concentration and purity of fissile material contained in solution, ^{235}U and ^{239}Pu in particular; location of equipment materials that serve as neutron reflectors, moderators, and poisons; equipment shape; and volume are the key equipment design parameters. The plant must be designed to provide radiation shielding and prevent release of radioactive material to the surroundings. Equipment design and an operator culture that always follows approved process procedures are required to ensure safe reprocessing plant operation.

The dissolved metals and the extractor upstream wash waters are combined and analyzed. The uranium and plutonium concentrations are used to adjust the pH of the solution to optimize the separation from the fission products. Solutions about 1 M in uranium and plutonium and 2–3 M HNO_3 were the feed for the extraction.

Tributyl phosphate (TBP) is the most versatile agent for the extraction of uranium and plutonium from fission products and also for separation of plutonium from uranium. A 30% solution of TBP in normal hydrocarbons is the usual organic phase in the Purex process. The U and Pu are extracted by TBP as unionized complexes, free of hydration water, and solvated by a definite number of TBP molecules. The complex-forming reactions proceed according to the following:[12]

$$UO_2^{2+}(aq) + 2NO_3^-(aq) + 2TBP(org) \rightarrow UO_2(NO_3)_2 \cdot 2TBP(org)$$

$$PuO_2^{2+}(aq) + 2NO_3^-(aq) + 2TBP(org) \rightarrow PuO_2(NO_3)_2 \cdot 2TBP(org)$$

$$Pu^{4+}(aq) + 4NO_3^-(aq) + 2TBP(org) \rightarrow PuO_2(NO_3)_4 \cdot 2TBP(org)$$

The initial countercurrent extraction stages transfer the U and Pu to the organic or TBP phase with the fission products and the higher actinides remaining in the aqueous phase. Beyond the feed point, the organic phase continues to extraction stages where it is scrubbed with acid to remove traces of the fission products. Americium and curium in the +3 state stay in the aqueous phase. Neptunium is partially in the +6 (extractable) and the +5 state, so it splits between the organic and the aqueous phases. Careful control of the solution pH and metal ion concentration maintains the plutonium in the +4 state leading to essentially complete extraction of the plutonium and uranium values into the organic phase.

Solvent degradation by radiation damage is a problem during the initial separation, so the temperature is kept low and centrifuge extraction units minimize the contact time between the aqueous and organic phases.[9] The aqueous raffinate containing the fission products is processed to reduce the water content and recover nitric acid values. Volatile radioactive fission products released during extraction must be contained for disposal. This fission product stream accumulated during military production of weapons grade plutonium and the selection of a final form for permanent disposal is still pending. Weapons grade plutonium production is the source of most of the legacy wastes.

Separation of plutonium from the uranium in the TBP phase proceeds by countercurrent stripping of the plutonium into dilute nitric acid, which reduces the Pu to the Pu^{3+} soluble species. The uranium remains in the organic phase. This countercurrent stripping section is followed by a scrubbing section that completes the removal of the plutonium from the uranium held in the TBP phase.

Plutonium purification proceeds by reducing the aqueous phase pH that oxidizes the plutonium to Pu^{4+}, which then extracts into the TBP phase. Impurities stay in the aqueous phase. The TBP phase stripping/extraction cycle is repeated to complete the plutonium purification. The uranium is purified using the same TBP/nitric acid extraction/stripping cycle. Careful control of the each element's oxidation state in the extraction cascade produces the plant-scale separations of uranium from plutonium of 10^6. Fission product decontamination factor was 10^8. The plutonium and uranium recovery is about 99.9% with 95% of the nitric acid values and 99.7% of the organic solvent recycled.[12]

An advantage of the Purex process is the low salt content of the aqueous waste stream so the liquid volume can be reduced by evaporation. The HNO_3 values are recycled to the process. The Purex process produces nearly pure plutonium and recovers uranium and it is the process that has been adapted to treat domestic spent nuclear fuel.

CHARACTERIZATION OF DOMESTIC NUCLEAR FUEL

There are two major sources of radioactive materials in the United States that must be isolated to protect the public. The spent nuclear fuel accumulating at each of more than 100 power plant sites is the largest source.

Second is the Department of Defense legacy wastes, residues from weapons production, and the experimental nuclear reactor experiments to produce military nuclear power systems. These wastes are a heterogenous mix of solids and liquids, each requiring special handling and processing designed to reduce the total mass and isolate the radioisotopes for safe storage. Military legacy wastes require special treatment.

Nuclear power plants in the United States use light water moderated nuclear reactors (LWR) that produce the steam to generate electricity. The fuel elements for boiling water reactors and pressurized water reactors (PWR) are nearly the same. The fuel is uranium dioxide enriched with 3–4% ^{235}U and this produces a nearly uniform spent fuel, which would be the feed for domestic fuel reprocessing.

Ceramic UO_2 fuel pellets are machined to uniform size cylinders [1.26 cm (diameters) $\times$ 1.26 cm (length)], placed in zircaloy tubes about 4 m long, pressurized with helium, and sealed with free space at the top and bottom to collect fission product gases.[13] The tubes are set in fuel bundles with 15 $\times$ 15 or 17 $\times$ 17 arrays supported by end plates and intermediate spacers to secure each tube in a fixed position. The PWR fuel bundles provide flow channels for cooling water and the stable geometry ensures the neutron path length and moderates the neutrons to the thermal energy range necessary to sustain fission. Some of the grid positions are used for instrumentation and control rods. Each fuel assembly weighs about 658 kg and contains 523 kg of UO_2 (461 kg of U metal).[14] The total fuel loading varies with the reactor design, so for a PWR the core loading may be between 80 and 120 metric tons of the fuel. A fuel bundle stays in the reactor between 3 and 4 yr and the spent fuel is stored in water pools located on the power plant site. This is the current once through fuel cycle for all U.S. reactors.

There are more than 45,000 MTIHM [metric tons (tons) of initial heavy metal—actinides—elements with atomic number greater than 89] of spent nuclear fuel in storage and it is accumulating at the rate of about 2000 tons/yr. Without reactor operating license extensions for the reactors in service, the nuclear power production in the United States will end in about 2030 with the spent fuel inventory approaching 87,000 MTIHM. The current mandated limit for the Yucca Mountain repository is 63,000 MTIHM. Additional spent fuel storage will be required or there must be fuel reprocessing to meet the Yucca Mountain storage limit.

Irradiated uranium fuel elements contain fission product isotopes, activation products produced by atoms exposed to the intense neutron, α, β, and γ radiation in the reactor core, and actinides, produced by neutron capture of the nuclei of atoms with atomic number in the actinide series. The spent fuel assemblies are stored in water pools for γ-radiation shielding and the water is the heat sink for the thermal energy release from radioactive decay. Boron ions added to the water absorb decay neutrons.

Three characteristics of irradiated LWR low-enriched uranium spent fuel that are significant in fuel reprocessing are the total mass of the fission products and the transuranic elements, the thermal energy released by spontaneous radioactive decay that requires cooling, and the neutron and γ radiation released that requires biological shielding. The irradiation time and intensity when the fuel is in the reactor determine the isotopic composition of the spent fuel. There are more than 350 nuclides in the fuel immediately following reactor shutdown.[15] Many of these have very short half-lives that quickly follow a spontaneous decay sequence to more stable nuclides.[16] The total mass of all the isotopes remains essentially constant, but the rate of thermal energy release and the radiation intensity decrease as the spent fuel ages. Table 1 lists the major radioactive isotopes that require transmutation or long-term storage.

DOMESTIC FUEL REPROCESSING

The Purex process is the only one with commercial-scale operating history. This military technology has been modified to treat domestic spent nuclear fuel. The focus of international commercial efforts to reprocess domestic spent fuel is to recover uranium and plutonium in the spent fuel.

Table 1 Major components in LWR of spent nuclear fuel

Major components
955.4 kg U
8.5 kg Pu (5.1 kg ^{239}Pu)
Minor actinides
0.5 kg ^{237}Np
0.6 kg Am
0.02 kg Cm
Long-lived fission products
0.2 kg ^{129}I
0.8 kg ^{99}Tc
0.7 kg ^{93}Zr
0.3 kg ^{135}Cs
Short-lived isotopes
1.0 kg ^{137}Cs
0.7 kg ^{90}Sr
Stable isotopes
10.1 kg lanthanides
21.8 kg other stable isotopes

Basis, 1 metric ton, irradiation, 33,000 MWD/MT, 10 yr cooling. (From Ref.[17].)

The extended radiation time for the domestic fuel increases the quantity of fission products and the higher actinides. Pure plutonium product poses nuclear weapons proliferation risk and is the primary reason reprocessing is not practiced in the United States. The modified PUREX process has been practiced on an industrial scale in Europe and supports the production of mixed uranium–plutonium fuel. Blended UO_2 and PuO_2 powder is compacted and sinter to form the mixed oxide (MOX) fuel pellets much like the enriched UO_2 fuel. Natural and depleted uranium can be used to prepare MOX fuel and is the demonstrated option to recover fuel values from spent fuel.

Decladding the fuel pellets is the first step in domestic fuel reprocessing.[18,19] A practical method is to chop the fuel bundles into short lengths, 2.5–5.0 cm long, so that the metal oxide fuel pellets can be dissolved in strong nitric acid. The helium, which is in each fuel pin, and about 10% of the fission product gases are released during this step. The chopped material can be oxidized in a kiln to produce U_3O_8 from the UO_2. This increases the solid volume that pulverizes the ceramic fuel and releases occluded gases, and the tritium oxidizes to tritium water. Off-gas treatment must be in place to retain dust and collect the iodine, krypton, xenon, and tritium water that are released.

