solution, after being oriented along the high shear rate direction, will persist for a long period of time, as the driving force to reform helicoidal structure may be limited. So far, there are a few reports that discuss the relationship between the relaxation behavior and chiro-optical properties of the mesophases. In the case of a lyotropic polypeptide system, poly(γ-benzyl-glutamate) (PBG) solutions containing a single optical isomer of either poly(γ-benzyl-l-glutamate) (PBLG) or poly(γ-benzyl-d-glutamate) (PBDG) or in the case of a racemic mixture of these two, there is no support for the idea that the chiro-optical properties of the chiral nematic PBG/*m*-cresol solution has any significant effects on the relaxation behavior.[52] This may be because of the fact that the mesophases of both optical isomers and the racemic mixture have a large pitch and are nematic-like.

In our recent study, relaxation behaviors upon shear force removal were investigated for lyotropic solutions of AEC in AA with different chiro-optical properties.[84] Ethylcellulose and AEC can form chiral nematic liquid crystalline solutions in many solvents and were found to change handedness as well as pitch with the change of degree of acetylation. In acrylic acid, EC forms a left-handed mesophase, while fully acetylated AEC forms a right-handed mesophase.[85] At a certain critical degree of acetylation (DA*) the pitch becomes infinite and an untwisted, nematic-like structure forms. When the degree of acetylation of AEC increases across DA*, the handedness of cholesteric liquid crystalline solutions changes from left-handedness to right-handedness. The pitch of the lyotropic solution of EC or fully acetylated AEC in AA is about one-tenth that of PBG solutions. Therefore, the effect of chiro-optical properties on relaxation behavior is expected to be more pronounced in AEC system than in PBG system.

The values of pitch for lyotropic AEC solutions in AA (50% w/w) are given in Table 1, where AEC-2 is a pure AEC with medium DA and AEC-3 is the mixture of EC and fully acetated AEC, which has the same average DA as AEC-2. However, in the liquid crystalline solutions, even at the same concentration, AEC-2 and AEC-3 have different pitch and handedness. This phenomenon was also observed in the lyotropic AEC/chloroform system.[86] The difference in chiro-optical properties may come from the complex interactions of multiple chiral centers present in each repeating unit of the cellulose chain, not from simple racemic mixtures as in the PBG system.

At the same concentration, the viscosities of AEC solutions are different such that the larger the pitch, the smaller the viscosity.[29] To eliminate the influence of viscosity of LCP solutions on the relaxation behaviors, the concentrations of AEC solutions were adjusted so that all solutions had similar viscosities under shear. As shown in Fig. 8, when the shear rate is between 0.5 and 6 s^{-1}, the four AEC solutions had the same viscosity.

Stress relaxation

Stress relaxation reflects fast relaxation at the molecular level and is independent of the previous shear rate. In the tumbling region (low pre-shear rate region), the final part of the stress relaxation curve is determined by the textural contribution because its time of evolution scales with the previous shear rate. This reflects the decrease in domain size with shear rate, which controls the scaling relations. In the flow align region, the textural contribution disappears and fast relaxation becomes nearly independent of shear rate.[87]

As shown in Fig. 9, the stress relaxation curves of all AEC/AA solutions collapse into one curve when the solutions were presheared with the same rate. Because the stress relaxation is at the molecular level and the chiro-optical properties reflect the suprastructural level, it is expected that the lyotropic solutions with different chiro-optical properties have the same stress relaxation behavior in both the tumbling and flow-align regions.

Dynamic modulus evolution upon cessation of flow

The development of storage and loss moduli after flow cessation is a useful tool to analyze structural relaxations on LCPs. Upon flow cessation, the flow-induced orientation is lost. The evolution of the moduli with time is because of the reformation of a chiral nematic phase that had become nematic under flow. In Fig. 10, the relaxation in complex modulus with time for various AEC samples is shown.

As seen in Fig. 10, the larger the pitch, the slower the rate the modulus evolution. The modulus of the right-handed mesophase (AEC-4) developed faster than that of the left-handed mesophase (AEC-1) with similar pitch. The difference in relaxation behavior of the AEC solutions may be because of the smaller driving force to reform helicoidal structures of chiral nematic phases from flow-induced nematic mesophases for the mesophases with larger pitch (nematic-like).

The reformation of chiral nematic phase from nematic phase sometimes goes through the transient state of band texture. The formation of band texture is also a relaxation phenomenon. For HPC/H_2O solutions, the band texture is only observed when the molecules have been well orientated in the shear direction.[76] A critical lower shear rate limit exists because of the stability of chiral nematic textures.

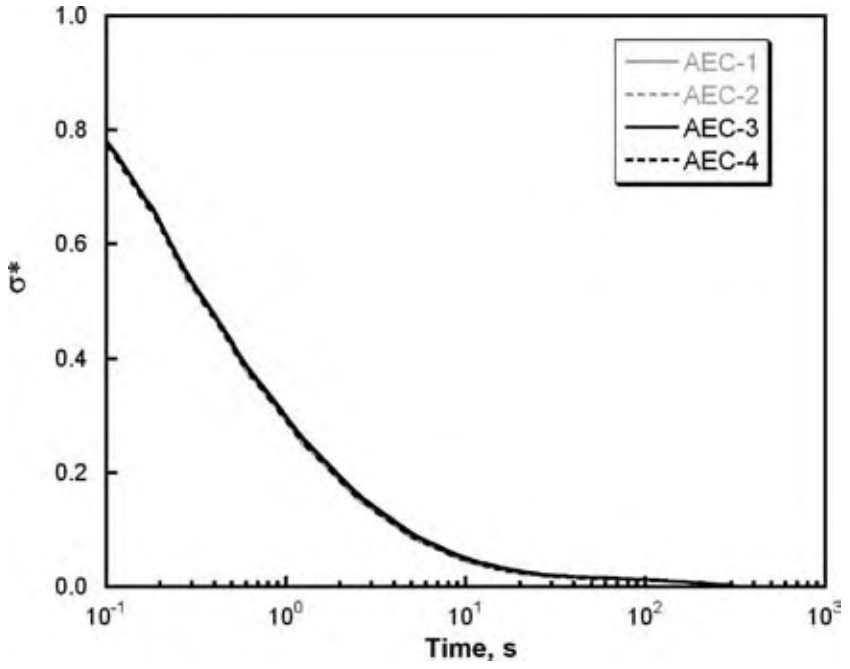

Fig. 9 Reduced shear stress $\sigma^*(\sigma^* = [\sigma(t) - \sigma_{fin}]/(\sigma_{in} - \sigma_{fin}))$ vs. time for all AEC/AA solutions.

An upper shear rate limit also exists above which no bands are formed.[88] The upper critical shear rate is associated with the flow-aligning region of molecular dynamics. Band texture formation is driven by the release of energy, which has been stored in the mesophase during shear.[76] The evolution of the band texture depends on the previous shear rate applied to mesophase. The rate of evolution of the band texture will increase, remain constant, or decrease according to whether the mesophase is sheared at low, intermediate, or high rates.[89] When the band texture appears during recoil, the appearance of the band texture stops the strain recovery process until the band texture disappears, and then recovery continues. Therefore, the presence of the band texture during recoil enhances the strain recovery.[90]

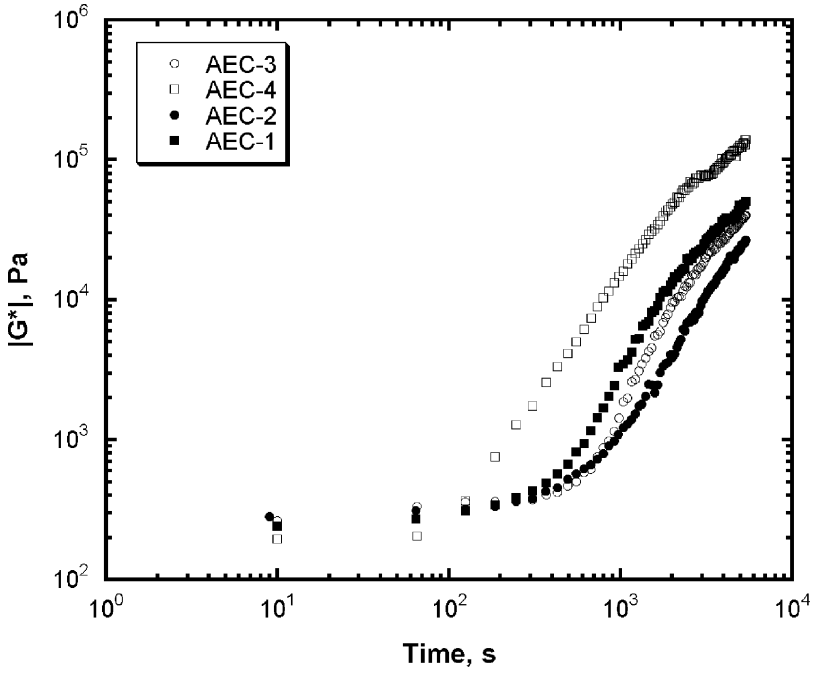

Fig. 10 Complex modulus evolution of AEC solutions vs. time.

CONCLUSIONS

Over the last three decades extensive information pertaining to the properties and behaviors of liquid crystalline cellulose derivatives has been obtained. However, the fact remains that fibers and films produced from cellulosic mesophases are inferior to those predicted by theory. A number of questions still remain surrounding these unique polymer systems. For example, what role, if any, do the pitch and handedness of the helicoidal structure play in determining the transient rheological behavior of lyotropic cellulosic mesophases. A correlation between the chiro-optical properties and relaxation behavior should be established. From our recent study, the relaxation behavior of lyotropic liquid crystalline solutions of (acetyl) (ethyl) cellulose was affected by the chiro-optical properties of the mesophase. In stress relaxation, handedness and pitch had no obvious effect. However, the development of complex modulus upon flow cessation was affected by pitch and handedness; the larger the pitch, the slower the rate the moduli evolved. Interestingly, however, the moduli of the right-handed mesophase developed faster than that of the left-handed one. Under flow, the cellulosic mesophases become nematic (shear aligned). Therefore, in samples with large pitch (nematic-like), the driving force to reform the helicoidal structures of chiral nematic phases upon removal of shear will be smaller than those with smaller pitch.

Rotational Molding of Polymers

Céline T. Bellehumeur
Department of Chemical and Petroleum Engineering, University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

Rotational molding, also known as rotomolding or rotocasting, is used to fabricate hollow plastic parts such as tanks used for chemical, agricultural, and automotive applications, toys, boat shells, and outdoor furniture. This process offers advantages over other processes in the fabrication of extremely large containers and of parts with intricate contours and free of weld lines. It is economically suited for short-run production and very large hollow articles, or for parts that have special constraints, which cannot be molded using other techniques. On the other hand, there are several disadvantages related to this process. The cycle time is long and typically ranges from 10 to 40 min, depending on the product size and molding conditions. The material cost is usually high due to the need for pulverization, and the choice of resins used in rotational molding is quite limited with polyolefins dominating the market. The process remains labor intensive, although some progress has been seen over the years in its automation. The rotational molding process has caught the attention of several major resin suppliers as well as mold and machine suppliers. The last few decades have also seen growing interest among researchers and designers, leading to significant technological advances through process modification, process control, part design, and the development of new materials.

In this entry, we focus on fundamental phenomena that control the quality of the end product from a processing and material perspective. The information will provide the reader with a better understanding of the process, which is necessary for the formulation of successful strategies in the development and processing of new resins for rotational molding applications. First, a detailed description of the rotational molding process is presented. This is followed by a discussion about particular features of the process, namely, melt densification and melt solidification phenomena. Recent technological advances in the development of resins new to rotational molding are also reviewed and presented in the last section of this entry.

ROTATIONAL MOLDING PROCESS

Process Description

The concept of rotational molding is illustrated in Fig. 1. The polymer is first loaded into a mold, which is then heated and rotated about its two primary axes (Figs. 1A and 1B). During the heating process, the tumbling powder gradually melts and sticks to the mold surface. Heating is continued after the powder has melted until complete densification is achieved. The mold is then cooled and the molded part is removed once it has reached a temperature safe for manual handling (Figs. 1C and 1D). Unlike most other polymer processes, rotational molding does not utilize pressure to force the melt into shape but relies primarily on the gradual deposition and adhesion of the polymer onto the mold. The mold rotation speed is relatively low (4–20 rpm) and the uniform coverage of the mold surface is ensured by the biaxial motion of the mold. The heating and cooling of the mold rely mostly on convective transport of energy. The most common method of heating is by means of gas combustion, while cooling relies on exposing the mold to forced air flow, water mist, water spray, or a combination of these methods.

In the rotational molding process, the resin is used mostly in powder form, the majority of which is produced through grinding between rotating metal plates. The quality of the powder depends on the pulverization process variables, such as the gap size between the plates, the temperature and blade conditions. Past studies have shown that the powder characteristics, namely, the shape, size, and size distribution, influence both the rotational molding cycle and the final product performance.[1,2] The quality of the powder affects heat transfer, the coverage of the mold cavity, as well as the initial size of bubbles during the melt deposition process. Simple screening procedures for the quality assessment of polymeric powder for rotational molding include particle size distribution, dry flow index, and bulk density. Typically, 35-mesh powder with a particle size distribution ranging from 100 to 500 μm is used in rotational molding as it provides a good balance between pulverization cost, powder flow characteristics, and powder packing

density. Both the flow index, which quantifies the ease of flow, and the bulk density are dependent on particle shape and size distribution.

Devices have been commercialized that allow for monitoring the temperature profile of the mold and the mold cavity during the molding process.[3] Such capability has led to important advances in the development of control protocols and process design. During the rotational molding cycle, all polymers exhibit a characteristic mold inside air temperature profile (see Fig. 2). Changes in the temperature profile are characteristic of key transitions in the processing of polymers. In Fig. 2, the region between points A and B represents the induction stage, where the solid polymer particles tumble freely in the mold and are heated primarily through conduction. Point B corresponds to the onset of powder adherence onto the mold surface and coalescence between individual particles, while point C marks the end of the melting phase. During the stage between B and C, semicrystalline polymers will undergo a melting transition that results in a reduction in the heat transfer to the mold inside air cavity and thus a reduction in the slope of the temperature profile. Such a change in the slope of the temperature profile is not as significant for amorphous polymers. The insulating effect of the deposited layer of polymer on the mold surface also causes a reduction in the heat transfer to the inner air. As the polymer particles adhere to the mold surface, pockets of air are trapped within the melt and form bubbles. The region from C to D corresponds to the fusion stage, where the bubbles undergo dissolution. Point D is often referred to as the peak internal air temperature (PIAT). The region between D and E characterizes the melt cooling stage. Point E indicates the residence time at which the melt undergoes recrystallization.

Molding Cycle Time

The rotational molding process is inherently transient, and the selection of optimal molding conditions will depend on several factors such as mold size, shape, and material, charge of the polymer, polymer thermal and rheological properties, convection conditions inside the oven, and cooling conditions. The measurement of the mold inside air temperature has been established as one of the means to control the molding cycle. Correlations between the PIAT and the mechanical properties of the molded part were first recognized by Crawford and Nugent.[4] Over the years, it has become a standard procedure to use the inside air temperature of the mold as an indicator in the determination of the time required for the completion of the heating cycle (melt densification) prior to the occurrence of polymer degradation upon exposure to high temperatures.

One important challenge in rotational molding is maximizing the mechanical properties of the end product while minimizing the molding cycle time. In many rotational molding applications, stiffness, dimensional stability, chemical resistance, and impact properties determine the performance of the final product. Processability encompasses the ability of a given resin to produce a final part with adequate properties when processed under a wide range of conditions (e.g., oven temperature, heating time, cooling conditions). The coalescence and melt solidification phenomena play a major role in both the molding cycle and the properties of the final parts. Resins with poor coalescence behavior require a longer heating time in the molding cycle, or the result will be the production of parts with large and numerous bubbles, which negatively impact the properties and appearance of the final product. The melt solidification behavior of the resins dictates the development of residual stresses and morphological features in the molded parts, which in turn contribute to the performance of the final products in commercial applications.

Over the years, guidelines that have to do with processing conditions, process control, powder quality, and material properties have been defined to optimize the process. A great deal of study has been carried out by Crawford's group, resulting in a number of

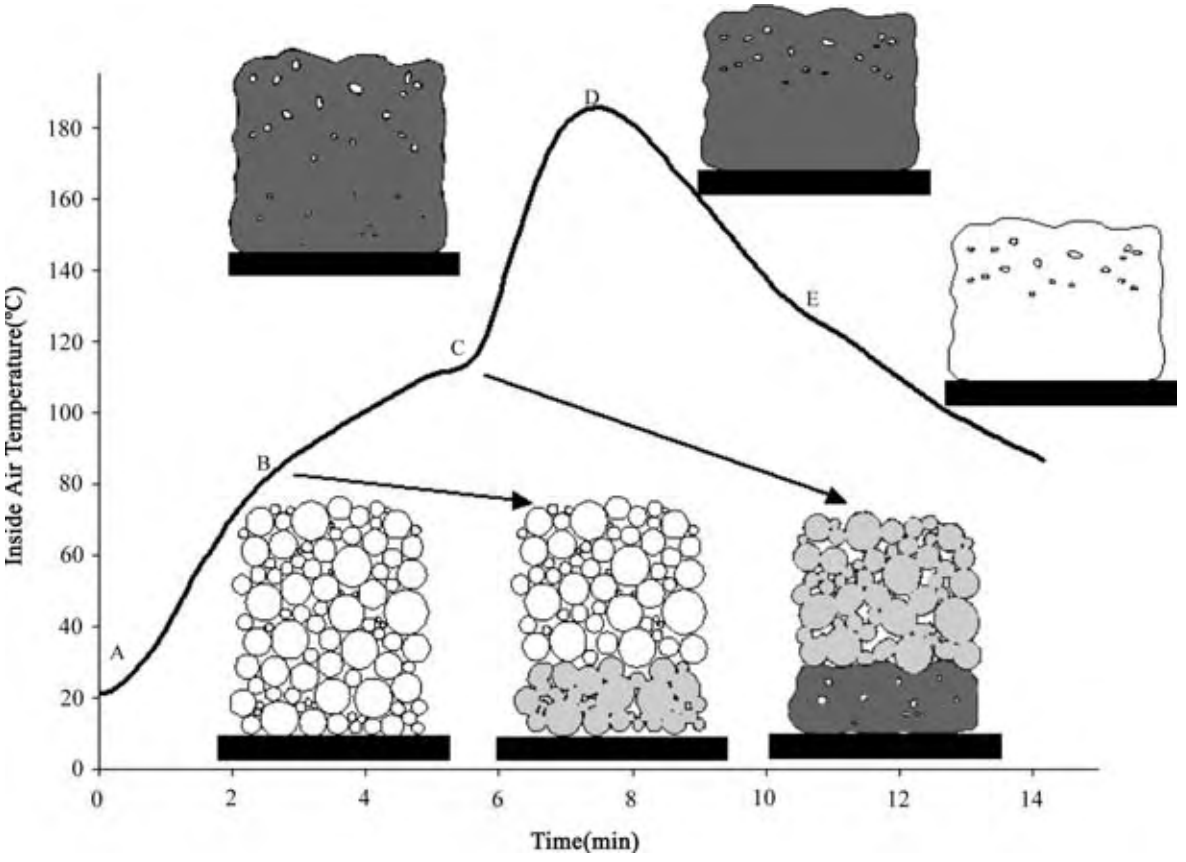

Fig. 2 Typical inside air temperature profile of mold.

patented technologies. The continuous monitoring of the inside air temperature as well as the inside pressure of the mold has been shown to provide useful information about the state of the material during the molding process and has been implemented into control strategies.[3,5] Strategies to reduce the molding time include preheating the powder and the mold, as well as using internal mold pressure in the late stage of the heating cycle for the removal of bubbles formed.[5] Along the same lines, mold pressurization during the cooling stage can significantly help reduce the cooling cycle time and also lead to improved dimensional stability of the molded product.[5,6] The identification of key material properties and their effect on the molding cycle and the performance of the final product are discussed in more detail in the following sections.

MELT DENSIFICATION

In rotational molding, two bulk movements dominate the melt deposition and densification: 1) the adhesion of particles on the mold surface and 2) the melting and collapse of the particulate structure.[7,8] The latter movement causes the entrapment of air into the melt and, thus, the formation of bubbles. Two distinct stages have been identified in the densification process: 1) particle coalescence and 2) bubble dissolution, as illustrated in Fig. 2.

Powder Coalescence

The coalescence of polymers is driven by the work of surface tension, which counteracts the viscous dissipation associated with the molecular diffusion within the coalescing domain. This phenomenon is often referred to in the literature as polymer sintering. In the rotational molding process, coalescence occurs at temperatures above that of the material melting point when dealing with semicrystalline polymers, or above the glass transition temperature for amorphous resins. The first analytical model describing the coalescence process was proposed by Frenkel:[9]

$$\frac{y}{a} = \left(\frac{\Gamma t}{\eta a}\right)^{1/2} \quad (1)$$

where y, a, Γ, t, and η are the neck radius formed between the particles, the radius of the particles,

material surface tension, time, and material viscosity, respectively. The model is based on the balance of the work of surface tension and the viscous dissipation. All other forces, including gravity, are neglected. The shape of the two spheres evolves, as shown in Fig. 3.

The validity of Frenkel's model is limited to Newtonian flow and can only be used to predict the early stage of the coalescence process, when the diameter of the two spherical particles remains nearly unchanged. The inadequacy of a Newtonian model in describing the coalescence of polymers was also demonstrated in other studies, as reviewed by Mazur, and has led to the development of models as well as alternative methods for the characterization of the coalescence behavior of polymers for rotational molding applications.[10] Based on theoretical and experimental analyses of the coalescence phenomenon, the material properties of primary interest in the evaluation of resin coalescence behavior in rotational molding have been identified as the resin viscosity, surface tension, and elasticity.

Most practitioners define the flow behavior of polymers based on the melt flow index; however, this property is not entirely relevant to the rotational molding process because it is essentially a shear-free and pressure-free process. The use of zero-shear viscosity has been proposed as a better way to assess the coalescence behavior of resins. Resins with lower zero-shear viscosity coalesce at a faster rate and can thus be processed using a shorter molding cycle.[11] The coalescence of individual powder particles is initiated as the particles stick and melt onto the mold surface or melt front. As the melt deposition process continues, pockets of air remain trapped between partially fused particles and lead to the formation of bubbles. In the rotational molding process, the coalescence of particles occurs at a temperature range close to the melting point of the material; thus, from a processing standpoint, low values of zero-shear viscosity at low temperatures (i.e., close to the temperature at which the particles adhere to the mold surface) are preferable.

In addition to zero-shear viscosity, material elasticity plays an important role in determining coalescence behavior in the rotational molding process.[10,12,13] For rotational molding grade material, this effect was first recognized from the experimental results obtained with impact modified polypropylenes and is illustrated in Fig. 4.[12] In this work, the relative elasticity of resins was evaluated based on stress relaxation measurements. The time required for the complete relaxation of the material was used as a measure of the melt elasticity. Resins with increased elasticity, but otherwise comparable zero-shear viscosities, produced parts with higher bubble content and, thus, lower density (see Fig. 4). In more recent studies, the relative elasticity of a resin has been evaluated from rheological oscillatory measurement, by comparing the ratio of the loss modulus over the elastic modulus (G''/G'). When comparing resins with similar molecular weight, low values of G''/G' at low frequencies are indicative of high elasticity, which translates into lower coalescence rates. The relative elasticity alone rarely explains poor coalescence behavior because resins with increased elasticity will often show variations in thermal and diffusion properties that are critical in the densification process. For instance, changes in the molecular structures leading to the broadening of the melting range can be detrimental to the coalescence process. Particles that soften at low temperatures and adhere to each other prior to a substantial movement of the bulk of the material cause the entrapment of large bubbles, as illustrated in the results presented in the literature.[8,14] Moreover, the presence of heterogeneities in the molecular formulation that cause the formation of segregated amorphous regions can seriously affect molecular interdiffusion and, thus, the coalescence process.

Molecular structure has an evident influence on a resin's rheological characteristics and expected coalescence behavior. Polymers with higher molecular weight have a slower coalescing rate because viscosity increases with molecular weight. Narrow molecular weight distribution results in lower elasticity and lower viscosity at low deformation rates, which is beneficial to the coalescence process. The comonomer content in polyethylene copolymers has mixed effects on the coalescence process. The increase of comonomer content generally results in a reduction in the melting temperature and the heat of fusion, which lead to earlier melting and onset of coalescence in transient molding processes. However, the incorporation of short-chain branches on linear polymer chains causes a reduction in the coalescing rate, as illustrated in Fig. 5. The effect of short-chain branches content on the coalescence rate may originate with the differences in the chain mobility due to variations of the chain linearity. The more linear the chains, the faster they are expected to diffuse.

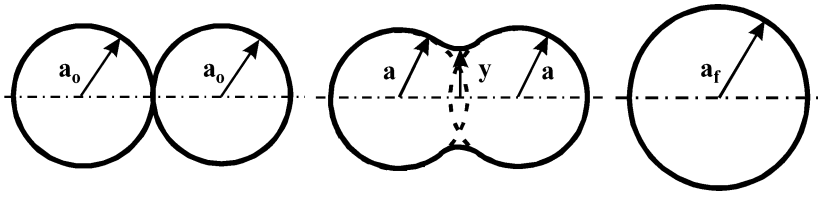

Fig. 3 Shape evolution of two coalescing spheres.

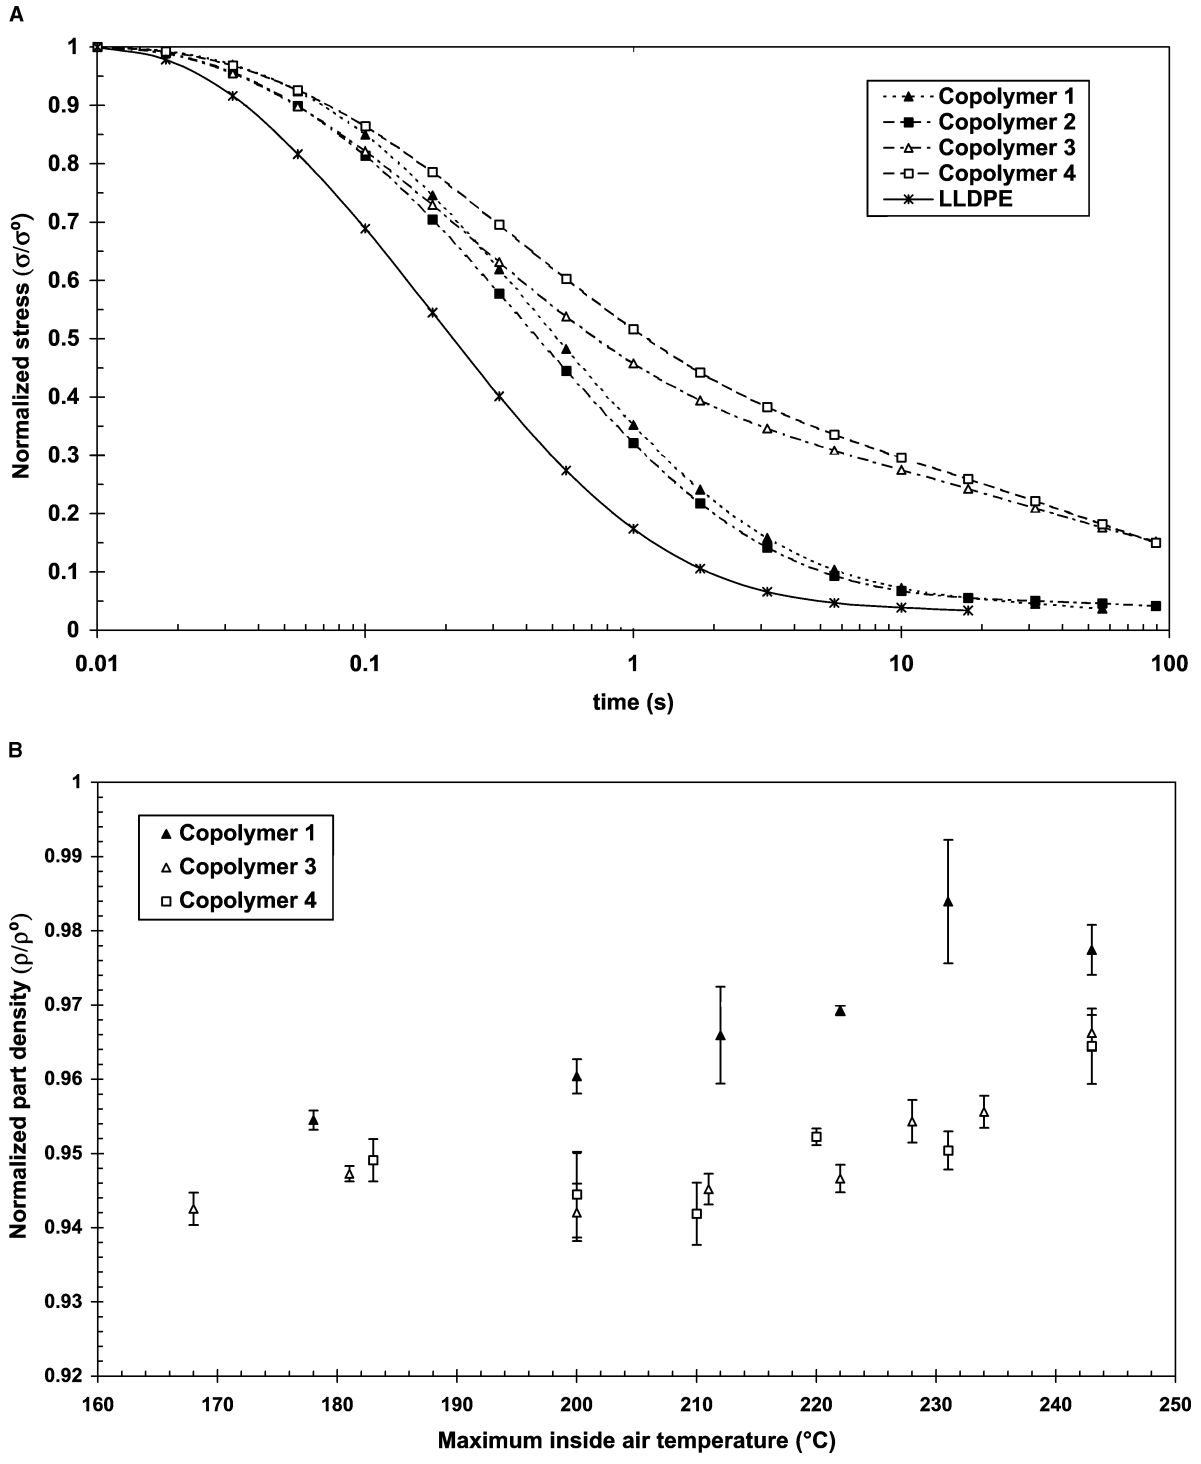

Fig. 4 (A) Stress relaxation curve of rotational molding grade ethylene copolymers. (B) Part density, which is indicative of the bubble content, measured after interrupting the rotational molding heating cycle at different heating times. (From Ref.[12].)

Variations in chemical composition and molecular structure can also have important repercussions on the surface energy of the material. Several techniques have been proposed for the experimental determination of surface tension, the sessile and pendant drop methods being the most promising and commonly used techniques. The common limitation of these techniques is that the melt surface energy is not directly measured; thus, the validity of the results depends on the underlining assumptions of the models used to fit the experimental observations. While surface tension has long been recognized as a controlling parameter in polymer

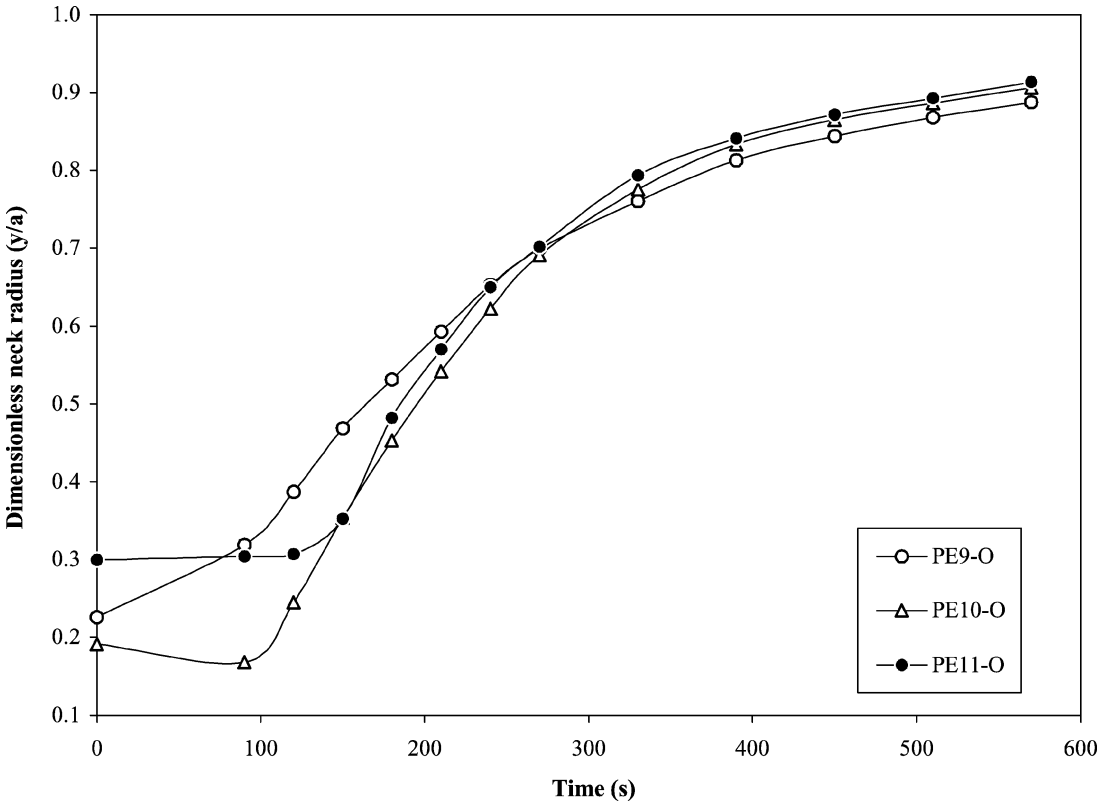

Fig. 5 Effect of comonomer content on the coalescence behavior of polyethylene copolymers at ramped temperature (111–226.5°C at 11°C/min). The relative methyl content for PE9-O, PE10-O, and PE11-O is 0.95, 0.56, and 0.15, respectively. (From Ref.[15].)

coalescence, limited work has been done in determining its effect on the processability of the resin in the rotational molding process.[16] The primary reason is that the measurement of the interfacial energy of polymer melts is challenging, owing to the viscous nature of the material and the potential for thermal degradation of the material upon exposure to high temperature and the long time scale of the experiments that have been defined for this type of measurement.

Dissolution of Bubbles

The level of coalescence between particles, the size of the particles, and the packing arrangement dictate the size of air cavities and, thus, the size of the bubble initially formed in the melt. Once formed, the bubbles remain stationary in the melt.[7] A relatively small bubble diameter, combined with the high viscosity of the melt, prevents the movement of the bubbles into the melt. The bubble removal is known to be a diffusion-controlled process. The identification of key parameters in the dissolution of bubbles formed in the melt has been done using a theoretical model that describes this process. The disappearance of the air bubble formed into the melt was modeled based on the analytical solution presented by Gogos:[17]

$$\left(R_0^2 - R^2\right) + \alpha_1(R_0 - R) + \alpha_1\alpha_2 \ln\left[\frac{R + \alpha_2}{R_0 + \alpha_2}\right] = 2D\frac{c_{s,P_\infty} - c_\infty}{\rho_\infty}t \tag{2}$$

where R_0 and R are the initial bubble radius and the bubble radius for the time interval t, respectively, and D is the diffusion coefficient of the gas into the melt (see Fig. 6).

The terms α_1 and α_2 in Eq. (2) are defined as follows:

$$\alpha_1 = \frac{4\Gamma}{R_g T}\left[\frac{2}{3} - \frac{c_{s,P\infty}}{c_{s,P\infty} - c_\infty}\right] \tag{3}$$

$$\alpha_2 = \frac{2\Gamma}{R_g T}\frac{c_{s,P\infty}}{\rho_\infty(c_{s,P\infty} - c_\infty)} \tag{4}$$

with R_g and T being the ideal gas law constant and the temperature of the melt–bubble system, respectively. The terms ρ_b and ρ_∞ symbolize the density of gas at the bubble/polymer melt interface for nonzero and zero surface tensions, respectively. The terms c_∞ and $c_{s,P\infty}$, which symbolize the dissolved gas concentration

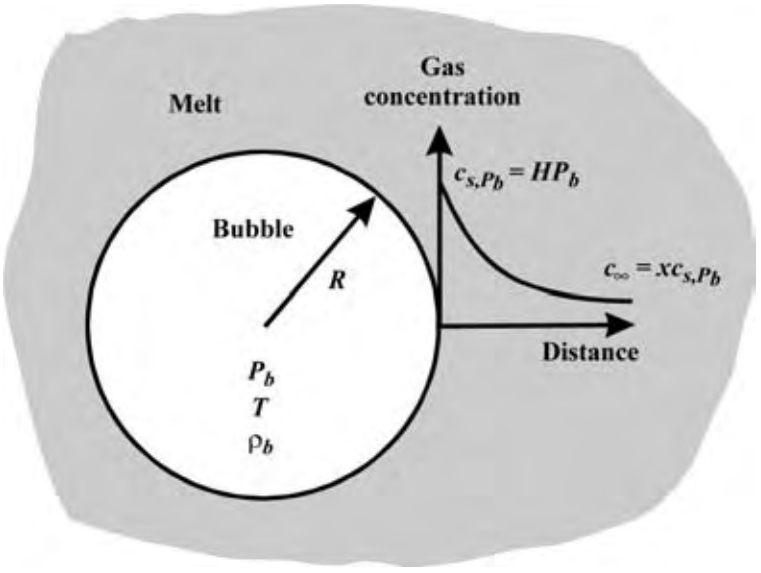

Fig. 6 Schematic of gas bubble dissolving into polymer melt with C_{s,P_b} being the dissolved gas concentration at the bubble/melt interface, c_∞ the dissolved gas concentration in the melt when partially saturated, x the degree of saturation in the melt, H Henry's law constant, P_b the bubble pressure, R the bubble radius, T the temperature, and ρ_b the density of the gas in the bubble.

in the melt when partially saturated and saturated for zero surface tension, respectively, are determined as follows:

$$c_{s,P_b} - c_{s,P\infty} = \frac{2\Gamma}{R_g T_P} \frac{c_{s,P\infty}}{R\rho_\infty} \quad (5)$$

$$c_\infty = xc_{s,P_b} \quad (6)$$

The dissolved gas concentration at the bubble/melt interface, c_{s,P_b}, can be related to the bubble pressure P_b through Henry's law. Gogos compared his model's predictions with the experimental data produced by Spence.[18] The model predictions fit very well with experimental data when selecting a degree of saturation close to 100% (91.9–99.6%). An alternative approach has been proposed by Kontopoulou and Vlachopoulos, who modeled the dynamics of bubble dissolution into the melt using conservation of mass and momentum.[19]

Factors that can affect the rate of bubble dissolution are the initial size of the bubbles, the temperature, the melt diffusion characteristics, the surface tension, and the solubility characteristics. The rate of consumption of oxygen due to degradation reactions probably contributes to the disappearance of bubbles, but this phenomenon has not yet been considered in the analysis of the process. It has been shown that within the range of viscosity typical to polyethylene rotational molding grade resins, the effect of viscosity on the dissolution of bubbles is marginal.[19] The level of air saturation in the polymer melt, however, was found to be crucial. While it cannot be determined accurately in the process, small variations in the level of saturation were found to cause large changes in the dynamics of the bubble dissolution.[17,19] Interfacial tension was shown to be important under conditions where the melt saturation level is close to unity.[17] The model proposed by Gogos was also useful in providing an explanation for the effect of mold pressurization on the bubble dissolution process. A sudden increase in the melt pressure causes a sudden shrinkage of the bubble. It also affects the level of melt saturation and causes an instep concentration gradient at the bubble/melt interface (see Fig. 6), leading to an increased rate of dissolution and faster removal of bubbles, as illustrated in Fig. 7. Experimental and theoretical results clearly showed that a small increase in the mold cavity pressure can lead to a significant reduction in the heating time required for complete melt densification in the rotational molding process.

Nonisothermal Densification

The densification process in rotational molding has been studied from both fundamental and practical perspectives. The models presented in the previous sections have furthered the understanding of the densification process in rotational molding; however, their use has been limited to the prediction of the densification process carried out under isothermal conditions. It is well known that heat transfer, powder coalescence, bubble formation, and bubble dissolution are collectively important in rotational molding; however, very few studies have addressed all aspects in modeling the densification process in rotational molding.

Heat transfer in the rotational molding process was first modeled by Rao and Throne.[20] Since this initial attempt at modeling the heating cycle, several studies

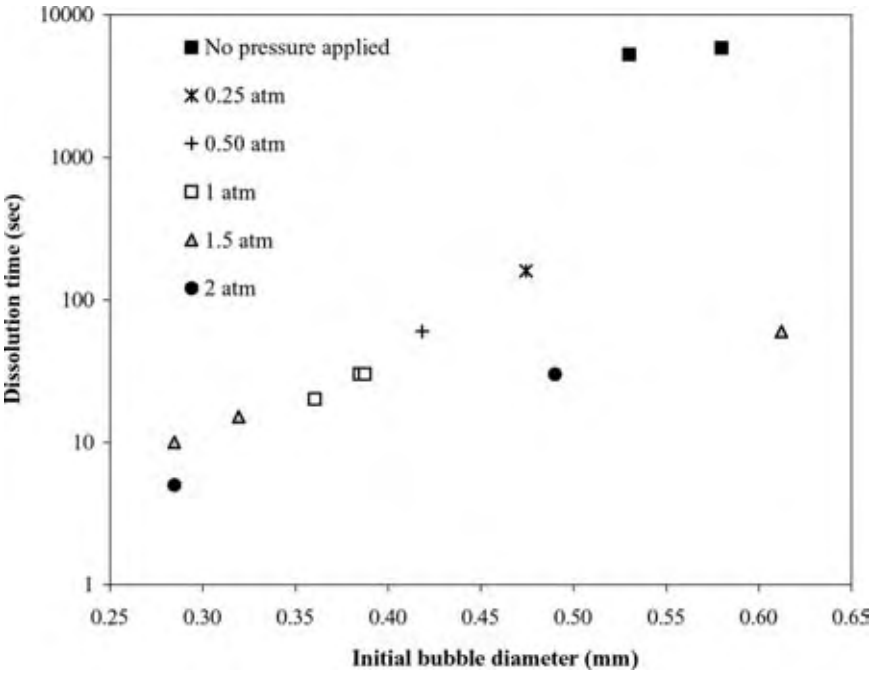

Fig. 7 Effect of mold cavity pressurization on the bubble dissolution time, based on experimental data presented by Spence. (From Ref.[18].)

have been undertaken to improve the model with consideration of different powder flow patterns, multidirectional heat transfer, complex mold geometry, internal heating, and the temperature dependence of the material properties. The thermal resistance within the mold wall was usually neglected. Moreover, it was generally assumed that the powder remains well mixed under conditions typically used in the rotational molding process. This assumption greatly simplified the modeling of the process, and model predictions have been found to be in good agreement with experimental results published in the literature.[21] However, the powder flow pattern may be better modeled using an avalanche or rolling type of flow, based on experimental evidence of the development of segregation patterns.[22,23] In most models presented in the literature, the mold curvature was neglected and only unidirectional heat transfer was considered. However, the trend toward the fabrication of more technically challenging parts with tighter specifications has provided some impetus to develop models that consider multidirectional heat transfer.[24] Moreover, the consideration of the kinematic of the mold rotation has been an important milestone in the development of commercial simulations that are used as design tools in the selection of rotation speed and heating conditions to ensure uniform melt deposition onto the mold surface for given mold geometry and polymer thermal properties.

The combined effect of heat transfer and sintering on the nonisothermal densification of polymer powder in rotational molding has been examined by Bellehumeur and Tiang.[25] For modeling purposes, the heating cycle was divided into three regimes: 1) heating of the mold and its contents until the mold temperature reaches the polymer melting point; 2) the polymer powder gradually melts and deposits on the mold surface; and 3) starts once all the powder has disappeared. In modeling the early stage of melt densification, the powder deposition process was treated as occurring in a layer-by-layer manner. The coalescence time allocated for each layer was determined by the rate of melt deposition. The initial size of the bubbles formed in the melt was determined by the neck growth achieved between particles, the size of the particles, and their packing arrangement. Bellehumeur and Tiang examined the relative importance of the powder characteristics and the material rheological properties on the melt densification process.[25] Their results showed that the initial size of the bubbles formed into the melt is primarily controlled by the powder particle size and packing arrangement (Fig. 8). This observation highlights the importance of powder quality on the molding cycle and the quality of the final product.

The time required by the melt deposition process is roughly proportional to the square of the molded part thickness and is significantly faster for polymers with lower melting points. A decrease in the heat of fusion also accelerates the deposition process, though not as much as a decrease in the melting temperature. A consequence of a fast melt deposition is that larger bubbles are formed in the melt, making them more difficult to remove during the heating cycle and negatively affecting the densification process. This problem can be surmounted with a reduction in the oven temperature; however, this reduction results in an increase in the total molding cycle time.

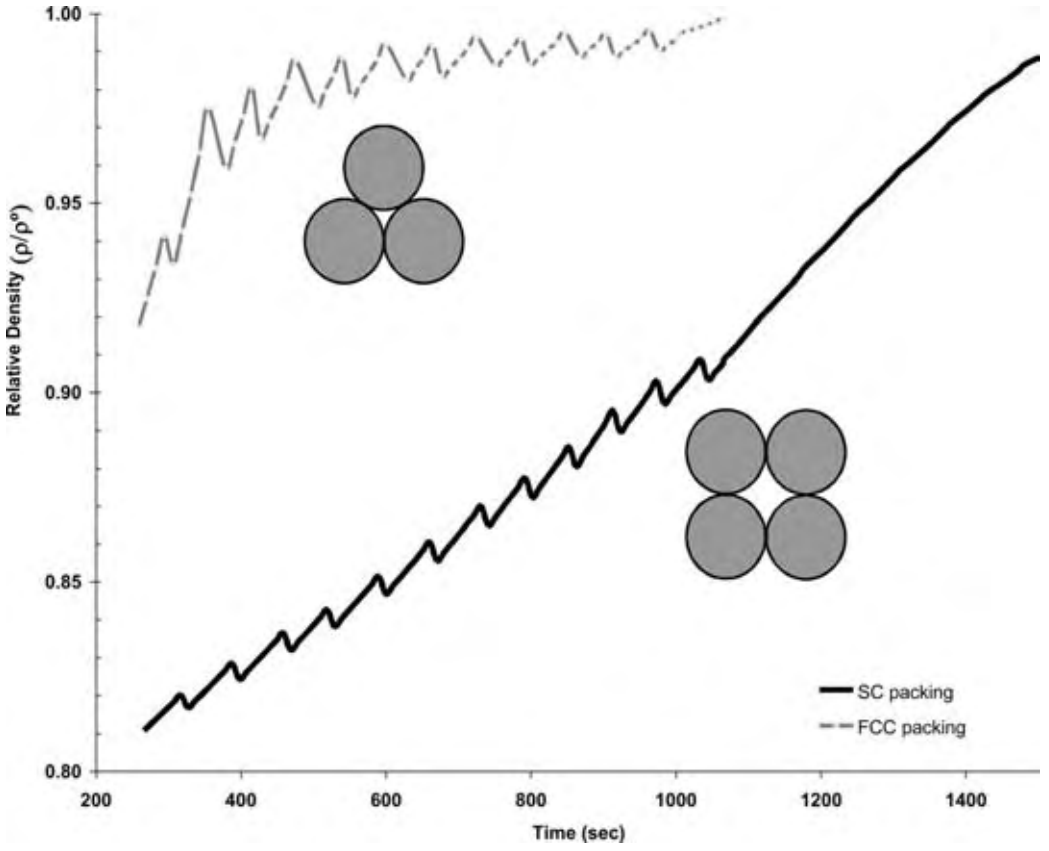

Fig. 8 Effect of the particle packing arrangement on the relative density of a rotational molding grade polyethylene with heating time. (From Ref.[25].)

MELT SOLIDIFICATION

The solidification of the polymer melt in rotational molding is relatively slow, in comparison to other processes, and is estimated to be in the range of 10–30°C/min. Moreover, the melt solidification is gradual and nonuniform across the molded part thickness, leading to important variations in the morphological features, as illustrated in Fig. 9, and dictating the properties and overall performance of the final product. The effects are more dramatic for resins with slower crystallization rates, such as polypropylene, compared to that observed with polyethylene.

Many thermoplastics used in rotational molding applications are semicrystalline in nature. The temperature and rate of crystallization vary with the material composition and molecular structure. Polymers that tend to crystallize have flexible backbones, regularly ordered atomic structure, and either small or no pendant groups. Crystallization occurring at higher temperatures is associated with a lower nucleation rate and the formation of coarse morphological structures. This usually results in the formation of structures that have a higher degree of stability and perfection but a lower failure strain, because the increase in the size of the spherulitic structure (common in polyethylene and polypropylene) is accompanied by a reduction in the interspherulitic boundary links. This, in turn, allows for the easier transmission of energy through the material and thus causes a loss in the ductility. This problem can be alleviated by using a faster cooling rate, which, on the other hand, leads to the generation of residual stresses in the parts. Because the material in contact with the mold is cooled at a faster rate than that near the inner surface, an asymmetrical residual stress profile is generated across the molded part thickness, inducing a bending moment of the part. If these induced residual stresses are high enough to overcome the structural integrity of the part, the molded part will deform and warp. Other factors that affect the development of residual stresses and the dimensional stability of the molded part include the material density, molded part thickness, mold material and thickness, rotation speed, and the application of mold release. The presence of residual stresses is associated not only with dimensional stability but also with the overall integrity of the molded part and is known to most severely affect the environmental stress cracking resistance of the product.

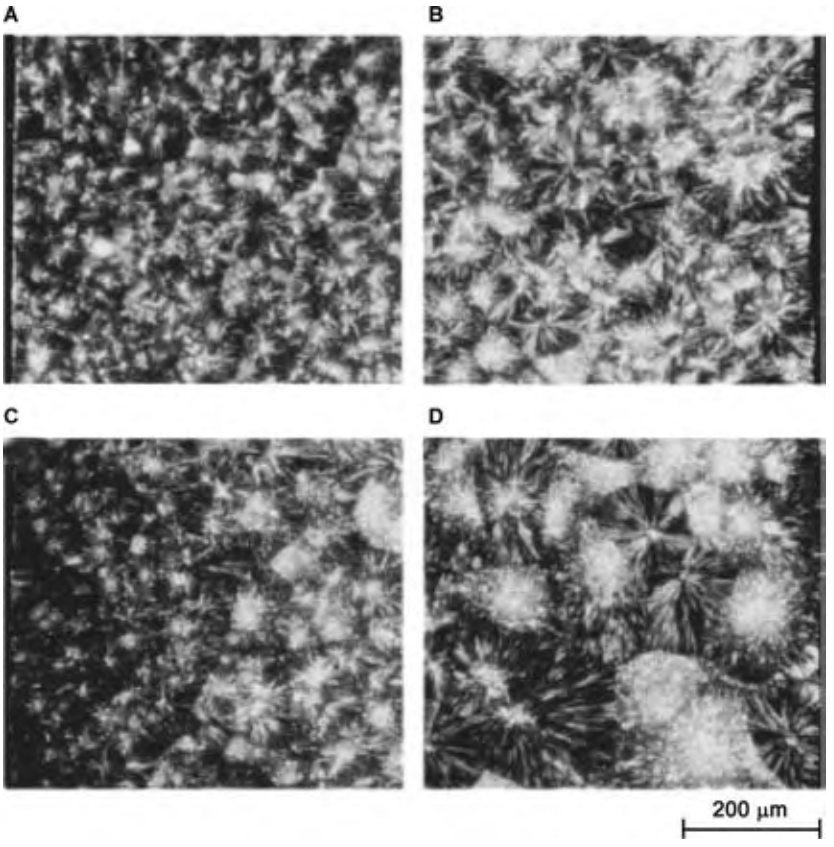

Fig. 9 Microphotograph of rotationally molded polypropylene parts subjected to water spray cooling (A, mold surface and B, inner surface) and parts initially subjected to water spray and subsequently air flow in the range of temperatures where crystallization occurs (C, mold surface and D, inner surface).[26]

In the rotational molding process, the polymer is subjected to high temperatures for relatively long periods of time to allow for melt deposition and full densification of the powder particles. As a consequence, thermo-oxidative degradation reactions can be severe if the material is not adequately stabilized. Degradation can often be determined by visual inspection of the molded part (change in color). Subtle changes can be detected through polarized or fluorescence microscopy (illustrated in Fig. 10) or infrared spectroscopy for the detection of carbonyl groups. The rheological characterization of specimens collected from the molded part can also provide useful information for degradation reactions can cause either chain scission or cross-linking reaction within the materials. Signs of degradation are usually first seen on the inner surface of the molded part for it is exposed to air during the entire molding process. Degradation reactions can be minimized with the use of an inert atmosphere in the mold. Excessive degradation of the material due to long exposure at high temperatures leads to the deterioration of the morphology (spherulitic structure) and the reduction in the mechanical properties of molded parts.[26,27]

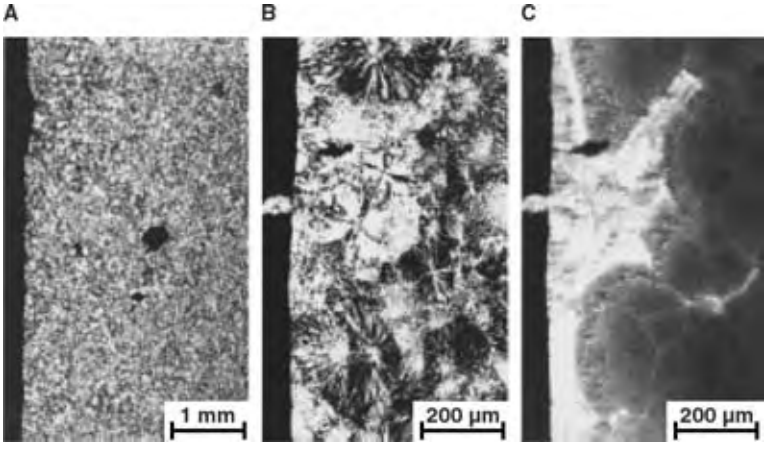

Fig. 10 Microstructure of rotationally molded polypropylene samples: (A) undercured specimen viewed under polarized light microscopy; (B) overcured specimen viewed under polarized light microscopy; and (C) overcured specimen viewed under fluorescence microscopy. In these pictures, the degraded layer shows higher birefringence. (From Ref.[26].)

Despite the importance of the melt solidification phenomena in rotational molding, only a few studies have been conducted with respect to modeling the cooling stage of the rotational molding process. One of the challenges resides in the nonlinearity of the model, which arises due to the unknown position of the moving solid/melt interface, and which is very similar to that encountered in modeling the heating stage of the rotational molding process. Throne pioneered this topic and investigated the various factors influencing the cooling rates.[28] Further work has been conducted to model this stage of the process with consideration of shrinkage, which can also greatly affect the molding cycle time.[24] Methodologies have also been proposed for the development of morphological features during processing based on half-time crystallization data, determined from differential scanning calorimetry, and spherulitic growth rate, which was obtained from optical microscopy experiments.[29] These are important steps toward the establishment of material–structure–properties–processing relationships for the rotational molding process.

TECHNOLOGICAL ADVANCES IN THE DEVELOPMENT OF NEW MATERIALS

Polyethylenes account for over 80% of all rotational molding production. They dominate the rotational molding market because of their thermal stability, availability in powder form, and relatively low cost. Over the last decade, polyolefins based on metallocene and single-site catalyst technologies have found their way into the rotational molding market. These technologies allow for better control of the molecular structure, which can have important repercussions on the processing behavior of the material as well as on the physical, chemical, and mechanical performance of the molded parts. Early results obtained with metallocene polyolefins suggested that these resins could be processed using a shorter heating time in rotational molding. In most studies, the reduction in the heating cycle was attributed to differences in the thermal properties (melting point and heat of fusion) between metallocene and Ziegler–Natta resins. However, warpage was commonly reported as a problem associated with using metallocene-based polyethylene. A more recent study showed that, with careful control of the molecular structure and the introduction of a certain level of heterogeneities, a significant reduction in the molding cycle time (up to 30%) could be achieved while maintaining adequate physical and mechanical properties.[30]

One important limitation in expanding the markets for rotational molding applications is the small range of resins suitable for the process. One cause for this limited choice of resins used commercially resides in poor processability behavior and the cost of pulverization, which is particularly important for resins that require cryogenic conditions. Alternatives to the use of powder particles in rotational molding have been proposed, thus eliminating the need for pulverization. The underwater pelletizing technology can be used to produce small cylindrical particles called micropellets, which are being used increasingly for rotational molding applications. It is well established that micropellets have better flow properties than powder particles. This characteristic has a significant impact on the thickness uniformity of molded parts and mold filling for complex geometries. However, one disadvantage of using micropellets is their narrow particle size distribution and their larger particle size. The packing of micropellets during the melt deposition process is such that larger bubbles are formed, compared to that seen when using a 35-mesh powder. These larger bubbles require a longer exposure to high temperatures for their complete dissolution.

Recent years have seen increased interest in the development of new rotational molding grade resins, which include polypropylene, acrylonitrile butadiene styrene, acetals, polyamides, thermoplastic foams, polyolefin blends, polyolefin plastomers, thermotropic liquid crystal polymers and nanocomposites. Two major concerns exist for the development of new resins: 1) obtaining adequate product performance and 2) achieving adequate processability. The most important roadblock in the development of many new resins, such as styrenic copolymers and polypropylene, resides in the fact that good impact properties can only be obtained with the incorporation of an impact modifier, often taking the form of a copolymer. Unfortunately, such a change in the material formulation often results in an increase in the material's relative elasticity, which is detrimental to the densification process and results in the production of parts with high bubble content and poor surface finish. Similarly, while the successful incorporation of nanoparticles in a polymer matrix can lead to the improvements of properties such as barrier resistance, it can also result in a dramatic increase in the linear viscoelastic properties. This proves to be an important drawback because increased zero-shear viscosity and elasticity are detrimental to the processability of the material. The traditional approach to solving this problem has consisted in varying the parameters known to affect properties that are key to the coalescence process (i.e. viscosity, elasticity, surface tension) with the incorporation of lubricants and other additives.[31] Promising results were also obtained for processing polyolefin plastomers with the uniform incorporation of the copolymer using metallocene catalyst technologies.[14] Alternative approaches have also included the careful selection of processing conditions that favor the completion of the coalescence

process between individual particles prior to the formation of bubbles into the melt.[32]

CONCLUSIONS

The rotational molding industry has seen a steady growth in the last two decades with the development of new process control strategies, machinery, and, to some extent, automatization. Yet, the development of new rotational molding applications is restricted for the processing cycle times are long and the choice of resins that can economically be used in this process is shockingly limited. The development of new resins is possible only if adequate product performance can be obtained while maintaining adequate processability. This can only be achieved with a good understanding of the phenomena that govern the quality of the end product. From a material formulation perspective, the key aspects to consider are the melt coalescence and melt solidification. While there has been significant progress in the development of methods for the rapid assessment of the processability and performance of resins, further work is required in defining strategies to overcome many of the process limitations.

Rubber Devulcanization

David A. Benko
Roger N. Beers
The Goodyear Tire & Rubber Company, Akron, Ohio, U.S.A.

INTRODUCTION

During the preparation of many rubber articles such as tires a variety of additives including sulfur, accelerators, and activators are used to induce sulfur cross-links between the rubber chains. These are formed during the heating or curing process and together with reinforcing fillers give the article its strength. Table 1 shows the composition of a rubber compound typical of that used in a body ply of a radial passenger tire.

The cross-links are composed of structures containing various sulfide lengths, usually described as monosulfidic, disulfidic, or polysulfidic, which are determined by the type, amount, and proportion of additives used in the rubber compound.

Devulcanization in a sulfur cured rubber is defined as the cleavage of the mono-, di-, and polysulfidic cross-links formed during vulcanization (Fig. 1). The vulcanization process is irreversible and additional heating induces changes in the network with a shift toward shorter cross-links but does not devulcanize the compound. Other methods are therefore needed to induce devulcanization.

BACKGROUND INFORMATION

Because of the large numbers of used tires existing in stockpiles throughout the United States it is desirable to recycle these tires back into new products. Unfortunately, simply grinding up the used tire and adding the resultant material to virgin rubber causes a significant drop in properties including reducing the strength and flexibility of the compound.

The need for a commercially viable devulcanization process has existed for years and continues to be a goal. Devulcanization without rubber chain degradation offers the potential for recycling used tires back into new products without sacrificing performance.

Considerable effort has been directed to solving this problem.[1,2] Although chemical probes have been developed that selectively cleave carbon–sulfur and sulfur–sulfur bonds but not carbon–carbon bonds, most of the effort on devulcanization processes has been focused on providing a usable form of rubber suitable for use as a reclaimed material in new articles.[3] In most cases direct evidence for actual devulcanization, i.e., breaking sulfur–sulfur and carbon–sulfur bonds without polymer chain scission, is lacking. However, in many instances the so-called devulcanization process increases the suitability for reuse (Fig. 2).

This article will review the classical chemical methods of devulcanization and their inherent limitations. The newer methods of devulcanization currently under development will also be reviewed. These include devulcanization using microbes, microwave, ultrasonically induced devulcanization, and devulcanization using supercritical fluids.

CHEMICAL DEVULCANIZATION

A large number of chemical devulcanization agents for natural and synthetic rubbers have been developed. These include phosphines and phosphates, numerous sulfides and mercaptans, metal salts such as methyl iodide, phenyl lithium, lithium aluminum hydride, and phase-transfer catalysts.[3–25]

Included in the list of sulfides and mercaptans are diphenyl disulfide, dibenzyl disulfide, diamyl disulfide, bis(alkoxy aryl) disulfides, butyl mercaptan and thiophenols, xylene thiols and other mercaptans, phenol sulfides and disulfides.[6–13,26,27]

Cook and coworkers reported the preparation, evaluation, and structural correlation of alkyl phenol sulfides as devulcanizing agents for styrene–butadiene rubber (SBR).[13] The effect of these alkyl phenol sulfides as reclaiming agent was compared with that of many aromatic thiols. Some *N*,*N*-dialkyl aryl amine sulfides were shown to be highly active reclaiming agents for vulcanized SBR in both neutral and alkaline reclaiming processes.[12]

A review of the science and technology of reclaimed rubber was published by Le Beau in 1967.[14] Knorr has shown the action of diaryl disulfide on the natural and synthetic rubber scraps of technical goods.[15]

A reaction mechanism for the breaking of polysulfide bonds in the presence of propane thiol/piperidine probe was proposed by Saville and Watson.[28] The thiol-amine combination gives an associate, possibly piperidinium propane-2-thiolate ion pair where sulfur atoms enhance the nucleophilic character that is responsible for cleaving

[b]Diene rubber includes natural rubber, polyisoprene rubber, butadiene rubber, and styrene–butadiene rubber.

organic polysulfide linkages. The cleavage of polysulfide cross-links takes place possibly as a result of p_π–d_π delocalization of the displaced sigma electron pair of RSS^-. Campbell found hexane-1-thiol to be more reactive and thus capable of cleaving both polysulfide and disulfide linkages while leaving the monosulfides intact (Fig. 3).[29]

Moore and Trego described the use of triphenyl phosphine and di-*N*-butyl phosphate as chemical probes to establish a cross-link network structure in rubber vulcanizates.[4,5] Triphenyl phosphine and trialkyl phosphates cleave di- and polysulfide, as illustrated in Fig. 4.

Studebaker identified the use of lithium aluminium hydride as a chemical probe.[23,24] Under the right conditions it cleaves poly- and disulfide bonds, leaving the monosulfide intact. Lithium aluminum hydride reacts with polysulfides in an etheral solvent at moderate temperatures and then with a weak acid, the terminal groups are liberated as thiols and interior sulfur atoms are converted to hydrogen sulfide.[30–39] Lithium aluminum hydride under appropriate reaction conditions also cleaves disulfide bonds in organic disulfide, which is structurally related to cross-links, into two thiol groups.[32]

Similarly Gregg and Katrenick found that phenyl lithium will cleave polysulfides and disulfides but not monosulfide linkages.[21,22]

Methyl iodide can be employed to estimate monosulfide linkages in vulcanized natural rubber (NR).[33,34] After swelling the rubber in methyl iodide for several days the level of network bound iodine after reaction would reflect the concentration of monosulfide groups because the simple saturated monosulfide group reacts as shown in Fig. 5.

Simple disulfides reacted very slowly with methyl iodide but their reaction and those of monosulfides could be catalyzed by mercuric iodide.[35,36]

Anderson patented the reclaiming of sulfur vulcanized rubber in the presence of oil, water vapor, and a mixture of aryl disulfides (diphenyl disulfide, dicresyl disulfide, and dixylyl disulfide) at elevated temperature and pressure.[40]

Desulfurization of suspended rubber vulcanizate crumb (10–30 mesh) was carried out in a solvent such as toluene, naphtha, benzene, or cyclohexane in the presence of sodium.[41] The alkali metal cleaves mono, di- and polysulfidic cross-linkages of the swelled and suspended vulcanized rubber crumb at around 300°C in the absence of oxygen. As claimed by the authors, such treatment yielded a rubber polymer having a molecular weight substantially equal to that of rubber prior to vulcanization.

2-Mercaptobenzothiazole was also found to be effective as a reclaiming agent.[42] In this process

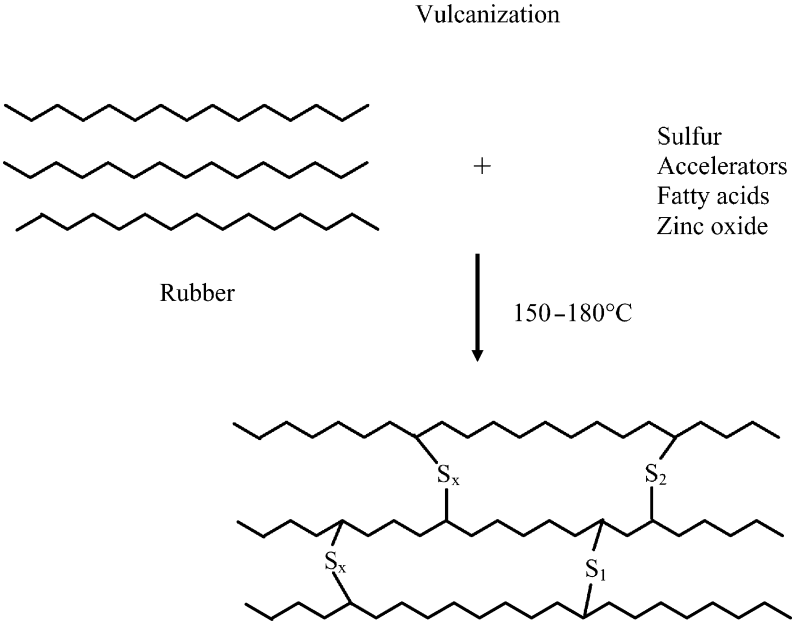

Fig. 1 Vulcanization.

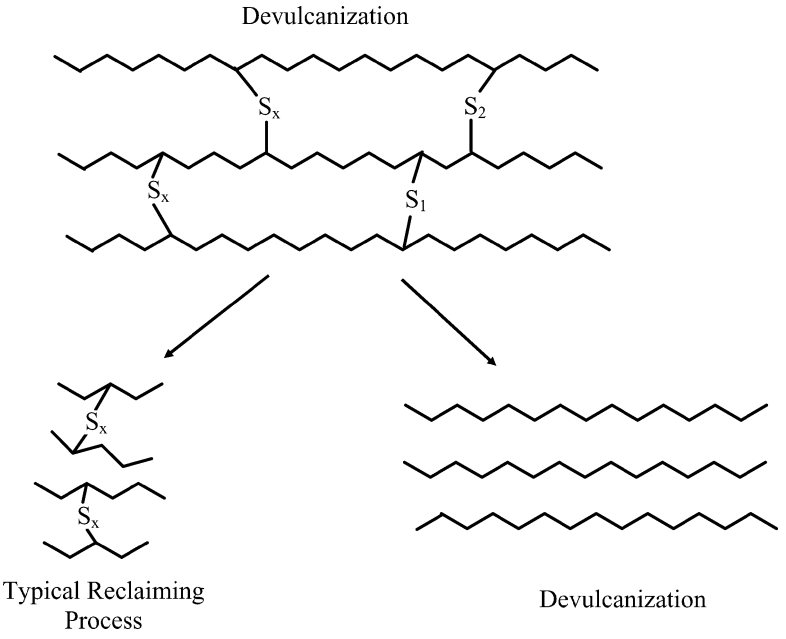

Fig. 2 Devulcanization.

powder rubber from waste tires was kneaded with process oil in the presence of 2-mercaptobenzothiazole or its cyclohexylamine salt to give reclaim rubber.

Vehicle tire scrap containing polyisoprene rubber, SBR, and butadiene rubber was devulcanized by low-temperature phase-transfer catalyst. Both the devulcanizing agent composition and the process were patented. The novelty of this process lies in the use of low-temperature phase-transfer catalyst and a process temperature lower than 150°C. The devulcanized rubber of this invention is distinguishable from conventional reclaimed rubber in that the devulcanized rubber is substantially free from polysulfide cross-links, which are selectively broken during the process with negligible main chain scission.[25,43]

Microwave Method

The microwave method is useful because it provides an economical, ecologically sound method of reusing elastomeric waste to return it to the same process and products in which it was originally generated. In this technique a controlled dose of microwave energy is used at a specified frequency and energy level to cleave carbon–carbon bonds.[44–46] Thus, in this process elastomer waste can be reclaimed without complete depolymerization to a material capable of being recompounded and revulcanized having physical properties essentially equivalent to the original vulcanizate.

In typical commercial processes the ''devulcanized'' rubber is not degraded. In this process it is claimed that

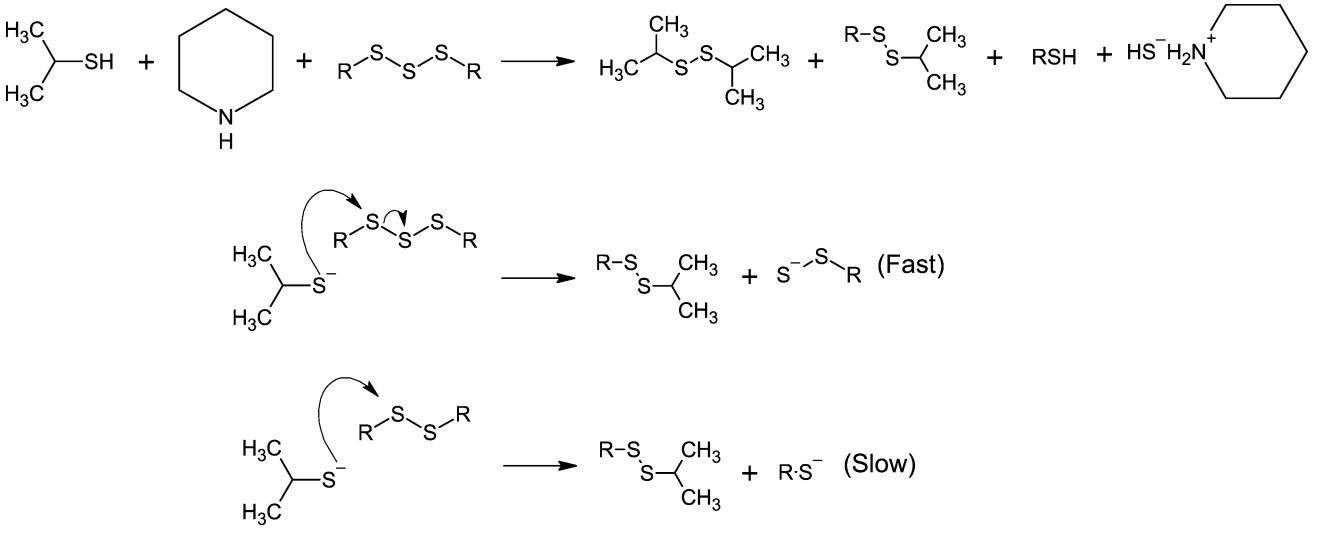

Fig. 3 Polysulfide bond breaking with thiols.

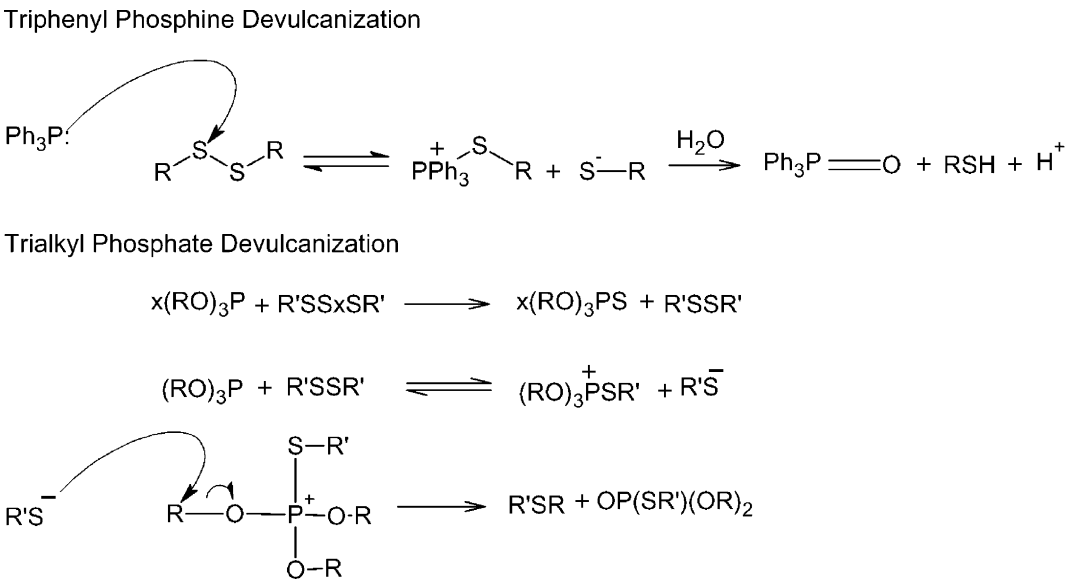

Fig. 4 Phosphine and phosphite devulcanization.

sulfur vulcanized elastomer containing polar groups is suitable for microwave devulcanization. Tyler and Cerny claimed their microwave devulcanization process as a method of pollution controlled reclaiming of sulfur vulcanized elastomer containing polar groups.[47] The microwave energy devulcanization device generates heat at a temperature in excess of 260°C to yield a mass, which is fed to an extruder that extrudes the rubber at a temperature of 90–125°C. The extrudate can be used per se as a compounding stock. Another process was developed for reclaiming waste elastomers by microwave radiation. The process involves the impregnation of the waste rubber with an essential oil and then heat treating the impregnated material under reduced pressure with microwave radiation.[48]

The waste material must be polar so that the microwave energy will generate the heat necessary to devulcanize. Microwave energy between 915 and 2450 MHz and between 41 and 177 W/hr/lb is sufficient to sever all cross-link bonds but insufficient to sever polymer chain degradation. The cost of devulcanized

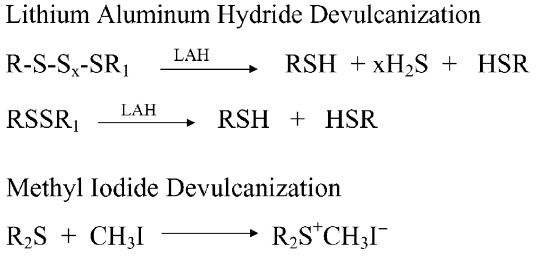

Fig. 5 Lithium aluminum hydride and methyl iodide devulcanization.

hose and inner tube material by the microwave method is only a fraction of the cost of the original compound. The transformation from waste to refined stock ready for remixing takes place in only 5 min with usually 90–95% recovery of the rubber. Therefore, it appears that this microwave technique is a unique method of reclaiming in terms of properties and fastness of the process.

Ultrasonic Method

After the microwave techniques, ultrasonic energy was used for the devulcanization of cross-linked rubber. The first work with ultrasonic energy was reported by Pelofsky in 1973, which was patented.[49] In this process solid rubber articles such as tires are immersed into a liquid, which is then kept under a source of ultrasonic energy whereby the bulk rubber effectively disintegrates upon contact and dissolves into liquid. In this process ultrasonic irradiation is in the range of about 20 kHz and at a power intensity of greater than 100 W.

Ultrasonic reclaiming of NR was reported by Okuda and Hatano in 1987, which was also patented.[50] They subjected the NR vulcanizate to 50 kHz ultrasonic energy for 20 min to achieve devulcanization followed by revulcanization and obtained reclaimed rubber with similar properties to those of original rubber. Isayev and coworkers reported in a number of publications the phenomenon of devulcanization by ultrasound energy and they also patented their developments.[51–59]

The devulcanization process requires a high energy level to break carbon–sulfur and sulfur–sulfur bonds.[1] An ultrasonic field creates high-frequency extension–contraction stresses in various media.[1] Isayev and his group also made a percolation simulation of the network degradation during ultrasound devulcanization in which they claimed an excellent agreement of experimental data for SBR and ground rubber from used tires (GRT) with the predicted dependence of the gel fraction of devulcanized rubber on cross-link density. Curing behavior, rheological properties, structural characteristics of devulcanized rubber from model SBR and GRT rubbers, as well as mechanical properties of vulcanized rubber samples were studied and a possible mechanism of devulcanization was also discussed. They characterized the degree of devulcanization by the measurement of cross-link density and gel fraction of the devulcanized rubber. Later, they published on the ultrasound devulcanization of sulfur vulcanized SBR and on vulcanization of ultrasonically devulcanized SBR elastomers.[60]

Isayev and coworkers studied the devulcanization of SBR at various temperatures, viz., 121°C, 149°C, and 176°C, different clearances at various flow rates, and the ultrasonic oscillation amplitudes.[51–53] The extent of devulcanization was studied by measuring percentage and cross-link density of the gel fraction. It was reported that both the cross-link density and the gel fraction decrease in the devulcanization process. For original ground rubber tire the measured gel fraction is 83% and cross-link density of gel is 0.21 kmol/m^3, but after ultrasound treatment at 121°C barrel temperature it reduces to 64–65% with cross-link density of 0.02 kmol/m^3. The cross-link density also decreases with higher residence time in the treatment zone and with higher specific ultrasonic energy.

The mechanical properties of the revulcanized sample were also studied. With decrease in the cross-link density of the devulcanized rubber, the tensile strength of revulcanized samples varies from 1.5 to 10.5 MPa and elongation at break varies from 130% to 250%. Based on the results of mechanical properties, Isayev et al. proposed that the devulcanized sample having a cross-link density lower than 0.06 kmol/m^3 can be regarded as overtreated, and samples with cross-link density higher than 0.10°kmol/m^3 can be regarded as undertreated.[52] Thus, overtreatment causes main chain breakage and undertreatment causes insufficient devulcanization. They also reported that ultrasound treatment of SBR results in low molecular weights of the sol fraction: $M_n = 2 - 4 \times 10^3$.[53] Ultrasonic devulcanization, therefore, causes significant degradation of polymer chains. A simple model based on a purely topological consideration was proposed and simulation of the process was carried out.[61–64] In the model they have assumed a breakup of the main chain bond and cross-link bonds as independent random events. Such random scission of cross-links and main chain results in the formation of soluble branched rubber chains regarded as fragmented gel structure or microgel. It is found that during ultrasound devulcanization the molecular weight of sol fraction decreases, from which it may be understood that during ultrasound treatment not only C–S or S–S bonds but also C–C bonds break. Isayev et al. suggested a revulcanization scheme.[55] They concluded that devulcanized rubber contained a larger amount of sulfidized molecules that were responsible for cross-linking during revulcanization.

Biotechnological Processes

Biodegradation of NR was recognized as early as 1914.[65] But an effective process was not discovered because rubber is a hydrophobic substance that is subject to attack only at the surface, rubber vulcanizates are highly cross-linked and highly branched, and rubber vulcanizates contain a large number of biologically active additives that retard biodegradation. Various biodegradation processes were tried over the years since, with some success reported, particularly after about 1985.

Fermentation methods were studied extensively at Rutgers University by Nickerson and coworkers and by Elmer in the 1970s on ground scrap tires.[65] Their work was aimed at producing commercially valuable products via the fermentation process from scrap tires. This work led to many important findings and showed that although technically feasible, this was not a solution to get rid of scrap tires. Even under ideal conditions only minor reduction of the rubber occurred.

An interesting recent approach was reported in a patent application to utilize a chemolithiotrope bacterium in aqueous suspension for attacking powder elastomers on the surface only, so that after mixing with virgin rubber, diffusion of soluble polymer chains is facilitated and bonding during vulcanization becomes again possible.[66,67]

A biotechnological process was developed by Straube et al. for the devulcanization of scrap rubber by holding the comminuted scrap rubber in a bacterial suspension of chemolithotropic microorganisms with a supply of air until elemental sulfur or sulfuric acid is separated.[68] This seems to be an interesting process, which obtains reclaim rubber and sulfur in a simplified manner.

The biodegradation of the *cis*-1,4-polyisoprene chain was achieved by Tsuchi, Suzuki, and Takeda.[69–71] They used bacterium that belonged to the genus *Nacardia* and led to considerable weight loss of different soft-type NR-vulcanizates. The microbial

desulfurization or devulcanization of particle surfaces was investigated to increase the possibility of producing high-quality rubber products containing a larger percentage of recycled rubber.[72]

In a typical process rubber powder, mainly SBR of old tires with 1.6% sulfur, was treated with different species of *Thiobacillus*, i.e., *Thiobacillus ferrooxidans*, *Thiobacillus thiooxidans*, and *Thiobacillus thioparus* in shake flasks and in a laboratory reactor. The sulfur oxidation depends to a large extent on the particle size. The best results were obtained with *T. thioparus* with a particle size of 100–200 μm. Of the total sulfur of the rubber powder, 4.7% was oxidized to sulfate within 40 days.[72]

In a recent paper Steinbuchel studied the biological attack of microorganisms on rubber materials to evaluate the possible contributions of biotechnology for the development and recycling of used rubber products.[73] Adaptation of microbial enrichment cultures with tire crumb material for several months resulted in enhanced growth of microorganisms, especially for NR and SBR.

Romine and Snowden-Swan developed a process for exposing fine powdered rubber to an enzyme that attacks the sulfur cross-links on the surface of the rubber particles.[74] This process is carried out at ambient temperature and takes approximately 3 days. The devulcanization reaction is halted at the sulfone ($R–SO_2–R$) or sulfoxide (R–SO–R) stages and not allowed to proceed to the unwanted sulfate ($R–OSO_2–R$) form. The sulfone and sulfoxide forms are reactive with virgin rubber and allow more of the devulcanized rubber to be used. The specific thiophyllic microbes used include *T. ferrooxidans*, *T. thiooxidans*, *Rhodococcus rhodochrous*, and *Sulfolobus acidocaldarius*. About 10–20% by weight of this devulcanized rubber can be added to a virgin rubber matrix. Rubber particles processed with *S. acidocaldarius* exhibited an increase of 15% in the modulus of elasticity when added at 15% by weight to a virgin rubber compound.

A patent was issued to Fliermans and Wicks in 2002 for combining microwave and biological techniques to treat vulcanized rubber particles.[75] Samples of 40 mesh crumb rubber were incubated with bacillus-type bacterium. The best results were obtained with a 10/40 volume ratio of bacterium to crumb rubber at a temperature of 60–65°C for a 20 hr treatment period. The devulcanized rubber was evaluated in a tire tread compound at 20% with definite improvement over untreated crumb in terms of Mooney viscosity, tensile strength, and elongation. It was found that by treating the biologically devulcanized rubber with microwave energy, the overall properties of the resulting cured rubber are improved over the comparable control mix using either untreated crumb rubber or rubber treated solely with the biotreatment or microwave protocols.

Supercritical Fluid Devulcanization

Hunt and Kovolak discovered that cured rubber could be devulcanized by heating with 2-butanol under supercritical conditions.[76] By heating rubber compounds to at least 150°C under a pressure of 3.4×10^6 Pa in the presence of 2-butanol the molecular weight of the rubber was maintained at a relatively high level and its microstructure was unchanged.

For example, sulfur-cured SBR samples that contained no filler, carbon black, silica, or a combination of carbon black and silica were heated with the 2-butanol under supercritical conditions. The SBR had an original weight average molecular weight of about 400,000. The weight average molecular weights of the devulcanized SBR samples recovered are reported in Table 2.

Several related alcohols were also investigated and were found to be less effective, although most did induce devulcanization. Table 3 shows the cumulative amounts of SBR polymer recovered from a cured sample after heating at various temperatures. It can be seen from Table 3 that 2-butanol was far better than any of the other alcohols evaluated.

Benko and Beers found that by treating ground rubber obtained from used tires in a similar process they could devulcanize the surface of the ground particle.[77–79] This enabled its reuse as new rubber compounds with only minimal loss of properties.

Although 2-butanol is a preferred solvent, a number of other alcohols and ketones are described. The alcohol or ketone employed as the solvent will have a critical temperature that is within the range of about 200°C to about 350°C. It is preferred for the alcohol or the ketone used as the solvent to have a critical temperature that is within the range of about 250°C to about 320°C. The term ''critical temperature'' is defined as the temperature above which the gas of a compound (the alcohol or the ketone) cannot be liquefied by the application of pressure. Some representative

(From Ref.[76].)

examples of alcohols that can be used include methanol, ethanol, allyl alcohol, 1-propanol, isopropyl alcohol, *n*-butanol, *iso*-butanol, 2-butanol, *tert*-butanol, 1-pentanol, 2-methyl-1-butanol, 3-methyl-1-butanol, 3-methyl-2-butanol, 2,2-dimethyl-1-propanol, methyl isobutyl ketone, and 1-hexanol. Some representative examples of ketones that can be used include acetone, methyl ethyl ketone, methyl *n*-propyl ketone, methyl isopropyl ketone, and diethyl ketone. Mixtures of such alcohols and ketones can be utilized as the solvent.

In this series of experiments, whole tire reclaim rubber was ground to a particle size of 40 mesh (about 420 μm) and the surface of the ground crumb rubber was then devulcanized. The surface devulcanization was carried out in 2-butanol under the conditions of time, pressure, and temperature specified in Table 3. Then, the samples of surface devulcanized reclaimed rubber made were analyzed by a thermogravimetric technique to determine the volatile content and the polymer content. The results of this analysis are also reported in Table 4 along with the analysis of a control that was not subjected to the devulcanization procedure.

The samples of surface devulcanized reclaimed rubber made in this series of experiments were then compounded with a blend of virgin rubbers and cured. The blends were made by mixing 20 parts per 100 parts of rubber (phr) of the surface devulcanized reclaimed rubber samples with 70 phr of Plioflex® 1712 SBR, 30 phr of Budene® 1254 polybutadiene rubber, about 9 phr of aromatic oil, about 70 phr of carbon black, about 2 phr of stearic acid, about 4 phr of wax, about 1 phr of accelerator, about 2 phr of zinc oxide, about 1.5 phr of sulfur, and about 1 phr of antioxidant. The Plioflex® 1712 has a bound styrene content of about 28.5% and was oil extended with about 37.5% of an

aromatic oil. The blends were then cured at 150°C for 20 min. The cure properties of the blends are reported in Table 5 and the physical properties of the cured blends are reported in Table 6.

As can be seen from Table 5, the blends made with the surface devulcanized reclaimed rubber crumb did not have cure characteristics that differed substantially from the blend made without including any of the reclaimed rubber (the series labeled ''None''). In fact, the blends made with the surface devulcanized reclaimed rubber crumb had cure characteristics that were more similar to those made with no ground rubber than they were to those made with untreated whole tire reclaim rubber (the series labeled ''Original'').

As can be seen from Table 6, the physical properties of some of the cured blends made with the surface devulcanized reclaimed rubber crumb samples were equivalent to those made with only virgin rubber. For instance, the 100% modulus, 300% modulus, and percent elongation measured in Examples 19 and 20 were very similar to those found in the control using only virgin rubber (the series labeled ''None'').

CONCLUSIONS

Because of the large numbers of used tires existing in stockpiles it is desirable to recycle these tires back into new products. Unfortunately, simply grinding up the used tire and adding the resultant material into virgin rubber causes a significant drop in properties including reducing the strength and flexibility of the compound.

The need for a commercially viable devulcanization process has existed for years and continues to be a goal. Devulcanization without rubber chain degradation offers the potential for recycling used tires back into new products without sacrificing performance.

Chemical processes have been known for many years but are either ineffective in selectively cleaving cross-links or commercially not viable. Recent developments may eventually provide a true devulcanization process that is commercially viable. These include ultrasonic devulcanization, biotechnological devulcanization, and supercritical fluid devulcanization.

Scrubbers

S. Komar Kawatra
Department of Chemical Engineering, Michigan Technological University, Houghton, Michigan, U.S.A.

INTRODUCTION

Scrubbers are pollution control devices, which remove pollutants from gas streams, particularly from the combustion gases produced by facilities such as coal-fired power plants. Scrubbers may use absorbents in slurry or solution form (wet scrubbers), or in powder form (dry scrubbers), with wet scrubbers being more often used. Modern scrubbers can consist of several cleaning steps such as dust separation, sulfur removal, capture of mercury, lead, or other heavy metals, and breakdown of nitrogen oxides. Scrubbers of the future will also need to capture and sequester carbon dioxide. Currently, the most common application of scrubbers is still the removal of sulfur, frequently combined with capture of fly-ash.

POLLUTANTS REMOVED BY SCRUBBERS

Sulfur

In sulfur scrubbers, the sulfur oxides that are produced during coal combustion are removed from the combustion gases using an absorptive chemical, such as calcium oxide. As nitrogen oxides are also produced during combustion, it is possible to develop combined desulfurization methods that can remove both sulfur dioxides and nitrogen oxides.[1] Postcombustion absorbers capture the sulfur in a solid form for disposal. There are two basic approaches to capturing the sulfur: 1) divert the combustion gases through a scrubber unit that is separate from the combustor and 2) design the combustor so that the sulfur absorbent can be injected directly along with the fuel and sulfur is captured in the combustion chamber. Sulfur scrubbers have been widely used by the industry for some time and have been highly developed. Separate sulfur scrubber units have the advantage that they can be used to retrofit existing plants.[2] There are several types of scrubber available, and many different chemical reactions have been used for the extraction of sulfur oxides, as shown in Table 1.

Nitrogen Oxides

Nitrogen oxides are one of the primary sources of acid rain that are emitted during combustion. There are several different oxides produced, which are collectively referred to as NO_x. These oxides are generated from two mechanisms:[16]

1. *Thermal NO_x*. This is formed directly from the nitrogen in the combustion air because of the high temperatures and the presence of oxygen. Formation by this mechanism is strongly affected by temperature and residence time, with significant amounts produced at temperatures above 1200°C. Unfortunately, the factors that generally lead to complete combustion (high temperatures, long residence times, and thorough mixing of fuel and air) all tend to promote thermal NO_x production. NO_x from this source is usually controlled by some combination of reductions in flame temperatures, staged combustion, and flue-gas recirculation, which tend to slightly degrade the combustion efficiency.
2. *Fuel NO_x*. This comes from combustion of nitrogen that is contained in the chemical structure of the fuel. This can account for up to 50% of the NO_x from oil, and as much as 80% of the NO_x from coal. Conversion of the nitrogen that was chemically combined with the fuel into NO_x is strongly dependent on the fuel/air stoichiometry, but is relatively unaffected by combustion temperature, unlike thermal NO_x, which is strongly affected by combustion temperature. Fuel NO_x emissions are reduced by burning the fuel with low oxygen availability, causing the nitrogen to form N_2 in preference to NO_x.

Once the NO_x has been formed in the combustion process, if it is not removed it largely converts to NO_2. This is the source of the brownish plume often seen from power plant stack discharges. Unlike sulfur, it is not easily reacted with absorbents to form a solid sludge. Instead, it is catalytically reduced with ammonia or urea to form N_2 and water. This catalytic reduction requires injection of the reductant into the flue gases within a particular temperature window, with adequate residence time and catalytic surfaces to complete the reduction process. This can be integrated with scrubbers for other materials, such as sulfur and

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007955

Table 1 Absorbents that have been studied for removal of sulfur oxides from coal combustion gases

Absorbent	Regenerable?	Product	Reference
$CaCO_3$	No	$CaSO_3$ or $CaSO_4$	[3]
$Ca(OH)_2$	No	$CaSO_3$ or $CaSO_4$	
CaO	No	$CaSO_3$ or $CaSO_4$	
MgO	Yes, heat to release SO_2	SO_2	[4]
Na_2SO_3	Yes, heat to release SO_2	SO_2	[3]
$CeO_2 + Al_2O_3$	Yes, heat to release SO_2	SO_2	[5]
$Ca(OH)_2$ + fly-ash	No	Calcium silicate sulfates	[6]
$CuO + MnO_2$	Yes, heat with H_2 at 200–560°C	H_2S	[7]
$Ca(OH)_2$ + methanol	No	$CaSO_3$ or $CaSO_4$	[8]
CaO + MgO	No	$CaSO_3$ and $MgSO_3$	[9]
$NaHCO_3$	Yes, react with $Ca(OH)_2$	$CaSO_4$	[10]
Gaseous oxidation	Nothing to regenerate	H_2SO_4	[11]
$CaCO_3$ + NaCl	No	$CaSO_3$ or $CaSO_4$	[12]
Chalk	No	$CaSO_3$ or $CaSO_4$	[13]
Cement flue dust	No	Calcium silicate sulfates	
Alkali + Al_2O_3	Yes, heat with CO at 700–800°C	S, SO_2	[14]
Ca–Mg Acetate	No	$CaSO_3$ or $CaSO_4$	[15]

Some are low-cost throw-away absorbents, while others are regenerable and convert the sulfur oxides into marketable products.

fly-ash, which provide the necessary residence time and control of process conditions.

Carbon Dioxide

A variety of methods for sequestration of CO_2 from combustion of fossil fuels have been suggested in the literature to deal with the estimated 1583 million metric tons carbon equivalent annually released into the atmosphere in the U.S.A.[17,18] These methods include use of photoautotrophic organisms to convert it to biomass, deep-ocean disposal as a liquid, reaction with minerals to form stable carbonates, and industrial utilization. All of these sequestration methods can be made more efficient if the carbon dioxide is first separated from the flue gases and concentrated. The ideal approach would be for carbon dioxide to be absorbed from the flue gas, with the CO_2-laden absorbent then regenerated by a rapid, low-energy process, releasing the CO_2 in a purified, concentrated form. This CO_2 could then be sequestered or utilized by any appropriate method.

To date, all commercial plants for separation and concentration of CO_2 use chemical absorption with a monoethanolamine solvent. This solvent was developed over 60 years ago to remove acid gases, such as CO_2 and H_2S, from natural gas streams. Monoethanolamine absorption is popular for the existing markets for high-purity CO_2, because it produces a very high-grade product. The process has also been used to remove CO_2 from flue gases, but it had to be modified to resist solvent degradation and equipment corrosion. Also, to minimize reagent costs, the solvent strength was kept relatively low. This resulted in large equipment sizes and high regeneration energy requirements. Other CO_2-absorption strategies have tended to make use of advanced technologies such as pressure-swing absorption, membrane technology, and hollow-fiber permeators. These are all highly efficient at producing a high-purity CO_2 stream, but are expensive to apply on a large scale. As a result, the technologies that are receiving the most attention are not sufficiently economical for wholesale capture of CO_2 from fossil fuel combustion, and a lower-cost absorbent is needed for flue-gas CO_2 fixation applications.

A survey of the technologies used for capturing sulfur oxides has indicated that certain low-cost commodity chemicals used for capturing sulfur could also be useful for capturing carbon dioxide.[19] One of these absorbents can be used to produce an aqueous solution which will efficiently capture carbon dioxide at temperatures less than approximately 25°C, as shown in Fig. 1. This solution can then be completely regenerated at only 100°C, releasing concentrated carbon dioxide that can be easily utilized or permanently sequestered.[20]

Mercury/Heavy Metals

Even though coal is not enriched in mercury relative to the components of the rest of the Earth's crust,

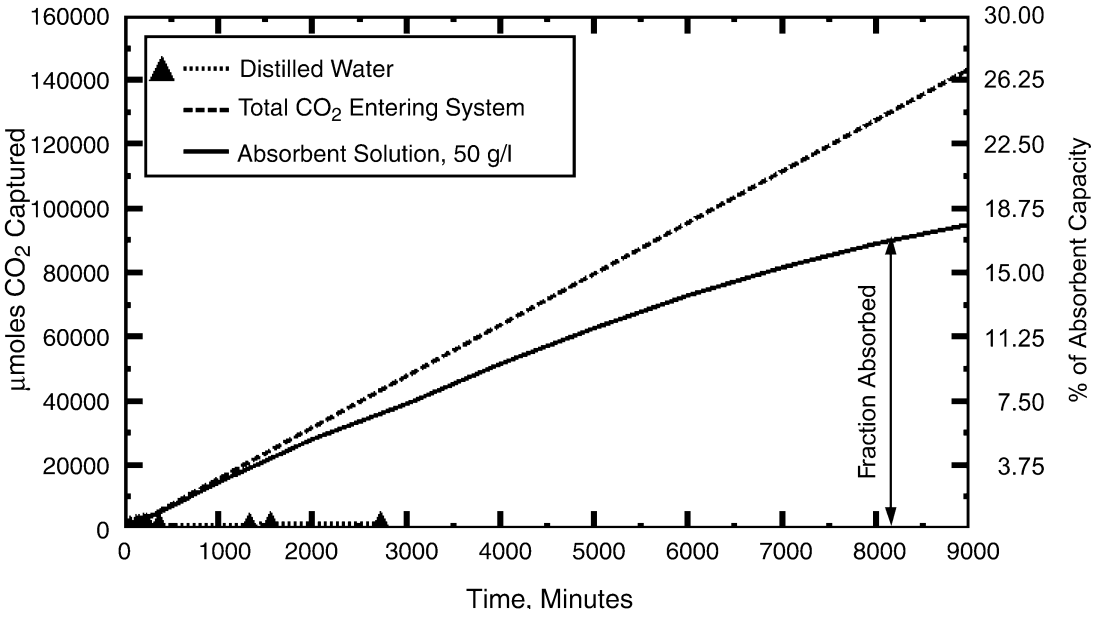

Fig. 1 Capture of carbon dioxide by a 50 g/L solution of absorbent in a 500 ml batch absorber. The gas being treated was ambient air, at a carbon dioxide concentration of 403 µmoles/mole and a flow rate of 0.96 slpm. The fact that this absorbent can reduce CO_2 levels to less than that of ambient air shows that a properly designed countercurrent scrubbing unit could use this solution to keep CO_2 levels in a combustion gas stream from exceeding the normal levels present in the atmosphere. It should be noted that, under these conditions, the ability of pure water to absorb carbon dioxide was negligible.

combustion of coal is nevertheless a significant source of mercury emissions. This is because of the high volatility of metallic mercury and its compounds, which are efficiently vaporized by the heat of coal combustion. As a result, mercury is emitted as a trace component at levels of a few parts per billion in coal combustion gases. As mercury is highly toxic and tends to accumulate in the ecosystem, it has become clear that coal-fired power plants must prevent even these highly diluted mercury emissions from escaping into the environment. However, it is highly uneconomical to have a dedicated scrubber that captures only mercury. This is because the need to contact the entire volume of gases with mercury absorbent results in the need for an absorbent mass that is thousands of times greater than the mass of the mercury captured. It is much more feasible to ''piggy-back'' the mercury capture capacity with scrubbers for other, higher-concentration pollutants produced by the plant. Possibilities include

1. Injection of activated carbon particles into the flue gas to absorb the mercury or operation of the coal combustion to convert a portion of the coal into activated charcoal. The mercury-laden charcoal is then captured by the fly-ash removal system (which may be an electrostatic precipitator, filter, or dust scrubber).
2. Capture of mercury in the sludge from a sulfur oxide scrubber.
3. Capture and sequestration along with carbon dioxide.

To capture mercury simultaneously with capture of sulfur oxides and carbon dioxide, it is necessary to ensure that the mercury is in a form that will be absorbed by the scrubber. The reducing environment of coal combustion results in a large fraction of the vaporized mercury being in the elemental state, which is unreactive, volatile, and can be transported worldwide over a period of years before it finally oxidizes and precipitates as a contaminant. It has been determined that, if mercury is in an oxidized state, it is readily captured by many existing scrubbers. This is because of oxidized mercury having a much higher solubility in water than elemental mercury, and a greatly increased reactivity with scrubbing agents. Therefore, the key to efficient capture of mercury is to ensure that it is in the oxidized state while it passes through the scrubber. This will require that the scrubber actively promote the oxidation of mercury. However, such oxidation cannot be achieved by the current generation of scrubbers.

WET SCRUBBERS

Wet scrubbers use a slurry or solution of a sulfur absorbent in water, which is generally contacted with the flue gases using a scrubber tower such as that

shown in Fig. 2. Flue gases rise through the tower through a falling spray of absorbent. The absorbent spray removes the sulfur oxides from the gases and collects in the base of the tower, where it is removed. The mist eliminator at the top of the column is to prevent fine droplets of absorbent from being carried up the stack, where they could cause corrosion or deposition problems in the stack or be released as particulate pollution.

In general, when designing a wet scrubber for capturing pollutants from gases, there are several steps that should be taken into consideration: 1) selection of absorbent material; 2) equilibrium data evaluation; 3) estimation of operating data, including mass and energy balances; 4) absorption column selection; 5) column diameter calculation; 6) estimation of column height and/or number of plates or other transfer units; 7) determination of pressure drop through the column.[21] In the case of wet flue-gas scrubbers, the units are fairly standardized and much of this work has already been done.

Absorbents

The most common absorbents are lime (calcium hydroxide) and limestone (calcium carbonate) slurries. Limestone is the preferred absorbent in many modern scrubbers, because of its low cost compared with lime and other absorbents.[22,23] However, lime is also used because of its higher reactivity, which allows it to absorb sulfur more rapidly. This makes it possible to use smaller scrubbers to treat a given quantity of gas when lime is the absorbent. When lime or limestone are used as the sulfur absorbents, the following reactions are believed to occur:[24]

- sulfur dioxide hydration:

$$SO_2(g) + H_2O(l) \Longrightarrow H_2SO_3(aq) \quad (1)$$

$$H_2SO_3(aq) \Longrightarrow H^+(aq) + HSO_3^-(aq) \quad (2)$$

- lime reactions:

$$Ca(OH)_2(s) \Longrightarrow Ca^{2+}(aq) + 2OH^-(aq) \quad (3)$$

$$Ca^{2+}(aq) + HSO_3^-(aq) + \frac{1}{2}H_2O(l) \Longrightarrow CaSO_3 \cdot \frac{1}{2}H_2O(s) + H^+(aq) \quad (4)$$

$$H^+(aq) + OH^-(aq) \Longrightarrow H_2O(l) \quad (5)$$

overall:

$$Ca(OH)_2(s) + SO_2(g) \Longrightarrow CaSO_3 \cdot \frac{1}{2}H_2O(s) + \frac{1}{2}H_2O(l) \quad (6)$$

- limestone reactions:

$$H^+(aq) + CaCO_3(s) \Longrightarrow Ca^{2+}(aq) + HCO_3^-(aq) \quad (7)$$

$$Ca^{2+}(aq) + HSO_3^-(aq) + \frac{1}{2}H_2O(l) \Longrightarrow CaSO_3 \cdot \frac{1}{2}H_2O(s) + H^+(aq) \quad (8)$$

$$H^+(aq) + HCO_3^-(aq) \Longrightarrow H_2CO_3(aq) \quad (9)$$

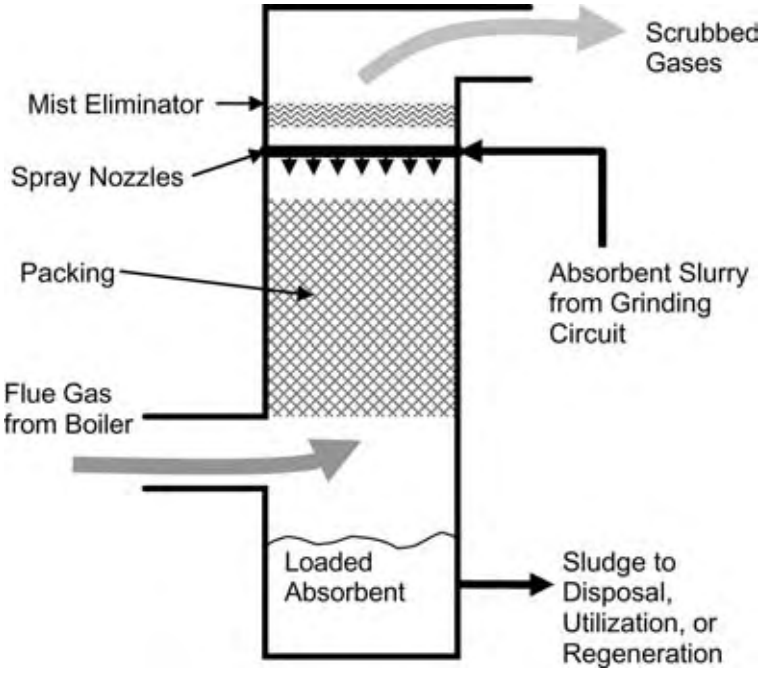

Fig. 2 Basic schematic of a wet scrubber column. Absorbent slurry percolates down through the packing, while the flue gases flow upward. The most common absorbents for sulfur oxides are limestone (calcium carbonate), lime (calcium hydroxide), and magnesium-enhanced lime made from dolomite. The sulfur-bearing sludge for some scrubbers is market-grade gypsum, but for other scrubbers it is a waste product that must be landfilled.

$$H_2CO_3(aq) \Longrightarrow CO_2(g) + H_2O(l) \quad (10)$$

overall:

$$CaCO_3(s) + SO_2(g) + \frac{1}{2}H_2O(l) \Longrightarrow CaSO_3 \cdot \frac{1}{2}H_2O(s) + CO_2(g) \quad (11)$$

The solid product from each of these sets of reactions is primarily calcium sulfite hemihydrate ($CaSO_3 \cdot \frac{1}{2}H_2O$), which has been confirmed by x-ray diffraction analysis of scrubber sludges.[25,26] A similar set of reactions collects sulfur trioxide (SO_3) from the flue gases, forming gypsum ($CaSO_4 \cdot 2H_2O$) as the solid product, but under normal boiler conditions sulfur trioxide makes up only about 0.5% of the total sulfur oxides, and so its removal is less important than the removal of sulfur dioxide.[24,27]

Equilibrium and Operating Data

The factor that determines the size of a wet scrubber needed to produce a given capacity is the mass transfer rate of sulfur dioxide from the gas phase to the liquid phase, as shown in Eq. (1).[16] This mass transfer rate can be expressed as:

$$N_g = \int \frac{dy}{y - y^*} = \int \frac{k_g a}{G} dV \quad (12)$$

where G is the molar gas flow rate (moles/s), y the mole fraction of sulfur dioxide in flue gas, k_g the gas film mass transfer coefficient (moles/m^2s), a the interfacial surface area (m^2/m^3), y^* the equilibrium sulfur dioxide concentration at the gas/liquid interface, V the volume of the gas/liquid intermixing region (m^3), and N_g the number of gas-phase transfer units (dimensionless).

As not all of the parameters needed can be calculated in advance (k_g can only be approximated, and a must be determined experimentally), the gas-phase mass transfer rate for a given scrubber design must be determined experimentally by operating the scrubber under conditions where y^* approaches zero. Under these conditions, Eq. (12) can be integrated to give:

$$N_g = -\ln(1 - E) = k_g a \frac{V}{G} \quad (13)$$

where E is the overall sulfur dioxide absorption fractional efficiency.

The number of gas-phase transfer units that exist in a given column design depends on a number of factors, including: 1) slurry spray rate; 2) droplet size and distribution; 3) gas-phase residence time, which is controlled by the height of the spray zone; 4) liquid residence time; 5) wall effects; and 6) gas flow distribution.[16]

In a limestone-based wet scrubber, the dissolution of calcium carbonate [Eq. (7)] is the primary rate-limiting reaction, because of the low solubility of calcium carbonate. The rate for the dissolution reaction can be expressed as:

$$\frac{d[CaCO_3]}{dt} = k_c([H^+] - [H^+]_{eq}) \cdot S_{spc}[CaCO_3] \quad (14)$$

where $[CaCO_3]$ is the calcium carbonate concentration in the slurry (moles/l), $[H^+]$ the hydrogen ion concentration (moles/l), $[H^+]_{eq}$ the equilibrium hydrogen ion concentration at the limestone surface (moles/l), S_{spc} the specific surface area of the limestone in the slurry, and k_c the reaction rate constant.

The limestone dissolution rates at various pH values and partial pressures of carbon dioxide are shown in Fig. 3.

Slurry–Gas Contact

The heart of a scrubber column is the slurry–gas contact zone, where gases are intimately combined with the absorbent slurry so that the pollutants can be captured by the reactions given previously. There are a number of possible methods for designing the contacting zone, including sprays, crossflow plates, baffle plates, counterflow plates, and packed columns. These all have the purpose of maximizing the interfacial area between the gas phase and the liquid phase, to allow rapid transport of gases across the surface.[29]

A serious problem occurs in many wet scrubbers if the sulfur dioxide is partially oxidized to sulfur trioxide. In this case, the main precipitate is calcium sulfite hemihydrate, with up to 15% calcium sulfate in solid solution in the sulfite particles. If more than 15% is as calcium sulfate, then it can no longer precipitate with the sulfite crystals, and instead precipitates as separate crystals of gypsum. However, there is a shortage of gypsum seed crystals in the slurry in this situation, and so much of the gypsum crystallizes in the scrubber, particularly in the slurry–gas contact zone. This can rapidly plug the scrubber and must be avoided. Many plants prevent this problem by adding thiosulfate ($S_2O_4^{-2}$) to the scrubber slurry as a reducing agent. This prevents the oxidation of sulfur dioxide and thus eliminates the formation of gypsum and the buildup of gypsum scale in the scrubber. A second solution to the plugging problem is to completely oxidize the calcium sulfite to gypsum, which provides more seed crystals for the gypsum and also prevents plugging.

When the solid sludge is removed from the scrubber as unoxidized calcium sulfite, as is done in many older

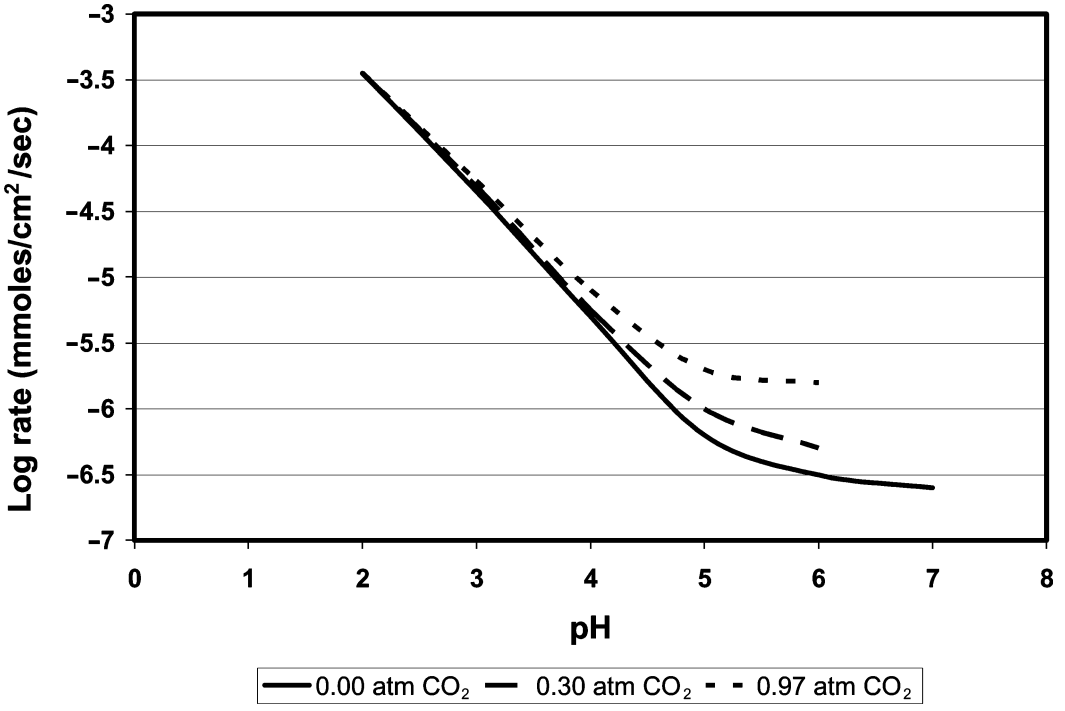

Fig. 3 Limestone dissolution rates as a function of pH and carbon dioxide partial pressure, at a temperature of 25°C. (From Ref.[28].)

scrubbers, it has no market value and must be disposed of by landfilling. The more advanced scrubbers include an oxidation step, which converts the sulfite to sulfate, and the solid product is then gypsum.[23] If it is sufficiently pure, this synthetic gypsum can be marketed to make plaster, wallboard, cement, and other construction products. The major barrier to widespread marketing of scrubber sludge is that it contains a number of impurities, and is of uneven quality, which makes it unattractive for most purposes in its raw form. Potential users are therefore not eager to purchase the material, even with significant price breaks.[30,31] Typical quality requirements for gypsum for use in wallboard manufacture are given in Table 2. For the gypsum to be salable, it should meet or exceed these requirements.

A complete circuit for an advanced scrubber is shown in Fig. 4, which includes oxidation of the sludge to form gypsum.[9] In this circuit, limestone is first reduced to a fine particle size by a grinding mill, producing a slurry. The slurry is then added to the absorber tank, and pumped into the scrubber tower. A portion of the descending absorbent is diverted back to the absorber tank, which provides more time for the sulfur dioxide and limestone to react. The remaining absorbent collects in the base of the tower, where it is oxidized by injected air while being recirculated in the lower portion of the scrubber. A portion of the absorbent is continuously drawn off to a hydrocyclone, which separates the gypsum particles from the absorbent slurry, and returns the liquid to the scrubber.

The most efficient wet-scrubber technology, from the standpoint of sulfur removal efficiency and equipment size, is the magnesium-enhanced lime process. This type of scrubber uses lime that contains up to 12% magnesium, which increases the absorption capacity of the lime to approximately 10–15 times that of the limestone scrubbers described previously. The principal advantage is that the magnesium-enhanced lime is soluble enough that the SO_2 removal is governed by the degree of gas–liquid contact in the

Table 2 Impurity limits for gypsum for use in plaster or wallboard manufacture

scrubber, and not by the degree of absorbent dissolution as is the case with limestone. A disadvantage is that the magnesium-enhanced lime is comparatively expensive because it must be calcined by heating before use. Also, the magnesium specifically inhibits the formation of gypsum, which helps to prevent plugging and scaling, but also results in the sludge being an unmarketable sulfite sludge instead of gypsum. Finally, the magnesium content of the sludge is too high for use in most synthetic gypsum markets.

Power Consumption Example

Assume a 180 MW boiler burning coal with 2.5% sulfur by weight, and a heating value of 12,767 BTU/lb. An appropriate limestone scrubber with forced oxidation would operate with a liquid/gas ratio of 130 gal. liquid per 1000 ft.^{3} of flue gas, and a pressure drop of 5 in. water. Such a scrubber would consume 2.549 MW to operate, with the breakdown as shown in Table 3. This corresponds to 1.42% of the total power output of the plant. Such a scrubber would remove approximately 93% of the sulfur, while consuming approximately 13,000 lb/hr of limestone being added at 35% solids.[16]

Other Types of Wet Scrubber

In addition to lime and limestone, a number of other absorbents have been used to improve the efficiency of sulfur removal or to recover the sulfur in a marketable form while regenerating the absorbent. Next-generation scrubbers are therefore under development to improve the efficiency and reduce the quantity of unmarketable waste products.[33–35] Several of the scrubber technologies that use other absorbents are listed here:

- *Dual alkali process.* In this process, the absorption of the sulfur dioxide is first carried out using a solution of a sodium alkali, such as NaOH, Na_2CO_3, or Na_2SO_3. Because these are all very soluble in water, they can absorb the sulfur dioxide very rapidly and completely, and can be easily oxidized afterward. Also, the absorbent is a clear liquid rather than a slurry, and so the problems with scaling and plugging of the scrubber are much reduced.[10] The oxidized sulfur-bearing alkali is then circulated to a vessel where it reacts with lime or limestone, which precipitates the sulfur as calcium sulfate and regenerates the sodium alkali. A flow diagram of the

process is shown in Fig. 5. The dual-alkali process is reported to be stable and resistant to disturbances, and to be capable of removing more than 99% of the sulfur dioxide from flue gases.[10,36]

- *Wellman–Lord process.* This is a regenerable-sorbent process, producing SO_2 gas, which can be sold for industrial uses. It uses a solution of sodium sulfite (Na_2SO_3), which absorbs SO_2 and becomes a sodium bisulfite solution ($NaHSO_3$). The sodium bisulfite is then decomposed in a forced circulation evaporator, releasing the SO_2 at sufficiently high concentration to be compressed and sold as SO_2 gas, or used for producing elemental sulfur or sulfuric acid.[3]
- *Magnesium oxide process.* The magnesium oxide slurry is used to collect SO_2, and the resulting magnesium sulfite is thermally treated to release the SO_2 and regenerate the absorbent, as shown in Fig. 6. Like the Wellman–Lord process, this process is relatively complex and has a capital cost about 14% higher than that of limestone scrubbers.[4] It is therefore only economically viable when there is a reliable market for the by-products.[38]

SPRAY-DRY SCRUBBERS

Spray-dry scrubbers are an alternative to conventional wet scrubbers. In this type of scrubber, an alkaline slurry or solution is sprayed in fine droplets into a reaction vessel, along with the flue gas. The droplets rapidly react with the sulfur dioxide while drying to a fine powder of sulfite salts. This powder is entrained in the gas stream, and is carried to a dust precipitator where it is collected, as shown in Fig. 7. Most of the sulfur dioxide is collected in liquid-phase reactions while the droplets are drying, but 10–15% additional sulfur dioxide can be absorbed in gas/solid reactions, as the absorbent powder is swept through the ductwork and particulate collector. These are cocurrent devices, and so the limestone utilization and sulfur removal efficiency are inherently lower than those of countercurrent devices such as wet scrubbers. Partial recycle of the sorbent is often used to improve the sorbent utilization.

It is typical to install the spray-dryer before the plant fly-ash collector, so that the existing dust control equipment can be used to collect the used absorbent. Slaked lime [$Ca(OH)_2$] is the most common absorbent, although sodium carbonate (Na_2CO_3) is used in some plants. Spray-dryers have also been used with regenerable magnesium oxide absorbent.[4]

Spray-dryers are simpler and more compact than conventional wet scrubbers and have a lower capital and operating cost. Also, they do not produce large quantities of wastewater, and the spent absorbent is dry, thereby eliminating the need for thickening and filtration of the sludge. However, if the same dust precipitator is used for both the fly-ash and the spray-dryer product, the mixture of fly-ash and spent absorbent that they produce is unmarketable, and must be disposed of. Also, they require more expensive absorbents than conventional wet scrubbers. They are most suitable for retrofitting small plants that burn medium-sulfur coals, where capital costs and space restrictions are more of a consideration.[38]

VENTURI SCRUBBERS

Venturi scrubbers are mainly used for collecting fine particulates (such as fly-ash) from gas streams,[39] but they have also been adapted for absorption of sulfur dioxide.[40] These units are mechanically very simple, consisting of a reducing inlet with liquid sprays,

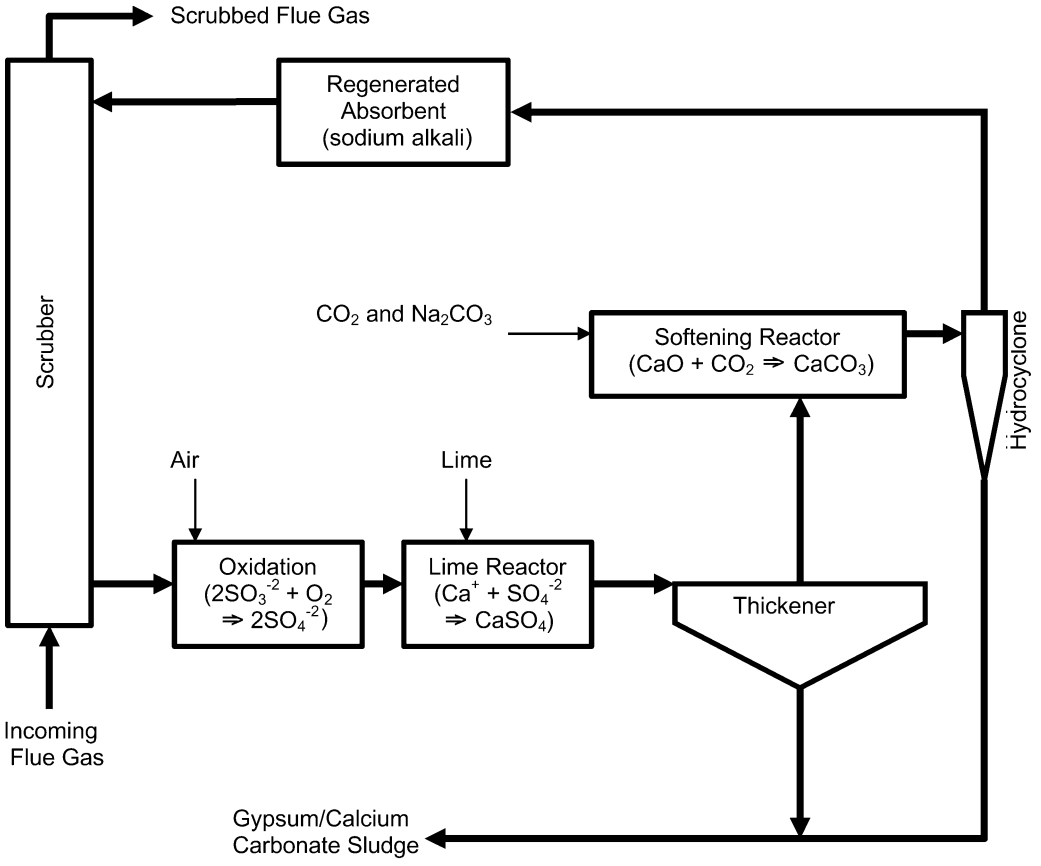

Fig. 5 Flow diagram of the dual-alkali scrubber process, using lime to regenerate the sodium alkali. The clarified liquid from the thickener contains dissolved calcium sulfate, which would produce calcium carbonate scale in the scrubber when it contacts the carbon dioxide in the flue gas. It is therefore precipitated in the softening reactor by a combination of carbon dioxide and sodium carbonate, and the resulting calcium carbonate precipitate is removed by the hydrocyclone.

a narrow throat where the gas/liquid contact occurs, and an expanding region, as shown in Fig. 8. The flue gases are injected into the venturi at the contracting inlet, along with an absorbent, such as lime slurry. The gas accelerates to high speed as it enters the throat, and atomizes the absorbent, providing good gas/liquid contact. The gas and the atomized liquid then expand and slow in the expander region and are then diverted to a mist eliminator to separate the liquid droplets from the scrubbed gases.

Venturi scrubbers have lower capital cost than other types of scrubber because they are mechanically simple; but they have a high energy consumption because of the need for pressurizing the gas to force it through the venturi. They also double as a fly-ash collection device, and so there is no need for separate scrubbers and fly-ash collectors when these units are used.[40] Because venturi scrubbers are cocurrent devices, with both the flue gas and absorbent traveling in the same direction, they cannot remove sulfur dioxide as completely as countercurrent devices, such as wet-scrubber towers, do.[29,41] They also produce a wet mixture of fly-ash and alkaline absorbent, which is unmarketable and can form a cement-like substance upon disposal.

A number of theoretical studies of venturi performance have been made to produce theoretical models that can predict performance from first principles. One of the key areas of uncertainty has been the droplet size formed by the venturi. Typically, this is estimated using the Nukiyama and Tanasawa equation to estimate the surface-mean droplet diameter:[39]

$$D_0 = \frac{1920\sqrt{\sigma_L}}{V_0\sqrt{\rho_L/62.3}} + 75.4\left(\frac{\mu_L}{\sqrt{\sigma_L\rho_L/62.3}}\right)^{0.45}\left(\frac{1000Q_L}{Q_G}\right)^{1.5} \quad (15)$$

where D_0 is the drop diameter (μm), V_0 the gas velocity (ft/s), σ_L the liquid surface tension (dynes/cm), ρ_L the liquid density (lb/ft^3), μ_L the liquid viscosity (centipoises), Q_L the liquid flow rate (ft^3/s), and Q_G the gas flow rate (ft^3/s).

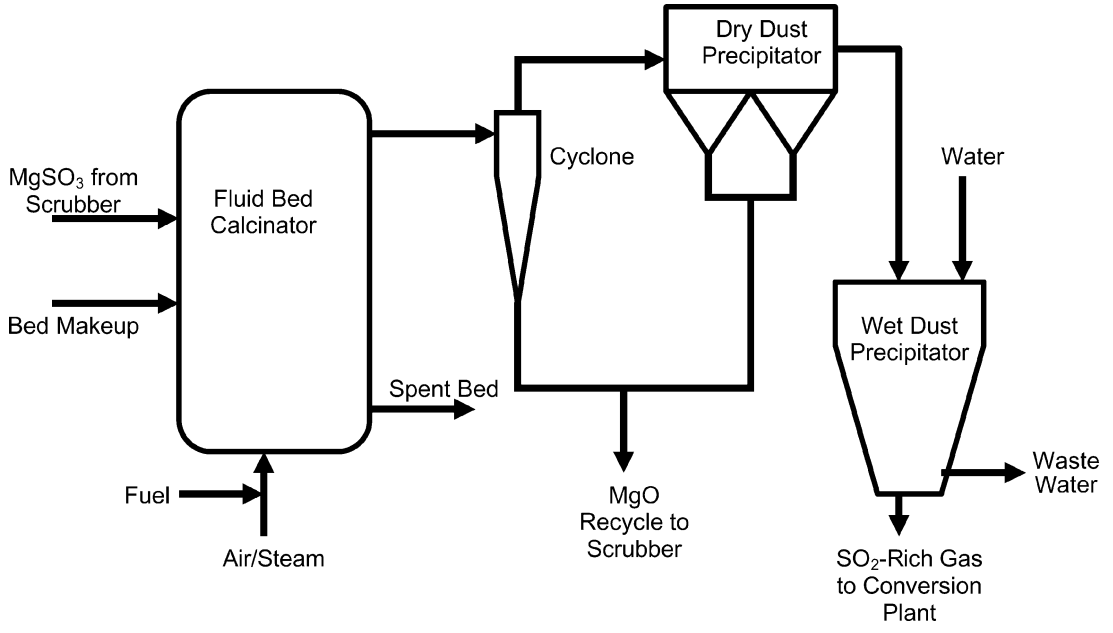

Fig. 6 Magnesium oxide regeneration and sulfur dioxide recovery section for a magnesium oxide scrubber. (From Ref.[37].)

This equation unfortunately has a number of severe shortcomings, including its lack of dimensional homogeneity and the fact that the effect of nozzle size on the drop diameter is not defined. It was originally derived for small diameter atomizing nozzles, and drop sizes reported by various investigators have varied from the equation prediction by as much as two to three times, and so this approach has not been highly successful.

In general, the ability of these scrubbers to collect particles improves, as the energy input to the system increases, and so collection of very fine particles requires increased flow rates and operating pressures. This has lead to a fairly useful scrubber design method based on the dissipation of power in the gas–liquid contactor. A number of studies have concluded that the collection efficiency of a scrubber on a given dust

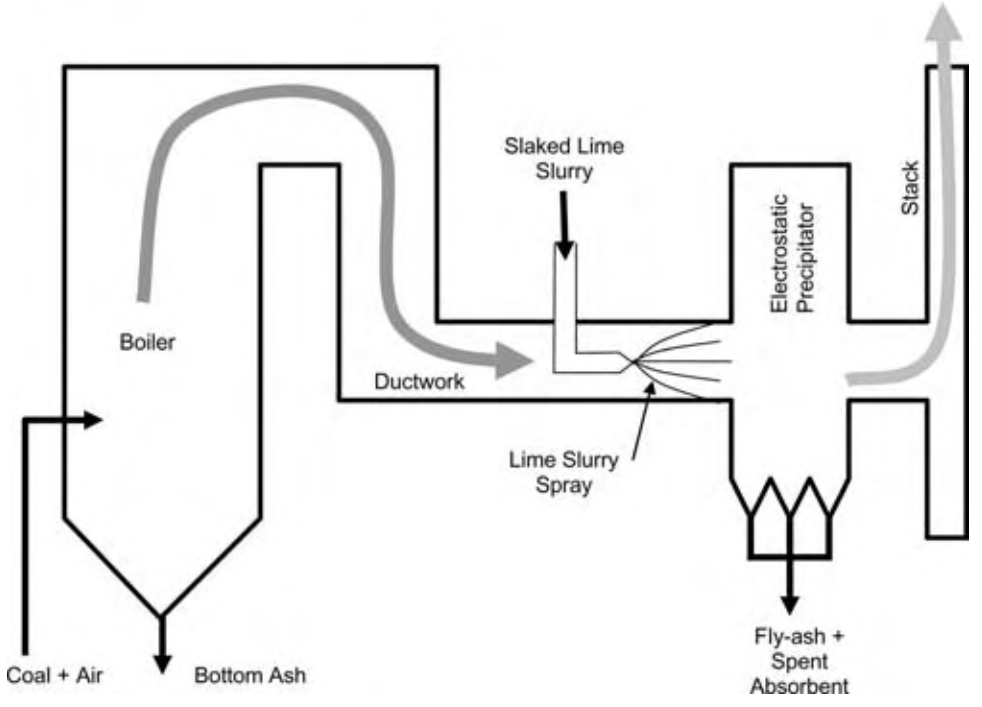

Fig. 7 Basic configuration for a single-stage spray-dry sulfur absorber, with no recycle of absorbent.

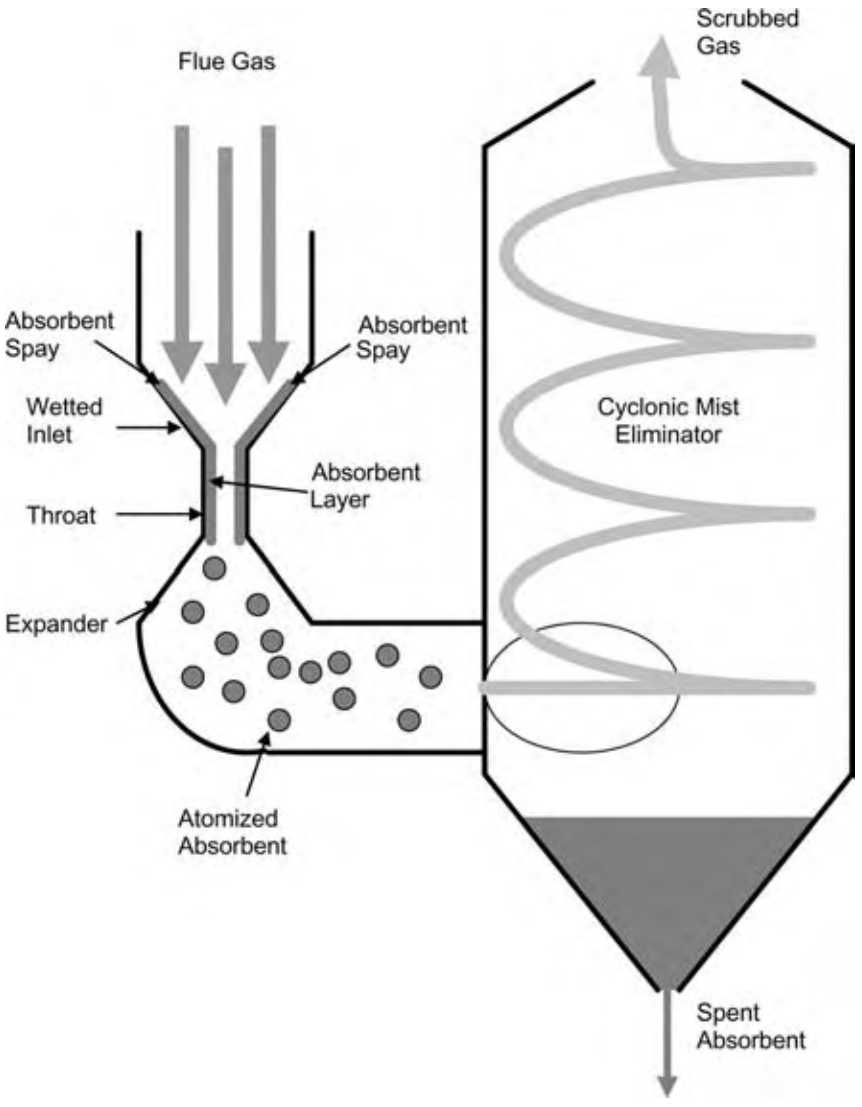

Fig. 8 Schematic diagram of a venturi scrubber with a cyclonic mist eliminator. The wetted inlet, throat, and expander make up the venturi section.

is dependent only on the contacting power, with only minor effects from the size or geometry of the scrubber.[39] The contacting power is commonly given in units of MJ/1000 m^3, and may conveniently be broken into three parts:

1. Gas-phase contacting power, P_G. In SI units, this is equal to the effective friction loss of the gas as it flows through the contactor, in kPa.
2. Liquid-phase contacting power. This is given by the equation $P_L = p_f(Q_L/Q_G)$, where p_f is the nozzle feed pressure in kPa, and Q_L and Q_G are the liquid and gas flow rates, respectively, in m^3/s.
3. Additional power supplied separately, P_M, such as by a power-driven rotor.

The total contacting power is then $P_T = P_G + P_L + P_M$. The collection efficiency, expressed as the number of equivalent contacting units (N_t), then becomes:

$$N_t = aP_T^{\gamma} \tag{16}$$

where α and γ are empirical constants that depend on the character of the particles being collected.[39]

DRY SORBENT INJECTION

Dry sorbent injection is very similar to the use of spray-dryers, except that the sorbent is injected as a dry powder rather than as an atomized slurry.[42,43] The most common sorbent is hydrated lime, but other sorbents can also be used. The sorbent is usually injected directly into existing ductwork, and so the amount of space required is negligible compared with that of other flue-gas desulfurization processes. This makes dry sorbent injection a very low-cost option.

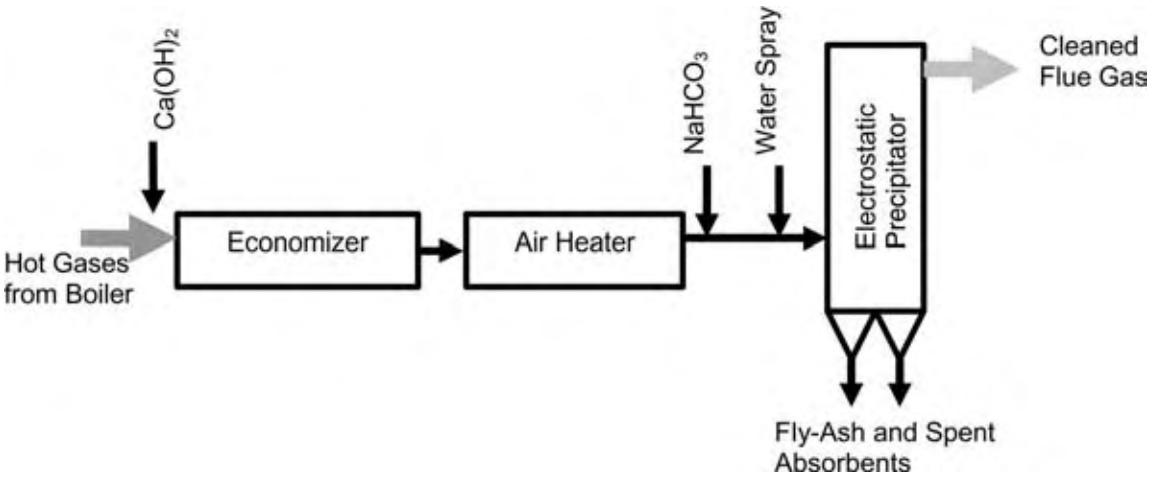

Fig. 9 Integrated dry injection process utilizing both calcium hydroxide and sodium bicarbonate to reduce sulfur dioxide and nitrogen oxide emissions. Calcium hydroxide is added to the hot flue gases before they are cooled in the economizer and combustion air heater, while sodium bicarbonate is added to the cooled gases before they enter the electrostatic precipitator. (From Ref.[44].)

Unfortunately, the reactivity of dry absorbents is much lower than that of absorbent slurries or solutions, and so dry sorbent injection is only suitable for applications where less than 70% of the sulfur dioxide needs to be removed from the flue gases.[38]

In cases where hydrated lime does not remove enough of the sulfur dioxide, but economics makes more efficient absorbents impractical, a two-stage absorbent injection scheme can be used, as shown in Fig. 9. Here, the relatively low-cost calcium hydroxide is used to remove the bulk of the sulfur dioxide, and is then followed by a spray of more effective (but higher-cost) sodium bicarbonate. In addition to further reduction of the sulfur dioxide content, the sodium bicarbonate spray also reduces the content of nitrogen oxides.

It is also possible to use limestone in dry sorbent injection, as is done in the limestone injection multistage burner (LIMB) system (Fig. 10). In this system, pulverized limestone is injected into the boiler directly, where the temperature is high enough to flash-calcine

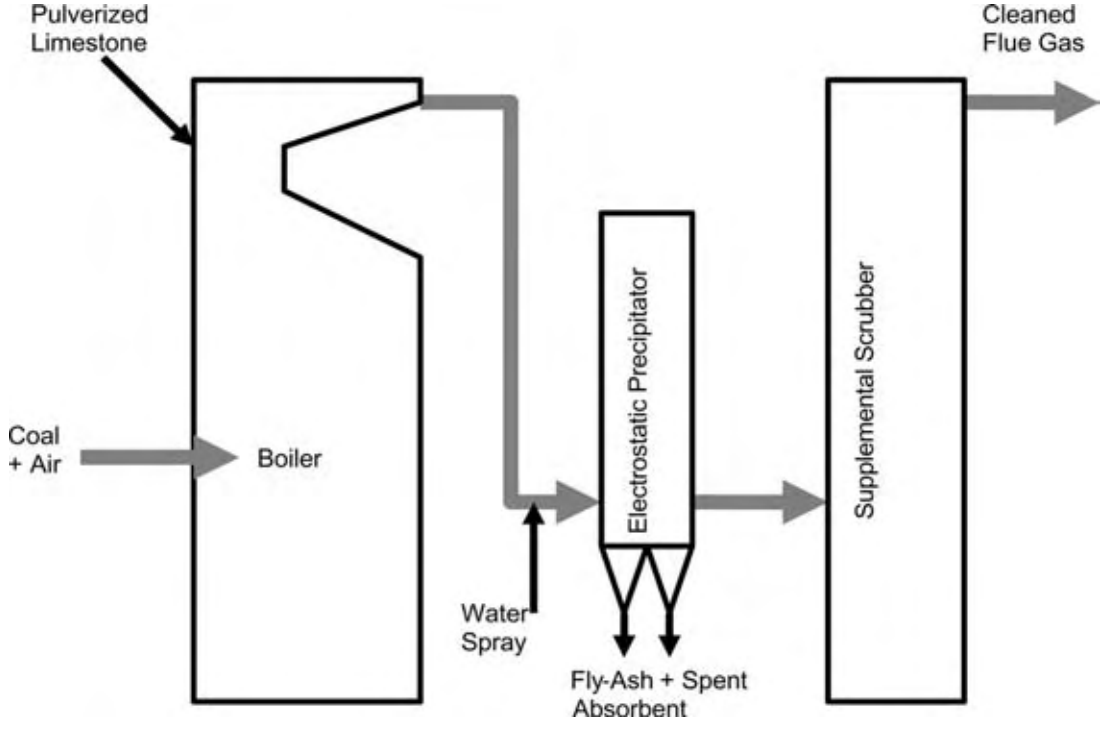

Fig. 10 The basic integrated LIMB dry sorbent injection system.

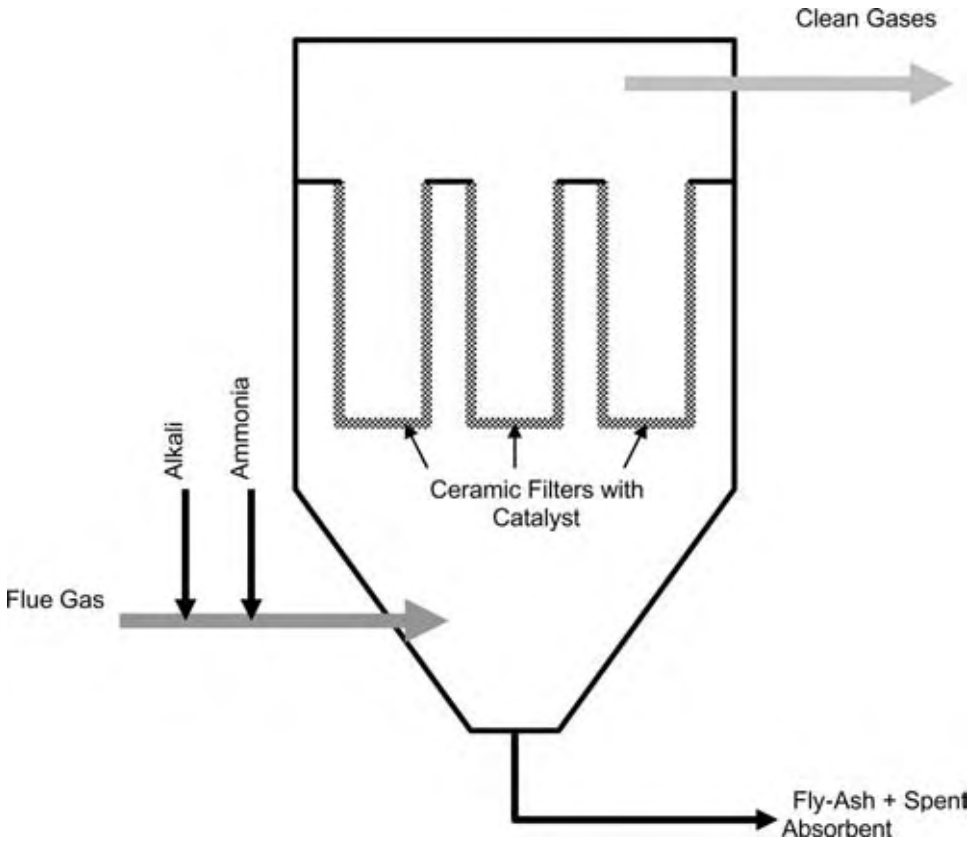

Fig. 11 Schematic of the SNRB catalytic baghouse. (From Ref.[46].)

the $CaCO_3$ to CaO. The CaO dust is carried off with the flue gases until the temperature drops enough for $CaSO_3$ to become stable. The CaO then captures the SO_2 to form $CaSO_3$, which is removed by the electrostatic precipitators, along with the fly-ash. If necessary, a second, wet SO_2 scrubber is used to finish the sulfur removal.[37]

A related technology, the SOx-NOx-Rox Box™, or SNRB, also destroys nitrogen oxides while removing sulfur dioxide.[45,46] This unit is a replacement for electrostatic precipitators and is installed in the flue-gas stream between the economizer and the combustion air heater, where the flue gases are still hot. An alkali is injected as sulfur absorbent, along with anhydrous ammonia. The gases then enter the high-temperature catalytic baghouse, which consists of catalyst-impregnated ceramic filter ''bags,'' as shown in Fig. 11. The ceramic filters capture and remove the sulfur-loaded absorbent, and the catalyst in the filters catalyzes the reduction of the nitrogen oxides by the ammonia, producing nitrogen gas and water.

SNOX SYSTEM

The SNOX system is designed for removing both sulfur oxides and nitrogen oxides from flue gases, and is unusual in that it does not use an alkali as an absorbent to collect the sulfur dioxide. Instead, it oxidizes the sulfur dioxide to sulfur trioxide and uses a special condenser to collect the sulfur trioxide as marketable sulfuric acid. This is combined with catalytic destruction of the nitrogen oxides with ammonia, producing the overall circuit shown in Fig. 12. The system is reported to be capable of better than 90% removal of both SO_2 and NO_x, while producing sulfuric acid at 93–95% concentration.[11]

RELATIVE COSTS OF SCRUBBERS

A comparison of the estimated sulfur removal ability and costs for various postcombustion processes is given in Table 4. It can be seen from this table that there is considerable variation in costs, depending on factors such as the size of the plant, fraction of the time that the plant operates at full capacity, ability to retrofit existing facilities, differences in fuel prices, sulfur content of the coal, and ability of existing equipment such as electrostatic precipitators to cope with changes in the process. Other techniques for reducing sulfur emissions, such as fuel switching or advanced combustion technologies, are included for comparison.

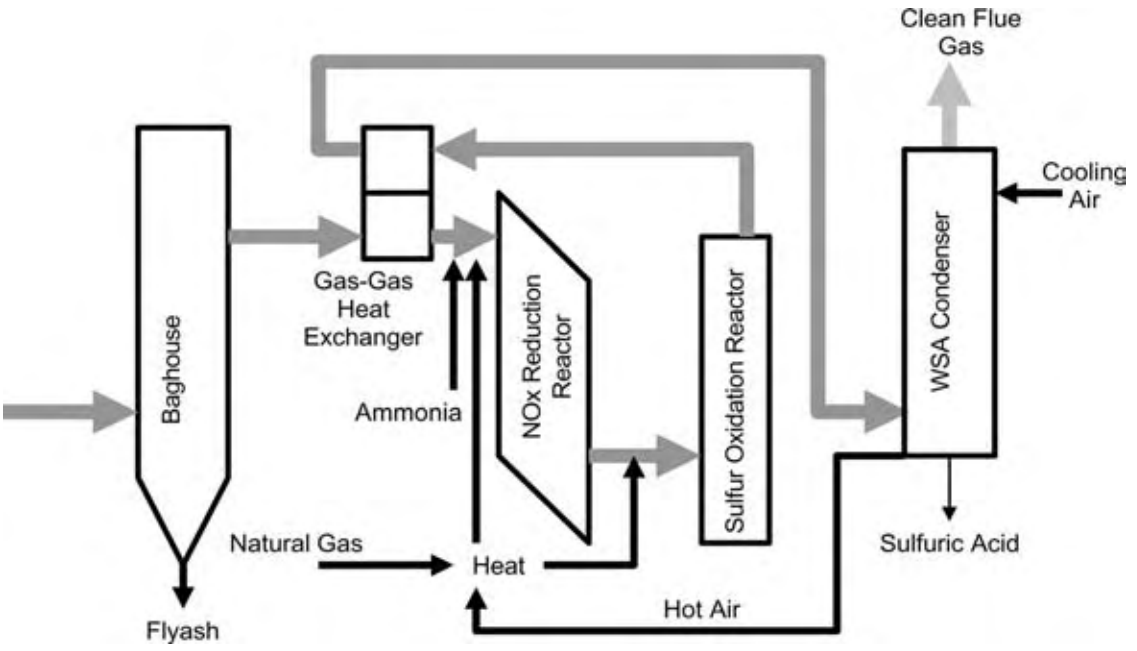

Fig. 12 Diagram of the SNOX system for production of sulfuric acid from flue gases while simultaneously destroying nitrogen oxides. (From Ref.[11].)

In general, fuel switching is currently the cheapest option at the current price difference of $10/ton between high-sulfur and low-sulfur coals. However, as low-sulfur coal prices increase, this will become less economical. Dry processes are the next most economical option, but they may not be able to meet emission control standards. The various types of scrubber have broadly similar costs, and the choice will depend on the specific plant under consideration. It appears from Table 4 that advanced combustion technologies such as integrated gasification combined cycle (IGCC) and fluidized bed combustion are drastically more expensive than scrubbers, but it should be remembered that the comparison is between retrofitting existing plants (for the scrubbers) and building new plants (for the IGCC and fluidized bed). The price differential between the two types of pollution control process is much less for completely new plants or for repowering existing plants.[38]

In general, the performance of a scrubber process will be improved if the sulfur content of the feed coal

Table 4 Cost comparison of various SO_2 control options

Technology	% SO_2 removal	Capital costs ($/kW)			Operating costs (mills/kWhr)			Most sensitive parameters
		Low	Base	High	Low	Base	High

(From Ref.[47].)

is reduced. A lower sulfur feed provides the following benefits:

1. Gas-scrubbing processes require less absorbent.
2. A lower percentage of the total SO_2 can be removed and still reach emission targets, allowing the less-efficient, lower-cost technologies to be used.
3. The quantity of desulfurization waste which must be disposed of is reduced.

It is therefore beneficial to pretreat the coal to remove as much sulfur as is practical before combustion, so that the expense of postcombustion desulfurization can be reduced. Combined with the other benefits of coal cleaning, it is evident that precombustion coal treatment is valuable even when it is not sufficient to completely desulfurize the coal by itself.

CONCLUSIONS

A wide range of postcombustion technologies are available for reducing the emissions of sulfur and other pollutants from coal-fired power plants. These include both wet and dry scrubbers, which produce either sulfur-bearing wastes or marketable by-products. In general, the less-expensive techniques are also the least effective for reducing emissions, and so the choice of which process to use depends on the quantity of pollutants in the fuel, the types of pollutants, and the emissions target, as well as on many other factors such as plant size, whether it is a retrofit of an existing plant or a new plant, availability of cleaner fuel, cost of waste disposal, and availability of markets for by-products.

Spray-dryers or dry sorbent injection are a good choice if there is little space in the plant for installing new equipment, there is no market for by-products, and the plant emissions can be brought into regulatory compliance with relatively modest reductions in emissions.

Wet scrubbers are well suited for plants with significant room for expansion, and which need to remove a large proportion of the pollutants from their emissions. Scrubbers with throw-away absorbents are the best choice when waste disposal is cheap, while those with regenerable absorbents and/or marketable by-products are the best choice when waste disposal is expensive and markets for by-products are nearby.

Precombustion and postcombustion pollutant removal technologies should not be considered to be in competition. Rather, they are complementary technologies that should be used together for maximum benefit. Many precombustion processes are low in cost, but cannot remove all of the pollutants, while postcombustion treatment can often capture nearly all of the emissions from the combustion gases, but their costs increase as the coal pollutant content increases. By using both types of process together, the maximum reduction of emissions can be achieved at the minimum cost.

Six Sigma Design: An Overview of Design for Six Sigma (DFSS)

Sean A. Curran
Kwok-Wai Lem
Steve Sund
Mina Gabriel
Honeywell International, Inc., Morristown, New Jersey, U.S.A.

INTRODUCTION

Traditional six sigma methodology has become a standard process optimization tool for process industries. However, it has become clear that the ''Holy Grail'' of six sigma, 3.4 defects per million opportunities (DPMO), is simply unachievable after the fact. Consequently, there has been a growing movement to implement six sigma design usually called design for six sigma (DFSS). This methodology begins with defining customer needs and leads to the development of robust processes to deliver those needs.

In this entry, we introduce the DFSS approach to product/process development. This is based on a systematic application of powerful tools to define customer requirements and relate them to producer capability. This is followed by a detailed discussion of the various tools and their use. We show how the linkage of customer needs to product requirements and subsequent linkage of product requirements to process requirements drive to the development of robust processes.

DEFINITIONS AND THEORY

What Does DFSS Mean?

Ultimately any supplier's objective is to deliver on customer expectations 100% of the time.[1,2] DFSS is a systematic approach to develop processes that are capable of delivering on those expectations.[3–5] Ideally, all products would behave the same way all the time. In the real world, errors (i.e., defects) can and do occur because all processes exhibit variation. Consequently, all products manufactured via those processes will exhibit variation.[6] DFSS is a systematic methodology to predict that variability and the ability to meet customer needs. The methodology applies a suite of tools to define customer expectations and couples them directly with manufacturing capabilities so that the customer is always satisfied, and the manufacturer can earn adequate returns.

What Is Sigma?

The simple answer is that it is a measure of variability. Generally, in chemical processing we deal with normally distributed variables such as temperatures, flow rates, pressures, purity, mechanical strength, etc. These variables will have a nominal value or a specific setting and some level of variation. The average of all values is referred to as the mean (μ) and the spread is defined by the standard deviation, sigma (σ). We can describe these distributions statistically and predict the probability of a certain value occurring as illustrated in Fig. 1. In cases where the variables are not normally distributed, such as high purity materials where the distribution becomes highly skewed as one approaches the physical limits of 100% purity or 0% impurity, the data must be handled appropriately. The correct distribution can be modeled, or the data can be transformed into a normal distribution by using averages of multiple measurements. The central limit theorem predicts that such averages will be normally distributed. Strictly speaking, one cannot know the true mean and standard deviation unless the entire population is measured. In practice, we use a sample to predict the true mean and standard deviation. Consequently, there is always a finite probability that the sample chosen does not represent the true population.

What Is Six Sigma?

The discussion of sigma (σ) given earlier deals with the natural variation in the process.[1,7–10] Consequently, we denote the measurement of σ as a measure of the voice of the process. This is clearly an internally focused assessment of process capability, i.e., the ''voice of the process.'' The probability of a defect in the process, i.e., failure to meet customer expectations, is commonly defined in terms of DPMO. The focus of DFSS is to achieve a minimum of six standard deviations between the mean and the nearest specification ($\pm 6\sigma$), corresponding to 3.4 DPMO. Because the specifications are set to meet customer needs, six sigma in this

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016185

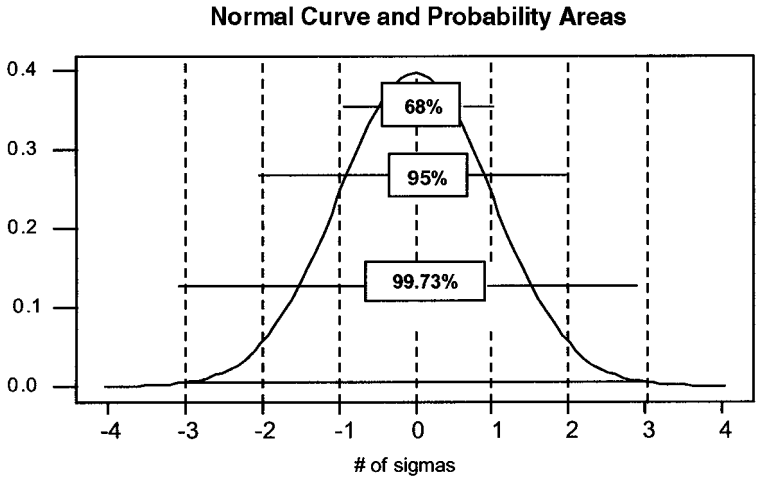

Fig. 1 Normal probability curve. *(View this art in color at www.dekker.com.)*

context is the ratio between the voice of the customer and the voice of the process. This ratio is the sigma score, commonly referred to as "Z" score and is calculated as shown in Eq. (1), where μ is the process mean, σ is the process standard deviation, USL is the upper specification limit, LSL is the lower specification limit, and the sigma score (Z) is the smaller of the calculated values. Brief inspection of the equation shows that Z is dimensionless.

$$Z = \frac{\min(\text{USL} - \mu, \mu - \text{LSL})}{\sigma} \quad (1)$$

In effect this calculation normalizes all processes to a number of sigmas rather than absolute values. The relationship between DPMO and Z score is illustrated in Fig. 2. Z refers to the white area under the curve and the shaded area shows the area where there is a probability of failure. DPMO is the integration of the shaded areas, i.e., the proportion of the results beyond the calculated Z value. Obviously, as Z increases the defective part of the distribution shrinks. The exact probability associated with a specific Z score can be easily obtained from Z score tables or calculated with common software packages such as Excel® or statistical packages such as Minitab®.[a] In the case of Excel, such calculations are not part of a standard package, but macros can easily be written to perform the needed calculations.

Why Six Sigma?

Naturally, all producers wish to minimize their production cost while maintaining quality. Likewise, all customers desire 100% defect free products at minimum cost. Infinite repetitions of product enhancements are only useful if they provide value to the customer. Further improvements add cost, without adding value. Brief inspection of a Z score table shows that a Z score of 6 actually corresponds to a probability of 10^{-9} for a failure. However, most studies of process capabilities are relatively short term in nature. After all, the supplier's interest is in making product, not continuously evaluating the process. Experience has shown that over time, processes will drift off the original mean. Typically this drift amounts to 1.5σ (for example, see p. 512 of Ref.[5]), so one compensates for the long-term variation by subtracting 1.5 from the short-term sigma score.[1,5] In effect, a short-term 6σ process becomes a long-term 4.5σ process, and this corresponds to the often quoted 3.4 DPMO.

What is a CTQ?

The acronym CTQ stands for critical to quality. At the highest level, CTQs are those benefits that accrue to the customer when they use a product/process. Top level CTQs are not specific to either product or process.

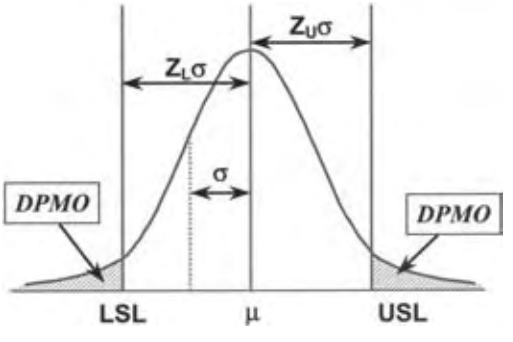

Fig. 2 Relationship of Z score with DPMO. *(View this art in color at www.dekker.com.)*

[a]Excel® is a registered trademark of Microsoft, Inc. and Minitab® is a registered trademark of Minitab®, Inc.

These are the performance attributes that the customer is actually paying for such as load bearing capacity, stability in a harsh environment, etc. In the following section, we discuss requirement flow down. As those requirements flow down, we establish lower level CTQs. These are those process and/or product requirements that are critical for delivering the customer CTQs, i.e., those parameters one must control in order to deliver the desired performance.

DFSS TOOLS

Quality Function Deployment

Once the customer needs (top level CTQs) have been defined a DFSS team needs to determine how process parameters that can be addressed, such as raw materials, process control parameters, etc. are related to the ability to deliver customer CTQs. This is done by generating a series of quality functional deployment (QFD) matrices as sketched in Fig. 3. There is no hard and fast rule on how many levels a QFD needs. Frequently, polymer and chemical QFDs have only three levels as there are no subassemblies, and consequently, there is no need for a ''parts'' QFD because process specifications relate directly to the process design CTQs.

We discuss QFD at some length because it is one of the pillars of a successful DFSS effort. A proper QFD relates customer CTQs to product features and assesses various competing alternatives for delivering the desired features.[4,5] Quality functional deployment then relates product features to product design, product design to process design, and finally process design to process specifications. Naturally, any product has an array of features and customer needs are rarely monofunctional. A successful DFSS effort focuses on the most critical features. Quality functional deployment provides a mechanism for defining product design CTQs based on customer CTQs, then defining process design CTQs based on product design requirements and process specification based on process CTQs, as illustrated in Fig. 4. Usually, the most difficult part of a QFD is the definition of customer needs. Rarely, if ever, is the first attempt at a QFD complete. Customers frequently do not know their total needs, and can only detect them as deficiencies, well after the initial QFD definition. The only way to compensate for this initial failing is to maintain close customer contact and treat the QFD as a living document. Once initial designs are developed, customer feedback must be used to update and refine the QFD.

The first matrix (QFD1) relates the customer needs, i.e., top level CTQs, to the required functions and features a product needs to deliver those CTQs.

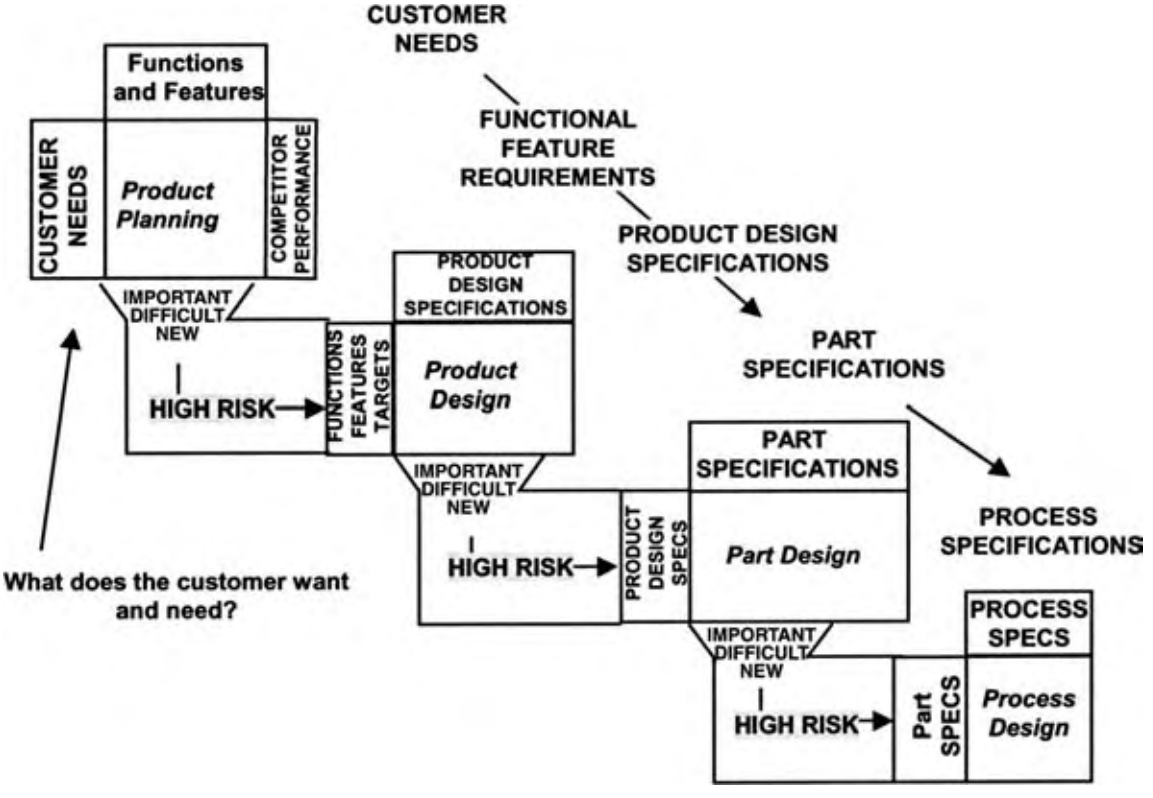

Fig. 3 Linkage of customer needs to process controls via QFD. *(View this art in color at www.dekker.com.)*

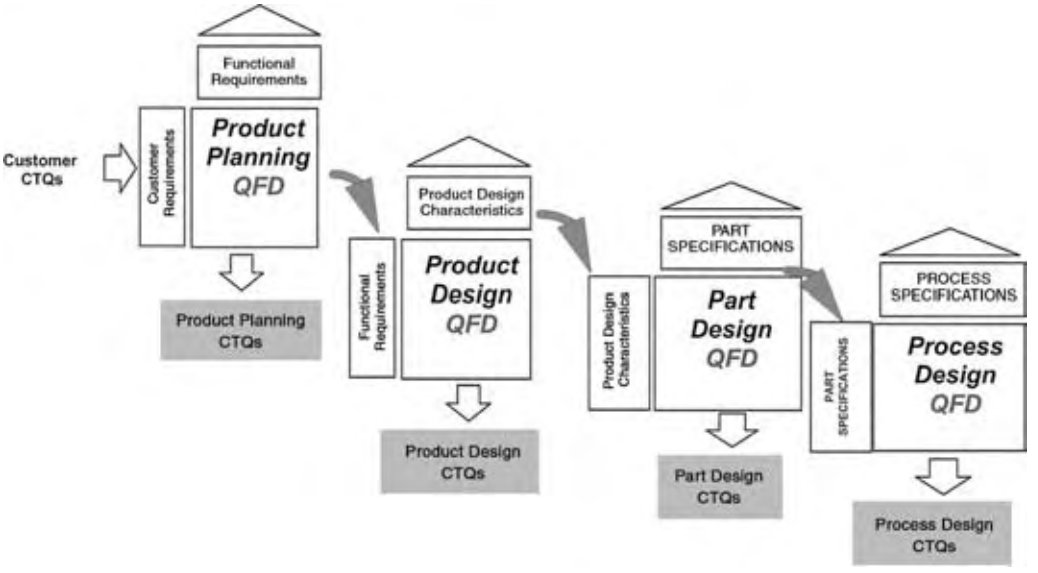

Fig. 4 Flow down of customer requirements to process specifications. *(View this art in color at www.dekker.com.)*

For example, if the customer CTQ is stability in harsh environments, the related features might be the ability to withstand 100°C exposure at pH 1 for 1000 hr. Note that the features still have not defined a specific product or process, but they have defined measurable criteria that relate to the desired CTQ. At this stage, the DFSS team assesses what competitive alternatives exist that might deliver the same features, and proceeds to flow the functional requirements downward to eventually define process specifications.

We do not have the space here to explore all the aspects of QFD, but there are excellent sources available in print and online that provide this kind of detail.[4,5,11–13] We now delve briefly into the mechanics of the QFD. This is a tool that is simple to understand, but can be very difficult in practice.

An illustrative example of a typical QFD is given in Figs. 5 and 6. A customer desires high purity alcohol, at reasonable cost with just in time delivery. The five steps in a QFD1 (Fig. 5A) are:

1. Assess customer needs, typically through customer interviews, surveys, trade groups, marketing contacts, etc. Once the needs have been identified they are prioritized via numerical rankings. A variety of approaches to these rankings can be used. In Fig. 5A, we have used a 1,3,5 ranking for denoting importance. The customer must absolutely have high purity and reasonable cost; hence these needs are rated 5. The delivery schedule is important, but there is some flexibility generating a rating of 3. The exact ranking scheme is not critical, provided the DFSS team understands how important these performance CTQs are to the customer.
2. Determine what types of existing solutions and competitive approaches already exist to deliver the desired product features and contrast them with the DFSS team's potential solution. Again a numerical ranking is used to assess how well each of the alternatives addresses the customer CTQs. In Fig. 5A, we have used a logarithmic 1,3,9 scale for these ratings. Competitor 1 can deliver high purity alcohol, but at a high cost and poor delivery schedule. Competitor 2 has low cost, but lower purity. The rating of each alternative is multiplied by their importance rating and their products are summed to provide an overall weighted performance rating. Thus Competitor 1's overall rating is 53 $\{(9 \times 5) + (1 \times 5) + (1 \times 3)\}$. This exercise allows the team to quickly assess how big the gap is between potential solutions, as well as defining potential strong points.
3. The DFSS team assesses what types of product features are needed to deliver the required customer benefit, and how they will measure those features—measurement system, targets, and ranges. Those items are listed as functional product requirements.
4. The DFSS team evaluates how strong the relationship is between the functional requirements and each customer CTQ. The DFSS team defines the rating scale for the relationship strength, although in our experience a logarithmic 0,1,3,9 scale, with 9 being the strongest relationship, works quite well. This type of ranking helps to rapidly make an assessment rather than arguing about which relationships are slightly stronger than the others.

Fig. 5 QFD1 and QFD2 for high purity alcohol. *(View this art in color at www.dekker.com.)*

5. Each relationship strength is multiplied by each CTQ importance rating and the products are summed to give a weighted relative importance for each feature.

Examination of Fig. 5 shows how all these different pieces of information are correlated to generate a numerical ranking of functional product requirement importance. Clearly, QFD is at best a ''semi'' quantitative tool, particularly at the top level. CTQ importance ratings are based on the customer's opinion. The strengths of the relationships are based on the DFSS team's experience and knowledge of what types of features will drive performance. Nevertheless, this is an extremely powerful tool because it focuses the team on what the product should be designed to do for the customer rather than what their existing product can do.

Once the team has completed the prioritization of functional requirements, they proceed to QFD2 (Fig. 5B) where the process is repeated, but this time

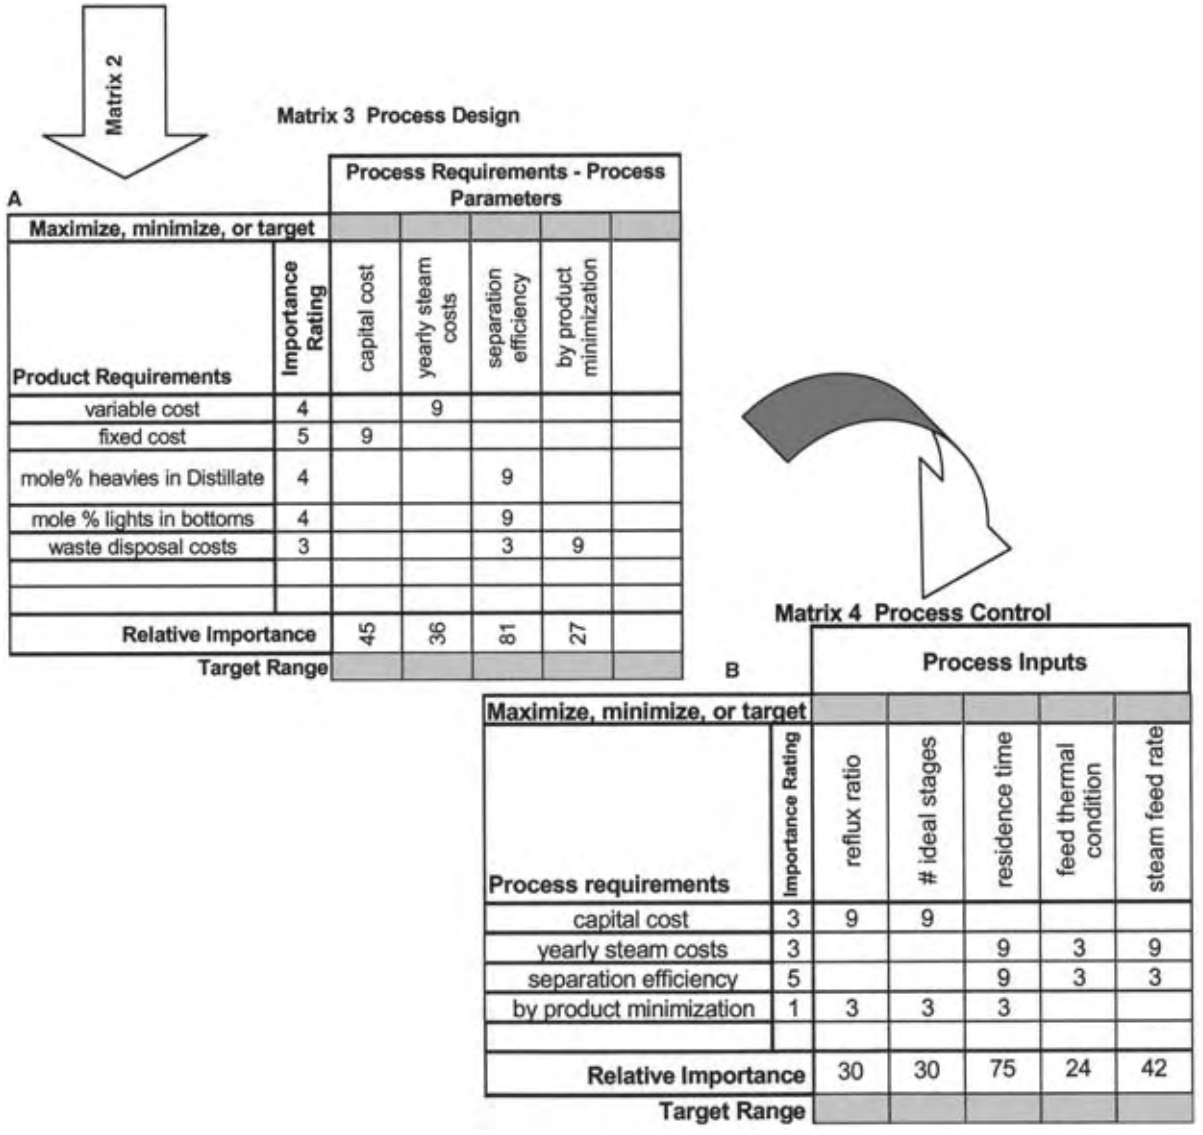

Fig. 6 QFD3 and QFD4 for high purity alcohol. *(View this art in color at www.dekker.com.)*

linking functional product requirements with product design requirements. The prioritized functional requirements are reranked, typically on a 1–5 scale; the product design requirements to deliver those functions are defined; potential competitive approaches are defined; and the numerical evaluations in terms of competitive performance and relationship strength are evaluated. Once the product design requirements are defined and prioritized, they are linked to the process requirements via QFD3 as shown in Fig. 6A. The process is repeated in QFD4 to link process requirements to process controls (Fig. 6B). Note that there are no operating ranges specified in Fig. 6. If one is designing a new process or product, the design requirements may well be known while the required process parameter settings to reach those design requirements need to be evaluated. The strength of the QFD is that it helps illustrate those process parameters that need to be defined. The approach for defining them is discussed in the sections on transfer functions, design of experiments (DOE), and setting specifications.

Transfer Functions

Simply put, the DFSS definition of a transfer function is:

$$\begin{aligned} Y &= f(x_1, x_2, x_3, \ldots, x_n), \\ S_Y &= g(S_{x_1}, x1, S_{x_2}, x2, \ldots) \end{aligned} \tag{2}$$

This shows that there is a definable relationship between the output of a process and its inputs, and between the variability of the inputs and variability

in the output. A simple illustration is given in Fig. 7. Two aspects of a given feature are important: first its direct effect on the output (Y), second the variability of the feature and the consequent variability of the output (S_Y). Variability is unavoidable as raw material lots change, processes change, and environmental influences affect a process. Therefore, simply defining the targets is only half the story.

As with QFD, transfer functions are an essential pillar of the DFSS methodology. In fact once QFD has defined what is required, then the transfer functions are a mathematical model of how the process can deliver customer CTQs. If we understand how process settings affect product features and how features affect performance, then it is feasible to design a product that will meet customer requirements, with yields matching model predictions. If we do not understand these relationships, then the probability of success diminishes rapidly.

There are two sets of transfer functions one should be concerned with: target settings and effects of variability.[4,14] These are illustrated in Fig. 8, which shows the relationship between controllable inputs and their variability with the desired output and its variability. Thus, QFD defines how one flows the customer CTQs downwards, while the transfer functions define how one predicts process capability and defines the critical control points.[4,5] The transfer functions allow the team to establish this linkage early in the development, rather than try to do it once products are in production. In addition when customer requirements change, the team does not have to begin a new project. With the transfer functions in hand, they can quickly evaluate capability and predicted reliability for the required process changes.

The most difficult part of using transfer functions is defining them in the first place. Once they exist, they are simple to use. The process map in Fig. 9 illustrates schematically how one can define transfer functions. These functions can take a variety of forms and arise from a variety of sources as illustrated in Fig. 10. The functions can be derived from known mechanistic models, e.g., based on the ideal gas laws, one can predict gas pressure at a given temperature, or an Arrhenius equation can be used to predict kinetics. The appropriate model parameters may be known a priori or can be determined by experimentation. One can also develop empirical models based on experimental data. Mechanistic models are preferable, because they explain why the output depends on the input and there is a clear understanding of the mechanism. Empirical models are also quite useful with the caveat that they are based on an observation of correlation. There is always a possibility that the observed correlation is serendipitous; so the DFSS team must carefully review the model to be sure that the observed function is reasonable. In practice, empirical models are more prevalent in complex chemical systems, but it is essential that the model only be used for the same experimental space that was used in the model. Extrapolation outside this area is at best highly questionable. If the team wishes to extrapolate, then additional experimentation is required to make sure the model fits in the new region.

We illustrate transfer function development with the high purity alcohol example as mentioned earlier. Assuming we have an empirical function, with known parameters, we can formulate a mathematical model to product performance and cost. Using the approach of Chang,[15] we can solve the short cut distillation equations of Hengstebeck, Geddes, Fenske, Underwood, and Gilliland.[16–21] This provides the transfer functions for technical requirements. We then need to incorporate the financial requirements. We have developed a Monte Carlo simulation program to couple the transfer functions for each level of the QFD leading to a final result, which optimizes for technical specifications while minimizing the cost.

The program obtains a standard normal value and transforms based on the input mean and standard deviation for each of the input variables. All these

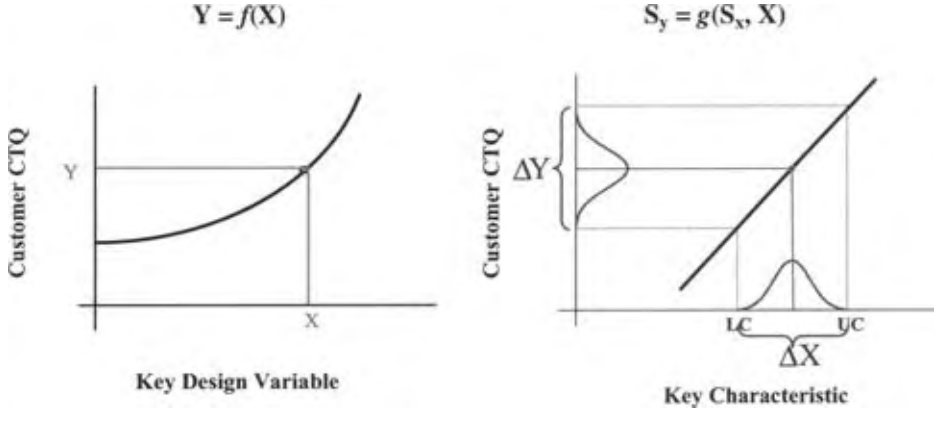

Fig. 7 Schematic illustration of transfer functions for targets and variability in a key variable. *(View this art in color at www.dekker.com.)*

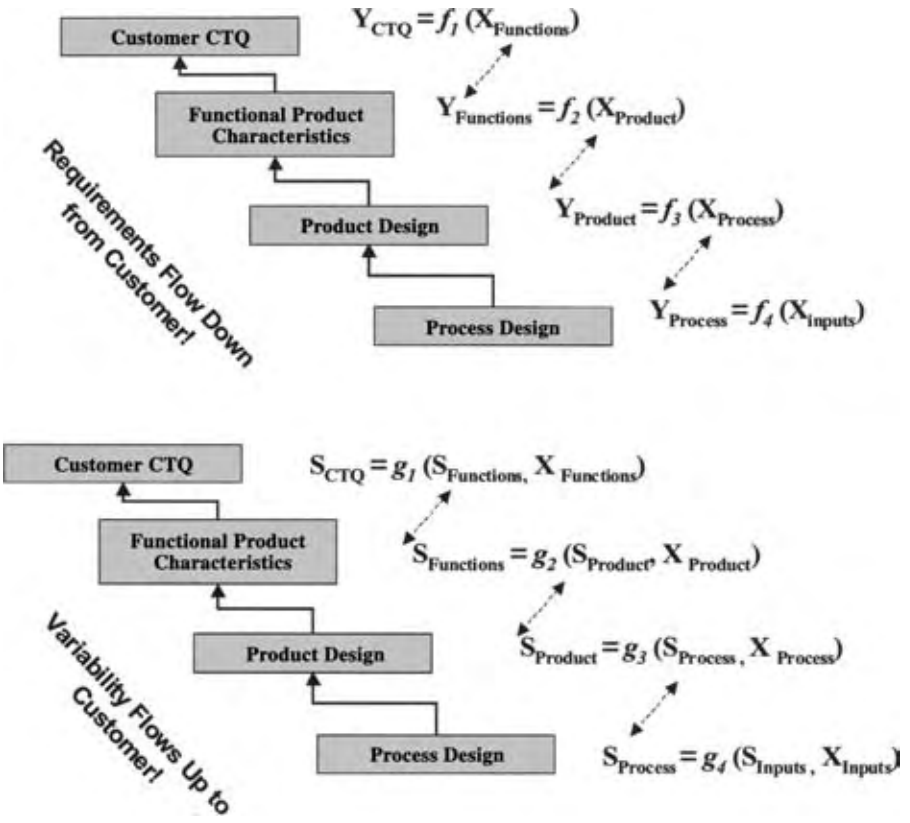

Fig. 8 Linkage of transfer functions from process parameters through customer CTQs. *(View this art in color at www.dekker.com.)*

are sent to the trays subroutine to calculate ideal stages (IS). These are then stored in an array of responses, and statistics such as mean, standard deviation, skewness, and kurtosis are calculated on the results. In addition, a factor response summary is calculated for each of the four input variables. The method used is that found in Refs.[22,23] The results of this simulation are shown in Fig. 11. We then extended the model to incor-

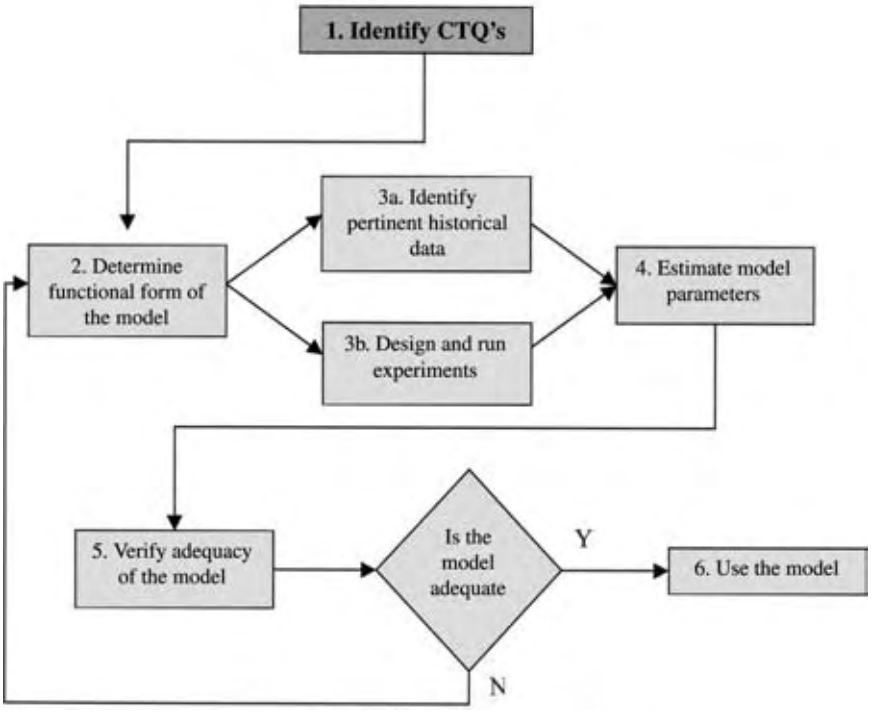

Fig. 9 Process map for creating transfer functions. *(View this art in color at www.dekker.com.)*

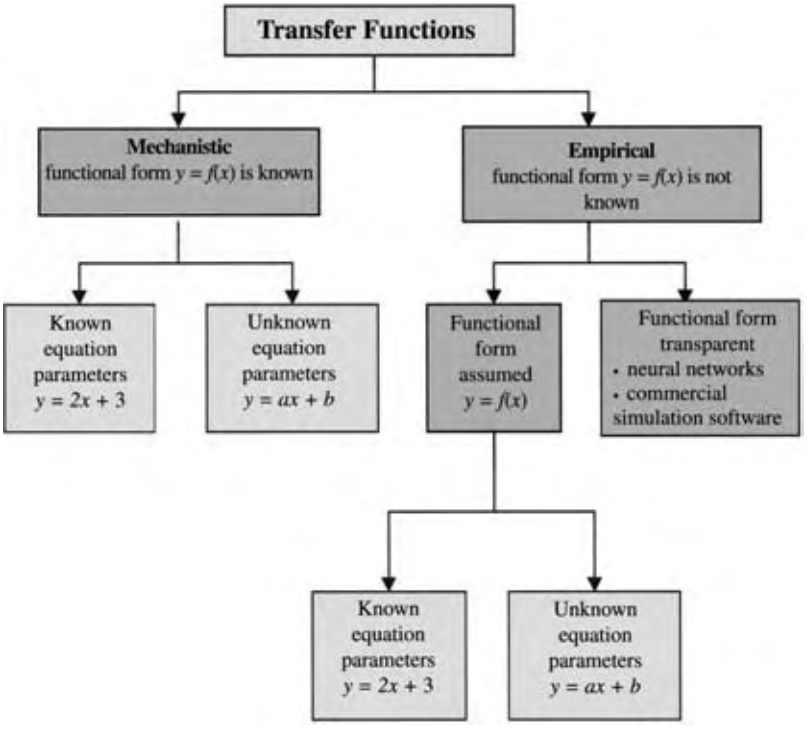

Fig. 10 Types of transfer functions. *(View this art in color at www.dekker.com.)*

porate those factors related to cost. This was of more interest, because it incorporates multiple levels of transfer function. In effect, we can manipulate the input variables and see how the ultimate outputs, which are four levels higher in the QFD, are affected.

This comprehensive model uses the same method described earlier; transforming a standard normal value using the first four means and standard deviations as depicted in Fig. 11.

Submission to the trays subroutine returns the number of IS and reflux ratio (RR). These are then used to calculate total cost (TC) of the column based on the algorithm (i.e., transfer functions) shown below.

Capital cost (CC) [$/yr] is calculated by Eq. (3), which is a function of the number of IS and RR.

$$CC = 1353278.3 + 44483.4 \times IS - 949840.14/RR \quad (3)$$

Fixed cost (FC) [$/yr] is calculated by Eq. (4), which is a function of CC.

$$FC = (0.0000759 + 0.0933 \times CC \times CC)^{1/2} \quad (4)$$

Yearly steam cost (YSC) [$/yr] is calculated based on 8000 hr in a year and Eq. (5) is a function of steam rate (SR) and steam cost (SC).

$$YSC = SR \times 8000 \times SC \quad (5)$$

Variable cost (VC) is calculated by Eq. (6) and is a function of YSC.

$$VC = 327322 + 1.31 \times YSC \quad (6)$$

Finally, TC [$/yr] is a function of FC and VC, and is calculated by Eq. (7).

$$TC = VC + FC \quad (7)$$

The results of this simulation are shown in Fig. 12.

Design FMEA

Simply knowing the required controls is insufficient to guarantee consistent performance. The DFSS team must design controls and safeguards into the system. The primary tool in this effort is the design failure modes and effects analysis (DFMEA). Failure mode and effects analysis (FMEA) is a well-known tool, which has been extensively used in a wide range of industries.[1–5,7–8] It is an approach that allows prioritization based on the highest failure risks in the development process. Failure mode and effects analysis couples the severity, frequency, and detectability of failure to meet customer CTQs to assess overall risk of a given failure type. There are different types of FMEA for manufacturing processes, administrative processes, and design processes. A DFSS team will

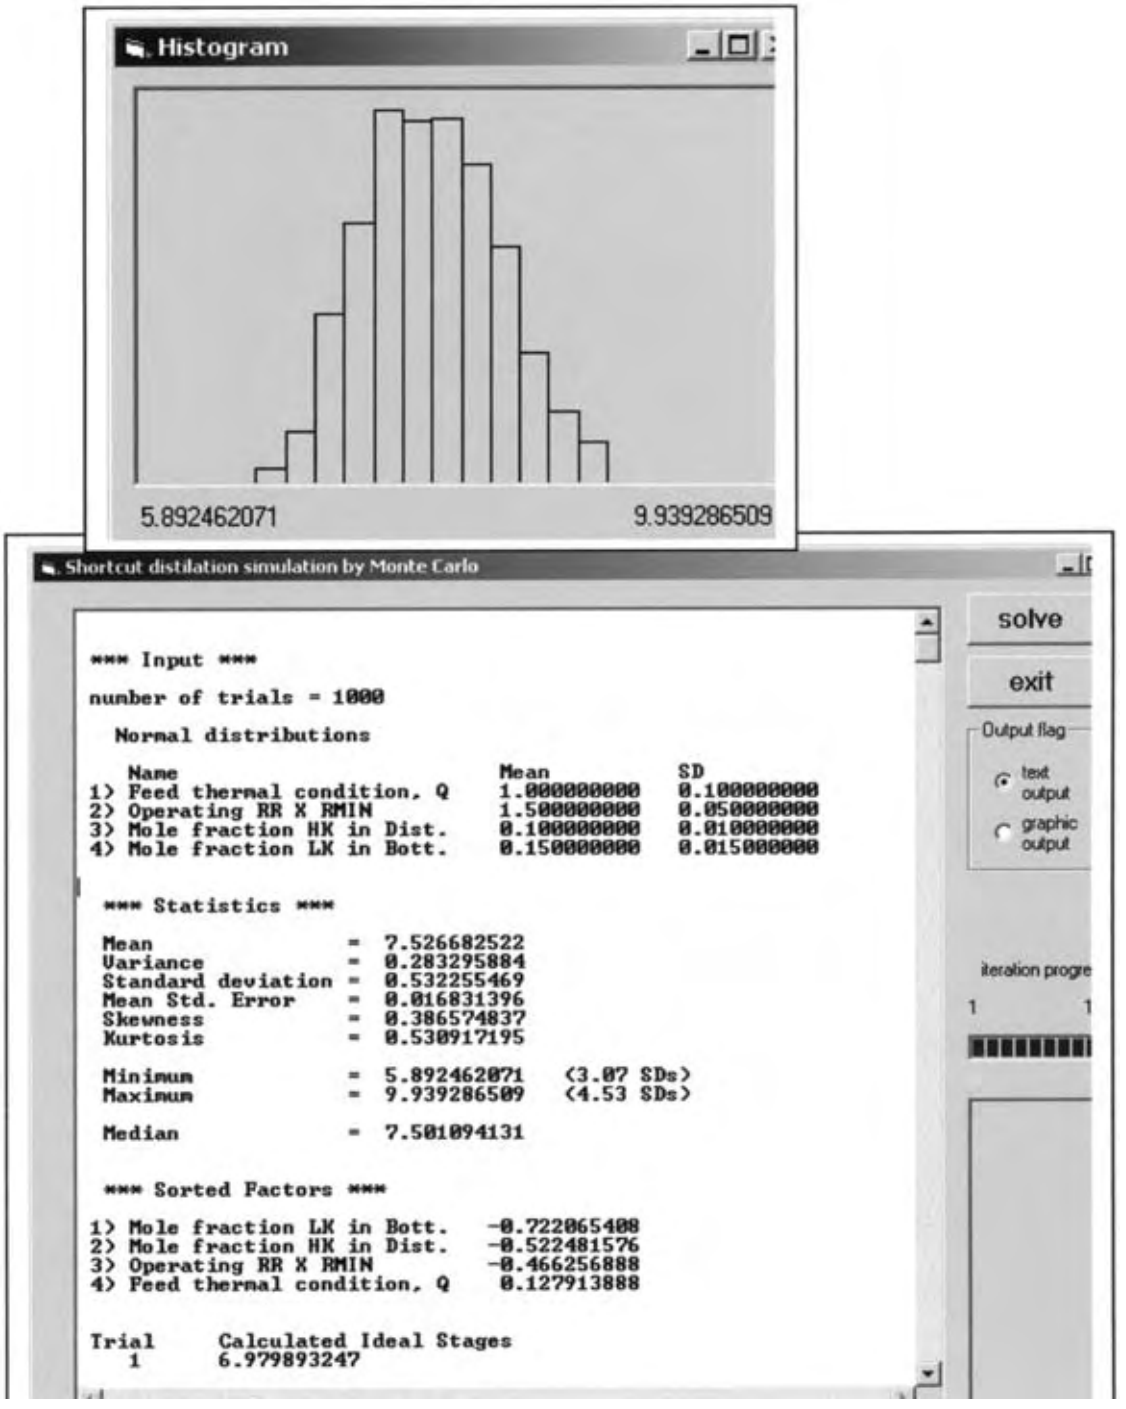

Fig. 11 Monte Carlo simulation of separation efficiency for alcohol purification. *(View this art in color at www.dekker.com.)*

be involved in the DFMEA and at the very least a preliminary manufacturing FMEA.