The second step is to dissolve the metal oxide fuel using strong nitric acid. The object is to bring all the fission products, uranium, and transuranics, into solution to feed the extraction process. Some of the fission products exceed solubility limits and the fine solids formed must be removed before extraction. Provisions to recover nitrogen oxides and collect gaseous fission products released during this step must be in place. The stainless steel and zircaloy fuel jackets from the fuel assemblies do not dissolve and are separated from the solution, washed, checked for radioactivity, and packaged for disposal as low-level radioactive waste.

The classic Purex process produces pure uranium and plutonium from the feed solution. The Purex waste stream contains the fission products and the other actinides totaling about 4% of the heavy metal content of the spent fuel. Reagents that form solids are avoided because they increase the mass of the waste stream to long-term storage. The actinides have very long half-lives that increase the solid waste storage time. Fission products that produce thermal energy complicate the waste storage problem. The high-energy γ radiation always requires shielding for handling, transporting, and storing the solid wastes. Technical, social, and political solutions to the spent fuel-storage problem remain even if there is no long-term future for nuclear energy. Plans to expand use of nuclear energy must also address the accumulated spent fuel inventory as new reactor fuel cycles evolve.

NUCLEAR ENERGY FUTURE

Sustainability is the keyword in discussions of the energy future to meet increasing global demands for thermal energy and electricity. There is a general international agreement that nuclear energy will play a role in supplying future energy demand. Nuclear power is the only technology now available that can produce economic, base load quantities of electricity without emitting pollutants associated with global climate change. About one-fifth of the U.S. electric power is now produced economically, safely, and reliably by nuclear power plants. The next 50 yr will see the end of the operating licenses of these reactors and that generating capacity must be replaced. Finding an acceptable and safe way to dispose of the spent nuclear fuel that remains radiotoxic for several hundred thousand years represents a serious open technical issue that must be addressed.

The National Energy Policy of 2000 includes initiatives that recommend deployment of additional nuclear power plants. This policy calls for expanded international cooperation to develop advanced technologies to improve reactor thermal efficiencies, recover fuel values remaining in spent nuclear fuel, and improve processing of fission products to reduced isolation times for repository disposal. The Advanced Fuel Cycle Initiative under the Department of Energy has been approved.[20] The task includes optimizing the cost and performance of the Yucca Mountain spent fuel repository, providing nuclear weapons proliferation resistant recovery of energy contained in spent fuel, and supporting the development of Generation IV nuclear reactor systems. Reduction in the volume of radioactive waste for burial and new reactor designs to fission or transmute the long-lived radioisotopes are the major objectives of this effort. Separation processes that isolate long-lived isotopes are the key to spent fuel management. Combining separation with new generation reactors that produce energy as they fission or transmute the long-lived isotopes is an important long-term goal. The World Nuclear Association web site provides current information on international nuclear research, technology, economics, and power plants under construction.

Proposed Generation IV Reactors

The international group has identified six Generation IV reactor systems for development.[21] All of these reactors should be ready for deployment by 2030. The fast neutron spectrum reactors can use the fuel values of all of the fissile and fertile transuranic isotopes in reprocessed fuel. This does not occur in the current thermal spectrum reactors. Producing energy

by fission of the transuranics rather than treating them as waste significantly reduces the long-term waste storage problem.

There are three fast-flux reactors proposed for development: the sodium cooled, the gas cooled, and the lead cooled. The fission cross sections for fast neutrons (high-energy spectrum neutrons) for all of the fissile actinides are nearly the same so the fast-flux reactors use all of the fissile actinides as fuel. The fast-flux isotopic fission cross sections are smaller than for thermal neutrons so the fraction of fissile isotopes (e.g., ^{235}U, ^{239}Pu, ^{241}Pu) in the fuel must be in the range of 10–20%.[22] The fertile isotopes (e.g., ^{238}U, ^{240}Pu, ^{242}Pu) have fast-flux neutron capture cross sections that are also high so neutron capture produces additional fissile material. Using these long-lived isotopes as fuel removes them from the waste stream. Converting fertile isotopes to fissile adds to the energy produced and is the practical way to use all of the natural uranium as fuel.

Liquid metal cooled reactor development began during the mid-1940s. Early experimental reactors led to the Experimental Breeder Reactor-II (EBR-II) designed to include complete on-site fuel reprocessing, fuel fabrication, and electricity generation. Experimental Breeder Reactor-II went critical in 1963 with metallic alloy fuel pins in stainless steel jackets cooled by liquid sodium circulated through a heat exchanger to produce steam.[23] During the 30 yr the reactor was in service, it was the test bed for new fuel assemblies for advanced reactor systems. The inherent safety of the EBR-II was demonstrated with the reactor coasting to shut down without operator intervention with safety systems off or with a total loss of coolant. The fuel cycle facility processed over 30,000 fuel elements and produced more than 300 subassemblies. New fuel irradiation tests were part of the experimental program. Initially designed as a fuel breeder reactor, it was successfully converted to a plutonium burner reactor. The EBR-II program produced much of the technical data that inform the fast-flux Generation IV reactor designs.

The thermal and nuclear properties of sodium (it scatters neutrons without absorbing them) made it the heat exchange fluid of choice for fast-flux reactors in spite of its nasty chemical properties when exposed to air or water. The French Superphenix, a commercial-scale sodium cooled reactor, was beset with technical problems, but demonstrated that fast-flux reactors can produce electric power at the 1000 MW level.

Liquid lead cooled reactors have been demonstrated by the Russian nuclear community. Lead has a higher melting point than sodium, an advantage for a reactor to operate at high temperature. At these higher temperatures, lead is corrosive to the steel structures and other metal components in the reactor core. Material selection and development are required for full deployment of this technology.

Helium cooling was seriously considered in 1943 for the Hanford plutonium production piles.[5] Helium cooled fast-flux reactors may be the first Generation IV reactors deployed.[20] The fuel forms are designed to operate at temperatures greater than 850 °C and they must contain the fission products. Candidates include composite ceramic fuel, advanced fuel particles, or ceramic clad elements of actinide compounds. The reactor core configuration might be based on prismatic blocks, pins, plates, or spheres. Electricity would be generated using a direct cycle gas turbine and compressor in a Brayton cycle. High-temperature thermal energy could be used for chemical processing such as production of hydrogen.

The fast-spectrum reactors with full recycle of actinides would be designed with on-site spent fuel reprocessing and fuel fabrication to minimize the on-site inventory of long-lived radioactive waste. Modern robotic equipment can be used for reactor refueling and for fuel reprocessing. The spent fuel reprocessing and fuel fabrication facilities must be developed to close the nuclear fuel cycle and use all the energy available in natural uranium.

Reprocessing Advanced Spent Fuel

The classical Purex process was designed to produce nearly pure uranium and plutonium. The Chemical Engineering Division of Argonne National Laboratory has demonstrated UREX+, an advanced aqueous process with five extraction trains that split commercial reactor spent fuel into five streams: 1) a nearly pure uranium stream (95.5% of the heavy metal in the spent fuel); 2) technetium sent to transmutation (0.08%); 3) Pu/Np converted to MOX fuel for LWR fuel and Am/Cm for transmutation or fast-flux reactor fuel (0.962%); 4) Cs/Sb decay heat producers sent to interim decay storage (0.017%); and 5) a mixed fission product stream (3.44%) composed of gases and solids incorporated into a waste form for geological repository disposal.[24] The percentages shown are computed from Table 1.

Developments during the EBR-II program included dry (nonaqueous) electrochemical separation of uranium (relatively high-enriched ^{235}U) from the spent fuel. These metallic fuel elements were chopped into an anode basket, submerged in molten salt (LiCl/KCl eutectic) and the uranium electrochemically deposited on an inert metal cathode. The stainless steel fuel casings, the salt containing the higher actinides, and fission products were immobilized (glassified) for disposal.

Recent advances on pyrometallurgical technology have shown that metallic reactor fuel can be processed

using reductive extraction between the salt phase (adding Li to reduce the metal chloride) and collecting the metals as an alloy of cadmium or bismuth.[25] The liquid metal alloy becomes the anode in an electrochemical cell collecting the mixed actinides metals on an inert cathode. Remote processing of highly radioactive, ''young'' spent fuel is possible because there is no radiation damage to the inorganic solvents.

Development of a one-step electrochemical process to reduce LWR spent fuel (UO_2) to metallic form is under development at Argonne National Laboratory.[26] The transuranic metals are separated by pyroprocessing technology. This reduces waste that requires repository disposal. The transuranic metals could be cast into fuel suitable for the Generation IV reactors or transmuted reducing them to fission products.

Economic factors will certainly impact the future of nuclear power. Members of the University of Chicago Department of Economics and the Harris School of Public Policy participated in a detailed study of the economic factors affecting the future of nuclear power.[27] In the long term nuclear power can be competitive with other sources given initial financial incentives.

CONCLUSIONS

In the 60 yr since discovery, plutonium is the most studied element and it will be the key to unlocking uranium as an energy source into the future.[28] It is only 50 yr since nuclear power was introduced. Commercial power plants use 1970s reactor technology. It is anticipated that the technical problems of nuclear fuel reprocessing and Generation IV nuclear reactor deployment can be solved. The Department of Energy Nuclear Power 2010 program represents a government–industry study designed to map strategy for the future of nuclear power.

The University of Chicago study has shown that advanced nuclear power production can be economically competitive with fossil fuel plants. The second 50 yr of nuclear power can be a period when research provides answers to safe nuclear power production and safe disposal of the nuclear wastes. The remarkably rapid development of nuclear science and technology in the 1940s can now proceed at a slow, deliberate pace. The technical research must be followed by government–industry cost-shared reactor deployment program. The initial economic barrier of capital funds for new facilities plus the extra engineering and financing costs that come with building and operating the expensive first-of-a-kind new nuclear plants must be shared. The national and international economics, culture, and politics will shape the path to future energy sources. Remember to train the next generation of nuclear scientists and technologists that can make it happen.

ACKNOWLEDGMENT

The hospitality and encouragement of the Chemical Engineering Department faculty made this work possible.

Resid Conversion

James G. Speight
CD & W Inc., Laramie, Wyoming, U.S.A.

INTRODUCTION

A residuum (pl. residua, also shortened to resid, pl. resids) is the residue obtained from petroleum after nondestructive distillation has removed all the volatile materials. The temperature of the distillation is usually maintained below 350°C (660°F) because the rate of thermal decomposition of petroleum constituents is minimal below this temperature but the rate of thermal decomposition of petroleum constituents is substantial above 350°C (660°F). If the temperature of the distillation unit rises above 350°C (660°F), as happens in certain units where temperatures up to 395°C (740°F) are known to occur, cracking can be controlled by adjustment of the residence time. This entry introduces some of the basic chemistry behind the synthesis and conversion processes.

DEFINITION

Residua are black, viscous materials and are obtained by the distillation of a crude oil under atmospheric pressure (atmospheric residuum) or under reduced pressure (vacuum residuum, 25–100 mm Hg). They may be liquid at room temperature (generally atmospheric residua) or almost solid (generally vacuum residua) depending on the nature of the crude oil. Resids have high molecular weights (usually in excess of 800 number average molecular weight for vacuum resids) and they contain polynuclear aromatic compounds as well as heteroatom compounds of nitrogen, oxygen, and sulfur. Metal compounds also occur in residua.

When a residuum is obtained from crude oil and thermal decomposition has commenced, it is more usual to refer to this product as pitch. The differences between conventional petroleum and the related residua are due to the relative amounts of various constituents present, which are removed or remain by virtue of their relative volatility.

The chemical composition of a residuum is complex. Physical methods of fractionation usually indicate high proportions of asphaltenes and resins, even in amounts up to 50% (or higher) of the residuum. In addition, the presence of ash-forming metallic constituents, including such organometallic compounds as those of vanadium and nickel, is also a distinguishing feature of residua and the heavier oils. Furthermore, the deeper the cut into the crude oil, the greater the concentration of sulfur and metals in the residuum and the greater the deterioration in physical properties.

It is the polynuclear aromatic system and the heteroatom species that pose the greatest limitation to resid conversion. The polynuclear aromatic and heteroatom species: 1) have high thermal stability; 2) poison catalysts by deposition of heteroatoms and metals; and 3) readily form coke that deposits on the catalyst and detracts from liquid production.

Conversion Chemistry

Understanding the chemical transformations of the macromolecules that occur in resids during conversion is greatly limited by the wide diversity (over a million chemical structures) of these complex macromolecules.

Therefore, in a mixture as complex as petroleum, the reaction processes can only be generalized because of the difficulties in analyzing not only the products but also the feedstock as well as the intricate and complex nature of the molecules that make up the feedstock. The formation of coke from the higher molecular weight and polar constituents of a given feedstock is detrimental to process efficiency and to catalyst performance. One method by which the process chemistry can be rationalized is to separate the resid and its conversion products into fractions using solubility/insolubility in volatile liquids as well as adsorption/desorption on solids. In this way a number of resids and resid conversion products were separated into coke (toluene insoluble), asphaltenes (toluene soluble/*n*-heptane insoluble), resins (*n*-heptane soluble, adsorbs on alumina), aromatics (*n*-heptane soluble, does not adsorb on alumina), and saturates (*n*-heptane soluble, does not adsorb on alumina).

The asphaltene constituents produce the highest amount of coke (relative to the other fractions of the resid). The formation of a coke-like substance during resid upgrading is dependent on several factors: 1) the degree of polynuclear condensation in the feedstock; 2) the average number of alkyl groups on the polynuclear aromatic systems; and 3) the hydrogen-to-carbon atomic ratio of the pentane-insoluble/heptane-soluble fraction.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120022536

Nitrogen species also appear to contribute to the pattern of the thermolysis. For example, the hydrogen or carbon–carbon bonds adjacent to ring nitrogen undergo thermolysis quite readily, as if promoted by the presence of the nitrogen atom. If it can be assumed that heterocyclic nitrogen plays a similar role in the thermolysis of asphaltenes, the initial reactions, therefore, involve thermolysis of aromatic-alkyl bonds that are enhanced by the presence of heterocyclic nitrogen. An ensuing series of secondary reactions, such as aromatization of naphthenic species and condensation of the aromatic ring systems, then lead to the production of coke. Thus, the initial step in the formation of coke from asphaltenes is the formation of volatile hydrocarbon fragments and nonvolatile heteroatom-containing systems.

The prevalent thinking is that the asphaltene nuclear fragments become progressively more polar as the paraffinic fragments are stripped from the ring systems by scission of the bonds (preferentially) between the carbon atoms alpha and beta to the aromatic rings. The polynuclear aromatic systems that have been denuded of the attendant hydrocarbon moieties are somewhat less soluble in the surrounding hydrocarbon medium than their parent systems. Two factors are operative in determining the solubility of the polynuclear aromatic systems in the liquid product. The alkyl moieties that have a solubilizing effect have been removed and there is also enrichment of the liquid medium in paraffinic constituents. There is an analogy with the deasphalting process, except that the paraffinic material is a product of the thermal decomposition of the asphaltene molecules and is formed in situ rather than being added separately.

In this model, there are four common features that apply to resid conversion and these features are: 1) an induction period prior to coke formation; 2) a maximum concentration of asphaltenes in the reacting liquid; 3) a decrease in the asphaltene concentration that parallels the decrease in heptane-soluble material; and 4) the high reactivity of the unconverted asphaltenes. Thus, the model can be represented as:

$$\mathrm{H}^{+} = a\mathrm{A}^{*} + (1 - a)\mathrm{V} \qquad \text{reaction constant } k_{\mathrm{H}}$$

$$\mathrm{A}^{+} = m\mathrm{A}^{*} + n\mathrm{H}^{*} + (1 - m - n)\mathrm{V}$$

reaction constant k_{A}

$$\text{Solubility limit: } \mathrm{A}^{*}_{\mathrm{max}} = S_{\mathrm{L}}(\mathrm{H}^{+} + \mathrm{H}^{*})$$

$$\mathrm{A}^{*}_{\mathrm{ex}} = \mathrm{A}^{*} - \mathrm{A}^{*}_{\mathrm{max}}$$

$$\mathrm{A}^{*}_{\mathrm{ex}} = (1 - y)\mathrm{TI} + y\mathrm{H}^{*}$$

where a is a stoichiometric coefficient; A^{+}, reactant asphaltenes; A^{*}, asphaltene cores; $\mathrm{A}^{*}_{\mathrm{max}}$, maximum asphaltene cores that can be held in solution; $\mathrm{A}^{*}_{\mathrm{ex}}$, excess asphaltene cores beyond what can be held in solution; H^{+}, reactant, nonvolatile heptane-soluble materials; H^{*}, product, nonvolatile heptane-soluble materials; k_{A}, first-order reaction rate constant for reactant asphaltene thermolysis (min^{-1}); k_{H}, first-order reaction rate constant for the thermolysis of reactant heptane-soluble materials (min^{-1}); m, stoichiometric coefficient; n, stoichiometric coefficient; S_{L}, solubility limit (wt%/wt%); TI, toluene-insoluble coke; and V, volatile materials. The first two parallel first-order reactions for the thermolysis of unreacted heptane-soluble materials and unreacted asphaltenes are the only reactions that occur during the coke induction period.

Conversion Processes

Resid processes can be made up of combinations of separations, thermal conversion, hydroconversion or hydrotreating, and fluid catalytic cracking. Distillation is the most common separation choice because of its low cost. However, fuel deasphalting is becoming more popular because it can separate the saturate constituents and small ring aromatics out of resids. Nevertheless, the selection of the conversion process depends on the quality of the resid or the selection of the crude for the refinery depends on the resid conversion process. Resids high in saturates and small ring aromatics and low in resins and asphaltenes are more appropriate for catalytic processing. On the other hand, resids high in resins and asphaltenes are more suited for coking.

Visbreaking

Visbreaking is a relatively mild thermal (noncatalytic) cracking process that is used to reduce the viscosity of residua. A visbreaker reactor may be similar to a delayed coker with a furnace tube followed by a soaker drum. However, the drum is much smaller in volume to limit the residence time with the entire liquid product flowing overhead. Alternatively, the entire visbreaker may be a long tube coiled within a furnace. Coke formation can occur and the coke accumulates on visbreaker walls; periodic decoking (cleaning) is necessary.

The visbreaking process uses the approach of mild thermal cracking to improve the viscosity characteristics of a residuum without attempting significant conversion to distillates. Low residence times are required to avoid gas and coke production and the hot liquid is quenched as it exits the reactor. Visbreaking conditions range from 450°C (840°F) to about 510°C (950°F) at the heating coil outlet with pressures varying from 50 to 300 psi. There are a number of different configurations for visbreaking units that depend on the product slate and refinery requirements.

In general, the resid is passed through a furnace where it is heated to a temperature of 480°C (895°F) under an outlet pressure of about 100 psi. The heating coils in the furnace are arranged to provide a soaking section of low heat density, where the charge remains until the visbreaking reactions are completed. Cracking is initiated in the liquid phase and continues in the reaction chamber and the cracked products are then passed into a flash-distillation chamber. The overhead material from this chamber is then fractionated to produce a low-quality gasoline as an overhead product and light gas oil as bottoms.