A typical design FMEA is given in Fig. 13 for the alcohol example discussed earlier. The headings across the top of the FMEA define the types of information it requires. The DFSS team must evaluate the risk associated with failure of the CTQs. We discuss the functional requirement FMEA, but the same approach applies to any FMEA. The first column specifies the requirement that is being evaluated. The second column specifies the failure mode. A failure mode is the way in which the requirement is not met. The third column specifies the effect on the customer if that requirement is not been met. The next column is a numerical rating of severity, i.e., how badly does it affect the customer. The fifth column addresses causes

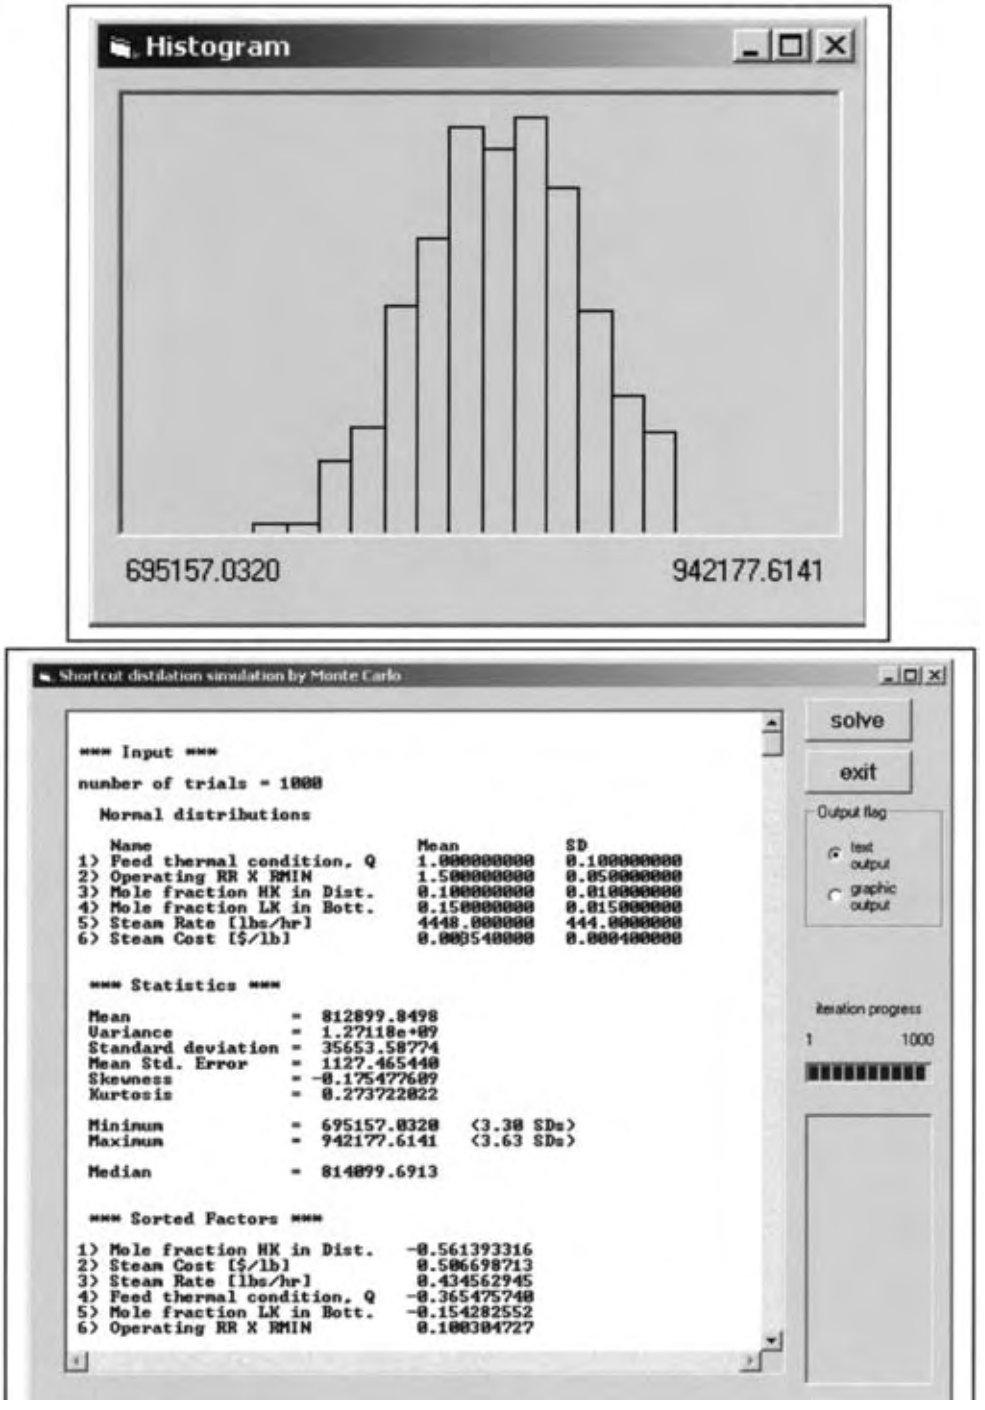

Fig. 12 Monte Carlo simulation for separation efficiency, incorporating cost transfer function. *(View this art in color at www.dekker.com.)*

for the failure mode. The next is a numerical rating of the likelihood for the occurrence of this cause. The seventh column is an assessment of the types of systems being employed to determine the occurrence of failure and to eliminate it before product release. The next is a numerical rating of the effectiveness of that particular detection system. The total risk is computed by multiplying the severity rating by the frequency rating by the detectability rating, generating the next column titled the risk priority number (RPN). The remaining columns are for tracking what corrective actions are needed, who is responsible, and the effect on the RPN after taking the required actions. Inspection of the RPN values immediately focuses the DFSS

team on the highest risk failure modes, which in this illustration are rise in energy cost and poor model. This is not to imply that the other failure modes are unimportant. It is simply a mechanism to reduce or eliminate the highest risks. Failure mode and effects analysis is an iterative process. Once the high RPNs are reduced, the DFSS team needs to determine if the overall risk is sufficiently small to justify product manufacturing. If not, then the ongoing efforts taken must be aimed at reducing the other high risk items.

Developing an FMEA is a DFSS team effort. The numerical ratings for severity, detectability and frequency must be agreed on by the team, so that everyone agrees on the definitions. Otherwise one team member may consider the effect to be mild, another moderate, and yet another severe. As with QFD, the numbers here are ''semi'' quantitative, and round table team discussions help to achieve a more accurate picture of the true risks associated with the specific failure modes. If possible, the team should formalize the rating system as much as possible. A sample of such a formalized scale is given in Fig. 14.

Experimental Design and Process Simulation

Design of experiments is a fundamental tool in DFSS.[4,5] Systematic experimentation is frequently needed to determine the functional form of a transfer function.[14,24–29] This applies in particular to chemical reactions and polymer processing, where predicting yields of complex, multistep processes is difficult. DOE has been widely used to determine optimized settings for chemical processes. In DFSS one must also evaluate the effect of input variation on the output. There are various types of DOE that address this. Taguchi designs systematically evaluate the effect of noise variables on the outputs. Schematically, this approach is illustrated in Fig. 15A for a two-factor design, with two levels for each factor and two noise variables. The corners of the large square (the outer array) define the factor settings. Around each corner is a smaller square (the inner array) with the various settings for the noise factors. For example, the factors DV1 and DV2 might be RR and residence time. The noise variable might be steam feed rate and lot to lot

Rating	Effect (Severity of the Impact on Performance)	Cause (Likelihood of Occurance)	Control (Difficulty of Detection; Likelihood of "Escape")
10	Very high severity; hazardous without warning	Very High; failure is almost inevitable	No control in place; Cannot detect
9	Very high severity; hazardous with warning		Very remote chance of detection
8	Loss of primary function performance	High; repeated failures	Check for expected results; Remote chance of detection
7	Reduced primary function performance		Very low chance of detection
6	Loss of secondary function performance	Moderate; occasional failures	Low chance of detection
5	Reduced secondary function performance		Moderate chance of detection
4	Minor defect noticed by most customers		Moderately high chance of detection
3	Minor defect noticed by some customers	Low; relatively few failures	High chance of detection
2	Very minor defect detected by discriminating customers		Very high chance of detection
1	No effect	Remote; failure is unlikely	Prevent root cause; Almost certain detection

Fig. 14 Typical rating scale used for FMEA. *(View this art in color at www.dekker.com.)*

changes in raw materials. Minimizing the influence of noise variables then makes the design inherently more robust, i.e., stable to external influences. The major advantage for the Taguchi designs is the direct assessment of the effects of noise variables. Frequently, experimenters refrain from using these designs because they require a large number of experimental runs. Note that this two level two-factor design requires 16 experiments to define a main effects model.

An alternative approach is the use of response surface or mixture designs to determine the transfer function. A schematic of a two-factor response surface design is given in Fig. 15B. This is accomplished in nine experimental runs and evaluates main effects, as well as factor interactions. If the variability of the inputs is known, then one can model the predicted variability using propagation of error techniques or Monte Carlo simulations based on the transfer function. The major advantage relative to the Taguchi approach is the need for significantly fewer experimental runs.[24,25] However, this approach assumes that the experiment has adequately mapped the experimental space, and that the input variations are known.

TRANSITION TO MANUFACTURING

Setting Specifications

The achievement of six sigma is typically a balance of the cost and customer requirement. Consequently, there are two ways to achieve six sigma. One can develop a

Current Control Plan

Process	Process Step	Input	Output	Process Spec (LSL, USL, Target)	Cpk / Date (Sample Size)	Measurement System	%R&R or P/T	Current Control Method (from FMEA)	Who	Where	When	Reaction Plan
Distillation	Vaporization	feed thermal condition		Q=1 +/- .3	1.3	IR	5% R+R	pre-heat power	Operator	Control room	start of run	power to heat
Distillation	Vaporization	Steam feed		2000-7000lb/hr	1.7	Thermocouple	10%	Mass flow controller	Operator	Steam line	1/shift	shut down
Distillation	Vaporization	Residence time		10-15 min	1.8	Flow sensor	1%	on line sensor	Operator	Column inlet	Constant feedback to DCS	Adjust flow

Fig. 16 Sample control plan for high purity alcohol production. *(View this art in color at www.dekker.com.)*

very narrow process, which typically drives up the cost. Alternatively one can set wide specifications, but the customer CTQs must still be met. In DFSS one attempts to predict the variability as discussed earlier. This allows a prediction of achievable specifications.[30]

In practice, variation in customer CTQs is driven by multiple factors. For example, if the customer CTQ is a water white polymer (i.e., a transparent, colorless polymer), variations might depend on melt temperature, vacuum levels, quench speed, stabilizer content, etc. The strength of DFSS is that one will predict the set of conditions that minimize the variation around the target level of yellowing. Thus one might opt for rapid quenching and higher stabilizer because the oxygen level cannot be maintained at a sufficiently low level.

Finally, one can set specifications based on known process capability. If a sufficient number of lots have been produced, one can statistically evaluate the variation and set the specification limits outside the statistical control limits. Typical DFSS efforts do not lead to a sufficient number of sample lots for such a statistical evaluation. However, once the product is scaled up and in production, the specifications should be re-evaluated to make sure they will remain at six sigma performance.

Establishing Control Plans

The final critical piece of the DFSS puzzle is a control plan.[1–5,8–10] This is a document that specifies which are the critical inputs, where their limits need to be, and how they will be evaluated. Such a document should be part of any transfer to manufacturing. It needs to specify standard operating procedures that are required and what the capability of the measurement system is. DFSS teams should preferably include, but at the very least work with, manufacturing to make sure that any product or process designed can, in fact, be produced. Consequently, a preliminary control plan should be developed in parallel with the assessment of transfer functions and the FMEA. It should then be updated as more knowledge is developed about the control points and product performance. A good control plan has all the elements required to assess performance and take action to prevent failures. It includes the process points to be monitored, the specification limits, the measurement technique and measurement capabilities, as well as responsibility to take action. A typical control plan for our alcohol example is shown in Fig. 16.

CONCLUSIONS

Design for six sigma is not a radical new idea. It is in fact simply a codification of the scientific method. DFSS is a systematic application of good scientific and engineering practices. The tools employed are very powerful if used correctly. Fundamentally, DFSS is a road map and set of tools to provide the researcher with clear insight into customer needs and the customer with clear insight into producer capabilities.

Size Reduction

Sunil Kesavan
Akebono Corporation, Farmington Hills, Michigan, U.S.A.

INTRODUCTION

The comminution or size reduction process is an important unit operation in the process industries in which solid materials are broken or cut into smaller sizes by the application of mechanical stress. Solids can be reduced in size by crushers and grinders which employ compression, impact, attrition, shear, or combinations thereof. Depending on the degree of particle size reduction desired, the end result is achieved in one or several steps. Devices that are used for size reduction operations can be classified into primary and secondary crushers, grinders, and pulverizers. Explosive blasting is used in many instances for primary size reduction of ore formations into sizes workable by primary crushing machines. The primary crushers are slow-speed machines that reduce the run-of-mine product into 15–25 cm lumps. A secondary crusher reduces these lumps to 5 mm product. Grinders reduce the products of crushing operations into powder. An intermediate grinder typically produces a product that passes a 40-mesh screen. Fine grinders reduce feed into product that passes a 200-mesh screen. Ultrafine grinders can convert the product of secondary crushers into 1–10 μ product. Cutting machines produce particles with a definite size and shape in the 2–10 mm size range.

Size reduction machines can be classified as follows:

a. Primary and secondary crushers
    1. Gyratory crushers
    2. Jaw crushers
    3. Roll crushers
b. Intermediate and fine grinders
    1. Impact mills
        a. Hammer mills
        b. Centrifugal pin mill
    2. Attrition mills
    3. Tumbling mills
        a. Ball and pebble mills
        b. Rod mills
        c. Tube mills; compartment mills
    4. Rolling-compression mills
        a. Ring roll mills
        b. Bowl mills
c. Ultrafine grinders
    1. Fluid-energy mills
    2. Agitated mills
    3. Impact mills with internal classification
d. Cutting machines
    1. Knife cutters, dicers, slitters.

GRINDING ENERGY REQUIREMENTS

Given the relatively large power consumption accompanying size reduction, it is important to quantify the energy requirements of these unit processes. Comminution theory dates back to the works of Kick[1] and Rittinger[2] that were done in Germany. A generalized differential equation that governs crushing can be written as:

$$dW = -K(dD/D^n) \quad (1)$$

where W is the energy input, K and n are constants, and D is the particle size.

Eq. (1) represents Kick's law when $n = 1$ and Rittinger's law when $n = 2$.

Kick's law[1] essentially states that the work required to obtain a given reduction ratio is the same irrespective of starting size. According to Rittinger's law[2], work is proportional to surface created. Rittinger's and Kick's laws are only useful over a limited particle size range and are not utilized today.

Bond[3] proposed that work is inversely proportional to the square root of particle diameter. Bond's theory of comminution is represented by Eq. (1) when $n = 1.5$ and can be written as:

$$W = 100W_i(1/D_P^{0.5} - 1/D_F^{0.5})$$

where W_i is the Bond work index or work required to reduce a unit weight of product from a theoretical infinite size to a product with 80% passing 100 μ. Extensive data are available on the work index and the Bond law is widely used today.

PRIMARY AND SECONDARY CRUSHERS

Gyratory Cone Crushers

These types of crushers employ a conical crushing element that gyrates in an eccentric manner in a shell

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018807

resembling an inverted cone (Fig. 1). The material to be crushed enters the top of the crusher where the crushing surfaces are most widely spaced. The product becomes wedged and squeezed between the mantle and the hopper and is progressively broken down until it discharges through the narrow opening at the bottom of the crusher. Gyratory crushers are available in large sizes used for primary crushing and smaller sizes for secondary crushing of soft to medium-hard materials. These continuous-discharge crushers are available in capacities up to 3500 ton/hr and are more cost effective to operate than jaw crushers.

Jaw Crushers

These devices suited for coarse and intermediate crushing of large volumes of hard and semihard materials employ swinging jaws that work against a hardened stationary surface. The jaws, which are essentially flat, form a V-shaped crushing chamber with a wide inlet at the top and a narrow discharge at the bottom. The large feed material gets progressively reduced in size and falls down toward the narrow throat section.

There are three types of jaw crushers (Fig. 2)—the Blake, the Dodge, and the single-toggle type. In the popular double-toggle Blake jaw crusher (Fig. 3), the moving jaw is hinged at the top with the maximum movement at the bottom of this jaw. In the Dodge crusher, the swinging jaw is hinged at the bottom. This gives a fixed discharge opening, giving a more uniform product than the Blake crusher. The greatest movement acts on the large feed at the top of the jaw. The Dodge crusher is not used much in commercial large volume crushing operations. The single-toggle jaw crusher is pivoted at the top like the Blake crusher but has an additional movement in the downward direction. The Blake crusher costs more than the single-toggle machines but the operating costs are less for hard feed materials.

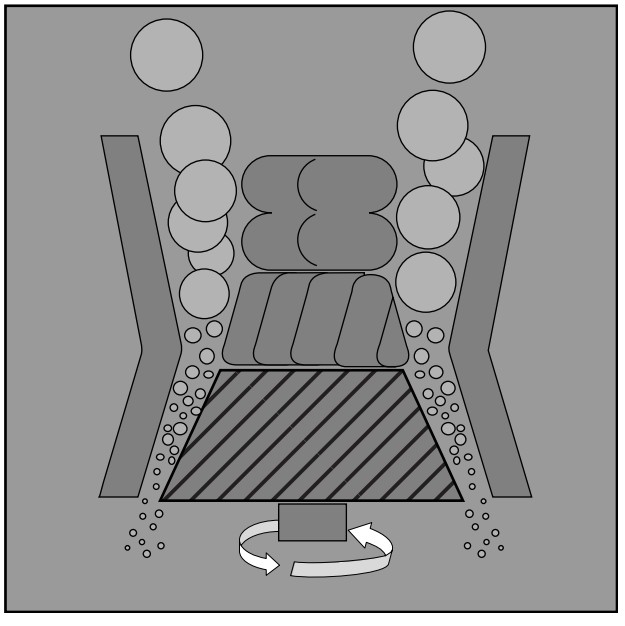

Fig. 1 Schematic representation of the operating principle of a gyratory cone crusher.

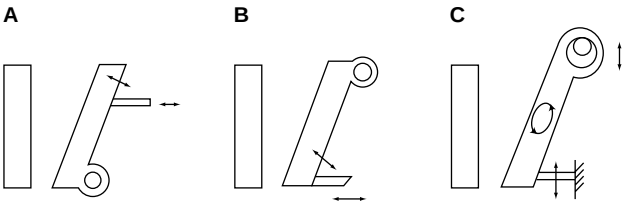

Fig. 2 The essential features of (A) Dodge, (B) Blake, and (C) single-toggle jaw crushers.

Taggart[4] proposed a rule-of-thumb that a jaw crusher would be the economically preferred size reduction equipment if the required throughput in tons per hour was less than the square of the crusher gap in inches. Depending on size, jaw crushers can handle up to a 48-in. size feed and create product smaller than half an inch. Jaw crushers are available in a variety of sizes up to about 1000 ton/hr and can be stationary, portable, or skid mounted.

Roll Crushers

These tertiary crushers employ smooth or toothed heavy-duty impact and abrasion-resistant steel-rimmed rolls. The rolls are mounted inline in a horizontal manner and turn toward each other at equal speeds to create a nip into which a friable feed material is introduced (Fig. 4). Heavy-duty compression springs with automatic reset are used to dampen crushing shock and to protect the crusher from tramp iron and oversize material. An adjustable screw that adjusts spring tension changes the crusher opening. A flywheel is used to even out pulses and economize on power consumption. These crushers have a theoretical maximum reduction ratio of 4 : 1 and will only crush materials to about 10 mesh. Roll crushers produce a controlled product size distribution without a lot of fines. The narrow particle size distribution is achieved by controlling a combination of variables including roll speed, gap measure, differential speed, feed rate, and roll surface.

Toothed single roll crushers that crush materials by working on a breaker plate are also available. The crushing teeth are set in segments to facilitate replacement.

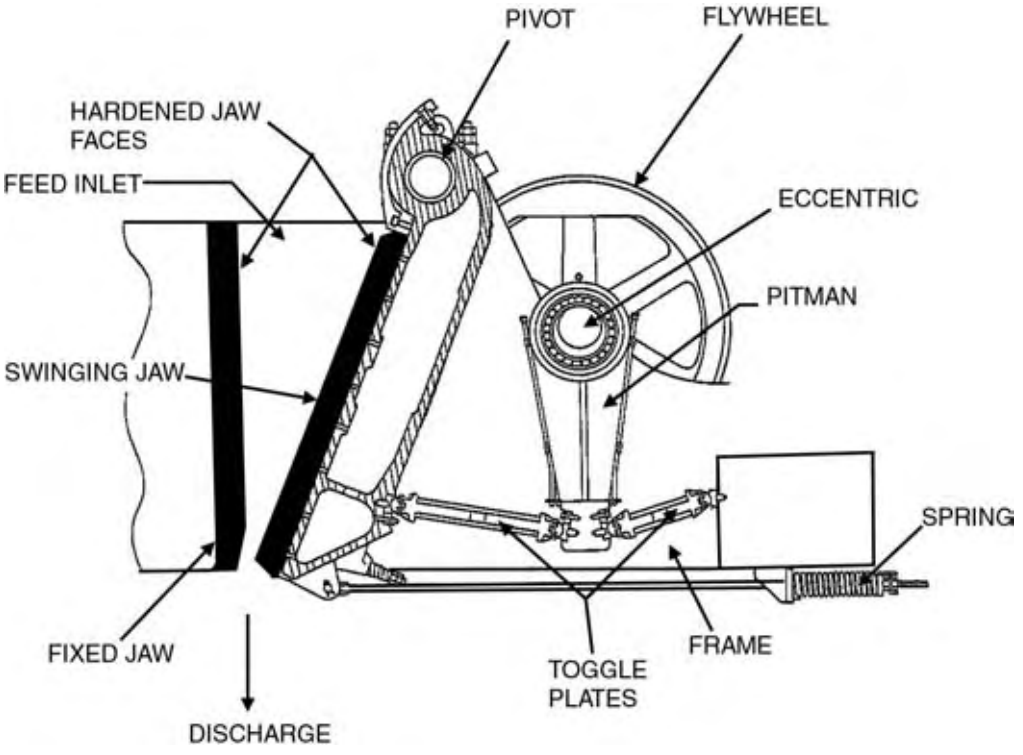

Fig. 3 Cross section of a Blake-type jaw crusher showing the nonchoking design of the swing jaw.

INTERMEDIATE AND FINE GRINDERS

Impact Mills

Hammer mills

Impact mills like the hammer mill use swinging hammers (typically running at 750–1800 rpm) to pulverize the solid feed by impact and attrition. As shown in Fig. 5, these hammers are mounted by pins on the periphery of a number of disks mounted on a horizontal rotating shaft and are free to swing. The hammers force the product against a rugged breaker plate. The product gets broken down until it is small enough to fall through a discharge grate at the bottom. For some applications like the grinding of dried animal byproducts, a vertical hammer mill that uses a vertical drive shaft with horizontal hammers and screens is more efficient. Hammer mills are used in primary, secondary, and tertiary crushing operations. These mills are relatively inexpensive but tend to produce a lot of fine material. They are best suited for soft or semihard materials, as harder materials tend to rapidly wear out the hammers.

Hammer mills can handle feed sizes of up to 10–20 in. and throughputs up to 500 ton/hr. Air-swept hammer

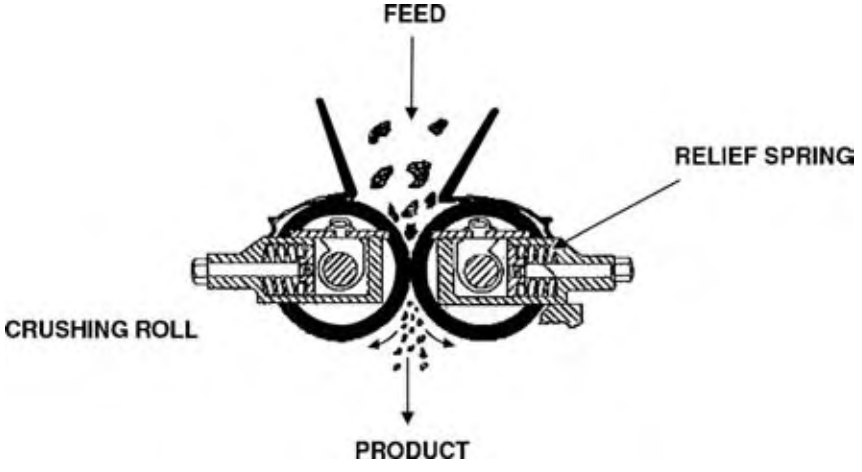

Fig. 4 Schematic of a smooth-roll crusher.

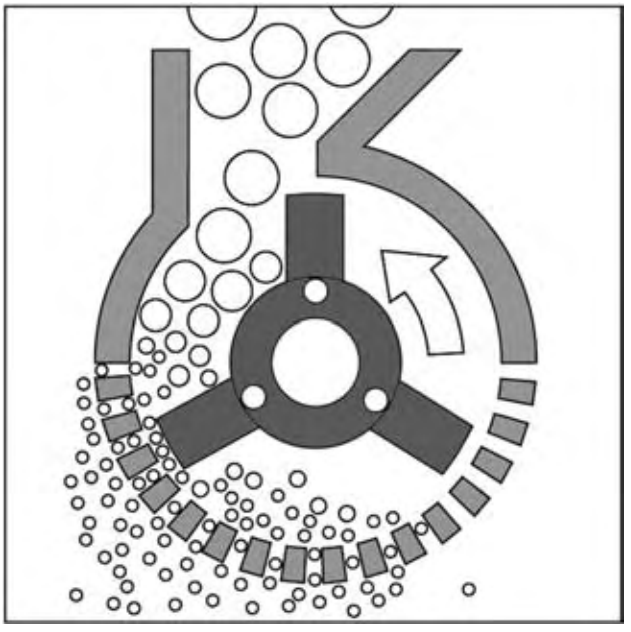

Fig. 5 Schematic representation of the operating principle of a hammer mill. (Courtesy of Sturtevant, Inc., Boston, MA.)

mills use air to help convey the particle product out of the mill.

Centrifugal pin mills

An example of a pin mill is shown in Fig. 6. It applies centrifugal forces to grind feed particles by impact. Feed entering the mill is divided into two streams that drop down on to a rotating plate. Centrifugal force directs the feed outward on to intermeshing pins or blocks mounted on the plate. Pin mills are available in capacities up to 200 ton/hr. These mills are economical, easy to operate, produce a uniform grind, are suitable for wet or dry grinding, and provide high throughput with low energy consumption.

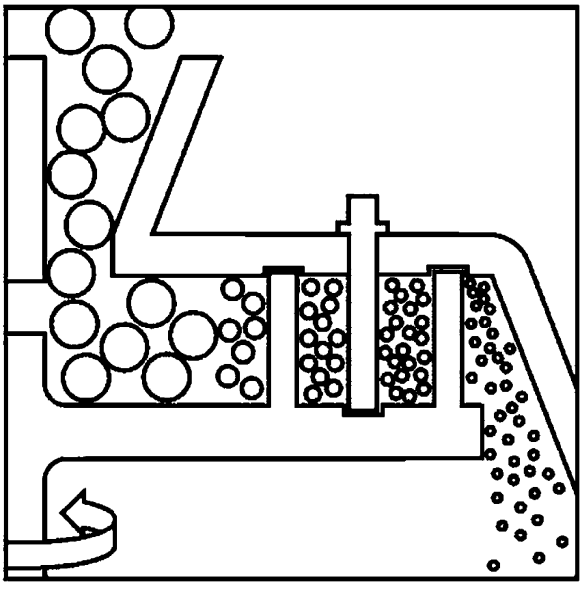

Fig. 6 Simpactor centrifugal pin-type impact mill. (Courtesy of Sturtevant, Inc., Boston, MA.)

Attrition/Disk Mills

These mills use a combination of impact, shear, and cutting action to grind materials between the replaceable wearing surfaces of two grinding disks. One or both of the disks can rotate; if both, they are run counter to each other. The distance between the disks can be adjusted to vary the product particle size. Fig. 7 is a schematic representation of a typical attrition mill. Liquid cooling of the disks is used with heat-sensitive materials to prevent degradation. Air is sometimes drawn through the mill to help remove product and prevent choking. Attrition mills can grind up to 8 ton/hr of product to a particle size passing 200 mesh.

Tumbling Mills

Ball mills

These mills employ attrition and impact to grind the product by tumbling in cylindrical mills partly filled with grinding media. The media can be round metal balls or nonmetallic pebbles that are 1/2 in. or larger in size. Ball mills for grinding hard materials are usually lined with heavy-duty steel alloy liners. Some ball mills employ internal baffles to prevent slippage of the grinding media over the internal shell surface.

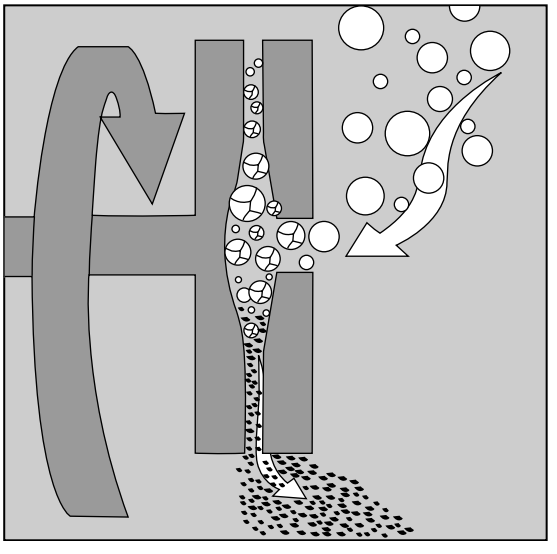

Fig. 7 Schematic of a disk-type attrition mill. (Courtesy of Sturtevant, Inc., Boston, MA.)

Mills for dry grinding are available with either full or semi air-swept capability.

Ball mills can operate either in a batch or a continuous mode. Batch mills typically use a charge of 50–55% of the mill volume, while continuously operating mills use a media charge of 40–45%. In the continuous mode, the mill can operate in such a mode that the product can leave the mill through a discharge grate. When operating in a continuous mode, the effluent of the grinding mill is sent through a classifier to separate out the oversize product to be reprocessed through the mill.

Commonly used types of grinding media are carbon steel, stainless steel, chrome steel, tungsten carbide, ceramic, or zirconia. Ball mills produce up to 50 ton/hr of powder substantially passing a 200-mesh screen. Temperature control can be achieved by the use of jacketed ball mills through which a heat transfer fluid is circulated.

Critical and Operating Speed. In operation, the balls in the mill are carried up in contact with each other and with the walls until the centrifugal force is overcome by the centripetal force. The critical speed N_{cr}, of a ball mill is the speed in rpm above which the grinding media will centrifuge and all milling effectively stops.

The critical speed of a mill is given by:

$$N_{cr} = 42.3/D^{0.5}$$

where D is the internal diameter of the mill in meters.

The operating speed of ball mills is usually 55–75% of the critical speed. Operating close to N_{cr} drastically reduces the effectiveness of the grinding action.

Conical ball mills like the Hardinge mill shown in Fig. 8 have their larger diameter closer to the feed inlet.

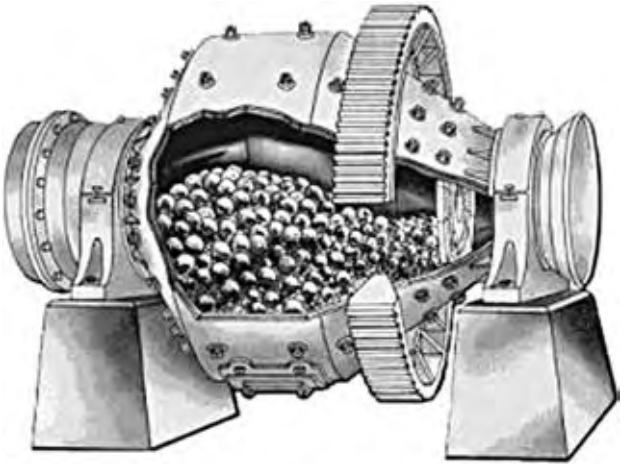

Fig. 8 Hardinge conical ball mill. (Courtesy of Metso Minerals, York, PA.)

The grinding media in the mill fall through different heights depending on their relative location. This provides a classifying action within the mill resulting in increased crushing energy efficiency.

Ball mills with centrifugal and planetary action are also available. Retsch manufactures a planetary ball mill in which multiple grinding chambers are turned around their own axes, and, in the opposite direction, around the common axis of a sun wheel that is driven by a rugged motor. This movement results in the superimposition of centrifugal forces that change constantly (Coriolis motion). The grinding media describe a semicircular motion, separate from the inside wall and collide with the opposite surface at high impact energy. Fig. 9 illustrates the forces encountered in the operation of this grinding mill that can reduce particles to submicron sizes through the imposition of impact and friction forces.

The Retsch centrifugal ball mill uses grinding chambers that move in a horizontal plane at speeds of 100–580 rpm. The centrifugal forces that are generated propel the grinding media against the inside walls of the mill where they roll over the product (Fig. 10). Size reduction is achieved by a combination of impact and friction. The mill is furnished with an automatic reversal system to counter any agglomeration effects and to enhance homogenization.

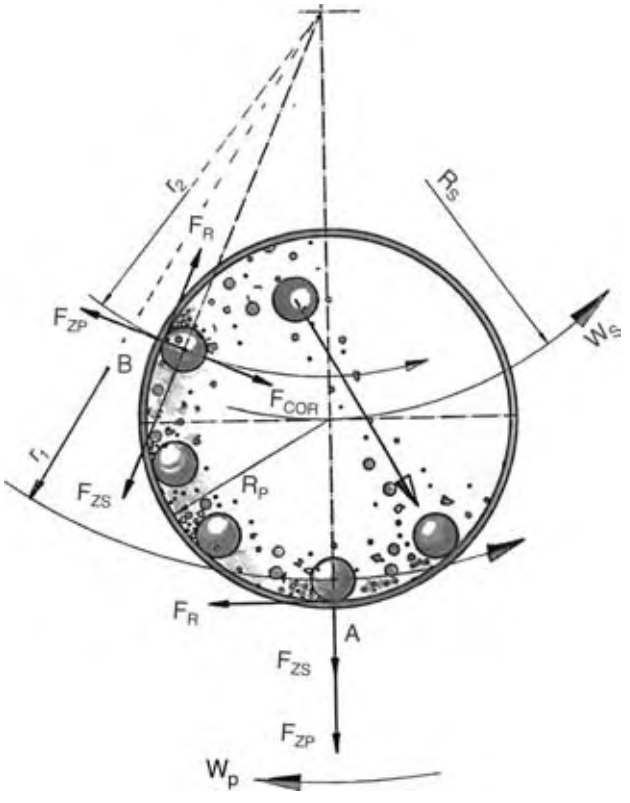

Fig. 9 Schematic of forces operating in a planetary ball mill. (Courtesy of Retsch, Inc., Newtown, PA.)

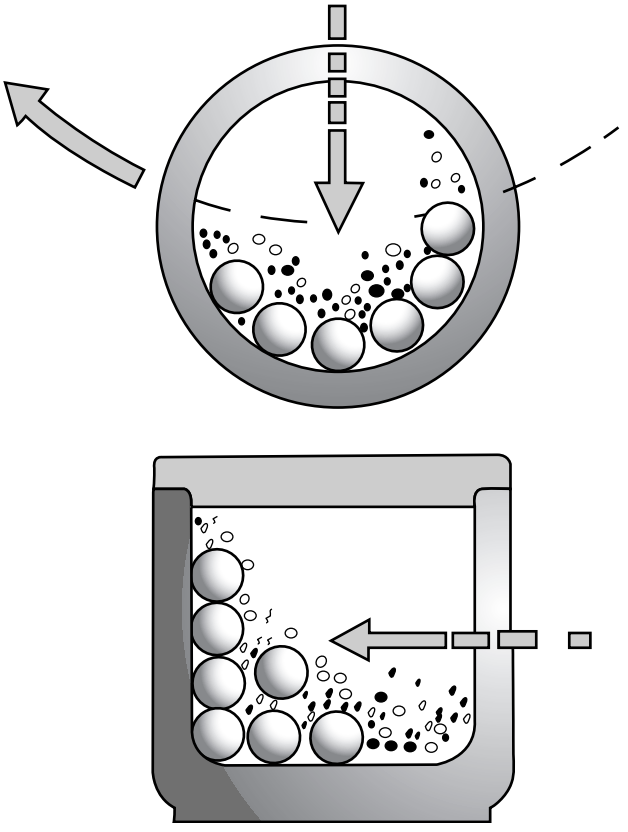

Fig. 10 Schematic of centrifugal ball mill action. (Courtesy of Retsch, Inc., Newtown, PA.)

Tube mills

Tube mills are basically finish-grinding ball mills with mill length several times the diameter. Tube mills can be made with a uniform diameter throughout the mill length or may be made with several compartments with different section diameters and lengths. Compartment mills are tube mills with slotted transverse partitions that separate grinding media of different sizes with the larger media working on coarser product.

Rod mills

Rod mills are regarded as intermediate grinding mills and are basically tube mills that employ grinding rods that are about as long as the mill. Rod mills employ rolling compression and attrition and produce very small amounts of oversize or fines. Feed sizes up to 50 mm (2 in.) can be reduced to product in the 5–10 mesh range in open circuit grinding and to a minus 35 mesh range in closed circuit grinding with a classifying device. These mills require operator attention to minimize rod misalignment or entangling during grinding.

Autogenous and semiautogenous mills

Autogenous mills are mechanically similar to ball mills but employ the product to be crushed as the grinding medium. These mills can be used for hard, soft, as well as sticky products. The product is discharged through a discharge grate designed to retain oversize product. Autogenous grinding reduces metal wear, eliminates secondary and tertiary crushing stages, and offers savings in capital and operating costs. A variation called air autogenous milling uses air to transport and classify the product and uses no discharge screens or grills that can become blocked. Semiautogenous mills use a combination of the feed, product, and grinding media to achieve the desired size reduction.

Rolling Compression Mills

These mills resemble a mortar and pestle in principle and use a rolling ball or roller member moving against the face of a ring or a casing to grind soft to medium-hard product at rates of up to 50 ton/hr. Pressure is applied by either using heavy springs or by the centrifugal force of the roller. Either the roller or ring may be stationary. Built-in air classification is used to improve the grinding efficiency of these mills. The common types of rolling compression mills are rolling-ring pulverizers, bowl mills, and roller mills. These mills are widely used for grinding coal, cement clinker, and limestone.

ULTRAFINE GRINDERS

Fluid-Energy Mills

These energy-intensive mills have no moving parts and use pressurized air, steam, or inert gases to grind particles to ultrafine sizes. The particles to be ground are suspended in a high-velocity fluid stream that carries the particles around in a circular or an elliptical path. The majority of the particle size reduction is accomplished by interparticle attrition with additional grinding caused by particles rubbing against the walls. The particles get classified as they go around the closed path provided by the mill. The larger particles are thrown toward the outer walls and stay in the mill, while the finer particles stay on the inner walls and are removed from the mill through an exit port. The effluent from the mill is sent to a particle separator to collect the ground product. No one jet mill is suitable for all process applications. Several configurations are available to serve specific needs: fluid bed, opposed jet, and multiple-port types.

The Jet-O-Mizer (Fig. 11) from Fluid Energy Processing can produce product with a 1–50 μ average size and a narrow particle size distribution. This

Fig. 11 Cutaway of Jet-O-Mizer showing fluid jets. (Courtesy of Fluid Energy Processing, Telford, PA.) *(View this art in color at www.dekker.com.)*

vertical jet mill can also be used for combined operations like grinding/blending and grinding/coating.

For finer finished product down to the submicron size range, the Sturtevant Micronizer jet mill or the

Fig. 13 Cutaway of the Micro-Jet mill showing fluid jets. (Courtesy of Fluid Energy Processing, Telford, PA.) *(View this art in color at www.dekker.com.)*

Fluid Energy Processing Micro-Jet grinders are suitable. The mills use a circular grinding chamber. The feed metered into the mill enters an air or a gas vortex created by precisely aligned jet nozzles along the mill periphery (Figs. 12 and 13). The tangential angle of the fluid flow causes interparticle impact resulting in size reduction. The desired product and oversize material are separated by air classification in the mill. The mill provides narrow particle size distribution with uniform shape and no heat build-up. Micronizers are available in capacities up to 5 ton/hr.

The Roto-Jet fluid-bed jet mill (Fig. 14) supplied by Fluid Energy Processing is designed to grind products to the 0.5–40 μ average size range with specific top

and/or bottom size requirements. The machine uses a variable-speed rotor for tight control of product size.

Agitated Mills

Agitated mills are stirred vertical ball mills in which the grinding media are agitated by vibratory energy or by a rotating impeller that can run at speeds up to 1700 rpm. These mills are suited for both wet and dry grinding in batch or continuous mode. The fast grinding machines are energy efficient, compact, easy to operate, and are best suited for reduction of particles to submicron sizes. Particle size reduction is achieved by both shear and impact.

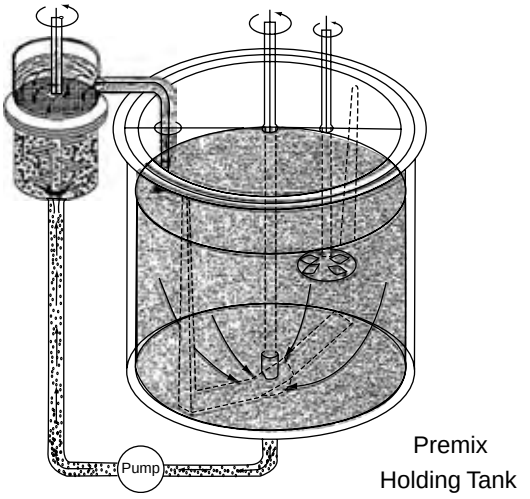

Fig. 16 Circulation attritor. (Courtesy of Union Process, Inc., Akron, Ohio.)

Attritors

The Szegvari attritor uses 1/8–3/8 in. grinding media agitated at speeds up to 350 rpm. Attritors are available that operate in three different modes:

1. Batch attritor shown in Fig. 15.
2. Circulation attritors that use an attritor in association with a holding tank that can hold about

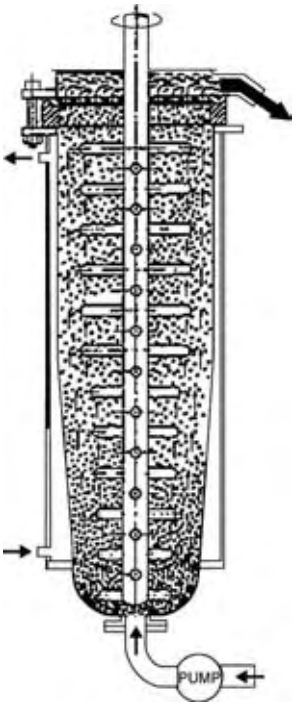

Fig. 17 Continuous attritor. (Courtesy of Union Process, Inc., Akron, Ohio.)

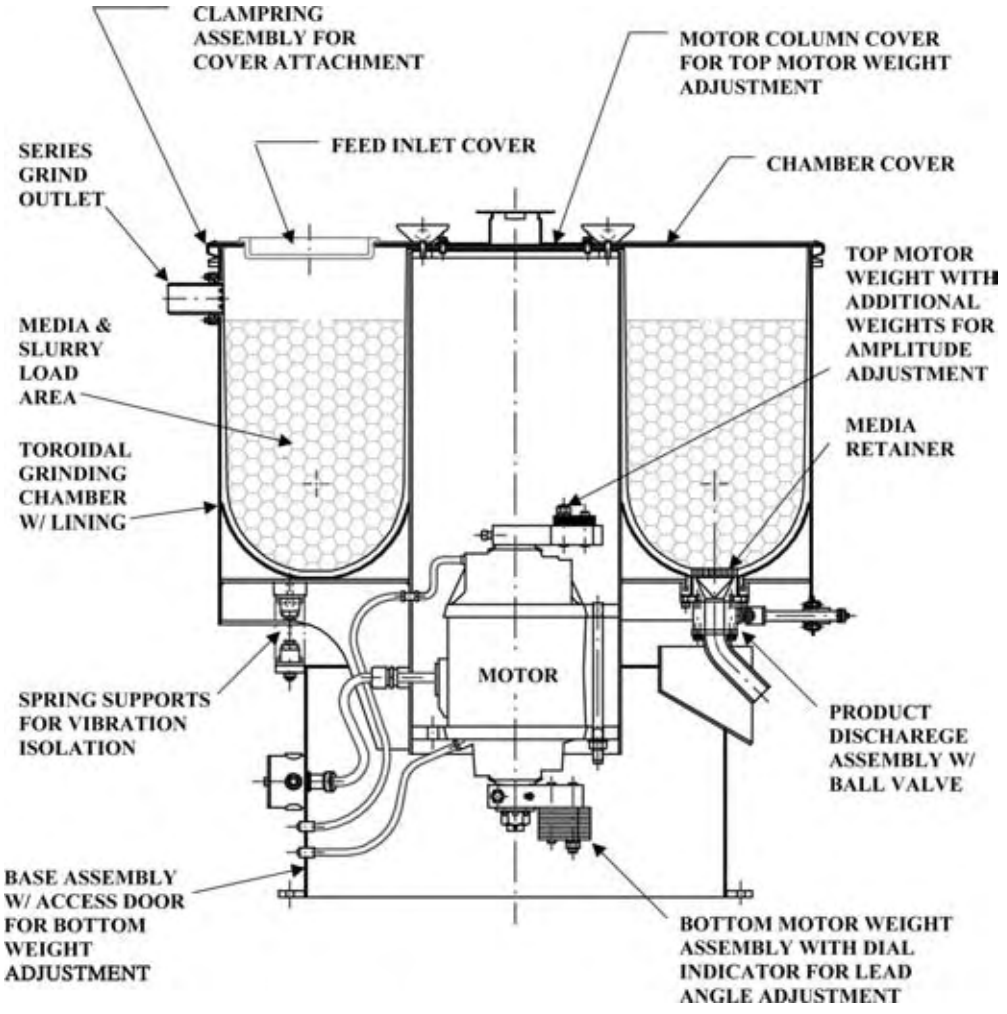

Fig. 18 Cross section of the Sweco vibro-energy mill. (Courtesy of Sweco, Florence, KY.) *(View this art in color at www.dekker.com.)*

10 times the volume of the attritor (Fig. 16). The contents of the holding tank are passed through the attritor multiple times until the desired reduction in size is achieved. This combination allows the use of small attritors for large grinding jobs through the use of high circulation rates.

4. Continuous attritors with the grinding time controlled by the feed pumping rate (Fig. 17).

A high-speed attritor that uses 0.5–3 mm grinding media and impeller speeds of up to 1700 rpm has been developed recently for dry grinding.

Vibratory mills

The Sweco vibro-energy mill (Fig. 18) applies high frequency, three-dimensional vibrations to the grinding chamber that contains small cylindrical grinding media. This helps produce an ultrafine product with a narrow particle size distribution.

The Vibra-Drum vibratory grinding mill supplied by General Kinematics uses a static grinding drum containing grinding media akin to a ball mill. Vibration energy is imparted to the drum from an external mechanism. A subresonant two-mass drive and spring system alternately stores and releases grinding power. Once in motion, the natural frequency design ensures that energy is only needed to move the grinding media as a fluid mass. This mill has lower capital investment, installation, maintenance, and energy costs as compared to conventional rotational mills.

Impact Mills with Internal Classification

An example of a classifying impact mill is the Powderizer marketed by Sturtevant, Inc. (Fig. 19). The feed to the mill enters the grinding chamber where it is broken by the action of impactors/pins mounted on a rotating disk. A column of air sweeps up the pulverized product

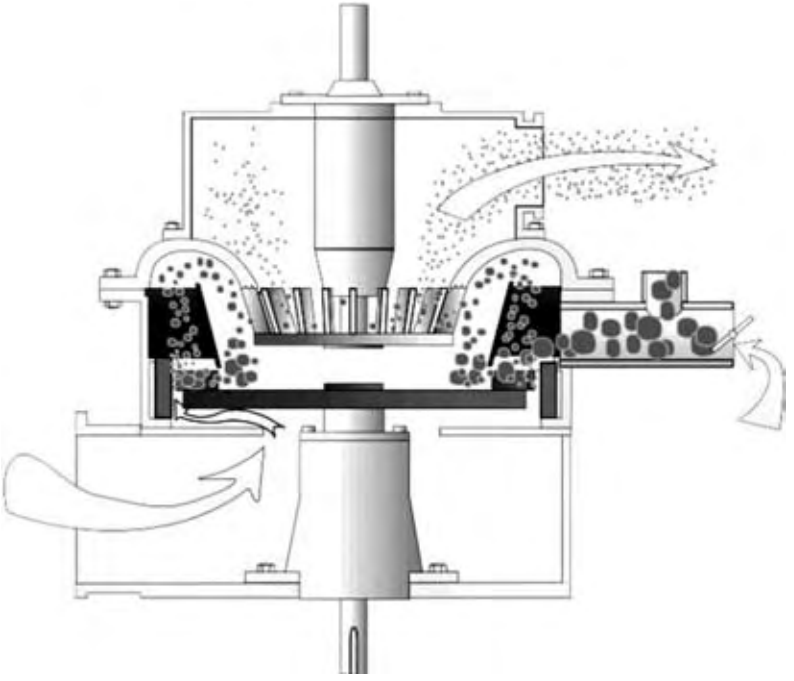

Fig. 19 Schematic of Powderizer air-swept impact mill. (Courtesy of Sturtevant, Inc., Boston, MA.)

through a rotating classifier that rejects oversize products that are returned back for further size reduction. Particle size can be adjusted by changing the classifier speed without shutting down the mill. The product can be pulverized to sizes below 10 μ with narrow size distribution. Pulverizers are available in sizes that can handle 20–7000 kg/hr. The Powderizer is also suitable for heat-sensitive materials.

ROTARY CUTTERS

Cutting mills are used for reducing the size of soft, medium-hard, tough, elastic, fibrous, and temperature-sensitive materials. Examples of products handled in such mills are electronic scrap, film, rubber, foil, foodstuffs, paper and paper products, textiles, and domestic waste. The mills cut, chop, or tear feed using a rotor-mounted set of blades or cutters. Fig. 20 shows the cutting action of the SM2000 cutting mill supplied by Retsch. The feed material is taken up by the rotor and is crushed by the stainless steel cutting strips inserted in the housing. Helically arranged reversible cutting plates of hard metal operate by successive cutting.

EQUIPMENT OPERATION

Open and Closed Circuit Grinding

Comminution is one of the most inefficient unit operations from the viewpoint of energy consumption. Continuous crushing and grinding equipment can operate in an open circuit mode, where the product being crushed passes through the mill only once. This mode of operation is inefficient as a considerable amount of energy is wasted in regrinding product that has reached the desired product size. A more efficient mode of operation is called closed circuit grinding (Fig. 21). In closed circuit grinding, the mill discharge is sent to size classification equipment that separates out the product that has reached the desired size.

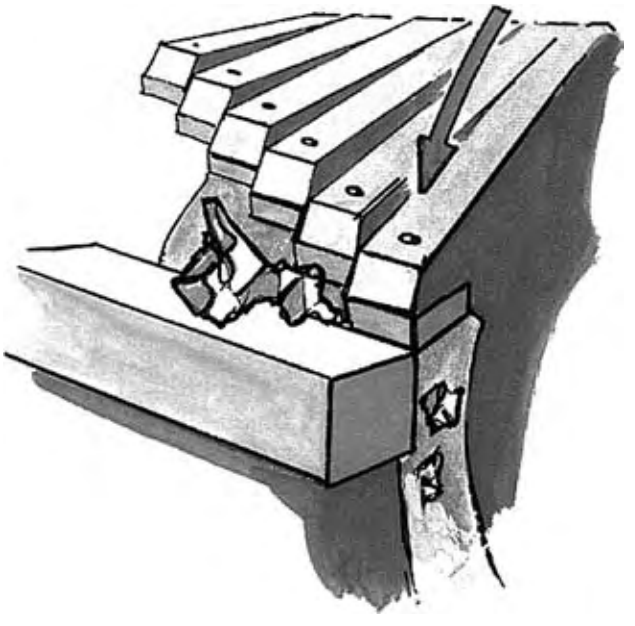

Fig. 20 Schematic showing the cutting action of the SM2000 cutting mill. (Courtesy of Retsch, Inc., Newtown, PA.)

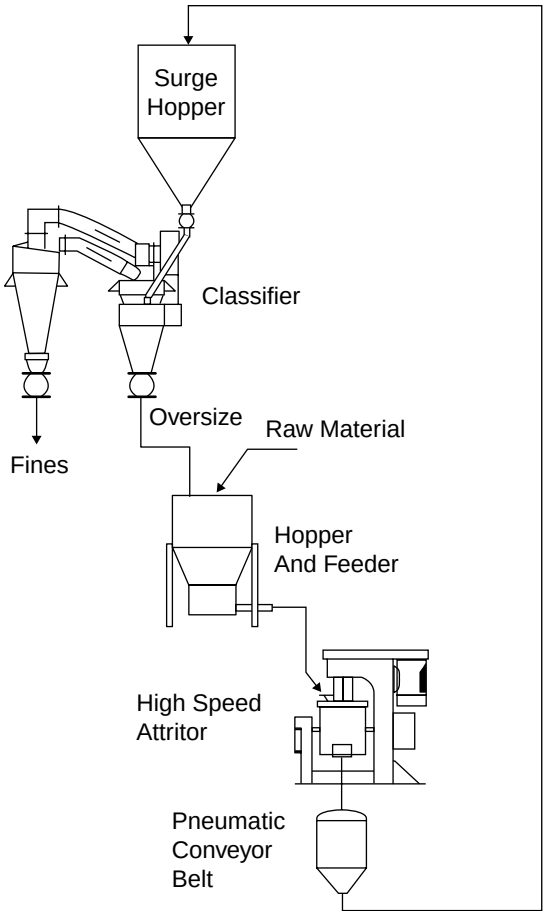

Fig. 21 Representation of a closed-circuit grinding operation employing an attritor. (Courtesy of Union Process, Inc., Akron, Ohio.)

Oversize material is returned to the mill for further size reduction. Closed circuit grinding is suitable for either wet or dry grinding of materials.

CONCLUSIONS

The greatest advancements in grinding technology in the recent past have been made in ultrafine grinding equipment like fluid-energy mills that can generate products in the micron and submicron ranges. This trend is expected to continue as comminution processes evolve to address technical issues in the production of ultrafine particles for high technology applications. As comminution is a very important unit operation in the conversion of run-of-mine raw materials, a considerable amount of effort was spent in the early and middle part of the last century to develop efficient size reduction equipment. The basic principles employed in the operation of crushing and grinding machines have not changed substantially over the past few decades. Saving energy, reducing costs, and cutting pollution have been the main areas targeted for continuous improvement in size reduction operations. The technical areas for future improvement of comminution processes fall into the following general categories: 1) Advanced sensors to provide integrated online physical and chemical characterization of feed and product to help in automated process control; 2) Utilization of the knowledge of real-time feed characteristics to optimize comminution processes; 3) Improved modeling of grinding mill operations like three-dimensional simulation of charge motion in tumbling mills; 4) Advanced abrasion-resistant milling media and surfaces; and 5) Novel or improved physical separation processes to be used in conjunction with size reduction equipment. As in the past, it is expected that future developments in conventional comminution will be evolutionary rather than revolutionary.

Soave's Modified Redlich–Kwong Equation of State

J. Richard Elliott, Jr.
Department of Chemical Engineering, University of Akron, Akron, Ohio, U.S.A.

INTRODUCTION

Throughout the 1970s and 1980s, chemical engineering process design underwent a virtual revolution. By increasing computational speed and the accuracy of thermodynamic models, computer simulation transformed the design process from hand calculations with charts and tables to a modern engineering methodology. In 1996, the Chief Executive Officer of Dow Chemical, Frank Popoff, proclaimed, ''Process modeling is the single technology that has had the biggest impact on our business in the last decade.'' Soave's equation played a central role in that revolution. It was the first thermodynamic model to provide feasible accuracy for physical properties of a wide variety of compounds, over a wide range of conditions. Even now, applications and adaptations of Soave's equation abound. What follows is a short presentation of the nature of these applications and adaptations, how Soave's equation relates to other equations of state, and why Soave's approach has stood the test of time. An excellent reference on this subject is provided in Soave's own words with a greater emphasis on the historical context of Soave's development.[1]

THREE-PARAMETER CORRESPONDING STATES

The primary key to Soave's early success was the recognition of the need to extend from two-parameter to three-parameter corresponding states. With two parameters, it is possible to fit the critical temperature and critical pressure of any compound, but a general description of the vapor pressure curve is unattainable. The slope of the reduced vapor pressure ($P_r^{sat} \equiv P^{sat}/P_c$) curve varies substantially from one compound to another, but a two-parameter equation of state assumes that it is invariant. Because the vapor pressure varies as an exponential of temperature, small errors near the critical temperature are greatly amplified at reduced temperatures ($T_r \equiv T/T_c$) near 0.45.

Vapor pressure is a key property in modeling phase behavior because it represents the vapor–liquid equilibria (VLE) of the pure fluid. Accurate vapor pressure characterization is essential to VLE correlation. As the most common operation in chemical processing is distillation, accurate modeling of VLE had a tremendous impact on process modeling.

Characterization of the vapor pressure curve was readily accessible in the form of Pitzer's acentric factor. The definition of the acentric factor is

$$\omega \equiv -1 - \log_{10}(P^{sat}/P_c)_{|Tr=0.7}$$

Hence, the third parameter, ω, implicitly contains information about the vapor pressure, making vapor pressure prediction something like a circular loop. But Soave went beyond this simple observation. Wilson had previously recognized these issues,[2,3] but his equation met with limited success, especially at low reduced temperatures. Soave was careful to analyze the temperature dependence of his equation of state in great detail at the outset. He achieved this by introducing an adjustable parameter into the attractive contribution of the Redlich–Kwong[4] equation.

$$Z \equiv \frac{PV}{RT} = Z^{ig} + Z^{rep} + Z^{att} = 1 + \frac{b\rho}{1 - b\rho} - \frac{a}{bRT}\frac{b\rho}{1 + b\rho} \quad (1)$$

where ρ is the molar density, Z the compressibility factor, Z^{ig} the ideal gas contribution, Z^{rep} the repulsive contribution, Z^{att} the attractive contribution, P absolute pressure, T the absolute temperature, R the gas constant, and a and b are parameters characterizing each compound. The repulsive contribution approaches infinity as the density approaches a close-packed value. The attractive part depends on temperature and approaches zero at infinite temperature.

For pure fluids, a and b can be characterized by matching the critical criteria: $(\partial P/\partial\rho)_T = 0$; $(\partial^2 P/\partial\rho^2)_T = 0$. The resulting equations are

$$a = \frac{\alpha R^2 T_c^2}{P_c}\left(\frac{1}{9(2^{1/3} - 1)}\right); \quad b = \frac{RT_c}{P_c}\left(\frac{(2^{1/3} - 1)}{3}\right) \quad (2)$$

where α is a special temperature dependent adjustable parameter. Soave's principal modification of the Redlich–Kwong equation was to redefine α. Whereas,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007869

the original Redlich–Kwong definition was effectively:

$$\alpha \equiv \sqrt{T_c/T} \tag{3}$$

Soave modified the definition of α to be:

$$\alpha \equiv \left[1 + \kappa\left(1 - \sqrt{T/T_c}\right)\right]^2 \tag{4}$$

where

$$\kappa = 0.480 + 1.574\omega - 0.176\omega^2 \tag{5}$$

Note that the discussion so far relates only to the model for pure fluids, while the primary application is for VLE of mixtures. Extending the model to mixtures requires characterization of the a and b parameters for the mixture. These characteristic equations are called mixing rules. They are discussed in the section titled ''Mixing Rules.''

Soave's method of developing this definition is instructive. First, he tabulated values of α that would exactly match the experimental vapor pressures of methane through n-hexane for $T_r \in [1.0, 0.3]$. Then, he plotted these with respect to temperature. As that plot did not generate linear correlations, he plotted several other candidate relations. By shortening the temperature range to $T_r \in [1.0, 0.45]$ and plotting $\sqrt{\alpha}$ vs. $\sqrt{T_r}$, Soave obtained a simple linear trend. He noted that α was constrained to unity at the critical temperature by its definition, and that the acentric factor establishes a second point for this linear trend, resulting in the form of Eq. (4). This form is sufficient for ~3% accuracy in the vapor pressure of hydrocarbons, if the critical properties and acentric factor are accurately known.

Note that the term ''critical properties'' in the present context refers to the critical temperature and pressure, not including the critical density. Matching the critical density might be considered an alternative version of three-parameter corresponding states that deserves a brief review in the present context. Hougen and coworkers explored this alternative for a number of years, but they focused on density in the critical region rather than vapor pressure. Density in the critical region is difficult to measure and fraught with theoretical challenges related to the nonclassical behavior of the coexisting densities in the critical region. Although relatively unimportant for most process simulations, density is important in the critical region for supercritical extractions. Despite these challenges, Lee and Kesler were able to develop an equation of state that fits the critical density and the vapor pressure curve. The Lee–Kesler equation interpolated between the equations of state for methane and octane in the form of:

$$Z = Z^{CH_4} + \omega(Z^{nC_8} - Z^{CH_4}) \tag{6}$$

By adapting the multiparameter Benedict–Webb–Rubin (BWR) equation for methane and n-octane as their basis, they approached an effective implementation of what might be called as four-parameter corresponding states. Unfortunately, their equation never achieved the widespread application of the Soave equation, despite having greater accuracy for liquid density and comparable accuracy for VLE. This observation may shed some light on an additional strength of the Soave equation. Soave's equation was much simpler than the multiparameter BWR two-compound interpolation form of the Lee–Kesler equation. Soave's equation can be rearranged into the form of a cubic polynomial, which can be solved analytically, eliminating the convergence difficulties that plagued early programmers. Thus, the popularity Soave's equation relative to the Lee–Kesler equation is a testament to the merits of a simpler form.

APPLICATIONS AND ADAPTATIONS OF SOAVE'S EQUATION

Applications of the Soave equation are too numerous to list comprehensively. Soave's original paper has been cited in roughly 1600 publications since 1980, and 88 times in 2003 alone. These citations include applications to petroleum recovery and refining, natural gas production, coal liquefaction, cryogenic gas separation, refrigeration, wax precipitation, hydrate formation, polymerization, interfacial tension, supercritical fluid processing, and petrochemical production. Interested readers should perform a ''cited reference'' search of the citation index to obtain a detailed list. Restricting the search to 2003 suffices to indicate the scope of coverage listed above.

Beyond applications reported in the literature, process simulation is ubiquitous throughout the chemical industry and academia. Every time users select the Soave, or SRK, thermodynamics model, they apply the Soave equation. One motivation for this selection is the long experience with the model and the compilation of correction factors, when the basic model is deficient. For example, binary interaction parameters (k_{ij}'s) have been compiled for a large number of binary mixtures to improve VLE correlation.[5] It is also possible to compensate for inaccuracies in density through volume translations.[6]

In light of the broad scope of applications and adaptations, the discussion here is restricted to general observations about the nature of adaptations and the accuracy to be expected. The Peng–Robinson equation

is included as an early adaptation as given below:

$$Z \equiv \frac{PV}{RT} = 1 + \frac{b\rho}{1 - b\rho} - \frac{a}{bRT}\frac{b\rho}{1 + 2b\rho + (b\rho)^2} \tag{7}$$

Some might consider the Peng–Robinson equation to be entirely independent of the Soave equation, but they have used exactly the same form for α that Soave developed in Eq. (4). Therefore, the only difference is the form of the denominator. The Peng–Robinson denominator results in slightly improved density correlations, especially for the low-boiling compounds of interest to the Gas Processors Association, sponsors of the Peng–Robinson research. In general however, density predictions are inaccurate, such that volume translations like those of Ref.[6] are still worthwhile. Moreover, comparisons generally indicate only marginal distinctions between the accuracy of the two equations for VLE correlations.[7,8] Hence adaptations like extended α correlations and advanced mixing rules are equally applicable to the original Soave form or the Peng–Robinson form with little distinction. We draw the line at the Peng–Robinson equation, however. Other equations of state might also be considered as incremental adaptations. For example, replacing the repulsive term with a more realistic hard sphere term might be considered to be a small adaptation, but that would be considered a major revision by this author.

One further adaptation of Soave's equation for pure fluids played a major role in maintaining the relevance of his model over the years. Soave himself was aware that his α correlation was deficient for mixtures involving hydrogen. This deficiency is not surprising when it is realized that, at room temperature, hydrogen's reduced temperature approaches $T_r \sim 10$. Graboski proposed an improved α correlation for hydrogen mixtures. Graboski also proposed a modified form of Eq. (5) based on optimizing the coefficients with a larger database than Soave's. Graboski's modification is occasionally referred to as the API equation. Soave's original α correlation is also deficient for polar compounds. Whereas the slope of the vapor pressure curve for hydrocarbons tends to drop at low temperatures, it remains relatively constant for polar compounds. Several authors proposed α adaptations for the Soave and Peng–Robinson equations. Notable references should include Stryjek and Vera,[9] Patel and Teja,[10] Soave,[1] and references cited therein. The disadvantage of these adapted α correlations is that they are no longer predictive. Whereas the acentric factor and Eq. (5) suffice for the original model, specific regressions must be performed for each compound of interest, when applying adapted α correlations. Stryjek and Vera[9] have tabulated the parameters for roughly 50 common compounds in their adaptation for the Peng–Robinson equation.

MIXING RULES

Another major adaptation of Soave's equation involved application to asymmetric nonideal mixtures. The original mixing rules proposed by Soave were in the quadratic form originally suggested by van der Waals as given below:

$$b = \sum_{i=1}^{NC} x_i b_i; \quad a = \sum_{i=1}^{NC}\sum_{j=1}^{NC} x_i x_j a_{ij};$$
$$a_{ij} = \sqrt{a_{ii}a_{jj}}(1 - k_{ij}) \tag{8}$$

Quadratic mixing rules are sufficient for symmetric deviations from ideality, but not for highly asymmetric mixtures like alcohols mixed with hydrocarbons. In symmetric mixtures, the k_{ij} parameter can be adjusted to characterize large nonidealities, but it primarily adjusts the magnitude of the Gibbs excess energy, and not the skewness. Negative values of k_{ij} indicate strong solvation interactions, as in inorganic acid + water mixtures. Positive values of k_{ij} indicate weak solvation interactions, as in acetone + hydrocarbon mixtures. In mixtures like alcohols + hydrocarbons, both the magnitude and skewness of the Gibbs excess curve are affected, because the alcohols associate except at infinite dilution.

Huron and Vidal[11] showed that equating the infinite pressure Gibbs energy of mixing to that of an activity model like the NRTL[12] or UNIQUAC[13] models provided a mixing rule that was sufficiently flexible to describe very complex phase behavior. With this modification, simple cubic equations like Soave's could be applied to nearly any kind of mixture at any conditions, including supercritical conditions. The Huron–Vidal mixing rule combined with NRTL activity model is illustrated below.

$$\frac{a}{b} = \sum_{i=1}^{NC} x_i \left[\frac{a_i}{b_i} - \frac{1}{\ln 2}\frac{\sum_{j=1}^{NC} x_j G_{ji} C_{ji}}{\sum_{k=1}^{NC} x_k G_{ki}}\right];$$
$$b = \sum_{i=1}^{NC} x_i b_i \tag{9}$$

$$G_{ji} = b_j \exp\left(-\alpha_{ji}\frac{C_{ji}}{RT}\right) \tag{10}$$

where C_{ji}, C_{ij}, and α_{ji} are adjustable binary parameters. (There is no relation between α_{ji} of the mixing rule and Soave's pure component α.)

A notable adaptation that combines complex mixing rules, the Stryjek–Vera α correlation, and the Peng–Robinson equation is the PRWS model of Wong

and Sandler.[14] The principal difference from the Huron–Vidal rule is that the Wong–Sandler rule degenerates to the quadratic mixing rule at low density. Technically, quadratic mixing at low density is required for thermodynamic consistency, but the small magnitude of nonidealities in the vapor phase means that the inconsistencies there have small impact on the accuracy of the correlation. The Wong–Sandler mixing rule is

$$b = \frac{Q}{1 - D} \tag{11}$$

$$\frac{a}{RT} = \frac{QD}{1 - D} \tag{12}$$

$$Q = \sum_i \sum_j x_i x_j \left(b - \frac{a}{RT}\right)_{ij} \tag{13}$$

$$D = \sum_{i=1}^{\mathrm{NC}} x_i \left[\frac{a_i}{b_i RT} - \frac{\sqrt{2}}{\ln(\sqrt{2} - 1)} \frac{\sum_{j=1}^{\mathrm{NC}} x_j G_{ji} C_{ji}}{\sum_{k=1}^{\mathrm{NC}} x_k G_{ki}}\right] \tag{14}$$

$$\left(b - \frac{a}{RT}\right)_{ij} = \left[\left(b_i - \frac{a_i}{RT}\right) + \left(b_j - \frac{a_j}{RT}\right)\right] \frac{(1 - k_{ij})}{2} \tag{15}$$

Note that k_{ij} values vary over large ranges $(-1, 0.5)$ in the PRWS model. An implementation of the PRWS model is available through the author's website.

A number of related efforts have studied the impact of applying the infinite pressure limit, or the zero pressure limit.[15] The zero pressure limit would appear to be closer to the basis applied in developing activity models. Once again, the more complex model is technically more correct, but the improvement in accuracy is small. A reasonable compromise in accuracy and simplicity is offered by the PRWS mixing rule.

In general, the Huron–Vidal mixing rule provides flexibility but the optimal parameters for the activity model alone are not optimal when adapted to the advanced mixing rule, necessitating regression of each specific binary mixture. Michelsen and Dahl,[16] on the other hand, showed how UNIFAC predictions could be implemented directly into the mixing rules, circumventing the regression step. This is the basis of the predictive SRK model of Holderbaum and Gmehling.[17] Gmehling has published a recent review that favors adaptation of a volume translated Peng–Robinson equation with temperature-dependent parameters in the complex mixing rules to improve excess enthalpy correlation.[18] His model is also capable of treating electrolytes and polymer solutions[19] within this general methodology. The inclusion of such a large number of adjustable parameters is made feasible by maintaining an extremely large database with perpetual global optimization of all parameters for all data.

An alternative to incorporating empirical activity models into the mixing rules is to seek an alternative physical explanation of solution nonidealities. Hydrogen bonding models are noteworthy in this regard. Most of the nonideality in the interaction between water and oil, for example, can be attributed to water hydrogen bonding while oil cannot. A hydrogen-bonding model would account for this observation explicitly, reducing the magnitude of the parameters in the mixing rules. Most inclusions of hydrogen bonding have also included corrections of the Van der Waals repulsive contribution,[20,21] and elimination of any parameter resembling Soave's α correlation. Such extensive generalizations are judged to be outside the scope of the this entry. On the other hand, Tassios and coworkers[22] have managed to include a hydrogen bonding contribution while maintaining the Soave model for the remainder of the equation of state. Unfortunately, including the hydrogen bonding contribution does not guarantee elimination of the need for complex mixing rules. Hence, the benefit of including an additional term in the model is not readily apparent. Ultimately, this benefit may be recognized as molecular modeling becomes integrated with chemical process and product design. Its future prospects are discussed below.

FUTURE

It is reasonable to ask, "What next? Is there anything left to be done?" Of course, the need for research is never ending. The primary criticism against the current incarnation of Soave's initiative is the lack of a strong relation between the form of Soave's equation and the rigorous physics that can be determined from statistical mechanics. For example, the van der Waals repulsive contribution is known to be inconsistent with molecular simulations.[23] Furthermore, there is no basis in statistical mechanics for the $\sqrt{T_r}$ dependency in Soave's α correlation. The presumption is that an improved physical basis would improve the capability for extrapolating the model to conditions at which experimental measurements are unavailable. So far, this presumption has been impossible to prove. By perpetually introducing new parameters and new data and reoptimizing, Gmehling and coworkers have demonstrated that adaptation of Soave's equation is

sufficiently flexible to correlate the vast majority of what is known about phase equilibria. One caveat in this regard would be variations related to "proximity effects." These are changes that depend on details of the molecular structure that first order group contributions cannot address. One example would be differences between *p*-xylene and *m*-xylene. One obvious answer to this problem is higher order corrections for proximity effects, and these are on the way. By proceeding in this manner, it will be many years before such adaptations of Soave's equation are supplanted.

Alternatives to Soave's approach and group contribution adaptations would be better focused on capabilities not offered by such approaches. For example, pure component properties like vapor pressure are assumed to be available when applying Soave's methodology. In the coming world of chemical product design, this assumption may not be satisfactory. Molecular simulation offers the prospect of being able to make these predictions for transport properties as well as equilibrium properties.[24–27] Proximity effects would also be naturally included within molecular modeling. While the National Research Council has estimated that such predictive capability may not be available for a "decade or two,"[28] viable preliminary versions may come much sooner than that.

The rise of molecular product design will ultimately lead to questions about molecular simulations of mixtures, which make it difficult to rationalize distinctions between molecular scale models and models that derive their justification primarily from macroscopic measurements. When this happens, systematic analysis that can be rationalized on both the molecular and macroscopic scales will take precedence. It is in this context that hydrogen-bonding models will begin to play a more significant role. Such a development would present little difficulty to researchers like Gmehling because they could easily add new terms to their model equations. The effort will be motivated by complementary goals that can be achieved through a consistent molecular perspective applied to phase equilibria, transport phenomena, adsorption, membrane permeation, ion exchange, protein folding, and a host of other diverse applications. Thus, phase equilibrium can teach us things about molecular interactions that can be applied in fields that are far removed from traditional phase equilibrium applications. This is where the future lies and Soave's equation has paved the way to such an ambitious goal.

CONCLUSIONS

The SRK equation has played a major role in the development of chemical process design and will continue to play a similar role. Adaptations may obscure the role of the original model, but it can be discerned through the recollection of a brief history. These adaptations include the Peng–Robinson equation, extended vapor pressure correlations, the Huron–Vidal and Wong–Sandler mixing rules, and group contribution extensions by Gmehling and coworkers. The strength of the SRK approach has been a heavy emphasis on correlating key engineering data. As future adaptations continue to recognize which data are key and accurately correlate larger databases, the SRK approach will be perpetuated for many years to come.

INTRODUCTION

Solid–liquid mixing processes find numerous applications in industry. The modeling of these mixing operations using first principles is still limited, although some progress has been made in recent years. This study assesses the real capability of the network-of-zone approach in the case of a complex mixing problem involving a coaxial mixer. Coaxial mixers are very popular for the preparation of pastes and slurries in the chemical, food, and coating industries. The mixer considered is composed of two rotating shafts: a fast-driven shaft supporting an open impeller and a slow shaft driving a scraping anchor arm.

LITERATURE SURVEY

The dispersion of solids in liquids, the preparation of solid suspension in liquid media, and the make-down of pigment slurries in agitated vessels are typical solid–liquid mixing problems that find numerous applications in the process industries. For instance, they are involved in the preparation of paints and coatings, the manufacturing of food products, as well as suspension polymerization.

In solid–liquid mixing design problems, the main features to be determined are the flow patterns in the vessel, the impeller power draw, and the solid concentration profile versus the solid concentration. In principle, they could be readily obtained by resorting to the CFD (computational fluid dynamics) resolution of the appropriate multiphase fluid mechanics equations. Historically, simplified methods have first been proposed in the literature, which do not use numerical intensive computation. The most common approach is the dispersion–sedimentation phenomenological model. It postulates equilibrium between the particle flux due to sedimentation and the particle flux resuspended by the turbulent diffusion created by the rotating impeller. Based on this concept and assuming a one-dimensional distribution of particles along the vessel height, an analytical expression for the concentration profile can be derived:

$$\frac{\phi}{\bar{\phi}} = \frac{Pe_s}{1 - \exp(-Pe_s)} \exp(-Pe_s z/H) \quad (1)$$

where $\bar{\phi}$ represents the average volume fraction of the suspension, z the vertical coordinate, H the fluid height in the vessel, and Pe_s the Peclet number of the solid particles. The Peclet number is defined as

$$Pe_s = v_t \times H/D_{e,p} \quad (2)$$

where v_t is the settling velocity at equilibrium and $D_{e,p}$ the turbulent diffusion coefficient. This dimensionless number is a model fitting parameter, and it is generally correlated with the operating conditions and the physical properties of the suspension.[6] The model has been verified experimentally in a tank provided with four Rushton turbines (radial discharge impeller) at a very low solids concentration.[1,2] Several improvements have been proposed in the literature to make the model more general. Ferreira, Rasteiro, and Figueiredo[3] introduced new terms in Eq. (1) to take into account the radial variation of the particle concentration. Rasteiro, Figueiredo, and Friere[4] suggested the use of the Richardson and Zaki's expression[5] for the settling velocity, as this velocity is strongly dependent on the solid volume fraction in the suspension.

The application of CFD in the modeling of solid–liquid mixing is fairly recent. In 1994, Bakker et al.[6] developed a two-dimensional computational approach to predict the particle concentration distribution in stirred vessels. In their model, the velocity field of the liquid phase is first simulated taking into account the flow turbulence. Then, using a finite volume approach, the diffusion–sedimentation equation along with the convective terms is solved, which includes D_s, a

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018056

turbulent diffusion coefficient of the particles, defined as:

$$D_s = \frac{\sqrt{k_t}}{3\pi n_p D_p^2} \tag{3}$$

where n_p is the overall volume of the particles, D_p their diameter, and k_t the turbulent kinetic energy density. As the authors did not use iterative coupling between the computation of the flow field and that of the solids concentration, the effect of the solids on the fluid mechanics in the vessel was not taken into account. As an example, they investigated the suspension of 20 μm particles with several radial discharge impellers. They showed that their approach was capable of predicting the solid–liquid interface in the vessel and the effect of the position and number of turbines on the solid distribution. Unfortunately, no experimental validation of this approach was carried out.

All the above models do not consider the particle–particle interactions, although these interactions influence the settling velocity and ignore the effect of the solid phase on the hydrodynamics in the vessel. As a consequence, the practical range of application is restricted to low solids concentrations.

A particle migration model was proposed by Gadala-Maria and Acrivos[7] to describe experimental shear-induced migration observations. This model allows for a better understanding of the shear effects on particle diffusion for concentrated suspensions.[8–11] Based on these studies, a conservation equation for the solid phase was established by Phillips, Amstrong, and Brown,[12] which takes into account convective transport, diffusion due to particle–particle interactions, and the variation of viscosity within the suspension, namely:

$$\frac{\partial \phi}{\partial t} + v \cdot \nabla \phi = \nabla \cdot \left(K_c a^2 \phi \nabla(|\dot{\gamma}|\phi)\right) + \nabla \cdot \left(K_\eta \frac{a^2}{\eta} |\dot{\gamma}| \phi^2 \frac{\partial \eta}{\partial \phi} \nabla \phi\right) \tag{4}$$

where ϕ is the volume fraction, v the suspension velocity, a the particle radius, $|\dot{\gamma}|$ the magnitude of the rate-of-strain tensor. K_c and K_η are empirical constants equal to 0.41 and 0.62, respectively. In order to describe the variation of the viscosity η with the particle volume fraction, the authors suggested the use of the Krieger–Dougherty phenomenological model.[13] This approach was applied to investigate the diffusion of suspensions consisting of poly(methylmethacrylate) monodisperse particles ($D_p = 675\,\mu m$) at high concentration ($\phi > 45\%$) in Newtonian silicon oil. Two geometries were tested: a Couette flow (flow between parallel plates with one plate in motion) and a Poiseuille flow (flow in a cylindrical channel). For these two cases, as the concentration varies only in the radial direction, several analytical expressions could be established for the solid volume fraction and the suspension velocity profile. The computational results were compared to concentration measurements based on nuclear magnetic resonance and a qualitative agreement was obtained. It should be noted here that in principle Eq. (4) can be applied at any solids concentration, but it is however restricted to noncolloidal systems.

A different numerical strategy to simulate multiphase mixing was introduced by Mann [14] and Mann and Hackett.[15] The idea of the method, called the network-of-zone, is to subdivide the flow domain in a set of small cells assumed to be mixed perfectly. The cells are allowed to exchange momentum and mass with their neighboring cells by convective and diffusive fluxes. Brucato and Rizzuti[16] and Brucato et al.[17] applied this idea to the modeling of solid–liquid mixing. An unsteady mass balance for the particles was derived to estimate the solid distribution in the vessel, namely:

$$V_c \frac{dC_c}{dt} = Q(C_p - C_c) + \sum_{i=1}^{2} \alpha Q(C_i - C_c) + \sum_{i=3}^{5} (v_t S_i C_i - v_t S_c C_c) \tag{5}$$

where the subscript c is the cell on which the balance is applied, the subscript i refers to the adjacent cells, and the subscript p denotes the feeding cell, i.e., the one yielding convective momentum, V is the cell volume, C the concentration in the cell, S the cell surface area where the particles settle from, Q the volume flow rate of fluid entering the cell, α an adjustable parameter that describes the turbulent diffusion, and v_t the particle settling velocity. In this model, the sedimentation and the diffusive flow were in the vertical direction, and the convective flow was radially oriented. These assumptions were justified on the basis of the radial discharge flow generated by the impellers. Brucato et al.[17] verified the model prediction with the experimental data of Fajner et al.[2] and Magelli et al.[1] It was shown that the axial concentration profile was very well predicted, however the validation was limited again to extremely low concentration suspensions.

The attractiveness of the network-of-zone method to compute solid–liquid mixing flows resides in its relative simplicity while being capable of capturing the main flow phenomena for a wide range of concentrations. The objective of the present work is to assess the real capability of this approach in the case of a complex mixing problem involving a coaxial mixer. Coaxial mixers are very popular for the preparation of pastes and slurries in the chemical, food, and coating industries. Another mixer setup is also tested,

which consists of a single marine propeller rotating in a vessel (see description in the appropriate section below). This setup is used to validate the numerical model.

DESCRIPTION OF THE COAXIAL MIXER SETUP

The experimental setup is shown in Fig. 1. It consists of the following items: (1) an AC drive with a nominal speed of 1760 rpm; (2) a gearbox with a reduction ratio 3.53:1 yielding a rotating speed of 500 rpm; (3) a torquemeter with a measurement range between 0 and 22.6 Nm (accuracy of $\pm$ 0.1% at full scale); and (4) a transparent vessel with a hemispherical bottom.

Table 1 Operating range of the agitators

Speed ratio N_c/N_a	N_a (rpm)	N_c (rpm)
0 (anchor only)	(0–125)	0
4	(0–125)	(0–500)
8	(0–62.5)	(0–500)
24	(0–20.8)	(0–500)
∞	0	(0–500)

The vessel diameter D_c and the height of the cylindrical section H_c are both equal to 40.64 cm, yielding a maximum volume of fluid of about 60 L. The impeller configuration is the following:

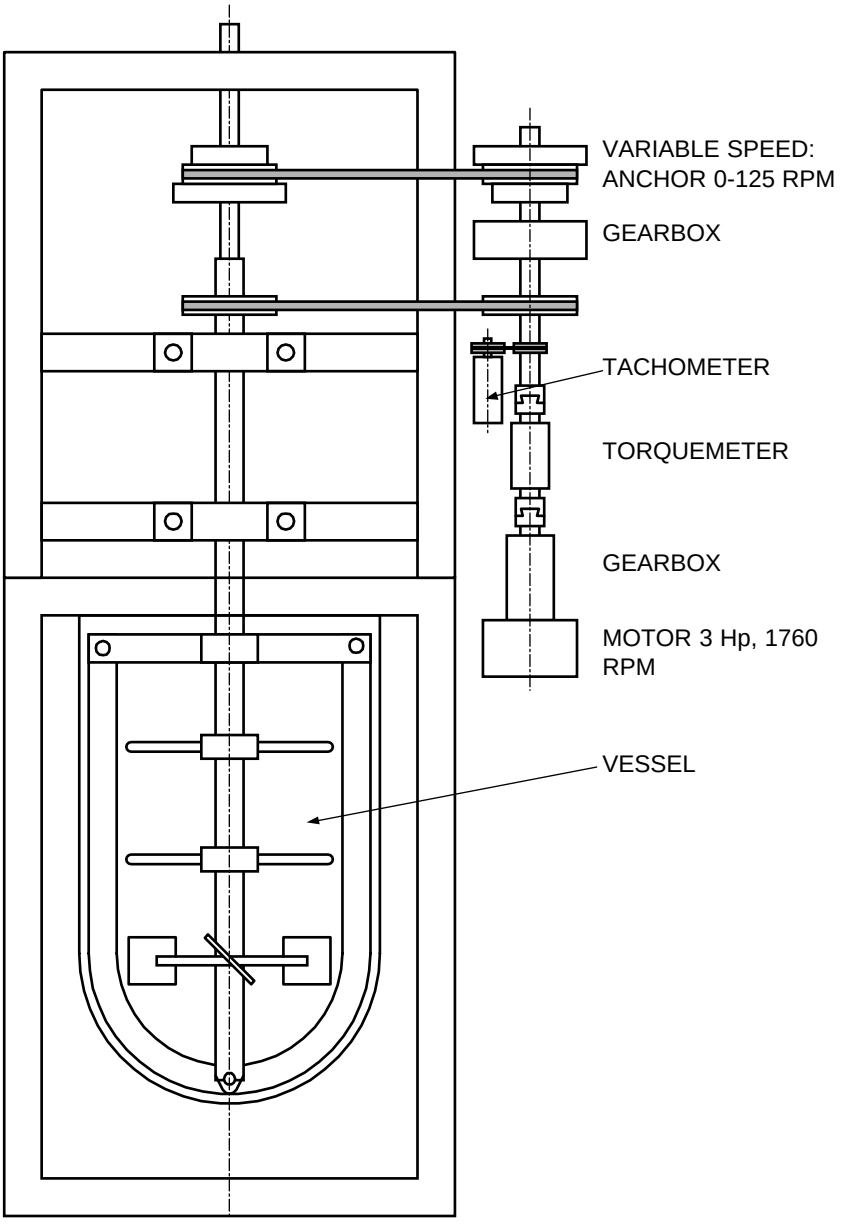

Fig. 1 Coaxial mixer setup.

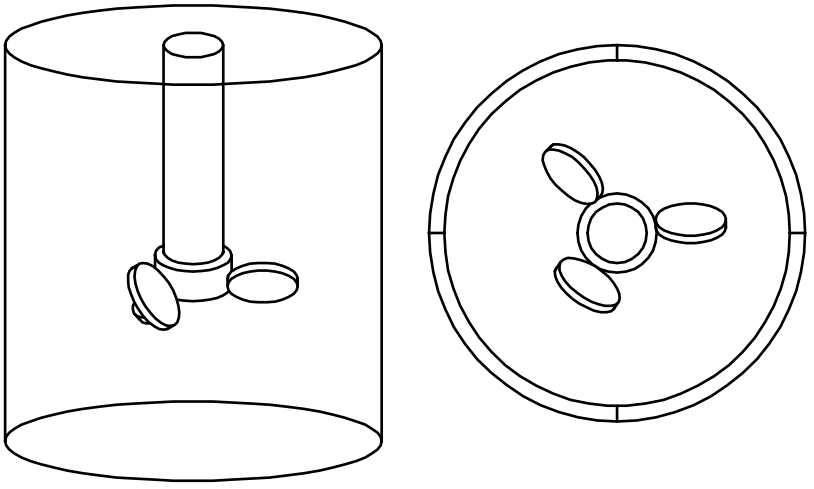

Fig. 2 Marine propeller mixer.

An anchor arm:

- Diameter $D_a = 36.83\,\text{cm}$
- Width $W_a = 3.81\,\text{cm}$
- Wall clearance $C_w = 1.9\,\text{cm}$

Four rigid rods at 90° used for pigment wetting:[18]

- Length $D_t = 23.77\,\text{cm}$
- Cross-section diameter $D_{st} = 0.95\,\text{cm}$

A pitched blade turbine with two blades at 45°:

- Diameter $D_p = 20.2\,\text{cm}$
- Width $W_p = 5\,\text{cm}$
- Length $L_p = 7\,\text{cm}$
- Bottom clearance $C_b = 20.32\,\text{cm}$.

This configuration yields the following dimensionless ratios $C_w/D_c = 0.047$, $D_a/D_c = 0.906$, and $W_a/D_a = 0.103$ for the anchor, $D_t/D_c = 0.585$ for the rods; and $D_p/D_c = 0.5$ and $C_b/D_c = 0.5$ for the pitched blade turbine.

In this coaxial mixer, the primary role of the anchor is to clean up the wall from any accumulated solid lumps and reincorporate them back in the bulk. It also acts as a moving baffle, hampering the creation of a vortex at the liquid free surface. The purpose of the pitched blade turbine is to provide axial pumping so as to promote the resuspension of the solids, and radial dispersion to avoid solids reagglomeration. Finally, the aim of the wetting rods is to ease hydrophobic pigment incorporation by avoiding the creation of surface lumps.[19]

Two driving shafts are installed in this mixer: a fast rotating shaft drives the four rods and the turbine in a counterclockwise direction at speed N_c, whereas a slow rotating shaft entrains the scraping anchor in the clockwise direction at speed N_a. The operating range used in this work was as described in Table 1. In order

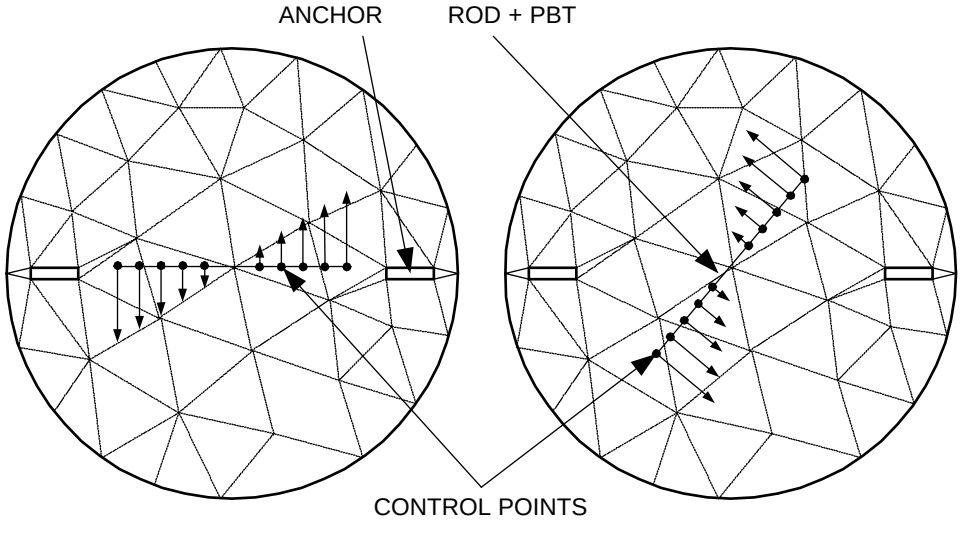

Fig. 3 Virtual finite elements method concept in 2-D.

to investigate the particle motion inside the coaxial mixer, a Newtonian solution of corn syrup with a viscosity of 1.05 Pa.s and a density of 1360 kg/m^3 was used in conjunction with red Ballotini glass beads. The beads had an average diameter of 1 mm and a density of 2500 kg/m^3. The maximum packing factor (ϕ_m) was 0.6.

MARINE PROPELLER MIXER

This simple mixing system (Fig. 2) involves a marine propeller in an unbaffled vessel (actually a laboratory beaker). The geometrical characteristics are the following:

- Distance shaft-impeller edge = 2.6 cm
- Blade diameter = 1.8 cm
- Bottom clearance = 2.6 cm

The propeller rotates clockwise in a down-pumping mode. The vessel (glass beaker) has a diameter of 7.2 cm and the fluid height is 6.5 cm corresponding to a stirred volume of 264 cm^3. The same fluid as the one considered in the coaxial mixer experiments was used. The rotating speed and the volume concentration of the particles were varied in order to investigate the resuspending mechanism in such a mixer. The operating conditions were as follows: $N = 173$ rpm and $\bar{\phi} = 2.8\%$; $N = 230$ rpm and $\bar{\phi} = 7.1\%$; and $N = 350$ rpm and $\bar{\phi} = 11.9\%$. For all the experiments, the particles were initially at rest on the tank bottom and the stirrer was suddenly set in motion.

Computational Model

Let us consider the incompressible flow of a suspension in a given domain Ω. The governing equations are:

$$\rho_m\left(\frac{\partial \mathrm{v}}{\partial t} + \mathrm{v}\cdot\mathrm{grad}\,\mathrm{v}\right) + \mathrm{grad}\,p + \mathrm{div}\,\tau = \rho_m g \quad \text{in } \Omega \tag{6}$$

$$\mathrm{div}\,\mathrm{v} = 0 \quad \text{in } \Omega \tag{7}$$

where v, p, g, and ρ are the velocity, pressure, gravity, and specific gravity, respectively. For a solid–liquid medium, the density ρ_m can be expressed as:

$$\rho_m = \rho_l(1 - \phi) + \rho_s\phi \tag{8}$$

where ρ_l and ρ_s represent the density of the liquid phase and the solid phase, respectively.

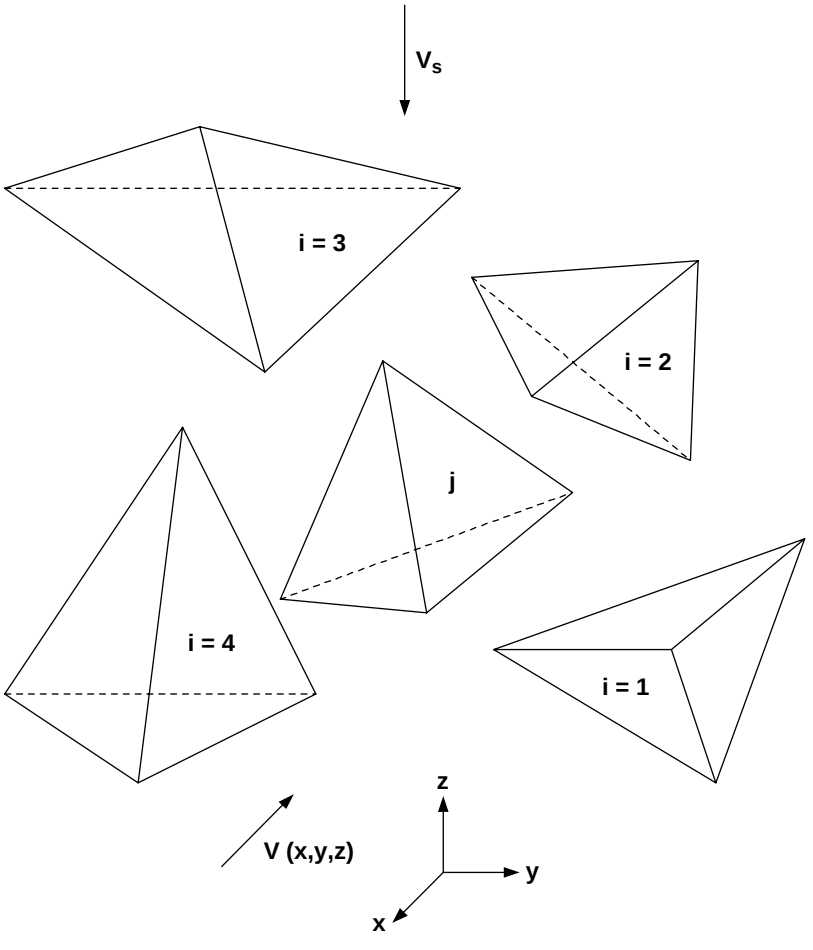

Fig. 4 Tetrahedral finite volumes.

The stress tensor τ in Eq. (6) is related to the rate-of-strain tensor by a rheological equation of state such as:

$$\tau = -2\eta_s\dot{\gamma} \tag{9}$$

where η_s is a function of $|\dot{\gamma}|$ and ϕ,

$$\dot{\gamma} = \tfrac{1}{2}[\text{grad v} + (\text{grad v})^{\text{T}}] \tag{10}$$

and

$$|\dot{\gamma}| = (\dot{\gamma} : \dot{\gamma})^{\frac{1}{2}} \tag{11}$$

The suspension viscosity η_s may or may not be a function of $|\dot{\gamma}|$ depending on the rheological behavior of the suspending medium. In a nondilute suspension, it is, however, always a function of the particle volume fraction ϕ. In this work, the Krieger–Dougherty model for a Newtonian suspension was used:

$$\eta_s(\phi) = \eta_l(1 - \phi/\phi_m)^{-1,82} \tag{12}$$

where η_l is the viscosity of the suspending liquid and ϕ_m the maximum packing factor.

For mathematical convenience, boundary conditions and initial conditions must be prescribed. For the simple marine propeller problem, a Lagrangian viewpoint was adopted. The frame of reference was attached to the propeller so that the propeller was fixed but the vessel was rotating. The boundary condition was then a zero velocity on the impeller, while the vessel wall rotated at $-\Omega_{\text{impeller}}$. The free surface was considered to be flat, therefore the normal velocity was zero and a shear-free condition was assumed. It should be noted that in the Lagrangian viewpoint, the frame of reference is in rotation. The fluid is therefore subjected to a constant acceleration and the momentum conservation equation [Eq. (6)] must be modified to account for centrifugal forces and Coriolis forces.[20] An advantage is, however, that the flow can be solved numerically at steady state provided the flow is fully periodic, which limits the computational efforts significantly.

In the case of the coaxial mixer, the rotation kinematics is much more complex since the two sets of agitators counter-rotate at different speeds. For the sake of simplicity, we decided to simulate the flow using the frame of reference of the anchor. In this Lagrangian viewpoint, the anchor is fixed but the vessel wall rotates at $-\Omega_{\text{anchor}}$ and the turbine rotates at $\Omega_{\text{anchor}} + \Omega_{\text{turbine}}$. In such a situation, contrary to the simple propeller problem, the resolution of the flow equations is time-dependent as the position of the central agitator changes with time.

The finite element method was used for the discretization of the flow equations. Considering the complex kinematics in the coaxial mixer and the associated change of topology at each time step, a new mesh should a priori be built for every topology considered in the time discretization. As a large number of time steps would be required to depict the agitator kinematics accurately, this approach would be a tremendous chore. To alleviate this difficulty, several alternatives have been proposed in the literature:

1. The description of the agitator by momentum sources or sinks inside the domain.[21] The major drawback of this method is the evaluation of a force equivalent to the representation of a body in rotation.
2. The arbitrary Euler–Lagrange method. It consists of moving the finite element mesh nodes with time.[22] This method works well as long as the mesh is not too distorted. In practice, remeshing is usually required after a few time steps.
3. Domain decomposition with sliding meshes.[23] This strategy is very popular in the finite volume literature and implemented in finite volume-based software (Fluent™, CFX™, and Star-CD™). The idea is to decompose the flow domain into several concentric cylindrical meshes and allow slipping of the meshes between the partitions. The continuity of the solution at the mesh interface is imposed by

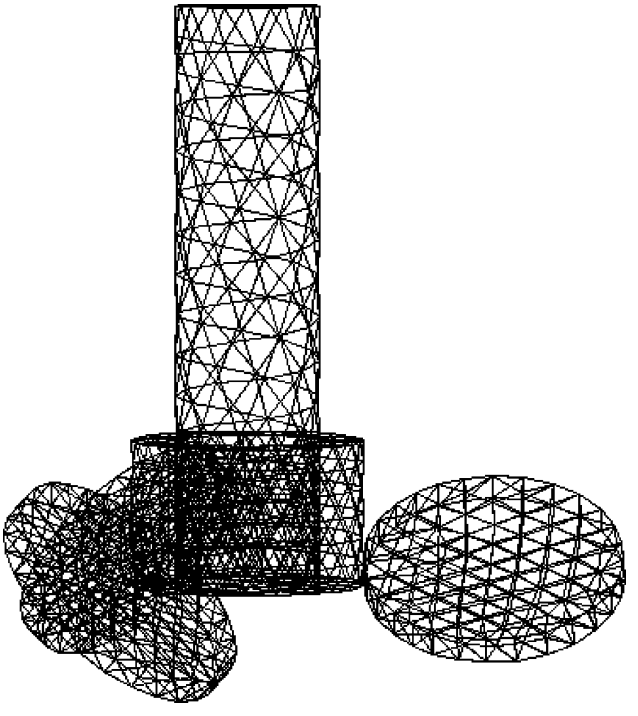

Fig. 5 Mesh of the propeller.

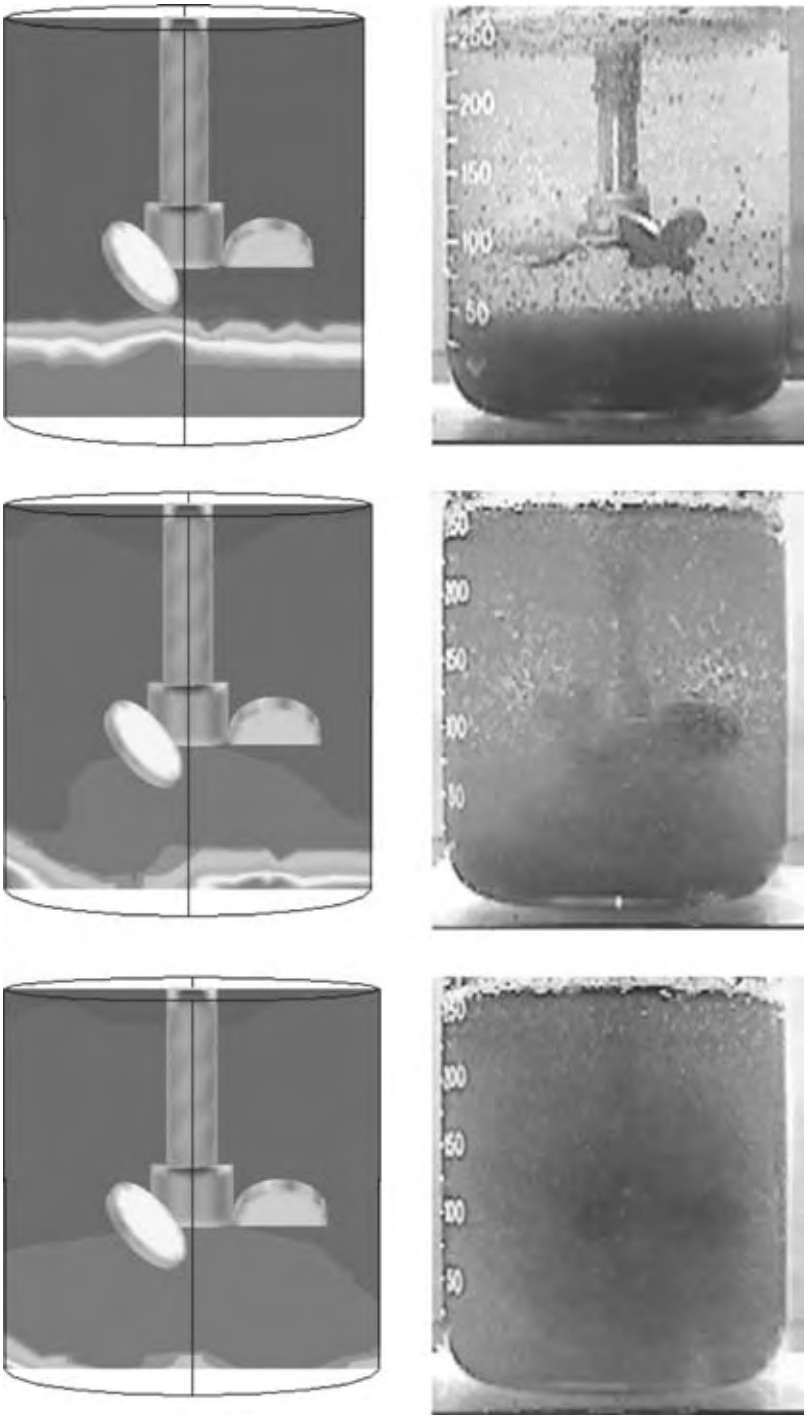

Fig. 6 Suspending mechanism as a function of time.

conservative interpolation. This method is powerful but limited to simple agitator configurations. It seems to work when very fine meshes are used although no error analysis has been published so far.

4. Mesh superimposition. This technique used in commercial finite element CFD software, like FIDAP^{TM} and PolyFlow^{TM}, consists of generating a volume mesh without the moving impellers and a surface mesh of each impeller. At each time step, the surface mesh is projected in the volume mesh and a procedure has been developed to determine if the nodes of the volume mesh are located inside the surface mesh. When it is the case, the velocity of the impeller is imposed on these nodes. This technique is fairly simple to implement, however, it does not allow a precise representation of the impeller shape.

Table 2 Variation of the average concentration with the rotation speed

N (rpm)	Average volume fraction	Predicted volume fraction
173	2.8%	0.5%
230	7.1%	1.7%
350	11.9%	7.3%

5. The virtual finite element method VFEM.[24] The method that was chosen for this work has been developed specifically to simulate flows around moving bodies in fixed enclosure. The principle of VFEM is the following: a volume mesh of the vessel with the anchor arm is first generated. Then, the surface of the moving bodies (in our case, the impeller and the rods) is meshed; the discretization nodes generated being stored as control nodes. Knowing the kinematics of the impellers, the velocity is imposed on these control nodes as constraints in the momentum equation and their position is updated with time according to the impeller rotation. A constrained optimization technique based on Lagrange multipliers and a penalty strategy is used to impose the velocity constraints. The VFEM approach was applied by Bertrand, Tanguy, and Thibault[24] to investigate the complex flow patterns in a planetary kneader and by Tanguy and Thibault[25] for the characterization of the hydrodynamics in a coaxial mixer provided by a helical ribbon and a Rushton turbine. Contrary to the mesh superimposition technique, the VFEM does not require that the control nodes coincide with the volume mesh nodes. They can be located inside finite elements as they are treated like external solicitations or optimization constraints. Fig. 3 illustrates the VFEM concept in 2-D. The above method was implemented in our POLY3-D^{TM} CFD finite element code using unstructured meshes made of tetrahedral elements. The reader is referred to Bertrand, Tanguy, and Thibault[24] for detailed information.

The modeling of solid–liquid mixing requires an additional equation to predict the dispersion of the solid phase in the vessel. As mentioned before, the network-of-zones approach was used in this work, which is based on unsteady mass balances on the solid phase carried out on a set of cells. In the literature, such mass balances are predominantly made on regular cells (finite volumes) in structured grids. The cells typically consist of quadrangles in 2-D and hexahedra in 3-D. In the present work, due to the use of unstructured grids, the mass balances were performed on the same elements as those used for the resolution of the flow equations, i.e., tetrahedral finite volumes (Fig. 4).

Let us consider the following mass balance on a tetrahedral element subjected to the velocity field $v(x,y,z)$ of the suspension (as computed from the solution of the flow equations) and a sedimentation velocity, namely:

$$V_j \frac{d\phi_j}{dt} = \sum_i Q_{cj,i}\phi^*_{cj,i} + Q_{sj,i}\phi^*_{sj,i} \tag{13}$$

where the subscript i represents the neighboring finite elements adjacent to the four sides of finite element j, V_j the volume of finite element j, $Q_{cj,i}$ the convective flux of solid particles going through a common face to elements i and j, $Q_{sj,i}$ the sedimentation flux going

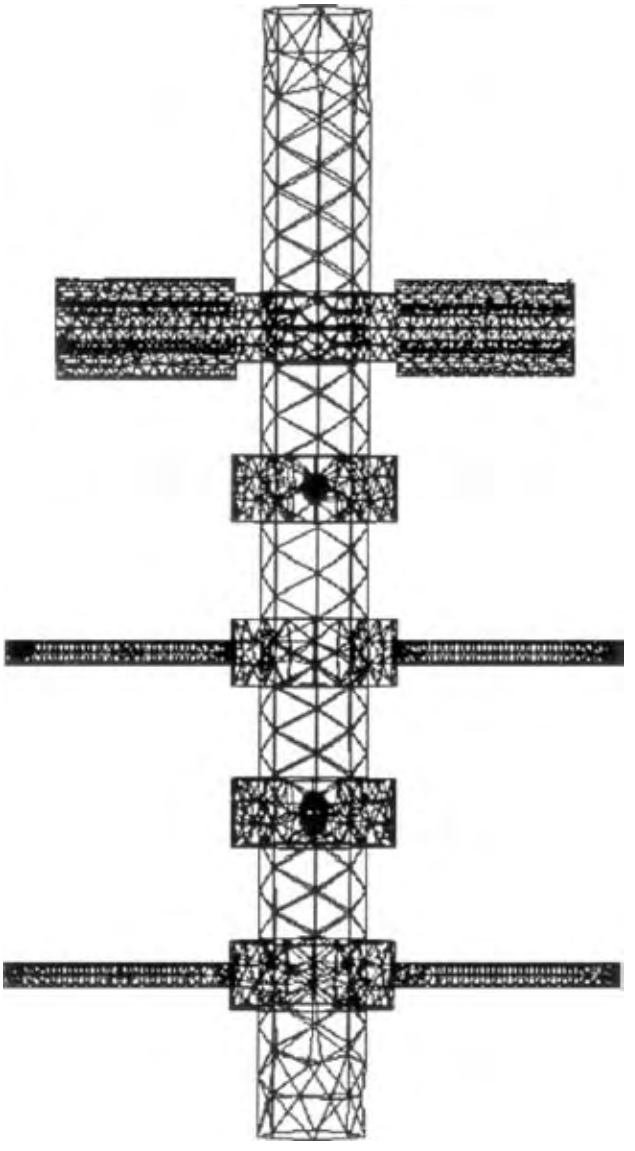

Fig. 7 Surface mesh of the moving impellers.

through a common face to elements i and j, and $\phi_c j^*{}_{,i}$ and $\phi_s j^*{}_{,i}$ the volume fraction of solid particles defined as follows:$\phi_c j^*{}_{,i} = \phi_I$, if $Q_{cj,i} > 0$ is the convective flux of particles leaving element i and entering element $j\phi_c\ j^*{}_{,i} = \phi_j$, if $Q_{cj,i} < 0$ is the convective flux of particles leaving element j and entering element $i\ \phi_s\ j^*{}_{,i} = \phi_i$, if $Q_{sj,i} > 0$ is the sedimentation flux of particles leaving element i and entering element $j\ \phi_s\ j^*{}_{,i} = \phi_j$, if $Q_{sj,i} < 0$ is the sedimentation flux of particles leaving element j and entering element i.

This model assumes perfect mixing inside the element, as the particles enter the cell with different concentrations but leave the cell with a homogeneous concentration. Moreover, inertia is neglected, as well as slipping, between the solid and liquid phases. In Eq. (13), the fluxes can be expressed using the following equations:

$$Q_{cj,i} = \int_{S_{j,i}} \left(v_{cj,i}(x,y,z) \cdot \vec{n}_{j,i}\right) \mathrm{d}S \tag{14}$$

$$Q_{sj,i} = \int_{S_{j,i}} \left(v_{sj,i} \cdot \vec{n}_{j,i}\right) \mathrm{d}S \tag{15}$$

where $\vec{n}$ represents the unit vector of each face pointing to inward element j, S the surface area of the face, v_c the suspension velocity, and v_s the settling velocity determined using the classical sedimentation relations,[26] namely:

$$\mathrm{Ar} = 24\,\mathrm{Re_p} \quad (\mathrm{Ar} < 4,8) \tag{16}$$

$$\mathrm{Ar} = 24\,\mathrm{Re_p} + 3,6\,\mathrm{Re_p}1.687 \quad (4,8 < \mathrm{Ar} < 10^5) \tag{17}$$

$$\mathrm{Ar} = 4/9\,\mathrm{Re_p^2} \quad (\mathrm{Ar} > 10^5) \tag{18}$$

where Ar is the Archimedes number defined as:

$$\mathrm{Ar} = \frac{4}{3} D_p^3 (\rho_s - \rho_l) \frac{\rho_l g}{\mu_l^2} \tag{19}$$

and $\mathrm{Re_p}$ is the particle Reynolds number defined as:

$$\mathrm{Re_p} = \frac{D_p v_l \rho_l}{\mu_l} \tag{20}$$

In order to compute the unsteady term $\mathrm{d}\phi/\mathrm{d}t$, the following expression can be used:

$$\frac{\mathrm{d}\phi}{\mathrm{d}t} = \frac{a_t \phi^{t+1} + b_t \phi^t + c_t \phi^{t-1}}{\Delta t} \tag{21}$$

where $a_t = 1$, $b_t = -1$ and $c_t = 0$ at the first time step (Euler implicit scheme), and $a_t = 3/2$, $b_t = -2$ and $c_t = 1/2$ for the subsequent steps (second order Gear scheme). After substitution in Eq. (13), the following implicit numerical problem is obtained:

$$V_j \left[\frac{a_t \phi_j^{t+1} + b_t \phi^t + c_t \phi^{t-1}}{\Delta t}\right] = \sum_i Q_{cj,i} \phi_{cj,i}^{*t+1} + Q_{sj,i} \phi_{sj,i}^{*t+1} \tag{22}$$

This problem can then be resolved with the appropriate initial conditions of the mixing problem considered.

Several mixing cases were considered in this work:

1. Simple solid–liquid mixing experiments for the validation of the numerical model
2. Hydrodynamic studies in the coaxial mixer without solid particles
3. Coaxial solid–liquid mixing experiments.

VALIDATION OF THE NUMERICAL MODEL

The propeller setup was used for this purpose. From a computational standpoint, a mesh of the vessel–propeller set was created containing 8746 elements yielding 54,333 velocity equations and 8746 concentration equations. The surface mesh of the propeller (Fig. 5) comprised 964 control points. A maximum of three control points per element was used to avoid locking. Unsteady state flow simulations were performed with a 1-s time step and three coupling iterations between the Navier–Stokes equations and the solid transport equation were required per time step. Steady state was deemed obtained when the solids concentration coefficient of variation did not change.

Fig. 6 illustrates the suspending mechanism versus time. At 350 rpm, all the particles are suspended

and uniformly distributed. An attempt has been made to evaluate the minimum suspending speed N_{js} using the work of Armenante and Nagamine.[27] We found that $N_{js} = 855$ rpm for an average particle concentration of 11.9% v/v, which seems to contradict our visual observations. However, as mentioned by Ibrahim and Nienow,[28] published N_{js} correlations largely overestimate the suspending velocity when the suspending medium viscosity is larger than 0.1 Pa.s. Fig. 6 also shows the time evolution of the computed volume fraction until stability is reached. As we do not know the experimental solids concentration distribution in the vessel, the numerical results can only be compared with the experimental results on a qualitative basis. We noted that the computation allows the prediction of the solid accumulation below the agitator. In agreement with the experiments, the network-of-zone model also predicts an increase in the resuspension mechanism when the rotation speed and/or the average concentration in the vessel increase (Table 2).

The accumulation of solids in the vessel bottom at equilibrium was also well captured. For instance at $N = 230$ rpm and a volume fraction of 7.1%, a solid layer with a volume fraction greater than 60% accumulates at the bottom and at the wall, which has been observed experimentally. At $N = 350$ rpm and a volume fraction of 11.9%, almost all the solid particles are suspended, except in a small region close to the bottom edge, again in agreement with the experiments. The performance of the computational model appears therefore satisfactory as fine hydrodynamic details can be predicted for intermediate concentration values. At very low concentration, as the solid layer thickness is reduced, a finer mesh would be required to enhance the model precision.

COAXIAL MIXER RESULTS AND DISCUSSION

Considering the prediction of the power consumption, classically, the power drawn by the impeller is expressed with power curves, i.e., plots of the power number N_p versus the Reynolds number, Re, where:

$$N_p = \frac{P}{\rho N^3 D^5} \tag{23}$$

$$\mathrm{Re} = \frac{\rho N D^2}{\mu} \tag{24}$$

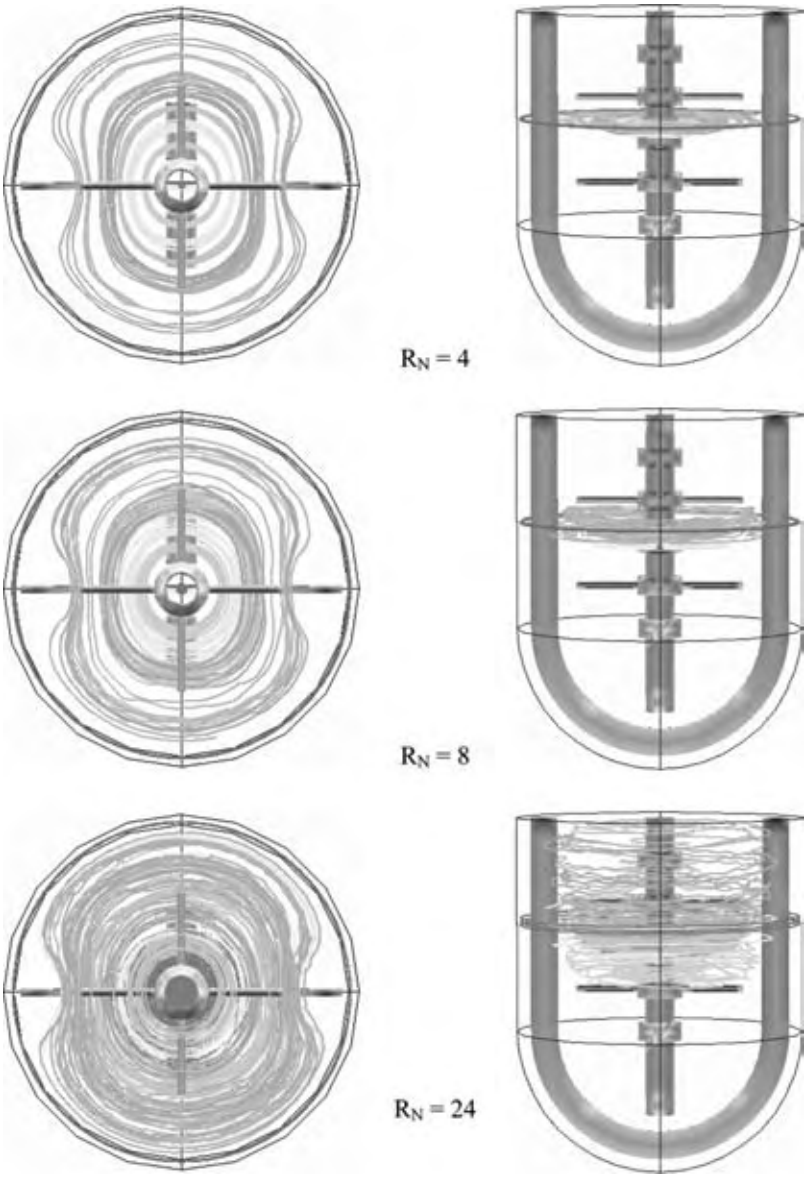

Fig. 9 Effect of speed ratio on the flow field (upper part of the vessel).

P is the mixing power, N and D the rotation speed (in rps) and the impeller diameter respectively, and μ and ρ the fluid viscosity and density. The following relations apply for the laminar and turbulent regimes, respectively:

$$K_p = N_p \quad \mathrm{Re} = \frac{P}{\mu N^2 D^3}, \quad \mathrm{Re} < 10 \tag{25}$$

$$N_p = C \quad \mathrm{Re} > 300 \tag{26}$$

where K_p and C depend only on the mixer geometry for a given fluid.

In a coaxial mixer, the selection of the characteristic speed and dimension that appear in the expression of these dimensionless numbers is ambiguous, as we have two different speeds (N_a and N_c) and three impeller diameters that can be considered. In this work, we used N_a and D_a as the characteristic parameters. The reader is referred to the discussion of this particular choice in Refs.[29,30]. The coaxial mixer power curve and the value of K_p have been obtained by numerical simulation, varying the impeller speed and the speed ratio. For each simulation, the velocity field was used to compute the power by a macroscopic energy balance, namely:

$$P = -\int\int\int_{\Omega} \tau : \nabla v d\Omega \tag{27}$$

Numerical simulations employed the virtual finite element method described above combined with a

Lagrangian flow description (anchor frame of reference). The finite element mesh (generated by IDEAS^{TM} software from SDRC) included 17,083 tetrahedral elements, yielding 106,295 velocities degrees of freedom. Twenty time steps per revolution (angular displacement of 18 degrees per time step) were used, the value of the time step depending on the revolution speed. Typically, the time step was in the range 0.03–0.135 s. For each time step, the control points located on the surface mesh of the moving impellers (Fig. 7 had to be updated. The number of control points required is given in Table 3. The flow simulations carried out for several revolutions showed that the flow was periodic. Moreover, it was found that only one single revolution was enough to obtain a stable, converged solution at low Reynolds number. Finally each simulation required between 12 and 24 CPU hours on an IBM RISC6000/550 server.

Table 4 shows a comparison of the computed and experimental values of K_p for the anchor only. An excellent agreement is obtained. The comparison with literature data shows that the computed values are larger than the data published. The difference is believed to originate from the shape of the vessel bottom (hemispherical in the present work, flat in the literature results).

We show in Fig. 8, a comparison of the numerical and experimental power curves for three different speed ratios ($R_N = N_c/N_a = 4$, 8 and 24). These results have been obtained with $\mu = 15$ Pa.s and $\rho = 1500$ kg/m^3. It can be seen that there is good agreement between the predicted and experimental

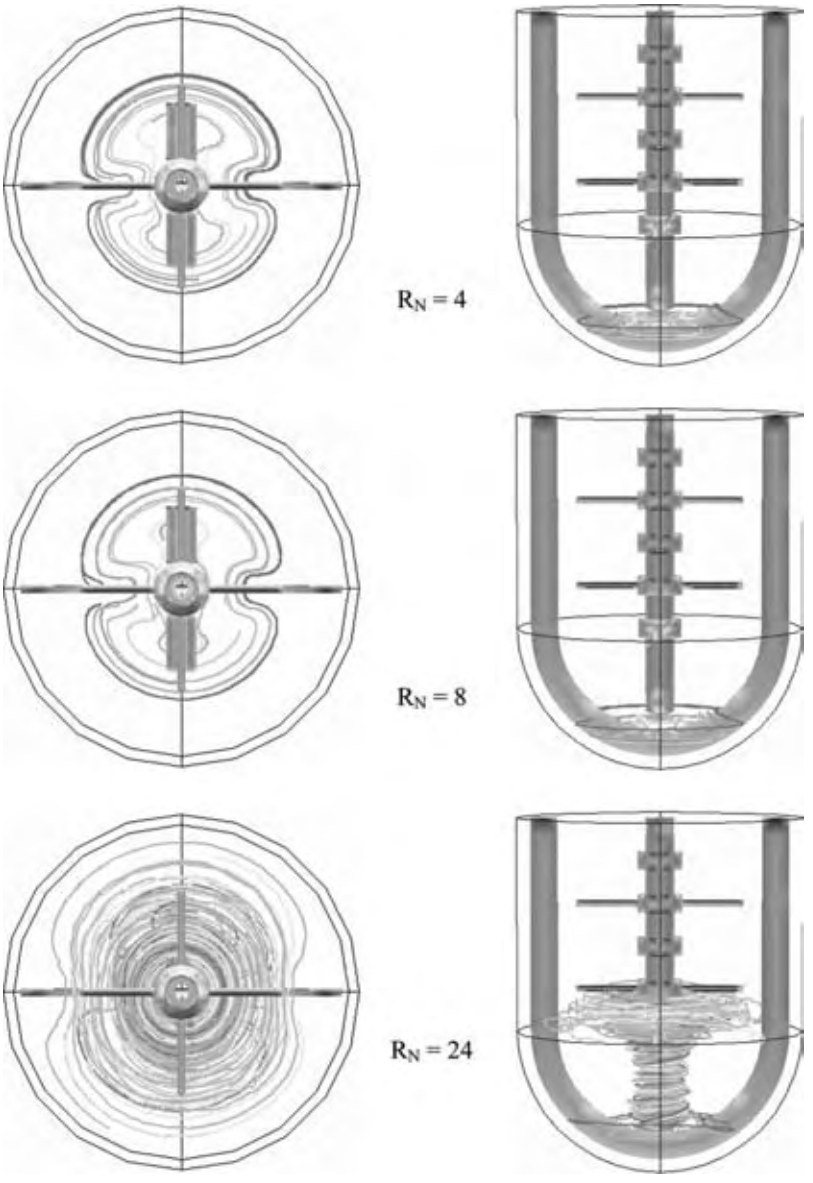

Fig. 10 Effect of speed ratio on the flow field (lower part of the vessel).

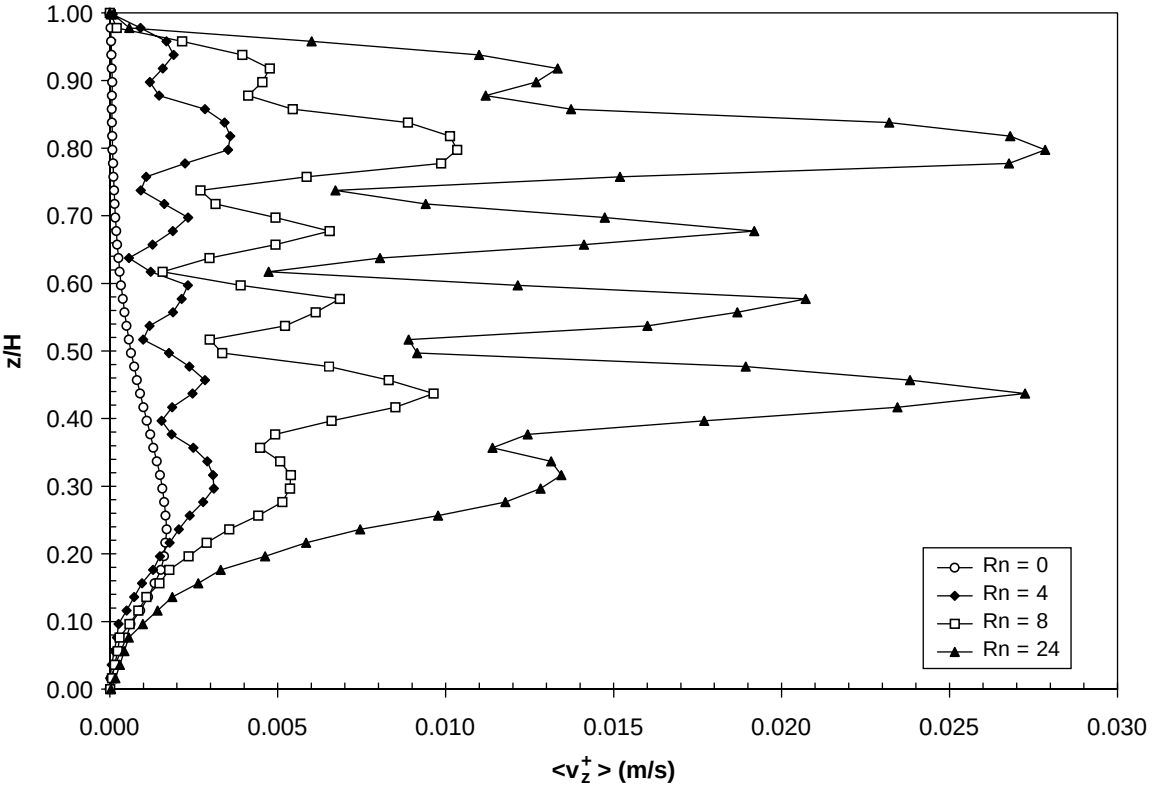

Fig. 11 Axial velocity in the upward direction as a function of the speed ratio.

values. The slope of –1 in the laminar region is captured by the simulation. The onset of the transition regime (decrease of the slope of the *Np* versus Re curve) occurs for a Re value below 10, and the threshold value is sensitive to the value of R_N. For a given Re value, the power increases with R_N. This result seems logical as the Reynolds number has been defined with the anchor parameters and when R_N increases, the central shaft speed rotates faster. This speed increase enhances the average shear rate in the tank, which entrains an increase in the power draw.

The values of the constant K_p of the coaxial mixer versus R_N were also established. Results are shown in Table 5. Here again, the agreement between the predictions and the experimental data is very good.

It is usual in laminar mixing simulations to represent the flow using tracer trajectories. The computation of such flow trajectories in a coaxial mixer is more complex than in traditional stirred tank modelling due to the intrinsic unsteady nature of the problem (evolving topology, flow field known at a discrete number of time steps in a Lagrangian frame of reference). Since the flow solution is periodic, a node-by-node interpolation using a fast Fourier transform of the velocity field has been used, which allowed a time continuous representation of the flow to be obtained. In other words, the velocity at node i was approximated with a Fourier series taking the following form:

$$v^i = a_0^i + a_n^i \cos nt + \sum_{k=1}^{n-1} (a_k^i \cos kt + b_k^i \sin kt) \tag{28}$$

where n is the number of harmonics and coefficients $a_k{}^i$, $k = 1, 2, \ldots, n-1$, and $b_k{}^i$, $k = 1,2, \ldots, n-1$ are obtained from the whole set of velocity values at node i during an impeller revolution. In practice, 10 harmonics were employed according to the Shannon sampling theorem.[34]

We show in Figs. 9 and 10 the effect of the speed ratio on the flow field for an anchor speed of 4.43 rpm. It can be seen that for the two injection points considered (upper part and lower part of the vessel), the radial dispersion increases significantly with the speed ratio. The axial dispersion is also enhanced but less dramatically. A speed ratio of four does not lead to good dispersion and therefore should yield longer mixing times. These results show the synergy between the anchor and the turbine, the axial pumping increasing with the speed ratio. To quantify this axial pumping, the axial velocity in the upward direction is plotted in Fig. 11 versus the speed ratio. An additional advantage of the coaxial mixer can be seen as the axial

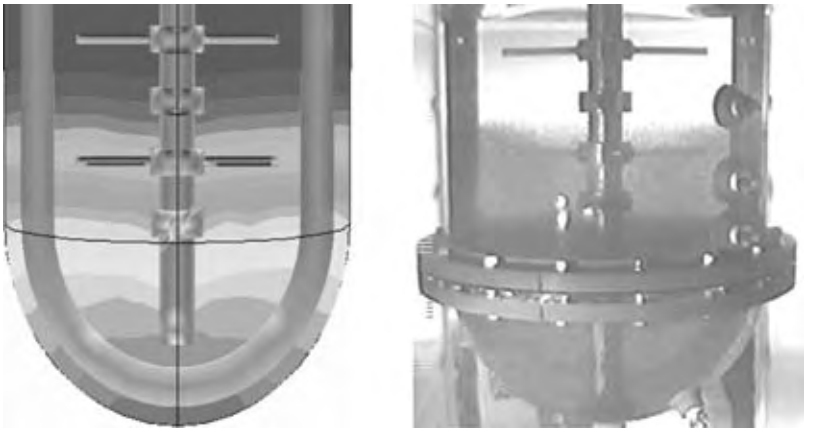

Fig. 12 Predicted and experimental solid volume fraction at equilibrium.

pumping in the upper part of the vessel is enhanced when the speed ratio is augmented.

We now turn to the prediction of the suspension mechanism of the ballotini versus the speed ratio in the coaxial mixer. The average volume concentration is 1%, and the solids are initially at rest in the tank bottom. The first case investigated corresponds to the motion of the sole anchor arm at a speed of 40 rpm. Simulations are carried out in the Lagrangian frame of reference (fixed anchor, rotating vessel). Fig. 12 shows the predicted and experimental solid volume fraction at equilibrium. The computation of the solid–liquid interface at the bottom is fairly well captured by the numerical model as in the previous case dealing with the propeller. The next case considered is the resuspension with the only central shaft in rotation at 160 rpm. This simulation has been carried out with the virtual finite element method described before. Steady state was achieved after 20 revolutions. In Fig. 13, we compare the numerical and experimental distribution of particles in the tank. The agreement is again noteworthy, and the computation predicts that no particle has been resuspended. In fact, although the rotation is counterclockwise, particles have moved in the clockwise direction and accumulated behind the anchor arm. The Mann model is therefore capable of

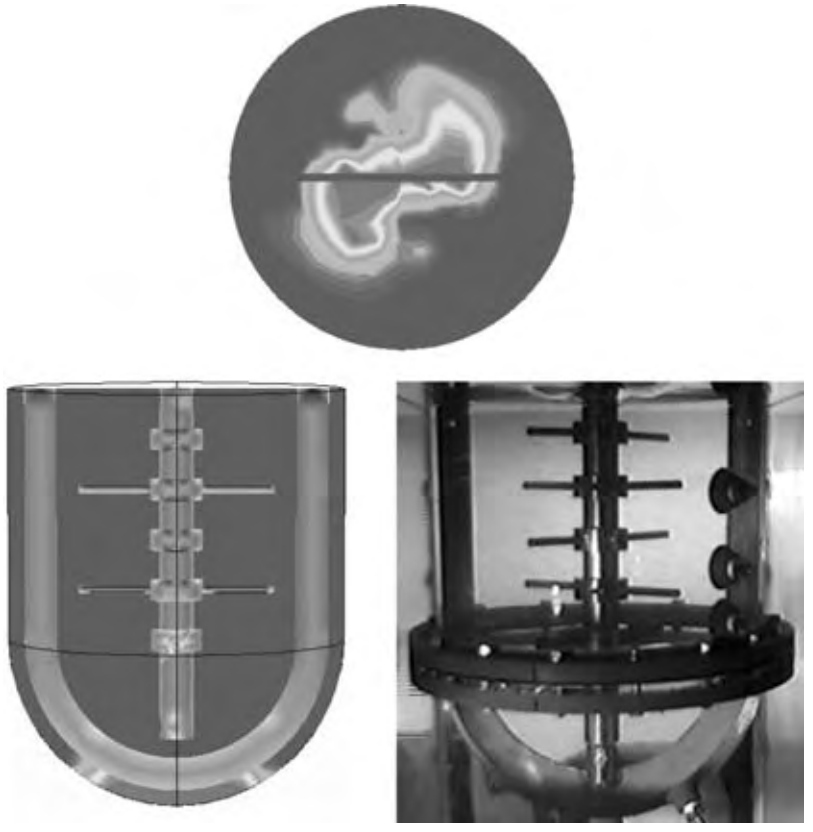

Fig. 13 Numerical and experimental distribution of particles.

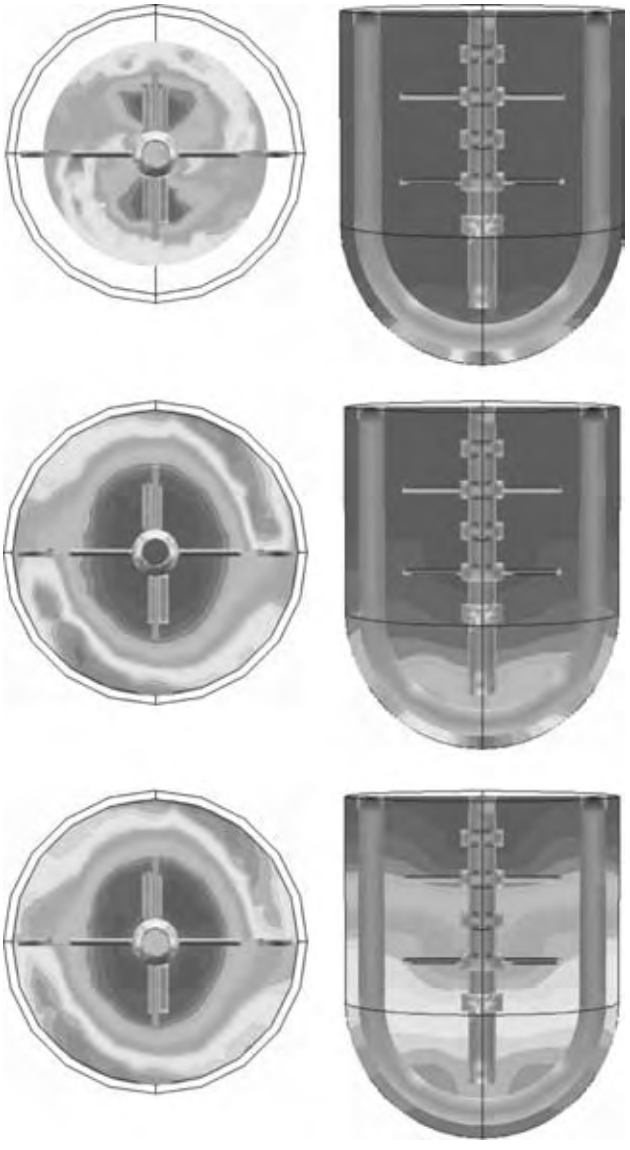

Fig. 14 Resuspending of ballotini a central shaft speed of 160 r.p.m. and a speed ratio of 4.

predicting this odd motion phenomenon at the bottom. Finally, we show in Fig. 14 the resuspending of ballotini for a rotation speed of the central shaft of 160 rpm and a speed ratio R_N of 4 ($N_c/N_a = 4$) after 60 revolutions. This number of revolutions is the maximum that we were capable of computing in a reasonable timeframe (a few days of CPU time). Interesting information can already be obtained from this snapshot result. First, an overconcentration is noticeable in the anchor arm wake in agreement with the experiment. This overconcentration decreases with time as the tank bottom becomes leaner in particle, thereby decreasing the number of particles that can be entrained in the wake. As far as the solid–fluid interface is concerned, the interface rises in the bulk with time but it has not yet reached its eventual position after 60 revolutions.

CONCLUSIONS

Solid–liquid mixing processes can be simulated with good precision when sound CFD methods are used. The application of a combination of the virtual finite element method and the network-of-zone approach was used in this work to analyze the complex flow and suspension mechanisms in a coaxial mixer. Experiments carried on the laboratory scale confirmed the validity of the predictions.

Coaxial mixing shows strong performance capabilities in the case of tough mixing problems involving complex rheology, which should prove more and more useful in industry. Tools are now available to design these systems without resorting to empirical rules.

Solid–Liquid Separation

Frank M. Tiller
Wenping Li
Department of Chemical Engineering, University of Houston, Houston, Texas, U.S.A.

INTRODUCTION

Solid–liquid separation (SLS) involves operation of solid and liquid systems with the objectives of:[1]

1. Recovering solids (the liquid being discarded).
2. Recovering liquid (the solids being discarded).
3. Recovering both solids and liquid.
4. Removing pollutants, solutes, micro-organisms, etc.

Solid–liquid separation is encountered in all stages of manufacturing processes ranging from raw material purification through product separation to waste management. Solid–liquid separation operations include screening, cake and deep-bed filtration, gravitational sedimentation, sedimenting and filtering centrifugation, expression (cake squeezing), hydro-cycloning, washing, membrane separation, flotation, etc. Selection of proper equipment and optimum operating conditions are among the most important problems faced by engineers involved in SLS. Because of the complex nature of fluid/particle systems and a general lack of fundamental training, SLS operations are often a problem area, or bottle neck in a plant. Various SLS operations are described as follows.[2]

SEDIMENTATION

Separation involving sedimentation is dependent upon settling velocity, which requires a difference in density between solid particles and the suspending liquid. Gravitational sedimentation operations are divided into clarification and thickening. Clarification involves dilute suspensions and frequently has the objective of liquid recovery. Thickening refers to solid recovery by forming more concentrated slurries. Particle size, liquid and particle densities, and liquid viscosity are important factors in sedimentation processes.

CAKE FILTRATION

In cake filtration (Fig. 1A), solids and liquid are separated by filter medium, which retains the solids as a cake and permits the liquid to pass through under pressure, vacuum or centrifugal forces. Once the cake is formed, it becomes the primary filter medium and particles finer than the openings of the medium can be separated.

CROSS-FLOW FILTRATION

In cross-flow filtration (Fig. 1B), shear forces are introduced at the cake surface to reduce cake thickness and total cake resistance. It is exclusively used in membrane separation applications to prevent fouling on membranes.

SCREENING

Screening (Fig. 1C) is a type of surface filtration to separate solids and liquid by screens with openings smaller than particle size. It is usually employed among the first few steps of a SLS process. Vibrations and other mechanism are often applied to avoid blinding of the screens.

DEEP-BED FILTRATION

In deep-bed filtration (Fig. 1D), particles are caught inside the filter medium. Examples of deep-bed filters are granular beds and some cartridge filters. Deep-bed filtration is used for dilute suspensions (<100 ppm) containing fine particles that are not easy to be removed by sedimentation or cake filtration.

CENTRIFUGATION

Centrifugation increases the separating driving force by developing centrifugal forces on particles. A difference in density between the liquid and the particles is also a prerequisite. Centrifuges are employed in filtering and sedimenting modes. The terms ''perforated bowl'' and ''solid bowl'' differentiate the two types of operations.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007766

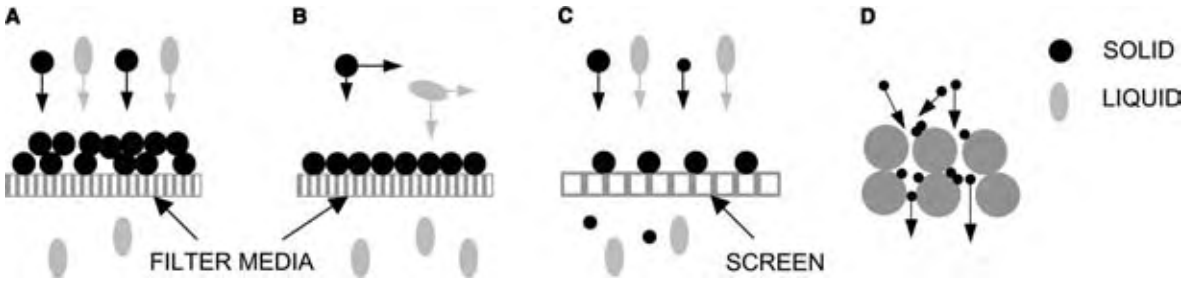

Fig. 1 Schematic mechanisms of four types of filtration: (A) cake filtration; (B) cross-flow filtration; (C) screening; (D) deep-bed filtration. *(View this art in color at www.dekker.com.)*

CAKE WASHING

Cake washing is a common operation for removal of soluble materials in filter cakes. There are displacement washing and dilution washing. A clean liquid is used in this step. Direct introduction of wash liquid behind the slurry is called displacement washing. As a rough guide, about half of the liquor in the cake is displaced at the full initial concentration. Breakthrough occurs at that point, and the concentration of the wash rapidly drops off as solutes gradually diffuse out of inaccessible pores. Dilution washing is accomplished by reslurrying the cake and refiltering the diluted slurry. Cocurrent or countercurrent washing can be used in dilution washing. Ideally, displacement washing would be used until the wash liquid reached a predetermined concentration, then the cake would be reslurried, and displacement washing would follow.

EXPRESSION

Expression operations include mechanic squeezing of a wet filter cake with stationary diaphragms, moving belts, rollers, or screws. For further deliquoring, blowing with gas is frequently used after expression.

MEMBRANES

Membranes are used for a wide variety of separations. A membrane serves as a barrier to some particles while allowing others to selectively pass through. The membrane pore size, shape, and electrostatic surface charge are fundamental to particle removal. Reverse osmosis (RO), nanofiltration (NF), ultrafiltration (UF), and microfiltration (MF) relate to separation of ions, macromolecules and particles in the 0.001–10 μm range.[3]

HYDROCYCLONES

Hydrocyclones are closely related to centrifuges in that centrifugal forces are employed for liquid and particles separation by introducing the slurry radially into the upper periphery of the cyclone at high velocity. solids are thrown out to the wall, and flow down the inclined walls, and exit at the bottom. In general, hydrocyclones operate as classifiers with large particles in the underflow and small particles in the overflow.

FLOTATION

Flotation is commonly employed for beneficiation of minerals. Frothers are added to the vigorously agitated mixture. Air bubbles attach to the collector-mineral particles, which then rise and are removed along with the froth or foam. The valuable components are separated from the waste or gangue by preferential floating of one of the components to the top while the other sinks to the bottom.

PARTICLE SIZE AND CLASSIFICATION OF SLS OPERATIONS

Sizes of particle are important in selecting the method of separation. Different authors do not necessarily use the same nomenclature in classifying separations in terms of ''size.'' A crude relationship of particle size to particle size measurements and methods of SLS and particle size analysis is provided in Fig. 2.[2]

As illustrated in Fig. 2, there is a weak relationship between particle size and the methods for separation. Particle size measurements are usually made on dilute dispersed systems, where each particle is separated from all other particles. However, in practice, particles are usually combined into aggregates with sizes much larger than the individual units. Solid–liquid separation techniques depend more on the size of the aggregates than the size of the dispersed particles. In addition to size and the degree of aggregation, other properties, such as shape, density, internal porosity and surface charge, and suspension concentration are also significant factors in choosing fluid/particle

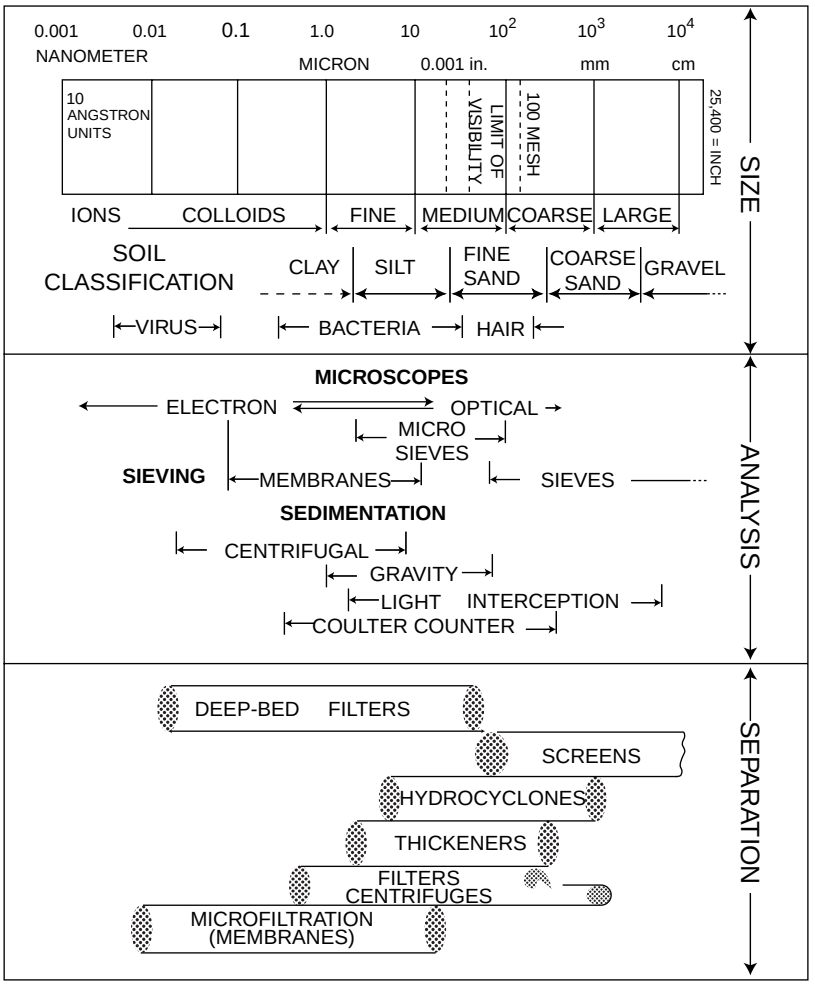

Fig. 2 Relationship of particle size and separation techniques.

separation systems. Characteristics of suspensions or slurries are fundamental to both natural and man-controlled processes.

FUNDAMENTAL OF SLS—FLOW THROUGH POROUS MEDIA

Mechanism of flow through porous media is fundamental in theoretical study of SLS process, such as filtration, thickening, centrifugation, expression, washing, etc. In the early study, with the development of fluid mechanics, interest was focused on flow in capillaries through incompressible sand beds. The beginning of present day theory can be traced to Hagen (1839), Poiseuille (1840), and Darcy (1856).[4]

Darcy's Law

Based on fluid mechanics, extensive theoretical and experimental studies by Poiseuille and Hagen led to a formula for viscous flow through capillaries, which can be written as

$$\frac{dp_L}{dx} = 32\mu\frac{u_L}{D_p^2} \tag{1}$$

where dp_L/dx is the pressure gradient, μ the viscosity, and u_L the average velocity in a tube of diameter D_p. For general viscous or turbulent flow in a circular tube

$$\frac{dp_L}{dx} = f\frac{\rho_L u_L^2}{2D_p} \tag{2}$$

where f is the friction factor of flow through the tube.

Darcy[4] carried on a series of experiments involving the flow of water through sand placed in a vertical iron pipe and found the flow rate to be proportional to the head of pressure, which is called Darcy's law as expressed by the following equation

$$\frac{dp_L}{dx} = \frac{\mu q_L}{K} = \frac{\mu u_L \varepsilon_L}{K} \tag{3}$$

where K is the permeability, m^2, and q_L is the superficial flow rate (volume of fluid per unit area of sand bed per unit time), $m^3/(m^2\,s)$. ε_L is the average porosity of

Table 1 Permeability of various materials

	m^2	$ft.^2$	darcies	m-darcies
Sand bed	E(10)	E(9)	100	100,000
Filter aids	E(13)	E(12)	E(1)	1.0
Clay	E(15)	E(14)	E(3)	0.01

sand bed, and the average pore velocity u_L is related to q and ε_L by

$$q_L = \varepsilon_L u_L \tag{4}$$

Petroleum and geotechnical engineers frequently use a unit of permeability called the *darcy*. One *darcy* approximately equals $10^{-12}\,m^2$. The order of magnitude of the permeability is provided in Table 1.

Basic Filtration Theory

Ruth modified Darcy's law for filtration in the form

$$\frac{dp_L}{dw} = \mu\alpha_w q_L \tag{5}$$

where w is the mass of dry solid deposited per unit area, kg/m^2, and α_w is the specific flow or filtration resistance in the mass basis, m/kg. The mass of dry solids is related to thickness by

$$dw = \rho_s(1 - \varepsilon_L)dx \tag{6}$$

Ruth's equation in mass basis required knowledge of density of solids. To get a better view of cake solids, and cake porosity, volume of cake solids instead of mass is used in Tiller's theory[2,5–7]

$$\frac{dp_L}{d\omega} = \mu\alpha q_L \tag{7}$$

in which ω is the volume of cake solids m^3/m^2, and α is the specific resistance of cake in volume basis, $1/m^2$. Eq. (6) is simplified as

$$d\omega = (1 - \varepsilon_L)dx \tag{8}$$

The volume fraction of solids (solidosity) ε_s is given by

$$\varepsilon_s = 1 - \varepsilon_L = d\omega/dx \tag{9}$$

In Eqs. (3), (5), or (7), the permeability K or specific resistance α_w or α are the key parameters to solve problem of flow through porous media. Many investigators have sought theoretical expressions from flow through incompressible beds by transforming parameters in pipe flow [Eqs. (1) and (2)] to flow through compactible porous media.

Flow Through Compactible Porous Media

Fig. 3 shows a simplified compactible filter cake. Darcy's law and a stress balance involving the accumulated friction drag F_s on the particulate structure (Fig. 3) are used to develop basic theory of flow through compactible porous media.

Assuming the particles are in point contact and the liquid pressure is effective over the entire cross-sectional area A, the force of the liquid at x will be $F_{Lx} = p_L A$. In the absence of measurable momentum change, the total force at the cake surface pA, because of the pump pressure p must be balanced by the force of the liquid, F_{Lx}, and the accumulated frictional stress F_s on the network of solid particles in the cake between x and L, then

$$pA = F_s + p_L A \tag{10}$$

Dividing by A and defining the effective stress as $p_s = F_s/A$ yields

$$p = p_L + p_s \tag{11}$$

where p is constant or a function of time and p_L and p_s are functions of x and t. At constant t,

$$dp_L + dp_s = 0 \tag{12}$$

Eqs. (11) and (12) must be modified if gravitational and centrifugal body forces are involved.

In Darcy's equations [Eqs. (3) and (7)], the permeability K and the specific resistance α are functions of the effective stress p_s in the particulate structure. Replacing dp_L by $-dp_s$ in accord with Eq. (12), and involving both spatial coordinate x and material

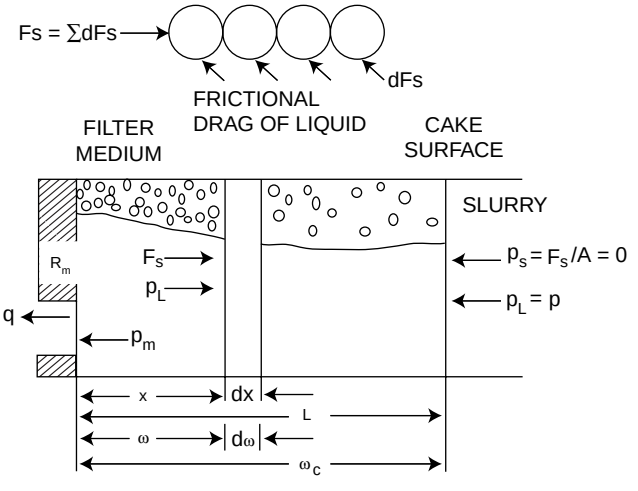

Fig. 3 Diagram of a cake with spatial, x, and material, ω, coordinates.

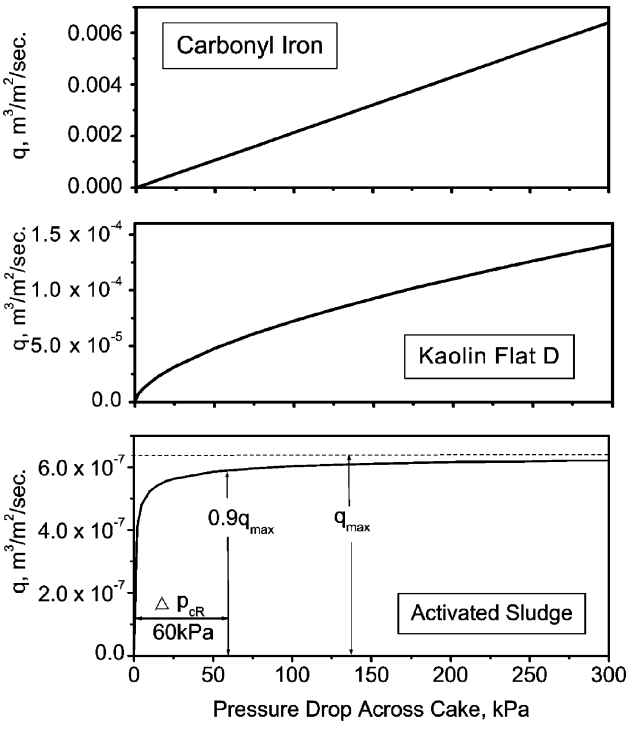

Fig. 4 Variation of q against Δp_c.

coordinate ω (Fig. 4) yields the Darcy's equation as:

$$q = \frac{K}{\mu}\frac{\mathrm{d}p_L}{\mathrm{d}x} = \frac{1}{\mu\alpha}\frac{\mathrm{d}p_L}{\mathrm{d}\omega} = -\frac{K}{\mu}\frac{\mathrm{d}p_s}{\mathrm{d}x} = -\frac{1}{\mu\alpha}\frac{\mathrm{d}p_s}{\mathrm{d}\omega} \tag{13}$$

Empirical constitutive equations relating the local permeability K, specific resistance, and solidosity to the effective stress p_s are

$$(\varepsilon_s/\varepsilon_{so})^{1/\beta} = (\alpha/\alpha_0)^{1/n} = (K/K_0)^{-1/\delta} = 1 + p_s/p_a \tag{14}$$

where α_0, K_0, ε_{so} are null stress values, and p_a is an empirical parameter. We have the relations

$$K\alpha\varepsilon = 1 \quad \text{and} \quad K_0\alpha_0\varepsilon_{so} = 1 \tag{15}$$

Combining the spatial Darcy and constitutive equations and integrating across the cake with limits of $(0, L)$ on x and $(0, \Delta p_c)$ on p_s yields[8]

$$\int_0^L \mu q \mathrm{d}x = \mu q L = \int_0^{\Delta p_c} K_0(1 + p_s/p_a)^{-\delta}\mathrm{d}p_s = \frac{K_0 P_a}{1-\delta}\left[\left(1 + \frac{\Delta p_c}{p_a}\right)^{1-\delta} - 1\right] \tag{16}$$

Repeating the process with the material coordinate form of the Darcy equation leads to

$$\mu q \omega_c = \int_0^{\Delta p_c} \frac{\mathrm{d}p_s}{\alpha_0(1 + p_s/p_a)^n} = \frac{P_a}{\alpha_0(1-n)} \times \left[\left(1 + \frac{\Delta p_c}{p_a}\right)^{1-n} - 1\right] \tag{17}$$

Dividing Eq. (17) by Eq. (16) produces an equation for the average cake solidosity:

$$\frac{\omega_c}{L} = \varepsilon_{sav} = \varepsilon_{so}\left(\frac{1-\delta}{1-n}\right) \times \frac{(1 + \Delta p_c/p_a)^{1-n} - 1}{(1 + \Delta p_c/p_a)^{1-\delta} - 1} = \varepsilon_{so}\left(\frac{\delta - 1}{n - 1}\right)\frac{1 - 1/(1 + \Delta p_c/p_a)^{n-1}}{1 - 1/(1 + \Delta p_c/p_a)^{\delta-1}} \tag{18}$$

where ω_c is the volume of solids/unit area in the entire cake, ε_{sav} the average solidosity in cake, and $1/\alpha_0 K_0$ has been replaced by ε_{so} in accord with Eq. (15). When medium resistance is negligible, the pressure drop across the medium can be neglected; and the pressure drop across the cake Δp_c can be replaced by the pump pressure p.

Table 2 Empirical constitutive parameters for five different materials

Materials	N	δ	ε_{s0}	K_0 (m^2)	p_a (Pa)
Carbonyl iron, grade E[15]	0	0	0.6	1.03E-13	—
Kaolin flat D[12]	0.4	0.52	0.14	2.4E-13	11
Mierlo biosolids[13]	1.83	2.3	0.03	8.3E-12	1000

Activated sludge[14]	1.4	1.66	0.05	5.53E-14	190

Cake Compactibility[8–11]

Classification of cake compactibility is based on values of n and δ as shown in the following table:

Incompressible	$n = 0$	$\delta = 0$
Moderately compactible	$n \approx 0.5$–0.6	$\delta \approx 0.6$–0.8
Highly compactible	$n \approx 0.7$–0.8	$\delta \approx 0.9$–1.0
Super-compactible	$n > 1$	$\delta > 1.0$

The empirical constitutive parameters for five materials with different compactibilities are shown in Table 2. The 9-μm spheres with $n = \delta = 0$, and $K = K_0 =$ constant correspond to an incompressible material. The Kaolin flat D[12] is moderately compactible and the Mierlo biosolids,[13] water treatment residue,[14] activated sludge (AS)[14] with n and δ exceeding unity are classified as super-compactible materials.

For super-compactible cakes, when $\delta > 1.0$ and $n > 1.0$, Eqs. (16)–(18) can be written better, respectively, as

$$q = \left[\frac{K_0 P_a}{\mu L(\delta - 1)}\right]\left[1 - 1/(1 + \Delta p_c/p_a)^{\delta-1}\right] \quad (19)$$

$$q\frac{P_a}{\alpha_0(1 - n)}\left[1 - 1/(1 + \Delta p_c/p_a)^{n-1}\right] \quad (20)$$

$$\varepsilon_{sav} = \varepsilon_{so}\left(\frac{\delta - 1}{n - 1}\right)\frac{1 - 1/(1 + \Delta p_c/p_a)^{n-1}}{1 - 1/(1 + \Delta p_c/p_a)^{\delta-1}} \quad (21)$$

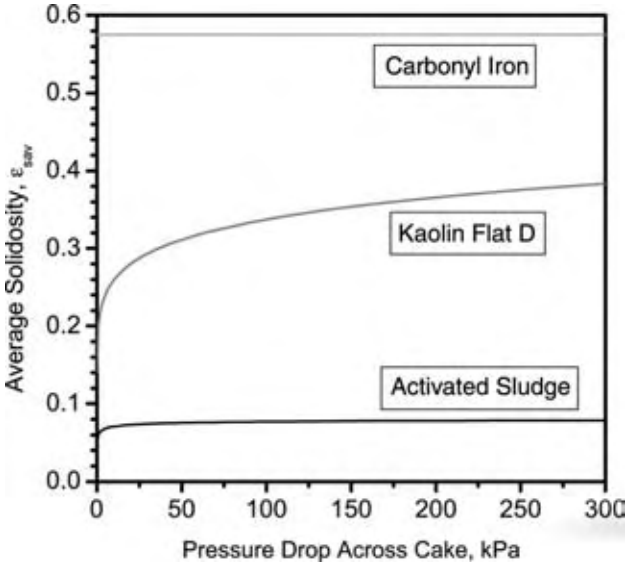

Fig. 5 Variation of ε_{sav} against Δp_c. *(View this art in color at www.dekker.com.)*

As Δp_c increases indefinitely in Eqs. (19)–(21), the term with Δp_c approaches zero, and the flow rate and the average solidosity reach constant. Plots of calculated values of flow rate and average solidosity as functions of pressure drop across cakes with $\omega_c = 0.02\,m^3/m^2$ for carbonyl iron, Kaolin flat D, and AS (in Table 2) are shown in Figs. 4 and 5. Whereas the flow rate q increases linearly with Δp_c for incompressible carbonyl iron, the flow rate increases with a power of Δp_c for compactible kaolin. For super-compactible materials with $n > 1$, and $\delta > 1$, increasing the pressure drop beyond some low value has negligible effect on the flow rate and average solidosity. The behavior of super-compactible materials that has little or no effect of pressure on either the flow rate or the average solidosity, when pressure is beyond some critical value, is unique and different compared to incompressible and moderately compactible materials. Special attention should be paid for filtration design and operation of this type of materials.

SLS SYSTEM[2,5,16]

Four Stages in SLS System

Solid–liquid separation systems generally consist of four stages, which are: 1) pretreatment to increase particle size; 2) solid concentration in thickeners; 3) solid separation in filters and centrifuges; and 4) post-treatment to remove solubles and reduce liquid content. Fig. 6 shows the relationship among these stages.

Solid–liquid suspension pretreatments are employed to improve performance of the following SLS processes. Coagulation and flocculation pretreatment for colloidal systems aim at increasing the effective particle size and particle settling velocity in sedimentation operations. Addition of $FeCl_3$, $Al_2(SO_4)_3$, acidifying, cationic polyelectrolytes, and other methods are used to produce flocculation of suspensions. Aging to allow slow reactions to occur, freezing, and addition of filter aids are representative of other pretreatment methods. It is relatively difficult to determine the best pretreatment practice. Large flocs generally mean a higher chemical cost and a lower capital investment.

In the second stage, the suspension is concentrated in a thickener. Although gravity thickeners dominate the field, cross-flow filter thickeners, hydrocyclones, and electrophoretic devices can be also used. A large fraction of the liquid can be removed economically in thickeners, thereby leading to smaller units in the third stage.

In the third stage, cakes are produced in diverse types of filters and centrifuges. Wet cakes and filtrate or centrate are the products of filters and centrifuges.

The fourth (post-treatment) stage involves further processing of both the filtrate and the wet solids from

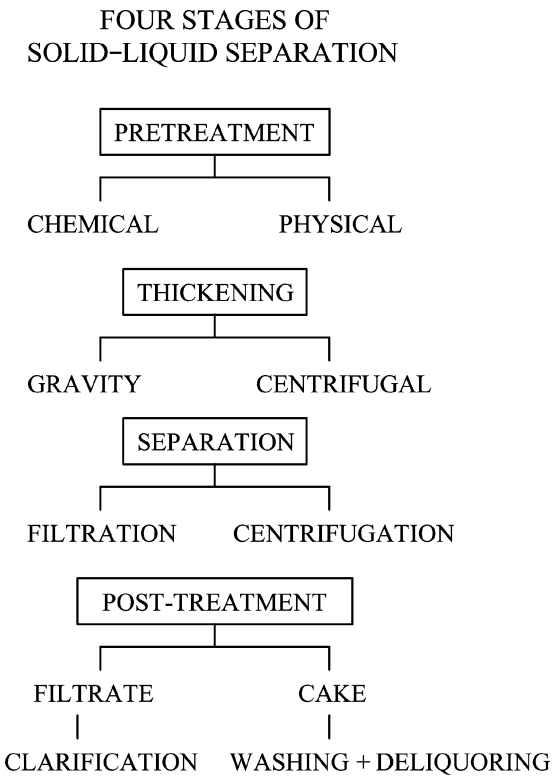

Fig. 6 Stages of solid–liquid separation.

stage 3. A small fraction of colloidal particles which migrate through the pores of both the cake and the medium appear as turbidity in the filtrate or centrate, and require some sort of deep-bed operation for further clarification in some applications. Specifications on the product liquid determine the need for additional processing.

For the cake, if the mother liquor in the slurry contains soluble substances, it may be necessary to wash the cake. Deliquoring is a process after cake washing. Decreasing the liquid content of cakes has become a major objective of many SLS processes. Although the term *dewatering* is widely used, *deliquoring* is more general and covers both aqueous and nonaqueous liquids. Deliquoring operations consist of expression (squeezing), blowing, sucking with a vacuum, and gravitational and centrifugal drainage.

Fractional Liquid (Solid) Recovery of a SLS System

In any separation process, three streams are involved as shown in Fig. 7 for a filter with cake formation, a cross flow filter without cake formation, and a thickener or clarifier based upon gravitational sedimentation. The filter is assumed to have a fixed volume into which slurry is fed and cake is formed as filtrate flows through the filter medium. The fraction of filtrate or overflow, compared to the liquid in the slurry, is called the fractional recovery of liquid, which can be obtained based upon material balance. The fractional recovery for cake filter, cross-flow filter, and thicker or clarifier are as follows:

$$\text{Fractional recovery} = \frac{V}{V_F(1 - \varphi_s)} = \left\{ \begin{array}{l} (1 - \varphi_s/\varepsilon_{sav})/(1 - \varphi_s)\ \text{(Filter)} \\ (1 - \varphi_s/\varphi_{sc})/(1 - \varphi_s)\ \text{(Cross-flow)} \\ (1 - \varphi_s/\varepsilon_{su})/(1 - \varphi_s)\ \text{(Thickener, clarifier)} \end{array} \right\} \tag{22}$$

The fractional removal, which is defined as the fraction of liquid removed in the cake (sediment) or concentrate then becomes

$$\text{Fractional removal} = \frac{\left\{ \begin{array}{l} V_c(1 - \varepsilon_{sav})\text{(Filter)} \\ V_c(1 - \varphi_c)\text{(Cross-flow)} \\ V_c(1 - \varepsilon_{su})\text{(Thickener, clarifier)} \end{array} \right\}}{V_F(1 - \varphi_s)} \tag{23}$$

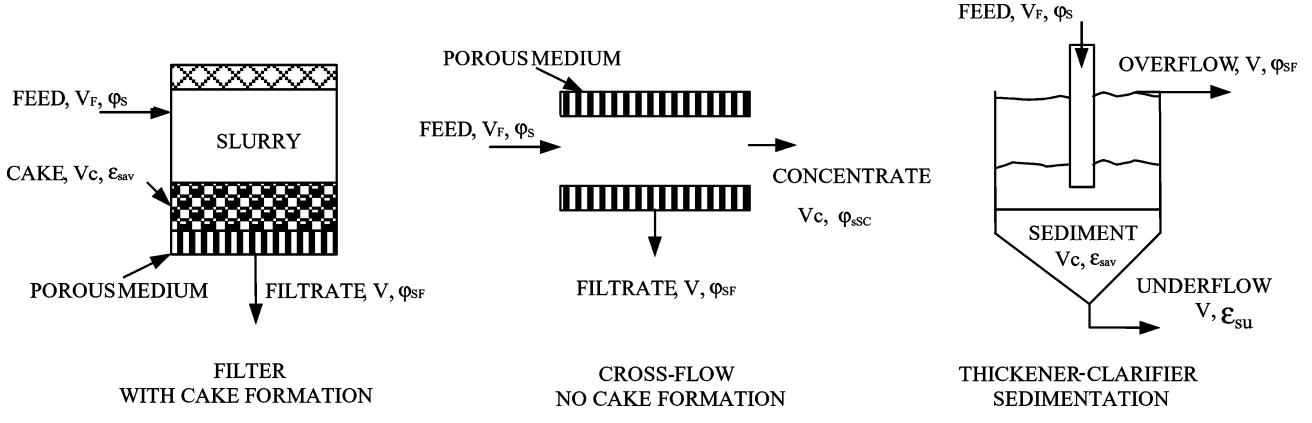

Fig. 7 Three streams involved in SLS systems.

Table 3 Fractional removal of liquid

Example	Stage	Vol.% solids	Void ratio (volume of liquid/ volume of solid)	Liquid removed (volume of liquid/ volume of solid)	Liquid removed (%)	Total liquid removed (%)
Example 1, feed vol.% solids = 1%	Feed	1	99	—	—	—
	Thickener	10	9	90	90.9	90.9
	Filter, centrifuge	25	3	6	6.1	97
	Deliquoring	50	1	2	2.0	99
Example 2, feed vol.% solids = 5%	Feed	5	19	—	—	—
	Thickener	10	9	10	52.6	52.6
	Filter, centrifuge	25	3	6	31.6	84.2
	Deliquoring	50	1	2	10.5	94.7

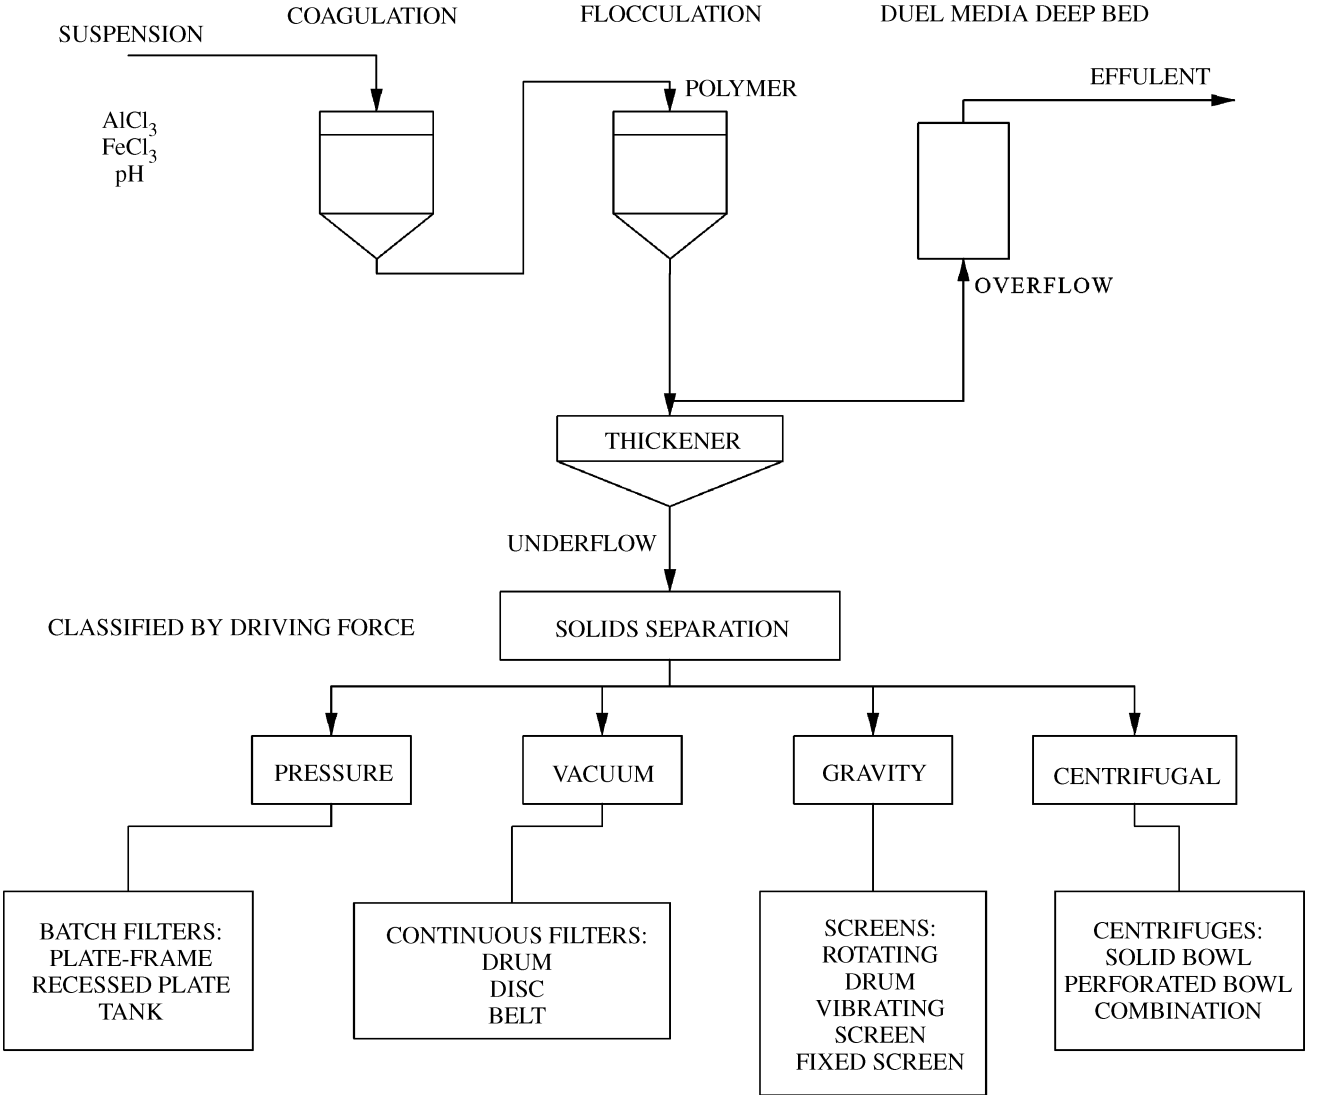

Fig. 8 Equipment used for the four stages of solid–liquid separation.

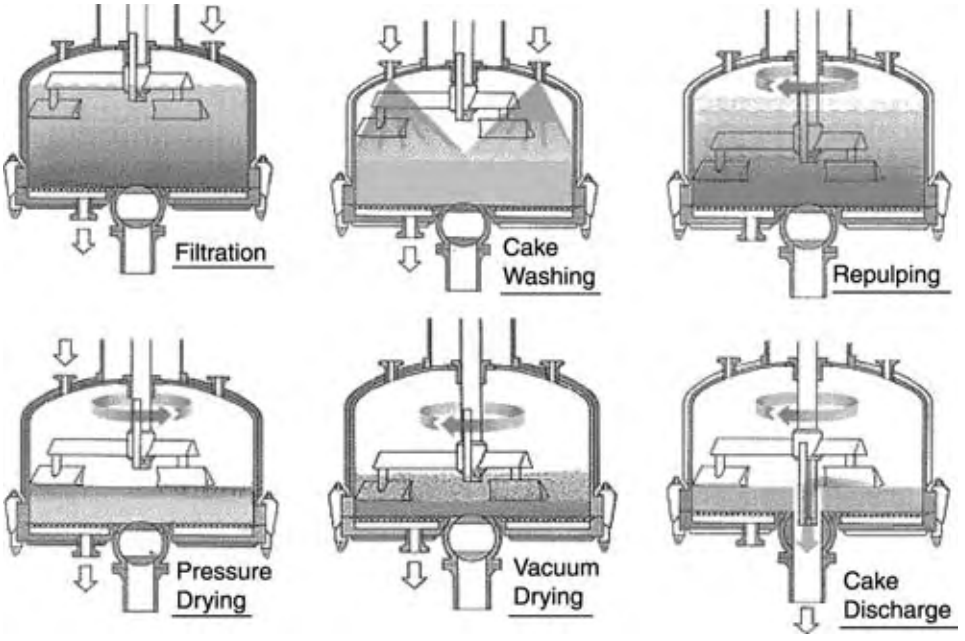

Fig. 9 Operations of nutsche filters. (Courtesy of the Rosenmund Guedu Group.) *(View this art in color at www.dekker.com.)*

Eqs. (22) and (23) are equivalent as "fractional recovery = 1 − fractional removal."

Liquid Recovery of Different Stages of SLS

It is instructive to consider the fraction of liquid removed in the second through the fourth stages shown in Fig. 6. Two examples with feeds containing 1.0 and 5.0% solids (volume), and going through sedimentation, filtration, and deliquoring will be considered. It is assumed that 1) the thickener produces a 10% by volume slurry; 2) a cake containing 25% by volume; and 3) the deliquored cake contains 50% by volume after expression, blowing with gas, or spinning in a centrifuge. To facilitate comparisons, the concentrations have been converted to void ratios. The results are shown in Table 3.

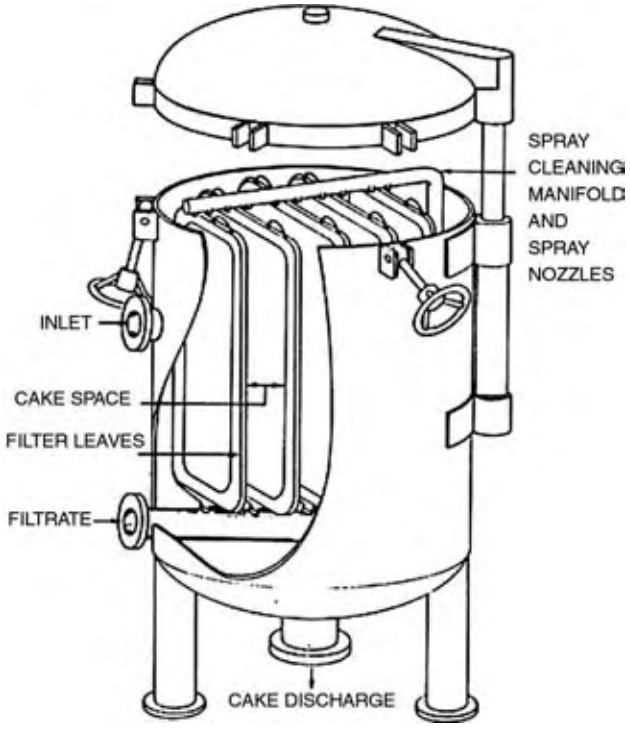

Fig. 10 Vertical tank-vertical leaf filter.

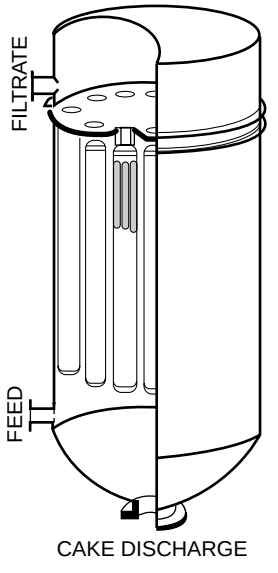

Fig. 11 Candle filter. *(View this art in color at www.dekker.com.)*

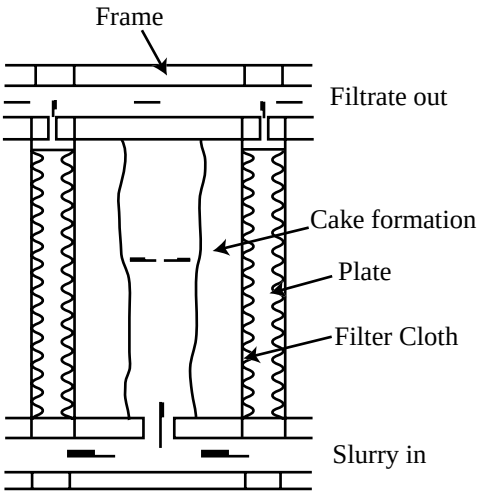

Fig. 12 Schematic of a plate-and-frame filter chamber.

From Table 3, the preponderance of liquid removed in the thickener is apparent. As slurries become dilute, larger fractions of the liquid are removed in the thickener operation. Small changes in the concentration of the stream from the thickener can have a large effect on the size of the filter or centrifuge. If the thickener effluent could be increased to 11% solids, the corresponding void ratio would be $89/11 = 8.09$. The amount of liquid to be removed in the filter or centrifuge would change from 6 (9–3) to 5.09 (8.09–3) volumes of liquid per unit volume of solid. The size of the filter or centrifuge could then be reduced about 15%.

Recognizing the importance of removing as much liquid as possible in the thickener, John Chandler pioneered a process in which the height of the red mud in the thickener was increased from the usual value of 1.0 to 10–15 m. The additional stress produced by the super-thick bed led to a much higher underflow concentrations. In some cases, the filter was actually eliminated.

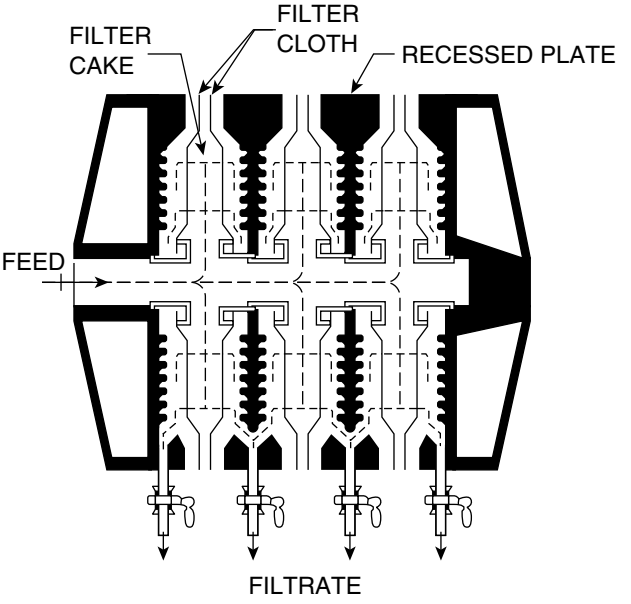

Fig. 14 The recessed plate provides space for cakes and eliminates the need for frames.

SLS EQUIPMENT[2,5,16]

An overview of some of the major types of equipment in relation to the four stages of SLS is provided in Fig. 8. After inorganic salts and polymers are used in the pretreatment, the resulting slurry is fed to a gravity thickener. The overflow from the thickener passes through a deep-bed for removal of fine particles. The underflow goes to the solids separation operations that are classified according to the driving force, i.e., gravity, vacuum, pressure, or centrifugal.

Gravity separation involving large particles is usually accomplished with screens that may be stationary, vibrating, or rotating cylinders. Large screens have slot openings greater than 0.5 in and small screens have openings of less than 0.5 in. Slot openings in rotary

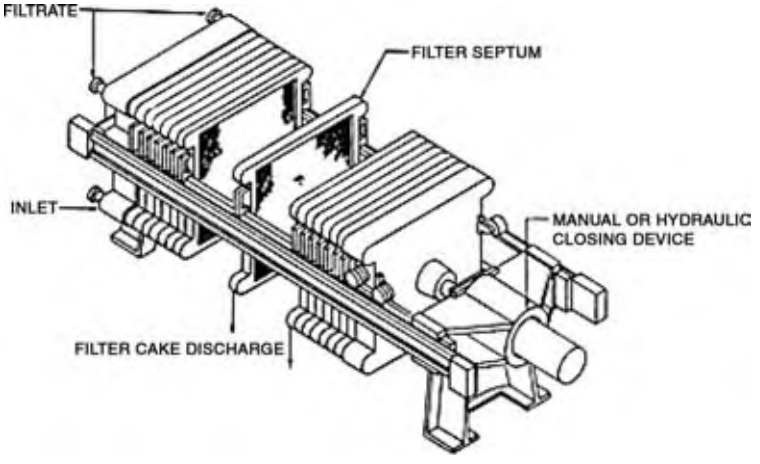

Fig. 13 Plate-and-frame filter.

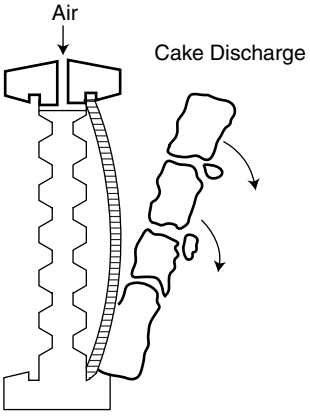

Fig. 15 Cake discharge in a membrane filter press.

screens run from 0.01 to 0.1 in. (254–2540 μm). Microscreens frequently fall in the 15–60 μm range.

In vacuum filtration, the driving force (~20 in Hg = 10 psi, 1 psi = 6895 Pa) is slightly higher than the gravity. The vacuum operation is frequently tied with continuous equipment such as drum, disc or belt filters, in which cake is removed continuously. As the permeability of cakes diminishes, pressure becomes an important element in producing a satisfactory flow rate.

Pressure filters are operated in the range of 30–60 psi and some times up to 100 psi. In contrast to vacuum filters, pressure filters normally operate in batch mode. The rate of cake buildup in batch operation is slow in comparison with continuous drum filters. The time required to dump the cake and clean and reassemble a pressure filter is called "dead time." It is a significant element in determining the capacity of a pressure filter.

In addition to vacuum and pressure, centrifugal forces are also used to increase driving force in separation of particles from liquids.

Solid–liquid separation equipment can also be classified according to principle of each unit operation. A list of equipment based on operating principle is given as follows and will be discussed.

- Batch pressure filters.
  a. Pressure vessel filters.
  b. Filter press.
- Continuous filters.
  a. Rotary drum and disk filters.
  b. Horizontal belt filters.
  c. Indexing belt filters.
- Deep-bed filters.
- Croos-flow filters.
- Membrane filters.
- Thickeners and clarifiers.
- Centrifuges.
- Hydrocyclones.
- Expression equipment.

Batch Pressure Filters[2,5]

Pressure filters are usually operated batch-wise. The batch pressure filters can be classified as tank (pressure vessel) filters or presses. Tank filters have different types of filter elements in pressure vessels. Presses consist of a series of filter surfaces (plates). The elements are mounted on a frame and are pressed together mechanically.

Tank filters

Tank (pressure vessel) filters are useful where noxious vapors are involved, and a completely closed system is desirable. Pressure vessel filters are divided into the following types:

1. Pressure nutsche filters (Fig. 9).
2. Leaf filters (Fig. 10).
3. Candle or tubular filters (Fig. 11).

Pressure Nutsche. Nutsche filters contain a single horizontal filtering surface in a pressure vessel. Gas is used to provide pressure for filtration. Because of the limited filtration area, they are often operated with thick cakes and are suitable for small batches. Automatic nutsches are available to perform reaction, crystallization, filtration, reslurry washing, drying, and cake discharging in the same vessel. Operations of Nutsche filter are shown in Fig. 9.

Leaf Filter. In comparison to nutsche filters, leaf filters provide more filtration area in the same volume of pressure vessel. They are more suitable for handling

Table 4 Brine sludge dewatering—Comparison of recessed press and membrane filter

Press type	Cake % solids	Cake structure	Cake thickness (mm)	Cake compr. strength (tpf)	Average rate (pph/ft2)
100 psig std. recess	59	Soft core	30	3.5	1.70
25 psig membrane	67	Very firm	25	>5.0	2.04

(From Ref. [20].)

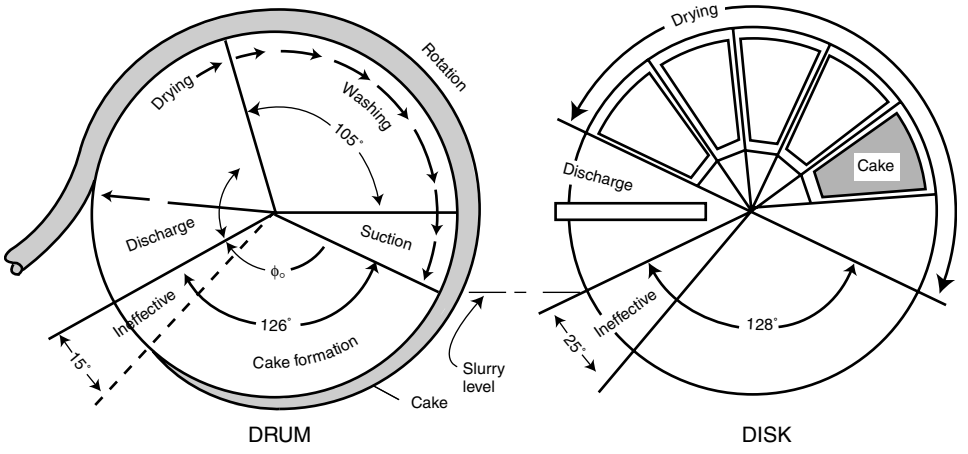

Fig. 16 Cycles for disc and drum filters show cake formation, suction, washing, drainage, and discharge areas. (From Ref.[21].)

larger quantities of slurry. Fig. 10 shows a vertical tank–vertical leaves filter. In general, cake can be discharged more easily from vertical leaf-type filters. During cake formation, to prevent dropping cake, the thickness is normally restricted to 3.5–4.0 cm. A space of about 2.0 cm must be maintained between the cakes to prevent arching and facilitate discharge.

Candle Filter.[17] Tubular filter elements contained in a matching vessel are known as candle filters. The actual filter vessel may contain one or more filter candles, and may be used as pressure or suction filters for the filtration of liquids and gases. A particular advantage offered is that candles may readily be changed to different types, to suit particular requirements or applications. A typical candle filter[18] is shown in Fig. 11. Materials of candles are selected to fit a particular process.

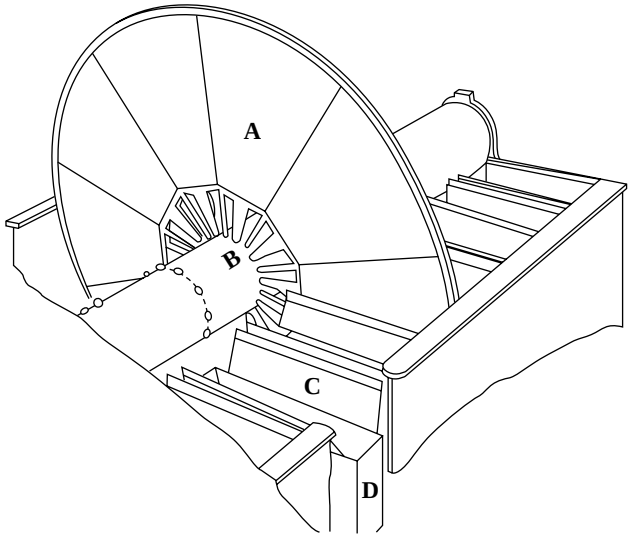

Fig. 17 Isometric view of disc filter.

Filter presses

The filter presses play a significant role in the SLS industry, where it is unnecessary to operate in a closed atmosphere. The most typical filter presses is the plate-and-frame filter press. The recessed filter press and the membrane filter press are revised, based on the plate-and-frame filter press.

Plate-and-Frame Filter Press. The major elements of the plate-and-frame version of the press are illustrated in Fig. 12. Feed to a plate-and-frame press is generally through openings at the bottom to reduce sedimenting tendencies. A filter medium (usually cloth or paper) placed over a grooved plate serves as the support for the cake, which is deposited in an adjoining frame. Plates and frames are alternated as shown in Fig. 13. The medium serves as a gasket when mechanical closure is affected. Where washing is desired, every other plate in a plate-and-frame press is constructed, so that liquid can be passed from one plate through the cake contained in the frame to the opposite plate. Thus, the wash passes through two cakes.

Recessed Plate Press.[19] Recessed plate press shown in Fig. 14 does not require a frame. The edges of the plate are extended outward leaving a space for a cake.

Membrane Filter Press. Membrane filter presses use impermeable, flexible membranes, or diaphragms to squeeze the cake for further cake deliquoring, as shown in Fig. 15. This type of filter provides less dead time in a filtration cycle, better washing, and drier cake compared to traditional plate-and-frame and recessed plate filter presses. A comparison of a recessed press operated at 100 psi and a membrane filter operated at 25 psi for sludge dewatering is shown in Table 4.[20]

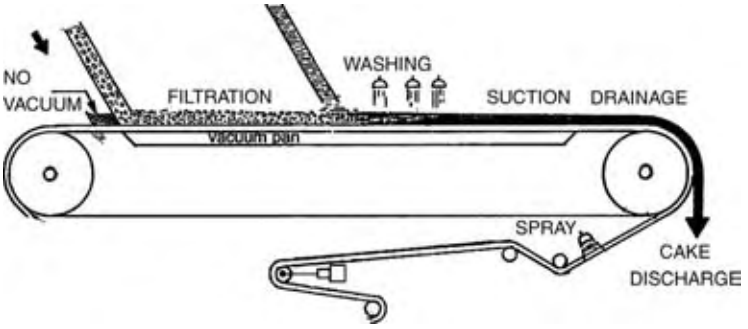

Fig. 18 Horizontal belt filter illustrating filtration, washing, and drainage stages.

Firmer cake with higher % cake solids, and faster filtrate rate were obtained for the membrane filter.

Continuous Filters[21]

Continuous filters work best on medium sized particles in the range of 5–50 μm. The larger particles generally encountered exert minor capillary forces, and cake drying or ''drainage'' can be accomplished by sucking air through the cakes under vacuum. Continuous filters are normally used for materials that are relatively concentrated and easy to filter with a cake buildup rate at cm/min. Types of continuous filter are characterized by different type of traveling filter surfaces. Rotary drum (Fig. 16), disc (Figs. 16 and 17), and horizontal belt filters (Fig. 18) will be discussed.

With drum filters (Fig. 16), the feed is below the filter surface; the slurry flows upward; and the cake faces downward. Disc filters (Figs. 16 and 17) have a vertical surface. Operations of drum and disk filters with different cycles including cake formation, washing, drying, and cake discharge are shown in Fig. 16.

A horizontal belt filter is shown in Fig. 18. It occupies more space than drum and disc filters for the same filter area. When settling is acute, it must be used in preference to the drum the disc filter. Unlike the drum and disk filters with strict requirements on cake formation, washing, drainage, and discharge time, the various stages on the horizontal filter are completely adjustable, and the entire filter surface can be utilized in contrast to the limitations of the disc and drum types.

Deep-Bed Filter

Deep-bed filters are employed for slurries with very dilute concentration less than 1000 ppm (parts per million by weight). The deep-bed has pores in which the fine particles are caught. Capture of particles in deep-beds depends upon transport mechanisms that carry the particles to the surface of the medium. As the deposit builds up, the permeability ultimately drops to a point where the bed must be regenerated or discarded. The deep beds are in the form of granular media (sand, crushed anthracite coal, garnet, usually backwashable)

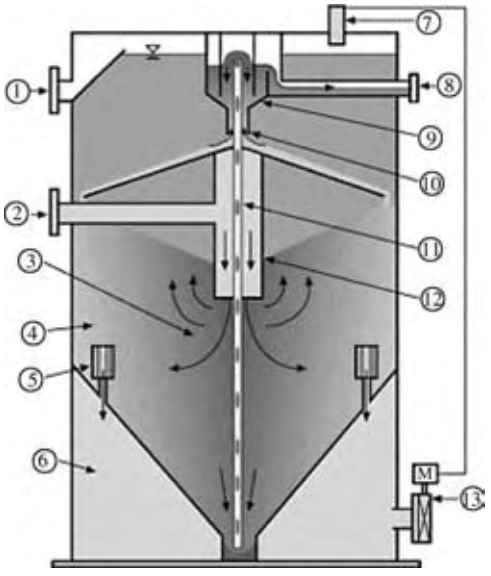

Fig. 19 Automatic backwash sand filter (Centra-flo™): 1, Overflow; 2, filter influent; 3, coarse media; 4, fine media; 5, filtrate nozzles; 6, filtrate chamber; 7, level controller; 8, filter reject; 9, washbox; 10, counter-current washer; 11, airlift; 12, central feed chamber. *(View this art in color at www.dekker.com.)*

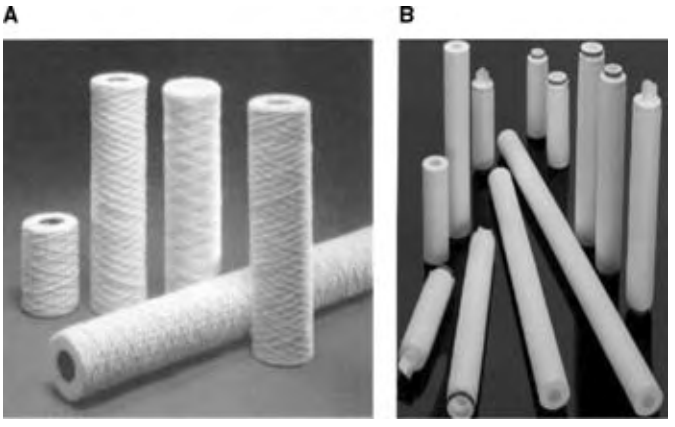

Fig. 21 Cartridge filters: (A) Wound cartridge and (B) melt blown cartridges. (From Ref.[22].) *(View this art in color at www.dekker.com.)*

(Figs. 1D and 19) or cartridges (usually disposable) (Figs. 20 and 21), which are cylinders containing a variety of materials for trapping the particles. An example of the wide application of cartridge filters includes removing particles from lubricating oils in automobiles and trucks.

Cross-Flow Filters

In cross-flow filtration (Fig. 1B) or delayed cake filtration, the slurry flows parallel to the cake surface with sufficient velocity to prevent partially or entirely the deposition of cake. It is used successfully to increase flow rate in membrane filtration. It is also employed for concentrating and recovering very fine particles in dilute suspensions when deep-bed or cake filtration would not applicable.

There are basically two types of cross-flow filter. One is without rotating element in which slurry is usually pumped into the filter in the direction parallel to the filter media to produce a cross-flow. Another type of cross-flow filter is equipped with rotating elements, such as rotary filter press with agitators or turbines attached to a rotary shaft as shown in Fig. 22.[23]

Membrane Filters[22]

Membrane separation has advantages of low energy consumption, effective multiple fine particle removal, and small waste stream. Developing of high performance and low cost membranes is a major factor in hindering the advances of membrane processes.

Based on the size of particles separated, membrane filtrations are categorized as MF (0.1–2.0 μm), UF (0.005–0.1 μm), NF (0.0005–0.005 μm) and RO (<0.5 nm). In UF and NF, a term called molecular weight cut off (MWCO—molecules with molecular weight greater than the MWCO will be rejected by this membrane) is also used for classification.

Membrane filters include flat sheet, spiral wound, and hollow fiber (Fig. 23). In addition, there are also rotating discs, annual gap, and vibrating disc systems for membrane cross-flow filtration.

Thickeners and Clarifiers[2,5,12]

Clarifiers are employed to remove small quantities of solids where the liquids are the main product.

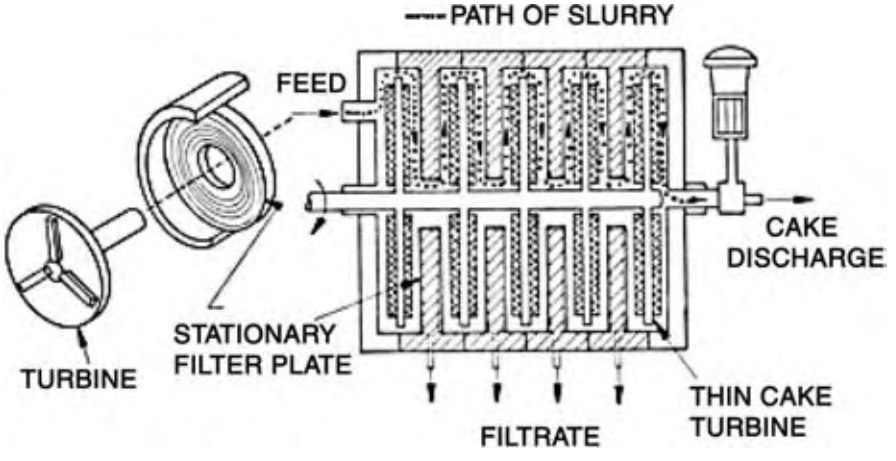

Fig. 22 Rotary filter press.

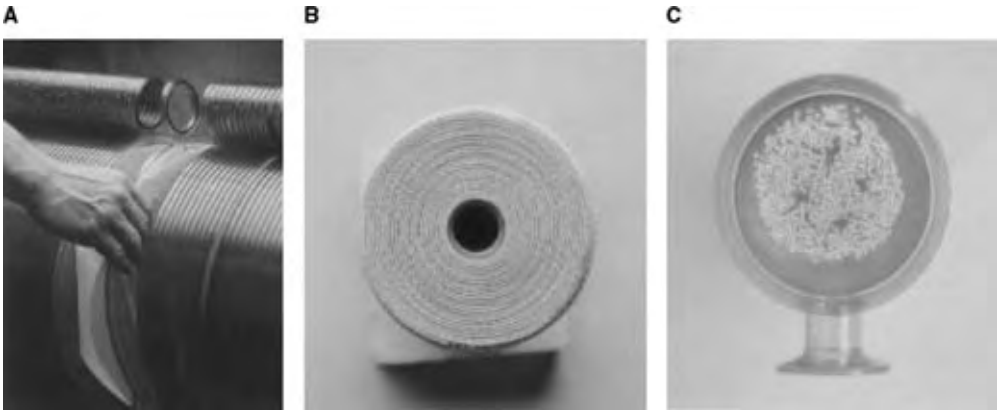

Fig. 23 Membrane filters: (A) Flat sheet; (B) spiral; (C) hollow fiber. (From Ref.[22].) *(View this art in color at www.dekker.com.)*

Thickeners are used to concentrate dilute suspensions in preparation for further separation in filters and centrifuges. As previously shown in Table 3, thickeners frequently lead to removal of a large fraction of the liquid in a slurry. A schematic continuous thickener is shown in Fig. 24. In the figure, a clear liquid overflows the top while a thickened sediment flows out of the bottom as underflow. Thickeners are widely used in fields such as wastewater, aluminum, coal, pulp and paper, cement, and sugar.

Centrifuges[2,5]

Centrifuges are operated as classifiers, sedimentors, and filters. Centrifugal classification and sedimentation are carried out in solid bowl units (frequently called decanters) as illustrated in Fig. 25. Most decanters are operated on a continuous basis. The slurry enters as shown in Fig. 25. The solids settle out and are conveyed toward discharge by a scroll, which is turning at a lower speed than the bowl. The clear liquid moves to the left and flows over a weir and is removed as "centrate."

In filtering centrifuges (Fig. 26), the solids settle out as in the decanter. However, the liquid flows in the same direction and out through the perforated bowl. As the liquid flows in the same direction as the solids, it increases the rate of deposition. In addition, as the liquid flows through the cake, the frictional effect results in sharply increased stresses on the cake. At low speeds, the stress because of the frictional flow may be larger than the centrifugal body forces.[24]

Hydrocyclones

The hydrocyclone is a type of fixed wall sedimenting centrifuge shown in Fig. 27. Compared with a sedimenting centrifuge (Fig. 25) in which the liquid is driven by the rotation of the inner wall of the centrifuge, the driving force in hydrocyclone is obtained by pumping the liquid tangentially into the upper

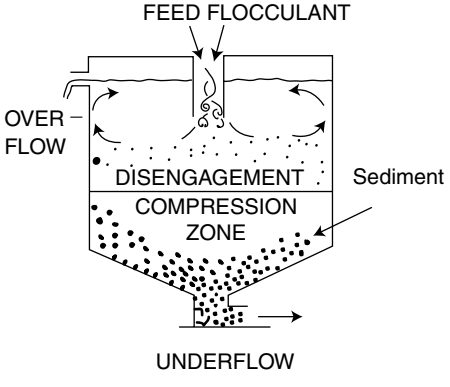

Fig. 24 A typical thickener.

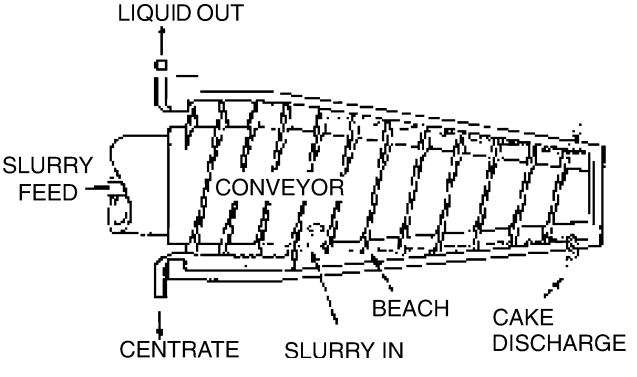

Fig. 25 Sedimenting centrifuge.

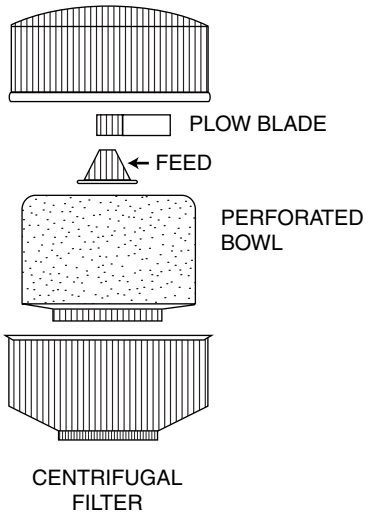

Fig. 26 Filtering centrifuge.

cylindrical section of the equipment. The total separation efficiency E_T is[22]

$$E_T = \frac{\text{Total solids in underflow}}{\text{Total solids in feed}} = \frac{U\varphi_{su}}{Q\varphi_{sF}} = \frac{U\varphi_{su}}{U\varphi_{su} + O\varphi_{so}} = \frac{Q\varphi_{sF} - O\varphi_{so}}{Q\varphi_{sF}} \quad (24)$$

where Q is the feed volumetric flow rate (m^3/s), U the underflow volumetric flow rate (m^3/s), O the overflow volumetric flow rate (m^3/s), φ_{sF} the solid concentration in the feed (volume fraction), φ_{su} the solid concentration in the underflow (volume fraction), and φ_{so} the solid concentration in the overflow (volume fraction).

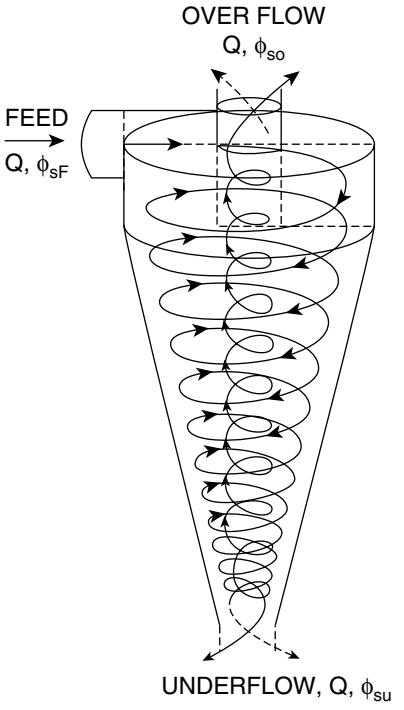

Fig. 27 Hydrocyclone.

Expression Equipment

Decreasing the liquid content of cakes has become a major objective of many SLS processes. Although the term ''dewatering'' is widely used, ''deliquoring'' is more general and covers both aqueous and

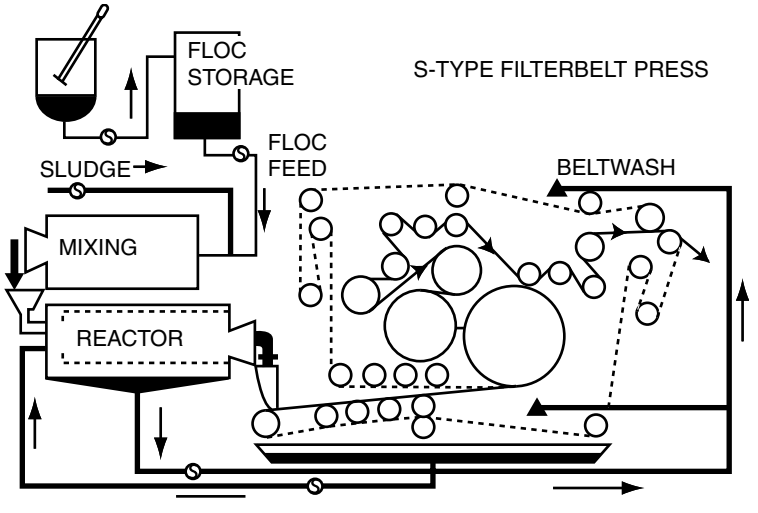

Fig. 28 S-type filter belt press.

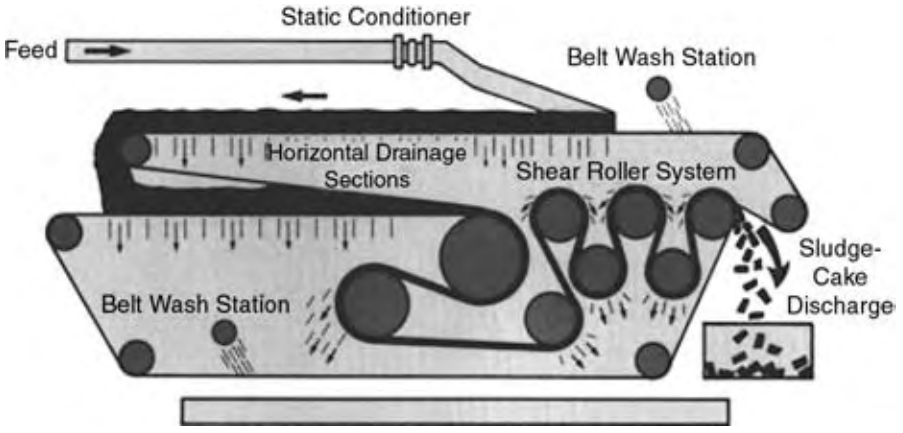

Fig. 29 Klampress belt press. (Courtesy of Ashbrook.)

nonaqueous liquids. Deliquoring operations consist of expression (squeezing), blowing, sucking with a vacuum, and gravitational and centrifugal drainage.

Fig. 28 shows the mechanically deliquoring of flocculated, fragile, and high porosity cakes by belt press filter. In the process, large flocs settle out rapidly on the porous belt, and the liquid flows through quickly. Sedimentation and filtration are accomplished quickly, but at a cost of producing a very soupy cake. Expression (the fourth stage of Fig. 5) of the liquid from the cake is essential. It is accomplished by the squeezing action of the two moving belts.

Fig. 29 shows a Klampress belt press manufactured by Ashbrook. The Klampress utilizes a combination of gravity and mechanical pressure to process porous compactible cakes. It is the type of equipment used for deliquoring of AS at many wastewater treatment plants.

SLS SYSTEM DESIGN[25–29]

Philosophy of SLS Design, Operation and Modification[25]

The facts governing the philosophy of design, operation, and modification of SLS system are as follows:

1. Many combinations of SLS equipment are capable of doing a specified job, and there are number of satisfactory and alternative choices of flocculants, filter aids, media, and filters or centrifuges.
2. The complexity of SLS phenomena frequently renders mathematical analysis inadequate. Testing and experience play predominant roles in SLS design.
3. Almost all solid–liquid systems change with time and treatment, and parameters in SLS design such as settling rate, permeability and porosity depend upon history of slurry. Therefore, continuous monitoring of operation and characteristics of suspension system is important.
4. For scale-up, certain tests, such as test for settling rate to evaluate flocculation, design of thickeners, and pressure-bomb or vacuum-leaf experiments to determine the rate of cake buildup, are easy to perform on a bench scale. On the other hand, for design of centrifuges, small-scale test results are not sufficient, and pilot or full-scale units are necessary for final design.

Selection of SLS equipment

Specifications

In approaching the initial selection of equipment, flows to be processed, filtrate clarity, and cake liquid, and solute contents must first be fixed. The product may be the solids, liquid, or both. Purchas[26] provided a conceptual model for initial specifications as illustrated in Fig. 30.

Comparative performance profiles

Fitch[27] discussed the general problem of matching process specifications to SLS equipment and the necessity of considering trade-offs involving such items as filtrate clarity, cake dryness, reliability, maintenance, versatility, and cost. A comparative equipment profile of the principle types of SLS is given in Table 5. A wide range of information about power, space, and costs as well as equipment performance parameters are provided in the table.

Rate of cake buildup

The rate of cake thickness growth is perhaps the single most important guide in selecting equipment. Growth rate determines whether pressure, vacuum or gravity filters, or solid or perforated bowl centrifuges are indicated. Initial choice of equipment is suggested in Table 6 as an approximate guide only.

The basic ideas of the table can be summarized as follows:

1. Rapid settling slurries lend themselves to gravity separation and screen-bowl centrifugation.
2. Medium speed filtering materials are suited to vacuum equipment and peeler centrifuges.
3. Slow filtering materials require pressure equipment or sedimenting centrifuges.
4. Dilute materials that result in high resistance cakes are generally best handled in deep-bed filters or mixed with filter aids.

Table 6 Slurry characteristics

Type	Buildup	Characteristics
Rapid filtering	CM/SEC	High concentration Fast setting Hard to suspend
Medium filtering	0.05–5.0 CM/HR	Forms cake easily Can be suspended Medium concentration
Slow filtering	0.1–5.0 CM/HR	Low concentration High resistance May blind media
Clarification	No cake	Very high resistance Less than 1000 ppm

(From Ref.[25].)

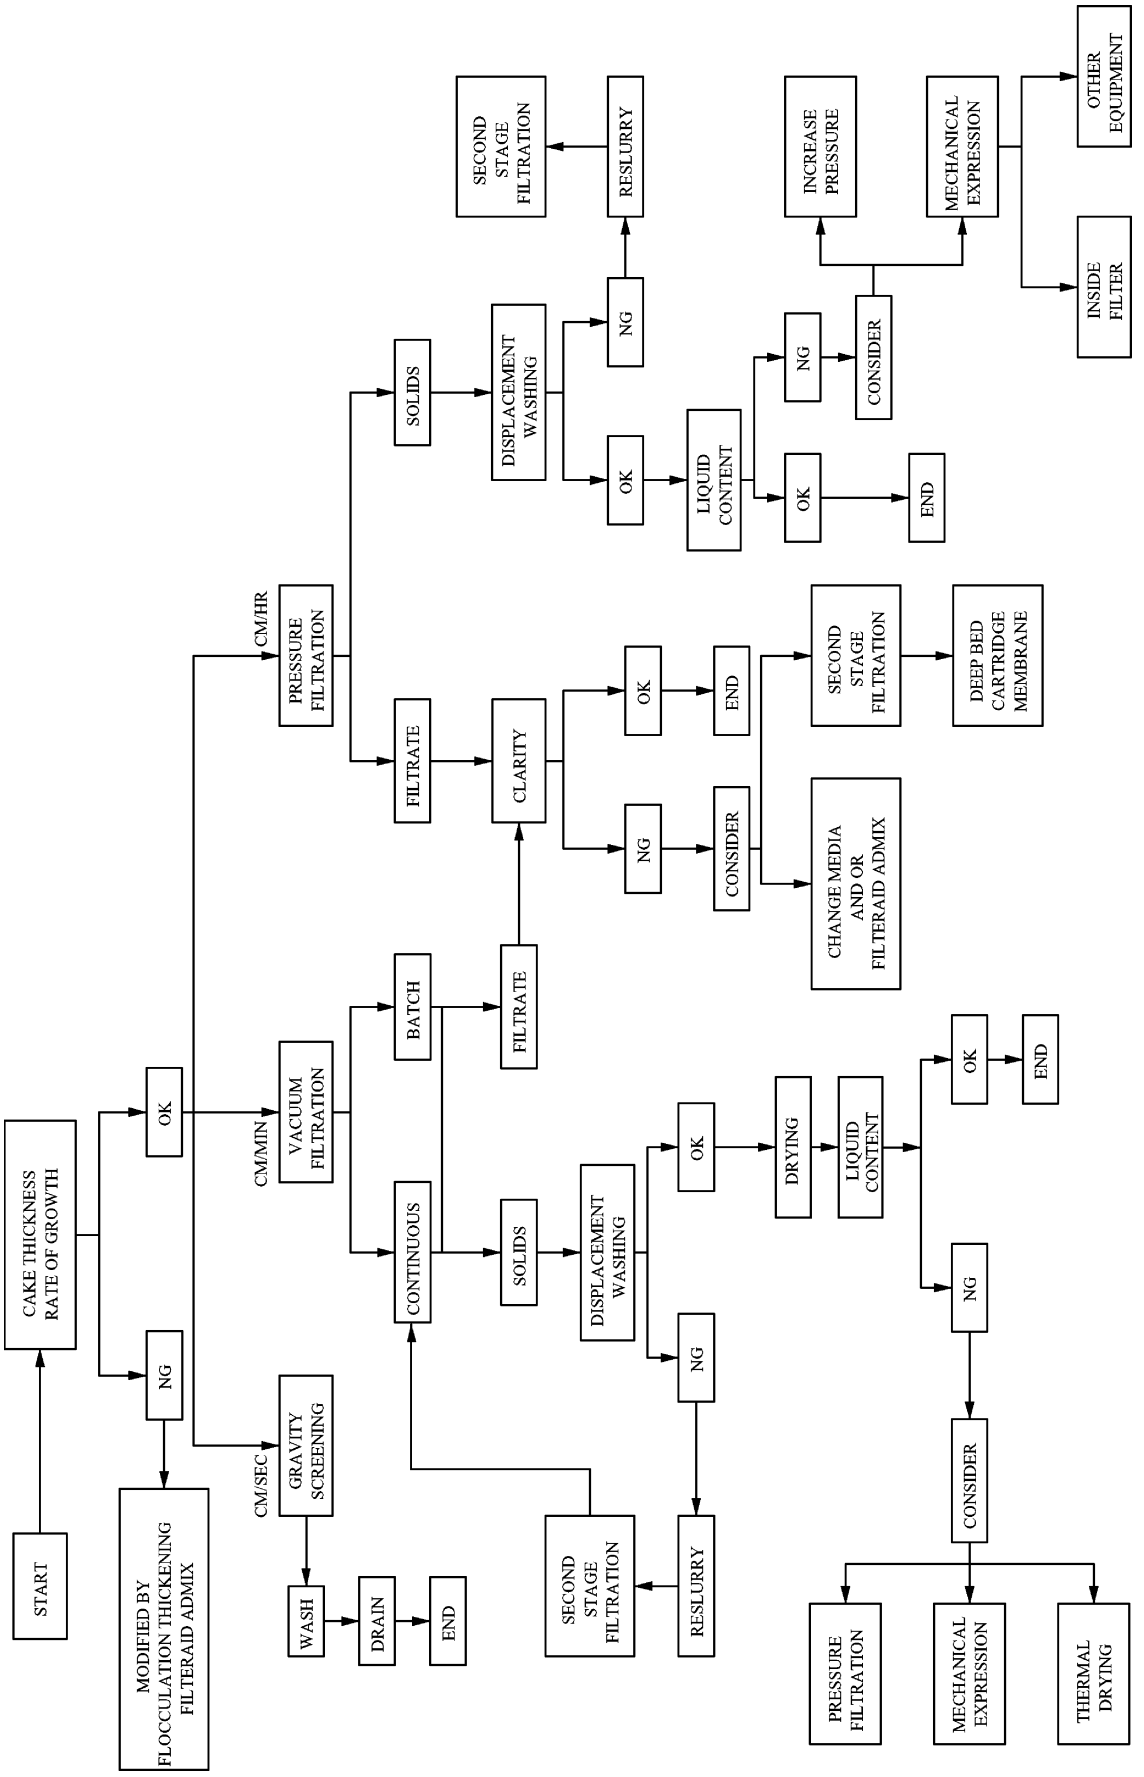

Fig. 31 Decision network for SLS system design. (From Ref.[25].)

Decision Network for Design of SLS Systems

A series of decisions must be made concerning the following factors in designing new or revising existing SLS systems:

1. Rate of cake buildup.
2. Filtrate clarity.
3. Solubles in cake.
4. Liquid content of cake.

In Fig. 31, a framework for making decisions at different junctures is provided. At the first step, a decision must be made as to whether or not pretreatment may increase the rate of filtration and enable the process to progress from pressure toward gravity filtration. Once a particular filter has been chosen, attention then focuses on the filtrate and wet cake. If the clarity is not satisfactory, a second stage deep-bed filter (cartridge or granular bed) may be utilized. Alternatively a tighter medium or a change in filter aid quality or quantity might provide a solution.

CONCLUSIONS

Solid–liquid separations are important operations in chemical engineering ranging from upstream raw material purification, to downstream product separation and waste managements. They are usually low cost, and low energy consumption. A successful operation of a SLS system upstream a major chemical engineering unit such as a catalyst bed will help to improve the efficiency the catalyst, and decrease overall cost of the whole process.

Particle size, shape, inter-particle forces, zeta potential, liquid surfactant phenomena, and liquid viscosity are important characteristics of a solid–liquid suspending system. Mechanism of flow through porous medium is fundamental to theories of sedimentation, filtration, centrifugation, and expression operations. Most solid–liquid materials are compactible. Unique and strange behavior of pressure filtration of compactible materials has been identified. More attention should be paid for separation of those materials.

Solid–liquid separation systems generally consist of four stages including pretreatment, solid concentration in thickeners, solid separation in filters or centrifuges, and post-treatment by expression and washing operations. There are different types of SLS equipment served for different functions in relation to the four stages. Product specification, characteristics of solid–liquid suspension, solid settling velocity, rate of cake buildup should be considered in equipment selection and SLS system design. Many combination of SLS equipment are capable of doing a specific job. Equipment cost, operating cost, separation efficiency, and separation specification should be considered in design and optimization of a SLS system and selection of flocculants, filter aids, filter medium, and separation equipments.

Solvent Refining Processes

Roland H. Heck
Princeton University, Princeton, New Jersey, U.S.A.

INTRODUCTION

Solvent refining can be a very effective method for separating chemicals or groups of chemicals based on their solubility or chemical affinity. As such, solvent refining processes are among the group broadly known as separation processes. For separation processes in general, the desired component or components of a feed are selectively concentrated in one phase, while the less desirable components concentrate in a second phase. In solvent refining, the solvent must be separated from the products so that the products can be recovered and the solvent can be recycled. A major issue with any solvent refining process is finding a relatively inexpensive solvent that can affect the desired separation and then can itself be recycled cost effectively. Although solvent refining is used in a number of industrial applications, the largest volume and perhaps the most economically important applications are in petroleum refining where they are used in the production of high quality lubricants and for removal of light aromatics from refinery steams. Accordingly, these processes will be the main focus of discussion that follows.

BACKGROUND

The most commonly employed and oldest of the separation processes is fractional distillation, a process in which compounds are separated based on their dissimilar volatility or boiling points. In fractional distillation, components are fractionated between the liquid and the gas phase, with the lighter, lower boiling components preferentially concentrating in the gas phase and the heavier, higher boiling components concentrating in the liquid phase. Fractional distillation equipment normally employs a cylindrical column in which the phases are separated and remixed a number of times as they move vertically through the column. It is important that the phases remix and separate a number of times in the column so that the phases are enriched in their desired component as they move toward the end of the column.

Solvent extraction is analogous to fractionation, except that two immiscible liquid phase are employed instead of gas and liquid phases. Extraction equipment usually involved a vertical cylindrical vessel in which the lower density liquid phase rises up the column, while the high density liquid phase moves down the column. These phases are remixed and resettled several times as they pass through the column, with the desired component concentrating toward one end of the column and the undesired component concentrating in the other end. Understanding the physical principles and design methodology of separation processes has long been the parlance of chemical engineers, and their textbooks on separation processes teach the mathematical and graphical analysis of both fractional distillation and extraction in an analogous fashion.[1]

Perhaps the earliest recorded attempt at solvent processing occurred in Vega, Rumania in 1909 where a process attributed to Erdeleanu was developed to reduce the smoke in flames produced when burning kerosene derived from Rumanian crude oils.[2] The solvent of choice in this operation was liquid sulfur dioxide. The first commercial application of this process was in Rouen, France in 1911.

Development efforts aimed at using solvent refining to improve the quality of lubricating oils in a manner similar to that of Erdeleanu soon followed.[3,4] Solvent dewaxing, solvent deasphalting, and solvent extraction processes to improve the cold flow properties, viscosity index, and oxidative stability of lube oils were commercialized in the 1930s and 1940s.

Efforts to identify better solvents and process configurations for solvent refining continue to this day; however, in recent years even more effort has been devoted to finding catalytic or membrane-based processes that could potentially replace the relatively expensive solvent-refining processes. Catalytic processes invariably involve hydroprocessing either to isomerize or crack linear alkanes and improve the cold flow properties, or to hydrocrack to selectively remove aromatics.[5] The literature on membrane processes to displace solvent refining is sparse;[6] however, this area holds the most promise if suitable membranes can be developed. Although a search for more cost-effective processes to replace solvent refining will continue, it is doubtful that they will displace solvent refining for several decades, even if successful.

The important commercial solvent-refining processes are covered every other year in a special Refining Handbook which appears in a monthly issue of

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120038527

Hydrocarbon Processing. In this handbook many licensors of currently available processes present a description of their process along with operating conditions and yields. Numerous solvent-refining processes, including those described below, are covered in this handbook.[7]

LUBE MANUFACTURING

A primary use of solvent refining is in the production of lubricating oils. There are a number of crude oil components that impart undesirable properties to lube oils, and their removal from lube base stocks is required if high quality lubes are to be produced. These undesirable components include waxes, heavy aromatics, asphaltenes, and organic compounds containing oxygen, sulfur, and nitrogen. For most of the last century, solvent refining has been found useful for the effective removal of these components from lube base stocks. The most difficult part of solvent extraction is identifying a suitable solvent that preferentially dissolves or rejects the desired component. This solvent must also be stable at the conditions to be employed and must be easily recovered for recycling. There are only a dozen or so solvents that have been used commercially in lube manufacturing over the last several decades.

Lube Treating

Lube treating generally refers to a solvent extraction process whereby aromatics and heteroatom-containing molecules (e.g., sulfur, nitrogen, oxygen) are removed to improve lube base stock properties. The most important lube properties impacted in solvent treating are viscosity index, oxidative stability, color, additive response, and sulfur content. The earliest lube-treating processes employed liquid sulfur dioxide as a solvent, but this has been largely phased out in favor of the organic compounds phenol, furfural, and n-methyl-2-pyrrolidone (NMP). Of these, NMP is considered the least toxic and several refiners have converted their phenol or furfural units to NMP in recent years.

Several companies have commercialized lube-treating processes that they now offer for licensing by others. For example, Bechtel offers a process based on the solvent n-methyl-2-pyrrolodine. In their literature, they offer the process flow diagram shown in Fig. 1.[8] Most of the process equipment in Fig. 1 is downstream of the extraction tower, illustrating the effort involved in recovering product and clean solvent for recycle. A major part of the expense associated with this and most solvent-refining processes is the energy cost. Bechtel gives the following estimates for typical utilities required per barrel of feed:

Fuel, absorbed, 10^3Btu	130
Electricity, k Wh	0.8
Steam, lb	8.1
Water, cooling (25°F), gal	550

The Bechtel process shown in Fig 1 has been employed in 13 licensed units, with two additional units being planned in 2001. Of the 13 units on stream in the year 2000, eight were conversions of existing phenol or furfural units. In a previous article on lube treating, Texaco claimed that over 100 units were at that time utilizing their furfural-based lube-treating process.[9] Although some furfural and phenol units have been converted to NMP, the preponderance of lube-treating units use furfural as solvent.

In the manufacture of lube base stocks, the product from solvent extraction using furfural, NMP, or other solvent is sent to lube dewaxing. The objective in dewaxing is to remove enough of the waxy components (e.g., long straight chain alkanes) to reduce the pour point of the base stock to acceptable levels (as low as −35°C). In dewaxing, the feed is mixed with ketone solvent and then chilled to a sufficiently low temperature to cause the wax to crystallize and drop out of the solution. The crystallized wax is recovered by filtration, and the solvent is recovered from the filtered product and recycled. The wax produced can also be a valuable product as it is the major source of waxes for consumer products, such as candles, crayons, and wax coatings. ExxonMobil offers their DILCHILL process for license and provided the flow diagram shown in Fig. 2.[10] A key unit in this scheme is the crystallizer tower in which ExxonMobil claims to have proprietary technology that achieves a number of mixing stages. The DILCHILL process can produce lube base stocks having low pour points from a wide range of stocks. As with any solids-handling process in refining, a great deal of know-how is involved in the detailed design of the equipment in this process.

Deasphalting

A principal source of the heaviest lube base stocks is vacuum-reduced crude (vacuum residuum). The primary application of the deasphalting process is to reduce the Conradson carbon residue (CCR), metals (Ni, V, etc.) content and viscosity of a vacuum residuum in order to produce an acceptable quality heavy lube base stock. The CCR content of a refinery stream is determined in an ASTM analytical test that involves

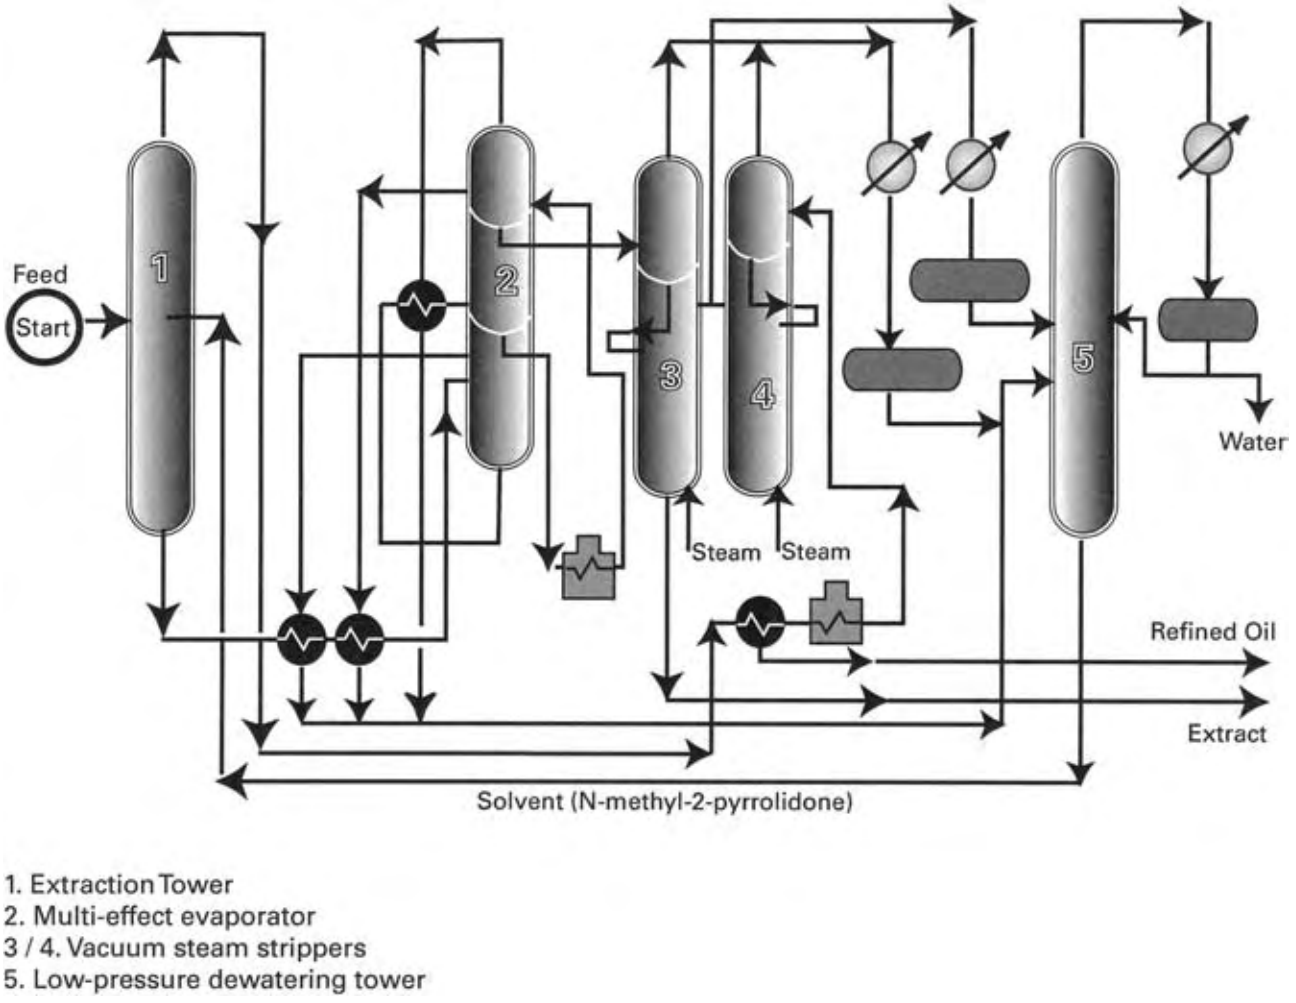

Fig. 1 Lube treating. (From Ref.[9].)

destructive distillation of the sample to dryness. The amount CCR (wt% solid residue) that is measured in this test correlates well with an oil's tendency to break down and form carbon deposits in many petroleum processes. Metals are usually associated with asphaltenes and are themselves undesirable lube components.

Deasphalting in lube manufacture is a precipitation process that usually employs propane as the solvent. Asphaltenes are large complex organic structures composed largely of aromatic rings. They contain primarily hydrogen and carbon atoms, but contain sulfur, nitrogen, nickel, vanadium, and iron, as well as trace amounts of many other atoms. Asphaltenes have a limited solubility in crude oil, but are believed to remain in solution as a result of their ability to absorb resins on their exterior surface. When lower molecular weight alkanes are mixed with a heavy oil, the resins desorb from the asphaltenes thus causing the asphaltenes to flocculate and drop out of solution. The lower the molecular weight of the alkane added, the greater the amount of the oil that precipitates as asphaltenes. Often, a little butane is included along with the propane in order to slightly modify the selectivity of the deasphalting process. The solvent to oil ratio for most deasphalting processes ranges from about 2 to 8 depending on the solvent employed, the feed stock, and the desired product quality.

In recent years, deasphalting has also been used to reduce the CCR, nickel, and vanadium content of petroleum residua as a pretreatment for catalytic cracking or hydrocracking. In this application, a heavier alkane solvent such as pentane or hexane is usually preferred, since it yields a higher volume of deasphalted oil of acceptable quality for catalytic cracking feed. All catalytic units can tolerate some level of CCR and metals in the feed; however, operation of any cracking unit is improved if they are removed. Each refiner determined the level of these contaminants acceptable for their cracking unit, but the feed to conventional catalytic crackers rarely contains more than a few parts per million of metals and a few weight percent CCR.

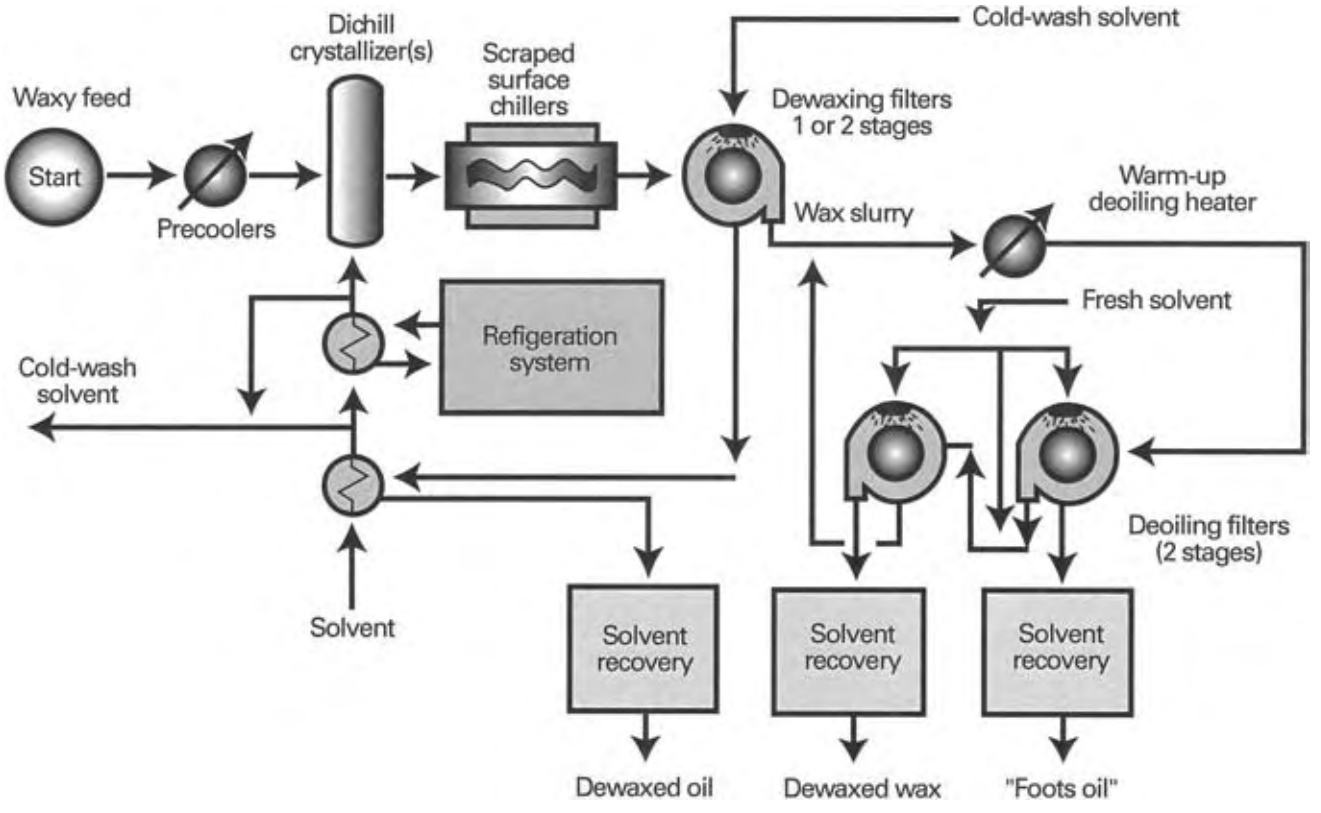

Fig. 2 Lube dewaxing. (From Ref.[9].)

Three licensors, Foster Wheeler USA Corp, Kellogg Brown & Root, Inc., and UOP LLC, offer flow diagrams and a discussion of their process in *Hydrocarbon Processing*.[11] These process vendors cumulatively report over 110 commercial applications of this technology. Each licensor offers their process for application in lube processing or in the preparation of catalytic cracker or hydrocracker feed. All vendors also discuss the use of supercritical conditions for solvent recovery. This is discussed later under ''Solvent Recovery.''

Alternative Routes to Lube Manufacturing

In recent years, efforts have been made to improve the yield and quality of lube manufacturing, while at the same time greatly improving operating costs by eliminating many of the solvent processes. Two different approaches are worthy of note. The first is to use a membrane separation process in lube dewaxing, and the second is to use catalytic hyrdroprocessing[5] for both dewaxing and lube treating.[6] Although the membrane concept has been around for several years, its use has been limited to that described in the above publication.

Although the hydrocatalytic lube-processing methods have been commercialized and are available from a number of licensors, still their application has been limited to date.

AROMATIC EXTRACTION

Benzene, toluene, and xylene (BTX) are valuable as chemical feedstocks and have been solvent extracted for this purpose from refinery streams for decades. Governmental regulations limiting the amount of benzene in gasoline have provided incentives for the extraction of aromatics from gasoline components in recent years and are found in most refineries today.

UOP, a worldwide leader in aromatics processing, has three aromatics extraction processes[12] (Udex, Sulfolane, and Carom^{TM}), which employ liquid–liquid extraction for the production of BTX from petroleum naphtha and other gasoline-blending components. The Udex process is the oldest and although there are many Udex units operating today Sulfolane and Carom have largely displaced Udex in new installations. The Carom process is a two-solvent process that can be employed to debottleneck or revamp an older glycol-based UDEX unit. There are 89 Udex/Carom units operating today. The Sulfolane process uses sulfolane as solvent and 136 of these units have been licensed since 1962. Other companies offer similar aromatics

extraction processes, with many of the processes employing a two-column system, the first being a liquid–liquid extraction column and the second an extractive distillation column. Sulfolane is effective both in extraction and extractive distillation.

Extraction and extractive distillation can also be accomplished using N-Forylmorpholin (NFM) as the solvent. Krupp Uhde[13] offers an extractive distillation process for license that employs NFM as the solvent. N-Forylmorpholin is employed in the extractor and in the distillation column to lower the vapor pressure of the aromatics relative to nonaromatics of a similar boiling point. In this way aromatics can be separated from nonaromatics in a very small and simple distillation column. N-Forylmorpholin has properties that make it an excellent solvent for this application. It is highly selective, thermally stable and has a boiling point in the range of the products to be separated. A flow diagram for this extractive distillation process is given in Fig. 3.

Aromatics concentrate in the solvent-rich stream that comes off the bottom of the extractive distillation column, while the nonaromatics concentrate in the column overhead. The main column bottoms are sent to a stripper column for solvent and aromatics recovery. Extensive heat exchange to recover energy from the hot solvent is required to achieve acceptably low energy consumption in this process. Krupp Uhde, the process licensor, claims that 45 commercial plants are operating with this technology. They also claim their process can produce excellent purity benzene (99.95%) and toluene (99.98%).

SOLVENT RECOVERY

As can be seen in the flow diagrams included in Fig. 3, solvent recovery is a very important part of any solvent process. Not only is there a large capital cost associated with solvent recovery, recovery by vaporization/distillation also requires a great deal of energy leading to high operating cost. A number of alternatives to straight distillation have been developed over the years in an effort to reduce the operating costs of solvent recovery in these processes. Three such developments are discussed below.

1. *Multieffect evaporization*: This is a classical engineering technique in which a solvent is removed by successive evaporation steps.[14] The solvent removed from the first step is used to heat the liquid which is again fed to the

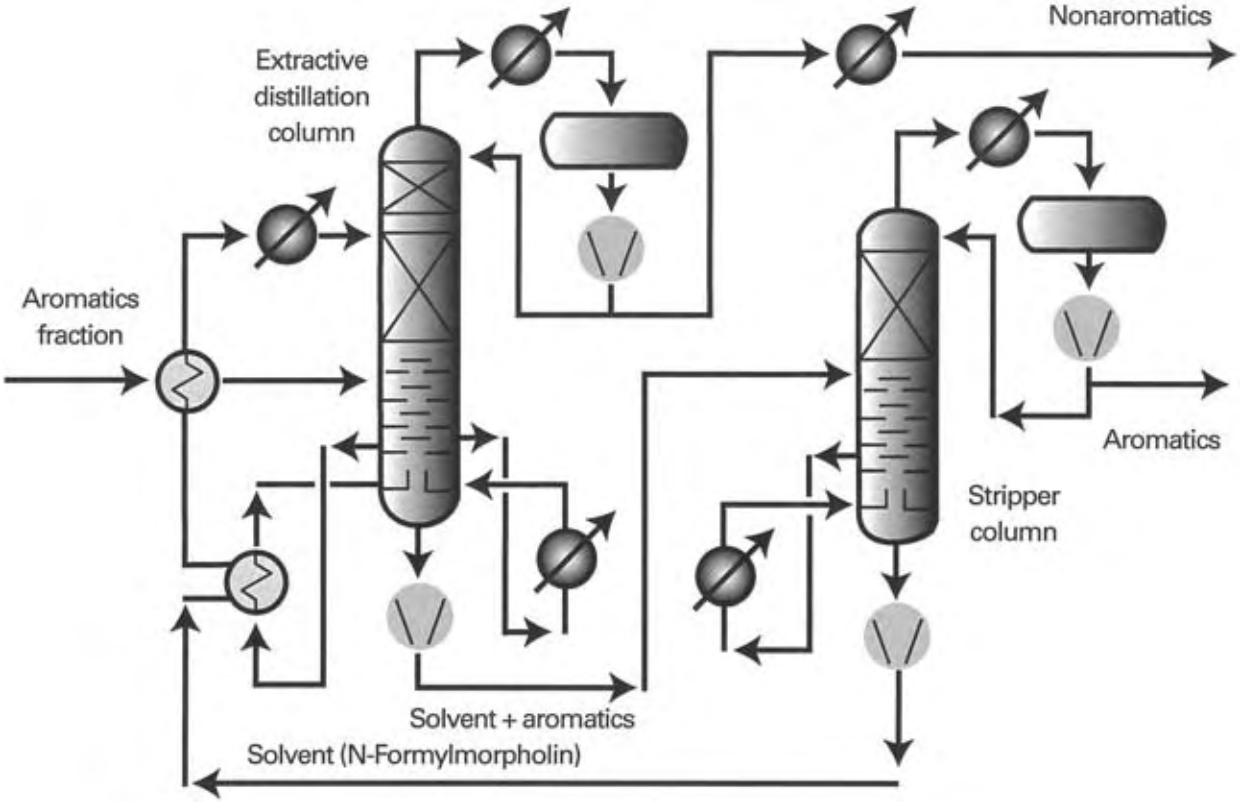

Fig. 3 Aromatics extractive distillation. (From Ref.[13].)

second evaporator where the pressure and boiling point are lower than in the previous evaporator. In this manner, the external heat applied to the first evaporator is employed a number of times. Although multiple-effect evaporators save energy, they add complexity and capital cost to a solvent recovery system. Both forward feed and backward feed have been employed in multieffect evaporators.

2. *Supercritical solvent separation*: This method has been employed to recover solvent in deasphalting.[15] In recovering solvent from deasphalted oil by this method, the deasphalted oil laden with solvent is pumped to a pressure slightly higher than that of the critical pressure of the solvent (e.g., propane critical pressure = 42.1 Atm). At this supercritical condition, the solvent is no longer completely miscible with the deasphalted oil and two phases result, the supercritical solvent phase and the deasphalted oil phase that is devoid of much of its solvent. These two phases can be separated in a simple liquid/liquid separator. The result is solvent recovery without solvent vaporization.
3. *Membrane separation*: The newest scheme for solvent separation/recovery involves the use of a proprietary polyimide membrane for recovering methyl-ethyl ketone and toluene from a solvent dewaxed oil filtrate.[6] A major advantage of this selective membrane process is that it removes about 25% of the cold solvent as a liquid at or near dewaxing temperatures (–18 to 0°C), thus debottlenecking the refrigeration unit by about 10%. Mobil and W.R. Grace jointly developed this new technology and utilized it commercially to debottleneck the refrigeration and solvent recovery system in Mobil's Beaumont, Texas refinery. An advantage of the process is its ability to remove solvent at or near dewaxing conditions, thus saving significantly on refrigeration/energy costs compared to an evaporative recovery method.

CONCLUSIONS

Solvent-refining processes belong to the general set of processes known as separation processes. Fractional distillation is usually the separation process of choice; however, when a separation is based on chemical type rather than molecular size or boiling point, solvent refining may be the preferred separation process. Solvent-refining processes have been extensively used in the refining industry for several decades for the production of high quality lubricants and for the removal of aromatics from gasoline. In the production of lubricant base stocks, hundreds of solvent-refining units are employed in a variety of licensable processes aimed at:

1. *Solvent dewaxing*: Solvent-enhanced precipitation to remove waxes and improve low temperature fluidity of lube base stocks.
2. *Solvent deasphalting*: Solvent-enhanced precipitation process to remove asphaltenes from heavy lube base stocks and for improving the feed quality of catalytic cracker feed.
3. *Lube treating*: Solvent extraction process for removal of aromatics and heteroatom containing molecules (e.g., sulfur, nitrogen, oxygen) to improve oxidative stability of lube base stocks.

Another important extraction process in refining is the removal of aromatic compounds from gasoline-blending stocks. This is done because the aromatics compounds have considerable value as chemical feedstocks and because environmental regulations greatly restrict the benzene content of gasoline. A number of commercial liquid–liquid extraction processes are employed in hundreds of commercial units that can accomplish this separation.

Often, the extraction is followed by extractive distillation. In these cases the solvent must not only preferentially extract aromatics, it must also lower the volatility of the aromatics so that they can be more easily separated from the solvent by distillation.

A major concern in solvent refining is the high energy consumption of these processes. Much of this is associated with recovery and recycling of solvent. The bulk of the process equipment in solvent refining is devoted to energy-efficient recovery and recycling of the solvent. Three energy-efficient solvent recovery processes are multi-effect evaporation, supercritical separation, and membrane separation.

In addition, efforts have been directed in recent years to catalytic processing as an alternative route particularly for removal of contaminants from lube base stocks. Although these processes are commercial and offer advantages over the solvent-refining processes for grass root applications, the advantages are usually not large enough to justify shutting down and replacing an operating solvent-refining unit. It is anticipated that solvent-refining processes will be important for separating undesirable components from hydrocarbon streams for many decades.

Solvents

Satish C. Mohapatra
Advanced Fluid Technologies, Inc., Dynalene Heat Transfer Fluids, Whitehall, Pennsylvania, U.S.A.

INTRODUCTION

Solvents are chemical compounds or mixtures that can dissolve other substances. In many applications, the substances need to be separated from the solvent after a process is over. Most of the solvents are in liquid form at room temperature and pressure. However, some fluids under certain temperature and pressure conditions can form ''supercritical solvents,'' which are neither liquid nor gas. These types of solvents are finding more applications in the recent times, because some of them are considered to be environmentally benign. Solvents are normally classified as follows:[1]

1. Nonpolar solvents (such as hexane and tetrachloromethane).
2. Solvents of low polarity (such as toluene and chloroform).
3. Aprotic dipolar solvents (such as acetone and *N,N*-dimethylformamide).
4. Protic and protogenic solvents (such as ethanol and nitromethane).
5. Basic solvents (such as pyridine and 1,2-diaminoethane).
6. Acidic solvents (such as 3-methylphenol and butanoic acid).

There are few other ways to classify fluids based on their dielectric constant, dipole moment, the hydrogen bond formation ability, acidity or basicity (relative to water) of the solvents, and extent of self-dissociation. Commercially available solvents can be obtained in several categories of purity, and the desired or required purity depends on their application. For example, a ''spectrophotometric'' grade solvent meets the requirement of not absorbing light at specified wavelength ranges. ''HPLC'' grade solvents are used in different liquid chromatography applications, where in addition to UV-transparency a low residue on evaporation is desired. Solvents used for ''electrochemical'' purposes should not contain any ionizable and electroactive, oxidizable or reducible impurities.

Another important aspect of solvents is their toxicity or their effect on humans and environment. Nowadays, the more hazardous solvents are being replaced with less hazardous ones. One example is the replacement of benzene (a known carcinogen) with toluene or xylene. Permissible exposure limit (PEL) has been determined for most of the widely used solvents. Immediate danger to life or health (IDLH) values have also been published for many toxic solvents (Table 1).[1,2] These values provide an indication of how toxic a solvent is when it evaporates into the atmosphere. Flammability of a solvent is determined from its flash point, autoignition temperature, and explosive limits (Table 1). The higher the flash point and autoignition temperature, the lesser is the flammability of the solvent. The toxic effect on ingestion is commonly reported in terms of LD_{50} in mg/kg body weight (Table 2).[2] This value indicates how much of the substance needs to be consumed into the body to cause mortality of 50% population.

TYPES OF SOLVENTS

In this entry, solvents are classified into four major categories, viz. organic solvents, aqueous solvents, supercritical solvents, and ionic liquids. This classification is based on the evolutionary approach to solvent design.

Organic Solvents

Organic solvents incorporate carbon and hydrogen in their molecule. Additionally, organic solvents can have oxygen, nitrogen, sulfur, chlorine, fluorine, phosphorous, and silicon atoms in the molecular structure. Incorporation of each of these atoms imparts some unique property to the solvent. For example, fluorination can make a resulting fluorinated hydrocarbon nonflammable and dense. Oxygenation can make a solvent more hydrophilic. Different categories of organic solvents do exist. They are hydrocarbons (aliphatic and aromatic), alcohols, ethers, ketones, carboxylic acids, esters, fluorocarbons, silanes and siloxanes, amines, amides, sulfides and sulfoxides, and phosphate esters.

Organic solvents are the most common solvents in a variety of applications ranging from cleaning to coating, and reaction and separation solvent.[1–5] These solvents

are mostly inexpensive, their physical and chemical properties are well established,[1–4] and the process design is relatively simple. However, some of the popular organic solvents are very toxic, environmentally unfriendly, and could be carcinogenic. One example is the chlorinated compounds such as trichloroethylene, methylene chloride, and carbon tetrachloride. Because of this reason, chlorinated compounds and many other toxic solvents are slowly being phased out. These solvents are being replaced by more environmentally benign water-based solvents and supercritical solvents.

Aqueous Solvents

Aqueous solvents incorporate water as a major component in the solvent mixture. Water being a nontoxic, nonflammable, and inexpensive solvent, with excellent heat transfer properties is highly suitable for many of the applications. Water-based solvents are already used in certain types of paint and coating formulations. Water is also a major component in the household and industrial cleaning solvents.

The drawback of water as a solvent is that it cannot dissolve a variety of nonpolar compounds. In many aqueous solvent formulations, surfactants are used to emulsify the nonpolar components. One widely used example is emulsion polymerization for the manufacturing of latex. In this process, a nonpolar monomer such as styrene is emulsified with a surfactant first. Then, a free-radical initiator is added to the process, which starts the polymerization within the emulsion. This method creates colloidal polymer particles of very uniform shape and size that are used in a variety of applications.

Supercritical Solvents

A supercritical fluid is defined as a substance above its critical temperature (T_C) and critical pressure (P_C). The critical point represents the highest temperature and pressure at which the substance can exist as a vapor and liquid in equilibrium (Tables 3 and 4). Supercritical fluids are highly compressed fluids that combine properties of gases and liquids in a synergistic manner. Fluids such as supercritical xenon, ethane, and carbon dioxide (CO_2) offer a range of unusual chemical possibilities in both synthetic and analytical chemistry.

Supercritical CO_2 has been used for years to extract chemicals from foodstuffs. Commercial plants have

Table 3 Critical properties of supercritical fluids

Supercritical solvents	T_C(K)	P_C(MPa)	*dc* (g cm^{-3})
Nitrogen	126.20	3.40	0.157
Xenon	289.8	5.88	1.105
Methane	190.65	4.64	0.162

(From Ref.[1].)

been scaled up for the extraction of caffeine from coffee and tea, as well as the extraction of biological products from herbs, spices, and vegetables, including soy beans, corn, and hops.[6]

In a typical process, liquid CO_2 is compressed and heated before being transferred to a vessel for extraction. Solute laden CO_2 is fed into a separator, where the pressure and temperature are adjusted to reduce the dissolving power of the CO_2, causing the extracts to be precipitated. Pressure adjustments can be performed in several stages, allowing different extracts to be isolated. Low density CO_2 is then fed to a refrigerated condenser and collected as liquid.

CO_2 is completely nonflammable. This property provides a tremendous advantage for some traditionally hazardous chemical processes and reactions. For example, fluoroethylene monomers used for the production of tetrafluoroethylene (TFE) are rendered nonexplosive when mixed with CO_2. In addition, highly reactive free-radical polymerization of these monomers can be carried out directly in a supercritical CO_2 continuous phase.

Widespread application of near-critical and supercritical CO_2 to process industries has been hindered up to now by a very weak solvent strength. In many applications where the physical and environmental properties of CO_2 would otherwise be favorable, the fact that CO_2 cannot dissolve or carry the required solute has blocked its application. One reason being the low dielectric constant (1.4–1.5) compared to the typical organic solvents (2.0–4.0). The very hydrophobic nature of CO_2 makes it a bad solvent for many solutes. Improving the solvent strength has been the focus of research in recent decades.

One approach to increasing CO_2 solvent strength relies on the fact that most volatile materials (such as alcohols, ketones, and hydrocarbons) are soluble in supercritical and near-critical CO_2. This allows the employment of a wide range of cosolvents to enhance the CO_2's solvation properties. The use of such cosolvent-modified CO_2 as a solvent medium is most recognized in the Unicarb spray-coating process commercialized by Union Carbide (now with Dow Chemical, Midland, MI) in the early 1990s. In this process, the majority of traditional solvents used in the spray coatings are replaced by supercritical CO_2. This process has been implemented in automotive and furniture industries.

Although the use of a cosolvent improves the solvation properties of CO_2, there are some drawbacks that were subsequently addressed. With the addition of these cosolvents, CO_2 loses its designation as a zero volatile organic carbon (VOC) solvent. Solvents are also not effective where heterogeneous processes are involved (such as dispersion polymerization). In these cases, a surfactant is required. Silicone and fluoroacrylate-based surfactants have been developed for stabilizing insoluble, dispersed polymer particles. Isolation of a dry powder is accomplished simply by depressurization. Although still in the early stages of implementation for dispersion processes, surfactant-modified CO_2 has a potential impact for almost all process technologies that rely on water or other solvent systems. In addition to the stabilization of polymer dispersions and latexes, surfactant-modified CO_2 is expanding into traditional-hydrocarbon-solvent, halogenated-solvent and aqueous-solvent cleaning processes.

CO_2-based solvent technology cannot be implemented in normal process equipment. More commonly, implementation requires installation of pressurized equipment in place of existing lines that operate at ambient conditions. Guidelines for design, operation, and maintenance of these systems are established by the International Standards Organization (ISO, Geneva), American Society of Mechanical Engineers (ASME, New York), American National Standards Institute (New York), the U.S. Occupational Safety and Health Administration (OSHA, Washington, D.C.), and CPI operating codes.

Another challenge that the high-pressure process puts on utilization of near-critical and supercritical CO_2 is a push toward batchwise processing methodologies. Batch pressurization and depressurization cycles are typical because ideally both the end product and the feed streams will be at ambient conditions. For example, decaffeination of raw coffee beans is usually done in a semibatch process. Beans are loaded in and out of the pressurized CO_2 solvent with lock-hopper type feed and discharge valves. In this design, engineers must consider the sealing methods for locks and chamber doors, as well as the potential cyclic load on

chambers or systems that shuttle materials in or out of the process.

Ionic Liquids

This class of materials is ionic compounds that can remain in liquid state at room temperature. The ions in these compounds are, in general, large and bulky with the cations usually being organic and asymmetrical.[7,8] The forces holding such unwieldy components together are weak; hence, the crystal lattice tends to fall apart at relatively low temperatures. As a result, the salts form colorless fluids at temperatures ranging from 96 to 200°C. Additionally, their melting point, viscosity, density, and miscibility can be varied by changing the structure of the ions or, in binary systems, their relative ratios.

Theoretically, a trillion or more ionic liquids are possible. To make an ionic liquid, researchers can select it from dozens of small, negatively charged ions, such as hexafluorophosphate ($[PF_6]$-) and tetrafluoroborate ($[BF_4]$-), and hundreds of thousands of larger, positively charged ions, such as 1-hexyl-3-methylimidazolium or 1-butyl-3methylimidazolium.

Unlike typical organic solvents, ionic liquids tend not to give off vapors; hence they are less hazardous and more convenient in the laboratory, and are less likely to pose air pollution problems. Products and chemical catalysts can be recovered or extracted easily from ionic liquids and then the liquid can be recycled and used over and over again. Reactions that occur in organic solvents have been the standard way to make countless products. Now, many of these old reactions are carried out in these new solvents.

SOLVENT MIXTURES

Water is one of the most widely used solvents because of its availability, low cost, nontoxicity, and safety as well as its ability to dissolve a wide variety of substances. Sometimes when the solubility or any other property of water does not allow it to be used, a polar or a nonpolar organic solvent can be used. In certain applications, neat organic solvents fall short of the mark as far as their dissolving power or other properties are concerned. It is then necessary to use solvent mixtures. These mixtures can be binary (two components), tertiary (three components), or a multicomponent mixture. Many times, one of the components may be a solid. One very common example of this can be found in liquid chromatography where an electrolyte solution (buffer + salt) is used in many applications as a mobile phase.

In aqueous mixtures, the solvents that are completely miscible with water may be called cosolvents. The complete miscibility of solvents with water depends on their hydrophilic character, expressed as the log P. This is the logarithm of the partition coefficient of the substance considered as a solute between 1-octanol and water. Normally, the solvents with negative log P values are completely miscible with water, and solvents with $\log P > 1.3$ show very limited miscibility with water. Solvents with intermediate values ($0 < \log P < 1.3$) are somewhat miscible with water.

Mixtures of nonpolar solvents are normally characterized by the term ''solubility parameter'' (δ). The difference in solubility parameters of mixture components provides a measure of solution nonideality.[3] Mixtures of aliphatic hydrocarbons are nearly ideal, whereas mixtures of aliphatic hydrocarbon with aromatics show appreciable nonideality. Sometimes, it is difficult to predict the behavior of highly nonideal mixtures. Thermodynamic properties of binary and multicomponent mixtures have been dealt with extensively in the literature.[3,4]

PROPERTIES OF SOLVENTS

The proper choice of a solvent for a particular application depends on several factors, among which its physical properties are of prime importance. In most applications, the solvent is preferred to be in its liquid state under the temperature and pressure conditions at which it is been employed. Other properties, such as density, vapor pressure, heat capacity, surface tension, and transport properties, are also very important. Electrical, magnetic, and optical properties are, in some cases, relevant to the application. All these are physical properties of the solvents.

Chemical properties of solvents, like the physical properties, are very important. Solubility parameters or the solvency factors provides an idea of how good a solvent is to solubilize certain types of materials. Polarity, acid–base properties, hydrogen bonding ability, and water miscibility are important chemical properties of solvents and are somewhat related.

Physical Properties

Under ambient conditions, solvents are normally liquid, unless a supercritical solvent is considered. The freezing/melting points and boiling points of some widely used solvents are listed in Table 4.[1,2] A solvent could form solids if it is stored outside during winter, and the temperature drops below its freezing point. Several freeze thaw cycles can damage the performance of paints and coatings. Solvents with low boiling points

have high vapor pressure, which leads to a quick drying or separation time. But sometimes, slow drying is necessary for coating applications where a solvent with high boiling point may be utilized.

Specific heat capacity is another important property of solvents. This is defined by the energy required to raise one unit mass of the solvent by one degree. This term becomes important if a solvent is used in a reaction process, which is either exothermic or endothermic. Solvents with high specific heat capacity can absorb more heat per unit temperature rise, compared to those with low specific heat capacity.

The response of a solvent to an electric field depends on the intrinsic dipole moment of its molecules, and also on cooperative effects of adjacent dipoles, when these are correlated in the liquid. The dipole moment μ is the measure of the separation of the positive and negative centers of charge in the molecule, and is measured best for the solvent vapor, where such cooperative effects are absent.[1] When this is impractical because of low volatility of the solvent, then the dipole moment may be measured for a dilute solution with the solvent being the solute in an inert solvent. The inert solvent is normally chosen from a group of solvents with very low polarity, such as benzene, hexane, and tetrachloromethane. Solvents with highly symmetrical molecules have zero dipole moments, but electronegative atoms connected to aliphatic or aromatic skeletons cause the molecules to have finite dipole moments. Table 5 lists dipole moments for some common solvents.[1,2] It also lists dielectric constants (ε) for these solvents. The higher is the dielectric constant, the more polar is the solvent and vice versa. Low dielectric constant fluids, also known as ''dielectric fluid,'' are used in electronics industry as cleaning solvents for circuit boards. Examples are fluorocarbons (because of their nonflammability), high flash point hydrocarbons, and silicones.

Surface and transport properties of solvents are very important for solvents. Surface tension of a solvent shows how easy or difficult it would be to wet the surface on which the solvent is being applied. Low surface tension implies better wetting ability and vice versa. Water and other polar organic solvents have very high surface tension, whereas silicones, fluorocarbons, and aliphatic hydrocarbons have low surface tension. Solvents with low surface tension are easier to leak through threaded joints compared to those with high surface tension.

Viscosity is another important property of solvents. High viscosity implies high power requirement for the flow of the solvent. Low viscosity means the solvent will flow easily; however, it may not be desirable in many applications. For example, a paint may need a solvent with optimum viscosity, which will neither drip out of the brush easily nor will stick to the brush so

Table 5 Dipole moment (μ) and dielectric constants (ε) of common solvents

μ is Debey unit and ε is dimensionless.
(From Refs.[1,2].)

hard that it will be difficult to apply on a surface. Both surface tension and viscosity are temperature dependent. In formulations involving solvents, the viscosity behavior of the final formulation may be quite different from the solvent itself. Many times, solvent-based formulations such as paints exhibit non-Newtonian behavior with the viscosity being a strong function of shear stress. However, most of the pure solvents exhibit Newtonian behavior.

Chemical Properties

Chemical properties of solvents affect their usefulness in various applications. The solvent should selectively dissolve the desired solutes, should be inactive/inert in the chemical reactions, and solvate the transition states and products really well. This can be achieved by the proper blend of chemical properties such as solvency, polarity, hydrogen bond donation or acceptance ability, acidity or basicity, hydrophilicity, and redox properties.

A particularly common test for ranking hydrocarbon solvent strength is the kauri-butanol test. The kauri-butanol value (KB) of a solvent represents the maximum amount of the solvent that can be added to a stock solution of kauri resin (a fossil copal) in butyl alcohol without causing cloudiness. Because kauri resin is readily soluble in butyl alcohol but not in hydrocarbon solvents, the resin solution will tolerate only a certain amount of dilution. ''Stronger'' solvents such as toluene can be added in a greater amount (and thus have a higher KB value) than ''weaker'' solvents like hexane.

Another common test for solvency is called aniline point test. The aniline point is called the ''aniline point temperature,'' which is the lowest temperature (°F or°C) at which equal volumes of aniline ($C_6H_5NH_2$) and the oil form a single phase. The aniline point (AP) correlates roughly with the amount and the type of aromatic hydrocarbons in an oil sample. A low AP is indicative of higher aromatics, while a high AP is indicative of lower aromatics content. Diesel oil with AP below 120°F (49°C) is probably risky to use in oil-base mud. In general, the lower the aniline point, the more the number of unsaturants that are present and the higher the potential for swelling certain rubber compounds. The American Petroleum Institute has developed test procedures that are the standard for the industry.

Solvent polarity is related to the dipole moment as discussed in the earlier section. A solvent without a permanent dipole must be classified as nonpolar. However, a solvent may exhibit local polarity, if it possesses two mutually canceling dipoles. One such example is 1,4-dioxane, where the two oxygen atoms can participate in electron-pair donation to nearby acceptor atoms in solutes, although the molecule as a whole does not have a permanent dipole moment. Furthermore, highly polarizable molecules may interact via induced dipoles, so that polarizability may contribute to the chemical aspect of polarity.

The acidity and basicity properties of solvents play an important role in various processes, especially in chemical reactions. A solvent may accept or donate a proton, thereby increasing or decreasing the rate of a chemical reaction. This behavior is similar to that of a catalyst. Sometimes, a solvent mixture may be a better alternative than the single components.

Aqueous solubility of solvents is related to polarity and dipole moment. Many solvents are hygroscopic and need drying agents, such as molecular sieves to remove moisture from them. Solubility of solvents in water and vice versa are listed in Table 6. It is observed that the solvents with –OH, –C(O)Me, –COOH, –NH2, and –CN groups have high degree of miscibility with water, whereas hydrocarbons, esters, and chlorinated compounds have a low solubility in water.

As discussed earlier, solubility parameter is important when nonpolar solvents are mixed. Table 7 provides a list of molar liquid volume and solubility parameter for some common solvents.[3] Aromatics have a higher value of this parameter compared to the aliphatics.

APPLICATIONS OF SOLVENTS

Major applications of solvents are found in paints/coating and cleaning applications. However, they are also widely used in chemical processes (as solvent as well as raw material), inks, solvent extraction, heat transfer systems, and electrochemistry. Some solvents are also used as catalysts in a chemical reaction.

Paints/Coatings

Paints and coatings consume the largest amount of solvent among all the applications.[5] Because of regulatory concerns, the consumption of organic solvents in coating applications is being reduced and replaced with water-based as well as nonsolvent coatings (powder coating). Use of green solvents is being encouraged in recent years.

Solvents in paint or a coating serve multiple purposes. These include solubilization of resins and other ingredients, wetting, viscosity reduction, adhesion promotion, and gloss enhancement. Initially, the resin or polymer is dissolved in the solvent to form a continuous phase.

(From Ref.[3].)

Dyes and pigments are then added to this solution to provide color. When a coating is applied, the solvent starts to evaporate leaving a thin continuous film on the surface. The solvent can also increase adhesion by softening the primer coat. In most of the coating applications, a solvent blend is used instead of a single solvent. Thus, each solvent component serves a particular purpose.

In water-based paints, the dominant solvent is water. There may be a small amount of other solvents to carry out certain functions. There are two types of water-based paints—one with latexes (composed of fine polymer particles dispersed in the solvent) and the other with water-soluble polymers. Latex paints are very common in the architectural market with flat, semigloss, and gloss coatings. More and more industrial coating applications are switching to water-based paints for environmental reasons.

Cleaning

The dry cleaning industry is one of the largest consumers of solvents. Perchloroethylene (PCE) is used in as high as 80% of the dry cleaning applications. Although this solvent is nonflammable, easy to recover, and exhibits good solvency, its environmental impact is severe. There is work underway to reduce the emission of this solvent from the dry cleaning plants. At the same time, many plants have switched to hydrocarbon-based solvents.

Another cleaning application involving solvents is the degreasing of metal parts and other objects in manufacturing plants and automotive repair facilities. Mineral oils and other high flash point hydrocarbon solvents are used in these applications.

Reaction Solvents

Chemical reactions normally require a solvent that can dissolve all the raw materials. Reaction kinetics and selectivity may be affected by the choice of solvent. Thermophysical properties of solvents are also very important for endothermic and exothermic reactions. Water, hydrocarbons, alcohols, ketones, chlorinated solvents, and amines are the most widely used solvents in the chemical process industry. In many applications, the solvent is consumed as a raw material. One example is the manufacture of esters, where alcohol takes part in the reaction.

Solvent Extraction

Solvent extraction is widely used in pharmaceutical and food processing industries. Oil seed extraction, manufacturing of neutraceuticals, decaffeinated coffee, intermediates, and some reactive-separation processes utilize solvent extraction. Hydrocarbons are common solvents for oil seed extraction. Supercritical solvents are gaining popularity in producing neutraceuticals and other active ingredients.

CONCLUSIONS

Innumerable production processes and applications rely on the proper selection of solvents. Organic solvents, although most widely used, are being slowly replaced with aqueous and supercritical solvents. Ionic liquids are still in the research stage and commercial applications are just beginning to appear. Solvent mixtures are used in many applications where a single solvent cannot do the job.

Both physical and chemical properties of the solvents are important. In addition, toxicity, flammability, and environmental friendliness should not be overlooked while selecting a solvent. All the properties are assessed to design the most optimum solvent for a particular need. The most widely used applications for solvents are paints/coatings, cleaning, reaction medium, and solvent extraction.

Sonochemical Reaction Engineering

David A. Bruce

Department of Chemical and Biomolecular Engineering, Clemson University, Clemson, South Carolina, U.S.A.

INTRODUCTION

Sonochemical reaction processes, which are relatively new, use the transmission of ultrasonic waves (20 kHz to 1 MHz) through liquid media to initiate chemical transformations and enhance mass transfer. These processes are similar to other chemical treatment methods, such as those employing plasma, flame, and thermo chemistries, in that a large amount of energy is introduced to the material in a very short period of time. However, the highly reactive zones in a sonochemical process are micrometer sized and the bulk fluid, which is generally at ambient conditions, is not exposed to these harsh conditions for extended periods. The chemical effect of these sound waves is derived from the formation, growth, and sudden collapse of micrometer size bubbles via a process known as acoustic cavitation. The microbubbles formed during cavitation are slowly filled with vaporized liquids until they reach a critical size, whereupon they undergo violent collapse in less than a microsecond. This rapid implosion causes the gases inside the bubble to be adiabatically compressed, which leads to significant increases in temperature and pressure inside the cavity. In fact, the temperature inside a bubble during implosion can be as high as 5000 K and the pressure greater than 500 atm, which equates to heating rates of more than a billion degrees per second during bubble collapse. Such extreme conditions lead to the formation of highly reactive species that can readily react with chemicals in the surrounding liquid phase. Cavitation phenomena can also produce reactive radicals and ions via localized electrical discharges that result from positively and negatively charged ions becoming separated during microbubble oscillation and collapse. Interestingly, this entire reaction process occurs repeatedly in a fluid medium whose temperature and pressure are only slightly above ambient conditions. Thus, ultrasound irradiation can significantly improve reactions rates, while simultaneously allowing the overall process to operate at milder reaction conditions.

The unique reaction environment generated in sonochemical reactors has been shown to greatly enhance reaction rates for a variety of chemical transformations. However, the commercial scale application of sonochemical technologies is still limited. It is only recently that advances in electromechanical transducers have enabled high powered ultrasonic waves to be efficiently generated in industrial scale reactors. To date, sonication has been used to fabricate nanomaterials, epoxidize and oxidize unsaturated hydrocarbons, couple halogenated aromatics, and cause a variety of degradation reactions as well as a number of other organic and inorganic chemical reactions. Many of the reactive species formed by acoustic cavitation are free radicals; hence, reaction pathways that include the formation of free radicals are often accelerated by sonochemical processing. However, there are many factors, some of which are still not fully understood, which determine whether a given reaction process will be accelerated by ultrasonic irradiation. Therefore, much of the research and process development in this field is still Edisonian in nature.

HISTORY

Though sonochemistry is a relatively new field of study, cavitation phenomena have been of interest for over 200 years. Leonhard Euler first mentioned the effects of cavitation in 1754 and the first article on cavitation by Thornycroft and Barnaby was printed in 1895.[1] However, it was not until the work of Lord Rayleigh in 1917 and Loomis and others in 1927 that the physical, chemical, and biological effects of cavitation were fully described.[2–4] Later studies by Harvey et al. defined the underlying mass transfer phenomena controlling bubble growth (i.e., rectified diffusion), and shortly thereafter the first computer simulations of a cavitating bubble were reported by Noltingk and Neppiras.[5,6] A decade later, Naude and Ellis suggested that bubbles collapsing near solid surfaces undergo asymmetric implosions that lead to the formation of microjets (see Fig. 1).[7] These microjets are believed to cause solid surface pitting and can readily explain the microscale surface erosion that is observed with dispersed particulates (e.g., oxide catalysts), which leads to their decreasing in size during sonication. Since the 1980s, numerous studies have provided insights on the physical environment (temperature

and pressure) inside an imploding microbubble, as well as information about the types of reactive species formed in this environment (e.g., free radicals such as $H^{\bullet}$ and $OH^{\bullet}$).[8–10] During the same period, the production of low cost sonication equipment has led chemists to discover a wide array of chemical reactions whose rate is greatly enhanced or whose product distribution is significantly altered by the cavitation process.[11–16]

GENERATION OF ULTRASOUND WAVES

Ultrasound is sound energy with a frequency beyond human hearing. It is a form of acoustic radiation with a frequency range between 20 kHz and 500 MHz. Depending on the frequency, it is divided into three regions: power ultrasound (20–100 kHz), high frequency ultrasound (100 kHz–1 MHz), and diagnostic ultrasound (1–500 MHz). Diagnostic ultrasound has a low intensity and has long been used in the medical field for therapeutic, operative, and diagnostic procedures. Power and high frequency ultrasound, commonly called destructive ultrasound, are used in a variety of industries. Common industrial applications include: welding plastics, cleaning and decontamination, beneficiation of coal, soldering, and processing that includes emulsification, extraction, crystallization, and filtration.

In sonochemistry, physical and chemical changes are brought about by the usage of power ultrasound. Three types of transducers are used to generate power ultrasound: gas driven transducers, liquid driven transducers, and electromechanical transducers. Of these, electromechanical transducers are the most widely used and include piezoelectric transducers and magnetostrictive transducers.[12,17] Piezoelectric transducers convert electric energy into kinetic energy or sound waves. When piezoelectric materials, such as quartz or $BaTiO_3$, are subjected to an alternating electric field, corresponding dimensional changes in the crystal generate high energy mechanical vibrations (sound energy). These transducers are highly efficient and can be used over the entire range of ultrasonic frequencies, but they are generally restricted to small volume processes for short terms and often operate at a fixed frequency; hence, they are more commonly used for laboratory scale experiments or processes. The magnetostrictive transducers, on the other hand, are used when large volumes are to be processed and when the reaction times are long. The magnetostrictive transducers utilize the Joule effect in which a ferromagnetic material (e.g., nickel or iron) in an external magnetic field alternately expands and contracts producing sound waves. These transducers are very robust, have high driving force, and can be operated at elevated temperatures (250°C) for extended periods of time. These characteristics make the magnetostrictive transducers a good choice for largescale industrial applications.

ACOUSTIC CAVITATION

Acoustic cavitation is a nonlinear process that effectively concentrates the diffuse energy of sound in

liquids. The microbubbles formed during cavitation result from sound wave generated compression and rarefaction cycles, which cause the local fluid density to momentarily increase or decrease, respectively. When the local density decreases during a rarefaction cycle to a sufficiently low value, such that the spacing between molecules exceeds the cohesive forces in the liquid, voids or cavities are formed. These voids, during the subsequent compression and rarefaction cycles, grow because of inertial effects and the rectified diffusion of mass from the bulk liquid. The growing cavity eventually reaches a critical size, where the combination of internal pressure and surface tension effects no longer balance the compression forces generated by the next sound wave. At this instant, the bubble implodes. This bubble collapse leads to a highly reactive environment, localized in a micrometer sized region in the bulk fluid. To gain a better understanding, the three discrete stages of cavitation, viz., nucleation, bubble growth, and implosive collapse, are described below with respect to homogenous (liquid) sonochemical reaction systems.

Nucleation

Nucleation refers to the formation of bubbles or cavities and is the origin of all cavitation processes. These cavities are formed when the acoustic energy applied to the liquid is sufficient to overcome the attractive forces binding neighboring liquid molecules. This energy, which equates to the tensile strength of the liquid is of the order of 1000 atm for pure water. However, the presence of dissolved gases and suspended particulates can reduce this tensile strength to the order of 1 atm. These gas pockets serve as nucleation sites for ultrasound cavitation bubbles and are often called ''weak spots.'' Ultrasound transmitted through a liquid consists of alternate compression and rarefaction cycles. When the acoustic amplitude during the rarefaction cycle is sufficiently large and exceeds the average intermolecular bonding forces in the liquid, neighboring liquid molecules are pulled apart forming voids or cavities.[18] Depending on the vapor pressure of dissolved organics and inorganics, these voids can be rapidly filled with vapor content and form bubbles. Hence, bubble formation and the chemical effects of ultrasound can only be seen when there are impurities, such as dissolved gases, in the liquid and when the sound intensity exceeds the cavitation threshold (i.e., the surface tension of the liquid near weak spots).[12] Fig. 2 provides an illustration of the relationship between the acoustic pressure (which varies) and bubble creation, growth, and collapse processes.

Bubble Growth and Dynamics

Bubble growth is very complex, in that it is highly nonlinear with time and also different for each of the millions of bubbles formed in the liquid. Fundamentally, the gas bubbles generated almost instantaneously during nucleation are inherently unstable.[19] In the absence of further acoustic irradiation, large bubbles will float to the surface and burst, while small bubbles will slowly dissolve owing to the excess internal gas pressure. In the presence of ultrasound, a bubble can grow many times larger than its initial size over a period of time much longer than bubble nucleation or collapse. Depending on the acoustic intensity and frequency, these bubbles will form a stable cavity and oscillate around a mean radius for several acoustic cycles or they will continue to grow until they reach a critical size and collapse. In general, this bubble growth process occurs at sufficiently slow rates so that it can be considered isothermal; hence, extremely little or no reaction is thought to occur during the growth phase of the cavitation process.

Bubble growth with high intensity ultrasound arises primarily from inertial effects. At this high intensity,

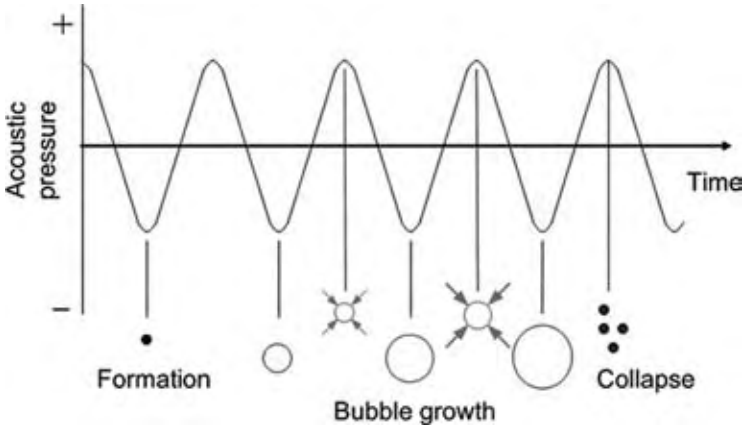

Fig. 2 The cavitation process: growth and collapse of a microbubble as a function of time and ultrasound frequency. *(View this art in color at www.dekker.com.)*

bubbles gain so much momentum during the negative pressure cycle that they will have no time to recompress during the positive pressure cycle and grow rapidly in the course of a single cycle of sound.[19] These bubbles, no longer in phase with the ultrasonic field, become unstable and implode in the subsequent compression cycle.

At low ultrasound intensities, bubble growth primarily occurs via rectified diffusion, which is the unequal mass transfer of species into the bubble during rarefaction and compression cycles. This phenomenon was first recognized by Harvey et al. during their experiments on animals, and Leighton has recently expounded on a well established theory that describes rectified diffusion in terms of an ''area effect'' and a ''shell effect.''[5,20] These two effects derive directly from basic mass transfer principles, which demonstrate that the rate of mass transfer is directly related to the surface area across which transfer can occur and the concentration (or more exactly, chemical potential) driving force.

The ''area effect'' can be described by the following. During rarefaction, when the bubble expands, concentrations and pressure inside the bubble decrease, and so dissolved gases and other volatile species diffuse from the liquid into the bubble. However, bubble compression yields high pressure and concentrations inside the bubble, which causes gas to diffuse from the bubble's interior into the bulk liquid. Because the surface area of the bubble is greater during the expansion phase than in the compression phase, the amount of gas diffused is greater during the expansion cycle. Therefore, over a complete cycle, there will be a net inflow of gas into the bubble causing it to grow over time, as depicted in Fig. 2.

Similarly, the ''shell effect'' arises because the diffusion rates of dissolved volatile species are proportional to their liquid phase concentration gradients. Consider a thin spherical shell of liquid surrounding an acoustically generated bubble. This liquid shell will change volume as the bubble pulsates, which in turn causes the concentration gradients of dissolved species to change, as shown in Fig. 3. Note that in Fig. 3, x_i and y_i equal the bulk concentration of the diffusing species i in the liquid shell and gas phases, $x_{i,\text{int}}$ and $y_{i,\text{int}}$ equal the concentration of species i at the gas–liquid interface, x_i^* equals the concentration of species i that would exist in the liquid phase if it were in equilibrium with a gas having concentration y_i, and y_i^* equals the concentration of species i that would exist in the gas phase if it were in equilibrium with a liquid having concentration x_i. At equilibrium conditions, there is no concentration gradient in the liquid surrounding the bubble; hence, no net mass transfer occurs. During bubble expansion (rarefaction), the shell contracts and the concentration of volatile species in the

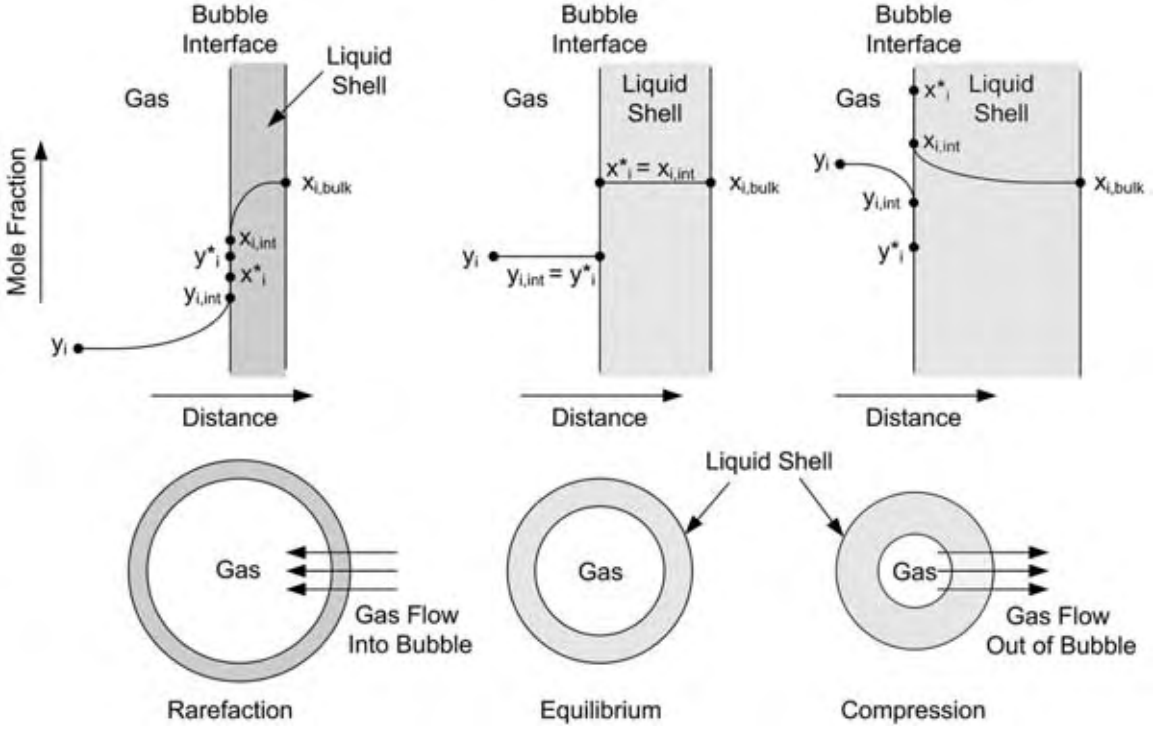

Fig. 3 Concentration profiles for species i in the gas and liquid phases of a microbubble undergoing rectified diffusion: the shell effect.

gas and surrounding liquid decreases. However, the concentration gradient is high because of the thinner shell and so the rate of diffusion of gas into the bubble from the bulk liquid is high. The opposite trend occurs when the bubble contracts. During bubble compression, the liquid shell expands and the concentration of volatile species in the gas and liquid shell increases. The increased shell thickness causes the concentration gradient to be small, thereby lowering the rate of gas diffusion. Hence, the amount of gas diffused is greater during the expansion phase because the high concentration gradient drives the gas a shorter distance, whereas in the compression phase the lower concentration gradient is driving gas a longer distance. Thus, both the area and shell effects lead to a net mass transfer of material into the bubble during each acoustic cycle.

Various mathematical models have been put forth to describe the rate of bubble growth and the threshold pressure for rectified diffusion.[14,20–25] The most widely used model quantifies the extent of rectified diffusion (i.e., the convection effect and bubble wall motion) by separately solving the equation of motion, the equation of state for the gas, and the diffusion equation. To further simplify the derivation, Crum and others made two assumptions: 1) the amplitude of the pressure oscillation is small, i.e., the solution is restricted to small sinusoidal oscillations, and 2) the gas in the bubble remains isothermal throughout the oscillations.[23,24] Given these assumptions, the wall motion of a bubble in an ultrasonic field with an angular frequency of $\omega = 2\pi f$ can be described by the Rayleigh–Plesset equation:

$$r\ddot{r} + \frac{3}{2}(\dot{r})^2 + \left(\frac{P_\infty + 2\sigma/r_0}{\rho}\right)\left(1 - \left(\frac{r_0}{r}\right)^{3\gamma}\right) - \frac{P_A}{\rho}\sin\omega t + r_0\omega_r b\dot{r} = 0 \quad (1)$$

In this expression, r and r_0 are, respectively, the instantaneous and equilibrium (i.e., when no sound field is acting on the liquid) values of the bubble radius; and $\dot{r}$ and $\ddot{r}$ represent, respectively, the first and second order time derivatives of the instantaneous bubble radius; ρ is the liquid density; γ is the polytropic exponent of the gas inside the bubble (i.e., the ratio of heat capacities, C_p/C_v); P_A is the acoustic pressure amplitude; P_∞ is the hydrostatic (ambient) pressure; b is the bubble pulsation damping term that accounts for thermal, viscous, and radiation effects; σ is the liquid surface tension; t is time; and ω_r is the resonance frequency of the bubble, which is defined by the equation below:

$$\omega_r^2 = \left(\frac{1}{\rho r_0^2}\right)\left(3\gamma P_\infty + \frac{2\sigma(3\gamma - 1)}{r_0}\right) \quad (2)$$

This equation of motion for bubble growth includes inertial terms that lead to a nonlinear solution; hence, the pressure threshold of bubble growth is dependent on the frequency of the sound field.

The diffusion of gas in and out of the bubble results from a linear response to the concentration driving force and can be adequately described by Fick's law of mass transfer:[26]

$$\frac{dC}{dt} = \frac{\partial C}{\partial t} + \nu\cdot\nabla C = D\nabla^2 C \quad (3)$$

where C is the molar concentration of gas in the liquid, ν is the liquid velocity, and D is the gas diffusivity in the liquid. By simultaneously solving the equation of state for the gas, the equation of motion for the bubble wall [Eq. (1)], and the equation for the diffusion of dissolved gas [Eq. (3)], it is possible to derive an expression for the mean rate of gas flow into the bubble:

$$\frac{dn}{dt} = 4\pi D C_\infty r_0 H\left[\langle r/r_0\rangle + r_0\left(\frac{\langle (r/r_0)^4\rangle}{\pi D t}\right)^{0.5}\right] \quad (4)$$

where the angled brackets represent time averages of the enclosed variables, n is the number of moles of gas in the bubble, C_∞ is the concentration of dissolved gas in the bulk liquid for the mean ambient pressure P_∞, and H is defined by the equation:

$$H = (C_i\ C_0) - \frac{\langle (R/R_0)^{4-3\gamma}(1 + 2\sigma/r_0P_\infty)\rangle}{\langle (R/R_0)^4\rangle} \quad (5)$$

Further refinements to theories involving bubble growth account for the fact that in a high energy cavitating system the cavitation effects are a result of the entire bubble population rather than a single bubble.[20] The acoustic effects of power ultrasound largely depend on the size distribution of bubbles in the liquid. Depending on the characteristics of the local field, there is a critical size range in which a free floating bubble must lie to undergo transient cavitation. The bubble nuclei formed can grow to provide intense cavitational effects or grow to a resonant size where it will oscillate stably for many cycles. Church predicted that the number of bubble nuclei growing by rectified diffusion to transient collapse decreased with increasing frequency.[25] Leighton also observed that the measured growth rates were often much greater than the predicted values and he attributed this to a phenomenon called "microstreaming."[20] Microstreaming continuously refreshes the liquid at the bubble wall by bringing the liquid from further out close to the bubble wall. This helps to counteract the depletion of gas occurring during rectified diffusion. Microstreaming

also plays a role in dissolution by removing the excess dissolved gas concentration from the region adjacent to the bubble wall.

Bubble Collapse and Splitting

The splitting or implosion of a transient cavity occurs when the bubble has reached a sufficiently large size so that the compression forces of an incoming sound wave exceed the stabilizing forces generated by the internal pressure and the surface tension of the bubble. The time required for bubble collapse is inversely related to the frequency of the ultrasonic wave and often occurs in only a few microseconds. Because the time required for thermal transport is significantly longer than that required for bubble collapse, the gases within the bubble undergo adiabatic compression, generating a localized ''hot spot,'' where temperatures can be as high as 5000 K. Further, the heating rates during bubble collapse are more than a billion degrees per second, and the sudden inrush of the surrounding fluid compresses the bubble contents to pressures of hundreds of atmospheres.[8,19] The high temperature is responsible for some of the production of highly reactive radicals, while the high pressure accounts for additional increases in chemical reactivity.[18] The maximum temperature and pressure reached during adiabatic collapse are given by the following equations:[27]

$$T_{\max} = T_0\left[\frac{(P_A + P_\infty)(\gamma - 1)}{P}\right] \quad (6)$$

$$P_{\max} = P\left[\frac{(P_A + P_\infty)(\gamma - 1)}{P}\right]^{\gamma/(\gamma - 1)} \quad (7)$$

where T_0 is the ambient temperature and P is the pressure in the bubble at its maximum size (sum of the vapor pressure of the liquid and the pressure of the gas in the bubble).

There also exists a second mechanism for producing reactive ions and radicals via cavitation, and it involves the concepts of localized charging and electrical discharge.[14] There is a tendency for a surface potential to be developed at the vapor–liquid interface of a microbubble because of orientational effects and the presence of charged species in the liquid (e.g., low concentration impurities). Following the Helmholtz model, this surface potential leads to the formation of an electrochemical double layer, which has an inner layer of weakly solvated ions and an outer layer of oppositely charged, fully solvated species that can more freely diffuse through the liquid. During bubble collapse or splitting, the ions at the gas–liquid interface (inner Helmholtz layer) become separated from the oppositely charged ions in the outer Helmholtz layer yielding local unbalanced electrical charges having a field strength above the critical electric field strength, which induces electrical microdischarges in the fluid. The discharge of these high energy electrons in the vicinity of other chemical species leads to the formation of highly reactive ions and free radicals.

During cavitation, both hot spot and electrical discharge phenomena lead to the formation of active intermediates (ions and free radicals) that can survive for extended periods and react with species in the liquid layer surrounding the recently collapsed microbubble.

REACTION ZONES OF SONOCHEMICAL REACTIONS

Electron paramagnetic resonance (EPR) and spin trapping studies have shown that there are three regions of sonochemical activity in liquid systems undergoing cavitation, as shown in Fig. 4.[28] Zone 1 contains a mixture of gas and vapor, where the amount of vapor in the bubble is directly related to the vapor pressure of species in the liquid phase. The high temperature and pressure generated during bubble collapse cause organic compounds to undergo pyrolysis reactions. Also, highly reactive radicals (e.g., $OH^\bullet$, $H^\bullet$, and $O^\bullet$) are generated in this zone because of the thermal dissociation of solvent (water) molecules in the vapor. The interfacial region, Zone 2, is also called the supercritical fluid region because the temperature and pressure in this zone during bubble collapse are above the critical temperature and pressure of the liquid (e.g., for water, 647 K and 221 bar). In this region, less

Fig. 4 Three reaction zones generated by acoustic cavitation. Zone 1 is the vapor phase, Zone 2 consists of the supercritical fluid region, and Zone 3 represents the bulk liquid. *(View this art in color at www.dekker.com.)*

volatile and less polar organic molecules are oxidized by the reactive radical species (e.g., $OH^{\bullet}$ and $H^{\bullet}$) generated in Zone 1. Zone 3 consists of the bulk liquid phase outside the bubble. This zone is near ambient temperatures and no primary sonochemical activity takes place in this zone.

The type of sonochemistry a given species will undergo is determined by its vapor pressure, polarity, and chemical composition (i.e., the nature and strength of its bonds). For example, hydrophobic compounds with high vapor pressure readily diffuse into the gas phase of growing microbubbles (assuming a polar solvent is used for the sonication reaction). Thus, these species very often undergo pyrolysis reactions in Zone 1 during bubble collapse, whereas less volatile hydrophobic species tend to accumulate at the vapor liquid interface during bubble growth and undergo reactions with reactive radical species generated in Zone 1 during bubble collapse.[29] Finally, nonvolatile, hydrophilic compounds do not readily diffuse into the vapor phase nor do they accumulate at the bubble interface; thus, they tend to be less affected by cavitation processes because they can react only with longlived radical species that diffuse out of Zone 1.

FACTORS AFFECTING SONICATION CHEMISTRY

This section briefly discusses the factors that significantly affect cavity formation and cavitational intensity (i.e., the temperature and pressure generated during collapse).

Acoustic Frequency

Put simply, acoustic energy manifests itself as an oscillating pressure wave. The frequency of this pressure fluctuation (defined as the number of oscillations per second) is known to directly affect the critical size and number of cavitation bubbles. At very high frequencies (1 MHz), cavitation reduces or ceases to occur because of the very short rarefaction and compression cycles that either reduce cavity formation or prevent bubble collapse. At high frequencies (100 kHz–1 MHz) more cavities are formed, but the intensity of cavitation is lower because the average bubble volume before collapse is small (i.e., less material compressed during collapse). At low frequencies (20–100 kHz) fewer cavities are formed, but the resonance bubble size before collapse is larger; hence, cavitation is more violent, leading to higher localized temperatures and pressures at the cavitation sites.[12] For example, sonic irradiation of water at 20 kHz creates resonant bubbles with a radius of 161 mm, whereas the bubble radius is 6.77 mm at 520 kHz.[30] Also, bubble lifetimes in water are shorter at higher frequencies (e.g., 3×10^{-7} sec at 514 kHz as compared to 3×10^{-5} sec at 20 kHz).[12] Thus, as acoustic frequency increases, production of cavities in the liquid increases (up to 1 MHz) and the intensity of cavitation decreases.[18]

Acoustic Intensity

Acoustic intensity (I) is a measure of the amount of energy transmitted to the liquid and is defined as the rate at which the acoustic energy passes across a unit area perpendicular to the direction of the propagating sound wave. It can be shown that the acoustic intensity is proportional to the square of the amplitude (P_A) of the acoustic wave divided by the density of the liquid (ρ) and the speed of sound in the liquid (c) (e.g., $c = 1500$ m/sec for water):[20]

$$I = \frac{P_A^2}{2\rho c} \tag{8}$$

To achieve any significant sonochemical effect, the sound intensity must be sufficiently high to overcome the cohesive forces in the liquid (i.e., break the intermolecular bonds) so that significant quantities of cavities can be formed. For degassed water at 25°C, the energy necessary to overcome the cohesive forces in the liquid is 6000 W/cm^2 at an acoustic frequency of 500 kHz. With increases in the intensity value, the sonochemical rate increases because of the large number of cavities formed. Also, the range of bubble sizes undergoing transient cavitation increases, increasing reaction rates. However, several experiments have shown that there is an upper limit to the power input. When the intensity is increased beyond this upper limit, bubbles grow so large in a single rarefaction cycle that they have insufficient time to collapse before the next rarefaction cycle.[16] Additionally, these large bubbles shroud the surface of the acoustic generator, reducing the coupling of sound energy to the liquid. Thus, sonochemical reaction rates increase with increasing acoustic intensity up to some limit where mechanical damage to the sound generator can occur or the presence of large bubbles reduces the overall efficiency of the cavitation process.[16,12]

External Pressure

An increase in the ambient (or hydraulic) pressure has two effects. First, there is an increase in the minimum acoustic intensity required to initiate cavitation, which occurs when the acoustic wave has sufficient amplitude to overcome both the tensile strength of the liquid and the external pressure. The second effect is the increase

in the intensity of cavitation collapse, leading to higher collapse temperatures and pressures. This is because the total pressure inside the cavitation bubble, just before collapse, is higher owing to the increased external pressure and applied ultrasound power. Even though the temperature and pressure in the final stages of collapse will increase, the overall sonochemical rate may or may not increase depending on the types of active intermediates formed and which reaction zone they are formed in. In contrast, as the external pressure is reduced, the severity of bubble collapse decreases and the dissolved gas content in the liquid decreases, eventually leading to a smaller number of microbubble nucleation sites (i.e., fewer cavitation bubbles). These effects combine to reduce the overall sonochemical reaction rate. Thus, the liquid surface tension and the nature of the specific chemical reaction determine the optimal external pressure for a sonochemical reaction.[12,16,18]

Bulk Temperature

Most homogenous reactions are accelerated by moderate increases in temperature; however, sonochemical reactions are often slowed down by increases in the bulk fluid temperature. This counterintuitive observation is easily explained once one considers the cavitation processes that lead to the formation of reactive radicals and ions. As the fluid temperature increases, the vapor pressure of the solvent and dissolved species increases, which leads to greater quantities of vapor entering into the gas phase of cavitation microbubbles. This increased quantity of vapor in the bubble cushions the collapse, lowering the temperature and pressure generated during bubble implosion, thereby lowering the number of reactive intermediates formed. Additionally, increased temperatures decrease the cavitational threshold for the liquid, which leads to the formation of large numbers of microbubbles that serve to dampen the passage of ultrasound energy through the liquid medium.[17] Hence, sonochemical reactions are usually carried out within a temperature range of 10–35°C.

Presence and Nature of Dissolved Gases

The presence of dissolved gas is essential for cavitation to occur in a liquid. The dissolved gas molecules disrupt intermolecular bonding between solvent molecules and hence, serve as nucleation sites for cavitation. There are three properties of dissolved gases that have significant influence on the degree of nucleation and cavitational intensity: solubility of gas in the liquid, ratio of specific heats (γ or C_P/C_V), and thermal conductivity (λ). More soluble gases reduce the cavitational effects because the bubbles formed redissolve before collapse can occur.[12] Also, the greater the solubility of the gas, the greater the amount that penetrates the bubble, thereby inducing the cushioning effect and lowering the intensity of shock waves released after collapse.[17,18] As the gas content in the liquid increases, both the cavitation threshold and the cavitational intensity are reduced.[18]

High degradation of organic compounds is achieved when a gas with high average specific heat ratio is employed. From Eqs. (6) and (7), the maximum temperature and pressure generated during adiabatic collapse increase with an increase in the value of γ, leading to higher degradation. This has been confirmed by sonochemical degradation studies of aqueous solutions of carbon tetrachloride, which showed that the initial rate of formation of free chlorine was less when the solution was saturated with nitrogen ($\gamma = 1.40$) instead of argon ($\gamma = 1.66$).[31] Solutions saturated with monatomic (inert) gases (Ar, Ne, He) give the highest rate with diatomic gases (O_2 and N_2) proceeding at an intermediate rate, and the lowest rate occurs for polyatomic gases (CO, etc.).

The thermal conductivity of the gas also has an important effect on cavitation intensity. Dissolved gases with high thermal conductivity can more rapidly dissipate heat generated during collapse to the surroundings, effectively reducing the maximum temperature (T_{max}) attained. Hence, even though helium ($\gamma = 1.66$), being an inert gas, has a high γ value, the maximum temperature attained during collapse is lower (with all the other conditions maintained the same) than that of nitrogen ($\gamma = 1.4$) because of the higher λ value of the former ($\lambda_{He} = 14.30 \times 10^{-2}\,W/m/K$ and $\lambda_{N2} = 2.52 \times 10^{-2}\,W/m/K$). Thus, greater cavitation intensity is achieved when the liquid is saturated with a high γ and low λ inert gas.

Solvent

The nature and strength of solvent intermolecular interactions (especially the presence of hydrogen bonding) can greatly influence the physical and chemical outcomes of ultrasound irradiation. These interactions determine the intensity of bubble collapse and the ease with which bubble nucleation can occur (recall that nucleation occurs when the pressure amplitude of the ultrasound wave exceeds the natural cohesive forces in the liquid). Increases in solvent viscosity and surface tension reduce the rate of bubble nucleation (i.e., fewer microbubbles are formed) but increase the intensity of bubble collapse (i.e., higher temperatures and pressures).[17,18] Some of the adverse effects of high surface tension can be overcome with the addition of small amounts of surfactants, which reduce the solvent surface tension and facilitate bubble nucleation.[12,17]

Solvent vapor pressure also has a significant effect on the cavitation phenomenon because the intensity of cavitation decreases as the vapor pressure of the solvent increases. This is because more vapor is enclosed in the microbubble, which cushions the collapse, leading to lower collapse temperatures and pressures. On the other hand, solvents with low vapor pressure tend not to diffuse into the growing microbubble; thereby reducing the size of the bubble, which lessens the intensity of bubble collapse.[17] Thus, a delicate balance of solvent properties must be achieved to attain the desired sonication conditions.

TYPES OF CAVITATION REACTIONS

Ultrasound irradiation can affect chemical reactions in two basic ways. It will either activate a new reaction or enhance the rate of an existing reaction pathway. Most primary activation processes involve reactions that occur in Zone 1 during bubble collapse, which are generally thought to be thermally initiated processes. During collapse, vaporized molecules are dissociated into smaller fragments (e.g., $H^{\bullet}$, Cl^{-}, $CH_3^{\bullet}$), which diffuse into the surrounding liquid media and react with other compounds, degrade into even smaller reactive species, or recombine to form low molecular weight compounds, such as CO_2, H_2O, and HCl. Also, solvent molecules are commonly dissociated into highly reactive radical species (e.g., $CH_3^{\bullet}$, $OH^{\bullet}$, $H^{\bullet}$). This reaction mechanism is the main degradation path for volatile organics with high vapor pressure and is predominant at lower ultrasound frequencies. The concentration of these high energy dissociation products is relatively small and their lifetimes short, but it is possible for them to diffuse to Zones 2 and 3 where they can react with other nonactivated species.

Secondary reactions involving free radicals (e.g., $OH^{\bullet}$ and $H^{\bullet}$), which were created by pyrolysis reactions in Zone 1, take place in the supercritical fluid region (Zone 2) and in the bulk liquid (Zone 3). These reactions involve species that strongly associate with the solvent or low volatility organics that cannot easily diffuse into the bubble. Higher ultrasound frequencies generally enhance these types of reactions. This is because at low ultrasound frequencies, the decomposition of the vapor gas mixture inside the microbubble is very efficient, yielding numerous free radicals. However, the proportion of radicals undergoing recombination to form unreactive species is also very high, whereas, at higher ultrasound frequencies fewer radicals are formed, but a greater percentage escape from the bubble; hence, the concentration of radical species exiting Zone 1 is greater at higher ultrasound frequencies.[32]

The number of organic reactions that have been initiated or enhanced by sonochemical methods is vast. Table 1 provides a brief listing of some of these. More detailed and thorough reviews of this subject can be found in the literature.[11,12,16,19,30–36] Sonochemical methods have proven to be efficient means to achieve a wide array of addition, isomerization, and oxidation reactions, while slightly fewer studies have examined the use of ultrasound for reduction and substitution reactions. In general, ultrasound irradiation has been shown to play varying roles in homogeneous and heterogeneous synthetic chemistry. For some reaction systems, the extreme conditions encountered during bubble collapse cause the initiation of a new reaction (e.g., the reduction of alkoxysilanes using $LiAlH_4$), whereas other reaction systems simply experience an increase in reaction rates that results from enhanced mixing and, in some cases, an increase in the number of highly reactive free radical intermediates (e.g., the oxidation of organics using $KMnO_4$). Most industrial applications of sonochemistry have involved the degradation of organic compounds, especially the destruction (pyrolysis or oxidation) of organics, such as aromatics and chlorinated organics, dissolved in water. These compounds are major contaminants in industrial and agricultural wastewater, and near-complete destruction (conversion to CO_2 and H_2O) of low molecular weight organics having high volatilities has been achieved. Further, dehalogenation reactions have been shown to occur with organic species having much lower volatilities (chlorobenzene, polychlorobiphenyls, etc.).

SONOLYSIS OF WATER

Though there are many important reactions initiated by ultrasound, water dissociation is by far the most important, and hence, is discussed here in detail. Weiss proposed and many have confirmed the mechanism shown below for the formation of $H^{\bullet}$ and $OH^{\bullet}$ radicals in Zone 1 during bubble collapse:[37]

$$H_2O \rightarrow H^{\bullet} + OH^{\bullet}$$

The formation of these free radical intermediates and subsequent sonochemical reactions carried out by them depend largely on the nature of the dissolved gases in the aqueous medium. Studies have shown that the sonolysis of distilled water saturated with different pure gases and their mixtures has different hydrogen peroxide yields and cavitation threshold values.[31] In general, these studies show that a gas with a high ratio of heat capacities and low thermal conductivity yields higher rates of production of hydrogen peroxide, indicating increased levels of free radical production

Table 1 A representative list of organic reactions that are initiated or enhanced via irradiation with ultrasound

Homogenous organic reactions	
Addition reactions	
Aldol condensations	Hydroboration reactions
Alkene hydrosilations	Knoevenagel condensations
Alkylation reactions	Michael addition reactions
Claisen–Schmidt condensations	Reformatsky reactions
Diels–Alder cyclizations	Ring opening polymerizations
Enantioselective Barbier reactions	Ullam coupling reactions
Esterification reactions	Wittig reactions to form olefin
Nucleophilic and electrophilic substitution reactions	
Ester hydrolysis	Halogenation of aromatics
Friedel–Crafts acylations	Nitration of aromatics
Friedel–Crafts alkylations	Solvolysis of halogenated alkanes
Oxidation reactions	
Alcohol oxidation to ketones and carboxylic acids	Oxidation of halogenated alkanes/aromatics
Epoxidation of olefins	Oxidation of arylalkyls
Reduction reactions	
Clemmensen reduction of carbonyls	Reduction of alkoxy silanes
Hydrogenation of carbonyls	Selective reduction of olefins
Degradation reactions	
Complete pyrolysis of organics	Polymer degradation
Dehalogenation reactions	Ozonolysis

via the thermal decomposition of water. The following free radical reactions were proposed for water upon ultrasonic irradiation under argon:[16]

$$H_2O \leftrightarrow H^\bullet + OH^\bullet$$
$$H^\bullet + H^\bullet \rightarrow H_2$$
$$OH^\bullet + OH^\bullet \rightarrow H_2O_2$$

Hydrogen peroxide is more readily formed when water contains oxygen, but the presence of oxygen is not necessary for hydrogen peroxide formation.[31] In the presence of oxygen, more H atoms are scavenged via the following reaction:

$$H^\bullet + O_2 \rightarrow HOO^\bullet$$

This reaction prevents the recombination of $H^\bullet$ and $OH^\bullet$ radicals to form water molecules and hence, increases the rate of other oxidation processes. In general, free radical reactions similar to those shown for water could occur with any organic or inorganic species capable of being present as a vapor during bubble collapse.

TYPES OF SONOCHEMICAL REACTORS

There are a variety of sonochemical reactor designs that have been developed for laboratory use as well as large scale production units. The method of ultrasound generation depends largely on the size of the reactor with piezoelectric transducers being used for small systems and magnetostrictive transducers more commonly found in large scale reactors. There are three basic types of sonochemical reactors: 1) reactors having the ultrasonic source in direct contact with the reacting fluid; 2) reactors with the ultrasound source mounted on the exterior walls of the reactor (i.e., a vibrating wall reactor); and 3) reactors that receive sound energy from an exterior coupling fluid that is in direct contact with the ultrasound source. There are several recent reviews of sonochemical reactors in the literature, and these works should be consulted before deciding on a particular sonochemical reactor configuration.[11,12,16] There are three major factors that must be taken into consideration when selecting the appropriate reactor type: cost, level of contaminants (from the erosion of the ultrasound source), and ultrasound energy density required.

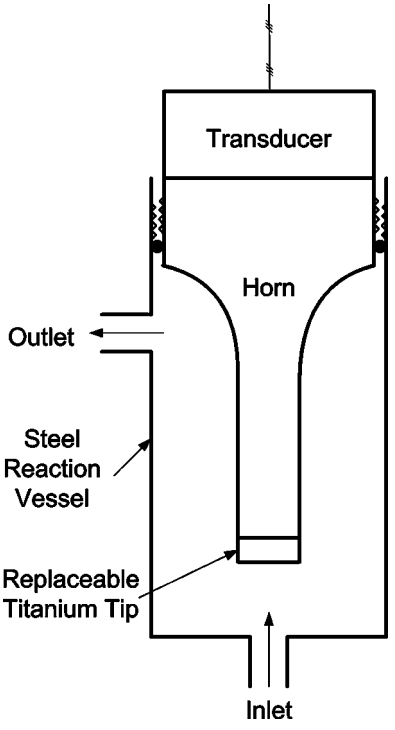

Fig. 5 Flow through reactor with direct sonication via an amplifying horn.

The first reactor type, which employs direct sonication, is represented by the lab scale system shown in Fig. 5. This flow reactor assembly consists of a titanium horn assembly, a piezoelectric transducer capable of variable energy output, and a flow through reaction chamber. This design provides for maximum utilization of the sound energy output from the transducer, but at a price. The replaceable tip of the titanium horn is prone to erosion and pitting, which can lead to a reduction in energy utilization as well as contamination of the process stream.

The second type of sonochemical reactor normally consists of a flat walled vessel that has multiple piezoelectric transducers mounted on the exterior surface of the reactor (in much the same way ultrasonic baths are arranged). These reactors have noncylindrical geometries because of difficulties associated with mounting the ceramic transducers on a curved surface (the transducer is normally glued to the exterior surface of the reactor). More optimized reactor designs of this type have multiple transducers located on opposing sides of the reactor, which creates a more uniform sound field for cavitation. An advantage of this reactor type is that corrosion byproducts from the ultrasound source cannot contaminate the reacting media; however, the coupling of the transducers to the reactor wall can be inefficient, and it is difficult to transmit high energy fluxes through the reactor walls.

The final reactor configuration type usually has the reacting fluid pass through a metal tube that is surrounded by a coupling fluid that is in direct contact with an ultrasound source. An efficient variant of this reactor type is the Branson sonochemical reactor shown in Fig. 6. This reactor configuration consists of a straight pipe for the reacting media and a series of external pipe sections that are arranged perpendicular to the reactant flow. This design is nonintrusive, hence there is little chance of contamination of the reagents; however, any design that uses probes

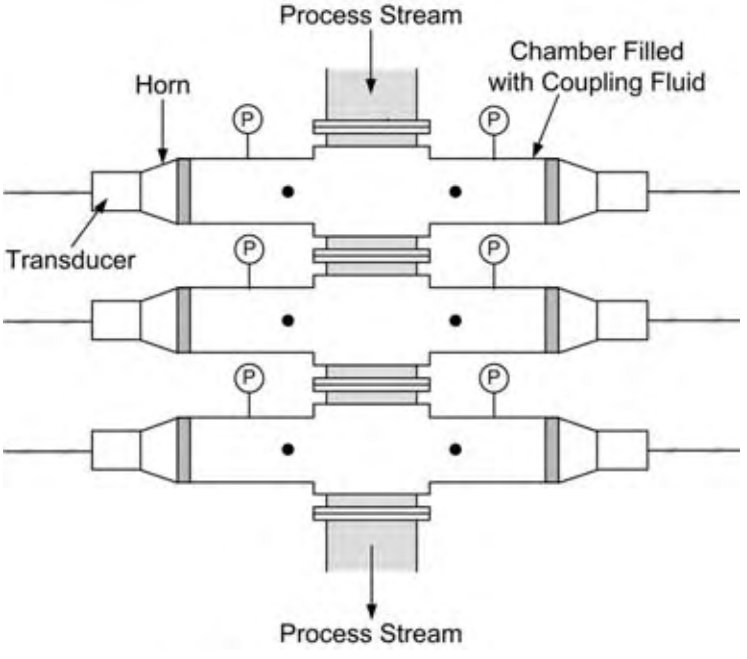

Fig. 6 Branson sonochemical reactor employing indirect sonication in a tubular configuration.

or horns to focus the acoustic energy is at a disadvantage because of tip erosion, which ultimately leads to greater maintenance costs.

CONCLUSIONS

Acoustic cavitation provides a relatively simple means for accessing high energy species in a reactor assembly that operates at near-ambient conditions. All sonochemical reaction processes are initiated by the introduction of high intensity sound waves into a liquid with moderately high surface tension. These high frequency pressure waves generate micrometer size bubbles that grow until they suddenly collapse (acoustic cavitation), generating extremely high pressures and temperatures (up to 1000 atm and 5000°C) in localized regions of the fluid. Such extreme thermal conditions lead to the formation of a variety of highly reactive free radicals and charged species. The interaction of these reactive intermediates with neighboring (cooler, low energy) species results in unique homogeneous, and in some cases heterogeneous, chemical conversions. To date, sonochemical transformations have been effectively employed in a wide variety of wastewater treatment applications; however, a number of efficiency and contamination issues have limited their use in the large scale production of organic chemicals and inorganic materials. As the technology for introducing high energy sound waves into liquids continues to advance, it is likely that sonochemical processing will become an ever more widely used tool to prepare high value added chemicals and materials.

Sorbent Technology

Shuguang Deng
Chemical Engineering Department, New Mexico State University, Las Cruces, New Mexico, U.S.A.

INTRODUCTION

This article covers the fundamentals, status, and future developments of sorbent materials and their applications in adsorptive separation and purification processes. A sorbent is usually a solid substance that adsorbs or absorbs another type of substance. It is the sorbent that makes a sorption process a unique and different separation and purification process from others. With the rapid development in novel sorbent materials and innovative cyclic adsorption processes, sorption has become a key separation process in many process industries including chemical, petrochemical, environmental, pharmaceutical, and electronic gases. A brief review of the fundamentals of adsorption and the basic requirements for sorbent materials is presented, followed with a summary of the status of commercial sorbents and their applications. The focus of this article is placed on recent advances in novel sorbent materials including oxide molecular sieves, sol–gel derived xerogels and aerogels, metal organic framework, hydrogen storage media, π-complexation and composite sorbents, and high-temperature sorbents for oxygen or carbon dioxide sorption. A concluding section outlines the future research needs and opportunities in sorbent technology development for new energy and environmental applications.

ADSORPTION MECHANISMS AND SORBENT MATERIALS

According to King, a mass separating agent is needed to facilitate separation for many separation processes.[1] The mass separating agent for adsorption process is the adsorbent, or the sorbent. Therefore, the characteristic of the sorbent directly decides the performance of any adsorptive separation or purification process. The basic definitions of adsorption-related terminologies are given in the following to clarify and standardize these widely used terms in this field.

Adsorption: The adhesion of molecules (as of gases, solutes, or liquids) to the surfaces of solid bodies or liquids with which they are in contact.

Absorption: The absorbing of molecules (as of gases, solutes, or liquids) into the solid bodies or liquids with which they are in contact.

Sorption: Formation from adsorption and absorption.

Adsorbent: A usually solid substance that adsorbs another substance on its surface.

Sorbent: A usually solid substance that adsorbs and absorbs another substance.

Adsorbate: Molecules (as of gases, solutes, or liquids) that are adsorbed on adsorbent surfaces.

Microporous: Pore size smaller than 20 Å.

Mesoporous: Pore size between 20 and 500 Å.

Macroporous: Pore size larger than 500 Å.

Adsorptive separation can be achieved through one of the following mechanisms. Understanding the fundamentals of adsorptive separation mechanisms will allow us to better design or modify sorbent materials to achieve their best possible separation performance.[2–4]

Adsorption equilibrium effect is because of the difference in the thermodynamic equilibria for each adsorbate–adsorbent interaction. The majority of adsorptive separation and purification processes are based on equilibrium effect. One example is to generate oxygen-enriched air or relatively pure oxygen (95%) from air using a zeolite molecular sieve 5A or 13X in either a pressure swing adsorption (PSA) or a vacuum swing adsorption (VSA) process. In this case, nitrogen is selectively adsorbed by the zeolite adsorbent, and oxygen is collected from the adsorption effluent stream.

Adsorption kinetics effect arises because of the difference of rates at which different adsorbate molecules travel into the internal structure of the adsorbent. There are only a few commercial successes using adsorption kinetic difference to achieve adsorptive separation of gases. The typical example is separation of nitrogen from air using a carbon molecular sieve (CMS). The CMS adsorbent has a similar adsorption equilibrium capacity for both nitrogen and oxygen, but the diffusivity of oxygen in CMS is at least 30 times larger than that of nitrogen in CMS.[5] High-purity

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007963

nitrogen can be recovered from the adsorption effluent stream in a PSA process because oxygen moves much faster than nitrogen into the micropores of CMS adsorbent. However, the cycle time of this CMS-based PSA process is much shorter than that of a typical PSA process based on adsorption equilibrium effect. This is because there will be no separation if both nitrogen and oxygen are allowed to reach adsorption equilibrium with the CMS adsorbent.

Molecular sieving effect, also called steric effect, is derived from the molecular sieving properties of some adsorbents with a microporous structure. In this case, the pore openings of the adsorbent structure are small enough to exclude large adsorbate molecules from penetrating the micropores of the adsorbent. This is the extreme case of the kinetic effect. There are several commercial applications based on this mechanism in adsorptive separation processes. One typical example is separating normal paraffin from *iso*-paraffin and aromatics in an adsorption process using zeolite 5A as an adsorbent. *n*-Paraffin, with a long straight chain, has a smaller effective diameter than the well-defined aperture of zeolite 5A. Therefore it adsorbs in the micropores of the adsorbent during the adsorption step, and is recovered from the adsorbed phase in the desorption step. A representative process for *n*-paraffin separation from naphtha and kerosene is UOP's Molex process that employs a simulated moving bed with binderless zeolite 5A as an adsorbent and light paraffin as a desorbent.[6]

We can define separation factor and selectivity as the ability of an adsorbent to separate molecule A from molecule B as:[7]

$$\text{Separation factor}: \alpha_{AB} = \frac{X_A/Y_A}{X_B/Y_B} \quad (1)$$

Here X_A, Y_A are strictly equilibrium mole fractions for component A in the adsorbed phase and adsorbate (fluid) phase, respectively; as are X_B, Y_B for component B. For equilibrium-based adsorptive separation process, the adsorbent selectivity is the same as the separation factor as defined in Eq. (1). Apparently, this definition is not applicable to other processes based on kinetic and steric effects. In a kinetically controlled adsorption process, the adsorbent selectivity depends on both equilibrium and kinetic effects. A simplified definition for adsorbent separation factor is given by Ruthven et al.:[8]

$$S_{AB} = \frac{K_A}{K_B}\sqrt{\frac{D_A}{D_B}} \quad (2)$$

where S_{AB} is the adsorbent selectivity, K is the adsorption equilibrium constant or isotherm slope, and D is the effective diffusivity. Although the above equation is strictly valid under the assumptions that components A and B have independent linear adsorption isotherms and independent diffusion process, it provides a good estimate of adsorbent selectivity for kinetically controlled processes.

Theoretically speaking, selectivity for adsorbents with a molecular sieving effect should be infinitely large because the larger molecules are excluded from getting into the adsorbent micropores. In reality, the adsorbent selectivity for steric effect is somewhat reduced by combining with the equilibrium effect from adsorption on the surface of large pores. So adsorption processes based on molecular sieving are usually considered as adsorption equilibrium effect.

Another very important adsorbent property affecting the adsorption process is the adsorption capacity because it determines the size of an adsorbent vessel, the amount of adsorbents required, and the related capital and operating costs. The requirements for commercial sorbents are discussed briefly as follows.

Characteristics of Sorbent Materials

Commercial sorbents used in cyclic adsorption processes should ideally meet the following requirements:

- Large selectivity derived from equilibrium, kinetic, or steric effect;
- Large adsorption capacity;
- Fast adsorption kinetics;
- Easily regenerable;
- Good mechanical strength;
- Low cost.

The above adsorbent performance requirements can simply transfer to adsorbent characteristic requirements as follows:

- Large internal pore volume;
- Large internal surface area;
- Controlled surface properties through selected functional groups;
- Controlled pore size distribution, preferably in micropore range;
- Weak interactions between adsorbate and adsorbent (mostly on physical sorbents);
- Inorganic or ceramic materials to enhance chemical and mechanical stability;
- Low-cost raw materials.

These basic requirements are usually proposed for adsorbents used in cyclic adsorption processes that are based on physical adsorption. There is an increasing demand for strong chemical adsorbents used in

purification processes to remove trace contaminants from main stream fluids such as the removal of very toxic contaminants from electronic process gas streams, and the removal of toxic, or radioactive species from contaminated water. In these cases, the sorbents are used as getter materials; no regeneration is needed, and instead, the spent sorbent materials are disposed of in designated areas regulated by government environmental policies.

COMMERCIAL SORBENTS AND APPLICATIONS

An excellent review and detailed coverage on commercial adsorbents and new adsorbent materials has been presented by Yang in his newly published monograph on adsorbents.[2] A very brief overview of existing commercial adsorbents is given here. Commercial sorbents that have been used in large-scale adsorptive separation and purification processes include activated carbon, zeolites, activated alumina, silica gel, and polymeric adsorbents. Although the worldwide sales of sorbent materials are relatively small as compared with other chemical commodities, sorbents and adsorption processes play a very important role in many process industries. The estimated worldwide sales of these sorbents are as follows:[2]

- Activated carbon: $1 billion
- Zeolite: $1.07 billion
- Activated alumina: $63 million
- Silica gel: $71 million
- Polymeric adsorbents: $50 million

Activated Carbon

Activated carbons are unique and versatile adsorbents because of their large surface area, microporous and mesoporous structure, universal adsorption effect, high adsorption capacity for many nonpolar molecules including organic molecules, and high degree of surface reactivity. They are used widely in industrial applications that include decolorizing sugar solutions, personnel protection, solvent recovery, volatile organic compound removal from air and water, water treatment, hydrogen and synthesis gas separation, and natural gas storage.[4,9,10] Activated carbons are produced in two main steps: carbonization of the carbonaceous raw materials at temperatures below 800 °C in the absence of oxygen, and activation of the carbonized products.[10] The properties of activated carbon depend largely on the nature of the raw materials, the activating agents and activation conditions. For gas-phase applications, activated carbons are usually made in pellets with mostly micropores; while for liquid-phase applications, activated carbon is produced in powder form with relatively large mesopores to enhance mass transfer rate in the carbons.

Fig. 1 compares the pore size distributions of major commercial adsorbents discussed in this section. Activated carbons have a broad pore size distribution like activated alumina and silica gel. Although activated carbon is thought to be "hydrophobic," it does adsorb

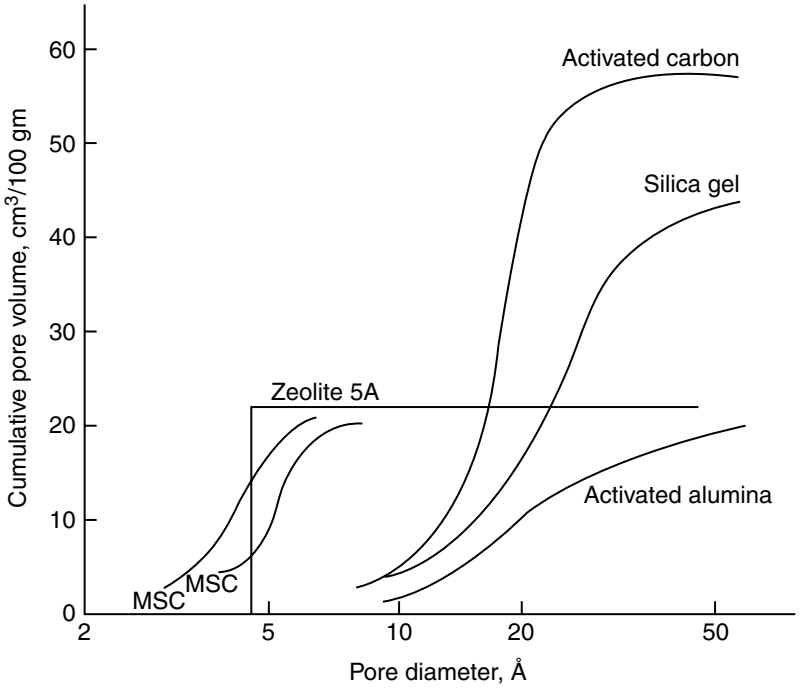

Fig. 1 Pore size distributions for activated carbon, silica gel, activated alumina, two molecular sieve carbons (MSCs), and zeolite 5A. (From Ref.[3].)

quite significant amount of water (>30 wt%) when relative humidity is higher than 50%. An example isotherm of water on activated carbon, along with water isotherms on other commercial adsorbents, is plotted in Fig. 2. The change from ''hydrophobic'' to ''hydrophilic'' on the activated carbon surface is attributed to the initial adsorbed water film on the carbon surface. This occurs because when the carbon surface is fully covered with a layer of water molecules, the adsorbed water molecules exhibit strong affinity to other polar molecules including water. Carbon molecular sieve (CMS) is a specially made carbonaceous material with very narrow pore size distribution (4–9 Å). The major application of CMS is in the generation of high-purity nitrogen from air in a PSA process. The representative physical properties of commercial adsorbents and their major applications are summarized in Tables 1 and 2, respectively.

Zeolites

Zeolites are porous crystalline aluminosilicates that are made of assemblies of SiO_4 and AlO_4 tetrahedra joined together through shared oxygen atoms. The general chemical formula for zeolites is:

$$M_{x/n}[(AlO_2)_x(SiO_2)_y]zH_2O \quad (3)$$

where x and y are integers with y/x (Si/Al ratio) equal or larger than 1; n is the valance of cation M, and z is the number of water molecules in each unit cell. The tetrahedra can be arranged in many different ways to form different crystalline structures. Some zeolites exist as minerals in nature, but all commercially important zeolites are synthetic. Zeolites are unique adsorbents owing to their special surface chemistries and crystalline pore structures. It should be pointed out that probably only 10% of $1 billion worldwide sales of zeolite is used as adsorbents; the majority of commercial zeolites are used as detergent additives (zeolite 4A), animal food additives (zeolite 4A), ion exchange, and catalyst supports. Among all commercial sorbents zeolites are probably the most extensively investigated and documented. Many excellent monographs and review articles are available.[2,11–13] Please refer to Tables 1 and 2 for properties and major applications of zeolites.

Activated Alumina

Activated alumina is a porous high-surface area form of aluminum oxide with the formula of $Al_2O_3 \cdot nH_2O$. Commercially, it is prepared either from thermal dehydration of aluminum trihydrate, $Al(OH)_3$, or directly from bauxite ($Al_2O_3 \cdot 3H_2O$), as a by-product of the Bayer process for alumina extraction from bauxite. Its surface is more polar than that of silica gel and, reflecting the amphoteric nature of aluminum, has both acidic and basic characteristics. Surface areas are in the range 250–350 m^2/g depending on the activation temperature and the source of raw materials. Because activated alumina has a higher capacity for water than silica gel at elevated temperatures it is used mainly as a desiccant for warm gases including air, but in many commercial applications it has now been replaced by zeolitic materials in a thermal swing

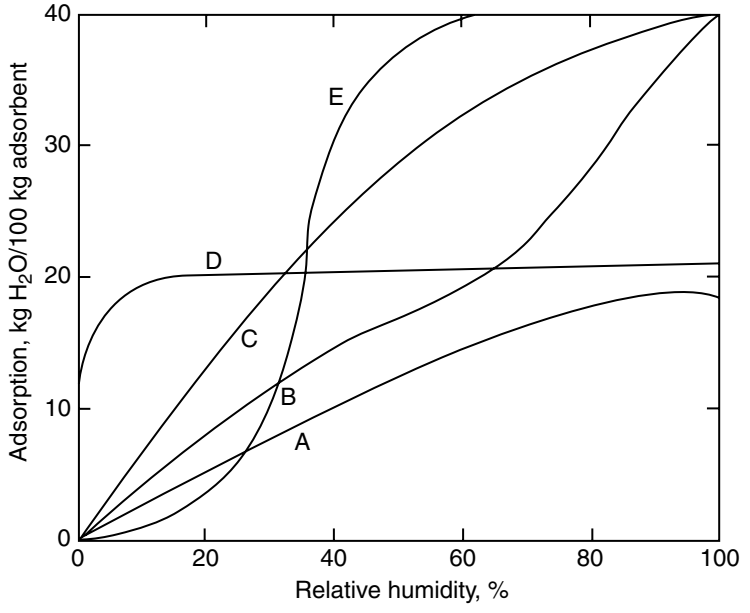

Fig. 2 Equilibrium sorption of water vapor from atmospheric air at 25 °C on: (A) alumina (granular), (B) alumina (spherical), (C) silica gel, (D) 5A zeolite, and (E) activated carbon. The vapor pressure at 100% relative humidity is 23.6 torr. (From Ref.[3].)

Table 1 Representative physical properties of commercial adsorbents

Adsorbent	Nature	Specific surface area (m^2/g)	Pore diameter (Å)	Porosity	Particle density (g/cm^3)
Activated carbon	Hydrophobic amorphous				
Small pore		400–1200	10–25	0.4–0.6	0.5–0.9
Large pore		200–600	>30	$\sim$0.5	0.6–0.8
Zeolite	Hydrophilic/hydrophobic crystalline	600–700	3–10	0.6	1.0
Activated alumina	Hydrophilic crystalline/x-ray amorphous	200–350	10–75	0.5	1.25
Silica gel	Hydrophilic/hydrophobic amorphous				
Small pore		750–850	22–26	0.47	1.09
Large pore		300–350	100–150	0.71	1.62
Polymeric adsorbent	Hydrophilic/hydrophobic	450–1100	25–90	0.5	1.25
Carbon molecular sieve	Hydrophilic	$\sim$400	3–9	0.5	1.0

adsorption (TSA) process. However, activated alumina has a low adsorption heat for water and other polar molecules as compared with zeolite; it is possible to regenerate activated alumina under PSA conditions. Activated alumina also demonstrates moderate adsorption affinity for carbon dioxide, which makes it a suitable sorbent for removing water and carbon dioxide from air in a PSA process. These adsorption properties of activated alumina have been explored extensively for air purification applications by industrial gas companies.[14–17] This is a perfect example to demonstrate the importance of sorbent regenerability over sorption capacity and selectivity in pressure swing adsorption processes. Activated alumina is also an excellent catalyst support. More applications and representative properties of activated alumina are listed in Tables 1 and 2.

Silica Gels

Silica gel is the most widely used desiccant because of its large adsorption capacity for water (40 wt%), as shown in Fig. 2, and easy for regeneration ($\sim$150°C, compared with 350°C for zeolites). Silica is a partially dehydrated polymeric form of colloidal silicic acid with the formula of $SiO_2 \cdot nH_2O$. Its water content, which is typically about 5 wt%, is presented in the chemically bonded hydroxyl groups. Silica is an amorphous material comprising spherical particles of 20–200 Å in size, which aggregate to form the sorbent with pore sizes in the range of 60–250 Å and surface areas of 100–850 m^2/g, depending on gel density. Its surface has mainly Si–OH and Si–O–Si polar groups; this is why it can be used to adsorb water, alcohols, phenols, amines, etc. by hydrogen bonding mechanisms. Other commercial applications include the separation of aromatics from paraffins, the chromatographic separation of organic molecules, and modified silica in chromatography columns.[2,18–20]

Polymeric Adsorbents

A wide range of synthetic, nonionic polymers are available for use as sorbents, ion-exchange resins, and particularly for analytical chromatography applications. Commercially available resins in bead form (typically 0.5 mm in diameter) are based usually on copolymers of styrene/divinyl benzene (DVB) and acrylic acid esters/divinyl benzene, and have a wide range of surface polarities, porosities, and macropore sizes. The porosities can be built through emulsion polymerization of relevant monomers in the presence of a solvent that dissolves the monomers and serves as a poor swelling agent for the polymer. This creates a polymer matrix with surface areas ranging up to 1100 m^2/g.[2,4] The major application of polymeric adsorbents is in water treatment. The macroporous polymeric resins can be modified by attaching different functional groups to mimic activated carbon, and to replace activated carbons for certain specific applications in food and pharmaceutical industries where color contamination by the black carbons of the final products is a major concern.

NEW DEVELOPMENTS IN SORBENT MATERIALS AND APPLICATIONS

The past two decades have witnessed major advances in new nanostructured sorbent materials including

Table 2 Selected applications of commercial sorbents

Adsorbent	Applications (the first molecule is the product)
Activated carbon	Hydrogen separation from syngas and hydrogenation processes Ethylene from methane and hydrogen Vinyl chloride monomer (VCM) from air Removal of odors from gases Recovery of solvent vapors Removal of SO_x, and NO_x Purification of helium Clean-up of nuclear off-gases Decolorizing of syrups, sugars, and molasses Water purification, including removal of phenol, halogenated compounds, pesticides, caprolactam, chlorine
Carbon molecular sieve	Nitrogen separation from air
Zeolite	Oxygen from air Drying of gases Removing water from azeotropes Sweetening sour gases and liquids Purification of hydrogen Separation of ammonia and hydrogen Recovery of carbon dioxide Separation of oxygen and argon Removal of acetylene, propane, and butane from air Separation of xylenes and ethyl benzene Separation of normal from branched paraffins Separation of olefins and aromatics from paraffins Recovery of carbon monoxide from methane and hydrogen Purification of nuclear off-gases Separation of cresols Drying of refrigerants and organic liquids Separation of solvent systems Pollution control, including removal of Hg, NO_x, and SO_x from gases Recovery of fructose from corn syrup
Activated alumina	Drying of gases, organic solvents, transformer oils Removal of HCl from hydrogen Removal of fluorine and boron–fluorine compounds in alkylation processes Removing of water and carbon dioxide from air in a PSA process
Silica gel	Drying of gases, refrigerants, organic solvents, transformer oils Desiccant in packings and double glazing Dew point control of natural gas
Polymeric adsorbents	Water purification, including removal of phenol, chlorophenols, ketones, alcohols, aromatics, aniline, indene, polynuclear aromatics, nitro- and chlor-aromatics, polychlorinated biphenyls (PCBs), pesticides, antibiotics, detergents, emulsifiers, wetting agents, kraftmill effluents, dyestuffs, and radionuclides Recovery and purification of steroids, amino acids and polypeptides Separation of fatty acids from water and toluene Separation of aromatics from aliphatics Separation of hydroquinone from monomers Recovery of proteins and enzymes Removal of colors from syrups Removal of organics from hydrogen peroxide
Clays (acid treated and pillared)	Removal of organic pigments Refining of mineral oils Removal of PCBs

(From Ref.[4].)

mesoporous molecular sieves, sol–gel-derived metal oxide xerogels and aerogels, metal organic framework, π-complexation and composite adsorbents, new carbonaceous materials (carbon nanotubes, carbon fibers, superactivated carbons), high-temperature ceramic sorbents, and strong chemical sorbent materials. Although these new sorbent materials have demonstrated promising sorption properties for many existing and new applications, systematic studies on synthesis methods and characterization of these new materials are necessary to fully explore and realize their potential as commercial sorbents. The review that follows aims at attracting more research efforts to develop novel sorbent materials to meet the increasing needs of new energy, environmental, and other emerging technologies.

Oxide Molecular Sieves

Microporous and mesoporous oxide molecular sieves that have the characteristics of large internal surface area and pore volume are ideal candidates for use as sorbent materials and catalyst supports of many heterogeneous catalysts. Oxide molecular sieves are generally synthesized by hydrothermal methods that involve both chemical and physical transformations within an amorphous oxide gel, often in the presence of a template species. The gel eventually converts to a crystalline material in which the template species and/or solvent molecules are guests within the channels and cages of an oxide host framework. A porous material is obtained upon removal of the guest molecules from the oxide framework. By manipulating the synthesis parameters, including starting precursors, synthesis temperature, pH, template species, drying, and calcination conditions, it is possible to tailor the pore size and shape of these porous materials for different applications. However, tailoring of porosity in oxide molecular sieves in terms of a priori structural design is extremely difficult because of the inherent complexity of the synthetic procedures employed.[21]

Recent advances and applications of oxide molecular sieves have been summarized in several review articles.[2,21–23] Microporous zeolite materials synthesized with molecular templates and their applications in host–guest chemistry have been covered elsewhere.[13] A new class of silicate/aluminosilicate mesoporous molecular sieves designated as M41S was discovered in the former Mobil research laboratory by extending the concept of zeolite templating with small organic molecules to large long-chain surfactant molecules.[24] A representative member of this family is MCM-41, which has a honeycomb-shaped hexagonal arrangement of uniform mesopores in the range of 15–100 Å, specific surface area of $1040\,m^2/g$, pore volume above $0.7\,cm^3/g$, and significantly high sorption capacity for hydrocarbons (49 wt% for *n*-hexane at 40 torr and 21°C, and 67 wt% for benzene at 50 torr and 25°C).[24] Other significant members of the M41S family include MCM-48 (cubic phase), MCM-50 (stabilized lamellar phase), SBA-1 (cubic phase), and SBA-2 (cubic phase).[21]

Although M41S type mesoporous oxide molecular sieves have exhibited unique properties of large surface area and exceptionally large pore volume ($> 0.7\,cm^3/g$), their large pore volume may not be attractive for gas sorption because the adsorbate–adsorbent interactions are not enhanced inside the internal pores of these materials.[2] Therefore, M14S type mesoporous oxide molecular sieves without surface modification are rarely used as sorbents. Significant research efforts were devoted to surface modification of M41S materials for different applications.[2] An amine-grafted MCM-48 sorbent, synthesized from tetraethoxysilane (TEOS), has been shown to have a surface area of $1389\,m^2/g$, a silanol number of 8, higher thermal stability than MCM-41, high adsorption selectivity, and high capacity for both carbon dioxide and hydrogen sulfide.[25]

Sol–Gel-Derived Xerogels and Aerogels

Sol–gel processing refers to the fabrication process of ceramic materials by preparation of a sol, gelation of the sol, and removal of the solvent.[26] Sols are dispersions of colloidal particles in a liquid solvent, and a gel is a solid matrix encapsulating a solvent. In a sol–gel process, the sol can be formed from a solution of colloidal powders or hydrolysis and condensation of alkoxides or salt precursors. In the latter approach, which is much more popular, primary particles of uniform size are formed and grow in a sol and connect to each other to form aggregates during gelation. These aggregates forming the network of the gel are broken apart into the primary particles in the drying step. Upon calcination and sintering, these primary particles are bound together strongly to form a very rigid solid network, and large interparticle space with uniform nanoscale pores is formed. *Xerogels* are obtained by drying the gels through evaporation at normal conditions under which capillary pressure causes shrinkage of the gel network, while *areogels* are produced by drying the wet gels at supercritical conditions where the liquid–vapor interface is eliminated, and relatively little shrinkage of the gel network occurs. Xerogels and aerogels typically have relatively large surface area, high porosity, and internal pore volume, and are ideal candidates as sorbent and catalyst support materials for many applications. The sol–gel process offers a very high flexibility to tailor xerogels and areogels for specific applications by manipulating the synthesis conditions.

Silica xerogel is probably the most studied and documented porous material in the sol–gel system.[27,28] Although silica has several crystalline forms, only amorphous silica gel is used as a desiccant (sorbent). A microporous silica that was synthesized with TEOS as precursor has an average pore size of 6.4 Å, pore volume of 0.24 cm^3/g, and Brunauer–Emmett–Teller (BET) surface area of 588 m^2/g.[29] However, this material lost about 90% of its microporosity when it was heated at 600°C for 30 hr. By doping with 1.5% of alumina, the thermal stability of this microporous silica was significantly improved.[29]

Crystalline sorbent materials including γ-alumina, zirconia, and titania were also synthesized using the sol–gel process in Lin's group;[29] the representative pore size distribution and pore texture data of xerogels of γ-alumina, zirconia, and titania are summarized in Fig. 3 and Table 3, respectively. As shown in Fig. 3, the pore size distributions of these materials are rather narrow, with an average pore diameter of about 3 nm. Such narrow size distribution and nanoscale average pore size are determined by the primary crystallite particles. The particles of the sol–gel-derived alumina, titania, and zirconia, owing to the Ostwald ripening mechanism,[26] are usually of nanoscale size; the uniform particle size distributions of γ-alumina crystallites are plate-shaped with size ranging from about 5 to 20 nm. The sol–gel-derived γ-alumina consists of such plate-shaped crystallite particles, which give rise to a relatively large surface area. Crystallites of tetragonal zirconia and rutile are of more spherical shape, with a crystallite size of about 15 and 11 nm, respectively.[29]

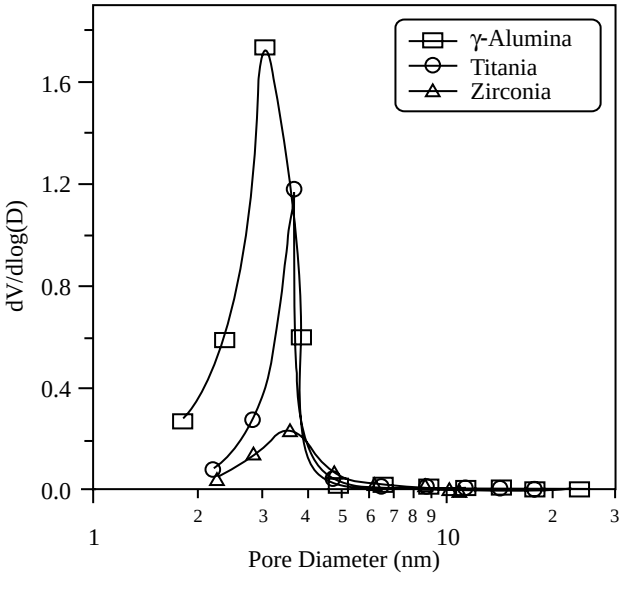

Fig. 3 Pore size distribution of sol–gel-derived alumina, zirconia, and titania. (From Ref.[29].)

Table 3 Pore texture sol–gel-derived alumina, zirconia, and titania (calcined at 450°C for 3 hr)

Xerogel	Average pore size (Å)	Pore volume (cm^3/g)	BET surface area (m^2/g)
γ-Al_2O_3	28	0.33	373
ZrO_2	38	0.11	57
TiO_2	34	0.21	147

One of the outstanding characteristics of sol–gel-derived γ-alumina xerogel is its excellent mechanical properties. Preparation of porous γ-alumina granules with good mechanical properties and desirable pore structure is of great importance in the development of novel catalysts and sorbents for various applications. The superior mechanical properties can be derived from the unique microstructure of the granule, which is defined by compacting small γ-alumina crystallite particles bound together by the bridges of the same material formed through coarsening or sintering. Such nanostructured γ-alumina can be prepared by combining the Yoldas process and the ''oil-drop'' method.[30–34] Table 4 compares the crush strength and attrition rate of sol–gel-derived γ-alumina xerogel granules with those of several commercial sorbents. It is clearly shown in Table 4 that the sol–gel-derived γ-alumina xerogel granules have excellent mechanical properties as compared with commercial sorbents. The excellent mechanical properties makes sol–gel-derived alumina granules very suitable for fluidized bed and other applications including separation and purification process for food and healthcare products that have very strict regulations on sorbent power contamination.

Sol–gel-derived xeorgel sorbents have been investigated for gas separation, purification, and environmental applications. γ-Alumina sorbents and membranes doped with cuprous and silver ions have been studied for selective adsorption or transfer of CO and ethylene through π-complexation.[35–37] Significant efforts have been devoted to explore the possibility of using CuO-doped γ-alumina sorbents for removing SO_x and NO_x from flue gas.[38–44] The sol–gel-derived CuO/γ-alumina sorbents have demonstrated high sorption capacity, high reactivity for SO_2, and high thermal and chemical stability. The excellent mechanical and desulfurization properties of sol–gel-derived sorbents make them ideal sorbent candidates for fluidized bed desulfurization process. However, the relatively high cost of sol–gel-derived alumina xerogels may prevent them from being used in many large-scale adsorption processes. Research efforts are needed to look for less expensive precursors to replace alkaoxides used in the Yoldas process.

Table 4 Comparison of crush strength and attrition rate of sol–gel-derived γ-alumina xerogel granules with commercial sorbents

Sorbents	Granular shape	Granular size (mm)	Average crush strength (N/granule)	Attrition rate (wt%/hr)
Sol–gel alumina	Spherical	2.0–2.5	160	0.033
Sol–gel alumina	Spherical	2.6–2.8	190	
Alcoa alumina (LD-350)	Spherical	4.0–4.6	42	0.177
UOP silicalite	Cylindrical	1.4–1.6	16	0.575
Degussa DAY zeolite	Cylindrical	3.5–3.5	40	0.073

Sol–gel-derived metal oxide xerogels were also investigated for water adsorption because most of these metal oxides are good sorbent candidates for desiccant applications.[45–47] Significant research works have been carried out to study the adsorption/complexation properties of heavy metal ions including mercury, Cu(II), $CdCl_2$, etc. in waste water on different sol–gel-derived xerogels.[48–54] The sol–gel-derived xerogels seem to be promising sorbent candidates for waste water treatment. Modified xerogel sorbents also showed promising adsorption properties for removing acid gas CO_2 and H_2S from natural gas, or as CO_2 storage sorbents.[25,55] There are several advantages of using xerogels for enzyme immobilization, including the opportunity to produce them in defined shapes or thin films and the ability to manipulate their physical characteristics including porosity, hydrophobicity, and optical properties.[56,57] Metal oxide composite xerogels can also adsorb methyl orange.[58] There are also reports on microporous and mesoporous carbon xerogels for gas separation and purification.[59,60]

As compared with xerogels, aerogels have larger surface area, larger pore volume, and higher porosity.[61–64] Alumina aerogels with a specific surface area as high as $1000\,m^2/g$, and a pore volume as high as $17.3\,cm^3/g$ have been synthesized by supercritical carbon dioxide drying, but a very limited information on their adsorption properties was found.[61,62] A super water adsorbent consisting of 17–30% of $CaCl_2$ doped on SiO_2 aerogel showed an effective reversible adsorption capacity of 100 wt%; the adsorption capacity of hydrophilic silica aerogels can be fully recovered after regeneration.[64–66] CaO- and MgO-modified SiO_2 aerogel sorbents can be used to capture pollution gases including CO_2, SO_2, CO, and NO_x emitted from power plants based on fossil fuels.[67] Several studies reported the use of aerogels as destructive sorbents for toxic gases and radionuclide removal from contaminated environments.[64,68–70] Carbon aerogels can also be made from carbon materials under supercritical carbon dioxide drying conditions; these carbon aerogels were studied for removing uranium and other inorganic ions from contaminated water.[71–73] Aerogels are special sorbent candidates with excellent pore texture, which may play a major role in environmental protection. However, more studies on their synthesis and adsorption properties are needed.

Metal Organic Framework (MOF)

Recently, Yaghi's group reported a novel crystalline nanoporous material that consists of metal atoms occupying the vertices of a lattice, with the lattice size, porosity, and chemical environment defined by the organic linker molecules that bind the metal atoms into a robust periodic structure.[74–76] These so-called metal organic framework (MOF) materials have been demonstrated to have an exceptionally high specific surface area of $4526\,m^2/g$, and find use as adsorbents for methane and as hydrogen storage materials.[74,77–80] A reticular synthesis method was developed to realize the bottom-up synthesis through top-down design logic by using inorganic, metal organic, and organic molecules to build frameworks and large molecules.[81] Well-defined molecular building blocks that will maintain their structural integrity throughout the construction process were used to build the MOF molecules. It allows remarkable control over composition and structure of the material formed and employs the full range of the molecular synthetic methods and compounds in the preparation of this new type of porous sorbent materials. The ability to molecularly engineer the lattice size, chemical environment, and possibly structure by careful choice of the metal centers and organic linkers offers the opportunity for the development of new types of sorbents that could potentially meet the Department of Energy (DOE) target for hydrogen storage and that can be used for other applications in separation and purification.

It is reported that metal organic framework-5 (MOF-5) of composition $Zn_4O(BDC)_3$ (BDC: 1,4-benzenedicarboxylate) with a cubic three-dimensional extended porous structure and octahedral Zn–O–C clusters with benzene links can adsorb hydrogen up to 4.5 wt% at 78 K, and 1.0 wt% at room temperature and pressure of 20 bar.[74,79] It is identified by inelastic neutron scattering spectroscopy of the rotational

transitions of the adsorbed hydrogen molecules that zinc and the BDC linker in MOF-5 are the two hydrogen binding sites responsible for hydrogen adsorption on this material. Higher hydrogen adsorption capacity at ambient temperature and 10 bar were observed on similar isoreticular metal organic framework-6 and -8 (IRMOF-6 and -8) having cyclobutylbenzene and naphthalene linkers.[79] A different microporous MOF sorbent [microporous metal coordination materials (MMOM)] was reported to have hydrogen sorption capacities (~1.0 wt% at room temperature and 48 bar) similar to those of the best single-wall carbon nanotubes.[80] The adsorbed hydrogen can be released when the gas pressure is reduced.

MOF sorbents have also been investigated for methane adsorption.[77] The reported methane storage capacity of MOF-6 is 155 cm^3 (STP)/cm^3 at 298 K and 36 atm, which is significantly higher than that of zeolite 5A (87 cm^3 (STP)/cm^3) and other coordination framework (213 cm^3 (STP)/cm^3).[77] Adsorption and desorption of carbon dioxide, nitrogen, and argon on a microporous manganese-based MOF sorbent has been reported.[78] Another interesting porous MOF sorbent, Cu-BTC (polymeric copper(II) benzene-1,3,5-tricarboxylate) with molecular sieve character, was studied for its sorption properties of various adsorbates including nitrogen, oxygen, carbon monoxide, carbon dioxide, nitrous oxide, methane, ethylene, ethane, and *n*-dodecane.[82,83] A detailed investigation of sorption thermodynamics was performed for carbon dioxide by a sorption-isosteric method. It was demonstrated that Cu-BTC sorbent can be used for the separation of carbon dioxide–carbon monoxide, carbon dioxide–methane, and ethylene–ethane mixtures. In addition, this sorbent can also be used to remove carbon dioxide, nitrous oxide, high molecular weight hydrocarbons, and moisture from ambient air before cryogenic separation to produce oxygen and nitrogen.[82]

Hydrogen Storage Media

The development of hydrogen-fueled transportation system and portable electronics will demand new materials that can store large amounts of hydrogen at ambient temperature and relatively low pressures with small volume, light weight, fast charging and discharging time, cyclic stability, and low cost. Table 5 summarizes the targets for hydrogen storage system for automotive applications set by USDOE. The hydrogen storage capacities are calculated as both weight and volume percentage of the storage system.[84] To achieve these goals, the hydrogen storage media (sorbent) should have a high reversible hydrogen sorption capacity, low weight and high packing density as well as fast sorption/desorption kinetics, and low cost.

Table 5 USDOE FreedomCAR hydrogen storage system targets

	Year		
Target factor	**2005**	**2010**	**2015**
Specific energy (MJ/kg)	5.4	7.2	10.8
Hydrogen (wt%)	4.5	6.0	9.0
Energy density (MJ/L)	4.3	5.4	9.72
System cost ($/kg/system)	9	6	3
Operating temperature (°C)	−20/50	−20/50	−20/50
Cycle life-time (adsorption/desorption cycles)	500	1000	1500
Flow rate (g/sec)	3	4	5
Delivery pressure (bar)	2.5	2.5	2.5
Transient response (sec)	0.5	0.5	0.5
Refueling rate (kg H_2/min)	0.5	1.5	2.0

(From Ref.[84].)

Hydrogen can be stored both physically and chemically in a confined vessel with or without the assistance of a storage media. The most commonly used methods for hydrogen storage are: gaseous and liquid hydrogen storage, solid state storage in complex metal hydrides, chemical storage materials, and in nanostructured materials.[2,85] The representative hydrogen storage capacities, hydrogen storage, and release conditions in various materials are summarized in Table 6.

Carbon nanotubes are probably the most investigated and documented hydrogen storage sorbent materials. Several excellent reviews on carbon nanotubes for hydrogen storage are available.[2,86] As shown in Table 6, the hydrogen storage capacities on representative carbon nanotubes are below 6 wt%, the most referred DOE target for 2010.[84,87,88] The following concerns about carbon nanotubes as hydrogen storage materials have driven research in this area to other directions:[85]

1. Difficult to meet the DOE's long-term target (9 wt%);
2. Mechanisms for hydrogen sorption in carbon nanotubes are not well understood;
3. Part of the adsorbed hydrogen can only be recovered at high temperatures;
4. Preparation and purification of carbon nanotubes involve complicated and expensive processes, which leads to high cost of carbon nanotubes;
5. Hydrogen storage capacity is quite sensitive to sorbent preparation conditions;
6. Mixed results on hydrogen adsorption capacity have been reported.

Table 6 Summary of hydrogen storage capacity of various nanostructured materials

Materials	H_2 storage capacity (wt%)	H_2 storage conditions	H_2 release conditions	Reference
Carbon nanotubes				
Single-walled	4.2	10 MPa, 300 K	1 bar, 300 K	[87]
Multi-walled	3.6	7 MPa, 298 K	1 bar, 298 K	[88]
Non-carbonaceous nanotubes				
BN	4.2	108 bar, 298 K	1 bar, 298 K	[89]
TiS_2	2.5	40 bar, 298 K	1 bar, 298 K	[90]
Microporous MOF				
MOF-5	4.5	0.75 bar, 77 K	1 bar, >77 K	[74]
MMOM	$\sim$1.0	48 bar, 298 K	1 bar, 298 K	[80]
Metal hydrides				
Mg_2NiH_4	3.6	1 bar, $\sim$500 K	1 bar, >528 K	[91]
$NaAlH_4$	8.0	90 bar, 403 K		[92]
$Mg(AlH_4)_2$	6.6		1 bar, >436 K	[93]
$LiBH_4$	13.3		1 bar, >473 K	[94]
Nitrides				
Li_3N	9.3	1 bar, 443–473 K	1 bar, >700 K	[95]
Clathrate/molecular compounds				
$H_2(H_2O)_2$	5.3	$\sim$1 bar, 77 K	1 bar, >77 K	[97]
$H_2(H_2O)$	10.0	$\sim$6000 bar, 190 K	<6000 bar, >190 K	[97]
$(H_2)_4(CH_4)$	33.3	$\sim$2000 bar, 77 K	<2000 bar, >77 K	[97]

Noncarbonaceous nanotubes including boron nitride (BN) and titanium sulfide (TiS_2) have been prepared and studied for hydrogen sorption.[89,90] Hydrogen storage capacity (2.5–4.5 wt%) similar to those for carbon nanotubes have been obtained on these noncarbonaceous materials. MOF-based sorbents for hydrogen sorption was discussed in the previous section. As suggested in Table 6, the hydrogen sorption capacities on MOF-5 and MMOM are lower than those on carbon nanotubes. However, MOF sorbents look more promising than carbon nanotubes as hydrogen storage media for the following reasons:

1. MOF is easy to make and is less expensive;
2. Sorption sites for hydrogen on MOF are better defined;
3. MOF sorbents may have extremely high specific surface area ($>4000\,m^2/g$);
4. It is possible to tailor the interaction between hydrogen and MOF by manipulating synthesis parameters including different building blocks.

Metal hydrides were widely investigated for hydrogen storage, and are believed to be ideal hydrogen storage system because they have the following characteristics:[2,84,91–94]

1. Relatively high hydrogen storage capacity at modest pressures as indicated in Table 6;
2. Fast hydrogen charging and discharging rates; and
3. Moderate temperature for hydrogen desorption.

However, metal hydrides also suffer from the following disadvantages as hydrogen storage materials:

1. High sensitivity to impurities in hydrogen (CO, H_2O, O_2, CO_2, and H_2S);
2. Storage capacity and rates decay with hydrogen charge–discharge cycles; and
3. Relatively high cost as compared with gaseous and liquid hydrogen storage methods.

Another interesting hydrogen storage material is lithium nitride (Li_3N), which shows 9.3 wt% useful hydrogen storage capacity between thermal swing cycles (473–700 K).[95] The requirement for high-temperature desorption will greatly limit its applications. Most recently, hydrogen clathrate hydrate and other

molecular compounds were found to have hydrogen storage capacities as high as 33.3 wt%.[96–98] This is a very innovative way to store hydrogen with exceptionally high capacity to meet the DOE long-term target. However, these clathrate and hydrogen storage compounds were synthesized at extremely high pressures and at liquid nitrogen temperature. It is unlikely these clathrate hydrates will be used for hydrogen storage until we find new clathrate hydrate compounds that can be synthesized and are stable at much lower pressures.

π-Complexation Sorbents and Composite Sorbents

A very good review article based on a panel study of status, future research needs, and opportunities for porous sorbent materials was published several years ago.[99] It was pointed out that very significant advances have been made in tailoring the porosity of porous sorbent materials in terms of size and shape selectivity. Relatively little progress has been achieved in terms of chemoselectivity of sorbents based on specific interactions between adsorbate molecules and functional groups in the sorbents. Incorporation of active sites into sorbents is of high priority in the development of sorbents.

The π-complexation bond is a weak chemical bond that is slightly stronger than van der Waals interaction, which governs physical sorption processes. Sorbents with π-complexation capability tend to have higher selectivity than other physical sorbents for certain adsorbate molecules. Several different types of π-complexation sorbents with Cu^+ or Ag^+ ions supported on different supports (SiO_2, γ-Al_2O_3, TiO_2, variety of zeolites, polymer resin, and activated carbon) were synthesized using different methods including thermal dispersion, wet-impregnation, sol–gel, microwave heating, ion-exchange zeolite, and ion-exchange resin.[34–36,99–105] It was found that the CO adsorption capacity increases with Cu^+ loading in an activated alumina supported sorbent.[100,101] To achieve the highest sorption capacity, the active species should be dispersed as a monolayer form.[99] The potential applications of these π-complexation sorbents include:[2]

1. Desulfurization of gasoline and diesel fuels;
2. Separation of olefins and paraffins;
3. CO separation from synthesis gases;
4. CO removal from hydrogen;
5. Removal of aromatics; and
6. Removal of volatile organic compounds (VOCs).

A π-complexation sorbent can also be viewed as a composite sorbent especially when the sorbent support contributes significantly to the adsorption. Composite sorbents are typically made by physically mixing the powders of constituent sorbents with different sorption properties; they tend to have multiple sorption sites for different adsorbate molecules. One example of a composite sorbent is a mixture of activated alumina and zeolites for removing moisture, carbon dioxide, and other trace components from air in an air-purification process prior to cryogenic air separation.[106–108] Conventionally, moisture is removed by activated alumina, carbon dioxide by zeolite 13X, and hydrocarbons by zeolite 5A.[107,108] Traditional air-purification processes employ multiple layers consisting of activated alumina, zeolite 13X, and optional zeolite 5A sorbents in a single vessel to achieve significant removal of moisture, carbon dioxide, and hydrocarbons from air. The major disadvantages of layered bed are nonuniform sorbent packing for a short sorbent layer, very significant temperature variation ($> 30°C$, sometimes called cold spots) between the zeolite and the activated alumina sorbent layers. The large temperature difference could upset the sorption process operation if it is designed to be operated isothermally. It is beneficial to have a single sorbent with multiple sorption features for different impurities and eliminate sorbent layering and temperature variations.

High-Temperature Ceramic O_2 Sorbents

Lin et al. disclosed in a U.S. patent a new group of sorbents for air separation and oxygen removal using oxygen-deficient perovskite-type ceramics as sorbents.[109] Perovskite-type ceramics are a group of metal oxides having the general formula of ABO_3. The ideal perovskite structure for ABO_3 is shown in Fig. 4. It consists of cubic array of corner-sharing BO_6 octahedra, where B is a transition metal ion. The A-site ion, interstitial between the BO_6 octahedra, may be occupied by an alkali, an alkaline earth, or a rare earth ion. Alternatively, the perovskite structure may be regarded as a cubic close packing of layers of AO_3 with B cations placed in the interlayer octahedral interstices.[110] This group of the sorbents can be viewed as chemisorbents that can selectively adsorb a considerable amount of oxygen at high temperatures ($> 300°C$), and theoretically has an infinitely high selectivity for oxygen over nitrogen or other nonoxygen species. The presence of other gases has negligible effect on the separation properties of these new sorbents. High-temperature membrane separation of oxygen has also received increasing interest from other industrial gas companies.[111–113] Development of high-temperature oxygen separation technology opens up several high-temperature applications of oxygen including syngas production, hydrogen production, and partial oxidation fuel reforming processes.

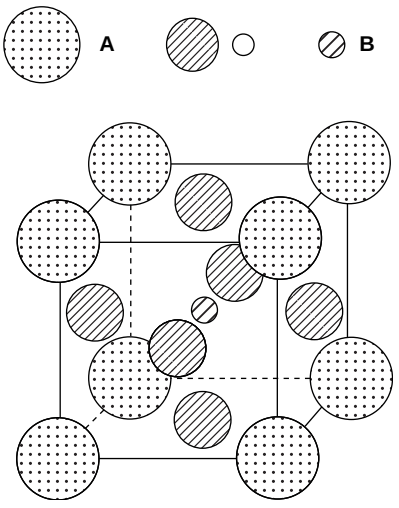

Fig. 4 Ideal perovskite structure for ABO_3 type oxides.

The oxygen equilibrium and kinetic properties of perovskite-type ceramics have been extensively studied primarily for applications as fuel cell electrodes and oxygen permeable membranes,[110] and only a few for oxygen sorption.[114–117] Oxygen nonstoichiometry (δ) occurs in some perovskite-type ceramics with B-site cations of variable oxidation states and A-site cations partially substituted by another cation with a lower oxidation state. Oxygen nonstoichiometry, or oxygen content, for a perovskite-type ceramic of a given composition is a function of temperature and oxygen partial pressure. Therefore, by changing temperature or oxygen partial pressure, the value of oxygen nonstoichiometry or the degree of oxygen vacancy in the material changes. Within a certain range of temperature and oxygen partial pressure the change of the oxygen nonstoichiometry does not affect the perovskite structure, and the change of the oxygen content in the material is a reversible process. The oxygen nonstoichiometry of the perovskite sorbents can be measured gravimetrically at different temperatures and oxygen partial pressures. Oxygen sorption capacity on the sorbent can then be calculated from the oxygen nonstoichiometry data once the initial state (zero sorption capacity) of the sorbent material is defined.[114] Figs. 5 and 6 are examples of oxygen nonstoichiometry of $La_{1-x}Sr_xCo_{1-y}Fe_yO_{3-\delta}$ perovskite oxide sorbents as a function of oxygen partial pressure or temperature, respectively.[114] The corresponding oxygen sorption isotherm of $La_{1-x}Sr_xCo_{1-y}Fe_yO_{3-\delta}$ perovskite oxide sorbents that were calculated from the oxygen nonstoichiometry data are shown in Fig. 7.[114] From these oxygen isotherms we can conceive a high-temperature vacuum swing sorption or temperature swing sorption process for oxygen separation or oxygen removing applications by using the $La_{1-x}Sr_xCo_{1-y}Fe_yO_{3-\delta}$ perovskite oxide sorbents. Future studies on perovskite oxide sorbents are needed to address the issues of slow desorption rate, potential sorbent structure stability in cyclic processes, and effective regeneration methods.

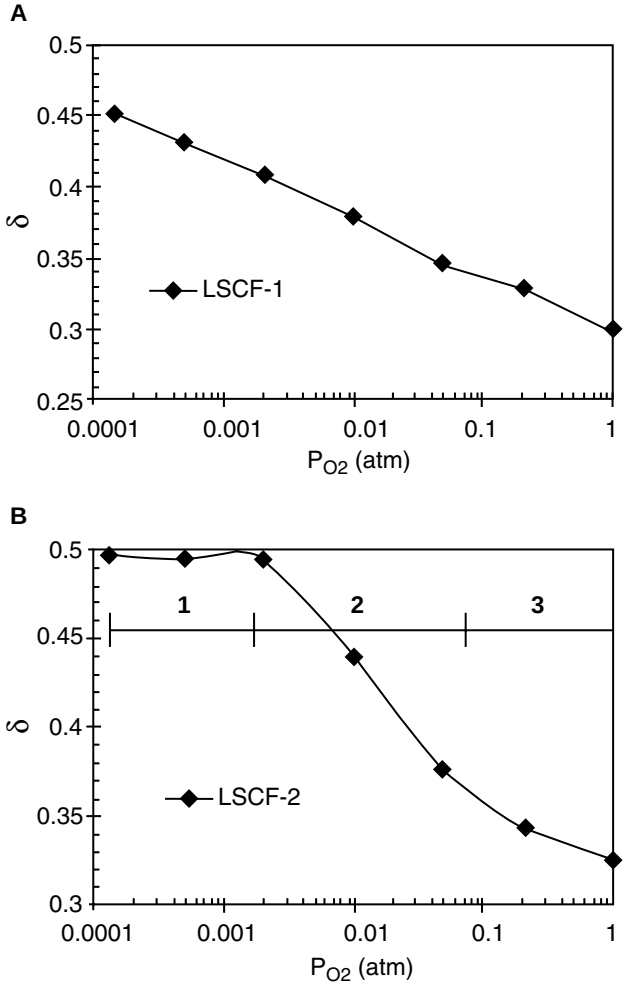

Fig. 5 Change of oxygen nonstoichiometry δ with oxygen partial pressure (LSCF-1. $La_{0.1}Sr_{0.9}Co_{0.5}Fe_{0.5}O_{3-\delta}$; LSCF-2, $La_{0.1}Sr_{0.9}Co_{0.9}Fe_{0.1}O_{3-\delta}$). (From Ref.[114].)

High-Temperature CO_2 Sorbents

Increased awareness of the global warming trend has led to worldwide concerns regarding ''greenhouse gas'' emissions. Greenhouse gases include CO_2, CH_4, and N_2O and are mostly associated with the production and utilization of fossil fuels, with CO_2 being the single greatest contributor to global warming. Significant research efforts are being devoted worldwide on looking for economical ways of mitigating CO_2 emission problem.[118–122] Carbon capture and sequestration costs can be considered in terms of four components: capture, compression, transport, and injection. Typically about 75% of this cost is attributable to capture

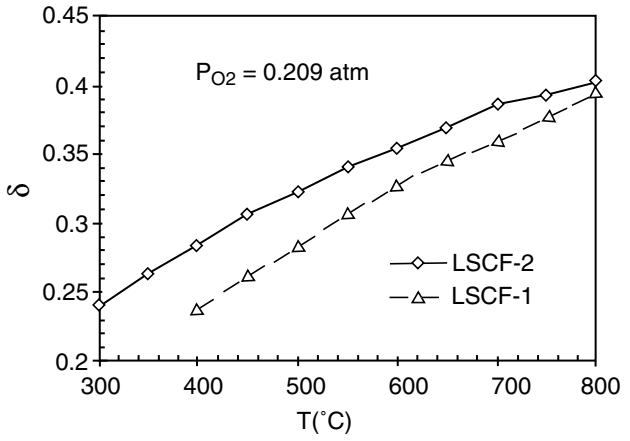

Fig. 6 Change of oxygen nonstoichiometry δ with temperature (LSCF-1, $La_{0.1}Sr_{0.9}Co_{0.5}Fe_{0.5}O_{3-\delta}$; LSCF-2, $La_{0.1}Sr_{0.9}Co_{0.9}Fe_{0.1}O_{3-\delta}$). (From Ref.[114].)

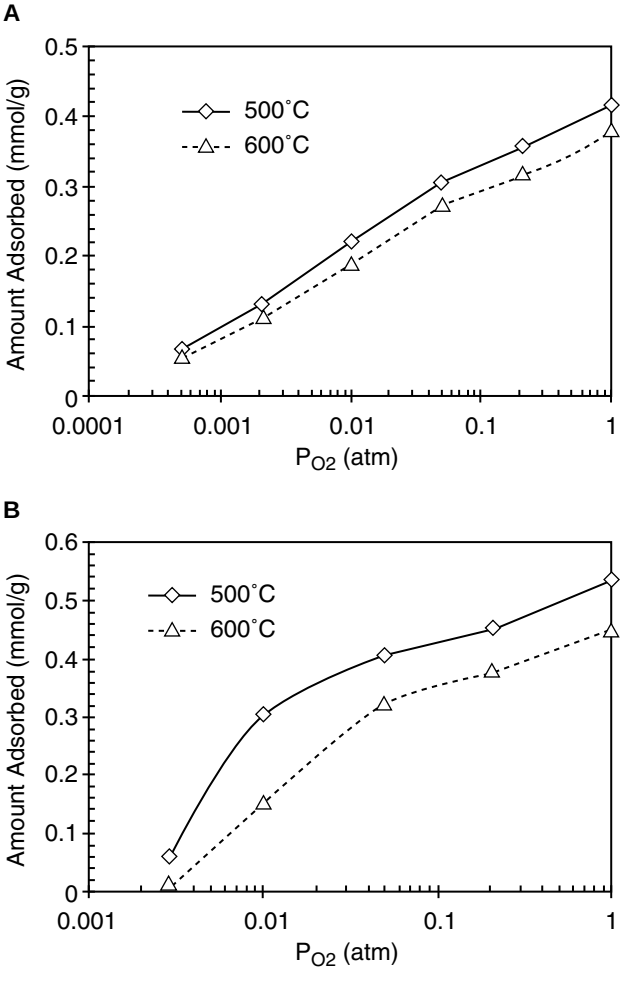

Fig. 7 Sorption isotherms of: (A) $La_{0.1}Sr_{0.9}Co_{0.5}Fe_{0.5}O_{3-\delta}$ and (B) $La_{0.1}Sr_{0.9}Co_{0.9}Fe_{0.1}O_{3-\delta}$ at 500 and 600°C. (From Ref.[114].)

and compression processes. Sorption of carbon dioxide on solid sorbents is receiving increased attention in view of the importance of both the removal and the recovery of carbon dioxide from flue gases.[123,124]

Physical sorbents for carbon dioxide separation and removal were extensively studied by industrial gas companies.[125–127] Zeolite 13X, activated alumina, and their improved versions are typically used for removing carbon dioxide and moisture from air in either a TSA or a PSA process.[125–128] The sorption temperatures for these applications are usually close to ambient temperature. There are a few studies on adsorption of carbon dioxide at high temperatures. The carbon dioxide adsorption isotherms on two commercial sorbents hydrotalcite-like compounds, EXM911 and activated alumina made by LaRoche Industries, are displayed in Fig. 8.[123,124] As shown in Fig. 8, LaRoche activated alumina has a higher carbon dioxide capacity than the EXM911 at 300°C. However, the adsorption capacities on both sorbents are too low for any practical applications in carbon dioxide sorption at high temperature. Conventional physical sorbents are basically not effective for carbon dioxide capture at flue gas temperature (>400°C). There is a need to develop effective sorbents that can adsorb carbon dioxide at flue gas temperature to significantly reduce the gas volume to be treated for carbon sequestration.

Only a handful of studies on high-temperature carbon dioxide sorbents have been published in the past few years.[123,124,129–133] It is believed that lithium zirconate (Li_2ZrO_3) is one of the most promising sorbent materials for carbon dioxide separation from flue gas at high temperature because it can absorb a large amount of carbon dioxide at around 400–700°C.[130,131] The carbon dioxide adsorption and desorption uptake curves on lithium zirconate are shown in Fig. 9.[131] As shown in this figure, about 20% carbon dioxide was captured by the lithium zirconate sorbent during sorption step at 500°C based on the following reaction:

$$Li_2ZrO_3 + CO_2 \rightarrow Li_2CO_3 + ZrO_2 \quad (4)$$

About 80% of adsorbed carbon dioxide can be desorbed with hot air 780°C. Addition of potassium carbonate (K_2CO_3) and Li_2CO_3 into Li_2ZrO_3 remarkably improves the CO_2 sorption rate of the Li_2ZrO_3-based sorbent materials. X-ray diffraction (XRD) analysis for phase and structural changes during the sorption/desorption process shows that the reaction between Li_2ZrO_3 and CO_2 is reversible.[131] Based on this work, a TSA process can be developed for carbon dioxide removal from flue gas using Li_2ZrO_3-type sorbent materials.

High-temperature carbon dioxide sorbents can also find applications in fuel reforming process to enhance fuel to hydrogen conversion efficiency. It was reported

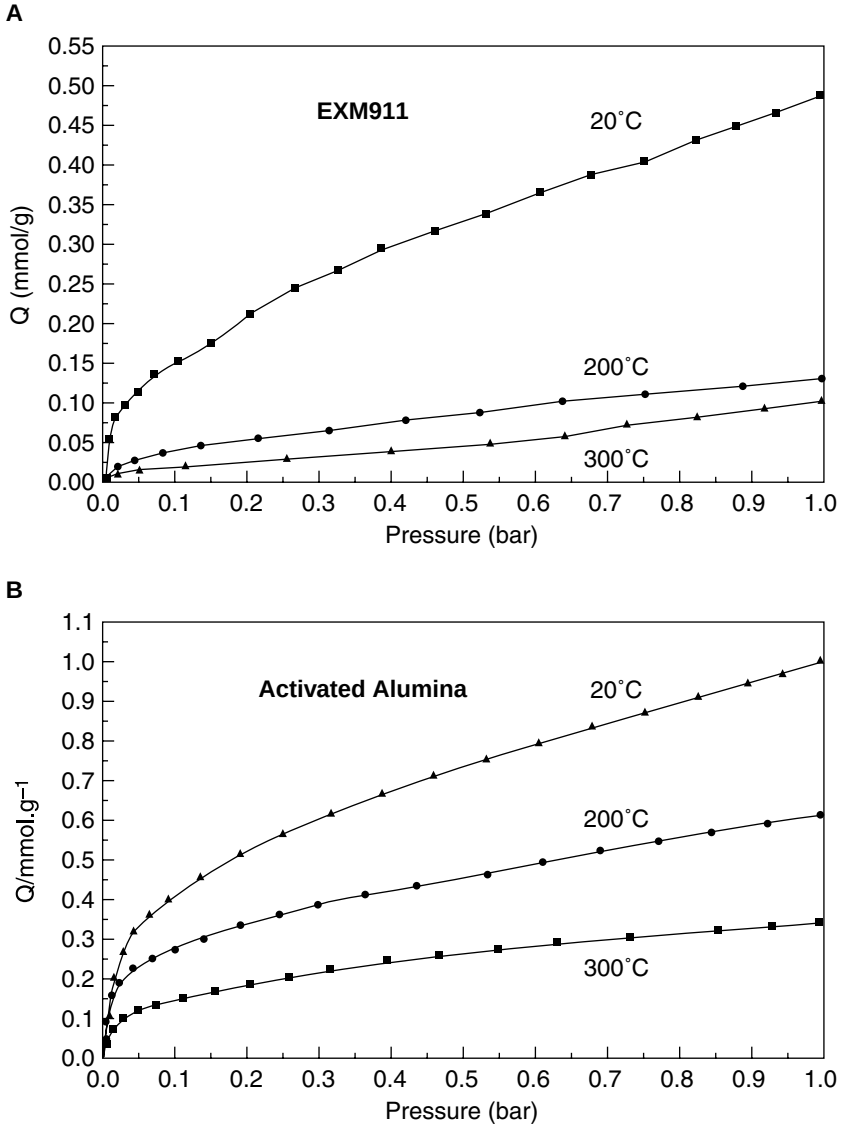

Fig. 8 Adsorption isotherms of carbon dioxide on commercial sorbents. (A) Hydrotalcite-like compound, EXM911; (B) LaRoche Industries activated alumina at 20, 200, and 300°C. (From Refs.[123,124].)

that sorption of carbon dioxide can enhance the production of hydrogen for a steam–methane reforming process using a mixture of Ni-based reforming catalyst and a Ca-based sorbent. The rates of the reforming, water-gas shift, and carbon dioxide removal reactions are sufficiently fast that combined reaction equilibrium was closely approached, allowing for >95 mol% hydrogen to be produced in a single step.[134]

CONCLUSIONS AND FUTURE DIRECTIONS

Existing commercial sorbents including activated carbon, zeolites, activated alumina, and silica gels will continue to play important roles in adsorptive separation and purification for current process industries in the near future. However, they cannot meet the needs of future technological developments in the new energy economy and the stringent environmental regulations. The newly developed nanostructured sorbent materials have shown some very promising features, but they are basically unexplored and systematic investigations are needed on both synthesis methods and adsorption characteristic studies. The following are the author's views on future research needs in both sorbent synthesis and applications:

1. Explore entirely new sorbent synthesis routes to better control of both sorbent pore texture and surface property.
2. Design new sorbent materials from basic building blocks and introduce active sorption sites according to sorbent–adsorbate interaction requirements. MOF material syntheses using

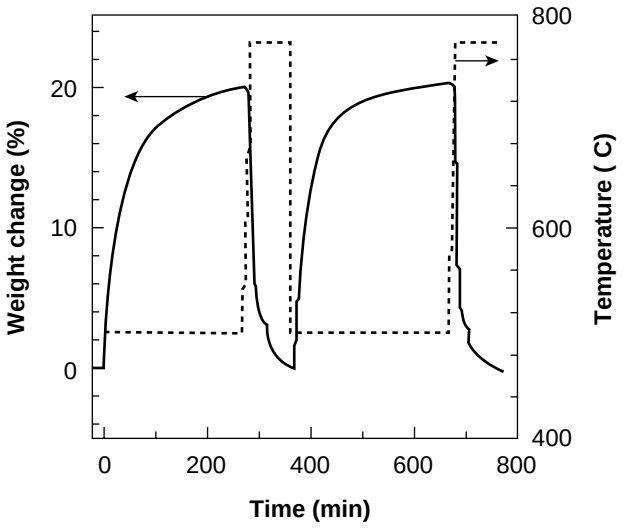

Fig. 9 CO_2 sorption and regeneration on the modified Li_2ZrO_3. Sorption process: 50% CO_2 balanced by dry air at 500°C. Desorption process: 50% CO_2 balanced by dry air at 780°C → dry air at 780°C. Gas flow rate: 150 ml/min. (From Ref.[131].)

the isoreticular method and sol–gel technique are two examples of this approach.

8. A better understanding of the relationship between sorbent–adsorbate interaction, sorption equilibrium, and kinetics through molecular simulation, and provide guidance for sorbent synthesis.

In terms of applications, new sorbents should be developed to meet the following pressing needs:

1. Deep desulfurization of fossil fuels for fuel cell application.
2. Hydrogen purification (H_2S, CO, and CO_2 removal).
3. Hydrogen and methane storage sorbents and processes.
4. Water treatment (arsenic, radionuclides and heavy metal ions and anions removal).
5. Air pollution control (SO_x, NO_x, and other toxic gases removal).
6. Chemisorbents as effective getter materials for toxic process gas and liquid streams.
7. Effective high-temperature carbon dioxide sorbents for carbon dioxide sequestration.

ACKNOWLEDGMENT

Professor Y.S. Lin is acknowledged for providing his publications and comments on high-temperature sorbents discussed in this entry.

INTRODUCTION

The concept of process intensification aims to achieve enhancement in transport rates by orders of magnitude to develop multifunctional modules with a view to provide manufacturing flexibility in process plants. In recent years, advancement in the field of reactor technology has seen the development of catalytic plate reactors, oscillatory baffled reactors, microreactors, membrane reactors, and trickle-bed reactors. One such reactor that is truly multifunctional in characteristics is the spinning disk reactor (SDR). This reactor has the potential to provide reactions, separations, and good heat transfer characteristics.

SPINNING DISK REACTOR

The SDR technology utilizes the effects of centrifugal force, which is capable of producing highly sheared thin films (Fig. 1) on the surfaces of rotating disks or cones. Extensive heat and mass transfer studies using SDRs have shown that convective film heat transfer coefficients as high as $14\,kW/m^2$, K, and mass transfer coefficients, K_L, with values as high as 30×10^{-5} m/sec, and K_G values as high as 12×10^{-8} m/sec, can be achieved while providing micromixing and appropriate fluid dynamic environment for achieving faster reaction kinetics.[1] The size of the disk may range from 60 to 500 mm in diameter and the surface characteristic may be smooth, grooved, or meshed depending on the application and the throughput requirement. The rotational speeds may range from 100 to about 6000 rpm (typically around 1500 rpm). The SDR, which has been successfully used to perform free radical as well as condensation polymerizations, fast precipitation reactions for the production of mono-dispersed particles and catalyzed organic reactions, has the following characteristics:[2–4]

- Intense mixing in the thin liquid film.
- Short liquid residence time (may allow the use of higher processing temperatures).
- Plug flow characteristics.
- High solid/liquid heat/mass transfer.
- High liquid/vapor heat/mass transfer.

A schematic diagram of an SDR is shown in Fig. 2

For the purpose of clarity and continuity this entry has been subdivided into the following sections: hydrodynamics of liquid flow on a rotating surface, variation in SDR configuration, performance estimators, and process application of SDRs.

HYDRODYNAMICS OF LIQUID FLOW ON A ROTATING SURFACE

Synchronized Flow Model

The simplest model for flow over a rotating disk surface assumes that the liquid is rotating at the same speed as the disk itself and is thus fully synchronized with the disk rotation. Under these conditions, the centrifugal acceleration driving the liquid film across the disk surface at radius r can be simply estimated as $r\omega^2$. With this assumption, the flow over the disk can be made analogous to flow over an inclined surface.

Nusselt provided a simple model for laminar liquid flow down an inclined plane.[5] This assumed that the liquid had reached fully developed conditions in which drag due to viscous shear exactly balanced the weight of the film. Under these conditions, Nusselt showed that for a Newtonian fluid of kinematic viscosity, ν, film thickness, f, could be written in terms of the liquid flow rate, Q, moving over a vertically inclined surface of width, w, under a gravitational acceleration, g, using the following relationship:

$$f = \left(\frac{3\nu Q}{wg}\right)^{1/3} \tag{1}$$

By substitution of gravitational acceleration g with centrifugal acceleration $r\omega^2$ and the width of the inclined surface w with the perimeter of the disk at radius r, the following equation for film thickness on

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120022537

Fig. 1 View of sheared liquid films on an SDR. *(View this art in color at www.dekker.com.)*

a rotating disk surface can be written as [6]

$$f = \left(\frac{3\nu Q}{2\pi r^2\omega^2}\right)^{1/3} \tag{2}$$

This equation assumes that the liquid velocity can instantaneously adjust to the balance drag against centrifugal force. This assumption has been shown to be a reasonable one. Burns et al. and Eq. (2) can be used as the starting point for film thickness modeling.[7]

The fully synchronized flow model can be used to provide reasonable estimates for a wide range of measures that characterize the flow over the spinning disk. The first of these is the radial velocity of the film at radius r that can be calculated from

$$u = \frac{Q}{2\pi rf} = \left(\frac{1}{12\pi^2}\right)^{1/3}\left(\frac{Q^2\omega^2}{r\nu}\right)^{1/3} \tag{3}$$

For a fully developed flow profile the radial velocity can be used to provide an estimate of surface shear, S, using the following equation:

$$S = \frac{3u}{f} = \left(\frac{3}{2\pi}\right)^{1/3}\left(\frac{Qr\omega^4}{\nu^2}\right)^{1/3} \tag{4}$$

Integration of the equations for film thickness and velocity can be used to provide calculations for other global measures of conditions on the disk surface. The first of these is the measurement of the volume of liquid on the disk surface. This can be calculated by integration of Eq. (2) to give

$$V = \left(\frac{81\nu Q\pi^2}{16\omega^2}\right)^{1/3} R^{4/3} \tag{5}$$

Residence time of the liquid on the disk can be estimated from the volume calculation above and the liquid flow rate Q using the following equation:

$$t = \frac{V}{Q} = \left(\frac{81\pi^2R^4\nu}{16Q^2\omega^2}\right)^{1/3} \approx 3.68\left(\frac{R^4\nu}{Q^2\omega^2}\right)^{1/3} \tag{6}$$

A measure of average film thickness and velocity can also be generated from Eq. (5). In the case of average film thickness, f_{AV}, it is defined as the volume of liquid on the disk per unit disk area and characterizes film thickness for the system. In the case of average radial velocity it is defined as the radius divided by the residence time and again characterizes conditions for the process. These two measures are given by

$$f_{AV} = \left(\frac{81}{16\pi}\right)^{1/3}\left(\frac{Q\nu}{R^2\omega^2}\right)^{1/3} \approx 1.17\left(\frac{Q\nu}{R^2\omega^2}\right)^{1/3} \tag{7}$$

$$u_{AV} = \frac{R}{t} \approx 0.27\left(\frac{Q^2\omega^2}{R\nu}\right)^{1/3} \tag{8}$$

Eqs. (7) and (8) allow for a characteristic radial surface shear rate to be calculated as

$$S_{AV} = \frac{3u_{AV}}{h_{AV}} \approx 0.69\left(\frac{QR\omega^4}{\nu^2}\right)^{1/3} \tag{9}$$

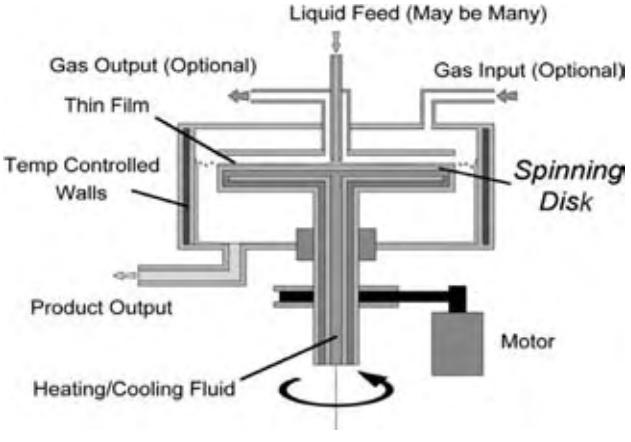

Fig. 2 A schematic view of an SDR. *(View this art in color at www.dekker.com.)*

Wetting of the disk surface

Wetting is an important aspect of the SDR. If the disk is not wetted then dry spots are created and rivulets are formed, which significantly reduce the transport rates achieved on the disk. Hartley and Murgatroyd provided a list of theoretical models for calculating the wetting film for liquid flows under gravity.[8] The equations derived for these models were based on physical principles rather than empirical data but have compared favorably with experimental results. Because

of this these models can be used for initial calculations of wetting of smooth spinning disk surfaces.