The reactions are not allowed to proceed to completion; the hot liquid reaction mix is quenched by the addition of light gas oil and then sent to a vacuum fractionator. This yields a heavy gas oil distillate and a residuum of reduced viscosity. Quench oil may also be used to terminate the reactions. An alternative process design uses lower furnace temperatures and longer reaction (contact) time, which is achieved by installing a soaking drum between the furnace and the fractionator. The disadvantage of this approach is the high potential for coke deposition in the soaking drum and the subsequent need to remove the coke.

The reduction in viscosity of distillation residua tends to reach a limiting value with conversion, although the total product viscosity can continue to decrease. The minimum viscosity of the unconverted residue can lie outside the range of allowable conversion if sediment begins to form. When shipment of the visbreaker product by pipeline is the process objective, addition of a diluent such as gas condensate can be used to achieve a further reduction in viscosity.

Conversion of residua in visbreaking follows first-order reaction kinetics. The minimum viscosity of the unconverted residue can lie outside the range of allowable conversion if sediment begins to form. When pipelining of the visbreaker product is the process objective, addition of a diluent such as gas condensate can be used to achieve a further reduction in viscosity. However, the main limitation of the visbreaking process, and for that matter all thermal processes, is that the products can be unstable. Thermal cracking at low pressure gives olefins, particularly in the naphtha fraction. These olefins give a very unstable product, which tends to undergo secondary reactions to form gum and intractable residua. Modification of visbreaking (thermal) chemistry is possible and more stable products are produced by application of the hydrogen donor solvents as in the hydrogen donor visbreaking process. There also remains the (potential) issue of sediment disposal, especially when the sediment is too contaminated for further use.

Important variables in the visbreaking process include temperature, pressure, and residence time. Any one variable can be changed (within predetermined limits) to alter the product slate. For example, raising the heater outlet temperature increases the yield of distillates and gaseous products.

Coking

Coking is a thermal process for the continuous conversion of resids into lighter products. The feedstock can be reduced crude, straight-run residua, or cracked residua, and the products are gases, naphtha, fuel oil, gas oil, and coke. The gas oil may be the major product of a coking operation and serves primarily as a feedstock for catalytic cracking units. The coke obtained is usually used as fuel, but processing marketing for specialty uses, such as electrode manufacture, production of chemicals, and metallurgical coke, is also possible and increases the value of the coke. For these uses, the coke may require treatment to remove sulfur and metal impurities.

In the coking processes the resid is heated to high temperatures (450–500°C) with the light boiling products distilling overhead and leaving the solid coke behind. Coking is the most popular conversion choice for resids as it reactively separates the polynuclear aromatic systems and the heteroatoms) into a low-value by-product (coke) that is counterbalanced by an increase of hydrogen content in the liquid product.

The yield of coke in a given coking process tends to be proportional to the carbon residue content of the feed (measured as the Conradson carbon residue), which is, in turn, related to the atomic hydrogen/carbon ratio.

Delayed Coking

The delayed coking process is the oldest and the most popular choice for resid upgrading. It is a semicontinuous process that can be applied to the conversion of most types of resids and residua.

The feedstock is introduced into a furnace whose outlet temperature varies from 480°C to 515°C (895–960°F). The heated feedstock enters one of a pair of coking drums where the cracking reactions continue. The cracked products leave as overheads and the coke deposits form on the inner surface of the drum. To give continuous operation, two drums are used; while one is on steam, the other is being cleaned. The temperature in the coke drum ranges from 415°C to 450°C (780–840°F) at pressures from 15 to 90 psi. Overhead products go to the fractionator, where naphtha and heating oil fractions are recovered. The heavy recycle material is combined with preheated fresh feed and returned to the reactor.

The coke drum is usually onstream for about 24 hr before becoming filled with porous coke. The following

procedure is used to remove the coke: 1) the coke deposit is cooled with water; 2) one of the heads of the coking drum is removed to permit the drilling of a hole through the center of the deposit; and 3) a hydraulic cutting device that uses multiple high-pressure water jets is inserted into the hole and the wet coke is removed from the drum. Normally, 24 hr is required to complete the cleaning operation and to prepare the coke drum for subsequent use onstream.

The Selective Yield Delayed Coking (SYDEC) process allows adjustment of the yields of coke and liquid products by adjusting the temperature. For example, increasing the temperature increases the yield of liquid products and the gas oil end point. Increasing the pressure and/or the recycle ratio increases the gas yield and the coke yield whereas the yield of liquid product and the gas oil end point are decreased.

Fluid Coking and Flexicoking

Fluid coking is a continuous process that employs the fluidized solids technique for the conversion of heavy low-grade feedstocks to lighter, more valuable products. The feedstocks charged to a fluid coker may be any type of resid or residuum where the carbon residue falls into the range 5–50 wt% or those materials having an API gravity less than 20.

The feedstock is sprayed onto a fluidized bed of hot coke particles that are agitated by the gaseous products rising through the bed in the reactor. The fluidized solids technique permits the use of higher temperatures (than delayed coking) but without the usual over abundance of coke formation because of the shorter contact times with the result that higher yields of liquid products are produced.

The residuum is decomposed by being sprayed into a fluidized bed of hot, fine coke particles, which permits the coking reactions to be conducted at higher temperatures and shorter contact times than can be employed in delayed coking. Moreover, these conditions result in decreased yields of coke; greater quantities of more valuable liquid product are recovered in the fluid coking process. The process employs two vessels, a reactor and a burner with coke particles circulated between the two to transfer heat (generated by burning excess coke in the burner) to the reactor. The preheated feedstock (260–370°C; 500–700°F) is injected directly onto the hot coke (480–565°C; 895–1050°F), at approximately atmospheric pressure, to crack to additional coke and liquid products that leave the reactor as overhead oil.

In the reactor, the coke particles flow down through the vessel into a stripping zone at the bottom. Steam displaces the product vapors between the particles, and the coke then flows into a riser that leads to the burner. Steam is added to the riser to reduce the solids loading and to induce upward flow. The average bed temperature in the burner is 590–650°C (1095–1200°F), and air is added as needed to maintain the temperature by burning part of the product coke. The pressure in the burner may range from 5 to 25 psi. Flue gases from the burner bed pass through cyclones and discharge to the stack. Hot coke from the bed is returned to the reactor through a second riser assembly.

The yields of products are determined by the feed properties, the temperature of the fluid bed, and the residence time in the bed. The use of a fluidized bed reduces the residence time of the vapor-phase products in comparison to delayed coking, which in turn reduces cracking reactions. The yield of coke is thereby reduced, and the yield of gas oil and olefins increased. An increase of 5°C (9°F) in the operating temperature of the fluid-bed reactor typically increases gas yield by 1% wt/wt and naphtha by about 1% wt/wt.

The bed temperature in the burner is of the order of 590–650°C (1095–1200°F), and any excess coke that is not removed as part of the burning is periodically removed from the burner. The coke yield from the process may be as little as 1.2 or as high as 1.7 times the carbon residue of the feedstock. As with delayed coking, the fluid coking process is capable of producing liquid products with substantially lower sulfur contents than the feedstock, but part of the sulfur in the feedstock is concentrated in the coke. There is elimination of sulfur into the gaseous products but uses for the coke depend very much on the amount of feedstock sulfur.

Flexicoking

Flexicoking is a direct descendent of fluid coking and uses the same configuration as the fluid coker but includes a gasification section in which excess coke can be gasified to produce refinery fuel gas. The flexicoking process was designed during the late 1960s and the 1970s as a means by which excess coke could be reduced in view of the gradual incursion of the heavier feedstocks in refinery operations. Such feedstocks are notorious for producing high yields of coke (>15% by weight) in thermal and catalytic operations.

In the process, excess coke is converted to a low-heating value gas in a fluid bed gasifier with steam and air. The air is supplied to the gasifier to maintain temperatures of 830–1000°C (1525–1830°F), but is insufficient to burn all of the coke. Under these reducing conditions, the sulfur in the coke is converted to hydrogen sulfide, which can be scrubbed from the gas prior to combustion.

Yields of liquid products from flexicoking are the same as from fluid coking because the coking reactor is unaltered. As with fluid coking, the extent of desulfurization depends on the sulfur content of the feedstock as well as on the chemical nature of the sulfur in the feedstock.

Catalytic Cracking

Catalytic cracking is a conversion process that can be applied to resids. It is one of the several practical applications used in a refinery that employ a catalyst to improve process efficiency. The original incentive to develop cracking processes arose from the need to increase gasoline supplies. Because cracking could virtually double the volume of gasoline from a barrel of crude oil, the purpose of cracking was wholly justified. The process employs a variety of reactors with bed types varying from fixed beds to moving beds to fluidized beds.

The fixed-bed process was the first to be used commercially and uses a static bed of catalyst in several reactors, which allows a continuous flow of feedstock to be maintained. Thus, the cycle of operations consists of: 1) flow of feedstock through the catalyst bed; 2) discontinuance of feedstock flow and removal of coke from the catalyst by burning; and 3) insertion of the reactor onstream. The moving-bed process uses a reaction vessel in which cracking takes place and a kiln in which the spent catalyst is regenerated; catalyst movement between the vessels is provided by various means. The fluid-bed process differs from the fixed-bed and moving-bed processes insofar as the powdered catalyst is circulated essentially as a fluid with the feedstock. The several fluid catalytic cracking processes in use differ primarily in mechanical design. Side-by-side, reactor–regenerator configuration or the reactor either above or below the regenerator is the main mechanical variation. From a flow standpoint, all fluid catalytic cracking processes contact the feedstock and any recycle streams with the finely divided catalyst in the reactor.