Two models for wetting of falling films were provided by Hartley and Murgatroyd.[8] Both these are based on the stability of dry patches rather than wetted films with the assumption that if a dry patch is not stable a wetting film should form. The first model is derived from minimizing surface energy and the second is from force balance at a contact line surrounding a dry spot. These are given by

Surface Energy Criterion

$$f_{\min} = 1.34\left(\frac{\sigma}{\rho}\right)^{1/5}\left(\frac{\nu}{g}\right)^{2/5} \tag{10}$$

Force Criterion

$$f_{\min} = 1.72\left(\frac{\sigma(1 - \cos\theta)}{\rho}\right)^{1/5}\left(\frac{\nu}{g}\right)^{2/5} \tag{11}$$

These equations produced very similar results with the exception that the force criterion approach included details of contact angle θ between the liquid and the surface and was therefore a more complete description. This theory can be related to the conditions on a spinning disk by the substitution of gravitation acceleration g with centrifugal acceleration $r\omega^2$. A stability parameter β for the film can then be given by comparing the film thickness at the edge of the disk with the minimum wetting film thickness above. This can be written as

$$\beta = \frac{f}{f_{\min}} \quad \text{at } r = R \text{ with } g = r\omega^2 \tag{12}$$

Using Eqs. (10) and (11) with Eq. (2) gives

$$\beta = 0.454\left(\frac{\rho^3 Q^5 \omega^2}{\sigma^3(1 - \cos\theta)^3 \nu R^4}\right)^{1/15} \tag{13}$$

Experimental data on falling films have suggested that this theory provides a very conservative measurement of minimum wetting film thickness as it is derived from the principle of the stability of dry patches rather than the breakdown of films. In general, it was observed that films could be maintained down to close to an order of magnitude lower than the above equations suggest, although under very contrived conditions.[8] Based on this, it can be assumed that

$\beta > 1 \Rightarrow$ Stable wetting film
$1 > \beta > 0.1 \Rightarrow$ Metastable film
$\beta < 0.1 \Rightarrow$ Rivulet flow

Examination of conditions used during a range of experimental work on SDR (Woods, Auone and Ramshaw, and Burns et al.) has shown that wetting films for β values within the ''metastable film'' region can be obtained.[7,9,10] In particular, the use of preflooding of the disk or the use of surface roughening can push the limit of the wetting film thickness down to the lower end of the metastable film region, further details of which will be discussed in the later sections. However, the above wetting parameter calculations can be used to examine how likely it is for a process to achieve a stable wetted disk surface.

Nonsynchronized Flow Model—Spin-up Zone

The synchronized flow model discussed in the previous sections can be used to provide estimates for general conditions on the spinning disk surface. However, to examine conditions close to the central feed requires a more complex two-dimensional model for fluid flow. In particular, this is required to provide information on the radial distance needed to achieve synchronization with the disk rotation, commonly referred to as the spin-up zone.[7]

A two-dimensional model for flow over a rotating disk, incorporating inertial and viscous influences, was described by Wood and Watts.[6] This was termed the Pigford model, owing to its origin. Burns et al. gave a comparison of the model with measurements of flow over a spinning disk.[7] A review of those findings and the model derivation are given below. The two-dimensional Pigford model can be written in terms of the radial and tangential flow velocity, u and v, respectively, relative to the disk using the following equations.

$$u\left(\frac{\partial u}{\partial r}\right) - \frac{v^2}{r} = -\left(\frac{12\pi^2 r^2 K_1 \nu}{Q^2}\right)u^3 \tag{14}$$

$$u\left(\frac{\partial v}{\partial r}\right) + \frac{uv}{r} = \left(\frac{12\pi^2 r^2 K_2 \nu}{Q^2}\right)u^2(r\omega - v) \tag{15}$$

where K_1 and K_2 were used as empirical correction factors to adjust the viscous terms in the equation. No specific data were given on the values of the constants K_1 and K_2, although it was assumed that they were close to unity. The solution of these equations was shown by Burns et al. to be strongly linked to the Eckman length scale λ, which was defined as[7]

$$\lambda = \left(\frac{Q^2}{\omega\nu}\right)^{1/4} \tag{16}$$

This scale was derived from the Eckman number that describes the ratio of viscous momentum transfer

through the film to that of the angular momentum of the film and can be used to gauge the ability for synchronized rotating flow to be achieved. Burns et al. found that K_1 had an unclear link with other experimental parameters and generally was in the region of 0.5–0.7 with an average of 0.61. In contrast, the value of parameter K_2 was found to be strongly linked to the Eckman length scale λ. The best fit of experimental results to the Pigford model was reported by Burns et al. as

$$K_1 = 0.61 \tag{17}$$

$$K_2 = \left(\frac{\lambda}{\lambda_0}\right) \tag{18}$$

where $\lambda_0 = 10.8\,\text{cm}$ and is an empirical constant whose units served only to balance the dimensions in Eq. (26). It is likely, however, that λ_0 may depend on other parameters not examined within the scope of the reported experiments, such as nozzle diameter, and may be a more complex function of several other dimensionless groups.

The experimentally determined values of parameters K_1 and K_2 allow the Pigford model to be used to examine the extent of the spin-up zone on the disk surface. Before this can be done, however, an unambiguous mathematical definition for the spin-up zone is required. This was provided by Burns et al. as the location at which the radial velocity stops accelerating and starts following the decelerating profile described by the synchronized flow model as shown in Eq. (3).[7]

Mathematically, this was defined as

$$\frac{\mathrm{d}u}{\mathrm{d}r} = 0 \quad \text{and} \quad \frac{\mathrm{d}^2u}{\mathrm{d}r^2} < 0 \text{ at } r = r_S \tag{19}$$

Numerical analysis of the Pigford model, combined with Eqs. (17) and (18), implied that the spin-up zone r_S based on this definition should be given by

$$r_S = 0.88\lambda\left(\frac{d}{2\lambda}\right)^{-0.025}\left(\frac{\lambda}{\lambda_0}\right)^{-0.37} \tag{20}$$

where d is the nozzle diameter used to inject the liquid. This result implies that the spin-up zone is approximately proportional to $\lambda^{2/3}$. A criterion for the accuracy of the synchronized flow model can also be derived from this analysis by comparison of the extent of the spin-up zone with the radius of the disk. This can be written simply as

$$\frac{r_S}{R} \ll 1 \Rightarrow \text{Synchronized flow} \tag{21}$$

Variation in Configuration

Surface structuring

Surface structuring can be used on SDR to achieve a variety of effects on the processing conditions. These can be categorized by the scale of the features being made to the disk. At the film-thickness scale or lower, surface structuring or roughening can be used to increase the wetting of the disk surface by the interference with the liquid–solid–gas interface contact. It can also be used to generate greater surface area at the base of the film and sites to promote small-scale convective mixing for situations with low-viscosity fluids and high flow rates.

Structuring at the larger than film-thickness scale can include surface grooves and channels and possible incorporation of surface meshes. These act to influence the velocity distribution across the disk allowing the liquid in some cases to detach and reimpact on the surface many times as it crosses the disk. This can be used to introduce a greater variation in the transport rates for the liquid flowing over the disk compared to the more steady conditions on the smooth disk surface.

At the large end of the scale changes in the configuration can be a change in the whole inclination of the surface to the centrifugal field the influence of which is discussed in the next few sections.

Spinning cone reactor

The SDR can be described as just one of the many reactor designs based on rotating surfaces. In particular, the SDR can be treated as a special case of the more general spinning cone reactor. These devices generally have a flat spinning disk close to the center followed by a conical section inclined to the centrifugal field. The equations describing the flow over these devices can, however, be shown to be more general versions of the previous equations given for the spinning disk reactor.

For the case of a spinning cone inclined at an angle α to the plane of rotation, film thickness, velocity, residence time, and surface shear can be related to that for the spinning disk using the following scaling relationships:

$$f_{\text{CONE}} = (\cos\alpha)^{-2/3} f_{\text{DISK}} \tag{22}$$

$$u_{\text{CONE}} = (\cos\alpha)^{2/3} u_{\text{DISK}} \tag{23}$$

$$t_{\text{CONE}} = (\cos\alpha)^{-5/3} t_{\text{DISK}} \tag{24}$$

$$S_{\text{CONE}} = (\cos\alpha)^{4/3} S_{\text{DISK}} \tag{25}$$

It should be noted that the relationships described above assume that the cone extends to the same radius

as the disk rather than the same length in the direction of flow and, hence, results in a strong influence on residence time due to slower flow combined with a longer distance to travel. It should also be noted that the flow velocity is given in Eq. (23) rather than the strict radial velocity and is therefore in the direction of the inclined surface. Eq. (24) gives an equivalent residence time scaling assuming that the cone extends to the axis of rotation. In reality, this is not often the case and the device will have a flat disk surface close to the center that leads to a cone further out. A more complete calculation for residence time can be given using the following equation:

$$t = \left(\frac{81\pi^2\nu}{16Q^2\omega^2}\right)^{1/3}\left(\frac{r_2^{4/3} - r_1^{4/3}}{\cos^{5/3}\alpha} + r_1^{4/3}\right) \tag{26}$$

where flow is over a flat disk up to a radius r_1 and then a cone inclined at an angle α up to a radius r_2. It should be noted that Eqs. (22)–(26) neglect the influence of gravity on the flow over the cone. Under most operating conditions, this will probably be a reasonable assumption; however, for systems with a vertical axis of rotation and low rotational speeds the validity of the previous equations may break down. A limit for the applicability of Eqs. (22)–(26) can be expressed as

$$\cos\alpha \gg \frac{R\omega^2}{g} \Rightarrow \text{Gravity may be neglected} \tag{27}$$

Nested cone reactor

A further modification of the rotating surface concept is that of the nested cone. This allows the use of inclined surfaces to the centrifugal acceleration in a similar manner to the cone but with two major differences. The first is that the design is more compact as the axial component of flow alternates as the liquid moves from conical surface to conical surface, which reduces the axial space required for the device. The second difference is that the liquid detaches from the surface as it moves from surface to surface, leading to periodic impacts and the potential for increased mixing at the point of impact. This can further be enhanced by the use of nested cones where the upper and the lower sections are moving at different rotational speeds, or even in opposite directions of rotation at the expense of increased power demand on the shaft.

Modeling of the flow on the conical surfaces can be approximated by the same scaling rules as shown in Eqs. (22), (23), and (25). However, residence time cannot be modeled in such a simple manner as it includes contributions both from flow over the conical sections and from detached flow between surfaces. In modeling the latter, the following equations can be used.

If it is assumed that the liquid leaving one conical section at a radius r_1 has a radial velocity component that is small compared to that of the rotational speed $r_1\omega$ of the surface, then the liquid can be assumed to leave the surface at a velocity $r_1\omega$ traveling at a tangent to the cone in the same direction as its rotation. Under these circumstances, the distance x traveled by the liquid before impacting on a second cone surface at radius r_2, assuming deflection due to the surrounding gas flow or gravity, can be written as

$$x = \sqrt{r_2^2 - r_1^2} \tag{28}$$

Assuming that the liquid travels between the surfaces without any change in velocity, as viewed from a nonrotating Cartesian frame of reference, the time required to travel between the cone surfaces can be written as

$$t = \frac{x}{r_1\omega} = \frac{1}{\omega}\sqrt{\frac{r_2^2}{r_1^2} - 1} \tag{29}$$

In comparison, the estimated time spent on the conical surface prior to this can be estimated from the following equation, which is a modified version of Eq. (26):

$$t = \left(\frac{81\pi^2\nu}{16Q^2\omega^2}\right)^{1/3}\left(\frac{r_1^{4/3} - r_0^{4/3}}{\cos^{5/3}\alpha}\right) \tag{30}$$

This assumes that the conical surface extends from radius r_0 to a radius r_1. This equation neglects the influence of gravity and is therefore subject to the same limitations as those expressed in Eq. (27). A total residence time for the nested cone system can therefore be calculated by a sum of Eqs. (28) and (29) for each conical surface. The velocity of the liquid hitting the second surface can also be calculated using the previous assumptions. The perpendicular component of velocity relative to the rotating surface as radius r_2 can be written as

$$u_{\text{imp}} = r_1\omega\sqrt{1 - \frac{r_1^2}{r_2^2}} \tag{31}$$

The tangential component of impact velocity on the second surface will also depend on whether it is moving at the same or a different rotational speed. Assuming the first surface is rotating at ω_1 and the second surface at ω_2 the tangential impact velocity can be written as

$$v_{\text{imp}} = \frac{r_1^2\omega_1 - r_2^2\omega_2}{r_2} \tag{32}$$

Thus, it can be seen that substantial impact velocities, and hence energy available for mixing, can be

Table 1 SDR—scaling influences

	Film thickness	Residence time	Flow velocity	Surface shear
Double liquid flow	26% increase	37% decrease	59% increase	26% increase
Double disk rotation	37% decrease	37% decrease	59% increase	152% increase
Ten times viscosity	115% increase	115% increase	54% decrease	78% decrease
Double disk radius	37% decrease	152% increase	21% decrease	26% increase
Disk to 30° cone	10% increase	27% increase	9% decrease	17% decrease
Disk to 75° cone	146% increase	851% increase	59% decrease	84% decrease

obtained by the use of surfaces moving at different rotational speeds even when the surfaces are in close proximity.

Scaling Rules for Hydrodynamic Properties

In the previous sections equations have been given to estimate a range of properties of the fluid flow over the rotating systems, spinning disks, and more generally spinning cones. These equations can be used to estimate general rules for examining the scaling of conditions from one rotating device to another and also from one set of operating conditions to another. Table 1 summarizes these implied scaling influences.

It should be noted that these rules assume that the liquid flowing over the system has Newtonian properties and is fully synchronized with the disk rotation. The influence of gravity is also neglected and it is assumed that the surface is completely wetted.

Performance Estimators

Estimating transport by diffusion

Owing to the nature of thin films generated by both spinning disks and spinning cones, transport by diffusion can become a significant method of transport of both heat and mass within the film. In the case of heat transfer this is especially true and will be the dominant mode of transport within the film. The equations for transport by diffusion have been studied and solved for many simple systems. One of the most comprehensive studies of this process was given by Crank in which the equations for diffusion are examined for several generalized systems.[11] In the solution of the diffusion equation one parameter is of paramount importance: that is, the Fourier number, *Fo*. This can be expressed as

$$Fo = \frac{Dt}{\delta^2} = \frac{DL}{u\delta^2} \tag{33}$$

where D is the diffusion coefficient for the process, t is the exposure time, and δ is the characteristic path length for diffusion. This can alternatively be written in terms of flow velocity u perpendicular to the process and the length traversed, L, in the direction of flow. In the case of thin films, the diffusion path length can be replaced by the film thickness f. However, for flow over a rotating surface film thickness and velocity are constantly changing and so an integrated form of Eq. (33) is required to examine the potential for diffusive transport through the rotating film. Fourier number for an SDR can be developed based on the following integration:

$$Fo = \int_0^R \frac{D}{uf^2}\,\mathrm{d}r \tag{34}$$

Combining Eqs. (2), (3), (22), (23), and (34) gives

$$Fo = \left(\frac{9\pi^4}{32}\right)^{1/3}\left(\frac{\omega^2 R^8 D^3}{\nu Q^4}\right)^{1/3}\cos^{2/3}\alpha \tag{35}$$

It should be noted that the diffusivity D in Eq. (35) is the molecular diffusivity in the case of mass transfer, which is typically of the order of $10^{-9}\,\mathrm{m}^2/\mathrm{sec}$ or thermal diffusivity defined as

$$D_{\mathrm{HEAT}} = \frac{k}{c_{\mathrm{P}}\rho} \tag{36}$$

in the case of heat transfer. For heat transfer, Eq. (34) will provide a measure of the capability of the film to reach the temperature of the solid surface assuming that it is maintained at a constant temperature. Burns and Jachuck showed that this parameter correlated well for a mass transfer limited process using the conversion of calcium hydroxide into calcium carbonate by diffusion of carbon dioxide through the liquid film on an SDR.[7] Results showed complete conversion for *Fo* in the region of 0.1–0.2. For nonreactive processes and heat transfer, however, efficient transport by diffusion should be expected for *Fo* in excess of 0.3 and preferably in excess of 1.

It can be seen from Eq. (35) that the performance for increased flows can be maintained by use of either higher rotational speed or increased surface area.

Eq. (34) also shows that inclined surfaces should yield slowly, decreasing diffusive transport capabilities compared to the spinning disk, owing to the thicker films. However, for reactions with some kinetic limitations the increased residence time may be more beneficial. It should also be noted that the results of mixing by collisions, motion over structured surfaces and through surface waves, are convective processes not considered in this formulation.

Estimating mass transfer coefficients

Correlations for mass transfer can be divided into diffusive and nondiffusive processes. The simpler of the two to predict is that of diffusive transfer and, in particular, the penetration of a species at either the solid–liquid or liquid–gas interface.

Gas–liquid mass transfer by diffusion

Estimation of liquid-side mass transfer coefficients for gas–liquid transport through the upper surface of the film can be most readily made by assumption of a purely diffusive transfer. Under these conditions, a mass transfer coefficient can be approximated using the following equation for mass transfer:[12]

$$k_{\mathrm{LG}} = \sqrt{\frac{4D}{\pi t}} \tag{37}$$

This assumes that a chemical species is penetrating into a static film over a time period of t with a diffusivity in the liquid of D. If it is assumed that the exposure time constant t in the equation is equal to the residence time of the liquid on a spinning disk surface, given by Eq. (6), then the liquid-side mass transfer coefficient k_{LG} for diffusion into the film can be estimated as

$$\begin{aligned} k_{\mathrm{LG}} &= \left(\frac{1024Q^2\omega^2D^3}{81\pi^5\nu R^4}\right)^{1/6} \\ &\approx 0.59\left(\frac{Q^2\omega^2D^3}{\nu R^4}\right)^{1/6} \end{aligned} \tag{38}$$

A measure of the transport performance can be given by considering the flux through the surface compared to the flux passing over the surface, which is the liquid flow rate. This produces the following dimensionless group:

$$\begin{aligned} \text{Transport performance} &= \frac{k_{\mathrm{LG}}\pi R^2}{Q} \\ &= 1.85\left(\frac{\omega^2D^3R^8}{\nu Q^4}\right)^{1/6} \end{aligned} \tag{39}$$

It may be suggested that the transport performance is proportional to *Fo* defined for the spinning surface given by Eq. (35) as the assumptions used for the diffusive processing are the same.

Liquid–solid mass transfer by diffusion

Mass transfer coefficients for the lower surface of a laminar film are strongly influenced by the shear at the liquid–solid interface. A solution for liquid–solid mass transfer coefficients for a diffusive process in a laminar film was provided by Bird et al. as the following equation:[12]

$$k_{\mathrm{LS}} = \frac{2D}{\Gamma(7/3)}\left(\frac{S}{9DL}\right)^{1/3} \tag{40}$$

where the function $\Gamma(7/3)$ is defined as

$$\Gamma(7/3) = \int_0^\infty x^{4/3}\,\mathrm{e}^{-x}\,\mathrm{d}x = 1.1906 \tag{41}$$

For a spinning disk, the standard model for falling film flow is complicated by the changing thickness and shear as the liquid flows over the disk. An approximation of this to conditions on a spinning disk surface can, however, be made by substitution of Eq. (9) for average liquid–solid surface shear into the above equation for mass transfer. If it is also assumed that the characteristic distance L traveled by the liquid is equal to that of the disk radius then an equation for the liquid–solid mass transfer coefficient k_{LS} can be written for an SDR as

$$k_{\mathrm{LS}} = 0.71\left(\frac{\omega^4D^6Q}{R^2\nu^2}\right)^{1/9} \tag{42}$$

A similar transport performance estimate can be provided for the liquid–solid process through the following equation:

$$\begin{aligned} \text{Transport performance} &= \frac{k_{\mathrm{LS}}\pi R^2}{Q} \\ &= 2.23\left(\frac{\omega^4D^6R^{16}}{\nu^2Q^8}\right)^{1/9} \end{aligned} \tag{43}$$

It should be noted that the grouping shown here is not identical to the *Fo* shown in Eq. (35) because of the strong influence of surface shear as well as molecular diffusion on the overall transport rates.

Mass transfer with surface wave convection—liquid/gas

The influence of surface waves on transport within a film has been shown to lead to enhanced mass transfer above that expected from pure diffusion.[10] This enhancement can be represented in terms of an improvement in the Sherwood number (Sh) as defined by

$$Sh = \frac{k_{LG} f_C}{D} \tag{44}$$

where f_C is a characteristic film thickness for the process. A series of publications have been produced modeling the structure of surface waves produced by liquid flow over a rotating disk surface. Sisoev et al. produced a series of publications examining the fluid dynamics of surface waves on an SDR.[13] Data describing surface waves produced by the disk rotation combined with the mass transfer results produced by Auone and Ramshaw were used to formulate a mathematical model for the mass transfer process.[9,10] Their results indicated that (G. M. Sisoev, O. K. Matar, and C. J. Lawrence, personal communication)

$$Sh = 0.154 Pe_K^{1/2} \tag{45}$$

where

$$Pe_K = \frac{Pe}{\kappa} = \left(\frac{\omega^2 f_C^4}{\nu D}\right)\left(\frac{\rho\omega^2 R^4}{\sigma f_C}\right)^{1/3} \tag{46}$$

and the characteristic film thickness is defined as

$$f_C = \frac{2}{3} f_{AV} = 0.54\left(\frac{Q\nu}{R^2\omega^2}\right)^{1/3} \tag{47}$$

Combining these equations mass transfer coefficient k_{LG} can be estimated as

$$k_{LG} = 0.154\left(\frac{f_C^5 \omega^8 R^4 \rho D^3}{\nu^3 \sigma}\right)^{1/6} \tag{48}$$

Transport performance can therefore be estimated as

$$\text{Transport performance} = \frac{k_{LG}\pi R^2}{Q} = 0.29\left(\frac{\omega^{14} R^{38} \rho^3 D^9}{\nu^4 \sigma^3 Q^{13}}\right)^{1/18} \tag{49}$$

It can be seen that performance under this model has a stronger positive dependence on rotational speed and a weaker negative influence from liquid flow rate owing to the increased surface wave generation under conditions of high speed and high flow. This can aid in the scale-up of spinning disk processes as transport rates are likely to improve in reality if scaling is based on the more simplistic diffusion-only models shown by Eqs. (38) and (39).

SCALING CALCULATIONS

In scaling up of an SDR process it is assumed that liquid properties, such as density and viscosity, are constant and that radius R is altered in the scaling to allow for greater throughput Q. The three parameters in the scaling are therefore liquid flow rate Q, rotational speed ω, and disk radius R. To examine the implications of scaling, the geometry scaling factor F for the system is used and is defined by

$$F = \frac{R_2}{R_1} \tag{50}$$

where a process on a disk radius R_1 is to be scaled to a disk of radius R_2. The following sections provide scaling methods that link the two remaining parameters to the scaling factor F.

Scaling with Residence Time and Film Thickness Constant

The first method of scaling is to preserve residence time and average film thickness. Using Eqs. (6) and (7) implies that

$$\left(\frac{R_1^4}{Q_1^2\omega_1^2}\right) = \left(\frac{R_2^4}{Q_2^2\omega_2^2}\right) \Rightarrow \text{Constant residence time} \tag{51}$$

$$\left(\frac{Q_1}{R_1^2\omega_1^2}\right) = \left(\frac{Q_2}{R_2^2\omega_2^2}\right) \Rightarrow \text{Constant film thickness} \tag{52}$$

Therefore, scaling for this requirement would be

$$Q_2 = F^2 Q_1 \tag{53}$$

$$\omega_2 = \omega_1 \tag{54}$$

This implies that flow rate is proportional to disk area while rotational speed should remain constant. Centrifugal acceleration would be increased in proportion to F for this system, as would radial velocity. Mass transfer performance based on the previous correlation would indicate increased performance from this scaling.

Scaling with Residence Time and Mass Transfer Performance Constant

If it is desired to scale while maintaining the same theoretical mass transfer performance and residence time then the following conditions must be met:

$$\left(\frac{R_1^4}{Q_1^2\omega_1^2}\right) = \left(\frac{R_2^4}{Q_2^2\omega_2^2}\right) \Rightarrow \text{Constant residence time} \tag{55}$$

This means that flow is scaled according to

$$Q_2 = Q_1\left(\frac{\omega_1}{\omega_2}\right)F^2 \tag{56}$$

Fixed mass transfer performance implies

$$\left(\frac{R_1^4\omega_1}{Q_1^2}\right) = \left(\frac{R_2^4\omega_2}{Q_2^2}\right) \tag{57}$$

(Model 1: liquid–gas diffusive)

$$\left(\frac{R_1^4\omega_1}{Q_1^2}\right) = \left(\frac{R_2^4\omega_2}{Q_2^2}\right) \tag{58}$$

(Model 2: liquid–solid shear/diffusion)

$$\left(\frac{R_1^{38}\omega_1^{14}}{Q_1^{13}}\right) = \left(\frac{R_2^{38}\omega_2^{14}}{Q_2^{13}}\right) \tag{59}$$

(Model 3: liquid–gas convective)

Therefore, the scaling rules for these three mass transfer models are

- Liquid–gas diffusive

$$Q_2 = F^2Q_1 \tag{60}$$

$$\omega_2 = \omega_1 \tag{61}$$

- Liquid–solid shear/diffusion

$$Q_2 = F^2Q_1 \tag{62}$$

$$\omega_2 = \omega_1 \tag{63}$$

- Liquid-gas with surface wave convection

$$Q_2 = F^{22/9}Q_1 \tag{64}$$

$$\omega_2 = F^{-4/9}\omega_1 \tag{65}$$

This implies that mass transfer by shear and by diffusion scales flow in proportion with disk area, while keeping rotational speed constant. If, however, convective transport due to surface waves is included the rotational speed is reduced as disk size is increased and flow is increased slightly more than proportional with disk area. However, wetting characteristics and absolute applied acceleration are not kept constant under these laws and will change as the disk is scaled up for a given mass transfer and residence time performance. Ultimately, their effects on the process will need to be studied before the scaling laws can be used; however, these can be used to provide a rough engineering guide to process capabilities.

Estimating Heat Transfer Performance for an SDR

In the previous sections we have discussed mass transfer into the thin centrifuged film occurring on a disk surface. For many processes diffusive transport can be seen to be a significant, if not the most significant, mechanism for transport. In the case of heat, transport by diffusion, that is, conduction, can be considered even more effective as diffusion coefficients for that process are substantially higher. Therefore, transport by conduction can be used as a good estimate for heat transfer performance through the film.

Substituting thermal diffusion for molecular diffusion allows the computation provided for liquid–solid mass transfer to be transferred to thermal diffusion using the following equation:

$$h_{\text{FILM}} = k_{\text{LS,THERM}}c_{\text{P}}\rho \tag{66}$$

where $k_{\text{LS,THERM}}$ is the equivalent transport coefficient for thermal diffusion as defined by Eq. (36). Combining this with Eq. (42) for transfer assuming a constant surface temperature gives an effective heat transfer coefficient for the film as

$$h_{\text{FILM}} = 0.71\left(\frac{\omega^4k^6Qc_{\text{P}}^3\rho^3}{R^2\nu^2}\right)^{1/9} \tag{67}$$

If the disk surface temperature is assumed to be held constant then the thermal power transfer capability into the film can be estimated using the following equation:

$$\text{Power} = 0.71\left(\frac{\omega^4k^6Qc_P^3\rho^3}{R^2\nu^2}\right)^{1/9}\pi R^2\Delta T_{\text{LMTD}} \tag{68}$$

where ΔT_{LMTD} is the log-mean temperature difference between the film and the disk surface. Heat transfer in practice, however, is limited by the design of the spinning disk system below the film. One common design route used for the reactors is the supply of heating or cooling using a heat transfer fluid. If it is assumed that this fluid can transfer heat to the underside disk of thickness d with a performance of h_{HTF}, then the overall heat transfer

coefficient U for the system can be estimated using

$$U = \left(\frac{1}{h_{\mathrm{FILM}}} + \frac{k_{\mathrm{DISK}}}{d} + \frac{1}{h_{\mathrm{HTF}}}\right)^{-1} \quad (69)$$

where k_{DISK} is the thermal conductivity of the spinning disk material.

Quantifying Power Input to the Fluid

Power consumed by a spinning disk and cone processes can be divided into various contributions. These include the power losses to bearing friction as well as drive inefficiencies, neither of which contributes directly to the power input of the fluid. A large component of power may also be required to initially spin-up the disk surface, this being a function of the disk mass and start-up time allowable. Power input to the fluid itself, however, may only be a fraction of the total power demand but is that which can be related to the processing conditions.

For a spinning disk and spinning cone reactor, power input to the fluid can be represented as that given to accelerate the liquid up to the tip speed of the disk. This can be written as

$$\text{Power} = \frac{\rho Q R^2 \omega^2}{2} \quad \text{(spinning disk/cone)} \quad (70)$$

Power is input to the fluid from a nested cone system that has nonsynchronized upper and lower rotating surfaces. An equation to estimate the power input from that design can be written as

$$\text{Power} = \frac{\rho Q R^2 \omega^2}{2} + \sum_{i=1}^{n}\left(\frac{u_{\mathrm{imp},i}^2 + v_{\mathrm{imp},i}^2}{2}\right)\rho Q \quad \text{(nested cone)} \quad (71)$$

where the nested cone has n impacts with relative velocities of u_{imp} and v_{imp} as given by Eqs. (31) and (32) before the liquid leaves at the edge of the system at a radius R. Energy input to the liquid per unit volume can also be calculated from the above equations using

$$\frac{\text{Energy}}{\text{Volume}} = \frac{\text{Power}}{Q} \quad (72)$$

This can be used to compare these reactors with that of a batch stirred reactor by using the following equation:

$$\frac{\text{Energy}}{\text{Volume}} = \frac{\text{Power} \times \text{Batch time}}{\text{Batch volume}} \quad (73)$$

Process Application of SDRs

The ability to handle viscous and inviscid fluids with considerable ease makes the SDR ideally suited for performing a range of process operations. It has considerable use in food, fine chemicals, polymers, energy, household products, water treatment, and the pharmaceutical industry. It is a unique treatment of fluids under the centrifugal field and has been shown to enhance rates of reaction by orders of magnitude. The SDR polymerization of styrene, butyl acrylate, and esters has been successfully demonstrated by Boodhoo and Jachuck.[2,3] Thin films on the disk also offer the opportunity to use ultraviolet radiation to trigger fast chemical reactions. Intense mixing within the films has been used to generate micro to submicrometer sized particles of barium sulfate and calcium carbonate.[14,15] Nano composites and continuous production of fine particles for high-value application are attractive possibilities with SDRs. The high mass transfer rates coupled with the ability to provide short sharp bursts of high temperature have been exploited by Protensive Limited to perform devolatilization of polymers or removal of lighter organic molecules from viscous polymer melts. In conclusion, it may be stated that SDR technology offers several opportunities for the processing sector, such as process flexibility, improved product quality, speed to market, just-in-time manufacturing, reduced footprint, improved inherent safety and energy efficiency, distributed manufacturing capability, and ability to use reactants at higher concentrations.

CONCLUSIONS

This chapter has provided a summary of the characteristics, potential applications, hydrodynamic equations, and transport expressions that govern the operation of SDR. The reader is encouraged to refer to the References particularly for more information on the application of SDR. Currently, these reactors are being studied extensively by industry under pilot-plant programs and it is expected that details of the case studies will be published soon.

Styrene

Guy B. Woodle
UOP LLC, Des Plaines, Illinois, U.S.A.

INTRODUCTION

Styrene is one of the most important aromatic monomers used for the manufacture of plastics. Small-scale commercial production of styrene began in the 1930s. Demand for styrene-based plastics has grown significantly, and in 2003 the worldwide annual production capacity was approximately 24.5 million metric tons.[1]

About 65% of styrene is used to produce polystyrene. Polystyrene is used in the manufacture of many commonly used products such as toys, household and kitchen appliances, plastic drinking cups, housings for computers and electronics, foam packaging, and insulation. Polystyrene finds such widespread use because it is relatively inexpensive to produce and is easy to polymerize and copolymerize, resulting in plastics with a broad range of characteristics. In addition to polystyrene, styrene is used to produce acrylonitrile–butadiene–styrene polymer, styrene–acrylonitrile polymer, and styrene–butadiene synthetic rubber (SBR).

The development of styrene technologies was mainly driven by demand for cheap synthetic rubber during and immediately after World War II. Between 5% and 10% of total styrene produced becomes a component of synthetic rubbers, which are copolymers of styrene and butadiene (SBR). Styrene copolymers containing acrylonitrile are specialty materials that are used for specific applications. Demand for styrene for the period 2004–2009 is estimated to grow at a rate of approximately 4% per year.[1]

PHYSICAL AND CHEMICAL PROPERTIES

Styrene is a colorless aromatic liquid. It is only very slightly soluble in water, but infinitely soluble in alcohol and ether. Additional properties are listed in Table 1.

Styrene is chemically reactive with the most important reaction being its polymerization to form polystyrene. Styrene can also copolymerize with other monomers, such as butadiene and acrylonitrile, to produce a variety of industrially important copolymers.

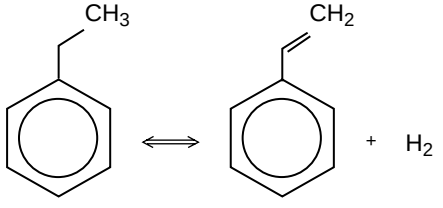
In addition to polymerization, styrene can undergo other types of reactions due to the chemical nature of its unsaturated side chain and aromatic ring. For example, styrene can be oxidized to form benzoic acid, benzaldehyde, styrene oxide, and other oxygenated compounds. Styrene oxide is used in the production of various cosmetics, perfumes, agricultural and biological chemicals.

REACTION KINETICS AND THERMODYNAMICS

Essentially all commercially produced styrene uses ethylbenzene (EB) as a feedstock. Between 85% and 90% of worldwide styrene production is based on EB dehydrogenation. The remaining 10–15% of styrene is obtained as a coproduct in a process to produce propylene oxide.

Ethylbenzene Dehydrogenation

Ethylbenzene is catalytically dehydrogenated in the presence of steam according to the equation:



The reaction is highly endothermic and conversion is limited in extent by equilibrium. The reaction equilibrium constant is defined as:

$$K\mathrm{eq} = (P\mathrm{sty} * P\mathrm{h2})/P\mathrm{eb}$$

where *P*sty is the partial pressure of styrene, *P*h2 is the partial pressure of hydrogen; and *P*eb is the partial pressure of ethylbenzene.

High temperature, steam dilution, and low system pressure produce an equilibrium more favorable to styrene. For endothermic vapor-phase reactions, the equilibrium constant increases with temperature and

can be determined according to the following equation:[2]

$$\ln Keq = 16.12 - (15,350/T)$$

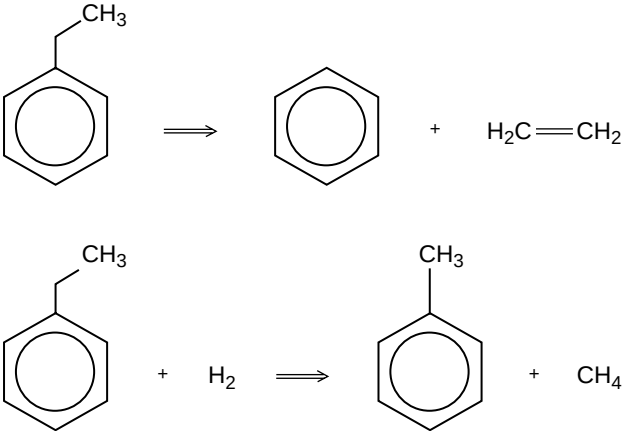
where Keq is the equilibrium constant in atmospheres and T is the temperature in K.

The equilibrium constant has the dimension of pressure since two moles of products are formed for each mole of EB converted. Therefore, a higher total pressure will shift the reaction equilibrium to the left and reduce EB conversion. Lower pressure results in greater EB conversion without an accompanying significant decrease in styrene selectivity.

Another method to create a positive shift in equilibrium is the use of steam dilution to reduce the partial pressures of EB, styrene, and hydrogen. Steam dilution provides the same effect as a reduction in total pressure.

Steam dilution has several other important benefits. First, steam supplies heat to the reacting mixture. Consequently, the drop in temperature for a given EB conversion is lower, allowing greater EB conversions to be obtained with the same inlet temperature. Second, a minimum amount of steam appears to keep the catalyst in the required oxidation state for high activity. The actual quantity of steam varies with the type of catalyst used. Third, steam is believed to suppress the deposition of carbonaceous material on the catalyst. If the carbonaceous material is allowed to accumulate, the catalyst will become fouled and its activity will decline to unacceptable levels.

The reaction feed mixture undergoes certain other reactions that are not equilibrium limited under typical operating conditions. Most important among these are the dealkylation reactions that result in the formation of benzene and ethylene or toluene and methane. Other reactions produce small amountsof α-methylstyrene and other high boiling components. The key dealkylation reactions can be described by the following equations:



Both methane and ethylene undergo steam reforming reactions according to the following equations:

$$CH_4 + H_2O \rightarrow CO + 3H_2$$

$$C_2H_4 + 2H_2O \rightarrow 2CO + 4H_2$$

The water–gas shift reaction also occurs and is generally near equilibrium at the reaction temperature:

$$CO + H_2O \leftrightarrow CO_2 + H_2$$

The combination of dealkylation, steam reforming, and water–gas shift side reactions should be avoided, if possible. In addition to losing valuable EB feed by dealkylation, the resultant net formation of carbon dioxide and hydrogen by this combination of reactions inhibits the primary dehydrogenation reaction. The net hydrogen formation gives an unfavorable shift in equilibrium, while the presence of carbon dioxide has a negative effect on dehydrogenation catalyst activity.[3]

Typically, there is less methane and ethylene present in the effluent of a reactor than would be expected from the benzene and toluene formation. Carbon monoxide is generally about 10 mol% of the total carbon oxides.

The critical operating and design parameters for EB dehydrogenation are discussed in the following paragraphs.

Reaction temperature

Because the dehydrogenation reaction is endothermic, the reaction mixture temperature decreases as the reaction proceeds. The reaction rate slows because of the closer approach to equilibrium and the decrease in kinetic reaction rate with the decreasing temperature. Furthermore, the equilibrium constant is less favorable at lower temperature. Therefore, in a normal design, about 80% of the temperature drop occurs in approximately the first third of the catalyst bed.

As a result, a high inlet catalyst temperature is required. However, high temperature also increases the rates of nonselective thermal reactions and dealkylation reactions, which form benzene and toluene by-products. In particular, as temperature is increased, the rate of benzene formation increases significantly relative to the rate of styrene formation. This means there is an effective upper limit to the inlet temperature if high styrene selectivity is a required criterion. Reaction temperature is generally adjusted by changing either the steam temperature or the steam-to-oil ratio.

Catalyst quantity

The amount of catalyst relative to EB feed is an important parameter for optimum reactor performance. Too little catalyst will prevent a close approach to equilibrium. If EB conversion is low, then distillation costs associated with recovery and recycle of the unconverted EB can become significant. With too much catalyst, the EB conversion reaches equilibrium before the outlet of the catalyst bed, while the side reactions continue leading to loss of selectivity.

The optimum catalyst quantity is achieved by balancing the EB conversion level and the styrene yield. Catalysts typically lose activity with time on-stream, which has the effect of decreasing the effective active catalyst quantity for reaction. Compensation for aging catalyst is achieved by adjusting other operating parameters, in particular, the reaction temperature.

Reaction pressure

Ethylbenzene dehydrogenation results in a significant increase in the volume of reactants due to the reaction stoichiometry. Lower pressure favors higher equilibrium conversion to styrene. Reaction pressure is established during the plant design at the lowest practical level. Modern commercial reactors operate below atmospheric pressure. Pressures as low as 300 mm Hg or lower are common. The key side reactions are largely independent of reaction pressure; hence, operating at lower pressures also provides higher styrene yield.

Steam dilution or steam-to-oil ratio

The main functions of steam dilution are to act as a diluent to reduce the hydrocarbon partial pressures, providing heat for the endothermic dehydrogenation reaction, and maintaining the catalyst's active surface in a desirable state. Increasing the steam-to-oil ratio has the net effect of improving the EB conversion and styrene yield. However, costs associated with generating and superheating the dilution steam also increase and eventually offset the reaction advantages.

Catalyst type and properties

Ethylbenzene dehydrogenation is generally catalyzed by a potassium-promoted iron oxide catalyst. The most widely used catalysts are composed of iron oxide, potassium carbonate, and various metal oxide promoters. Examples of metal oxide promoters include chromium oxide, cerium oxide, molybdenum oxide, and vanadium oxide.[4] The potassium component substantially increases catalyst activity relative to an unpromoted iron oxide catalyst. Potassium has been shown to provide other benefits. In particular, it reduces the formation of carbonaceous deposits on the catalyst surface, which prolongs catalyst life.

Properties such as catalyst size and shape also impact performance. In theory, smaller sized catalyst will increase reaction rates by providing more available catalyst surface area than larger sized catalyst. Small catalyst particles, however, have a disadvantage in that they result in greater pressure drop through a reactor and higher overall reaction pressures. To address this, catalyst developers have used specialized shapes, such as ribbed extrudates, to gain the advantage of increased surface area without incurring the penalty of increased pressure drop and reaction pressure.

The Sud-Chemie Group and Criterion Catalysts are the major catalyst developers and manufacturers for the styrene industry. Both companies offer a wide range of catalysts to suit individual processing needs. Ethylbenzene conversion, styrene selectivity, catalyst activity, and catalyst stability can be optimized by selecting the best catalyst or a combination of catalysts for a particular application. Dow and BASF manufacture proprietary catalysts, which have been mainly for use in their own respective technologies.

Propylene Oxide with Styrene Co-production

In the late 1960s, a method was discovered to produce propylene oxide by the epoxidation of propylene using organic hydroperoxides as the epoxidizing agent.[5] During the epoxidation reaction, the hydroperoxide is essentially converted to the corresponding alcohol, which in turn can be dehydrated to a more desirable coproduct. Styrene is coproduced in the form of this process that uses EB hydroperoxide as the epoxidizing agent. The chemistry of this process can be broken down into three main reactions as shown in Fig. 1.

The first step is oxidation of EB to form EB hydroperoxide. The oxidation is carried out in the liquid phase with a target EB conversion of approximately 13%.[6] Although higher conversions are attractive from an EB recovery and recycle standpoint, there is a significant disadvantage because the EB hydroperoxide selectivity declines sharply. The second step is epoxidation of propylene to form propylene oxide product and 1-phenylethanol. In the last step, the 1-phenylethanol is dehydrated to styrene and water. The dehydrated reaction mixture is typically stripped of light components and rerun in a styrene column to remove heavy by-products, resulting in a purified styrene product.

The design and operation of a propylene oxide/styrene process plant is complicated and includes numerous pieces of equipment. As a result, the total investment cost for a commercial-scale plant is about four times that of an EB dehydrogenation plant to produce the same quantity of styrene product.

COMMERCIAL PRODUCTION

Reactor Design

One important aspect of modern day EB dehydrogenation reactor design is managing the operating conditions to minimize thermal reactions. The major by-product from the thermal reaction of EB to styrene is benzene with significant subsequent conversions to a complex mixture of higher aromatics, such as anthracene and/or pyrene, as well as coke. Thermal reactions do not occur at a significant level below about 600°C, but become a considerable factor affecting overall yield when temperatures rise above 655°C.

One technique to reduce thermal reactions is to delay heating the EB to the reaction inlet temperature until the last possible moment before being exposed to the catalyst. The method involves superheating EB vapor, along with a portion of the dilution steam, to a temperature below approximately 580°C. The EB is vaporized with a certain amount of steam—commonly called primary steam—to suppress coking. The EB primary steam is combined with the major part of the dilution steam immediately prior to entering the dehydrogenation catalyst bed. The major portion of the dilution steam is generally referred to as main steam. The main steam is superheated to a temperature such that, when it is mixed with the EB and the primary steam, the total combined feed mixture reaches the desired catalyst inlet temperature.

Reactor design and catalyst bed configuration are key factors for controlling thermal reactions.

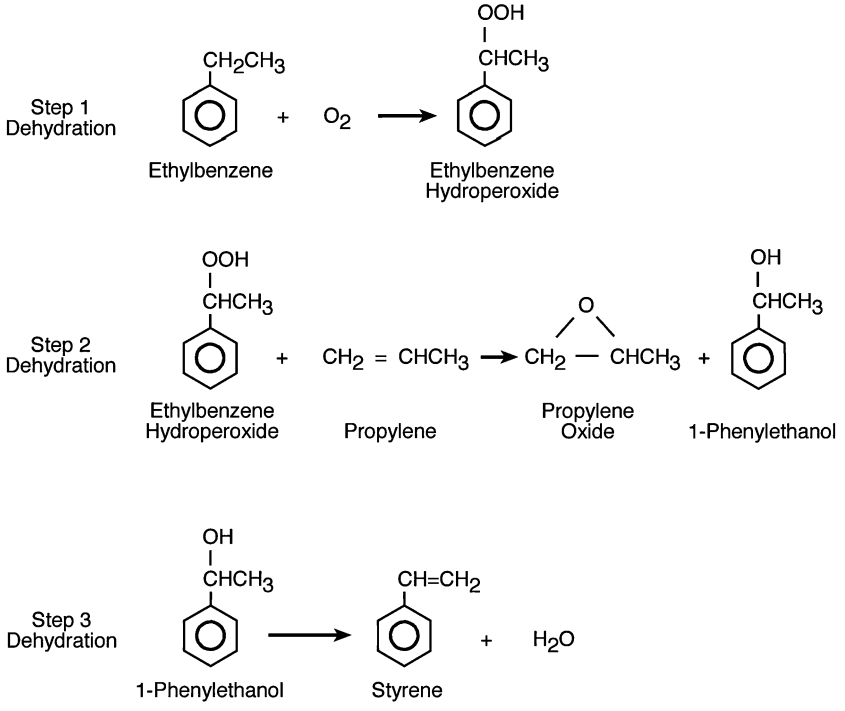


Fig. 1 Propylene oxide–styrene process chemistry.

Commercial adiabatic reactors are typically of radial flow construction with the flow path moving from in to out. This radial outflow geometry requires a much lower inlet volume to obtain proper distribution of the feed vapor through the catalyst bed than either an axial flow or a radial inflow reactor configuration. The radial flow reactor design also provides the advantage of low pressure drop since the flow path through the catalyst is much shorter relative to an axial flow reactor. To minimize thermal reactions, the reactor centerpipe diameter should be as small as possible to minimize residence time at the highest temperature throughout the reactor. However, too small a diameter will produce a high pressure drop through the centerpipe, potentially causing flow maldistribution and causing the feed vapor to enter the catalyst bed with a velocity that can result in erosion and attrition of catalyst particles.

A single-stage reactor with practical limits of temperature, pressure, and steam dilution is limited to 40–50% per pass conversion of EB. If the single-stage reactor effluent is reheated, the reaction mixture moves away from equilibrium allowing for higher EB conversion. When the reheated reaction mixture is fed to a second stage of catalyst, then total EB conversions of 60–75% per pass can be achieved. This process of reheating and adding catalyst stages can be repeated as frequently as economically feasible. With each additional reaction stage, however, a progressively smaller incremental EB conversion is achieved, generally with a corresponding decrease in styrene selectivity.

To obtain high EB conversions, typically two or three reactors are used in series with some type of reheating between the reactors to raise the temperature of the reaction mixture. Modern day commercial reactors are highly engineered. Designers use specialized computational fluid dynamics programs to study flow characteristics throughout a reactor.

Commercial Adiabatic Dehydrogenation Processes

Most commercial styrene plants are based on either the Lummus/UOP technology or the Fina/Badger technology. Dow Chemical is a major styrene producer and uses its own technology. These technologies are generally similar, but there are key differences in the details.

Lummus/UOP Classic SM™ Process

The first commercial plant based on the Lummus/Monsanto technology, which later became the Lummus/UOP technology, was commissioned in 1972. Since that time, more than 50 projects have been licensed with more than 40 plants in commercial operation as of 2004.

A typical Lummus/UOP Classic SM process flow diagram is shown in Fig. 2. Fresh and recycled EB are combined with steam and fed to the dehydrogenation reaction section of the plant. The reactor effluent is condensed and separated into off-gas, process condensate, and a dehydrogenated mixture. The hydrogen rich off-gas stream is recovered through an off-gas compressor for use as a fuel gas. The process condensate is stripped of organics and either recycled for use within the styrene plant or exported. The dehydrogenated mixture, consisting mainly of unconverted EB, styrene product, benzene, and toluene, is fed to the distillation section of the plant.

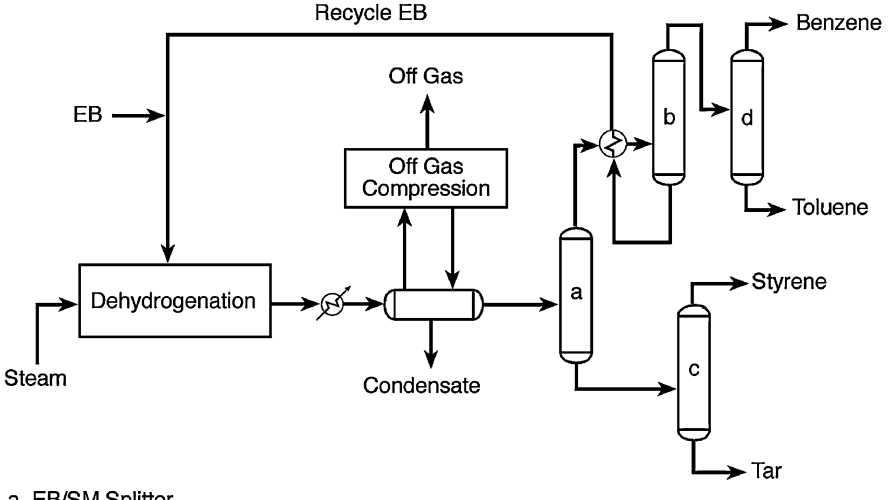

Fig. 2 Lummus/UOP classic SM process.

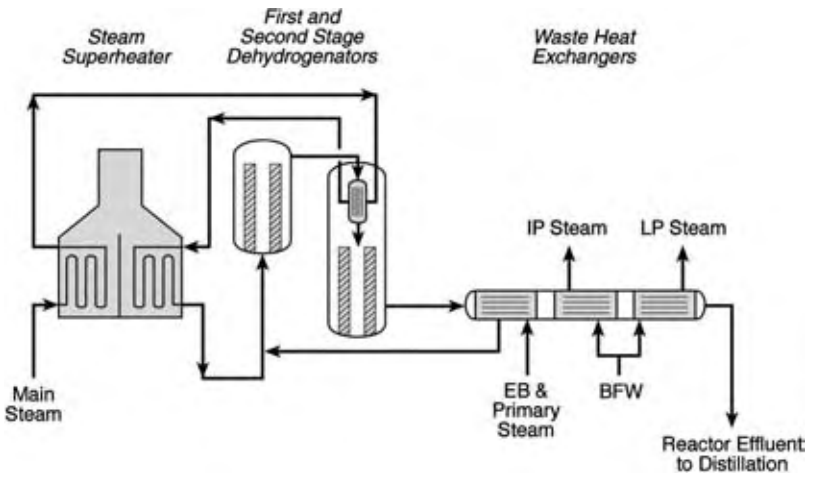

Fig. 3 Lummus/UOP classic SM process dehydrogenation section.

The main equipment in the dehydrogenation reaction section of a Lummus/UOP Classic SM plant includes a steam superheater, two dehydrogenation reactors, a series of waste heat exchangers, and an off-gas compressor (Fig. 3). The equipment is designed to minimize pressure drop from the dehydrogenation reactors inlet to the off-gas compressor.

The main steam is superheated and used to reheat the reaction mixture for the second stage dehydrogenator. The reaction mixture is reheated in a specially designed interchanger located inside the second stage dehydrogenator vessel shell. The cooled steam exiting the interchanger is reheated in the steam superheater prior to being fed to the first stage dehydrogenator. The superheated steam can range from 700°C to as high as approximately 850°C to achieve the desired inlet temperature for the first stage dehydrogenator.

Superheated main steam is mixed with the EB and the primary steam immediately before entering the first stage dehydrogenator. The reactor is designed to provide a uniform reaction mixture while minimizing residence time in the centerpipe to avoid thermal reactions. The reactor effluent is cooled in a series of three waste heat exchangers before final cooling and condensing.

The first stage of waste heat recovery is used to superheat the EB and the primary steam. Subsequent stages are used to generate steam at different pressures. Typically intermediate pressure steam and low pressure steam are generated, which are directed for use elsewhere in the styrene plant or larger EB–styrene complex.

Hydrogen and light hydrocarbons removed from the condensed reactor effluent are compressed and used as fuel gas in the steam superheater. The process steam from the reactor effluent stream is condensed and separated by gravity from the liquid hydrocarbon components. The condensate is stripped of hydrocarbons and revaporized for use as process steam.

The distillation section of a Lummus/UOP Classic SM plant consists of four distillation columns. The first column in the sequence splits the EB and the lighter components from styrene. The EB/styrene monomer (EB/SM) splitter is operated under vacuum and uses structured packing, such as Sulzer Mellapak Plus packing, to minimize temperature and polymer formation.[7] Polymerization inhibitors are injected into the splitter to restrict polymer formation, in particular into the bottom section of the column.

The overhead product from the EB/SM splitter is fed to an EB recovery column. The EB recovery column net bottoms' stream is recycled to the dehydrogenation section. Benzene and toluene by-products in the recovery column overhead stream are separated in a benzene/toluene splitter. Oftentimes, the benzene recovered in this scheme is recycled as feed to the upstream EB plant.

The EB/SM splitter bottoms' stream is fed to the SM column where the styrene is purified by removal of any heavy residual tars. Tertiary-butyl catechol (TBC) is injected into the overhead of the SM column, and the column is operated under vacuum to minimize polymer formation.

A unique feature of the Lummus/UOP Classic SM process is the noncompressive azeotropic heat recovery option.[8] In this option, the EB/SM splitter overhead vapor is used to boil an EB–water azeotrope mixture, which is then fed to the dehydrogenation reactors. The condensation of the splitter overhead vapor produces approximately 500 kcal/kg styrene. This energy savings potential makes the azeotropic heat recovery option economically attractive, in particular, in regions with moderate to high steam costs.

Lummus/UOP Smart SM™ Process

The Lummus/UOP Smart SM process is based on an oxidative reheat technology invented by UOP.[9] Although this technology can be used in the design of

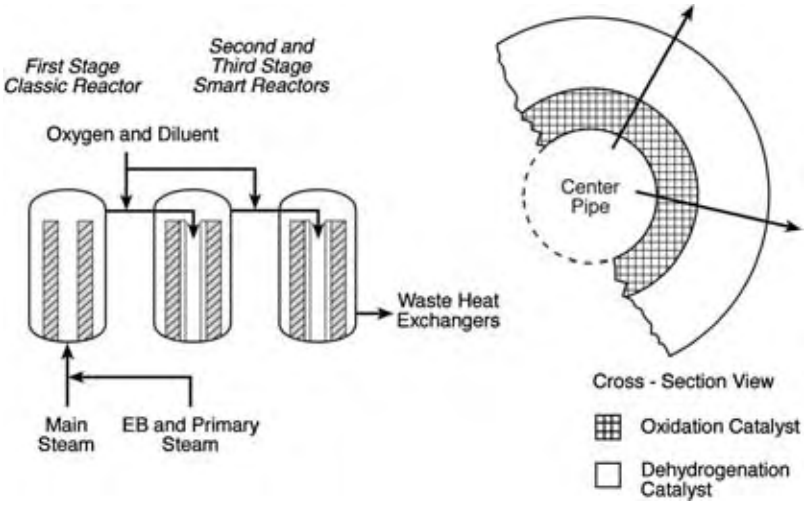

Fig. 4 Lummus/UOP smart SM process dehydrogenation section.

a grassroots plant, it is most commonly used in a revamp of an existing plant to increase styrene production by as much as 60% with minimal capital investment cost.

The Lummus/UOP Smart SM technology uses a specially designed reactor that contains two concentric catalyst zones. A cross-sectional view of the concentric oxidation and dehydrogenation catalyst beds is also shown in Fig. 4. In the first zone, hydrogen is selectively oxidized across a noble metal-containing catalyst. The direct combustion of hydrogen reheats the reaction mixture, which is directly fed into the second zone where the standard EB dehydrogenation reaction occurs. In addition to providing the full reheating requirement, another benefit of this technology is it shifts the reaction equilibrium in a favorable direction by removing the hydrogen by-product. This shift in equilibrium allows for higher EB conversion without a corresponding decrease in styrene yield.

The Lummus/UOP Smart SM technology was first commercialized in 1995 at Mitsubishi Chemical in Kashima, Japan. The Mitsubishi Chemical plant was designed with a dehydrogenation section containing two combination oxidation–dehydrogenation reactors as shown in Fig. 4.

The temperature rise in the oxidation zone is proportional to the amount of oxygen reacted across the catalyst bed. The oxygen is diluted in steam and the oxygen/steam mixture is well mixed to ensure the reaction mixture remains outside the flammability envelope at all times.

Fina/Badger Styrene Process

The Fina/Badger styrene process has evolved through many generations. The most recent design uses a flow diagram as shown in Fig. 5. Recycled and fresh EB

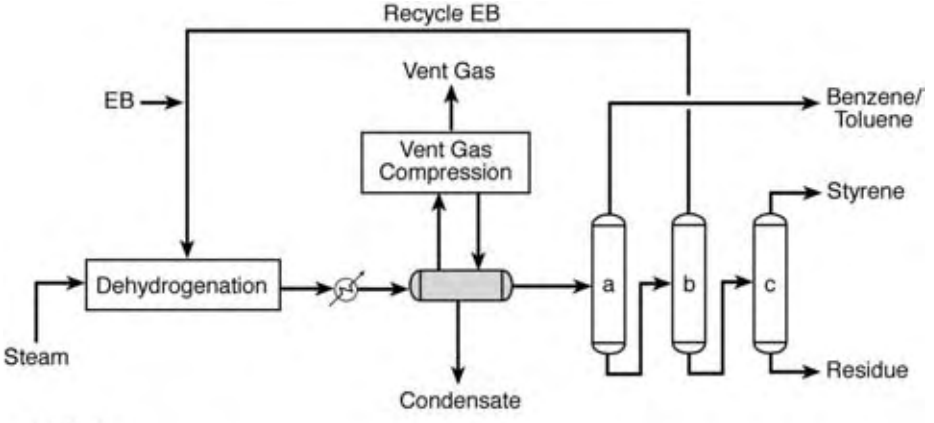

Fig. 5 Fina/Badger styrene process.

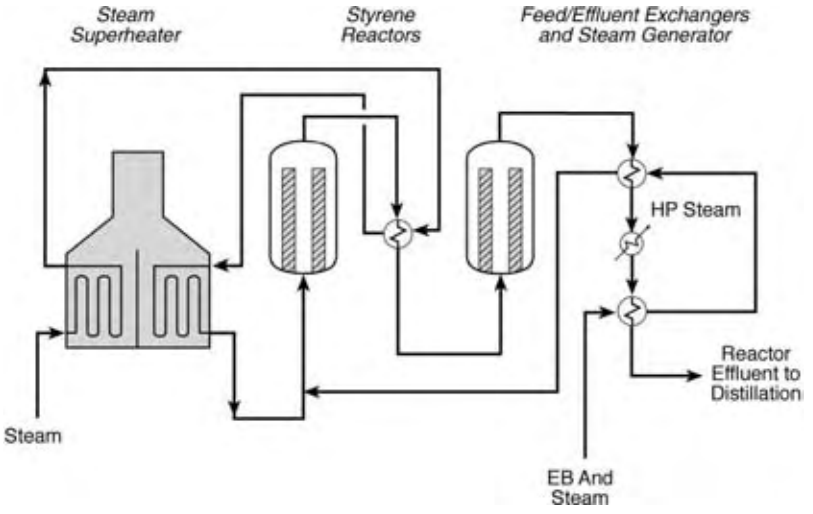

Fig. 6 Fina/Badger styrene process dehydrogenation section.

are mixed with steam and fed to the primary and the secondary dehydrogenation reactors. The reactor effluent is condensed and separated into vent gas, condensate, and hydrocarbon. The vent gas, the majority of which is hydrogen, is used as fuel gas. The condensate is stripped and used as feed water for steam generation. The hydrocarbon portion of the reactor effluent is fed to the distillation section of the plant, which consists of three distillation columns.

The main types of equipment in the dehydrogenation section of the plant are the steam superheater, the primary and secondary dehydrogenation reactors, and a series of feed/effluent exchangers (Fig. 6). High pressure steam is also generated by the recovery of heat from the reactor effluent stream.

The major portion of steam is superheated and used to reheat the reaction mixture for the secondary dehydrogenation reactor. As the cooled steam exits the reheater it is superheated again in the steam superheater, prior to being fed to the primary dehydrogenation reactor. The dehydrogenation reactors are designed to provide low pressure drop and uniform flow distribution. The reactor effluent is cooled in a series of three heat exchangers that heat the EB and steam feed to the reactors and generate steam.

The Fina/Badger distillation section consists of three distillation columns. All the columns are designed to operate under vacuum to minimize temperature and polymer formation. The first column in the sequence splits the benzene and toluene by-products from the unconverted EB and styrene product. The benzene and toluene mixture is typically sent to an integrated EB plant where it is further fractionated. In this case, the benzene by-product is ultimately consumed in the EB unit and the toluene becomes a by-product stream from the EB plant.

The EB recycle column separates the unconverted EB for recycle to the dehydrogenation reactors. Recent EB recovery columns use high efficiency packing to obtain minimum pressure drop through the column. This allows the column bottoms' temperature to be maintained below 100°C. This is an important aspect of the design as styrene polymerization becomes significant at temperatures higher than approximately 100°C.

The EB recovery column bottoms' stream is fed to a finishing column where the styrene is purified by the removal of any heavy residue. Tertiary-butyl catechol is injected into the overhead of the finishing column to prevent polymerization. Tertiary-butyl catechol is widely used to prevent styrene polymerization during storage.

In 1997, Fina/Badger joined with Shell Technology Ventures, a subsidiary of Shell Oil Company, to develop a reheating technology called Flameless Distributed Combustion (FDC) for application in EB dehydrogenation.[10] Flameless Distributed Combustion technology is patented by Shell Oil Company and was originally used as a heat injector for enhanced recovery of hydrocarbons from subterranean formations.

Flameless Distributed Combustion technology enables specific constraints in the conventional dehydrogenation system to be overcome, in particular designing for low steam-to-oil ratios. A low steam-to-oil ratio is desirable because of the substantial energy savings associated with superheating less steam. However, a practical lower steam-to-oil ratio limit exists due to the metallurgy of the steam superheater, steam transfer lines, and interstage reheater. Flameless Distributed Combustion allows for operation at molar steam-to-oil ratios less than 7:1 without a costly metallurgy upgrade. This is accomplished by heating the reaction mixture more directly through a combustion and convective heat transfer process.

Flameless Distributed Combustion technology, unlike the Lummus/UOP Smart SM technology, does not directly combust hydrogen from the reaction mixture; hence it does not obtain the benefit of a favorable shift in equilibrium.

Other Processes

Propylene oxide/styrene process

Aside from EB dehydrogenation, the only other commercial-scale production of styrene is through a propylene oxide/styrene process that produces roughly 15% of worldwide styrene. This technology was developed as an alternative to the chlorohydrin method for producing propylene oxide.

Styrene from Butadiene

Because the conventional EB dehydrogenation technologies are relatively mature, there is little room for significant additional reduction in production costs. This situation has motivated a lot of research toward using alternative, lower cost feedstocks for styrene production. One area that has been examined involves a two-step process to convert butadiene to styrene.

The first step of the process involves the cyclodimerization of butadiene to 4-vinylcyclohexene. The reaction is exothermic and can be catalyzed by either a copper-containing zeolite catalyst or an iron dinitrosyl chloride catalyst complex. Although both vapor-phase and liquid-phase processes have been studied, it appears that liquid-phase reactions are preferred because they achieve higher butadiene conversion levels. The second step is oxidative dehydrogenation of the 4-vinylcyclohexene to produce styrene. Dow has led the research effort in this area and has identified catalyst formulations that provide more than 90% conversion of 4-vinylcyclohexene with approximately 92% selectivity to styrene.[11]

Storage

Preventing polymerization is the key to successful styrene storage. Special handling and storage procedures are required to maintain the styrene product quality and to avoid a potentially dangerous situation involving uncontrolled polymerization.

During storage, styrene polymerization is prevented by maintaining low temperature and using an appropriate polymerization inhibitor. The industry standard styrene storage inhibitor is TBC and is typically used at concentrations between 10 ppm and 15 ppm. To be effective, TBC requires dissolved oxygen to be present in concentrations roughly equal to the TBC concentration.

In addition to adding TBC inhibitor, maintaining the styrene at the lowest practical temperature is critical to preserving product quality. Styrene storage facilities are generally maintained at temperatures below about 20°C, which allows for storage times of around 10 weeks. Even a 5°C increase in the storage temperature to 25°C can reduce the storage time to less than 4 weeks.[12] Tertiary-butyl catechol is added occasionally during storage to maintain the concentration in the desired range.

ECONOMICS

The cost of styrene production can be broken down into three main components: raw materials, utilities, and the fixed cost associated with the plant. The utilities cost includes fuel, electricity, steam, cooling water, catalyst, and chemical costs required to

operate the plant. The major cost components for styrene production using conventional adiabatic dehydrogenation process are listed in Table 2. The major cost of production is for the ethylene and benzene raw materials, which account for approximately 80% of the total cost of production. The benzene cost is the largest cost component; hence, the economics of styrene production are highly dependent on benzene price.

The raw materials cost has two components—one dictated by the stoichiometry and the other caused by

yield losses occurring as a result of the process technology. If the unalterable stoichiometric raw material consumption is removed from the cost of production, the resultant distribution of cost components appears very different, as shown in Fig. 7. From this perspective, the raw materials' cost is only about 15% of the incremental cost of production and the utilities and fixed costs become dominant. Recent catalyst and process design improvements have reduced the variable costs of styrene production, while ever-increasing complexity and more stringent regulations have greatly increased the fixed costs. Other recent trends, such as larger plant capacities and globalization of the styrene market, have also resulted in higher fixed costs.[13]

The result of the shift of focus from variable to fixed costs is that plants are being designed for larger capacities. For example in 2003, typical new styrene plants in the Asia Pacific Region produced an average of 350 KMTA styrene per year, nearly double the capacity of typical plants started up just 5 years earlier. The drive to reduce fixed costs has led to numerous revamps of existing plants to substantially increase capacity. In many cases, capacity expansions on the order of 50% are being implemented.

The propylene oxide/styrene process, the only other commercial process for production of styrene, is a growing influence on the overall styrene market economics. When viewed from the perspective that styrene is the primary product and propylene oxide is a by-product, the economics of this process appear encouraging (Table 3). Depending on the credit value assigned to the propylene oxide coproduct, the total cost of styrene production can be approximately 50% of conventional EB dehydrogenation technology. Approximately 33% of the styrene capacity added between 1998 and 2003 was produced using propylene oxide/styrene technology. More recently, the trend appears to be reversing and propylene oxide/styrene processes are accounting for less of newly installed capacity. Although propylene oxide/styrene plants are built to produce propylene oxide, there is a profound impact on the styrene market supply/demand balance.

CONCLUSIONS

Since the first commercial-scale production in the 1930s, styrene, mainly through its derivatives, has become an integral part of life. Most people come in contact with numerous styrene-based products throughout the course of a normal day. Demand for styrene is expected to continue growing at a rate comparable to the gross domestic product growth rate.

The chemical processing technologies that have been developed are sophisticated, producing styrene to meet the demand at low cost. Research and development efforts are aimed at further improvements in existing technologies and identification of new technologies for styrene production opportunities.

Styrene–Butadiene Rubber

Jing Peng
Department of Applied Chemistry, College of Chemistry, Peking University, Beijing, People's Republic of China

INTRODUCTION

Styrene–butadiene rubber (SBR) is a random polymer made from butadiene and styrene monomers. It possesses good mechanical property, processing behavior, and can be used like natural rubber. Moreover, some properties such as wear and heat resistance, aging, and curing property are even better than in natural rubber. Styrene–butadiene rubber was the first major synthetic rubber to be produced commercially. Now it has become the most common rubber with the largest production and consumption in the synthetic rubber industry. It can be widely used in tire, adhesive tape, cables, medical instruments, and all kinds of rubberware.

Styrene–butadiene rubber could be produced by using emulsion and solution process, thus it can be divided into emulsion-polymerized styrene–butadiene rubber (E-SBR) and solution-polymerized styrene–butadiene rubber (S-SBR). In this entry, we will describe their development and introduce their synthesis process, relationship between structure and property, processing property, blends, and applications.

EMULSION-POLYMERIZED STYRENE–BUTADIENE RUBBER

History

In the 1930s, I. G. Farbenindustrie in Germany prepared the first E-SBR known as Buna S. The American government in 1940 established the Rubber Reserve Company to start storage of natural rubber and a synthetic rubber program. These programs were expanded when the United States entered World War II. These E-SBR grades were called GR-S (government rubber styrene). Initially, the synthesis of E-SBR was focused on a hot polymerized (41°C) E-SBR. Production of a 23.5% styrene and 76.5% butadiene copolymer began in 1942. Cold polymerized E-SBR (5°C), which has significantly better physical properties than hot polymerized SBR, was developed in 1947. Thereafter, the oil extended E-SBR was produced in 1951.

Synthesis

The emulsion polymerization process has several advantages. It is normally carried out under mild reaction conditions that are tolerant to water in the absence of oxygen. The process is relatively resistant to impurities and amenable to using a range of functionalized and nonfunctionalized monomers. Additional benefits include the fact that emulsion polymerization gives high solid contents with low reaction viscosity and is a cost-effective process. The physical state of the emulsion (colloidal) system makes it easy to control the process. Thermal and viscosity problems are much less significant than in bulk polymerization.

Table 1 shows the raw materials required in the polymerization of E-SBR, which include monomers (styrene and butadiene), water, emulsifier, initiator system, modifier, terminal agent, and a stabilizer system. The original polymerization reactions were carried out in batch reactors in which all the ingredients were loaded to the reactor and the reaction was terminated after it had reached the desired conversion. Current commercial productions are run continuously by feeding reactants and polymerizing through a chain of reactors before terminating at the desired monomer conversion. The monomers are continuously metered into the reactor chains and emulsified with the emulsifiers and catalyst agents.

In cold polymerization, the most widely used initiator system is the redox reaction between chelated iron and organic peroxide using sodium formaldehyde sulfoxide (SFS) as a reducing agent [see Eqs. (1) and 2]. In hot polymerization, potassium persulfate is used as an initiator.

$$\mathrm{Fe(II)EDTA} + \mathrm{ROOH} \rightarrow \mathrm{Fe(III)EDTA} + \mathrm{RO^{\bullet}} + \mathrm{OH^{\bullet}} \quad (1)$$

$$\mathrm{Fe(III)EDTA} + \mathrm{SFS} \rightarrow \mathrm{Fe(II)EDTA} \quad (2)$$

Mercaptan is added to provide free radicals and to control the molecular weight distribution by terminating existing growing chains while initiating a new chain. The thiol group acts as a chain transfer agent to prevent the molecular weight from attaining the

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120019881

excessively high values possible in emulsion systems. The sulfur–hydrogen bond in the thiol group is extremely susceptible to attack by the growing polymer radical and thus loses a hydrogen atom by reacting with polymer radicals [Eq. (3)]. The $RS^{\bullet}$ formed will continue to initiate the growing of a new chain as shown in Eq. (4) below. The thiol prevents gel formation and improves the processability of the rubber.

$$P^{\bullet} + RSH \rightarrow P-H + RS^{\bullet} \quad (3)$$

$$RS^{\bullet} + M \rightarrow RS-M^{\bullet} \quad (4)$$

During polymerization, parameters such as temperature, flow rate, and agitation speed must be controlled carefully to get the right conversion. Polymerization is normally allowed to proceed to about 60% conversion in cold polymerization and 70% in hot polymerization before it is stopped with a terminal agent that reacts rapidly with the free radicals. Common terminal agents include sodium dimethyldithiocarbamate and diethyl hydroxylamine.

Once the latex is properly terminated, the unreacted monomers are removed from the latex. Butadiene is stripped by degassing the latex by means of flash distillation and reduction of system pressure. Styrene is removed by steam stripping the latex in a column. The latex is then stabilized with the appropriate antioxidant and transferred to blend tanks. In the case of oil-extended polymers or carbon black master batches, these materials are added as dispersions to the stripped latex. The latex is then transferred to finishing lines to be coagulated with sulfuric acid, sulfuric acid/sodium chloride, glue/sulfuric acid, aluminum sulfate, or amine coagulation aid. The type of coagulation system is selected depending on the end use of the product. Sulfuric acid/sodium chloride is used for general purposes. Glue/sulfuric acid is used for electrical grade and low water sensitivity SBR. Sulfuric acid is used for coagulations where low-ash polymer is required. Amine coagulating aids are used to improve coagulation efficiency and reduce production plant pollution. The coagulated crumb is then washed, dewatered, dried, baled, and packaged.

On the other hand, due to the difference in producing E-SBR, E-SBR grades have different properties. Hot emulsion polymerization is the original SBR process. The major characteristic of this process is that these grades have excellent processing behavior in terms of low mill shrinkage, good dimensional stability, and good extrusion characteristics. However, high content of microgels is also produced in hot polymerization; therefore, there is a trend toward using cold emulsion grades in many applications. Nevertheless, hot rubbers are still used in applications such as adhesives and flow modifiers for other elastomers where good flow properties are required.

Properties of E-SBR

E-SBR is commercially available in Mooney viscosities ranging from 30 to about 120 [ML (1 + 4) 125°C]. Lower Mooney viscosity E-SBR grades adhere more easily to the mill, incorporate fillers and oil more readily, show less heat generation during mixing, and are calendered more easily, shrink less, give higher extrusion rates, and have superior extrudate appearance than the higher Mooney viscosity grades. On the other hand, the high Mooney viscosity SBR grades have better green strength, less porosity in the vulcanizate, and accept higher filler and oil loadings.

As the molecular weight of the SBR increases, the vulcanizate resilience and the mechanical properties, particularly tensile strength and compression set, improve. The processability of SBR can be improved as its molecular weight distribution broadens. However, the formation of high molecular weight fractions with the increase in the average molecular weight can prevent improvements in the processability. This is due to the fact that the tendency for gel formation also increases at higher molecular weights.

In addition to the polymer viscosity, polymerization temperature also plays an important role in shaping the processability. Emulsion-polymerized SBR grades produced at low polymerization temperatures have less chain branching than those produced at higher temperatures. At an equivalent viscosity, cold polymerized E-SBR is normally easier to process than hot polymerized E-SBR, and this applies particularly

to a better banding on mills, less shrinkage after calendering, and a superior surface of green tire compounds. Hot rubbers give better green strength because they have more chain branching.

The styrene content of most emulsion SBR varies from 0% to 50%. The percentage of styrene in most commercially available E-SBR grades is 23.5%. In vulcanizates of SBR, as styrene content increases, dynamic properties and abrasion resistance decrease while traction and hardness increase. Polymerization temperature also affects the microstructure of E-SBR. In the cold polymerized E-SBR grades, the butadiene component has, on average, about 9% *cis*-1.4, 54.5% *trans*-1.4, and 13% of vinyl-1.2 structure. At the 23.5% styrene level, the glass transition temperature, T_g, of SBR is about –50°C. As the styrene content in the SBR increases, the glass transition temperature also increases. Rubbers with very low T_g values posses a high resilience and good abrasion resistance, but have poor wet traction. By contrast, those rubbers with high T_g (for instance, SBR 1721) exhibit a low resilience and poor abrasion resistance with an excellent wet traction.

The emulsifier remains in the rubber after coagulation and can also have an influence on the processability. Rosin acid emulsifiers impart better knitting, tack, and adhesion to the SBR polymer. Generally, polymers emulsified with rosin acid have better extrusion rates, slower cure rates, poorer heat resistance, and can cause mold fouling and polymer discoloration. Fatty acid emulsified SBR polymers generally have less tack, faster curing, and high tensile properties. A compromise of the above properties is obtained by using a mixed rosin acid/fatty acid emulsifier system.

Chemical Activity of E-SBR

It has been proved that incorporation of carboxylic acid groups in the polymeric chain has a significant effect on colloidal properties of latex, processability, and end-use property. Carboxylated styrene–butadiene latexes (XSBR) are prepared via batch emulsion copolymerization with different amounts of acrylic acid in the absence of emulsifier. They are among the most important polymeric colloids, and can be used as binder in paper coatings, carpet backing, paints, and nonwoven. There are several studies on the preparation and properties of XSBR latexes.

To improve the aging property of E-SBR, Parker and Roberts used the diimide reduction method to prepare hydrogenated E-SBR. In the system containing hydrazine hydrate, oxidant, and a metal-ion catalyst, hydrogenated E-SBR with 97% of hydrogenation could be obtained.[2] The hydrogenated E-SBR not only exhibited excellent ozone, oxidation, and UV resistance as expected, but also showed better mechanical properties in some circumstances than unhydrogenated E-SBR.

Moreover, E-SBR can be grafted with some polar monomers such as acrylic acid or organic chlorium to give modified E-SBR with good heat resistance and tensile strength.

Cure Properties and Processing

Styrene–butadiene rubber can be cured with a variety of cure systems including sulfur (accelerators and sulfur), peroxides, and phenolic resins. In addition, some papers have reported that the SBR could be vulcanized using gamma irradiation in the presence of polyfunctional monomers. The efficiencies of seven functional monomers toward radiation vulcanization of SBR are in the following order: tertamethylol methane tetraacrylate (ATMMT) = toluene diisocyanate (UA306T) > trimethylol propane trimethacrylate (TMPT) > diethylene glycol dimethacrylate (2G) > dipentaerthritol hexaacrylate (DPE6A) > hexamethylene diisocyanate (UA101H) > triallyl cyanurate (TAC).[3]

Processing of SBR compounds can be performed in a mill, internal mixers, or mixing extruders. Styrene–butadiene rubber compounds are cured in a variety of ways by compression, injection molding, hot air or steam autoclaves, hot air ovens, microwave ovens, and combinations of these techniques.

Types of E-SBR

There are a large variety of E-SBR types based on the styrene content, polymerization temperature, antioxidants, oil and carbon black content. Each of these basic classifications includes a variety of SBR polymer variations with respect to Mooney viscosities, coagulation types, emulsifier type, oil levels, and carbon black types and levels. Table 2 shows the basic series of E-SBR.

Table 2 The types of E-SBR

Series	Comments
1000	Hot polymerized polymers
1500	Nonextended cold polymerized polymers
1600	Non-oil-extended cold carbon black masterbatches
1700	Cold oil-extended polymers
1800	Cold oil-extended carbon black masterbatches
1900	Miscellaneous high styrene resin masterbatches

(From Ref.[1].)

Applications of E-SBR

Emulsion-polymerized SBR is predominantly used for the production of car and light truck tires and truck tire retread compounds. A complete list of the uses of SBR includes houseware mats, drain board trays, shoe soles and heels, chewing gum, food container sealants, tires, conveyor belts, sponge articles, adhesives and caulks, automobile mats, brake and clutch pads, hose, V-belts, flooring, military tank pads, hard rubber battery box cases, extruded gaskets, rubber toys, molded rubber goods, shoe soling, cable insulation and jacketing, pharmaceutical, surgical, and sanitary products, food packaging, etc. The typical applications of E-SBR polymers are presented in Table 3.

SOLUTION-POLYMERIZED STYRENE–BUTADIENE RUBBER

History

During the 1960s, Phillips produced the first solution-polymerized random SBR grades, which are named as Solprene X-40, commercially. In 1969, Firestone produced the commercial S-SBR grades named as Duradone. The original aim to produce SBR with lower styrene content than products made by emulsion polymerization is to counteract the increase in styrene price. Standard S-SBR grades now have comparable styrene content to emulsion types. These grades have superior mechanical properties to E-SBR.

(From Ref.[1].)

In 1983, the high *trans*-SBR grades were synthesized in America.

Solution-polymerized SBR grades have superior mechanical properties, particularly tensile strength, low rolling resistance, and handling, when used in tire applications. The ratio of butadiene configurations varies. Generally speaking, S-SBR grades have a lower *trans* and vinyl and a higher *cis* butadiene content than E-SBR grades. In initially making S-SBR grades, producers attempted to replicate the stereochemistry of E-SBR grades. However, solution polymerization differs from emulsion polymerization because of its flexibility and enables SBR grades with varying styrene–butadiene ratios and *cis*, *trans*, and vinyl contents to be produced by changing the catalyst and monomer ratios and reaction conditions. This enables S-SBR producers to synthesize grades specifically tailored for individual applications.

Synthesis

Solution-polymerized SBR is made by termination-free, anionic/live polymerization initiated by alkyl lithium compounds. Other lithium compounds are suitable (such as aryl, alkaryl, aralkyl, tolyl, xylyl lithium, and α/β-naphtyl lithium as well as their blends), but alkyl lithium compounds are the most commonly used in industry. The absence of a spontaneous termination step enables the synthesis of polymers possessing a very narrow molecular weight distribution and less branching. Carbon dioxide, water, oxygen, ethanol, mercaptans, and primary/secondary amines interfere with the activity of alkyl lithium catalysts, so the polymerization must be carried out in clean, near-anhydrous conditions. Stirred bed or agitated stainless steel reactors are widely used commercially.

Polymerization is carried out in a solution of inert aliphatic or aromatic solvent. The polymerization rate of butadiene in the presence of lithium-based catalysts is lower than styrene. However, when butadiene and styrene monomers are mixed, the rate of polymerization is reversed, resulting in the production of block copolymer with a high proportion of butadiene blocks. Block formation must be suppressed because the property requirements of traditional SBR markets cannot be met by block copolymers. Random copolymerization is encouraged by incorporating into the solution ''randomizing'' agents such as dialkyl and heterocyclic ethers, which act as a Lewis base on the catalyst, or by controlled monomer charging (i.e., some of the styrene is added later in the polymerization cycle). The resulting copolymer is precipitated, separated, dried, and baled.

By adjusting the reactivity of the initiator/modifier system toward metallation of the polymer backbone, Kerns and Henning have developed synthetic strategies that effectively control the relative level of branching and polydispersity in S-SBR. This development has allowed for the optimization of both the microstructure and the macrostructure of solution elastomers to meet the demands of a given application. They have taken the approach to control the polymer macrostructure by adjusting the initiator/modifier system so as to mediate the propensity for backbone metallation to occur. Several synthetic strategies were employed to impose control over the levels of branching in solution SBR grades. They found that the macrostructure is the independent variable and subtle differences can have profound effects on the rheology and, thus, mixing, extruding, and even physical properties of the resultant compound.[4]

Compared with the E-SBR, S-SBR has different structures and properties. Some typical characteristics of S-SBR grades are shown in Table 4.

Properties of S-SBR

The optimization of property has been achieved by conventional solution SBR technology. By modifying the way in which monomers are added, the polymerization conditions, the use of cocatalysts and randomizing agents, the proportion of *cis* and vinyl isomers, the chain structure of the resulting ''tailored'' polymer can be varied.

Generally, the Mooney viscosity of S-SBR is higher than E-SBR. Thus, it accepts higher filler and oil loadings. The effect of composition on the property of S-SBR is similar to that of E-SBR. As the styrene content increases, the rolling resistance, traction, and hardness increase, while the wear resistance decreases. With the increase of vinyl content, the wet traction increases.

Mechanical Property

Styrene–butadiene rubber is generally compounded with a vulcanization system, reinforcing filler (usually carbon black), processing/extending oil, and an antioxidant/stabilizer package prior to molding/fabrication. Standard S-SBR grades have comparable styrene content to emulsion types. These grades have superior mechanical properties to E-SBR. The typical mechanical properties of some commercial S-SBR grades are listed in Table 5.

Cerveny investigated the development of the dynamic glass transition in styrene–butadiene copolymers by dielectric spectroscopy in the frequency range from 10^{-2} to 10^{6} Hz. Two processes were detected and attributed to the alpha- and beta-relaxations. The alpha relaxation time has a non-Arrhenius temperature behavior that is highly dependent on styrene content

Table 4 The typical characteristics of some S-SBR grades

	Types							
	S-SBR							
	Low vinyl-1,2 structure		Medium vinyl-1,2 structure			High vinyl-1,2 structure		
Entry	Tufdene 2000R	NS 118	Solprene 1204	SL 552	NS 114	SL574	NS110	E-SBR 1500

Structure of butadiene								
cis-1,4 (%)	35		24	20		16		12
trans-1,4 (%)	52		40.5	40		27		68.5
vinyl-1,2 (%)	13	11.5	35.5	30	38	57	72.5	19.5
Molecular weight distribution	Narrow	Two peaks	Two peaks	Two peaks	Two peaks	Two peaks	Two peaks	Wide
Glass transition temperature (°C)	~−70	−75	~−50	−64	−53	−55	−28	~−60

while the beta relaxation time shows an Arrhenius behavior with an activation energy that is independent of styrene-content. Furthermore, the shape of the alpha-relaxation is strongly influenced by the styrene content while the shape of beta-relaxation is independent of styrene content. Someone interprets these results as follows. The observed beta-relaxation is primarily due to local motions of butadiene monomers and is therefore not affected by the presence of styrene. The alpha-relaxation, on the other hand, is highly sensitive to the styrene content owing to its cooperative character.[6]

Chemical Activity of S-SBR

Using chemical modification such as cyclization, chlorination, hydrogenation, and epoxidation, the different S-SBR derivatives could be obtained.

Controlled cyclization of SBR was achieved with the aid of cationic catalyst system based on diethylaluminum chloride ($AlEt_2Cl$) and benzyl chloride ($C_6H_5CH_2Cl$) and by working in xylene solution at high temperature ($T > 100°C$). Elastomers with low intrinsic viscosity, ready solubility, and free gel were produced by Wang et al. The cyclized products have been expected to be photoresists with high photosensitivity.[7]

Dichlorocarbene-modified SBR prepared by the alkaline hydrolysis of chloroform using cetyltrimethylammonium bromide as a phase-transfer agent resulted in a product that showed good mechanical properties, excellent flame and solvent resistance, and good thermal stability. The molecular weight of the polymers, determined by gel permeation chromatography, showed that chemical modification was accompanied by an increase in molecular weight. Proton nuclear magnetic

(From Ref.[5].)

resonance and Fourier transform infrared (FTIR) studies revealed the attachment of chlorine through cyclopropyl rings to the double bond of butadiene.[8]

Because of the existence of unsaturation bonding in the SBR backbone, the material is susceptible to degradation under oxygen and ozone atmosphere. This drawback can be overcome by hydrogenating the copolymer to give hydrogenated styrene–butadiene copolymer. The hydrogenation of a copolymer of styrene and butadiene (SBR) catalyzed by $Ru(CH{=}CHPh)Cl(CO)(PCy_3)_2$ was experimentally investigated within the temperature range of 120–160°C at P_{H_2} of 300–1200 psi, and a catalyst concentration of 1.0–7.8 $\times$ 10^{-5} M. Special attention was paid to minimizing the catalyst metal residue and cross-linking in the product. The results indicated that high-quality hydrogenated SBR could be achieved without cross-linking and the metal residue was less than 7 ppm without post-treatment.[9] In addition, the hydrogenated SBR under certain conditions is more stable than its unsaturated precursors. They can be used as model compounds for predicting the unperturbed dimensions of polymer chains.

Cure Properties and Processing

Compared with E-SBR, the curing rate of S-SBR grades is faster by about 10–20%. Generally, the processing of S-SBR compounds is the same as for E-SBR. The difference is that the molecular chain of S-SBR cannot be broken in the internal mixer with high power; therefore, all the components can be added into the mixer simultaneously without precalendering.

Usually, the mechanical strength of raw S-SBR is lower than that of E-SBR; it is necessary to reduce the distance between two rolls by 10–20% to avoid the peeling off of the roll. On the other hand, S-SBR bonds easily on the cold roll. It will be better to ensure that the temperature difference between two rolls is about 5–10°C during the processing of S-SBR.

Applications of S-SBR

S-SBR grades have excellent balance between wet traction and rolling resistance; therefore, they can be used for low fuel consumption tire treads in all-season tires and high-quality rubber goods. In applications of S-SBR, carbon black and silica will often be added to enhance the property.

Blending

Rubber goods usually require a combination of properties that cannot be provided by one elastomer only and two or more polymer components have to be mixed to meet specific requirements such as lowering the compound cost, for ease of fabrication and to improve the performance of the industrial rubber. Natural rubber (NR) and SBR have been blended for a long time for these reasons. The tensile, hardness, and wear properties of the NR/SBR blends with the increment of NR percentages were greatly enhanced.[10]

For the system of natural rubber (NR) and styrene butadiene rubber (SBR) in a 1:1 ratio, the best properties were found when the NR/SBR mixture was prepared in such a way as to favor the vulcanization of the SBR phase while preserving the NR phase from excessive vulcanization.[11]

The morphology and mechanical and viscoelastic properties of a series of blends of NR and SBR latex blends were studied in the uncross-linked and cross-linked states. The morphology of the blends indicated a two-phase structure in which SBR is dispersed as domains in the continuous NR matrix when its content is less than 50%. A cocontinuous morphology was obtained at a 50/50 NR/SBR ratio and phase inversion was seen beyond 50% SBR when NR formed the dispersed phase. As the NR content and time of prevulcanization increased, the mechanical properties such as the tensile strength, modulus, elongation at break, and hardness increased. This was due to the increased degree of cross-linking that leads to the strengthening of the three-dimensional network. In most cases the tear strength values increased with the prevulcanization time. The effects of the blend ratio and prevulcanization on the dynamic mechanical properties of the blends were investigated at different temperatures and frequencies. All the blends showed two distinct glass transition temperatures, indicating that the system is immiscible. It was also found that the glass transition temperatures of vulcanized blends are higher than those of unvulcanized blends.[12]

Styrene butadiene rubber/epoxidized natural rubber (ENR) blends were prepared with an internal mixer, Haake Rheomix. The scorch time, t_2, and curing time, t_{90}, were found to decrease with increasing ENR composition in the blends. The mechanical properties such as tensile strength, tear strength, and tensile modulus, M_{300} (modulus at 300% elongation), increase with increasing ENR composition in the blends. However, elongation at break shows an opposite trend. At similar immersion times, SBR/ENR blends containing a higher ENR content exhibit better oil resistance.[13]

The mixing of incompatible polymers such as polyethylene terephthalate (PET) and SBR produces a blend with poor mechanical and impact properties, because polymeric phases interact weakly with each other and segregate. The use of SBR grafted with maleic anhydride (MAH) could increase the compatibility of the SBR–PET system by generating higher interactions and chemical bonds between the ingredients of the

blend. The induced compatibility is reflected in the 2.5-fold increase in the impact resistance of the blend as compared to that of pure PET. The grafting reaction to produce SBR-*g*-MAH is carried out by reactive extrusion using a reaction initiator benzoyl peroxide (BPO), and the extent of the reaction depends on the concentration of MAH and BPO. Results indicated the close relationship between processing conditions and microstructural parameters, such as particle diameter and interparticle distances of the dispersed rubber phase, which is necessary to achieve the best impact resistance.[14]

The morphology of ternary polystyrene/SBR/polyethylene (PS/SBR/PE) blends has been investigated in the limits of a constant content of the major component (PS: 75 wt%) while changing the weight ratio of the two minor constitutive polymers. A core-shell structure for the dispersed phase has been predicted from the spreading coefficients and observed by transmission electron microscopy. Actually, with the increase in the relative content of PE with respect to SBR, the structure of the dispersed phase changes from a multicore structure to a PE/SBR core-shell morphology. The size of the PE subphase in the mixed dispersed phase increases sharply at a PE content that corresponds to phase inversion in the parent SBR/PE binary blends. The ultimate mechanical properties of these blends are sensitive to the strength of the SBR interphase between PS and PE. Some synergism has been observed in the PE/SBR composition dependence of the tensile strengths at yield and break.[15]

Because SBR lacks the self-reinforcing qualities of natural rubber due to stress-induced crystallization, gum vulcanizates of SBR have lower tensile properties. The tensile property of E-SBR vulcanizates depends significantly on the type and amount of filler in the compound. Cured gum stocks have only 2.8–4.2 MPa in tensile strength, while fine particle carbon black loadings can produce tensile strength of 27.6 MPa. Though the compression set of some of the common E-SBR compounds is high, by proper compounding and blending, it is possible to obtain E-SBR vulcanizates with a low compression set. Some studies also indicated that filler affects the physical and mechanical properties of the blends. In such cases, the additives normally employed in rubber formulations are unevenly distributed, depending on the affinity of each compound to each polymeric phase. Thus, the dispersion of each one of these ingredients in the different rubbers will influence the rate and degree of vulcanization and, in consequence, the performance of the final composite.

Recently, nanocomposites were prepared with different grades of nitrile rubber with acrylonitrile contents of 19%, 34%, and 50%, with SBR (23% styrene content), and with polybutadiene rubber with Na-montmorillonite clay. The clay was modified with stearyl amine and was characterized by x-ray diffraction (XRD), FTIR spectroscopy, and transmission electron microscopy (TEM). At the degree of filler loading up to a certain level, mechanical properties of nanocomposites could be improved.[16]

A new kind of rubber powder with ''salami'' structure (RPS) was prepared by spray drying the mixture of SBR latex and nano-$CaCO_3$ slurry. It was found that RPS is an effective toughener with synergistic toughening effect on polypropylene (PP). The Izod impact strength of PP/RPS blend is not only higher than that of PP/rubber powder or PP/nano-$CaCO_3$ blends, but also higher than that of a PP/rubber powder/$CaCO_3$ blend. Transmission electron microscopy images showed that the microstructure of the PP/RPS blend is an ''island-sea'' structure with ''salami'' structure in RPS, in which nano-$CaCO_3$ particles are embedded in SBR particles. Perhaps this morphology resulted in the improvement of mechanical properties of blends.[17]

Technical Development of SBR

In recent years, SBR developments have been predominantly initiated by the tire industry. This is not surprising when several of the SBR producers have put their assets up for sale in recent times such as Polimeri in Europe, DSM in the United States, and others. This is partly due to the commoditization of SBR and also to butadiene price rises, which are difficult to pass for the tire producers. This has created severe pressure on margins for SBR producers. Therefore, the majority of recent developments have been undertaken by the tire companies themselves rather than the SBR producers who were more active in the past. Property optimization of SBR has been achieved, to some extent, by conventional S-SBR technology.[18]

The automotive industry is under continued pressure to improve the environmental performance and useful life of automotive components. S-SBR producers are responding to develop SBR grades with optimum combination of rolling resistance, wear resistance, blow-out resistance, chipping/chunking resistance, road traction under a variety of weather conditions, handling, noise transmission, and other performance properties for different tire applications.

There are many ways in which some improvements are being achieved:[18]

- Reformulating compounds and using high-performance additives in conjunction with ''tailored'' S-SBR grades.
- Developing novel additives/modifiers that can be added to the SBR at the compound stage.
- Further modification of polymerization conditions to enable both block and random copolymerization.

- Introduction of postpolymerization steps to obtain the copolymer with end group structure, thus significantly altering the properties of the resulting SBR grades.
- Introduction of postpolymerization steps to facilitate better interaction with the reinforcement system. This is one of the most radical developments affecting the rubber industry because it enables silica to significantly displace carbon black as the favored reinforcement for the applications.

CONCLUSIONS

With global demand at around 3.7 million tons per year, SBR is one of most important synthetic elastomers. Nearly 70% of SBR is consumed by the automobile industry for tires and tire products.

There is growing competition between emulsion SBR and solution SBR grades. S-SBR has superior physical properties (particularly wear resistance) and blendability with other rubbers. However, they have been failing to make significant inroads, owing to processing difficulties and higher price. Therefore, E-SBR grades are used widely in the markets due to their low cost. While S-SBR has been paid more and more attention, people are striving to reduce the cost of preparation of S-SBR. New synthesis procedure and more effective catalysts are required in the future.

Superabsorbents

Takamasa Nonaka
Faculty of Engineering, Department of Applied Chemistry and Biochemistry, Kumamoto University, Kurokami, Kumamoto-shi, Japan

INTRODUCTION

Woven cloth, cotton wadding, cellulose fiber batt, papers, and foamed polyurethane have been used as traditional absorbent materials for water. These materials can absorb 1–20 g of water per gram material and the water absorbed is easily removed from the materials by applying low pressure. In recent years, superabsorbent polymers, which can absorb up to 1000 g of water per gram of polymer and up to about 100 g of dilute salt solution per gram of polymer and the water absorbed can hardly be removed from the polymers even by applying high pressure, have been prepared and commercially used in many applications.

Superabsorbents are superabsorbent polymers, which are loosely crosslinked hydrophilic polymers and have ionic charges in the polymers. They absorb water, swell, and retain aqueous solution above hundred times their own weight. Because of the excellent characteristics, the superabsorbents have been widely used in many applications such as disposable diapers, feminine napkins, soil additives in agricultural or horticultural applications, gel actuators, water-blocking tapes, materials for drug delivery system, absorbent pads, etc., where water absorbency or water retention is important.

HYDROPHILIC POLYMERS FOR WATER ABSORPTION

It is known that papers, cotton, and cellulose are natural hydrophilic polymers, which can absorb water, but are insoluble in water. Therefore, they have been used as disposable diapers, feminine napkins, etc. They absorb water by capillary action. Therefore, they absorb only a small amount of water and the water absorbed is easily removed by applying low pressure. Synthetic crosslinked poly(vinyl alcohol) and crosslinked poly(oxyethylene) are also hydrophilic polymers and they have almost the same water-absorption capacity of about 1–20 g water per gram of polymer as natural polymers. Those natural polymers and synthetic polymers do not essentially have ionic groups. On the other hand, superabsorbent polymers having anionic groups that were made from low crosslinked starch or synthetic polymers were found to have high water-absorption capacity of more than 100 g water per gram of polymer. The water absorbed can hardly be removed even by applying high pressure. Thus, superabsorbent polymers should be hydrophilic polymers and low crosslinked and have ionic groups such as anionic groups, cationic groups, or betaine in the polymers.

CLASSIFICATION OF SUPERABSORBENTS[1]

The first polymer hydrogels called as superabsorbents were prepared by hydrolysis of starch-graft-poly(acrylonitrile) at Northern Research Institute of Department of Agriculture of the U.S.A. in 1974. Since then, many superabsorbents consisting of modified natural hydrophilic polymers such as starch, cellulose, and alginic acids have been prepared. Most of them have anionic moieties such as poly(sodium acrylate) or poly(vinyl sulfonate). Now, many types of superabsorbents having not only anionic groups but also cationic groups or betaine have been prepared from both natural hydrophilic polymers and synthetic hydrophilic polymers. The classification of superabsorbents is listed in Table 1.

As given in Table 1, superabsorbents can be classified in four kinds of parts:[1]

1. Superabsorbent polymers should be essentially hydrophilic polymers. Therefore, natural polymers such as starch and cellulose or synthetic polymers such as poly(acrylate), poly(vinyl alcohol), poly(acrylamide), or poly(oxyethylene) are used as hydrophilic base polymers.
2. Superabsorbents are low crosslinked to prevent to dissolve in water. Several methods for crosslinking are used:
   a. Crosslinked polymers can be prepared by copolymerization of hydrophilic vinyl monomers with crosslinking monomers such as methylenebisacrylamide, polyethyleneglycol dimethacrylate, divinylbenzene, etc.
   b. Water-soluble polymers such as poly(vinyl alcohol) or poly(oxyethylene) can be crosslinked by annealing or the reaction with crosslinking reagent such as glutaraldehyde.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007973

Table 1 Classification of superabsorbents

Base polymer	Starch—graft copolymerization, carboxymethylation Cellulose—graft copolymerization, carboxymethylation Synthetic polymers—poly(acrylate), poly(vinyl alcohol), poly(acrylamide), poly(oxyethylene), cationic polymer
Method of crosslinking	Copolymerization with crosslinking monomers Crosslinking of water-soluble polymer Irradiation of radioactive ray Self-crosslinking Introduction of crystal structure
Method of introduction of ionic groups	Polymerization of ionic monomer Caboxymethylation of hydrophilic nonionic polymers Graft copolymerization of hydrophilic monomer to hydrophobic polymer Hydrolysis of nitrile or ester group
Shape of products	Powder—spherical Film—amorphous Fiber—long fiber, short fiber, nonwoven cloth

   c. Many polymers can be crosslinked by irradiation of radioactive rays such as γ-ray.
   d. Poly(sodium acrylates) are partially crosslinked by self-crosslinking during polymerization at high monomer concentration.
   e. Water-soluble polymers such as poly(vinyl alcohol) can be crosslinked by crystallization by annealing or freeze-drying.

3. Superabsorbents should have ionic groups in the polymers.
   a. Ionic groups can be introduced by polymerization of monomers having ionic groups.
   b. Ionic groups can be introduced by carboxymethylation of nonionic polymers such as starch and cellulose.
   c. Ionic groups can be introduced by graft copolymerization of monomers having ionic groups on nonionic polymers such as starch, cellulose, or poly(vinyl alcohol).
   d. Ionic groups can be introduced by graft copolymerization of monomers having nitrile groups or ester groups on starch or cellulose, followed by hydrolysis.
4. Superabsorbents are commercialized in many shapes of products. Most superabsorbents are amorphous powders. Film and fiber types of superabsorbents are also used.

PREPARATION OF SUPERABSORBENTS[2]

Up to the present, many types of superabsorbent polymers have been prepared and commercialized. Some commercial superabsorbents and their manufacturers are listed in Table 2. Several examples are described here:

1. Starch/acrylonitrile copolymers. These are the first superabsorbents, which were prepared at Northern Research Institute of Department of Agriculture of the U.S.A. in 1974. These were prepared by graft copolymerization of acrylonitrile on starch using ammonium cerium(IV) nitrate as initiator, followed by hydrolysis with sodium hydroxide aqueous solution. Therefore, these have anionic charges of carboxylic group. The copolymers are easily subject to disintegrate with microorganism, because basic polymers are natural polymer. Therefore, these polymers do not retain water for a long period.
2. Starch/acrylic acid copolymers. These were prepared by graft copolymerization of acrylic acid on starch. The crosslinking of the polymers was carried out by simultaneous graft copolymerization of crosslinking monomers or post-crosslinking with crosslinking reagent such as epichlorohydrin or glutaraldehyde. The polymers cannot retain water for a long time, because the copolymers are subject to disintegration with microorganism. The types of polymers are mostly amorphous powder.
3. Carboxymethylated celluloses. These were prepared by the reaction of celluloses with monochloroacetic acid, followed by crosslinking. These are mostly used in fiber form.
4. Poly(sodium acrylates). Poly(acrylic acids) or poly(sodium acrylates) were obtained by i) solution polymerization of acrylic acid or sodium

Table 2 Commercial superabsorbents and their manufacturers

	Manufacturer	Commercial name	Compositions
Europe	BASF	Luquasorb	Poly(sodium acrylate)
	Enka	Akucell	Carboxymethylcellulose
	Stockhausen	Favor	Poly(sodium acrylate)
	Unilever	Lyogel	Hydrolyzed starch/acrylonitrile copolymer
U.S.A.	Buckeye	CLD	Carboxymethylcellulose
	Dow Chemical	DWAL	Poly(sodium acrylate)
	Grain Processing	GPC	Hydrolyzed starch/acrylonitrile copolymer
	Henkel	SGP	Hydrolyzed starch/acrylonitrile copolymer
	Hercules	Aqualon	Carboxymethylcellulose
	National Starch	Permasorb	Poly(sodium acrylate)
	Super Absorbent	Magic Water Gel	Hydrolyzed starch/acrylonitrile copolymer
Japan	Nippon Shokubai	Aqualic	Poly(sodium acrylate)
	Sanyo Kasei	Sanfresh	Starch/acrylic acid copolymer
	Daicel	CMC Daicel	Carboxymethylcellulose
	Nippon Exlan	Espec	Acryl fiber/sodium acrylate composite fiber
	Sumitomo Seika	Aquakeep	Poly(sodium acrylate)

acrylate in water or by ii) reverse suspension polymerization in organic solvent. Crosslinked poly(acrylic acids) or poly(sodium acrylates) were prepared by copolymerization with crosslinking reagent such as methylenebisacrylamide or ethylene glycol dimethacrylate or post-crosslinking with diglycidyl compounds or higher alcohols. Crosslinked poly(acrylic acids) or poly(sodium acrylates) can also be obtained, when the polymerization is carried out at high concentration of the monomer in an aqueous solution. This crosslinking is called self-crosslinking. Crosslinked poly(sodium acrylates) are mostly prepared by solution polymerization and used as superabsorbents in hygienic application.

5. Vinyl alcohol/acrylic acid copolymers. Vinyl alcohol/sodium acrylate copolymers were obtained by hydrolysis of vinyl acetate/methylacrylate copolymers with alkaline solution. The vinyl alcohol/sodium acrylate copolymers obtained are insoluble in water, although they are not crosslinked with crosslinking monomer. This is because of crystal structure of vinyl alcohol moieties in the copolymers. Therefore, the vinyl alcohol/sodium acrylate copolymers have higher mechanical strength than crosslinked poly(sodium acrylates) in water.
6. 3-Methacrylamidepropyl trimethylammonium chloride/*N,N′*-methylenebisacrylamide (MBAAm) copolymers.[3] This type of crosslinked 3-methacrylamidepropyl trimethylammonium chloride/*N,N′*-methylenebisacrylamide copolymers were prepared by copolymerization of 3-methacrylamidepropyl trimethylammonium chloride and *N,N′*-methylenebisacrylamide (crosslinking monomer). The copolymers have ammonium groups, which exist as cationic polymers in water.
7. Trialkyl-4-vinylbenzyl phosphonium chloride/acrylamide copolymers.[4] This type of crosslinked trialkyl-4-vinylbenzyl phosphonium chloride (TRVB)/acrylamide (AAm) copolymers were prepared by copolymerization of TRVB, AAm, and MBAAm (crosslinking monomer) in dimethyl sulfoxide. Three TRVBs with different alkyl chain lengths (butyl, hexyl, and octyl) in phosphonium groups were used. They are abbreviated as TBVB, THVB, and TOVB, respectively. The copolymers obtained have phosphonium groups. Therefore, they are crosslinked cationic polymers.
8. Trialkyl-4-vinylbenzyl phosphonium chloride/*N*-isopropylacrylamide (NIPAAm) copolymers.[5] These types of crosslinked TRVB/NIPAAm copolymers were prepared by copolymerization of TRVB, NIPAAm, and MBAAm in dimethyl sulfoxide. Poly(NIPAAm) is a thermosensitive polymer, which has a lower critical solution temperature (LCST) at around 33°C. Therefore, the copolymers are crosslinked cationic polymers and thermosensitive polymers, which swell and deswell below and above the LCST (about 33°C) of poly(NIPAAm).

In Fig. 1, the structures of superabsorbent polymers (a)–(d), (g), and (h) are shown.

PROPERTIES OF SUPERABSORBENTS

Water-Absorption Capacity of Superabsorbent Polymers

The water-absorption capacity of superabsorbent polymers is usually measured by the following methods. The water-absorption capacity is greatly affected by not only the chemical structures of the polymers but also the external conditions such as kinds of solutions, temperature, pressure, etc. under which it is measured.

Tea bag method[6]

The water content of superabsorbent polymers is usually measured by a tea bag method as follows: The dried copolymers are put into a tea bag made of nonwoven fabric. Then they are soaked into excess deionized water or salt solutions for 24 hr at desired temperature. After the tea bag containing polymers are soaked in aqueous solution, the water unabsorbed into gels is removed by placing the tea bag in air for a short time. The water on the surface of the gels and the tea bag is immediately wiped with filter paper, and the weight (W_w) of the tea bag containing superabsorbent polymers is measured. The water content (Q) (H_2Og/g-polymer) of the polymers is calculated using Eq. (1):

$$Q = \frac{W_w - W_t - W_d}{W_d} \quad (1)$$

where W_t and W_d are the weights of the wet tea bag and the dried polymers, respectively.

In some cases, the water unabsorbed into superabsorbents can be removed by filtration or centrifugation.

UV absorption method[7]

A prescribed amount of superabsorbent polymer is soaked in a prescribed aqueous solution containing blue dextrin, which does not penetrate into superabsorbent polymers. The concentration of blue dextrin in outer solution after equilibrium swelling of the polymers is measured by UV spectrophotometer. And the

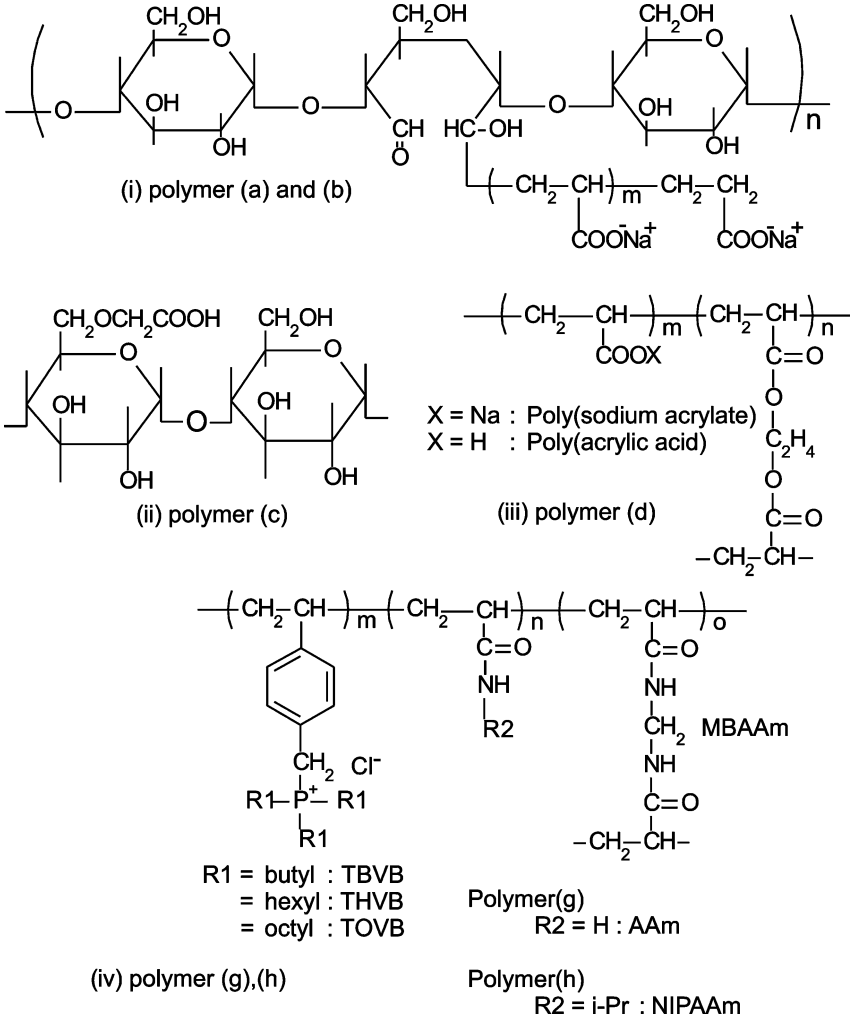

Fig. 1 The structure of super absorbent polymer (a)–(d), (g), and (h).

water-absorption capacity of the polymers is calculated from the difference of the concentration of dextrin in the presence of polymers and that in the absence of polymers.

Vortex time method[8]

A prescribed amount of superabsorbent polymer is mixed with a prescribed amount of the desired aqueous solution, which is stirred by means of a magnetic stirring bar in a small beaker. As the water absorption proceeds, the viscosity of the suspension increases until the stirring vortex disappears at the "sorption time," t_v. The swelling capacity at equilibrium (Q_{max}) is calculated by using Eq. (2):

$$t_v = \frac{-1}{k} \ln\left(1 - \frac{Q}{Q_{max}}\right) \tag{2}$$

where k is the first-order rate constant and Q is the swelling capacity (H_2Og/g-polymer) at any time t.

Mechanism of Water Absorption with Superabsorbents

As mentioned before, superabsobents should be essentially low crosslinked hydrophilic polymers and have ionic groups such as anionic groups, cationic groups, or betaine in the polymers. They usually have a high water-absorption capacity of more than 100 g-water/g-polymer even in dilute salt solution. In Fig. 2, swollen crosslinked poly (sodium acrylates) are illustrated.

In general, the swelling ratio of hydrogels, which corresponds to water content, can be expressed by Eq. (3):[9]

$$Q^{5/3} = \left\{\left[\frac{1}{2} \times \frac{i}{V_u} \times \frac{1}{S^{1/2}}\right]^2 + \frac{(1/2 - X_1)}{V_1}\right\} \Big/ \frac{\nu}{V_0} \tag{3}$$

where Q is the swelling ratio, i/V_u the charge density attached to polymer matrix, $((1/2) - X_1)$ the affinity between polymer matrix and water, $S^{1/2}$ the ionic strength of outer solution, and ν/V_0 the crosslinking density.

The first term $[(1/2) \times (i/V_u) \times (1/S^{1/2})]$ in this equation represents the osmotic pressure because of ions, the second term $\{[(1/2) - X_1]/V_1\}$ represents the affinity of polyelectrolyte for water, and the third term (V_0/ν) represents the degree of crosslinking. Therefore, this equation indicates that the water content of the superabsorbent polymers depends on the hydrophilicity, crosslinking density, charges of the crosslinked polymers, and the concentration of neutral salts in an aqueous solution.

The various effects on the water-absorption ability of the polymers were investigated with superabsorbent polymers having anionic or cationic groups. Several effects on the water-absorption capacity of the superabsorbent polymers having carboxyl groups(1) or phosphonium groups(4) are described in the following section.

Effect of ionic groups on the water-absorption ability of superabsorbent polymers

In Figs. 3A and B the effect of the content of ionic groups on the water-absorption ability of starch/acrylic acid copolymers [polymer (d)] and the

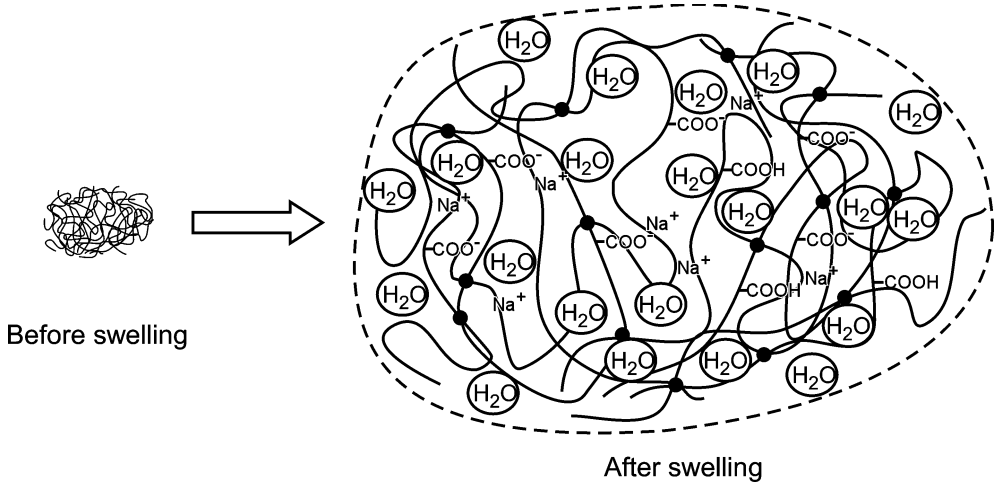

Fig. 2 Illustration of swollen crosslinked poly(sodium acrylate).

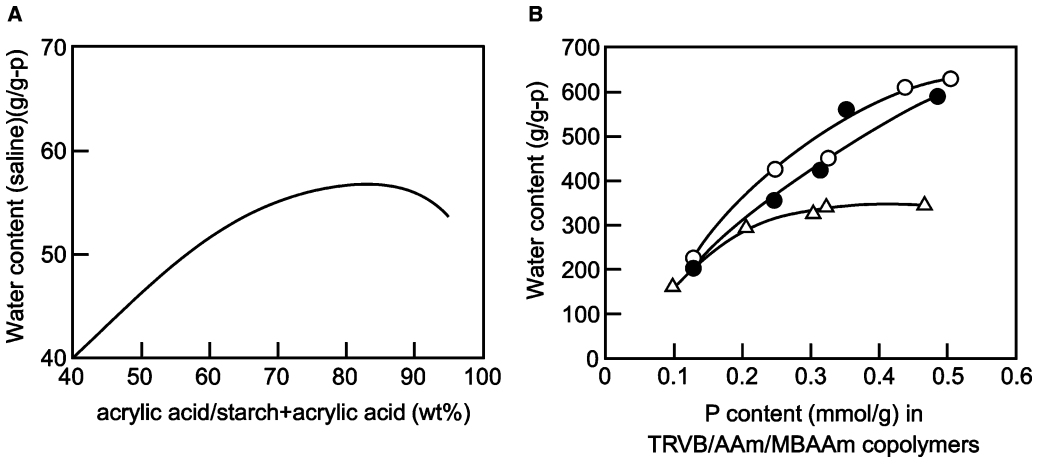

Fig. 3 Effect of ionic groups on the water absorption of (A) starch/acrylic acid and (B) TRVB/AAm/MBAAm [X : (97 - X) : 3] copolymer. Measured at room temperature in 0.9% NaCl aqueous solution. Copolymer: (○) TBVB–AAm–MBAAm, (●) THVB–AAm–MBAAm, and (△) TOVB–AAm–MBAAm. Measured at room temperature in deionized water.

TRVB/AAm/MBAAm copolymers [polymer (g)] containing phosphonium groups is shown, respectively. It is shown in Fig. 3A that the water content of the starch/acrylic acid copolymers increased with increasing content of acrylic acid, and then decreased above 90 wt.% of acrylic acid in the copolymers. In Fig. 3B, the water content of the TRVB/AAm/MBAAm copolymers having various contents of phosphonium groups in deionized water is shown. The water content increased with increasing phosphonium content in the copolymers, although the water contents of copolymers were different depending on the chain length of alkyl groups in phosphonium groups. This increase in water content with increasing content of ionic groups in the copolymers is because of the increasing osmotic pressure between the inner and outer sides of the polymer gels. It is also shown in Fig. 3B that the water content increased in the order of TBVB/AAm/MBAAm > THVB/AAm/MBAAm > TOVB/AAm/MBAAm copolymer.

This order is inversely proportional to the chain length of alkyl chain in the phosphonium groups in the copolymers. This indicates that hydrophilic polymers with shorter alkyl chain in phosphonium groups absorb more water, although they have almost the same ionic groups in the copolymers.

Effect of the degree of crosslinking on the water-absorption ability of superabsorbent polymers

In Figs. 4A and B the effect of the degree of crosslinking on the water-absorption ability of starch/acrylic acid copolymers [polymer (d)] and the TRVB/AAm/MBAAm copolymers [polymer (g)] containing phosphonium groups is shown, respectively.

It is shown in Fig. 4A that the water content of the starch/acrylic acid copolymers increased first, and then decreased with increasing content of crosslinking reagent, although the water content of starch/acrylic acid copolymers is different depending on the kind of crosslinking reagents. This indicates that hydrophilic copolymers should be crosslinked to some extent to retain high water content, and then the water content of the copolymers decreased with increasing degree of crosslinking of the copolymers.

In Fig. 4B, the water content of the TBVB/AAm/MBAAm copolymers having different degree of crosslinking and almost the same phosphonium groups in deionized water is shown. The water contents of AAm–MBAAm copolymer carrying no phosphonium groups are also shown for comparison.

The water content of the copolymers having phosphonium groups was fairly high and it decreased remarkably with increasing degree of crosslinking in the copolymers. However, the water content of the AAm–MBAAm copolymer carrying no phosphonium groups was fairly low compared with that of the copolymers having phosphonium groups and it decreased slightly with increasing degree of crosslinking of the copolymers. This result indicates that the introduction of ionic groups such as phosphonium groups into AAm–MBAAm zcopolymer is necessary to retain high water content.

In recent years, it is reported that the water-absorption capacity of crosslinked poly(sodium acrylates) can be increased by increasing the crosslinking density near the surface and by decreasing the crosslinking density at the inner side of superabsorbent copolymers.[10] It is also reported that this type of superabsorbent polymer has high mechanical strength.

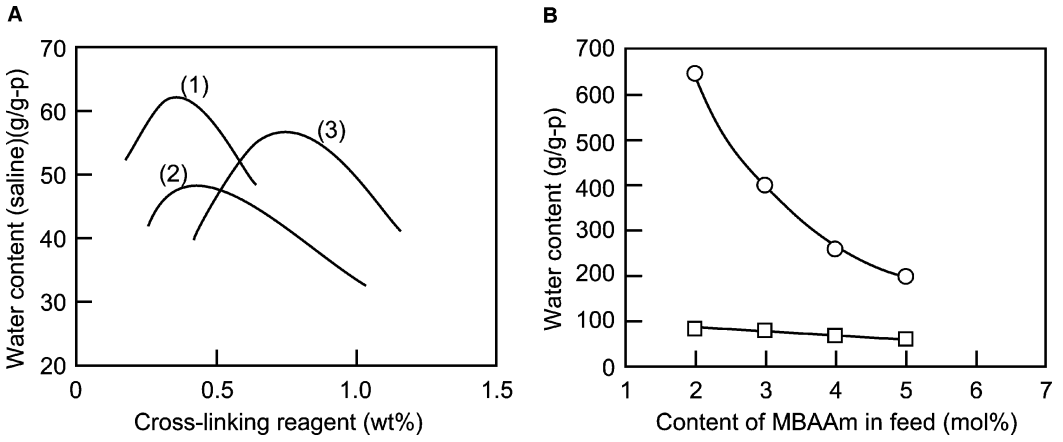

Fig. 4. Effect of degree of crosslinking on the water absorption of (A) starch/acrylic acid and (B) TBVB/AAm/MBAAm copolymer. (A) Crosslinking reagent: 1) MBAAm; 2) ethyleneglycol diglycidyl ether; and 3) poly(ethyleneglycol) diglycidyl ether. Measured in 0.9%NaCl solution. (B) (○) TBVB/AAm/MBAAm [2 : (98 - Y) : Y], (□) AAm/MBAAm. Measured in deionized water.

Effect of inorganic compounds in water on the water-absorption ability of superabsorbent polymers

In Figs. 5A and B the effect of inorganic compounds in water on the water-absorption ability of starch/acrylic acid copolymers [polymer (b)] and the TRVB/AAm/MBAAm copolymers [polymer (g)] containing phosphonium groups is shown, respectively.

It is shown in Fig. 5A that the water content of the starch/acrylic acid copolymers decreased sharply with increasing concentration of neutral salts (NaCl, $MgCl_2$) or NaOH in aqueous solutions up to about 1 wt.% and then decreased gradually.[11] The order of effect is as follows:

$$MgCl_2 > NaCl > NaOH$$

This result indicates that $MgCl_2$ containing divalent Mg^{2+} has a more pronounced effect than does NaCl containing monovalent Na^+.

The decrease in the water absorption by an addition of neutral salts is because of the decrease in the osmotic pressure between inner and outer sides of the polymer hydrogels in their aqueous solution.

In addition, it is known that the expansion of polymer chains because of the electrolytic repulsion between ionic groups of the polymers reduces, because an addition of these inorganic electrolytes shields the ionic charges of the polymers. This also results in the reduction of the water absorption of the superabsorbent polymers.

In NaOH solution, parts of acrylic acid groups in starch/acrylic acid copolymers are neutralized with NaOH, and sodium acrylates formed dissociate easily

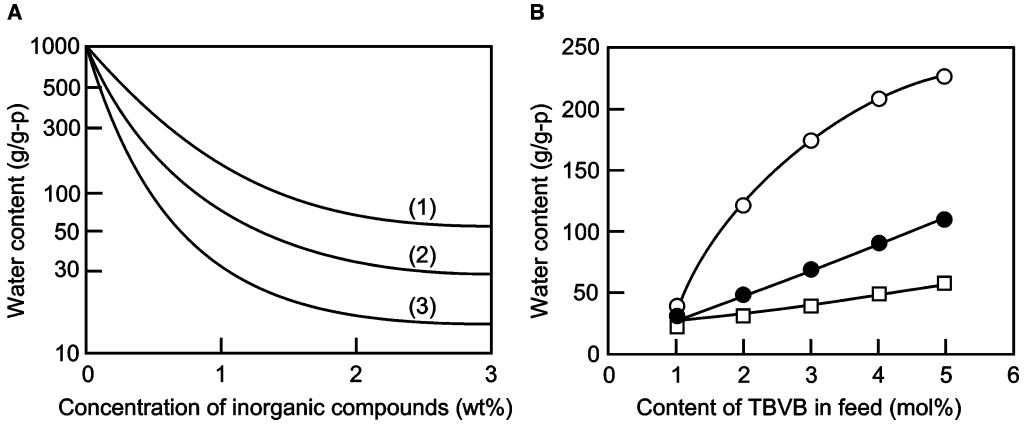

Fig. 5. Effect of addition of inorganic compounds on the water absorption of (A) starch/acrylic acid and (B) TBVB/AAm/MBAAm [X : (97 - X) : 3] copolymer. (A) Inorganic compounds: 1) NaOH; 2) NaCl; and 3) $MgCl_2$. (B) NaCl concentration (wt.%): (○) 0.009, (●) 0.09, and (□) 0.9.

in water. Therefore, starch/sodium acrylate copolymers become more polar hydrophilic polymers. This is the reason for the higher water content of the copolymers in NaOH solution than in other neutral salt solutions. However, the water content decreased also with increasing concentration of NaOH even in this aqueous solution.

In Fig. 5B, the water content of the TRVB/AAm/MBAAm [X : (97 - X) : 3] copolymers having different phosphonium groups and constant degree (3 mol%) of crosslinking in 0.009, 0.09, and 0.9 wt.% NaCl solutions is shown. The water content of TBVB/AAm/MBAAm copolymer increased with increasing TBVB content in the copolymers and decreased with increasing concentration of NaCl in solutions and they were considerably depressed in NaCl solutions above 0.09 wt.%. The degree of the decrease in water content by the addition of NaCl increased with increasing content in phosphonium groups in the copolymers. Therefore, the decrease in water content of the copolymers by an addition of inorganic compounds is because of both the decrease in the difference of osmotic pressure between the inner side and the outer side of the copolymer hydrogels and shielding effect of ionic charges of the copolymers by an addition of inorganic compounds.

Effect of physical structure of superabsorbent polymers on the water-absorption rate or water-absorption capacity

The water-absorption rate of superabsorbent polymers is affected by: 1) the specific surface area of the polymers; 2) the capillary action; and 3) the formation of fish-eyes in the polymer hydrogels.

1. Specific surface area of polymer hydrogels can usually be increased by decreasing the particle size of the polymers. In Fig. 6A, the relationship between water adsorption rate or absorption capacity and flaky particle size of crosslinked poly(sodium acrylates) is shown. The water adsorption rate increased with decreasing particle size in the range of particle size from 800 to 100 μm and then decreased. The decrease in the water-absorption rate with decreasing particle size (less than 100 μm) is because of the formation of fish-eyes in polymer hydrogels. The water-absorption rate can also be increased with decreasing apparent density (g/ml) of flaky polymer particles [Fig. 6B]. The decrease in apparent density of the polymers results in the increase in specific surface area of the polymers. This indicates that the water-absorption rate of the polymers increases with the specific surface areas of the polymers.
2. The water-absorption rate of the polymers can be increased by use of capillary action. It is reported that fibrous carboxymethyl celluloses, which were crosslinked with epichlorohydrin and had the carboxymethylation degree of 0.2–0.4, had high water-absorption rate of 20–40 ml/g-polymer/min.
3. The water-absorption rate of the polymers can be increased by mixing inorganic particles such as kaolin, talc, etc. with superabsorbent polymers. This mixing procedure results in the decrease in the formation of fish-eyes in polymer gels. In addition, the increase in the water-absorption rate is because of the fact that inorganic particles adsorbed on superabsorbent copolymers give space between polymer particles.

Effect of temperature or pH on water-absorption rate or -absorption capacity

The water-absorption rate of usual superabsorbent polymers can be increased by increasing the temperature, but the water-absorption capacity after equilibrium at

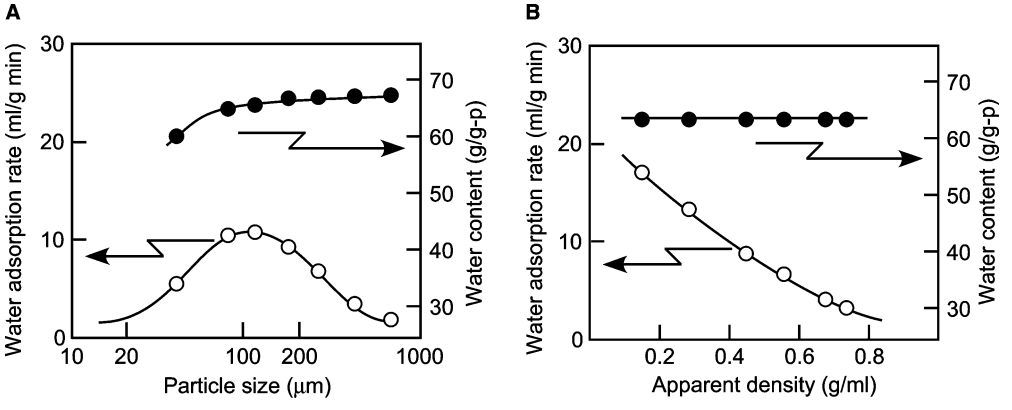

Fig. 6 Effect of particle size (A) and apparent density (B) on the water-absorption rate and water content of crosslinked poly(sodium acrylate).

each temperature is almost constant. The effect of pH on the water-absorption rate or -absorption capacity depends on the kind of ionic groups in the superabsorbent polymers. Usually the water-absorption capacity of superabsorbent polymers having weak acids such as acrylic acid increases with increasing pH. This is because of the formation of poly(acrylic salt) such as poly(sodium acrylate). On the other hand, the water-absorption capacity of superabsorbent polymers having weak bases such as amino groups increases with decreasing pH. This is because of the formation of ammonium groups by protonation of amino groups. In both cases, the water-absorption capacity decreases at too high pH or at too low pH. The water-absorption capacity of superabsorbent polymers having strong acids such as sulfonic acid groups or strong bases such as ammonium groups or phosphonium groups essentially does not depend on pH of outer solution, but even in this case, the water-absorption capacity decreases at too low and too high pH. The decrease in the water-absorption capacity at too high and low pH is because of both the decrease in the difference of osmotic pressure between the inner side and the outer side of the polymer hydrogels and shielding effect of ionic charges of the polymers.

Effect of organic solvent on the water absorption of superabsorbent polymers

In Fig. 7, the water absorption of crosslinked poly(sodium acrylate) in various alcohols/water mixtures is shown. The water absorption decreases with increasing alcohol content and decreases abruptly at above certain limit of alcohol content. The content at which the abrupt decrease occurs depends on the kinds of alcohols. The similar phenomena are also observed in other organic solvents such as acetone/water mixtures.

OTHER PROPERTIES OF SUPERABSORBENT POLYMERS

Evaporation of Water Absorbed in the Polymers[2]

Water imbibed with superabsorbent polymers can hardly be removed even by applying high pressure, but the water absorbed is gradually removed by drying in air. In Fig. 8, the time dependence of decrease of water absorbed with vinyl alcohol/acrylic acid copolymers by drying at the temperatures of 20°C, 50°C, and 100°C is shown.

It takes long time for water to evaporate from the superabsorbent polymers, although the rate of evaporation of water increased with increasing temperature. This result suggests that superabsorbent polymers can be used to retain water for a long time in soils for the agriculture in dry land.

Stability of Superabsorbent Polymers Against UV Light[1]

The stability of superabsorbent polymers against UV irradiation was evaluated by measuring the decrease of viscosity of swollen gels of poly(acrylate). In Fig. 9, the changes of the retention of the viscosity of the polymer gels UV-irradiated as a function of the degree of neutralization of acrylic acid moiety in crosslinked poly(acrylic acids) with alkali are shown.

The degree of the retention of the viscosity of swollen gels increased with increasing degree of

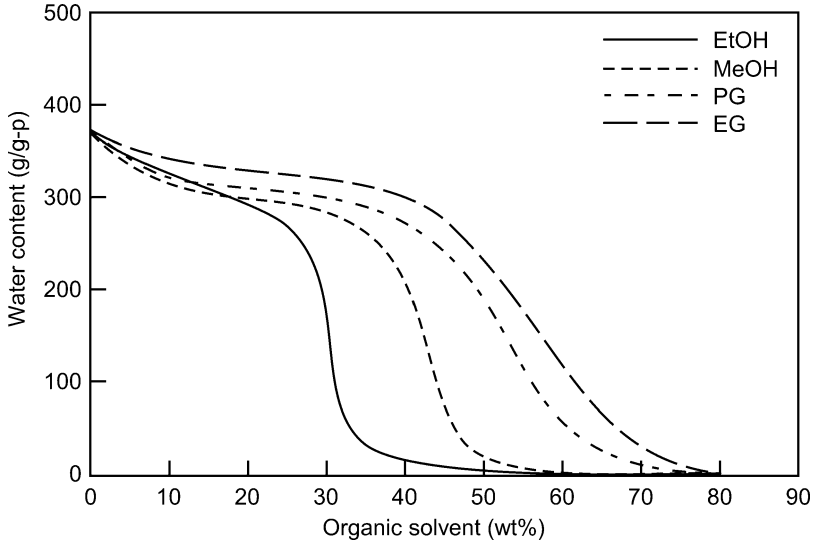

Fig. 7 Absorption of water in alcohol/water mixtures with crosslinked poly(sodium acrylate): EtOH, ethanol; MeOH, methanol; PG, propylene glycol; EG, ethylene glycol.

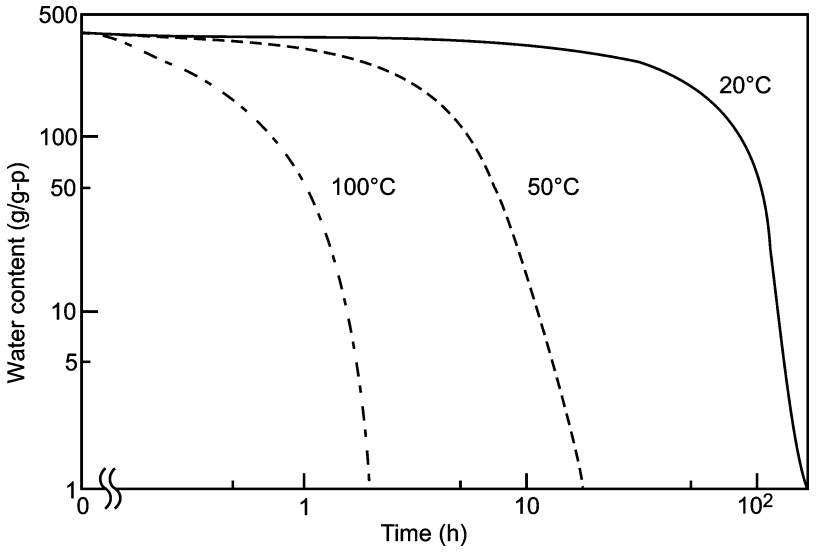

Fig. 8 Time dependence of the decrease of water absorbed with vinyl alcohol/acrylic acid copolymer at different temperatures.

neutralization of acid moiety in crosslinked poly (acrylic acids). It was found that poly(sodium acrylates), which was completely neutralized with alkali, are quite stable against UV light. It is reported that the significant decrease in the viscosity of crosslinked poly(acrylic acid) having a degree of neutralization less than 90% is because of the fact that radicals formed by UV irradiation to hydrogen of carboxyl group decomposed the main chain of poly (acrylic acids).

Adsorption of Ammonia with Superabsorbent Polymers Containing Carboxyl Groups[1]

Superabsorbent polymers consisting of poly(sodium acrylates) have partially carboxyl groups, which are weak acid groups. Therefore, they can adsorb ammonia, which is a weak base. It is shown in Fig. 10 that crosslinked poly(acrylic acid) adsorbs ammonia, which is formed by the decomposition of urine with urease.

Antibacterial Ability of Superabsorbent Polymers Containing Cationic Groups[5]

It is reported that cationic polymers having ammonium groups, pyridinium groups, or phosphonium groups exhibit antibacterial activity against bacteria such as *Escherichia coli* or *Staphylococcus aureus*.[12–14] It is shown in Fig. 11 that TBVB–NIPAAm–MBAAm copolymer [polymer (h)], which has phosphonium groups and high water-absorption ability, had high antibacterial activity against *S. aureus*.

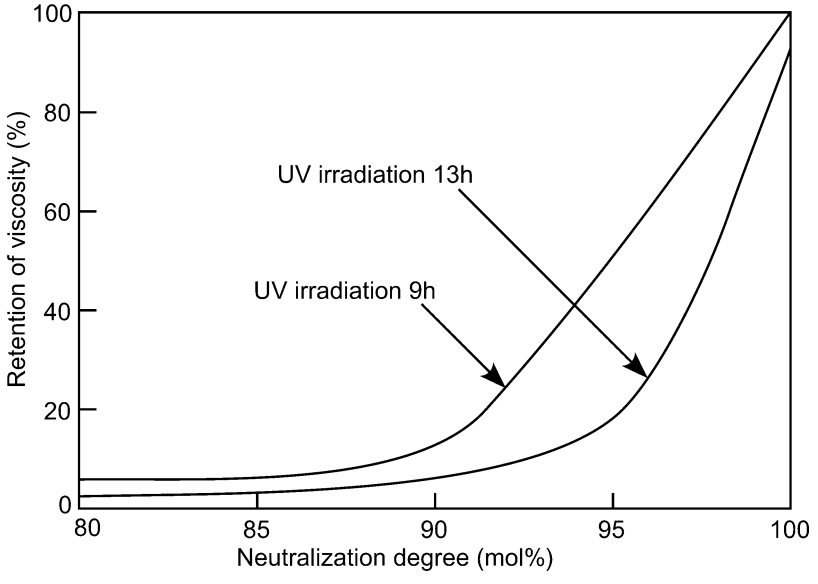

Fig. 9 Stability of swollen crosslinked poly (acrylate) neutralized with alkali against UV irradiation gel swollen about 50 times its own weight in water was used for this experiment.

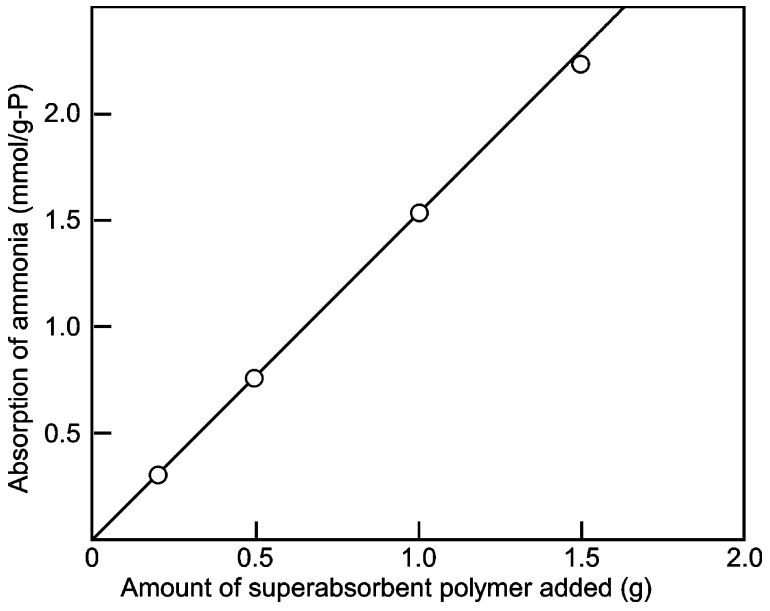

Fig. 10 Adsorption of ammonia with crosslinked poly(acrylic) acid. Conditions: urine, 50 ml; urease, 10 mg; 37°C; 2 hr.

It is also shown that the polymer having higher content of TBVB had higher antibacterial activity than did the copolymer with lower content of TBVB. They had the maximum antibacterial activity at 30°C and the water-absorption capacity of the copolymers decreased with increasing temperature and, in particular, decreased rapidly above 33°C, because the copolymers have LCST at around 33°C. The copolymers remaining in water can be separated by raising the temperature of aqueous solution above the LCST of the copolymers after using as an antibacterial reagent, because they are insoluble in water above the LCST of the copolymers, and they can be reused.

APPLICATION[15]

Superabsorbent polymers have been used in a variety of fields. In Table 3, the applications of superabsorbent polymers are listed.

Personal Hygiene Products[16–18]

The most widely spread use of superabsorbent polymers is in personal hygiene products such as disposable infant diapers, feminine sanitary napkins, and adult incontinence articles. In particular, over 90% of the total superabsorbent polymers are sold as infant

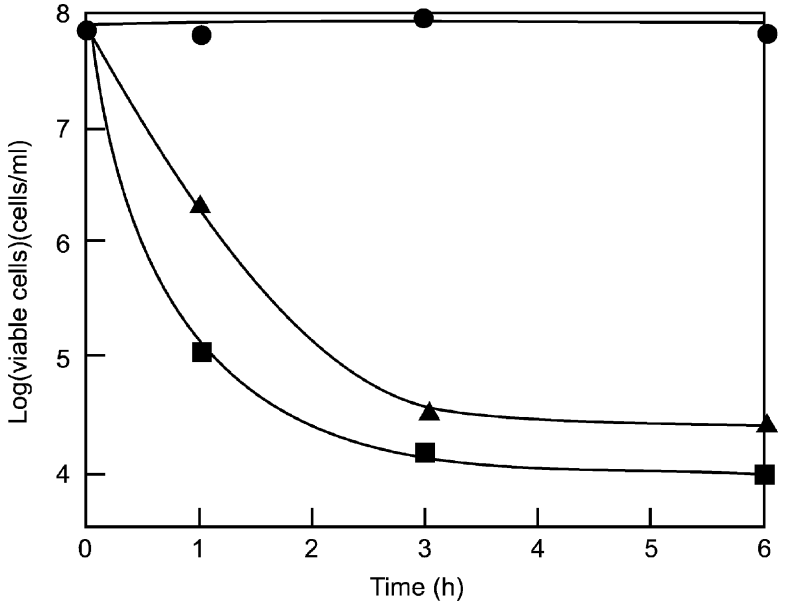

Fig. 11 Antibacterial activity of TBVB–NIPAAm–MBAAm copolymer against *S. aureus* in deionized water at 30°C: (●) blank, (▲) TBVB–NIPAAm–MBAAm (1 : 100 : 3), and (■) TBVB–NIPAAm–MBAAm (3 : 100 : 3) copolymer.

Others	Water sensor Artificial snow Fire extinguishing water Water swellable toys Paint for prevention of water leakage Removal of water in oil

diapers. In Fig. 12, the schematic diagram of diapers is given. A diaper consists of an absorbent core that is sandwiched between a porous top-sheet and impermeable back-sheet. The top-sheet is made of a porous, hydrophobic substance, e.g., polyester or propylene nonwoven fabric, and the back-sheet is a nonporous, hydrophobic substance, e.g., polyethylene film. The absorbent core has a composite structure, with the cellulose pulp fluff and superabsorbent polymers randomly mixed. The superabsorbent polymers are also used for feminine hygiene products or adult incontinence products in the same manner as in infant diapers.

Agricultural and Horticultural Application[19]

Superabsorbents can also help conserve water in a variety of agricultural and horticultural applications. Mainly, the polymers are used in the same way as much, to help the soil retain moisture as soil additives. The polymers are mixed into soil at a concentration of about 1 wt.%. The resulting soil mixture retains moisture longer, and plants live longer after germination.

Food Packaging[20]

Superabsorbent polymers are used as a liquid-absorber in food packaging systems. In these systems, the superabsorbent polymers absorb juice or water from fresh foods such as raw chicken, shellfish, and other meats or from frozen foods as they thaw. Chilled superabsorbent polymer gels may also be used as a dry-cooling medium. The water-swollen gel, contained in a durable plastic bag, is frozen and used to keep perishable foods cold. In addition to its liquid-water-absorption characteristic, superabsorbent polymers absorb water from the vapor state and therefore may be used to control humidity.

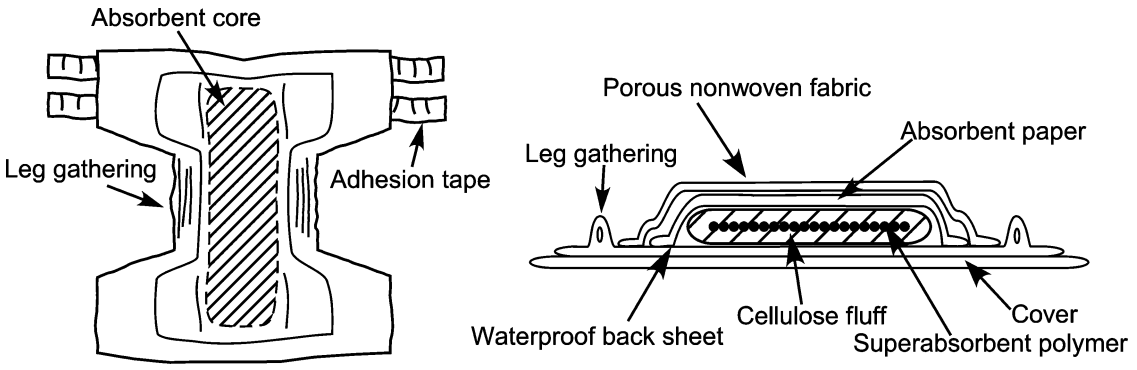

Fig. 12 Schematic diagrams of infant diapers.

Civil Engineering and Construction Industry[21–24]

Superabsorbent polymers have a number of uses in the civil engineering and the construction industry. One advantage of using superabsorbents in construction is to use the volume increase of the gel to form a barrier to further the water flow. Sealing composites made by blending a superabsorbent into a rubber such as chloroprene or thermoplastic elastomer such as poly (ethylene-co-vinyl acetate) have been developed for sealing around the joints of various building materials. The sealing composite may be used like mortar between the concrete blocks that make up the walls of the structure. If any gaps were left during construction or created by shifting after construction, the superabsorbent swells in any leaking water to fill any gaps and prevents water from leaking through the joint. A water-blocking construction filler that is composed of cement, water-absorbing polymer, and an asphalt emulsion has also been developed.

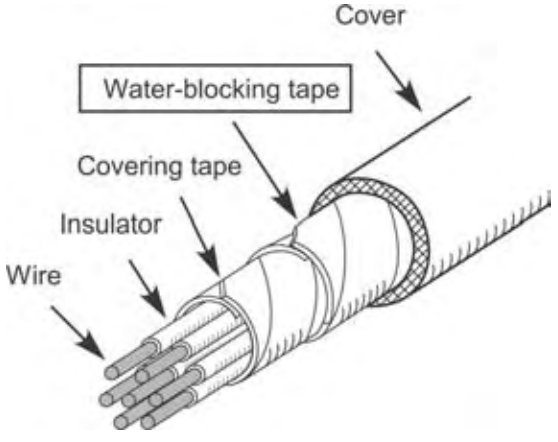

Fig. 13 Wire protected with a water-blocking tape containing superabsorbent polymer.

Electronics and Cabling[25,26]

The swelling property of superabsorbents is also applied to protect communication cables from water damages. Leaking water degrades the performance of fiberoptic communication cables and power transmission cables. Water-blocking tapes prevent intrusion of water into the cables. A flexible, water-blocking tape may be made by mixing a superabsorbent polymer and a polymeric binder, and then spreading the mixture on to a nonwoven fabric. Alternatively, the superabsorbent is mixed with a rubber such as butyl rubber and solvent and then coated onto a polyester tape. The tape is wrapped around the cable, beneath the plastic covering, as shown in Fig. 13.

Controlled Release and Medical Field[27,28]

Superabsorbent polymers may also be used to control the release of substances that are initially dissolved or trapped within the polymer phase, such as pesticides, fertilizers, and pharmaceuticals. Just as the absorption of water by superabsorbent polymer is caused by unequal activities of water inside the gel and in the external liquid phase, substances that are initially at a higher activity in the polymer will diffuse out of the particle and into the surroundings. The swelling of crosslinked poly(acrylic acid) and other acidic or basic polymers depends on the pH and ionic strength of the swelling medium, and the changes in pH or ionic strength may serve as switches for controlled release. Superabsorbent polymers are also used as materials in the sheet for surgical operation, stupe, or dressing for protection of wound.

Toiletry[29,30]

Superabsorbent polymers have been used in several cosmetic formulations. A skin-cream emulsion that

was prepared with a crosslinked superabsorbent in addition to branched poly(acrylic acid) thickener for cosmetic exhibited a long-term moisturizing effect than did the emulsion without the superabsorbent polymer. Superabsorbents have also been used as a component in a gel-form cosmetic face mask. Superabsorbent polymers are also used as materials for fragment gel, sweat band, portable toilet, etc.

Others[31–33]

1. Sensor: The swellability of superabsorbent polymer gels, their mechanical modulus and rubbery character, and their sensitivity to changes in water content, pH, and ionic strength make them suitable for use in various sensing systems.
2. Artificial snow: The fake snow can be made by mixing a superabsorbent polymer with up to 100 times its mass of water and then aerating the gel whole freezing it. The artificial snow is maintained with refrigeration system in indoor ski arenas. The frozen gel layer groomed to yield snow with a realistic feel, similar to ''powder'' snow. By using superabsorbent polymer in this way, the air temperature in the building can be at least 10°C higher than when using snow made from only water and it is more comfortable to the skiers.
3. In addition to this, superabsorbent polymers are used as additives in fire extinguishing water, materials for water-swellable toys, paint for prevention of water leakage, for removal of water in oil, etc.

CONCLUSIONS

Superabsorbents are superabsorbent polymers, which are loosely crosslinked hydrophilic polymers and have ionic charges. They absorb water, swell, and retain aqueous solutions up to 100 times their own weight. The water absorbed can hardly be removed even by applying high pressure.

Many types of superabsorbents have been prepared from various materials, by various methods, and in different shapes. They are modified natural hydrophilic polymers such as starch, cellulose, alginic acids, etc. and synthetic hydrophilic polymers such as poly (acrylic acid) and poly(sodium acrylate). Most of them have anionic moieties such as poly(sodium acrylate) and poly(vinyl sulfonate). Now, many types of superabsorbents having not only anionic groups but also cationic groups such as ammonium groups, phosphonium groups, or betaine have been prepared from both natural hydrophilic materials and synthetic hydrophilic polymers. Superabsorbents can be made in a variety of shapes such as powder, granules, fiber, sheet, etc.

It has been clarified that, to have high water-absorption ability, superabsorbent polymers should be essentially low crosslinked hydrophilic polymers having ionic charges. The water-absorption ability of the superabsorbent polymers depends on the hydrophilicity, crosslinking density, charges of the polymers, and the concentration of neutral salts in an aqueous solution. This suggests that much water invade into polymers because of high osmotic pressure between inside and outside of polymer gels in aqueous solutions and the electrostatic repulsive expansion of polymers. The synthesis of new type of superabsorbents, the modification of the superabsorbents synthesized to enhance their absorbency, gel strength, and absorption rate, and the development of new application of the superabsorbent have been investigated by many researchers in recent years.

Supercritical CO_2-Assisted Surface Coating Injection Molding

Masahiro Ohshima
Department of Chemical Engineering, Kyoto University, Nishikyo-ku, Kyoto, Japan

INTRODUCTION

Carbon dioxide (CO_2) becomes supercritical at pressures and temperatures above 7.38 MPa and 31.1°C. At the supercritical condition, the CO_2 has a higher diffusivity and a lower viscosity than liquids and the surface tension becomes absent, which allows a rapid penetration of molecule into the pores of heterogeneous matrices.[1] Taking advantage of these characteristics together with its nontoxicity, nonflammability, and inexpensiveness, CO_2 has been used in a variety of industries, i.e., food, pharmaceutical, fiber, and chemical and plastic industries. Moreover, the fact that CO_2 is a gas under ambient condition makes its removal from the plastic product possible without using the costly drying and solvent removal processes.[2] Because of this feature, it also has the potential of replacing many environmentally harmful solvents in industry.

A successful application reported in the polymer processing was the microcellular plastic foams,[3,4] where CO_2 was used as a physical foaming agent (PFA) to create microscale size cellular structure in plastics. After creating the cell structure in plastics, the CO_2 diffuses out and does not stay long in the plastics, unlike chemical browning agents. This feature gives some benefits of plastic recycling. In addition to the microcellular foaming, many potential applications of CO_2, such as polymer blending, additive impregnation, and surface modifications, have been investigated for polymer processing purposes.

In the polymer processing field, the usage of supercritical CO_2 ($scCO_2$) offers several exciting possibilities.[5] One major advantage of applying $scCO_2$ to polymer processing is that the processing conditions and the morphology of polymers can be controlled by $scCO_2$. This is because the presence of CO_2 in polymer changes the rheological and thermal properties in both the molten and solid states. For example, when CO_2 dissolves in polymer, the surface tension, shear viscosity, and the glass transition temperature are reduced and the crystallization rate is changed. This is called plasticization effect of CO_2. This effect provides many opportunities of improving the processing condition and quality of plastic products. Recently, by utilizing the plasticization effects of dissolved CO_2, an injection molding process called Asahi Mold Technology with CO_2 (AMOTEC) was invented to reduce surface roughness and prevent the surface defection in solidified plastic products,[6,7] where pressurized CO_2 is introduced in a mold cavity, the CO_2 is dissolved into polymer at the melt front of polymer running in the mold cavity, and the dissolved CO_2 reduces the polymer viscosity at the surface of the plastics owing to the plasticization effect. The viscosity reduction at the plastic surface increases the transferability of the mold shape on the plastics and improves the surface roughness. Extending and twisting the idea of the AMOTEC, a CO_2-assisted surface modification injection-molding technique was developed.[8] It utilizes the plasticization effect of CO_2 on polymer, solubility of low molecular compounds in $scCO_2$ and infusion mechanism of CO_2, and the low molecular compounds mixture into the injected polymer from its surface. By using a dye pigment as a low molecule to be dissolved in $scCO_2$, the surface of the solidified plastic products in the mold cavity can be dyed.[9] In this entry, fundamental properties of CO_2/polymer systems are briefly reviewed with some explanation of recent advancements in property measurements. The principle of the developed CO_2-assisted surface modification injection molding is then explained with a validation experiment.

FUNDAMENTAL PROPERTIES

Solubility of CO_2 in Polymer

Solubility and diffusivity of CO_2 in molten polymer are two fundamental properties for the proposed CO_2-assisted polymer processing. Several researchers have been studying the solubility of gases in polymers in conjunction with polymeric membrane and microcellular foaming. Durill and Griskey studied the solubility of CO_2 and nitrogen (N_2) gases into several polymers such as polypropylene (PP), low density polyethylene (LDPE), high density polyethylene (HDPE), and polystyrene (PS).[10,11] Liu and Prausnitz also investigated the solubility of several gases including CO_2 in PE and in ethylene-vinyl acetate (EVA). Their experiments were carried out in the temperature range from 125°C to 200°C under a fairly low-pressure

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120040332

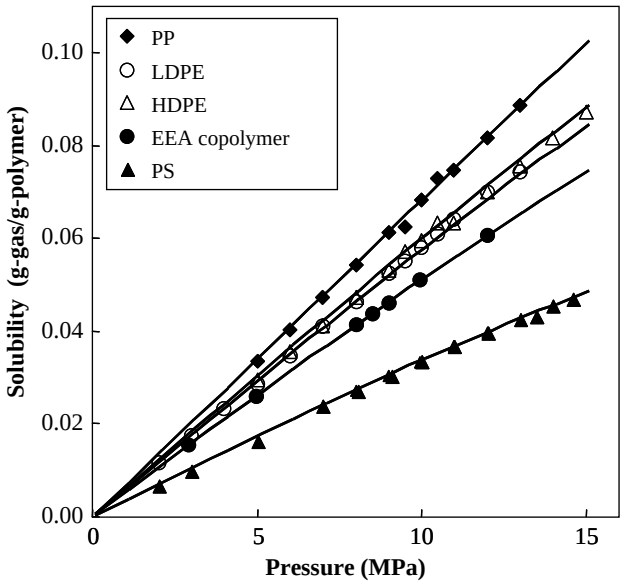

Fig. 1 Solubility of CO_2 in several polymers (at 200°C, a gravimetric method). (From Ref.[27].)

region (approximately 2.5 MPa).[12] Lee and Flumerfelt studied the solubility of N_2 in LDPE at the range from 120°C to 177°C and pressure up to 12.5 MPa.[13] Sato et al. studied the solubility of CO_2 and N_2 in PS, PP, and HDPE at 100°C to 200°C and pressure up to 20 MPa and in PVAc at 40°C to 100°C, pressure up to 17.5 MPa.[14,15,16,17]

Fig. 1 shows the solubility of CO_2 in LDPE, HDPE, PP, ethylene-ethylacrylate copolymer (EEA), and PS, which were measured at temperatures from 150°C to 200°C and pressure up to 12 MPa using a magnetic suspension balance (MSB).[18] As shown in Fig. 1, the solubility of gases in polymers increases as the saturation pressure increases and it follows the Henry's law. Thus, the Henry's constant is used to evaluate the solubility of low molecular gases in molten polymer systems as listed in Table 1. The solubility of CO_2 increases as temperature decreases. The van't Hoff equation is often used to describe temperature dependence of the solubility:

$$H_P(T) = H_O \exp\left(-\frac{E_a}{RT}\right) \quad (1)$$

where E_a is the heat of solution, R is the gas constant, and T denotes temperature. Note that the temperature dependency of the N_2 solubility in polymer shows a different behavior, i.e., the solubility of N_2 in molten polymer increases as temperature increases in a certain temperature range.[15] Furthermore, the Henry's law could not hold when the temperature is below the glass transition temperature due to the fact that the solution mechanism is changed to a combination of adsorption and dissolution.

Diffusivity of CO_2 in Polymer

In addition to the solubility, many researchers have also investigated the diffusivity of gas into polymer and several models have been proposed for estimating the diffusivity of gas in polymer. The most widely accepted concept for developing the models is based on the free volume. The free volume concept for diffusion has an origin at the theoretical work of Cohen–Turnbull, where the thermodynamic diffusion coefficient of the solute was given by an exponential function of inversed free volume fraction. Recently, Thran et al. analyzed the correlation between the free volume fraction and diffusion for six gases, O_2, N_2, CO_2, CH_4, He, and H_2, and 71 polymers.[19] They derived the exponential relationship between the specific free volume and the diffusion coefficient and reported empirical constants of the exponential correlation model. Extending the free volume model, Areerat et al. proposed a model for estimating the diffusivity of CO_2 in polymer,[18,27] where pressure, temperature, and concentration dependences of diffusivity were described by

$$D_{\text{mutual}} = \frac{x_2 D_{\text{self}}}{RT}\left(\frac{\partial \mu_1}{\partial \ln x_1}\right)_{T,P} = A\left(\frac{\partial \mu_1}{\partial \ln x_1}\right)_{T,P} x_2 \exp\left[\frac{-B}{(\hat{V}_{\text{mix}} - \hat{V}^0_{\text{mix}})}\right] \quad (2)$$

$$\hat{V}^0_{\text{mix}} = (1 - m_{CO_2})\hat{V}^0_{\text{poly}} + m_{CO_2}\hat{V}^0_{CO_2} \quad (3)$$

where A and B are parameters; x_2 is the mole fraction of polymer; $\hat{V}_{\text{mix}}$ is the specific volume of polymer/CO_2

mixture at a given temperature and pressure and $\hat{V}^0_{mix}$ is the occupied specific volume of the mixture at the absolute zero temperature, which is estimated by Eq. (3). $\hat{V}^0_{poly}$ and $\hat{V}^0_{CO_2}$ are the occupied specific volume of polymer alone and pure gas, respectively. m_{CO_2} is the weight fraction of CO_2 in the solution. $\hat{V}_{mix} - \hat{V}^0_{mix}$ is an estimate of the free volume at the given temperature, pressure, and CO_2 concentration. They proposed a scheme of calculating the $\hat{V}_{mix}$ from the swelling of polymer/CO_2 mixture, which could be estimated using an equation of state from the solubility data, pressure–volume–temperature (PVT) data of polymer alone.

Fig. 2 shows a temporal change in the weight of four different polymers, PP, LDPE, PS, and ethylene-propylene-diene rubber (EPDM) during sorption measurement of CO_2 at 200°C. Those data were acquired using a gravimetric measurement scheme, i.e., the magnetic suspension balance (MSB), which was the same apparatus used for solubility measurement. When the diffusivity of CO_2 is measured, CO_2 pressure in the MSB cell is increased in a stepwise manner 1.0 MPa from a saturated state, the temporal change in weight, as shown in Fig. 2, was obtained and the diffusion coefficients were then determined assuming the diffusion process follows the Fick's second law of diffusion. Fig. 3 shows the diffusivity of CO_2 in PS at different temperatures and its estimates.

The diffusivity is not only a function of temperature and pressure, but also concentration of dissolved CO_2. The diffusivity increases as the temperature increases and decreases as the pressure increases. When CO_2 dissolves, the polymer swells and its free volume increases. The diffusion coefficient then becomes larger as the dissolved CO_2 concentration becomes higher. Although the diffusivity does not change drastically with the concentration at temperature high enough to keep the polymer molten, the effect of dissolved CO_2 concentration on diffusivity becomes prominent around the glass transition temperature. Koga et al. investigated the CO_2 sorption into poly(methyl methacrylate) (PMMA) as well as PS polymers using in situ neutron reflectivity.[20] They observed that both PMMA and PS swell by approximately 30%, and at the same time, they observed an anomalous diffusion of CO_2 in these polymers at temperatures below their original glass transition temperature.

Diffusivity of $scCO_2$ and Low Molecular Compounds Mixture in Polymer

There are several papers discussing the diffusivity of one single penetrant in polymer. However, few papers could be found for measuring diffusivity of $scCO_2$ and low molecular compounds mixture into polymer, i.e., diffusivity of multicomponents in $scCO_2$, which is the key factor for determining the operating condition of the proposed surface coating injection molding techniques. In order to analyze the diffusion behavior of $scCO_2$ and low molecule mixture into polymer, an online measurement system using near infrared (NIR) spectroscopy was developed.[21]

Fig. 4 shows a schematic diagram of the NIR measurement system. The fiber optic probes of on-line Fourier transform NIR unit (FIR1000L, Yokogawa Electric CO.) were equipped with a high-pressure

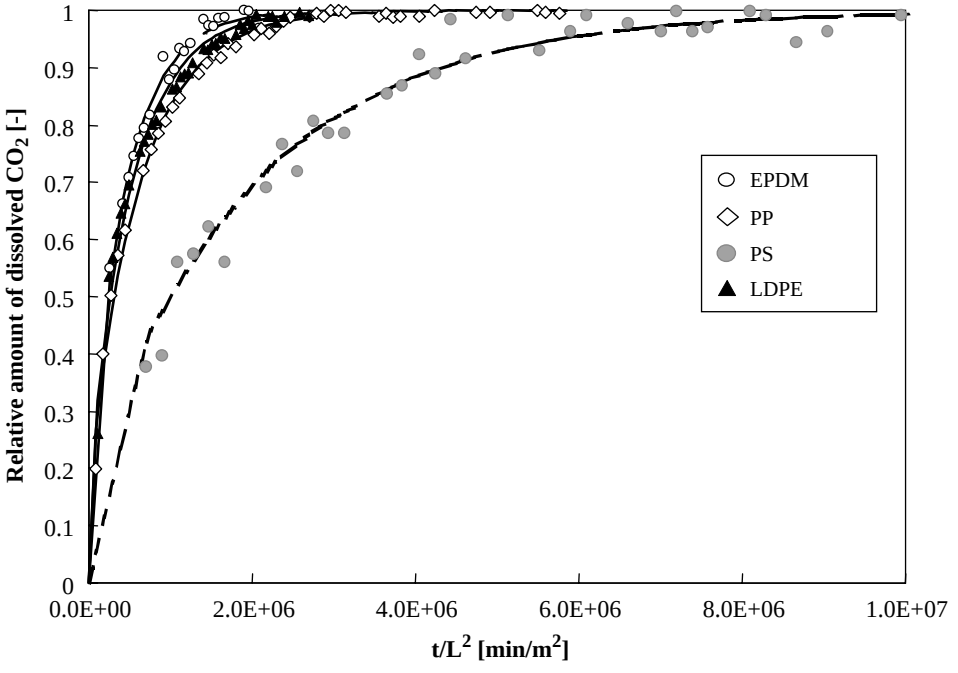

Fig. 2 Diffusivity of CO_2 in polymers (temperature at 200°C and pressure step 10–11 MPa for EPDM, PP, PS, 10.5–11 MPa for LDPE. L is the thickness of the sample).

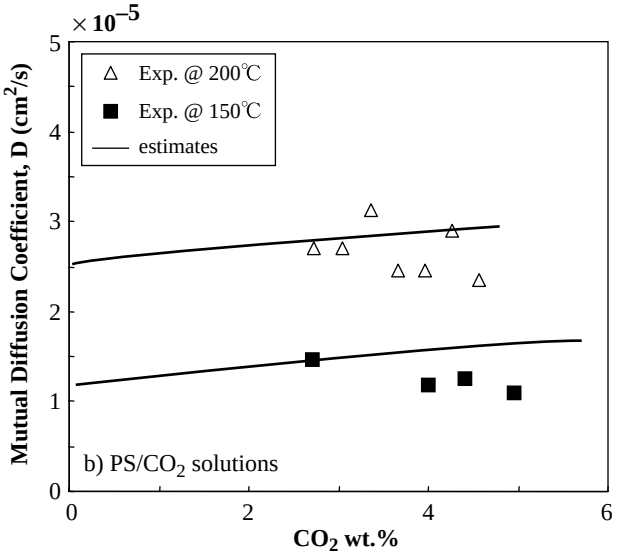

Fig. 3 Mutual diffusion coefficients of CO_2 in PS (experiments and estimates). (From Ref.[27].)

autoclave. The sample cell of the autoclave takes a cylindrical shape, in which a cylindrical sample polymer was charged and melted in the cell by increasing the temperature, so as to leave no space between the sample and the wall, while making an open space over the sample polymer. CO_2 alone, or a mixture of CO_2 and low molecule, was introduced to the open space and diffused into the molten polymer. The NIR light was transmitted through the molten polymer at a certain distance from the interface between the polymer and CO_2 or mixture. When some NIR light passed through a layer of solution having a concentration of chemical species, the power of the light is absorbed and attenuated by

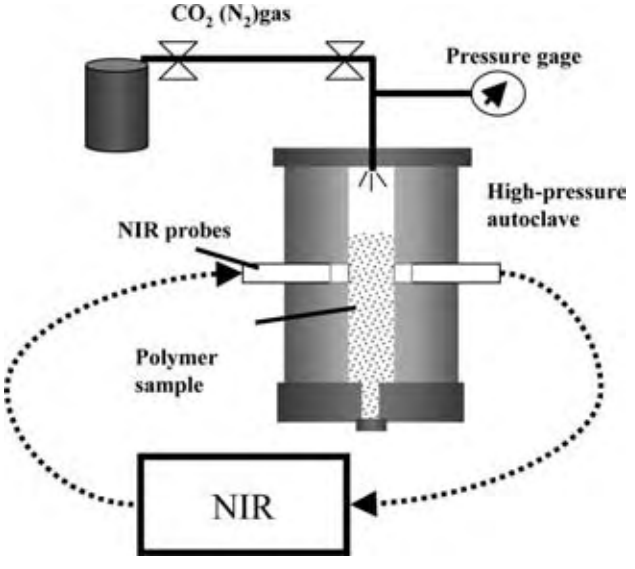

Fig. 4 NIR measurement system.

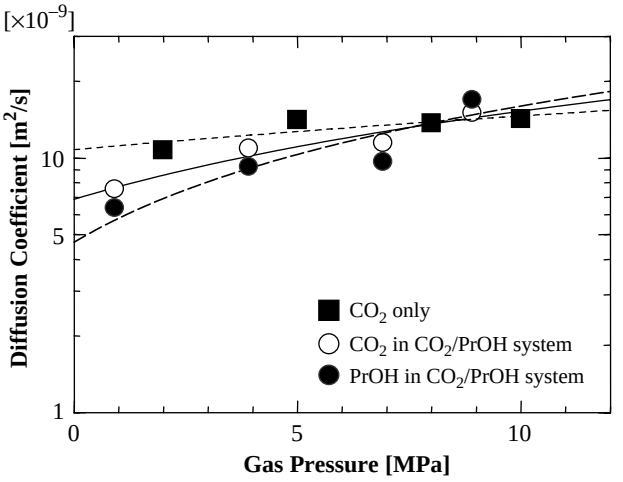

Fig. 5 Diffusion coefficients of CO_2 in LDPE measure by NIR at 175°C.

the chemical species due to the interaction between the photons and absorbing chemical bonds. The wavelength at which adsorption occurs depends on the species of chemical bonds. For example, CO_2 can be detected at 2019 nm. The absorbance, which is defined by logarithmic fraction of the light transmitted by the solution, is directly proportional to the path length through the solution and the concentration of the absorbing chemical bond in the solution. This is called the Lambert–Beer law. Nagata et al. clarified that the Lambert–Beer law could be established at the polymer CO_2 systems in the transmitted NIR measurements.[21]

Applying the law, the change in concentration of CO_2 and low molecular compounds in molten polymer could be monitored by measuring the NIR absorbance on-line at the autoclave. Fig. 5 shows the NIR measured diffusion coefficients of CO_2 alone, and those of CO_2 as well as propanol, of their mixture to LDPE (MI = 8.0 g/10 min; Mw = 1.05×10^5 g/mol; Mw/Mn = 6.94) at 175°C by changing the pressure from 0.1 MPa to a specified level. As can be seen in Fig. 5, both propanol (PrOH) and CO_2 of mixture could diffuse into the polymer even under the critical pressure of CO_2, i.e., 7.38 MPa. Since the propanol is volatile, it mixes with CO_2 in gas phase at 175°C. Therefore, the propanol could diffuse into polymer even at the low pressure. It could be worthwhile to note that the diffusivity of propanol was lower than that of CO_2 at low-pressure level, but it increased close to that of CO_2 over the critical pressure.

Nonvolatile molecules, such as dye pigments, cannot be infused into polymer without using $scCO_2$. Fig. 6 shows the change in absorbance at 1493 nm when CO_2 and dye pigment (disperse blue) mixture was introduced to the autoclave and diffused into the LDPE at 175°C by changing the CO_2 pressure from

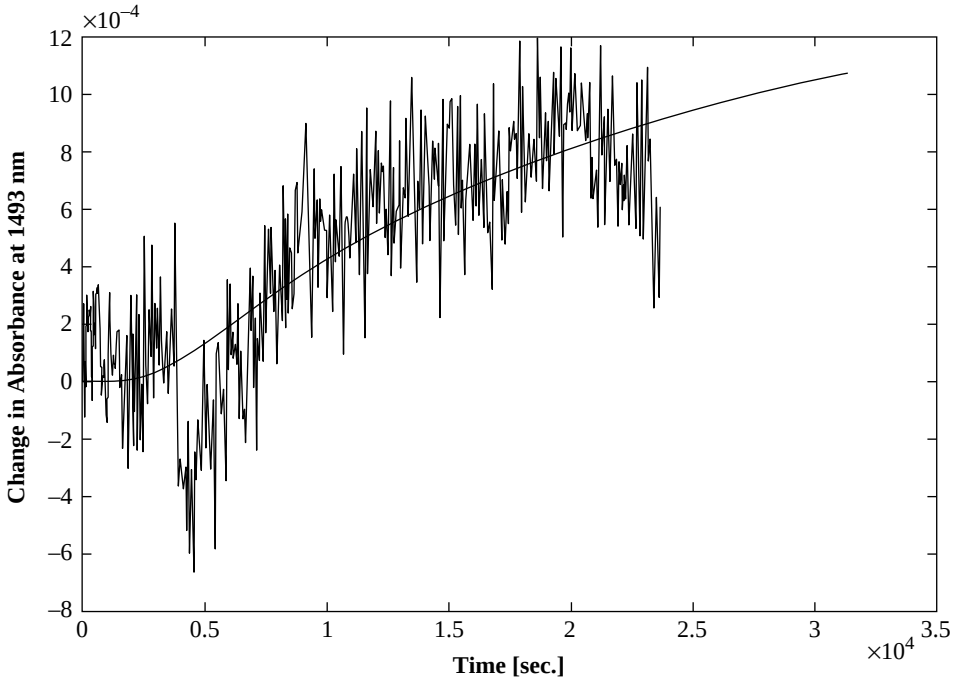

Fig. 6 Diffusion behavior disperse blue with CO_2 into LDPE measured by NIR at 175°C. *(View this art in color at www.dekker.com.)*

0.1 to 10 MPa. Although the signal over noise ratio was low, it was clearly observed that the blue pigment was diffusing into the polymer. As shown by the experimental data, nonvolatile molecules could be infused into polymer using $scCO_2$ as far as the molecule could be dissolved into $scCO_2$.

CO_2 Induced Viscosity Reduction

The other factor of controlling the proposed injection molding is the plasticization effect of CO_2, i.e., polymer viscosity reduction by CO_2 dissolution. During the last decade, the study of CO_2 induced viscosity reduction has been advanced drastically. Gerhardt et al. measured viscosity reduction of polydimethylsiloxane (PDMS)/CO_2 solutions by using a high-pressure plunger-type capillary rheometer.[22] Kwag et al. also measured the viscosity of PS/CO_2 solutions by employing the same technique as Gerhardt.[23] Lee et al. measured the viscosity of PS/CO_2 solutions.[24] Gendron et al. measured the viscosity of PS/hydrofluorocarbon (HFC) solutions, as well as PS/CO_2 solutions, and developed a viscosity prediction model for these mixtures by employing the William–Landle–Ferry (WLF) equation with a variable glass transition temperature, T_g.[25] They calculated T_g as a function of dissolved gas concentration by extending the Chow model. Royer et al. modified Gendron's model so that the pressure effect could be taken into account when the viscosity of PS/CO_2 mixtures was predicted.[26] Areerat et al. proposed the following practical model for predicting the viscosity of the polymer/CO_2 solutions.[27,28] The model was developed by integrating the Cross–Carreau model with Doolittle's equation by means of a variable free volume. The Cross–Carreau model was given by

$$\eta(\dot{\gamma},) = \frac{\eta_O}{\left(1+\left(\frac{\eta_O\dot{\gamma}}{\tau}\right)^a\right)^{\frac{(1-n)}{a}}} \tag{4}$$

where η and η_O are the shear and zero-shear viscosities, respectively; $\dot{\gamma}$ is the shear rate; and n, τ, and a are parameters which determine the shape of the viscosity-shear rate curve.

At high shear rates where $\left(\frac{\eta_O\dot{\gamma}}{\tau}\right) \gg 1$ can hold, Eq. (4) can be simplified into

$$\eta(\dot{\gamma}) \cong \eta_o^n\left(\frac{\dot{\gamma}}{\tau}\right)^{(n-1)} \tag{5}$$

It is assumed that the parameters n, τ, and a are constant and the viscosity reduction due to the CO_2 dissolution could be described only by the changes in zero-shear viscosity. The zero-shear viscosity, η_O, is given as a function of free volume fraction as described by

$$\eta_o = A\exp\left(\frac{B}{f(T,P,w_g)}\right) \tag{6}$$

where A and B are unique constant parameters for the polymer and they are determined when the polymer is given. $f(T,P,w_g)$ denotes the free volume fraction. Then, the free volume fraction is assumed to be a function of temperature, T, pressure, P, and weight percentage of dissolved CO_2, w_g.

Substituting Eq. (6) into Eq. (5) results in

$$\eta = \exp\left(C_3 + \frac{C_2}{f(T,P,w_g)}\right)\dot{\gamma}^{C_1} \quad (7)$$

where

$$C_1 = (n - 1)$$
$$C_2 = nB$$
$$C_3 = [n \ln A - (n - 1)\ln \tau]$$

Assuming that C_1, C_2, and C_3 are not affected by temperature, pressure, and dissolution of CO_2, they can be determined from a viscosity-shear rate curve of the neat polymer. Namely, the coefficient, C_1, which is equivalent to $n - 1$, can be determined by the slope of the viscosity and shear rate curve. The values of C_2 and C_3 can be determined from data of viscosity vs. free volume fraction of the neat polymer. The data of free volume fraction required for determining C_2 and C_3 can be obtained from PVT data of the neat polymer at temperatures and pressures where the viscosity measurements of the neat polymer are performed.

To predict the viscosity reduction, the change in the free volume fraction caused by CO_2 dissolution has to be calculated. Extending the definition of free volume fraction, the free volume fraction is given as a function of temperature, pressure, and dissolution of gas:

$$\begin{aligned} f(T,P,w_g) &= f_r + \left(\frac{\partial f}{\partial T}\right)_{P_r,T_r,w_{gr}} (T - T_r) \\ &\quad + \left(\frac{\partial f}{\partial P}\right)_{P_r,T_r,w_{gr}} (P - P_r) \\ &\quad + \left(\frac{\partial f}{\partial w_g}\right)_{P_r,T_r,w_{gr}} (w_g - w_{gr}) \quad (8) \\ &= f_r + (1 - f_r)\alpha(T - T_r) \\ &\quad - (1 - f_r)\beta(P - P_r) + \phi(w_g - w_{gr}) \end{aligned}$$

where f_r is a reference free volume fraction given at a reference temperature, T_r, pressure, P_r and weight percentage of dissolved CO_2, $w_g r$. $\alpha(:= \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_{P_r,w_{gr}})$ is the thermal expansion coefficient, $\beta(:= -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_{P_r,w_{gr}})$ is the isothermal compressibility coefficient and ϕ is the gas expansion coefficient.

Since zero-CO_2 concentration is taken as a reference condition, the parameter f_r is not a function of CO_2. Then, f_r, α, and β can be determined from the PVT measurement of the neat polymer. There remains only gas concentration coefficient, φ, as a variable affected by CO_2 dissolution. The gas expansion coefficient, φ, is determined by solubility measurements, the models with these parameter values could predict the viscosity of polymer/CO_2 single-phase mixtures.[27]

Fig. 7 shows the CO_2 induced viscosity reductions of PP and PS polymers. The viscosities of the polymer/CO_2 mixtures were measured by a capillary rheometer equipped with a foaming extruder. As can be seen in Fig. 7, the viscosity of PS was reduced by 40% by dissolving CO_2 3.5 wt% and that of PP was reduced by 25%. The solid lines in Fig. 7 represent the estimates of the aforementioned models.

CO_2-ASSISTED SURFACE MODIFICATION INJECTION MOLDING

As shown in the previous section, CO_2 enhances the mobility of polymer and plasticizes the polymers. Furthermore, it can dissolve a variety of low molecular compounds, such as dye pigments, additive agents, monomer, and crystal nucleation agents, when it becomes a supercritical state. Integrating these characteristics of CO_2 can create an scCO_2-assisted surface coating injection molding technique. Two different injection schemes of coating the plastic surface are described in the following sections.

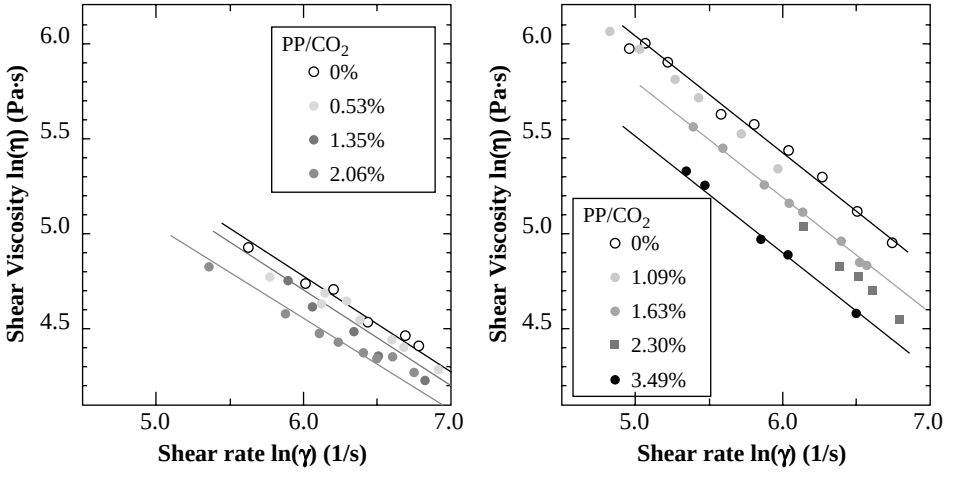

Fig. 7 CO_2-induced viscosity reduction at PS/CO_2 and PS/CO_2 systems at 200°C.

Direct Injection Scheme

One of the $scCO_2$-assisted surface coating schemes is illustrated in Fig. 8. $scCO_2$ is introduced into a mold cavity of an injection molder. On the line of introducing the $scCO_2$ from a high pressure CO_2 generator to the cavity, low molecular solutes, such as dye pigments, alcohols, and monomers, low molecular weight polymers are dissolved into the $scCO_2$. The cavity is pressurized and filled with the $scCO_2$ dissolving the substance (Fig. 8A). Then, the molten polymer is injected into the pressurized cavity (Fig. 8B). When the polymer is flowing in the cavity, the CO_2 and the low molecular solutes diffuse from the melt front of the flowing polymer. In the mold cavity, the injected polymer shows a so-called fountain flow. As shown in Fig. 9, the polymer at the melt front moves from the centerline of the stream to the cavity wall when it runs in the cavity. The polymer surface, where CO_2 as well as low molecular solute are dissolved, is carried toward the cavity walls on the fountain flow and is solidified at the wall, which normally remains below the transition temperature (Fig. 8C). The viscosity of the polymer surface containing the CO_2 is reduced owing to the plasticization effect. The reduced viscosity increases the transferability of polymer against the mold shape and reduces surface roughness. Furthermore, the dissolved CO_2 in polymer eventually diffuses out to atmosphere while low molecular substance remains in the products. This produces solidified plastic products whose surface is modified by the low molecular substances.

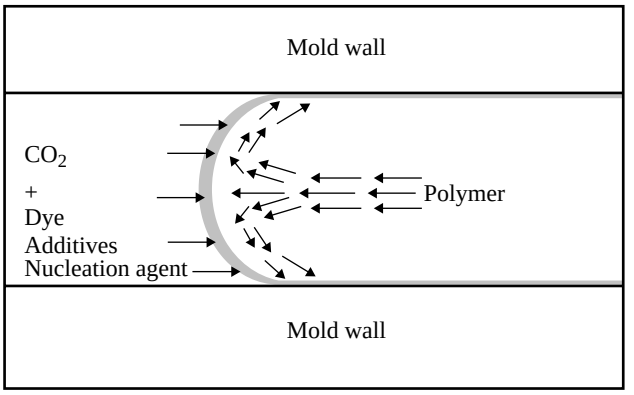

Fig. 9 Fountain flow behaviors of polymer and diffusion of CO_2 and additives into polymer melt front in a mold cavity. (From Ref.[9].)

Core-Back Molding Scheme

In the aforementioned direct injection scheme, the contact time, which is a period that the polymer front contacts $scCO_2$, becomes a critical factor of determining the thickness of modified polymer layer. The contact time, which is almost equivalent to the injection period at the method, cannot be made longer due to

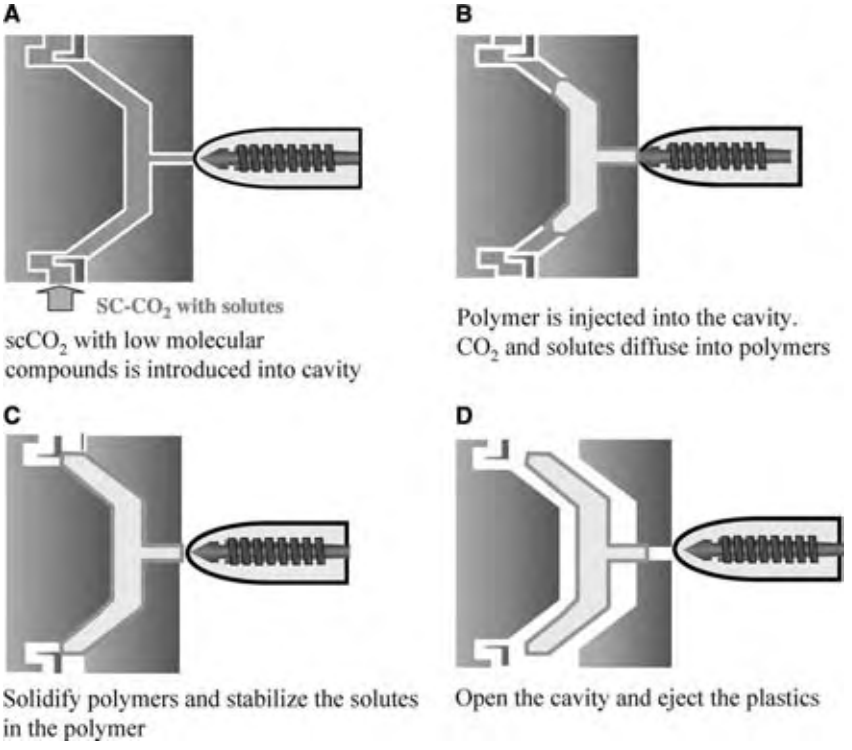

Fig. 8 Direct injection scheme of surface coating with $scCO_2$. (From Ref.[9].)

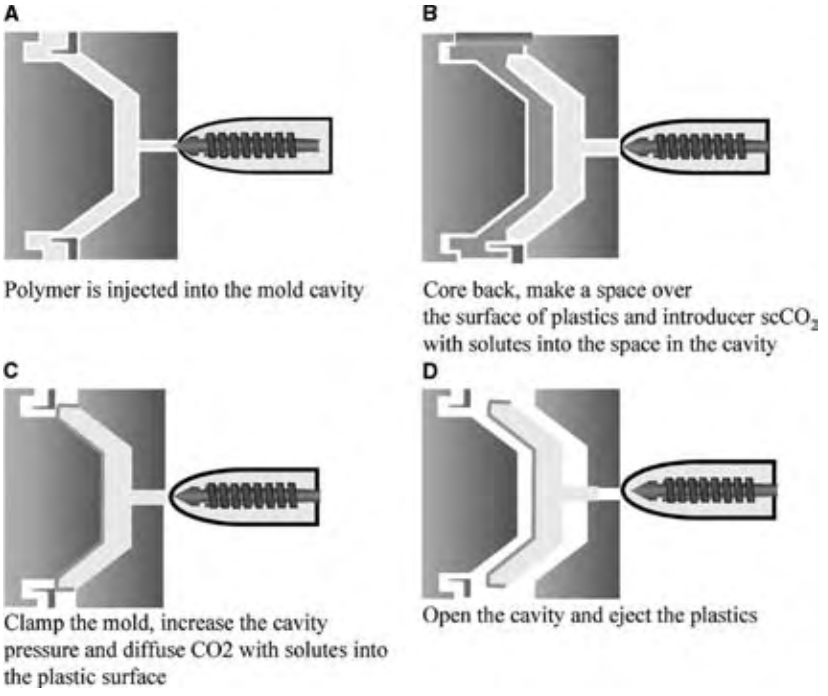

Fig. 10 Core-back injection molding of surface coating with $scCO_2$. (From Ref.[9].)

the fact that the lower injection speed reduces processability of the polymer. In order to manipulate the contact time of CO_2, solutes to polymer, and control the thickness of the polymer layer modified by a low molecular solute, the other scheme, which is named the core-back molding scheme, is developed as shown in Fig. 10. The polymer is injected into the cavity (Fig. 10A). At a certain moment in time, part of the mold is shifted back so as to make a narrow space while keeping the pressure sealing, and the $scCO_2$ containing the low molecular substance is introduced into the space (Fig. 10B). Then, part of the mold is clamped back and the pressure of CO_2 in the space is increased so as to dissolve both the CO_2 and the low molecular substance in the plastic in the mold (Fig. 10C). By varying the volume of the space and the pressurizing time, the thickness of the modifying layer can be changed.

EXPERIMENTAL RESULTS

Fig. 11 shows the experimental setup of the CO_2-assisted surface coating injection molding. A 35-ton injection molder was used. The molder cavity was sealed so that the cavity pressure can be kept at a higher value than critical pressure 7.38 MPa. The high pressure CO_2 was generated, by pumping the liquid CO_2, and introduced into a buffer tank. A low molecular compound to be dissolved in $scCO_2$, which

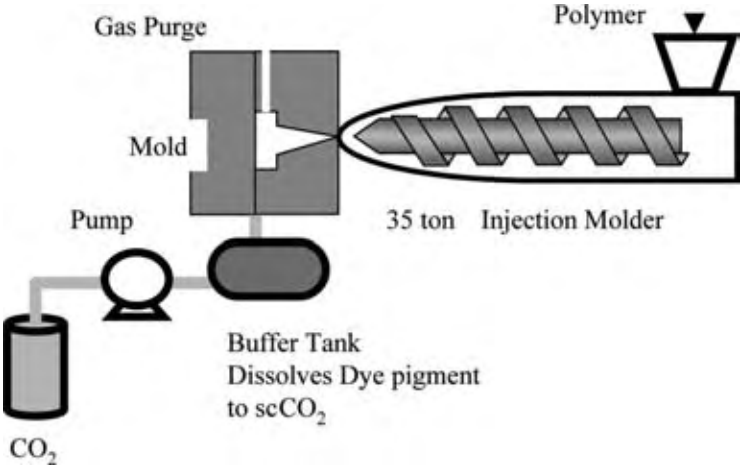

Fig. 11 Experimental setup for a surface coating injection molding. (From Ref.[9].)

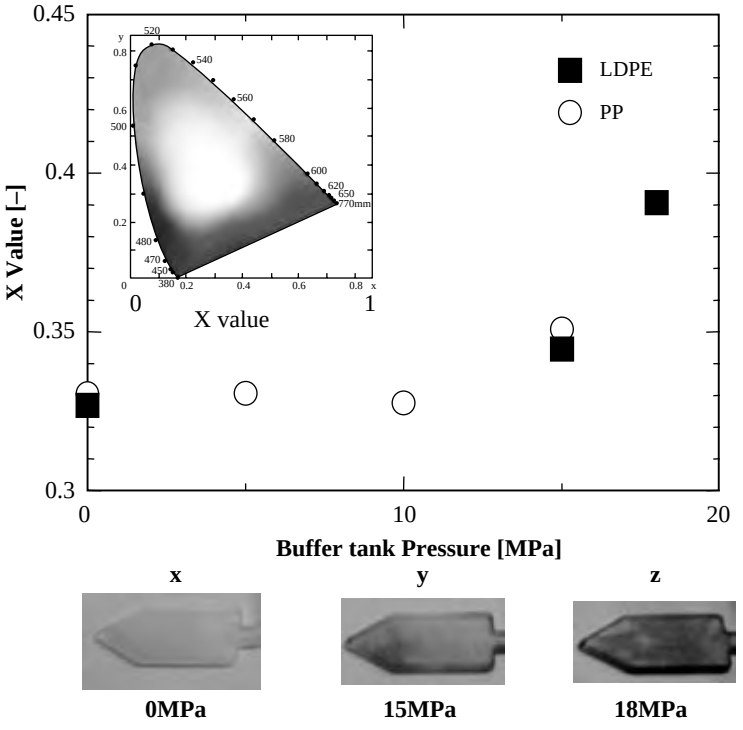

Fig. 12 The darkness of the red-colored surface of plastics. *(View this art in color at www.dekker.com.)*

in this experiment was Oil Red-O dye pigment, was placed inside the buffer tank. By keeping the buffer tank temperature higher than critical temperature and pressure of CO_2, the low molecular compound is dissolved in $scCO_2$ in the tank. A gas line for supplying $scCO_2$ and low molecule mixture is connected from the buffer tank to the mold.

The direct injection scheme of surface coating was performed by this experimental setup. Low density polyethylene (LDPE) and polypropylene (PP) were used as sample polymers and a disperse dye pigment, Oil Red-O, whose melting point is 120°C, was used as a low molecule to be dissolved in $scCO_2$ and coat the surface of LDPE and PP of injection products. The buffer tank temperature was kept at 60°C and the molder barrel temperature was 220°C, which is a normal temperature setup. By varying $scCO_2$ pressure at the buffer tank, the direct injection scheme was performed. The color of injected plastic product was evaluated using the x-y-z color system as shown in Fig. 12, which also shows a result of experiments. The X-value indicates the degree of red color. As can be seen, the red color of the plastic products' surface becomes darker as the pressure of $scCO_2$ increases over critical temperature.

CONCLUSIONS

In this entry, the fundamental aspects of CO_2/polymer systems, such as solubility, diffusivity of CO_2 in polymers, and CO_2 induced viscosity reduction, as well as the basic principles of supercritical CO_2 technique in polymer processing, were discussed. It was shown that utilization of these fundamental aspects of $scCO_2$ and polymer systems is one of the promising schemes and has great potential for inventing a new polymer processing technology. As an example, a novel CO_2-assisted surface coating injection-molding technique was introduced, which utilizes the plasticization and the solvation effects of $scCO_2$ for processing several plastic products. Two supercritical CO_2-assisted surface coating injection-molding schemes were proposed. By the developed technique, the surface of plastic products could be modified with low molecular substances and the new functionality can be added to plastic products.

Supercritical Fluid Extraction (SFE)

Ram B. Gupta
Department of Chemical Engineering, Auburn University, Auburn, Alabama, U.S.A.

INTRODUCTION

A fluid is supercritical when it is compressed beyond its critical pressure (P_c) and heated beyond its critical temperature (T_c). Supercritical fluid technology has emerged as an important technique for supercritical fluid extraction (SFE). In many of the industrial applications, it has replaced conventional solvent-based or steam extraction processes, mainly due to the quality and the purity of the final product and environmental benefits.

SUPERCRITICAL FLUIDS AND THEIR PROPERTIES

There are several fluids of interest as listed in Table 1.

In this list, carbon dioxide is the supercritical fluid of choice because it is nonflammable, nontoxic, inexpensive, and has mild critical temperature. Hence, much of the attention has been given to supercritical carbon dioxide for practical extraction applications.

No amount of compression can liquefy the supercritical fluid. In fact pressure can be used to continuously change the density from gas-like conditions to liquid-like conditions. Near the critical region, small changes in the pressure can give rise to large changes in the density. Fig. 1 shows how density of carbon dioxide is varied by pressure at different isotherms.

In addition to density, diffusivity of the supercritical fluids is higher than that of liquid solvents, and can be easily varied. For typical conditions, diffusivity in supercritical fluids is of the order of $10^{-3}\,cm^2/sec$ as compared to 10^{-1} for gases and 10^{-5} for liquids. Typical viscosity of supercritical fluids is of the order of $10^{-4}\,g/cm/sec$, similar to that of gases, and about 100-fold lower than that of liquids. High diffusivity and low viscosity provide rapid equilibration of the fluid to the mixture to be extracted, hence extraction can be achieved close to the thermodynamic limits. However, the main extraction benefit of supercritical fluids is their adjustable density that provides adjustable solvent strength. The compounds of choice can be dissolved/extracted in the supercritical fluid at high pressure and then this fluid mixture is carried to another vessel where simple lowering of the pressure precipitates the compound. A simple extraction scheme is shown in Fig. 2.

SUPERCRITICAL FLUID EXTRACTION SCHEMES

Most of the industrial SFE is for the extraction from a solid matrix. Because of the challenge in the pumping of the solids to high-pressure extractor, the process is usually carried out in a semibatch mode. A number of high-pressure extractors are used in parallel; the solid mixture is filled, extracted, and emptied in a sequential fashion, allowing almost a continuous stream of the extract product.

The lowering of pressure to precipitate the extract is not always necessary. For example, in the case of decaffeination of coffee beans, water can be used to extract caffeine from the CO_2/caffeine mixture, as caffeine is readily soluble in water (Fig. 3).

Additional benefits of the supercritical carbon dioxide extraction are: 1) oxygen-free system prevents oxidation of the extract; 2) low temperature minimizes the thermal degradation; 3) microbes or their spores are not soluble, hence aseptic extracts are obtained; and 4) solvent-free extract is obtained because CO_2 is gas at ambient and is not retained by the extract.

When designing SFE, the most important factor to consider is the solubility of the desired compound in supercritical carbon dioxide. Because of the benign (noninteracting) molecular nature of carbon dioxide, solubilities are usually small. Nonetheless, with the recycle of CO_2, multiple passes can be used to achieve the desired extraction. For illustration, solubilites of two compounds in orange skin, linalool, and limonene are shown in Figs. 4 and 5.[1] The solubility is highly dependent on the pressure and temperature of the supercritical carbon dioxide.

Solubility increases with the pressure owing to increase in the solvation power of the supercritical fluid. An increase in the temperature causes a drop in the density of the fluid (hence the solvation power); however, the substance itself is more volatile at the increased temperature. For the SFE, density, rather than pressure or temperature, appears to be the more natural variable for describing the solubilities. The solubility data in Fig. 4 are replotted vs. density in Fig. 5.

Table 1 Critical constants and safety data for various supercritical solvents

Supercritical fluid	T_c (°C)	P_c (atm)	Safety hazard
Ethylene	9.3	49.7	Flammable gas
Trifluoromethane (fluoroform)	25.9	46.9	
Chlorotrifluoromethane	28.9	38.7	—
Ethane	32.3	48.2	Flammable gas
Carbon dioxide	31.1	72.8	—
Dinitrogen monoxide (laughing gas)	36.5	71.7	Not combustible but enhances combustion of other substances
Sulfur hexafluoride	45.5	37.1	—
Chlorodifluoromethane (HCFC 22; R 22)	96.4	48.5	Combustible under specific conditions
Propane	96.8	42.4	Extremely flammable
Ammonia	132.4	111.3	Flammable and toxic
Dimethyl ether (wood ether)	126.8	51.7	Extremely flammable
Trichlorofluoromethane (CFC 11; R 11)	198.0	43.5	—
Isopropanol	235.2	47.0	Highly flammable
Cyclohexane	280.3	40.2	Highly flammable
Toluene	318.6	40.6	Highly flammable
Water	374.0	217.7	—

SOLUBILITY ENHANCEMENT USING COSOLVENTS

The problem of the poor solubility of the extractant in supercritical carbon dioxide, can be overcome by the addition of a small amount of the cosolvent, such as methanol, ethanol, or acetone.[2] The carbon dioxide by itself is almost nonpolar (it has some polarity owing to its quadrupole moment); addition of a polar cosolvent that is fully miscible with supercritical carbon dioxide can provide a more polar solubilizing environment needed for the extraction of polar substances. For example, solubility of fish liver oil in supercritical carbon dioxide increases by addition of small amounts of ethanol (Fig. 6).[3] Depending on the amount of the cosolvent added, critical temperature and critical pressure of the binary mixture also change.

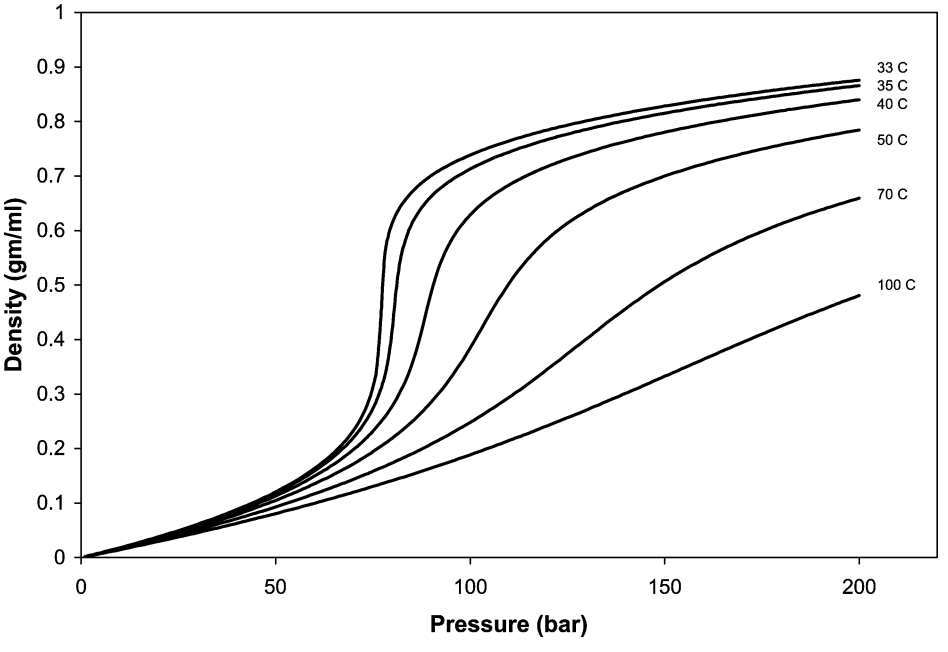

Fig. 1 Density dependence of carbon dioxide.

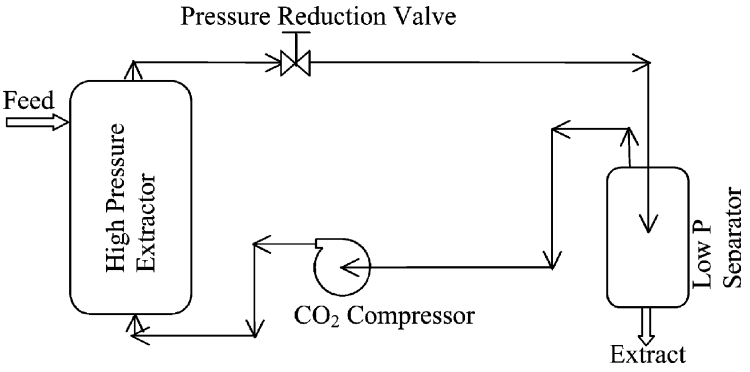

Fig. 2 Schematic of a typical supercritical fluid extraction process.

RAPID EXPANSION OF SUPERCRITICAL SOLUTION TO OBTAIN MICROPARTICLES

Once the solute is dissolved in the supercritical fluid, if the recovery of the solute is done by rapidly expanding the fluid, the solute can be recovered as fine particles or droplets. The pressure can be reduced as fast as the speed of sound, hence very high supersaturation can be achieved in a fraction of seconds. The solute precipitates out as a microparticles (if solid) or microdroplets (if liquid). Hence, it is possible to perform both extraction and micronization in a single step.

APPLICATIONS OF SUPERCRITICAL FLUID EXTRACTION

The SFE has been applied in a variety of industrial applications including: 1) foods: flavor extraction and concentration of flavors and fragrances, processing essential oils and edible oils; infusion of flavors and fragrances into the solid matrices; 2) neutraceuticals: vitamin extraction, antioxidant extraction, and the concentration of active ingredients; 3) petroleum: propane deasphalting, residuum oil extraction; 4) polymers: removal of monomers and oligomers, infusion of compounds into the polymeric matrix, and removal

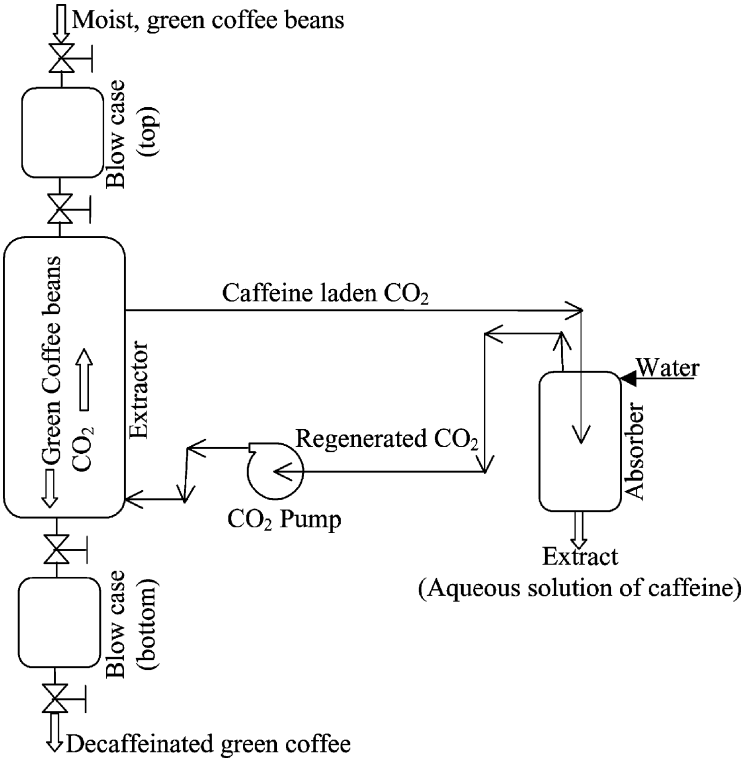

Fig. 3 Decaffeination of coffee beans using supercritical fluid extraction.

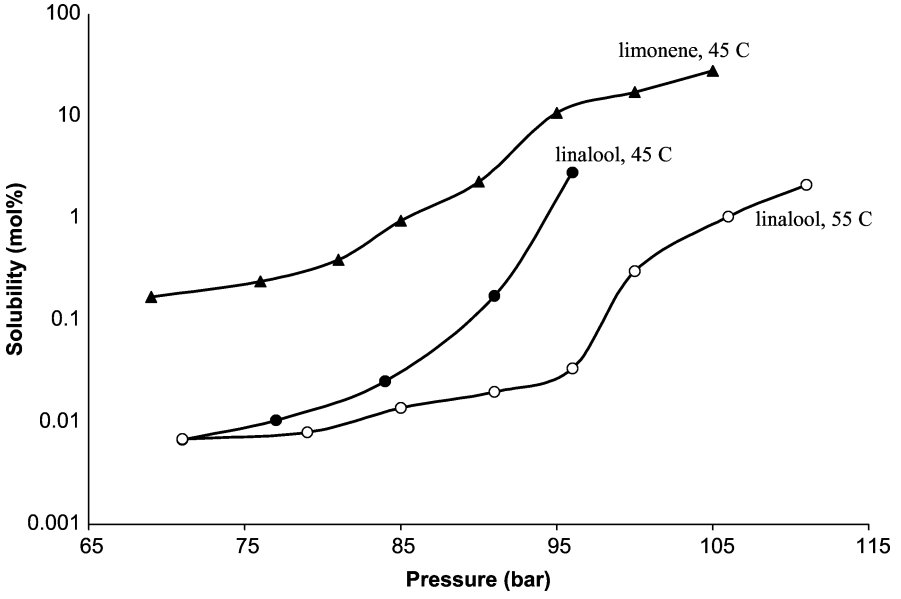

Fig. 4 Solubility of limonene and linalool in supercritical carbon dioxide. (From Ref.[1].)

of binder from powdered metals; 5) cleaning: precision machined components, silicon wafers, medical implants, and electronic components; 6) analytical: for extraction of the analytes from samples of food, cosmetics, polymers, and pharmaceuticals. Only a few of these applications are described here in detail.

DECAFFEINATION

Out of the above six major application areas, the applications in food, flavor, and fragrance have been heavily adopted by the industry. A good example is the coffee industry. Caffeine contents of coffee and tea are 3.5–5.0% and 1–3.5%, respectively, and depend on the soil, altitude, and climate of the plantation. There is a significant consumer demand for decaffeinated coffee that contains less than 0.4% caffeine. The SFE to decaffeinate coffee has been in industrial practice since more than two decades. Nearly 90% of the coffee consumed in the United States is now decaffeinated by supercritical CO_2 extraction.[4] Caffeine is extracted from the green coffee beans and then the aroma is simply developed later by roasting. In the case of decaffeination of tea, the extraction is conventionally performed on black tea. Because the enzymes in the green tea are to be protected, as they are needed in the development of the flavor and color at a later

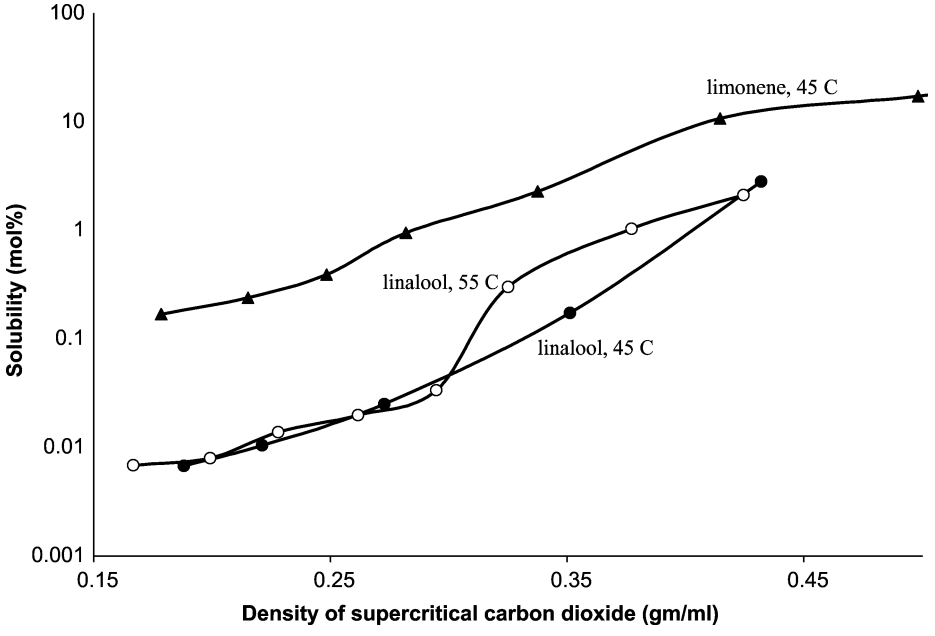

Fig. 5 Log of solubility vs. density shows a more linear behavior.

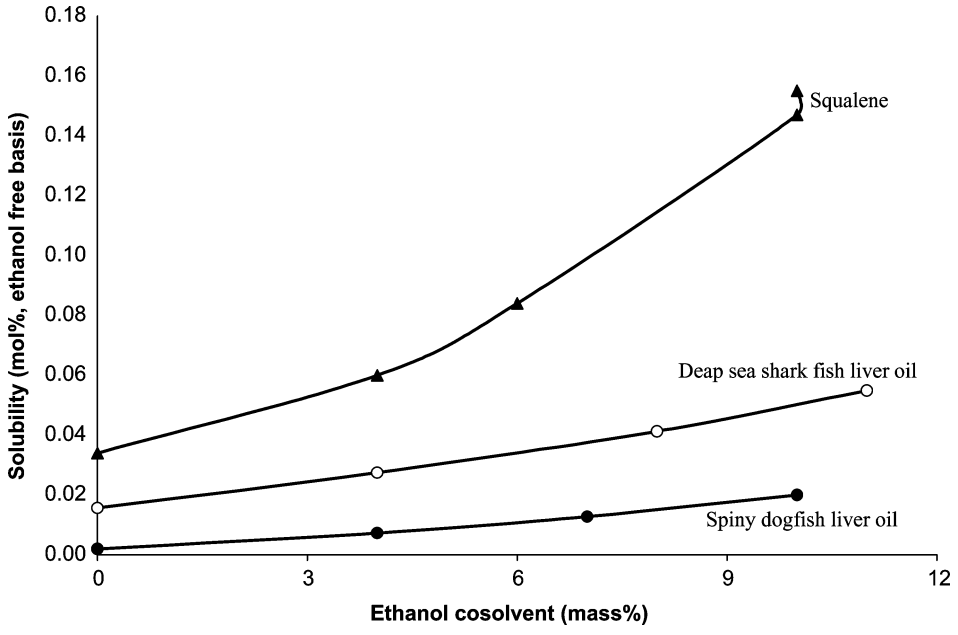

Fig. 6 Enhancement of fish oil solubility in supercritical carbon dioxide by addition of ethanol cosolvent, at 60°C and 250 bar. (From Ref.[3].)

stage, there were some concerns that supercritical CO_2 may inactivate the enzymes.

EXTRACTION OF FLAVORS AND FRAGRANCES

The flavors and fragrances extracted using supercritical carbon dioxide are significantly different from those extracted using steam distillation or solvent extraction. The SFE extract can almost be viewed as a new product, as usually the amount extracted is higher (Table 2) and the composition of the extract is somewhat different (Table 3), as more aromatic molecules are extracted. In many instances the extract using supercritical carbon dioxide is closer to the natural fragrance or flavor.[5–7] The higher SFE equipment cost can be easily offset by the higher yield of the product and the lower operating cost, as compared to steam distillation or solvent extraction.

Table 2 Comparison of percent yields of flavor and fragrance extracts from various natural products

Natural substance	Steam distillation (% yield)	Supercritical CO_2 (% yield)
Aniseed	2.1–2.8	7
Carrot	0.2–0.5	3.3
Cardamom	4–6	7
Clovebud	15–17	22
Cumin	2.3–3.6	14
Ginger	1.5–3.0	4.6
Garlic	0.06–0.4	4.6
Oregano	3–4	5
Pepper	1.0–2.6	8–18
Rosemary	0.5–1.1	7.5
Sage	0.5–1.1	4.3
Vetiver	0.5–1.0	1.0

(From Refs.[5,6].)

EXTRACTION OF EDIBLE OIL

There are several published studies on the use of supercritical carbon dioxide to extract oils from potato chips and other snack foods, motivated because of the increasing consumer awareness toward low-fat foods. About one-half of the oils in a potato chip containing about 40% oil can be extracted while maintaining the original flavor and texture. The extracted oil can be recovered by depressurization and reused in a subsequent frying operation. Supercritical carbon dioxide evenly dispersed the excess oil on the surface, thus removing the greasy taste. The processed fried snacks were found to have improved flavor and taste.[8]

POLYMER FRACTIONATION

Supercritical fluid can be used to extract low-molecular-weight polymers/oligomers from the given mixture, leaving the high-molecular-weight polymer behind. The pressure of the extract fluid is lowered sequentially in different vessels causing the precipitation of the polymer depending on its molecular weight. The lowest-molecular-weight polymer is precipitated the last. Thus, the broad-molecular-weight polymer mixture

Table 3 Composition of lavender extract by supercritical CO_2 and steam distillation

Chemical component	Supercritical CO_2 extract (%)	Steam distillation product (%)
1,8-Cineole	5.83	6.75
Linalool	25.29	35.31
Camphor	7.90	7.81
Borneol	2.30	2.98
4-Terpineol	3.79	3.34
Linalyl acetate	34.69	12.09
3,7-Dimethyl acetate	3.08	4.38
β-Farnescene	2.23	1.00
α-Bisabolol	2.09	3.76

(From Ref.[7].)

can be separated into the cuts of narrower-molecular-weight fractions. Carbon dioxide usually has extremely poor solubility for the polymers; however, it can be easily used to remove residual solvent or monomers. Also, the fractionation of softer polymers such as poly(ethylene glycol) is feasible using carbon dioxide.[9] Propane, ethylene, ethane fluids are needed for the fractionation of commercial polymers including poly-(methyl methacrylate), polyethylene using high pressures.[10] Isothermal pressure profiling in the liquid polyethylene/supercritical propane regime yielded 14 fractions with narrow polydispersity. This process can be used as an alternative to temperature rising elution fractionation, which was developed to fractionate linear low-density polyethylene on the basis of short-chain branching.

Supercritical fluid fractionation of hydroxyl-terminated polybutadiene was investigated by Watkins and Krukonis, as this polymer is used as a binder in solid propellants and the molecular weight plays an important role in the performance of the explosives.[11] The original polymer had a high polydispersity (ratio of weight average molecular weight to the number average molecular weight). On fractionation, 10 different cuts of narrower distribution were obtained in the pressure range 34–552 bar (Table 4).

WAX FRACTIONATION

Supercritical carbon dioxide, ethane, and propane have been examined for the fractionation of paraffin wax.[12] The original feed contained wax molecules with 10–35 carbon atoms. A narrower carbon distribution is needed in the printing ink, cosmetics, and pharmaceutical applications. Based on the cost analyses, vacuum distillation was proposed to be a cheaper option for light paraffin wax, whereas supercritical fractionation is a more attractive option for the fractionation of medium to heavy waxes.

Table 4 Fractionation of hydroxyl-terminated polybutadiene using supercritical propane at 130°C

Fraction	Pressure range (bar)	M_w	M_w/M_n
Original mixture	—	6,250	2.12
1	34–35	970	1.24
2	124–165	1,690	1.20
3	152–207	2,540	1.23
4	193–207	3,300	1.17
5	207–234	4,110	1.19
6	234–262	5,010	1.16
7	248–276	6,010	1.28
8	276–317	7,420	1.27
9	303–338	9,050	1.30
10	517–552	21,540	1.83

(From Ref.[11].)

EXTRACTION FROM ALCOHOLIC BEVERAGES

In addition to extraction from solids, supercritical fluids can be used to extract aromatic molecules from liquids. Señoráns et al. have utilized carbon dioxide to extract high-quality brandy aroma using a countercurrent supercritical fluid extractor.[13] The aroma quality is influenced by the extraction conditions. Medina and Martinez studied alcohol removal from beverages using supercritical carbon dioxide, to produce beverages with low-alcohol content but sufficient flavor, because of three key benefits: 1) water and salts are not appreciably removed by the carbon dioxide; 2) proteins and carbohydrates are not extracted or denatured; and 3) there is a good control in the aroma recovery. The alcohol removal efficiency increases with the extraction pressure; raffinate alcohol concentration can be reduced up to 3 wt.% at 250 bar and 40°C, from 6.2 wt.% in the feed.[14]

SAFETY AND HEALTH ISSUES

When dealing with supercritical carbon dioxide, there are two safety and health issues that are to be kept in mind when designing and operating the extractor: 1) the high pressure involved requires that the personnel are protected from the plant by proper isolating walls and 2) if carbon dioxide is released in the closed atmosphere, it can lead to asphyxiation, as it can replace the oxygen in the surroundings. If one is using a more flammable supercritical fluid (e.g., propane),

then the flammability becomes an additional concern. The concentrations should be not be allowed to fall between the explosive limits. In the case of ammonia, toxicity hazard also exists.

CONCLUSIONS

Supercritical fluid extraction offers several advantages over conventional extraction processes. The extraction is carried out at high pressures and then the extract is usually recovered by lowering the pressure, as the solubility is a strong function of fluid pressure. The compositions of the extracts are different from those from the liquid extraction. Supercritical fluid extraction has been well accepted for coffee decaffeination and is being applied in other food, cosmetics, and pharmaceutical applications. Supercritical carbon dioxide is an environmentally benign nonflammable fluid.

Supercritical Fluid Technology: Reactions

Aydin K. Sunol
Sermin G. Sunol
Naveed Aslam
University of South Florida, Tampa, Florida, U.S.A.

INTRODUCTION

Significant and steady inroads toward wider and more effective utilization of supercritical fluids have been made over the past three decades. Although the widely stated suitability for synthesis of high-value-added differentiated products is on the mark, continued interest in the displacement of key basic chemical processes with greener and superior supercritical ones is equally worthy owing to the longevity of such processes and the resulting socially responsible manufacturing practice in an era when the new major technology shifts and construction of new plants are far in between. Furthermore, a new wave of second-generation supercritical technologies started to emerge, particularly in materials, bringing forth new roles for dense gases. The motivation of this entry is to assess the current status of the reactions in supercritical fluids in an effort to extricate the challenges both in the current practice and in the potential areas into which we have not as yet ventured.

BACKGROUND

One of the significant paradigm shifts in chemical processing for the new millennium is the increased use of environmentally benign technology. The effectiveness of green solvents such as supercritical water and supercritical carbon dioxide for carrying out reactions, difficult separations, and materials processing is naturally very promising. These solvents are preferred due to their low cost, nontoxicity, nonflammability, and thermal stability. The effectiveness of the supercritical solvents is related to their state, critical temperature, and pressure. Supercritical fluids have the mobility of gases and the dissolving power of liquid solvents resulting in efficient penetration into porous matrices, high mass transfer and reaction rates, and high solvency. Furthermore, these properties are extremely sensitive to perturbations in temperature, pressure, and composition resulting in innovative processing concepts with tunable performance parameters suitable for devising creative processing strategies. Obviously, synergy between the physical characteristics of solvent and the conditions favorable for the desired chemistry is of paramount importance for the success of the application. Thus, over the last three decades, a spate of supercritical processes have been developed, particularly for manufacture of high-value-added products that are superior in performance and exhibit conscious regard for a more socially responsible manufacturing practice.

Despite the higher capital charges associated with relatively high pressures, the necessity to often add a new component into the processing environment, and operational challenges at conditions foreign to most process engineers, the interest in supercritical fluids had been growing steadily since the early 1980s beyond the select number of areas. We see applications in the food and beverage industries, pharmaceuticals, biomedical, microelectronic industries, textiles, forest products, petrochemicals, chemicals, environmental cleanup, syn-fuel production, polymeric materials, ceramics, auto industry, coatings and paint industry, energetic materials, and fuels.

More polymerization reactions carried out at supercritical conditions, select biomass conversion supercritical fluid technologies for hydrogen production, wider use of supercritical water oxidation processes, portfolio of self-assembly applications, a spate of opportunities in process intensification, many supercritical fluid aided materials synthesis applications, and numerous reactions for synthesis of specialty chemicals are expected for years to come.

The entry will start with fundamentals, focusing on the unique properties and the resulting opportunities covered in a generic fashion. Applications in different domains and reactive environments will follow. Some concluding remarks will summarize reactions in supercritical fluids and provide some perspectives for the years to come. Supercritical as well as other reactions can be facilitated through supercritical fluid aided synthesis and functionalization of catalysts. These are discussed elsewhere in the Encyclopedia.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039329

FUNDAMENTALS

Properties and Opportunities

The unique properties of supercritical fluids make them attractive as a reaction medium as well. Although reactive supercritical fluids processes such as extraction of coal and supercritical water oxidation started to emerge in the 1970s and early 1980s, the first review on reactions in supercritical fluids was presented by Subramanian and McHugh, followed by many more recent and thorough reviews.[1–3] Earlier work on reactions at high pressure provided both fundamental understanding and technical readiness.[4–10]

The motivations for using supercritical fluids solvents in chemical reactions are many and most of the opportunities are due to the unique properties including density tuning as shown in Fig. 1.[5,11] In this section, these unique properties will be briefly discussed in the context of reactions, followed by the resulting opportunities and other related issues.

There are several reasons for carrying out the reactions at supercritical conditions. Naturally, some of the reasons are coupled. Nevertheless, they, in general, relate to favorable transport properties, unique solvency characteristics, favorable kinetic considerations, and their sensitivity to operating conditions (manipulated variables). These unique properties lead to opportunities in process synthesis, process intensification, and controllability. These advantages, coupled with the environmentally friendly nature of these processes, make reactions in supercritical fluids attractive. The effect of these properties on opportunities for these favorable reaction environments is summarized in Table 1.

Enhanced Reaction Rate

Reactions in supercritical media utilize high pressures. Therefore, the effect of pressure on reaction equilibrium as well as reaction rate plays an important role in supercritical phase reactions. Supercritical fluids that exhibit very high negative activation volumes for certain reactions will improve the rate and equilibrium conversion of the reaction.

The kinetics of the reaction can be explained in terms of the transition state theory. According to the theory, the reaction occurs via a transition state species M^* and the generic elementary reaction can be written as:

$$aA + bB + \cdots \leftrightarrow M^* \rightarrow \text{Products} \tag{1.1}$$

The effect of pressure on the rate constant is given as:

$$\left(\frac{\partial \ln k_x}{\partial P}\right)_T = \left(\frac{\partial \ln K_x^*}{\partial P}\right)_T + \left(\frac{\partial \ln \kappa}{\partial P}\right)_T = \frac{\Delta \overline{V}^*}{RT} + \left(\frac{\partial \ln \kappa}{\partial P}\right)_T$$

where k_x, rate constant; P, pressure; T, temperature; K_x^* mole fraction based equilibrium constant for reaction involving reactants and transition state κ_T, isothermal compressibility; $\Delta\overline{V}^*$, activation volume (difference between partial molar volume of activated complex and reactants), $\Delta \overline{V}^* = \overline{V}^* - a\overline{V}_A - b\overline{V}_B - \cdots$; R, universal gas constant.

The rate constant in the above equation is expressed in terms of pressure independent units (mole fraction). If the rate constant is expressed in terms of pressure

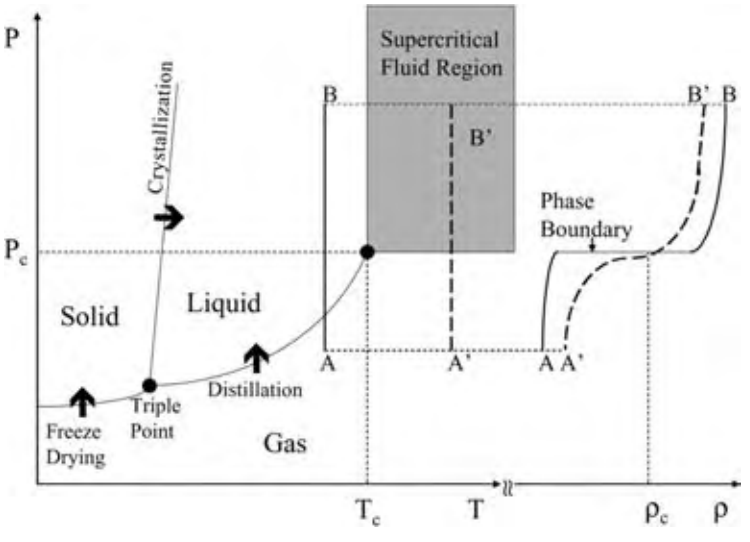

Fig. 1 Supercritical fluid region and density tuning.

Table 1 Effect of properties on opportunities for favorable reaction environments in supercritical media

	Homogenization	Tunability and control	Increased catalyst activity	Enhanced mass transfer	Increased selectivity	Ease of downstream separation
Enhanced reaction rate	Significant	Significant	Most significant	Not significant	Significant	Not significant
Enhanced solubility and selective solvation	Most significant	Significant	Significant	Significant	Significant	Significant
Transport properties (mobility)	Significant	Significant	Significant	Most significant	Significant	Significant
Sensitivity to operating conditions	Significant	Most significant	Significant	Significant	Significant	Significant

dependent units (such as concentration), the relevant equation is:

$$\left(\frac{\partial \ln k}{\partial P}\right)_T = -\frac{\Delta \overline{V}^*}{RT} + \left(\frac{\partial \ln \kappa}{\partial P}\right)_T + \kappa_T(1 - a - b - \cdots)$$

If the volume of activation is positive, the reaction is hindered by pressure. However, for high negative values of the volume of activation, the pressure enhances the rate of the reaction. Therefore, supercritical fluids that exhibit very high negative activation volumes for certain reactions will improve the rate of the reaction.

The volume of reaction, rather than activation, is crucial in determining the effect of pressure on the equilibrium constant:

$$\left(\frac{\partial \ln K_x}{\partial P}\right)_{T,x} = -\frac{\Delta \overline{V}_f}{RT}$$

where $\Delta \overline{V}_f$ is the reaction volume (difference between partial molar volume of products and reactants).

If the equilibrium constant is expressed in terms of pressure dependent units (such as concentration), the relevant equation is:

$$\left(\frac{\partial \ln K}{\partial P}\right)_{T,x} = -\frac{\Delta \overline{V}_f}{RT} + \kappa_T \sum \upsilon_i$$

where υ_i is the stoichiometric coefficient.

As the above equation implies, supercritical fluids that exhibit very high negative activation volumes for certain reactions will improve the equilibrium conversion of the reaction.

Enhanced Solubility

The enhancement factors for solubility of compounds, over ideal solubility, in supercritical fluids is typically around 10^4–10^6 and is discussed elsewhere. This enhancement implies that very heavy macromolecules can be solubilized in supercritical fluids to react or be selectively removed from the reaction environment. In another class of reactions, light noncondensable components such as hydrogen or oxygen will dissolve in supercritical fluids for effective hydrogenation or oxidation. Supercritical fluids can also dissolve in and expand liquids for a more favorable reaction and processing environment. This solubility behavior is synchronized with favorable reaction conditions through judicious selection of solvents and/or cosolvents.

Transport Properties (Mobility)

The supercritical fluids exhibit gas-like viscosities, diffusivities, and liquid-like densities. These favorable transport properties lead to enhanced mass transfer, permeation, and wetting characteristics. The mass transfer limited multiphase reactions will benefit from reduction of a number of phases, as in the case of most oxidation, hydrogenation, or replacement of the more viscous liquid phase with a supercritical or a less viscous expanded liquid phase. The mobility combined with tunability results in effective maintenance of catalyst activity in heterogeneous catalysis.

Sensitivity to operating conditions

The solubility including retrograde behavior, number and nature of coexisting phases, rate of phase creation, reaction rates, and transport properties are very sensitive to the operating conditions such as temperature, pressure, composition including cosolvents, and other external fields such as electric and magnetic as well as the rate of change of these operating conditions. The sensitivities to manipulated variables are usually coupled leading to novel processes and enable tuning of the process to impart the desired product properties.

Dramatic reduction of surface tension and reduction of dielectric constant affect the interfacial transport and solubility as well as reaction rate tuning, respectively.

Homogenization

Reactions that otherwise would be carried out in more than one phase (heterogeneous reactions) can be transformed to homogeneous ones, with the aid of supercritical fluids, where interphase transport limitations are eliminated. This is realized due to enhanced solubilities of the supercritical fluids. Typical examples are reactions in water (supercritical water can solubilize organic compounds), homogeneous catalytic reactions, reactions of organometallic compounds. Homogenizing one compound more than the other may also affect relative rates in complex reactions and enhance the selectivity.

In supercritical solutions, in a microscopic sense, molecules are nonuniformly distributed. There is aggregation of the solvent molecules around the solute and clusters are formed. The local clustering of solutes or solvents under supercritical condition increases the local concentration of the substrate or the catalyst in the solution and may result in enhanced reaction rates.

Supercritical fluids aid rapid diffusion of solutes or weakening of the solvation around reacting species. This may result in changes of the reaction pathways.

The homogenization could be effectively coupled with nucleation/crystallization to allow in-unit separation and phase transfer catalysis.

Increased Catalyst Activity

Some heterogeneous catalytic reactions are carried out in supercritical phase, to increase catalyst activity and life through in situ regeneration of surfaces with tuning of operation conditions. For example, supercritical fluids are capable of dissolving carbon, which may be irreversibly deposited on the catalyst otherwise.

Tunability and Control

Some properties of supercritical fluids can be monitored (manipulated) continuously by adjusting the temperature and pressure or density of the fluid. Dielectric constant is such a property and the solvent's dielectric constant can influence the rate of the reaction.

Supercritical fluids can be combined with polar cosolvent, which enhances the solubility selectivity and sensitivity of the environment to manipulated variables such as temperature and pressure. This combination also tunes the reaction to adjust the product distribution.[12]

Enhanced Mass Transfer

In many instances, reaction rates are limited by diffusion in the liquid phase. The rate of these reactions can be increased if the reaction is carried out in the supercritical phase. Typical examples are enzyme-catalyzed reactions as well as very fast reactions such as some free radical reactions. Selectivity considerations usually dominate in complex reactions. If some steps of the complex reaction are controlled by diffusion, changing the diffusivity changes relative rates of the reaction steps and affects the selectivity.

The mass transfer rates are also enhanced in porous media allowing effective in situ regeneration and removal of products/reactants as they become solubilized. The reduced viscosities play an important role here.

Ease of Downstream Separation

Another utility of supercritical fluids as the reaction medium is fractionation and purification of the products or removal of unreacted reactants from the product stream. Supercritical fluids can be used as a solvent or as an antisolvent in this instance.

In the case of homogeneous catalysis, employing supercritical fluids enables complete recovery of the expensive transition metal species. Also, these species may have environmentally unfriendly effects if not recovered completely. The combination of ionic liquids with the supercritical fluid can lead to product isolation as well as catalyst immobilization. Thus, catalysts can be recycled batchwise.[7]

Induced Reaction Selectivity

Supercritical carbon dioxide introduces changes in the selectivity of the reactions. These changes include chemical selectivity, as well as stereoselectivity. The selectivity changes originate from the solvent as well as the modification of the catalysts with the carbon supercritical carbon dioxide.

Energy Demand Reduction

The mechanical and thermal energy requirements depend on operating conditions, excursions in these conditions throughout the process, and heat integration. Naturally, we do have pressurization requirements

for all supercritical reactions, particularly high for supercritical water. Thermal energy loads for reactions at elevated conditions such as reactions in supercritical water are rather high as well. The energy demand reduction opportunities are due to favorable transport properties and enhanced rates as well as sensitivity to operating conditions bringing efficient recovery.

In instances where supercritical reactions displace mass transfer limited reactions, less stringent agitation or no agitation results in reduction of mechanical energy requirements. When enhanced reaction rates are coupled with higher mass and heat transfer rates, energy required and volume per unit product decrease substantially. Furthermore, efficient recycling and ease in downstream separation imply reduction in energy consumption. More systematic studies in heat and mass integration of these processes will eventually be done as industrial deployment of supercritical fluids reaches a critical threshold.

Safety

Safety issues often relate to process safety as well as end-product safety. The inherent process safety concern with supercritical fluids/reactions is due to pressurized inventory. For operation of these processes, effective pressurization, depressurization, and relief systems are a prerequisite. When these safety concerns are adequately handled, one sees the safety advantages that supercritical reactions and processes bring about. In most supercritical environments, which are water or carbon dioxide based, we replace flammable and toxic alternatives. The enhanced rates and increased throughputs imply smaller equipment and inventories, further reducing the safety hazards. Furthermore, gases like hydrogen, carbon monoxide, and oxygen can be handled more safely in the presence of supercritical carbon dioxide. This is crucial in hydrogenation as well as oxidation reactions. In the case of product safety, the end products are inherently contaminant free, posing less of a safety concern.

Naturally, a systematic study on safety of high-pressure reactions, particularly for runaway reactions is well overdue.

APPLICATIONS

Supercritical fluids have been utilized as a reaction medium from basic industries such as syn-fuels, biomass conversion, environmental remediation to high-value-added specialty chemicals and materials. An exposition of the underlying mechanism along with application domain will follow in this section. Homogeneous and heterogeneous reactions will be followed by biochemical and polymerization reactions, all with supercritical fluids. The typical examples for which original references are too numerous to cite individually are summarized in Tables 2 to 4.

Homogeneous Reactions in Supercritical Solvents

Homogeneous reactions carried out in supercritical fluids can be either catalytic or noncatalytic. The objective of carrying catalytic and noncatalytic reactions in supercritical fluids is to increase the overall rate of the reaction by eliminating the interfacial transport effects.

Homogeneous Reactions Catalyzed by Organometallic Compounds

Homogeneous catalysts have advantages over heterogeneous catalysts such as the possibility of carrying out the reaction under milder conditions, higher activity, and selectivity, ease of spectroscopic monitoring, and controlling the tunable reaction sites. A recent review by Noyori et al. discusses homogeneous catalytic reactions under supercritical conditions.[13] Examples of homogeneous catalytic reactions carried out under supercritical conditions are summarized in Table 2.

Because most organic reactants and products are not soluble in water, it cannot be utilized as the solvent in most catalytic reactions, although most catalytic materials are soluble in water. Therefore, liquid solvents for homogenization of catalytic reactions are usually organic solvents. An alternative to environmentally unacceptable organic solvents is a supercritical solvent that has several advantages over organic solvents. The aforementioned advantages are increased reaction rate, higher selectivity, and ease in separation of reactants, products, and the catalyst after the reaction. Because the properties of supercritical solvents are sensitive to operating conditions, reaction rate and selectivity are more readily tunable when the reaction is carried out in supercritical solvents.

Carbon dioxide is the supercritical solvent that is used most in homogeneous catalytic reactions. In addition to being environmentally acceptable (nontoxic, nonflammable), carbon dioxide is inert in most reactions, is inexpensive, and is available in large quantities. Its critical temperature is near ambient. Supercritical carbon dioxide dissolves nonpolar, nonionic, and low molecular mass compounds. However, addition of cosolvents enhances the solubility of many compounds in supercritical carbon dioxide.

When homogeneous reactions are carried out under supercritical conditions, liquid gas interfacial transport

Table 2 Homogeneous reactions in supecritical fluids

Reaction	Supercritical medium	Catalyst
Hydrogenation		
CO_2 to formic acid	CO_2	Ruthenium(II) phosphine complex
Asymmetric hydrogenation of tiglic acid	CO_2	Ruthenium catalyst
Asymmetric hydrogenation of enamides	CO_2	Cationic rhodium complex
Asymmetric hydrogenation of imines	CO_2	Iridium complex
Cyclopropene	CO_2	Manganese catalyst
3,3-Dimethyl-1,2-diphenyl cyclopropene	CO_2	Manganese catalyst
Isoprene	CO_2	Rhodium catalyst
C–C bond formation		
Ring opening metathesis polymerization	CO_2	Ruthenium catalyst
Ring closing metathesis of dienes to cyclic olefins	CO_2	Ruthenium catalyst
Cyclotrimerization of alkynes	CO_2	Cobalt catalyst
Olefination of arylhalides	CO_2	Palladium catalyst
Hydrovinylation of styrenes	CO_2	Nickel catalyst

Propylene	CO_2	$CuI/Cu_2O/MnO_2$ on Al_2O_3
Benzyl alcohol	CO_2	Pd/Al_2O_3
Ethanol	CO_2	Pt/TiO_2
Methanol	CO_2	Iron oxide on Mo aerogel
Propene	SC reactant	CaI_2, CuI, Cu_2/MgO on Al_2O_3
Isobutane	SC reactant	SiO_2, TiO_2, Pd/carbon
1,4-Dichlorobenzene	Water	V_2O_5
NH_3	Water	MnO_2/CeO_2
Acetic acid	Water	Cu/Zn/Co oxide supported catalyst
Pyridine	Water	MnO_2/CeO_2, Pt/Al_2O_3, MnO_2/Al_2O_3
Phenol	Water	Cu/Zn/Co oxide, MnO_2/CuO, MnO_2
Chlorophenol	Water	CuO supported on zeolites
Cracking		
Heptane	CO_2	Zeolite
Rearrangement and isomerization		
1-Hexene	CO_2 and cosolvents	Pt/Al_2O_3
Xylene	SC reactant	Solid acid catalyst
Cyclohexene to methyl-cyclopentene	Water	Solid acid catalyst
Alkylation		
Benzene, ethylene, isopentane, isobutene isobutane	CO_2 or SC reactant	Zeolite
Metislene propene, propan2-ol	CO_2	Acid catalyst
Disproportionation		
Toluene to *p*-xylene, benzene	SC reactant	Zeolite
Ethylbenzene to benzene and diethylbenzene	Butane, pentane	Zeolite
Coupling		
Alkene-arene coupling	Water	Palladium catalyst
Esterification		
Oleic acid	CO_2	Biocatalyst
Glycerol and CO_2	CO_2	Zeolite
Hydroformylation		
Oct-1-ene	CO_2	Supported rhodium catalyst
Propylene	CO_2	Supported rhodium and iron catalyst
1-Hexene	CO_2	Rhodium catalyst

is eliminated, which is an advantage for reactions such as hydrogenation, where diffusion of gas into the liquid may be limiting the reaction rate. In asymmetric hydrogenation reactions, hydrogen and the supercritical solvent are miscible and this results in better enantioselectivity.[6] In Diels–Alder reactions, the advantage of the supercritical solvent is higher selectivity obtained rather than increased rate of the reaction due to the solvent. Although most of the oxidation reactions are carried out in supercritical water, recently, homogeneously catalyzed reactions in supercritical carbon dioxide are increasingly reported.

Table 4 Polymerization reactions in supercritical solvents

Polymerization mechanism	Substrate
Transition metal catalyzed, ring opening polymerization	Norbornene polymer, polycarbonate
Dispersion, cationic polymerization	Isobutylene polymer
Homogeneous/precipitation, cationic polymerization	Vinyl ether polymer
Homogeneous, free radical/cationic polymerization	Amorphous fluoropolymers
Precipitation, free radical polymerization	Vinyl polymer, semicrystalline fluoropolymers
Dispersion, free radical polymerization	Polyvinyl acetate and ethylene vinyl acetate copolymer

Homogeneous Reactions of Supercritical Water

Homogeneous reactions carried out at supercritical conditions within water are organo-metallic reactions and Diels–Alder reactions. Reactions in supercritical water are well studied and will be described in the following section.[14]

Supercritical water has a low dielectric constant compared to liquid water. The dielectric constant changes significantly with the density of the supercritical fluid. Also, the effect of hydrogen bonding is less pronounced at supercritical conditions, one consequence of which is high solubility of organics in supercritical water. When the homogeneous reaction is carried out in supercritical water, we get a high reactant concentration and the reaction can proceed in the absence of interphase mass transfer resistances. Also, ion dissociation constant of water is higher in the critical region and is lower as supercritical conditions are accessed. These properties also vary continuously in the supercritical region, so that they can be tuned during the reaction by changing temperature and/or pressure.

Examples of the homogeneous reactions in supercritical water are included in Table 2. Use of acid or base catalysts enhances the rates of some of the reactions.[14]

Homogeneous Noncatalytic Reactions in Supercritical Solvents

The use of supercritical fluids as reaction media for organometallic species is also investigated.[15] Reactions include photochemical replacement of carbon monoxide with N_2 and H_2 in metal carbonyls, where the reaction medium is supercritical xenon. Also, photochemical activation of C–H bonds by organometallic complexes in supercritical carbon dioxide is investigated. More recent studies on photochemical reactions also include laser flash photolysis of metal carbonyls in supercritical carbon dioxide and ethane and laser flash photolysis of hydrogen abstraction reaction of triplet benzophenone in supercritical ethane and CHF_3.[16,17]

Heterogeneous Reactions in Supercritical Solvents

Heterogeneous reactions in supercritical fluids can be catalytic or noncatalytic. Catalytic heterogeneous reactions are carried out on solid catalysts and are of great importance in the chemical process industries. The advantages of carrying out these reactions in a supercritical medium include enhanced interphase and intraparticle mass and heat transfer and in situ regeneration of catalyst and are described in the next section. Catalytic supercritical water oxidation also utilizes favorable properties of supercritical water, which are also discussed. Other heterogeneous reactions that will be described are fuels processing reactions and conversion and treatment of biomass.

Heterogeneous Catalytic Reactions in Supercritical Solvents

Obviously, a solid-catalyzed reaction takes place only on the active sites of the porous catalyst with the implication of some mass and heat transport steps prior to and after the reaction. The first step is the diffusion of the reactants through the film surrounding the catalyst particle to the external surface of the catalyst and diffusion of the reactants in the catalyst pore to the active site in the pores. These steps are limited by the diffusivity and viscosity of the reactants. In the case of a supercritical fluid phase reaction, the diffusivity is higher than the liquid diffusivity, the viscosity is less than the liquid viscosity, and, therefore, the rate of transfer to the active site will be higher. After adsorption, reaction, and desorption steps, the products have to diffuse out of the pore, and through the film surrounding the particle into the bulk fluid. The rates of these steps can be accelerated utilizing a supercritical medium for the reaction. Heat transfer effects are also important in a solid-catalyzed reaction. Higher thermal conductivity of supercritical fluids is an advantage as well.[18]

For two-phase reactions (typically hydrogenation and oxidation reactions), the first step is the diffusion

of the gas reactant to and through the gas–liquid interface and then into the bulk liquid. This mass transfer limitation is also eliminated if the reaction is carried out in a supercritical medium since the reactants are going to be in a single phase.

Supercritical fluids bring other benefits to solid-catalyzed reaction rate through eliminating or minimizing mass and heat transfer resistances. Supercritical solvents have the ability to regenerate the catalyst during the course of the reaction, which increases the catalyst life and activity, because undesirable deposits on the catalyst, such as carbon deposits, are soluble in the supercritical fluids. The rate of the intrinsic reaction is increased in supercritical fluids and by tuning the properties of the supercritical medium, one can control the selectivity.[18–20]

Supercritical fluids may also bring opportunities in downstream separation of the reactants and products. Examples of solid-catalyzed reactions in supercritical fluids are given in Table 3.

Catalytic supercritical water oxidation is an important class of solid-catalyzed reaction that utilizes advantageous solution properties of supercritical water (dielectric constant, electrolytic conductance, dissociation constant, hydrogen bonding) as well as the superior transport properties of the supercritical medium (viscosity, heat capacity, diffusion coefficient, and density). The most commonly encountered oxidation reaction carried out in supercritical water is the oxidation of alcohols, acetic acid, ammonia, benzene, benzoic acid, butanol, chlorophenol, dichlorobenzene, phenol, 2-propanol (catalyzed by metal oxide catalysts such as CuO/ZnO, TiO_2, MnO_2, $KMnO_4$, V_2O_5, and Cr_2O_3), 2,4-dichlorophenol, methyl ethyl ketone, and pyridine (catalyzed by supported noble metal catalysts such as supported platinum).[21,22]

Heterogeneous Noncatalytic Reactions in Supercritical Solvents

Use of the supercritical fluids as the reaction medium in syn-fuel processing is one of the earlier applications in the field. The advantage of the supercritical fluid as the reaction medium is again threefold. During thermal degradation of fuels (oil-shale, coal), primary pyrolysis products usually undergo secondary reactions yielding to repolymerization (coking) or cracking into gas phase. Both reactions decrease the yield of the desired product (oil). To overcome this problem, dense (supercritical) hydrogen donor (tetralin) or nonhydrogen donor (toluene) or inorganic (water) medium is used. Also, supercritical medium provides ease of transport in and out of the porous coal matrix. Finally, downstream processing (separation of the products) becomes an easier task, when supercritical medium is used. A review of the use of supercritical fluids in coal processing is given by Kershaw, while the mechanism is discussed by Sunol.[23,24]

The forest product applications in this category include biomass conversion and delignification for pulping purposes. Both provide unique opportunities, the first for hydrogen generation and later to obtain pulp within reaction times that are reduced almost two orders of magnitude.[25,26]

Polymerization Reactions in Supercritical Solvents

Supercritical carbon dioxide is a promising green alternative to traditional solvents in polymer synthesis because of gas-like transport properties and liquid-like solubility. It can be removed easily from the polymer solution by depressurization during drying of the polymer. It provides easy separation of the polymer from the unreacted monomers and catalysts. Finally, it also exhibits Lewis acid–base interactions with electron donating functional groups of polymer chains.[27] Examples of homogeneous and heterogeneous polymerization reactions carried out in supercritical carbon dioxide are given in Table 4.

Butane, pentane, and propane are also used as the reaction medium in polymer synthesis because carbon dioxide is not a strong solvent for most polymers.[28] Furthermore, some polymerization reactions (such as polyethylene synthesis) are carried out under supercritical conditions of the monomer.

Biochemical Reactions in Supercritical Solvents

Because of their tunable properties, supercritical solvents provide a useful medium for enzyme-catalyzed reactions.[29] The mechanism of enzyme-catalyzed reactions is similar to the mechanism described for solid-catalyzed reactions. External as well as internal transport effects may limit the reaction rate. Utilizing supercritical fluids enhances external transport rate due to increase in the diffusivity and therefore mass transfer coefficient. Internal transport rate depends on the fluid medium as well as the morphology of the enzyme. Supercritical fluids can alter both.

Water is known to be essential for the enzyme activity.[30] Small amounts of water enhance enzyme activity; however, excess water hinders the rate of some enzyme-catalyzed reactions. The active site concentration on enzymes, hence the enzyme activity, is found to be higher in the presence of hydrophobic supercritical fluids (ethane, ethylene) compared to hydrophilic supercritical carbon dioxide.

The effect of pressure on enzyme-catalyzed reactions can be explained in terms of the transition theory. Supercritical fluids that exhibit very high negative activation volumes for certain reactions are expected to improve the rate of the reaction.

Although, supercritical carbon dioxide has the advantage of being nontoxic and abundant, it is practically immiscible with water. Therefore, supercritical fluids used as the reaction medium in enzyme-catalyzed reactions include fluoroform, sulfur hexafluoride, and ethane, while lipases are the enzymes utilized in such reactions.[31]

In addition to advantages like higher initial reaction rate and higher conversion, supercritical fluids provide an easy separation of products and unreacted substrates. This ecologically safe recovery of the products is a unique advantage provided by supercritical carbon dioxide.[29]

CONCLUSIONS

A variety of chemical and biological reactions involving supercritical fluid technology are being explored and developed. They include polymerization reactions, biomass conversion, hydrogen production, applications of supercritical water oxidation, self-assembly applications, synthesis of specialty chemicals, manufacture of materials with tailored properties, and much more. These developments and new ones are expected to mature and be commercially deployed in years to come.

Supercritical Water Oxidation

Ram B. Gupta
Department of Chemical Engineering, Auburn University, Auburn, Alabama, U.S.A.

INTRODUCTION

A fluid is supercritical when it is compressed beyond its critical pressure and heated beyond its critical temperature. Hence, water is supercritical at >374°C temperature and >22.1 MPa pressure. Supercritical water has liquid-like density and gas-like transport properties, and behaves very differently than it does at room temperature. For example, it is highly nonpolar, permitting complete solubilization of most organic compounds and oxygen. The resulting single-phase mixture does not have many of the conventional transport limitations that are encountered in multi-phase reactors. However, the polar species present, such as inorganic salts, are no longer soluble and start precipitating. The physiochemical properties of water, such as viscosity, ion product, density, and heat capacity, also change dramatically in the supercritical region with only a small change in the temperature or pressure, resulting in a substantial increase in the rates of chemical reactions. For example, Fig. 1 shows, how density, dielectric constant, and ionic product of water vary with temperature at 24 MPa.

From the above figure, it is interesting to see that the dielectric behavior of 200°C water is similar to that of ambient methanol, for 300°C water it is similar to that of ambient acetone, for 370°C water it is similar to that of methylene chloride, and for 500°C water it is similar to that of ambient hexane. In addition to the unusual dielectric behavior, transport properties of water are significantly different from the ambient water as shown in Table 1.

WASTE OXIDATION

Owing to the lack of mass transfer limitations and high thermal energy, oxidation in supercritical water is very fast. Usually, in less than 1 min of reaction time, complete oxidation of organics to CO_2 and mineral acids is achieved. Supercritical water has been successfully used to completely oxidize chemicals including polychlorinated biphenyls, organic solvents, and other industrial wastes. In fact, it is emerging a promising alternative to the incineration of aqueous organic waste streams and has received enormous interest during the last decade. Supercritical water oxidation (SWO) can be seen as a further development of the well-established wet air oxidation (WAO) process, running at temperatures up to 320°C and pressures up to 20 MPa. Treatment times in the WAO process are normally as high as several hours, and complete destruction of the organic material is seldom achieved, so a further waste treatment is necessary. In SWO, treatment times are in the range of seconds to a few minutes and more than 99% destruction is achieved in most cases. Incineration, WAO, and SWO are further compared in Table 2.

In a typical SWO operation, organic waste and high-pressure oxygen (or air, or H_2O_2) are fed to the reactor. The reaction products are then cooled and depressurized to collect the benign products (Fig. 2).

Owing to the use of excess oxygen, various elemental species from waste convert into their highest oxidation form. For example, carbon converts to CO_2, hydrogen converts to H_2O, nitrogen converts to HNO_3, sulfur converts to H_2SO_4, etc. Early reactors were simple tube reactors as shown in Fig. 3.

The above tube reactor is also designed to have intermittent ports for the entry of oxidant (e.g., oxygen) and/or quench water. This reactor design is cheaper than the other designs mainly owing to the ease of fabrication and installation. However, if the corrosive species are present then severe wall corrosion can occur. Hence, tube reactors are recommended for use in oxidation of waste that does not contain heteroatomic molecules (e.g., chlorine, sulfur, nitrogen, phosphorous). A typical flow diagram for SWO reactor is shown in Fig. 3.

Problems of SWO

Supercritical water oxidation has been successfully tested for the oxidation of a variety of waste including radioactive waste, rocket propellants, chemical warfare agents, pulp and paper waste sludge, polymer plant waste, organic waste, and municipal waste sludge. Oxidants used in the process include pure oxygen, compressed air, hydrogen peroxide, permanganates, and other industrial oxidants. The SWO process has had some success in

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007978

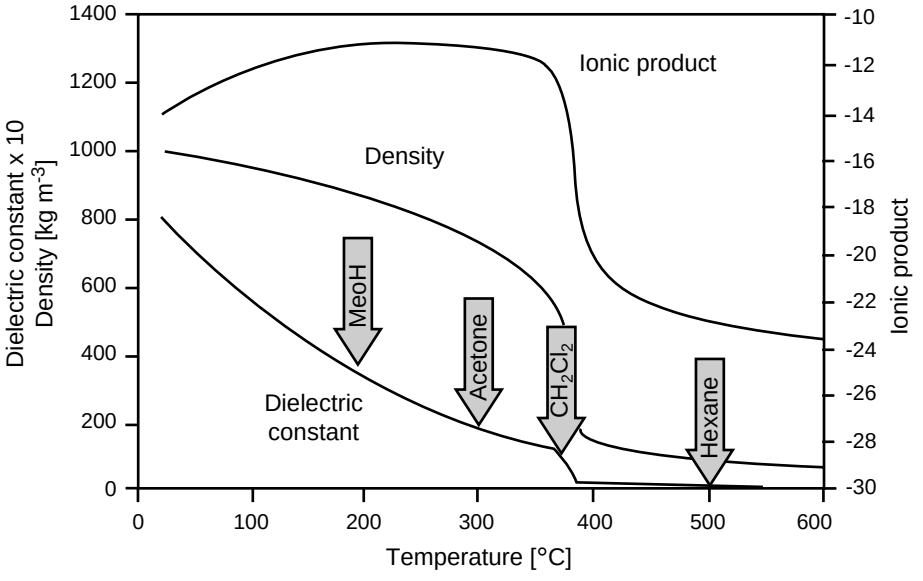

Fig. 1 Physical properties of water vs. temperature at 24 MPa. Dielectric constants of typical organic solvents at room temperature are also indicated. (From Ref.[2].)

military applications and some commercial installations. The lack of widespread industrial adaptation can be attributed to three major factors:[1,2]

1. Severe corrosion problems due to the formation of acids when elements such as S, P, Cl are present in the waste streams.
2. Serious plugging of the reactor, valves, and pipes caused by the precipitation of salts. Most waste streams contain salts that are not soluble in supercritical water.
3. Difficulty of scale-up and cost evaluation due to the lack of data on industrial scale SWO plants.

The corrosion of the heat exchanger is sometime more than that of the reactor, owing to intermediate temperatures in the heat exchanger. To avoid acid formation, a base can be added with the feed stream. The acids and base combine to yield salts, which then precipitate out causing the plugging problem.

Supercritical water oxidation poses a unique corrosion problem that has not been experienced in other chemical processes. Development of new materials is needed to address the problem. The material needs to withstand a chemically harsh environment along with the high temperature and pressure conditions. Even if some current materials are available for

Table 1 Comparison of ambient and supercritical waters

	Ambient water	Supercritical water
Dielectric constant	78	<5
Solubility of organic compounds	Very low	Fully miscible
Solubility of oxygen	6 ppm	Fully miscible
Solubility of inorganic compounds	Very high	~0
Diffusivity (cm^2 sec)	10^{-5}	10^{-3}
Viscosity (g/cm/sec)	10^{-2}	10^{-4}
Density (g/cm^3)	1	0.2–0.9

Table 2 Comparison of WAO, SWO, and incineration for waste oxidation

	Temperature (°C)	Pressure (bar)	Reaction time (min)	Efficiency (%)
WAO	150–325	20–200	15–120	20–97
SWO	380–650	220–500	1–2	60–99.9+
Incineration	490–1200	1	<1	75–99.9+

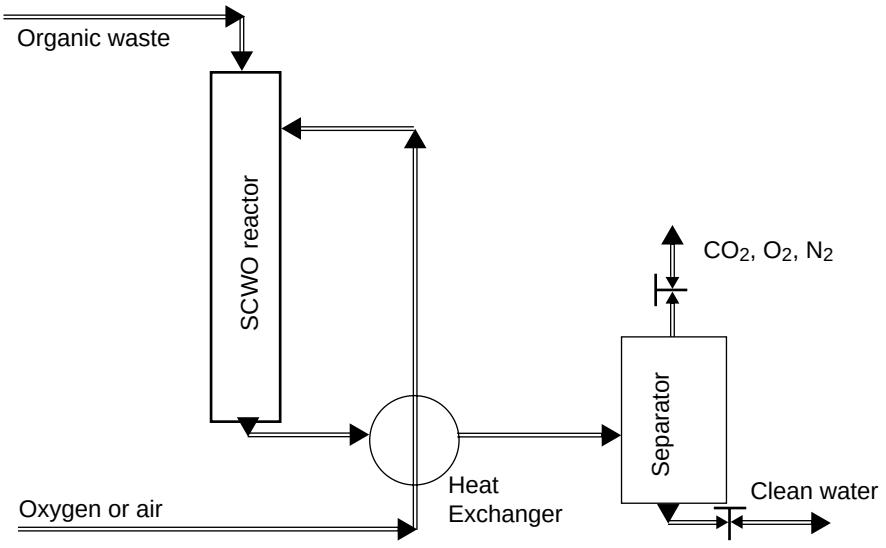

Fig. 2 Flow diagram for SWO process.

resisting one corrosive species, they fail in the presence of other corrosive species or mixtures of species. One such example is titanium, which is resistant to HCl but is prone to corrosion in the presence of sulfuric and phosphoric acids. Another aspect of the corrosion is study of the nature of the corrosive species under different processing conditions. At subcritical conditions, corrosive species exhibit extreme pH values resulting in a highly corrosive environment. Supercritical water with a lower density and dielectric constant reduces the extent of ionic species present in the system, thus reducing the extreme pHs. This guides the process condition to go far away from the critical point to avoid severe corrosion.

Different reactor concepts have evolved to meet the challenges posed by the highly reactive nature of supercritical water, as described below.

Reverse-flow tank reactor

The reverse-flow tank reactor is based on the use of a high-pressure tank with hot and cold zones (Fig. 4).[3] The high-pressure feed is injected downward into the center region where oxidation of the organics and precipitation of salts occur. The produced gases move up and leave through the exit at the top. The lower section is cooled by injecting cold water, and hence remains in the liquid phase in which salts dissolve. The salts are easily removed off the reactor as brine from the bottom outlet. With the reverse-flow tank reactor, oxidation of waste rich in salts is easier.

Transpiring wall reactor

The transpiring wall reactor addresses problems of both corrosion and salt plugging.[4] In this reactor, the platelet liner uniformly meters the flow of water to protect the liner from salt deposition and corrosion while providing a thermal and corrosion barrier for the pressure vessel (Fig. 5). This allows for higher reaction zone operating temperatures and shorter residence times. The reactor pressure boundary is exposed to controlled-temperature deionized water, resulting in a safer design. The platelet technology was borrowed from the cooling of high-pressure rocket engines from military and aerospace applications.

Microparticulate catalytic reactor

Keeping in mind the low cost of the tube reactor, Muthukumaran and Gupta have designed a reactor concept that uses tube reactor while addressing both corrosion and salt plugging concerns.[5] In this SWO reactor, in situ microparticles of a benign substance (e.g., sodium carbonate or other noncorrosive, nonsticky substances) are created so that the surface area of the microparticles is much greater than that of the reactor wall. The corrosive species generated in SWO deposit on the

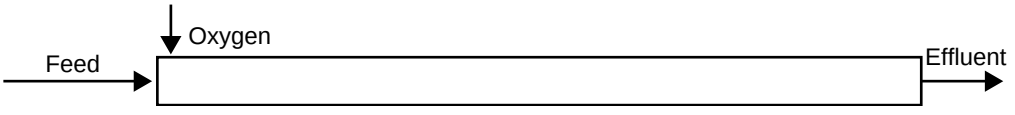

Fig. 3 Tube SWO reactor.

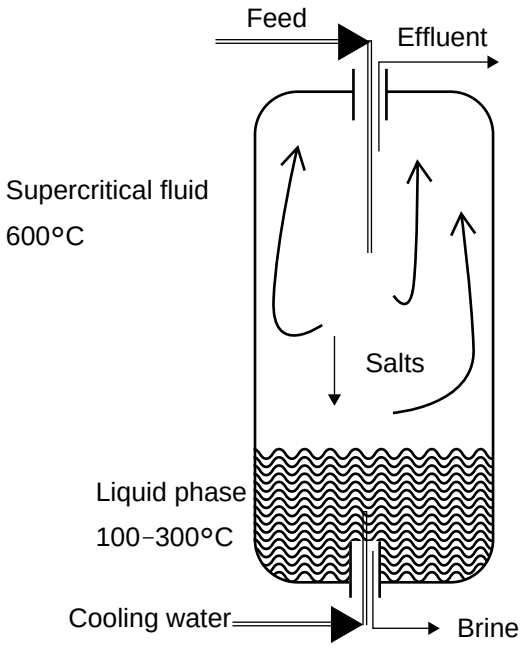

Fig. 4 Reverse-flow tank reactor with provision for the removal of salts.

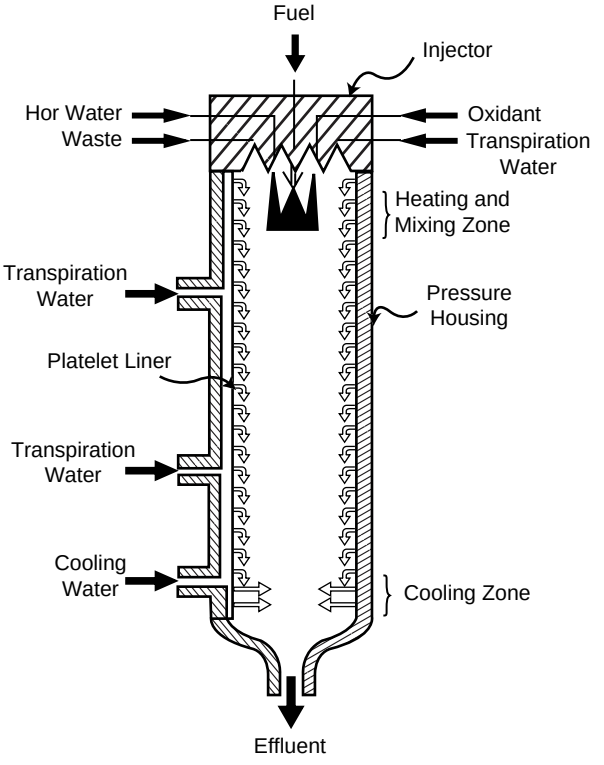

Fig. 5 Transpiring wall reactor. (From Ref.[4].)

microparticle surface and not the reactor wall. Thus, the reactor wall is protected. A schematic of the microparticulate reactor concept is shown in Fig. 6

Sodium carbonate is soluble in ambient water but is insoluble in supercritical water; the microparticles are generated as a result of the antisolvent effect of supercritical water. Because the surface area per unit mass for sodium carbonate microparticles is high, only a small amount of sodium carbonate needs to be injected in the reactor. For example, only 0.5 wt% sodium carbonate is able to provide a microparticle surface area about 100-fold that of the reactor wall.

In addition to protection against corrosion, the microparticles can also be highly catalytic for the oxidation of organics. The reaction time needed for complete oxidation can be reduced several fold. The significant catalytic activity is due to the newly generated irregular surface on the sodium carbonate microparticles. The organic molecules attach to the surface and become more susceptible to oxidation.

Additional reactor designs and flow configurations are described in the recent review paper by Marrone et al.[6]

Partial Oxidation in Supercritical Water

Complete oxidation in supercritical water occurs at a high rate; usually, complete conversion to carbon dioxide is achieved in the reaction time of about 1 min for most organics. New applications of supercritical water are emerging where only partial oxidation is carried out and oxygenated hydrocarbons are produced. Here, the reaction time has to be limited to the order of seconds.

Richter and Vogel oxidized cyclohexane in supercritical water for a varying reaction time from 5 to 80 sec range.[7] The partial oxidation resulted in the desired cyclohexanone product, but the yield was very low (Fig. 7). The by-products included carboxylic acids, carbon monoxide, and carbon dioxide.

The higher oxygenate by-products (carboxylic acids, CO, CO_2) are not desired; these were formed as a result of too much oxidation. These compounds were formed for even the lowest reaction time of 5 sec used in this

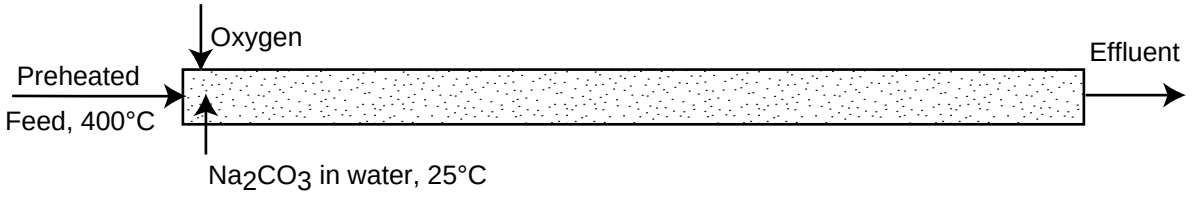

Fig. 6 Microparticulate catalytic reactor. (From Ref. [5].)

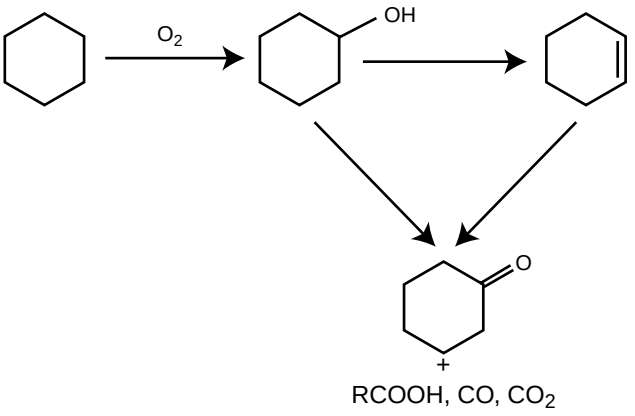

Fig. 7 Partial oxidation of cyclohexane in supercritical water.

study. Hence, even lower reaction times are required to limit the oxidation.

For the reaction time of less than 1 sec, a special quick-heating quick-quenching reactor (SWQH-QQ) was developed by Ikushima et al., as shown in Fig. 8.[8] The organic stream is mixed with the preheated water stream using a T-joint so that the process stream is heated in merely 0.05 sec. The reactor is composed of a small tubing of 50 μL volume. After the reaction the mixture is again quickly quenched to stop the reaction.

This reactor was tested for the production of ε-caprolactam from cyclohexanone-oxime (Fig. 9).

The various reaction conditions explored are listed in Table 3, where these are compared with the conventional techniques. Almost complete selectivity and yield were obtained when the oxidation was carried out for 0.7 sec in supercritical water containing 0.04–0.9 mM acid catalyst.

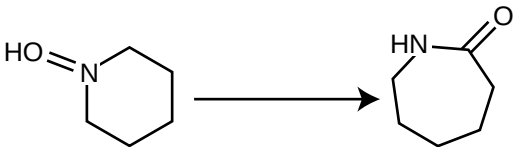

Fig. 9 Conversion of cyclohexanone-oxime to ε-caprolactam.

For commercial scale production, one would need to employ an array of microreactors. For example, a 50 mL microreactor can produce 0.25 kg of product per day, whereas an array of 1000 microreactors can produce 0.25 tons of product per day.

Safety and Health Issues

When dealing with supercritical water, there are two safety and health issues that are to be kept in mind when designing and operating the reactor: 1) the high pressure involved requires that personnel is protected from the plant by proper isolating walls and 2) the high temperature involved requires proper heat protection. Because of the concern of corrosion, reactor rupture is a possibility. Effluent water from the reactor should be checked for the presence of metal ions for on-line diagnostics of corrosion. In addition, periodic shut down and maintenance is very important. Additional safety concerns are due to the presence of high-pressure air or oxygen.

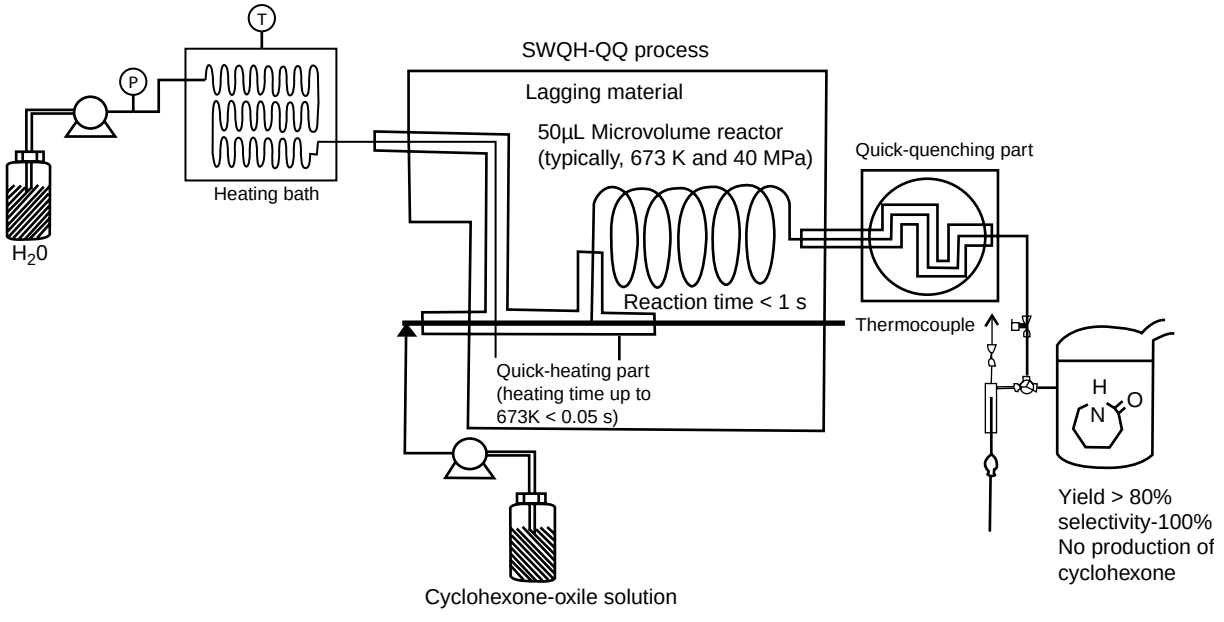

Fig. 8 Quick-heating quick-quenching supercritical oxidation reactor. (From Ref.[8].)

Table 3 Production of ε-caprolactam from cyclohexanone-oxime via various techniques

Reactor	T (°C)	P (bar)	Reaction time (sec)	Selectivity (%)	Yield (%)

CONCLUSIONS

Supercritical water offers a unique reaction environment. Most organic compounds and oxygen are fully miscible in supercritical water. Use of excess oxidant and about a minute of reaction time can usually cause complete oxidation of the organics to carbon dioxide. Hence, SWO is emerging as an alternative technology to incineration for waste treatment from a variety of sources. However, current challenges are due to reactor corrosion and plugging when acid forming compounds are present in the feed. If the oxidation is carried out with limited oxygen or for a limited time (say milliseconds), intermediate oxygenated products are obtained. The partial oxidation can be used to produce the oxygenated products.

Synthesis Gas

Kim Aasberg-Petersen
Haldor Topsøe A/S, Lyngby, Denmark

INTRODUCTION

Synthesis gas (syngas) is a gaseous mixture containing mainly hydrogen, carbon monoxide, and carbon dioxide in various amounts. In most cases, these three compounds constitute more than 90% of the syngas, but other components including methane and inert gases such as nitrogen and argon are often present in the mixture. Syngas is only seldom a product by itself, and its major role is as a key intermediate in the synthesis of a range of chemicals. Syngas may in principle be produced from any carbon-containing feedstock, but today only coal and hydrocarbons are used as raw materials to any significant extent. New plants are normally designed based on natural gas or other hydrocarbon feedstock, because the investment is only about one-third of that of a plant based on coal. The production of synthesis gas depends upon the type of feedstock and the desired end product.

Today, synthesis gas is mainly used for the production of ammonia (120×10^6 t/yr[a]) and methanol (30×10^6 t/yr[a]) followed by pure hydrogen for hydrotreating in refineries. Other current applications are in the production of higher alcohols by hydroformulation and a number of products including acetic acid, formaldehyde, dimethyl ether (DME), and methyl-*tert*-butyl ether (MTBE); in all cases methanol is used as a coreactant.

In recent years, new areas have emerged that may open the way for an increased production and use of synthesis gas. One example is the large-scale production of syngas using synthetic hydrocarbon fuels, produced by the Fischer–Tropsch synthesis. Similarly, a considerable effort is currently being undertaken in the development and commercialization of various types of fuel cells for both small- and large-scale power production. A successful market introduction will require efficient and cost effective technologies for converting the hydrocarbon feedstock into a syngas that is acceptable for the fuel cell. This entry describes the applications of syngas and focuses on the technologies for its production using hydrocarbon feedstock. The role of the catalysts and key parts of the technologies is outlined and the reasons for deactivation are emphasized. The main criteria for selection of the optimum route for syngas production for various applications are also described.

REQUIREMENTS TO SYNGAS PROPERTIES

The capital cost of the synthesis gas often accounts for more than 50% of the cost of the complete plant. The optimal choice of technology depends upon the size of the plant and the desired syngas composition for the subsequent synthesis. In Table 1, the optimum syngas composition for a range of final products is given.[1]

For most of the chemical products given in Table 1, the synthesis takes place at elevated pressures from typically 20 bar and above. Most syngas plants operate at 20–40 bar, although the thermodynamics shows that higher conversions can be obtained at lower pressures. However, the cost associated with larger equipment and syngas compression renders often syngas manufacture at low pressures prohibitive for these applications.

For fuel cell applications, the situation is often the reverse. With power as the end product, the compression of air should be minimized, especially in (small) plants in which coupling with turbine systems is not economical. The requirement for the syngas production in this case is a simple and low-cost design with a low pressure drop.

SYNGAS MANUFACTURE

The production of syngas from natural gas and other hydrocarbons takes place by steam reforming, partial oxidation, or combinations thereof.

Steam Reforming

Steam reforming is highly endothermic, involving the reactions listed in Table 2.[2] High temperatures and the addition of a significant amount of steam are needed to obtain maximum conversion as illustrated in Fig. 1.[1] Steam reforming is always accompanied by the shift Reaction (2) in Table 2, which is generally fast and can be considered in equilibrium at most conditions. Steam can be partially substituted for CO_2 to reduce the (H_2/CO) ratio in the product gas. This effect is illustrated in Fig. 2, which also shows that the methane conversion is almost unaffected as long as the $(H_2O + CO_2)/CH_4$ ratio is constant.

A considerable amount of heat input is needed to achieve sufficient conversion of methane at high

temperatures. As an example, above 10 MJ/Nm^3, CH_4 is needed for converting a feed of methane at 600°C and steam ($S/CH_4 = 2.5$) to its equilibrium composition at 900°C at 25 bar. Normally, the reaction takes place in high alloy tubes filled with nickel catalysts placed in a furnace. The heat is supplied by a series of burners placed on the walls of the furnace. The furnaces are designed with a variety of burner arrangements as illustrated in Fig. 3.[3] In industry today, the top-fired and side-fired reformers are, in most cases, used for new plants. The industrial reformer consists of a box-type radiant section including the burners and a convection zone to recover the waste heat of the flue gas that is leaving the radiant section.

The reformer tubes typically have a length of 10–13 m and outer diameters that do not exceed 15 cm. The tubes are mostly designed for maximum heat transfer taking into account the mechanical limitations when considering the heat flux and temperature. Tubular reformers are today designed for an average heat input exceeding 100,000 $kcal/m^2/hr$.[1]

The typical inlet temperatures to the reformer are 450–650°C and the exit temperatures typically range from 700°C to 950°C, depending on the type of feedstock and the application. A tubular reformer can be designed with capacities up to the equivalence of 300,000 Nm^3/hr of syngas.[1]

In general, the gas leaving a steam-reforming reactor is close to chemical equilibrium for Reaction (1) in Table 2. In industry, the approach to equilibrium at the outlet of the reformer tubes is expressed by a temperature difference defined by:

$$\Delta T_R = T(\text{exit catalyst}) - T(Q_R) \quad (5)$$

Table 2 Steam reforming reactions

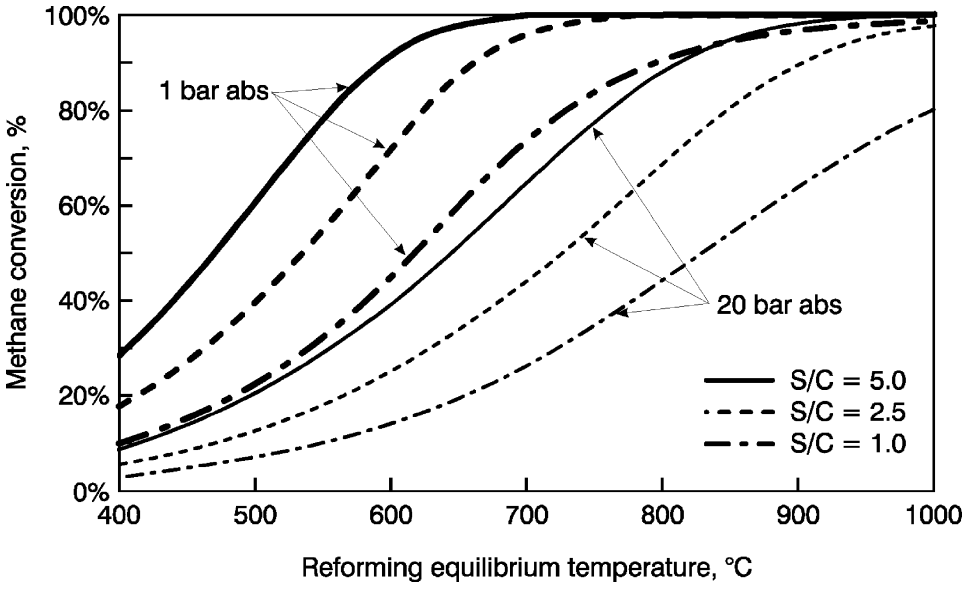

Fig. 1 Equilibrium methane conversion at various H_2O/CH_4 (S/C) ratios at 20 bar abs. (From Ref.[1].)

$T(Q_R)$ is the equilibrium temperature for the reaction corresponding to the reaction quotient Q_R, calculated by:

$$Q_R = \frac{P_{CO}\, P_{H_2O}^3}{P_{CH_4}\, P_{H_2O}}$$

P is the partial pressure of the gases at the reformer exit. T_R is usually less than 10–15°C throughout the catalyst lifetime. The thermal efficiency of a tubular steam reformer with waste heat recovery system approaches 95% of which 50–60% is transferred to the process.[4] The remaining heat is recovered by production of steam, preheating of air, feedstock, etc.

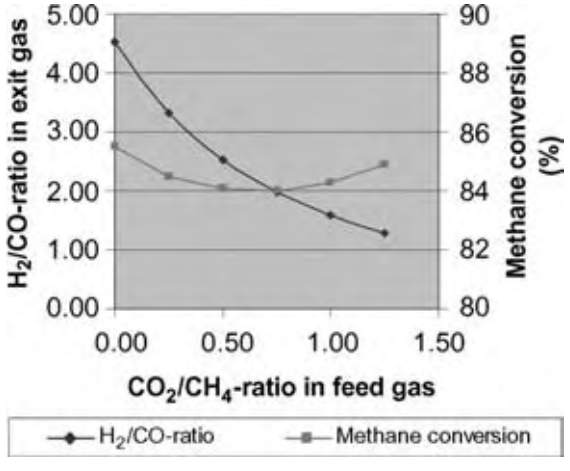

Fig. 2 Methane conversion and H_2/CO-ratios in combined CO_2- and steam reforming. $\frac{H_2O + CO_2}{CH_4} = 2.5$. *(View this art in color at www.dekker.com.)*

Other types of more compact steam reformers are also used. In most cases, the heat transfer is then accomplished by convection with the reformed gas itself, a flue gas, or by a combination as illustrated in Fig. 4.[5] In this case, about 80% of the heat is transferred to the process and export of steam from the plant can be reduced or avoided.

Another type of steam-reforming reactor that is attracting increasing attention is known as gas heated reformers or heat exchange reformers. In such reformers, heat is transferred by convection and the heat source is a hot process gas from another reformer or a partial oxidation reactor. A number of different installations of heat exchange reformers can be envisaged. In Fig. 5, the installation of a heat exchange reformer either in series or in parallel to an autothermal reformer (ATR) is illustrated.

In the series arrangement, all the feed pass through both the reformers. Both the amount of gas and the driving force for heat transfer are highest with a series scheme. The feed is split into two parts in the parallel arrangement, allowing the possibility of using different inlet gas compositions. The heating gas and the gas leaving the catalyst section are mixed in the scheme illustrated in Fig. 5. In principle, a parallel scheme without mixing the two gasses is also possible.

The use of heat exchange reformers decreases the steam export and the consumption of feed and fuel, in plants using only steam reforming. The efficiency is increased and the oxygen consumption is reduced in plants with a combination of partial oxidation and heat exchange reforming. As an example, process simulations show that the efficiency of a syngas generation unit in a plant for production of synthesis fuel increases approximately 5% by introducing a heat

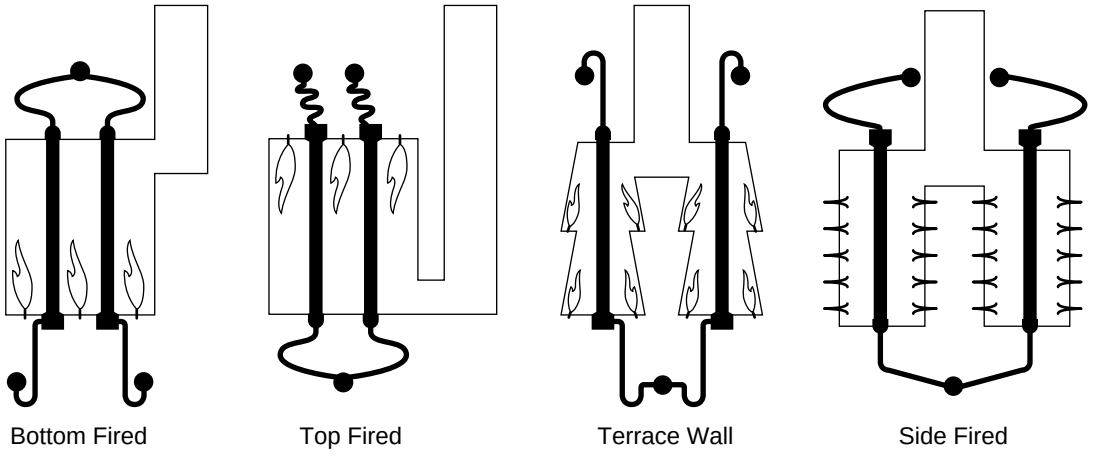

Fig. 3 Typical configurations of reformer furnaces. (From Ref.[3].)

exchange reformer in combination with autothermal reforming.[27] This combination also reduces the required amount of oxygen by 5–10% as compared to autothermal reforming alone.

A typical layout of the steam-reforming section of a syngas plant with hydrocarbon feedstock is illustrated in Fig. 6. The first step is purification of the feedstock to remove sulfur so as to avoid poisoning of the downstream reformer catalysts. This is typically accomplished in a two-step process. In the first step, organic sulfur compounds are converted into hydrogen sulfide by a hydrogenation catalyst. In the second step, H_2S is absorbed by zinc oxide by the following reaction:

$$ZnO + H_2S \Leftrightarrow ZnS + H_2O \quad (6)$$

The desulfurization typically takes place at temperatures between 200°C and 400°C, depending on the sulfur compounds of the feed. Carbon dioxide in the feed may react with hydrogen to generate steam, which may push the equilibrium of Reaction (6) to the left and increases the sulfur leakage. This must be considered in the design of the desulfurization section, and special methods exist to eliminate sulfur leakages in this case also.

In many (but not all) situations, an adiabatic prereformer is located upstream the main reformer to convert the higher hydrocarbons (hydrocarbon compounds with two or more carbon atoms) into an equilibrated mixture of carbon oxides, methane, hydrogen, and steam. Prereforming takes place at temperatures between 350°C and 550°C, depending on the feedstock. The prereforming step allows the use of higher preheat temperatures for the feed in the tubular reformer without the risk of cracking of the higher hydrocarbons, which may result in carbon formation on the catalyst and/or cause fouling of heat exchangers. A higher preheat temperature increases the energy efficiency and reduces the size of the steam reformer. Prereforming of LPG, naphtha, and refinery off-gas is practiced in the industry, allowing significant feedstock flexibility. The feasibility of prereforming of logistic fuels of interest to the fuel cell market has been demonstrated in pilot plant tests.[8]

The heat in the exit gas is recovered downstream the tubular reformer, usually by the production of steam, preheating of boiler feed water, etc. The final separation into the desired product compositions depends on the application. Pressure swing adsorption (PSA) is in most cases used if pure hydrogen is desired. Pure carbon monoxide can be obtained by cryogenic separation in a cold box. Adjustment of the H_2/CO ratio can be accomplished by polymer membrane modules with different selectivities for permeation of the two compounds.

Steam-Reforming Catalysts

Most steam-reforming catalysts are based on nickel as the active material. Also, cobalt and noble metals catalyze the steam-reforming reaction, but they are generally too expensive to find widespread use. A number of different carriers including alumina, magnesium–aluminum spinel, zirconia, and calcium aluminate are employed.

The activity of the catalyst is roughly proportional to the surface area of nickel used. In an adiabatic prereformer, a high activity is desired to maximize the space velocity. In a tubular reformer the activity may be of less significance because the reactor volume is settled by mechanical criteria. Most industrial tubular reformers operate at space velocities of 2000–4000 hr^{-1}. However, equilibrium conversion can be achieved at much higher space velocities, exceeding 10^4–10^5 $Nm^3/m^3/hr$, as determined by extrapolation

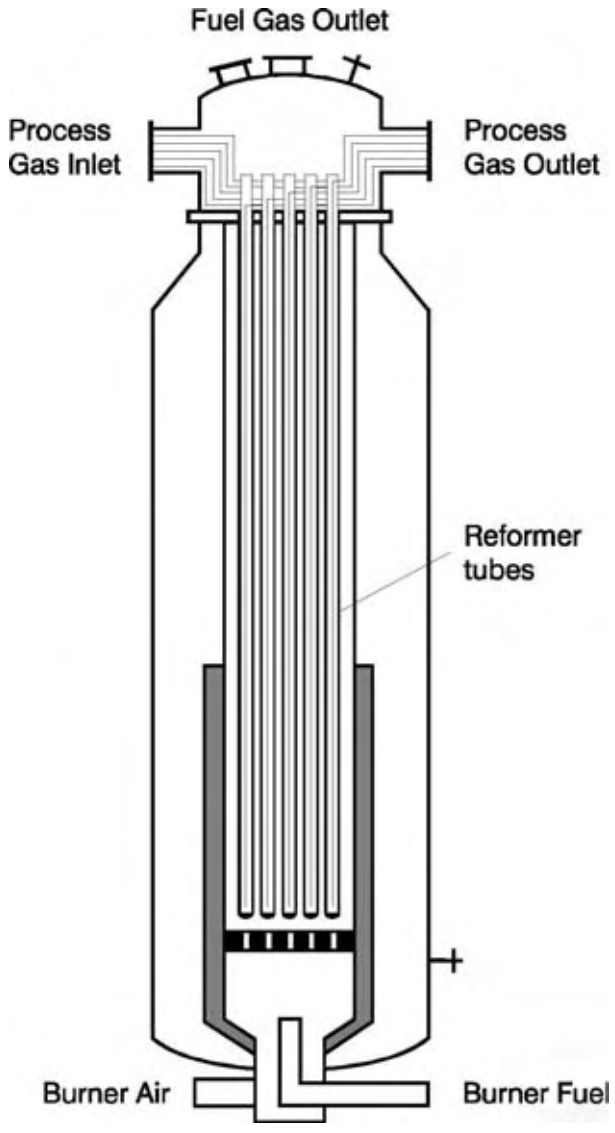

Fig. 4 Schematic illustration of a compact convection reformer. (From Ref.[5].)

of intrinsic rates.[1] Higher intrinsic rates can be obtained with noble metals where especially rhodium and ruthenium exhibit very high activities.[9]

Higher hydrocarbons are more reactive than methane, with aromatics showing the lowest reactivity as illustrated in Fig. 7.

Catalyst Deactivation

Steam-reforming catalysts may deactivate because of sintering, poisoning, or by carbon formation.

The mechanism for sintering is migration and coalescence of nickel particles on the carrier surface, leading to a smaller surface area.[11] Sintering is a complex process influenced by several parameters including chemical environment, catalyst structure and composition, and support morphology. Factors that enhance sintering include high temperature and high steam partial pressure.[11]

Steam-reforming catalysts are susceptible to sulfur poisoning. At reforming conditions, all sulfur compounds are converted to hydrogen sulfide, which is chemisorbed on the metallic surface

$$H_2S + Ni \leftrightarrows Ni - S + H_2 \quad (7)$$

This surface layer has a structure like a two-dimensional sulfide. The adsorption takes place well below the H_2S/H_2 ratio that is needed to form bulk nickel sulfides.

With an H_2S/H_2 ratio in the gas of 1 ppb, the equilibrium surface coverage of nickel at 500°C is around 70%. This means that all sulfur in the feed is quantitatively adsorbed on the nickel catalyst of a prereformer. The result is not only the deactivation of the prereformer catalyst even at very low sulfur levels, but also the protection of downstream catalysts from poisoning.[13] Sulfur uptake on the catalyst will initially take place as shell poisoning and because of pore diffusion restrictions, it may take years before sulfur reaches the center of the particle.[12]

Other components that poison the reformer catalysts include silica and alkali metals. Silica may act by blocking the pore mouth of the catalyst. The alkali metals reduce the turnover frequency of the catalyst.[12]

Steam reforming involves the risk of carbon formation especially when operating at low steam-to-carbon (S/C) ratios to decrease the H_2/CO ratio. Carbon may be formed from higher hydrocarbons, methane, or carbon monoxide as illustrated in Table 3.

A typical mechanism for carbon formation is the formation of whisker structures on the catalyst. Adsorbed hydrocarbons may react and form adsorbed carbon, which is dissolved in the nickel particle. After saturation, carbon may nucleate and grow with the nickel crystal at the tip.[13]

The whisker carbon has a higher energy than graphite.[13] Hence, operation in conditions at which thermodynamics would predict the formation of graphite is feasible without carbon formation on the catalyst. In Table 3, the equilibrium constant for whisker carbon formation from methane on a nickel catalyst is given. The equilibrium constant depends on the size of the nickel crystals, with smaller sizes resulting in lower values. The risk of whisker carbon formation from methane at equilibrium may be assessed by the so-called ''principle of equilibrated gas.'' According to this principle, carbon will form if there is a potential for carbon formation [according to Reaction (8) in Table 3] after equilibration of the gas mixture at the given temperature and pressure.[13] It can be shown that this thermodynamic carbon

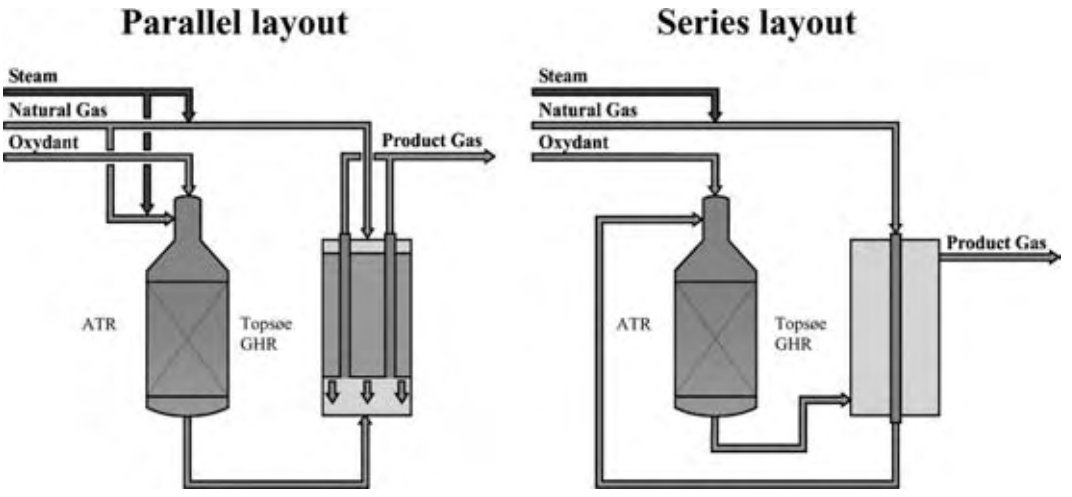

Fig. 5 Series and parallel arrangement of heat exchange reformers with ATR as the main reformer. (From Ref.[27].) *(View this art in color at www.dekker.com.)*

limit is a function of pressure, temperature, and the feed gas composition expressed as atomic ratios (O/C and H/C).[10]

Lower equilibrium constants for carbon formation from methane can be obtained by using noble metals.[9]

The irreversible formation of carbon from higher hydrocarbons on the catalyst may be in the form of either a type of gum layer or a whisker carbon. Gum formation is polymerization of higher hydrocarbons adsorbed on the catalyst surface into an encapsulating film on the nickel surface.[12] Low temperature, highly aromatic feedstock, and low amount of steam and hydrogen compared to the content of higher hydrocarbons are among the factors known to enhance the risk of gum formation. Deactivation by gum formation is mainly relevant for prereforming, but may be very fast especially at low temperatures.[7,12]

Higher hydrocarbons do not exist at equilibrium and any risk of whisker formation from these compounds can be disregarded at these conditions. Nevertheless whiskers may still form from higher hydrocarbons because at nonequilibrium conditions a potential for the irreversible carbon formation [e.g., Reaction (11) in Table 3] may exist. The formation of whisker carbon at these conditions depends on a kinetic balance between the rate of the carbon forming and steam-reforming reactions. A simplified reaction sequence outlining the kinetic balance is shown in Fig. 8. The key step is whether the adsorbed hydrocarbon species will react to form adsorbed carbon and whiskers or react with oxygen species to produce gas.[13]

The risk of carbon formation from higher hydrocarbons depends also on the type of hydrocarbon. Olefins will result in rapid carbon formation on the

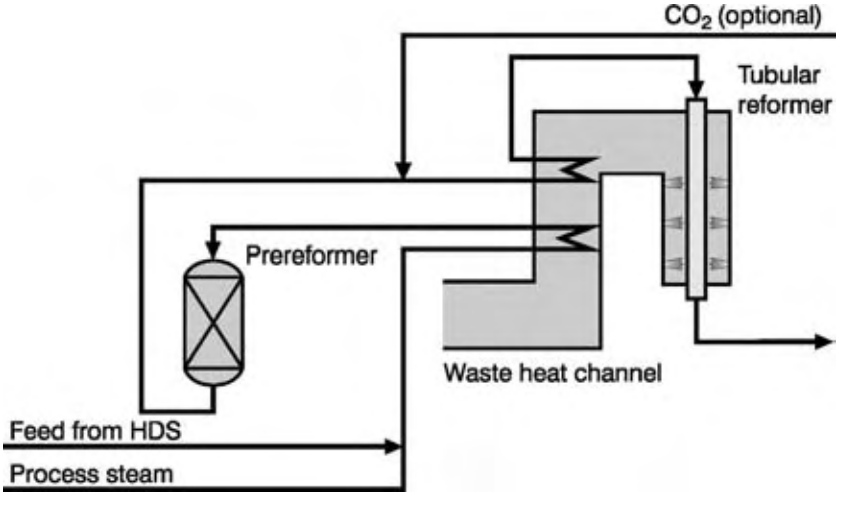

Fig. 6 Schematic layout of the steam-reforming section of a syngas plant with hydrocarbon feedstock. HDS, hydrodesulfurization. (From Ref.[7].) *(View this art in color at www.dekker.com.)*

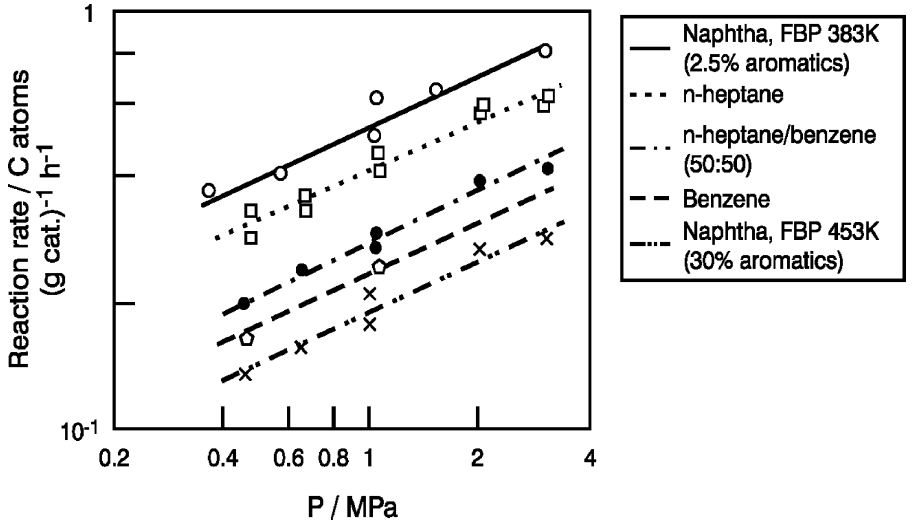

Fig. 7 Reactivity of liquid hydrocarbons. $H_2O/C = 4$ mol/mol C, 500°C, 20 bar. (From Ref.[10].)

catalyst, and aromatic compounds are in general more critical than paraffins.[10,13] Operation at low S/C ratios and at high temperatures increases the risk of whisker carbon formation from higher hydrocarbons. As indicated above, the risk of carbon formation must be assessed by a complex analysis involving the kinetics of both the carbon forming and the steam-reforming reactions.

It is imperative that carbon formation is avoided in tubular reformers. Carbon formation may lead to the breakdown of catalysts resulting in an uneven flow distribution between different tubes in the reformer, causing local overheating and shorter tube life. Formation of pyrolytic carbon may result in carbon deposits near the tube wall. This may lead to a reduced heat transfer coefficient and development of ''hot bands'' as evidenced by the reddish zone on the tube wall during operation.

One method that is used to prevent carbon formation is to promote the steam-reforming catalyst with alkali, usually potassium.[14] Alkali serves to increase the resistance to carbon formation on the catalyst and promotes the carbon (re)gasification.[14]

Carbon formation from carbon monoxide on the catalyst may take place according to Reaction (9) by a route similar to methane. However, decomposition of carbon monoxide may also occur on the surface of equipments such as heat exchangers downstream the tubular reformer (or the partial oxidation reactor). A given gas will have potential for carbon formation from carbon monoxide below a certain temperature by either Reaction (9) or Reaction (10) in Table 3. In this case, carburization of the metallic components may occur leading to a severe type of corrosion known as metal dusting. Metal dusting is, at least in its initial stages, often characterized by a series of spot attacks known as pits. Metal dusting may be very rapid and may lead to quick failure of equipment. Irrespective of the thermodynamic potential, metal dusting will not occur if the metal surface temperature is low enough.

In heat exchange reformers, special precautions must be taken to avoid corrosion. In such reformers the metal temperature is often high enough for metal dusting to occur and low enough for thermodynamic potential to exist. Special alloys or other techniques are needed to prevent metal dusting in these cases. This area is the subject of considerable research to widen the limits of operation to more severe operating conditions.

Partial Oxidation

Several processes, including noncatalytic partial oxidation (POX), catalytic partial oxidation (CPO), and ATR may be used to perform partial oxidation of hydrocarbons. In all cases, some or all of the reactions listed in Table 4 are involved. Normally, these reactions are accompanied by the steam-reforming and shift reactions. The oxidation reactions are irreversible at all conditions of practical interest.

The feed to the partial oxidation reactor is a mixture of hydrocarbons, steam, and air or oxygen (or mixtures thereof). The reactor is in general adiabatic or autothermal and the exit gas is in many cases close to equilibrium at the exit temperature and pressure at chemical equilibrium. The exit composition can be determined based on the inlet temperature and composition, and on the assumption that all oxygen has reacted. In Fig. 9, product gas compositions are given at various conditions with oxygen as oxidant, assuming that chemical equilibrium is obtained.

The overall reaction in a partial oxidation reactor is highly exothermic. The desired reactions may be accompanied by thermal cracking of hydrocarbons or oxidative dehydrogenation into nonsaturated compounds including olefins, polyaromatics, and soot. The control of the heat balance and the formation of by-products are important considerations in the design of partial oxidation reactors.

Noncatalytic Partial Oxidation

In noncatalytic partial oxidation reactors for the production of syngas, the feed is substoichiometrically combusted with oxygen in a burner designed for intensive mixing of the reactants.[15] A small amount of steam may be added to the oxygen to moderate the flame temperature.[16] Plants based on POX are and have been used for the production of hydrogen for refineries and syngas for methanol (and ammonia) synthesis. No catalyst is included in the reactor.

A key part of the POX reactor is the burner. The burner must be able to withstand the highly severe conditions in the combustion chamber. A multiorifice coannular burner with alternative passages for feed and oxidant is described in Ref.[28].

Partial oxidation units may operate with feedstock, ranging from natural gas to heavy oil fractions such as asphalt.[15] Heavy feedstock may contain large amounts of both sulfur and heavy metals. In many cases these compounds are removed from the raw syngas downstream the POX reactors. Some residual carbon or soot may be formed in the combustion chamber of the reactor.[15] To avoid the carbon lay-down in the heat exchanger downstream the POX reactor, special coils and high gas velocity are used. The carbon may be removed downstream the heat exchanger in a suitable water wash or scrubbing system.[15,16]

Table 4 Reactions occurring in partial oxidation of methane

Reaction no.		
12	$CH_4 + \frac{1}{2}O_2 \rightarrow 2H_2 + CO$	$-\Delta H^0_{298} = +38\,kJ/mol$
13	$CH_4 + O_2 \rightarrow CO + H_2O + H_2$	$-\Delta H^0_{298} = +278\,kJ/mol$
14	$CH_4 + 3/2O_2 \rightarrow CO + 2H_2O$	$-\Delta H^0_{298} = +519\,kJ/mol$
15	$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$	$-\Delta H^0_{298} = +802\,kJ/mol$

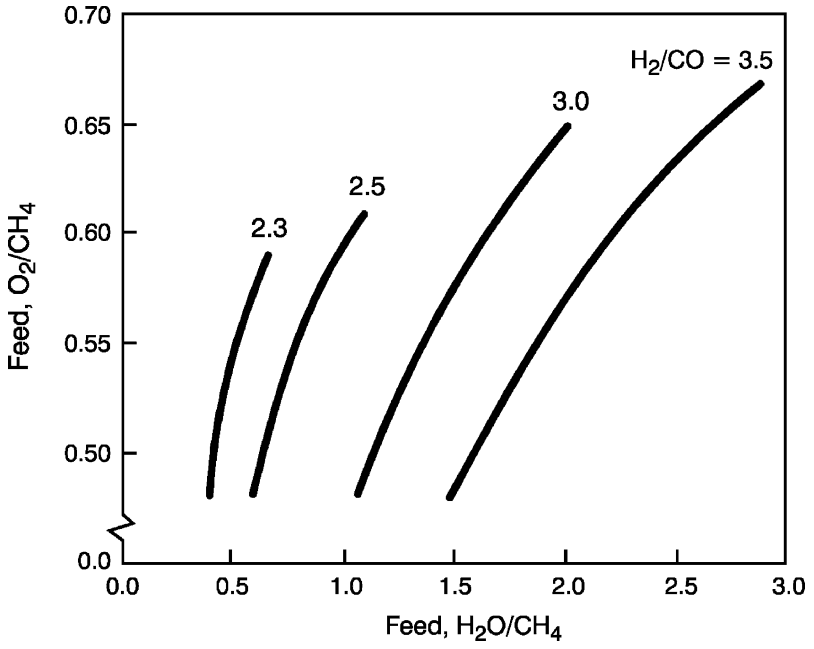

Fig. 9 H_2/CO ratios in exit gas from partial oxidation reactor. (From Ref.[22].)

The H_2/CO ratio produced by POX units is often 1.7–1.8 with natural gas as feed. Addition of steam to increase this ratio may not be feasible because the resulting lower exit temperature could substantially increase the amount of carbon formed in the reactor. In some cases the POX reactors may be combined with steam reforming in parallel if a higher H_2/CO ratio is required. This combination has been used in a plant for producing hydrocarbons in Malaysia.[29] A similar concept will be used for a large plant that is to produce synthetic hydrocarbons to be located in Qatar.

Catalytic Partial Oxidation

In catalytic partial oxidation, no burner is used. The hydrocarbon feedstock and the oxidant are mixed in an inlet zone and pass to the catalyst where the reaction takes place. Catalytic partial oxidation is today considered by many as a (potential) technology for producing syngas at very high space velocity and short contact time. As such, CPO is under development. It is considered by many as a promising technology for converting hydrocarbons into a syngas that is useful for fuel cells. Larger-scale applications may also be feasible.

A CPO reactor may operate adiabatically, and operation without preheat of the feedstock during normal operation is feasible. The reactor may be very compact, and complete conversion of oxygen has been demonstrated at atmospheric pressure with space velocities exceeding 500,000 hr^{-1}.[17] Catalytic partial oxidation can, at least with natural gas feed, be operated without steam in the feed. It has been catalytically proven that CPO at elevated inert temperature and pressure is feasible.[18,19]

The reactor is often divided into a mixing zone and a reaction zone with catalyst; both are normally refractory lined. Safety is a prime concern in the design of CPO reactors. The mixing of the hydrocarbon feed with air or oxygen involves the risk of thermal ignition and even explosion. Ignition may for example occur if the gas composition is between the lower and upper flammability limits of the mixture or if the temperature is above the autoignition temperature. In Table 5, the flammability limits for selected compounds in air are given.

The flammability limits depend on the temperature and pressure. At elevated temperatures and pressures, a given mixture may be flammable, even if this is not the case at ambient conditions. It is a key objective of the design of the inlet zone of a CPO reactor to prevent ignition and thermal combustion.

The surface temperatures of the catalyst may be very high. Some CPO reactors are designed with shields between the catalyst zone and the mixing zone

Table 5 Lower (LFL) and upper (UFL) flammability limits for hydrocarbons in air at ambient temperature and pressure

Fuel	LFL (vol.%)	UFL (vol.%)
Methane	5	15
Ethane	2.9	13
Propane	2.3	9.5
n-Octane	0.8	6.5

(From Ref.[20].)

to avoid ignition that could be caused by back radiation. The catalytic zone can be very compact because of the high rate of reaction. Catalysts primarily in the form of pellets and monoliths (or foams) are used. It may be desirable to use monoliths in cases (e.g., for fuel cells) where the pressure drop should be minimized.

Most CPO catalysts are based on noble metals on a ceramic carrier. The use of a number of different carriers including zirconia and alumina has been reported. Most of the noble metals and nickel are active for CPO, and rhodium is probably the superior metal and is in general superior to platinum at comparable conditions.[17]

The performance of a CPO reactor is, in the literature, often characterized by the hydrocarbon conversion and selectivities to carbon monoxide and hydrogen. Methane conversion and selectivities are often reported to be more than 80–90%. This corresponds in general to conditions at which the exit gas is close to equilibrium for the shift reaction and the methane steam-reforming reaction with a low value of ΔT_R in Eq. (5). The most likely reaction sequence is total oxidation in the initial part of the catalyst zone followed by other reactions including steam-reforming, shift, and possibly partial oxidation.

Autothermal Reforming

Autothermal reforming combines partial oxidation and adiabatic steam reforming for conversion of the hydrocarbon feedstock into synthesis gas free of soot and higher hydrocarbons. The ATR reactor design consists of burner, combustion chamber, and catalyst bed placed in a refractory lined vessel, as illustrated in Fig. 10. The hydrocarbon feedstock with steam is reacted with oxygen in a substoichiometric flame, often represented by Reaction (14) in Table 4. Typically, the molar ratio of oxygen (as O_2) to carbon in the hydrocarbon feed stream is 0.5–0.6, depending on the application. The steam-reforming and water gas shift reactions do also take place thermally to some extent in the combustion chamber. The temperature in the core of the flame may be higher than 2000°C and the design of the combustion chamber is made to minimize the transfer of heat to the burner. All oxygen is consumed by the reactions in the thermal zone.

Residual methane is present at the exit of the combustion zone. In the catalytic bed, the methane steam-reforming and the water shift reactions take place. The gas leaving the ATR reactor is in chemical equilibrium. Normally, the exit temperature is above 900–1100°C. The catalyst must withstand very severe conditions when exposed to very high temperatures and steam partial pressures. One example of an ATR catalyst is nickel supported by magnesium aluminum spinel. For compact design, the catalyst size and shape is optimized for a low pressure drop and high activity.

Autothermal reformer has been used for the production of syngas since the late 1950s. In the early years its main application was for production of syngas for methanol and ammonia. The ATR was operated at high S/C ratio to maximize the yield of hydrogen, especially for the latter application. Later developments in the 1990s have proven its operability at low S/C ratios. Industrial demonstration at S/C = 0.6 was carried out in 1999[26] and at these conditions, the first industrial plant was started in 2002.[22] This technology at low S/C ratio will also be used for syngas generation in a plant in Qatar for production of synthesis fuels with a capacity of 34,000 barrels/day, to be started in 2006.

A typical process diagram for producing syngas with ATR is shown in Fig. 11.[23] Adiabatic prereforming

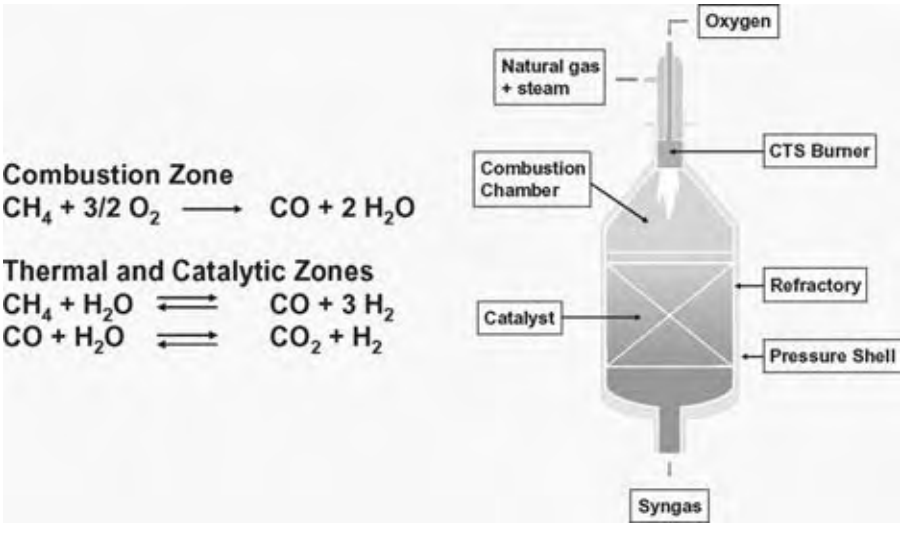

Fig. 10 Autothermal reforming reactor. *(View this art in color at www.dekker.com.)*

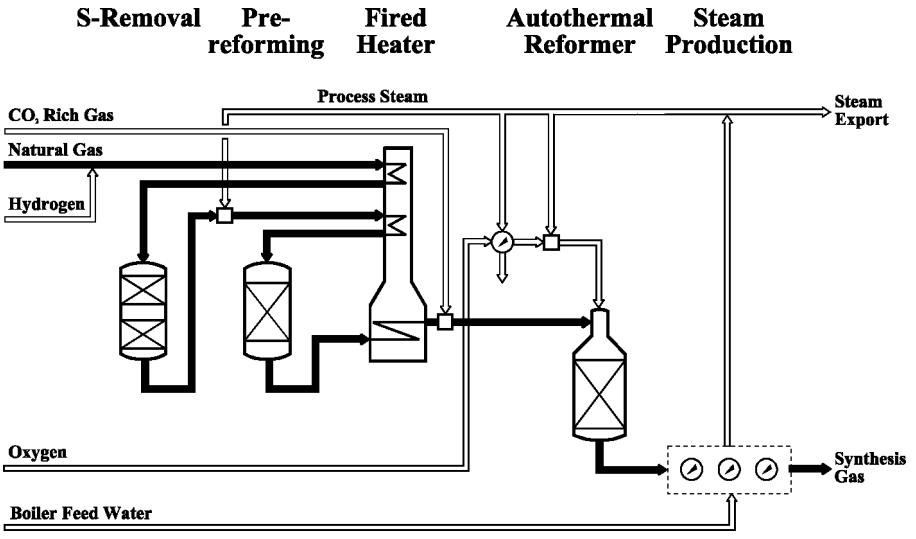

Fig. 11 Typical process diagram for an ATR-based plant for production of syngas. (From Ref.[23].)

of the hydrocarbon feedstock allows a higher preheat temperature without the risk of thermal cracking and reduces the oxygen consumption and the total plant investment. In the scheme given in Fig. 11, a fired heater is used for feed preheat. A carbon dioxide-containing stream can be added to the reactor feed stream to adjust the H_2/CO ratio in the syngas to the desired value. In a plant for the production of synthetic fuels, a tail gas from the Fischer–Tropsch synthesis can be used.

Autothermal reformer involves the risk of soot formation, especially when operating at low S/C ratios. The combustion in the flame proceeds through a large number of homogeneous radical reactions. The local stoichiometry in the flame zone will vary from being very fuel lean to very fuel rich. Fuel-rich combustion may lead to incomplete conversion of hydrocarbons in the feedstock into to nonsaturated compounds including ethylene and acetylene.[21,22] These compounds may be considered as precursors for the formation of polyaromatic hydrocarbons and soot, as illustrated by the simplified mechanism given in Fig. 12.[21] It is essential that the design and operating conditions are selected in such a way that the soot precursors are converted into syngas by the catalytic bed. One element is to ensure intensive mixing of the feed and oxidant by proper design of the burner.

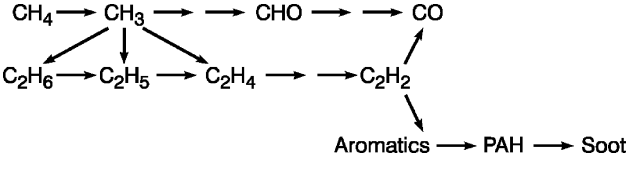

Fig. 12 Simplified model for the formation of soot in an ATR. (From Ref.[22].)

For a given design, the operating conditions determine whether or not soot is present in the exit gas from the ATR. High temperatures in the combustion chamber and sufficiently high amounts of steam in the feed suppress the formation of soot. Pilot plant experiments show that soot free operation at S/C ratios well below 0.6 is feasible.[6,21]

Ceramic Membrane Reforming

A large part of the cost of a syngas production plant based on partial oxidation is for the air separation unit. Continuous research efforts are going on for reducing the cost of this step. One possibility is to use oxygen-selective membranes integrated in a partial oxidation reactor, as illustrated in Fig. 13. Air is introduced

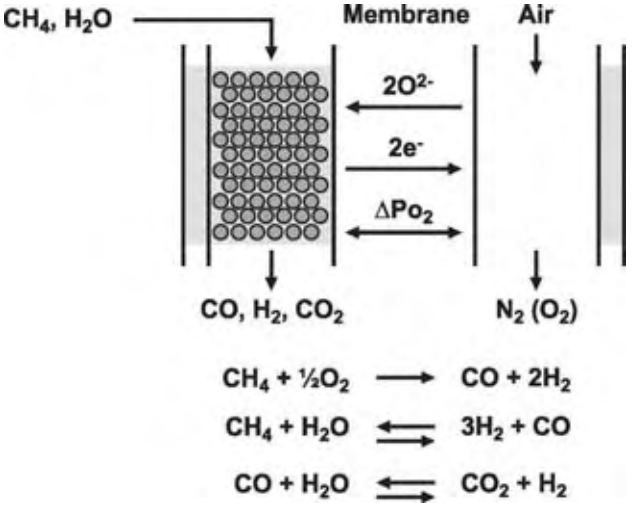

Fig. 13 Principle of ceramic membrane reforming.

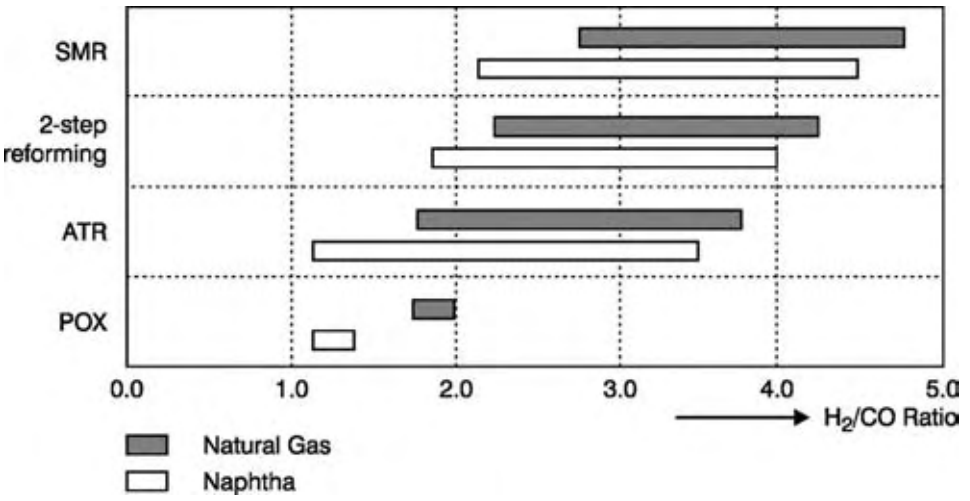

Fig. 14 H_2/CO ratios from various syngas production technologies. (From Ref.[1].)

at one side of the membrane through which oxygen with 100% selectivity is transported to the other side where it reacts with the hydrocarbons to produce syngas. This takes place at elevated temperatures that exceed 750°C or even higher than that. Membrane materials with oxygen conductivities in excess of $10\,Nm^3/m^2/hr$ have been identified, but several challenges remain for the development of this technology.

CHOICE OF TECHNOLOGY

The optimum technology for producing a syngas with a desired composition depends on the feedstock and the capacity. A very important parameter in selecting the best technology is the desired H_2/CO ratio. In Fig. 14, the syngas composition, which may be produced by various technologies with natural gas and naphtha feedstock, is illustrated.[1]

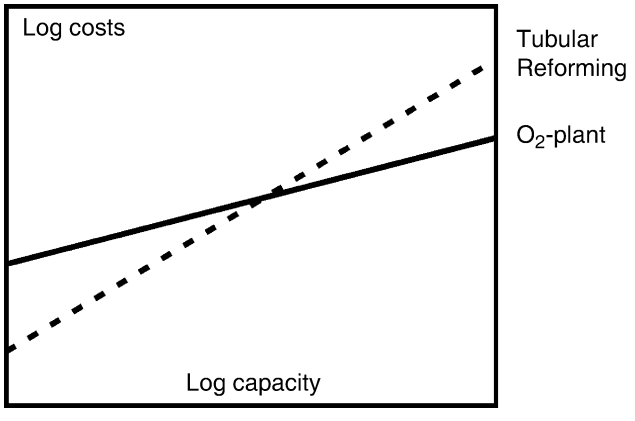

Fig. 15 Economy-of-scale for tubular reforming and air separation. (From Ref.[25].)

For small-scale applications, the cost may be more important than the efficiency of a given plant. In most cases, the partial oxidation reactors give a highly expensive plant layout because of the inherent, high cost of air separation (unless a low-cost source of oxygen is available). The use of air as oxidant makes the final separation very difficult, especially if carbon monoxide is needed either in a pure form or with hydrogen.

The situation may be different if a syngas for a high-temperature fuel cell (molten carbonate or solid oxide fuel cells) is needed. In this case, there is no need for separating the hydrogen and carbon monoxide from the nitrogen diluent when air is used as oxidant and methane can be processed directly by internal reforming in the fuel cell. The dilution with nitrogen may result in lower fuel cell efficiency and the use of partial oxidation will result in lower electrical efficiencies than with steam reforming.[a] However, this disadvantage may be more than offset by a simpler layout with fewer heat exchangers and no steam system.

For applications of larger scale, the selection of either steam-reforming or partial oxidation for the syngas section of a plant is often governed by the differences in the economy-of-scale of the tubular reformer and the oxygen plant as illustrated in Fig. 15. For the fairly low capacities, the cost of the air separation unit is prohibitive and steam reforming is the preferred choice. If possible and necessary, the H_2/CO ratio can be adjusted to the desired value by adding CO_2 either from import or by recirculation. Increasing

[a]Partial oxidation and steam reforming generally generate 3 and 4 moles of hydrogen per mole of methane, respectively (Tables 2 and 4). The difference is released in the form of heat in the case of partial oxidation.

the capacity of a tubular reformer means adding identical tubes and the scaling is therefore not as favorable as for an air-separation plant. At very large capacities, partial oxidation with air separation is the most economical technology. At intermediate capacities, tubular reforming followed by partial oxidation, which is known as secondary reforming, is often preferred.

CONCLUSIONS

Syngas is a key intermediate in the production of a number of important chemicals including ammonia, methanol, isocyanates, and higher alcohols. The desired end product determines the requirement of the syngas composition, ranging from pure hydrogen to pure carbon monoxide. In the coming years, the use and production of syngas may substantially increase if a market for synthetic fuels develops and/or fuel cells are commercialized.

The technologies for production of syngas from hydrocarbons are based on either steam-reforming or partial oxidation. In the former case, the hydrocarbons react with steam with considerable addition of heat to produce a syngas with a H_2/CO ratio of 3 or more. Partial oxidation may be carried out either thermally or catalytically (or by a combination) to produce a syngas with an H_2/CO ratio less than 2. Regardless of technology, CO_2 may be added to the feed to adjust the gas composition to a low H_2/CO ratio. In all cases, limits for the formation of carbon on catalysts or soot in the condensate must be considered to avoid rapid deactivation and low on-stream factors.

The choice of technology depends on the scale of operation and the desired end product. For small-scale syngas generators for fuel cells, partial oxidation may result in a simple layout, but steam reforming results in higher electrical efficiencies. For larger-scale syngas generators, the optimal technology is often dictated by differences in economy-of-scale of steam reforming and the air separation unit needed for partial oxidation plants. If the capacity is too low, the air separation unit may be too expensive; but in a larger scale, the superior economy-of-scale of the oxygen plant favors the partial oxidation technology.

The use of heat exchange reforming in which the heat is supplied by cooling a process gas is attracting increased attention. These reformers, working in combination with partial oxidation reactors, increase the plant energy efficiency and reduce the oxygen consumption. A main challenge in the further development of these types of heat exchange reformers is to prevent metal dusting. The use of heat exchange reforming may become more widespread in the coming years.

Tar Sand

James G. Speight
CD & W Inc., Laramie, Wyoming, U.S.A.

INTRODUCTION

Tar sand is sand saturated with a highly viscous hydrocarbonaceous material, not recoverable in its natural state through a well by ordinary production methods, including enhanced oil recovery methods. Thus, it is not surprising that the properties of bitumen from tar sand deposits are significantly different to the properties of conventional crude oil (Tables 1 and 2). Chemically, the material should perhaps be called bituminous sand rather than tar sand, since the organic matrix is bitumen, a hydrocarbonaceous material that consists of carbon and hydrogen with smaller amounts of nitrogen, oxygen, sulfur, and metals (especially nickel and vanadium).

Current recovery operations of bitumen in tar sand formations involve use of a mining technique. This is followed by bitumen upgrading and refining to produce a synthetic crude oil.

DISTRIBUTION

Tar sand deposits are distributed throughout the world in a variety of countries and the various tar sand deposits have been described as belonging to two types: 1) materials that are found in stratigraphic traps and 2) deposits that are located in structural traps. There are, inevitably, gradations and combinations of these two types of deposits and a broad pattern of deposit entrapment are believed to exist. There are no very large tar sand accumulations having more than 4 billion barrels (4×10^9 bbl) in place either in purely structural or in purely stratigraphic traps.

In Canada, the town of McMurray, about 240 miles north–north–east of Edmonton, Alberta lies at the eastern margin of the largest accumulation in the world There are, in effect, three major accumulations within the Lower Cretaceous deposits. The McMurray-Wabasca reservoirs are found toward the base of the formation and the deposit dips at between 5 ft and 25 ft per mile (1.5 m and 8 m per mile) to the south–west. The Bluesky-Gething sands overlie several unconformities between the Mississippian and Jurassic deposits.

In terms of specific geological and geochemical aspects of the formation, the majority of the work has, again, been carried out on the Athabasca deposit. Attention has repeatedly been focused on the variation in physical properties of crude oil produced in multiple-zone fields or in some instances within a single reservoir.

In the more localized context of the Athabasca deposit, inconsistencies arise presumably because of the lack of mobility of the bitumen at formation temperature (approximately 4°C, 39°F). For example, the proportion of bitumen in the tar sand increases with depth within the formation. Furthermore, the proportion of the nonvolatile asphaltenes or the nonvolatile asphaltic fraction (asphaltenes plus resins) in the bitumen also increases with depth within the formation that leads to reduced yields of distillate from the bitumen obtained from deeper parts of the formation. In keeping with the concept of higher proportions of asphaltic fraction (asphaltenes plus resins), variations (horizontal and vertical) in bitumen properties have been noted previously, as have variations in sulfur content, nitrogen content, and metals content. Obviously, the richer tar sand deposits occur toward the base of the formation, but the bitumen is generally of poorer quality.

The Canadian Melville Island deposits lie on the north shore of Marie Bay, Melville Island, some 1450 miles north of Edmonton. Deposits of Triassic sandstone of the Bjorne Formation are impregnated with a bituminous material.

The major tar sand deposits of the U.S.A. occur within and around the periphery of the Uinta Basin, Utah. These include the Asphalt Ridge, Sunnyside, Tar Sand Triangle, and Peor (PR) Springs deposits. Asphalt Ridge lies on the north–eastern margin of the central part of the Uinta Basin at the contact of the tertiary beds with the underlying Cretaceous Mesaverde Group. The Mesaverde Group is divided into three formations; two of which, the Asphalt Ridge sandstone and the Rim Rock sandstone are beach deposits containing the viscous bitumen.

The Californian deposits are concentrated in the coastal region west of the San Andreas Fault. The largest deposit is the Edna deposit, which is located midway between Los Angeles and San Francisco. The Sisquoc deposit (Upper Pliocene) is the second largest in California and occurs in a sandstone in which there are as many as eight individual tar sand units.

The Sisquoc deposit (Upper Pliocene) is the second largest in California and occurs in a sandstone in which there are as many as eight individual tar sand units. The third California deposit at Santa Cruz is located approximately 56 miles (90 km) from San Francisco.

South Texas holds the largest reserves in the state of tar sand deposits. The tar sand deposits occur in the San Miguel tar belt (Upper Cretaceous) mostly in Maverick and Zavala counties, as well as in the Anacadro limestone (Upper Cretaceous) of the Uvalde district. The Kentucky tar sand deposits are located at Asphalt, Davis-Dismal Creek, and Kyrock; they all occur in nonmarine Pennsylvanian or Mississippian sediments. The three deposits appear as stratigraphic traps and are thought to have received their bitumen or bitumen precursor from the Devonian Chattanooga shale. Tar sand deposits in New Mexico occur in the Triassic Santa Rosa sandstone, which is an irregularly bedded, fine- to medium-grained micaceous sandstone. Finally, the tar sand deposits in Missouri occur over an area estimated at 2000 square miles in Barton, Vernon, and Cass Counties.

Tar sand deposits in Venezuela occur in the Officina/Tremblador tar belt that are believed to contain bitumen-impregnated sands of a similar extent to those of Alberta, Canada. The Guanaco Asphalt Lake occurs in deposits that rest on a formation of mid-Pliocene age and is closely associated with the Guanaco crude oil field that produces heavy crude oil from shale and fractured argillite of the Upper Cretaceous group. The tar sands of the Orinoco deposit are located along the southern flanks of the eastern Venezuelan basin.

The Bemolanga (Madagascar) deposit is the third largest tar sand deposit presently known and extends over some 150 square miles in western Madagascar with a recorded overburden from zero to 100 ft (zero to 30 m). The average pay zone thickness is 100 ft (30 m) with a total bitumen in-place quoted at approximately two billion barrels (approximately 2×10^9 bbl).

The largest tar sand deposit in Europe is that at Selenizza, Albania, that also contains the Patos oil field throughout which there occurs extensive bitumen impregnation.

The Trinidad Asphalt Lake [situated on the Gulf of Paria, 12 miles west-south–west of San Fernando and 138 ft (43 m) above sea level] occupies a depression in the Miocene sheet sandstone.

The Rumanian deposits are located at Derna and occur (along with Tataros and other deposits) in a triangular section east and north–east of Oradia

between the Sebos Koros and Berrettyo rivers. The reservoir rock is nonmarine, representing freshwater deposition during a period of regression.

Tar sands occur at Cheildag, Kobystan and outcrop in the south flank of the Cheildag anticline; there are approximately 24 million barrels (24×10^6 bbl) of bitumen in place. Other deposits in the former USSR occur in the Olenek anticline (north–east of Siberia) and it has been claimed that the extent of asphalt impregnation in the Permian sandstone is of the same order of magnitude (in area and volume) as that of the Athabasca deposits. Tar sands have also been reported from sands at Subovka and the Notanebi deposit (Miocene sandstone) is reputed to contain 20% bitumen by weight. On the other hand, the Kazakhstan occurrence, near the Shubar-Kuduk oil field, is a bituminous lake with a bitumen content that has been estimated to be of the order of 95% by weight of the deposit.

Tar sands also occur in the Southern Llanos of Colombia below 1500 ft (457 m). The tar sands at Burgan in Kuwait and at the Inciarte and Bolivar coastal fields of the Maracaibo Basin are of unknown dimensions. Those at Inciarte have been exploited and are directly or closely associated with large oil fields. The tar sands of the Bolivar coastal fields are above the oil zones in Miocene beds and are in a lithological environment similar to that of the Officina-Tremblador tar belt. The tar sand deposits in the Leyte Islands (Philippines) are extreme samples of stratigraphic entrapment. Those of the Mefang Basin in Thailand are in Pliocene beds that overlie Triassic deposits and their distribution is stratigraphically controlled. There is a small accumulation at Chumpi, near Lima (Peru) from which a petroleum-type was distilled as a result of volcanic activity. Finally, tar sand deposits have also been recorded in Spain, Portugal, Cuba, Argentina, Thailand, and Senegal, but most are poorly defined and are considered to contain (in-place) less than 1 million barrels (1×10^6 bbl) of bitumen.

STRUCTURE

Tar sand is a mixture of sand, water, and bitumen with the sand component occurring predominantly as quartz. The arrangement of the sand, water, and bitumen has been assumed to be an arrangement whereby each particle of the sand is water-wet and a film of bitumen surrounds the water-wetted grains. The balance of the void volume is filled with bitumen, connate water, or gas; fine material, such as clay, occurs within the water envelope.

One additional aspect of the character of Athabasca tar sands that plays a role in research and practice is that the sand grains are not uniform in character. Grain-to-grain contact is variable and such a phenomenon influences attempts to repack mined sand, as may be the case in studies involving bitumen removal from the sand in laboratory-type in situ studies. This phenomenon also plays a major role in the expansion of the sand during processing where the sand to be returned to the mine site might occupy 120–150% of the volume of the original as-mined material.

PROPERTIES

Tar sand properties that are of general interest are bulk density, porosity, and permeability. Porosity is, by definition, the ratio of the aggregate volume of the interstices between the particles to the total volume and is expressed as a percentage. High-grade tar sand usually has a porosity in the range from 30% to 35%, that is somewhat higher than the porosity (5–25%) of most reservoir sandstone. The higher porosity of the tar sand has been attributed to the relative lack of mineral cement (chemically precipitated material that binds adjacent particles together and gives strength to the sand, which in most sandstone occupies a considerable amount of what was void space in the original sediment).

The bitumen content of the tar sand of the U.S.A and Canada varies from zero to as much as 22% by weight. There are, however, noted relationships between the bitumen, water, fines, and mineral contents for the Canadian tar sands. Similar relationships may also exist for the U.S.A. tar sands, but an overall lack of study has prevented the uncovering of such data.

For the Canadian tar sands, bitumen contents from 8% to 14% by weight may be considered as normal (or average). Bitumen contents above or below this range have been ascribed to factors that influence impregnation of the sand with the bitumen (or the bitumen precursor). There are also instances where bitumen contents in excess of 12% by weight have been ascribed to gravity settling.

COMPOSITION

Elemental Composition

The elemental composition of tar sand bitumen is generally constant and falls into a narrow range:

Carbon	3.4–0.5%
Hydrogen	0.4–0.2%
Nitrogen	0.4–0.2%
Oxygen	0.0–0.2%
Sulfur	0.0–0.5%
Metals (Ni and V)	1000 ppm

Chemical Composition

The precise chemical composition of bitumen is, despite the large volume of work performed in this area, largely speculative. In very general terms (and as observed from elemental analyses), tar sand bitumen is an extremely complex mixture of: 1) hydrocarbons; 2) nitrogen compounds; 3) oxygen compounds; 4) sulfur compounds; and 5) metallic constituents. However, this general definition is not adequate to describe the composition of petroleum as it relates to the behavior of the feedstocks.

Finally, during the fractionation of petroleum, the metallic constituents (metalloporphyrins and nonporphyrin metal chelates) are concentrated in the asphaltene fraction. The deasphaltened oils (petrolenes and maltenes) contain smaller concentrations of porphyrins than the parent materials and usually very small concentrations of nonporphyrin metals.

Fractional Composition

Bitumen can be separated into a variety of fractions using a variety of techniques that have been used since the beginning of petroleum science. In general, the fractions produced by these different techniques are called saturates, aromatics, resins, and asphaltenes. Much of the focus has been on the asphaltene fraction because of its high sulfur content and high coke-forming propensity.

The available evidence is specific to the Athabasca deposit. For example, bitumen obtained from the northern locales of the Athabasca deposit (Bitumount, Mildred-Ruth Lakes) has a lower amount (by weight values approximately 16–20%) of the nonvolatile asphaltene fraction than the bitumen obtained from southern deposits (Abasand, Hangingstone River; approximately 22–23% by weight asphaltenes). In addition, other data indicate that there is also a marked variation of asphaltene content in the tar sand bitumen with depth in the particular deposit.

Thus, bitumen from a specific deposit is not a uniform material. The chemical and physical (fractional) composition can vary not only with the location and age of the deposit but also with the depth.

Properties

The specific gravity of bitumen shows a fairly wide range of variation. The largest degree of variation is usually due to local conditions that affect material lying close to the faces, or exposures, occurring in surface tar sand deposits. There are also variations in the specific gravity of the bitumen found in beds that have not been exposed to weathering or other external factors.

Bitumen gravity primarily affects the upgrading requirements needed because of the low hydrogen content of the produced bitumen. The API gravity of known U.S.A tar sand bitumen ranges downward from about 14° API (0.973 specific gravity) to approximately 2° API (1.093 specific gravity). Although only a vague relationship exists between density (gravity) and viscosity, very-low-gravity bitumen generally has very high viscosity.

The pour point is the lowest temperature at which the bitumen will flow. The pour point for tar sand bitumen can exceed the natural temperature of tar sand deposits. It is important to consider because for efficient production a thermal extraction process to increase the reservoir temperature to beyond the pour point temperature must supply supplementary heat energy. Elements related to pour point are depth, bitumen viscosity, original reservoir temperature, and atomic hydrogen/carbon ratio.

Other properties such as calorific value, carbon residue, specific heat, softening point, flash point, molecular weight, and thermal conductivity are also used to determine the suitability of the bitumen for conversion options.

MINING TECHNOLOGY

The Athabasca Tar Sands deposit in Canada is the site of the only commercial tar sands mining operations. The Suncor mining and processing plant, located 20 miles north of Fort McMurray, Alberta, started production in the year 1967. The Syncrude Canada mining and processing plant, located five miles (8 km) away from the Suncor plant, started production in the year 1978. In both projects, about half of the terrain is covered with muskeg, an organic soil resembling peat moss, which ranges from a few inches to 23 ft (7 m) in depth. The major part of the overburden, however, consists of Pleistocene glacial drift and Clearwater Formation sand and shale. The total overburden varies from 23 ft to 130 ft (7–40 m) in thickness. The underlying tar sand strata averages about 150 ft (45 m), although typically 16–33 ft (5–10 m) must be discarded because of a bitumen content below the economic cut-off grade designated by either plant and generally on the order of 5% by weight.

In the Suncor pit design, the ore body is divided into two layers, or benches, each nominally 23 m high. The pit floor and the dividing plane between the upper and lower bench are roughly horizontal and 8000 ton/hr/hr bucket-wheel excavators are employed as the primary mining equipment. Tar sands loosened from the face of each bench by the bucket wheels are

discharged on to a series of conveyors. The overburden is stripped by an electric shovel that discharges to trucks for removal of the overburden material. Syncrude utilizes a single-bench design with 80 yd^3 (60 m^3) capacity draglines as the primary mining equipment. The draglines that pile the tar sands in windrows along the edge of the pit; four 64,000-ton/hr bucket wheels transfer the tar sands to a system of trunk conveyor belts that move the material to the extraction plant. The mining operations at the two plants differ by virtue of the choice of the primary mining equipment; the bucket-wheel excavators sit on benches whilst the draglines sit on the surface.

The bucket wheel excavators are units having a 33-ft (10-m) diameter digging wheel on the end of a long boom. Each wheel has a theoretical capacity of 9500 tons/hr, but the average output from digging is about 5000 tons/hr. Tar sand is transferred from the mine to the separation plant at a rate of 140,000 ton/day (140×10^6 per day) by a system of 60 inch wide (152 cm) conveyor belts and 72 inch (183 cm) trunk conveyors that operate at 1090 ft/min (333 m/min). The bucket wheel excavators are supplemented by front-end loaders that are used to dig overburden and load it through twin chutes on to 150-ton-capacity trucks. Additional equipment is used for maintaining the haul roads and for spreading and compacting the spoiled material. On the other hand, overburden may be stripped with 18 yd^3 hydraulically operated shovels and a fleet of 150-ton trucks.

The draglines are equipped with a 92 yd^3 (71 m^3) bucket at the end of a 364 ft (111 m) boom. They can be employed to dig both a portion of the overburden, which is free-cast into the mining pit, and the tar sand, which is piled in windrows behind the machine. Bucket wheel reclaimers, similar to bucket wheel excavators, load the tar sand from the windrows on to conveyor belts that transfer it to the plant.

Underground mining options have also been proposed, but for the moment have been largely discarded because of the fear of collapse of the formation on to any operators or equipment. This particular option should not, however, be rejected out of hand because a novel aspect or the requirements of the developer (which remove the accompanying dangers) may make such an option acceptable.

EXTRACTION TECHNOLOGIES

The Hot-Water Process

In terms of bitumen separation and recovery, the hot-water process is, to date, the only successful commercial process to be applied to bitumen recovery from mined tar sands in North America. Many process options have been tested with varying degrees of success and one of these options may even supersede the hot-water process.

The process utilizes the linear and nonlinear variation of bitumen density and water density, respectively, with temperature so that the bitumen that is heavier than water at room temperature becomes lighter than water at 80°C (180°F). Surface-active materials in the tar sand also contribute to the process. The essentials of the hot-water process involve conditioning, separation, and scavenging.

In the hot-water extraction process, the tar sand feed is introduced into a conditioning drum. In this step, the tar sand is heated, mixed with water, and agglomeration of the oil particles begins. The conditioning is carried out in a slowly rotating drum that contains a steam-sparging system for temperature control, as well as mixing devices to assist in lump size reduction and a size ejector at the outlet end. The tar sand lumps are reduced in size by ablation and mixing action. The conditioned pulp has the following characteristics: (1) solids 60% by weight to 85% by weight and (2) pH 7.5–8.5.

In the conditioning step, also referred to as mixing or pulping, tar-sand feed is heated and mixed with water to form a pulp of 60% by weight to 85% by weight solids at 80–90°C (175–196°F). The conditioned pulp is screened through a double-layer vibrating screen. Water is then added to the screened material (to achieve more beneficial pumping conditions) and the pulp enters the separation cell through a central feed well and distributor. The bulk of the sand settles in the cell and is removed from the bottom as tailing, but the majority of the bitumen floats to the surface and is removed as froth. A middlings stream (mostly of water with suspended fines and some bitumen) is withdrawn from approximately midway up the side of the cell wall. Clays accumulate in the middlings layer.

The separation cell acts like two settlers, one on top of the other. In the lower settler the sand settles down, whereas in the upper settler the bitumen floats. The bulk of the sand in the feed is removed from the bottom of the separation cell as tailings. A large portion of the feed bitumen floats to the surface of the separation cell and is removed as froth. A middlings stream consists mostly of water with some suspended fine minerals and bitumen particles.

The combined froth from the separation cell and scavenging operation contains an average of about 10% by weight mineral material and up to 40% by weight water. The dewatering and demineralizing is accomplished in two stages of centrifuging. In the first stage, the coarser mineral material is removed but much of the water remains. The feed then passes through a filter to remove any additional large-size mineral matter that would plug up the nozzles of the second stage centrifuges.

The third step in the hot-water process is scavenging. Froth flotation with air is usually employed. The scavenger froth is combined with the separation-cell froth to be further treated and upgraded to synthetic crude oil. Tailings from the scavenger cell join the separation-cell tailings stream and go to waste.

Froth from the hot-water process may be mixed with a hydrocarbon diluent, e.g., coker naphtha, and centrifuged. The Suncor process employs a two-stage centrifuging operation and each stage consists of multiple centrifuges of conventional design installed in parallel. The bitumen product contains 1% by weight to 2% by weight mineral (dry bitumen basis) and 5% by weight to 15% by weight water (wet diluted basis). Syncrude also utilizes a centrifuge system with naphtha diluent.

Other Processes

The proposed cold-water process for bitumen separation has been developed to the point of small-scale continuous pilot plants. The process uses a combination of cold water and solvent and the first step usually involves disintegration of the tar sand charge that is mixed with water, diluent, and reagents. The diluent may be a petroleum distillate fraction such as kerosene and is added in approximately a 1:1 weight ratio to the bitumen in the feed. The pH is maintained at 9–9.5 by the addition of wetting agents and approximately 0.77 kg of soda ash per ton of tar sand. The effluent is mixed with more water, and in a raked classifier the sand is settled from the bulk of the remaining mixture. The water and oil overflow the classifier and are passed to thickeners where the oil is concentrated. Clay in the tar-sand feed has a distinct effect on the process; it forms emulsions that are hard to break and are wasted with the underflow from the thickeners.

The sand-reduction process is a cold-water process without solvent. In the first step, the tar-sand feed is mixed with water at approximately 20°C (68°F) in a screw conveyor in a ratio of 0.75 ton to 3 ton per ton of tar sand (the lower range is preferred). The mixed pulp from the screw conveyor is discharged into a rotary-drum screen, which is submerged in a water-filled settling vessel. The bitumen forms agglomerates that are retained by an 840-micron (20-mesh) screen and withdrawn as oil product. The sand readily passes through the 840-micron (20 mesh) screen and is withdrawn as waste stream.

The spherical agglomeration process resembles the sand-reduction process. Water is added to tar sands and the mixture is ball-milled. The bitumen forms dense agglomerates of 75% by weight to 87% by weight bitumen, 12% by weight to 25% by weight sand, and 1% by weight to 5% by weight water.

An anhydrous solvent extraction process for bitumen recovery has been attempted and usually involves the use of a low-boiling hydrocarbon. The process generally involves up to four steps. In the mixer step, fresh tar sand is mixed with recycle solvent that contains some bitumen and small amounts of water and mineral. Solvent-to-bitumen weight ratio is adjusted to approximately 0.5. The drain step consists of a three-stage countercurrent wash. Settling and draining time is approximately 30 min for each stage.

The other aboveground method of separating bitumen from tar sands after the mining operation involves direct heating of the tar sand without previous separation of the bitumen. Thus, the bitumen is not recovered as such, but is an upgraded overhead product.

UPGRADING

The quality of tar sand bitumen is low compared to that of conventional crude oil and heavy oil. The high carbon residue of bitumen dictates that considerable amounts of coke will be produced during thermal refining (Table 3).

The current oil sands bitumen upgrading processes for the production of synthetic crude oil (Table 4) begin with diluted bitumen being processed through the diluent recovery units. The diluent recovery units are atmospheric distillation units that serve three purposes: 1) distill off diluent naphtha and return it to the froth treatment process; 2) distill off light gas oil and send it directly to a light gas oil hydrotreater; and 3) produce hot atmospheric topped bitumen as feedstock for vacuum distillation unit and downstream bitumen conversion processes.

The vacuum distillation unit cuts deeper into the atmospheric topped bitumen. It distills off the remaining light gas oil and heavy gas oil that are sent directly to hydrotreaters. The remaining vacuum topped bitumen can be blended with atmospheric topped bitumen and then sent to bitumen conversion units.

Table 3 Predicted coke yields from various feedstocks

API gravity of feedstock	Carbon residue % by weight	Coke yield	
		Delayed coking	Fluid coking
2	30	45	35
6	20	36	23
10	15	28	17
16	10	18	12
26	5	9	3

Table 4 Properties of synthetic crude oil from Athabasca bitumen

Property		Bitumen	Synthetic crude oil
Gravity, API		8	32

0	30	0	5
30	85	0	30
220	430	1	60
345	650	17	90
550	1020	45	100

Coking Processes

The overall upgrading process by which bitumen is converted to liquid products is accomplished in two steps. The first step is the primary upgrading process that improves the hydrogen-to-carbon ratio by either carbon removal or hydrogen addition, cracking the bitumen to lighter products which are more easily processed downstream. The secondary upgrading process involves hydrogenation of the primary products and is the means by which sulfur and nitrogen are removed from the primary products.

There are two processes that have been applied to the production of liquids from Athabasca bitumen. In this respect, these processes are proven but are not necessarily the best or ultimate processes. Delayed coking is practised at the Suncor (formerly Great Canadian Oil Sands) plant, whereas Syncrude employs a fluid coking process which produces less coke than the delayed coking in exchange for more liquids and gases (Table 5).

Product Upgrading

The primary liquid product is then hydrotreated (secondary conversion or refining) to remove sulfur and nitrogen (as hydrogen sulfide and ammonia, respectively) and to hydrogenate the unsaturated sites exposed by the conversion process. It may be necessary to employ separate hydrotreaters for light distillates and medium-to-heavy fractions; for example, the heavier fractions require higher hydrogen partial pressures and higher operating temperatures to achieve the desired degree of sulfur and nitrogen removal. Commercial applications have therefore been based on the separate treatment of two or three distillate fractions at the appropriate severity to achieve the required product quality and process efficiency.

Table 5 Potential emissions from a tar sand plant

Source of emission	Potential contaminants
Process waste water	Suspended solids
	Dissolved solids
	Organic compounds
	Ammonium compounds
	Inorganic (metal) compounds
Upgrader area runoff	Suspended solids
Upgrader heaters	Particulate matter
	Carbon oxides
	Sulfur oxides
	Nitrogen oxides
Coke storage pile	Suspended solids
	Sulfur
Solid waste landfill	Suspended solids
	Organic compounds
	Inorganic (metal) compounds
	Sulfur
Power plant	Particulate matter
	Carbon oxides
	Sulfur oxides
	Nitrogen oxides
Sulfur plant	Particulate matter
	Hydrogen sulfide
	Sulfur oxides

Other Processes

There are several other processes that have received some attention for bitumen upgrading. These processes include partial upgrading (a form of thermal deasphalting), flexicoking, the Eureka process, and various hydrocracking processes. In addition, a partial coking or thermal deasphalting process provides a minimal upgrading of bitumen.

Most hydrocracking processes start with an upflow reactor system in which the 524°C (975°F) material is cracked or converted. To prevent coking, the processes operate at high pressure with direct contact between the bitumen feed and circulating hydrogen. Hydrocracking processes include the H-Oil process, the LC-Fining process, the Veba-Combi Cracking process, and the Chiyoda process.

ENVIRONMENTAL ASPECTS

A major aspect of tar sand resource development is the influence of the various integral parts of the development on the surrounding environment and recognition of the various emissions from the plant (Table 5).

Thus, regulations could clearly state conditions for resource development in terms of:

1. Foliage removal-to what extent and how or to where.
2. Flora-endangered species should be transplanted.
3. Fauna removal to another (similar) location.
4. Till removal.

The mining operation poses a potential threat to the environment because:

1. Large ''holes'' have to be dug to retrieve the ore.
2. The overburden must first be removed from the immediate mine site

The first constraint is an inevitable part of the mining operation, but regulations may require that the site be returned to at least the original (unspoiled) condition. This is being achieved in Alberta by the techniques in which the mineral matter from the hot water separation process is returned to the mine site as fill material, thereby bringing the ground level back to the original premine level. In a similar manner, overburden handling can also be achieved with minimal stockpiling of the earth. Revegetation programs will complete the return of the site to the ''predevelopment'' state.

One of the greatest problems that has emerged from tar sand resource development is the disposal (and control) of the tailings streams that arise from the hot-water separation. The extent of this problem had not been appreciated until the commercialization of the tar sands commenced.

There are three major aspects of tailings disposal that need to be addressed:

1. Each ton of oil band in-place has a volume of approximately 16 ft^3; the tailings has a volume of approximately 22 ft^3, a volume gain of approximately 40%.
2. The clay discharged as part of the tailings stream does not settle and, therefore, limits the amount of the stream that can he used as recycle water.
3. The tailings stream contains bitumen.

Thus, tailings disposal requires a larger hole than that from which the tar sand originated or the level of the land will/must be raised at site abandonment. Until a satisfactory means of clay settling can be achieved that will allow reuse of the water, the tailings ponds will grow in size with the life of the plant. Currently, a recycle stream from the tailings ponds produces some 40–60% of the daily water requirements of the tar sand plants; the remainder is makeup water from the nearby Athabasca River.

CONCLUSIONS

Coking processes have served well in the production of synthetic crude oil from tar sand bitumen. However, new processes for the conversion of bitumen will probably be used in place of the coking processes with some degree of hydrocracking as a primary conversion step. Other processes may replace or augment the deasphalting processes in many refineries.

When catalytic processes are employed, complex molecules (such as those that may be found in the original asphaltene fraction) or those formed during the process, are not sufficiently mobile (or are too strongly adsorbed by the catalyst) to be saturated by hydrogenation.

Theoretical Aspects of Liquid Crystals and Liquid Crystalline Polymers

T

James J. Feng
Department of Chemical and Biological Engineering and Department of Mathematics, University of British Columbia, Vancouver, British Columbia, Canada

INTRODUCTION

Liquid crystallinity refers to an intermediate state of matter where the molecules exhibit a degree of order that is between that of ordinary liquids and solids. Typically, these molecules have an elongated shape and an intrinsic tendency toward alignment. Yet, the inter-molecular forces are not so strong as to bind them into a regular lattice as in crystalline solids. Thus, the orientational order among the molecules makes the material anisotropic and ''crystalline,'' while the lack of strong positional order allows the material to flow like ordinary fluids. This liquid–solid duality gives rise to much of the ''anomalous'' behavior of liquid crystalline materials. When understood, however, their unique dynamics can be harnessed to produce high-performance materials with unique properties.

In this entry, we review the state of the art in theoretical modeling and computation of the flow and rheology of low-molecular-weight liquid crystals (LCs) and liquid crystalline polymers (LCPs). The latter can be viewed as macromolecular liquid crystals, and the significance of the molecular weight will be made clear shortly. We restrict our scope to nematics, one of the several types of LCs with no positional order altogether;[1] they seem to have the most important applications and have been the focus of theoretical efforts. Owing to the long-standing academic and industrial interest in these materials, their dynamics have been summarized in several reviews, e.g., Refs.[1–4]. While overlapping those in certain aspects, we emphasize constitutive modeling and numerical simulation of defects and texture. The latter nicely demonstrates the interplay between macroscopic flow and mesoscopic orientation, a hallmark of liquid crystalline dynamics. Due to space limitation, we will attempt to construct a coherent framework instead of an exhaustive literature review. Based on their conceptual origins, we discuss continuum theories and molecular theories separately. In addition, a theory for liquid crystalline materials has been proposed based on nonequilibrium thermodynamics.[5] As the theoretical framework and mathematical representation are quite independent of the other theories, we will not discuss this theory but refer the reader to Beris and Edwards' monograph.[5]

Because of similar molecular attributes, LCs and LCPs share enough common features to be discussed in this single entry. A significant difference is that the large LCP molecules have a much longer relaxation time. Thus, the molecular conformation of LCPs is easily disturbed by flow and deformation. Rheologically, therefore, the material exhibits ''molecular viscoelasticity'' as macromolecular fluids normally do. Small-molecule LCs relax so fast that their molecular configuration remains almost always at equilibrium; there is no viscoelasticity. Both LCs and LCPs resist spatial distortion to their orientational pattern. This tendency is known as ''distortional elasticity.'' The continuum theories were originally developed for small-molecule LCs, capturing distortional elasticity but not molecular viscoelasticity. Molecular theories, on the other hand, have evolved to contain both ingredients. Not surprisingly, a properly constructed molecular theory should reduce to a continuum theory in the limit of vanishing molecular relaxation time.

CONTINUUM THEORIES

The tendency of LCs to resist and recover from distortion to their orientation field bears clear analogy to the tendency of elastic solids to resist and recover from distortion of their shape (strain). Based on this idea, Oseen, Zocher, and Frank established a linear theory for the distortional elasticity of LCs.[1] Ericksen[6,7] incorporated this into hydrostatic and hydrodynamic theories for nematics, which were further augmented by Leslie[8] with constitutive equations. The Leslie–Ericksen theory has been the most widely used LC flow theory to date.

Frank Elasticity

Viewing the LC as an anisotropic continuum, a pseudo-vector $\boldsymbol{n}$ of unit length, called the director, is used to indicate the orientation field. Thus, orientational

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030566

distortion is described by the spatial gradient $\nabla \boldsymbol{n}(\boldsymbol{r})$. Retaining quadratic terms, one may write the free energy density for orientation distortion as:[1]

$$F_d = \frac{K_1}{2}(\nabla \cdot \boldsymbol{n})^2 + \frac{K_2}{2}(\boldsymbol{n} \cdot \nabla \times \boldsymbol{n})^2 + \frac{K_3}{2}|\boldsymbol{n} \times \nabla \times \boldsymbol{n}|^2 \quad (1)$$

where the coefficients K_1, K_2, and K_3 are elastic constants corresponding to three canonical forms of orientational distortion: splay, twist, and bend.[1] The K's have the dimension of force, and F_d has the dimension of energy per unit volume. When the three K's are equal, the free energy takes on a particularly simple form:

$$F_d = \frac{K}{2}\nabla \boldsymbol{n} : (\nabla \boldsymbol{n})^{\mathrm{T}} \quad (2)$$

Thus the ''one-constant approximation'' is often used in theoretical analysis.

Leslie–Ericksen Theory

When $\boldsymbol{n}(\boldsymbol{r})$ is disturbed, say by an external magnetic field, an elastic torque arises:

$$h = -\frac{\delta F_d}{\delta \boldsymbol{n}} = -\frac{\partial F_d}{\partial \boldsymbol{n}} + \nabla \cdot \left(\frac{\partial F_d}{\partial \nabla \boldsymbol{n}}\right) \quad (3)$$

Known as the molecular field, $\boldsymbol{h}$ tends to restore $\boldsymbol{n}$ to its former orientation. Minimizing the total free energy shows that an equilibrium is achieved when $\boldsymbol{h}$ is parallel to $\boldsymbol{n}$. Furthermore, when the LC is deformed, the variation of $F_d(\boldsymbol{n},\nabla \boldsymbol{n})$, with respect to the strain, gives rise to an elastic stress known as the Ericksen stress:[1]

$$\sigma^{\mathrm{E}} = -\frac{\partial F_d}{\partial(\nabla \boldsymbol{n})} \cdot (\nabla \boldsymbol{n})^{\mathrm{T}} \quad (4)$$

The above two equations form the core of Ericksen's theory of LC hydrostatics.

Leslie recognized from early experiments that the anisotropy of the materials calls for multiple viscosity coefficients corresponding to different orientation of the LC relative to the flow. Combining this idea with the Ericksen theory leads to the Leslie–Ericksen (LE) theory, which comprises two elements: one describing the evolution of $\boldsymbol{n}(\boldsymbol{r})$ in a flow field, and the other prescribing an extra stress tensor due to the evolving $\boldsymbol{n}(\boldsymbol{r})$ field.

The evolution of $\boldsymbol{n}(\boldsymbol{r})$ is governed by a balance between viscous and elastic torques:

$$\boldsymbol{h} = \gamma_1 \boldsymbol{N} + \gamma_2 \boldsymbol{D} \cdot \boldsymbol{n} \quad (5)$$

where γ_1 and γ_2 are viscosity coefficients,

$$\boldsymbol{N} = \frac{d\boldsymbol{n}}{dt} - \boldsymbol{\Omega} \cdot \boldsymbol{n} \quad (6)$$

is the rotation of $\boldsymbol{n}$ relative to the background fluid, $\boldsymbol{\Omega} = [(\nabla \boldsymbol{v})^{\mathrm{T}} - \nabla \boldsymbol{v}]/2$ and $\boldsymbol{D} = [(\nabla \boldsymbol{v})^{\mathrm{T}} + \nabla \boldsymbol{v}]/2$ being the rotation and strain rate tensors. The molecular field $\boldsymbol{h}$ is given by Eq. (3) in terms of $\boldsymbol{n}$. The Leslie–Ericksen stress tensor is written as

$$\sigma^{\mathrm{LE}} = \sigma^{\mathrm{E}} + \alpha_1 \boldsymbol{D} : \boldsymbol{nnnn} + \alpha_2 \boldsymbol{nN} + \alpha_3 \boldsymbol{Nn} + \alpha_4 \boldsymbol{D} + \alpha_5 \boldsymbol{nn} \cdot \boldsymbol{D} + \alpha_6 \boldsymbol{D} \cdot \boldsymbol{nn} \quad (7)$$

where the α's are viscosity coefficients, related to the γ's of Eq. (5) by $\gamma_1 = \alpha_3 - \alpha_2$ and $\gamma_2 = \alpha_2 + \alpha_3 = \alpha_6 - \alpha_5$ (see Ref.[1] for explanation).

We must point out two related limitations of the LE theory. First, it applies to small-molecule LCs and to LCPs in the limit of vanishing strain rate. This is because the LE theory uses a vector $\boldsymbol{n}$ to represent the orientation state of the fluid, tacitly assuming that the molecular orientation distribution stays at its equilibrium state. This is reasonable when the molecular relaxation time is much shorter than the characteristic time of the flow. Second, the theory does not allow orientational defects, which would be singularities in the $\boldsymbol{n}$ field. In reality, LCs and LCPs tend to have a high density of defects.[1,9,10] Near the defect core, large spatial gradients distort the molecular orientation distribution, thus invalidating the LE theory.

Predictions of the Leslie–Ericksen Theory for Shear Flows

The LE theory has been applied to simple shear, Poiseuille, and nonviscometric flows.[4,11] If $\alpha_3/\alpha_2 > 0$, the LE theory predicts a steady ''flow-aligning'' solution in shear flows. If $\alpha_3/\alpha_2 < 0$, however, no steady solution exists, and $\boldsymbol{n}$ rotates continuously. The latter type, known as ''tumbling'' nematics, exhibits much richer dynamics. We will focus on instabilities in sheared tumbling LCs, for these reveal the most interesting physics, especially regarding the nucleation of defects. The key parameter in this problem is the Ericksen number: $Er = \gamma_1 VH/K_1$, V and H being the characteristic velocity and length, respectively. It represents the interplay between the viscous torque exerted by shear and the elastic torque emanating from the wall anchoring.

Consider the shear flow geometry in Fig. 1, with three different anchoring conditions on the top and bottom planes. The initial condition is a uniform $\boldsymbol{n}$ field consistent with the wall anchoring. Cases (a) and (b) are similar in which $\boldsymbol{n}$ lies initially in the y–z plane. In both cases, the LE theory predicts an in-plane tumbling instability and an out-of-plane twist instability.[12]

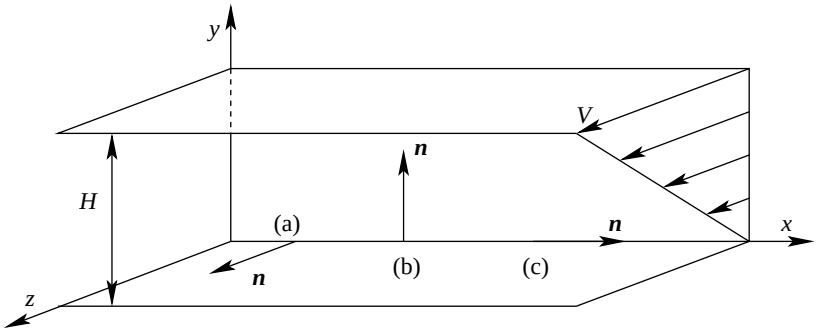

Fig. 1 Geometry for shear flow, with three possible anchoring conditions on the top and bottom planes: (a) ***n*** fixed along the flow direction (planar anchoring); (b) ***n*** fixed along the velocity gradient (homeotropic anchoring); and (c) ***n*** fixed along the vorticity direction (log rolling).

If ***n*** is restricted to the y–z plane during the shear, a steady ''windup'' solution obtains for low shear rates, with ***n*** rotating the most at the center and less toward the walls. This windup picture becomes unstable at a critical shear rate, where the director tumbles discontinuously to a new solution with reduced elastic energy. The critical Er depends on material parameters, and falls roughly between 10 and 100. Mathematically, this instability is represented by the existence of multiple in-plane solutions at certain ranges of the shear rate.[13] An example is shown in Fig. 2.

If one relaxes the constraint of in-plane orientation, a second instability appears in roughly the same Er range, with the director being driven out of the flow-gradient (y–z) plane toward the vorticity (x) direction.[12] This twist instability is accompanied by secondary flows orthogonal to the primary flow. Critical Er values for the tumbling and twist instabilities have been determined,[12] and detailed bifurcation diagrams constructed.[14] With increasing Er, ***n*** approaches the vorticity direction except for a thin layer next to the walls; the whole field approaches the initial condition in Fig. 1 with the anchoring condition (c).

This ''log-rolling'' configuration, be it the initial state with condition (c) or the result of a twist instability with conditions (a) or (b), is itself unstable to the formation of counter-rotating pairs of rolls aligned with the flow (Fig. 3A). This roll-cell instability was first recognized by linear analyses.[15,16] Along the vorticity direction, the rolls disturb the ***n*** field periodically and produce alternating dark and light stripes parallel to the primary flow, which have been experimentally confirmed.[17–19]

Experiments demonstrate that at even higher Er, the rolls become unstable and irregular. Ultimately, defect lines called disclinations form in the flow direction. As the linear analysis concerns the behavior of infinitesimal disturbances, the growth of the instability and further bifurcations are inaccessible to such analyses. This motivated Feng, Tao, and Leal[20] to carry out a direct numerical simulation of a sheared nematic. Using the LE theory, with the one-constant approximation, they predicted a cascade of instabilities illustrated in Fig. 3. Steady state rolls first appear at $Er = 2368$. The director twists toward the flow (z) direction at the center of the cells. With increasing Er, the secondary flow and the director twisting intensify,

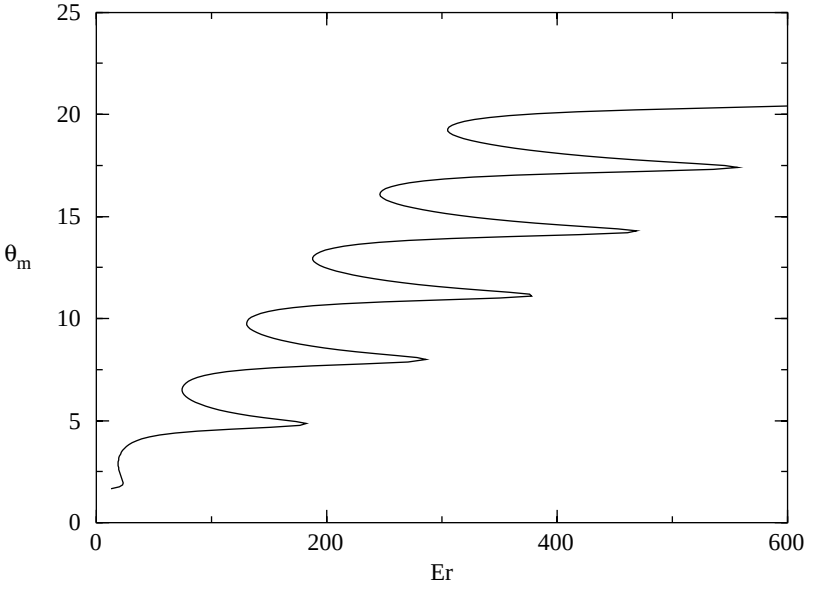

Fig. 2 The maximum orientation angle θ_m (in radians) as a function of Er for in-plane windup solutions of the LE theory using parameters for 8CB.[12] Multiple values of θ_m indicate multiple solutions at one shear rate, the jumps among which are the tumbling instability.

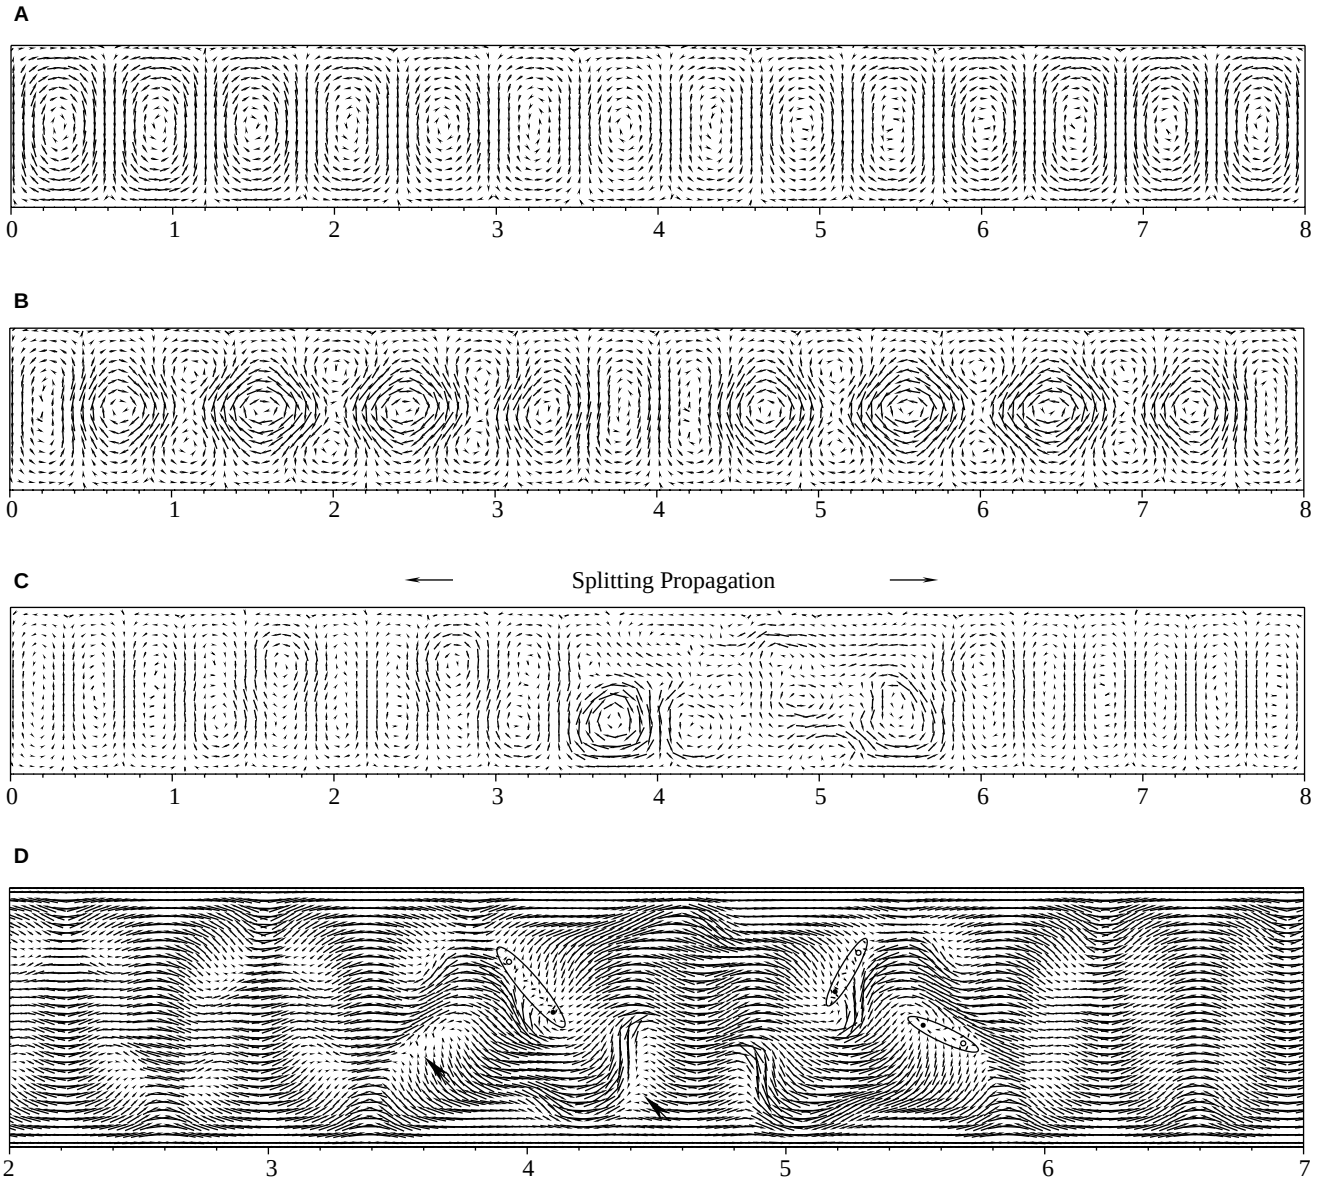

Fig. 3 Secondary flows in the x–y plane showing instabilities in a sheared nematic: (A) velocity vectors showing steady roll cells at $Er = 2602$; (B) a snapshot of oscillating roll cells at $Er = 4336$; (C) cell splitting at $Er = 8672$; and (D) ridges, indicated by arrows, break up to produce pairs of ± 1 defects marked by the ellipses. (From Ref.[20].)

while the wavelength of the dominant mode shrinks. When Er reaches 4026, the steady solution gives way to a time-periodic one: the roll cells begin to oscillate (Fig. 3B). When Er exceeds 6867, the cells split and evolve into an irregular pattern (Fig. 3C). Meanwhile, the director field forms ''ridges,'' namely elongated regions where $\boldsymbol{n}$ is mostly aligned with the primary flow (Fig. 3D). If the local secondary flow is favorable, the ridges break up to produce pairs of ± 1 disclinations of the escaped type with a diffuse core. This is the first detailed understanding of the process of flow-induced defect formation. More recently, Tao and Feng[21] extended this work to allow three unequal elastic constants, and explored the interaction among the three modes of distortion during the nucleation of defects. Note that the LE theory is generally incapable of describing defects. Fortunately, the disclinations produced by broken roll cells in both experiments[18] and numerical simulations[20,21] are nonsingular lines with a diffuse core.

Generalizations of the Leslie–Ericksen Theory

The inability of the LE theory to describe orientational defects has motivated efforts to generalize it.

The origin of the difficulty is the assumption of an equilibrium orientation distribution. In reality, the large spatial gradients at the defect would distort the molecular orientation distribution and severely reduce the local order parameter.

Ericksen[22] introduced a variable scalar order parameter; this amounts to assuming a spheroidal orientation distribution, with the axis of symmetry along the unit-length director. Liu and Walkington[23] proposed a conceptually related model by allowing the director length to vary. Its deviation from unity incurs a penalty in the Ginzburg–Landau form, and the Frank energy with the one-constant approximation can be rewritten as

$$F_{CW} = K\left[\frac{1}{2}\nabla \boldsymbol{n} : (\nabla \boldsymbol{n})^{T} + \frac{(\boldsymbol{n}\cdot\boldsymbol{n} - 1)^2}{4\delta^2}\right] \quad (8)$$

The small parameter δ indicates the extent of the defect region where $|\boldsymbol{n}|$ deviates from unity; singularity is avoided as $|\boldsymbol{n}|$ shrinks. Thus, $|\boldsymbol{n}|$ serves the role of Ericksen's scalar parameter. Tsuji and Rey[24,25] represented the molecular orientation distribution by a second-rank tensor. Thus, the distribution is allowed an ellipsoidal shape with three distinct eigenvalues. The free energy assumes the Landau–DeGennes form.[26] Now defects correspond to points where the two largest eigenvalues are equal and a unique director cannot be defined. This theory has been used to study the appearance and evolution of spatial textures.[24,25] Finally, the Larson–Doi theory[27] is an ingenious generalization of the LE idea to a larger length scale to account for polydomain textures.

MOLECULAR THEORIES

The starting point of a molecular constitutive theory is a simple mechanical model for the molecule that captures its most salient traits. Thus, flexible polymer molecules have been represented by elastic dumbbells and bead-spring chains,[28] and rigid polymers by rigid dumbbells[28] and rigid rods.[29] For its simplicity, the evolution of the model molecule is easily described by a convection-diffusion equation. Then a Fokker–Planck equation is written for the probability distribution function of an ensemble of these molecules. Finally, the macroscopic stress tensor is derived in terms of the distribution function. This kinetic theory framework was pioneered by Kirkwood (see, for example, Ref.[29]).

Nematic Potentials

The orientational order in a nematic derives from inter-molecular forces of various origins. We represent such molecular interactions by a mean-field potential energy known as the nematic potential. The Onsager and the Maier–Saupe potentials have played prominent roles in the development of the subject.

The Onsager potential is based on the excluded-volume effect among rod-like molecules.[1] Consider an ensemble of rigid rods of uniform length L and diameter b, with a number density ν and an orientation distribution function $\Psi(\boldsymbol{u})$ for the molecular orientation $\boldsymbol{u}$. For a test molecule oriented in $\boldsymbol{u}$, the effect of all the other molecules can be represented by a mean-field Onsager potential:

$$V_{ON}(\boldsymbol{u}) = \nu kT \int \Psi(\boldsymbol{u}')\beta(\boldsymbol{u},\boldsymbol{u}')d\boldsymbol{u}' \quad (9)$$

where $\beta(\boldsymbol{u},\boldsymbol{u}') = 2bL^2|\boldsymbol{u}\times\boldsymbol{u}'|$ represents the excluded-volume interaction between two molecules along $\boldsymbol{u}$ and $\boldsymbol{u}'$, k is the Boltzmann constant, T is temperature, and the integration is over a unit sphere representing all possible orientations.

The Maier–Saupe potential is a phenomenological model originally proposed for thermotropic small-molecule LCs.[1] It is obtained by replacing the excluded-volume interaction in Eq. (9) by

$$\beta(\boldsymbol{u},\boldsymbol{u}') = \text{const} - \beta_1 bL^2(\boldsymbol{u}\cdot\boldsymbol{u}')^2 \quad (10)$$

where β_1 is a constant. Then, the Maier–Saupe nematic potential can be written as:

$$\begin{aligned} V_{MS}(\boldsymbol{u}) &= \text{const} - \frac{3}{2}UkT\boldsymbol{u}\boldsymbol{u} : \int \Psi(\boldsymbol{u}')\boldsymbol{u}\boldsymbol{u}'d\boldsymbol{u}' \\ &= \text{const} - \frac{3}{2}UkT\boldsymbol{u}\boldsymbol{u} : \boldsymbol{S}, \end{aligned} \quad (11)$$

where

$$U = \frac{2}{3}\beta_1 \nu bL^2 \quad (12)$$

is called the nematic strength, and

$$S = \int \Psi(\boldsymbol{u}')\boldsymbol{u}'\boldsymbol{u}'d\boldsymbol{u}' \quad (13)$$

is the second-order moment of the orientation distribution.

With either nematic potential, the equilibrium orientation distribution $\Psi_{eq}(\boldsymbol{u})$ can be computed via a self-consistency condition, and the isotropic-to-nematic transition has been analyzed in terms of nematic strength parameters.[1,29]

Doi Theory for Monodomain LCPs: Molecular Viscoelasticity

Doi developed a dynamic theory for rigid-rod polymers using the Onsager potential.[29,30] Subsequent applications mostly used the Maier–Saupe potential for mathematical simplicity; we will illustrate Doi's theory using the latter. Consider the evolution of the orientation distribution $\Psi(\boldsymbol{u})$ for an ensemble of rods in a linear flow with a constant velocity gradient $\nabla \boldsymbol{v}$. $\Psi(\boldsymbol{u})$ is assumed to be spatially uniform; the nematic is a single crystal, or "monodomain." The conservation of probability leads to the following Fokker–Planck equation:

$$\frac{\partial \Psi}{\partial t} = -\Re \cdot (\boldsymbol{u} \times \boldsymbol{\kappa} \cdot \boldsymbol{u} \Psi) + D_r \Re \cdot \left[\Re \Psi + \frac{1}{kT} \Psi \Re V_{\mathrm{MS}} \right] \tag{14}$$

where the rotational operator $\Re = \boldsymbol{u} \times (\partial / \partial \boldsymbol{u})$, and $\boldsymbol{\kappa} = (\nabla \boldsymbol{v})^{\mathrm{T}}$. D_r is a "pre-averaged" rotational diffusivity for the rods.[29] The nematic potential V_{MS} enters as it modifies the rotation of rods by exerting a torque $-\Re V_{\mathrm{MS}}$. An evolution equation for the second-moment tensor $\boldsymbol{S}$ follows from Eq. (14):

$$\frac{\partial \boldsymbol{S}}{\partial t} = -6D_r \left(\boldsymbol{S} - \frac{\delta}{3} \right) + 6D_r U (\boldsymbol{S} \cdot \boldsymbol{S} - \boldsymbol{S} : \boldsymbol{Q}) + \kappa \cdot \boldsymbol{S} + \boldsymbol{S} \cdot \kappa^{\mathrm{T}} - 2\kappa : \boldsymbol{Q} \tag{15}$$

where $Q = \int \boldsymbol{uuuu} \Psi(\boldsymbol{u}) d\boldsymbol{u}$, and $\boldsymbol{\delta}$ is the second-rank unit tensor. An elastic stress tensor can be derived by the virtual work principle:

$$\sigma_E = 3\nu kT [\boldsymbol{S} - U(\boldsymbol{S} \cdot \boldsymbol{S} - \boldsymbol{S} : \boldsymbol{Q})] \tag{16}$$

In addition, a viscous stress tensor arises from viscous friction on the rods:

$$\sigma_V = \frac{\nu}{2} \zeta_r \boldsymbol{\kappa} : Q \tag{17}$$

where ζ_r is a rotational friction constant defined by Doi and Edwards.[29]

For Eqs. (15)–(17) to be a self-contained rheological theory, the fourth-order moment $\boldsymbol{Q}$ has to be related to the second-moment $\boldsymbol{S}$ by a closure approximation. Such a closed theory describes the LCP orientation by the second-rank tensor $\boldsymbol{S}$, and the director can be identified as the eigenvector for the largest eigenvalue. Doi[30] introduced a decoupling approximation: $\boldsymbol{S}:\mathbf{Q} = \boldsymbol{S}:\boldsymbol{SS}$, which turns out to be unsatisfactory as it artificially suppresses director tumbling.[31] More sophisticated closure models have since appeared, and their impact on the theory's prediction has been carefully examined (for example, Refs.[32,33].) The best closure models to date preserve most of the qualitative features of the theory.

The Doi theory captures the molecular viscoelasticity of LCP, i.e., the relaxation of the orientation distribution under flow. But it completely ignores distortional elasticity and is limited to monodomains. The assumption of spatial uniformity underlies all its key elements: the nematic potential, the kinetic equation, and the elastic stress tensor. Therefore, its successes are restricted to situations where distortional elasticity is insignificant.

One such success is the prediction of anomalous normal stress differences in shear flow. Measurements indicate that the normal stress differences N_1 and N_2 undergo two sign changes as the shear rate increases. For small and large shear rates, $N_1 > 0$, $N_2 < 0$ as expected of flexible polymers. In an intermediate range, however, $N_1 < 0$, $N_2 > 0$.[34] When Eq. (14) is solved without closure approximations, the Doi theory predicts three regimes of director dynamics with increasing shear rate: tumbling, wagging, and steady alignment.[31,35,36] The first sign change occurs within the tumbling regime, while the second occurs in the steady alignment regime. These transitions are linked to the spreading or narrowing of the orientation distribution Ψ. For N_1 and N_2, quantitative agreement has been achieved between prediction and measurements.[34] Using the closure-approximated Doi theory, Feng and Leal[37] simulated inhomogeneous LCP flows, and showed that director tumbling can lead to defect-like patterns. They also predicted a flow-orientation instability resembling experimental observations in channel flows.[38]

Complete Theories with Molecular Viscoelasticity and Distortional Elasticity

To add distortional elasticity to the Doi theory, one has to start with a more general nematic potential that accounts for spatial gradients. Marrucci and Greco[39] derived such a potential for nonlocal interaction among rigid-rod molecules in a distorted nematic material. For a test molecule oriented along $\boldsymbol{u}$ at position $\boldsymbol{r}$, Marrucci and Greco delineated an interaction region V enveloping the test molecule. Spatial averaging of the molecular interaction inside a spherical V produces a nonlocal nematic potential:

$$V_{\mathrm{MG}}(\boldsymbol{u}) = \text{const} - \frac{3}{2} UkT \left(\boldsymbol{S} + \frac{\Lambda^2}{24} \nabla^2 \boldsymbol{S} \right) : \boldsymbol{uu} \tag{18}$$

where the interaction length $\Lambda \sim V^{1/3}$ is the only free parameter in the theory. Eq. (18) is a molecularly-based generalization of the Maier–Saupe potential.

Following the procedure in deriving the Doi theory, one arrives at a kinetic equation for $\boldsymbol{S}$:[40,41]

$$\frac{\partial \boldsymbol{S}}{\partial t} + \boldsymbol{v}\cdot\nabla S = -6D_r\left(\boldsymbol{S} - \frac{\delta}{3}\right) + 6D_r U(\boldsymbol{S}\cdot\boldsymbol{S} - \boldsymbol{S}:\boldsymbol{Q}) + \boldsymbol{\kappa}\cdot\boldsymbol{S} + \boldsymbol{S}\cdot\boldsymbol{\kappa}^{\mathrm{T}} - 2\boldsymbol{\kappa}:\boldsymbol{Q} + \frac{D_r U\Lambda^2}{8} \times (\nabla^2\boldsymbol{S}\cdot\boldsymbol{S} + \boldsymbol{S}\cdot\nabla^2\boldsymbol{S} - 2\nabla^2\boldsymbol{S}:\boldsymbol{Q}) \quad (19)$$

where the last line represents the consequences of the spatial gradients. Derivation of the elastic stress tensor involves subtleties in treating the nonlocal interaction among molecules. Feng, Sgalari, and Leal[41] generalized the virtual work principle to cover a finite volume of the LCP, and imposed a condition of zero work on the boundary. This leads to an elastic stress tensor:

$$\sigma_E = 3\nu kT[\boldsymbol{S} - U(\boldsymbol{S}\cdot\boldsymbol{S} - \boldsymbol{S}:\boldsymbol{Q})] - \frac{\nu kTU\Lambda^2}{8} \times \left(\boldsymbol{S}\cdot\nabla^2\boldsymbol{S} - \nabla^2\boldsymbol{S}:\boldsymbol{Q} + \frac{\boldsymbol{P} - \nabla\nabla\boldsymbol{S}:\boldsymbol{S}}{4}\right) \quad (20)$$

where $P_{ij} = (\partial S_{kl}/\partial x_i)(\partial S_{lk}/\partial x_j)$. With a proper closure approximation, Eqs. (19) and (20) constitute a ''complete'' constitutive theory for LCPs that incorporates both molecular viscoelasticity and distortional elasticity.

This theory has two notable features. The nonlocality of molecular interaction is reflected by the ellipticity of Eq. (19) [cf. Eq. (15)]. Thus, the LCP configuration is globally coupled by distortional elasticity. In addition, the elastic stress tensor is asymmetric. The mean-field torque on LCP molecules amounts to a ''volume torque'' on the material, which modifies the usual conservation of angular momentum. The antisymmetric part of the stress tensor precisely balances the volume torque computed by averaging the molecular torque.[41]

Eq. (18) is actually a special form of the Marrucci–Greco potential obtained by taking a spherical interaction region around a test molecule. This corresponds, in the limit of weak distortion, to the one-constant approximation in Frank elasticity. Accounting for the molecular length in an oblong interaction region, Marrucci and Greco[39] derived a more general potential that produces three unequal elastic constants. Wang[42] has built this general nematic potential into a dynamic theory. Finally, we note several alternatives to the kinetic approach of LCP rheology.[5,24,43] Despite the different starting points, the complete theories obtained are essentially the same.

Predictions of the Complete Theories

As the complete theories include both molecular viscoelasticity and distortional elasticity, an outstanding question is: do they predict the correct dynamics for texture evolution that have eluded previous simpler models? So far, efforts to answer this have been limited to numerical simulations on shear flows.

Kupferman, Kawaguchi, and Denn[40] assumed no streamwise (along z in Fig. 1) or spanwise (along x) variations and a two-dimensional orientation with all molecules lying on the y–z plane. A one-dimensional ''windup'' picture emerges, similar to the Leslie–Ericksen predictions.[13] At low shear rates, a steady state is reached. At higher shear rates, the director continues to tumble in the interior of the domain, with the near-wall distortion being released periodically. A disappointing feature of the result is the lack of an inherent texture length scale that would reflect the balance between elastic and viscous torques.[3]

Rey and Tsuji[24,25] permitted two-dimensional variations of orientation on the y–z plane, but decoupled the flow field from the kinetic equation so that the linear velocity profile is fixed and unperturbed by LCP stress. Results reveal the conflict between the tumbling tendency far from the anchoring walls and the fixed orientation at the walls, which is resolved by periodic nucleation of a pair of defects. Again, no inherent texture length scale emerges. The common features of the above solutions—a windup structure and periodic appearance and annihilation of $\pm 1/2$ defects—are similar to the prediction of the original Doi theory.[32,37,38] Thus, a key expectation of the complete theories, namely the prediction of a texture length independent of macroscopic geometry, is not fulfilled, perhaps owing to the simplifications in these simulations.