Catalytic cracking using a fluidized bed is the most popular form of cracking and is the emphasis of this section. To reaffirm this statement, there are more than 370 fluid catalytic cracking units in use worldwide with the capacity to produce more than 460,000,000 gal of gasoline from heavier feedstocks.

In the fluidized-bed (fluid catalytic cracking) units, the cracking reactions take place in the riser to form products, including coke. In the riser, the catalyst and the feedstock and products rise up the reactor pipe, and because the reactions are predominantly endothermic, the reaction temperature declines from bottom to top. At the top of the riser, the mixture enters a solid–gas separator, and the product vapors are led away. The coked catalyst passes to the stripper where steam is added and unreacted/reacted feedstocks adsorbed on the catalyst are released. The stripped catalyst is then directed into the regenerator where air is added and the combustion of coke on the catalyst (and any feedstock/product still adsorbed that was not stripped) occurs with the liberation of heat. Regenerator temperatures are typically 705–760°C (1300–1400°F). Heat exchangers and the circulating catalyst are used to retain and capture the regeneration heat for use in preheating the feedstock.

The entire catalyst inventory is continually circulated through the three parts of the unit. The catalyst residence time in the riser reactor section is typically 1–3 sec (with current trends to even shorter residence times), and the entire reactor–stripper–regenerator cycle is less than 10 min. To achieve cycle times of this order, catalyst circulation rates as high as 1 ton/sec are observed in large units.

The catalyst, which may be an activated natural or synthetic material, is employed in bead, pellet, or microspherical form and can be used as a fixed-bed, moving-bed, or fluid-bed configurations. Moving-bed units often employ catalysts in the form of beads or cylinders ($\frac{1}{8}$ – $\frac{1}{4}$ in. diameter). Fluid-bed units usually employ the catalyst in much smaller form where particle sizes may be of the order of 50 μm (50×10^{-4} cm).

Catalytic cracking in the usual commercial process involves contacting the feedstock with a catalyst under suitable conditions of temperature, pressure, and residence time. Catalytic cracking processes produce coke and overheads (volatile materials). The coke deposits on the catalyst and, therefore, markedly decreases catalyst activity. This problem is surmounted by transference of the catalyst from the reactor to a vessel (regenerator) where the coke is burned from the catalyst in air; movement of the catalyst between the vessels is continuous, thereby maintaining feedstock flow and production of products. The reactor temperature is usually on the order of 465–510°C (870–950°F) and pressures in the range 10–16 psi. The regenerator temperature may be substantially higher at 565–675°C (1050–1250°F) and 8–10 psi. The feedstock temperatures vary from 315°C to 455°C (600–850°F) at the point of entry to the reactor.

Although catalytic cracking was originally designed to convert gas oil to gasoline, process modifications have allowed the feedstock types to include resids and residua. The manner in which a feedstock will crack depends on a number of process variables such as feedstock composition, boiling range, structural types present, reactor conditions, and catalyst type. Thus, it is not surprising that the heavier feedstocks present special problems when used to feed a catalytic cracker. The susceptibility of the catalyst to the various

nitrogen compounds, as well as the metals (iron, nickel, vanadium, and copper) in the feedstock, represents a major drawback in using resids and residua as catalytic cracker feedstock. For example, if the concentration of metals (expressed in ppm) on the catalyst fulfills the following relation:

$$4V + 14Ni + Fe + Cu > 1000$$

the catalyst is severely contaminated and may actually have to be replaced.

Nevertheless, it is possible to process the heavier feedstocks in catalytic crackers and bring about some degree of desulfurization in the process. The degree of desulfurization depends on the amount of sulfur in the feedstock. It is generally believed that to optimize use of a catalytic cracking unit, feedstocks should be treated to remove excess high molecular weight material and metals by processes such as visbreaking, coking, or deasphalting to prolong catalyst activity.

Sulfur compounds are changed in such a way that the cumulative sulfur content of the liquid and nonvolatile products is lower than the sulfur content of the original feedstock. The decomposition of sulfur constituents into hydrocarbons and hydrogen sulfide (or other gaseous sulfur products) occurs.

Hydroconversion

Hydroconversion (variously referred to as hydrotreating and hydrocracking) is a group of refining processes in which the feedstock is heated with hydrogen under pressure. The outcome is the conversion of resids to a range of products.

Hydrotreating is generally used for the purpose of improving product quality without appreciable alteration of the boiling range. Mild processing conditions are employed so that only the more unstable materials are attacked. Thus, nitrogen, sulfur, and oxygen compounds undergo hydrogenolysis to split ammonia, hydrogen sulfide, and water, respectively. Olefins are saturated, and unstable compounds, such as di-olefins, which might lead to the formation of gums or insoluble materials, are converted to more stable compounds. Heavy metals present in the feedstock are also usually removed during hydrogen processing.

On the other hand, hydrocracking is a process in which thermal decomposition is extensive and the hydrogen assists in the removal of the heteroatoms as well as mitigates the coke formation that usually accompanies thermal cracking of high molecular weight polar constituents. Hydrocracking is similar to catalytic cracking, with hydrogenation superimposed and with the reactions taking place either simultaneously or sequentially. Hydrocracking was initially used to upgrade low-value distillate feedstocks, such as cycle oils (highly aromatic products from a catalytic cracker that usually are not recycled to extinction for economic reasons), thermal and coker gas oils, and heavy-cracked and straight-run naphtha. These feedstocks are difficult to process by either catalytic cracking or reforming, because they are usually characterized by a high polycyclic aromatic content and/or by high concentrations of the two principal catalyst poisons, sulfur, and nitrogen compounds.

Hydrocracking is perhaps the single most significant advance in petroleum refining technology over the last several decades. It is essentially an efficient thermal catalytic method of converting resids to lower boiling products. However, hydrocracking should not be regarded as a competitor for catalytic cracking. Catalytic cracking units normally use virgin gas oils as feedstocks; hydrocracking feedstock usually consists of refractive gas oils derived from cracking and coking operations. Hydrocracking is a supplement to, rather than a replacement for, catalytic cracking.

The problems encountered in hydrocracking resids can be directly equated to the amount of complex, higher boiling constituents that may require pretreatment. Processing these feedstocks is not merely a matter of applying know-how derived from refining conventional crude oils but also requires knowledge of composition.

The choice of processing schemes for a given hydrocracking application depends on the nature of the feedstock as well as the product requirements. The single-stage process can be used to produce gasoline but is more often used to produce middle distillate from heavy vacuum gas oils. The two-stage process was developed primarily to produce high yields of gasoline from straight-run gas oil, and the first stage may actually be a purification step to remove sulfur-containing (as well as nitrogen-containing) organic materials. Both processes use an extinction–recycling technique to maximize the yields of the desired product. Significant conversion of resids can be accomplished by hydrocracking at high severity. For some applications, the products boiling up to 340°C (650°F) can be blended to give the desired final product.

Product yields and hydrogen consumption vary with the feedstock but the process can be used in many different ways. One of the major advantages of hydrocracking is that it may be used to process the higher-boiling refractory feedstocks that may be produced by catalytic cracking or by any of the coking processes. Hydrocracking can also be applied to the conversion of the more difficult feedstocks, such as residua and resides, and there are a variety of hydrocracking processes that are designed specifically for this particular use.

Hydrocracking is an extremely versatile process that can be utilized in many different ways. One of the

advantages of hydrocracking is its ability to break down high-boiling aromatic stocks produced by catalytic cracking or coking. This is particularly desirable when maximum gasoline and minimum fuel oil must be made.

However, it must not be forgotten that product distribution and quality vary considerably depending on the nature of the feedstock constituents as well as on the process. In modern refineries, hydrocracking is one of several process options that can be applied to the production of liquid fuels from the heavier feedstocks. The most important aspect of the modern refinery operation is the desired product slate, which dictates the matching of a process with any particular feedstock to overcome differences in feedstock composition.

The reactions that are used to chemically define the processes (i.e., cracking and subsequent hydrogenation of the fragments, hydrogenation of unsaturated material, hydrodesulfurization, hydrodenitrogenation) may all occur. Hydrocracking a feedstock will, in all likelihood, be accompanied by hydrodesulfurization, thereby producing not only low-boiling products but also low-boiling products that are low in sulfur.

Hydroprocesses offer direct desulfurization of resids and high conversion. These processes were not originally designed for resids and yet the evolution of the various processes and catalysts has seen their application to resids and residua. Application of a hydroprocess as a pretreatment process has some merit. Changing the character of the feedstock constituents can make for easier conversion in a later stage of the refining sequence. The advantages are:

1. The products require less finishing.
2. Sulfur is removed from the catalytic cracking feedstock, and corrosion is reduced in the cracking unit.
3. Carbon formation during cracking is reduced and higher conversions result.
4. The catalytic cracking quality of the gas oil fraction is improved.

The downside to the direct application of hydroprocesses to the resids is always the cost of hydrogen and the short lifetime of the catalyst (which in effect is also a cost). There is the potentially wasteful use of hydrogen with hydrogen sinks within the feedstock whereupon hydrogen is used, but with little, if any, effect on the product character.