Sgalari, Leal, and Feng[44] sought to relax the geometric and physical restrictions in simulating shear flows. The constitutive and momentum equations are fully coupled, with the flow affecting the LCP orientation, and the resulting stress tensor modifying the flow in return. Two-dimensional variations on the y–z plane are allowed, though the configuration tensor $\boldsymbol{S}$ is assumed to be symmetric about the shear plane as in Tsuji and Rey.[24] Finally, the dependence of the rotational diffusivity on the order parameter, the so-called tube dilation effect,[29] is included. Upon startup of shear, the interior of the domain tumbles as seen before. In time, however, this tumbling is arrested by distortional elasticity, and narrow strips containing much-reduced order emerge along the flow direction. These strips are roughly parallel to each other and are taken to be disclination lines. A characteristic texture length h_{text} is identified from the Fourier spectrum of the order parameter profiles. h_{text} refines in time and approaches an equilibrium level in about 100 strain

units (Fig. 4A). Marrucci's argument for the inherent texture length,[3] carried over to the complete molecular theory, yields the following scaling:

$$h_{\text{text}} \propto \Lambda\left(\frac{U}{De}\right)^{1/2} \tag{21}$$

where De is the Deborah number of the flow. The numerical data appear to be consistent with the square-root scaling (Fig. 4B). Sgalari, Leal, and Feng[44] further removed the restriction on $\boldsymbol{S}$ being symmetric about the shear plane. Then, the complete theory predicts an out-of-plane twist instability resembling the predictions of the LE theory.[12]

More recently, Sgalari, Leal, and Meiberg[45] and Klein and Leal[46] examined the instability of simple shear to secondary flows in the x–y plane. The initial instability takes on a similar form to that predicted by the LE theory, with the appearance and subsequent breakup of roll cells.[20] But the complete theory allows these authors to probe director turbulence and the Deborah-number cascade at much higher shear rates.[18] The authors argued that $\pm 1/2$ strength "thin" defects would eventually appear in addition to the escaped ± 1 disclinations noted before.

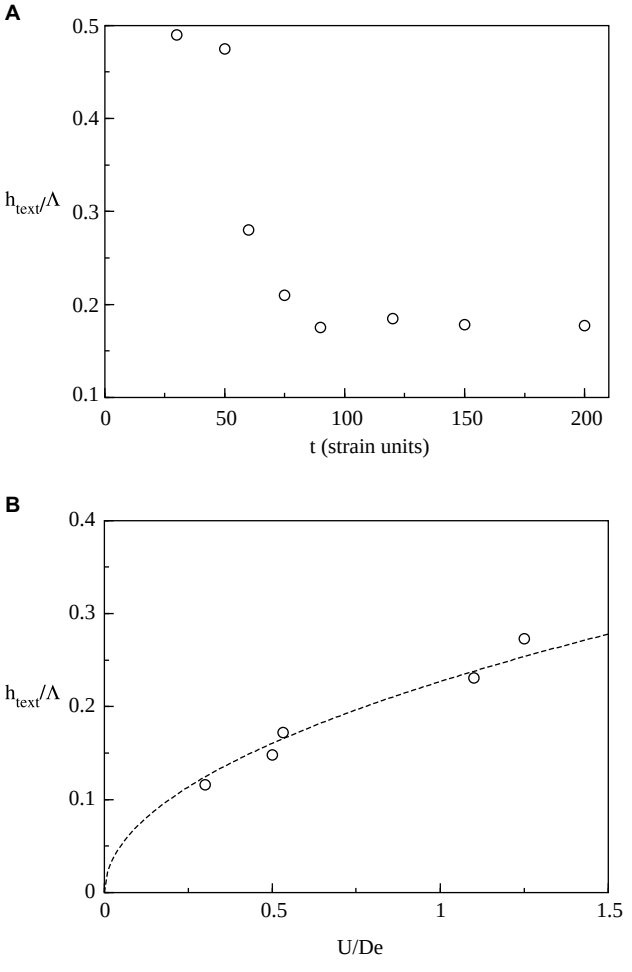

Fig. 4 (A) Evolution of h_{text} in time for $U = 8$, $De = 15$, $Er = 8 \times 10^6$, $\Lambda/H = 10^{-3}$ and (B) scaling for h_{text} when U/De is varied. The data points are numerical results and the dotted line indicates the square-root law of Eq. (21). (From Ref.[44].)

Connection Between Molecular and Continuum Theories

As alluded to in the introduction to this entry, the LE theory was conceived for small molecule LCs while molecular theories are intended for LCPs. LC molecules retain their equilibrium orientation distribution. LCPs are susceptible to disturbances to their distribution function $\Psi(\boldsymbol{u})$; its temporal relaxation gives rise to molecular viscoelasticity, while its spatial gradient produces distortional elasticity. A natural question is whether the molecular theories reduce properly to the continuum LE theory in the limiting case of an undisturbed orientation distribution. This situation arises in the "weak flow limit" where the flow is weak ($De \ll 1$) and spatial distortions are small ($|\nabla \boldsymbol{S}| \ll 1/\Lambda$). In this limit, Feng, Sgalari, and Leal[41] has proved that their version of the complete theory reduces properly to the LE theory.

Their proof relies on the fact that in the limit of small spatial distortions, The Marrucci–Greco potential of Eq. (18) reduces to the Frank elastic energy of Eq. (2) with

$$K = \frac{1}{8}\nu kTUS_{\text{eq}}^2\Lambda^2 \tag{22}$$

S_{eq} being the equilibrium order parameter. Feng, Sgalari, and Leal[41] followed the unusual perturbation procedure outlined by Kuzuu and Doi,[47] in which the base state is undetermined because a uniform single crystal does not have a preferred orientation. The kinetic equation and stress tensor reduce precisely to the LE forms, with the phenomenological elastic and viscous constants determined by equilibrium molecular parameters.

As indicated above, such an agreement is perhaps expected. On the other hand, it is remarkable that a rather complex phenomenological theory postulated for an LC continuum can be reconciled with an even more complex molecular theory built on the concept of intermolecular potential. Perhaps the only other such happy instance is the agreement between the continuum Oldroyd-B model for viscoelastic liquids and the molecular model based on a dilute suspension of linear Hookean dumbbells in a Newtonian solvent.[28]

The idea that the LE theory applies to weak flows, while the molecular theories to strong flows provides a convenient framework for interpreting experimental

observations. Larson and Mead[18] identified the so-called Ericksen number (*Er*) and the Deborah number (*De*) cascades for sheared nematic polymers. At lower shear rates, the molecular distribution remains largely undisturbed although the preferred orientation–the director–rotates. The dynamics are thus dictated by *Er*, the ratio between viscous and distortional elastic effects. The LE simulations of Feng, Tao, and Leal[20] and Tao and Feng[21] fall in this cascade, and their results indeed correlate well to observations in the *Er* cascade. Higher flow rates start to distort the molecular distribution, and molecular viscoelasticity becomes significant once *De* rises to O(1).[18] This is the *De* cascade, where distortional elasticity no longer has a major effect on certain macroscopic properties such as rheology. That is why the original Doi theory, with distortional elasticity omitted entirely, is able to reproduce the anomalous normal stress differences to quantitative accuracy.[34] For other features such as defect generation, distortional elasticity remains locally important. This is the case for the simulations of Sgalari et al.[44,45] and Klein and Leal.[46]

CONCLUSIONS

In this brief review, we strive to construct a coherent picture of our current theoretical understanding of the flow and rheology of small-molecule and polymeric nematic liquid crystals. Owing to space limitations, we have presented results selectively, based more on the need to tell a somewhat coherent story than the significance of the work.

To sum up, there have been two types of constitutive theories for LCs and LCPs: one based on phenomenological modeling that treats the material as a continuum, and the other based on a molecular picture and a statistico-mechanical approach. The molecular theories contain the continuum LE theory as a limiting case for weak flows and small spatial distortions. Shear-flow simulations using the LE theory capture qualitative features of the Ericksen number cascade, including shear-induced defect formation. More recent simulations using a complete molecular theory have reproduced some experimental observations at higher shear rates extending into the Deborah number cascades. In particular, an inherent texture length emerges and follows a scaling expected from balancing the viscous and elastic effects.

Thermal Analysis Techniques: Overview

John O. Hill
La Trobe University, Melbourne, Victoria, Australia

INTRODUCTION

The techniques that constitute the field of ''thermal analysis'' are reviewed in terms of the changes in a specified physical property of a material being monitored as a function of temperature, the instrumentation involved, and selected applications in the fields of materials science and chemical processing. The basic thermal analysis techniques—thermogravimetric analysis (TGA), differential thermal analysis (DTA), differential scanning calorimetry (DSC), thermomechanical analysis (TMA), and dynamic mechanical thermal analysis (DMTA) —together with some ''less common'' thermal analysis techniques such as thermal emanation analysis (TEA), thermosonimetry (TS), and dielectric thermal analysis (DETA) are discussed in detail. The application of these techniques in various fields indicates that ''thermal analysis'' is recognized as a major analytical science in its own right and together with calorimetry comprises the core of the experimental thermal sciences.

BACKGROUND

The generic title ''thermal analysis'' is inclusive of a range of analytical techniques, which all measure the change in a physical property of a material as a function of temperature. Thermal analysis can now be considered as a ''mature science,'' having been continuously developed for more than 11 decades. A variety of developments were seen particularly in the last decade. Many of these developments are directly related to the associated techniques, which include new analytical methodologies such as temperature modulation, sample controlled regimes, on-line data analysis, and ''robotic'' operational regimes. Major instrumental developments have also taken place, which enabled the analysis of ''small'' sample sizes over an ''extended'' temperature range. Essentially, the development in the field of thermal analysis over the last decade has revolutionized materials science and the chemical processing industry, because thermal analysis techniques have been intensively used to study and characterize the thermal behavior of a wide range of materials, of both natural and synthetic origins. They have played a pivotal role in both the processing of chemical materials and in quantifying the quality control procedures inherently associated with such operations on an industrial scale. The aim of this overview is to discuss the full range of thermal analysis techniques in terms of the type of measurement involved in each technique, the application range of that technique, and the interpretation of data obtained on using the technique. The applications are chosen with specific reference to the broad concept of ''chemical processing,'' so as to align with the overall objectives of this encyclopedia.

THE BASIC THERMAL ANALYSIS TECHNIQUES

It has become increasingly difficult to differentiate between the fields of thermal analysis and calorimetry, and some thermal analysis techniques can be classified as calorimetric techniques as well. One such example is the ''differential scanning calorimetry.'' Thermal methods of analysis have been developed in accordance with the need to study the changes in the properties of a material as a consequence of heating, whereas calorimetric methods measure such heat changes directly. Thermal analysis techniques and the associated fields of application are uniquely complementary. Thermal analysis investigates changes in a wide range of physical properties of a material with change in temperature. The change in property may be physical, such as a mass, linear, or three-dimensional change, melting, crystalline transition, or vaporization, or it may be a chemical change involving a reaction that alters the chemical structure of a material. The change may also be biological when related to the metabolism, interaction, or decomposition. Thus, the application field of thermal analysis is wide, diverse, and of paramount analytical significance in a wide range of areas, particularly in chemical processing.

Hemmingner[1] has recently defined ''thermal analysis'' as ''the analysis of a change in a property of a sample which is related to an imposed temperature alteration.'' The ''temperature alteration'' can involve a stepwise change from one constant temperature to another, a linear rate of change of temperature, modulation of a

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120041306

constant or linearly changing temperature with constant frequency and amplitude, and uncontrolled heating or cooling. The direction of temperature change may involve either heating or cooling and the modes of operation of temperature change may be combined in any sequence—adding to the diversity of the operational modes of thermal analysis techniques. The temperature may also be programmed to maintain a constant rate of reaction—leading to ''sample controlled thermal analysis.''

As there are many properties of a material that can be measured, the number and range of thermal analysis techniques is large. However, it is generally recognized that there are five basic thermal analysis techniques—TGA, DTA, DSC, TMA, and DMTA.

Thermal analysis instrumentation is complex but all thermal analysis instruments have common features, as shown schematically in Fig. 1.

Such instruments usually comprise four major parts: the sample in a container or holder, sensors (transducers) to detect and measure a particular property of the sample as a function of temperature, a sample enclosure within which the experimental parameters, such as temperature, pressure, and gas atmosphere, can be controlled, and a computer to control the experimental parameters and to collect and process the data from the sensors to produce meaningful results and cumulative records. Measurements are usually continuous and the heating rate is often, but not necessarily, linear with time. The results of such measurements are generated as thermal analysis curves and the features or characteristics of these curves, such as peaks, discontinuities, and slope changes, are related to thermal events in the sample, thereby characterizing its thermal behavior. Many analytical techniques require samples in a specified ''form,'' thereby imposing a pretreatment process. Pretreatment essentially destroys the structure of the matrix containing the sample. Thermal analysis methods generally require no significant pretreatment, and thereby the integrity of the sample is retained and its

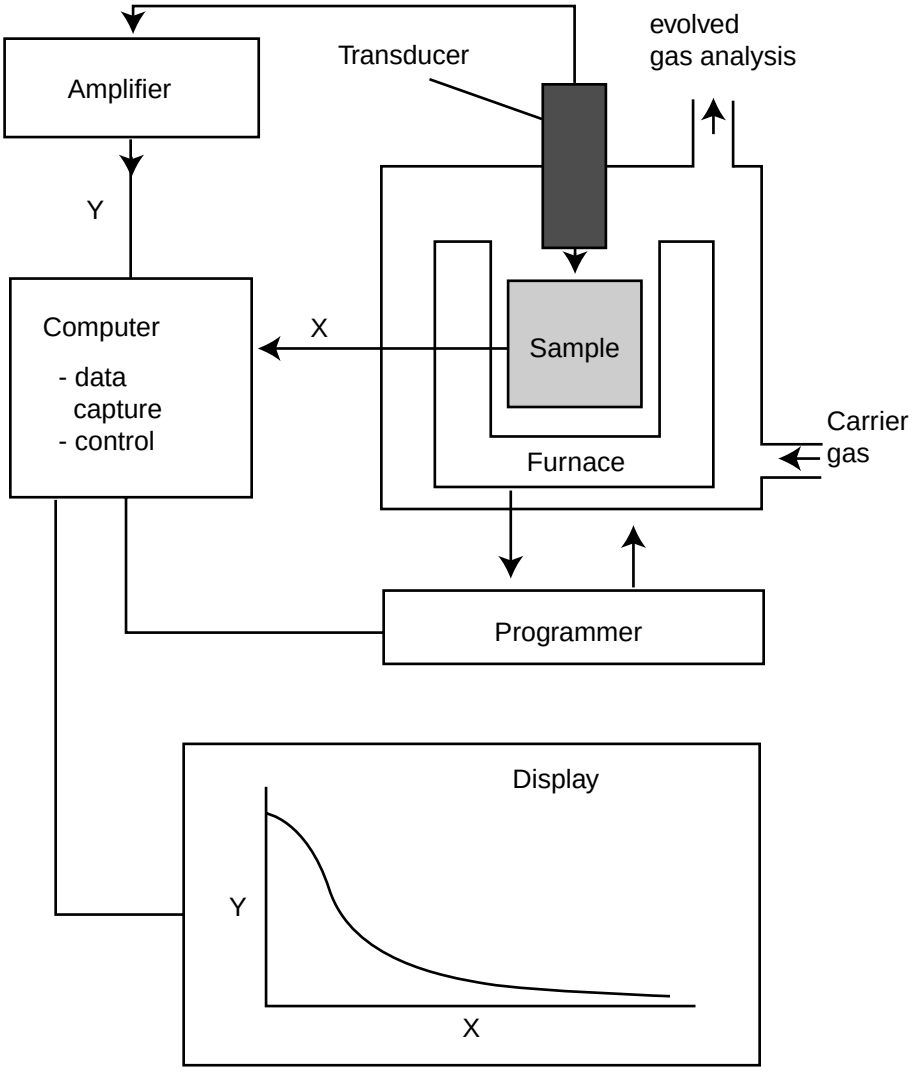

Fig. 1 Schematic diagram of a thermal analysis system.

thermal and molecular history is not changed prior to analysis. The information received from the subsequent analysis can therefore be related directly to the sample, ''as received,'' and to the situation or process where it is actually used. This feature has major significance in the chemical processing technology.

It is important in thermal analysis, as for any other analytical techniques, to obtain reproducible results. However, there are many experimental variables associated with thermal analysis and it is necessary to define at least five of these for each thermal analysis investigation. These five variables are the nature of the sample and its container (crucible), the heating (or cooling) rate, the sample-chamber atmosphere, and the sample mass. Some thermal analysis techniques require the recording of other variables, such as the load on the sample in thermomechanical analysis. In thermal analysis, the ''samples'' are usually in the solid state, but liquids can also be studied using special sample preparation techniques. Gases are not normally studied by thermal analysis techniques.

It is generally accepted that the ''basic'' thermal analysis techniques are TGA, DTA, DSC, and the thermomechanical techniques such as TMA and DMTA. Thermogravimetric analysis involves the measurement of the change in mass of the sample with change of temperature, DTA involves the measurement of the temperature difference between the sample and a thermally inert reference material with change of temperature, DSC involves the measurement of the differential power input to the sample with change of temperature, TMA involves measurement of the linear dimensional change of the sample (under static load) with change of temperature, and DTMA involves measurement of the dimensional change of the sample (under dynamic load) with change of temperature. Differential scanning calorimetry is essentially ''quantitative DTA.'' Thermogravimetric analysis and DTA may be combined into a single thermal analysis system, giving rise to the simultaneous thermal analysis (STA). It is also possible to couple TGA with DSC to produce a simultaneous TGA–DSC system. There are advantages and disadvantages of simultaneous thermal analysis systems. The principal advantage of such systems is that two types of measurement are made on the same sample over the same time interval. The disadvantage is that the sensitivity of the coupled thermal analysis systems is generally less than the individual systems operated independently and, particularly for TGA–DSC, the effective operational temperature range is restricted.

Thermal analysis systems require calibration both in terms of temperature and the physical property being measured, so as to detect and eliminate the inherent systematic errors associated with the analysis. Thus, for example, TGA systems require both temperature and mass calibration in accordance with the defined procedures for calibration of thermal analysis systems.[2]

Thermogravimetric analysis involves the measurement of the change in sample mass with change in temperature, using a ''thermobalance.'' A thermobalance is a combination of a suitable electronic microbalance with a furnace, a temperature programmer, and an on-line computer for control of the overall experiment and data analysis. The system allows for the sample to be simultaneously weighed and programmed and heated or cooled, and the mass, time and temperature data to be recorded and processed. The balance should be in a suitably enclosed system so that the nature and pressure of the atmosphere surrounding the sample can be controlled. The microbalance mechanism is maintained at or close to the ambient temperature throughout the experiment.

In TGA, mass loss is observed if a thermal event involves the loss of a volatile component. Processes such as melting do not involve any mass loss. These may be studied using DTA and DSC. Thermogravimetric analysis data are presented as a plot of mass, m vs. temperature, T, or time, t. The TGA curve shape is sigmoid, indicating that most of the mass loss occurs at a particular temperature or over a narrow temperature range where the curve has greatest slope. However, the thermal event commences before the region of greatest mass loss and continues thereafter. A more convenient representation of the character of the overall thermal event is to give the derivative of the original TGA curve as dm/dt, or rate of mass loss, and to plot this vs. temperature, T, or time, t. Thereby, the DTG curve is obtained and thus, the spread of the thermal event over a broad temperature range appears as a peak. The DTG curve is of particular assistance if two or more thermal events overlap within similar temperature ranges. Double peaks or a shoulder on a main peak appear in such cases. Slow processes, superimposed with other fast processes, appear as gradient changes in the DTG curve. Thus the DTG curve can kinetically characterize overlapping thermal events. Further, the DTG peak area is directly proportional to the corresponding mass loss; therefore, relative mass losses may be compared. The peaks in a DTG curve can act as ''fingerprints'' of components in a mixture by comparison with DTG curves of the suspected individual components.

It is common practice to check the performance of a TGA system by running a sample of calcium oxalate monohydrate. This salt is known to thermally decompose in three stages over well-defined temperature ranges. The first step involves the loss of the single water of hydration molecule followed sequentially by the conversion of anhydrous calcium oxalate to calcium carbonate with the loss of carbon monoxide, and thence the decomposition of calcium carbonate to calcium oxide with the evolution of carbon dioxide.

Thermogravimetric analysis applications are extensive and diverse and include oxysalt decompositions, natural and synthetic polymer characterization, metal oxidation and corrosion analysis, compositional analysis of coals, polymers, and rubbers, study of glass-making processes, and a wide range of chemical processing phenomena. Thermogravimetric analysis has been used very successfully to study the kinetics of chemical processes.[3,4] A quintessential TGA application has been the determination of the proximate analysis of coal. The procedure involves the in situ determination of the volatile components under an inert gas atmosphere and the combustible materials under an oxidizing atmosphere. The TGA system is fitted with a ''gas-switching'' devise to effect the overall analysis as a single run. The principal advantage of the TGA procedure is that the proximate analysis of a coal sample is achieved in less than 1 hr, whereas the conventional procedure, using classical analytical procedures, takes several hours. Using a 10 mg sample, the moisture loss is determined by heating to 110°C and the volatiles are determined by heating to 900°C, both determined in an atmosphere of pure, oxygen-free nitrogen. The carbon content is then measured by switching to an oxygen atmosphere and the residue mass gives the ash content. The entire analysis takes less than 1 hr.

Differential thermal analysis is the simplest and most widely used thermal analysis technique. The difference in temperature between the sample and a reference material is measured while both are subjected to the same heating program. In ''classical'' DTA, as represented schematically in Fig. 2A, a single block with symmetrical cavities or inserts for the sample and reference is heated in the surrounding furnace. The block is effectively a heat sink and ensures a measurable differential temperature signal during a thermal event. In conventional DTA, as represented schematically in Fig. 2B, the sample and reference material are contained in separate crucibles and both are subjected to the same temperature program.

If an endothermic event occurs in the sample, the temperature of the sample lags that of the reference, which follows the heating program. A typical DTA curve for such a thermal event is shown in Fig. 2C. If an exothermic process occurs in the sample, the response will be in the opposite direction. The negative peak shown in Fig. 2C is termed an ''endotherm'' and is characterized by its onset temperature. The area under a DTA peak is proportional to the enthalpy associated with the thermal event. Because such proportionality is not linear with temperature, only approximate enthalpy data can be obtained from DTA. The nature of the reference material is important. It must undergo no thermal events over the DTA operational temperature range and it must not chemically react with its container. Alumina has been

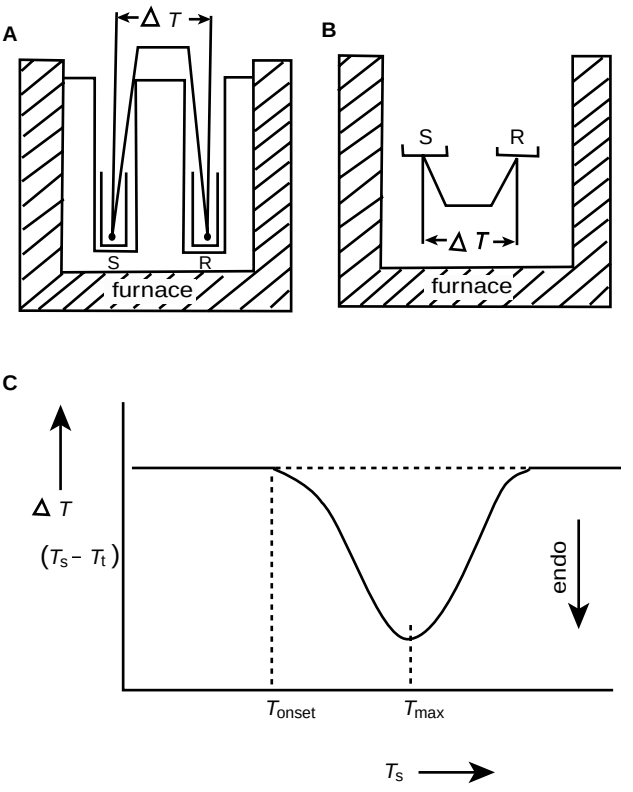

Fig. 2 Schematic diagram of a classical DTA system (A), a heat-flux DTA system (B), and a typical DTA curve (C).

extensively used as the reference material in DTA. Differential thermal analysis systems are calibrated using the ICTAC certified reference materials[2] consisting of a suite of metals with certified melting points.

Differential thermal analysis applications are extensive and wide ranging, which include the determination of melting points and the characterization of polymers, glasses, ceramics, oils, fats, waxes, clays, minerals, coals, lignite, wood, liquid crystals, explosives, propellants, pyrotechnics, pharmaceuticals, biological materials, metals, alloys, natural products, and synthetic catalysts. This list is not exhaustive. The most significant application of DTA has been the characterization of polymers and the most extensive thermal analysis study of synthetic polymers relates to polyethyleneterephthalate (PET).[5] The DTA curve of PET can be used to determine the glass transition temperature, the crystallization temperature range, and the melting range of the crystalline phase. Thus, DTA is a simple method for the complete thermal analysis of polymers and, additionally, assesses polymer thermal stability.

There are two types of DSC—heat-flux DSC and power-compensated DSC. The former is essentially a quantitative DTA. In power-compensated DSC, the aim is to maintain the sample and reference material at the same temperature throughout the controlled temperature program. The difference in the independent

supplies of power to the sample and reference material (alumina) is then recorded vs. the programmed reference temperature. A schematic of a power-compensated DSC is shown in Fig. 3, together with a representative DSC curve.

Thermal events in the sample thus appear as deviations from the baseline, in either an endothermic or exothermic direction, depending upon whether more or less energy is supplied to the sample compared with the reference material. The operational temperature range of DSC is less than that of DTA—being typically subambient to 750°C. Temperature and energy calibration of DSC instruments is achieved using the ICTAC certified reference materials.[2]

Differential scanning calorimetry has an application range similar to that of DTA but also offers additional application possibilities, the most important of which are the determinations of heat capacity and thermal conductivity of a wide range of materials. This facility makes DSC a very significant analytical technique in chemical processing. Differential thermal analysis is also used to characterize polymers and to study the curing characteristics of resins. It therefore has a widespread application in materials science. As an example, DSC has been used to identify the constituents of a plastic waste containing low density polyethylene (LPDE), high density polyethylene (HPDE), polypropylene (PP) and poly(tetrafluoroethylene) (PTFE)—''Teflon.''[6] The DSC peak areas are directly proportional to amounts of each constituent present in the waste mixture and thus, from a single DSC analysis, a complete analysis of such a sample is possible.

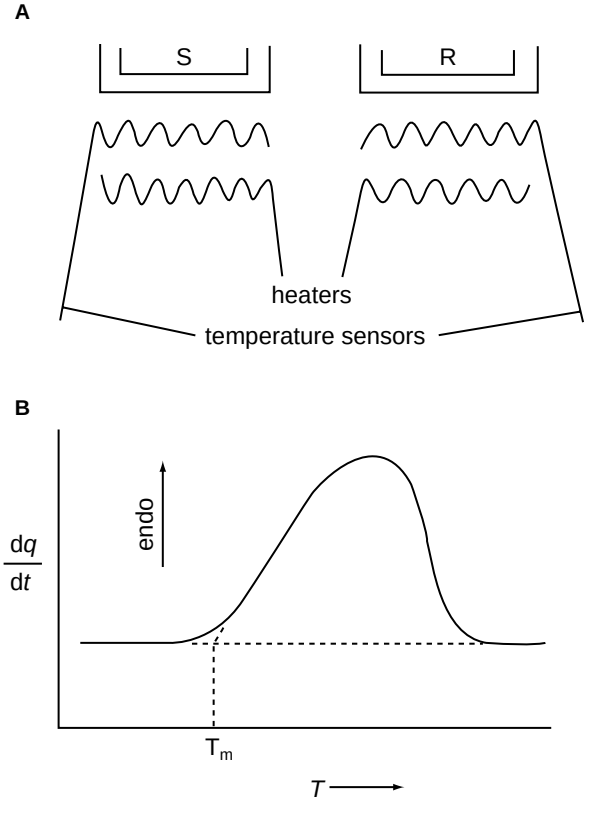

Fig. 3 Schematic diagram of a power-compensated DSC system (A) and a typical DSC curve (B).

Thermomechanical analysis embraces four different modes of measuring the dimensional change of a material as a function of temperature—penetration, extension, flexure, and torsion. The closely related technique of thermodilatometry is effected by measuring the expansion and contraction of a material under negligible load. Additional mechanical data may be obtained by measuring the penetration (the expansion or contraction of a sample while under compression) as a function of temperature. These techniques, together with flexure and torsion measurements, are collectively classified as TMA and are of paramount importance in materials characterization and testing. Thermomechanical analysis systems are calibrated using materials of known coefficient of expansion, such as aluminum,[7] and it is necessary to compensate for the many dimensional changes in the instrument as heating takes place. Temperature calibration in TMA is effected by using a suite of metals, indium, tin and bismuth.[7]

Applications of TMA are numerous and are largely confined to materials science. Thermomechanical analysis is widely used to measure the coefficient of thermal expansion of materials, to determine the glass transition and melting and crystallization characteristics of polymers, and for the determination of the structural integrity of films and fibers. Thus, TMA has been applied to study the change in length of a sample of silicone gum rubber under different applied loads.[8] At zero force, a change in length of the sample is apparent at $-60°C$ and is because of the sample undergoing a change from glassy to rubbery behavior. At this temperature, the polymer chains acquire additional degrees of mobility that is manifested as an increase in thermal expansion coefficient. The glass transition temperature can be defined by the intercept of tangents to the linear portions of the length vs. temperature plot, above and below this region. When a force is applied to the specimen, the probe deforms the material in inverse proportion to its stiffness. Below the glass transition, the polymer is rigid and is able to resist the applied force, and thus its deformation is negligible. Above the glass transition, the polymer becomes soft and the probe penetrates into the bulk of the specimen. The temperature at which this occurs is the ''softening temperature'' and is dependent on the applied force.

In dynamic mechanical analysis (DMA), the sample is subjected to a periodically varying stress (of usually sinusoidal or angular frequency). The response of the sample to this treatment provides information on the

''stiffness'' of the material, as quantified by its elastic moduli, and its ability to dissipate energy, as measured by its ''damping.'' For a viscoelastic material, the strain resulting from the periodic stress will also be periodic, but will be out of phase with the applied stress as a result of energy dispersion as heat or damping in the sample. The phase angle between the stress and the strain is an important parameter in DMA.

Dynamic mechanical analysis is routinely used to investigate the morphology of polymers, composites, and a wide range of other materials. The technique is particularly sensitive to low energy transitions, which are not readily observed by DSC. Many of these processes are time-dependent and by using a range of mechanical deformation frequencies, the kinetic characteristics of these processes can be investigated. A typical DMA application is the study of the thermal properties of polyesters.[5] The aliphatic polyester, poly(caprolactone), is typically highly crystalline and melts between 50°C and 60°C. However, the sample is not completely crystalline and contains domains of amorphous material which undergoes a glass–rubber transition at −40°C. The peaks in Tan delta at −85°C and −130°C correspond to the beta and gamma transitions of the polymer, respectively, and are because of the motion of short lengths of the polymer backbone rather than to a large scale increase in mobility that accompanies the glass–rubber transition. It is difficult to measure this type of behavior by DSC but DMA is able to detect such minor transitions, as it is able to monitor those that involve dissipation of mechanical energy as heat.

LESS COMMON THERMAL ANALYSIS TECHNIQUES

''Less common'' thermal analysis techniques encompass those that monitor changes in the ''less obvious'' properties of a material as a function of temperature and hence these are specialized techniques, which require specialized and sophisticated equipment. ''Less common techniques'' are not synonymous with ''less used'' techniques, but relate to a field of thermal analysis that is less well developed as a result of being highly specialized.

Emanation thermal analysis (ETA) involves the measurement of the release of inert (usually radioactive) gas from a solid sample, as a function of temperature. The rate of such gas release is essentially an indication of the changes taking place in the sample, and a comparison of ETA data with those of other thermal analysis techniques, particularly TGA and evolved gas analysis (EGA), provides information on the microstructure of the sample material. However, most of the solid samples studied by ETA are ''spiked'' with inert gas, which is trapped at lattice imperfections and the latter also provide diffusion pathways for adsorbed gases. It is this spiking procedure that characterizes ETA as a less common TA technique. Several methodologies are available to effect the required ''spiking.'' These are essentially divided into two groups: techniques for introducing the parent nuclide of an inert gas and techniques for introducing the inert gas itself. The former group of spiking techniques is preferable, because labeling the sample with the parent nuclide gives an enhanced time frame over which the inert gas can be desorbed from the sample, as it is formed continuously in situ. With the second group of techniques, the absorbed inert gas may be lost from the sample over the time frame of a single run. The development of ETA has been largely because of Balek and Tolgyseey.[9]

Emanation thermal analysis is usually carried out in conjunction with other TA techniques, most notably DTA and EGA. In this context, ETA can be considered as a ''coupled TA technique.'' Carrier gas at a constant flow rate is used to carry the released gas from the sample to appropriate detectors—usually radioactive counting devices. In the case of desorbed radon, a scintillation counter is used, whereas Geiger counters are used for krypton, xenon, and argon.

An ETA curve is a plot of ''emanating power'' E as a function of time and the E/time relationship has been developed and defined by Balek and Tolgyseey.[9] A major difficulty of ETA is that preparation and handling of samples require sophisticated radiochemical facilities coupled with all the associated precautions. However, the net amounts of radioactive gas incorporated into samples are so small that the evolved gas, after dilution with the carrier, does not pose a significant hazard.

The applications of ETA are numerous and have been discussed by Balek,[10] and one of the major applications is the characterization of powders. Emanating power is related directly to surface area and hence changes in grain size and the occurrence of sintering during heating can readily be detected. Kinetic parameters related to sintering can also be derived. Solid-state phase changes can also be manifested as changes in the emanating power. In this context, ETA data can be correlated with DTA, DSC, and TMA data that are related to phase changes of solid-state materials. Emanation thermal analysis has also been applied to study solid–gas reactions, such as the oxidation of metals and the reduction of metal oxides. In this respect, ETA data are useful for studying surface phenomena and hence ETA has potential for future applications in the study of corrosion and catalytic activity and catalytic processes. Solid–solid reactions, such as spinel formation between zinc oxide and iron(1 1 1) oxide can be studied using ETA, by

labeling ZnO with a radioactive thorium isotope. It is apparent that both the reactant oxides interact in a series of stages involving an initial surface diffusion process and a final bulk volume diffusion process. These processes are not readily detected by other TA techniques such as DTA or TMA, but are clearly revealed by increased emanation with clear definitions of the corresponding temperature ranges. The reactivity of oxides can be readily determined by ETA in terms of the mutual relativities toward spinel formation. Emanation thermal analysis therefore has major significance as an analytical technique in materials science.

Thermosonometry involves the measurement of sound intensity emitted by a sample as a function of temperature. Sound emission originates from the release of thermal stresses in the sample, such as movement of dislocations, generation and propagation of cracks, nucleation of new phases, relaxation processes, and discontinuous changes in physical properties. For example, at a glass transition temperature, a discontinuous change in free volume generates elastic waves that cause an acoustic effect. Such stress relief processes are not usually detectable by conventional TA techniques because of the low associated energy, and hence TS has many unique applications, such as the detection of radiation damage, crystal defect content, and degree of annealing of polymeric samples. It is also complementary to TMA for the detection of mechanical effects associated with melting, dehydration, and decomposition and for studying a range of solid-state phase changes.

Thermosonometry is usually carried out in conjunction with DTA and sound energy is emitted as mechanical vibrations prior to and during the thermal events associated with the sample over defined temperature ranges. Such sonic activity is detected by a specially adapted stethoscope. The mechanical waves are converted to electrical signals by conventional piezoelectric transducers. The stethoscope is constructed of fused silica for operation up to 1000°C and for higher operating temperatures, ceramics or noble metals are used. The sample is contained in the DTA sample head, which in turn acts as an acoustic transformer and is connected via a transmitting rod to a piezoelectric sensor, fixed on a recoil foundation and a seismic mount to prevent interference from external noise. A typical TS–DTA system has been described in detail by Clark.[11] Several special aspects of the instrumentation enhance sensitivity. The waveguide system transmits the acoustic emissions from the heated sample to the transducer at an ambient temperature so as to nullify the effect of temperature on the transducer, and the sample temperature thermocouple is located close to, but not in direct contact with the sample. This is because, the insertion of the sensor into the sample can cause mechanical damping effects, which directly affect acoustic activity.

The output of a TS experiment consists of a rapid cascade of decaying signals that may be recorded in several ways: as the number of signals of peak amplitude greater than a set threshold value in a given time, the time for which the signal amplitude exceeds the threshold value, the time frequency that signals pass through a preselected voltage level in a positive direction, or the root-mean-square amplitude of energy or a set of frequencies. In general, TS data are complex and difficult to interpret. Attempts have been made to relate frequency distributions to processes (thermal events) occurring in the sample. In the simplest interpretation, frequency distributions can be used as ''fingerprints'' of sample origin. Superficial interpretation of TS data is also possible, in that ''bubble release'' is associated with low frequencies and crystal fracture or distortion is associated with high frequencies. In general, TS is a powerful technique for rationalizing a wide variety of solid-state phenomena and is hence a valuable analytical technique in materials science.

Significant TS applications have been described by Butteridge et al.,[12] Bellchamber et al.,[13] and Shimada,[14] and one example is included here. Thermosonimetry has been applied to study the dehydroxylation behavior of kaolin, which show two regions of acoustic activity. The low temperature region corresponds to dehydroxylation and the high temperature region corresponds to recrystalization as metakaolinite. The relevant temperature regions of acoustic activity are defined by the coupled DTA analysis.

Thermoelectrometry or thermoelectrical analysis (TEA) is the generic title for a group of techniques involving the measurement of electrical properties of a sample as a function of temperature. The electrical properties commonly measured in TEA are conductance, capacitance, and dielectric properties. The most prominent TEA technique is DETA, which involves measurements of both the capacitance and the conductance of a sample as a function of time, temperature, and frequency. The former is a measure of the ability of the sample to store charge, whereas the latter is a measure of its ability to transfer charge. Four parameters are associated with DETA: the permittivity, the loss factor, the dissipation factor, and the ionic conductivity. These parameters provide information related to molecular motion within the sample and, as for most TA techniques, it is the variation of these parameters during thermal events that is of primary interest, rather than their absolute values. Hence, in DETA, the sample is subjected to an oscillating sinusoidal electric field and the applied voltage produces a polarization within the sample and causes a current to flow, which in turn leads the electric field

by a phase difference delta. Dielectric thermal analysis is somewhat related to thermomechanical techniques, in that the net current flow is similar in nature to the deformation induced by applied mechanical stress and represents a measure of the freedom of charge carriers in the sample to respond to the applied field. Also, DETA is able to differentiate between different types of charge carriers in the sample. Dipoles attempt to orientate with the applied electric field, whereas ions, which are often present as impurities, migrate toward the electrode of opposite polarity. Dielectric thermal analysis is therefore significant as an analytical technique for a wide range of ''quality control'' processing operations.

The instrumentation for DETA has been described in detail by Price.[15] The sample is presented as a thin film, typically no more than 1–2 mm thick, sandwiched between two parallel plates so as to form a simple electrical capacitor. A grounded electrode surrounding one plate, known as a ''guard ring,'' is incorporated to nullify stray electric fields. The sample temperature sensor is a thermocouple or a platinum resistance thermometer, which is placed in contact with one of the plates. The sample is connected to the inverting input of an operational amplifier, configured as a current-to-voltage converter with capacitive feedback. The measured phase shift of this network is directly correlated with the dielectric properties of the sample. There are two operational modes in DETA: using a continuous range of frequencies (50 Hz to 1 MHz) at preselected temperatures or over a continuous range of temperatures at selected frequencies. The latter is the more common operating mode for the study of phase transitions and chemical reactions in a sample. Temperature calibration of DETA is effected by measuring the melting transition of a low molar mass organic material, such as benzoic acid.

Dielectric thermal analysis is a highly specialized thermal analysis technique, but is particularly useful for detecting polar impurities in nonpolar materials such as commercial polymers. Thus, DETA and the thermoelectrometric techniques, in general, occupy a specialized niche in the TA application field in the context of addressing a specific problem in the microstructure of solids. For example, the thermal analysis of thin films can be problematic because of the very small amount of material involved. The glass transition behavior of adhesives affects the tack and bonding behavior, and the analysis of adhesive films by DSC is difficult unless the film is removed from any backing support material. Dielectric thermal analysis of such films is usually undertaken by swelling the adhesive in a suitable solvent and scraping it off the supporting substrate. However, the intrinsic properties of the adhesive may change in this process, even if the sample is subsequently dried to remove residual solvent. Dielectric thermal analysis, however, is ideally suited to direct analysis of thin films and so long as the support does not undergo any thermal transitions in the temperature region of interest, DETA can measure the thermal properties of the adhesive in situ, without any sample pretreatment. The DETA curves of a thin layer of pressure-sensitive adhesive on poly(ethyleneterephthalate) film at different electrical field frequencies have been interpreted by Price.[16]

Dielectric thermal analysis essentially involves monitoring the viscosity of a system via its ability to store and transport electrical charge. Changes in the degree of alignment of dipoles, together with the ion mobility, provide information relating to physical transitions in the sample and to changes in properties such as viscosity, rigidity, reaction rate, and cure state. Dielectric thermal analysis is particularly useful for characterizing the cure process of polymers. Polymers contain ionic impurities and the application of a voltage between two electrodes creates an electric field, which forces such ions to migrate to the oppositely charged electrode. However, the conductivity of the material depends on the magnitude of the viscous drag experienced by these ionic impurities. Ions moving through polymerized materials have low mobility and conductivity corresponding to the high viscosity of the medium. As the degree of cure in synthetic polymers is proportional to the degree of polymer cross-linking, the cure process can be monitored by monitoring the conductivity of the material throughout the entire curing process and DETA is able, more so than any other TA technique, to determine the ''cure endpoint.'' Dielectric thermal analysis applications to the curing process of synthetic polymers have been described in detail elsewhere.[16]

Dielectric thermal analysis can also be used very effectively for the in situ monitoring of the UV degradation of adhesives such as tinted selfadhesive plastic films, used to screen out direct sunlight from penetrating buildings and vehicles. Attached to the window glass, the adhesive directly receives solar radiation and must be stabilized against photodegradation by a suitable blend of polymer and stabilizer. A modified form of DETA, in which the sample temperature sensor is an interdigitized single surface dielectric sensor, can be used to study such systems.[16] The window film samples are mounted on glass plates for accelerated ageing. A small hole is cut into the plastic film and the interdigitized sensor is applied to the exposed surface of the adhesive after freezing the plate to aid the removal of the backing. Measurements of the dielectric and permittivity factors are made at an ambient temperature, as a function of frequency. Such measurements correlate UV aging of the film with changes in dielectric behavior of the adhesive and hence, optimized polymer/stabilizer formulations can

be identified. Dielectric thermal analysis is thus a powerful analytical technique in the processing of a wide range of polymer preparations.

CONCLUSIONS

This brief overview about the field of thermal analysis has concentrated on discussing some of the experimental techniques that constitute this analytical domain. Techniques such as differential thermal analysis were developed more than a century ago, whereas the dielectric thermal analysis technique was developed less than a decade ago. However, both the basic and the less common thermal analysis techniques have the same objective—to determine the change in a physical property of a material as a function of temperature. The power of these techniques lies in the diversity of physical properties of a material which can be investigated, the wide range of materials which can be studied, the wide temperature range over which variation in such physical properties can be determined, and the wide range of ''conditions'' in which the thermal properties and thermal behavior of a material can be evaluated. This overview provides an insight into the diversity, complexity, authenticity, and superiority of this category of analytical techniques, which collectively have revolutionized the studies of materials and chemical processing over several decades and promise unique analytical opportunities in support of the nanotechnological age.

School of Chemical Engineering, Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Thermal cracking of ethane, propane, butane, naphthas, gas oils, and/or vacuum gas oils is the main process employed for the production of ethylene and propylene; butadiene and benzene, toluene, and xylenes (BTX) are also produced. Thermal cracking of these hydrocarbons is also called pyrolysis of hydrocarbons. Ethylene is the organic chemical produced worldwide in the largest amounts and has been called keystone to the petrochemical industry.[1] This technology is well documented in the literature.[2–8] Somewhat similar thermal cracking processes are used to produce vinyl chloride monomer (VCM) from ethylene dichloride (EDC), styrene from ethylbenzene, and allyl chloride from propylene dichloride (PDC). Production of charcoal and coke from wood and coal is actually a pyrolysis process, but it is not discussed here.

The worldwide ethylene capacity in year 2000 was approximately 100 million metric tons per year and even greater production is being considered. Propylene capacity is approximately 60 million metric tons per year for which about half is produced by thermal cracking and the other half by refinery operations. The capacities of BTX are approximately 40, 20, and 30 million tons per year, respectively. Considerable BTX production is obtained by thermal cracking of naphthas and gas oils. The largest single train ethylene plant currently produces approximately 1.2 million tons per year (or 2.6 billion pounds/year). That was technically impossible or uneconomical 10 years ago. Recent improvements have been made as follows: a) thermal cracking or pyrolysis technology in the furnace plus coil metallurgy; b) separation and recovery techniques including the compression and refrigeration systems, and distillation towers often filled with packing material; and c) process control and optimization requiring major computer capabilities. The choices of feedstocks for the production of ethylene and other olefins are of major importance. Modern ethylene units are often designed so that different hydrocarbon feedstocks can be used. A modern plant often costs between US $500 million and 2 billion depending on the production capacity, the feedstocks, and the products obtained. Countries with considerable natural gas ethane and propane prefer using them as feedstocks; such areas include the United States, Canada, and the Middle Eastern countries. Europe and Japan, however, have and prefer liquid feedstocks (naphthas and gas oils). Ethylene operators typically employ sophisticated computer models and optimization techniques in choosing feedstocks.

Coil reactors employed in current thermal cracking furnaces are surrounded by hot combustion gases. The coils are often several vertical sections of high-alloy steel tubes connected by U-bends. In other cases, the coil is merely a single vertical tube. The gaseous feed to each coil is a mixture of the hydrocarbon plus steam. A chemical additive to minimize coking is also often incorporated in the feed stream. The gas mixture entering the coil is often at temperatures of 650–700°C. As the reactant gases pass through the coil, they are heated to approximately 850–950°C. As a result, thermal cracking occurs rapidly, often in about 0.06–0.6 sec depending on the design and the operation of the furnace. Since thermal cracking is highly endothermic and the temperature of the gas mixture is increased to a considerable extent, much heat is transferred–first, mainly by radiation from hot combustion gases to the outer surfaces of the coils; second, by conduction through the walls of the coil and any coke deposited on the inner coil surface; and third, by both convection and radiation to the gas mixture in the coil. Temperatures of the coil walls are frequently in the 900–1100°C range. Pressures of the gases in the coil frequently vary from 68 to 400 kPa, all above atmospheric pressure. The weight ratio of steam to hydrocarbon is often 0.25–0.30 with ethane and propane feeds, and 0.5–1.0 with naphthas and gas oils. The material of construction for the coil, usually a high-alloy steel, must be carefully selected in order to obtain three to five years' life expectancy. Flow velocities in the coil are always high, often at about 0.5–0.7 Mach number. Fuel requirements for the furnaces are relatively high, and methods to minimize them are considered later. Due mainly to the high temperatures, coke (essentially solid

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007934

carbon) is always formed; it is a highly undesirable by-product. The coke formation and the collection on the coil surfaces increase the heat-transfer resistances and the furnace has to be shutdown at intervals for decoking. Both complete shutdown of the furnace, or the so-called on-line decoking, reduce the ethylene production, and increase production cost. Coke formation increases carburization of the coil material, shortening the life of the coil. In addition to the production of the desired products reported above, hydrogen and methane are also produced. When naphthas and gas oils are used as feeds, fuel oil is also produced in significant amounts. These by-products can be used to supplement the main fuel for the furnaces (generally natural gas). Large amounts of steam and electricity are also required in the overall thermal cracking process, which includes in addition to furnaces, large compressors for the refrigeration system and to pressurize the product streams and distillation towers. Fig. 1 indicates the total energy requirements for ethylene production with different feedstocks and different ethylene yields. More propylene and more BTX are produced with liquid feedstocks. As indicated, energy demands per unit weight of ethylene decrease as the ethylene production increases. In this entry, we discuss the fundamentals of thermal cracking, the mechanistic modeling, and modern ethylene plant design and operation. New trends of development in thermal cracking and ethylene technology are discussed.

FUNDAMENTALS AND THERMAL CRACKING CHEMISTRY

Basic Chemistry and Mechanistic Modeling

Thermal cracking reactions can be divided into initiation steps that generate free radicals, chain propagation steps that form the desired products, and termination of free radicals. This classification of reaction steps permits the mechanistic modeling of the complicated reactions. The main chemical reactions are illustrated in Table 1.[9] Almost all reactions during thermal cracking occur in the gas phase and involve free radicals. Reactions 1 and 2 are key initiation reactions forming an increase of the number of gaseous free radicals. Reactions 3–16 are rapid propagation steps with no increase in the number of gaseous free radicals. They result in the production of ethylene, propylene, hydrogen, methane, plus other by-products (not shown in Table 1). Reactions 17 and 18 are termination steps with a decrease of gaseous radicals.

The main reactions for liquid feedstocks (naphthas, gas oils, etc.) are sometimes summarized according to the types and amounts of paraffins (n-paraffins and iso-paraffins), olefins, naphthenes (monocyclic naphthenes and multicyclic naphthenes), and aromatics (naphthenic aromatics and pure aromatics).[6] The basic chemistry and modeling efforts have been reported by numerous investigators including Dente et al.,[10–14]

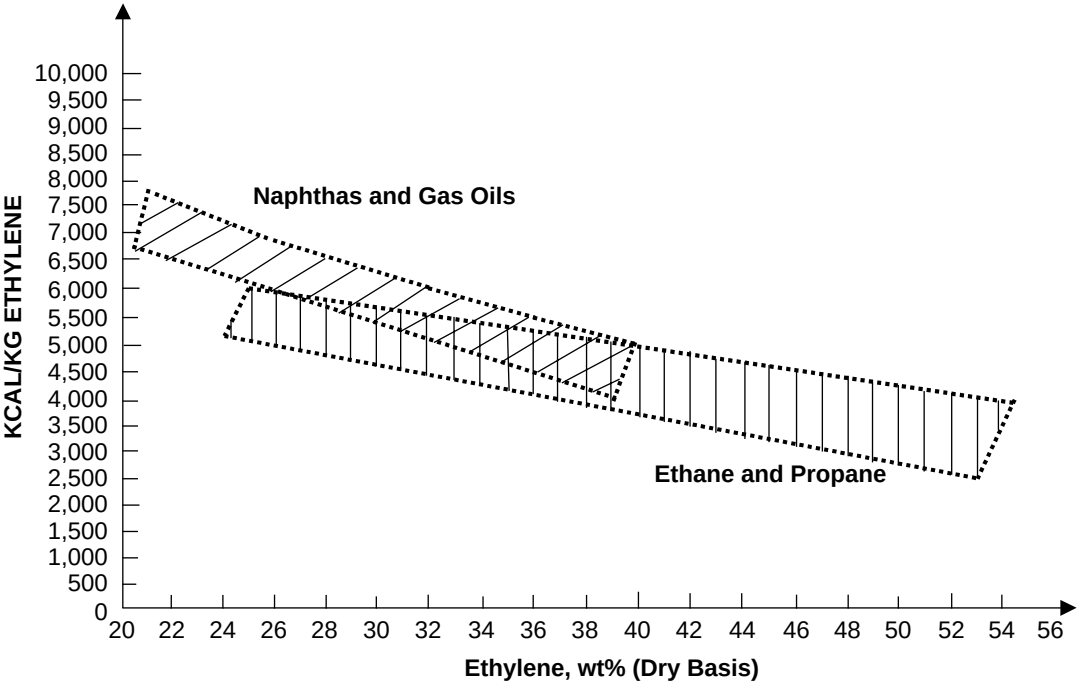

Fig. 1 Energy requirement of modern ethylene plant (total energy for pyrolysis furnaces, compressor units, and separation units).

Table 1 Mechanistic reaction model for ethane–propane cocracking

Reaction no.	Reactions	Reaction rate, r_i[a]	Kinetic parameters	
			A_i	E_i
1	$C_2H_6 \rightarrow 2\ CH_3^{\bullet}$	$r_1 = k_1\ [C_2H_6]$	5.185×10^{16}	90.75
2	$C_3H_8 \rightarrow CH_3^{\bullet} + C_2H_5^{\bullet}$	$r_2 = k_2\ [C_3H_8]$	2.074×10^{16}	87.63
3	$C_2H_6 + CH_3^{\bullet} \rightarrow CH_4 + C_2H_5^{\bullet}$	$r_3 = k_3\ [C_2H_6]\ [CH_3^{\bullet}]$	3.941×10^{11}	8.371
4	$C_2H_6 + H^{\bullet} \rightarrow H_2 + C_2H_5^{\bullet}$	$r_4 = k_4\ [C_2H_6]\ [H^{\bullet}]$	7.537×10^{10}	19.64
5	$C_2H_5^{\bullet} \rightarrow C_2H_4 + H^{\bullet}$	$r_5 = k_5\ [C_2H_5^{\bullet}]$	1.013×10^{14}	51.85
6	$C_3H_8 + H^{\bullet} \rightarrow H_2 + 1\text{-}C_3H_7^{\bullet}$	$r_6 = k_6\ [C_3H_8]\ [H^{\bullet}]$	5.096×10^{10}	7.545
7	$C_3H_8 + H^{\bullet} \rightarrow H_2 + 2\text{-}C_3H_7^{\bullet}$	$r_7 = k_7\ [C_3H_8]\ [H^{\bullet}]$	2.401×10^{10}	10.76
8	$C_3H_8 + CH_3^{\bullet} \rightarrow CH_4 + 1\text{-}C_3H_7^{\bullet}$	$r_8 = k_8\ [C_3H_8]\ [CH_3^{\bullet}]$	2.813×10^{10}	6.705
9	$C_3H_8 + CH_3^{\bullet} \rightarrow CH_4 + 2\text{-}C_3H_7^{\bullet}$	$r_9 = k_9\ [C_3H_8]\ [CH_3^{\bullet}]$	2.119×10^{9}	10.47
10	$C_3H_8 + C_2H_5^{\bullet} \rightarrow C_2H_6 + 1\text{-}C_3H_7^{\bullet}$	$r_{10} = k_{10}\ [C_3H_8]\ [C_2H_5^{\bullet}]$	3.440×10^{8}	13.07
11	$C_3H_8 + C_2H_5^{\bullet} \rightarrow C_2H_6 + 2\text{-}C_3H_7^{\bullet}$	$r_{11} = k_{11}\ [C_3H_8]\ [C_2H_5^{\bullet}]$	3.973×10^{8}	13.49
12	$1\text{-}C_3H_7^{\bullet} \rightarrow C_2H_4 + CH_3^{\bullet}$	$r_{12} = k_{12}\ [1\text{-}C_3H_7^{\bullet}]$	2.119×10^{13}	33.81
13	$2\text{-}C_3H_7^{\bullet} \rightarrow C_3H_6 + H^{\bullet}$	$r_{13} = k_{13}\ [2\text{-}C_3H_7^{\bullet}]$	3.195×10^{13}	50.17
14	$C_3H_6 + H^{\bullet} \rightarrow 1\text{-}C_3H_7^{\bullet}$	$r_{14} = k_{14}\ [C_3H_6]\ [H^{\bullet}]$	9.705×10^{9}	4.698
15	$C_3H_6 + H^{\bullet} \rightarrow 2\text{-}C_3H_7^{\bullet}$	$r_{15} = k_{15}\ [C_3H_6]\ [H^{\bullet}]$	1.151×10^{11}f	1.250
16	$C_2H_4 + H^{\bullet} \rightarrow C_2H_5^{\bullet}$	$r_{16} = k_{16}\ [C_2H_4]\ [H^{\bullet}]$	4.559×10^{9}	1.945
17	$CH_3^{\bullet} + CH_3^{\bullet} \rightarrow C_2H_6$	$r_{17} = k_{17}\ [CH_3^{\bullet}]\ [CH_3^{\bullet}]$	1.349×10^{10}	0
18	$C_2H_5^{\bullet} + H^{\bullet} \rightarrow C_2H_6$	$r_{18} = k_{18}\ [C_2H_5^{\bullet}]\ [H^{\bullet}]$	5.185×10^{10}	0

[a] k_i is the reaction velocity constant of reaction i expressed by the Arrhenius equation: $k_i = (A_i)^*(\exp[-E_i/(RT)])$ where A_i is the frequency factor of the *i*th reaction in the reaction model (s^{-1} or $1 \times s^{-1} \times mol^{-1}$); E_i is the activation energy of the *i*th reaction in the reaction model (kcal $\times$ mol^{-1}); *R* is the universal gas constant; and *T* is the reaction temperature, °K.

Allara and Edelson,[15,16] and Albright and McConnell.[17,18]

Tsai and Zhou[9] have presented a somewhat simplified mechanistic model for ethane and propane cocracking, as shown in Table 1. Their investigation indicated the positive effects relative to ethylene and propylene production for this cocracking, savings in the separation of ethane and propane from LPG mixtures, and feedstock reduction for constant olefins production due to higher olefin selectivity. Their model, however, does not include any surface reactions that may be important plus reactions causing coke formation.

Shorter residence times in the coils, such as 0.06–0.12 sec, employed in millisecond units, tend to give higher yields of ethylene. To obtain the shorter residence times and also high conversions, higher temperatures are needed. Table 2 indicates typical yields for a millisecond unit and a unit operated at 0.4–0.6 sec residence times.

Steam is used as the diluent to reduce hydrocarbon partial pressure and hence to improve selectivity toward olefins. Steam also gasifies (via oxidation) part of the coke deposited on the tubular reactor wall producing CO and CO_2 and hence promotes coke removal from the inner surfaces of the coils.

Temperature, Pressure, Residence Time, Steam Diluent, and Conversion Energy

During the evolution of the thermal cracking process, various parameters, such as the average residence time and average hydrocarbon partial pressure, were found to be important. Computing systems employing complicated mathematical techniques are used to solve stiff differential equations. As a result, operations can be optimized relative to product distribution, selectivity, yield, and economic profits. Design and operation of the thermal cracking units are of critical importance. Many thermal cracking units employ two furnaces (or reaction zones) with one convection zone (see Fig. 2). Thermal cracking occurs in the coils in the radiant zone. In the convection zones, heat is transferred as follows: first, to preheat and vaporize the hydrocarbons to be cracked; second, to preheat the steam to be mixed with the hydrocarbon feeds; third, to preheat the entering fuel (often natural gas) and air (used to burn the fuel); fourth, to preheat the boiler feed water; fifth, to produce steam from boiler feed water; and sixth, to superheat the steam. Preheating of the fuel and air results in higher flame temperatures, which increases both the rate and the amount of heat transfer to the reacting gases in the coils.

Table 2 Typical yields of millisecond versus conventional short residence time heaters

Furnace type	Conventional[1]		Millisecond[6]	Conventional[1]	Millisecond[6]
Feedstocks	Ethane		Ethane	Naphthas	Naphthas

[a]CO and CO_2 are reported based on carbon balance.

Furnace Coil Material of Construction and Selection

Tensile strength, creep strength, creep ductility, and hydrogen embrittlement are all important considerations in the selection of the high-alloy steel for the thermal cracking coils. Three requirements of the coil material in the radiant section are as follows: 1) excellent carburization resistance at high temperature; 2) high tensile strength combined with good ductility; and 3) low rates of creep. The following three alloys are widely used: 1) high silicon HK-40; 2) modified HP-40; and 3) modified 28/48 Cr-Ni alloy. These steels are employed at metal temperatures up to approximately 1065°C, 1120°C, and 1200°C, respectively.

As high-alloy steels are used, the surface compositions change with use; such changes occur in a matter of hours or even minutes. First, major increases occur in the chromium and manganese content. At or near the surface, the chromium content often increases from about 20% to 50–70%. The manganese content increases from <1% to 15–20%. Meanwhile the iron and nickel concentrations decrease from 40–50% and 25–35% to less than 5%. Significant increases of the surface compositions of silicon, aluminum, and titanium also occur sometimes. Second, the surface layer, often in 0–3 μm range, becomes largely metal oxides (and sometimes metal sulfides). Third, part of the surface layer frequently spalls off exposing sublayers with high iron and nickel concentrations. Conventional decoking significantly contributes to the spalling process that corrodes the inner surfaces of the coils, reduces coil life, and promotes coke formation (to be discussed later). Surfaces containing high concentrations of chromium and low concentrations of iron and nickel are desired since they minimize coke collection and/or formation on the inner surfaces of the coil.

Surface Pretreatment or Treatment

Understanding of the migration rates of metal elements in the coil walls has been utilized to create surface compositions that minimize coke formation.[19–21] Stainless steel coils for thermal cracking have been exposed to gases with low oxidative potentials at temperatures up to 1200°C for about 50 hrs.[22,23]

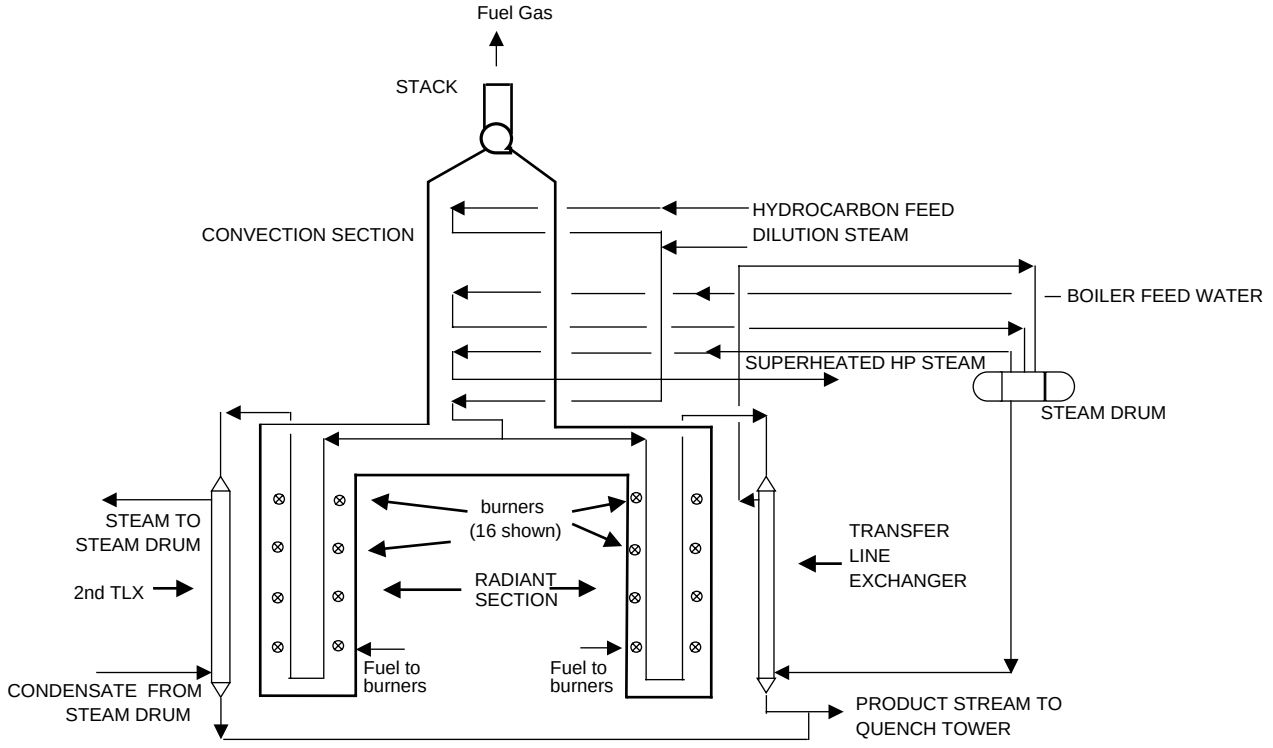

Fig. 2 Typical cracking furnaces.

The resulting coils in one plant test increased the run lengths before decoking from 31 days to 516 days.[24] Sulfiding the reactor surface by adding to the feed-stream sulfur-containing compounds, such as CS_2, dimethyldisulfide, or mercaptans, has been beneficial in reducing coke formation.[25] Some new coking inhibitors also contain rare earth elements such as Ce or La.[26]

Coking and Decoking

In the steam cracking of hydrocarbons, a small portion of the hydrocarbon feed gases decomposes to produce coke that accumulates on the interior walls of the coils in the radiant zone and on the inner surfaces of the transferline exchanger (TLX). Albright et al.[27–31] identified three mechanisms for coke formation. Mechanism 1 involves metal-catalyzed reactions in which metal carbides are intermediate compounds and for which iron and nickel are catalysts. The resulting filamentous coke often contains iron or nickel positioned primarily at the tips of the filaments. This filamenteous coke acts as excellent collection sites for coke formed by mechanisms 2 and 3. Mechanism 2 results in the formation of tar droplets in the gas phase, often from aromatics. These aromatics are often produced by trimerization and other reactions involving acetylene. Some, but not all, of these droplets collect on the inner walls where they decompose forming spherical or semispherical coke deposits. Mechanism 3 first involves the reactions of gaseous microspecies with the free radicals on the coke surfaces. These microspecies include acetylene, ethylene or other olefins, butadienes, and free radicals such as methyl, ethyl, or benzyl radicals; second, C—H bonds located on the surface break to produce coke. Both amorphous and graphite cokes form and collect on inner surfaces of the coils and TLXs. More graphitic coke appears to be formed near the interface next to the coil wall. Amorphous coke, however, is often predominant at the interface layer near the gaseous process hydrocarbon stream.

Zou[25] have published information pertaining to the mechanism and the kinetic models of coke deposition during both thermal cracking of propane and atmospheric gas oils (AGOs). Their findings, plus those of several other investigators, neglect the role of surface reactions. There is the need to better explain how and why the surface compositions and roughness of the coils have, on occasion, such a major effect on rates of coke that forms and/or collects on the inner walls of coils.

Analysis of coke samples from an industrial furnace cracking ethane and propane revealed some interesting phenomena. Coke samples from both the coils and the TLXs generally, if not always, contain appreciable amounts of metal and various elements including

sulfur, calcium, and silicon. Scanning electron microscopy plus EDAX, polarized light microscopy, and transmission electron microscopy have been employed to investigate coke samples, surfaces of coils; determine the metal contents; view the metal deposits; and determine the character of coke deposits, variations of coke deposits, and the porosity of the coke.

Plant data indicate that first the inner diameters of the coils increase and the wall thicknesses decrease as the coils are used. Spalling of the inner surfaces is apparently a major factor. The wall thickness sometimes decreased by as much as 30%. Decreases of the wall thickness may however vary from 5% to 30% around the circumference of the coil. Second, the roughness of surface varies greatly with location. Part of these variations likely depends on local overheating (and burner locations) relative to the coil.

TYPICAL COMMERCIAL UNITS

Contractors that specialize in the design and construction of cracking furnaces for ethylene plants include Technip, KBR, ABB Lummus, Stone and Webster, and Linde A.G. The height of the furnaces may vary from approximately 30 to 50 m. Currently, almost all tubes (or coils) are arranged vertically inside a combustion chamber. The capacity of a single furnace has reached well over 120,000 metric tons/furnace/year. Fig. 2 illustrates a typical industrial cracking furnace. A typical modern cracking furnace employs two radiant sections, one convection section, and two transfer line exchangers (TLXs).

Radiant Section and Combustion Chamber

Thermal cracking reactions occur in the tubular reactors positioned inside the combustion chambers. This is generally referred to as the radiant section. Coils of modern thermal cracking furnace are all arranged in a vertical fashion with double side radiant heating. Some furnaces also have floor burners. Thermal cracking coils are generally classified into the following four types (see Fig. 3):[32–34]

1. Coil A illustrates the conventional single diameter coil. This type contains 6–8 vertical tubes joined by 5–7 U-bends. The tube diameters range from approximately 100 to 125 mm and the total lengths may vary from approximately 65 to 75 m.
2. Coil B contains vertical tubes of different diameters. This type of coil can vary from 2 to 4 passes. The tube diameters range from approximately 38 to 83 mm and the total coil lengths range from approximately 20 to 45 m. This type of coil starts with smaller diameter tubes connected to larger diameter tubes.
3. Coil C represents the varying diameter split coils. This type of coil can vary from 4 to 6 passes. The number of tubes per pass can be 4-2-1-1, 8-4-1-1 for 4-pass coils and 4-2-1-1-1-1 for 6-pass coils. Diameters of the first pass are normally the smallest, being approximately 50–65 mm. The last pass tube is normally larger in diameter, being approximately 145–165 mm. The total coil lengths may range from approximately 44–62 m. These split coils begin with smaller diameter tubes that have higher surface to volume ratio to enhance the heat-transfer rates. This way, it can bring the process fluids to the cracking temperature more rapidly.
4. Coil D is employed in ''millisecond'' furnaces. They are straight tubes with diameters varying from approximately 25–38 mm and with lengths ranging from approximately 10–12 m.

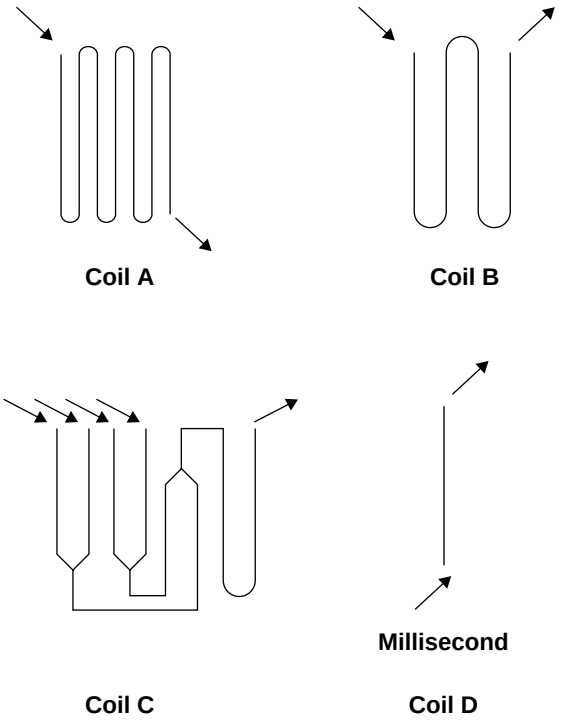

Fig. 3 Typical thermal cracking coils.

More details of thermal cracking coils and furnace design are given in Ref.[6].

Hydrocarbon and steam mixture flows from the convection section into the radiant section at approximately 525–700°C, depending on the feedstocks and the heater design. This is called the crossover temperature. For ethane and propane thermal cracking, the crossover temperature is approximately 700°C. For vacuum gas oil (VGO) and AGO cracking,

the crossover temperature is perhaps 525–550°C. The coil outlet temperature is generally in the range of 750–950°C, depending on the feedstocks cracked and the severity desired. Typical thermal cracking furnace characteristics are summarized in Table 3.

Shorter residence time and lower hydrocarbon partial pressure improve the selectivity toward ethylene at a constant conversion. Conversion is defined as follows for single components in either wt% or mol%:

$$\text{Conversion} = (C_{in} - C_{out})/C_{in}$$

for mixtures, the conversion can be defined as the weighted average of the individual component conversion if the componential analysis is known, i.e., $X = \sum W_i X_i$, where X_i is the conversion for the ith feed component, and W_i is the weighing factor (usually weight fraction or mole fraction). The term severity is used to describe the conversion or the extent or depth of hydrocarbon cracking. For liquid feeds, various methods such as n-pentane conversion, kinetic severity factor,[2] or molecular collision parameter[35–37] are employed to measure cracking severity. Tsai[37] has reported a quantitative yield correlation as a function of MCP (molecular collision parameter) for AGO cracking. For other complex multicomponent feedstocks of unknown composition, conversion or cracking severity has been defined as a function of molecular weights of the thermal cracking feedstock and the product effluent as follows:[7]

$$\alpha = [(m_f - m_e) - 1]/(\gamma - 1)$$

where m_f is the molecular weight of feed, m_e is the molecular weight of dry (steam-free) effluent, and γ is the molal expansion factor, i.e., moles of effluent produced per mole of feed converted. The empirical expression, $\gamma = (m_f/24.5)$, has been used. Another expression of conversion for feedstock of unknown composition uses the hydrogen content instead:

$$\alpha = (Y - 1)/(CY - 1)$$

where $Y = (H - 6)/(HF - 6)$; H is the hydrogen content in C_5 plus product, wt%; HF is the hydrogen content of the feed, wt%; and C is a constant for any given feedstock.

Other parameters, such as coil outlet temperature, propylene to methane ratio, propylene to ethylene ratio, or cracking severity index, have been used to indicate cracking severity. These parameters are, to some degree, dependent on feed properties and operating conditions.

For some liquid feedstocks such as naphthas, the componential composition is often obtained by gas chromatography (GC) and/or mass spectrometry (MS). For gas oils or heavier feedstocks, it is impossible to obtain the desired analysis. Paraffins, olefins, naphthenes, aromatics (PONA) grouping is sometimes used as a means of feed characterization. For gas oils, Bureau of Mines Correlation Index (BMCI) has been used as a parameter for feed characterization. Since the 1980s, nuclear magnetic resonance (NMR) spectroscopy has been used to characterize heavy feedstocks.

The radiant coils are always cleaned by burning the coke with mixtures of steam and air in different proportions and at different temperatures. Some radiant coil decoking is for a fixed period of time such as 12 or 24 hrs. Some decoking operations are monitored to determine CO or CO_2 in the effluent. Since hydrogen in the coke burns off very rapidly, the initial concentration of oxygen is often kept low to avoid overheating the coils. Usually, all coils in a given heater are decoked, and the effluent of decoking is sent to a decoking pot or to a firebox for burning. One patent[38] claims single-coil decoking, while other coils in the same furnace are cracking hydrocarbons; that is a true on-line decoking. However, the decoking effluent streams contain CO, CO_2, and carbon particles that affect the downstream operations. On-line decoking is probably limited in practice.

Table 3 Characteristics of modern thermal cracking furnaces

Ethylene production capacity, tons/furnace/year	**20,000–120,000**
Numbers of coils	2–180
Tube diameter, mm	25–200
Coil length, m	10–80
Coil (Gas) outlet temperature, °C	750–950
Tube wall temperature, °C (clean)	900–1100
Maximum tube wall temperature, °C	1040–1150
Average heat flux, kw/m_2 (of outside surface area)	50–120
Coil outlet pressure, kPa	168–300
Residence time, sec	0.06–0.60

CONVECTION SECTION

A conventional typical convection section often has tube bundles for fuel gas or air preheat, feed preheat, boiler feed water preheat, steam generation, and steam superheating. In the convection section, the heat transfer is mainly gas-to-gas heat transfer and the overall heat-transfer coefficients are relatively low. Finned tubes are generally used to improve heat-transfer rates. Material for the convection section tubes varies from carbon steel to a high temperature alloy. Sometimes, high-alloy tubes are positioned in the lower section

close to the radiant chamber. Condensation of acidic flue gases must be considered in the design of the convection section and the selection of tube material. Corrosion sometimes occurs at the tube inlet causing tube leaks. Fouling in both the inside and the outside of the tubes may also occur. The inside fouling is normally cleaned by burning with steam and air mixture. The outside of the tubes is normally cleaned by steam. On top of the convection section, stacks and induced draft (ID) fans help create a draft for flue gas that enhances heat transfer for the tube bundles.

Transfer Line Exchangers

The thermal cracking products from the radiant coils pass through TLXs (or TLEs) for steam production and heat recovery. From there, the pyrolysis gas leaves the TLXs at approximately 300–400°C for ethane, propane, or light naphthas cracking, and at approximately 550–650°C for heavy naphthas, gas oils, or VGO cracking. The transfer line exchangers outlet temperature is the lowest at the beginning of the operating cycle when the exchangers are clean. To minimize further thermal cracking, gas temperatures must be reduced rapidly.

In all modern ethylene plants, TLXs recover much of the energy in the furnace effluent product streams. Several vendors offer high pressure shell and tube TLXs. These include Struthers-Wells of the United States; Schmidtsche Heissdamp GmbH and Borsig of Germany; and Mitsubishi, Mitsui, and Babcock-Hitachi of Japan. More discussion on those individual TLXs is given in Ref.[1]. Both Mitsubishi and Mitsui TLXs differ drastically from other designs. Mitsubishi offers a TLX with an integral steam drum and cyclone for vapor–liquid separation. The pyrolysis gas flows in the shell side. Decoking of both the coil and the TLX is claimed to occur in one separation. The Mitsui TLX (or quench cooler) uses three concentric tubes as the tube element and requires steam-air decoking to clean the TLXs.

During decoking of the radiant coils, the TLXs can also be partially decoked. For complete decoking, the furnace is usually cooled down and the TLXs are separated from the coils and hydrojetted with high pressure water. In some cases, the coke in the TLXs can also be burnt off, and hence no mechanical cleaning is required.

The temperatures at the end of a run of the TLX are generally in the range of 600–650°C, depending on the specific design, material of construction, and the type of TLX used. For cracking of ethane and/or propane, the inner film fouling resistance and the outer film fouling resistance are often approximately 0.0000245 m^2-Hr-°K/kJ. The thermal conductivity of the TLX coke is approximately 20% of that of the coke in the coils. Different types of coke are apparently formed; perhaps the cokes are dehydrogenated to various degrees. Therefore, it is very important to select the proper TLX tube material of construction allowing higher TLX outlet temperature, which would increase the capacity and the furnace and TLX run lengths as well.

Product Separation, Recovery, and Purification

Fig. 4 represents a simplified schematic flow diagram for an ethane and/or propane cracking ethylene plant. The separation sequences are shown as follows:

1. *Quench tower.* This is accomplished by quenching the product effluent stream with water. Condensed hydrocarbons and water from the quench tower are separated in a coalescer. Hydrocarbons from this coalescer and the drips from the first stage compressor discharge drums are sent to the drip stripper to separate lighter hydrocarbons from the pyrolysis gasoline and fuel oil. Water from the coalescer is transferred to the process water stripper to separate the hydrocarbons before sending the water to the biopond for wastewater treatment. Quench tower design is a challenge. A considerable amount of water is recirculated, and coke particles in the water make this stream quite erosive requiring special pumps.
2. *Compression and condensation.* The pyrolysis gas leaving the quench tower is compressed to approximately 35 atmospheres in a four or five stage centrifugal compressor (normally referred to as cracked gas compressor). The number of stages is determined by the maximum temperature for the material of construction of the cracked gas compressor and the fouling tendency of the pyrolysis gas. The compressor consists of two or three compressor casings driven by a single or double extraction/condensing turbines depending on plant size. Between each stage of the compressor are condensers and drums that separate the condensed hydrocarbons and water.
3. *Acid gas removal.* Acid gases (CO_2 and H_2S) are removed by absorption after the third or the fourth compression stage. This is the optimum location since the gas volume is significantly reduced. Scrubbing with caustic solution, monoethanolamine (MEA), or diethanolamine (DEA) is generally used. More details can be found in the literature.[1,7,8]
4. *Water removal.* Complete removal of water vapor from the pyrolysis gas is generally

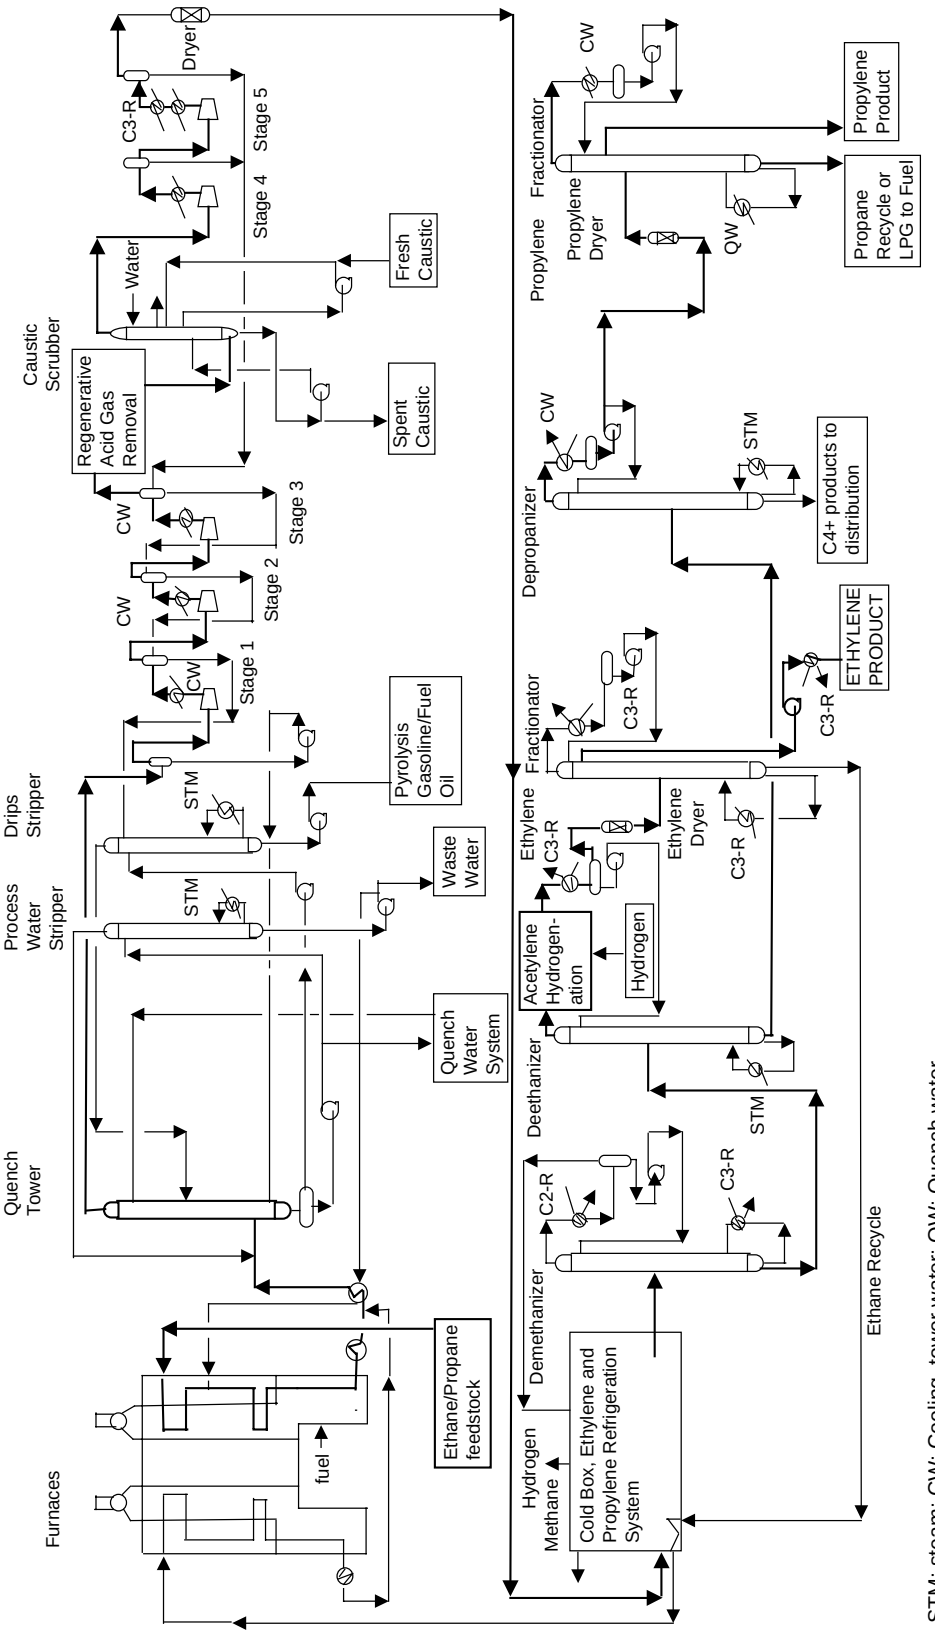

Fig. 4 Simplified schematic flow diagram for a typical ethane/propane cracking ethylene plant.

STM: steam; CW: Cooling tower water; QW: Quench water
C2-R: Ethylene refrigerant; C3-R: Propylene refrigerant

achieved using dryers packed with molecular sieves. One dryer is operated while the other is in the regeneration mode.

5. *Cold box and refrigeration system.* After the acid gas and water removal, the pyrolysis gas is cooled and condensed to approximately –165°C; only hydrogen and some methane remain in the vapor phase. The feed locations are determined via process simulation. Hydrogen and methane are drawn from the lowest temperature stage separator and sent to thermal cracking furnaces as fuel.
6. The demethanizer is designed for complete separation of methane from ethylene and heavier components. The demethanizer is normally operated at approximately 7 atm. The demethanizer overhead consists of methane, plus relatively small amounts of hydrogen, carbon monoxide, and traces of ethylene. Brazed aluminum plate-fin exchangers are used for the multipass cryogenic heat-transfer services. Some ethylene plants employ high pressure demethanizers operated at approximately 35 atm. They are generally combined with either a front-end deethanizer or depropanizer.
7. *Deethanizer and ethylene fractionator (ethylene/ethane splitter).* The C_2 and heavier hydrocarbons from the bottom of the demethanizer are sent to the deethanizer operated at approximately 25 atm. It is either a trayed tower or a packed column. Deethanizer overhead consists of C_2 hydrocarbons and the bottom products are C_3 and heaviers.
8. *Acetylene hydrogenation.* In modern ethylene plants, acetylene is generally hydrogenated to ethylene and ethane in a palladium catalyst bed. The reaction is quite exothermic, and intermediate cooling is required. The effluent normally contains less than 1 ppmv of acetylene. This is generally referred to as back-end acetylene hydrogenation, which exerts higher selectivity and more precise temperature control. Front-end acetylene hydrogenation is also practiced in the stream of an intermediate compressor. Front-end acetylene hydrogenation uses a different catalyst, and a deethanizer or a depropanizer column is ahead of the demethanizer; this scheme has become of increased importance in the recent past. In most acetylene hydrogenation reactor operation, some carbon monoxide is injected to monitor the catalyst activity and the reaction rate, especially after changeover of the fresh catalyst. The catalyst is deactivated over time because of deactivation; the catalyst is periodically regenerated. After acetylene hydrogenation, the dried gas enters the ethylene fractionator to separate ethylene from ethane. A section is provided near the top of the fractionator for removal of residual hydrogen, carbon monoxide, and methane. A closed loop heat pump is sometimes used, which uses propylene refrigerant as the coolant in the reflux condenser. Ethane is normally recycled back to the thermal cracking furnaces to be cracked.
9. *Depropanizer and propylene fractionator (propylene/propane splitter).* The deethanizer bottom is sent to the depropanizer where the C_3 hydrocarbons are the overhead product and the C_4 and heavier hydrocarbons are removed from the bottom. The overhead of the depropanizer is sent to the propylene fractionator where propylene is separated from propane. A two-tower propylene fractionator produces polymer grade propylene (99.5% plus). For the naphthas or gas oil cracking plants, the depropanizer bottom stream is normally further processed in a debutanizer, which separates the C_4 and lighter in the overhead, and the pyrolysis gasoline and heavier in the bottom. Also, the depropanizer overhead stream generally is sent to a methylacetylene and propadiene (MAPD) hydrogenation reactor, where MA is hydrogenated to propylene and propane.

Process Control and Optimization

Recent improvements of process controls have resulted in improved operations and higher profits. Real-time optimization of thermal cracking furnaces based on the feedstock and product flow rates, pricing, and fuel cost has become a reality. Implementation of pinch technology, process separation network analysis, and optimization has made significant reductions in energy demands.

ALTERNATE ETHYLENE PRODUCTION PROCESSES

The search continues for better and more economical processes for the production of ethylene. Those processes include catalytic thermal cracking, methanol to ethylene, oxidative coupling of methane, advanced cracking technology, adiabatic cracking reactor, fluidized bed cracking, membrane reactor, oxydehydrogenation, ethanol to ethylene, propylene disproportionation, and coal to ethylene. Much work is still needed before any such process can compete with current processes.

One process that potentially could be used employs a catalyst and is operated at approximately 1 ms.

It operates at 950°C and oxidizes ethane at almost 70% conversion with approximately 85% selectivity.[39] Major concerns include safe operation of potentially explosive ethane and air mixtures at elevated temperatures. If the process uses air instead of pure oxygen, then separating nitrogen from ethylene can be costly. Scale-up of such a catalytic reactor and the life of the catalyst are concerns.

CONCLUSIONS

Demand for ethylene in the world continues to grow. Capacities of modern ethylene plants and furnaces continue to increase in a highly competitive market. Current research concentrates on the following areas: a) selective cracking that produces higher yields; b) better metallurgy that allows higher temperature operation, shorter residence times, and higher conversions; c) coking or anticoking technology that minimize or eliminate coke formation and increase run lengths; d) advanced process control and optimization including real-time optimization; e) more efficient separation techniques such as new packing materials in distillation columns; f) new process sequences and networks that reduce energy demands and result in higher quality products; and g) improved compressor and refrigeration systems.

Thermal Desorption

Timothy P. Sullivan
Randolph Air Force Base, Texas, U.S.A.

INTRODUCTION

There are currently thousands of sites in the U.S.A. containing soil contaminated with volatile organic compounds (VOCs), semivolatile organic compounds (SVOCs), polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), pesticides, mercury, and mixed waste (radioactive and hazardous waste). One method used frequently to remediate these sites is thermal desorption.

Thermal desorption heats the contaminated soil to desorb and volatilize the contaminants, which are then either recovered or destroyed. This entry discusses the specifics of thermal desorption, including desorption kinetics, soil pretreatment requirements, types of thermal desorption units (TDUs), off-gas treatment, solids treatment, as well as system cost and performance.

EXTENT OF SOIL CONTAMINATION

The development of remediation technologies is driven by the large number of contaminated sites and the tremendous costs associated with cleanup. In the U.S.A., site cleanup is driven by two primary laws—the Recourse Conservation and Recovery Act (RCRA), which regulates operational sites, and the Comprehensive Environmental Response Compensation and Liability Act (CERCLA), which regulates historical sites (Superfund sites). Currently, there are 11,303 sites either on CERCLA's National Priority List (NPL) or under review for possible inclusion.[1] The numbers are even more striking in the underground storage tank (UST) portion of the RCRA program. The US Environmental Protection Agency (USEPA) estimates that as of March 2002, there have been 422,573 releases from USTs and that approximately 145,000 cleanups have yet to be completed.[2]

One technology suitable for remediating these sites is thermal desorption, which heats soils and sludge to remove volatile contaminants such as VOCs, SVOCs, PAHs, PCBs, pesticides, mercury, and mixed waste for recovery or further treatment. The success of thermal desorption is evidenced by how frequently it has been used since its initial demonstration. From fiscal years (October 1 through September 30) 1982 through 1999, thermal desorption was used in 14% of Superfund sites requiring ex situ source control, 2% of Superfund sites requiring in situ source control, and 9% of total Superfund sites.[3] (Please note that the USEPA classifies in situ thermal desorption as thermally enhanced recovery.) The utilization of thermal desorption in the RCRA cleanup program is similar, with thermal desorption employed at 9% of cleanup sites through August 1998.[4] As thermal desorption is used more frequently, it is important to understand the operational advantages, as well as limitations, of these systems.

APPLICABILITY OF THERMAL DESORPTION

Results of cleanup actions at various sites illustrate that thermal desorption is effective in treating soil and sludge contaminated with VOCs, SVOCs, PAHs, and PCBs under the right conditions.[5] Thermal desorption is also effective in treating soils contaminated with organic pesticides, although it is not considered effective in treating wastes contaminated with inorganic or metal-containing pesticides.[6] While not its primary use, thermal desorption may also be used to treat mercury and mixed (radioactive and hazardous) wastes. Studies conducted by the US Department of Energy indicate that thermal desorption is effective in treating mercury waste and that thermal desorption would be effective in removing hazardous constituents from mixed waste without volatilizing radioactive material.[7,8] This would separate the mixed waste into radioactive waste and hazardous waste allowing them to be managed separately.

DESORPTION KINETICS

An understanding of thermal desorption begins with an explanation of desorption kinetics. In thermal desorption systems, the portion of the contaminant in the liquid phase is removed as the soil temperature is increased above the boiling point of water and the contaminant. However, any portion of the contaminant bound to the soil must still be desorbed prior to removal.

The desorption of contaminants from soils is influenced by three primary parameters: temperature, soil moisture content, and soil type. A recent study evaluating

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007731

the temperature dependence of desorption looked at the sorption of PAHs to sediment and determined that PAHs have a high activation energy when bound to coal particles. The high activation energy indicates that the desorption of PAHs increases significantly with temperature.[9] Another study analyzed the desorption of motor oil and PCBs from porous materials and determined that PCBs have an onset temperature of 350°C below which desorption does not occur.[10] These results imply that it is essential to operate thermal desorption systems, such that the temperature of the soil exceeds the desorption onset temperature and ensures full desorption and volatilization of the contaminants of concern. A sufficient operating temperature is needed to ensure contaminant volatilization and is typically determined during trial runs of the thermal desorption system using contaminated soil from the actual cleanup site.

Soil moisture content also plays a critical role in the effectiveness of thermal desorption. At levels below 20%, soil moisture plays a beneficial role by removing contaminants through steam distillation. When the soil is heated, the water in the soil undergoes a phase change to steam. During the phase change, contaminants with lower boiling points boil with the water and partition into the gas phase where they are removed from the soil with the steam.[11] While steam distillation is beneficial at lower moisture contents, higher soil moisture contents inhibit thermal desorption systems as additional energy is required to volatilize the water. This also increases the cost of treatment, the complexity of the air pollution control (APC) system, and the residence time of the soil in the thermal desorption unit.

The type of soil also plays an important role in determining how readily contaminants will desorb when treated with thermal desorption. Studies conducted on harbor sediment indicate organic contaminants exhibit preferential sorption to coal and coal-derived particles over sand, silt, and clays.[12] Researchers found that while coal/wood derived particles only accounted for 5% of particles in the test soil, 62% of total PAHs were sorbed to these particles. Successive extractions were conducted and revealed that only 8% of the PAHs sorbed to the coal/wood-derived particles desorbed within three months, while 80% of PAHs sorbed to clay and silt particles desorbed within one month.[12] Another study demonstrated that it is more difficult to desorb contaminants from soils with a high humic content. In this study, aeration of a slurry containing PAHs revealed that 20% of the naphthalene bound to inorganic material was removed after 30 min of aeration, while only 10% of the naphthalene bound to humic material was removed.[13]

THERMAL DESORPTION SYSTEMS

Thermal desorption systems can be broken into three key components: pretreatment, the TDU, and post-treatment (Fig. 1) as discussed below. Additionally, thermal desorption systems are often used in conjunction with other treatment technologies as part of a treatment train. At previous RCRA and Superfund sites, thermal desorption has been used in conjunction with bioremediation, dechlorination, incineration, soil vapor extraction, soil washing, and solidification/stabilization.[3,4] In these cases, the combination of technologies was required to meet the site's cleanup goals.

Pretreatment

Pretreatment involves analyzing and preparing the waste stream for treatment in the TDU. The key steps involved are analyzing the waste, soil mixing, segregating large particles, and dewatering.

Under an RCRA or a Superfund cleanup, the waste is characterized prior to selection of the cleanup technology. With this information, the following pretreatment samples are taken as appropriate: contaminants of concern, total petroleum hydrocarbons (TPH), chlorinated pesticides, PCBs, chlorinated solvents, mercury, and/or radionuclides.[14] These samples are then used to determine the required removal efficiency of the cleanup technology to ensure the cleanup goals can be met. Prior to using a thermal desorption system (if selected), the waste must be sampled to spatially characterize the contamination so that the soil that is

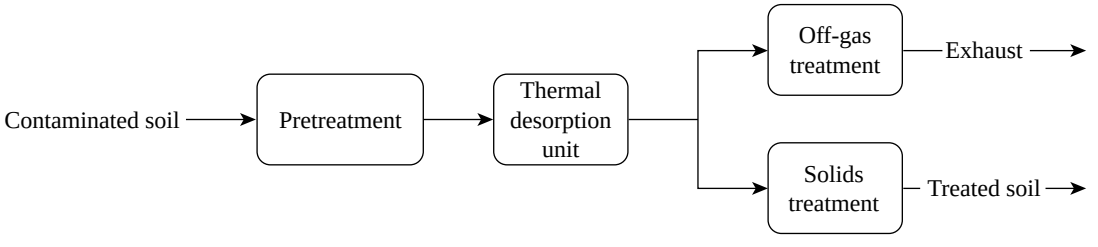

Fig. 1 Steps in a thermal desorption system.

most difficult to treat will be used during test runs of the TDU to establish the unit's operating parameters.[14]

Pretreatment samples are also useful at sites where wide variations in the contaminant concentration occur and soil mixing is utilized. Soil mixing is used to ensure a relatively homogeneous feedstock for the TDU so that it can operate effectively and efficiently. Soil mixing has been used at several cleanup sites to prevent clumping of soil, which impairs treatment, and to prevent temperature spikes within the TDU and consequent variations in off-gas properties.[5]

Segregation of larger particles is necessary to maintain the consistency of the feedstock and to ensure treatment goals are met. Particles greater than 5 cm in diameter can interfere with the TDU in the following ways: first, they can clog the waste feed system leading to lengthy system downtimes and operational upsets;[15] second, larger particles take longer to heat to the desired treatment temperature and may require a longer residence time for complete treatment. Since the TDU operates at a fairly constant feed rate, these larger particles are not likely to meet the treatment goals. Problems with larger particles are typically addressed by either crushing or passing the feedstock through a screen and removing the larger pieces for separate cleaning or disposal as hazardous waste.

Soils with a moisture content above 20% must also be dewatered or treated to prevent excessive energy costs and residence times in the TDU. Dewatering may be carried out with a filter press, air drying, or gravity separation.[5] Alternatively, contaminated soil is sometimes treated with lime to lower the moisture content and improve the material handling characteristics.[5] Whichever method is chosen, the goal is to achieve a soil moisture content of approximately 8–12%.[16] This allows for the benefits of steam distillation without excessive fines in the off-gas as would happen if the soil were too dry.

Thermal Desorption Unit

Once the contaminated material is pretreated, it is treated in the TDU. There are two broad categories of TDUs: in situ (also referred to as thermally enhanced recovery) and the more common ex situ. In situ involves heating the soil in place to remove contaminants, while ex situ units require the excavation of contaminated soil for treatment in the TDU.

In situ units

The two types of in situ TDUs are thermal blankets and thermal wells. Thermal blankets operate by placing heating elements directly on the contaminated soil, covering the area with an impermeable barrier to minimize fugitive emissions, and collecting the off-gas for further treatment. In one field test, a 3.05×3.05 m heater was installed at a site contaminated with hexadecane. In this system, approximately $5382\ W/m^2$ of electrical power was supplied to the soil for $2\frac{1}{2}$ days causing the soil to reach 576°C at the surface, 345°C at a depth of 15.2 cm, 195°C at 30.5 cm, and 102°C at 45.7 cm.[17] The results of this test indicate that 99.94% of the hexadecane was removed from the first 15.2 cm of soil, 98% was removed from the soil at depths of between 15.2 and 30.5 cm, and 75% was removed from depths of between 30.5 and 45.7 cm. Interestingly, in this demonstration, only 50 g of hexadecane was found in the off-gas, with the remainder being oxidized or pyrolized in the soil.[17] These results indicate that thermal blankets have the potential to successfully treat surface and near-surface volatile contamination. They also have the advantage of not requiring excavation, which involves increased cost and fugitive emissions.

While thermal blankets may treat contaminants near the surface, thermal wells offer the ability to treat contamination at much greater depths. In thermal well systems, heater wells are inserted into the contaminated soil to volatilize contaminants in situ. The generated off-gas is then collected in combination heater–vacuum wells and sent to an APC system. The number of heater–vacuum wells, and the well spacing, depend on site-specific parameters, but typically, one-third of the wells are heater–vacuum wells and the well spacing is 1.8–2.1 m.[11] With heaters operating at up to 800°C, thermal well systems are able to achieve soil temperatures of 300–500°C between wells.[18] In order to fully remediate contaminated sites, the wells are inserted up to 0.9 m below the contaminated layer and operate for 30–60 days depending on the soil characteristics and contaminants of concern.[19]

Much like thermal blankets, thermal well systems do not require costly excavation and they also offer additional benefits. They have been used to treat contaminants at depths up to 5.5 m below the surface and much of the contaminants are destroyed in situ through oxidation or pyrolysis reactions.[19] Furthermore, thermal well systems offer uniform heating and consequent treatment of contaminants is effective across a wide range of soil types. The long residence time favors desorption mechanisms that may be time dependent.[18,19]

Ex situ units

Ex situ units are used more commonly than in situ units for two primary reasons. First, in many locations, groundwater intrusion can limit the effectiveness and increase the cost of in situ units. This can be overcome

in ex situ units by dewatering the soil and treating the water in a wastewater treatment plant. Second, if the soil also contains metals, ex situ units can be used as the first step in treatment with solidification/stabilization used to immobilize the metals. The most common types of ex situ units are batch units, thermal screws, and rotary kilns.

Batch units

Batch TDUs are typically only used for smaller applications because their throughputs are often much lower than other thermal desorption systems. These systems do have the benefit of requiring less pretreatment of the contaminated media because feedstock consistency and particle size are not as crucial to control as they are in continuous feed units. Unlike continuous feed units, it is easy to vary the residence time and/or temperature between batches to handle different contaminant concentrations in the feedstock. Also, there is no material feeding equipment to clog with larger particles, although it is still not economical to treat extremely large particles in a batch process. However, particle sizes up to 15.2 cm have been treated effectively by batch units.[5]

After limited pretreatment, the batch unit is loaded with contaminated soil and sealed to allow generation of a vacuum. The amount of vacuum applied depends on the contaminants being treated. A system used to treat VOCs typically operates at a vacuum of up to 8 kPa, whereas one used to treat mixed waste containing mercury operates at a vacuum of 84.7 kPa.[5,7] In the presence of this vacuum, contaminants are volatilized at lower temperatures. Due to this and the lack of oxygen, combustion is prevented.[5] The vacuum is also beneficial when treating mercury waste as no sweep gas is used in the system, thereby allowing volatilized mercury to be condensed on cold-water impingers and recovered.[7] This helps to prevent fugitive emissions from the system, which is especially critical when dealing with mercury-contaminated wastes due to its high toxicity. If not properly controlled, mercury emissions from the thermal desorption system can reach concentrations high enough to cause unhealthy conditions for onsite workers and neighboring populations.[14]

With the vacuum applied, the feedstock is indirectly heated up to the operating temperature. Operating temperatures vary widely depending on the waste being treated. In one system, the operating temperature was limited to 82.2°C with a 60-min residence time for clay soils and a 120–150 min residence time for highly contaminated soils to prevent the volatilization of radioactive metals.[5] A system treating mercury-containing wastes, however, was operated at temperatures up to 750°C for 10–20 min.[7]

Thermal screws

In contrast to batch units, thermal screws operate with continuous feed as hollow flight rotary screws mix, heat, and convey the contaminated feedstock through the system. Either hot oil or steam is circulated through the flights to indirectly heat the feedstock. Typically, systems using hot oil can achieve operating temperatures up to 260°C while systems utilizing steam are limited to temperatures of 177°C.[20] These limitations make thermal screw systems more appropriate for treating contaminants with lower boiling points.

Operationally, the feedstock is loaded into the TDU with earthmoving equipment and then mixed, heated, and conveyed with one to four screws arranged either in series or parallel. Multiple screws are operated in series to increase the soil's residence time, and are operated in parallel to increase the system's throughput up to 25 tons per hour (tph).[21] The residence time is highly variable and depends on the soil moisture content, soil type, and contaminants being treated, but residence times up to 90 min have been reported.[5] Once the contaminants are removed from the soil, they are carried to the APC system by a sweep gas such as steam.

Notably, when thermal screw systems employ multiple interlocking screws, they are susceptible to damage from larger particles lodging between the screws. This can damage the flights and has even damaged the drive gearbox, although reversing the screws can clear minor jamming.[15] In one commercial system, this is avoided by screening the feed material down to 2.5 cm instead of the more common 5 cm.[21]

Despite the temperature limitations of thermal screw systems, there are some advantages. First, since thermal screws operate at a lower temperature, they require less fuel and do not combust the contaminants, thereby allowing for contaminant recovery. Second, since these systems are indirectly heated, the volume of off-gas generated is lower. Finally, the interlocking screws increase mixing of the feedstock, which improves treatment.[15]

Rotary kilns

The most common type of TDU is the rotary kiln where the contaminated soil is fed into a rotating drum at a slight incline. As the drum rotates, internal flights agitate the soil and convey it through the drum to the outlet. The drum is typically constructed of either carbon steel or stainless steel and is sized to meet the amount of soil to be remediated with drum sizes ranging from 6.1 m long by 1.5 m in diameter to 14.3 m long by 2.6 m in diameter.[5] In order to prevent fugitive emissions, induced draft fans are utilized to maintain a

negative pressure of 0.01–0.05 kPa throughout the system.[5]

Heating of the soil is achieved by burners located either inside the shell or near the outside surface operating on natural gas, propane, or fuel oil. Burner sizes vary between 6.15 and 117.12 MW.[5] When the combustion gases from the burner directly contact the soil, the unit is called direct-fired, and when the combustion gases heat the outer shell of the rotary kiln, the unit is called indirect-fired. A notable difference in the two firing methods is how they are perceived by regulatory agencies. The USEPA considers direct-fired rotary kilns incinerators and requires them to be permitted as such, while indirect-fired systems are considered a ''miscellaneous unit.''[22] Indirect units also allow the use of an inert sweep gas, such as nitrogen, to prevent the combustion of contaminants if the formation of dioxins and furans is a concern or if there is a desire to recover the volatilized contaminants. An additional distinction between direct and indirect-fired units is the residence time, which averages 15–20 min for direct-fired units and up to 2 hr for indirect-fired units.[5] During operation, the residence time is adjusted by altering the drum's rotational speed and incline.

The flow of the combustion gases in direct-fired systems may be concurrent (i.e., the gases flow in the same direction as the feedstock) or countercurrent (i.e., the gases flow opposite to the movement of the feedstock). The benefits of a concurrent system are higher treatment temperatures, longer residence times, and treatment of fines. Countercurrent systems offer more efficient heat transfer, and lower volumes and temperatures of off-gas.[20] In large part due to the beneficial aspects of the off-gas and consequent simplified APC system, countercurrent systems are used more commonly in rotary kilns.

There is a wide variation in the system throughput for rotary kiln TDUs with values ranging from 5 to 150 tph. However, most systems operate in the 15–30 tph range.[5] The actual throughput achieved depends not only on the design capacity of the rotary kiln, but also on the treatment criteria. Treatment criteria determine the maximum soil depth in the kiln and the required residence time.

All rotary kilns operate to achieve a desired soil output temperature to ensure complete treatment of the contaminated soil. The specific soil exit temperature is determined during startup testing to ensure the soil is properly treated in the TDU. This temperature generally falls into two groups based on residence time: (1) less than or equal to 260°C and a residence time of approximately 6–7 min and (2) greater than 260°C and a residence time of approximately 15–20 min.[5]

The benefits of using a rotary kiln over other ex situ TDUs include the ability to achieve high system throughputs and high soil temperatures during a fairly short residence time. This allows the treatment of multiple soil types and higher boiling point contaminants. Another important factor is that rotary kiln technology is mature and available from multiple vendors, thereby increasing availability and lowering cost.

System monitoring and safety interlocks

During operation, the TDU's operating parameters are measured and recorded to ensure correct operation and to prevent accidental releases of contaminants. While there are several possible parameters to monitor, the following are recommended where applicable: treated soil exit temperature, vacuum in the TDU, pressure drop in the APC, waste feed rate, afterburner temperature, off-gas exit temperature from the TDU, stack gas velocity and temperature, and the flow rate and pH of acid–gas scrubber liquor.[14]

The selected parameters can be tied in to a safety interlock system that provides a warning to the operator, adjusts system parameters, or shuts the system down during an upset to prevent the accidental release of contaminants. Instantaneous system shutdown is recommended if the following upsets are detected: primary burner or heater system failure; blower failure or loss of negative pressure; or a pressure drop in the APC outside allowable range. Shutdown after a 10-min delay is recommended for the following situations: soil exit temperature below limit; high carbon monoxide level in oxidizer exhaust; waste feed rate exceeds limit; or a significant change in the gas velocity through the APC. A final interlock will shut the system down in 30 sec to 2 min if the oxidizer temperature is below the minimum allowable level.[14]

Off-Gas Treatment

After exiting the TDU, the off-gas contains volatilized contaminants that are then either destroyed in an oxidizer (afterburner) or collected for further treatment. Treatment in a thermal oxidizer is a fairly common option in thermal desorption systems and is discussed first.

Thermal destruction

While there are several possible APC configurations to destroy volatilized contaminants, a typical system is shown in Fig. 2. The first step in the process involves removal of fines entrained in the off-gas using either a cyclone separator or a baghouse.

Cyclone separators operate by directing the air stream into a conical shell where the off-gas circulates downward along the outer edge of the shell. Due to their inertia, particles strike the shell and fall to the

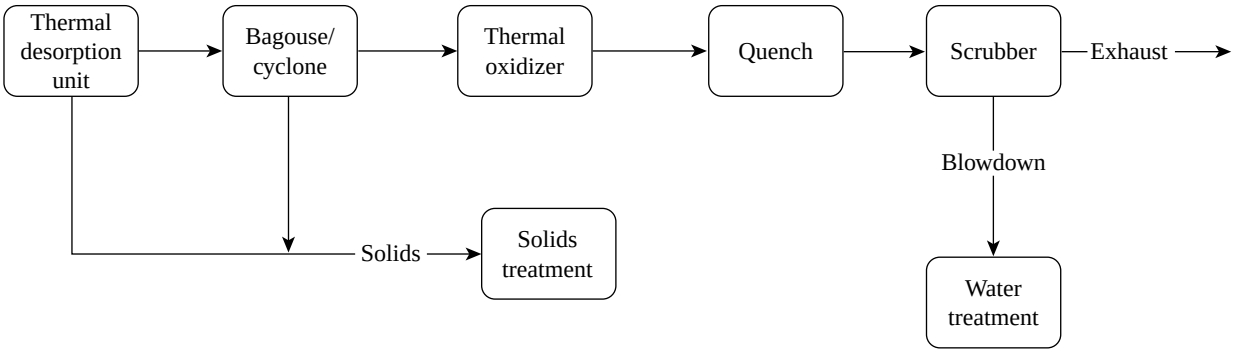

Fig. 2 Off-gas treatment with thermal destruction of contaminants.

bottom of the cone where they are collected. The air stream makes several rotations through the cone before changing direction at the bottom of the cone and exiting through the top of the cyclone. Cyclone separators may be operated individually or in series and can achieve particulate removal efficiencies of 90–95%, although they are not effective in removing particulate smaller than 10 μm.[23]

Baghouses are used to control particulate matter emissions to submicron size at control efficiencies greater than 99%.[23] In baghouses, gases are passed through several fabric bags and the particulate matter is deposited on the bag. During normal operation, the bags are periodically cleaned and the removed fines are combined with soils exiting the TDU for further treatment.

The bags may be made of several different materials depending on the off-gas temperature and the presence of acid gases. Common fabrics used in baghouses include fiberglass, Nomex®, Ryton®, and Teflon®[a] with their operating temperatures and acid gas resistance shown in Table 1.[24] After choosing the appropriate bag material, the bags are sized using the primary design criterion for baghouses, the air-to-cloth (A/C) ratio. The A/C ratio measures the ratio of actual cubic feet of air flow to the square feet of cloth area. In thermal desorption systems, typical values of A/C are 0.76 actual cubic meters per minute per square meter ($acmm/m^2$) for woven fabric bags and 2.13–3.05 $acmm/m^2$ for felt bags, which can lead to bags as large as 0.3×9.1 m.[24] The final important parameter in baghouse systems is the pressure drop across the bags, which is typically 0.5–3.0 kPa.[25]

After exiting the baghouse, the off-gas is directed to the thermal oxidizer consisting of a refractory lined cylinder with a burner. The burner rapidly heats the off-gas to oxidize the organic contaminants. The required organics destruction efficiency in the oxidizer is generally determined on a case by case basis during permitting, however, at a minimum, regulators use the standard Destruction and Removal Efficiency (DRE) specified under RCRA regulations of 99.99% for principle organic hazardous constituents, and 99.9999% for wastes containing dioxins and furans [40 Code of Federal Regulations (CFR) Parts 264 and 265]. Regulations promulgated under the authority of the Toxic Substances Control Act also require a DRE of 99.9999% for wastes containing PCBs (40 CFR Part 761).

The DRE in a thermal oxidizer is affected by the three T's of time, temperature, and turbulence. In order to achieve the required destruction efficiencies, the burner heats the off-gas to temperatures between 760°C and 982°C in a turbulent mixing environment where the contaminants are held for a residence time of up to 2 sec.[5] The turbulent environment is critical to ensuring thorough mixing of the off-gas in the combustion chamber thereby preventing any short circuiting where off-gas exits the combustion chamber prior to being treated.

RCRA also limits the amount of HCl contained in the thermal oxidizer exhaust to 4 lb/hr or less than 1%, whichever is less (40 CFR 264 and 265). Achieving this requires a quench process followed by an acid gas scrubber. The quench process lowers the gas temperature to the operating temperature of the acid gas scrubber, which must be below the boiling point of the acid gases to prevent revolatilization. Quench systems operate by spraying water into the gas stream to cool the gas as the water evaporates.

In the acid gas scrubber, water is again sprayed into the gas stream. However, the gas is forced through a packed bed of acid-resistant material, such as polyvinylchloride, to increase its contact with the water. By forcing the gas through this tortuous path, larger amounts of HCl are absorbed by the water. Removal efficiencies of 70% are achievable when using plain water and 93–96% when using water with an alkaline

material in it.[23] The wastewater from the acid gas process can then either be neutralized or treated in a wastewater treatment plant depending on its characteristics. As this represents the last step in the APC system, the off-gas leaves the scrubber through a stack and is vented to atmosphere.

Contaminant Recovery

An alternative to destroying contaminants in a thermal oxidizer is to recover them for further treatment. As shown in Fig. 3, the APC system for contaminant recovery also begins with a baghouse/cyclone to remove particulate matter. However, the off-gas is then directed to a condenser instead of a thermal oxidizer.

Condensers operate by cooling the off-gas stream, leading to the condensation of the volatilized contaminants. A typical system consists of a tube and a shell heat exchanger where the off-gas is passed through the shell containing refrigerant tubes. As refrigerant circulates through the tubes, the off-gas is cooled and the contaminants condense on the outside of the tubes. These contaminants then gravity drain to the bottom of the shell where they are recovered for further treatment. The removal efficiency of these systems depends on the contaminants in the off-gas, but efficiencies of 90% are attainable when using chilled water, ammonia, or chlorofluorocarbons as the refrigerant.[26] (Note: The Montreal Protocol phases out production of chlorofluorocarbons and they are no longer used in new equipment.)

After exiting the condenser, the off-gas still contains enough contaminants to be of concern; therefore the gas is then directed to a carbon adsorption unit as a final polishing step. In these systems, the off-gas is passed through a bed of activated carbon (either powdered or granular) and any entrained organic contaminants are adsorbed on to the surface of the carbon. The unit is sized based on the inlet contaminant concentration, gas flow rate, and desired outlet concentration. It should be noted that special designs are generally not required for thermal desorption systems because fixed bed adsorption units to treat VOC streams of 5000 ppm at 2832 standard cubic meters per minute (scmm) to an outlet concentration of 25 ppm are commercially available.[27] Periodic monitoring of VOCs in the adsorber exhaust will show when the carbon is saturated with VOCs. At this point, the carbon may either be regenerated through heating or disposed of

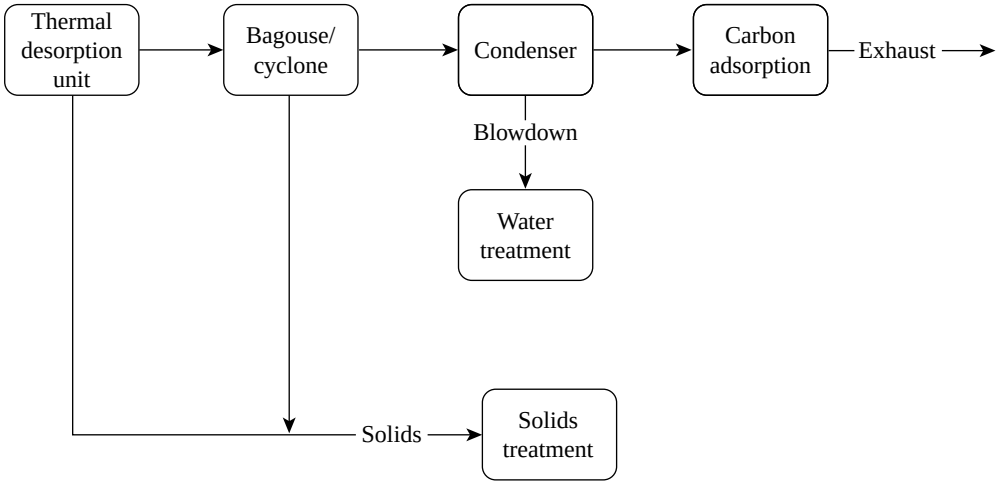

Fig. 3 Off-gas treatment with system with contaminant recovery.

as hazardous waste and replaced. After passing through the activated carbon bed, the off-gas is vented to the atmosphere through a stack.

Emission limits and monitoring

In addition to the minimum DRE and the limits on HCl for thermal oxidizers already mentioned, regulatory agencies will place emission limits on the exhaust gas depending on local regulations and the contaminants of concern. The most commonly regulated emissions for thermal oxidizer exhaust are particulate matter (PM), CO, HCl, sulfur oxides (SO_x), VOCs, total hydrocarbons (THC), and nitrogenoxides (NO_x). Alternatively, regulators typically place limits on PM, THC, and/or VOC emissions from contaminant recovery systems.[5]

Regulators verify that the emissions are within limits in different ways for thermal oxidizers and contaminant recovery systems. Since thermal oxidizers involve combustion, the combustion process parameters of CO, CO_2, and O_2 are often monitored continuously to verify that complete combustion of contaminants occurs in the thermal oxidizer.[5] The acceptable range for these parameters is determined during a performance test where the optimal operating conditions for treating the contaminants of concern are determined. Additionally, regulatory agencies typically require periodic exhaust gas sampling to further demonstrate that emissions limits are being met.

In contaminant recovery systems, regulators typically do not require continuous monitoring of the exhaust gas. As with thermal oxidizers, emissions are monitored during an initial performance test to determine the appropriate operating parameters. In these systems, the assumption is that exhaust gas emissions will meet the regulatory limits provided the system is operated in the same manner and within the limits established during the performance test. Regulators may, however, require periodic exhaust gas sampling to verify this assertion.

Solids Treatment

The second waste stream generated from the TDU is the soil. After exiting the TDU, the first step in secondary treatment of the soils involves adding water to both cool the soil and minimize the generation of fugitive dust. After this step, the soil is typically placed in piles for analysis to determine if the treatment standards were met and whether or not the soil is hazardous.

Depending on the results of the analysis, one of three things happens to the soil. In the case of nonhazardous soil, typically no further treatment is necessary and the soil is used as backfill on-site. Soil that fails to meet the cleanup goals is processed through the TDU again and reanalyzed. If the soil is hazardous but within the cleanup goals, which occurs when sufficient metals are present, it is either disposed of off-site as a hazardous waste or treated further with a method such as solidification/stabilization.[3]

COST AND PERFORMANCE

The cost of thermal desorption treatment can depend heavily on the amount of soil treated because the cost per ton of soil treated decreases as economics of scale are realized with increasing soil volume. An analysis conducted by the USEPA using 2000-yr dollars shows that for systems treating less than 15,000 tons of soil, the cost is between $125 and $275 per ton; for systems treating between 15,000 and 30,000 tons of soil, the cost is between $100 and $125 per ton; and for systems treating over 30,000 tons, the cost is between $60 and $100 per ton.[28] These costs compare favorably with 2002-yr dollars amounts for on-site incineration, the most comparable technology. For incineration systems treating less than 15,000 tons of soil, the cost ranges from $770 to $3200 per ton; when treating between 15,000 and 30,000 tons of soil, the cost ranges from $650 to $3300 per ton; and when treating over 30,000 tons of soil, the cost ranges from $230 to $800 per ton.[5]

The amount of soil treated is not the only factor affecting cost, however. The following are the most commonly identified factors affecting the cost of treatment: moisture content of the soil, soil characteristics, amount of debris with the waste, initial contaminant concentration, target contaminant concentration, and utility rates.[29]

While cost is an important consideration when selecting a remediation technology, the primary consideration is the technology's effectiveness in treating the contaminants of concern. Specific treatment goals are determined for each site based on acceptable residual risk, but it is useful to look at the range of removal efficiencies. Table 2 shows that thermal desorption has proven effective in treating a wide range of contaminants, which explains why thermal desorption has been used at several sites.

Table 2 Thermal desorption removal efficiencies[a]

Contaminant	High (%)	Low (%)
Polycyclic aromatic hydrocarbons	97.8723	92.5
Polychlorinated biphenyls	99.9999	98
Volatile organic compounds	99.9970	98.8889
Pesticides	99.9839	97.8723

[a]Developed from Ref.[5].

CONCLUSIONS

After its initial development as an innovative technology for treating soil contaminated with VOCs, SVOCs, PAHs, PCBs, mercury, and pesticides, thermal desorption has become a preferred method for treating these wastes. Thermal desorption has been successfully used in several sites, consistently achieving removal efficiencies greater than 97%, at an attractive cost.

The future of thermal desorption as a remediation technology is promising, and it has already been used in over 146 sites in the U.S.A. As of 2003, the USEPA's REmediation And CHaracterization Innovative Technologies (REACH IT) database lists 77 vendors offering thermal desorption services.[29] The expectation is that more and more contaminated sites will be identified, as insurers routinely require environmental investigations prior to the transfer of industrial properties and regulatory agencies continue to promulgate increasingly stringent cleanup standards. Since the USEPA identified thermal desorption as a presumptive remedy for treating many contaminated soils, its use has risen and will continue to grow and be refined and improved.[30]

Thermal Stability of Chemical Reactors

Haishan Zheng
Jason M. Keith
Department of Chemical Engineering, Michigan Technological University, Houghton, Michigan, U.S.A.

INTRODUCTION

Even the simplest of chemical reactors can exhibit complex steady-state behavior, including multiplicity and ignition–extinction hysteresis. In addition, there can be dynamic phenomena which can occur during reactor startup or in response to perturbations in operating variables in the approach to or from a steady state, or within a limit cycle or chaotic attractor. In the last couple of decades, a great deal of attention has been focused on purposely operating chemical reactors in unsteady-state conditions. To properly design such systems requires a knowledge of the thermal stability of the chemical reactor. After a brief historical review of the classical stability problem of a batch reactor and a continuous stirred tank reactor, an overview of thermal stability in two classes of transiently operated reactors is given: the periodic reverse-flow reactor (where thermal runaway is to be avoided) and the monolithic catalytic converter/diesel particulate filter (in which thermal ignition is desired to reduce vehicle emissions while maximizing fuel economy).

CLASSICAL MODELS

Reactor designs are characterized as either homogeneous or heterogeneous. Typically, homogeneous reactors are well mixed stirred tanks (either batch or continuous), but can also be tubular reactors. They are widely used in the chemical industry from pilot plant to full-scale production. Examples include decomposition of azomethane, production of ethylene glycol, and the copolymerization of styrene and butadiene.

Thermal runaway or instability can occur when exothermic reactions are carried out in homogeneous reactors, when the rate of heat generation is faster than the rate of heat removal. In this case, a small change in an operating variable can induce a large variation in the system behavior. In practice, operation in a parametrically sensitive region is usually to be avoided. However, the reaction engineer must still be aware of these regions to ensure ''safe'' operation. Therefore, there have been many published studies on the derivation of runaway criteria and analysis of the stability of steady states, which is the focus of this section.

The Batch Reactor

Stability and dynamics of chemical reactions within batch systems date back to the pioneering work of Russian scientist Nikolay Semenov[1] on chain reactions and combustion, for which he shared the 1956 Nobel Prize with Sir Cyril Hinshelwood. There have since been considerable literature contributions, the most widely studied system being the irreversible first order reaction $A \rightarrow B$ with Arrhenius kinetics $k(T) = k_o \exp(-E/RT)$. The mass balance (in dimensionless variables) within the reactor yields:

$$\frac{dy}{d\tau_b} = (1-y)\exp\left\{\frac{\theta}{1 + \theta/\gamma}\right\} \tag{1}$$

The energy balance is:

$$Le\frac{d\theta}{d\tau_b} = B(1-y)\exp\left\{\frac{\theta}{1 + \theta/\gamma}\right\} - \alpha(\theta - \theta_c) \tag{2}$$

where $y = (C_{A,f} - C_A)/C_{A,f}$ is the reactor conversion and $\theta = (T - T_f)\gamma/T_f$ is the dimensionless reactor temperature, with $\gamma = E/RT_f$ as the dimensionless activation energy. Time is rendered dimensionless with the reaction time at the initial state $t_r = 1/k(T_f)$, such that $\tau_b = tk_o \exp(-\gamma)$. Also, $B = (-\Delta H)C_{A,f}\gamma/(\rho C_p T_f)$ is the dimensionless adiabatic temperature rise and $\alpha = hAt_r/(V\rho C_p)$ is a ratio of the reaction time to the characteristic time for heat removal from the reaction mixture t_{co}. It must be noted that the ratio B/α is often called the Semenov number. The parameter Le is a ratio of the heat capacitance of the reaction vessel and its contents to that of the vessel contents, such that $Le = 1$ implies a negligible contribution of the reactor vessel.

The most customary assumption is that of negligible reactant consumption (i.e., $y = 1$) such that Eq. (1) disappears and one is only concerned with the relationship between the heat generation curve

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007987

$B\exp(\theta/(1 + \theta/\gamma))$ and the heat removal line $\alpha(\theta - \theta_c)$. It has been shown that bifurcations or critical conditions exist when the heat generation and heat removal curves are tangent to each other, such that the following pair of equations is satisfied:

$$\exp\left(\frac{\theta}{1 + \theta/\gamma}\right) = \frac{\alpha}{B}(\theta - \theta_c) \tag{3}$$

and its derivative

$$\exp\left(\frac{\theta}{1 + \theta/\gamma}\right)\frac{1}{(1 + \theta/\gamma)^2} = \frac{\alpha}{B} \tag{4}$$

This is illustrated in Fig. 1 below (with parameters $B = 1$, $\gamma = 3$ and $\theta_c = -1.75$) for two particular heat removal lines (the upper dashed line with $\alpha = 0.968$ and the lower dashed line with $\alpha = 0.199$). Three basic patterns arise: one "safe," stable steady state (to the left of the upper dashed line), multiple steady states (in between the two dashed lines, where the lower steady state is stable and "safe," the intermediate steady state is unstable, and there may be a stable but "unsafe" steady state at high temperature) and an "unsafe" region (to the right of the lower dashed line). The upper, "unsafe" steady state will only exist when $\theta/\gamma \gg 1$ (which is usually not the case for industrially relevant reactions). In this limit, the heat generation curve levels off asymptotically to a value of $B\exp(\gamma)$. It is also noted that the classical result obtained by Semenov[1] for "safe" operation in the limit of high activation energy (i.e., $\gamma \to \infty$) when $\theta_c = 0$ is $\alpha/B > e$.

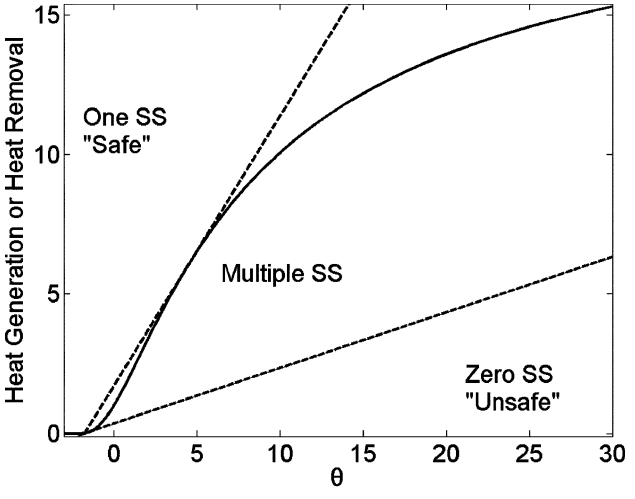

Fig. 1 Multiple steady states and their classifications in a batch reactor with negligible reactant consumption. The solid line is the heat generation curve, with $B = 1$, $\gamma = 3$, and $\theta_c = -1.75$. The upper dashed line is the heat removal line with $\alpha = 0.968$ and the lower dashed line is the heat removal line with $\alpha = 0.199$. [Data from Eq. (3).]

Since this initial work, analysis of these batch systems has been further expanded to include reactant consumption, beginning with the work of Rice, Allen, and Campbell.[2] Furthermore, an excellent study of stability with a generalized nth order reaction rate and the effect of the heat capacity of the reactor walls (when $Le \neq 1$) was presented by Balakotaiah, Kodra, and Nguyen.[3] They verified previous work which showed the boundary to runaway behavior occurs when two inflection points appear in the reaction trajectory between the initial and final states. In the limit of $\gamma \to \infty$ and $\theta_c = 0$, the "safe" criteria under adiabatic conditions ($\alpha = 0$) is given as $B < Le(1 + \sqrt{n})^2$ and for highly exothermic reactions ($B \gg 1$) with large cooling ($\alpha \gg 1$) the "safe" criteria approaches Semenov's classical result $\alpha/B > e$.

The Continuous Stirred Tank Reactor

The classical problem of steady-state multiplicity in a continuous stirred tank reactor (CSTR) was brought to popular attention in 1953 in the theoretical article by Van Heerden.[4] Large amounts of experimental work which measured these steady states were performed by the group of Schmitz beginning in 1970.[5] Schmitz also wrote two excellent reviews on multiplicity, stability, and sensitivity of steady states in chemical reactors[6] and the application of bifurcation theory to determine the presence of steady-state multiplicity in chemical reactors.[7] Even these reviews are not inclusive and it is our intention in this subsection to only provide a background to the novice in reactor design.

Consider a well-mixed stirred tank reactor with a first order, exothermic reaction A → B. A material balance about the reactor gives the following:

$$\frac{dy}{d\tau_c} = -y + Da(1 - y)\exp\left\{\frac{\theta}{1 + \theta/\gamma}\right\} \tag{5}$$

and the energy balance is given as:

$$Le\frac{d\theta}{d\tau_c} = -\theta + BDa(1 - y)\exp\left\{\frac{\theta}{1 + \theta/\gamma}\right\} - \beta(\theta - \theta_c) \tag{6}$$

where y, θ, γ, and B are defined in the previous subsection. The symbol $Da = t_c/t_r$ is a ratio of the residence time $t_c = V/F$ to the reaction time $t_r = 1/k_o\exp(-\gamma)$ at the feed conditions, and $\beta = hAt_c/(V\rho C_p)$ is a ratio of the residence time to the characteristic time t_{co} for heat removal from the reaction mixture. For the CSTR, time is rendered dimensionless as $\tau_c = t/t_c$.

The most widely occuring multiple solution in the published theoretical and experimental literature is an ignition–extinction plot with three steady states. As seen in Fig. 2, the upper and lower steady states

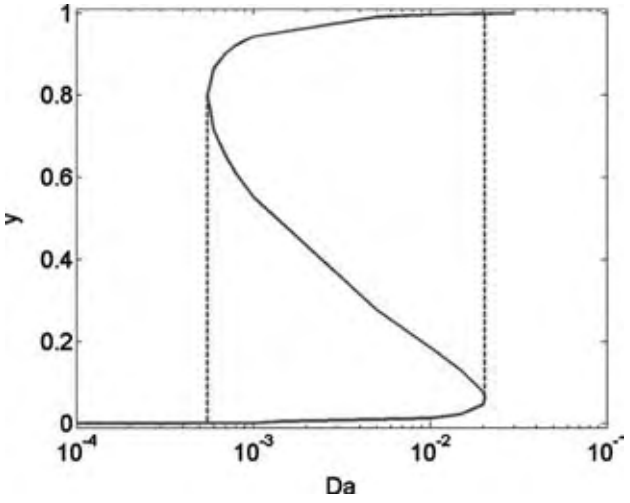

Fig. 2 Steady-state hysteresis in a CSTR with $\beta = 0$, $B = 20$, $\gamma = 20$, and $\theta_c = 0$. [Data from Eqs. (5) and (6) at steady state.]

are stable to small perturbations, but the middle steady state is unstable. Uppal, Ray, and Poore[8] analyzed the system of Eqs. (5) and (6) and found six different regions of multiplicity with nine different types of phase plots. The dynamical features include limit cycles and separatrices. They continued their analysis by redefining Da and β in terms of the residence time t_c.[9] Thus, they used $Da = Da_o/\tau_c$ and $\beta = \beta_o/\tau_c$ where $Da_o = k_o \exp(-\gamma)t$ and $\beta_o = hAt/(V\rho C_p)$ and added an additional adjustable parameter τ_c. Surprisingly, this seemingly minor change in the system led to increased bifurcation behavior, such as isolated steady states (''isolas'') and ''mushrooms.'' Beyond these studies, the complexity is seen to increase dramatically with multiple reactions and reaction orders, as well as within polymerization reactions.

Balakotaiah, Kodra, and Nguyen[3] also studied the CSTR. They found that the boundary between the insensitive and runaway region is where there are two limit points (a point of infinite slope – there are two such limit points in Fig. 2) in the reaction path connecting the initial and final states. They found identical criteria to the batch reactor in the special limit of $\gamma \to \infty$ and $\theta_c = 0$. That is, the ''safe'' criteria under adiabatic conditions ($\alpha = 0$) is given as $B < (1 + \sqrt{n})^2$. It is noted that there is no dependence on the Lewis number, Le, as there is no contribution due to the heat capacity of the reactor walls at steady state. Also, for the case of $B \gg 1$ and $\alpha \gg 1$, the ''safe'' criteria is $\alpha/B > e$.

Other Systems

Other systems also reviewed by Schmitz[5,6] include distributed reactor models such as catalyst pellets and fixed bed reactors, which also display interesting dynamical and steady-state behavior. Balakotaiah, Kodra, and Nguyen[3] also present stability criteria for homogenous tubular reactors. The equations for such a reactor are given by:

$$\frac{\partial y}{\partial \tau_b} + \frac{t_r}{t_c}\frac{\partial y}{\partial \xi} = \frac{t_r}{t_m}\frac{\partial^2 y}{\partial \xi^2} + (1 - y)\exp\left\{\frac{\theta}{1 + \theta/\gamma}\right\} \tag{7}$$

for mass conservation and

$$Le\frac{\partial \theta}{\partial \tau_b} + \frac{t_r}{t_c}\frac{\partial \theta}{\partial \xi} = \frac{t_r}{t_h}\frac{\partial^2 \theta}{\partial \xi^2} + B(1 - y)\exp\left\{\frac{\theta}{1 + \theta/\gamma}\right\} - \frac{t_r}{t_{co}}(\theta - \theta_c) \tag{8}$$

for energy conservation, where ξ is the dimensionless reactor length. It is noted that the tubular reactor has the three timescales from the CSTR: the characteristic reaction time t_r, the cooling time t_{co}, and the residence time t_c. In addition, there are two additional timescales: the mass dispersion time $t_m = L^2/D$, and the axial heat dispersion time $t_h = L^2/\kappa$. Depending upon the relative importance of these timescales, the stability behavior of the tubular reactor can be broken up into several classifications:

- A cooled plug flow reactor when axial dispersion is negligible, a usual assumption for tubular reactors with no mixing ($t_r, t_{co}, t_c \ll t_m, t_h$)
- A batch reactor when axial dispersion and convection are both negligible, as there is no outflow from the reactor ($t_r, t_{co} \ll t_c, t_m, t_h$)
- A CSTR when dispersion is very large and the conversion and temperature are independent of position due to perfect mixing ($t_m, t_h \ll t_c, t_r, t_{co}$).

In addition, it was found that the plug flow reactor had the same asymptotic behavior as the batch reactor, with reactor heat capacity unimportant ($Le \neq 1$) and the only difference being the interchange of time (batch) with reactor length (plug flow). The authors also stated that the uncertainty involved in determining kinetic and heat transfer parameters is greater than the differences between the respected criteria for batch, CSTR, and plug flow, and that one single thermal stability criterion based upon the CSTR would be more than adequate for all homogeneous reactor models. This paper[3] also described runaway limits for catalytic reactors and for multiple reactions.

Doraiswamy[10] presented a very detailed review on the role of heterogeneous catalytic systems on inducing multiplicity and instability. In particular, this review focuses on the role that the Langmuir isotherm and the Langmuir–Hinshelwood rate equations (resulting

from adsorption, surface reaction, and desorption) have on inducing instabilities in chemical reactors. Additional complexities are introduced through accounting for multilayer adsorption and lateral interactions between adsorbed molecules, and nonideal surfaces.

CURRENT APPLICATIONS OF THERMAL STABILITY

This section focuses on some current applications of thermal stability theory.

Reverse-Flow Reactors

The reverse-flow chemical reactor (RFR) has been shown to be a potentially effective technique for many industrial chemical processes, including oxidation of volatile organic compounds such as propane, propylene, and carbon monoxide; removal of nitrogen oxides; sulfur dioxide oxidation or reduction; production of synthesis gas; methanol formation; and ethylbenzene dehydration into styrene. An excellent introductory article in the topic is given by Eigenberger and Nieken[11] on the effect of the kinetic reaction parameters, reactor size, and operating parameters on RFR performance. A detailed review that summarizes the applications and theory of RFR operation is given by Matros and Bunimovich.[12]

A reverse-flow reactor operates by periodically opening and closing valves so that the gas flow through the RFR bed alternates back and forth. After a long startup time, the RFR can reach a cyclic steady state, where the temperature profile is identical to that during the previous full cycle. This behavior shows that heat storage during lean conditions is a strong advantage of RFR operation versus a conventional packed bed (single-pass) reactor, as seen in the following example.

Consider the comparison between an adiabatic RFR and a single-pass reactor to treat a feed with carbon monoxide (with data available in Table 1 and performance depicted in Fig. 3). Invoking the commonly cited psuedohomogeneous model, each reactor is described by Eqs. (7) and (8). The reactor is preheated to an ignited steady state by introducing CO at a large concentration $C_{in,COseed} = 100C_{in,CO}$ for $t < t_f$ (3.33 h). For times $t > t_f$, the flow is reversed with a switching time t_{rev} and a feed concentration $C_{in,CO}$ (such a stream with a low concentration may be an effluent from a chemical process elsewhere in the plant, and may need to be treated before exiting the plant). The reactors appear to behave similarly for times $t_f < t < t_f + t_{rev}$ even though the gases flow in different directions.

It is noted that the higher maximum temperature within the RFR is due to wrong-way behavior, a purely transient effect which was shown for a single-pass reactor by Pinjala, Chen, and Luss[13] in reverse-flow reactors by many investigators including Purwono[14] and Keith, Leighton, and Chang.[15] Upon flow reversal, the temperature in the feed stream is lower than that near the entrance of the reactor. Thus, a temperature step propagates into the reactor. Within this step there is some reactant that has not been depleted. Because the reaction rate is higher at the elevated temperature, there is a localized heat release at the step in the form of a thermal spike and the maximum reactor temperature increases.

It is also noted, for this example, that only after a time $t_f + t_{rev}$ do the reactors diverge in performance. In the RFR, the flow has again switched, and about one-third of the reactor is ignited for the remainder of the simulation and is able to treat the feed gas

Table 1 Data for carbon monoxide oxidation in a reverse-flow reactor

T_{in}	400 K
t_f	3.3 hr
$C_{in,CO}$	5.0×10^{-9} mol/cm^3
$C_{in,other}$	Trace
$\Delta T_{ad,COmax} = \Delta H C_{in,COmax}/(\rho_g C_{p,g})$	2.2 K
t_{rev}	2 hr

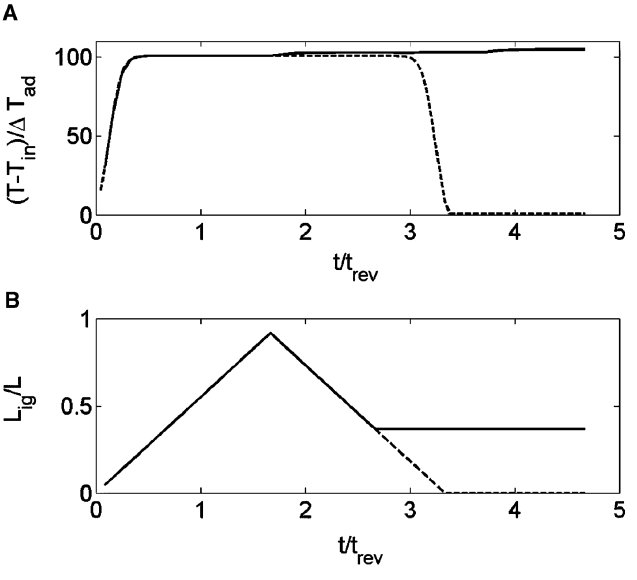

Fig. 3 Comparison of RFR (solid lines) with single-pass reactor (dashed lines). (A) the maximum temperature within the reactor and (B) the ignited length of the reactor. (Data taken from the numerical model in Ref.[15].)

adequately. The single pass reactor finally extinguishes after a time $2\,t_f$ when the maximum temperature within the reactor is equal to the feed temperature. Under these conditions, the feed gas may not be treatable and can exit the reactor unabated.

For systems where the adiabatic temperature rise is low (as is the case considered here) the thermal spikes introduced by the flow reversals do not dramatically affect the reactor performance. However, the concentration of feed streams to such treatment reactors can fluctuate to a high level which can result in a high temperature thermal spike developing within the reactor. Pinjala, Chen, and Luss[13] characterized this dynamic response and showed that reactor runaway could occur within the single-pass reactor. Their work is directly applicable to the RFR as the forced oscillations in the gas flow direction can result in a thermal spike formation at the beginning of each half cycle. Thus, there is a need to understand thermal stability within these systems. Further complicating the matter is the fact that the temperature spikes are very narrow and are thus difficult to detect using thermocouples or other sensors imbedded within the reactor.

Eigenberger and Nieken[11] demonstrated ignition–extinction hysteresis within the RFR. They illustrated that the maximum bed temperature extinguishes to a low, unignited cyclic steady state for high values of t_{rev}. One must reduce the value of t_{rev} below this extinction point to reignite the reactor to the upper cyclic steady state.

Often the ignited steady-state temperature can be high enough to damage the catalyst or lead to ''unsafe'' reactor operation. Purwono et al.[14] performed experiments and developed a numerical simulation of a two recuperator/catalyst bed reverse-flow reactor system. They measured runaway for propene oxidation and for carbon monoxide oxidation. They identified the reactor peak temperature as the primary indicator of reactor runaway. Keith, Leighton, and Cheng[15] stabilized the reactor by increasing the thermal dispersion by a factor of 200 by placing metal rods into the bed, parallel with the gas flow. The thermal dispersion that arises is a transient phenomenon, akin to the classical Taylor–Aris dispersion mechanism.[16,17] It smoothes out the temperature spikes after they form and allows for a lower temperature cyclic steady state within the reactor. This work also developed analytical expressions for the reactor maximum temperature as a function of cycle number which can be used to predict the time for runaway (if extremely high pollutant feed conditions exist) or extinction (if there is a very low concentration of pollutant in the feed stream).

Khinast and Luss presented a rigorous method for constructing parameter maps of the RFR which contain different bifurcation diagrams.[18] Using the Damköhler number as the bifurcation variable, five different regions were found for a single exothermic first-order reaction (these contained hysteresis, isola, and mushroom varieties). In addition, using the adiabatic temperature rise as the bifurcation variable, seven regions are found when there are two independent exothermic first-order reactions (these contained hysteresis and double limit varieties and five of these regions had three stable periodic states). Khinast, Gurumoorthy, and Luss also identified regimes where cooled RFR exhibit complex quasi-periodic states.[19] The maximum temperature within the reactor in many of these states was high which could possibly lead to catalyst deactivation or ''unsafe'' operation.

Catalytic Converters

Monolithic catalytic converters continue to receive attention in the literature because of their applications in air pollution control and clean energy production. They differ from packed-bed reactors in their configuration as there are many parallel channels coated with a layer of catalyst. The flow in the channels is typically laminar. Because of its large void fraction, it is expected that the temperature transients will exhibit a significant impact on the performance of the monolith, particularly with respect to thermal stability.

The light-off behavior of catalytic monolith is characterized by the presence of multiple steady states with an S-shaped hysteresis locus, which is similar to that of the CSTR. The catalytic monolith initially operates on the low conversion steady-state branch at the monolith entrance. As the fluid flows through the channel, the energy produced by the exothermic reaction is carried downstream in the channel. Beyond a point where the rate of heat generation is equal to the rate of heat removal, the catalytic monolith jumps to the high conversion branch. However, this ignition point may be beyond the finite length of the monolith for low inlet temperatures, which means no ignition occurs. With an increase in the inlet temperature, the ignition point should move into the reactor and then towards the monolith entrance.

Much effort has been made to study this light-off behavior of catalytic monolith. Oh and Cavendish[20] studied the response of the monolith to a step increase in the feed stream temperature by using a one-dimensional two-phase (gas and solid) model. They tracked the cross-sectional average temperature and concentration in each phase and used heat and mass transfer coefficients to describe interphase transport. The results indicated that the light-off occurs at the monolith entrance for a sufficiently high inlet exhaust temperature. For a lower inlet exhaust temperature, the light-off occurs in the downstream section, and the

thermal front moves upstream due to solid phase heat conduction. They also pointed out wrong-way behavior in catalytic monoliths, as described in the previous subsection and reported by Pinjala, Chen, and Luss.[13] Under certain operating conditions, a decrease in the inlet exhaust temperature can result in a downstream ignition within the monolith.

It should be emphasized that Oh and Cavendish[20] assumed that the reactions only occur on the surface of the channel wall. This assumption is less realistic for a layer of washcoat (typically γ-alumina) dispersed with catalyst applied on to the wall surface. Ramanathan, Balakotaiah, and West[21] showed that the diffusion in the washcoat has a profound influence on the light-off behavior of a monolith converter. They derived an analytical light-off criterion based on a one-dimensional two-phase model with position-dependent heat and mass transfer coefficients. The derivation of this criterion is based on the two key assumptions: a positive exponential approximation (i.e., the Frank–Kameneskii approximation) and negligible reactant consumption in the fluid phase. The light-off is defined as the occurrence of multiple steady states with the attainment of the ignited steady state. Here, we discuss only the results of their analysis, without going into the details of their derivation.

For a first-order reaction, their light-off criterion (deemed ''unsafe'' by the classical definition, but desired in this application) accounting for washcoat diffusion is given by

$$m\left(\phi_s\sqrt{\Lambda}\right)\left[\frac{n(Pe_h)B\phi_s^2}{eP} + \frac{4B\phi_s^2}{Le_f Nu_{H,\infty}}\right]^{-1} < e \qquad (9)$$

where m is a function of the product of the Thiele modulus ϕ_s and the square root of the dimensionless washcoat thickness Λ that accounts for the washcoat diffusion; n is a function of the axial heat Peclet number, Pe_h, that accounts for solid conduction; B is the dimensionless adiabatic temperature rise, P is the transverse Peclet number (a ratio of transverse diffusion time to the convection time), Le_f is the fluid Lewis number, a ratio of heat to mass diffusivities; and $Nu_{H,\infty}$ is the asymptotic value of the Nusselt number with a constant flux boundary condition.

The first term in the sum within Eq. (9) represents the ignition locus of the homogenous plug flow model. It can be seen that, in the case of infinite conductivity in the solid phase and negligible washcoat thickness (i.e., $n \to e$ as $Pe_h \to 0$ and $m \to 1$ as $\Lambda \to 0$), the above lightoff (''unsafe'') criterion reduces to the classic Semenov criterion $P/B\phi_s^2 < e$. It can also be seen from the above criterion that for a small value of P(i.e., long monolith or a low flow rate), the criterion for the homogenous plug flow model can be used. This principle has been used to derive the light-off criterion for monolithic diesel particulate filters in the case of low exhaust flow, which we will discuss in the next subsection.

The second term in the sum within Eq. (9) accounts for the heterogeneous contribution (i.e. washcoat diffusion). Ramanathan, Balakotaiah, and West[21] pointed out that ignition will occur at the back end when the first term is greater than one and the second term is much less than one. Furthermore, if the second term is greater than one, the ignition occurs at the leading edge independent of the value of the first term. If both terms are less than one but the sum is greater than one, the ignition will occur in the middle of the converter. It is worth noting that, for a given reaction kinetics and a fixed washcoat thickness, the dynamic behavior of the monolith can be classified into three regions: no ignition, ignition without washcoat diffusion limitations, and ignition with washcoat diffusion limitations. Their studies showed that the influence of the washcoat thickness on ignition becomes constant in the washcoat diffusion limitation region. In the region without washcoat diffusion limitations, ignition becomes easier as the washcoat thickness increases.

Catalytic monoliths have been extensively used in the control of automobile emissions. A large quantity of emissions are produced in the cold-start period. Thus, it is of practical interest to design a quick light-off catalytic monolith converter. Leighton and Chang[22] have shown that the Taylor–Aris dispersion mechanism[16,17] has a profound influence on the light-off time of the catalytic converter. They found that the ignition time depends on two key parameters: a Damköhler parameter χ, which is a ratio of axial dispersion to axial convection during the characteristic time for ignition, and the degree of monolith subcooling η. For a small value of χ (i.e., slow reaction), the Taylor–Aris dispersion smoothes the thermal front and delays the ignition process, and the ignition occurs downstream near the thermal front. For a large value of χ (i.e., fast reaction) the ignition occurs before the Taylor–Aris dispersion takes effect. Thus, the thermal dynamics of the leading edge of the monolith can be assumed to be homogenous, and ignition occurs at the leading edge of the monolith. The analytical expressions for the light-off time for these two distinct mechanisms have been derived based on Oh and Cavendish's[20] one-dimensional two-phase model. By use of these analytical expressions, it is found that preheating the exhaust flow is an effective way to reduce the light-off time for leading edge ignition. The leading edge ignition is preferred because the upstream propagation of the thermal front is slow when ignition occurs downstream. The ignition dynamics for downstream and leading edge ignition are shown in Fig. 4.[23]

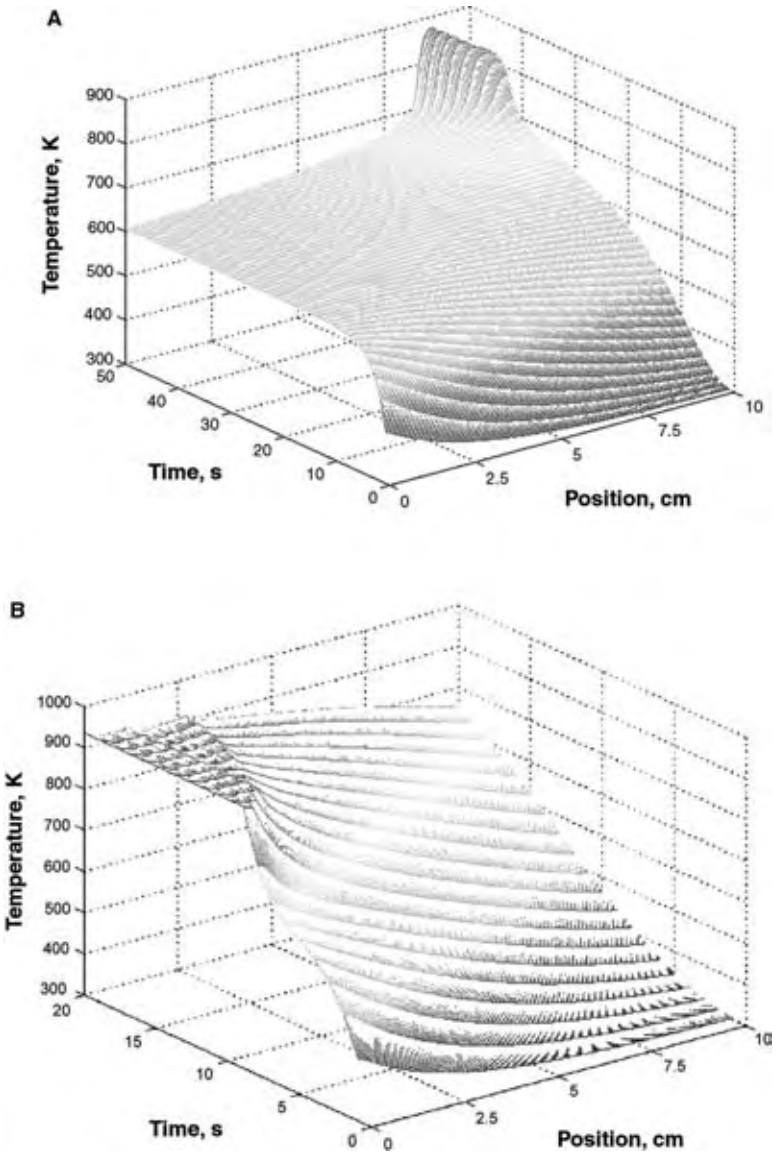

Fig. 4 Schematic illustrating downstream (A) and leading-edge (B) ignition within a catalytic converter. (Data taken from the numerical model in Ref.[23].)

Diesel Particulate Filters

Monolithic diesel particulate filters (DPF) are widely used in diesel particulate emission control. They consist of many parallel channels which are alternately plugged at either end in order to force the exhaust gases through the porous ceramic walls. The particulates are deposited on the inside wall of the inlet channel to form a thin, porous soot bed. Once a sufficient mass of particulates is collected, it is burned off to regenerate the filter. Thus, in order to achieve a successful regeneration, the DPF should operate in the thermal runaway region.

Many theoretical and experimental efforts have been devoted to study thermal runaway in the DPF during regeneration. The classic transient pseudohomogeneous model by Bissett and Shadman[24] is based on the assumption of a uniform flow distribution through the whole monolith channel. Although this assumption is only applicable in the case of high exhaust gas flow rates, this model successfully predicts the regeneration trends observed in experiments. McCabe and Sinkevitch[25] studied the ignition of soot beds by using the RVVR (reactor to visualize and video regeneration) system. They pointed out that there exists a critical value of the soot temperature beyond which thermal runaway occurs. Furthermore, Hayashi et al.[26] has shown that complete regeneration cannot be achieved without ignition, and that the efficiency of regeneration can be strongly affected by the inlet gas temperature, exhaust gas flow rate, and oxygen concentration.

Recently, Zheng and Keith[27] derived an analytical expression for the ignition time in a DPF and also showed that there exists a critical inlet exhaust gas temperature for thermal ignition to occur. Interest in

practical applications is usually in determining the critical value of the inlet gas temperature. Zheng and Keith[28] were the first to publish an explicit ignition criterion to predict the critical inlet gas temperature for the DPF. They simplified the model of Bissett and Shadman[24] by assuming a constant oxygen concentration through the soot layer. Although this assumption is violated after ignition, it is usually satisfied before ignition over most operating conditions and therefore introduces little error in the derivation of ignition criteria. With this assumption in mind, and using the Frank–Kamenetskii approximation for the combustion kinetics $\exp(-E/RT) \approx \exp(-E/RT_f)\exp(E(T - T_f)/RT_f^2)$(it is noted that this approximation is equivalent to the large γ limit) such that $\exp(-E/RT) \approx \exp(-\gamma)\exp(\theta)$, the reactor dynamics in the DPF system are described by the energy conservation equation

$$\frac{d\theta}{d\tau_d} = \frac{B_d Z e^{\theta} - \delta\theta}{1 + Le_d Z} \tag{10}$$

and the mass conservation equation

$$\frac{dZ}{d\tau_d} = -Ze^{\theta} \tag{11}$$

Since in the DPF the gas flows through a solid bed, with a non-Arrhenius reaction rate given by $k = k_o T \exp(-E/RT)$, we redefine, for the DPF, the following parameters: the characteristic reaction time $t_{r,d}$ (such that $\tau_d = t/t_{r,d}$), the characteristic time for thermal convection $t_{c,d}$ (such that the cooling parameter $\delta = t_{r,d}/t_{c,d}$), the dimensionless adiabatic temperature rise B_d, and the Lewis number, Le_d, as the ratio of the total heat capacity of the soot bed to that of the substrate wall. $Z = w/w_b$ is the dimensionless soot layer thickness, and θ is the dimensionless temperature, defined earlier.

The simplified model of the DPF presented in Eqs. (10) and (11) is similar to the classic batch reactor model. Accordingly, the ignition (''unsafe'') criterion for thermal runaway in a batch reactor can be directly used for the DPF system, such that

$$\frac{\delta}{B_d} < e \tag{12}$$

It is well known that Semenov theory is a good approximation for a highly exothermic reaction systems, i.e., $B_d \to \infty$. Zheng and Keith[28] have shown that Eq. (12) is too conservative when $B_d \ll 10$, which may occur in DPF systems. Thus, the effect of reactant consumption on ignition criterion needs to be considered.

Rice, Allen, and Campbell[2] first studied the effect of reactant consumption on thermal runaway. They defined the critical point as that which possesses a single inflection point before the maximum temperature in the temperature–time plane. Thus, a positive second-order derivative of temperature with respect to time before the maximum temperature is reached implies that the temperature increase with time is accelerated. This is necessary for thermal runaway to occur. Many other mathematical definitions of the critical point exist. The most widely used criteria was formulated in the $\theta - z$ plane by Adler and Enig:[29]

$$\frac{d^2\theta}{dZ^2} = 0, \quad \frac{d^3\theta}{dZ^3} = 0 \tag{13}$$

Zheng and Keith[28] applied this definition to derive an explicit ignition (''unsafe'') criterion accounting for the reactant consumption

$$\frac{\delta}{B_d} + f(Le_d)B_d^{-g(Le_d)} < e \tag{14}$$

where for most cases in DPF applications $f(Le_d) = 6.0$ and $g(Le_d) = 0.64$. This ignition criterion has a very good agreement with simulations of Bissett and Shadman's model in the prediction of the critical inlet gas temperature, as shown in Fig. 5. It is noted that Eq. (14) collapses into Eq. (12) in the limit as $B_d \to \infty$. Thus, the second term in Eq. (14) is due to reactant consumption.

Zheng and Keith[28] also studied the effect of the parameter Le_d on the critical value of the system temperature. They pointed that the critical temperature

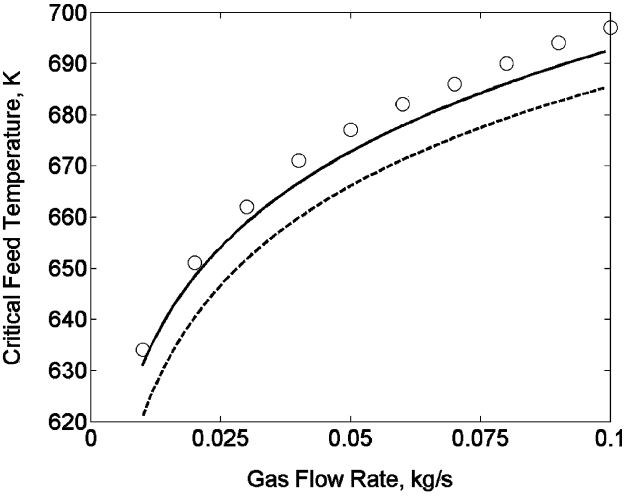

Fig. 5 The critical inlet gas temperature as a function of the gas flow rate. Simulation data, plotted as circles, the solid line is Eq. (14), and the dashed line is Eq. (12). (Data taken from the numerical model in Ref.[24].)

decreases as Le_d increases, which is reasonable since a large value of Le_d indicates a large amount of diesel particulate soot. This work also studied the influence of the various design variables and operating conditions on ignition, and concluded that a thin channel wall, a high total filtration area, a high initial loading, a low gas flow rate, and a high oxygen concentration are desirable for regeneration in the DPF. Combined with the explicit prediction of ignition time reported by Zheng and Keith,[27] the ignition criteria can be used to optimize regeneration strategies in the DPF system.

The Future of Thermal Stability Analysis

The discussion on stability analysis within DPF systems has been limited to the case of a high gas flow rate where axial thermal gradients within the DPF are negligible. This may not always be the case in practical applications. Thus, the location of the ignition within the DPF can strongly affect its overall performance. A leading-edge ignition is desired because it will lead to complete regeneration of the entire filter by convective gas flow. A downstream ignition may lead to flow channeling within the DPF, where the gas bypasses the area at the front of the filter where the particulate loading is high (as seen in Fig. 6). However, particulate may continue to accumulate at the leading edge of the DPF. Upon the next regeneration, a large heat release may crack or melt the DPF substrate and render it ineffective. The development of stability criteria that account for spatial and temporal variations in temperature within the DPF is expected to follow the work performed on automobile catalytic converters, particularly the influence of thermal dispersion. Through numerical and analytical modeling efforts, specific criteria will be formulated to ensure ''safe,'' long-term operation of the DPF.

In addition, with the growth in computational power it is easier to perform complex simulations and bifurcation analyses of multiphase reaction systems. Building upon prior experience with such techniques,[18,19] Wang et al.[30] recently measured multiplicity in multiphase bubble columns, finding four limit points in a plot of maximum temperature as a function of the Damköhler number. These results shows that three stable states exist, which they classify as cold, warm, and hot. The first two steady states are akin to the ignition–extinction behavior illustrated in the CSTR. The final steady state is due to multiplicity in the enhancement factor. Additional studies on detailed behavior such as this may help reduce byproduct formation and lead to more efficient industrial chemical processing.

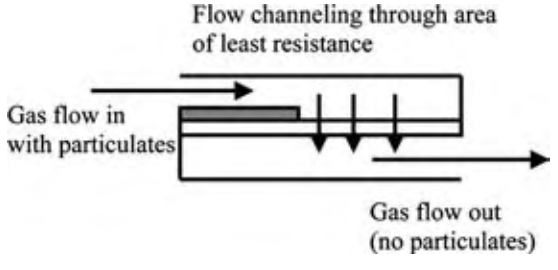

Fig. 6 Cartoon illustrating flow channeling in a DPF after ignition via the downstream mechanism. For proper performance, DPF filters should always be ignited at the leading edge.

CONCLUSIONS

Thermal stability of chemical reactors is a classic yet active area within chemical engineering science. Considerable research has focused on determining ''safe'' operating criteria for batch, CSTR, and tubular reactors. Current work has been directed towards understanding thermal stability in the presence of multiple phases (fluid/solid and gas/liquid) and multiple reactions with realistic, complex reaction rates expressions. The advent of computational methods has allowed for this field to continue to thrive. A sound understanding of these principles may help improve industrial reactor performance by reducing waste and costly separation operations and help maintain a clean environment.

ACKNOWLEDGMENT

Discussions with Professor Dan Crowl at Michigan Technological University were greatly appreciated in the preparation of this article.

t_h	Thermal dispersion time
t_m	Mass dispersion time
t_r	Reaction time
t_{rev}	Reversal time
V	Reactor volume
w	Soot layer thickness
w_b	Soot layer thickness prior to regeneration
y	Conversion
Z	Dimensionless soot layer thickness

Subscripts

c	Coolant
d	Values for DPF
f	Initial (batch) or feed (CSTR) value
ig	Ignited portion
in	Feed value
seed	Seed concentration used to ignite a RFR

Greek

α	Ratio of reaction time to cooling time
β	Ratio of residence time to cooling time
γ	Dimensionless activation energy
δ	Cooling parameter for the DPF
ϕ_s	Thiele modulus
η	Degree of monolith subcooling
Λ	Dimensionless washcoat thickness
κ	Axial thermal diffusivity
ρ	Density
θ	Dimensionless temperature
τ_b	Dimensionless time, $\tau_b = t/t_r$
τ_c	Dimensionless time, $\tau_c = t/t_c$
χ	Damköhler parameter for the catalytic converter
ξ	Dimensionless reactor length

Thermogravimetric Analysis

John O. Hill
La Trobe University, Melbourne, Victoria, Australia

INTRODUCTION

Thermogravimetric analysis (TGA or TG) is considered to be one of the five basic thermal analysis techniques. It involves the measurement of change of sample mass with change of temperature. In TGA, mass loss is observed if a thermal event involves loss of a volatile component. Chemical reactions, such as combustion, involve mass losses, whereas physical changes, such as melting, do not. The latter may be studied by differential thermal analysis (DTA) or differential scanning calorimetry (DSC), both of which measure the variation of heat flux in a sample with variation of temperature. Both physical and chemical changes in a sample can be measured simultaneously by using simultaneous thermal analysis (STA or TGA–DTA), which is a combination of TGA and DTA or, less commonly, DSC (TGA–DSC). Simultaneous thermal analysis involves measurement of both mass loss and heat flux of a sample simultaneously with variation of temperature. However, thermal analysis techniques cannot be used in general for the identification or characterization of a sample. A more detailed analysis of the thermal behavior of a sample is possible if the volatile components released from a thermal decomposition can be identified. While TGA provides mass loss data related to such volatiles, DTA gives the temperature range over which such volatiles are released; but neither data set unambiguously identifies such volatiles. This can be achieved by evolved gas analysis (EGA), which is a combination of TGA–DTA system and a gas analysis system such as an infrared spectrophotometer (TGA–DTA–FTIR), a gas chromatograph, or a mass spectrometer (TGA–DTA–MS). Recently, TGA has become refined and considerably augmented as the principal component of sample controlled thermal analysis (SCTA). In SCTA, the heating rate is varied so as to produce a constant rate of mass loss. Thus, the rate of mass loss, rather than its magnitude, controls the overall analysis process. It essentially overcomes the problems associated with linear heating rates in conventional thermal analysis techniques such as TGA, which can cause significant temperature and pressure gradients in the sample. Judicious use of heating regimes, which are modified in some way by the reaction rate, can greatly reduce these problems, giving enhanced resolution in analytical and characterization investigations.

The aim of this entry is to discuss the primary thermal analysis technique, TGA, in terms of the associated instrumentation, calibration procedures, and application range. Related techniques, such as TGA–DTA, EGA, SCTA, and modulated temperature TGA, are also discussed, as these reflect the significant developments of the TGA family of techniques that have occurred over the last decade.

THERMOGRAVIMETRIC ANALYSIS

Thermogravimetric analysis involves the measurement of change of sample mass with change of temperature using a ''thermobalance.'' A thermobalance is a combination of a suitable electronic microbalance with a furnace, a temperature programmer, and an online computer for overall experimental control and data collection and processing. The system allows for the sample to be simultaneously weighed and programmed to be heated or cooled, and the mass, time, and temperature data to be recorded and processed. The balance should be in a suitably enclosed system so that the nature and pressure of the atmosphere surrounding the sample can be controlled. The microbalance is shielded from the furnace environment and is maintained at ambient temperature throughout the analysis.

In TGA, mass loss is observed if a thermal event involves loss of a volatile component. Chemical changes in the sample, such as decomposition, combustion, and dehydration, involve mass loss (or mass gain) and may be thus studied by TGA. The data are presented as a plot of mass, m, vs. temperature, T, or time, t. The curve shape is sigmoid, indicating that most of the mass loss occurs at a particular temperature or over a narrow temperature range where the curve slope is greatest. However, the thermal event commences before the region of greatest mass loss and continues thereafter. A more convenient representation of the character of the overall thermal event is to compute the derivative of the original TGA curve as dm/dt, or rate of mass loss and to plot this vs. temperature, T, or time, t. Thereby, the DTG curve is obtained and the spread of the thermal event over a broad temperature range appears as a peak. The DTG curve is of particular assistance if two or more thermal events overlap within similar temperature ranges. Double peaks or

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007988

a shoulder on a main peak appears in such cases. Slow processes, with other fast processes superimposed, appear as gradient changes in the DTG curve. Thus, the DTG curve can kinetically characterize overlapping thermal events. Further, the DTG peak area is directly proportional to the corresponding mass loss, so relative mass losses may be compared. The peaks in a DTG curve can act as ''fingerprints'' of components in a mixture by comparison with DTG curves of the suspected individual components.

Thermal analysis systems require calibration prior to routine use. In TGA, calibration for mass is carried out by calibrating the microbalance using a set of standard weights, as for any balance system. Temperature calibration is effected by measuring the Curie point temperatures of a suite of International Confederation for Thermal Analysis and Calorimetry (ICTAC) Certified Reference Materials, which have well-defined Curie points.[1]

It is a common practice to check the performance of a TGA system by running a sample of calcium oxalate monohydrate. This salt is known to thermally decompose in three stages over well-defined temperature ranges. The first step involves the loss of a single water of hydration molecule followed sequentially by the conversion of anhydrous calcium oxalate to calcium carbonate with the loss of carbon monoxide and thence the decomposition of calcium carbonate to calcium oxide with the evolution of carbon dioxide.

The applications of TGA are extensive and diverse and include oxy-salt decompositions, natural and synthetic polymer characterization, metal oxidation and corrosion analysis, compositional analysis of coals, polymers, and rubbers, study of glass materials, foodstuffs, catalytic materials, biological materials, and a wide range of chemical processing phenomena. It has been used very successfully to study the kinetics of chemical processes;[2,3] however, there is much controversy surrounding this application, particularly in terms of relating TGA data to reaction kinetics models.

Thermogravimetric analysis has been used extensively to determine the thermal stability of materials. It provides useful information on the storage of explosives and on the shelf-life of drugs, foodstuffs, and biological materials such as tobacco and grain. By using an atmosphere of air or oxygen, the conditions under which processes such as metal oxidation, metal fatigue, spontaneous combustion of pyrotechnics, and degradation of synthetic polymers can be determined.

Thermogravimetric analysis has been widely used to study the thermal decomposition of oxy-salts, such as metal oxalates and metal sulfates. Dollimore, Griffiths and Nicholson[4] have reported TGA data for a wide range of metal oxalates. In an atmosphere of air, these all decompose in three stages, similar to the thermal decomposition of calcium oxalate monohydrate. However, the decomposition temperature ranges differ widely in accordance with the nature of the metal involved and the wide variation in thermal stability of the intermediate metal carbonates. Aluminium oxalate is anomalous in that its nonstoichiometric water of hydration is retained in the final residue, which corresponds to ''hydrated alumina.''

Other oxy-salts loose water of hydration in a stepwise sequence when heated. Copper sulfate pentahydrate loses water of hydration in three steps with the trihydrate as the intermediate.[5] Such studies are of importance for differentiating between coordinated water and water of hydration.

Because the effective operating temperature range for TGA is subambient to 1500°C and higher with special instrumental adaptations, the technique is of particular significance in materials science and in chemical processing. It has been widely used to study the oxidation characteristics of metals. Metal oxidation involves a mass gain instead of a mass loss and the process is controlled by transport across a layer of oxide formation. Metals other than gold spontaneously convert into the corresponding oxide when heated in dry oxygen, because of the metals being less thermodynamically stable than the corresponding oxide. Essentially, the oxidation process ceases long before the metal is completely converted to the oxide because of the formation of a surface oxide layer, which impedes oxygen transport through it. Thus, passivation prevails and the oxidation process is retarded. The temperature range and rate of oxide formation vary widely with the metal involved, as is the case for magnesium and niobium.[6] Such studies are of critical importance in metallurgy and more particularly in metal fatigue studies and, more generally, in studies of metal catalysts and metal surface phenomena.

A variation of TGA is thermomagnetometry (TM). A thermomagnetometry system is obtained by placing the sample in a magnetic field—achieved by using a permanent magnet as the sample chamber. The apparent mass of the sample corresponds to the sum of the actual sample mass and the applied magnetic force. The external magnetic field may be applied periodically so that TGA and TM curves can be compared. Warne and Gallagher[7] have published recent reviews of TM and its applications to minerals[8] and inorganic materials.[9] It is of particular significance in the investigation of the thermal characteristics of ferromagnetic materials. Thus, for example, TM has been applied by Gallagher[10] to examine the spinel phases formed during the decomposition of siderite. Siderite samples heated in nitrogen show the onset of decomposition at 400°C. As the wustite (FeO) formed originally is oxidized by the evolved carbon dioxide, magnetite is formed. The apparent mass gain in the TM curve is because of the progressive growth and crystallization

of the magnetite nuclei. This feature is not detectable by TGA alone and illustrates the additional advantages of TM over TGA. When the temperature exceeds the Curie point of magnetite, the TM curve coincides with the TGA curve in the absence of the applied magnetic field. In oxygen, the wustite intermediate is oxidized so rapidly to hematite that the strongly magnetic spinel phase is not formed. Such studies are of major significance in metallurgy and are of particular relevance to the quantitative characterization of ferromagnetic chemical processes.

SIMULTANEOUS THERMAL ANALYSIS

Simultaneous thermal analysis essentially involves the combination of TGA and DTA, although combination of TGA with differential scanning calorimetry (TGA–DSC) is also possible but less frequently undertaken. The pioneering simultaneous system was the ''derivatograph,'' developed by the Paulik brothers in 1955.[11] This type of instrumentation involves the mounting of a DTA head onto the thermobalance suspension or rise rod, which is connected directly to the microbalance. Modern simultaneous systems are capable of a resolution of the order of 1 μg with sample masses ranging from 5 to 100 mg. As for all thermal analysis techniques, temperature calibration is essential and is usually achieved by using the suite of ICTAC Certified Reference Materials[12] and/or the ICTAC Curie point temperature standards.[1]

There are advantages of simultaneous systems over independent TGA and DTA (or DSC). Fundamentally, it is difficult to correlate results obtained on different portions of a sample with different techniques because of ''sample'' and ''instrument'' factors, whereas, in general, results obtained on the same sample by two thermal analysis techniques simultaneously are reproducible. In general, simultaneous thermal analysis may be viewed as yielding data, which are more significant than the sum of the two sets of data obtained from the two noncoupled techniques because a synergistic effect operates. This effect is readily apparent—TGA can only detect thermal events associated with a mass change and hence a phase change such as ''melting'' is not detected by this technique but melting is readily detected as an endothermic change in DTA. Thus, simultaneous thermal analysis shows no sample mass change associated with the melting endotherm. Further, DTA (or DSC) alone is unable to differentiate between types of sample enthalpy changes such as melting and decomposition, whereas simultaneous thermal analysis is able to produce such differentiation because decomposition is associated with a mass change. Thus, simultaneous thermal analysis is able to characterize a thermal event both qualitatively and quantitatively. The synergistic effect operating in simultaneous thermal analysis is readily apparent from an examination of a material, which melts with decomposition. The overall event is readily characterized by simultaneous thermal analysis, whereas TGA and DTA alone can only partially define such a transformation. Other obvious advantages of simultaneous thermal analysis are ''time saving'' (only need to do one experiment instead of two), ''sample saving'' (only require one portion of a sample instead of two) and ''capital cost savings'' (only need one instrument instead of two). However, generally, the sensitivity of individual thermal analysis techniques is decreased on combination because of essential compromises in instrumental design. This is particularly apparent with the combination of TGA and DSC. Essentially, the major advantage of simultaneous thermal analysis is associated directly with the unambiguous correlation of two sets of thermal analysis data obtained on the same sample subjected to the same temperature regime. Peak measurements from DTA can be correlated with maximum rate of mass loss, which is determined from the corresponding TG curve, and DTA peak areas can be correlated with single process thermal events in cases where the corresponding TGA curves show that no decomposition or sublimation is taking place. These features are particularly advantageous in the high-temperature studies of complex materials.

Simultaneous thermal analysis has been widely applied to study the thermal behavior of minerals, coals, ceramics, polymers, pharmaceuticals, and superconductor materials. For example, the combustion of coal is highly sensitive to experimental conditions, and thermal analysis experiments on coal are usually associated with low reproducibility, which makes them of little value in the processing of coal and its derived products. However, STA can overcome these problems and is particularly useful for the determination of the thermal characteristics of coal samples. In general terms,drying of the sample is evident from the TGA curve and is complete at around 200°C, and the large exotherm at 500°C because of oxidation can be attributed to the ''dry weight'' of the coal sample. Comparison of the simultaneous TGA and DTA curves reveals that a substantial proportion of the oxidation occurs during a period of mass gain, a feature that would be difficult to ascertain by other means. Spontaneous ignition of coal samples can also be studied very effectively by simultaneous thermal analysis.

EVOLVED GAS ANALYSIS

Evolved gas analysis is a ''coupled'' thermal analysis technique and essentially characterizes the gases evolved during a thermal analysis investigation and hence augments the information obtained. The most common EGA techniques emerge from the coupling

of TGA and/or DTA with a gas chromatograph and/or a mass spectrometer. The coupling relies on a flowing purge gas stream through the system such that the evolved gases are swept into the coupled gas analysis system. The most comprehensive EGA system is a TGA–DTA–GC–MS system, which combines the advantages of simultaneous thermal analysis with the gas separation ability of GC and the identification ability of MS. Moreover, TGA–MS and TGA–FTIR systems are available commercially. For all EGA systems, the direct coupling of an analytical instrument to a thermal analysis system poses significant challenges and the interface has to recognize the different conditions associated with the individual instruments involved and the different time intervals required for sampling. For example, in TGA–MS, a TGA system usually operates at ambient pressure, whereas an MS operates at high vacuum. The most significant problem to overcome in this context is the possible condensation of vapors in the interface. Heating of the latter may remedy this problem but may also cause decomposition of the evolved gaseous components.

Fundamentally, EGA systems require powerful software control and data analysis systems, which, in addition to overall hardware control and displaying and analyzing output data, may also store reference libraries of MS or FTIR spectra to assist identification of the gaseous products of a thermal decomposition. However, EGA represents the most comprehensive group of thermoanalytical systems available for the characterization of the thermal behavior of materials.

Evolved gas applications are widespread and diverse. Coordination chemistry has been considerably enhanced by thermal analysis studies of a wide range of metal complexes. The emphasis of these studies has been to derive thermal decomposition mechanisms for such metal complexes. Prior to the development of EGA, such reported mechanisms were suspect because the volatile decomposition products and the solid intermediates were, in general, not identified directly but characterized indirectly on the basis of mass loss data. This procedure is flawed when multiple gaseous decomposition products and nonstoichiometric intermediates are involved. The thermal analysis of one such group of metal complexes, the metal dithiocarbamates, has been extensively studied and reviewed by Hill and Magee[13] and these are definitive studies in this field.

Evolved gas analysis, particularly in the form of TGA–DTA–MS, has obvious synthetic polymer applications. It has been applied to study the thermal behavior of homopolymers, copolymers, polymeric blends, composites, residual polymers, solvents, additives, and toxic degradation polymers. In the latter context, hydrogen chloride evolution from heated polyvinylchloride materials is readily quantified by TGA–DTA–MS and such data are of major significance in the design of fire-resistant polymeric materials. Pyrotechnic materials have also been studied by STA–MS. A complex sequence of thermal events relates to the decomposition of these materials involving interactions between the nitrocellulose, perchlorate, and metal components with periodic release of carbon dioxide and oxygen. Only by EGA is it possible to rationalize the thermal behavior of such materials. Various EGA systems have also been used to study materials of environmental significance such as contaminated soils, waste (polymeric) products, and packaging materials. Such studies are important in the context of chemical processing and recycling strategies.

An unusual application of EGA has been chosen for selected discussion. The EGA of a graphite–calcite schist has been studied by Warrington.[14] The DTA curve for this material under oxidizing conditions, together with the EGA curves for carbon dioxide evolution obtained in oxidizing and inert conditions have been interpreted. The large exothermic DTA peak reveals a superimposed endothermic peak because of calcite dissociation. Subtraction of the EGA peak recorded in nitrogen and arising from calcite dissociation from that in an oxidizing atmosphere gives the amount of carbon dioxide emerging for the graphite oxidation, which subsequently allows a quantitative estimation of the graphite content of the material. This is a very elegant and subtle application of EGA to a naturally occurring material.

SAMPLE CONTROLLED THERMAL ANALYSIS

Sample controlled thermal analysis is the generic title for a group of thermal analysis techniques in which the heating rate is varied so as to produce a constant rate of mass loss. It is a major development and refinement of TGA and is thus discussed in this review. The various forms and applications of SCTA have been comprehensively reviewed by Sorenson and Rouquerol.[15,16] It essentially overcomes the problems associated with linear heating rates in conventional thermal analysis techniques, which can cause significant temperature and pressure gradients in the sample and thus give rise to ambiguous data. Variation of the sample temperature to maintain a constant reaction rate essentially ensures that pseudo-equilibrium conditions are maintained throughout the sample over the entire temperature range scanned. A constant rate of reaction is maintained by using the measured mass loss as feedback to the furnace temperature controller. The resulting conditions for the analysis correspond to near isothermal and hence the so-called ''quasi-isothermal controlled rate thermal analysis'' results, which is more appropriately termed ''sample controlled thermal analysis.''

Several variations of SCTA have been developed by Parkes et al.,[17] in which the reaction rate for gas–solid reactions is controlled by programming the concentration of reactive gas whilst keeping the temperature constant. Also, further variants involve resolution in the temperature and time domains. Time-resolved SCTA techniques are useful in situations where it is necessary to isolate and collect gaseous products and/or the residual solids of a thermal analysis experiment for subsequent identification by other analytical techniques. Also, SCTA has been developed for the investigation of ''large'' samples of the order of 1 g—thereby characterizing SCTA as a ''preparative technique.'' A further variant within the SCTA family is ''Hi-Res'' TG^{TM}, in which the heating rate is reduced when the system crosses the upper threshold set for the reaction rate. The changes in heating and cooling rates are controlled by adjustment of the values of two numerical parameters: ''resolution'' and sample ''selfheating'' and ''sensitivity.'' As SCTA essentially eliminates sample ''selfheating'' and inhomogeneous reaction within a sample, the resolution and the sensitivity of SCTA are generally greater than those associated with the conventional TGA technique.

The essential difference between conventional TGA and SCTA is in the input to the control system. In conventional thermal analysis, a linear sample heating rate is imposed, whereas in SCTA, the heating rate is related directly to the reaction rate.

In addition, SCTA offers a unique possibility for ''preparative scale'' thermal analysis whilst maintaining high levels of sensitivity and resolution. Such an SCTA system has recently been developed.[18] The focus of the system is a microbalance and a high-temperature water-cooled furnace, located above the balance and allowing operation to 1000°C. The sample is contained in a silica or platinum crucible and sits on top of a rise rod connected directly to the balance pan. Samples in excess of 1 g can be investigated, but routinely, samples of 500 mg are usually involved. Grinding of powdered samples to mesh size 150–250 μm is advantageous. The sample temperature is monitored by a thermocouple located centrally within the furnace tube. Radiation shields attached to the thermocouple

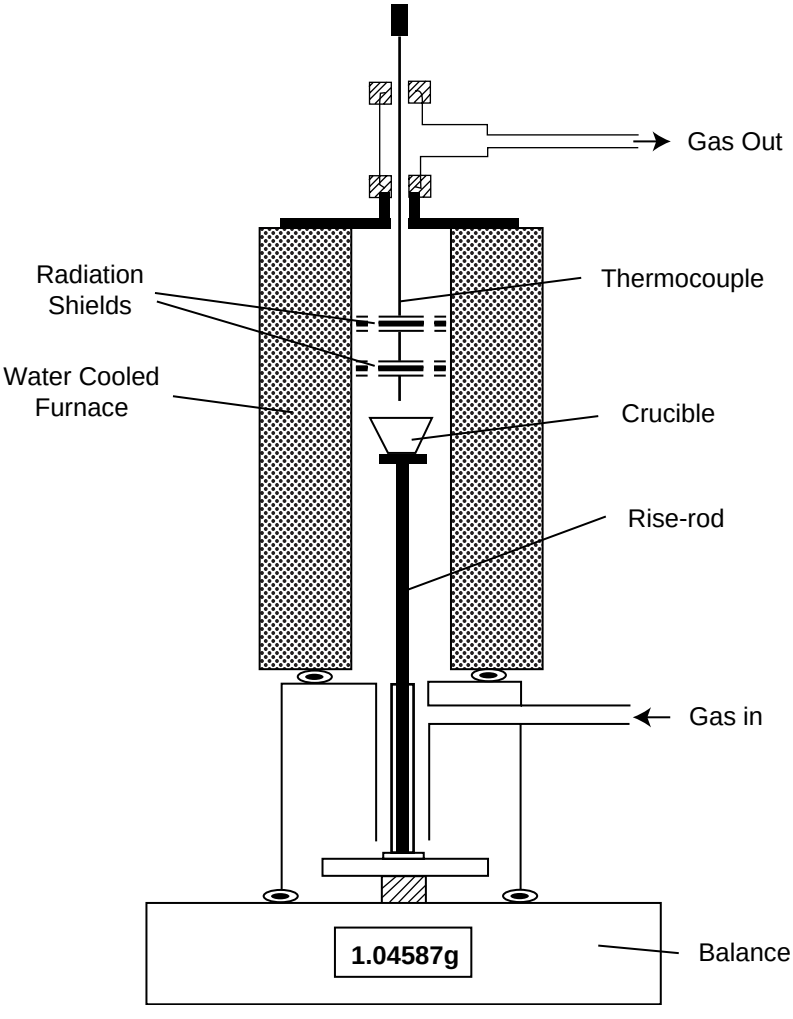

Fig. 1 Schematic diagram of an SC-TGA system.

reduce convection currents within the sample region. A gas diffusion chamber, situated between the balance and the furnace, permits experiments to be carried out in an upward flow of gas at a constant flow rate via continuously pumping the system. Although the overall system is not sealed, this net gas flow prevents air entering the system and results from the differential flow rates at the inlet and at the outlet, as measured by individual flow meters. Volatile decomposition products can be trapped using a combination of filters and activated charcoal and liquid nitrogen traps. A schematic diagram of this SCTA system is shown in Fig. 1 and a block diagram of the associated data acquisition and control systems is shown in Fig. 2.

The temperature of the furnace is continuously varied by a temperature controller, and the outputs from the balance and from the sample temperature thermocouple are logged by a computer fitted with a 16-bit dynamic range data acquisition board. The signals are processed via a program derived using a combination of Virtual Basic and C++ and the derivative of the TGA curve is used to control the heating program via the temperature controller.

Several SCTA modes are available with this system, including linear heating TGA and proportional heating TGA. In addition, the control software has a ''stop mass'' facility, by which ''products'' can be produced at any preselected degree of reaction, thereby conforming to the ''preparative'' aspect of the system. Modifications to the control system give rise to ''time-resolved SCTA,'' incorporating peak slope heating and dynamic rate modes. This ''in-house'' construction is thus a very versatile SCTA system, which incorporates the principal advantages of the ''sample controlled'' methodology.

Applications of SCTA take advantage of the enhanced uniform reaction environment provided by this technique, as compared with conventional thermal analysis techniques. A major problem with conventional thermal analysis techniques is that the imposed linear sample heating rates can cause temperature and pressure gradients within the sample. Thus, sample ''selfheating'' results, and this poses an experimental difficulty for rapid, highly exothermic decompositions. Essentially, in conventional TGA, it is impossible to unambiguously define the ''sample temperature'' throughout the analysis. In SCTA, ''selfheating'' of the sample is eliminated because it is the sample decomposition rate that determines the rate of heating and not the external heating program. Thus, with SCTA, thermal events associated with a material can be studied under controlled conditions and this feature characterizes SCTA as an enhanced thermal analysis technique, particularly suited to the study of microthermal events, reversible thermal events, and the kinetics of a wide variety of chemical and biochemical phenomena.

The Centre for Thermal Studies and the Centre for Applied Catalysis at the University of Huddersfield,

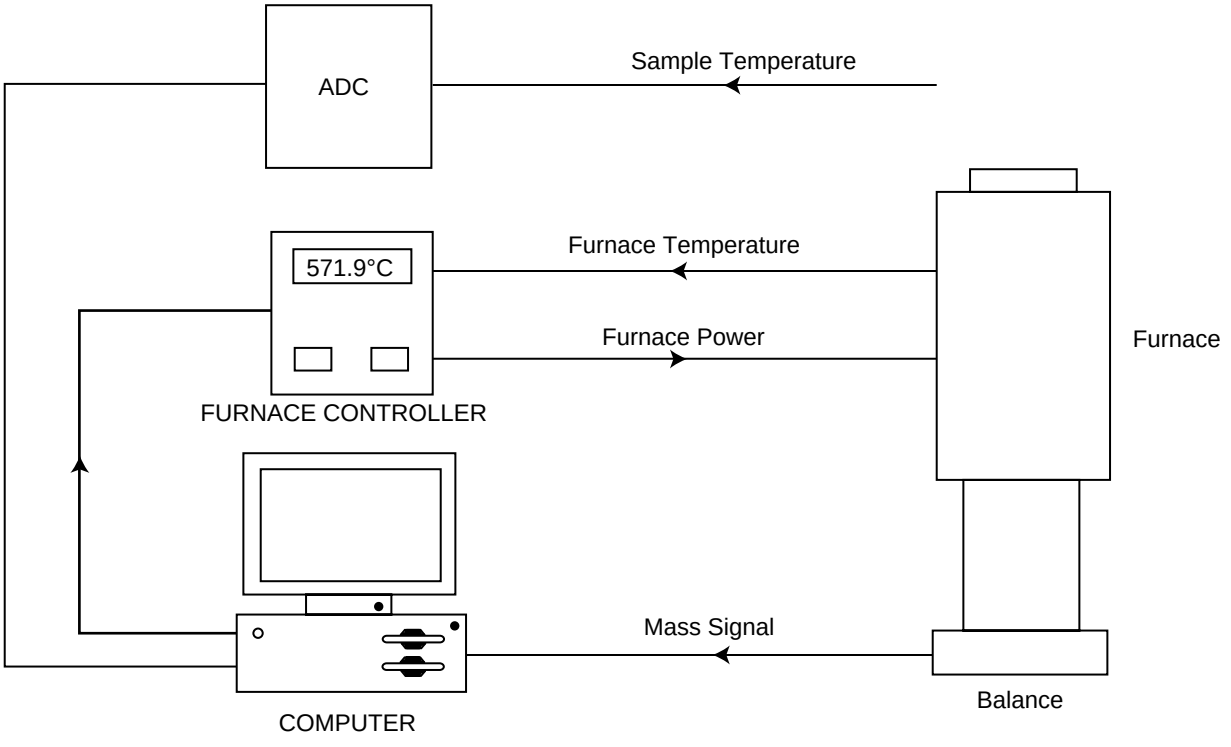

Fig. 2 SC-TGA control system.

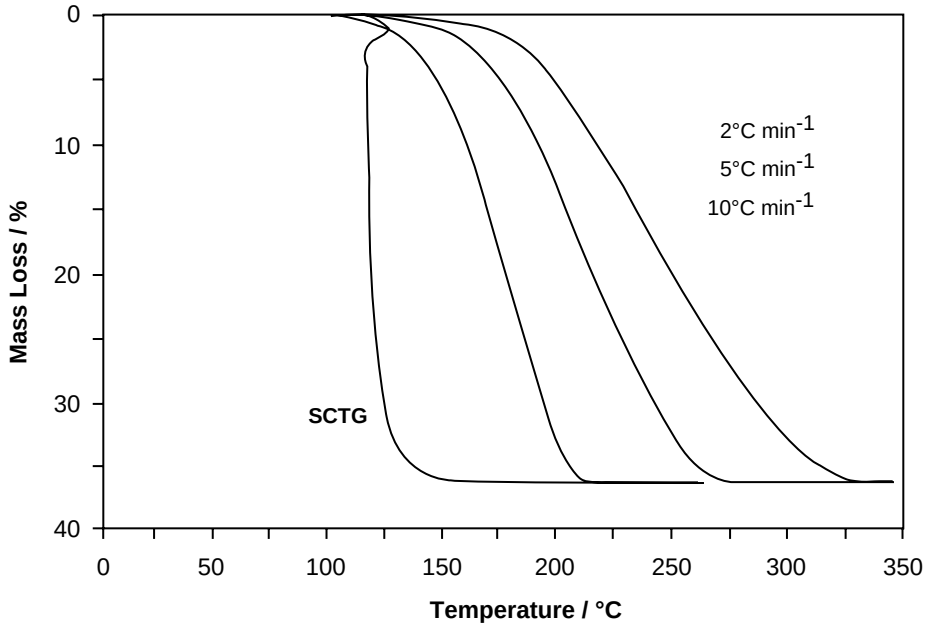

Fig. 3 SC-TGA and TGA curves of sodium bicarbonate.

U.K., have been pioneers in developing the ''preparative scale'' SCTA system described above and investigating its potential to study the thermal behavior of a wide range of materials. The principal advantage of SCTA over conventional TA techniques is that with the former, thermal events can be studied under controlled conditions. A simple example of ''controlled decomposition'' is the thermal decomposition of sodium bicarbonate, and SCTGA and TGA curves for this process are shown in Fig. 3.

The most striking feature of the (proportional heating) SCTGA curve is controlled decomposition over a narrow temperature range. The corresponding TGA curves show a reduction of the decomposition temperature range with decreasing heating rate, but the SCTGA decomposition temperature range corresponds to zero heating rate of the sample and hence, via SCTGA, the most realistic thermal decomposition temperature ranges are obtained. This feature is of particular significance for samples that violently decompose or ignite, such as pyrotechnics and coals in an oxidizing atmosphere. The primary advantage of the sample controlled approach in thermal analysis in reducing both the temperature and the gas concentration gradients in a sample is illustrated by the oxidation of a Drayton (Australia) coal sample (Fig. 4).

Even at a 500 mg sample mass level, a controlled oxidation is apparent and spontaneous ignition is

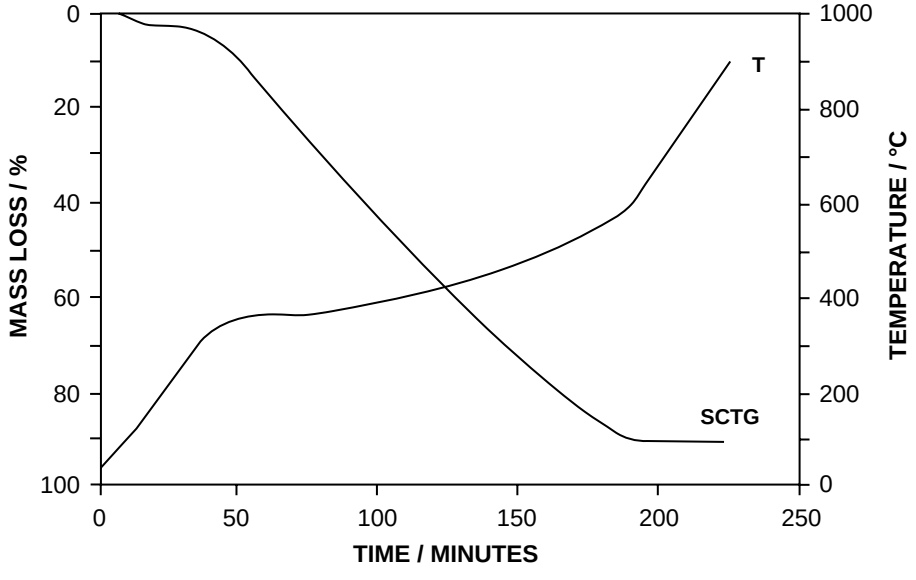

Fig. 4 SC-TGA curve for the oxidation of Drayton coal.

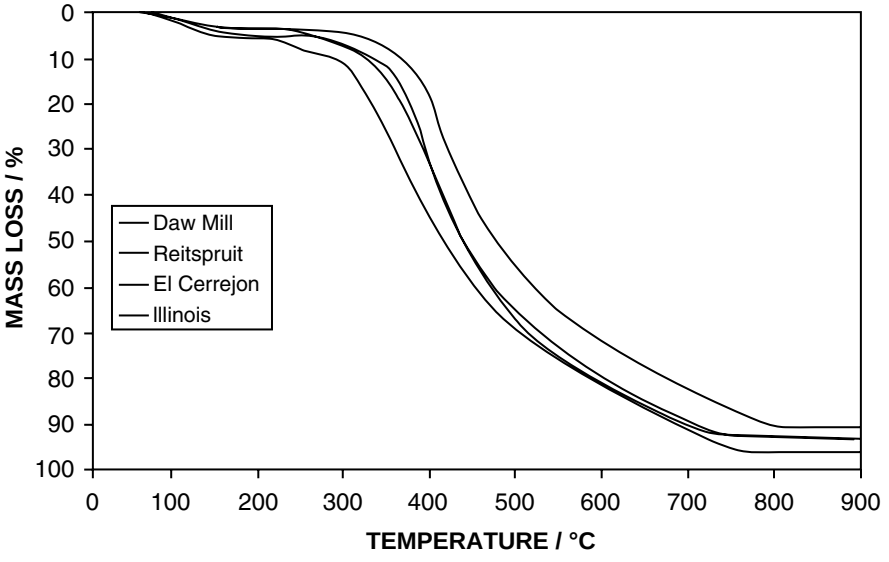

Fig. 5 SC-TGA curves for the oxidation of different coals.

avoided during the analysis. In conventional TGA using the same conditions, selfheating of the sample leads to ignition and hence a loss of meaningful data after ignition, coupled with ''apparent'' decomposition temperature ranges. Similarly, the controlled oxidation of four different coals is shown in Fig. 5.

Although the SCTGA profiles are similar in character and reveal controlled oxidation, the subtle differences in oxidation behavior of these coals are clearly revealed. Such differences are not readily deciphered from TGA curves because the dominating feature is ignition, which effectively masks the intermediate thermal events.

Coal pyrolysis can also be studied by SCTGA conducted in a nitrogen atmosphere. The proportional SCTGA curve for the pyrolysis of a sample of Illinois (U.S.A.) coal is shown in Fig. 6.

Initial pyrolysis occurs over a relatively narrow temperature range and the slow nature of the later stages of pyrolysis is indicated by the temperature program returning to maximum heating rate. The ''stop-mass'' facility of the SCTGA system provides ''preparative opportunities'' and in the context of coal pyrolysis, chars can be produced at any stage of the pyrolysis process, which can subsequently be characterized by other analytical techniques. Further, the oxidation of such chars can be monitored by SCTGA as shown in Fig. 7 for a Drayton coal char. Prior to the development of SCTGA, coal char thermal analysis was beset with controversy because of the indecisive nature of the derived data.

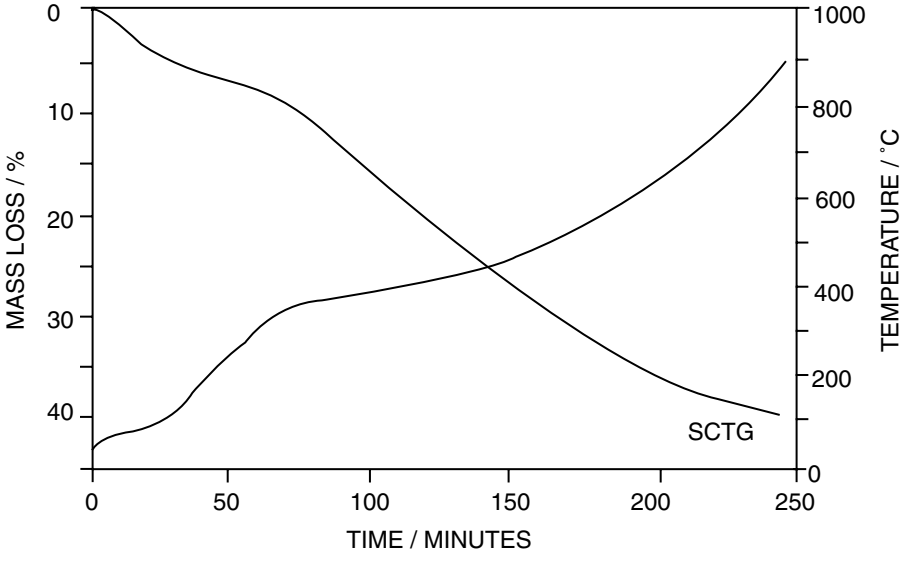

Fig. 6 SC-TGA curve for the pyrolysis of Illinois coal.

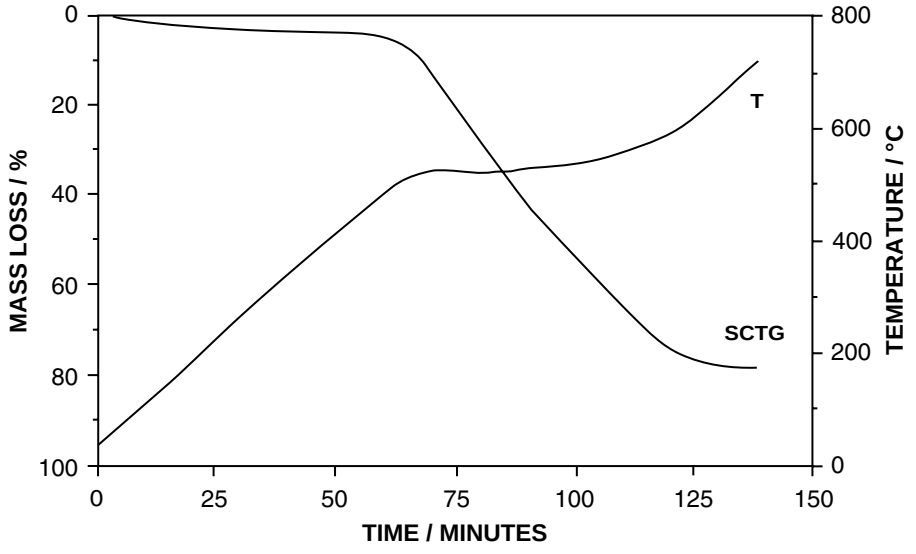

Fig. 7 SC-TGA curve for the oxidation of a Drayton coal char.

The high reactivity of finely divided zirconium powder toward aerial oxidation makes conventional TA studies difficult to perform under controlled conditions. Fig. 8 shows an SCTGA curve for a 10 mg sample of zirconium powder, which, in a TGA–DTA experiment under similar conditions but using a linear heating rate, shows ignition at about 410°C. However, it is apparent that under proportional heating SCTGA conditions, a smooth oxidation reaction process results, which is 50% complete below 400°C. These types of studies are most suitable for pyrotechnic mixtures, because reliable ignition data are generated.

The possibility of performing sample controlled thermomagnetometry is illustrated by an SCTM experiment on ICTAC nickel, with a permanent magnet placed above the thermobalance furnace (Fig. 9).

During the heating program, the sample oscillates between the magnetized and demagnetized states. If a zero cooling rate is applied, this transition can be made to take place over a narrow temperature range, thereby characterizing the magnetic property of the metal.

The scope of temperature- and time-resolved SCTGA has been revealed by Parkes, Barnes and Charsley,[17] via studies of the decomposition of inorganic salts. Temperature-resolved SCTA is particularly useful for resolving the dehydration characteristics of copper sulfate pentahydrate. A typical linear heating (LH) TGA profile for this salt is shown in Fig. 10, and is compared with a proportional heating (PH) SCTGA profile over the same temperature range.

The typical 2 : 2 : 1 water loss is shown in both profiles but the resolution of these peaks is superior

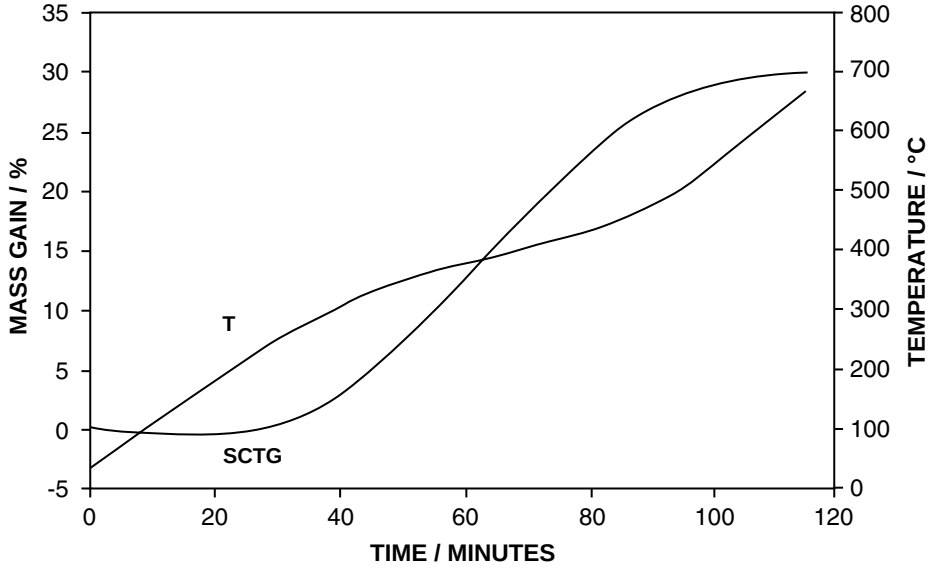

Fig. 8 SC-TGA curve for the oxidation of zirconium metal powder.

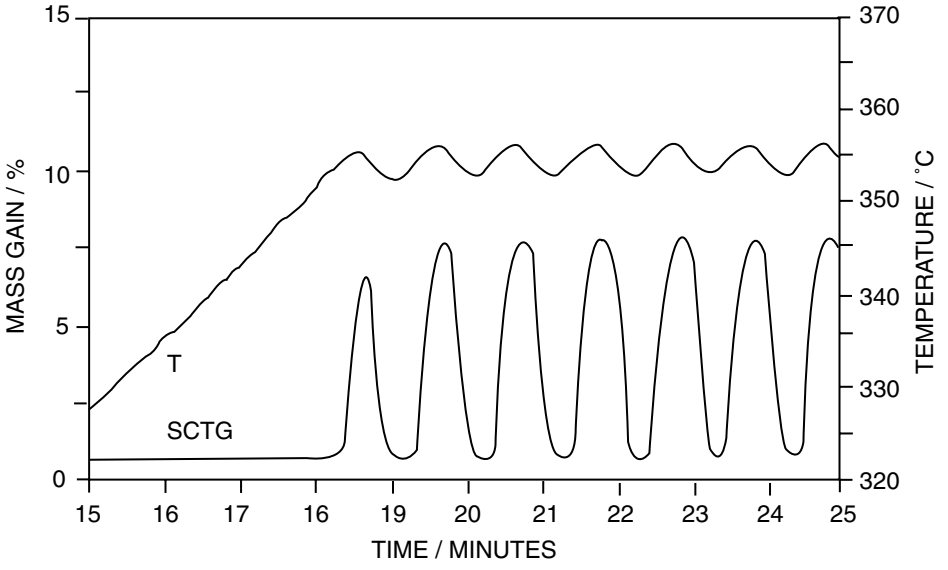

Fig. 9 SC-TM curve for "ICTAC Nickel."

in the SCTGA profile. Further, the latter shows how the heating rate is reduced over each dehydration peak and increased between the peaks, which is the defining feature of temperature-resolved SCTA. Further, temperature-resolved SCTA can be used in mechanistic studies of complex reactions. The decomposition of ammonium hydrogen carbonate is associated with the coevolution of ammonia, water, and carbon dioxide.

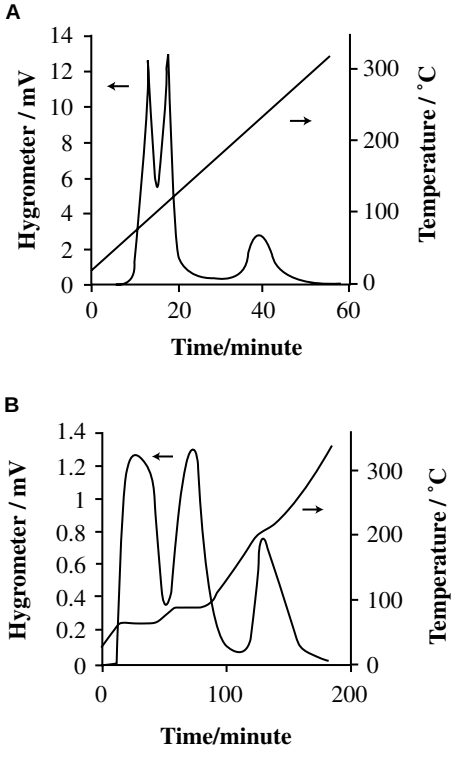

Fig. 10 LH (A) and PH (B) curves for the dehydration of copper sulfate pentahydrate.

Proportional heating SCTA in conjunction with mass spectrometry was applied to study this decomposition process, and linear heating and proportional heating TA curves are shown in Fig. 11.

A single decomposition peak, centered at 125°C, is apparent from the linear heating profile, whereas the proportional heating profile shows the presence of a nucleation stage prior to decomposition, thereby providing mechanistic indications of the decomposition mode.

An application of the time-resolved SCTA technique is shown in Fig. 12, relating to linear heating (LH) and peak slope heating (PSH) of a 1 : 2 mixture of copper hydroxycarbonate and zinc hydroxycarbonate.

Decomposition of this mixture yields both carbon dioxide and water, and the latter was monitored using a hygrometer. The principal feature of time-resolved SCTA is shown by the PSH profile. It is apparent that the switch to zero heating rate on the falling edge of each peak is rapid, whereas the increase in heating rate as the first decomposition approaches completion is slower. Also, the switching point between heating and nonheating is at the same relative point on each peak despite their difference in size. The enhanced resolution of the decomposition peaks without distortion of shape is apparent from the PSH profile and this feature is indicative of the ability of PSH to time-resolved gaseous decomposition products for "online" evolved gas analysis.

It should however be noted that although both proportional heating SCTA and peak-resolved SCTA provide enhanced resolution in the temperature and time domains, respectively, both of these modes are typically associated with increased experimental times compared with those of conventional TA experiments. This feature at present eliminates SCTA as an analytical technique for the rapid characterization of

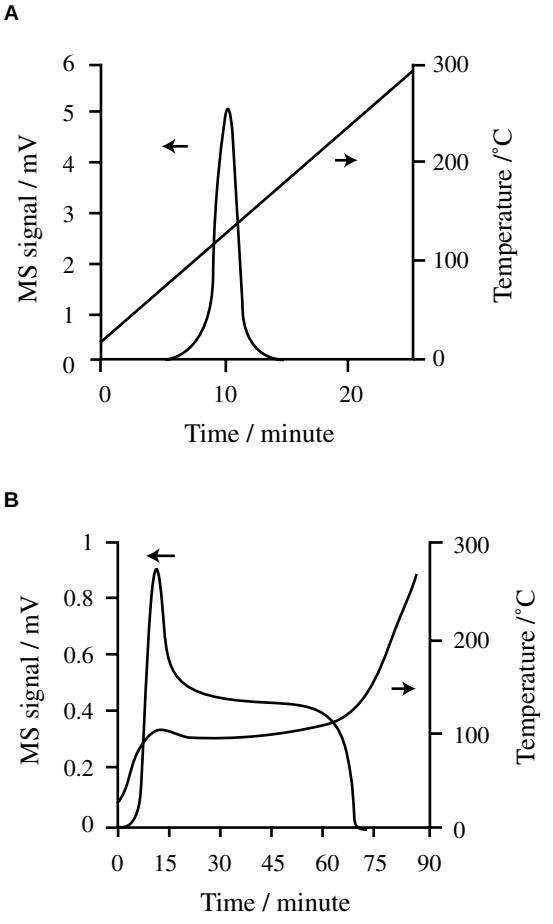

Fig. 11 LH (A) and PH (B) curves of ammonium hydrogen carbonate.

materials and in quality control applications. However, these techniques offer many other advantages, most notably in providing mechanistic and kinetic information on the thermal decomposition behavior of materials.

TA Instruments (U.S.A.) have recently produced a commercial SCTA system—known as ''hi-res'' TG or ''dynamic rate'' TG.[19] The basic principle of this system is that there is a marked decrease in heating rate when the system crosses a preset upper reaction rate threshold. The changes in heating and cooling rates are controlled by adjusting the values of two numerical parameters, referred to as ''resolution'' and ''sensitivity.'' Dynamic rate TG varies the heating rate smoothly and continuously in response to the rate of sample decomposition so that the resolution of the associated mass change is maximized. This mode allows rapid heating in regions where no thermal transitions occur and proportionally slow heating during thermal events. An illustrative example of the advantages of ''dynamic rate'' TG application is a study of a sodium/potassium bicarbonate mixture. It is apparent from the dynamic rate TG curve that enhanced resolution of the decomposition peaks is achieved in a time-frame of less than 10% of the conventional TA experiment.

MODULATED TEMPERATURE THERMOGRAVIMETRIC ANALYSIS

Modulated temperature thermogravimetry (MT-TGA or MT-TG) is a new TA methodology, which has particular application to the study of reaction kinetics.[20] Thermogravimetric analysis has been applied routinely to derive kinetic parameters for a wide range of reactions and this large and complex field has been comprehensively reviewed by Galwey[2] and Reading.[3] In MT-TGA, a sinusoidal temperature modulation is superimposed on the conventional linear heating rate. This modulated temperature stimulus results in an oscillatory response in the rate of mass loss, deconvolution of which via a real time discrete Fourier transformation produces the desired kinetic parameters. A typical MT-TGA profile of polytetrafluoroethylene (PTFE) is shown in Fig. 13.[20]

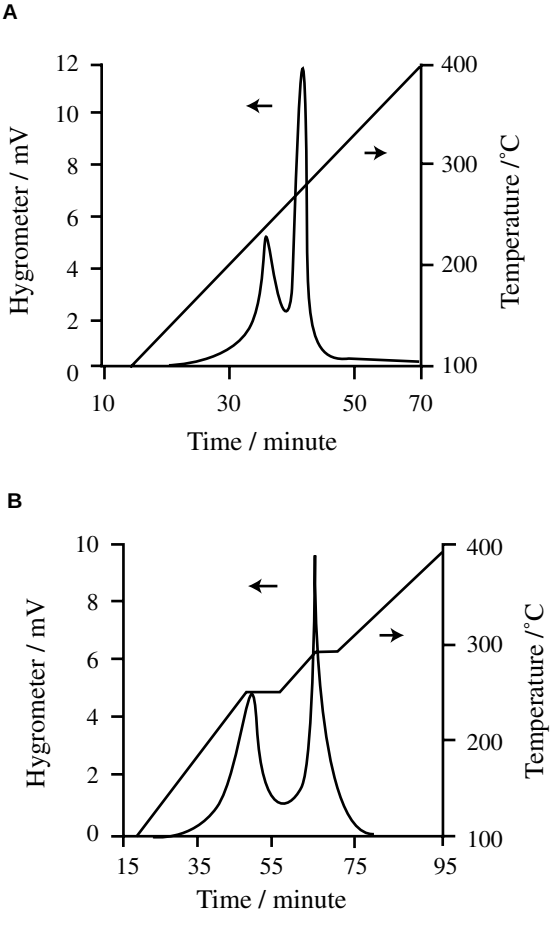

Fig. 12 LH (A) and PSH (B) curves of a 1:2 mixture of copper and zinc hydroxycarbonates.

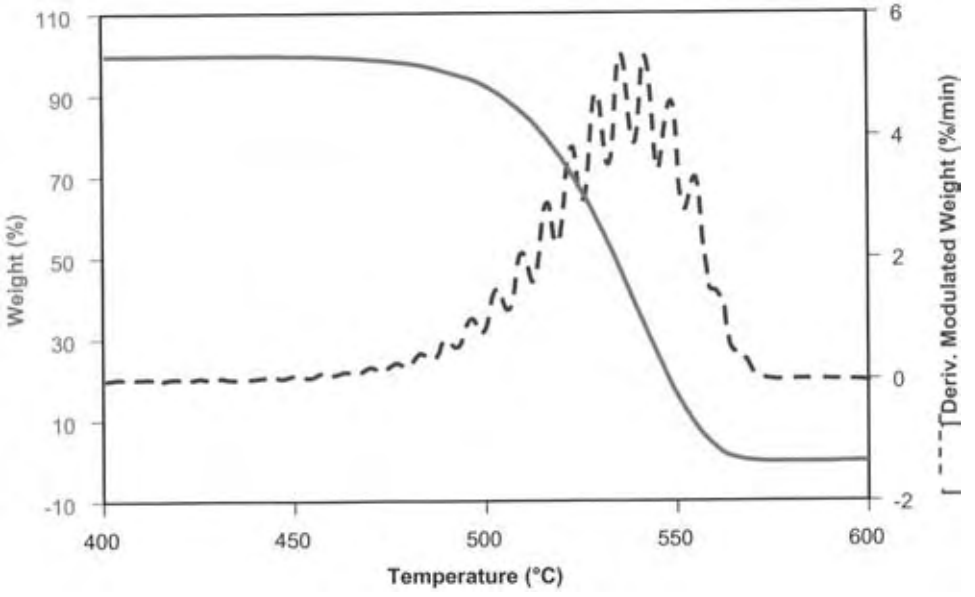

Fig. 13 TGA and MT-TGA curves of PTFE. *(View this art in color at www.dekker.com.)*

Derivation of kinetic parameters by conventional TGA is exceedingly difficult when multistep decomposition reactions are involved. Because the resolution of MT-TGA is much greater than that of conventional TGA, greater resolution of individual thermal events is achieved with the former, thereby simplifying the subsequent kinetic analysis of the overall decomposition process.

CONCLUSIONS

Conventional thermogravimetric analysis has considerably diversified over the last decade. Thermogravimetric analysis has successfully been combined with differential thermal analysis (DTA) to give simultaneous thermal analysis. The principal advantage of TGA–DTA is that both TGA and DTA are obtained simultaneously under identical experimental conditions for a single sample of material. This allows a direct comparison of the TGA and DTA curves and for greater characterization of thermal events at defined temperatures or over defined temperature ranges. The coupling of TGA with another analytical technique, such as mass spectrometry, has produced EGA. The principal advantage of EGA is that volatiles evolved from a thermal analysis of a sample are analyzed ''online'' by a directly coupled mass spectrometer. Thus, EGA further enhances the analytical potential of conventional TGA. The principal disadvantage of conventional TGA, ''selfheating'' of the sample, is overcome with sample controlled thermal analysis. In SCTA, the sample is heated slowly through thermal events and rapidly between them. Such a differential heating program leads to increased sensitivity and resolution in TGA but also to a much increased time-frame for the analysis. Dynamic rate TG appears to have addressed both of these features and hence has much potential as a ''high resolution/rapid'' thermal analysis system, which, unlike SCTA, can be applied for rapid and reproducible thermal analysis of a wide range of complex materials. Finally, modulated temperature thermogravimetric analysis has enhanced potential for the kinetic analysis of thermal decomposition reactions over conventional TGA because of its greater resolution of thermal events.

Thermomechanical Analysis

Kevin P. Menard
PerkinElmer Thermal Laboratory, University of North Texas Materials Science Department, Denton, Texas, U.S.A.

INTRODUCTION

Thermomechanical analysis (TMA) is the technique of measuring the dimensional changes in a specimen as a function of time or temperature. It can be argued that rheology and traditional mechanical tests should be included in this classification. In its purest form, the changes in a material's dimensions under minimal load are recorded and used as an indicator of the changes in the material's free volume. These data allow the calculation of a material's expansivity or coefficient of thermal expansion (CTE) as well as detection of transitions in the material. Thermomechanical analysis on inorganic glass was the first measurement of glass transition and still remains the best technique for that measurement in many applications. It is often said to be more sensitive to glass transition than differential scanning calorimetry (DSC) by an order of magnitude.

Pressure volume temperature (PVT) instruments are designed to probe more deeply into a material's free volume. They can be considered a subset of TMA and are treated here as such. Capable of applying literally tons of force and of reaching high temperatures, they are used to collect information of how pressure and temperature affect the volume of a material and how the transitions in a material shift as a function of pressure.

THEORY AND OPERATION OF TMA

The basis of TMA is the change in the dimensions of a sample as a function of temperature. A simple way of looking at TMA is as a very sensitive micrometer. It is believed to have developed from hardness or penetration tests and was used on polymers in 1948.[1] Subsequently, it has developed into a powerful tool in the analytical laboratory. Thermomechanical analysis measurements record changes caused by alterations in the free volume of a polymer.[2] While the latter tends to be preferred by engineers and rheologists, in contrast to chemists and polymer physicists who lean towards the former, both descriptions are equivalent in explaining behavior. Changes in free volume, v^f, can be monitored as a volumetric change in the polymer: by the absorption or release of heat associated with that change; loss of stiffness; increased flow; or by the change in relaxation time. The free volume of a polymer, v^f, is known to be related to viscoelasticity,[3] aging,[4] penetration by solvents,[5] and impact properties.[6] Defined as the space a molecule has for internal movement, it is schematically shown in Fig. 1.

The T_g in a polymer corresponds to the expansion of the free volume allowing greater chain mobility above this transition (Fig. 2). Seen as an inflection or bend in the thermal expansion curve, this change in TMA can be seen to cover a range of temperatures, of which the T_g temperature is an indicator calculated by an agreed upon method (Fig. 3). This fact seems to be forgotten by inexperienced users, who often worry why perfect agreement is not seen in the value of the T_g when comparing different methods. The width of the T_g can be as important as an indicator of changes in the material as the actual temperature.

Experimentally, TMA consists of an analytical train that allows precise measurement of position and can be calibrated against known standards. A temperature control system of a furnace, heat sink, and temperature-measuring device (most commonly a thermocouple) surrounds the samples. Fixtures to hold the sample during the run are normally made out of quartz because of its low CTE, although ceramics and invar steels may also be used. Fixtures are commercially available for expansion, three-point bending or flexure, parallel plate, and penetration tests (Fig. 4).

APPLICATIONS OF TMA

Applications of TMA are in many ways the simplest of the thermal techniques. Only the change in the size or position of a sample is being measured. However, they are also incredibly important in supplying information needed to design and process everything from chips to food products to engines. A sample of ASTM methods for TMA is shown in Table 1. Because of the sensitivity of modern TMA, it is often used to measure T_g's that are difficult to obtain by DSC, for example, those of highly cross-linked thermosets.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120028330

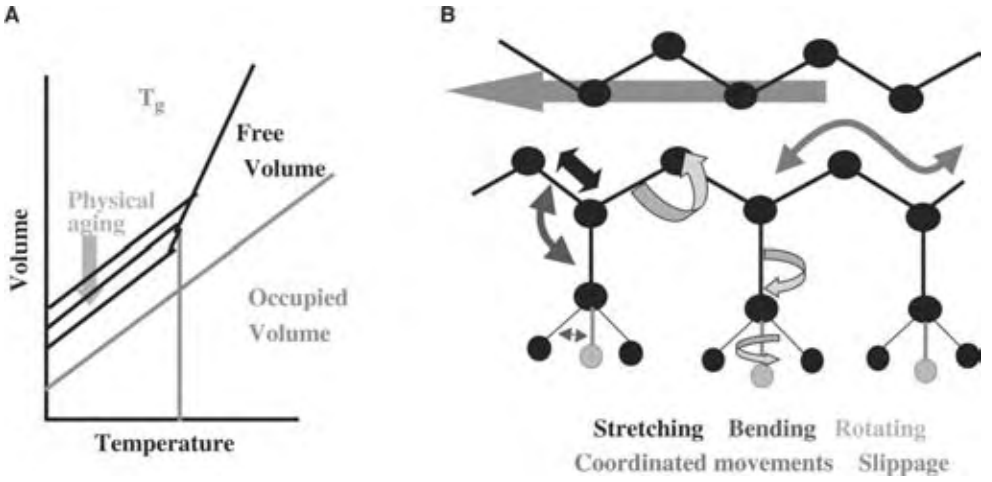

Fig. 1 Free volume, v^f, in polymers: (A) the relationship of free volume to transitions, and (B) a schematic example of free volume and the crankshaft model. Below the T_g in (A) various paths with different free volumes exist depending on heat history and processing of the polymer, where the path with the least free volume is the most relaxed. (B) shows the various motions of a polymer chain. Unless enough free volume exists, the motions cannot occur. (From Menard K.; *Dynamic Mechanical Analysis: A Practical Introduction*, CRC Press: Boca Raton, 1999).

Expansion and CTE

Thermomechanical analysis allows the calculation of thermal expansivity[a] from the same data set as used to calculate the T_g. Since many materials are used in contact with a dissimilar material in the final product, knowing the rate and amount of thermal expansion helps design around mismatches that can cause failure in the final product. These data are only available when the T_g is collected by thermal expansion, not by the flexure or penetration method. This is in many ways the simplest or most essential form of TMA measurement. A sample is prepared with parallel top and bottom surfaces and is allowed to expand under minimal load (normally 5 mN or less, ideally 0 mN) as it is slowly heated and/or cooled. The CTE is calculated by:

$$\alpha_1 = 1/l_0(\delta l/\delta T)F$$

where α_l is the linear coefficient of thermal expansion, l_0 is the original length, δl is the change in length and δT the change in temperature. F indicates that this is done under constant force. Once this value is obtained, it can be used to compare other materials used in the same produce. Large differences in the CTE can lead to motors binding, solder joints failing, composites splitting on bond lines, or internal stress build up. The T_g is obtained from the same data by measuring the inflection point in changes of the baseline slope. As a material's CTE changes dramatically at T_g, one would expect this to be an easily detected transition. It can be; however, for highly cross-linked materials, the T_g can be so broad and the change in CTE so slight as to be undetectable. Other approaches, such as flexure testing, are then used. Different T_g values are shown for each mode of testing[7] (Fig. 5) and the methods used to measure the Tg by TMA.

If the material is heterogeneous or anisotropic, it will have different thermal expansions depending on the direction in which they have been measured. For example, a composite of graphite fibers and epoxy will show three distinct thermal expansions corresponding to the x, y, and z directions. Blends of liquid crystals and polyesters show a significant enough difference between directions for the orientation of the crystals to be determined by TMA.[8] Similarly, oriented fibers and films have a different thermal expansivity in the direction of orientation to that in the unoriented direction. This is normally addressed by recording the CTE in the x, y and z directions (Fig. 6A). Bulk measurements or volumetric expansion can be made by dilatometry as shown in Fig. 6B and this is discussed in detail below.

Expansion studies can also be run on samples immersed in solvents to measure the swelling of a polymer. This test is commonly used with rubbers to measure the cross-link density of the rubber.[9] As cross-linking increases, the amount of swelling will decrease. Special fixtures are commercially available

[a]Thermal expansivity is often referred to as the coefficient of thermal expansion or CTE by polymer scientists and in the older literature. The terms are used interchangeably in this paper.

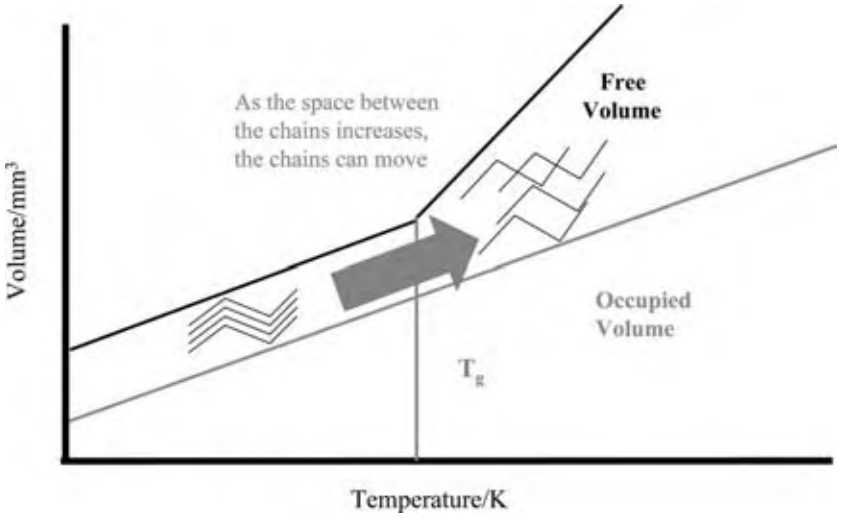

Fig. 2 The increase in free volume is caused by increased energy absorbed in the chains and this increased free volume permits the various types of chain movement to occur.

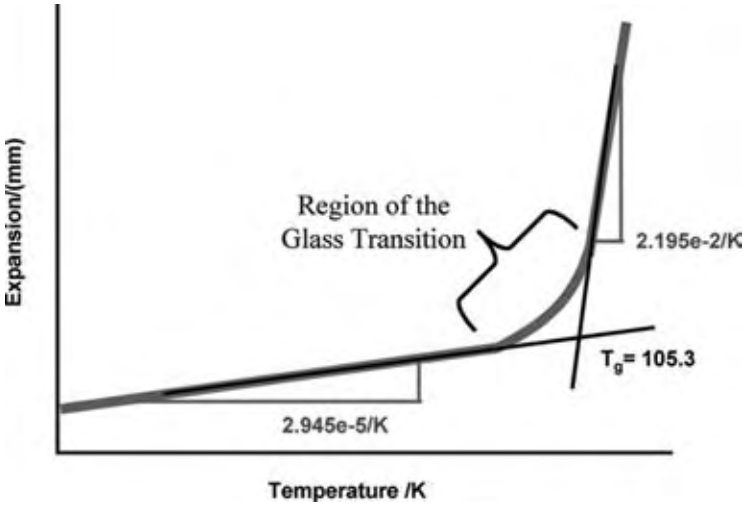

Fig. 3 The Tg is a region, shown here, between the points where the tangents depart from the curve. The Tg, by convention, is taken as the intersection of those two tangents.

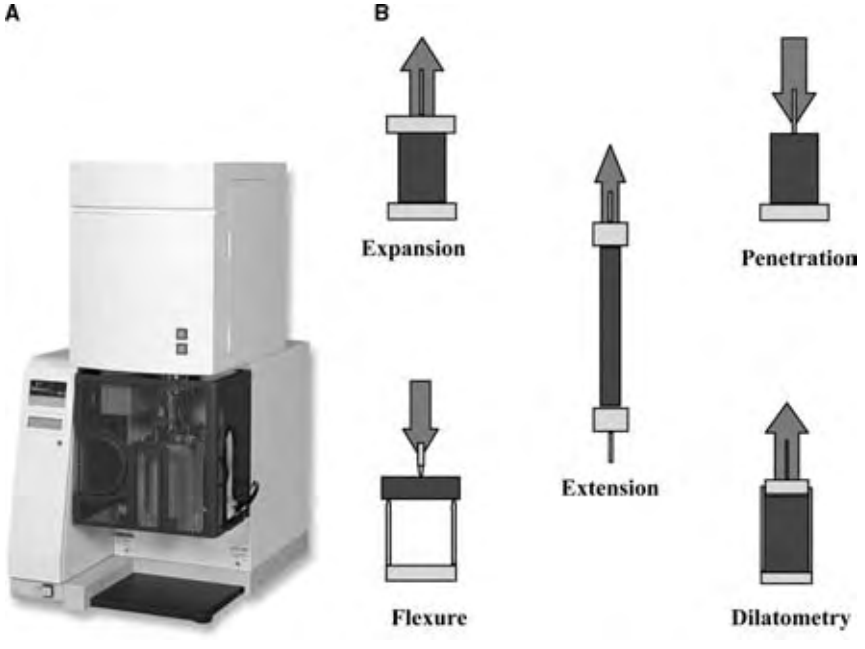

Fig. 4 A PerkinElmer TMA 7 is shown in (A) as a schematic. (Courtesy of Perkin-Elmer Instruments, Norwalk, CT.) Various test geometries are shown in (B). Normally these are made of quartz glass to take advantage of its low CTE values.

for this, or standard fixtures may be used in a lined furnace. A sample is immersed in oil and the degree of swelling measured. Fig. 7A shows the results from a rubber swelling study.

Flexure and Penetration

Thermomechanical analysis methods are used in geometries more commonly associated with traditional mechanical testing to increase sensitivity or to mimic other tests. The most common of these are the flexural and penetration modes. Flexure studies involve loading a thin beam, often a splinter of material, with a constant load of 100 mN or more and heating until the sample deflects. This is similar to a heat distortion test and is often used for QC as it gives clear, easily detected transitions.

Thin coatings are often better handled by penetration tests, when a small glass probe is used to penetrate the sample. This technique involves moderate force and allows the measurement of the transitions of material as thin as 10 microns. Baseline subtraction is often used to remove any effects from the substrate's thermal expansion during the test. As mentioned above, these methods often give different values for T_g, and O'Neill et al.[7] carried out an extensive study on how the method of testing affected the Tg. They reported that the expansion method gives the lowest value for T_g by TMA, and that the flexure method tends to give a T_g that is 5°C higher. By the penetration method, the T^g tends to be 10°C higher than the expansion method.

Dilatometry and Bulk Measurements

Another approach to anisotropic materials is to measure the bulk expansion of material using dilatometry (Fig. 6). The technique was used extensively to study initial rates of reaction for bulk styrene polymerization in the 1940s,[10] an experiment which the author has used in his thermal analysis class on TMA. By immersing the sample in a fluid (normally silicon oil) or

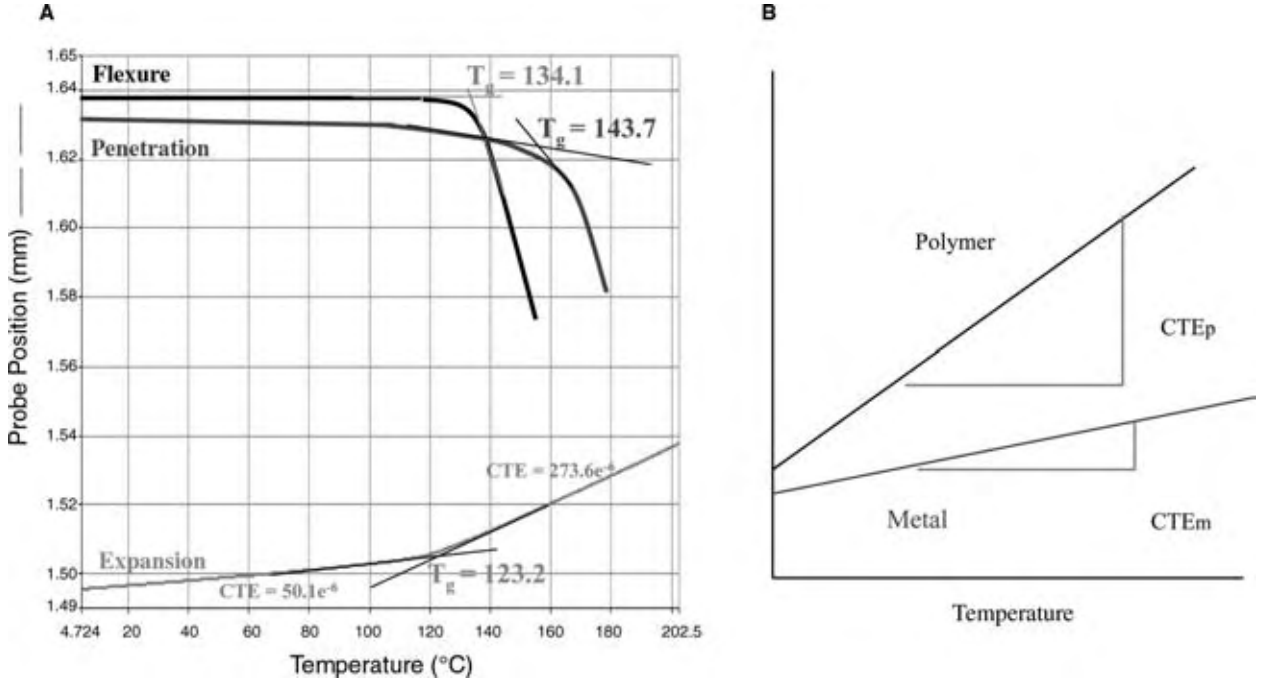

Fig. 5 Different methods of measuring the Tg in the TMA give different values as shown in (A) the overlay of the penetration, flexure and expansion runs above. In (B) we see the comparison of a polymer to a metal CTE run.

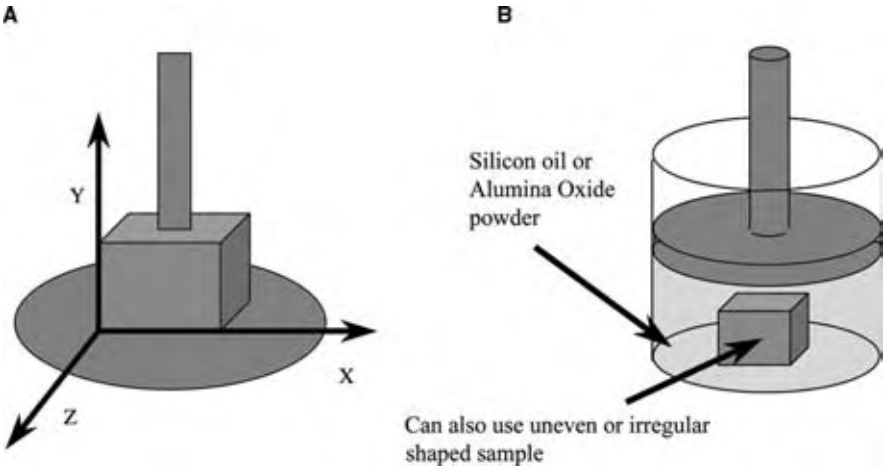

Fig. 6 Heterogeneous samples require the CTE to be determined in the x, y and z planes (A) or in bulk to obtain a volumetric expansion in the dilatometer (B). *(View this art in color at www.dekker.com.)*

powder (normally Al_2O_3) in the dilatometer, the expansions in all directions are converted to a vertical movement, which is measured by TMA. This technique has enjoyed a renaissance in the last few years because modern TMAs make it easier to perform than previously. It has been particularly useful for studying the contraction of a thermoset during its cure.[11,12] The technique itself is rather simple: a sample is immersed in either a fluid, such as silicone oil, or buried in alumina oxide in the dilatometry and run through the temperature cycle. If a pure liquid or a monomer is used, the dilatometer is filled with that liquid rather than the silicon oil or alumina oxide. A CTE can be determined and Speyer[13] reports that, as well as discussing the technique in detail.

PVT Relationship Studies

The temperature of a polymer's melting, glass transition, crystallization, and its solid–state annealing are all known to have pressure dependencies.[14] High-pressure instruments, such as the Gnomix Inc. (Colarado, U.S.A.), have been developed to study PVT relationships in polymers. In these experiments, the sample is placed in an incompressible fluid and then the desired pressure is applied. Full details of this technique, as well as a collection of P–V–T relationships for a wide range of polymers up to 200 MPa (~30,000 psi) and 400°C, have recently been published.[15] These data have mainly been collected isothermally to report the effects of pressure and temperature on the volume of

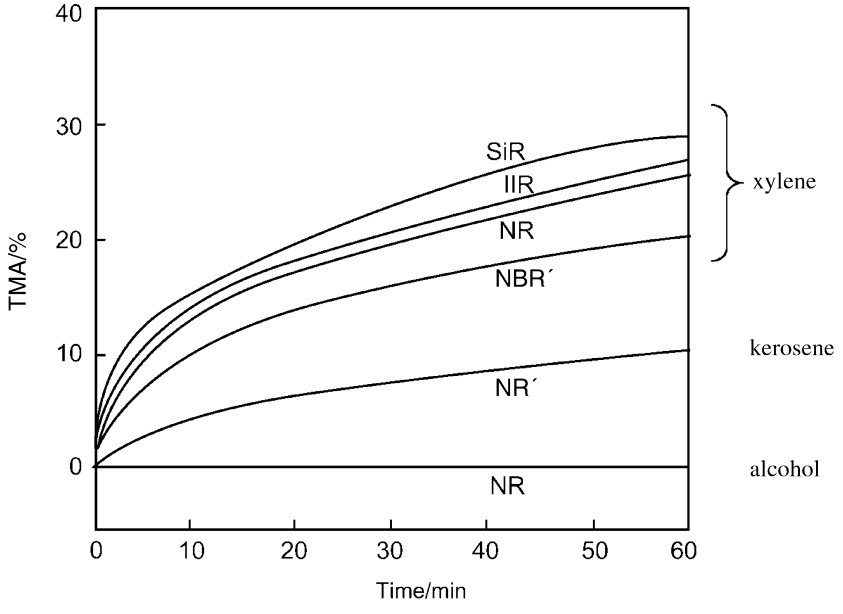

Fig. 7 Swelling of rubber samples in organic solvents measured in the Diamond TMA. NR, natural rubber; NBR, nitrile butyl rubber; SiR, silicon rubber; IIR, isobutyl rubber. (Courtesy of the PerkinElmer Instruments, Norwalk, CT.)

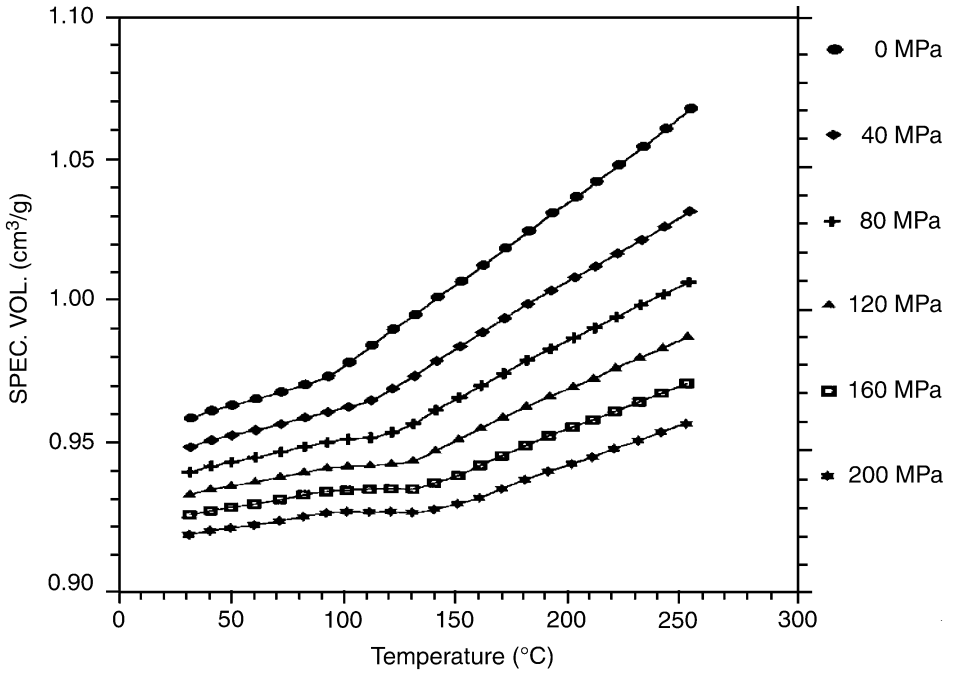

Fig. 8 The effect of pressure of the T_g of a polystyrene (M ~ 1.1ev, D ~ 1.06). (From *Zoller's Standard Pressure–Volume–Temperature Data for Polymers*, used with the permission of the Technomics Publishing Company, Inc.)

the polymer and to monitor the respective changes in melt and glass transitions. For example, data on polymer liquid crystals have been obtained as a function of the concentration of the liquid crystal (rigid) constituent in a series of copolymers.[16]

The measurement of the volume of the polymer above and below the glass transition under high pressure is an attempt to determine the occupied volume of the polymer. As the pressure is increased, the glass transition, which occurs in the free volume, becomes generally greater and broader (Fig. 8) as the material changes between two different types of glass before the T_g is reached. This pressure sensitivity can be useful in determining the processing condition. While the Gnomix can apply pressures that greatly exceed any high pressure differential scanning

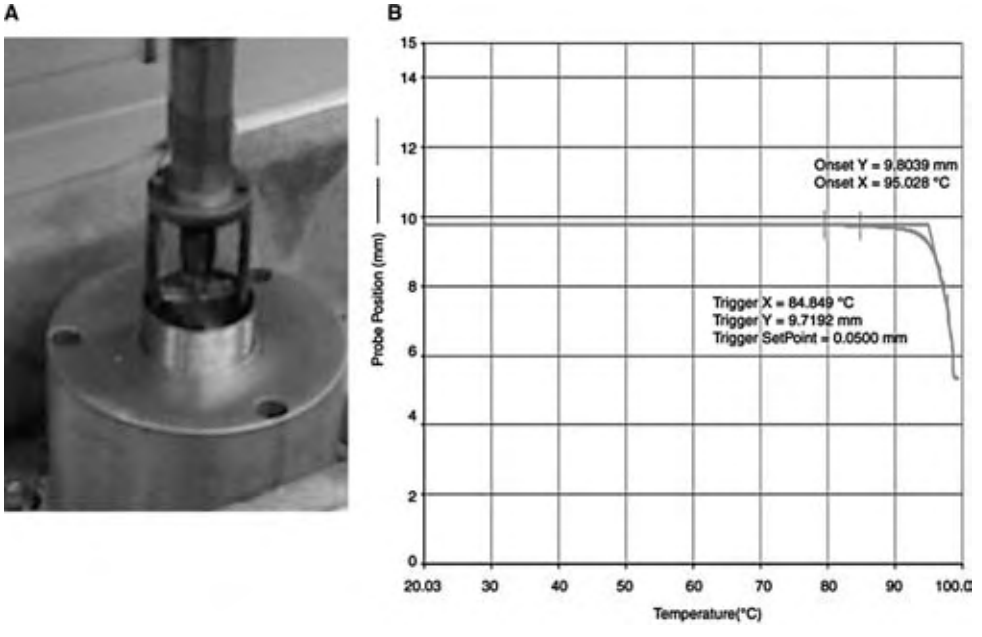

Fig. 9 Heat Distortation Tests, which look for sample flexure while the sample is immersed in oil, can be run in the TMA. (A) shows a TMA 7 with a furnace liner. (B) shows the results of the HDT runs.

calorimeter (HP DSC), the experimental times are long and DSC may be more useful for studies up to ~6.8 MPa (~1000 psi). The agreement between these techniques is quite good[16] and hence HP DSC, within its limits, is a suitable alternative in a number of cases to a P–V–T instrument.

Mechanical Tests

A wide variety of tests is performed in TMA, which are adapted from physical tests that were used before the instrument became commonly available.[17] These tests may also be modeled or mimicked in TMA, such as heat distortion (Fig. 9) and softening points.[17] Methods to obtain the modulus,[17] compressive viscosity,[18] and penetrative viscosity[19] have been developed. Many of these methods, such as ASTM D648 for example, will specify the stress the sample needs to be exposed to during the run. In D684, a sample is tested at 66 and 264 psi. Most TMAs on the market today have software available that allows them to generate stress—strain curves and to run creep—recovery experiments.[b] Some are also capable of limited types of stress relaxation studies (for example a constant gauge length test[20]).

CONCLUSIONS

While TMA is one of the older and simpler forms of thermal analysis, its importance is in no way diminished by its age. Advances in DSC technology and the appearance of dynamic mechanical analysis (DMA) as a common analytical tool have decreased the use of it for measuring glass transitions, but nothing else allows the measurement of CTE as readily as TMA. In addition, the ability to run standardized material test methods at elevated temperatures easily makes TMA a reasonable alternative to larger mechanical testers. As the electronic, biomedical, and aerospace industries continue to push the operating limits of polymers and their composites, this information will become even more important. During the last 5 years a major renewed interest in dilatometry and volumetric expansion has been seen. Other thermomechanical techniques will also likely be developed or modernized as new problems arise.

[b]See, for example, the product literature for Perkin Elmer's Diamond TMA and PYRIS™ software. The TMA and the DMA can both be used for running simple mechanical tests like stress-strain curves, creep-recovery, heat set and stress relaxation. Other vendors have similar packages.

ACKNOWLEDGMENTS

The authors wish to acknowledge the PerkinElmer Thermal Business Unit and the Material Science Department of the University of North Texas for their support and assistance. In addition, the help and advice of Professor Witold Brostow of the Materials Science Department of UNT, and especially my graduate students, John White and Dr Bryan Bilyeu, is greatly appreciated.

INTRODUCTION

One of the most significant developments in materials technology was the discovery of polymers. Over the last century, they have played an increasing role in a wide range of industries. ''Cheap plastic'' polymers have evolved into ''high technology composites'' for a myriad of structural applications. Polymers can be broadly classified into two major groups: thermoplastics and thermosets. Thermoplastics soften reversibly, can be easily deformed (or high damage tolerance), and made to flow when heated. They then harden to retain their shape on cooling from the liquid to the solid state, and may be reprocessed by reheating. Being able to reprocess the polymer is a significant economic advantage for thermoplastics. However, in use, thermoplastic polymers are susceptible to creep and deformation.

In contrast, thermosets harden irreversibly during processing. They form permanent crosslinks, i.e., covalent bonds between polymer chains that can only be broken by degrading the material. Heat, light, electricity, or catalysts to name a few can initiate such crosslinking reactions. Regardless of how crosslinking is initiated, the formation of permanent crosslinks makes it impossible to reprocess the material. This means that any mistake during processing generates waste. However, the advantages of thermosets in applications requiring complex shapes, high stability, structural integrity, or very high strength justify the care needed to avoid excessive waste.

The combination of processability and performance has driven significant growth in thermoset applications where dimensional stability and accuracy are critical. For example, thermosets (usually UV or e-beam cured) are the materials of choice as the ''medium'' for rapid prototyping. Similarly, the combination of processability, dimensional stability, and strength have driven the use of thermosets for automotive components, structural members in aircraft, and braking systems in both automotive and aircraft applications.

OVERVIEW OF THERMOSET TECHNOLOGY

Since the introduction of the first commercial thermoset, Bakelite, based on phenol formaldehyde condensation, a wide range of thermoset materials have been introduced. These are typically designed for specific properties related to their chemistry and processability. Some commercially important thermosets include phenolics, ureas, melamines, epoxy resins, unsaturated polyesters, silicones, rubbers, polyurethanes, acrylics, cyanates, polyimides, and benzocyclobutenes.[1]

Thermosets are particularly effective in the manufacture of large components. They and their composites are formed from precursors such as reactive monomers or low molecular weight oligomers. Because of their low molecular weight, these precursors flow easily, and can fill large molds without requiring large injection pressures. Once the mold is filled, the precursor crosslinks to form a solid product. While the part may shrink during cure, proper design allows for this shrinkage.

Typically, thermoplastics, because of their high melt viscosity, require higher temperatures and injection molding pressures, or expensive mold fabrication costs to design multiple gate systems and therefore are not cost effective materials for large parts. In addition to cost, the use of multiple gates may also lead to a less structurally sound part as a result of knit lines.

Thermosets have also found wide applicability where there is a need for high strength, low density, good heat resistance, and electrical performance. These properties can be enhanced by the addition of fillers, such as fibers, minerals, and glass, to form a composite structure. Alternatively, interpenetrating networks (IPN) can be formed to take advantage of the beneficial properties of two network polymers simultaneously. Typical fiber-reinforced thermosetting composites uses are automotive body panels, under-the-hood automotive applications, household goods, breaker switch boxes in the electrical industry, etc.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007991

Manufacturing, Processing, and Design

The first step in manufacturing is usually a process to wet the fillers and disperse them in the resin. This is followed by preparation of a preform which can be then cured or prepregs which can be laminated together. For example, thermoset tapes can be laminated with the direction of filler orientation varying between layers to distribute the strength of the reinforcement uniformly. The resins in these prepregs can be semi-solid (i.e., wet lay up) or solid (dry lay-up). In either case, the application of heat enhances resin flow, binding the layers together. Ultimately the entire layer structure becomes a single fused mass on complete cure.

The typical manufacturing processes for thermoset composites are summarized in Table 1 They may be divided into three broad categories: (1) manual; (2) semiautomatic; and (3) automatic.[2,3] Manual processes include hand lay-up, spray-up, pressure bagging, and autoclave molding. Semiautomatic processes include cold pressing, hot pressing, and compression molding of SMC (sheet molding compound) and BMC (bulk molding compound), and resin injection. Automatic processes are those such as pultrusion, filament winding, centrifugal casting, resin transfer molding, injection molding, reaction injection molding, and short cycle compression molding.

Fig. 1 is a schematic diagram of various composite-manufacturing processes following the design methodology process map given in Fig. 2. The description of some of these processes is summarized in Table 1. Karger-Kocsis[4] provided a very good overview of the manufacturing methods for thermoplastic composites, illustrating the inter-relationship between matrix, reinforcement, and preform/prepreg (Fig. 3). Their work can also apply to thermoset composites. Furthermore, Karger-Kocsis' scheme can be further extended to design the process and the final products with a simple combinatory approach as outlined in Table 2. For example, the combination route in line 1 of Table 2 corresponds to the use of chopped or continuous fiber (A1 in Fig. 3) combined with polymer (D1 in Fig. 3), processed to formulate the desired intermediate, and then processed to make the final part. Thus, a variety of combinations and approaches achieve the same nominal result. It is incumbent on the scientist and engineer to optimize for properties and cost.

The most significant aspect of a well-designed fiber-reinforced composite is that its end use performance may be predicted from the properties of each constituent.[5] In recent years, Quality by Design and Design for Six Sigma have advocated a set of predictive methodologies and protocols that ensure the delivered goods meet the market demands.[6–11] Elastic constants can be predicted for continuous reinforced composites using the Rule of Mixtures; discontinuous or chopped fiber-reinforced composites can also be modeled very well. Predictive relationships between constituents making up the composite and the resultant mechanical properties are well known. These methods are, therefore, invaluable additions to the Quality by Design and Design for Six Sigma efforts.

With advances in computer technology in recent years, simulation has often provided a very powerful tool to predict the end-use performance from the selected component properties and to establish structure-performance relations with a certain degree of confidence. This approach has been termed ''in silico'' design as opposed to in vitro or in vivo.[12–14] In silico experimentation – the ability to explore simulations rapidly reduces the need for in vivo experimentation: slow, multiple iterations of trial and error for design of new composite structures. The combination of design tools and computer modeling will drive development of new thermosets, with improved performance. This includes new structures based on known materials and the development of new chemistries for selected applications.

Optimization of the cure cycle is inextricably linked to the design of processes for specific applications. Typically, this involves a clear understanding of the influence of temperature and time used to cure the thermosets. This is key to predicting resin flow and the degree of cure.[15–19] Consequently, much attention has been placed on the curing process/morphology/structure relationship of thermosets.[20–22]

Resins and Fillers

Fig. 2 illustrates the selection process that may be used to design a composite material with specific, targeted performance characteristics. Thermosets have been the backbone of the advanced composites industry since it has gained commercial acceptance in the early 1960s. We can segment composites (Fig. 4), into two major classes: (1) high volume composites, i.e., commodity products and (2) high performance composites.[4] The type of matrix, composition, and fiber/filler interphase determines the performance of a composite. The concentration, type, and orientation of the fiber reinforcement affect the strength and stiffness. Random mat or chopped fibers are frequently used in high volume composites at maximum fiber loading (>30% by volume). Continuous oriented fibers are required for high performance composites. In both cases, performance depends strongly on the structure and performance of the component parts.

Table 3 summarizes the key properties of selected major types of thermosetting resins.[1,23–25] Their cross-linking reactions can occur by radical chain addition

Table 1 Typical molding processes in thermoset composites

Molding process	Description
Prepreg molding	Prepreg molding is in many respects the next step up from hand lay up. With prepreg molding the resin content of the finished component can be accurately controlled, which cannot always be said for hand lay up. Also, woven or unidirectional fiber reinforcements are used, rather than chopped strand mat. The reason is that they be aligned in the required orientation.
Compression molding	Compression molding is the most common method of forming thermosetting materials. It is simply the squeezing of a thermosetting preform into a desired shape by application of heat and pressure to the material in a mold at a desired duration time. Molding preform mixed with fillers and chopped fibers to strengthen the finished product, is put directly into the open mold cavity. The mold is then closed, pressing down on the preform and causing it to flow throughout the mold. It is while the heated mold is closed that the thermosetting material undergoes a chemical change which permanently hardens it into the shape of the mold.
Transfer molding	Transfer molding is most generally used for thermosets. This method is like compression molding in that the preform is cured into an infusible state in a mold under heat and pressure. It differs from compression molding in that the thermosetting preform is heated to a point of plasticity before it reaches the mold and is forced into a closed mold by means of a hydraulically operated plunger. The molten molding material in transfer molding flows around these metal parts without causing them to shift position. Transfer molding was developed to facilitate the molding of intricate products with small deep holes or numerous metal inserts.
Vacuum-assisted molding	In conventional SMC processes, charge loading and press closure speeds are selected with the primary aim of forcing out entrapped air. With vacuum assistance, the charge is selected to rapidly cover the mold surface and provide faster closure speeds without entrapping air. The increase in mold surface coverage by the charge has several additional benefits such as elimination of wave patterns and flow lines, better localized strength of components due to better retention of fiber orientation.
Injection molding	Injection molding is a major process in making thermoplastic materials. With proper modifications, the injection process is sometimes used for thermosetting plastics. In injection molding, material is put into a hopper which feeds into a heating chamber. A plunger pushes the material through this long heating chamber, where the material is softened to a fluid state. At the end of this chamber there is a nozzle which abuts firmly against an opening into a cool, closed mold. The fluid material is forced at high pressure through this nozzle into the cold mold. As soon as the material cools (in thermoplastics) or heated (in thermosets) to a solid state, the mold opens and the finished part is ejected from the press.
Resin transfer molding	In the resin transfer molding (RTM) process, a low viscosity resin is transferred into a closed mold containing all the appropriate reinforcements and inserts as a preform. The air is normally evacuated from the mold, allowing the use of low resin injection pressures and epoxy molds. Manhole covers, compressor casings, car doors, and propeller blades have all been manufactured by RTM.
Reaction injection molding	Reaction injection molding (RIM) is a relatively new processing technique that has rapidly taken its place alongside more traditional methods. Unlike liquid casting, the two liquid components, polyols and isocyanates, are mixed in a chamber at relatively low temperatures (75°–140°F) before being injected into a closed mold. An exothermic reaction occurs, and consequently RIM requires far less energy usage than any other injection molding system. The three major types of polyurethane RIM systems are rigid structural foam, low-modulus elastomers and high-modulus elastomers. Reinforced RIM (R-RIM) consists of the addition of such materials as chopped or milled glass fiber to the polyurethane to enhance stiffness and to increase modulus, thus expanding the range of applications.

(Continued)

Table 1 Typical molding processes in thermoset composites *(Continued)*

Molding process	Description
Pultrusion	In the pultrusion process, dry reinforcements are impregnated with a specially prepared low viscosity liquid resin system and drawn through a die heated to about 120–150°C where curing occurs. The solid laminate, which has assumed the shape of the die, is withdrawn by a series of haul off grippers, and is cut to length or coiled. Pultrusion is unique among the processes under consideration in that it is capable of producing complex components on a continuous basis. The process can basically produce any shape that can be extruded. It is also not allied to any one industry and applications range from civil engineering to electrical. These factors combine to give pultrusion one of the highest predicted growth rates of all composite processes.
Filament winding	Filament winding is a process of high speed precise laying down of resin impregnated continuous fibers on to a mandrel. The mandrel can be any shape. Pressure vessels, pipes, and drive shafts have all been manufactured using filament winding. Multi-axis winding machines can also be used. The process is usually computer controlled and the reinforcement can be oriented to match the design loads. The fibers may be impregnated with resin before winding (wet winding), pre-impregnated (dry winding), or post impregnated. Wet winding has the advantages of using the lowest cost materials with long storage life and low viscosity. The prepreg systems produce parts with more consistent resin content and can often be wound faster.

(unsaturated polyester resins, vinyl ester resins, benzocyclobutene, etc.), ionic ring opening (epoxies), condensation (urethanes, phenolics, polyimides, such as bismaleimides), and cyclotrimerization (cyanates, isocyanurates, etc.).

Table 4 compares the mechanical properties of various organic fibers, graphite/carbon fibers, ceramic fibers, and glass fibers, and lists commercially important applications. One major application of organic fibers, such as Spectra® and aramid fibers, is in ballistic armor.[26,27] In contrast, graphite, ceramic fibers, and glass fibers are primarily used in structural applications. One of the reasons that organic fibers find little structure applications is because of their poor compressive strength. (see Table 4 in Ref.[28].)

CHARACTERIZATION

The final morphology of a network system depends greatly on the flow properties and phase separation of the reactive components as seen in Fig. 5.[16–18,29] Naturally, design of appropriate processes requires the ability to directly investigate the progress of reaction. This includes monitoring the chemistry of cure with spectroscopic techniques such as FTIR, NMR,

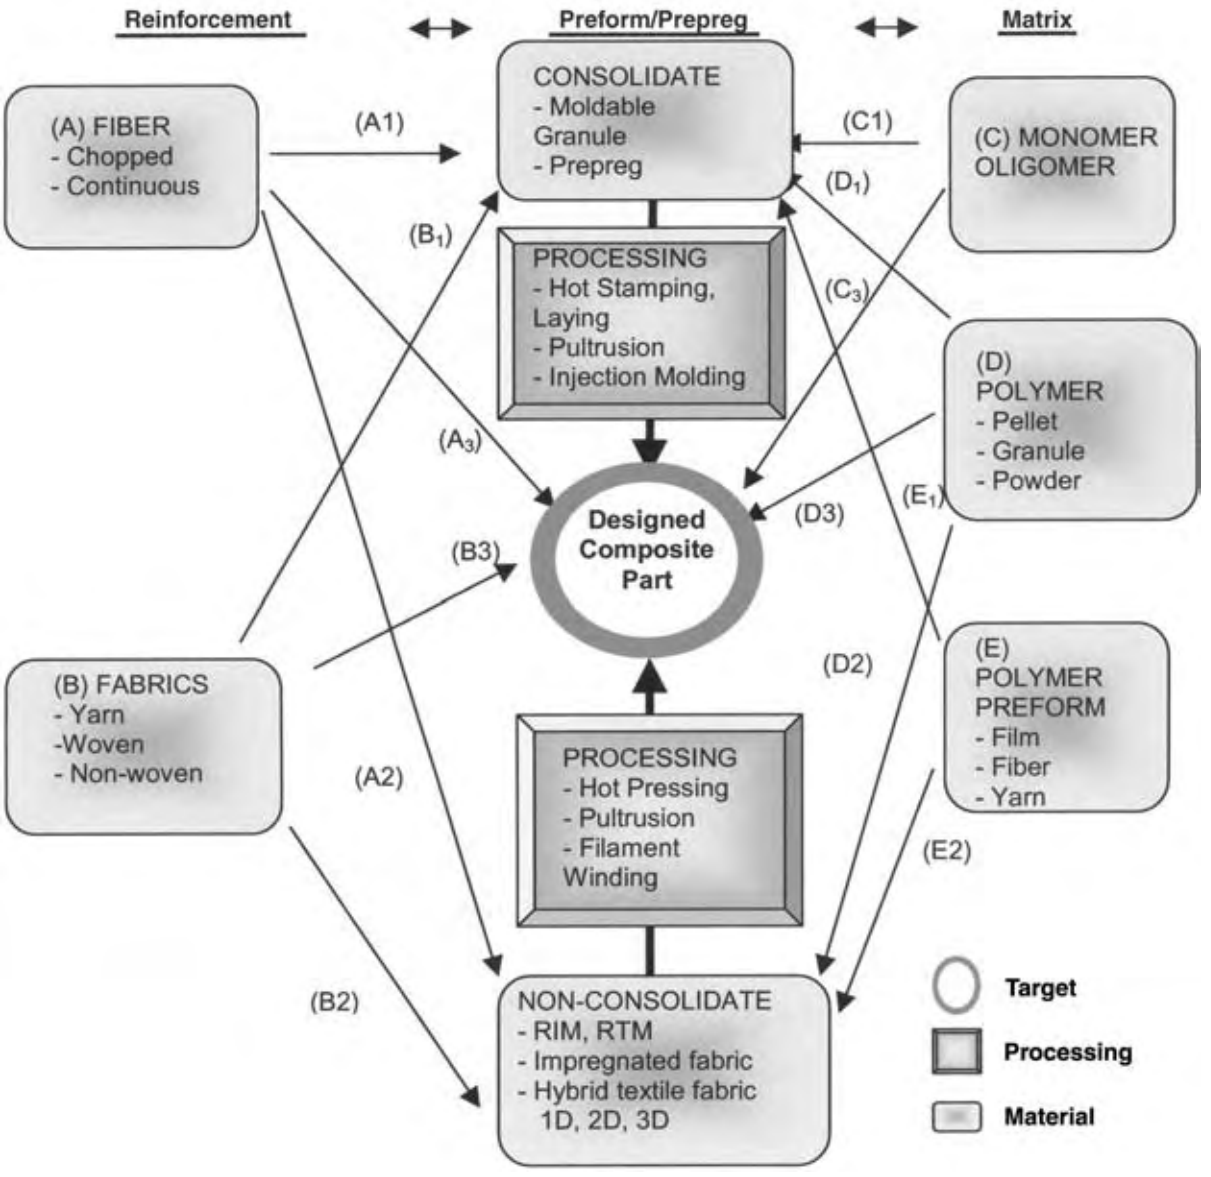

Fig. 3 Interrelationship of reinforcement-preform/prepreg-matrix. (From Refs.[4,29].)

UV-Vis, thermal analysis such as DMA, TMA, or rheological measurements. Fig. 5 illustrates the application of rheological techniques to monitor cure. Fig. 5A shows the relation of viscosity versus extent of reaction for a thermoset system, whereas Fig. 5B gives the relation of temperature versus extent of reaction in a liquid crystal thermoset. As an illustration, the effect of curing temperature on the structure of a cured liquid crystalline thermoset is given in Table 5.[30] Gillham[31] has postulated that the curing of a thermoset resin can be expressed in terms of a time–temperature transformation diagram (TTT), in which the entire curing cycle is represented by the resin rheology as a function of time and isothermal temperature. Similar to Fig. 5, the TTT diagram is divided into four sections: liquid, gelled rubber, ungelled glass, and gelled glass. This concept has found application to describe the structure–property relationship of thermoset epoxy resins using torsional braid analysis.

RECENT ADVANCES

With recent advances in the mixing of different types of thermosets and/or thermoplastics, the technology of IPN has provided very unique properties and performance.[32–34] IPN is a method to produce very special network polymer blends. Two materials which do not react with each other are blended and subsequently cured in place. The blended network polymers

share the same region of space (macroscopic volume) of the sample. Thus one has an intimate mixture of two normally immiscible systems. Consequently, the IPN exhibits a combination of properties from the two networks. This approach can generate unique advantages such as crack resistance,[34] improved modulus, strength, and hydrolytic resistance.[35] One can even generate organic/inorganic hybrid IPNs to impart specific properties such as permeability reduction.[36]

Advances in liquid crystalline thermosets in recent years,[30,37–40] have resulted in some fascinating thermosetting systems. Control of the liquid crystal type and morphology allows one to generate a wide range of properties. For example, the properties can be tuned from electrical insulators to conductors with addition of conductive fillers, while maintaining desirable high temperature performance.[39] In addition, can provide control of the degree of shrinkage on cure.[40]

Another area of current research is development of nanocomposites. Incorporation of nanometer-sized fillers in thermosets allows even broader application of thermoset technology. The processing techniques are quite similar to conventional thermosets, but the effect of filler can be quite dramatic. For example, incorporation of only 2.5% by weight of nanometer-sized silicates in a cyanate resin led to a marked improvement in physical and thermal properties while imparting a 30% increase in both the modulus and toughness.[29,41]

As discussed earlier, while the scale of the fillers is substantially different, nanocomposite materials concepts and technology are very similar to those of conventional composite materials. This is clearly demonstrated in the case of new thermosets for nonlinear optical (NLO) applications,[37,38,42,43] where nanocomposite of liquid crystalline thermosets, IPNs, and simple filled thermosets are evaluated. Tripathy et al.[42] discussed four different ways to prepare nonlinear optical polymers. (1) The polymer matrix is doped with NLO moieties in a guest/host system; (2) In side-chain polymer systems, NLO polymers with active moieties are covalently bonded as pendant groups; (3) In the main chain polymer, the chromophores are incorporated as parts of the main polymer backbone to enhance the temporal stability of the NLO properties; and (4) Stability of the optical noninearity in sol–gel-based thermosets is related to

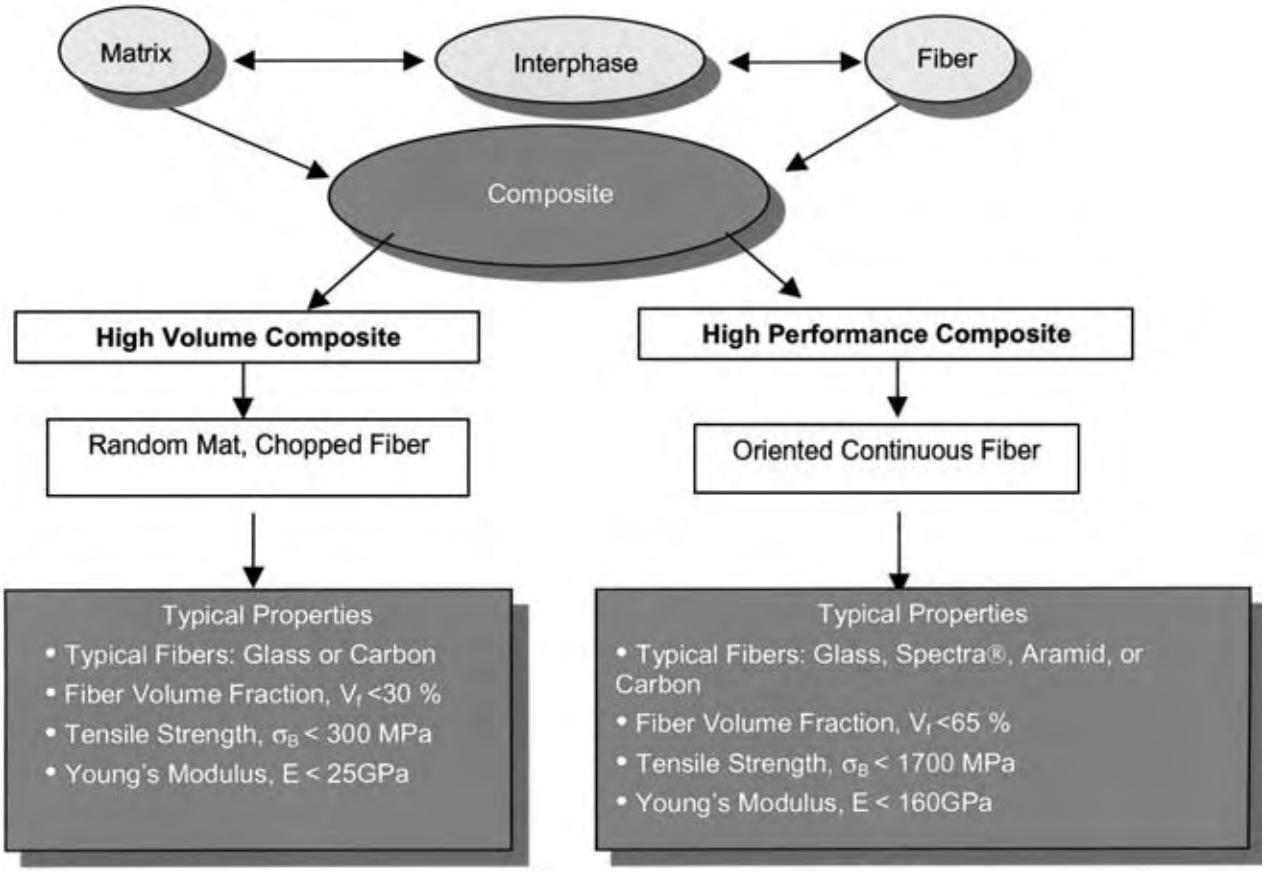

Fig. 4 Classification of composites. (From Ref.[29].)

the increasing crosslinking density. It was found that sol-gel technology can be used to prepare three-dimensional network glasses of optically clear and low loss properties at high temperatures.

The final structure can be further manipulated by employing IPN technology and/or using the AC electric field technique.[38] It has been reported that the combination of high T_g (glass transition temperature) polymers such as polyimides, high crosslink density, and permanent chain entanglement results in high temporal stability at elevated temperatures.[42,43]

By varying the structure of various component groups of the molecule, one can understand how to control the liquid crystallinity and the resultant properties of the materials (see the Fig. 5B).[44] A successful development of a practical device for NLO application will require optimization of properties in all aspects in materials and processes, such as optical loss, optical power handling, processability, and reproducibility.

WASTE MINIMIZATION

Finally, waste generation is a critical limitation for any industrial process.[45] Waste generation is unavoidable so waste minimization becomes a fundamental requirement for economic feasibility. Waste generation inherently decreases the overall value of any material. A clear understanding of the materials and processes is central to waste reduction. For example, development of (1) Laboratory definition of a robust model for cure kinetics lead to; (2) robust on-line cure monitors, which coupled to; (3) robust process controllers for manufacturing can significantly reduce the waste in production of glass filled epoxies.

Senge and Carstedt[45] recently offered a view in Fig. 6 of why industry produces waste. They suggested that a synthetic process can emulate nature to reduce the waste using a cyclic industrial system. This is accomplished by focusing on three key aspects of the manufacturing process: (1) resource productivity; (2) cleaning products; and (3) remanufacturing, recycle, and compost. Clearly in Fig. 6, preventing the waste generation from production, use, and disposal in the first place can eliminate the waste. One example is the industrial recycling of nylon 6 carpet patented by Honeywell (formally AlliedSignal), Inc. and DSM.[46,47] This process has addressed and overcome the economic, technical, and logistical barriers to commercialize a closed-loop recycling process to recover caprolactam

from waste nylon 6 articles. Nylon carpet is a composite structure containing 45% nylon fiber on a calcium carbonatefilled polypropylene backing. The fiber and backing are held together by a cure thermoset styrene butadiene (SBR) latex adhesive. The waste product derived from the medium-pressure depolymerization of nylon 6 carpet from this process is a composite of 65% calcium carbonate and 18% polypropylene dispersed in

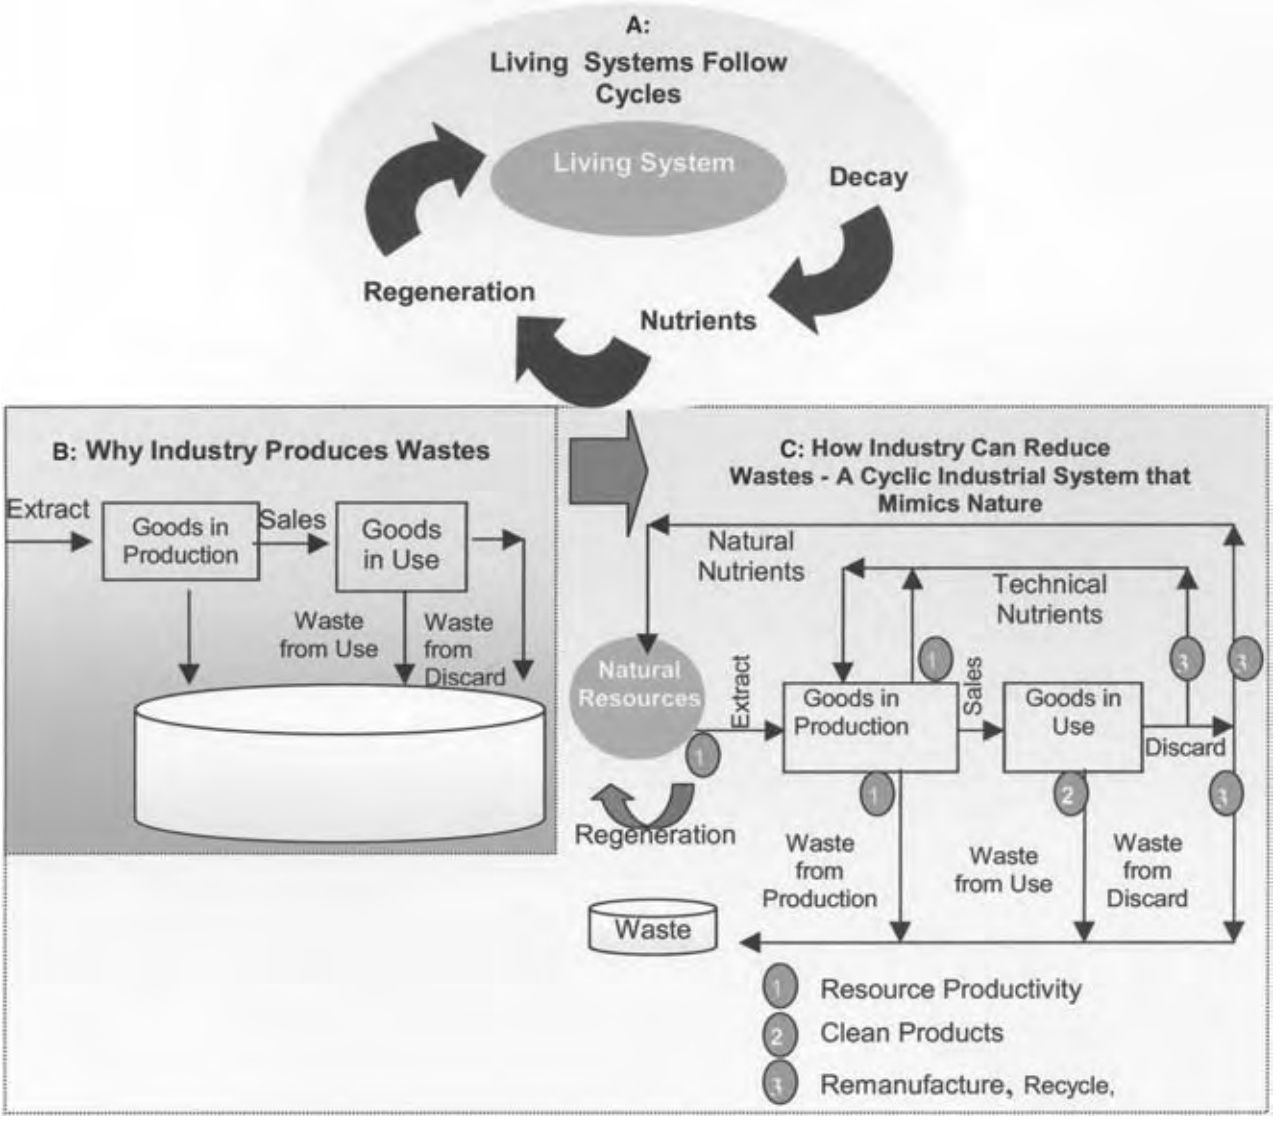

Fig. 6 Waste generation and reduction from current industry. (From Ref.[45].)

a styrene butadiene thermoset. This residue material can be used as a filler in road asphalt, asphalt roof membranes, molding compounds, and plastic lumber.[48,49] Thus, we have a real example of the closed loop recycle process as postulated by Senge and Carstedt.

Gutowski[50] has examined the product induced material flows through the product manufacturing system, and has suggested several research strategies to reduce material-related environmental loads. Fig. 7A gives a typical schematic of a materials processing flow map. Fig. 7B gives a typical fabrication process of flat laminate sheet found commonly in composite manufacturing.[50] In Fig. 7B, we can see that waste can be generated from the raw materials supply, from each step in the process, and from scrap. Sometimes, the total waste generated from these processes could be as high as 25% based on the raw materials.

The net flow balance in Fig. 7A, can be described by Eq. (1):

$$\begin{aligned}\text{Performance} = {} & af(\text{critical component selection} \\ & - \text{its wastes}) \\ & + bf(\text{process} - \text{its wastes}) \\ & + cf(\text{structure} - \text{its wastes}) \\ & + df(\text{products} - \text{its wastes}) \\ & - \text{performance wastes}\end{aligned} \tag{1}$$

$$\begin{aligned}\text{Performance} = {} & af(\text{critical component selection}) \\ & + bf(\text{process}) \\ & + cf(\text{structure}) \\ & + df(\text{products}) \\ & - \Sigma_{\text{wastes}} \text{ all sources}\end{aligned} \tag{2}$$

where a, b, c, d are the constants. In term of a continuous flow process, we can rewrite Eqs. (1) and (2) into Eq. (3)

$$P(x) = \int \lambda_j V(x_j)dx_j - \int \omega_j W(x_j)dx_j \tag{3}$$

where, $P(x)$ is a value performance function, $V(x_j)$ is the value generating function at component x_j stage or phase j, and $W(x_j)$ is the waste generating function at component x_j, and λ_j, and ω_j are constants. The variation of $V(x_j)$, $W(x_j)$, λ_j, and ω_j greatly affects the value of $P(x)$. From Eq. (3), we can see that wastes generated from the materials flow negatively to impact a wide range of factors. These range from the selection of materials and from innovation design to environmental concerns as seen in Figs. 6 and 7.

$V(x_j)$ is not restricted with any limitations in Eq. (3) and it is valid to include the feedback loops in Fig. 6. Thus, both processes in Figs. 6 and 7 can be described by Eq. (3) with different forms of $V(x_j)$ and $W(x_j)$, and different values of λ_j and ω_j.

Furthermore, this form of expression is not new and it has found uses in many applications in mathematics and science.[51–62]

The definition of wastes can be viewed as the gap(s) between the full (theoretical) potential of the resources supplied and the actual delivered. As can be seen in the examples in Table 6, the defects found in a fiber structure impair our ability to obtain much less than half of its theoretical tensile modulus.[28] We need to point out that the concepts in Figs. 6 and 7, and Eqs. (1)–(3) have been the background of the so called ''Six Sigma'' methodology used to minimize the wastes in manufacturing industries over the last decade.[6–10] Six Sigma is a strategy that was developed to accelerate improvements in processes, products, and services, radically reduce manufacturing and/or administrative costs, and improve quality by relentlessly focusing on eliminating waste and reducing defects and variation. Since the material processing is a very broad field, we have limited our focus in the discussion to thermosets and their fiber-reinforced composites. However, the same principle will apply for any materials development effort.

PROPERTY OPTIMIZATION CASE STUDY

We discussed ''in silico'' experimentation above. In particularly demanding applications, it is far more efficient to design the composite for the application before spending excessive time on trial and error. We will demonstrate this with a case study. On the basis of the design methodology illustrated in Fig. 2 and the processes given in Table 2, we will discuss the design of a helmet for ballistic protection. Figs. 8–10 show the design and simulated deformation of a helmet under ballistic impact.

Honeywell International Inc.'s Spectra Shield® composite has been used as the ballistic material for a lightweight helmet system since the mid-1990's. Spectra Shield composite is made from Honeywell's Spectra® fiber, one of the world's lightest and strongest fibers (see Table 4), which is, pound-for-pound 10 times stronger than steel. The use of this material in helmet construction results in substantially increased ballistic protection, while reducing weight. Before field use of Spectra Shield® material for this application, modeling of the composite helmet under ballistic impact was performed. The modeling was carried out to highlight the increased protection under the ballistic impact of Spectra fiber compared to metal. Finite element analysis (FEA) of the helmet configuration impacted by a standard projectile round to the front

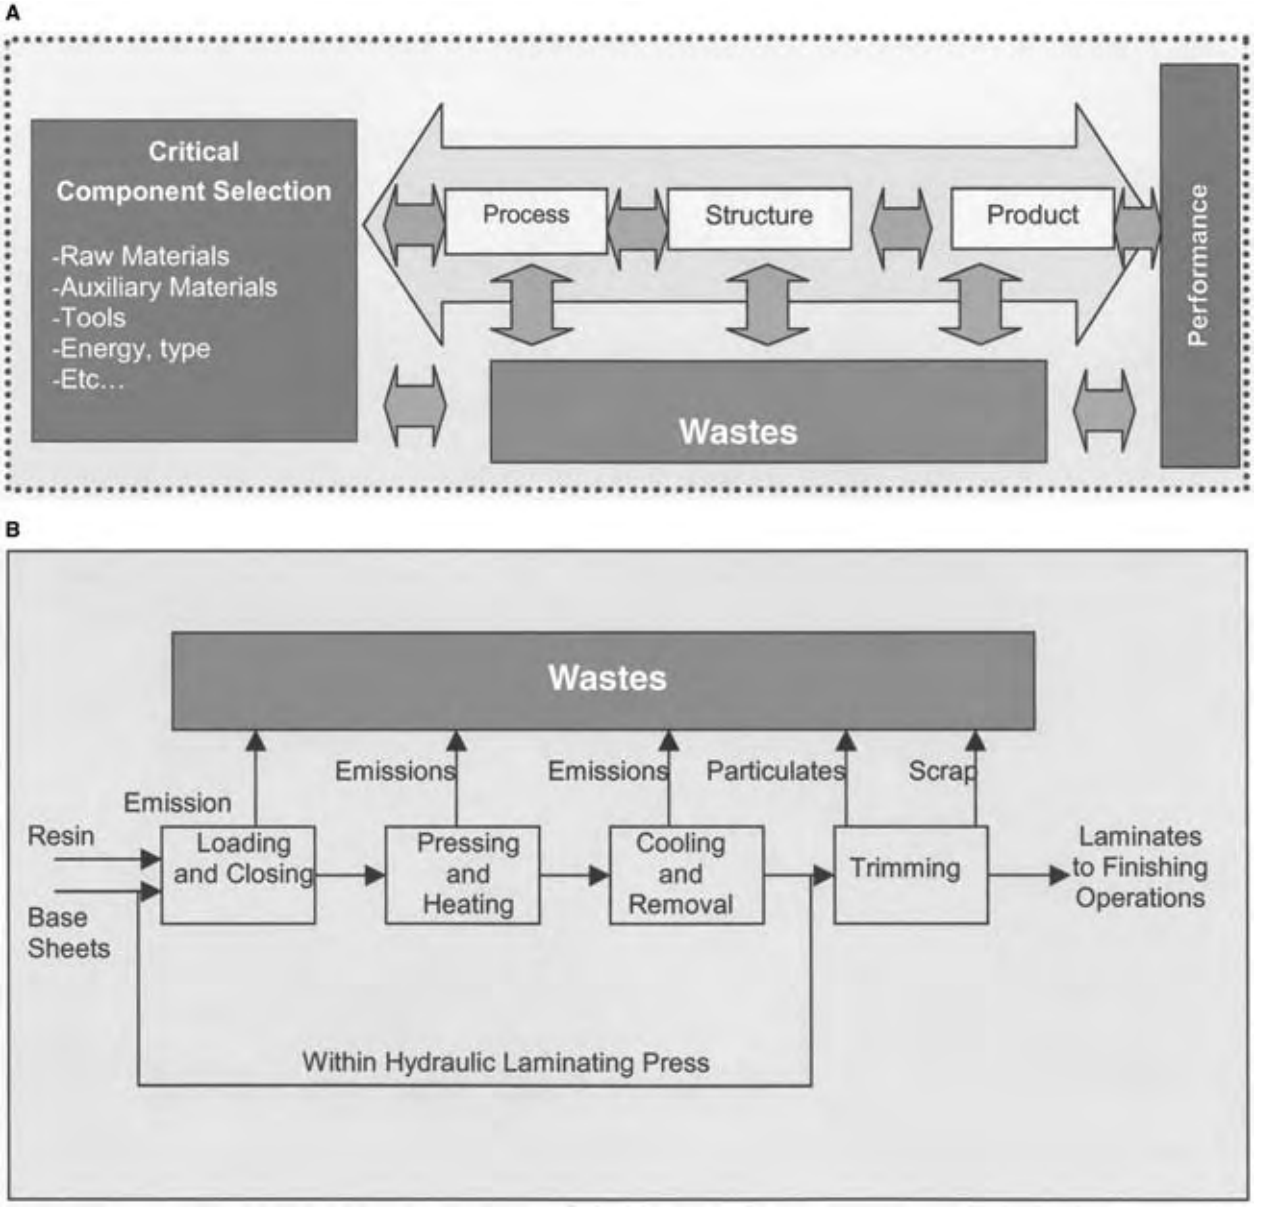

Fig. 7 Materials flow relationship. (A) Relationship of "component section–process–structure–product–performance." (B) schematic of a flat laminate sheet production process. (From Ref.[50].)

Fig. 8 Typical layout of a helmet.

Fig. 9 Helmet design for finite element analysis.

of the helmet was performed using the Abaqus FEA program (Abaqus Inc. Pawtucket, Rhode Island, U.S.A.).

A FEA analysis can be linear or nonlinear, but for our application nonlinear effects are significant and have to be taken into account. In a finite element analysis there are at least four primary causes of nonlinearity.

1. *Material nonlinearity.* This nonlinearity is present because of the fiber orientation in the composite. The effect of the Spectra fiber reinforcement on the composite structure was taken into account by a user subroutine which added the oriented fibers effect to the base material of the composite.
2. *Geometric nonlinearity.* This nonlinearity is applicable due to the relatively large deformations anticipated. As the helmet is a curved structure, the effect of this curvature on the stress distribution has to be taken into account.
3. *Force application nonlinearity.* This nonlinearity is applicable due to the expected nonlinear displacement loading as a function of time. A FEA contact analysis was required because we idealized the system as a nondeformable projectile impacting a deformable helmet.
4. *Boundary condition nonlinearity.* This nonlinearity is also applicable in FEA contact problems. This nonlinearity is expected during the projectile impact on the helmet due to the boundary conditions changing as a function of time and loading.

The model used consisted of a half helmet with three element layers of composite material through the thickness. A half model was used to take advantage of the symmetry present in the problem. The elements used were eight-noded brick elements because these elements can represent the deformation sufficiently. Anisotropic material properties were defined for each element using a user subroutine and impact was designated at the front of the helmet.

After the solution was obtained the results were analyzed. Each of the three principal stresses (σ_1, σ_2,

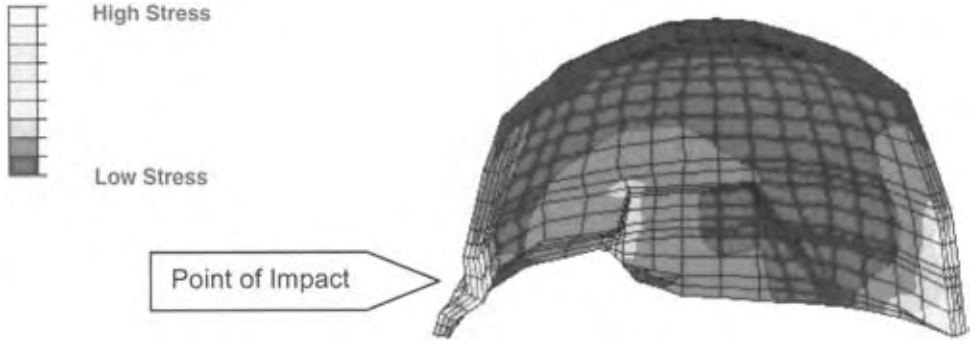

Fig. 10 Finite element analysis results for stress during ballistic impact on the helmet.

σ_3) are available in most FEA software packages and stresses are usually averaged by the FEA software packages to provide more accurate stress values when mapped (contoured) on to the mesh. A good first cut to the understanding of analysis results is the use of the von Mises stress (effective or equivalent stress). Fig. 10 shows the von Mises stress contour mapped to the FEA mesh in pounds/square inch (PSI).

The simulation shows that the helmet would deform at the location of impact, but the stresses would be distributed out and around the impact location thereby reducing penetration probability as compared with a metal helmet. Thus, we have used a combination of an understanding of material properties with computer simulation to deliver the required performance.

CONCLUSIONS

Environmental and economic drivers will accelerate the development of products generating minimal wastes. As Senge and Carstedt have pointed out, an understanding of the utilization of resource productivity is essential to the development of an industry that can reduce waste. An understanding of thermoset processing is of vital importance in many industries such as integrated chip manufacturers, aerospace technologies, automotive manufacturers, etc. Traditionally, design and control of these processes has relied on trial and error methods due to the complexity of the reacting systems. With the recent advances of modeling, kinetic tests, and chemorheological measurement, characterization of these complex reacting systems have found a foundation in the prediction of the processing-structure and performance of thermosetting systems. However, there is still a long way to go. Most of the test methods described in the paper by Halley and Mackay[15] have one thing in common: there are very few data to determine the waste generation function in material control. Some of the key drivers for waste are well known. In thermosets for example, compounded resin consistency is a key input variable for waste minimization. Since the final structure of the thermoset controls the performance, there is a need to have a measurement system to evaluate resin reactivity reliably. One such measurement system has been reported by Kranbuehl et al.[63] They developed an in-line frequency-dependent electromagnetic sensor to monitor cure in polyimide and epoxy thermosets. The sensor was then incorporated into a closed loop controller to monitor and control cure during manufacturing. Similarly, we have shown that phenolic resin composition directly affects carbon composite performance.[64] Control of the base resin system allowed production of carbon-carbon composites with minimal failures due to cracking. These types of capable measurement systems must be extended to the whole field of thermoset manufacturing so that the design engineer can reliably predict the effect of waste. If we want to minimize the waste generation function, and maximize the value generating function in materials processing, we need to develop a clear, consistent way to predict and minimize the waste generation function.

University of California–Berkeley, Berkeley, California, U.S.A.

INTRODUCTION

The integration of miniaturized mechanical components with microelectronic components has resulted in a new technology, known as microelectromechanical systems (MEMS), which extends the benefits of microelectronic fabrication to sensing and actuating functions. Several MEMS devices are in commercial use, such as accelerometers, pressure sensors, digital mirror displays, and gyroscopes. The first fully integrated single-chip MEMS accelerometer was manufactured in 1991 by Analog Devices. By September 2002, Analog Devices had sold more than 100 million MEMS accelerometers and gyroscopes. With size shrinking below the micrometer scale, nanoelectromechanical systems (NEMS) are also being realized.

Generally, MEMS and NEMS technologies are able to exploit properties that scale favorably with decreasing size. While this ability provides a unique capability, it also poses challenges to the fabrication and reliability of these devices. Conventional machining and assembly techniques cannot be easily applied to microsystems. Moreover, because of the dominance of surface effects on the micro- and nanoscale, strong adhesion, friction, electrostatic charging, and wear have been shown to be issues crucial to this technology. In this article, we present an overview of MEMS and NEMS fabrication processes, reliability issues, and ways to improve reliability with special emphasis on the chemical processes involved.

FABRICATION PROCESSES FOR MEMS AND NEMS

Historically, silicon and silicon based materials have formed the basis for the well-established integrated circuit (IC) technology. As a consequence, polycrystalline silicon (polysilicon) is one of the most commonly used structural materials for MEMS. Comparatively, silicon is a good structural material for the microscale.[1] However, the inherent mechanical nature of MEMS devices brings about a new level of complexity to their production and reliability compared to standard integrated circuits. Micromechanical structures can be fabricated from a variety of methods, including bulk micromachining, LIGA (a German acronym for lithography, electroplating, and molding), and surface micromachining.[2] Surface micromachining is one of the most common methods for MEMS fabrication, and it involves the deposition, patterning, and etching of thin films–processes that are commonplace in the IC industry.[1,3] As such, surface micromachining leverages heavily from the technology of the IC industry, and allows for the production of sophisticated microstructures with parallel fabrication and high fabrication yield. It should be noted that silicon is not always chosen as the structural material. Some commercialized MEMS products use aluminum as the structural material, e.g., the Texas Instruments DMD.™

A simplified surface micromachining process diagram is illustrated in Fig. 1. The process begins with a silicon wafer, which has an electrical isolation layer (typically silicon nitride) deposited on the surface. Next, the first polysilicon (poly) layer is deposited. This will form the ground plane and actuation pad for the device in this illustration, a cantilever beam. This poly layer is then lithographically patterned and anisotropically etched (using, e.g., plasma etching). The sacrificial (spacer) layer, typically silicon oxide, is then deposited over the patterned poly layer. The sacrificial layer is also lithographically patterned, and anisotropically etched to reveal access windows to the underlying poly layer. The structural poly layer is deposited, lithographically patterned, and anisotropically etched to complete the structure. Now, although the fabrication of the device is complete, it is not usable until the sacrificial layer is removed. This is accomplished by using an isotropic etch, to dissolve the sacrificial layer and leave a ''released'' device.

The general process for MEMS fabrication can also be applied to NEMS. Owing to the dimensions involved in NEMS, the patterning processes used differ from that of MEMS. For NEMS patterning, e-beam lithography or atomic force microscopy (AFM) writing can be used. E-beam lithography uses a highly focused electron beam to ''write'' on a thin film. The action of the electron beam alters the film material to the extent that it can be removed while leaving unaltered material intact. In this respect e-beam lithography is

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120037168

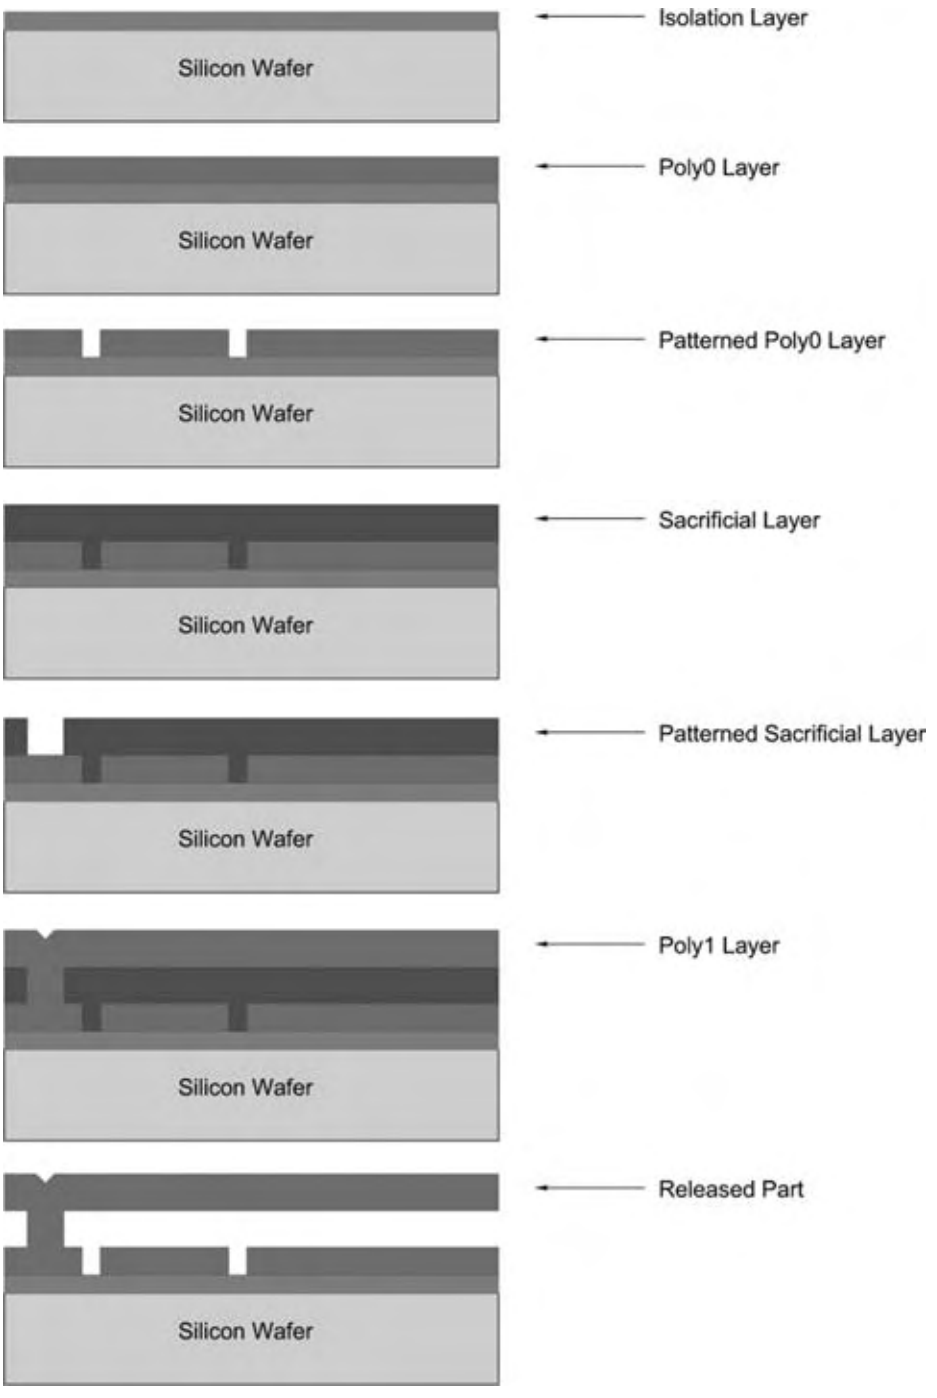

Fig. 1 Basic diagram of the surface micromachining process. *(View this art in color at www.dekker.com.)*

similar to conventional lithography. However, the e-beam must be traced over the mask (a serial process) and is not flash exposed as in conventional lithography. Atomic Force Microscopy writing can be done in several ways. One way is to apply a bias to the sharp tip and alter the material under the tip by exposing it to the high electric field. This may lead to localized oxidation, which can be used to transfer the pattern to the substrate. Alternatively, the tip can be scraped across the surface (especially on soft coatings) and mechanically remove material from the desired areas. Similar to e-beam lithography, AFM writing is a serial process. In addition to nanoscale writing, the so-called ''spacer lithography'' can be used to precisely define nanometer-wide gaps. This process consists of the conformal deposition of a nanometer thin film over an exposed step surface. Afterward, the plan surfaces are anisotropically etched, leaving only the nanometer thin ''spacer'' material on the sidewalls of the vertical step. Unlike e-beam lithography

and AFM writing, spacer lithography is a parallel process and is carried out over the whole surface of the sample at once.

CHEMICAL PROCESSES USED IN FABRICATION

There are a variety of chemical processes used in the manufacturing of MEMS and ICs. These include deposition and etching processes. Some of the more common examples of these processes are described briefly in the sections that follow.

Chemical Vapor Deposition

One of the most common deposition processes encountered in the fabrication of microsystems is chemical vapor deposition (CVD) (see, e.g., Ref.[2]). This broad category encompasses processes including low-pressure (LP), atmospheric-pressure (AP), plasma-assisted (PA), ion beam-assisted (IBA), and laser-assisted (LA) CVD. Regardless of the particular type of CVD, the process consists of exposing a target substrate to a supply of a gas (or gas mixture) and activating that gas to produce a chemical reaction at the surface of the substrate. This activation method may include heating, striking a plasma, laser irradiation, ion beams, or combinations thereof. The process parameters are carefully controlled so that the deposited material films are of high quality, and have the desired stress and composition properties.

In silicon based MEMS processing, common CVD films include polysilicon, silicon oxide, and silicon nitride. For polysilicon films (usually the structural layer), an LPCVD pyrolysis method is generally used with silane (SiH_4) as the source gas [see Eq. (1)]. To obtain a uniform film across the wafer, the process is carried out at low pressure to ensure that the deposition is surface reaction controlled and not diffusion limited. Typical process temperatures are in the range of 580–650°C, and pressures between 0.1 and 0.4 Torr.

$$SiH_4 \xrightarrow{\Delta} Si + 2H_2 \quad (1)$$

Another important material is silicon nitride, which is usually employed as an electrical isolation layer. It is typically deposited by the LPCVD or PECVD method. The process gases are dichlorosilane $SiCl_2H_2$ and ammonia NH_3 [see Eq. (2)] and the process parameters are in the range of 700–900°C and 0.2–0.5 Torr.

$$SiCl_2H_2 + NH_3 \xrightarrow{\Delta} Si_3N_4 + 2HCl + \frac{3}{2}H_2 \quad (2)$$

Silicon oxide, typically a sacrificial layer, can be deposited using PECVD and LPCVD methods. There are many source gases that can be used to produce silicon oxide. These include mixtures of silane and oxygen, tetraethoxysilane and oxygen, dichlorosilane and N_2O, and silane and N_2O. An example reaction is shown in Eq. (3). Because there are many options for source gases, the process parameters may range from 400 to 900°C and from 0.1 to 0.5 Torr.

$$SiH_4 + O_2 \xrightarrow{\Delta} SiO_2 + 2H_2 \quad (3)$$

Etching

To create micromachines, films that have been deposited must be patterned and etched to reveal the desired structures. Often, it is important to etch these structures with vertical sidewalls (anisotropic etching). In this case, most pattern transfer operations (lithography and etch) are carried out using plasma etching. Conceptually, this process is the reverse of deposition. The etching process consists of exposure of the patterned and masked substrate to a low-pressure plasma. The reactive species and ions preferentially etch those areas that are not masked, resulting in the definition of features on the surface. The key to plasma etching is that the products of the reaction of the activated gas and the material to be etched must be volatile (see e.g., Ref.[2]).

Reactive ion etching (RIE) and deep reactive ion etching (DRIE) are common examples of plasma etching. In this incarnation, the substrate to be etched is placed on a powered electrode in a plasma chamber. Process gases are admitted into the chamber and a plasma is struck. Because the substrate is directly in the ion flux of the plasma, the ions impinge on the surface and may participate in chemistry. For example, RIE of polysilicon may use SF_6 as the reactive gas, and etches the Si by a reaction with fluoride ions to form the volatile product SiF_4, as illustrated by Eqs. (4) and (5).[a]

$$SF_6 \xrightarrow{*} SF_5^+ + F^- \quad (4)$$

$$Si + 4F^- \xrightarrow{*} SF_4 \quad (5)$$

The anisotropic nature of the etching by RIE and DRIE is a result of the directionality of the impinging ions. Sometimes it is useful to etch very deep channels or holes. Using conventional DRIE, some tapering of the sidewall profile is expected. However, an etching process has been developed where sequential etch/passivate steps are performed. This etching process, called the Bosch process, uses conventional DRIE methods as process gases for a short period of time, interrupts

[a]Plasma chemistries are complex and these equations are meant only to indicate an example process.

this process with a fluorocarbon polymer deposit phase, and resumes DRIE. Because of the directionality of the etching process, the polymer on the plan surfaces is quickly removed and the etching process resumes. However, the material removal on the sidewalls is slower, and therefore sidewall surfaces are not readily etched. This process allows very deep features to be etched with little tapering. Because of the way this process is carried out, however, the sidewall surfaces are generally scalloped, and this is a characteristic feature of the Bosch etch process.

RELEASE PROCESSES

While MEMS technologies make much use of the preexisting integrated circuit fabrication processes, there is at least one critical step that is unique to MEMS processing. This step, called the release step, refers to the processing stage that frees the microstructure from the sacrificial layers that were used during the fabrication of the device. This is usually accomplished by exposing the micromachine to an etchant fluid that will selectively and completely remove the sacrificial material. In the case of polysilicon based microstructures, the sacrificial layers are typically silicon oxide, and the etchant fluid is an aqueous solution of HF. In some cases, an etching solution of concentrated HF and HCl is used. The presence of HCl helps to protect the silicon nitride from etching by HF. Next, the etchant is completely rinsed away with deionized water. If, at this point, the released structures are simply removed from the rinse liquid and air-dried, they are almost inevitably found adhering to each other. This phenomenon is called ''release stiction'' and is caused by the action of the curved receding air–liquid interface as it passes over the structures. Alternate processes are typically carried out to avoid the problem of release stiction.

One alternate approach is to change the water meniscus shape from concave (wetting) to convex (nonwetting), so that capillary forces are reduced.[4] This is accomplished by altering the composition of the surface by chemically grafting hydrophobic molecules to the surface. This approach is discussed in greater detail in the sections that follow. Other approaches involve the avoidance of liquid–vapor interfaces altogether through supercritical fluid, freeze sublimation drying, and dry-release methods such as the use of vapor HF etching. Fig. 2 shows a P–T diagram that depicts the concepts of supercritical drying and freeze sublimation. Supercritical drying is a process that begins with released microstructures, which have been kept submerged in liquid since their sacrificial layer etch, and then placed in a high-pressure chamber filled with a short alcohol (methanol, ethanol, and isopropanol) solvent. This solvent is then completely

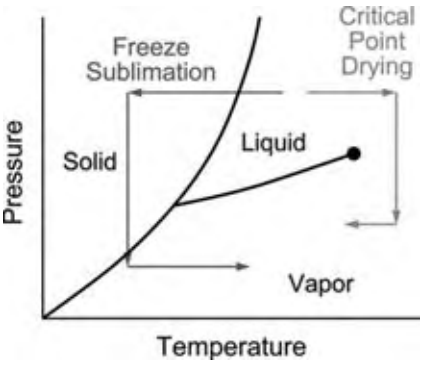

Fig. 2 Diagram depicting the phase paths of critical point drying and freeze- sublimation drying. Note that neither of these processes involve crossing the liquid–vapor line. *(View this art in color at www.dekker.com.)*

displaced by liquid carbon dioxide (CO_2). The chamber is pressurized and heated to cause the liquid CO_2 to become supercritical. The chamber is then carefully vented and the structures are removed.[5] Freeze sublimation drying is similar to supercritical drying. This process also begins with released microstructures, which are maintained in a solvent, such as isopropanol. This solvent is then displaced by another solvent (water/isopropanol mixture), which is then frozen. The vapor above this solid is pumped away by a vacuum pump until the solid is completely sublimated and the process is complete.[6] Vapor HF etching is a process that completely avoids the issue of solvent displacements, as the sacrificial layer etch is carried out by a gaseous isotropic etchant. Usually, the samples are placed above a solution of HF and water and the vapors above that solution are used to perform the etch.[7]

Polymer ashing is another process related method. This process is fairly complex and involves patterning of a polymer layer during the release. First, structures are partially released by a timed etch. Next, a polymer film is deposited onto the partially released structures. This film is patterned into support posts that hold the structure in position as the remainder of the sacrificial layer is etched away. Because the polymer support structures hold the devices in place, there is no concern for special drying techniques. Finally, the polymer supports are burned away, typically by ashing in an oxygen plasma.[8] This leaves behind fully released and free-standing microstructures.

SURFACE PROCESSING FOR INCREASED RELIABILITY

Surface microstructures typically have lateral dimensions of 50–500 μm with thicknesses of 0.1–2.5 μm, and are offset 0.1–2 μm from the substrate. The large

surface-area-to-volume ratios of surface and bulk micromachined micromechanisms lead to the dominance of surface and interfacial forces over body forces.[8–12] For commercial viability and industrial growth to continue, micromechanical systems must be built with high yields and reproducible device properties and must exhibit reliability over the expected device lifetime. The traditional high yields experienced in the IC industry extend to MEMS production only up to the point of microstructure release.

The release techniques discussed here do not prevent adhesion from occurring during micromachine operation. Microstructure surfaces may come into contact unintentionally through acceleration or electrostatic forces, or intentionally in applications where surfaces impact or shear against each other. When adhesive attractions exceed restoring forces, surfaces permanently adhere to each other causing device failure—a phenomenon known as ''in-use stiction.''

Stiction is not the only reliability issue that plagues microsystems. Owing to the dimensions of the devices and roughness of the surfaces involved, the mechanical properties of the structural material are very important. Although silicon is a good structural material for the microscale, owing to its high elastic modulus and low density, small area contacts (as in contact points between two rough surfaces) can generate enormous contact pressures, which can create plastic deformations in silicon. For example, the hubs on microgears can become visibly cluttered with wear debris after a few hundred thousand cycles. These microgears seldom last more than a few million cycles before the buildup of wear debris and increased friction irreversibly bind the gear.[13] Current research on the issue of wear seeks to understand the fundamental mechanisms responsible, as well as to address the practical issues by integrating hard materials into the micromachining process. Adhesion, friction, and wear are collectively referred to as tribology.

Owing to the extensive infrastructure related to the chosen materials base (silicon), and the relative ease in which silicon based microsystems can be produced, a convenient approach to overcoming some of these reliability issues is to apply coatings for stiction, friction, and wear control to the devices after they are produced. This is analogous to painting buildings or automobiles after they are constructed to make them more weather resistant. Therefore, facile and effective coating processes that satisfy the needs of the microsystems for reliable performance have been developed.

Methods to Quantify MEMS Tribology

To quantitatively study stiction, friction, and wear, micromechanical test devices have been designed and fabricated. One of the most common test devices for stiction quantification is the cantilever beam array.[8] With this device, stiction is tested by electrostatically bringing the beam into contact with the substrate and releasing the electrostatic force. By examination of the behavior of the interaction of the beam with the substrate, one can determine an apparent work of adhesion, which is related to stiction.

Other devices have been designed for friction and wear testing. Although there are many types of these devices, they generally consist of a movable structure and a fixed structure. To test friction, the movable structure is contacted against the fixed structure under a prescribed contact (normal) load and a tangential force is ramped up. The device is carefully monitored until a slip occurs and the tangential force at slippage is known. The coefficient of static friction can be determined by knowledge of the applied normal load and the tangential force required to produce a slip. Generally, devices that are used for friction testing can also be used for wear testing. Instead of a single slip event, the movable part is cycled against the fixed part under a given normal load. At the end of the test, scanning electron microscopy or AFM can be used to inspect the contacting parts to gage the amount of wear.

Self-Assembled Monolayer Coatings to Control MEMS Tribology

Coatings that are to be applied to micro- and nanostructures must satisfy a series of constraints related to their properties and the process used to generate them. They must be conformal and uniform because all surfaces of the device must be coated with the same amount of coating to avoid the introduction of extraneous stresses. Coatings must be very thin for design fidelity reasons, and so that it does not adversely influence the operation of the device. (For example, a coating must not adversely affect the resonance frequency or quality factor for a MEMS resonator.) They must be thermally and chemically stable because the device is expected to last a long time and endure packaging steps. The coating process must be compatible with the device and should be easily implemented.

In light of these constraints, an effective chemical modification for anti-stiction treatments involves the application of a molecular film to the micromachine surface. This is most often accomplished through a process known as self-assembled monolayer (SAM) deposition.[14] Self-assembled monolayers are molecular films that spontaneously form on a (usually pretreated) surface upon exposure to a reactive precursor molecule. SAM precursors generally consist of three main parts: a terminal group, a backbone, and a head group. Fig. 3 shows these parts on a model SAM

precursor molecule, octadecyltrichlorosilane (OTS). The head group is a chemically reactive group that is chosen to bind the molecule to the MEMS surface. The backbone is often an *n*-alkyl chain (i.e., $-(CH_2)_n-$) whose function is to assist in the assembly of a well-packed monolayer film. The terminal group is the part of the molecule that comprises the new surface after monolayer self assembly and imparts the desired surface functionality to the coating. For adhesion control, a highly hydrophobic surface is desired, and the terminal groups of choice are hydrophobic (water disliking) $-CH_3$ or $-CF_3$ groups (the $-CF_3$ terminal groups result in monolayer coatings that have nonstick behavior similar to Teflon®).

It has been demonstrated that, when properly integrated into the microstructure release process, SAM coatings deposited from solution can eliminate release stiction, reduce in-use stiction, and decrease both friction and wear in microengines.[11,12] Several classes of organic films have been explored as antistiction agents. For aluminum surfaces, perfluoroalkanoic acids have been successfully employed. On silicon surfaces, chloroilane based films, which include alkyl- and perfluoroalkyl-trichlorosilane SAMs, dialkyldichlorosilane, tris-dimethylaminosilanes, and primary alkene, alcohol and aminebased molecular films have been tested.

Perfluoroalkanoic acids

Perhaps the best example of antistiction technology for MEMS to date is the coating process employed by Texas Instruments on the DMD™ device. The DMD is a MEMS device, which consists of an array of a million or more rotatable aluminum mirrors. Photoresist is used as the sacrificial layer and is removed at the release step using a remote plasma containing oxygen and fluorine species. The device has contacting surfaces in relative motion, which are susceptible to adhesion, friction, and wear, and require lubrication. About 50 different lubrication schemes were investigated for DMD, ranging from SAMs to fluids to solid lubricants.[15] The most successful ones reportedly are perfluorinated *n*-alkanoic acids ($C_nF_{2n-1}O_2H$), which form self-assembled monolayers on aluminum oxide surfaces (see Fig. 4). Within this class of SAMs, perfluorodecanoic acid (PFDA, $n = 10$) was found to be the lubricant of choice to minimize the friction coefficient and the possibility of thermal decomposition. To keep moisture out and create a background pressure of PFDA, hermetic chip package is used. When properly lubricated, devices have operated for more than 350 billion cycles.

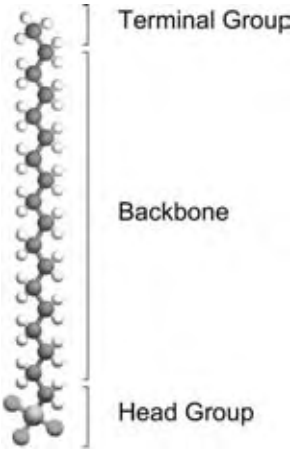

Fig. 3 An example SAM precursor molecule (OTS) with the major parts of the molecule labeled. Alternatively, the terminal group and backbone may be collectively referred to as the "pendant" group. *(View this art in color at www.dekker.com.)*

Chlorosilane based monolayers

Among the SAMs suitable for coating silicon, the OTS based variety is the most widely used. Some of the properties for the OTS SAM, of relevance to MEMS, are listed in Table 1. Although there is much debate concerning the true structure of the OTS monolayer on silicon oxide, Fig. 5 illustrates a simplified conceptual model of the film.

In addition to the OTS precursor molecule, there are many other molecules of the form $RSiCl_3$ and $R,R'SiCl_2$ that are used to produce oriented hydrophobic monolayers on silicon surfaces, with R and R′ denoting an aliphatic carbon chain. It has been demonstrated that the most effective chlorosilane reagents to produce hydrophobic coatings on oxidized silicon surfaces are perfluorinated alkyltrichlorosilanes.[19] Indeed, lower values for the apparent work of adhesion were reported for 1*H*,1*H*,2*H*,2*H*-perfluorodecyltrichlorosilane [$CF_3(CF_2)_7(CH_2)_2SiCl_3$; FDTS] in comparison to OTS.[17] Table 1 shows an interfacial property comparison among different surface preparations.

Although these SAM coatings have been shown to effectively alleviate both release and in-use stiction, they possess a number of limitations intrinsically related to their chemistry. A serious limitation arises from the ability of the precursor molecule to polymerize.[20] As long as the precursor molecule has a functionality greater than one, bulk polymerization can occur, and the higher the functionality, the greater the likelihood for polymerization. This is potentially dangerous for micromachines in that large particulates, such as polymerized clusters of SAM precursor molecules (which can be several micrometers

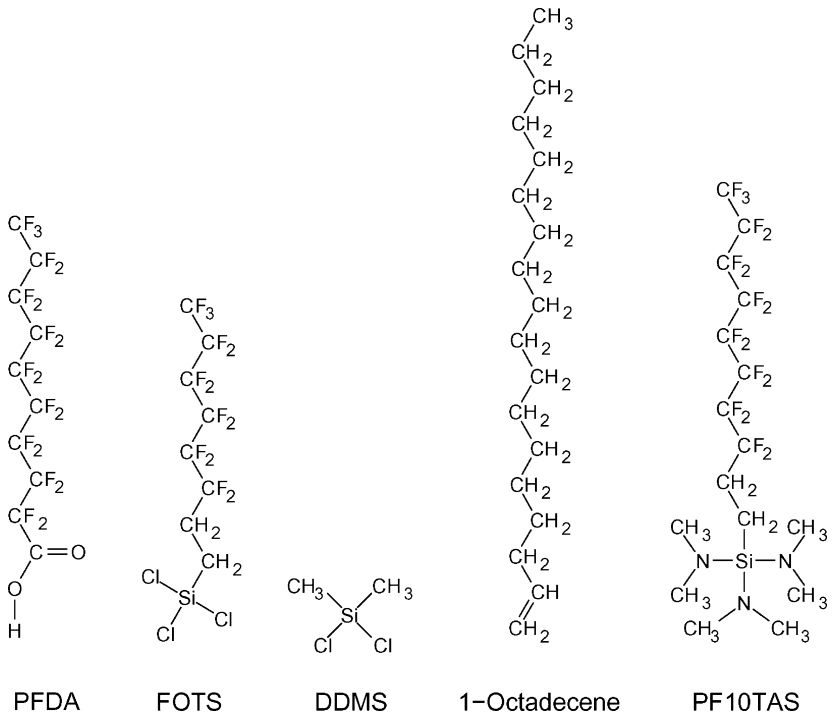

Fig. 4 Structural formulas for perfluorodecanoic acid (PFDA) perfluorooctyltrichlorosilane (FOTS), dimethyldichlorosilane (DDMS), 1-octa decene, and perfluorodecyl-tris-(dimethylamino)silane (PF10TAS).

in diameter), can mechanically interfere with the device operation. Unfortunately, there is no satisfactory method for removal of the polymerized clusters once they have agglomerated on the surfaces of the substrate or micromachines. Another limitation of long-chain chlorosilane SAM coatings (such as OTS) arises from the coating procedure, which must be performed from the liquid phase because of the extremely low vapor pressure of the precursor.

Recent developments in the chlorosilane based monolayer technology address some of these issues by performing the coating process in the vapor phase. Vapor phase processing eliminates the use of organic solvents and greatly simplifies handling of the samples. Moreover, the stoichiometry of the precursor molecules can be more precisely controlled. It has been demonstrated that monolayer films that are produced from the precursor tridecafluoro-1,1,2,2-tetrahydrooctyltrichlorosilane [$CF_3(CF_2)_5(CH_2)_2SiCl_3$; FOTS] in a low-pressure CVD style reactor exhibit low adhesion energies.[19] Fig. 4 shows the structure of FOTS. Additionally, in situ plasma cleaning of the sample as well as in situ measurement of the film growth provide excellent process uniformity, reproducibility, and monitoring capability.[21] This approach demands that the microstructures undergo some form of dry release process, such as critical point drying or vapor HF etching, before receiving the monolayer coating.

The dimethyldichlorosilane [$(CH_3)_2SiCl_2$; DDMS)] monolayer has also been proposed as a promising surface coating for MEMS. Fig. 4 shows the structure of DDMS. The monolayer has been compared to the OTS SAM with respect to the film properties and their effectiveness as antistiction coatings for micromechanical structures.[16,22] While water and hexadecane contact angles are comparable, the apparent work of adhesion for the DDMS monolayer is somewhat higher than that for OTS (Table 1). Furthermore,

Table 1 Physical property data for various surface treatments

Surface treatment	Contact angle (°)		Work of adhesion (mJ/m^2)	Coefficient of static friction	Thermal stability in air (°C)	Particulate formation	Selective to Si	Reference
	Water	Hexadecane						
OTS	110	38	0.012	0.07	225	High	No	[16]
FDTS	115	68	0.005	0.10	400	Very high	No	[17]
DDMS	103	38	0.045	0.28	400	Low	No	[16]
Octadecene	104	35	0.009	0.05	200	Negligible	Yes	[18]
Oxide	0–30	0–20	20	1.1	—	—	—	[16]

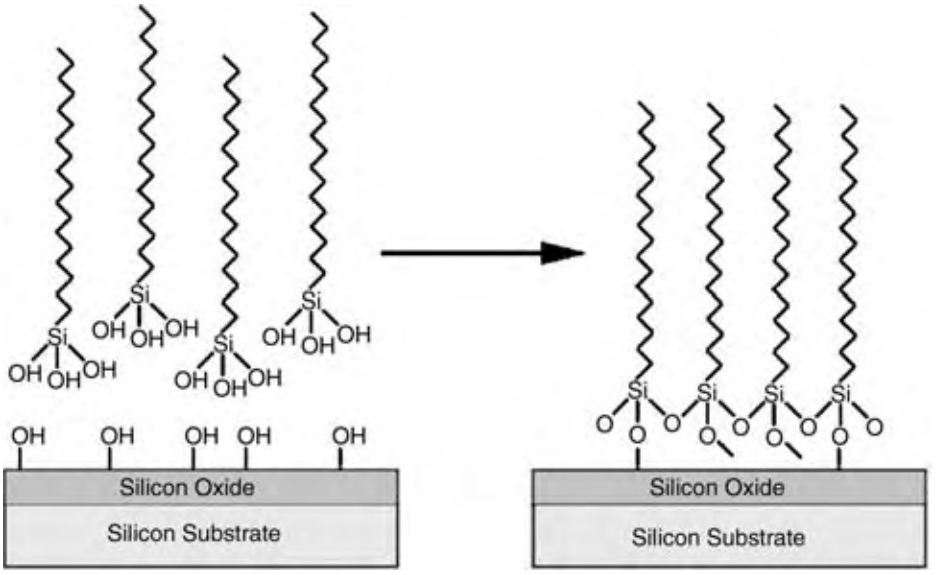

Fig. 5 A simplified diagram of the formation of an OTS monolayer. The first reaction (not shown) is the complete hydrolysis of the OTS molecule, resulting in the formation of 3HCl and the trisilanol form of OTS shown in the figure. Subsequently, water elimination reactions result in Si–O–Si linkages between adjacent OTS molecules and/or the oxidized substrate.

coefficient of static friction data indicate that the DDMS films are not as effective at lubrication as the OTS SAMs are, although both exhibit much improvement over chemical oxide. However, AFM data show that the samples that receive DDMS films accumulate fewer particles during processing than those that get the OTS SAM treatment. The thermal stability of the DDMS film in air far exceeds that of the OTS SAM, as the DDMS remains very hydrophobic to temperatures well upward of 400°C (Fig. 6).

Alkene based monolayers

Another surface modification technique involves the free radical reaction of a primary alkene (e.g., $C_{16}H_{33}CH{=}CH_2$, 1-octadecene) with hydrogen terminated silicon.[23] Fig. 4 shows the structure of 1-octadecene while Fig. 7 displays a simplified diagram of the resulting monolayer structure. This monolayer coating has several key advantages over OTS and FDTS based SAMs:

1. The coating does not produce HCl at any stage in the monolayer formation whereas chlorosilanebased chemistry does.
2. The coating does not require the formation of an intervening oxide layer.
3. The film formation procedure for alkene based monolayers is simpler than for chlorosilane based SAMs for two main reasons. First, the surface oxidation step is eliminated. Second, the coating solution does not need to be conditioned before use, as water is not a reagent in this process.
4. The coating process is much more robust because it is essentially insensitive to relative humidity.

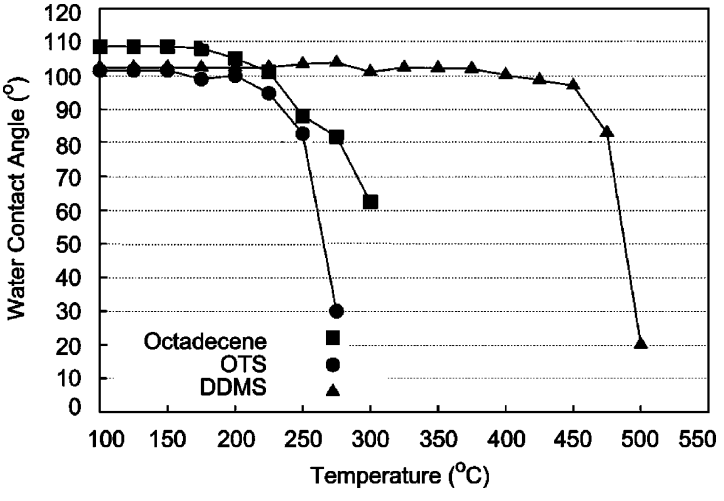

Fig. 6 Water contact angle as a function of substrate temperature. The substrate was exposed to high temperature for 5 min in laboratory air. Note the extreme stability of the DDMS monolayer in comparison to the OTS and octadecene monolayers.

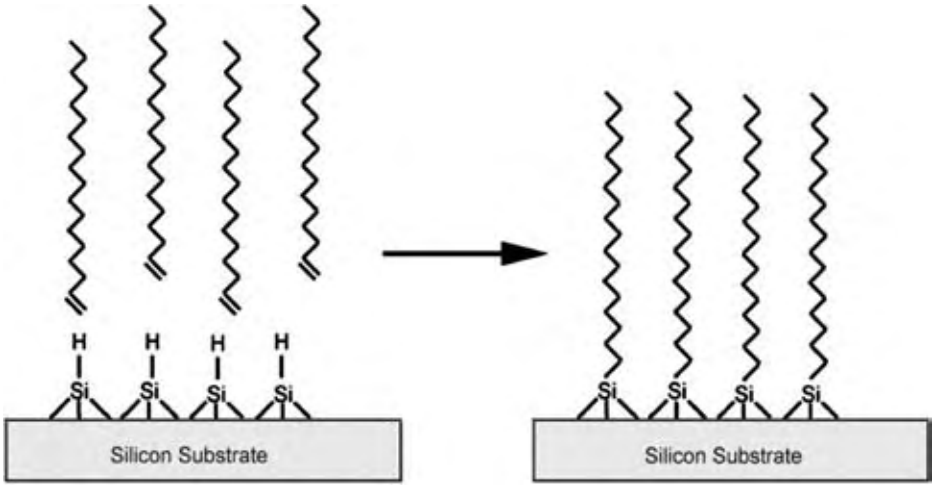

Fig. 7 A simplified diagram of the formation of an octadecene monolayer. The precursor molecule (1-octadecene) is bound directly to the silicon, with no oxide layer.

5. The coated surfaces have much fewer particulates in comparison to those coated with OTS.
6. The coating process can be made selective to coat only exposed silicon by generating radicals using a radical initiator.

These improvements have been achieved without sacrificing the antistiction characteristics of the film, in that water and hexadecane contact angles, apparent work of adhesion, and coefficient of static friction data are found to be similar to those of OTS, (see Table 1).[18]

In some devices, the lubrication properties of a film may be more critical than in others. Fig. 8 shows a complex torque multiplying transmission. In this example, the large number of gears brings the issue of friction and lubrication to the foreground. When the device is in operation, every gear experiences sliding contact at its hub, as well as at every tooth intermeshing location. Initial releases of the device that employed oxidized surfaces were not viable. Attempts at surface modification with OTS were marginally successful, but devices ultimately failed because of the high degree of particle contamination and binding friction on the gear hubs. To date, the only devices of this type to successfully and reliably operate are those that receive octadecene films as part of their release process.

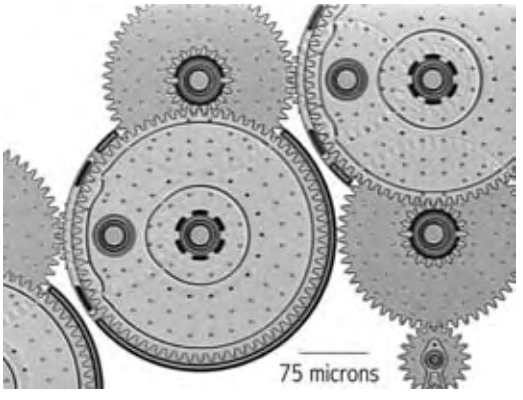

Fig. 8 Micrograph of a complex micromechanical system. Here, there are a large number of sliding contacts (gear hubs and intermeshing gear teeth) that must be properly lubricated for the system to function.

tris-Dimethylaminosilane based monolayers

Another binding chemistry that has been used to successfully attach perfluoroalkyl groups to micromachines surfaces is based on the precursors (tridecafluoro-1,1,2,2,-tetrahydrooctyl)tris-dimethylamino silane (PF8TAS) and (heptadecafluoro-1,1,2,2,-tetrahydrodecyl)tris-dimethylamino silane (PF10TAS).[24] Fig. 4 shows a structural diagram of PF10TAS. These precursors are not commercially available, but can be synthesized from their corresponding trichlorosilanes (FOTS and FDTS, respectively) and dimethylamine. It should be noted that the aminosilane precursors are extremely sensitive to water and must be kept rigorously anhydrous.

The process for applying the aminosilane to micromachines is essentially the same as that used for the chlorosilanes. However, an important distinction is that there is no water vapor added to the chamber during the deposition. Although detailed process parameters are not given, the apparatus used to deposit the aminosilane based monolayers is also similar to that which is used for chlorosilane deposition.[24]

The aminosilane coating PF8TAS has been characterized on Si(100) and on microengines. The AFM analysis on coated Si(100) confirms that the process does not generate particles. Ellipsometry measurements conducted on coated Si(100) in controlled humidity

environment revealed that the PF8TAS films were effective at preventing water sorption.[24]

Thin hard coatings for wear resistance

Although much progress has been made in the area of monolayer films for stiction and friction control, these techniques are not effective at controlling wear. Currently, the mechanism for wear on the micro- and nanoscale is not fully understood, and research has shown that wear in micromachines depends on a number of factors, including several related to the environmental conditions of the device. Although the full details about the mechanism of wear may not be well known, it is generally accepted that one approach to combat the problem of wear is to integrate harder materials at the contacting surfaces. This means that, for silicon structures, materials like diamond, SiC, W, Al_2O_3, or others must be coated on the micromachine surfaces. Of these materials, diamond is the hardest. However, for some applications diamond may not be the best choice as exposure to moderate temperatures in oxidizing ambients can etch diamond. A more chemically inert material with very high hardness is silicon carbide.

Silicon carbide is well known as an attractive material for demanding mechanical and high-temperature applications. Thin SiC coatings share many of the desirable properties of bulk SiC, such as exceptional tribological properties and corrosion resistance. Unfortunately, the conventional method for heteroepitaxial growth of 3C-SiC on Si (based on a dual-precursor CVD) requires high growth temperatures (typically $> 1000°C$).[25] Because released polycrystalline silicon (polysilicon) microstructures cannot withstand such high temperatures without some deformation or warpage, the conventional SiC CVD method cannot be used to coat existing polysilicon devices.

Another CVD process based on the single source precursor 1,3-disilabutane (DSB) has recently been developed.[26] The primary advantage of this method is that the deposition temperature can be much lower than in the conventional CVD method. In fact, the pyrolysis reaction of DSB [shown in Eq. (6) below] can be carried out at temperatures as low as 650°C. However, a deposition temperature of 800°C is chosen for micromachine coatings because it leads to reasonable growth rate, good uniformity, and low film stress.[27] Here, it is demonstrated that this CVD method is suitable for postprocessing of released polysilicon micromachine devices and leads to enhanced reliability and lifetime of microstructures.

$$SiH_3CH_2SiH_2CH_3 \xrightarrow{\Delta} 2SiC + 5H_2 \quad (6)$$

The integration of hard material coatings into the micromachining process scheme is also complicated by the need to coat all surfaces of the device. This requirement leads to deposition processes that occur after the micromachines are fabricated and released. It therefore becomes very important that the coating process be completely uniform and conformal as application of uneven film thickness can alter the stresses on a device and cause it to deform. Recently, much research has focused on atomic layer deposition (ALD) methods. The ALD method is, in principle, capable of depositing perfectly uniform and conformal thin coatings with atomic level control of thickness. Briefly, the method utilizes self-limiting, surface absorption reactions of alternating species to form the desired film one atomic layer at a time (see, e.g., Ref.[28]).

The viability of applying ALD films of Al_2O_3 to released micromachines has been shown.[28,29] It has been indicated that ALD Al_2O_3 films show promise for reduced friction and wear and reduced electrical shorting.[28,29] Another hard material of interest is titania (TiO_2). Owing to its optical, photochemical, and catalytic properties, as well as its biocompatibility and activity in certain sensor applications, TiO_2 has received attention in materials research. TiO_2 is also reported to have low friction and wear, and is chemically stable.[30]

In addition to these methods, the selective deposition of tungsten metal has been explored as an antiwear coating on polysilicon microstructures.[31] This coating is accomplished by heating polysilicon microstructures in a tungsten hexafluoride (WF_6) gas at about 450°C [see Eqs. (7) and (8)]. In this manner, only exposed silicon is coated with W, and the reaction is self-limiting because the deposition of W obscures the underlying Si. W coated micromachines have been shown to exhibit lower wear and improved lifetime vs. uncoated microstructures.[31]

$$2WF_6 + 3Si \xrightarrow{\Delta} 2W + 3SiF_4 \quad (7)$$

$$WF_6 + 3Si \xrightarrow{\Delta} W + 3SiF_2 \quad (8)$$

CONCLUSIONS

Thin film processes and the chemistry of surfaces play important roles in the technological implementation of MEMS and NEMS devices. Thin film deposition of a variety of materials is a mature technology, whereas MEMS surface coating technologies have only recently come of age.

Unlike the commercially employed Si and Al, the development of structural layers that can perform

reliably without further coatings is still in its infancy. Silicon carbide and diamond are emerging as the most promising technologies in this regard.

INTRODUCTION

Thin film science and technology is the deposition and characterization of layered structures, typically less than a micron in thickness, which are tailored from the atomic scale upwards to achieve desired functional properties. Deposition is the synthesis and processing of thin films under controlled conditions of chemical processing. Chemical vapor deposition (CVD) and gas-phase molecular beam epitaxy (MBE) are two processes that allow control of the composition and structure of the films. Characterization is the instrumentation that use electrons, X-ray, and ion beams to probe the properties of the film. Epitaxial films of semiconductors are used for their electronic properties to emit light in the infrared (IR) and the ultraviolet rays.

The remaining work discusses two techniques in thin film analysis, Rutherford backscattering spectrometry (RBS) and X-ray diffractrometry with emphasis on strain measurements. Rutherford backscattering spectrometry is illustrated with analysis of silicide formation as an example of thin film reactions. Silicon–germanium–carbon films serve as an example of strain calculations.

The critical aspect of modern thin film technology is the growth of epitaxial layers.[1] We illustrate the importance of epitaxial growth and strain-engineering in producing light emitting films on silicon substrates.

RUTHERFORD BACKSCATTERING SPECTROMETRY

The characterization of thin film structures is now a well-described laboratory technique.[2,3] Fig. 1 is a schematic representation of sources and detectors used in film analysis. The techniques provide film thickness and composition, lattice structure, and epitaxy and strain.

Rutherford backscattering spectrometry analysis determines how the composition varies as a function of depth and is used to characterize thin films and thin film reactions. During ion-beam analysis, the incident particle (typically a proton or helium ion) penetrates into the thin film and undergoes inelastic collisions, with target electrons, and loses energy as it transverses the sample.

Scattering Kinematics

During the penetration of the helium ions a small fraction undergo elastic collisions with the target atom, which defines the backscattering signal. Fig. 2 shows a schematic representation of the geometry of an elastic collision between a projectile of mass M_1 and energy E_0 with a target atom of mass M_2 initially at rest. After collision, the incident ion is scattered back through an angle ϑ and emerges from the sample with an energy E_1. The target atom after collision has a recoil energy E_2. There is no change in target mass, because nuclear reactions are not involved and energies are nonrelativistic. For $M_1 < M_2$, the ratio of the projectile energies, the kinematic factor (K) is given by the following:

$$\mathrm{K} = \frac{E_1}{E_0} = \left[\frac{(M_2^2 - M_1^2 \sin^2 \vartheta)^{\frac{1}{2}} + M_1 \cos \vartheta}{M_2 + M_1}\right]^2 \quad (1)$$

Eq. (1) shows that the energy of the backscattered particle is a function of the incident particle and target atom masses, the scattering angle, and incident energy.

Fig. 2 Schematic representation of an elastic collision between a particle of mass M_1 and initial energy E_0 and a target atom of mass M_2. After the collision, the projectile and target atoms have energies of E_1 and E_2, respectively.

Scattering Cross-Section

The identity of target elements is established by the energy of the scattered particles after an elastic collision. The number of target atoms is given by measuring the yield Y, the number of backscattered particles for a given value of incident particles Q. The detector's solid angle is given as Ω. The areal density, the number of atoms per unit area, N_S, is determined from the scattering cross-section $\sigma(\vartheta)$ by:

$$N_S = \frac{Y}{\sigma(\vartheta)\Omega Q} \tag{2}$$

This is shown schematically in Fig. 3. A narrow beam of fast particles impinges on a thin uniform target that is wider than the beam. At a scattering angle ϑ from the direction of incidence, an ideal detector is located that counts each particle scattered in the differential solid angle $d\Omega$. In the simplest approximation, the scattering cross section is given by:

$$\sigma(\vartheta) = \left(\frac{Z_1 Z_2 e^2}{4E}\right)^2 \cdot \frac{1}{\sin^4 \frac{\vartheta}{2}} \tag{3}$$

The cross-sections are relatively large, such that one can detect submonolayers of most heavy mass elements on silicon. For example, the yield of 2.0 MeV helium ions from $10^{14}\,cm^{-2}$ silver atoms (approximately 1/10th of a monolayer) is 800 counts for a current of 100 nano-amperes for 15 min and detector area of 5 msr. This represents a large signal for a small amount of atoms on the surface.

Depth Scale

Light ions, such as helium, lose energy through inelastic collision with atomic electrons. In backscattering spectrometry, where the elastic collision takes place at depth t below the surface, there is energy loss along the inward path and on the outward path as shown in Fig. 4. The total is given by the relationship:

$$\Delta E = \Delta t\left(K\frac{dE}{dX}\bigg|_{in} + \frac{1}{\cos\vartheta} \cdot \frac{dE}{dX}\bigg|_{out}\right) = \Delta t[S] \tag{4}$$

where dE/dX is the rate of energy loss with distance and $[S]$ is the energy loss factor. The particle loses

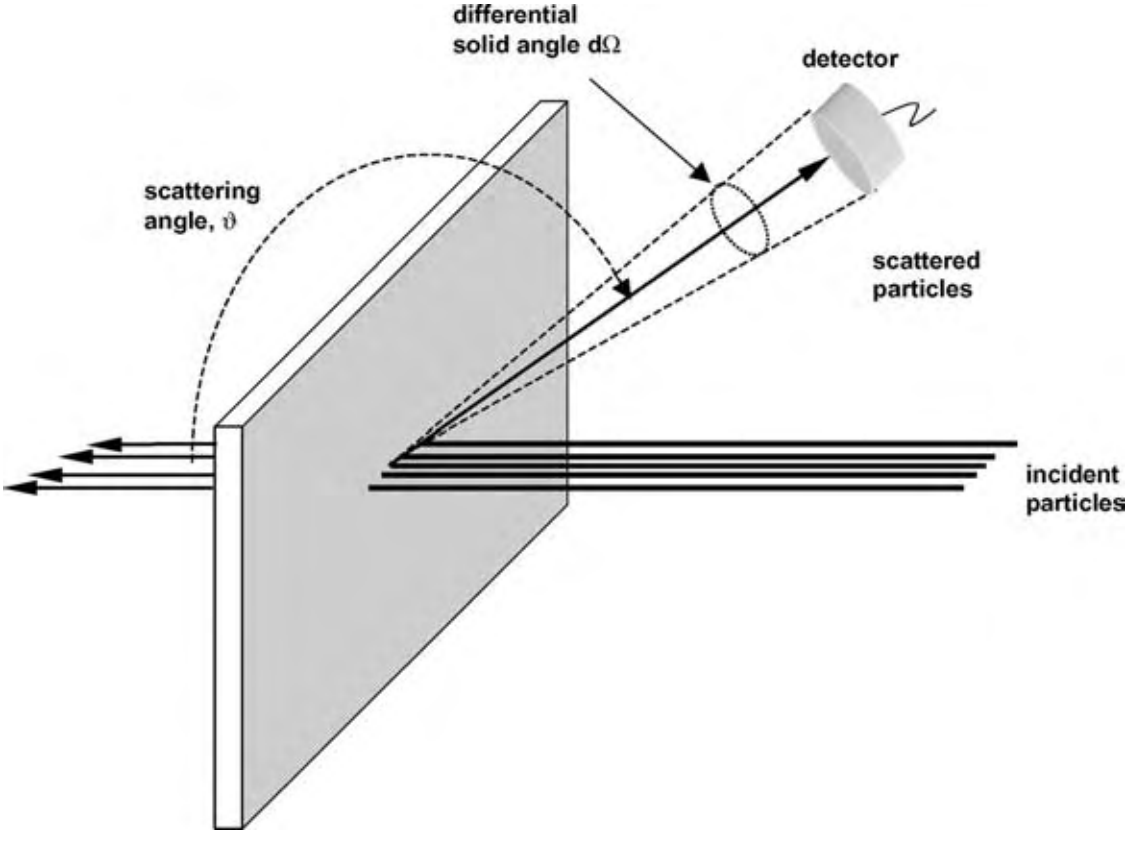

Fig. 3 Schematic of a typical scattering geometry. Only particles that are scattered within the solid angle Ω spanned by the solid-state detector are detected.

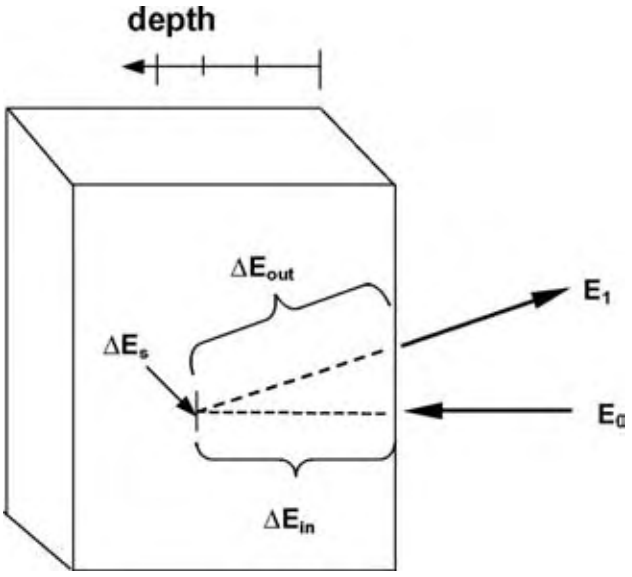

Fig. 4 Energy loss components for a projectile that scatters from depth t. The particle loses energy ΔE_{in} via inelastic collisions with electrons along the inward path. There is energy loss ΔE_s in the elastic scattering process at depth t. There is energy lost to inelastic collisions ΔE_{out} along the outward path. For an incident energy E_0, the energy of the exiting particle is $E_1 = E_0 - \Delta E_{in} - \Delta E_s - \Delta E_{out}$.

energy ΔE_{in} via inelastic collisions with electrons along the inward path. There is energy loss ΔE_s in the elastic scattering process at depth t. There is energy loss due to inelastic collisions ΔE_{out} along the outward path. For an incident energy E_0 the energy of the exiting particle is $E_1 = E_0 - \Delta E_{in} - \Delta E_s - \Delta E_{out}$.

Thin Film Reactions

Heat treatment of deposited thin metal films on Si leads to the formation of silicides. The analysis of these silicide layers is a strong demonstration of the power of Rutherford backscattering thin film technology. The thin metal films react with the Si at temperatures substantially below those indicated in equilibrium phase diagraph. The phase Ni_2Si forms at temperatures around 300°C, where the equilibrium phase diagram shows high temperatures above 800°C for this phase. This is clearly an interface reaction. Rutherford backscattering is a pioneering tool in the silicide formation studies.

We illustrate the analysis of the formation of Ni-silicide in Fig. 5, which plots backscattering yield versus the kinetic energy of the backscattered particles whose incident energy was 2.0 MeV. The solid line is the spectrum from a 200 nm layer of Ni deposited on Si. The thickness is indicated by the width of the energy signal. After heat treatment at 250°C, there is a step in the rear edge of the Ni signal and the forward edge in the Si signal. Analysis of the ratios of the heights of the Ni to Si signals indicates a composition of Ni_2Si. The phase Ni_2Si was confirmed by X-ray diffraction measurements (not shown). Upon further heat treatment, the width of the energy steps increased indicating that the compound has grown in thickness. By measurement of the thickness of the film as function of time and temperature, one can determine the growth mechanism (diffusion limited with $t^{1/2}$ growth rate). Other silicides, such as $CrSi_2$, exhibit limited interfacial interaction (growth proportional to t). One can also implant inert markers of Ar markers into the films and measure the displacement of the markers during heat treatment. If the marker displaces toward the surface, the metal is the moving species. If the marker displaces deeper into the sample, then the silicon is the moving species. Further examples of these studies are given in Tu, Mayer, and Feldman.[1]

ION CHANNELING

When a single-crystal sample is mounted on a goniometer such that a major crystallographic axis of the sample is aligned within approximately 0.1° or 0.5° of the incident beam, the crystal lattice can steer the trajectories of the incident ions penetrating into the crystal. It is this steering of the incident energetic beam that is known as ion channeling; the atomic rows and planes are guides that steer the energetic ions along the channels between rows and planes. The channeled ions do not approach close to the lattice atoms to be backscattered. Hence, the range (the total distance that a ion penetrates a solid) is increased by several fold. The reduced probability of scattering results in a two-orders of magnitude reduction in the yield by an aligned spectrum compared to that when the incident ions are misaligned from the lattice atoms, a random spectrum.

Fig. 6 shows schematically a random and aligned spectrum for MeV helium ions incident on silicon. The characteristic feature of the aligned spectrum is the peak at the high energy end of the spectrum. This peak is a result of ions scattered from the outermost layer of atoms directly exposed to the incident beam. This peak is referred to as the surface peak. Behind the surface peak, at lower energies, the aligned spectra drops to a value of 1/40th of the silicon random spectrum indicating that nearly 97% of the incident ions are channeled and do not make close impact collisions with the lattice atoms. The rise in the aligned spectrum at lower energies represent the ions that are dechanneled, deflected from the steering by the lattice

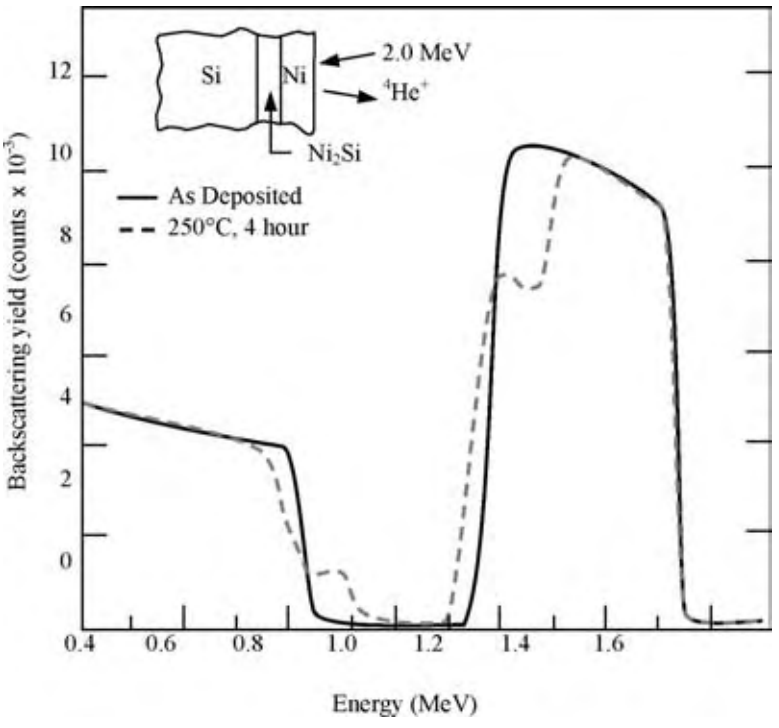

Fig. 5 Rutherford backscattering spectra of a 200-nm Ni thin film on a silicon substrate before and after annealing. *(View this art in color at www.dekker.com.)*

atoms, which can then collide in close impact collisions with the lattice atoms and hence directly contribute to the backscattering spectra. The ratio between the aligned minimum yield and random yield for the same channel number gives the χ_{min} value. The crystalline quality is given by the values of χ_{min} at a specific energy, e.g., it is equal to 0.028 for Si when using 2.0 MeV helium ions.

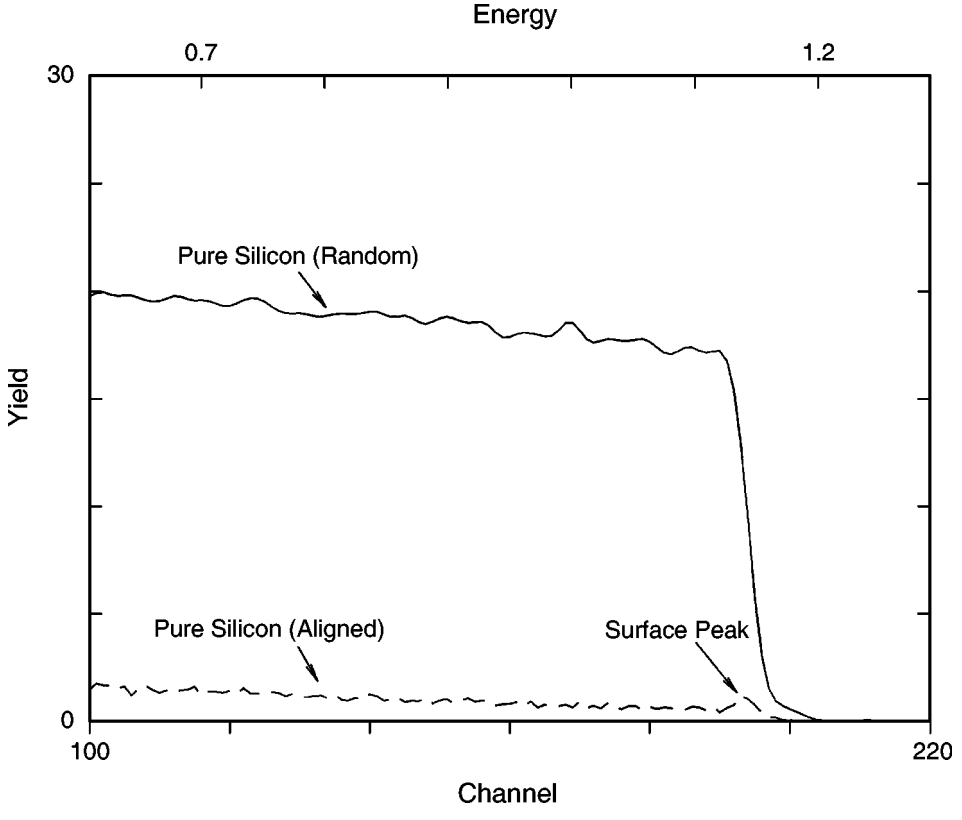

Fig. 6 Random and aligned (channeled) backscattering spectrum from a single crystal. The surface peak corresponds to the small peak at the high energy end of the spectrum signal. The yield behind the peak is reduced because the atoms are shielded from close encounter elastic collisions from the ion beam that is channeled along the axial rows of the crystal.

The application of channeling to RBS is used to determine the amount of damage in ion-implanted single-crystal silicon and the lattice location of ion-implanted dopant atoms. One important example of the contribution of channeling to integrated circuit technology is the analysis of damage evolution during thin film deposition. Modern day ion channeling analysis is done in unison with transmission electron microscopy and/or high resolution X-ray diffraction analysis.

X-RAY DIFFRACTOMETRY

Bragg derived a description for coherent scattering from an array of periodic scattering sites, i.e., atoms in a crystalline solid. The scalar description of diffraction considers the case of monochromatic radiation impinging on two sheets of atoms in the crystal spaced d_{hkl} between reflecting planes. The wavelength λ of the radiation is smaller than the interatomic spacing d_{hkl} of the specific (hkl) planes.

Bragg invoked the Law of Reflectivity (or Reflections) that states that the scattering incident angle and exiting angle must be equal, $\vartheta_{in} = \vartheta_{out}$ under the condition of coherent scattering. The wavelets scattered by the atoms combine to produce constructive inference if the total path difference $2^*\Delta P$ for the reflected waves equals integer (n) multiples of λ:

$$n\lambda = 2^*\Delta P = 2^* d_{hkl} \sin\vartheta \quad (5)$$

Hence, Bragg's Law, $n\lambda = 2d_{hkl}\sin\vartheta$ defines the condition for diffraction.

The typical X-ray spectrum is a plot of intensity verses angle, e.g., 2ϑ. The phase can be indentified by comparing the spectrum to the Powder Diffraction File compiled by the international Center for Diffraction Data, formerly known as Joint Committee on Powder Diffraction Standards.

Strain Measurements

The strain in a layer is determined by comparing the perpendicular and parallel lattice spacings (a) of the film to that of the underlying substrate a_{sub}, determining if they are larger or smaller and by how much. Fig. 7 shows a Si film containing Ge (large circles) on a substrate of Si to illustrate the perpendicular and parallel lattice constant. The film is psedomorphic because the lattice lines up with that of the substrate atoms. These values are expressed as $[\Delta a/a]_\perp$ and $[\Delta a/a]_{||}$, for the difference in the perpendicular and parallel lattice constants, respectively. Since these differences are measured relative to the substrate, the

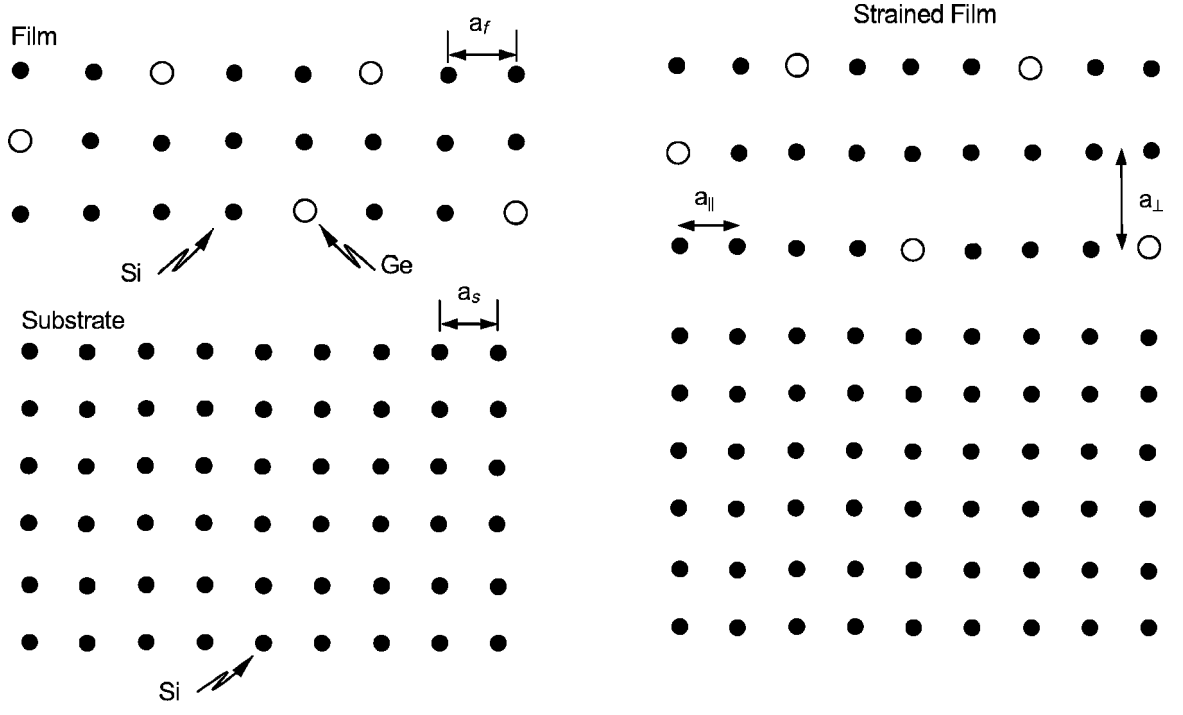

Fig. 7 Schematic of a Si film containing Ge (large circles) on a substrate of Si to illustrate the perpendicular and parallel lattice constant.

substrate lattice spacings must be known. From these parameters, a strain value is calculated by determining the difference in the lattice spacings of the film from its bulk relaxed state.

Silicon–Germanium–Carbon Films on Silicon

The application of X-ray diffraction in thin film samples is illustrated by diffraction measurement of epitaxial layers of Si–Ge–C on silicon. Initially, a scan is taken about a plane parallel to the surface; this is called a symmetrical scan, since ϑ_{in} and ϑ_{out} are identical. In Fig. 8, the Si substrate has an (0 0 1) orientation and the first allowed reflection that is parallel to the surface is the (0 0 4) reflection. The symmetrical scan in this case provides information about the perpendicular spacing ($a_\perp$) between the places. To obtain information about both $a_\perp$ and parallel spacing ($a_{||}$), an asymmetrical scan is taken. This involves scanning a plane that is not parallel to the surface. In Si this is typically the $(2\,2\,\bar{4})$ and (2 2 4) reflection as shown in Fig. 9. In one case the spectrum is a glancing incidence (2 2 4) reflection and the other is a $(2\,2\,\bar{4})$ glancing exiting reflection. In each of these scans, note the existence of a peak from the Si substrate and from the Si–Ge–C film. Satellite peaks above and below the primary reflection are due to thickness interference fringes. In strain calculations, the substrate is assumed to be unstrained and hence all measurements are made relative to the substrate's lattice constant.

Calculation of Strain

The perpendicular and parallel lattice constants are calculated by first measuring the angular peak separation from glancing incident {2 2 4} reflections, ω_1, and the glancing exit $(\bar{2}\,\bar{2}\,4)$ reflections, ω_2. The deviation of the Bragg angle between the substrate and layer, $\Delta\vartheta$, is calculated from

$$\Delta\vartheta = 0.5(\omega_1 - \omega_2) \tag{6}$$

Due to tetragonal distortion in the epitaxial layer, the angle between the (2 2 4) planes and the surface in the substrate will not be the same as this angle in the film. This difference, $\Delta\psi$ was calculated from:

$$\Delta\psi = 0.5(\omega_1 - \omega_2) \tag{7}$$

The perpendicular lattice constant of the film is calculated by

$$[\Delta a/a]_\perp = \Delta\vartheta \cot(\vartheta_B) + \Delta\psi \tan(\psi) \tag{8}$$

where ϑ_B is the Bragg angle for the reflection measured and ψ is the angle between the (2 2 4) planes and the surface. Both angles refer to the substrate. The parallel lattice constant of the film is calculated from:

$$[\Delta a/a]_{||} = -\Delta\vartheta \cot(\vartheta_B) - \Delta\psi \cot(\psi) \tag{9}$$

Negative values for $[\Delta a/a]_\perp$ and $[\Delta a/a]_{||}$ indicate that the dimension in the film is larger than that of the substrate. When the perpendicular lattice constant

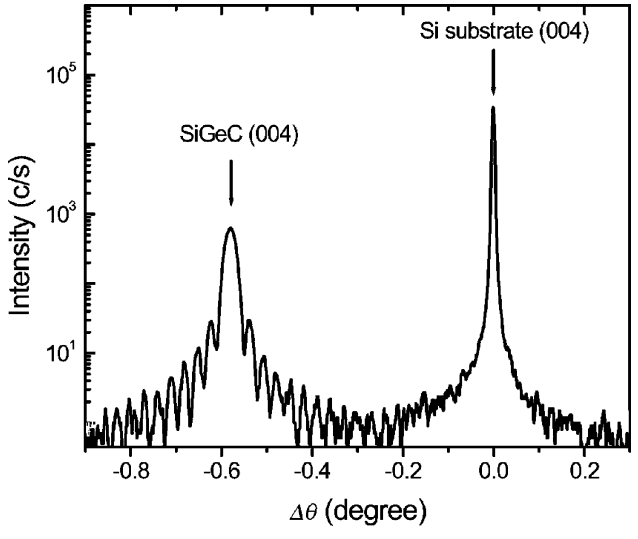

Fig. 8 Rocking curve XRD of an epitaxial layers of Si–Ge–C layers on silicon. The symmetrical scan is of the first allowed reflection that is parallel to the surface, i.e., the (0 0 4) reflection. Note the existence of a peak from the Si substrate and from the Si–Ge–C film.

for a pseudomorphic film is larger than the substrate, the film has a larger unit cell and is in compression for $[\Delta a/a]_{\perp} = 0.016638$ and $[\Delta a/a]_{||} = 0.016618$.

GROWTH OF THIN FILMS BASED ON Si–Ge–Sn SYSTEM BY CVD AND GAS PHASE MBE

Silicon is the most desirable substrate for the growth of semiconductor materials. Virtually defect-free Si wafers are available at low cost, and the range of applications of any semiconductor grown on Si can be enhanced by integration with silicon-based microelectronics. The growth of $Si_{1-x}Ge_x$ films on Si(1 0 0) has been the subject of intensive studies over the past two decades owing to their many important applications in high speed microelectronic devices.[4–7] A number of different methods have been used for the heteroepitaxial growth of $Si_{1-x}Ge_x/Si$, but the two most commonly employed techniques are molecular beam epitaxy utilizing solid Si and Ge, and ultrahigh vacuum chemical vapor deposition (UHV-CVD) or gas-source molecular beam epitaxy (GSMBE) utilizing SiH_4 and GeH_4 or Si_2H_6 and Ge_2H_6. There are two ultimate, but also diverse, objectives in the growth of $Si_{1-x}Ge_x/Si$. The first is the achievement of defect-free $Si_{1-x}Ge_x$ layers, which may take the form of strained layer superlattices, while the second is the growth of self-assembled coherent $Si_{1-x}Ge_x$ islands or quantum dots.

It has been known for many years—on theoretical grounds—that the Si–Ge–Sn alloy system should have very interesting properties, especially as high efficiency IR devices. This has stimulated intense experimental efforts to grow such compounds, but for many years the resulting material quality has been incompatible with device applications. Recently, we have achieved growth of device quality Sn–Ge and Si–Ge–Sn films using novel CVD methods. This is an important development for several reasons. First, Sn_xGe_{1-x} alloys have been predicted to undergo a transition from indirect to direct gap semiconductors so that this material may lead to the first direct-gap semiconductor fully integrated with Si technology.[7–9] Second, device-quality Sn_xGe_{1-x} layers of arbitrary thickness can be deposited directly on Si and these can be used as ''virtual substrates'' for the growth of $Ge_{1-x-y}Si_xSn_y$ ternary analogs. The fabrication of $Ge_{1-x-y}Si_xSn_y$ makes it possible to decouple strain and band gap engineering to achieve unique systems cover a wide range of operating wavelengths in the IR and new device structures that lead to novel photonic devices based entirely on group IV materials.[10]

In the following sections, we present the fabrication and discuss properties of device quality, strain-free Sn_xGe_{1-x} films, as well as strained engineered $Ge_{1-x-y}Si_xSn_y$ layers grown over time directly on Si wafers. We also describe synthesis of films and nanometer-scale islands of $Si_{1-x}Ge_x$ grown on Si(1 0 0) substrates via a unique single-source molecular precursor method. This new approach allows precise control of concentration and structure at the atomic level and it is particularly useful for development of compositionally homogeneous and uniform assemblies of nanoscale structures.

Growth of Si–Ge–Sn on Si for Strain-Balanced Heterostructures Via CVD

The binary Sn_xGe_{1-x} alloys are grown by a specially developed CVD method.[11–17] The combination of SnD_4 with high-purity H_2 (15–20% by volume) remains remarkably stable at 22°C for extended time periods. This formulation provides the simplest possible CVD source of Sn atoms for the growth of novel Sn–Ge systems. Depositions were conducted in a custom-built ultra-high-vacuum CVD reactor on Si(0 0 1) wafers. Growth temperatures between 250° and 350° produced thick films (50–500 nm) with Sn concentrations up to 20%, as measured by Rutherford backscattering. Fig. 10 shows a comparison between random and aligned RBS spectra for a $Sn_{0.02}Ge_{0.98}$ sample and a $Sn_{0.12}Ge_{0.88}$ sample. The ratio χ_{min} between the aligned and random peak heights is 4% in the $x = 0.02$ sample and about 30% in the $x = 0.12$ sample for both Ge and Sn. This provides proof that Sn occupies substitutional sites in the average diamond structure. The $\chi_{min} = 4\%$ value closely approaches the practical limit of about 3% for structurally perfect Si, which is unprecedented for a binary crystal grown directly on Si. The microstructural properties of the films were investigated by XTEM. Electron micrographs demonstrating nearly defect-free growth of $Sn_{0.06}Ge_{0.94}$ are shown in Fig. 11. The images show that the predominant defects accommodating the large misfit between the alloys and the Si substrate are Lomer edge dislocations at the interface with no dislocation cores propagating to the film surface. These are parallel to the interface plane and do not degrade the film quality. The surfaces of the films are very smooth, continuous, and atomically flat. Electron diffraction and high-resolution X-ray studies (including rocking curves and reciprocal space maps) show a monotonically increasing average lattice constant as a function of the Sn-concentration, with no evidence for a significant tetragonal distortion or strain. The full width at half maximum of the X-ray peaks range from 0.25 to 0.50° indicating tightly aligned crystal mosaics. Reciprocal space maps of the (0 0 4) reflection show that there is no epilayer tilt between the Si and the GeSn (0 0 4) Bragg planes. Comparisons of the (2 2 4) grazing incidence and

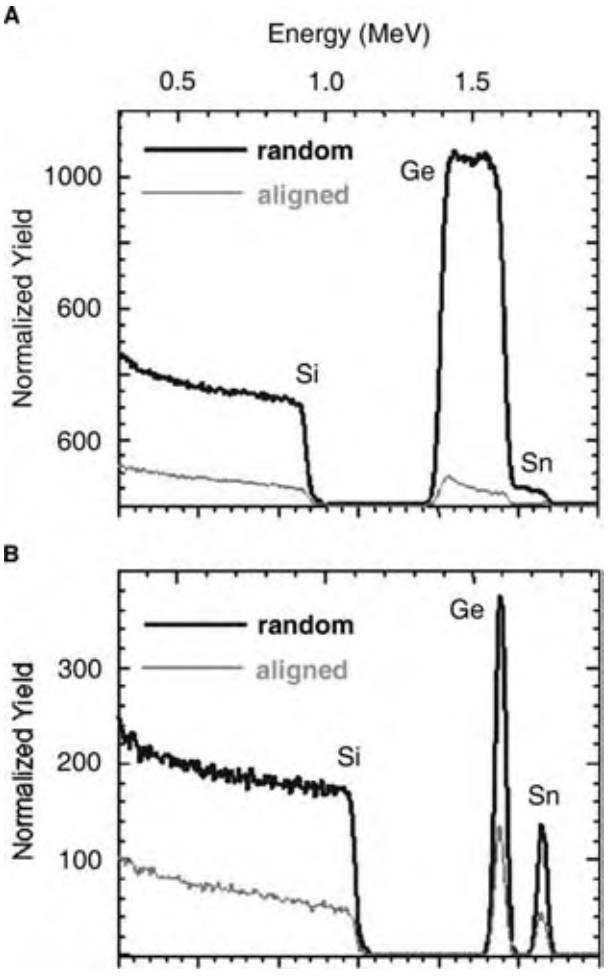

Fig. 10 (A) RBS aligned and random spectra of $Ge_{0.98}Sn_{0.02}$ with near perfect crystallinity. Channeling of Sn and Ge approaches the theoretical limit of pure Si. (B) Aligned and random spectra for $Ge_{0.88}Sn_{0.12}$ show the same χ_{min} for both Ge and Sn indicating that the entire Sn content is substitutional. (From Ref.[11].)

grazing exit $\omega/2\theta$ scans, show that the GeSn layers are 100 relaxed and this is confirmed with reciprocal space maps of the (0 0 4) peak and the off axis and (2 2 4) reflection. Specular X-ray reflectivity scans (reflectivity vs. sample angle ω) were obtained to characterize the density and layer thickness and determine the average roughness of the substrate film interface. The data for samples with 5% Sn content are shown by the curve in Fig. 12. Note that the reflectivity drops off steeply at 1100 sec, yielding the density of the Ge–Sn layer to be 5.32 g/cm^3,which is close to Ge. The fringes indicate that the thickness of the Ge–Sn layer is 57.8 nm, which is virtually identical to the RBS value of 58 nm. The fringes are reduced in amplitude at larger angles and disappear at about 6000 sec due to minor surface roughness. The best fit shows a roughness thickness for the substrate Si and the Ge–Sn layer to be 1.2 nm and 0.8 nm, respectively. The presence of a thin oxide layer on the film surface reduces the amplitude of the reflectivity at larger sample angles.

The ternary $Ge_{1-x-y}Sn_xSi_y$ are grown on Si (1 0 0) via $Ge_{1-x}Sn_x$ alloy buffer layers.[18,19] The depositions are carried out via ultra-high-vacuum chemical vapor deposition of unimolecular hydrides with direct Si–Ge bonds [SiH_3GeH_3, $Si(GeH_3)_4$, $(GeH_3)_2SiH_2$] with SnD_4. The crystal structure, elemental distribution, and morphological and bonding properties of the $Ge_{1-x-y}Sn_xSi_y$/$Ge_{1-x}Sn_x$ heterostructures are characterized by high-resolution TEM, including electron energy loss nanospectroscopy, high resolution X-ray diffraction, AFM and Raman. These techniques demonstrate growth of perfectly epitaxial, uniform, and highly aligned layers with atomically smooth surfaces and monocrystalline structures. The Raman spectral shifts are consistent with lattice expansion produced by the Sn incorporation into Si–Ge tetrahedral sites. The films possess a variable and controllable range of compositions (10–20% Si, 60–85% Ge, and 1–15% Sn), and exhibit lattice constants above and below that of bulk. A material with a tunable lattice constant above and below that of Ge is synthesized directly onto Si substrates. Representative RBS spectra and high-resolution TEM micrographs are shown in Fig. 13. The data are obtained from a sample with concentrations $Si_{0.20}Ge_{0.72}Sn_{0.08}$ grown on Si(1 0 0) via a $Ge_{0.98}Sn_{0.02}$

buffer layer at 320°C. The high degree of RBS He ion channeling indicates aligned, single-phase material in which the constituent elements in the heterostructure occupy random substitutional sites in the same average diamond cubic lattice. Note that the extent of channeling is identical for Si, Ge, and Sn indicating substitutionality of the elements in both the Ge–Sn buffer layer and the Si–Ge–Sn film of the sample. Fig. 13 shows a dark field image of the entire $Si_{0.20}Ge_{0.72}Sn_{0.08}/Ge_{0.98}Sn_{0.02}/Si$ heterostructure indicating highly uniform layers free from threading defects. High-resolution micrographs of the $Si_{0.20}Ge_{0.72}Sn_{0.08}/Ge_{0.98}Sn_{0.02}/Si(1\,0\,0)$ interfaces show highly commensurate microstructures. The $Si_{0.20}Ge_{0.72}Sn_{0.08}$ and $Ge_{0.98}Sn_{0.02}$ layers are nearly lattice matched and their interface is virtually defect-free as shown Fig. 13D. The large lattice mismatch between $Ge_{0.98}Sn_{0.02}$ and Si(1 0 0) is accommodated by periodic edge dislocations located at the interface as shown in Fig. 13C.

The strain properties of these materials have been investigated by high resolution XRD. Studies involving samples that span a wide range of concentrations show fully strained (tensile and compressively strained), as well as relaxed Si–Ge–Sn films are obtained on strain-free Ge–Sn buffer layers. These results show that strain engineering can be achieved in Si–Ge–Sn heterostructures and multilayers by tuning the lattice parameter of the Ge–Sn buffer layer.

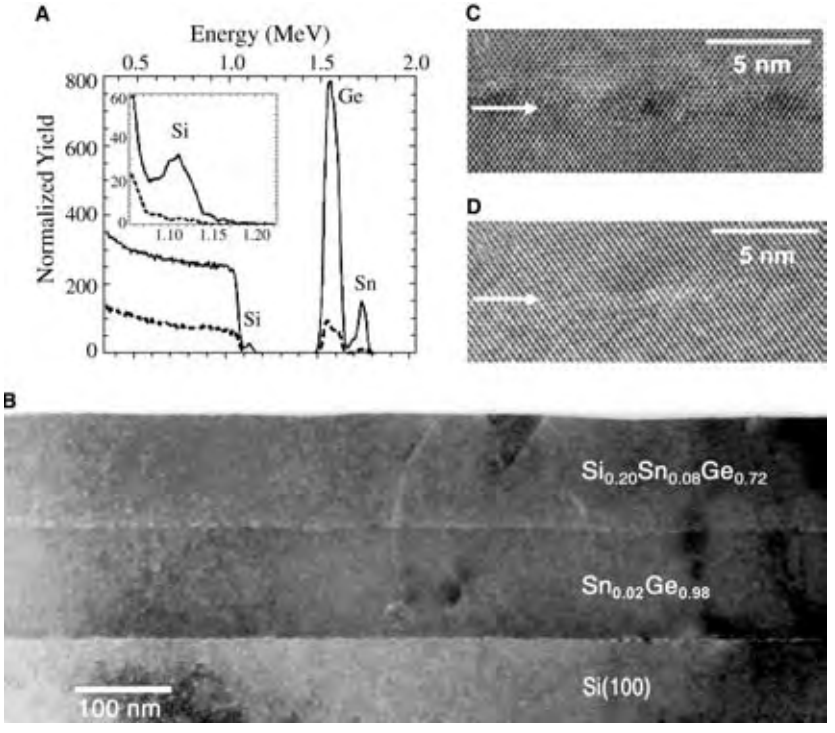

Fig. 13 RBS aligned and random spectra of $Si_{0.20}Sn_{0.08}Ge_{0.72}$ epilayer and $Sn_{0.02}Ge_{0.98}$ buffer layer showing a highly aligned heterostructure. Inset: (A) magnified view of the Si peak indicating complete substitutionality of Si in the Sn–Ge lattice; (B) XTEM of the entire heterostructure; (C) $Si/Sn_{0.02}Ge_{0.98}$ interface (indicated by arrow); and (D) $Si_{0.20}Sn_{0.08}Ge_{0.72}/Sn_{0.02}Ge_{0.98}$ interface. (From Ref.[19].)

A host of novel strained engineered optical and electronic devices have been designed based on this concept and are currently being fabricated and tested. It is interesting to note that the strain is reliably robust up to at least 400–500°C (400°C is the growth temperature of the films).

Growth of SiGe and Si_4Ge Epitaxial Materials by Gas Phase MBE of H_3SiGeH_3 and $Ge(SiH_3)_4$

Growth of $Si_{1-x}Ge_x$ films and nanometer scale islands has been demonstrated by using single source molecular hydrides containing direct Si–Ge bonds.[20] The growth process occurs via single source GSMBE directly on Si(1 0 0) and the concentration x of the film is predetermined by tailoring the composition of the molecular precursor. The technique was demonstrated by growing $Si_{0.5}Ge_{0.5}$ and $Si_{0.8}Ge_{0.2}$ epitaxial films and coherent islands on Si(1 0 0) via thermal dehydrogenation of H_3SiGeH_3 and $Ge(SiH_3)_4$, respectively, between 475 and 700°C. Note that the entire content of Si and Ge of the precursors is incorporated in the film. The major advantages of using single molecular sources with preformed Si–Ge bonds for the MBE growth of $Si_{1-x}Ge_x$ lie not only in the a priori control over the composition, but also the film morphology can be controlled by the adjustment of a single kinetic parameter, i.e., the flux rate of the precursor, at a given temperature.

The growth of the $Si_{0.5}Ge_{0.5}$ and $Si_{0.8}Ge_{0.2}$ films on Si(1 0 0) substrates is conducted in the sample chamber of a low-energy electron microscope (LEEM) where in situ observation of the GSMBE growth process takes place in real time. Fig. 14 shows a sequence of frame-captured LEEM video images over a field of view of 8 μm of $Si_{0.5}Ge_{0.5}$ growth on Si(100)-(2x1) at 550°C using H_3Si-GeH_3. The images were taken with the ($^1/_2$, 0) diffraction beam such that the (2 × 1) and (1 × 2) terraces separated by single-height atomic steps alternate in contrast from dark to bright due to the rotation of the dimer reconstruction across a step. The last LEEM frame taken at 46 min showing island formation was a bright-field image acquired using the (0, 0) beam. In Fig. 14, contrast reversal in the (2 × 1) and (1 × 2) terraces was observed during the time lapse from 0 to 190 sec as growth of $Si_{0.5}Ge_{0.5}$ proceeded. Such contrast reversal is indicative of layer-by-layer growth. The growth of a full $Si_{0.5}Ge_{0.5}$ monolayer (ML) is completed every 30 sec. The layer-by-layer growth continued after the completion of 6 ML, after which the LEEM contrast of the surface became very diffuse. The loss of contrast was due to new layers growing on top of incomplete layers, and this kind of growth results in a rough surface even though the domains are two-dimensional.

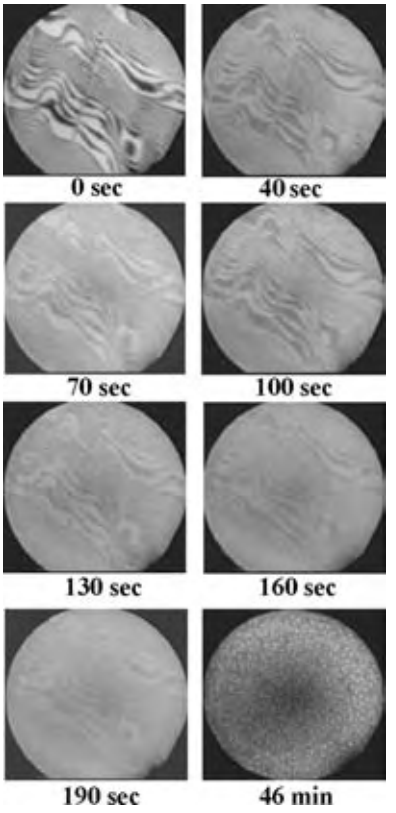

Fig. 14 Frame-captured LEEM video images showing Stranski–Krastanov growth of $Si_{0.5}Ge_{0.5}$. The elapsed time during growth is indicated under each frame. Approximate Si–Ge coverage for each frame: 0 ML at 0 sec; 1 ML at 40 sec; 2 ML at 70 sec; 3 ML at 100 sec; 4 ML at 130 sec; 5 ML at 160 sec; 6 ML at 190 sec; and 3D islands at 46 min. Field of view is 8 μm. (From Ref.[20].)

Three-dimensional (3D) islands began to appear after about 18 min of growth. The last frame shown in Fig. 14 is a bright-field LEEM image taken after 46 min of growth with the 3D islands appearing as bright spots. The LEEM results indicate that the growth mode of the $Si_{0.5}Ge_{0.5}$ is Stranski–Krastanov. AFM images show that the $Si_{0.5}Ge_{0.5}$ islands are primarily large dome-shaped structures. The dome shape of the islands with (1 1 3) and (15 3 23) facets is clearly demonstrated in the XTEM images, which also show that the islands are completely coherent. Similar islands, grown at 600 and at 700°C are also found to be completely coherent demonstrating the fact that the single source approach is capable of producing large coherently strained dome-shaped islands at a wide range of conditions.

Growth of $Si_{0.8}Ge_{0.2}$ films on Si(1 0 0) was conducted using the $Ge(SiH_3)_4$ gaseous precursor. In situ real-time LEEM observations indicated that the Stranski–Krastanov growth mode was also in operation in this case. AFM and XTEM images of films

grown at 500°C indicate growth of completely coherent islands with uniform size and spatial distribution. The images of films gown at 600 and 700°C show that large (200 and 400 nm) faceted dome-shaped islands are produced at both temperatures. These are both strain-free and dislocated. Selected area electron diffraction patterns show a lattice constant of 0.548 ± 0.001 nm, very close to the ideal 0.5476 nm for $Si_{0.8}Ge_{0.2}$. High spatial resolution electron energy loss spectroscopy (EELS) used to verify that the composition of the $Si_{1-x}Ge_x$ films indeed reflects the stoichiometry of the unimolecular precursor used for growth. Typical EELS composition line-scans across the interface from the substrate to the island using a electron beam with 1 nm diameter are given in Fig. 15. The EELS composition profile of a $Si_{0.5}Ge_{0.5}$ island grown at 700°C in Fig. 15 shows an almost constant 50% Ge within the island. Similarly, the EELS composition profile of a $Si_{0.8}Ge_{0.2}$ island shows a nearly constant 20% Ge. No segregation of Ge is observed in any of our EELS composition profiles of the islands.

The single-source MBE method growth of $Si_{1-x}Ge_x$ films permit control of composition x at the atomic level via the design of the single-source gaseous precursor containing precise atomic arrangements with direct Si–Ge bonds. Uniform composition reflecting the stoichiometry of the precursor is observed in all cases without any segregation of either Ge or Si. The growth of $Si_{1-x}Ge_x$ films proceeds via the Stranski–Krastanov growth mode. Morphological control of the size and shape of the islands is achieved by simple adjustments of the flux rate of the precursor and the growth temperature.

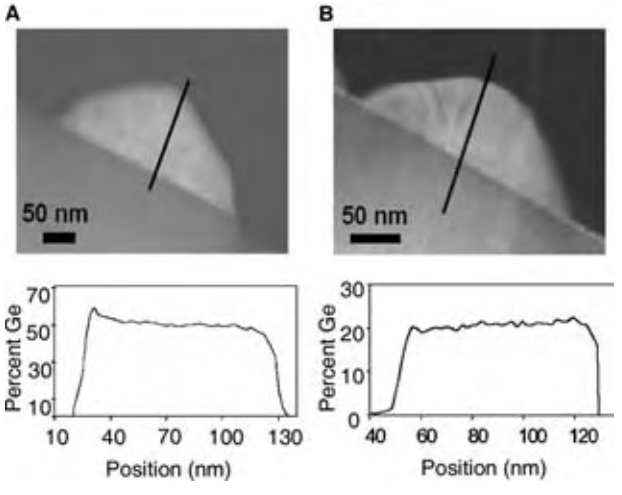

Fig. 15 Ge composition line scans determined by high-resolution EELS on (A) a $Si_{0.5}Ge_{0.5}$ island grown at 700°C, and (B) a $Si_{0.8}Ge_{0.2}$ island grown at 500°C. The profiles shown below each XTEM image correspond to the line across the substrate/island interface. Scan direction is from the substrate to the vacuum. (From Ref.[20].)

CONCLUSIONS

Thin film science and technology is a dynamic field. Illustrated by growth of thin films for silicon technology for optical and high speed microelectronics devices. Accepted technology is readily available. The key is control of the composition and structure of thin films and islands fully integrated with Si technology. The Ge–Si–Sn system makes it possible to decouple strain and ban-gap engineering to each achieve unique photonic devices.

In this work, the focus has been based entirely on group IV materials. This excitement can also be realized in photonic and high speed microelectronics. Growth methods and analysis are also readily available.

INTRODUCTION

Nano-films play a vital role in all aspects of human existence. This encompasses the spectrum extending from biological systems to small and large-scale electromechanical devices. Cell membranes encapsulate cells, while a film of tears lubricates eye movement. Grease lubricates the automobile wheel bearings by gradually releasing a thin film of oil into the ball-race interface. Due to the pervasiveness of nano-films in our life, many aspects of their physics and chemistry are being revealed through increasingly sophisticated methods of scientific investigation.

This entry focuses on the state-of-the-art in two related aspects of liquid nano-film physics, spreading and dewetting. The solid/thin liquid film system must be designed to either dewet and evaporate, as with water on automotive car finish, or to wet and spread as in well-designed lubrication systems. For example, when molecularly thin liquid films are employed to lubricate gears in a micro-electromechanical system, or in the head (slider) disk interface of a hard disk drive, certain properties are essential for them to function without an oil change for many years of continuous operation. These devices cannot be flooded with lubricant, or the small parts stick together. Lubricant must flow to where it is needed in asperity contacts by spreading, while at the same time the viscosity must be high enough to provide boundary lubrication and to avoid evaporation and spattering by dewetting or spin-off from the rapidly moving parts. This is especially true for open systems such as a hard disk drive. The lubricant spreads and the vapor pressure is suppressed by energetically favorable interaction with the surfaces, so there is little or even no evaporation at elevated temperature.

Here, we employ examples primarily from the magnetic recording industry to show how the physics of nano-films is derived from the properties of bulk liquids through the thermodynamics of interaction with the solid surface. The nano-film spreading rate is derived from the film thickness dependence of the surface energy. The nano-film viscosity is related to the nano-film vapor pressure, both of which increase due to dispersion force in the limit of molecularly thin film. Vapor pressure and evaporation are related to dewetting and capillary wave roughness through the surface energy for a typical perfluoropolyether (PFPE) lubricant Zdol which has a polar hydroxyl group on each end of the chain. Finally, the thermodynamic model is tied together by a description of the contemporary molecular dynamics (MD) and Monte Carlo (MC) simulation which graphically elucidates images of the chain conformation.