Fixed-Bed Processes

Because metal removal is one of the fastest reactions and the metals accumulate in the pores of supported catalysts, it is common to have a guard bed in front of the fixed bed. When insufficient demetallization activity occurs in the guard bed, the feed is switched to a second guard bed with fresh catalyst and the catalyst is replaced in the first guard bed. Thus, the fixed bed is protected from deposition of metals. To hydrogenate the largest macromolecules in the resid, the asphaltenes, some or all of the catalysts need to have pores 50–100 μm in diameter. Even with these precautions it is difficult to get longer than 1 yr run lengths on fixed-bed hydroconversion units with vacuum resid feeds and conversions to volatile liquids of 50% or more. This is due to catalyst deactivation with coke or to coke and sediment formation downstream of the reactor.

Ebullating Bed Processes

The LC Finer and H-Oil units mechanically ebullate the catalyst so that it can be mixed and replaced onstream. The conversion is greatly dependent on the feed but conversions of vacuum resids to volatile liquids of the order of 70% is possible. Often these units are limited by the deposition of coke and sediment downstream of the reactor in hot and cold separators.

Dispersed Catalysts Processes

If one cannot diffuse the asphaltenes to the catalyst, why not diffuse the catalyst to the asphaltenes? Dispersed catalysts also can be continuously added in sufficiently low enough amounts (i.e., 100 ppm) to consider them throwaway catalysts with the carbonaceous by-product. However, economics usually dictate some form of catalyst recycle to minimize catalyst cost. Nevertheless, by designing the reactor to maximize the solubility of the converted asphaltenes, the conversion of vacuum resids to gas and volatile liquids can be above 95% with greater than 85% volatile liquids. However, the last 5–10% conversion may not be worth the cost of hydrogen and reactor volume to produce hydrocarbon gases and very aromatic liquids from this incremental conversion. The answer depends on the value and use of the unconverted carbonaceous liquid by-product.

CONCLUSIONS

Resid conversion is now in a significant transition period as the demand for transportation fuels increases. To satisfy the changing pattern of product demand, significant investments in resid conversion processes

will be necessary and technologies are needed that will take resid conversion beyond current limits and, at the same time, reduce the amount of coke and other nonessential products.

More options are now being sought to increase process efficiency in terms of the yields of the desired products. New processes for resid conversion probably will be used in conjunction with visbreaking and coking options with some degree of hydroprocessing as a primary conversion step. In addition, other processes such as asphalt coking technology, the Cherry-P, or the eureka process may replace or, more likely, augment the deasphalting units in many refineries.

There remains room for improving coking and hydroconversion processes by reducing hydrocarbon gas formation, inhibiting the formation of polynuclear aromatic compounds not originally present in the resid, and separating an intermediate quality (low in cores) fraction before or during conversion. In addition, the challenge for hydroconversion is to take advantage of the nickel and vanadium in the resid to generate an in situ dispersed catalyst and to eliminate catalyst cost. Finally, resid catalytic cracking needs to move to poorer quality and lower-cost feeds by making more tolerant catalysts.

INTRODUCTION

Cellulose and many of its derivatives form liquid crystalline phases in solutions and melts. Because of the chirality of the cellulose backbone, cellulosic liquid crystalline phases form chiral nematic structures. Chiral nematic mesophases possess a unique structure in which the alignment of molecular sheets is at a slight angle to one another resulting in a helicoidal supramolecular structure. It can be described by a pitch p (or its inverse, the twist p^{-1}); $p = \lambda_0/\tilde{n}$, where λ_0 is the reflection wavelength and $\tilde{n}$ is the mean refractive index of a sheet, and the corresponding handedness of the twist; right-handed helicoidal structures being assigned to a positive pitch ($p > 0$) and left-handed helicoidal structures to a negative pitch ($p < 0$). This type of supramolecular arrangement results in unique optical and physical properties. As a result, many lyotropic cellulosic systems have been developed with potential applications ranging from liquid crystalline displays to high modulus, high strength regenerated cellulose fibers. In recent years, systems that display a reversal of their helical twisting sense by solvent or chemical modification have been of particular interest.

The viscosity of these chiral nematic mesophases is concentration-dependent and strongly influenced by shear rate. When the shear rate is high enough, the polymer chains will orient along the shear direction. The chiral nematic structure changes to a flow-aligned nematic-like phase and the dependence of viscosity on concentration decreases. Undoubtedly during the shear process, shear forces cause an orientation in the shear direction of the twisted macromolecules of the chiral nematic structure. A quasi-nematic phase is formed with some dispersed chiral nematic domains. Upon removal of the shear stress, the thermodynamically more stable chiral nematic phase will reform leading to a disruption in the macromolecular orientation within the forming products, and as a result lower than expected modulus and strength. In this entry, we report on the transient rheological behavior of lyotropic cellulosic mesophases with varying pitch and handedness and discuss the relationship between the chiro-optical properties and relaxation behavior.

CELLULOSIC LIQUID CRYSTALS

Cellulose is the most abundant natural polymer. Cellulose and its derivatives (cellulosics) have played an important role in developing and establishing the current concepts and industrial applications of polymer science. Current interests are based on their versatile properties, biodegradability, and status as a renewable resource (Fig. 1).

Discovery of the formation of liquid crystalline solutions by cellulosics in the mid-1970s[1] has resulted in attempts to develop new cellulosics products with properties superior to those of conventional cellulosic. Following the first observation of mesophases formed in aqueous solutions of hydroxypropyl cellulose (HPC),[1] a variety of other cellulose derivatives have been reported to form liquid crystals.[2–7] Liquid crystalline solutions of cellulose and its derivatives[8–12] provide a potential route to high-modulus and high-tenacity cellulosic fibers, films, and other high-performance products.

Efforts to make high-performance fibers and films from cellulosic mesophases have been made.[12–17] For example, cellulose fibers produced from cellulosic mesophases show properties superior to those of commercially available fibers.[16,18,19] Although these fibers are superior to commercial products, their physical properties are lower than theoretically predicted. This is in part because of that the ordered structures

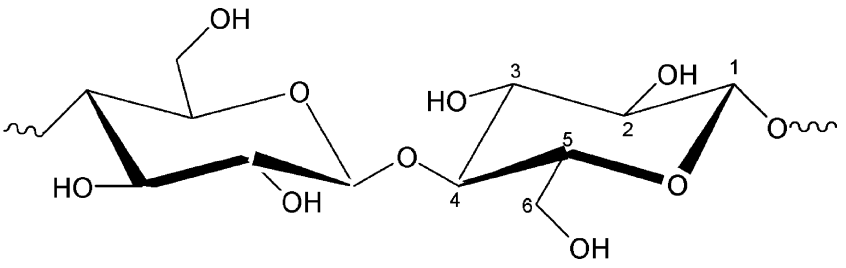

Fig. 1 Structural representation of cellulose.

are not well preserved because of the orientation relaxation during the processing steps.

Liquid crystalline (LC) solutions of cellulose derivatives form chiral nematic (cholesteric) phases.[6,20] Chiral nematic phases are formed when optically active molecules are incorporated into the nematic state. A fingerprint texture is generally observed under crossed polarizers for chiral nematic liquid crystals when the axis of the helicoidal structure is perpendicular to the incident light (Fig. 2).

In general, chiral nematic polymer liquid crystals (LCP) cannot form monodomains in which the rodlike polymers have a spatially uniform orientation within the sample. Typically, because of the high density of orientational defects, the LCPs are textured, with a distribution of polymer orientation. Microscopically, the polymer chains have a preferred orientation with a relatively narrow distribution around the average orientation. Macroscopically, the variation in space of the orientation results in a domain structure. Defects and orientational variations give rise to the polydomain texture and the overall LCP sample may be randomly ordered (Fig. 3).

Lyotropic liquid crystalline cellulose derivatives exhibit unique optical properties because of their helicoidal supramolecular structure.[21] The chiro-optical properties of the helicoidal structure can be described by a pitch p (or its inverse, the twist p^{-1}); $p = \lambda_0/\tilde{n}$, where λ_0 is the reflection wavelength and $\tilde{n}$ is the mean refractive index of a sheet, and the corresponding handedness of the twist; right-handed helicoidal structure being assigned to a positive pitch ($p > 0$) and left-handed helicoidal structures to a negative pitch ($p < 0$).[5,6,22] The nematic mesophase can be considered as a critical state of chiral nematic phase, in which the helicoidal structure has infinite pitch and no handedness. The supramolecular structure of chiral nematic mesophase indicates the effects of polymer–solvent and polymer–polymer interactions in the mesophase (Fig. 4).

The effect of polymer–solvent interactions on the mesophase can be derived from the rigidity of the polymer chain, the critical concentration to form liquid crystalline phase, and relaxation studies. After shearing a rigid polymeric liquid crystal, a banded texture is formed in which the direction of the bands

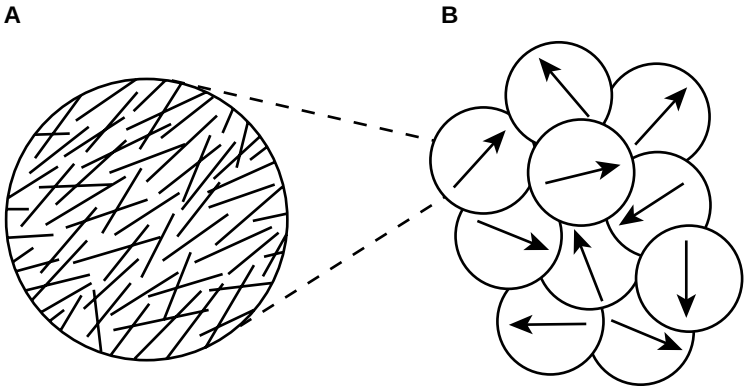

Fig. 3 Hierarchy of the distribution of the orientation of the molecules in a polydomain LCP. (A) Microscopic and (B) mesoscopic.

is perpendicular to the shearing direction after removing the shear force.[23,24] The banded structure forms because of a periodic packing of rigid/semirigid polymer chains in a zigzag fashion, which is believed to be owing to the relaxation of the polymer orientation.[25] For lyotropic LC solutions the banded texture is a transient phenomenon. After a period of time, the polymer chains fully relax and the banded texture disappears. The bandwidth and the relaxation time of the bands depend on the rigidity and pitch of the polymer chain resulting from specific polymer–solvent interactions. In fact, at the same concentration ethyl cellulose (EC) chains are more rigid in dichloroacetic acid (DCA) than in acrylic acid or glacial acetic acid and the pitch of EC/DCA mesophase is much higher than that of the EC/acetic acid[26] or acrylic acid,[27] resulting in wider bands and longer relaxation times for EC/DCA mesophase (Fig. 5).[28]

However, the rigidity of the polymer chain is not the only factor to determine the pitch of the mesophase. Guo and Gray[29] found that for acetylethylcellulose (AEC) in chloroform, with the increase of degree of acetylation, the rigidity of the cellulose chain increases monotonically. However, the pitch of the mesophase first increases to infinity and then decreases with an inversion of the handedness of the chiral nematic phase, from left-handed to right-handed.

As cellulosics are chiral, there must also be a chiral contribution to the interactions between the rods in the mesophase leading to the chiral nematic structure. Several theories have been proposed to account for the ''twisting'' force between chiral rodlike mesogens in the liquid crystalline phase. Goossens was the first to propose that the chiral nematic structure is the result of anisotropic dispersion energy between chiral mesogens.[30] Samulski and Samulski proposed that the macroscopic twist sense was dependent on the dielectric constant of the medium and the chirality of the constituent molecules.[31] They determined that the introduction of an asymmetric dispersion energy results in adjacent mesogens having a slight twist relative to one another, and that increasing temperature

increases the frequency of molecular rotation, causing a decrease in the dispersion energy and an increase in the pitch.

The observed handedness and pitch of the helicoidal structure is not only sensitive to temperature, but also depends on the concentration and structure of the components.[26,32–37] According to Lin-Liu, Shih, and Woo[38] the temperature dependence of pitch for chiral nematic polymers does not seem to follow any particular pattern. It is believed that as temperature is increased, specific interactions, e.g., hydrogen bonding, whether inter- or intramolecular or polymer–solvent interactions are destroyed. The polymer chains become more flexible and the side groups more easily relaxed, thereby changing the physical properties of the chiral nematic structure. Similarly, an increase in concentration leads to a decrease in pitch for most lyotropic cellulosic liquid crystals with the exception of cellulose tricarbanilate (CTC) in ethyl methyl ketone, 2-pentanone,[35] or triethylene glycol monoether[34] and the chlorophenyl urethane derivative in diethylene glycol monoether.[39]

Numerous investigators have proposed theories for the temperature dependence of pitch.[40–44] However, none completely explain the experimental results obtained for the various cellulosic systems. Of those proposed, Osipov's approach, which is based on a molecular statistical theory,[42] takes into account steric and chiral interactions in solution to predict the influence of temperature and solvent on the pitch and twist sense of cellulose derivatives.[43] Assuming the cellulosic chain adopts a "twisted belt" as opposed to a helix, and the persistence length, l, of the cellulose chains is much smaller than that of a rigid chain, the twisting power could be expressed by

$$2\pi/P = -\rho^2(\chi - \lambda kT)/2K_{22} \quad (1)$$

where χ is related to the attractive interaction between chains, P the pitch, k the Boltzmann constant, K_{22} the twist elastic constant, ρ the number density of rigid segments, $\rho = cL/l_0$, where c is the number density of the macromolecular chains, l_0 the length of the segments, L the total length of the chain ($L > l > l_0$), and the pseudo-scalar parameter λ is determined by the steric repulsion between chains.

The theory predicts that the handedness of cellulosic liquid crystalline solutions, designated by the sign of the pitch, depends not only on temperature (T) and on steric repulsion of the chain (λ), but also on an attractive interaction parameter, χ, which depends on the nature of the solvent. The chiral forces are balanced when $(\chi - \lambda kT) = 0$. In this compensated condition, the pitch of the mesophase should become infinite, and the mesophase resembles a normal nematic phase.

Besides degree of substitution, nature of substituents, solvent, concentration, and temperature, other factors that change the polymer–solvent interactions can affect the pitch of lyotropic cellulosic mesophases. Doping inorganic salts[45,46] or small chiral molecules[47] into the lyotropic mesophase changes the polymer–solvent interactions. As the results, the pitch of the chiral nematic mesophase changes accordingly.

RHEOLOGY OF CELLULOSE LIQUID CRYSTALLINE SOLUTIONS

The microstructure and polymer–solvent interactions of lyotropic cellulosic mesophases can be derived from rheological studies. The lyotropic LCP solution is a complicated system and a wide range of unusual rheological phenomena have been observed.

Because of the wide range of technological applications and complexity of liquid crystal polymers, there is a strong need for further advance in the understanding of their rheological phenomena. Several theories have been introduced to predict the rheological

behavior of LCPs. The classical Leslie–Ericksen (LE) continuum theory uses a rigid rodlike director to describe the local molecular orientation.[48,49] The rheological behavior is the result of the interaction between the director field and applied flow field. Leslie–Ericksen theory is applicable when the flow field only affects the direction of molecular orientation without changing the degree of molecular alignment. This theory has been successful in discussing the flow of low molecular weight nematic liquid crystals. For LCP, it is applicable only at very low shear rates in defect-free samples.[50]

Doi molecular theory adds a probability density function of molecular orientation to model rigid rodlike polymer molecules.[51] This model is capable of describing the local molecular orientation distribution and nonlinear viscoelastic phenomena. Doi theory successfully predicts director tumbling in the linear regime and two sign changes in the first normal stress difference,[52] as will be discussed later. However, because this theory assumes a uniform spatial structure, it is unable to describe textured LCPs.

Larson and Doi introduced a mesoscopic polydomain model based on LE theory. This model includes a domain orientation distribution function and incorporates director tumbling, distortional elasticity, and texture size.[53] Larson–Doi model can qualitatively predict the steady flow behavior and transient behavior. However, discrepancies between the theoretical predictions and the experiments of model systems were observed, especially when the shear history includes rest periods.[50] This model is restricted to low shear rates without perturbing the molecular orientation distribution function in each domain.[52]

The theory for LCP rheology is still evolving. Rey and Tsuji[54] proposed a complete tensor theory to take into account three major effects of LCP flow: 1) short range order elasticity; 2) long range order elasticity; and 3) viscous flow. This theory is based on the unification of the classical nonequilibrium theories. The complete theory can predict more complex phenomena of LCP behavior, e.g., banded texture, defect generation, and coarsening. Extensive and detailed reviews of LCP rheology theory were provided by Larson,[55,56] Burghardt,[52] Rey and Denn,[57] and Marrucci and Greco.[58]

All the above theories are derived for rigid rod nematic liquid crystal systems. The rheological behavior of chiral nematic liquid crystals is more complex and less understood than that of nematic systems. Rey introduced a model based on rigid rod chiral nematic liquid crystals to describe permeation shear flow and small amplitude oscillatory shear flow.[59–61] The model can predict some common phenomena of chiral nematic liquid crystals, e.g., the three-region apparent viscosity curve,[62] oscillatory underdamped stress relaxation,[62] helix uncoiling,[63] and the higher apparent viscosity, as compared to nematic LCPs.[64] However, cellulosics are semiflexible polymers. Experimental results have shown that semiflexible HPC/H_2O system[65] has different rheological behavior from that of the more rigid poly(γ-benzyl-glutamate)/*m*-cresol system.[66] So far, no theory has been proposed to model the rheology of semiflexible chiral nematic LCPs.

Following the first observation of mesophase formation of HPC/H_2O, the rheology of this system has been widely investigated. Rheological studies of other cellulosic mesophases, e.g., cellulose,[67] ethylcellulose,[26,68,69] and cellulose tricarbanilate,[70] have also been reported.

Concentration Dependence of Viscosity

Isotropic solutions exhibit a monotonic increase in shear viscosity with increasing concentration. The viscosity increases to a maximum when the isotropic to anisotropic transition is approached. Upon formation of the anisotropic phase, the viscosity begins to decrease, after which the viscosity increases strongly as the concentration continues to increase (Fig. 6). In the isotropic state, the hydrodynamic volume is large because of the random polymer orientation. This restricts the polymer diffusivity and causes an increase in viscosity. In the anisotropic phase, the aligned polymer leads to a small hydrodynamic volume and a decrease in viscosity as rotational diffusion is much easier with a net orientation.

Zugenmaier found that the correlation of the viscosity maximum with the formation of the anisotropic phase was only valid when the shear rate was low

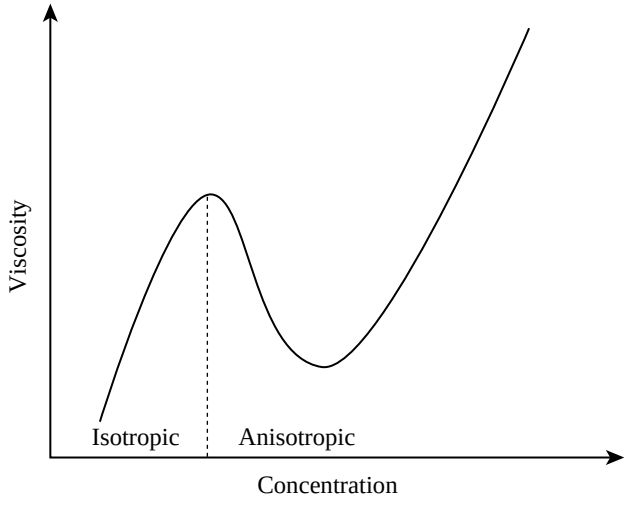

Fig. 6 Viscosity as a function of concentration for lyotropic LCPs.

(shear rate $\rightarrow$ 0).[70] At high shear rate, the concentration at which the maximum in viscosity occurs decreases. When the shear rate is high enough to cause shear-induced orientation (pseudo-nematic phase), entanglements of the random distributed polymers are released. The viscosity maximum disappears and a steady increase of viscosity vs. concentration is observed. This indicates that the viscosity of the nematic or pseudo-nematic mesophase is less sensitive to concentration than that of the chiral nematic phase.[70]

Steady Flow Behavior

Steady flow behavior is one of the most thoroughly studied rheological properties. Onogi and Asada[71] hypothesized the universal existence of three shear flow regimes to describe the viscosity of LCPs: a shear thinning regime at low shear rates (regime I), a Newtonian plateau at intermediate shear rates (regime II), and another shear thinning regime at high shear rates (regime III) (Fig. 7). The three-regime curve was observed in the anisotropic aqueous HPC solution[72] and HPC in acetic acid.[73] Asada proposed that some LCP systems do not exhibit all three regimes because not every regime lies in the accessible shear rate range.

In those systems that exhibit all three regimes, regime I is generally believed to reflect a defect structure, or stacked polydomain texture. The texture is a supramolecular disorder of the nematic structure and is composed of nematic domains with little or no macroscopic orientation.[72,74] This region is characterized by distortional elasticity associated with spatial variation in the director (average local molecular orientation) field. Regime II reflects a ''dispersed polydomain'' structure and regime III is believed to be characterized by nonlinear effects of flow on the molecular orientation. In regimes I and II, the flow is not strong enough to affect the molecular orientation. In regime III, the flow field is very strong and shear-induced molecular orientation becomes important. According to birefringence measurements for anisotropic HPC/H_2O solutions[65] and HPC/*m*-cresol solutions,[75] the molecular orientation is a monotonically increasing function of the steady state shear rate.

We found that the steady state flow of lyotropic AEC in acrylic acid (AA) showed three-regime curve, as shown in Fig. 8. Different AECs had different DA and the mesophases had different chiro-optical properties. The properties of different AECs are listed in Table 1. All the mesophases showed a typical three-regime curve. With the increase of shear rate, a shear-thinning is followed by a Newtonian plateau, and then followed by another shear-thinning region at high shear rate. The Newtonian plateau is in the shear rate range 1–5 S^{-1}. We also found that with the increase of pitch, the flow curve becomes flat and the three regimes are not as distinct as the one with smaller pitch. Even though several cellulosic mesophase systems show a three-regime flow curve, in fact, it appears that all three regimes are not typically accessible for all LCPs including cellulosics. Whether the three-regime flow curve is indeed universal or not remains a subject of debate.

The most striking phenomenon in the steady flow of LCPs is the occurrence of a negative first normal stress difference (N_1)—two sign changes in N_1 as a function of shear rate. In contrast, isotropic solutions only exhibit positive N_1 at all shear rates. Negative N_1 has been reported in HPC/H_2O[76–78] and HPC/*m*-cresol systems.[79]

The negative N_1 is the result of the coupling of molecular tumbling under flow and the local molecular-orientation distribution.[76] At low shear rates, the director tumbles with the flow and N_1 will be positive. At intermediate shear rates, nonlinear viscoelastic effects are important. The director tumbling competes with the steady director alignment along

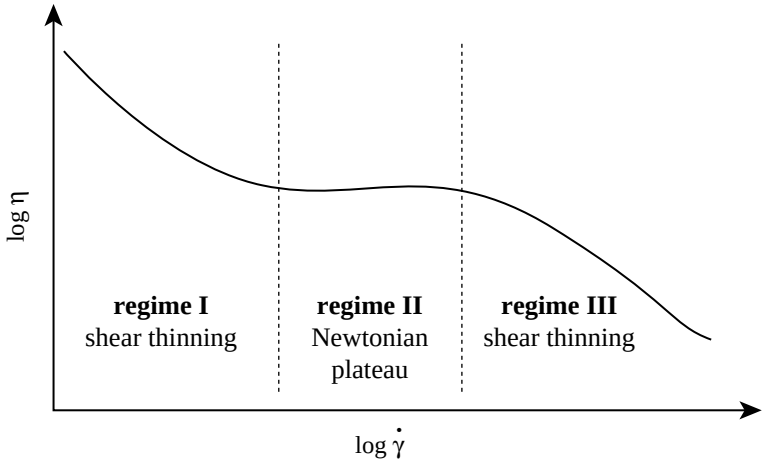

Fig. 7 Three-regime steady state shear viscosity for LCPs.

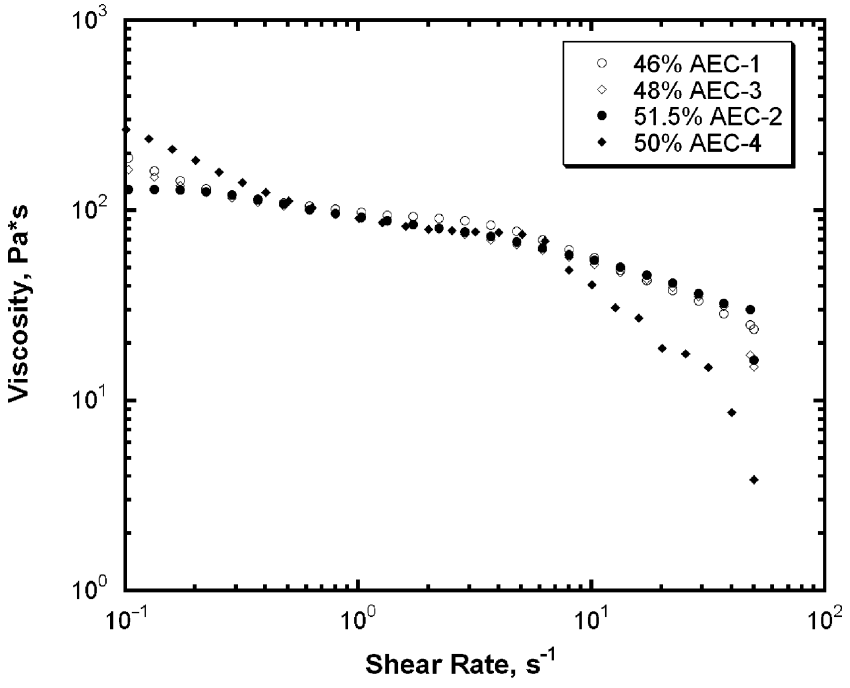

Fig. 8 Viscosity as a function of shear rate of AEC/AA solutions. (The properties of AEC samples are given in Table 1.)

the flow and the director oscillates about a steady value, N_1 becomes negative. At very high shear rates, the director aligns along the flow and N_1 is positive again. It is generally believed that the shear rate at which N_1 is minimum halts director tumbling and aligns the molecules.[79] However, negative N_1 behavior disappears at very high polymer concentration because of polymer–polymer friction interactions.[76]

Relaxation Behavior

The relaxation behavior, or the transient behavior of cellulosic liquid crystalline solutions upon the cessation of steady flow, is unique for LCPs. There are two kinds of relaxation. The bulk stresses relax quickly while the structures relax over a much longer time. Mewis and Moldenaers suggested that two levels of structures exist.[80] Stress relaxation reflects fast relaxation at the molecule level and is independent of the previous shear rate. Structure relaxation reflects the gradual change of the textures. This slow process is unique in that its time scale is inversely proportional to the previous shear rate. When the strain recovery (or recoil) after cessation of steady state flow is plotted against time multiplied by the previous shear rate, the curves superimpose one another.[50]

Table 1 Chiro-optical properties of lyotropic 50% AEC/AA solutions with different degrees of acetylation

AEC sample	Sample description	Degree of acetylation	Pitch
AEC-1	Low DA	0.13	−360 nm
AEC-2	Medium DA	0.34	−7.4 μm
AEC-3	AEC/EC mixture	0.34	+1.2 μm
AEC-4	High DA	0.50	+370 nm

It is generally believed that under high flow rate, the chiral nematic mesophase aligns along the flow direction and uncoils to form a nematic structure. Upon cessation of flow, the chiral nematic phase will reform and the molecular orientation will decrease.[81] By using evolution of the dynamic moduli[82] and birefringence[52] as a function of time, the structural change can be investigated. For lyotropic HPC/H_2O solutions, upon flow cessation, molecular orientation decreases to a globally isotropic condition at all rates[52] and the dynamic moduli increase to a maximum.[82] However, the final relaxed state depends on the shear history. After high shear rates, the solutions evolve toward an ''equilibrium'' state with a high modulus, while after low shear rates, the solutions relax to the ''equilibrium'' state with a low modulus.[65] The low-modulus state is ordered and evolves out of a state that has no macroscopic order upon cessation of flow. The high-modulus state is much less ordered, although it evolves from a rather well flow-aligned state upon the cessation of flow.[83]

At high shear rates the chiral nematic structure changes to a flow-induced nematic phase. However, the shear-oriented phase is easy to disrupt after removing the shear force. This is because of the driving force for the liquid crystalline solution to form the more thermodynamically stable chiral nematic structure.[82] Relaxation in a pseudo-nematic lyotropic