BACKGROUND AND MATERIALS

A fundamental understanding of the spreading behavior of the liquid film is required for the proper design of a number of engineering systems. Micro/nanoscopic spreading behavior is quite different from macroscopic behavior due to the difference in the driving forces between these two cases. Forces, such as surface tension gradient and gravity, drive spreading in macroscopic films.[1] However, a disjoining pressure gradient is the driving force for spreading in thin liquid films that have a thickness on the order of nanometer.[2] Although the spreading of liquid films on solid surfaces in the macroscopic regime has been studied extensively, the spreading phenomenon in thin films remains to be clearly understood and is the subject of this entry.

Nanoscale confined liquids are an important subject due to their ubiquitous nature and future industrial applications. The functionalities of polymer chain and solid surfaces, for example, are key control factors in determining the material design of lubricant used in nanotribology. Materials having constituents with dimensions on the nanometer scale behave remarkably different than when in bulk state, which has led to a new paradigm we now refer to as nanotechnology. Due to broad technological interests, numerous studies on nanoscale confined liquids have been investigated, both theoretically and experimentally, by scientists and engineers from a variety of backgrounds, including data storage, semiconductor devices, catalysis, polymer engineering and science, tribology, robotics, and medicine.[3]

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008083

The spreading behavior of small drops of polydimethylsiloxane (PDMS) on silica surfaces has been studied by many investigators including Cazabat et al.[4] Novotny[5] investigated the spreading of polyperfluoropropylene oxides on silica surfaces using scanning microellipsometry (SME) and scanning photoemission spectroscopy. The results revealed that the surface diffusion coefficient increases as the film thickness decreases down to 1 nm and remained constant below that thickness. The spreading characteristics of PFPEs have been investigated using SME equipped with temperature and humidity controls. They studied the effects of initial film thickness, end-group functionality, and molecular weight on silica surfaces[6,7] and on amorphous carbon surfaces.[8,9]

Molecularly thin PFPE films are mainly referred to in this entry which examines and illustrates the essence of the thin liquid film, especially the role of molecule-surface coupling. In particular, two examples of these materials are the commercially available Fomblin® PFPE Z and Zdol random copolymers with the linear backbone chain structure

$$X\text{—}[(OCF_2CF_2)_p\text{—}(OCF_2)_q]\text{—}O\text{—}X\ (p/q \cong 2/3)$$

where X (the ends-group) is CF_3 in PFPE Z, CF_2CH_2OH in Zdol (Fig. 1A). Notice that Zdol has a hydroxyl group at the end of the chain, which exhibits moderate interactions with solid surfaces.

EXPERIMENTATION AND MESOSCOPIC ANALYSIS

In this section, experiments on spreading properties using SME for various PFPE/solid surface pairs are discussed. The rheological characterization of PFPEs is also given. Further interrelationships among SME spreading profiles, rheology, surface energy or disjoining pressure, and dewetting, as well as a qualitative interpretation based on mesoscopic thermodynamics and transport phenomena, are provided.

Scanning Microellipsometry

To demonstrate the essence of the spreading phenomena, we invoke the ''thought experiments'' for different lubricant/surface and lubricant/lubricant interactions, which are shown in Fig. 1B.

In the experiments of O'Connor et al.,[7] monodisperse PFPE Z and Zdol, which were fractionated via supercritical fluid extraction in CO_2, were dip-coated onto the surface of silicon wafers as shown in Fig. 2A. Film thickness was controlled by altering the PFPE concentration and draw rate. An SME apparatus (Fig. 2B) was used to measure the thickness of the film as it spread with time. The coated wafer was placed on a pedestal-like plate housed in an environmental chamber with slits for passage of the incident and reflected beams. The chamber was mounted on a stage, which translated the sample across the beam area, and the thickness profiles were measured in the controlled temperature and humidity environment. The spreading profile obtained from SME strongly depended on the PFPE molecule–surface interactions, and provided a fingerprint for each pairing.

Typical SME thickness profiles for monodisperse Z and Zdol, as examined by O'Connor et al.,[6,7] are shown in Figs. 3A and B. As the film spreads with time, the spreading front travels along the surface of the silicon wafers. The sharp ''spike'' for the PFPE Z profile in Figs. 3A was observed to decay over time. The ''spike'' at the step did not affect the spreading rate, and could be avoided by eliminating free surface vibrations and decreasing the solvent evaporation rate by dip-coating with the solution in the bottom of a tall and thin container. The spreading of PFPE Zdol exhibits a characteristic layering structure or shoulder with a height on the order of the radius of gyration for the PFPE molecules and the separation of PFPE molecules from the initial film layer at a sharp boundary. Thicker films of Zdol appear

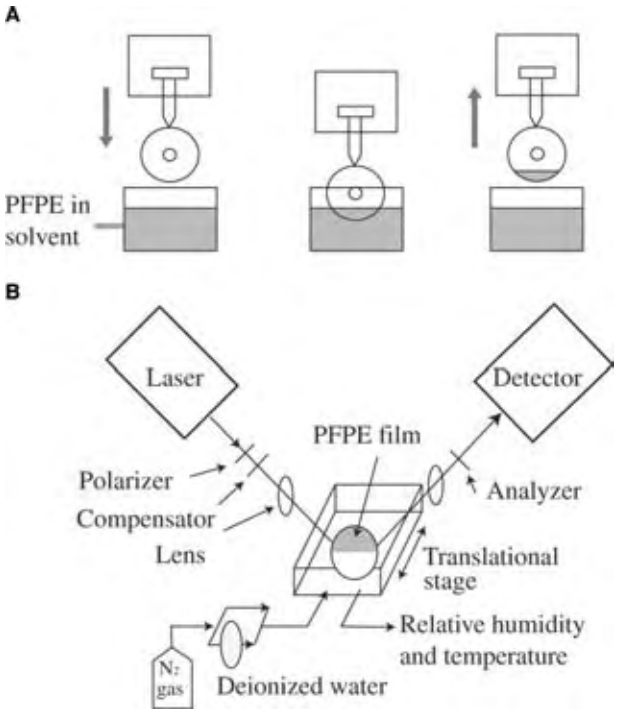

Fig. 2 (A) Partially dip-coating a disk in a PFPE solution and (B) schematic of the SME apparatus. The PFPE film is shaded. *(View this art in color at www.dekker.com.)*

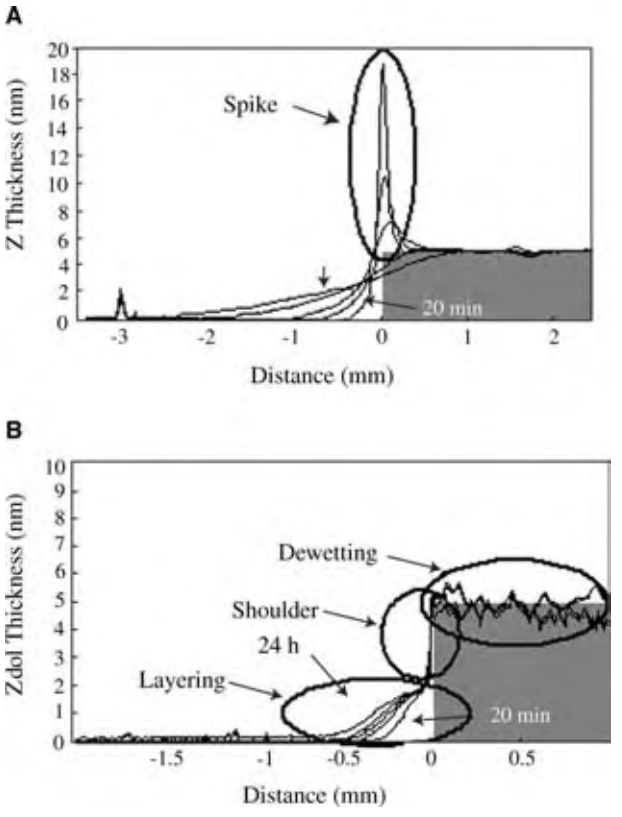

Fig. 3 SME spreading profiles for PFPE on silicon wafers: (A) Z (M_w = 13,800 g/mol) and (B) Zdol (M_w = 3100 g/mol). Both have the initial thickness of 5 nm for times of 20 min, 1.5, 3, 12, and 24 h at 26°C.

to experience partial "dewetting" as indicated by the rough appearance in the SME scan (Fig. 3B). Dewetting phenomena (investigated for mogul dynamics[10] in magnetic recording disk lubrication) are important for the nanoscale, multiphase system design and will be discussed in the section entitled Capillary Waves and Dewetting. Similar PFPE spreading experiments on carbon coated magnetic recording disks were performed by Ma et al.,[8,9] a few years after the observations made by O'Connor et al. In their measurement, however, mass build-up for PFPE Z was not observed, and dewetting characteristics for Zdol were somewhat suppressed. These phenomena clearly demonstrated the relevance of surface energy driven flow effects in nanoscale spreading processes, and will play a critical role in design criteria for nanodevices and/or sensors. Ma et al.[11] examined spreading characteristics for various carbon surfaces (α-C/hydrogenated/nitrogenated), illustrating the fingerprint for the various surface/PFPE molecular coupling.

Mesoscopic Thermodynamic and Transport Models

Disjoining pressure

The remarkable similarity of the PDMS and PFPE spreading profiles suggests that interactions between the polar entities of the liquid and the surface are at the root of the "anomalous" spreading in these liquids. In the case of PFPE terminated with functional end-groups, evidence for strong interactions between the end-groups and the polar active sites on the carbon surface has been reported.

The free energy function provides a mesoscopic framework for understanding the terraced spreading phenomena. Since the surface energy is defined as the free energy per unit area, the total disjoining pressure (Π) for these fluids can be derived from the experimental surface energy data by:

$$\Pi = -\frac{\partial}{\partial h}\left(\gamma^d + \gamma^p\right) \quad (1)$$

where, γ^d and γ^p are the dispersive and polar components of the surface energy, respectively, and h is the film thickness. The regression fit to the surface energy data, shown as the smooth curves in Fig. 4A and B, were numerically differentiated to obtain the disjoining pressure. The total disjoining pressure, as well as the individual contributions from the dispersive and polar components, is shown in Fig. 4C. Notice that

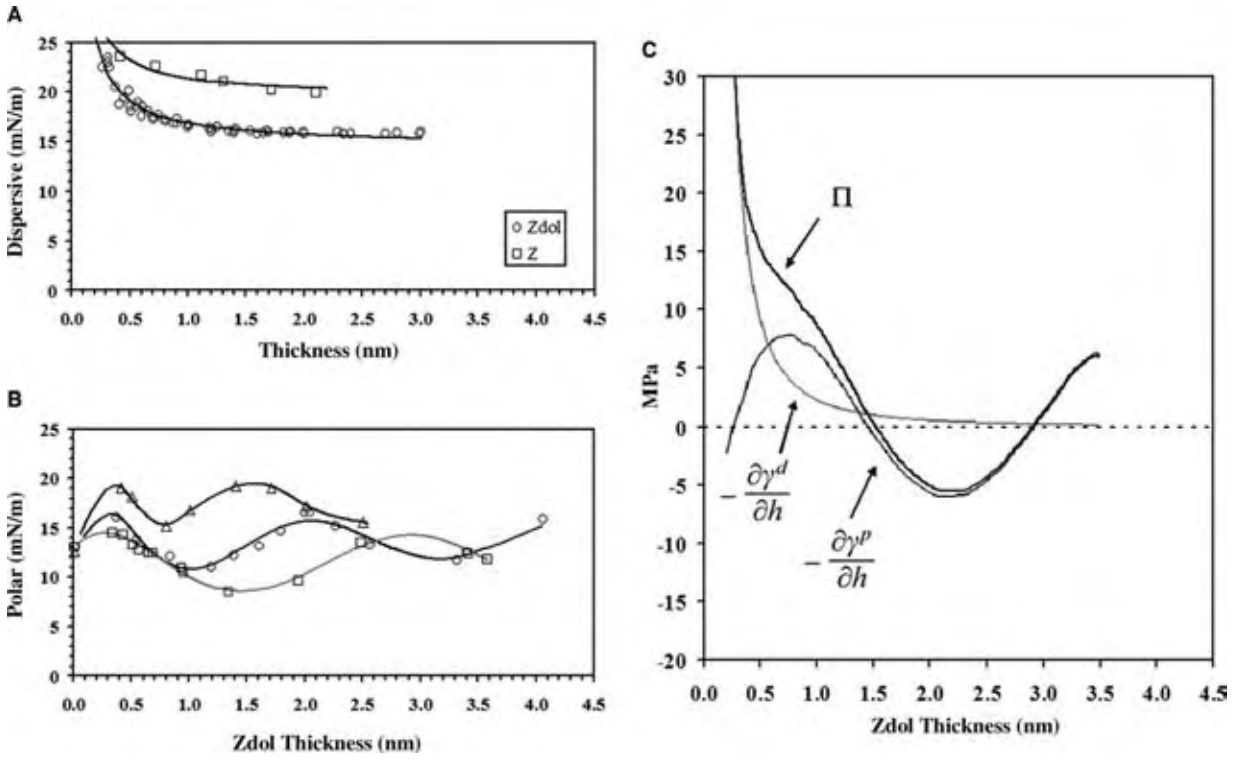

Fig. 4 The components of the surface energy measured on hydrogenated carbon overcoated thin film magnetic recording media: (A) The dispersive component of the surface energy for PFPE Z and Zdol; (B) the polar component of the surface energy for PFPE Zdol with molecular weight (M_W) of 1100 (△) 1600 (○), and 3100 (□) g/mol; and (C) the disjoining pressure as a function of film thickness for PFPE Zdol (M_W is 3100 g/mol).

γ^d decreases monotonically with h. Below film thickness of approximately 0.5 nm, Π at each molecular weight is dominated by γ^d, which increases rapidly with decreasing film thickness and is largely independent of molecular weight. The γ^p, however, oscillates with film thickness and becomes larger in magnitude than γ^d as h increases. Oscillations in γ^p provide an additional contribution to Π for PFPE Zdol that produces alternating regions of stable and unstable film thickness. The sum of the two contributions gives rise to oscillations in the total disjoining pressure. The shoulder height in the Zdol spreading profile corresponds to the film thickness at which $\partial\Pi/\partial h < 0$ and Π changes sign from positive to negative. The shoulder heights for two of the Zdol fractions were close to those expected from analysis of the disjoining pressure isotherm.[12]

Spreading characteristics from the mesoscopic transport model

To quantify the spreading characteristics, we examined the thickness-dependent diffusion coefficient $D(h)$, extracted from the SME via two methods. The first method utilizes the spreading data at constant height (isoheight), while the second method utilizes the entire spreading profile. The first method does not assume that the spreading is a diffusive process, whereas the second method does. The length L, which the leading edge of the advancing lubricant front traveled after time t, is defined as the difference between the initial position of the leading edge and its position in each of the subsequent profiles. To quantify the spreading rate, L and the corresponding times t (obtained from the profiles in Fig. 3B) are plotted. As shown in Fig. 5A, the L–t plot (in log) can be fit with the two piecewise straight lines for the entire range of t, i.e., $L \propto t^{\alpha}$. We found that $\alpha \cong 1$ at short times (Regime I), and after a gradual transition, $\alpha \cong 1/2$ (Regime II; diffusion region). Therefore, the surface diffusion coefficient D is estimated from the data in Regime II ($L \propto t^{1/2}$) alone via the relationship $D = L^2/t$.

We adopted a second method[9] called the Boltzmann–Matano interface method [see Eq. (5)], which is more accurate for the purely diffusive process. Notice that Ma et al.[8,9] successfully employed this method, since the spreading profiles they measured exhibit little mass buildup at the front and negligible dewetting.

The shape of spreading profiles can be derived from the diffusion coefficient D as follows: Since the flux vector $\mathbf{j}$ is proportional to the concentration (or related

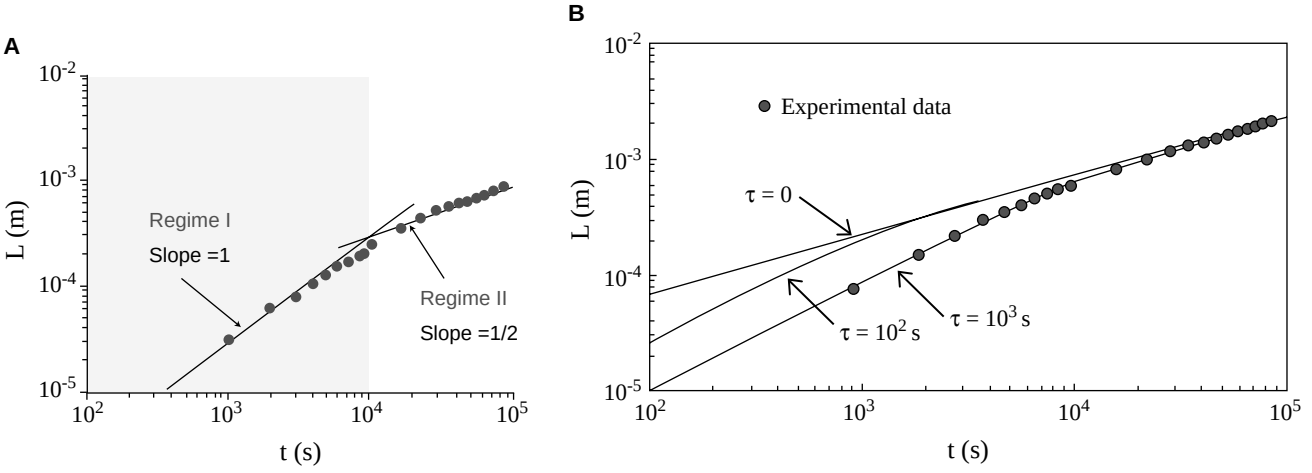

Fig. 5 (A) Travel length (L) as a function of time (t) obtained from Fig. 3B for monodisperse Zdol; $T = 26°C$, under dry nitrogen and (B) L–t plot results using the modified diffusion equation (Eq. 7) for several values of τ. *(View this art in color at www.dekker.com.)*

to film thickness, h) gradient ∇h we obtain,

$$\mathbf{j}(\mathbf{r},t) = -D(h)\nabla h(\mathbf{r},t) \tag{2}$$

Further, the mass conservation (or continuity) equation gives:

$$\frac{\partial h(\mathbf{r},t)}{\partial t} + \nabla \bullet \mathbf{j}(\mathbf{r},t) = 0 \tag{3}$$

By combining Eqs. (2) and (3), we obtain

$$\frac{\partial h(x,t)}{\partial t} = \nabla \bullet [D(h)\nabla h(x,t)] \tag{4}$$

where ∇ is the ''del'' operator and $h(x,t)$ is the film thickness.

On the other hand, the diffusion coefficient can be evaluated from Eq. (4). This 1-D analysis is called the Boltzmann–Matano technique:[9]

$$D(h) = -\frac{1}{2t}\left(\frac{\mathrm{d}x}{\mathrm{d}z}\right)_{z=h}\int_0^h x\,\mathrm{d}z,$$
$$\text{with the constraint } \int_0^{h_0} x\,\mathrm{d}z = 0 \tag{5}$$

where h_0 is the initial film thickness far from the step. Note that h and the coordinates x and z are shown in Fig. 1B(i). However, as shown from the L–t plot, the spreading cannot be described by the diffusive concept alone.

Since the theories developed by Novotny[5] [Eq. (4)] and Mate[13] (hydrodynamic model) fail to describe the $L \propto t$ behavior exhibited in Regime I, a simple mesoscopic model for the overall L–t behavior is described below. (The more rigorous molecular simulation is described later.) By introducing a time lag denoted as τ (which may be related to the relaxation time of the PFPEs), the Fick's constitutive equation can be modified as:[14]

$$\mathbf{j}(\mathbf{r},t+\tau) = e^{\tau\frac{\partial}{\partial t}}\mathbf{j}(\mathbf{r},t) = -D(h)\nabla h(\mathbf{r},t) \tag{6}$$

To derive Eq. (6), we imposed causality into the relationship between $\mathbf{j}$ and ∇h inspired by the microscale heat transfer theory or Cattaneo equation.[15]

By combining Eqs. (3) and (6), and assuming $\tau\partial/\partial t$ to be small, we obtained the following modified diffusion equation:

$$e^{\tau\frac{\partial}{\partial t}}\frac{\partial h}{\partial t} \cong \tau\frac{\partial^2 h(r,t)}{\partial t^2} + \frac{\partial h(r,t)}{\partial t} = \nabla \bullet [D(h)\nabla h(r,t)], \tag{7}$$

where τ characterizes the crossover behavior between Regimes I and II. Notice that Eq. (7) reduces to Eq. (4) when $\tau = 0$. We found that the transition between these two regimes depends on the value of τ. Increasing τ shifts the transition to a later time. By setting $\tau = 10^3$ s in Eq. (7), we attained an excellent fit for the experimental L–t data (Fig. 5B).

Relationship between diffusion coefficient and disjoining pressure

As will be shown later, the measured disjoining pressure Π can be used to qualitatively describe the spreading profile. Before that, the relationship between Π and D is established. Note that Π and D can also be calculated by MD simulation

The relationship between position dependent viscosity $\eta(z)$, Π, and $D(h)$ is developed by generalizing the hydrodynamic model (Reynolds equation):

$$D(h) = \int_0^h \frac{(h-z)^2}{\eta(z)}\left(\frac{\partial \Pi}{\partial h}\right) dz \tag{8}$$

or by substituting constant viscosity assumption, i.e., $\eta(z) = \eta_\infty$ in Eq. (8), we obtain Eq. (9) developed by Mate:[13]

$$D(h) = -\frac{h^3}{3\eta_\infty}\frac{\partial \Pi}{\partial h} \tag{9}$$

In deriving Eq. (9), we used the no-slip boundary condition at the lubricant/solid boundary. If we were to generalize the above analysis with the partial-slip boundary condition, e.g., $\partial v/\partial z = \beta v$ ($\beta \equiv$ slip parameter) instead of no-slip condition with $\eta(z) = \eta_\infty$, Eq. (9) could be modified as:

$$D(h) = -\frac{1}{\eta_\infty}\left(\frac{h^2}{\beta} + \frac{h^3}{3}\right)\frac{\partial \Pi}{\partial h} \tag{10}$$

We could use a simplified form of $\eta(z) = \eta_\infty f(z)$. Here η_∞ is the bulk viscosity, and $f(z)$ can be experimentally determined. Here, z is the distance normal to the solid surface. A partial justification for the above functional form can be drawn from the temperature dependence of the surface diffusion coefficient and the bulk viscosity,[7] or the fly stiction correlation with the bulk viscosity. To develop a rigorous hydrodynamic model, we need better rheological data and more details are given in the following section on Rheology Measurement.

An alternative approach to describe thin film spreading is the jump diffusion model developed by Karis and Tyndall.[16] In their analysis, the flow rate is calculated by integrating the velocity $\mathbf{v}$ throughout the depth of the film

$$\mathbf{j} = \int_0^h \mathbf{v}\, dz \tag{11}$$

The velocity ($\mathbf{v}$) is taken to be the drift velocity of the fluid particles in a disjoining pressure gradient, $\nabla\Pi$. The velocity is therefore proportional to the disjoining pressure gradient with the proportionality constant m representing the mobility [the units of m are (m/sec)/(Pa/m)], and

$$\mathbf{v} = m\nabla\Pi \tag{12}$$

The flow rate is calculated from the velocity by integrating through the film thickness according to Eq. (11)

$$\mathbf{j} = mh\nabla\Pi = mh\frac{\partial \Pi}{\partial h}\nabla h \tag{13}$$

$$\text{or} \quad D(h) = mh\frac{\partial \Pi}{\partial h} \text{ (in 1-D form)} \tag{13}'$$

In the integration of Eq. (11) to derive Eq. (13), the mobility was assumed to be independent of the distance from the surface between $z = 0$ and $z = h$, and therefore should be considered an ''effective'' mobility. In general, m is a function of end group chemisorption, and m could be rigorously calculated with the MD simulation. The differential equation that defines the 1–D spreading profile is obtained via substitution of Eq. (13)′ into the continuity Eq. (4).

$$\frac{\partial h}{\partial t} = \frac{\partial}{\partial x}\left(D(h)\frac{\partial h}{\partial x}\right) = \frac{\partial}{\partial x}\left[\left(mh\frac{\partial \Pi}{\partial h}\right)\frac{\partial h}{\partial x}\right] \tag{14}$$

Eq. (14) is solved numerically to calculate spreading profiles of nonpolar and polar PFPEs from the disjoining pressure measured from contact angles.[16] The calculated profiles, shown in Fig. 6A for Zdol, are in quantitative agreement with those measured by SME, Fig. 6B. The only adjustable parameter was $m\gamma_\infty/d_0$, where γ_∞ is the bulk surface tension of the lubricant, and d_0 is a characteristic dimension of the PFPE chain. Here $d_0 \approx 0.4$ nm, which is approximately the van der Waals diameter of the PFPE chain. For Zdol, $\gamma_\infty \approx 24$ mN/m.

A previously undescribed region for thin film spreading, which is particularly relevant to dewetting, is the region of film thickness h where $\Pi > 0$ and $\partial\Pi/\partial h > 0$, is predicted from this analysis. This region does not always show up in the spatially averaged spreading profiles measured by SME. It is referred to as the reverse flow region, where the free energy is lowered by decreasing the local film thickness. Thus, the flow in this region tends to decrease rather than increase the film thickness. A similar effect is observed in spinodal decomposition and is referred to as ''up-hill'' diffusion.[17]

Rheology Measurement

The bulk rheological properties of the PFPEs, including the melt viscosity, storage modulus, and loss modulus at several different temperatures, have been widely reported via steady shear and dynamic oscillation tests.[18] In this entry, the focus is on the confined geometry effects on viscosity.

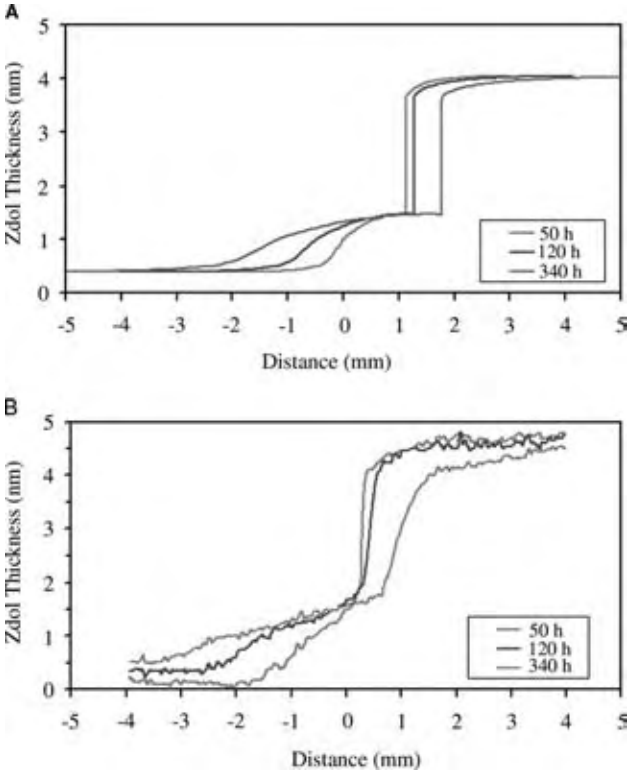

Fig. 6 (A) Calculated and (B) measured spreading profiles for Zdol. M_W is 3100 g/mol. *(View this art in color at www.dekker.com.)*

Dispersive interaction has a dramatic effect on the molecular layers closest to the surface, and can be explained in terms of the rate theory for viscous flow.[19] Within the rate theory, a flow event comprises the transition of a flow unit from its normal or quiescent state, through a flow-activated state, to a region of lower free energy in an external stress field. For small molecules, the flow unit is the whole molecule, while for longer chains, the flow unit is a segment of the entire molecule. By analogy with chemical reaction rate theory, there is a flow-activation enthalpy, ΔH_{vis}, and entropy, ΔS_{vis}, for transition into the flow-activated state.

A flow unit is approximated by a particle in a box, with the energy being partitioned among rotational and translational degrees of freedom, which govern the transition probability. On this basis, the viscosity $\eta = (Nh_p/V_l)\exp(\Delta G_{vis}/RT)$, where N is Avogadro's number, h_p is the Planck constant, V_l is the molar volume of the liquid, and $\Delta G_{vis} = \Delta H_{vis} - T\Delta S_{vis}$ is the flow-activation free energy. Here, $\Delta H_{vis} = \Delta E_{vis} + \Delta(pV)_{vis}$, where ΔE_{vis} is the flow-activation energy and $\Delta(pV)_{vis}$ is the pressure–volume work. At constant pressure, $\Delta(pV) = p\Delta V_{vis}$. For PFPE Z, the flow-activation volume $\Delta V_{vis} \approx 0.1\,\text{nm}^3$,[20] which is equivalent to a spherical region ≈ 0.6 nm in diameter. At ambient pressure (100 kPa), $\Delta(pV)_{vis} \approx 6.2$ J/mol, near ambient conditions, $\Delta H_{vis} \approx \Delta E_{vis}$. Therefore, the viscosity is given by:

$$\eta = \left(\frac{Nh_p}{V_l}\right)\exp\left[\frac{(\Delta E_{vis} - T\Delta S_{vis})}{RT}\right] \tag{15}$$

A regression fit to the bulk viscosity as a function of temperature,[19] provided $\Delta E_{vis} = 34.7$ kJ/mol) and $\Delta S_{vis} = 9.87$ J/mol-K. The flow-activation energy is close to that reported for bulk Zdol with a molecular weight of 3100 in Refs.[6,7]. A positive value for the flow activation entropy of bulk Zdol means that the entropy of the flow unit increases on going into the flow-activated state.

Changes in the lubricant flow-activation energy and entropy near the solid surface cause changes in the viscosity with decreasing film thickness. The flow-activation energy near a solid surface is estimated from the thin film vaporization energy as follows. In an ideal gas, the chemical potential μ (or partial molar Gibbs free energy) is given by:

$$d\mu = RTd\ln P \tag{16}$$

where P is the partial pressure of the lubricant in the vapor phase and R is the gas constant. The chemical potential per unit volume in the lubricant film $\mu/V_l = \Pi$. The ratio of the film surface vapor pressure, $P^0(h)$ to the vapor pressure of the bulk lubricant, $P^0(h)/P^0(\infty)$, is derived by integrating Eq. (16):

$$\mu(h) - \mu(\infty) = RTln\left[P^0(h)/P^0(\infty)\right] \tag{17}$$

The reference state is taken to be the chemical potential and vapor pressure of the bulk lubricant: $u(\infty) = 0$ and $P^0(\infty)$ is the vapor pressure of the bulk liquid. The surface chemical potential is approximated by the unretarded atom-slab dispersive interaction energy:

$$\mu = -\frac{V_l A}{6\pi h^3} \tag{18}$$

The dispersive interaction coefficient A is also referred to as the Hamaker constant, and $A = 10^{-19}$ J for Zdol.

The dispersive component of the vaporization energy near a solid surface is approximately given by Eq. (18). The vaporization energy is the energy required to remove a molecule from the liquid without leaving a hole behind. The free volume needed for a flow unit to make a transition into the flow-activated state is less than the size of the entire molecule. It is found that the ratio $n \equiv \Delta E_{vap,\infty}/\Delta E_{vis,\infty} > 3$, where $\Delta E_{vap,\infty}$ and $\Delta E_{vis,\infty}$ are the vaporization- and

flow-activation energy of the bulk liquid, respectively. Thus, the flow-activation energy near the surface is approximated by:

$$\Delta E_{vis} = \Delta E_{vis,\infty} - \mu/n \quad (19)$$

For linear chains longer than 5 or 10 carbon atoms, n increases due to the onset of segmental flow. In practice, n is experimentally determined from the measured values of ΔE_{vap} and ΔE_{vis}. For PFPE Zdol 4000, $\Delta E_{vap,\infty} = 166\,\text{kJ/mol}$, giving $n \approx 4.8$, which is consistent with segmental flow.

In order to calculate the thin film viscosity with Eq. (15), the flow-activation entropy near the surface is also needed. An experimental flow-activation entropy is calculated from the spin-off data[19] with Eqs. (15) and (19) as follows. The experimental η vs. h is determined from the dh/dt during air shear induced flow on a rotating disk. Eq. (19) is then solved for ΔS_{vis} versus h using Eq. (19) for ΔE_{vis}. Below 2.3 nm, $T\Delta S_{vis} \approx -1.9\,\text{kJ/mol}$, which corresponds to the critical configurational entropy change for flow ($-R\ln 2 \approx -5.76\,\text{J/mol-K}$).

Capillary Waves and Dewetting

Liquids are permeated by thermal fluctuations at finite temperatures. In quiescent bulk liquids, thermal fluctuations give rise to density fluctuations and diffusion, and these enable fluids to spread and flow. Molecular drift and shear flow, as discussed above, are present when an energy gradient is superimposed on the thermal fluctuations. According to the rate theory of flow, the likelihood that a thermal fluctuation will lead to a displacement event is determined by the ratio of the free energy change of the event taking place to the thermal energy. The same analogy holds for vaporization. Thermal fluctuations are present at the liquid vapor interface, as well as in the bulk, and governed by the same thermodynamic principles as diffusion and flow.

However, the present discussion focuses on molecularly structured liquids with at least 20 monomer units. Thermal fluctuations leading to cooperative motion in polymers pertain to segments consisting of several monomer units. A measure of the degree of segmental flow is provided by the ratio of the vaporization energy to the flow-activation energy, which is approximately four to five for Zdol 4000. If the entire molecule is the flow unit, then this ratio is closer to three. Therefore, with typical PFPE lubricant molecules, the size of the cooperative groups participating in thermal fluctuations is less than the entire chain.

Thermal fluctuations at the free liquid surface of molecularly thin hexane films on solid surfaces have been found to produce a fluctuating surface roughness, which is detected by X-ray reflectivity and diffuse scattering. For hexane, the whole molecule is the flow unit. Thus, for hexane, density fluctuations near the surface involve molecular rearrangement. In contrast, for PFPE, density fluctuations near the surface involve segmental rearrangements. Similar X-ray reflectivity and diffuse scattering measurements of PFPEs on carbon overcoats and silica have been reported by Toney, Mate, and Leach.[21] The surface smoothens as the lubricant thickness on carbon is increased, which probably reflects the lubricant filling in porosity of the overcoat.[22] Surface density fluctuations observed with fully bonded end-groups show that these fluctuations are segmental rather than cooperative motions of the entire chain.

Surface roughness induced by surface density fluctuations as a function of film thickness is estimated for the PFPE Zdol 3100 on amorphous carbon for which the spreading profile is shown in Fig. 3. The rms-roughness is given by the capillary wave continuum theory[23] as:

$$\sigma_{rms} = \sqrt{\frac{k_B T}{4\pi\gamma_\infty} \ln\left[1 + \frac{2\pi^3\gamma_\infty h^4}{a^2 A}\right]} \quad (20)$$

where a is a molecular length scale and k_B is the Boltzmann constant. The length scale $a \approx 0.75\,\text{nm}$ is roughly estimated from 60% of the maximum stable film thickness in the thin film region of Fig. 6. The peak to valley roughness, denoted $\sigma_{pp} = (2\sqrt{2})\sigma_{rms}$, is more relevant to magnetic recording slider disk spacing considerations. Fig. 7 shows the roughness due to thermal fluctuations at the free surface. The stable and unstable regions for PFPE Zdol with molecular weight of 3100 are superimposed in the roughness curve. The dashed region of the roughness curve denotes the unstable region, which is the step height in Fig. 6, and the region between the zero crossing and the first maximum of Π in Fig. 4C.

Separation into two stable regions of film thickness is not always observed when the mean film thickness is within the unstable region, even though the spreading film will not spontaneously flow to form a film with thickness in the unstable region. Films are routinely dip-coated and remain at the metastable thickness within the unstable region during measurement of the contact angle to determine the surface energy shown in Fig. 4A and B. No transition was observed in the viscosity during spin-off as the film thickness made a transition through the unstable region. As noted by Toney, Mate, and Leach,[21] thermal fluctuations of the free surface, at least at room temperature, do not appear to initiate the phase transition into two stable

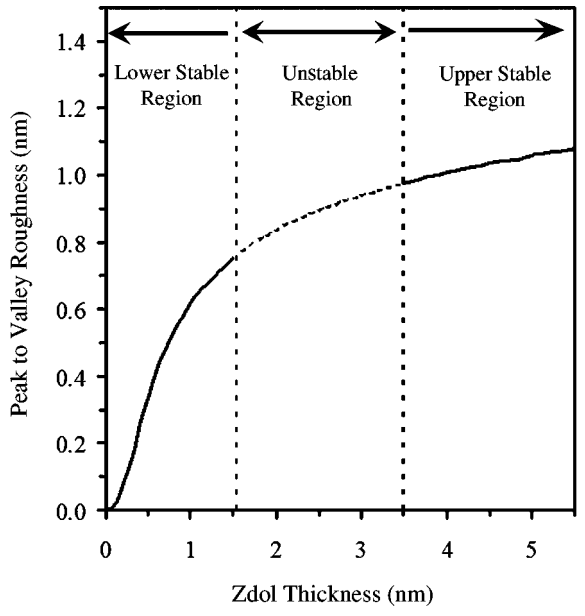

Fig. 7 Calculated peak to valley surface roughness due to thermal fluctuations at the liquid vapor interface of Zdol ($M_W = 3100\,g/mol$) as a function of the average film thickness.

regions of film thickness (i.e., dewetting) from the metastable state.

This is because the fluctuations represent only a small perturbation to the overall molecular configuration of the PFPE chain. For PFPE Zdol with a molecular weight of 3100, the number average degree of polymerization is approximately 31, and the contour length is 12 nm. By analogy with the number of atoms in a flow unit of linear alkanes, the fluctuation comprises two to four chain monomers, or 6–12% of the PFPE chain contour length. Much larger cooperative fluctuations, or external perturbations, are needed to nucleate the spinodal decomposition. However, thermal fluctuations in the lower stable region of film thickness may play a role in the critical flying height for the onset of bridge formation.[24]

SIMULATION

The immediate goal of the simulation is to construct reliable tools that accurately describe the static and dynamic behavior of thin liquid films. As should be apparent from the preceding sections, it is extremely difficult to measure the flow-activation energy, disjoining pressure, and dewetting due to thermal fluctuations accurately or directly. The molecular simulation provides a complementary tool and is described in detail in this section.

A multitude of references deal with the general methodology behind molecular simulations.[25] In this entry, the simple lattice-based, simple reactive sphere (SRS) MC techniques for examining the fundamentals of PFPE film structure are introduced first. An off lattice-based, bead-spring MC model is introduced later to capture the deailed internal structure of the PFPE molecules, and the molecular dynamics method is implemented for a full-scale nanostructural dynamic analysis of thin PFPE liquid films.

SRS Model

We adopted a spin analogy/lattice gas model, or SRS model, as shown in Fig. 8A, which illustrates the oversimplified molecular structure, while still capturing the essence of the molecule/surface interactions describing SME profiles. Notice that similar techniques using the Ising model have been previously investigated to study other physical systems.

MC simulations based on the SRS model were pioneered by Ma et al.[26] to explain the peculiar spreading profiles of PFPEs on amorphous carbon surfaces shown in Fig. 3 via the adoption of four different interactions: molecule/molecule, molecule/surface, end-group/end-group, and end-group/surface (a molecule is denoted as a backbone in the absence of polar end-groups). Molecules are approximated as reactive spheres, where a spin $S = 1$ is assigned to an occupied lattice site (for a vacant site, $S = 0$).

A comparison between MC simulation results for molecules with non-polar (e.g., PFPE Z) and polar (e.g., PFPE Zdol) end-groups is illustrated in Fig. 1. A drastic difference is apparent between Fig. 1B(i) and B(ii): the PFPE Z profile is relatively smooth and spreads more rapidly, while the Zdol profile exhibits a complex layering structure. These results are qualitatively consistent with the experimental observations given in Fig. 3, which reveal that molecules with polar end-groups demonstrate a first layer that is one molecule thick (the thickness of the first layer is on the order of the PFPE diameter of gyration in the bulk state), with subsequent layers approximately twice the thickness of the first layer. This simulation qualitatively explained the experimental spreading data on hydrogenated and nitrogenated carbon surfaces[11] by adjusting the screening length (descriptive for end-group/end-group coupling), which is related to the hydrogen and nitrogen content. Using the SRS model, the L–t plot was constructed by plotting the distance traveled from the initial sharp boundary versus the number of MC steps (the iso-height in the spreading profile). The simulated L–t response shows a distinct transition between short and long times, which agrees with the experimentally observed L–t behavior shown in Fig. 5. The long-term behavior exhibits $L \propto t^{1/2}$, thus meeting the criteria for the surface diffusion assumption.[27]

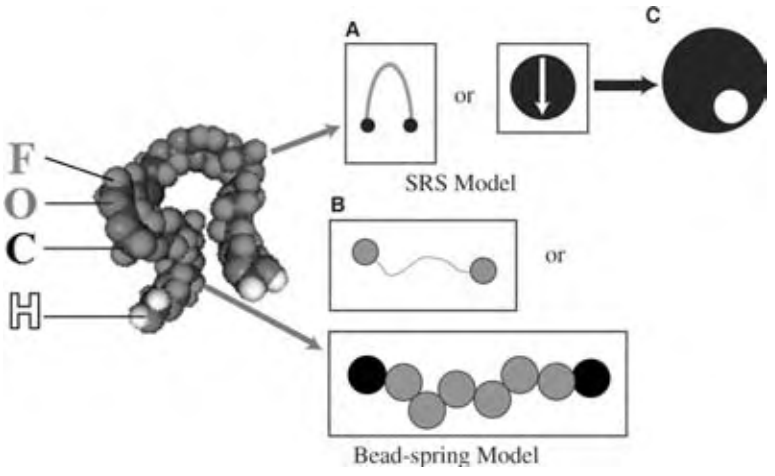

Fig. 8 Molecular model of PFPE Zdol: (A) SRS model with a discrete spin state; (B) bead-spring model, where gray spheres represent the backbone and black spheres represent the polar end-groups; and (C) SRS model with a continuous spin state (small end group sphere with the large backbone sphere). *(View this art in color at www.dekker.com.)*

The 3D results for PFPE Zdol, Fig. 9A provides more insight into the layer coupling. Due to the simplicity in this SRS model with lattice sites, an occupancy spin, and an end-group orientation spin (toward or away from the surface), we can qualitatively investigate the 3D steady state surface structure of PFPE films, describe its dewetting phenomenon and complex surface morphology, and examine its properties as a function of interaction parameters, surface loading, and initial surface structure. To illustrate the dewetting phenomenon as a function of end-group/end-group and end-group/surface interaction energies, simulations were conducted on a 3D lattice.[28] For an initial condition, we randomly distributed a layer with 90, 100, and 110% loading onto the surface to represent a very rough, highly damaged layer as seen for the 100% initial loading condition in Figs. 9B and C. If the end-group/end-group interactions are too strong, the layer does not relax, and the amount that a layer will relax is determined by the end-group interaction strength. The fractal dimension along with the simulated surface morphology described above can have a potential use for fingerprint analyses of PFPE molecule/surface pairs.

To better examine the disjoining pressure driving force behind the nanoscale spreading process, it is more advantageous to adopt a continuous spin state SRS model for an off-lattice scenario. The end-groups in this case are

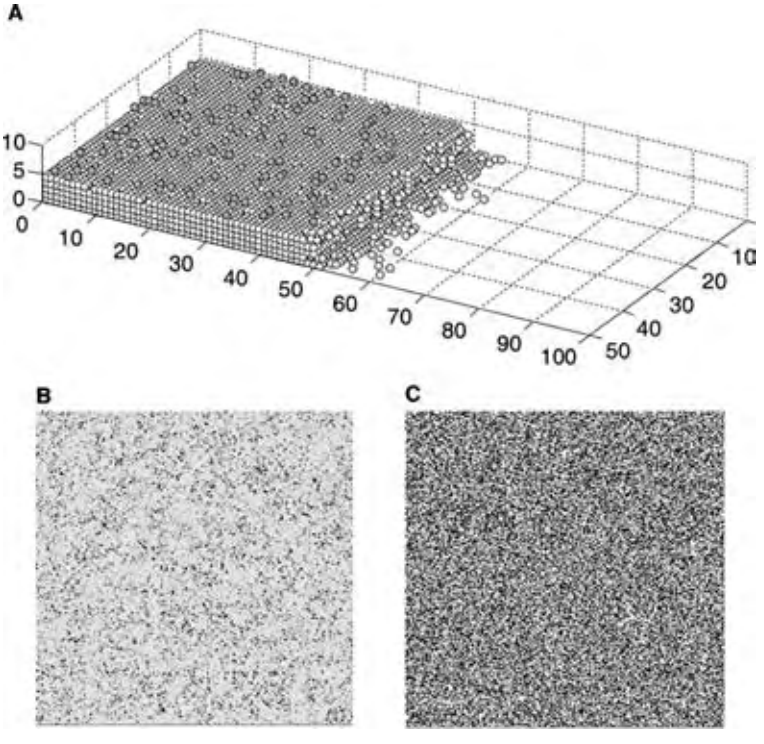

Fig. 9 (A) A typical simulation results for spreading 3-D dewetting simulation with (B) initial condition for 100% layer loading; and (C) relaxed film with a rough, dewetted surface. Black indicates a bare surface and white indicates peaks.

represented as smaller, internal spheres on the molecular backbone sphere surface, as shown in Fig. 8C.

Monte Carlo Simulation with Bead-Spring Model

To represent the molecular structure with reasonable accuracy, as well as to reduce computational time, the coarse-grained, bead-spring model (Fig. 8B) was employed to model a PFPE molecule. This simplifies the detailed atomistic information while preserving the essence of the internal molecular structure. The off-lattice MC technique was used to examine nanoscale PFPE lubricant film structures and stability with internal degrees of freedom.[29]

In this model, a PFPE molecule is composed of a finite number of beads with different physical or chemical properties. For simplicity, we assume that all the beads, including the end-beads, have the same radius. Lennard-Jones and van der Waals potentials were used for nonpolar bead–bead and bead–wall interactions, respectively. For polar interactions, exponential potential functions were added to both end-bead end-bead and end-bead wall interactions. For the bonding potential between adjacent beads in the chain, a finitely extensible nonlinear elastic model was used. For example, PFPE Zdol can be characterized differently from PFPE Z by assigning the end-bead a polarity originating from the hydroxyl group in the chain end.

The steady-state nanoscopic properties were examined and the result agrees qualitatively with the simulation results obtained via the SRS model. Our results provide a direct interpretation of the experimental surface energy data for PFPE films with functional end-groups.[12] The most remarkable achievement of MC simulation is its ability to predict equilibrium properties, including the surface morphology visualization. For example, in our simulation, stable films did not experience dewetting or film rupture. However, a rougher surface morphology was observed for smaller molecular weights (Fig. 10B) and strong end-bead functionalities (Fig. 10C).

To establish a qualitative relationship between the orientation and the layer structure, we examined the number of layers and the end-bead density. We found that the adsorption of functional end-beads results in an alternate ordering in the subsequent layers, i.e., upward orientation in the second layer, downward orientation in the third, etc. Our result provides a direct interpretation of experimental surface energy data for PFPE films with functional end-groups. The nondispersive component of surface energy exhibited an oscillatory pattern with increasing film thickness and was shown to be approximately proportional to end-group density, as demonstrated in our study.[29] Our simulation results also suggest that the density variation of the end-groups is related to the characteristic behavior of the surface energy of PFPE films.

Not only we can interpret experimental data, but we can also predict the nanostructure which is unobtainable experimentally. For example, we found that the observed expansion of layer thickness is attributed not to the bond stretching, but to the temperature dependence of the intermolecular interaction and excluded volume effect.

Molecular Dynamics Simulation

So far, we have demonstrated that the MC simulation (lattice-based SRS model and off-lattice bead-spring model) results are in qualitative agreement with the experimental results. A complementary approach is MD simulation using the bead-spring model.

Our preliminary MD simulations provided similar results as the MC method for the calculation of the static properties of confined PFPE nanofilms, especially the radius of gyration and end-bead density profiles. The anisotropic molecular conformation and experimental layering structures in the film were also verified. MD simulations[30] provide a powerful tool for examining the dynamics of nanofilms through correlation functions by tracking the trajectories of molecules, including the space and velocity coordinates. MD simulations, therefore, are suitable for

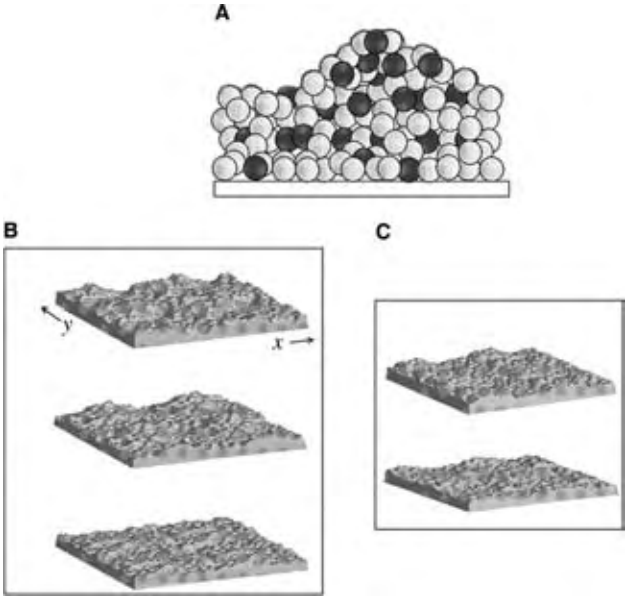

Fig. 10 Morphology of PFPE films from MC simulations: (A) schematic of simulated surface roughness for; (B) molecular weight dependence [$N_p = 10$ (upper), 15 (middle), 20 (bottom)]; and (C) end-bead functionality dependence [$\varepsilon_w^p = \varepsilon^p = 1$ (upper) and $\varepsilon_w^p = \varepsilon^p = 4$ (bottom)]. Here, N_p is the number of monomers and ε_w^p and ε^p are polar energy parameters.

calculating the transport coefficients from the correlation functions. In our preliminary study, self-diffusion coefficients of PFPE nanofilms were investigated with the Einstein relationship or Green–Kubo formula, to examine the effects of molecular weight, end-group functionality, external surface interaction strength, polydispersity, and temperature. Several autocorrelation functions were examined to study molecular motions. The Kohlrausch–Williams–Watts function and wavelet analysis were employed to interpret the molecular structure of PFPE nanofilms. Insight into physics of the disjoining pressure was revealed by calculating the internal pressure tensor during the simulation of nanofilms.

CONCLUSIONS

We reviewed fundamental scientific tools as well as potential applications relevant to the thin liquid film technology. We focused on understanding the behavior of molecularly-thin lubricant films relevant to the emerging field of nanotechnology, especially for achieving durability and reliability in nanoscale devices. The topics on the experimentation and theory for the physicochemical properties of ultra-thin PFPE films were reviewed by examining liquid film thickness from submonolayer to multilayer. By systematically tuning the end-group strength for PFPE, we can examine and control physicochemical properties for thin liquid films in various PFPE/solid surface combinations. Methods for extracting spreading properties from the SME and rheological properties (we only discussed surface-enhanced viscosity) of PFPEs are shown. The interrelationships among SME spreading profiles, surface energy or disjoining pressure, rheology, and tribology (dewetting and density/thermal fluctuations) are discussed from the viewpoint of thermodynamics. Mesoscopic theories, including microscale mass transfer, are introduced to interpret qualitatively thin PFPE film dynamics. Simulation tools, including a lattice-based SRS model, the off-lattice bead-spring MC, and MD methods were reviewed. These tools accurately describe the static and dynamic behaviors of liquid nano-films. The simulation results are consistent with experimental findings and are thus suitable for describing nanoscale molecular mechanisms in thin film fluid dynamics.

Thiochemicals: Mercaptans, Sulfides, and Polysulfides

Jeffrey H. Yen
Vijay R. Srinivas
Gary S. Smith
Arkema Inc., King of Prussia, Pennsylvania, U.S.A.

INTRODUCTION

The word ''thiochemicals'' is derived from the Greek word ''theion.'' Generally speaking, thiochemicals are sulfur analogs of oxygen-containing compounds; for example, thiochemicals containing sulfur in the +2 oxidation state, mercaptans and alkyl sulfides, are sulfur analogs of alcohols and ethers, respectively.

As the sulfur atom is a homolog of the oxygen atom, present in the VI Group of the Periodic Table, there are some similarities in character and occurrence in nature. The differences, however, are dramatic—oxygen being a colorless gas essential to sustain human life, while sulfur is a yellow solid. The most fundamental molecules that contain oxygen and sulfur, respectively, are water and hydrogen sulfide. Again, water is essential for all living beings and hydrogen sulfide is a deadly and poisonous gas. Many complex molecules of biological interest contain sulfur, and the capability of the sulfur atom to both oxidize and reduce is used extensively in the normal everyday biological processes. Generally, thiochemicals can be classified as follows:

Sulfur (II) compounds

- Basic thiochemicals: examples are sulfur dioxide, hydrogen sulfide, sodium sulfide, sodium thiosulfate, etc.
- Mercaptans (thiols): RSH; examples are methyl mercaptan, ethyl mercaptan, etc.
- Sulfides: RSR′; examples are dimethyl sulfide, diethyl sulfide, etc.
- Polysulfides: $RS_x R'$; dimethyl disulfide, diethyldisulfide, *t*-nonyl polysulfide, etc.
- Sulfenic acids RSOH and derivatives: benzenesulfenic acids/salts, benzenesulfenyl chloride.

Sulfur (IV) compounds

- Sulfoxides RS(O)R and derivatives; dimethylsulfoxide.
- Sulfinic acids and derivatives: RS(O)OH, RS(O)X; benzenesulfinic acid, *p*-toluenesufinyl chloride, other arenesulfinate esters and salts.
- Sulfite esters: $(RO)_2SO$; ethylene sulfite.

Sulfur (VI) compounds

- Sulfones: $R\text{-}SO_2\text{-}R$; sulfolane, dimethyl sulfone, etc.
- Sulfonic acids and derivatives; RSO_2OH, RSO_2X; methanesulfonic acid, *p*-toluenesulfonic acid, methanesulfonyl chloride, methanesulfonamide, etc.

To describe the full range of thiochemicals is beyond the scope of this entry, which will, therefore, place emphasis on the most common thiochemicals. This entry will cover mercaptans, sulfides, and polysulfides, while the next entry will cover sulfonic acids and its derivatives, some sulfoxides, mercaptoacids and their derivatives. The safety, health, and environmental issues for both entries are discussed at the end of this chapter.

MERCAPTANS

Mercaptans and alkyl sulfides are the sulfur analogs of alcohols and ethers, respectively. They can be characterized by their extremely unpleasant odor. These compounds play an important role in biological systems as well as in the application of chemistry to everyday life. Some of the alkyl sulfides are found in many plant and animal oils, and are minor components of petroleum distillates, shale oil, and coal tar.

Chemical and Physical Properties

The properties of mercaptans and alcohols are quite different, although they appear to be similar in nature. The bond dissociation energy of the S–H bond is over 10/kcal/mol lower than the corresponding O–H bond. The ease of free-radical hydrogen abstraction from a mercaptan supports this fact and permits these compounds to be included in preparative free-radical chemistry. The above fact, along with the different boiling points observed for the mercaptans compared to the corresponding alcohols and the differences in their acidities, helps explain why the chemistry of these two classes of compounds differs in so many ways.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120033979

Table 1 lists some properties for various straight-chain alphatic mercaptans (C_2–C_{12}). The boiling points range from 34°C to 277°C, while their solubility in water is the greatest for ethyl mercaptan (6.76/g/L) and decreases as the aliphatic chain length increases.

Manufacturing Technology

There are several methods for the preparation of mercaptans and sulfides.[1] It is our intention here to emphasize only the most facile methods that are safe to operate commercially, use inexpensive raw materials, produce minimum by-products, and allow for simple and easy by-product handling. While the sources of sulfur for thiolation can be many, the most common ones are hydrogen sulfide (H_2S), elemental sulfur, and carbon disulfide (CS_2). H_2S is a component of sour natural gas and can be separated for use in the manufacture of mercaptans and other sulfur chemicals. Additionally, H_2S is generated in the many hydrodesulfurizing units in a refinery. With minimal purification this could be used for the manufacture of thiochemicals. In many instances H_2S is manufactured by either the Girdler or the Folkins processes:

$$\text{Girdler process} \quad H_2 + S \xrightarrow{450^\circ C} H_2S$$

$$\text{Folkins process} \quad CH_4 + S \longrightarrow 2H_2S + CS_2$$

Mercaptans and sulfides are manufactured mainly by the thiolation of alcohols and by the addition of H_2S to olefins.

From alcohols via heterogenous catalysis

Alcohols react with H_2S in the presence of acid or base catalysts to give mercaptans. The nucleophilic substitution of alcohols by H_2S occurs at around 300°C on an alumina-type catalyst impregnated with alkali metal oxides such as Na_2O, K_2O or transition metal oxides such as WO_3. Phosphotungstate alkaline salts on alumina have also been used.

$$ROH + H_2S \xrightarrow[\text{catalyst}]{\text{ca. } 300^\circ C} RSH + H_2O$$

Mercaptans can further react with alcohols, under the same conditions, to produce sulfides. Therefore, the H_2S/ROH ratio must be high to optimize mercaptan selectivity over sulfide selectivity. The temperature also plays a key role in the selectivity and conversion. As the molecular weight of the alcohol increases, the temperature of the reaction needs to be minimized and controlled in the range of 270–400°C, to avoid dehydration of the alcohol to an olefin. Mercaptans ranging from methylmercaptan to dodecylmercaptan have been industrially synthesized by thiolation of primary alcohols. This route is generally used to make primary mercaptans from primary alcohols.

Thiolation of secondary alcohols is not the preferred route to synthesize secondary mercaptans, because of the facile dehydration that occurs under reaction conditions of the secondary alcohols. H_2S can also react with aliphatic or cyclic oxides, viz., ethers; to produce the corresponding thioethers or sulfides. This is one of the preferred ways to make tetrahydrothiophene or thiophene.

From olefins

The catalytic addition of H_2S to olefins follows the Markovnikov rule, with the –SH moeity attaching itself to the carbon atom connected to the least number of hydrogen atoms. With linear olefins, having terminal or internal double bonds, acid catalysis using zeolites, cation-exchange resins, and silica–alumina yields secondary mercaptans. The preferred route for secondary mercaptans is the H_2S addition to olefinic compounds.

$$RCH{=}CHR' + H_2S \longrightarrow RH\overset{\displaystyle SH}{\overset{|}{C}}{-}CH_2R'$$

With branched olefins, one usually obtains tertiary mercaptans as the major product. For example, tertiary mercaptans such as *t*-dodecyl mercaptan and *t*-nonyl mercaptan are manufactured starting from propylene oligomers and using the acid-catalyzed addition of H_2S. In the presence of strong acids, electrophilic addition of H_2S and mercaptans to olefins takes place, yielding Markovnikov adducts. Because divalent sulfur compounds are stronger nucleophiles than alcohol or water, the addition of mercaptans to an intermediate carbonium ion takes place quite readily.[2] This type of reaction yields secondary mercaptans and secondary thioethers from alpha olefins. Since 1965, the ready availability of alpha olefins has opened the possibility of utilizing several of their basic reactions known for a long time. Friedel Crafts catalysts such as anhydrous aluminium chloride, fluoboric acid, mixtures of hydrogen fluoride and boron trifiuoride, and their hydrocarbon complexes have been used for the addition of H_2S to olefins—specifically decene.[3,4] Silica–alumina has been used to make high-molecular-weight mercaptans, which have found use as rubber modifiers.[5] Elemental sulfur along with the bases ammonia or alkylamine or rubber vulcanizing agents such as mercaptobenzothiazole, thiurams, and dithiocarbamates have been used as catalysts to make mercaptans and sulfides from olefins and hydrogen sulfides.[6–12] Acid cation exchangers (e.g., wet sulfonated styrene-divinylbenzene copolymers in the acid form or more advantageously in combination

with sulfonated phenol–formaldehyde resins) have been used for making mercaptans and sulfides from olefins.[13–15] Acidified clays such as montmorillonite, cation-exchanged zeolites, and aluminum mercaptides have resulted in catalyzing the Markovnikov addition of H_2S and mercaptans to olefins to give mercaptans and sulfides, respectively.[16–19] When used, trifluoromethanesulfonic acid not only catalyzes the addition of H_2S to olefins but also polymerizes them to give higher-molecular-weight mercaptans than those corresponding to the initial olefin used.[20] The solid supported catalysts are now preferred. The Lewis acids that were formerly used had many disadvantages, such as the need to wash them away from the product mixture, leading to corrosion in specific areas of the process, and high catalyst consumption. The new catalysts give products of high purity and consistency, which can be easily separated by distillation. Consistency is required in many of their applications, especially when the mercaptans are used as chain transfer agents in polymerization. The above process manufactures tertiary mercaptans such as, *tert*-butyl, *t*-octyl, *t*-nonyl, and *t*-dodecyl mercaptan.

The majority of the normal mercaptans, e.g., *n*-dodecyl mercaptan and *n*-octyl mercaptan are currently manufactured by the direct addition of hydrogen sulfide and mercaptans to alpha olefins. It has been well established that in the presence of free-radical initiators or ultraviolet (UV) light of a frequency that would activate H_2S and mercaptans, H_2S and mercaptans add to olefins in an anti-Markovnikov fashion by a mechanism similar to the well-known inverse addition of hydrogen bromide to olefins.[21–24] Several free radicals and UV light catalyze this reaction.[25,26] Olefins exposed to air even for short periods contain enough peroxides to initiate this reaction, while radical inhibitors (e.g., hydroquinone) retard it. A general mechanism may be written, involving a secondary free-radical intermediate that undergoes chain transfer to give a primary mercaptan or sulfide from the addition of H_2S or mercaptan, respectively, to an alpha olefin.

$$RCH{=}CH_2 + H_2S \xrightarrow[\text{radical initiator}]{\text{hv or}} RCH_2CH_2SH \quad \text{(mercaptan)}$$

$$RCH{=}CH_2 + RCH_2CH_2SH \longrightarrow RCH_2CH_2SCH_2CH_2R \quad \text{(sulfide)}$$

If one desires to optimize the yield of mercaptan, there needs to be a large excess of H_2S used in the process. Acetophenone and its derivatives such as 2,2′-diethoxyacetophenone and benzoin ethyl ether, and organic phosphites are a few photoinitiators that can be used to make the above process more efficient.[27,28] A photochemical process starting from α-olefins has industrially manufactured primary mercaptans ranging from C_3 to C_{12} carbons.[29,30]

Other methods for preparation of mercaptans and sulfides

Nucleophilic substitution by salts of H_2S will react with halogenated compounds to make mercaptides that can be acidified to mercaptans. The most convenient salts are sodium and ammonium hydrosulfides. Mercaptoacetic acid is made by the reaction of ammonium hydrosulfide with monochloroacetic acid followed by acidification.

Applications

Mercaptans in general have been used in a wide array of applications, ranging from the production of agricultural chemicals and polymers to miscellaneous use in specific end-user consumer products.[31–33] The existing U.S. market for C_3–C_{12} mercaptans derived from C_3–C_{12} alpha olefins is approximately \$15–20 million/yr. Overall market for mercaptans is over \$300 million. The single largest volume mercaptan produced is methyl mercaptan.

Agricultural chemicals

Several compounds with high biological activity have one or more sulfur atoms. Mercaptans are used to introduce this sulfur atom into these compounds. They have probably been used because they couple high biological activity with good biodegradability. Methyl mercaptan, e.g., is a primary component in the manufacture of methionine, $CH_3SCH_2CH_2CH(NH_2)COOH$, an essential amino acid used to fortify poultry feed. In terms of herbicides and insecticides, the market is relatively mature in the western hemisphere; its growth, however, will come from the development of new and sophisticated agricultural chemicals and their increased use abroad especially in Asia. Propyl mercaptan is used in the manufacture of several herbicides.[34] Another major agricultural area where mercaptans and their derivatives find use is as pesticides or insecticides.[35] Mercaptans, sulfides, sulfoxides, and sulfones are used as plant growth protectors and stimulators.[36,37]

Detergents

Polyoxyethylene mercaptans, obtained from the reaction between an alkyl mercaptan and ethylene oxide, have been demonstrated to be good nonionic

surface-active agents.[38] In more recent years, this class of detergents has become more complex, probably because of the increased availability of inexpensive and sophisticated starting materials such as alpha olefins.[39] Finally, the salts and esters of long-chain aliphatic thioethercarboxylic acids act as wetting agents, emulsifiers, and thickeners for aqueous products.[40]

Lubricants

There are many organosulfur compounds, which have been used in formulating lubricant additives. The sulfide, disulfide, and polysulfide linkages, incorporated into novel compositions-of-matter, serve various functions, such as corrosion inhibition, oxidation resistance, high-temperature stability, and static prevention.[41]

Pharmaceuticals

Organosulfur compounds have been incorporated into various different classes of molecules, which have pharmaceutical utility as anti-inflammatory agents, analgesics, antiarrhythmic agents, antibiotics, antiobesity agents, and so on.[42,43]

Polymers

The uses of mercaptans in polymers fall into three major categories: chain transfer agents, additives such as stabilizers against heat or UV light, and monomers that incorporate an alkylmercapto group into their structure. Mercaptans *t*-dodecyl, *n*-dododecyl, etc. are excellent chain transfer agents used to control molecular weight of several different kinds of polymers, styrene butadiene rubber, acrylonitrile–butadiene–styrene, polyacrylates, to name a few.[33,44,45]

Gas odorants

Mercaptans and sulfides are used extensively to odorize natural gas.[46] The low-odor threshold limit values of most mercaptans and sulfides make them ideally suited for this purpose. Very small quantities can thus be used so as to not contribute to sulfur dioxide emissions when burned. Pure products such as tetrahydrothiophene, *tert*-butyl mercaptan, methylethyl sulfide, or mixtures/blends of these products and others such as isopropyl mercaptan, diethyl sulfide, dimethyl sulfide, ethyl mercaptan, and *n*-propyl mercaptan are used.

SULFIDES AND DISULFIDES

Chemical and Physical Properties

The common chemical and physical properties of commercial sulfides are shown in Table 2.[26,27]

Manufacturing Technology

A commonly used method to prepare sulfides is to react a chloride and sodium mercaptide. Mercaptans and alcohols will react in the presence of acidic catalysts, at elevated temperatures (300–400°C), to produce sulfides:

$$RCl + R'SNa \longrightarrow RSR' + NaCl$$
$$ROH + R'SH \longrightarrow RSR' + H_2O$$

Mercaptans can be added to olefins to produce sulfides. Markovnikov addition occurs readily in the presence of acidic catalysts, at relatively mild temperatures, especially with branched, unsymmetrical (i.e., polarized) olefins.

$$R_2C{=}CH_2 + R'SH \longrightarrow RH\,\overset{\displaystyle SR'}{\overset{|}{C}}\,{-}CH_3$$

Anti-Markovnikov additions occur in the presence of free-radical catalysts such as peroxides, azo

Table 2 Properties of commercial sulfides

Product	Physical state	Physical and chemical properties	Uses
Dimethyl sulfide CH_3SCH_3 CAS: 75-18-3 EINECS: 200-846-2	Water white and strongly odorous liquid	BP = 37.3°C $d(20/4)$ = 0.840	LPG gas odorant, methylation agent
Diethyl sulfide $C_2H_5SC_2H_5$ CAS: 352-93-2 EINECS: 206-526-9	Water white and strongly odorous liquid	BP = 92°C $d(20/4)$ = 0.840	Gas odorant, sulfiding additive for hydrotreating catalysts and anticooling additive for steamcrackers

(From Refs.[47,48].)

compounds, or UV light. This reaction proceeds readily, even at room temperature or lower.

$$RCH{=}CH_2 + R'SH \longrightarrow RCH_2CH_2SR'$$

So readily does this reaction occur, that care must be taken to avoid using olefins having appreciable peroxide levels when the Markovnikov addition product is desired, to prevent the formation of isomeric sulfides.

Disulfides are manufactured by the oxidation of unhindered mercaptans. This reaction is one of the most facile reactions in organic chemistry. On prolonged exposure to air, mercaptans become contaminated with several percent of the corresponding disulfides. Primary mercaptans oxidize more readily than secondary; while tertiary mercaptans oxidize the least readily.

$$2RSH + \frac{1}{2}O_2 \longrightarrow RSSR + H_2O$$

The oxidation is greatly accelerated by an alkaline medium. The mildest of oxidizing agents affect this reaction. Iodine will convert mercaptans quantitatively to their disulfides. Because overoxidation does not occur in this case, iodine can be used for the quantitative determination of mercaptans.

$$2RSH + I_2 \longrightarrow RSSR + 2HI$$

Under the proper mild conditions, chlorine can also be used, but overoxidation and sidereactions often result in some yield loss. Elemental sulfur can be employed, but it must be used in a molar deficiency to prevent the formation of tri- and higher polysulfides as by-products. Conversely, higher-rank polysulfides can be retrograded back to disulfides by reaction with mercaptans.

$$2RSH + S \longrightarrow RSSR + H_2S$$
$$RSSR + S \longrightarrow RSSSR$$
$$2RSS_XSR + 2RSH \longrightarrow RSSR + RSS_{X-1}SR + H_2S$$

Disulfides can also be produced by passing mixtures of the mercaptan and air (or dilute oxygen in an inert gas) over copper or cobalt oxide/molybdenum oxide catalysts at elevated temperatures.

Applications

Sulfides find use (Table 3) in the refinery and petrochemical industries.[49–55] Some refiners use dimethyl sulfide as a sulfiding agent to convert the metal oxide hydrotreating catalysts to their sulfide form.[56] In ethylene manufacture, ethane or other hydrocarbon liquid like naphtha is reacted at high temperatures with steam. The process would make an unacceptable amount of coke and produce too much carbon

Table 3 Properties of commercial disulfides

Product	Physical state	Physical and chemical properties	Uses
Dimethyldisulfide CH_3SSCH_3 CAS: 624-92-0 EINECS: 210-671-0	Colorless to pale yellow and strongly odorous liquid	BP = 109.6°C $d(20/4)$ = 1.063	Thiomethylation agent, sulfiding agent for catalysts, anticoking agent for steam crackers, deplugging agent for sour gas wells

(From Refs.[47,48].)

monoxide if no sulfur compounds are added. Therefore, almost all of the steam cracking furnaces in the world use a sulfur compound that can generate H_2S under conditions of operation to minimize coke and CO. Some of the lower-molecular-weight sulfides have been used as additives to aid in the metal mining industry.[57] Methyl ethyl sulfide is used as a gas odorant, in combination with other mercaptans and sulfides.

Among the disulfides, dimethyl disulfide (DMDS) is a very versatile product experiencing broad growth. Most recently, it has been shown to have superior nematocidal activity and will soon find application as a broad-spectrum fumigant. As a thiomethylation agent, it is used to produce methylthiophenols, which have found use as pesticide, pharmaceutical, and antioxidant intermediates. The synthetic method used is the electrophilic substitution of phenol with dialkyl disulfides, resulting in the formation of both *ortho*- and *para*-thiosubstituted products. Work continues to improve the regiospecificity of this reaction. With its lower odor and vapor pressure, it is safer to use instead of methyl mercaptan in some specific applications.

Dimethyl disulfide has been found to be the most efficient catalyst sulfiding agent in the refining industry. It is more efficient and easier to handle than competing products such as CS_2 and H_2S. In the refining industry, it is largely used for the sulfidation of metal oxide catalysts to metal sulfides, known to have sustained activity for various treatments such as hydrodesulfurization, hydrodenitrefication, and hydrocracking of crude petroleum. Dimethyl disulfide is also used to modify the selectivity of platinum-based catalysts in reforming and to prevent coke formation in hydrodealkylation processes. The clean breakdown of DMDS at relatively low temperatures into simple products like methyl mercaptan, H_2S, and methane, on typical hydrotreating catalysts, makes it the agent of choice for catalyst sulfiding. It is also used as a sulfur carrier in the steamcracking of hydrocarbons to produce ethylene and propylene. Dimethyl disulfide generates H_2S, which is known to minimize catalytic coke and also CO, a gaseous by-product that poisons the catalysts used downstream to partially hydrogenate acetylene, coproduced during ethylene manufacture.

Dimethyl disulfide is also an excellent ''solvent'' for sulfur. In fact, DMDS chemically reacts with sulfur in the presence of a base catalyst to form dimethylpolysulfide.[31]

$$CH_3SSCH_3 + S \xrightarrow[\text{catalyst}]{\text{base}} CH_3S_XCH_3$$

$$CH_3S_XCH_3 + H_2S \longrightarrow CH_3SH + (X-2)S$$

This property makes DMDS the agent of choice for the deplugging of sour gas wells ($H_2S < 60\%$). In the bottom of wells where pressure and temperature are high, sulfur is soluble in the gas, but at the top, where pressure and temperature decrease, the sulfur precipitates in the piping, thus plugging the flow of gas. Catalyzed DMDS, known as SulfaHitec®, a product made by Arkema, can be injected batchwise to unplug sour gas wells and to keep pipes and formations free of precipitated sulfur.

POLYSULFIDES

Chemical and Physical Properties

Most polysulfides with a sulfur rank higher than three, are mixtures where the different sulfur ranks coexist in equilibrium (Table 4). In many cases elemental sulfur is also involved in the above equilibrium. Changes in temperature and pressure sometimes alter this equilibrium and precipitate sulfur. Viscosity of the polysulfides also is a function of temperature, increasing dramatically with decreasing temperature. In most cases heating polysulfides results in their decomposition to the alkyl mercaptans. Some of the aromatic polysulfides are tacky solids. Many trisulfides can be isolated as pure compounds, and exhibit unique chemical properties. They are the only polysulfides that are not corrosive to copper.

Manufacturing Technology

Mercaptans can be reacted with elemental sulfur at moderate temperatures (50–120°C) in the presence of alkaline catalysts, such as trialkylamines, to produce polysulfides. The first step in the reaction sequence is always disulfide formation (with liberation of H_2S). The subsequent insertion of additional sulfur atoms occurs readily. The number of sulfur atoms inserted will depend on the molar ratio of sulfur to mercaptan employed, according to the stoichiometry of the following equations:

$$2RSH + 2S \longrightarrow RSSSR + H_2S$$

$$2RSH + 3S \longrightarrow RS_4R + H_2S$$

$$2RSH + 4S \longrightarrow RS_5R + H_2S$$

Solid catalysts such as zeolite (aluminosilicate), heteropolyacids and their alkali or alkaline earth metal salts on a metal oxide support and basic resins have been used as catalysts to manufacture polysulfides.

Polysulfides above RS_5R are generally unstable. The disulfides and trisulfides can be produced in fairly pure form by using appropriate reaction conditions and slightly less than the stoichiometric amounts of sulfur,

Table 4 Chemical and physical properties of poly-*ter*-alkylphenol disulfides

(From Refs.[47,48].)

but the higher-rank $-S_4-$ and $-S_5-$ polysulfides are generally produced as mixtures containing the tri–, tetra–, and pentasulfides. The higher dialkyl pentasulfides, such as *tert*-nonyl-S_5-*tert*-nonyl (TNPS), on standing, tend to precipitate some sulfur and equilibrate at an average sulfur ''rank'' of about 4.7.

Applications

The higher dialkyl polysulfides, such TNPS, find use as extreme-pressure lube additives, especially for cutting oils; the lower dialkyl polysulfides, such as $(CH_3)_2S_x$, as sulfur-donor agents, for example, to convert phosphites to thiophosphates:

$$(RO)_3P + R'S_XR' \longrightarrow (RO)_3P{=}S + R'S_{X-1}R'$$

Disulfides and polysulfides are useful for sulfiding hydrotreating catalysts, used in petroleum refining to convert metal oxides to the preferred metal sulfides. Hydrotreating is an essential process in the refining of petroleum. It removes heteroatoms, nitrogen, and sulfur from crude oil and its fractions, formulated into gasoline and diesel (Table 5).

SAFETY, HEALTH, AND ENVIRONMENTAL ISSUES

6.1 Material Handling[47]

Mercaptans are flammable. Normal precautions used in handling any flammable chemical are applicable. Flares used to burn vapors to reduce pressure on a storage tank should be situated as far away from the general storage area as practical. The flare should have a suitable flame arrestor. All potential sources of fire, flame, and sparks in the immediate area should be sought out and eliminated.

Plastic gloves and chemical goggles should be worn to protect the skin and eyes when handling mercaptans. If mercaptan contacts the skin or eyes, flush the affected area immediately and thoroughly with water. In handling mercaptans, avoid spills and leaks of liquid or vapor, avoid prolonged breathing of mercaptan vapors. Although the odor of mercaptan will normally become extremely disagreeable before the vapors reach dangerous concentrations, the nose may become temporarily desensitized after exposure. A self-contained breather-type mask is recommended for protection when working in areas of high vapor concentration or for prolonged exposure to lower concentrations of vapor.

Table 5 Chemical and physical properties of polysulfides

Commercial product	Physical state	Physical and chemical properties	Uses
TPS 20 Di-*tert*-dodecyl trisulfide CAS: 68425-15-0 EINECS: 270-335-7	Pale yellow and slightly odorous liquid	BP > 200°C (decomposition) $d(20/4) = 0.95$	Extreme pressure additive for lubricating and cutting oils
TPS 32 Di-*tert*-decyl pentasulfide CAS: 68425-15-0 EINECS: 270-335-7	Pale yellow and slightly odorous liquid	BP > 200°C (decomposition) $d(20/4) = 1.01$	Extreme pressure additive for lubricating and cutting oils; cross-linking agent for elastomers.
TPS 37 Di-*tert*-nonyl pentasulfide CAS: 68425-16-1 EINECS: 270-336-2	Yellow and slightly odorous liquid	BP > 200°C (decomposition) $d(20/4) = 1.024$	Extreme pressure additive for lubricating and cutting oils; cross-linking agent for elastomers
TPS 44 Di-*tert*-butyl polysulfide CAS: 68937-96-2 EINECS: 273-103-3	Yellow and slightly odorous liquid	BP > 178°C (decomposition) $d(20/4) = 1.007$	Extreme pressure additive for gear oils and cutting oils
TPS 54 Di-*tert*-butyl polysulfide CAS : 68937-96-2 EINECS: 273-103-3	Yellow and slightly odorous liquid	BP > 170°C (decomposition) $d(20/4) = 1.082$	Extreme pressure additive for cutting oils

(From Refs.[47,48].)

To prevent accidental ignition of mercaptan vapors, employees working in handling and storage areas should not wear metal heel- or toe-plates on shoes. Nonsparking tools should be used when working on mercaptan equipment or containers.

The general precautions discussed in handling mercaptans are applicable to Thiophene and tetrahydrothiophene. Di-*t*-nonyl polysulfide is a relatively safe nontoxic material. It can be handled in the same manner as any fuel oil.

Materials of Construction[47]

Steel, stainless steel, and copper-free steel alloys are the preferred materials of construction for mercaptan service. In particular, stainless steel should be used for any vessel or line that is to be open and exposed to air frequently. Aluminum is also suitable for mercaptan use provided the pressure rating of aluminum equipment or piping is sufficient to meet the pressure requirements of the application. Iron or carbon steel is less acceptable than stainless steels or aluminum although it can be used if appropriate measures are taken to condition the iron or carbon steel equipment before putting it into service. Allowing a small amount of mercaptan to stand in it for a period of time and subsequently keeping the equipment under a dry, inert atmosphere can prevent corrosion of the equipment. The hazard in using iron or carbon steel is the formation of iron–sulfur complexes, which are pyrophoric and constitute a potential fire hazard because of the flammability of mercaptans. If iron or carbon steel is used in mercaptan service, thorough washing with water during disassembly and cleaning is absolutely necessary.

Sulfonic acids are corrosive. Do not use copper or copper-bearing alloys for mercaptan service. Mercaptans readily attack these metals and are contaminated by them. Mercaptans are odorous; therefore, storage tanks should not be vented to the atmosphere. Venting should be to a flare or a scrubber to remove the mercaptan.

Toxicity[47]

All alkyl mercaptans have distinctive mercaptan odors, and their presence in air is quite evident. While this may present a problem in community relations, it is a built-in warning system. It is almost impossible to have an undetected mercaptan leak. However, there is a danger in ignoring the mercaptan odor. The lower-molecular-weight mercaptans, in high concentrations, tend to deaden the sense of smell; therefore, dangerous concentrations of vapors could go undetected.

The lower-molecular-weight mercaptans have the strongest odors. In very low concentrations (ppm range) they are recognized as gas leaks, because they are commonly used to odorize fuel gas. In intermediate concentrations their pungent odor has been likened to that of garlic, rotting cabbage, and other decomposed

organic matter. In higher concentrations, the desensitization effect takes place, and an alcoholic or somewhat pleasant odor may be experienced.

Although some oral toxicity data are available, inhalation is the most likely route of entry into the body. Most mercaptans have an LC_{50} greater than 2000 ppm. This is above the normally accepted ''Toxic Substance'' classification. The exception, *t*-octyl mercaptan, has been tested recently and has been found to be a ''highly toxic substance'' with LC_{50} of less than 200 ppm.

No cumulative or permanent sensitization effects have been reported from exposure to mercaptans. Long-term exposure to high concentrations of the lower-molecular-weight mercaptans can result in headache, nausea, loss of consciousness, and even death. This is possible because of olfactory desensitization. However, death from mercaptan inhalation is extremely rare, and if the victim is removed to fresh air, even if unconscious, recovery is complete.

CONCLUSIONS

Thiochemicals are among one of the more important intermediates and end-user chemicals, starting from a relatively simple molecule such as H_2S to complex molecules such as polysulfides. Many thiochemicals that are commercially manufactured provide building blocks for more specialized ones. Thiochemicals enjoy applications as intermediates in the manufacture of agricultural chemicals, pharmaceuticals, detergents, lubricants, etc. Some thiochemicals have played important roles, as solvents, chain transfer agents in polymer synthesis, electroplating solutions, presulfiding agents for hydrotreating catalysts, coke and CO inhibitors in the steam cracking process, etc.

Thiochemicals: Mercapto Acids and Organosulfur (IV/VI) Compounds

Jeffrey H. Yen
Gary S. Smith
Vijay R. Srinivas
Arkema Inc., King of Prussia, Pennsylvania, U.S.A.

INTRODUCTION

As discussed in the previous entry, ''Thiochemicals: Mercaptans, Sulfides, and Polysulfides,'' thiochemical is derived from the Greek word ''theion.'' Generally speaking, thiochemicals containing sulfur formally in the +2 oxidation state are analogs of oxygen-containing compounds; for example, mercaptans and alkyl sulfides are sulfur analogs of alcohols and ethers, respectively. Unlike oxygen, sulfur can also exist in the formal +4 and +6 oxidation states, thus affording a vast array of functionalities. Generally, thiochemicals can be classified into the following categories:

Sulfur (II) compounds

- Basic thiochemicals: Examples are sulfur dioxide, hydrogen sulfide, sodium sulfide, sodium thiosulfate, etc.
- Mercaptans (thiols): RSH; examples are methyl mercaptan, ethyl mercaptan, etc.
- Sulfides: RSR′; examples are dimethyl sulfide, diethyl sulfide, etc.
- Polysulfides: RS_xR'; dimethyl disulfide, diethyldisulfide, *t*-nonyl polysulfide, etc.
- Sulfenic acids RSOH and derivatives: benzenesulfenic acids/salts, benzenesulfenyl chloride.

Sulfur (IV) compounds

- Sulfoxides: RS(O)R and derivatives; dimethylsulfoxide.
- Sulfinic acids and derivatives: RS(O)OH, RS(O)X; benzenesulfinic acid, *p*-toluenesufinyl chloride, other arenesulfinate esters, and salts.
- Sulfite esters: $(RO)_2SO$; ethylene sulfite.

Sulfur (VI) compounds

- Sulfones: $R\text{-}SO_2\text{-}R$; sulfolane, dimethyl sulfone, etc.
- Sulfonic acids and derivatives: RSO_2OH, RSO_2X; methanesulfonic acid (MSA), *p*-toluenesulfonic acid (PTSA), methanesulfonyl chloride (MSC), methanesulfonamide, etc.

To describe the full range of thiochemicals is beyond the scope of this entry, which will therefore emphasize information on the most common thiochemicals of commerce. This entry will cover mercaptoacids, sulfonic acids and their derivatives, some sulfoxides, etc., while the previous entry covers mercaptans, sulfides, and polysulfides. The safety, health, and environmental issues for both entries are discussed at the end of the previous entry.

MERCAPTO ACIDS, SALTS, ESTERS

Chemical and Physical Properties

Mercaptocarboxylic acids are difunctional molecules with both carboxyl and thiol functionality. The general formula is $HS\text{-}R\text{-}CO_2H$, with R being alkyl or aryl. Both the carboxyl and thiol groups are acidic. For mercaptoacetic acid and thioglycolic acid the pK_a values are 3.6 and 10.2, respectively. The physical properties of commercial mercaptoacids, esters, and salts are given in Table 1. The carboxylic acid group can be readily converted to afford salts or esters. Mild oxidants such as I_2 convert the thiol to the disulfide. The generated disulfides can undergo thiol/disulfide exchange to afford unsymmetrical disulfides. The thiol group also reacts readily with aldehydes or ketones to afford dithioketals, with acyl chlorides or anhydride to afford thioesters, and with α,β-unsaturated carbonyl and nitrile compounds. As discussed below, the thiol readily reacts with alkyl halides to form dialkyl sulfides.

Manufacturing Technology

Mercaptoacetic acid, also known as thioglycolic acid, is prepared from the continuous reaction of chloroacetic acid with two molar equivalents of aqueous ammonium or metal hydrosulfide. The reaction is run under autogenous H_2S overpressure, derived from the neutralization of the chloroacetic acid with one equivalent

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016066

Table 1 Physical properties of selected mercapto carboxylic acids, esters, and derivatives

Name	Structure	MW	Melting point (°C)	Boiling point (°C/torr)	CAS Reg. No.
Mercaptoacetic acid (thioglycolic acid)	$HSCH_2CO_2H$	92.12	−16	123/29	68-11-1
2-Mercaptopropionic acid (thiolactic acid)	$HSCH(CH_3)CO_2H$	106.1		85/5	79-42-5
3-Mercaptopropionic acid	$HS(CH_2)_2CO_2H$	106.1	15.5	111/15	107-96-0
Thiodiglycolic acid	$S(CH_2CO_2H)_2$	150.2	128		123-93-3
Dithiodiglycolic acid	$(SCH_2CO_2H)_2$	182.2	100–102		505-73-7
Thiodipropionic acid	$S(CH_2CH_2CO_2H)_2$	178.2	130		111-17-1
Dithiodipropionic acid	$(SCH_2CH_2CO_2H)_2$	210.3	152–156		1119-62-6
Methyl mercaptoacetate		106.1		148/760	2365-48-2
Ethyl mercaptoacetate		120.2		155/760	623-51-8
Butyl mercaptoacetate		148.2		110/40	10047-28-6
2-Ethylhexyl mercaptoacetate		204.3		106/3	7659-86-1
Isooctyl mercaptoacetate (mixture of isomers)		204.3		107/4	25103-09-7
Methyl 3-mercaptopropionate		120.2		166/760	2935-90-2
Butyl 3-mercaptopropionate		162.3		101/12	16215-21-7
2-Ethylhexyl 3-mercaptopropionate		218.4		85–87/2	50448-95-8
Isooctyl 3-mercaptopropionate (mixture of isomers)		218.4		95/2.2	30774-01-7
Ethylene glycol dimercaptoacetate		210.3		137/2	123-81-9
Ethylene glycol dimercaptopropionate		238.3		101/0.3	22504-50-3
2-Mercaptoethyl tallate	$HSCH_2CH_2O_2C$–R (R = unsaturated C_{18}–C_{20})				68440-24-4

of hydrosulfide. Because H_2S ($pK_{a1} = 7.0$) has approximately 1000 times the acidity of the thiol group on the formed mercaptoacetic acid, the presence of the H_2S inhibits formation of the mercaptoacetate dianion and subsequent reaction with chloroacetate to form the sulfide. The crude mercaptoacetate salt from the reaction is acidified, extracted into organic solvents, and ultimately recovered by vacuum distillation. Principal by-products are the halide salts.

$$ClCH_2CO_2H + 2MSH \longrightarrow HSCH_2CO_2M + MCl + H_2S \quad (1)$$

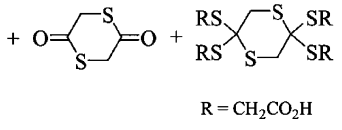
$$HSCH_2CO_2M + HCl \longrightarrow HSCH_2CO_2H + MCl \quad M = NH_4, Na, K, Ca \quad (2)$$

$$HSCH_2CO_2^- + HS^- \rightleftharpoons {}^-SCH_2CO_2^- + H_2S \quad (3)$$

$$ClCH_2CO_2^- + {}^-SCH_2CO_2^- \longrightarrow S(CH_2CO_2^-)_2 + Cl^- \quad (4)$$

The product mercaptoacetic acid will self-esterify on storage or heating. The self-esterification products are primarily the linear dimer ($x = 1$), along with some cyclic dimer, oligoesters ($x = 2+$), and solid orthothioester. These self-esterification reactions, with the exception of the formation of the orthothioesters, can be readily reversed in water with dilute acid or base catalyst.

$$HSCH_2CO_2H \overset{\Delta,\,H^+}{\rightleftharpoons} HS[CH_2C(O)S]_xCH_2CO_2H + H_2O$$



$$R = CH_2CO_2H \quad (5)$$

Most mercaptoacetic acid is sold in the form of esters, primarily for use in organotin stabilizers for poly(vinyl chloride) (PVC). The esterification is performed in batch or continuous mode, primarily using 2-ethylhexanol or isooctanol.

$$HSCH_2CO_2H + ROH \xrightarrow{H+} HSCH_2CO_2R + H_2O \quad R = \text{2-ethylhexyl, isooctyl, butyl, etc.} \quad (6)$$

Purified mercaptoacetic acid is sold in anhydrous or 85% aqueous forms, most often for subsequent conversion to the esters or to the ammonium, sodium, potassium, or calcium salts. 3-Mercaptopropionic acid is produced from metal hydrosulfides and either acrylic acid or acrylonitrile. Mercaptoethyl tallate is another mercapto-ester used in commercial organotin stabilizers. It is manufactured by a standard esterification of mercaptoethanol and tall oil, a mixture of fatty acids.

Applications

Mercaptoacetate salts have extensive applications in personal care, particularly in cold-waving of human hair, hair straightening, and as depilatories. Essentially, the dianionic mercaptide reacts with the cystine (disulfide) cross-links between the keratin polypeptide chains via mercaptan–disulfide exchange. This allows deformation of the keratin with resultant curling or straightening of the hair. The cystine disulfide linkages are then restored by use of a ''neutralizer,'' actually an oxidant such as H_2O_2, sodium perborate, or sodium or potassium perbromate. Similarly, mercaptoacetic acid has found applications in leather treatments, including dehairing and softening of hides, and in the treatment of wool fibers.

Mercaptoacetate and mercaptopropionate esters are key raw materials in the manufacture of organotin stabilizers for use in PVC. The mercapto-esters are reacted with organotin chlorides under two-phase aqueous conditions, with the liquid products being isolated by phase separation and stripping of residual water.[1,2] The generated organotin mercaptides are the workhorse thermal stabilizers for processing of PVC. Methyl and octyltin mercaptide stabilizers are used in PVC for food-contact applications because these materials offer very low migration from the PVC and low overall toxicity. Butyltin mercaptides are employed in the production of PVC films, sheet, injection moldings, floor tiles, and wall coverings, as well as for pipe extrusions and siding containing high levels of TiO_2.

Other applications for mercaptoacids and esters include the following. Mercaptoacetic acid serves as a cocatalyst with strong mineral acid or sulfonic acid resins for the condensation of phenol and acetone in the manufacture of bisphenol A. The acid and its ammonium and ethanolamine salts are components in descaling compositions for removal of iron oxides. Mercaptoacetic acid is used in oil drilling where it acts as an iron sequesterant and an acidizing agent. In concrete and cement applications, polymeric melamines and mercaptoacetic acid have been combined in a new class of ''superplasticizers'' that impart high fluidity, reduced water content, and improved mechanical properties. In this application, it is replacing sulfananilic acid. Alkanolamine salts of the dithiodipropionic acid are available as extreme pressure lubricants. Similar salts of dithiodiglycolic acid are also available.

SULFOXIDES AND SULFONES

Chemical and Physical Properties

The physical properties of the predominant alkyl sulfoxides and sulfones of commerce are listed in Table 2.

Table 2 Physical properties of selected sulfoxides and sulfones

Name	Formula	MW	Melting point (°C)	Boiling point (°C/torr)	CAS Reg. No.
Dimethyl sulfoxide	CH_3SOCH_3	78.1	18.6	189.0/760	67-68-5
Dimethyl sulfone	$CH_3SO_2CH_3$	94.1	108–110	238/760, sublimes 90–100/13	67-71-0
Sulfolane		120.2	28.5	287.3/760	126-33-0
3-Sulfolene		118.2	65	>110/760 (dec.)	77-79-2

Of these, dimethyl sulfoxide (DMSO) and sulfolane (tetramethylene sulfone) represent the largest volumes.

The physical, chemical, and solvent properties of DMSO and sulfolane are well documented.[3–5,6] Dimethyl sulfoxide decomposes only slowly at its normal boiling point (189°C) in air, exhibiting only 2% decomposition to $(CH_3)_2S$, $(CH_3)_2SO_2$, CH_3SH, CH_3SSCH_3, and $(CH_3S)_2CH_2$. Its decomposition (vide infra) is accelerated by acids, anhydrides, acid chlorides, amides, and glycols. Dimethyl sulfoxide has many applications as a solvent and reactant (vide infra).

Sulfones possess extraordinary thermal and chemical stability. Sulfolane is thermally stable to 220°C decomposing to SO_2 and polymeric materials. Dimethyl sulfone decomposes by C–S fission at 510–640°C at 0.7 torr. Sulfones are generally nonreactive materials except under extreme conditions. Nonetheless, sulfones with multiple chlorine or fluorine substituents can be hydrolyzed to sulfonic acids or cleaved by halogen to afford the sulfonyl halides.

Manufacturing Technology

While a number of synthetic routes are available to various sulfoxides, the primary methods for commercial production of DMSO involve oxidation of dimethyl sulfide by oxides of nitrogen or by air in the presence of NO_x catalyst.[3–5] Dimethyl sulfoxide is both the product and the reaction solvent. To alleviate the potential for exothermic, and potentially explosive, runaway reactions in these oxidations, the feed rate for dimethyl sulfide is adjusted to ensure complete conversion and, thus, low instantaneous concentrations at any time. Alternate oxidants for the conversion of sulfides to sulfoxides include nitric acid, H_2O_2/acetic acid, peracids, and halogen/water.[7]

$$(CH_3)_2S + NO_2 \longrightarrow (CH_3)_2SO + NO \quad (7)$$

$$(CH_3)_2S + \tfrac{1}{2}O_2 \xrightarrow{\text{cat.NO}_X} (CH_3)_2SO \quad (8)$$

In all oxidations of sulfides to sulfoxides, yield loss because of overoxidation to form the sulfones is common unless temperatures are low. Another source of yield loss in aliphatic sulfoxides with α-hydrogens arises from the Pummerer reactions, which occur at temperatures greater than 80°C under acidic conditions or in the presence of acid anhydrides/halides. The Pummerer reactions are quite general, leading to products of the general formula $RSCR'_2Z$, with Z being acetate, chloride, hydroxide, etc.

Because sulfoxide sulfur is in an intermediate oxidation state, formally +4, it undergoes a small degree of thermal disproportionation to the corresponding sulfone and sulfide, at elevated temperatures near or above the normal boiling point. The formation of dimethyl sulfide is in part responsible for the garlic-like odor in aged DMSO, and can be minimized by storage under air.

Ozone, H_2O_2, HNO_3, and O_2 with NO_x catalysts are all effective oxidants for converting sulfides to sulfones, albeit much more slowly and at higher temperatures than were used to make sulfoxides. Alkyl aryl sulfones are typically produced by the Friedel–Crafts reaction of an aromatic hydrocarbon with an alkanesulfonyl halide or anhydride. Symmetrical aromatic sulfones are generally prepared by the sulfonation of aromatic hydrocarbon with SO_3, H_2SO_4/SO_3, Cl_2SO_2, $ClSO_3H$, etc.[3–5] The corresponding aromatic sulfonic acids or sulfonyl chlorides are coproducts of the latter reaction.

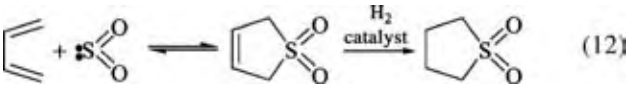
$$R_2SO \xrightarrow{[O]} R_2SO_2 \quad (9)$$

$$RSO_2X + ArH \xrightarrow[X = Cl,Br,OSO_2R]{\text{Lewis Acid Catalyst}} RSO_2Ar + HX \quad (10)$$

$$R_2SO \xrightarrow{\Delta} R_2SO_2 + R_2S \quad (11)$$

3-Sulfolene is produced from butadiene and SO_2, via classical cycloaddition chemistry, with hydrogenation

of the sulfolene affording the sulfolane. Sulfolane is available as a crystalline anhydrous material, or with 3% added water as a freezing point depressant.



(12)

Applications

Both DMSO and sulfolane are extensively used in the chemical, pharmaceutical, polymer, and electronics industries as polar aprotic solvents, with unique properties such as a high dielectric constant, high polarity, and high miscibility with organic and aqueous materials. For example, sulfolane finds use in the refining industry for the separation of benzene, toluene, and xylene (BTX) fractions from paraffins.

The use of DMSO as a reactant and as a solvent has been discussed in detail. Because of its highly polarized S^{+}–O^{-} bond, DMSO is a strong solvator of water, inorganic salts, and most moderately to highly polar organic molecules. Because of its ready permeation through the skin and strong solvating properties, it is used as a carrier solvent for transdermal delivery of pharmaceuticals. As a reaction solvent, DMSO serves to activate NH, OH, and CH functional groups in a variety of reaction chemistries. Dimethyl sulfoxide oxidizes aromatic thiols to disulfides at room temperature.

SULFONIC ACID AND DERIVATIVES

Chemical and Physical Properties

Sulfonic acids and their most common derivatives can be represented by the general formula $RSO_2 - Z$, with Z defined as shown below (R and R′ = substituted or unsubstituted aliphatic, aromatic or heterocyclic groups, and M = metal, ammonium, phosphonium).

Table 3 Estimated acidities for sulfonic acids and inorganic mineral acids

	pK_a in H_2O		pK_a in H_2O
CH_3SO_3H	−1.9	HNO_3	−1.5
$CH_3CH_2SO_3H$	−1.7	HCl	<−2.0
$CH_3CH_2CH_2SO_3H$	−1.5	$HOSO_3H$	−3.0
p-$CH_3C_6H_5SO_3H$	−2.7	CH_3OSO_3H	−3.5

As a class, sulfonic acids (RSO_3H) are the strongest uncharged organic acids. Their acidities are similar to those for the strong mineral acids. Selected physical properties for these materials are given in Tables 3, 4A and 4B. Selected physical properties for the alkanesulfonyl halides and anhydrides in common commercial and laboratory use are provided in Table 5.

Methanesulfonyl chloride is the largest-volume alkanesulfonyl chloride. Benzenesulfonyl chloride is the only aromatic sulfonyl halide with significant commercial production, primarily as a feedstock for the manufacture of *N*-butyl benzenesulfonamide. All sulfonyl chlorides are poorly water soluble, which limits their hydrolysis except at elevated temperatures or in the presence of a homogenizing agent such as a cosolvent, surfactant or phase-transfer agent.

The common commercial or laboratory alkanesulfonamides are listed in Table 6. Of these, methanesulfonamide, *N*-methyl methanesulfonamide, *N*-butyl benzenesulfonamide, and trifluoromethanesulfonimide are in commercial production, the latter in the form of its lithium salt. Measured pK_a values are available for a variety of aromatic and akanesulfonamides and sulfonamides along with a discussion on substituent effects.[3–5]

Manufacturing Technology

Alkanesulfonic acids and alkanesulfonyl chlorides from thiols and disulfides

Methanesulfonic acid and methanesulfonyl chloride (MSC) are the alkanesulfonic acids and alkanesulfonyl chlorides produced in the largest volumes.

Methanesulfonic acid is primarily manufactured by the batch or continuous oxidation of the methyl mercaptan or dimethyl disulfide with chlorine in saturated aqueous hydrochloric acid.[3–5,8,9] This chemistry is also the basis for much of the worldwide production of MSC, with photochlorination of methane (vide infra) being the most significant commercial alternative. Other alkanesulfonyl chlorides and sulfonic acids have also been produced in lesser quantities by the Cl_2/H_2O oxidation. Reaction yields are typically 92–100%. The HCl by-product separates as vapor from the saturated reaction mixture. It is absorbed into water to afford a concentrated hydrochloric acid coproduct.

$$RSH + 3Cl_2 + 2H_2O \xrightarrow[\text{aqueous HCl}]{10-35^\circ C} RSO_2Cl + 5HCl \quad (13)$$

$$RSO_2Cl + H_2O \xrightarrow[\text{aqueous HCl}]{>85^\circ C} RSO_3H + HCl \quad (14)$$

When the desired product is the alkanesulfonyl chloride RSO_2Cl, reaction, temperatures are maintained at 10–35°C to inhibit hydrolysis of the poorly soluble sulfonyl chlorides. Extraction with clean

concentrated HCl removes any H_2SO_4 or RSO_3H impurities, while residual HCl and water are removed by evaporation under vacuum. Alternately, the sulfonyl chloride can be vacuum distilled to separate the impurities.

The alkanesulfonic acids are produced at elevated temperatures to ensure complete hydrolysis of the intermediate RSO_2Cl, with residual HCl being stripped from the reaction product. Methanesulfonic acid and other alkanesulfonic acids are typically obtained as 60–70% aqueous solutions. Similarly, isolated alkanesulfonyl chlorides can be hydrolyzed to afford the aqueous or anhydrous sulfonic acids.[10] Anhydrous nonfluorinated alkanesulfonic acids can also be prepared by evaporative removal of water from the aqueous acids.[11]

Nitric acid has also been shown to be an effective oxidant for converting thiols or disulfides to the corresponding sulfonic acids.[12,13] When this reaction is performed in the presence of HCl at low temperature, the sulfonyl chlorides can also be obtained. The use of nitric acid oxidant has traditionally resulted in higher levels of overoxidation, affording H_2SO_4 as an impurity. In electroplating applications, the major market for MSA, the specification for H_2SO_4 is typically less than 150 ppm and occasionally much lower. In one recently launched commercial MSA process involving nitric acid oxidant, the H_2SO_4 levels in the product were minimized by performing the reaction in two sequential reactors, the first operating at 80–120°C where the bulk of the conversion occurs, the second at 130–150°C. Residual HNO_3 and NO_x were removed by evaporative stripping. Distillation of the MSA then afforded the final product with low impurities. In this process the HNO_3 was regenerated from the nitric oxide by-product by reaction with air. Similarly, the use of atmospheric O_2, catalytic HNO_3/NO_x, and Br^-/Br_2cocatalyst to oxidize aliphatic thiols and disulfides to alkanesulfonic acids and alkanesulfonyl chlorides has also been described.[14]

$$\frac{1}{2}\mathrm{RSSR} + \frac{5}{3}\mathrm{HNO_3} \xrightarrow[\mathrm{H_2O}]{80-150^\circ\mathrm{C}} \mathrm{RSO_3H} + \frac{5}{3}\mathrm{NO} + \frac{1}{3}\mathrm{H_2O} \qquad (15)$$

Alkanesulfonic acids can be prepared from the thiols or disulfides and air using cocatalytic DMSO and HBr.[15] The use of aqueous DMSO in the absence of air, but in the presence of a halogen or hydrogen halide catalyst, readily converts most aliphatic, aromatic, and heterocyclic thiols or disulfides to the corresponding sulfonic acid.[16,17] In effect, DMSO oxidizes the hydrohalide to the molecular halogen, which then reacts with the organosulfur substrates. Water serves as a proton and oxygen source, and inhibits the Pummerer-type decomposition of the DMSO.

Other oxidants for the conversion of alkanethiols and disulfide alkanesulfonic acids have been described. H_2O_2, in combination with catalysts, e.g., peroxycarbonates, alkanesulfonic acids, molybdates, tungstates, or HCl, was effective in producing alkanesulfonic acids.[18,19] At lower temperatures (25–35°C) the combination of H_2O_2 catalytic HCl afforded the alkanesulfonyl chlorides. Kinetic studies of the photooxidation with O_2 in acetonitrile and other solvents have been reported and the relative stabilities of the various

oxysulfur intermediates have been evaluated by ab initio methods.[20,21] Electrolytic oxidation of alkanethiols and disulfides has also been described.[22]

$$RSH + 3(CH_3)_2SO \xrightarrow[\text{catalyst HX or } X_2]{100-130^\circ\ H_2O} RSO_3H + 3(CH_3)_2S \quad (16)$$

$$2HX + (CH_3)_2SO \longrightarrow X_2 + H_2O + (CH_3)_2S \quad (17)$$

Alkanesulfonic acids and alkanesulfonyl chlorides from aliphatic hydrocarbons

Sulfoxidation of saturated hydrocarbons with SO_3, or SO_2 with O_2, is an effective but nonselective method for producing alkanesulfonic acids, invariably producing a mixture of alkanesulfonic acid products.[23] Despite the poor selectivity, this procedure has been used extensively in the manufacture of long-chain alkanesulfonate salts as surfactants since the 1940s. Methane is a particularly nonreactive hydrocarbon and early efforts to sulfoxidate CH_4 using mercury salt catalysts afforded mixtures of MSA, methanedisulfonic acid, and methyl esters.[24] More recent efforts have demonstrated highly selective sulfoxidations of methane with SO_3, or air and SO_2, to afford MSA, as well as a related sulfochlorination of methane with SO_2Cl_2 to make MSC.[25–28]

Photochemical sulfochlorination of saturated hydrocarbons has been used in the production of long-chain alkanesulfonyl chlorides, again as precursors to the salts as surfactants. These processes involve free radical intermediates. Analogous to the sulfoxidation of long-chain alkanes, these processes also provide mixtures of alkanesulfonyl chloride and chloroalkane products.[29] Nonetheless, pure products can be obtained for short C_1–C_3 alkyl chain lengths. A high-pressure gas phase process for the reaction of CH_4 with Cl_2 and excess SO_2 is used in one commercial manufacturing route to MSC.[30]

$$CH_4 + Cl_2 + SO_2 \xrightarrow[\text{gas phase}]{h\nu\ 32^\circ C} CH_3SO_2Cl + HCl \quad (18)$$

Alkanesulfonate salts from sulfite and alkyl halides, alkyl sulfate, olefins, or epoxides

Alkyl halides, alkyl sulfonates, and alkyl sulfates undergo nucleophilic displacement by aqueous sulfite to afford sulfonic acid salts under very mild conditions.[3–5] This chemistry is traditionally referred to as the Strecker reaction. It is currently used in the commercial production of disodium methanedisulfonic acid from CH_2Cl_2. Similarly, metal hydrogen sulfite also reacts with epoxides to afford 2-hydroxyethanesulfonates, the basis for the production of sodium isethionate (sodium 2-hydroxyethanesulfonate) used in the manufacture of surfactants. Free-radical addition of metal hydrogen sulfites to alkenes or alkynes is an alternate route to 2-alkyl- or 2-aryl-substituted ethanesulfonates or to geminal disulfonates.

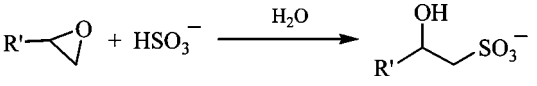
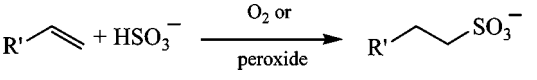
R = alkyl, X = Cl, Br, OSO_3R, OSO_2R



(20)

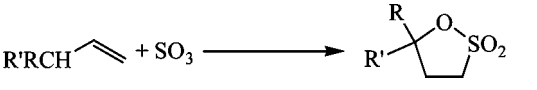


(21)

R' = H, alkyl, aryl

Sultones from olefins

Olefins react with SO_3 under free-radical conditions to afford cyclic sulfonate esters, i.e., sultones.[3–5] The initially formed products are believed to be the highly strained 1,2-adducts, which then rearrange to the 1,3-adducts. This is the commercial route to propanesultone.

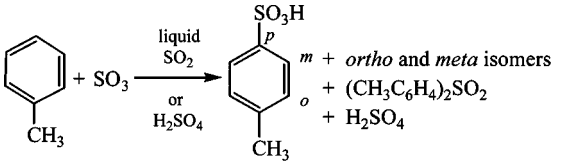


(22)

Aromatic sulfonic acids from aromatic hydrocarbons

The traditional manufacturing processes for making aromatic sulfonic acids involve sulfonation of an aromatic hydrocarbon (or polymers) by falling film technology using vaporized SO_3 in air. Alternate sulfonating agents include oleum ($H_2SO_4 + SO_3$), $ClSO_3H$, SO_3 in solvents, and SO_2 with air. A complete description is beyond the scope of this entry, and for a more thorough overview interested readers should see Ref.[31]. The industrial preparation of PTSA illustrates one approach. Toluene is reacted with SO_3 in liquid SO_2 in a falling film reactor.[32] The final reaction mixture is treated with water to separate unreacted toluene and convert residual SO_3 to H_2SO_4. The PTSA

product is then isolated by crystallization and drying.

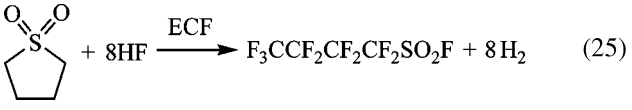


PTSA (23)

Fluorinated alkanesulfonic acids

Perfluoroalkanesulfonyl fluorides and of related materials are manufactured by the electrochemical fluorination of the corresponding alkanesulfonyl fluorides or cyclic sulfones.[3–5] This electrochemical synthesis results in replacement of all C–H bonds in the feedstock. The perfluorinated alkanesulfonyl fluoride products are neutralized to make the anhydrous salt, then acidified and distilled to afford the anhydrous sulfonic acid. Alkyl chain degradation in the electrochemical cell becomes more pronounced at longer chain lengths. Addition of short-chain divalent sulfur compounds (e.g., thiols, sulfides) to the cell inhibits buildup of tarry materials and loss of efficiency.

$$C_8H_{17}SO_2F + 17HF \xrightarrow{ECF} C_8F_{17}SO_2F + 17H_2 \quad (24)$$



(25)

Sulfonamides, sulfonimides, and sulfonate esters from sulfonyl halides

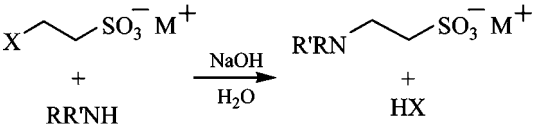
Aliphatic and aromatic sulfonamides are prepared from the corresponding sulfonyl halide (RSO_2X) and ammonia, 1°- or 2°-amines.[3–5] The reaction requires alkaline conditions and thus a stoichiometric amount of additional base to neutralize the by-product hydrohalide (see below Eq. (27)). This base may be a second molecule of the reactive amine, a 3°-amine, or an inorganic base. The reaction can be performed in organic or aqueous solvents, although excessive temperatures must be avoided in water to prevent hydrolysis of the sulfonyl chloride. The sulfonamide products are very polar materials and separation from the by-product salts is invariably a key processing issue. The general approach is to choose a reaction solvent with good solubility for the sulfonamide and poor solubility for the by-product salt, thus permitting removal of the salt by filtration. Such solvents have included nitroalkanes, toluene, chlorobenzene, tetrahydrofuran, other ethers, and nitriles.[33] Running the reaction in water and recovery of the alkanesulfonamide by extraction have also been demonstrated.[34] Alternately, the separation of aqueous mixtures of alkanesulfonamides and ammonium chloride by electrodialysis is also feasible.[35] Alkanesulfonate esters are similarly prepared from the alkanesulfonyl chloride, the appropriate alcohol, and base.[36]

Symmetrical *N*-sulfonyl sulfonamides, i.e., sulfonimides, can be prepared from the amine and two equivalents of sulfonyl chloride and base. The unsymmetrical *N*-sulfonyl sulfonamides and the related *N*-acyl sulfonamides can be obtained by the reaction of a sulfonamide or carboxamide with an acid halide.

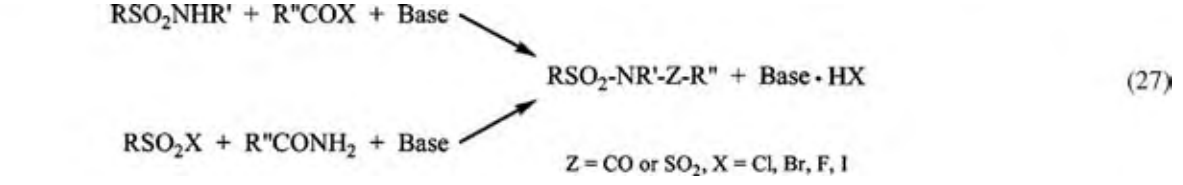
$$2RSO_2X + R'NH_2 + 2\ \text{Base} \longrightarrow (RSO_2)NR' + 2\ \text{Base} \cdot HX \quad (26)$$

Aminoalkanesulfonates

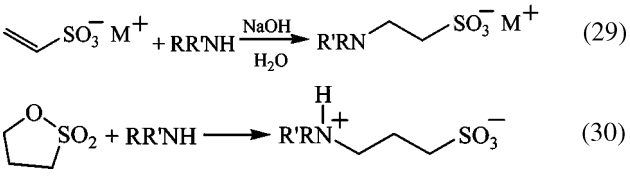
The 2-aminoethanesulfonates (i.e., taurines) are the prepared reaction of ammonia or 1°- or 2°-amines with metal 2-haloalkanesulfonate, vinylsulfonate, or hydroxyethanesulfonate salts under alkaline conditions.[37,38] The aminoethanesulfonate salts are then converted to the zwitterionic acids by cation exchange or acidification. 3-Aminopropanesulfonic acids are directly prepared by the reaction of propanesultone with the amine.



X = OH or halide (28)



(27)



(29)

(30)

Interconversion of Sulfonic Acid Derivatives

A variety of procedures have been identified for the interconversion of sulfonyl derivatives. Because of their high acidity, sulfonic acids can readily be neutralized with inorganic bases or organic amines to form salts. Conversion of metal salts back to the acid form is often desirable in synthetic or electroplating applications. Direct acidification of alkali metal sulfonates with HCl affords the sulfonic acid with precipitation of the formed metal halide salt. An alternative approach is to convert the salt back to the acid by electrodialysis.[39] Recovery and recycle of MSA from spent metal plating baths have been described.[36]

Sulfonic acids and alkali metal salts can be readily converted to the sulfonyl chlorides using a variety of reagents, including thionyl chloride, phosgene, phosphorous pentahalides, or phosphorous oxychloride. Sulfonyl bromides can be obtained from the corresponding chlorides by sequential reaction with alkaline Na_2SO_3 and Br_2. Sulfonyl fluorides are obtained from sulfonyl chlorides by reaction with aqueous KF. Aromatic sulfonyl chlorides can be obtained from the sulfonamides by reaction with PCl_5, but this is not applicable to the aliphatic analogs.

Applications

Sulfonic acids and their derivatives are used in innumerable industrial applications in chemical synthesis, electroplating of metals, surfactants, ion-exchange resins, and preparation of dyes, animal feeds, pesticides, and pharmaceuticals.

Methane sulfonic acid is used as an electrolyte for electroplating of tin onto sheet steel, for plating tin and tin/lead alloy onto nickel or other base metal substrates in the manufacture of lead frames and bump-contacts for microelectronic devices.[36] It can also be used for copper deposition during the manufacture of microprocessors. Other alkanesulfonic acids have also found use in electroplating applications. Disodium methanedisulfonate and other alkanedisulfonate salts are used in chrome plating.[40] As discussed previously, several processes for the recovery and recycle of alkanesulfonic acids from spent metal plating baths have been described.

Because of their high acidity, sulfonic acids are extensively used as Bronsted acid catalysts for esterification, aromatic alkylation, and etherification. The primary sulfonic acids in these applications include MSA, PTSA, trifluoromethanesulfonic acid (triflic acid), and nonafluorobutanesulfonic acid (nonaflic acid), as well as the aromatic and fluorinated alkanesulfonic acid resins. In these applications, they compete against the traditional strong inorganic acids such as H_2SO_4, HCl, or HF. Triflic acid and MSA are both liquids and are easily handled in a manufacturing environment. This lends these materials to use as both acid catalyst and reaction solvent.[41] Methane sulfonic acid bound to poly(vinylpyridine) has been shown to be an effective esterification catalyst that can be readily recovered and recycled.[42] Because of its much higher cost, the commercial uses of triflic acid are generally limited to reactions where its higher acidity is a requirement, e.g., the potential replacement for HF or H_2SO_4 in paraffin alkylation in petroleum refining. *p*-Toluenesulfonic acid is a solid at ambient temperatures and poorly soluble in some organic matrices at low temperature. Thus, it is recyclable by filtration.

In addition to its synthetic utility, MSA is employed as an amine-salt former in pharmaceutical final dosage forms. Other sulfonic acids are also used as pharmaceutical salt formers, but much less frequently.

The major commercial application of aromatic sulfonic acid salts is anionic surfactants.[43] These are predominately linear long-chain alkyl benzene sulfonates and the naphthalene analogs, or α-olefinsulfonates. Short-chain alkylarenesulfonates are used in liquid detergent formulations as coupling agents, solubilizers, and hydrotropes where high concentrations of organic surfactants and inorganic compounds must be kept in aqueous solution. Fatty acid esters of sodium isethionate are mild surfactants unaffected by hard water, but with limited hydrolytic stability. Cocoyl isethionate is the principle ingredient in detergent bars for personal use.

Aromatic sulfonic acid and perfluoroalkanesulfonic acids resins are widely used as ion-exchange resins in water treatment and multiple other industrial applications. In the form of membranes, they are routinely used in electrochemical cells, particularly in electroplating of metals and in battery applications. The lithium salts of trifluoromethanesulfonic acid and *N*-trifluoromethanesulfonyl trifluoromethanesulfonamide are both employed as electrolytes in secondary battery applications.

Taurine is an essential dietary nutrient in felines and is routinely added to packaged food for domestic cats.[3–5] Other aminoalkanesulfonic acids, e.g., *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES), 2-[*N*-morpholino]ethanesulfonic acid (MES), or 3-(*n*-morpholino)propanesulfonic acid (MOPS), are commonly referred to as biological buffers or as ''Good's'' buffers.

These are intensively used in fermentation and protein separation.[37,38]

Sulfonyl chlorides have extensive uses in organic synthesis in the preparation of sulfonamides and sulfonate esters. Methanesulfonyl chloride is a key raw material in the synthesis of critical components for photographic color developing formulations, as well as for herbicides and pharmaceuticals.

Methanesulfonamide and *N*-methyl methanesulfonamide are used as chemical intermediates in the manufacture of agrochemical herbicides and fungicides.[44,45] Methyl methanesulfonamide is also used in the synthesis of the anticholesterol agent rosuvastatin.[46] *N*-Butyl benzenesulfonamide serves as a plasticizer for polyamide resins.

CONCLUSIONS

Thiochemicals are among the important intermediates and end-user chemicals, varying from relatively simple molecules, e.g., H_2S, to complex molecules, e.g., polysulfides. Their manufacturing routes vary and depend highly on their properties and quantity of interest. Their intermediate applications include the manufacturing of agricultural products, pharmaceuticals, detergents, lubricants, etc. Some thiochemicals have played important roles in solvents, polymer synthesis, electroplating, presulfiding of hydrotreating catalysts, coke prevention in steam cracking process, etc.

Clayt Robinson
Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, Ohio, U.S.A.

INTRODUCTION

Tissue engineering is a combination of biology and engineering for producing biological substitute structures that can reconstitute cellular or tissue function, which is lost, declining, or insufficient. Theorized for a long time, the field has evolved greatly within recent decades to meet the challenges of disease and a limited organ donor supply. For tissue substitutes to be successful in replacing lost function, they must accurately and reliably perform the desired function that is dependent on a multitude of variables. Parameters that must be carefully investigated include the cell source, the polymeric scaffold support, the tissue culture protocol, and the implantation procedure. Tissue engineering research covers a wide range of applications including many tissue substitutes, cell therapy, and diagnostic modeling. Although faced with as yet unmet challenges, tissue engineering stands to provide momentous advancements to health in the 21st century.

First coined in 1987, tissue engineering, as a field, is defined by two main objectives. The first objective is to apply methods and principles of engineering and life sciences to understand the biological tissue construct.[1] In addition to deciphering the vast catalog of cellular functions, the interconnections of a cellular population, regulated by signaling pathways, and the interactions of a cellular composite with the noncellular surrounding environment must be understood. Since the three-dimensional structure and organization of tissue components are integral in defining proper function of the tissue, this environmental arrangement must be mimicked to produce a tissue substitute that functions appropriately. A fundamental understanding of a tissue environment structure and how it enables or affects the tissue function is essential. The second objective is to apply established knowledge of the tissue construct toward developing biological substitutes to restore, maintain, or improve natural function to tissues or organs that are structurally or physiologically altered.[1]

Included in this entry is a review of the development of tissue engineering, from theorized concepts and early experiments through advancements made in developing tissue substitutes in the recent past. A review of biological systems and components precedes a thorough discussion of the components utilized in tissue engineering constructs. The entry concludes with tissue engineering applications and the challenges that remain for full realization of the field's potential.

MOTIVATION

Motivation for further development in the field of tissue engineering is to save the lives of patients suffering from organ failure or loss, who are waiting for donor organs to become available, and those suffering from debilitating diseases, such as Parkinson's disease, in which essential cell or tissue function deteriorates or is lost over time. Further, people are victims to catastrophic events in which tissue repair or replacement is a grave concern with, commonly, no immediate remedy.

As a result, the annual health care costs in the United States alone exceed $400 billion for patients with tissue loss or organ failure. The cost includes 8 million surgical procedures and 40–90 million hospital days annually.[2] In 2002, the waiting list for organ recipients exceeded 81,700 candidates, with over 38,600 people added to the list. However, only 12,800 organs were transplanted in 2002 owing to a severe shortage of donors.[3] With a limited organ supply, accumulating costs, and limited medical procedures available, there is a void to fill.

FROM FICTION TO REALITY

There are several examples of tissue engineering well before the field was named in 1987. Stories that include the replacement of a person's body parts with those from another person are found in literature centuries old. Possibly, the first tale of a tissue engineering procedure is found in the Bible, when Eve is given life from the rib of Adam. In 1818, Mary Shelley wrote *Frankenstein* in which the title character is given life through the compilation of body parts garnered from donor corpses. In the legend of St. Cosmas and St. Damien, about 200 A.D., the two physicians performed a procedure in which the gangrenous leg of a

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120006824

man was successfully replaced with the leg of a recently deceased man.[4] More recently, Hollywood has produced films that portray ideas from tissue engineering. In 1991, the aptly titled *Body Parts* was released, in which a man loses his arm in an accident and receives a transplant from a recently executed inmate. Although successfully transplanted, incompatibility becomes an issue as the transplanted arm retains the murderous personalities of its donor.

The collection of stories that involve tissue engineering concepts shows the promise and spectacular possibilities that the future could bring. However, rarely do these stories fully conceptualize or even mention the challenges involved in performing these acts in reality. Until the advancement of tissue engineering in the 1970s, replacements for bodily tissues were prostheses made of wood, ceramics, and plastics. Replaced body parts included arms, legs, eyes, ears, teeth, and noses.

Experimentation with animals became more common for studying the growth of tissue. In the 1930s, the work done by Bisceglie became one of the earliest documented tissue engineering procedures.[2] Two important concepts were displayed including the transplantation of mouse tumor cells into the abdomen of a pig, while the cells were encased within a polymer membrane structure. First, the results showed that cells could survive within a foreign environment without rejection by the host immune system. Second, the procedure introduced the encapsulation approach. The semi-permeable polymer membrane system allowed for nutrient and waste fluxes into and out of the membrane system, respectively. Concurrently, the membrane selectively rejected the passage of immune system molecules and proteins, thus protecting the enclosed cells. In the work performed by Chick and coresearchers, islet cells were encapsulated within a semi-permeable membrane and transplanted into animal models to provide glucose level control as a cure for diabetes.[2]

In the laboratory setting, the first tissue to be reconstituted was skin because of its relatively simple two-dimensional structure. During the late 1970s and 1980s, artificial skin was created using skin cells distributed within natural collagen or collagen–glycosaminoglycan composite support structures. The growth of tissue engineering in the 1990s and early 2000s is due to interdisciplinary advancements in the fields of engineering, genomics, proteomics, cell biology, and material science.[5] As understanding of the important relationship between tissue structure and function became fully realized, three-dimensional synthetic polymers were utilized to mimic the bodily in vivo environment as a support for cells to attach and grow on. The liver was the first tissue to be cultivated using these three-dimensional constructs owing to its relatively simple composition. Utilizing these newly developed tools, a multitude of tissues have been or are being studied and mimicked with tissue-engineered products for possible future usage in a wide array of applications that is discussed later in this chapter.

CELLULAR SYSTEMS BIOLOGY

For a tissue substitute to function properly, many biological aspects of the tissue and component cells must be understood. Some aspects include the extracellular matrix, cell-specific gene expression and surface markers, cell growth parameters, population arrangement and behavior, and the immune system.

Tissues and Organs

An organ is a component of the human body system made of one or more tissue types and has specific jobs within the complex network. Tissue is a collection of similar cells and the surrounding supportive environment that together perform specific tasks. There are four basic categories of tissues: epithelium, which constitutes surfaces such as skin, connective tissue, muscle tissue, and nerve tissue.[4]

Extracellular Matrix

Tissue in vivo consists of cells that are engaged in an environment, called the extracellular matrix (ECM), that provides support to allow for proper cell function, cell–scaffold interactions, and tissue morphology. The ECM directly affects or controls cell shape, function, viability, and population structure. The ECM that supports the tissue structure and cells in vivo is a complex network of collagens, glycoproteins, such as fibronectin and laminin, hyaluronic acid, proteoglycans, glycosaminoglycans, and elastins to which cells adhere and interact. The three-dimensional ECM has a two-way interaction with the cells. The ECM surface properties and molecules provide cell-surface receptor-mediated signals to influence cellular spatial organization, migration, growth, differentiation, and death.[6] Important cell receptors that interact with the ECM include integrin and cadherin adhesion receptors.[7] The cells influence the ECM by remodeling the structure and secreting new ECM components.[8]

Genes and Proteins

The genes on chromosomes within each cell are the blueprints of the human body. The pattern in which the genes are expressed determines the cell type and behavior. Gene expression, which leads to protein

production, is a highly controlled process dependent on signals originating from other cellular components within the same cell, externally from other cells within the immediate environment, or from distant locations, such as part of the endocrine system. External signals are transduced, or passed, with the aid of surface molecules that are receptors for the signal molecules. Other molecules and proteins are expressed to perform cell-specific functions within the cell, or externally following secretion. The presence of these surface receptors or expressed functional proteins is characteristic of the cell type and can be used as cell markers for identifying proper cell function.

Cell Growth

As cells grow, or proliferate, they proceed through a highly controlled process called the cell cycle. The cell cycle consists of four phases during which the DNA set is accurately replicated and subsequently divided into two complete sets partitioned into two new cells derived from dividing the original cell via mitosis. Regulatory proteins guard progression between phases to ensure cellular readiness and DNA integrity preservation. Errors in this regulatory process can lead to DNA mutations and uncontrolled growth, both characteristics of cancer. With specific signals present, cells exit the cell cycle for a maturation process called differentiation before re-entering the cell cycle. As cells differentiate, their function becomes more defined and limited.

Morphology and Arrangement

Cellular morphology and population arrangement within the tissue culture environment are dependent on the support surface properties. Cells that are highly proliferating appear round and smooth. As cells adhere to a surface, spreading occurs across the surface, and the cells flatten. As population of cells increases, interaction and rearrangement occur among the cells. In a two-dimensional environment, interactions are limited, but in a three-dimensional environment, cellular aggregates can form within the structure of the supporting material. Aggregation and interaction among cells in all directions mimic the body environment and allows for similar cellular function.

Immune System

The immune system defends the body from infection and illness using cellular and molecular components to detect and clear objects from the body that are not identified as normal. When objects such as invading viruses, micro-organisms, implanted materials, and mutated cancerous cells are targeted by the immune system, the resulting immune rejection mechanism kills, disrupts, or encloses the foreign object to prevent further harm to the body. Cells are screened by immune system antibody molecules or T-cells to verify whether the surface molecules are native or foreign. A key determinant of whether a cell is native or foreign is the major histocompatibility complex genes contained within the cell and expressed on the cell surface. Therefore, for cells to be compatible and to avoid immune rejection in a new host, the similarity of the major histocompatibility complex genes must be high. This is important in determining the success of a tissue-engineered product within the host.

TISSUE ENGINEERING CONSTRUCT COMPONENTS

As summarized in Fig. 1, the components that must be customized based on the application include cell source, scaffold parameters, and cell culture procedures.

Cell Sources

The cells utilized for producing a tissue substitute come from multiple sources. When a specific cell type is needed to culture a certain tissue type, the availability of the cell type, the means of obtaining the cells, procedures for maintaining and multiplying the cell population in culture, and immune rejection upon transplantation must all be considered. Avoiding rejection is a huge challenge in the development of a tissue substitute, thus autologous cells obtained from the same person to whom the transplant will be given are ideal as the host body does not reject autologous cells. However, supply of autologous cells is frequently the problem. For example, in many situations, a large enough population of healthy cells is unavailable due to the extent of disease.[9] Further, the harvesting of cells from one location may cause long-term harm to the donor site. Once obtained, autologous cells are cultured, or grown, in a laboratory environment, or in vitro in the presence of a proper support structure and nutrient supply until a larger population is present. The autologous cells are then administered to the donor patient at the necessary site.

When autologous cells are not appropriate or available, the cells can come from either another donor of the same species or a different species. The transplantation of cells between similar or dissimilar species is called allotransplantation or xenotransplantation, respectively. Although the supply of these types of grafts is plentiful, immune rejection is very common, so some additional strategy must be utilized to avoid rejection. Cells provided by family members, or

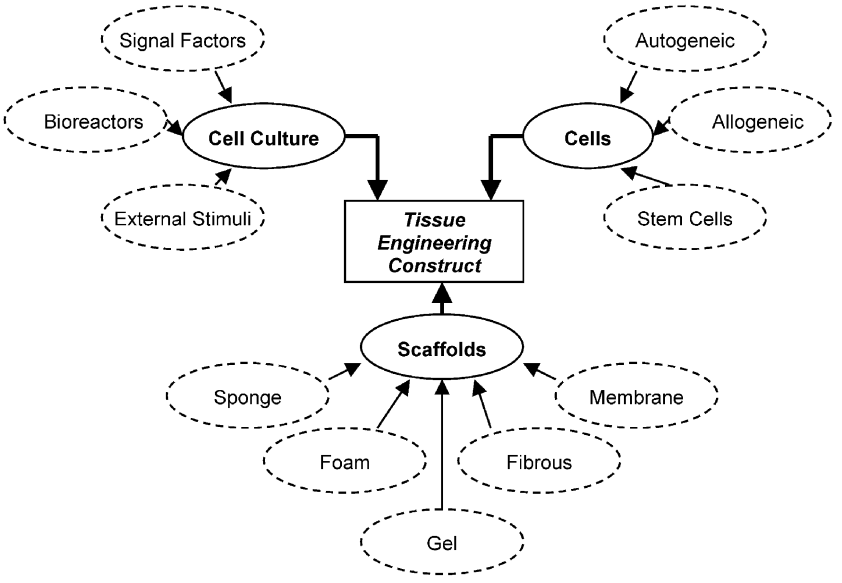

Fig. 1 Overview of the components utilized in tissue engineering constructs.

allogeneic cells, tend to be the most compatible source in order to avoid rejection due to similar gene sets, including, specifically, the histocompatibility complex genes. Xenografts provide an additional challenge since xenogeneic cells may contain components that are infectious when introduced into a human. This fact, in addition to ethical and moral issues regarding utilizing nonhuman parts in a human, has led to general unpopularity of this procedure.[9]

A fourth cell source is stem cells. Stem cells are characterized by the ability to proliferate indefinitely and develop into different cell types, or pluripotent, depending on the stem cell origin and given the appropriate signals. Embryonic stem cells are present as an embryo first begins to develop and differentiate to form all components of the human body. These stem cells allow for generation of any tissue cell type, however, ethics and regulations limit their usage. An adult retains a limited supply of adult stem cells in the bone marrow and in tissues throughout the body. Most of these progenitor cells are partially differentiated into a lineage of cell types, but remain multipotent to develop into a more limited range of cell types. Examples are neural stem cells, hematopoietic stem cells, and mesenchymal stem cells.

Owing to the limited supply of stem cells in the body, specialized techniques are necessary to find and separate them from the mixture. Stem cells may be isolated from an extracted tissue mass by digesting the ECM structure surrounding the cells, and then detecting the cells based on signature biomolecular expression profiles as a ''fingerprint'' for stem cells. Once identified, the stem cells can be separated from the total tissue population by passing the cells through a system that selectively removes the stem cells while allowing the remainder of cells to exit the system separately. Selective retention technology systems extract stem cells from the mixed population by customizing the system to have a high affinity for expressed stem cell surface molecules or to secondary molecules previously bound selectively to the cell surface. Example stem cell surface markers are CD34 and CD45 for hematopoietic stem cells and Oct-4 and SSEA-3 for embryonic stem cells.

Once harvested, stem cells can be cultured in specific biological, chemical, and physical stimuli to differentiate into the cell type of interest. Upon expansion in culture to a large enough population, the cells may be transplanted as therapy. However, strategies to avoid rejection are necessary unless the cells are autologous or cultured in such a way to disguise the fact that the cells are from a different source.[9] The difficulty lies in providing the correct composition, amounts, and timing of the stimuli to direct the differentiation to the desired cell type. A current approach is to direct the transformation of the stem cells in vitro until the cells are within one or two steps of the complete differentiation destination. The final transformation steps are accomplished in vivo, after transplantation to the site of the desired cell type where signals are provided to complete the differentiation.[10]

One concern with stem cell usage is that transplanted cells derived from stem cells can be tumorigenic owing to undifferentiated stem cells present in the population that proliferate uncontrollably.[9] The use of stem cells, however, is promising because of the limited cell supply for many tissues. Cells that are not autogeneous must be able to avoid immune rejection. Somatic cell and nuclear transfer procedures could provide cells that function appropriately and

yet will not be rejected.[9] The production of a universal donor cell source that can be used in any patient while avoiding immune rejection is a future goal. This probably involves altering the expression of or hiding the histocompatibility complex surface markers. Different types of stem cells are also being investigated as a source for multiple cell types if the differentiation can be precisely directed and controlled.

Scaffolds

Studies performed in vitro with cells growing on a two-dimensional surface have observed isolated cell function performance, such as proliferation, glycolysis, respiration, and gene expression, by optimizing the media nutrient, hormone, and growth factor compositions. However, the proper regulation and control of these functions are dependent on cellular interactions present within a three-dimensional structure.[1] Therefore, scaffolds are essential for creating tissue substitutes that mimic in vivo function.

Scaffolds can be foams, sponges, gels, membranes, or fibrous materials (Fig. 2). They are categorized as natural, synthetic, or a combination of both. Table 1 provides a list of scaffold materials and applications utilized in tissue engineering.[11–14] Natural biomaterials, such as collagen, are inherently equipped for cell interaction, but have the disadvantages of limited adaptability and customizable processing as well as relatively scarce availability compared to synthetic biomaterials.[15] The most commonly utilized synthetic biodegradable materials are poly(glycolic acid) (PGA), poly(lactic acid) (PLA), and poly(lactic co-glycolic acid) (PLGA), a blend of the former two polymers. Synthetic polymers can be used for the culture of many cell types, but it remains difficult to culture some cell types, such as nerve cells, on synthetic polymers.

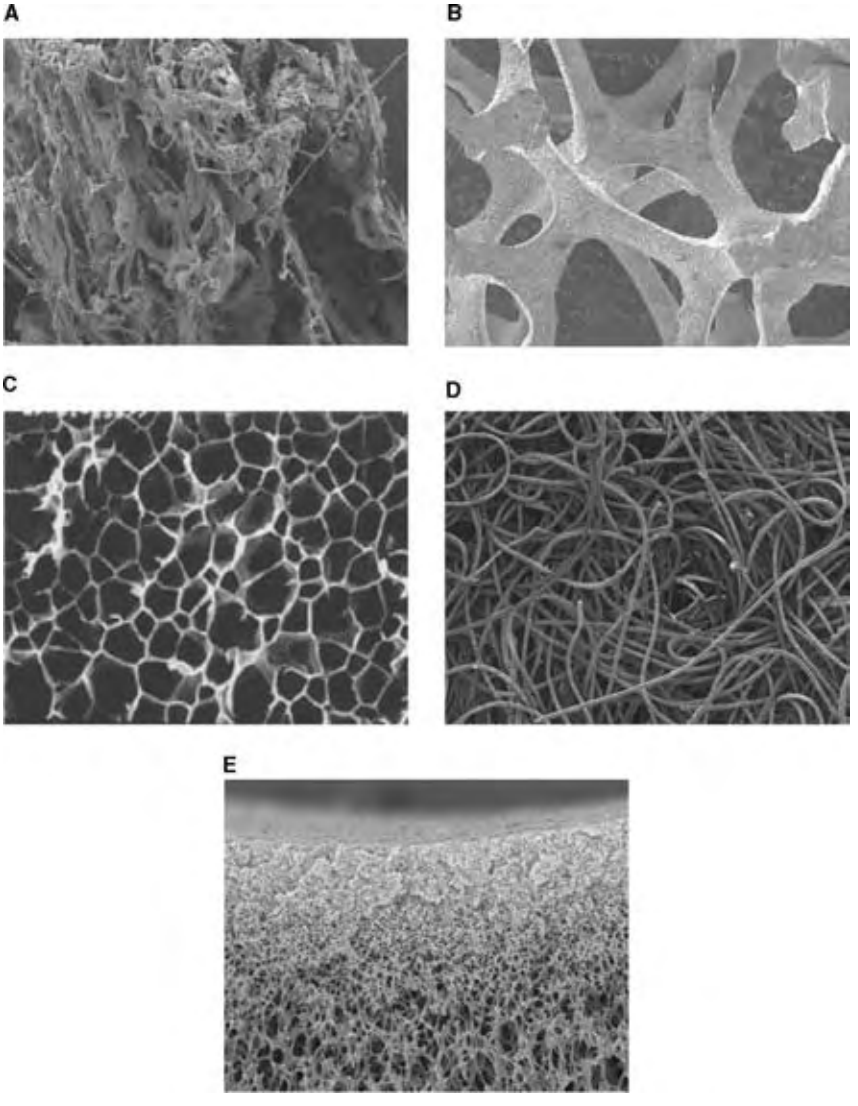

Fig. 2 Five scaffold types: (A) sponge; (B) foam; (C) gel; (D) fibrous; and (E) membrane.

Table 1 Commonly utilized scaffold materials

Polymer	Application	References
Natural		
Type I collagen	Skin, bone, cartilage, tendon, nerve, kidney, cornea, vessels	[7,11,12]
Alginate	Cartilage, muscle, soft tissue	[12]
Chitosan	Encapsulation, membranes	[11]
Fibrin	Cartilage	[12]
Laminin	Epithelial tissues, islets	[7]
Hyaluronic acid	Medical devices	[11]
Polyhydroxyalkanoates (PHA)	Skin, drug delivery, sutures	[11]
Isolated ECM from bone and small intestine	Bone, blood vessels, ureters	[7]
Synthetic		
Poly(esters) Poly(glycolic acid) (PGA) Poly(lactic acid) (PLA) Poly(caprolactone) (PCL) Poly(lactic-co-glycolic) (PLGA)	Cartilage, bone, muscle, nerve, blood vessel, valves, bladder, liver, cardiac tissue, drug delivery, sutures	[11,12]
Poly(anhydride)	Bone, drug delivery	[12]
Poly(hydroxybutyrate)	Valves	[7]
Poly(vinyl alcohol) (PVA)	Cartilage, nerve	[12]
Poly(ethylene glycol) (PEG)	Cartilage	[12]
Poly(ethylene terephthalate) (PET)	Cornea, blood vessels	[13,14]
Expanded poly(tetrafluoroethylene) (e-PTFE)	Cornea, blood vessels	[13,14]
Poly(propylene fumarate)	Bone, cardiovascular tissue	[12]

Advancement in three-dimensional polymer processing makes customization possible for polymer composition, mechanical strength, cell–surface attachment interactions, degradation rates, and high cell density.[15]

Scaffold properties influence a plurality of cell culture aspects including proliferation, differentiation, adhesion, migration, gene expression, and function. Characteristics on three size scales influence these aspects. On the macroscopic scale, the scaffold is conformed to a specific shape and size to direct the formation of a three-dimensional structure. For example, the scaffold utilized for blood vessel regeneration would be tubular in shape in order to direct cell growth and tissue morphology accordingly. A three-dimensional matrix has a high surface area to volume ratio that allows for high-density cell populations and sufficient space for nutrient transfer. The mechanical strength of the scaffold may be an important consideration depending on whether the implanted tissue is subject to a large amount of stress, as for example, with cartilage.

On the microscale, the porosity and pore structure regulate cell penetration, migration, interaction, and growth. Optimal porosities allow for penetration of cell seeding suspensions throughout the scaffold resulting in uniform distributions. The successful mixing and distribution of cells within a scaffold result in chondrocytes functioning properly by producing ECM molecules at high cellularity for enhanced cartilage strength characteristics of the tissue.[16] The morphogenesis of the developing tissue is influenced by the allowable migration of cells. The pore size distribution relates to the migration ability because it determines the amount of space available. The porosity of the scaffold and the size of the pores affect the supply of nutrients and mediation of the waste concentrations via fluid and mass transfer mechanisms. Transfer considerations are increasingly important as high cell density cultures are obtained which limit the available space for fluid and nutrient transport. In fibrous scaffolds, the fiber diameter and affiliated surface curvature affect the spreading ability of attached cells. Spreading allows cells to increase proliferation and this is regulated by fiber dimensions. Additionally, the diameter affects the degree of cell–cell interactions allowable around the fiber which are necessary for proper tissue function. Patterning of the scaffold surface, such as grooves, directs cell adhesion as well as cell growth and function for certain cell types.[17]

On the nanoscale, the surface chemistry of the scaffold must recreate the important cell–ECM properties of adhesion and control. Biocompatibility of the scaffold surface with cells is key for allowing adhesion and migration of cells. The amino acid sequence of arginine–glycine–aspartic acid (RGD) has been identified on fibronectin and other ECM glycoproteins as a key adhesion domain, and the design of synthetic scaffolds incorporating the peptide has been successful

in improving adhesion and cytocompatibility.[18] The organization of RGD peptides on the scaffold surface affects adhesion as well, with a clustered arrangement optimal rather than randomly positioned RGD peptides. Scaffolds can be supplemented with binding or signal molecules bound to the polymer surface. For enhanced proliferation and differentiation, scaffolds can be designed to release growth factors efficiently. Neural cells were cultivated in rats on a scaffold equipped with degrading beads that released nerve growth factor in a controlled manner.

If a scaffold is transplanted, the rate of biodegradability is important to ensure that the scaffold remains to support a transplant until a natural ECM replaces it. The biodegradation or resorption rate is a function of the scaffold composition, structure, and the mechanical load present at the site of transplantation.[7] The necessary rate at which the scaffold is degraded varies according to the tissue type. For example, slow degradation is allowable in bone tissue, whereas in other tissues chronic inflammation may occur if the rate is too low.[7] It is important that the degradation by-products are nontoxic to the body.

Cell Culture

To develop a tissue in culture for use as a tissue substitute, the tissue cell density must be high (commonly 10^9 cells/ml) and uniform within the scaffold. In neomorphogenesis, cells are brought into contact with a porous scaffold and they form a structure together. The cell seeding process must be optimized to achieve uniformity of cell distribution within the scaffold, to maximize utilization of the cells, and to minimize seeding process time in order to avoid damage to the cells. To seed a scaffold, cells and scaffolds are incubated together to allow for adhesion to take place. Dynamic seeding protocols incorporate mixing or flow to distribute cells throughout the scaffold efficiently. When introduced, cells attach to the scaffold surfaces if the surface chemistry of the scaffold is compatible. Scaffolds can be pre-treated to alter the surface chemistry thus allowing improved compatibility with the cells. For example, increasing the concentration of hydrophilic compounds of the surface will improve cell adhesion.

The medium utilized to provide complete nutrition for the growth of different cell types is based on a standard minimum essential nutrient composition. Most media consist of a sugar source, minerals, vitamins, and amino acids. Serum, such as fetal bovine serum, commonly supplements the medium to enhance cell growth. Growth factors and cytokines are utilized to accelerate cell growth through interaction with specific cell receptors. Differentiation inducers are added to direct the differentiation pathway of stem cells. Important parameters to control include the pH, pCO_2, and pO_2 of the media.

There are several types of bioreactor designs utilized for cultivating new tissue growth, and four are shown schematically in Fig. 3. The environment within may be static or mixed using internally designed or externally applied mechanisms. Static environments rely on diffusion as the mass transfer mechanism for nutrient supply. Mixing within a culture vessel provides convective flow of oxygen and nutrients to the cells while removing waste from the surroundings. Mixing-induced shear stress levels are an important consideration since they may cause cell death. The simplest design is the plate or Petri dish. The spinner flask is larger in scale and has an internal agitation mechanism to provide a uniform nutrient concentration within the medium and the enclosed cell–scaffold construct. Perfused bioreactors are culture environments in which media are circulated within a closed system past the immobilized cell–scaffold components. The continuous flow allows for uniform nutrient supply with enhanced mass transfer. Long-term stability of the culture is attained using continuous perfusion reactors.[19] Hollow fiber bioreactors are specialized perfusion bioreactor designs in which a semipermeable membrane in a tubular configuration creates an interior and exterior region. Media can pass through the interior region of the hollow fiber axially, while the membrane allows nutrient and product transfer into and out of the extracapillary region, respectively, where cells are located growing on the exterior surface of the membrane.[20]

As a novel bioreactor design, rotating-wall bioreactors spin on an axis, and the enclosed cell–scaffold constructs tumble within the rotating microgravity environment. Tissue culture in microgravity has been shown to improve cellular aggregation and produce highly differentiated tissue products.[21] Rotating-wall bioreactors avoid the high shear stress found within bioreactors that have agitation devices. As a result, altered gene expression favors improved aggregation resulting in aggregates up to ten times larger in diameter than those attained in conventional bioreactors. Additionally, necrosis of cells within the center of the aggregates due to mass transfer limitations is not seen. The stability of tissue constructs after removal from the microgravity environment remains to be proven in order to realize in vivo utilization.[21]

Other stimuli may be incorporated into the culture environment to cultivate proper tissue function. Mechanical or electrical stimulation, provided at frequencies simulating in vivo conditions, have been shown to improve the resulting properties of the cultivated tissue.[19] For example, pulsatile conditions that simulate a beating heart are utilized in the culture of blood vessels resulting in improved strength and function relative to cultures lacking this stimulus.[2]

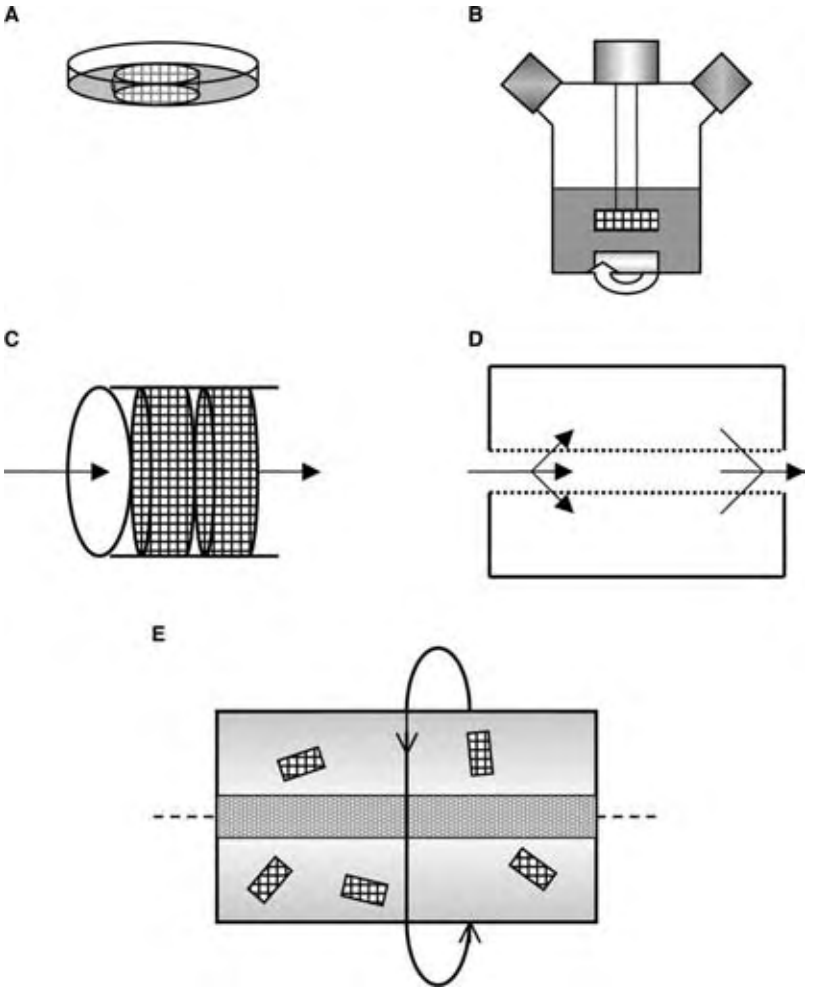

Fig. 3 Tissue engineering culture environment designs: (A) plate; (B) spinner flask; (C) perfusion; (D) hollow fiber; and (E) rotating wall bioreactor.

In cell culture, the essential nutrients must be present in the medium and be able to flow or diffuse to the cell membranes to allow for a viable culture. The bioreactor design needs to enable the cell population to expand to the cell density of the in vivo tissue; however, nutrient limitations deter this when cell growth decreases the space available within the scaffold for nutrient diffusion. Additionally, stagnant build-up of waste by-products increases acidity and harmful conditions. Therefore, the viability of a culture decreases within heavily populated regions of the scaffold. Supplying nutrients to these interior regions is a challenge, and currently, a tissue thickness of over 1 mm is not maintainable without cell death in the core of the tissue mass. In vivo, nutrient transfer within a tissue is achieved by a process called angiogenesis. As tissue mass increases, vasculature is established by promoting blood vessel growth within a starvation zone. A similar process of angiogenesis established within an in vitro culture would permit large-scale tissue growth. A tissue transplant can promote angiogenesis by providing angiogenic growth factors, such as vascular endothelial growth factor, along with the transplant that are released over time to allow for high cell density tissue regeneration.

Many tissues consist of more than one cell type. The fact that most major organs in the human body consist of more than one tissue and cell type adds to the complexity in recreating a functional organ replacement. The proper physiological function of these tissues depend on the interactions between these multiple cell types, so developing a tissue substitute with the ability to restore function should be a heterogeneous culture consisting of multiple cell types organized appropriately. Coculture of multiple cell types within one environment in order to accomplish this is very difficult. Currently, two different cell types are cultured together by growing each cell type in layers with membranes. The membranes allow for signal passage without direct cell–cell contact. The concept of ''organ printing'' may permit the generation of heterogeneous, vascularized, and three-dimensional organ constructs using a computer-controlled ''printing'' device that deposits multiple cell types, biomaterials, and other tissue components layer by layer to form an organized structure.[22]

TRANSPLANTATION AND CRYOPRESERVATION

When implanting a tissue substitute or therapy device, immune rejection by the host against the foreign implant is the primary concern unless a biocompatible scaffold with autologous cells is used. Several strategies exist to circumvent this challenge, depending on cell type, source, and desired function. Three specific strategies are immune system therapy before and after the transplantation procedure, gene modification in the cells prior to tissue development to allow immune system acceptance, and immunoisolation.[23] Traditionally, similar to organ transplants, the complete immune system is suppressed for a period of time following the transplant to increase the chances of the transplant eventually being accepted. There is a key 5–10 week period in which the successful integration of the transplant or graft rejection is determined.[23] However, during this period of immunosuppression, the patient is susceptible to other illnesses. A novel strategy involves building a tolerance in the host for a cell type prior to transplantation. By first performing a bone marrow transplant using donor hematopoietic cells, the host will circulate immune system components that match the future donor. Then, when the transplant occurs, the donor tissue is tolerated.[10] Immunoisolation strategies incorporate a semipermeable membrane enclosing the cell-based device, protecting the cells from immune recognition and yet allowing the transport of therapeutic cell-derived compounds to emanate from the device.

When a tissue-engineered product is not to be used for transplantation upon its creation, cryopreservation allows for long-term storage until future application. Cryopreservation is commonly used for preparing cells for storage, but its utility for storage of tissues remains in development. Cryopreservation is a major focus for researchers, though, as it is a key component for improving the marketability of tissue-engineered products, allowing the development of an on-demand tissue supply, preservation of tissue genetic stability, and establishment of production quality control archives.[24] During the cryopreservation process, both the freezing and thawing procedures are equally important in regulating water displacement and replacement, respectively, while maintaining cellular and tissue integrity. Cryoprotectants and thermal processing protocols are utilized in this process. Commonly utilized cryoprotectants are dimethyl sulfoxide and glycerol, which remove intracellular water to avoid damaging ice crystal formation. Owing to the larger scale of tissues compared to cells, the challenges are greater, including the induction of chemical and thermal gradients within tissue, which must be resolved by utilizing optimized mass and heat transfer operations, respectively. Technologies to improve these processes and to monitor tissue parameters for performance control and modeling will further help to develop applicable cryopreservation protocols.

APPLICATIONS

Tissue engineering applications can incorporate the aforementioned components in various combinations to achieve specific goals. There are five general applications of tissue engineering:

1. The development of human tissues in vitro for future implantation into the body to replace lost tissue function.
2. In vivo tissue regeneration by transplantation of a seeded or unseeded scaffold to aid in regeneration at a deficient site in the body.
3. Development of an in vivo or extracorporeal device that supplements reduced tissue function. The in vivo device is encapsulated within a semipermeable membrane to allow for provision of a therapeutic molecule to the site while protecting the cells from the host immune system. An externally positioned device would provide deficient tissue function compounds through a tube directed to the body site while avoiding cellular contact with the immune system.
4. Establishment of an environment for expanding a cell population that is later extracted from the scaffold for implementation within the body in a cell-based or gene therapy application.
5. Development of a model to promote in vivo-like function of a population of cells in vitro for studying tissue development, pathology, pharmacology, and toxicology projects instead of using animal models.

The future financial outlook for tissue engineering products have varied greatly with some predicting an $80 billion market in 2000.[2] However, owing to increasingly evident challenges involved in developing tissue replacements and a lack of realization of previous tissue engineering product success predictions, more recent market estimates have been around $15 billion annually.[5] Currently, over 20 different tissues have been researched for a tissue engineering application. A selection of these applications is shown in Table 2 and Fig. 4.[26–33] To successfully design a tissue substitute that mimics the normal in vivo counterpart, the cells must perform similar functions with the support of a biomaterial with appropriate biocompatibility, degradation, and strength characteristics and, subsequently, restore functionality of the tissue to the system.

Table 2 Selected tissue engineering applications

Tissue	Why	Cells	Scaffold	Application	Goal	References
Blood vessels	Vessel occlusion	Endothelial	PET, e-PTFE	Replacement	Thromboresistance	[13]
Bone	Disease, radiation	Periosteal, osteoblast, mesenchymal stem cells	PGA, PLA, calcium alginate	Repair, replacement, regeneration	Restored mechanical properties	[25,26]
Brain	Parkinson's and Huntington's diseases	Neurons	Membrane	Replacement, encapsulation	Dopamine production, neural network re-established	[27]
Breast	Lumpectomy, mastectomy	Smooth muscle cells (SMC), fibroblast, chondrocytes	PGA, PLA, PCL	Replacement	Flexible transplant with induced angiogenesis	[28]
Heart valves	Valvular disease	Endothelial, fibroblast	PGA	Repair, replacement	Durability over mechanical devices	[29]
Cornea	Disease, trauma	Epithelial	e-PTFE, PMMA, PVA	Repair, replacement	Elasticity, refractive properties, transparency, curvature	[14]
Pancreas	Diabetes	Islets of Langerhans	Alginate/poly(L-lysine)	Encapsulated, restore	Active glucose concentration control	[30]
Kidney	Renal failure	Endothelial	Hollow fiber	Support device, replacement	Blood filtration, homeostasis maintenance	[31]
Tendons and ligaments	Injury	Fibroblasts	Collagen	Repair, replacement	Mechanical durability	[32]
Red blood cells	Disease, shortage	Artificial with hemoglobin	Membrane	Micro-encapsulation	Avoid removal of artificial cells from circulation	[33]
Liver	Acute liver failure	Porcine hepatocytes	Polysulfone hollow fiber	Extracorporeal support device	Detoxification activity, bridge-to-transplantation	[20]

Skin

Skin was the first tissue to be produced as a tissue substitute. The relatively simple two-dimensional, bi-layered structure of skin primarily consists of keratinocytes, fibroblasts, and ECM components. Skin functions include roles as a protective barrier, fluid and heat regulator, and immune system reconnaissance for early warning of dangers. Common features are its flexibility, elasticity, and strength. The major application is to develop skin substitutes for use on burn victims, especially when skin from the same individual is not available for autogenous transplantation. The main role for the regeneration of skin is to re-establish the barrier function with the dermis and epidermis. Other functions can be developed in vivo via migration of other component cells from surrounding areas into the regenerated skin. Wound healing can be achieved by transplanting an unseeded scaffold at the wound site promoting migration of surrounding cells into the scaffold. Artificial skin substitutes were the first tissue engineering products to reach the market. One available dermal substitute on the market is Dermagraft®, produced by Smith & Nephew (Florida, U.S.A.), which consists of fibroblasts, extracellular matrix, and a bioabsorbable scaffold. When applied, usually for healing diabetic foot ulcers, healthy cells surrounding the wound, including keratinocytes, migrate into the scaffold to fully reconstitute healthy skin with natural barrier properties.[5]

Liver

The liver was the first tissue engineered in three-dimensional scaffolding. Proper differentiated function of a tissue-engineered construct containing hepatocytes includes the production of albumin and the completion of urea and bilirubin metabolism. The cells used to seed the scaffold should be highly proliferative in order to develop a high cell density tissue. Owing to the size of the liver, nutrient diffusion limitations are a concern, and, therefore, vascularization of liver construct is necessary for blood to supply nutrients within the liver mass. When the engineered liver is transplanted to the host site, vascularization promoters can be included to initiate the blood vessel migration into the new tissue. Hepatocytes have also been cultured in hollow-fiber membranes to supply liver function from a device outside the body. The HepatAssist System (Circe Biomedical, Inc., Massachusetts, U.S.A.) is an extracorporeal device supporting liver function in patients waiting for transplantation.[20] The device utilizes porcine hepatocytes immobilized in the outer space of a hollow-fiber design to perform liver functions while plasma is circulated inside the hollow fiber.

The polysulfone membrane allows for protein and toxin transport across the membrane while preventing the passage of foreign cells into the patient. Thus, hepatocytes in the device do not have to be compatible with the host immune system since there is no direct contact.

Bone

Autogeneous bone grafts are difficult because there is a limited supply of cells, and donor sites are subject to post-graft morbidity and bone deformations. Tissue-engineered bone structures consist of osteoblasts and osteocytes, which re-form in three-dimensional scaffolds to produce signature bone structures and features such as load-bearing ability and osteocalcin secretion for osteoblasts. The progenitor cells utilized in the osteogenesis can provide developmental signals such as bone morphogenetic proteins, which induce and promote bone growth. Periosteal cells, from the outer bone membrane periosteum, were seeded on calcium alginate hydrogel to allow for calcium extraction by the cells and to make customized bone-shaped molds for transplantation into bone defect sites.[25]

Gene Therapy

Gene therapy is introducing DNA, which codes for an essential protein, into cells that are lacking productivity of the protein. Gene therapy is an alternative to supplying the deficient region with the protein itself or replacing the defunct tissue with a functional tissue substitute. If stem cells are utilized, the regenerating source of corrected, functional cells will eventually replace expired, deficient cells. DNA is carried and introduced into cells using a delivery system which is commonly viral or plasmid based.[34] Once the gene is expressed within the cell, persistence of the essential protein supply is key. Accompanying the huge potential of this process are important safety concerns with regards to the implementation of the DNA correctly within the chromosomes. Incorrect incorporation of the gene could alter important control genes or other essential genes. Once the successfully transduced cells are selected, the cell population is expanded in vitro.

In Vitro Studies

Tissue engineering can also be used to develop laboratory tools using human cells to perform pathological, developmental, pharmacological, and toxicological studies. Tissue cultured as an in vitro model can be used to study tissue or organ development processes including signaling and control mechanisms. Additionally, toxicology and carcinogen studies on tissue models provide insight without utilizing animal models.[35] Cancer models can be used to study tumor biology, control, and progression as well as use in cancer treatment studies.[36]

Cell-Based Technologies

Additional cell-based technologies are being developed by utilizing the knowledge of cells and their interaction with materials attained from tissue engineering research. Biosensors take advantage of the specificity of cell surface receptors for select target molecules and the high signal amplification for detecting low levels of chemical or biological agents. The brain consists of a neural network that processes a large number of signals. Neurons organized on a support in specific patterns could produce in vitro neural networks that pass signals similarly to the electronic structure on microchips.[37]

CURRENT CHALLENGES

Although there has been some limited success in producing tissue substitutes, especially artificial skin, the overall tissue engineering aim of creating tissue that can replace, maintain, or improve deficient in vivo tissue is not an easy task. Multiple challenges remain in providing tissue products to meet demand. These include creating a greater supply of cells to avoid immune rejection, such as a universal donor cell supply. Advancements in biomaterial production and bioreactor design are necessary to provide customized support and environments to replicate the complex in vivo environment. When developing complex, three-dimensional tissues, challenging issues include promoting angiogenesis to overcome tissue size limitations, the heterogeneous coculture of multiple cell types within one tissue, and the cryopreservation of the resulting tissue before transplantation.

CONCLUSIONS

Through the multidisciplinary application of biological and medical knowledge and engineering skills, tissue engineering allows the development of tissues in the human body to restore, repair, or improve deficient biological components. Generally, utilizing cells, supportive scaffolds, and designed culture systems, tissue development processes face many challenges in reconstituting in vivo-like performance. Although many challenges remain, the field is a major research focus, and medical demand is strong, both ensuring that

tissue engineering stands to provide momentous advancements to health in the 21st century.

Trace Elements

Ian D. Brindle
Brock University, St. Catharines, Ontario, Canada

INTRODUCTION

It is a truism that nothing in the universe is free from trace elements. As analytical techniques have improved with the development of ever more sophisticated measuring devices, the impact of trace and ultratrace concentrations of elements has been revealed much more clearly over the last two decades or so. We know from nutritional studies the importance of ultratrace concentrations of several elements including, for example, cobalt in cyanocobalamine (vitamin B12), where the daily requirement for this vitamin is only 1 μg/day for an adult.

Some elements commonly occur in ores of other elements and so can become problems, even where they are present at ultratrace levels. These elements can have deleterious or beneficial effects upon the properties of the major element that is won from the ore. The impact of trace elements on properties of materials, even when they are present at ultratrace concentrations, can be striking, and understanding their influence on materials is important. Regulations, either environmental or prescriptive, will continue to have a major impact on our interest in trace elements.

ENVIRONMENTAL IMPACTS

Treatment of many materials results in the liberation of the trace elements into the environment, which can have an impact on health. Coal is a particularly useful example of a major source of trace elements poured into the environment from coal combustion. Coal contains an alphabet soup of trace elements, including arsenic, mercury, uranium, selenium, and chromium. Pyrite is a ubiquitous mineral found in coal, but coal can also contain a variety of other mineral phases. West Virginia coal, for example, includes clay minerals such as kaolinite (35%) and illite (35%), quartz (18%), pyrite (7%), and calcite (3%).[1] A number of projects that utilize coal for power generation while minimizing the impact on the environment have been described. An excellent example is the SNOX^{TM} (trademark owner Haldor Topsoe) demonstration project, which utilizes high-sulfur coal (2.8%).[2] The demonstration project of this technology, equally funded by the U.S. Department of Energy and participants at a total cost of U.S.$ 31.5 million, was able to reduce NO_x to nitrogen (>90% reduction) and to oxidize SO_2 to SO_3 (>95% transformation) and ultimately to make sulfuric acid for sale, and hence minimizing the amount of acid rain produced by the system. Mercury was not retained at all by the system and boron was only partially retained. Selenium and cadmium, normally problematic elements, were recovered in the processing of the spent gases. Particulate emissions were reduced by 99%. Mineral content of coal is variable and each new source must be evaluated closely for its trace element composition. For some applications, it may be a case where the raw material should not be processed. Thus, in Guizhou province of the People's Republic of China, coal is mined from a deposit that is very high in arsenic.[3] Germanium is also relatively high in coal. The highest reported value of germanium found in coal ash was 1.1% in a sample from a particular seam of coal in Durham, U.K. Chalcophilic elements are usually associated with sulfur minerals in coal, and some success in removing these elements prior to burning the coal has been achieved by washing the coal and removing the heavier mineral components.

Other fuels are also susceptible to contamination with trace elements at low, but significant, concentrations. A report prepared for the United States Environmental Protection Agency (USEPA) describes several sources of contamination from traces of mercury in oils and natural gas.[4] Elemental mercury is present in liquid petroleum oil or in natural gas, condensates at parts per million level, and must be removed from the product stream to prevent it from reacting with metallic components, particularly during the cryogenic treatments, where liquid mercury can be condensed from the gas phase. Mercury concentrations can vary considerably, and the EPA report describes one gas reservoir in Texas, where the concentration of mercury is sufficiently high to lead to the conclusion that the gas is in equilibrium with elemental mercury in the subsurface reservoir. In terms of processing of petroleum and natural gas, mercury is found in a variety of compartments and in a variety of forms or species including alkylmercury and inorganic mercury salts such as mercury halides and mercury sulfides (insoluble and largely found in suspension or in drilling wastes). Table 1, which presents predominant species in a variety of matrices, is adapted from the report.

Table 1 Approximate distribution and abundance of mercury compounds in hydrocarbons

	Coal	Natural gas	Gas condensate	Crude oil
Hg^0	T	D	D	D
$(CH_3)_2Hg$	[a]	T	T, (S[a])	T, (S[a])
$HgCl_2$	S[a]	N	S	S
HgS	D	N	Suspended	Suspended
HgO	T[a]	N	N	N
CH_3HgCl	[a]	N	T[a]	T[a]

Abundances, expressed as percentages of total Hg concentrations: D (dominant), greater than 50 percent of total; S (some), 10-50%; T (trace), less than 1%; N (none), rarely detected.
[a]Inconclusive data.
(From EPA-600/R-01-066.)

In view of the widely varying toxicities of these species and, in particular, the unexpectedly huge toxicity of dimethylmercury, for which we have only one reported human death (Professor Karen Wetterhahn of Dartmouth College, who died as a result of a single and very limited exposure to dimethylmercury in 1997), the significance of these trace concentrations of ''species'' must be considered when the health of workers who will be exposed to these compounds is evaluated.

An element that is also found in natural gas represents the world's best source for the element and that is helium which, in some U.S. and polishgas supplies, can reach 7% by weight. This valuable gas is collected by liquefaction of the natural gas, which leaves the remaining gas significantly enriched in helium. Helium originates from radioactive decay and, because it is a fugitive gas and can escape the earth's atmosphere, it is not practical to recover helium from the air.

TRACE ELEMENTS IN METALS

Trace concentrations of a variety of elements have huge effects upon metals and can, in many cases, determine the metals' fitness for various purposes in manufacture and use or the traces may disqualify a particular form of the metal from use either because of the changes in physical or chemical properties or because it may affect the end use or disposal of the metal.

Iron

Iron is one of the most recycled metals and the recycling process can introduce unwanted elements into the alloys and can play havoc when they are ignored. Iron, cast into the engine blocks of internal combustion engines, is often made from gray iron or nodular iron. Nodular cast iron has a crystallinity and hardness that enables the casting to support the continuous motion of pistons and piston rings, suitably lubricated, for more than 100,000 miles without significant wear. Reproducible production of nodular cast iron is clearly of great economic importance. One trace element that has been identified in guaranteeing the quality of nodular cast iron is lanthanum. Although not required as a pure additive, several rare earth elements confer advantages on the manufacturing process. Often, lanthanum is added as an ingredient in a rare earth mix of elements, which typically includes cerium at higher concentrations.

Much of the control of microscopic structure of iron depends on the management of the carbon content of the metal. Carbon at levels less than 5% precipitates in a variety of forms and can also react with iron and other metals in the alloy to make carbides. Trace elements can significantly alter the form in which carbon occurs, and manipulation and control of trace elements are major determinants of quality standards for categorizing irons by the American Society for Testing Materials (ASTM). The structure of precipitated carbon determines the properties of the alloy, in particular its tensile strength. Lead at levels in iron that exceed 50 parts per million (ppm) results in the formation of Widmanstätten graphite, which confers a mossy or fuzzy appearance to graphite flakes in the iron. Without an appropriate modifier, Widmanstätten graphite reduces the tensile strength of iron to less than 15,000 pounds per square inch (psi). Addition of cerium, in a process usually called ''inoculation,'' reduces the effect of lead to more manageable levels. Nitrogen also affects the form of carbon found in iron. Normally, nitrogen equilibrium concentrations are less than 70 ppm. When the values exceed 150 ppm, the graphite form in gray iron is ''fatter'' than it would be in the presence of low concentrations of nitrogen. Titanium, present at trace concentrations, reverses this trend and can restore graphite flakes to normal, filamentous morphology.

Boron-containing low-carbon steels have a number of advantages that are specifically because of the

presence of boron. Subtle effects relate to boride concentration appearing at grain boundaries. In combination with niobium, boron confers several advantageous properties to the so-called bainitic steels. Thus boron low-carbon steels have improved hardness, strength, weldability, and corrosion resistance, which has made them the steel of choice in machinery manufacture, oil pipelines, and maritime applications (bridges, drilling rigs, and ships). Furthermore, as they can be rapidly cooled, these steels are relatively energy efficient materials.

Trace concentrations of silicon and aluminum tend to decrease the strength and hardness of iron by increasing the ratio of ferrite to pearlite. Nickel, copper, and tin work in the contrary direction and, by increasing the amount of pearlite, increase the strength and hardness of iron. In some cases, not surprisingly, trace elements can confer benefits for some purposes and liabilities with others. The impact of trace elements on creep deformation and fracture was investigated in depth.[5] The conclusions were uncertain as to the effects of trace concentrations of several elements (P, As, Sn, etc.), but they determined that traces of titanium decrease embrittlement caused by trace elements. Other work suggested that arsenic and antimony reduce the ductility of steel and increase brittleness; antimony also improves the resistance of iron to corrosion.[6] Welz and Melcher[7] noted that traces of bismuth improve the machining properties of steel up to a point but, even at low levels, steels may break during cold working. Tin has a deleterious effect upon the hot working of steel.

As we are better informed about the fate of materials in the environment by our greater knowledge of the cycling of elements in the environment, the present-day regulators are increasingly concerned about ''cradle to grave'' management of materials. One critical aspect of such regulations is the anticipation of issue around the disposal of wastes at the end of the life of materials. Thus, some iron and steel manufacturers are anticipating the fate of iron and steels when they re-enter the environment as they rust and disintegrate. One striking example will serve to illustrate this case. A study was commissioned by the U.S. Department of Energy to review the fate of ferritic steels with regard to shallow burial or recycling.[8] The anticipated problems relate to the activation, by neutron absorption, of various elements adventitiously or deliberately present in the steel. The radioactive isotopes, generated by neutron activation, limit the disposal or recycling options, and elements including silver, molybdenum, and niobium were identified as potentially problematic. Niobium is deliberately added to iron, as noted above, and because it is readily activated, it can render radioactivity to the iron. Other elements, including silver and gold, appear at trace concentrations and are likely carried into the irons and steels from the processing of the iron ores, which can be problematic when activated by the neutron flux from a nuclear reactor.

Copper

High purity copper is an essential component in the electronics industry, and a number of trace elements can decrease the conductivity of copper. As electrical resistance translates into energy losses as heat (I^2R), manufacturers are anxious to ensure the lowest resistance of copper wiring in circuitry so that they can reduce both the energy and heat load in electrical and electronic equipment. Most trace impurities increase the resistivity of copper and so manufacturers look to develop the highest purity copper for applications in the electronics industry. Cadmium appears to have the least effect upon copper resistivity.

Zinc

The dry cell battery industry is a major consumer of zinc. The amount of current that can be withdrawn from a dry cell battery is limited because of polarization at the surface of the zinc, caused by the overpotential, which is in turn caused by hydrogen at the surface. This overpotential was traditionally reduced by incorporating an oxidizing agent (manganese dioxide) to react with the hydrogen. Incorporating small amounts of mercury in the battery extends battery life by limiting a phenomenon known as local action. Local action is caused by trace impurities in zinc, which set up independent galvanic cells that react and reduce the useful life of the battery. Incorporation of mercury in the zinc is proposed to separate the impurities from the zinc and thereby reduces the independent galvanic activity. As mercury has become increasingly regulated, indium has taken its place in dry cell batteries. Another concern for battery manufacturers is the concentration of the hydride-forming elements that appear to be responsible for significant losses in performance of dry cell batteries even at low concentrations. One of the products manufactured by the primary producers of zinc is a 30% m/v $ZnSO_4$ solution. The detection limits desired by the manufacturers for hydride-forming elements in this concentrated solution are 10 μg/L for arsenic, antimony, bismuth, tin, selenium, and tellurium, and 2 μg/L for germanium.[9]

CATALYST POISONING BY TRACE ELEMENT

Coal combustion remains the single largest source of energy used in the generation of electricity in the

U.S.A. Energy production in 2000 was 1968 TW hr and coal represented 51% of the total. By 2010, energy production is anticipated to rise to around 4600 TW, with coal burning being responsible for about 2200 TW hr or 48% of the total previously noted.[10] Coal is a source of many trace elements; while mercury may be a problem for human health, other elements create problems in other areas. As the large amounts of coal are burned (around 10 million tons per year for some power stations), efforts are underway to improve the quality of emissions to fulfill a mandate to use ''clean coal'' technology. Selective catalytic reduction (SCR) is employed to reduce NO_x emissions (a component of acid rain) into the environment from burning coal. Arsenic in the coal is usually oxidized to arsenic trioxide (As_2O_3), which has a significant vapor pressure in the flue gases and poisons SCR catalysts. Arsenic removal is possible when there are sufficient calcium oxide equivalents in the coal, which can react with the arsenic trioxide to give nonvolatile calcium arsenate [$Ca_3(AsO_4)_2$]. The desirable presence of calcium-containing minerals in coal in this application suggests that minerals should be retained in coal to deal with arsenic. This retention, however, appears to run contrary to the desirability of removing minerals as a source of both arsenic and other toxic elements noted above. As coal washing is used to discriminate coal from noncoal, it may be difficult to separate calcium minerals that confer benefits from iron sulfide minerals that are problematic.

Polyolefin production is enhanced by a new generation of metallocene cocatalysts that are used together with Ziegler–Natta catalysts. These metallocene catalysts are poisoned by the presence of oxygen in the feedstock. The presence of oxygen can also be problematic by causing some crosslinking, chain branching, and delay of induction of polymerization. Typical olefin feedstock has oxygen maintained at levels below 50 parts per billion (ppb).

Reforming catalysts are poisoned by sulfur and halogens. The complexity of reactions involved in reforming means that catalysts can work to the advantage of some reactions over others. This advantage can work against the process for, for example, the production of hydrogen. The Boudouard reaction, for example, removes carbon from the reforming process. Some catalysts need to be poisoned to some degree. Sulfur, present in most natural gas, is an appropriate poison for some catalysts, and it is not totally removed from the process stream, as it poisons the catalyst for the Boudouard reaction without materially affecting the reforming reactions. Several important reforming reactions are presented in Scheme 1.

Sulfur, chlorine, and phosphorus are classed as temporary poisons in reforming reactions, because the activity of the catalyst is recovered when the poison is removed from the gas stream. Permanent poisoning results from the presence of certain metal vapors including zinc, lead, and arsenic. Alkali and alkaline earths are also permanent poisons. The occurrence of permanent poisons is a rare event in reforming reactions. Sulfur often occurs at levels below 20 ppm, therefore sulfur removal may not be necessary, but the levels of sulfur should be monitored.

Steam reforming:	$C_nH_{2n+2} + nH_2O \rightarrow (2n+1)H_2 + nCO$
Watergas shift reaction:	$CO + H_2O \rightarrow CO_2 + H_2$
Boudouard reaction:	$2CO \rightarrow CO_2 + C$
Beggs reaction:	$CO + H_2 \rightarrow H_2O + C$
Carbon dioxide reforming:	$C_nH_{2n+2} + nCO_2 \rightarrow 2nCO + (n+1)H_2$

Scheme 1 Reforming reactions.

Carbon monoxide is a common impurity in hydrogen that has been generated by a reforming process. Portable power sources, used by the military for energy generation in remote locations, use a methanol reforming reaction as shown in the following equation:

$$CH_3OH + H_2O \rightarrow CO_2 + 3H_2 \quad (1)$$

Another significant reaction can also occur, which is shown in the following equation:

$$CH_3OH \rightarrow CO + 2H_2 \quad (2)$$

This reaction, or the hydrocarbon reforming reactions noted above, can generate sufficient carbon monoxide to poison the catalysts used for hydrogen-based fuel cells that are used to generate electricity. Thus, carbon monoxide is a trace component of concern, and as the hydrogen economy is further developed and reformation reactions may become more important in the development of hydrogen fuels, technologies for the efficient removal of carbon monoxide must be developed.

One of the most widely known examples of catalyst poisoning is taken from the automobile industry. Though tetra-ethyl lead has been removed from essentially all gasoline in North America, the ban on leaded gasoline is not worldwide, and leaded and unleaded gasoline is available in many countries. Catalytic converters, which contain precious metals like platinum, palladium, and rhodium, are used to both reduce NO_x and oxidize CO and unburned hydrocarbons. Lead irreversibly destroys the catalytic ability of the converter. Concentrations of lead in leaded gasoline are nominally 150 mg/L.

TRACE ELEMENTS IN SOLUTION

Treatment of solutions, when they are used to crystallize compounds, is done in various ways to change the size and the nature of crystals formed. Sudden cooling usually results in the formation of small crystals, whereas crystals formed by slow cooling tend to be large. In addition, rapid precipitation often results in the incorporation of traces of contaminants in the crystals. Finely divided crystals have a large surface area and can be used advantageously as a way to remove impurities from solutions. This technique has been used for a variety of purposes, from the removal of trace elements from drinking water to the removal of radionuclides from solutions derived from spent nuclear materials. Magnesium hydroxide has also been used analytically as a method to preconcentrate elements. Using this technique, Brindle et al.[11] were able to preconcentrate germanium and determine its concentration in the range of 1 pg/ml.

The impact that trace concentrations of elements in solutions can have on precipitation reactions is quite striking and can be problematic, or can confer economic benefits. Impurities at the levels of 10^{-3} to 10^{-4} M, which consist of relatively large organic molecules, have an inhibitory effect upon the growth of crystals but do not appear to fully inhibit their growth. Concentrations of inorganic complexes, even if they are low, can inhibit or ''poison'' the growth of crystals by adsorption at a surface step rather than their being adsorbed as a surface monolayer. Sears proposed such a mechanism for the inhibition of the growth of potassium bromide and lithium fluoride in the presence of FeF_6^{3-} at concentrations in the range of 10^{-5} to 10^{-6} M.[12]

In addition to affecting the crystal growth, these foreign ions can affect also the shape of crystals.[14] At higher concentrations, impurities can cause a variety of changes. If the impurity is isostructural with the major component, the morphology of the resulting crystal will be intermediate between the two forms. Where adsorption of ions onto a crystal surface takes place, small changes in the lattice position of ions on a facet of the crystal farthest from the center of symmetry have the largest effects on the surface energy, which in turn can modify the habit of the crystal. It appears to be a general principle that the adsorbed ions have a minor impact upon habit, and the ions that insert themselves into the crystal lattice have the greatest effect in altering crystal habit.

The normal crystal habit of many commodity chemicals is incompatible with their use. Not all crystalline materials can flow readily. In applications where a smooth-flowing powder is required, the natural shapes of crystals may not lend themselves to being free-flowing, and ''clumping'' can occur, which can clog feed tubes and hoppers. Thus if one can alter the crystal habit to a form which allows a more free-flowing powder, time and product can be saved. The modification of habit has occupied process chemists for many years, and a number of high-volume chemicals are routinely treated with habit modifiers to improve the flow characteristics, especially of these commercial products.

A crystal has several faces, and the nature of interactions with the surrounding solutions, including the impact of supersaturation, solvent, temperature, and the level of impurities in solution, varies widely according to the energies of the various faces. Because crystals expose a different chemical environment at each face, it should not be surprising that impurities will have a major impact on the crystal habit—all other conditions remaining the same. Face-specific interactions of impurities, even when they are present at low concentrations, can be considerable. As discussed in this entry, impurities tend to reduce the rate of growth at the site of adsorption, thus allowing other facets to grow at their expense. Manufacturers usually prefer granular or prismatic crystal habit, but other forms, including needle and flaky crystals, are sometimes desirable. There are thousands of papers in the literature that describe the modification of crystal habit, and this entry can only touch upon a few.

Highly charged and/or complex ions appear to have the greatest effect upon crystal habit. Thus, Al^{3+}, Cr^{3+}, Fe^{3+}, and $Fe(CN)_6^{4-}$ are commonly used in a variety of applications to modify habit. A number of excellent monographs have been published.[13] This reference also includes a number of sources that provide further reviews that discuss the impact of trace concentrations upon crystallization. In Table 2, the range of initial morphologies, habit modifiers, and the crystal forms that can result from trace concentrations of several different trace modifiers are shown.

TRACE ELEMENTS IN WATER

Drinking water is obtained from surface sources, including lakes and rivers, and from the subsurface aquifers that may be shallow or deep, ancient or relatively recent. Shallow aquifers are often recharged by rainwater at an aquifer recharge zone. Both surface and subsurface waters can be contaminated by toxic elements. Sometimes, surface waters can become contaminated ultimately by subsurface water and can create major environmental and potential health problems.

An example of the contamination of surface water by toxic elements is the case of northern California's problem with selenium in surface waters. This problem is acute in the area south of San Francisco and in the Kesterton National Wildlife Refuge. Groundwater flows through seleniferous formations and is used

Table 2 Habit modification by addition of trace ions or chemicals

Commodity	Normal habit	Habit modifier	New habit
Ammonium alum	Octahedral	Borax	Cubes
NH_4Cl	Dendrites	Cd^{2+}, Ni^{2+}	Cubes
$NH_4H_2PO_4$	Needles	Al^{3+}, Fe^{3+}, Cr^{3+}	Tapered prisms
$(NH_4)_2SO_4$	Prisms	Fe^{3+}	Irregular crystals
$MgSO_4{\cdot}7H_2O$	Needles	Borax	Prisms
$AgNO_3$	Plates	Sodium oleate	Dendrites
Potassium alum	Octahedral	Borax	Cubes
KCN	Cubes	Fe^{3+}	Dendrites
KCl	Cubes	$Fe(CN)_6^{4-}$	Dendrites
	Cubes	$PbCl_2$	Octahedral
K_2SO_4	Rhombic prisms	Fe^{3+}	Irregular needles
NaBr	Cubes	$Fe(CN)_6^{4-}$	Dendrites
NaCN	Cubes	Fe^{3+}	Dendrites
NaCl	Cubes	$Fe(CN)_6^{4-}$	Dendrites
	Cubes	$Na_6P_4O_{13}$	Octahedral
$NaClO_3$	Cubes	$S_2O_6^{2-}$	Octahedral

(From Ref.[4].)

mostly for irrigation. The surplus flow eventually finds its way into the wetlands where it is highly toxic to migratory birds and other wildlife that depend on the wetland for food and protection.

In a similar fashion, arsenic is found in groundwater in many countries including Argentina, Bangladesh, Malaysia, and Thailand, and also in some areas of the U.S.A. The levels of arsenic in the untreated groundwater in some parts of Bangladesh are sufficiently high to cause a number of health problems including keratosis and cancer. Regulations on the levels of arsenic in drinking water have been steadily modified and the acceptable levels have been lowered over the last three decades. Many municipal laboratories are currently incapable of measuring the levels of arsenic below 10 ppb, which is creating problems for regulatory agencies charged with protecting public health.

Aluminum, in the form of alum, is used in the treatment of water to remove trace elements and particulate matter. The reaction involves the hydrolysis of the aluminum ion to form aluminum hydroxide, which is a flocculent precipitate with a very large specific surface area that is useful for the adsorption of ions and also for the collection of microscopic particles that are carried down by the precipitate. In the management of water treatment plants, the kinetics of the reactions are taken into consideration in designing plants so that there is sufficient time to allow all of the aluminum to hydrolyze and precipitate as the hydroxide. When there are upset conditions, aluminum can be carried into the water supply. As the public is concerned about Alzheimer's disease and as there has been some considerable discussion about the involvement of aluminum in the disease, operators of water treatment plants need to be mindful of this transfer reaction. Some water treatment plants use iron(III) chloride (ferric chloride) instead of aluminum. The hydrolysis reaction in this case tends to be less problematic and the precipitation forms more rapidly.

Although water treatment tends to remove any traces of lead from water, lead still appears at the consumer's tap and can be a cause for concern. There are several sources for this lead. In the early years of municipal water distribution, leader pipes, i.e., the pipes that deliver water from the street main to the house, were made from lead. With the development of flexible copper piping, leaders in new houses were constructed of this material. As the technologies used in water treatment have changed, the protective layers of hydroxides and hydroxycarbonates have been eroded. In recent years, water in some areas, such as Washington, DC, has become increasingly contaminated with unacceptable levels of lead. These municipalities are now faced with replacing lead leaders with copper—in part because of increasingly stringent standards for lead in drinking water.

Other trace elements in drinking water become unacceptable because they undergo species transformation during the water treatment process. Both chromium and bromine as chromium(III) and bromide, respectively, are benign species and their presence in drinking water does not pose a hazard. As water is treated in the water treatment plant by strongly oxidizing reagents such as ozone, used to sterilize the water

and render it germfree, chromium and bromine can be transformed into chromium(VI) (as chromate, CrO_4^-) and bromate (BrO_3^-), respectively. Both of these compounds are carcinogenic. Thus, drinking water standards for chromium and bromide are put into effect to control their likely transformation into the more toxic species by chemical treatment.

TRACE ELEMENTS IN FOOD PROCESSING

Trace elements affect foods in a number of ways. Their effects also vary and can diminish or enhance the toxicity of trace concentrations of elements. As a result of the increased level of food processing that is done to increase the stability, shelf life, etc., many nutritionists feel that modern, highly processed foods are in fact missing many essential trace elements and that consumers in developed countries are showing deficiencies in a number of trace elements such as chromium and zinc that they would normally get through the husks, germs, and other parts of plants that are disposed off.

In wines, traces of iron, which are picked up, perhaps, from processing and/or storage, or copper, which are picked up from mildew sprays, such as Bordeaux mixture, affect the oxidative stability of wines by acting as the redox shuttles as they transfer between oxidation states. Winemakers discovered that adding ferricyanide to wine, in a process known as ''blue fining,'' precipitates copper and iron and thereby reduces their concentrations below 1 ppm, which is considered to be acceptable. Critical control of ferricyanide addition is necessary, as cyanide is also a contaminant that must be measured. Where vineyards have replaced cherry and apple orchards, low concentrations of arsenic have started to appear; but they are present at very low concentrations in high quality wines. The arsenic appears from arsenical compounds such as lead and calcium arsenates that were used for many decades as pesticides on apples and cherry orchards.

A bizarre manifestation of trace element interference with food processing was described in the early 1980s by Procter and Gamble food scientists. Their development of a lemon chocolate cake created very negative responses from the tasting panels that were set up to determine the acceptability of new formulae for foods.[15] In this case, the problem was iodine, which was present as iodide in the salt used in the formulation. The iodide was oxidized to iodine during the cooking process, which in turn reacted with one of the flavoring ingredients, cresol. This resulted in the formation of iodocresol, which has a very strong medicinal taste. This taste was responsible for stimulating the gag reflex in some members of the tasting panels. On the effect of iodide in various foods, UNICEF commissioned a report.[16]

It is rapidly becoming clear that trace elements in foodstuffs acquire greater significance when they can undergo important metabolic transformations in which simple inorganic salts are converted by enzyme systems within the organism or the ingestion of previously transformed compounds that may appear in a biomagnification scenario. A number of elements are particularly noteworthy in this regard, such as mercury, arsenic, and tin.

Mercury tends to occur at highest concentrations in fish, particularly the predatory fish at the top of the food chain. The toxicity of mercury compounds, as noted above, varies radically according to the chemical species. It is well known at this point that most of the mercury in fish is present as methylmercury. Bloom[17] reported that more than 90% of the mercury in fish muscle is present as methylmercury. The action of methylmercury is particularly troubling for women in the first trimester of pregnancy. Methylmercury, it is believed, coordinates with cysteine in the blood and this coordinated form can cross the blood–brain barrier, where it can result in a number of serious neurological problems and is implicated in mental retardation in babies. The mother typically exhibits no symptoms. The most infamous case of methylmercury poisoning amongst an adult population was in the Japanese community of Minamata. In the 1950s, methylmercury, a byproduct from the manufacture of acetaldehyde, was discharged into the bay at Minamata where it was rapidly incorporated into fish and shellfish. The effect on the population gave rise to the ''Minamata disease,'' which was characterized by tremors, hallucination, and death amongst the subsistence fishing families living around the bay. Similar but reduced effects were observed in northern Ontario amongst the aboriginal Cree tribes along the English–Wabigoon river systems, which were contaminated by phenylmercury from a local paper mill that had used phenylmercury salts as slimicides. Fish consumption guidelines are issued in many areas where mercury, and hence methylmercury, is a likely health problem. Recognizing the health benefits that derive from eating fish, consumption guidelines are often specific about the frequency of consumption recommended and particular warnings relating to women in the first trimester of pregnancy or women who intend to become pregnant. Dimethylmercury has not been reported as being present in fish, although there are reports of its presence in ultratrace concentrations in mangrove swamps and human breath.

Arsenic is another element that occurs in a variety of seafoods; both vegetable and animal sources contain varying amounts of several organic arsenic compounds as well as traces of inorganic arsenic. Measuring the total arsenic concentration in crab or lobster gives an alarmingly high number, but arsenic is present in the

Table 3 Arsenic species commonly found in seafood

Formula	Name
AsO_4^{3-}	Arsenate [As(V)]
AsO_3^{3-}	Arsenite [As(III)]
$(CH_3)AsO_3^{2-}$	Methylarsenate [As(V)]
$(CH_3)AsO_2^{2-}$	Methylarsenite [As(III)]
$(CH_3)_2AsO_2^{2-}$	Dimethylarsenate [As(V)]
$(CH_3)_2AsO^-$	Dimethylarsenite [As(III)]
$(CH_3)_3As^+CH_2CH_2OH$	Arsenocholine
$(CH_3)_3As^+CH_2CO_2^-$	Arsenobetaine

form of arsenobetaine, a compound whose acute toxicity has been estimated to be similar to table salt. Arsenobetaine is a water-soluble compound and is usually excreted through the urine within 48 hr. Commonly found arsenic species are listed in Table 3.

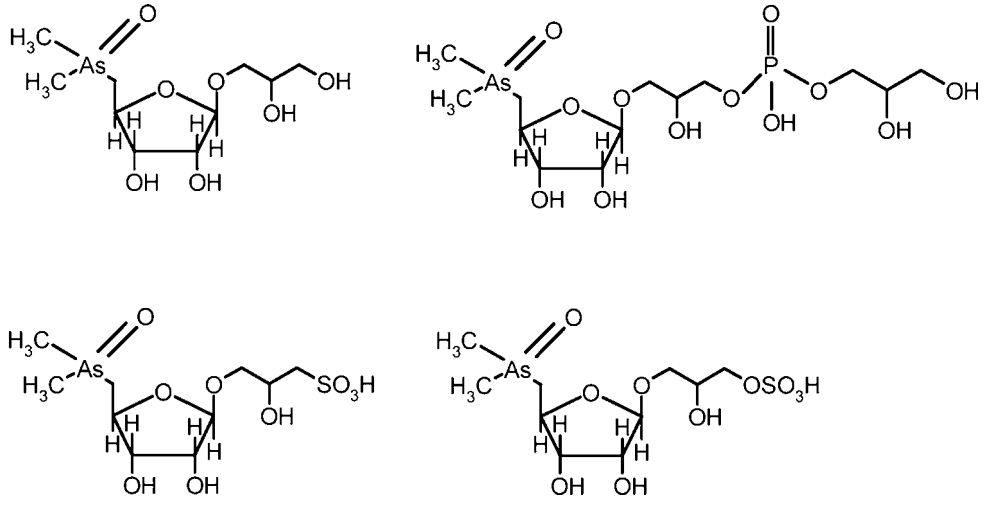
Arsenic also finds its way into the seaweed, which is eaten in a number of foods by the population in Japan, Wales, and Canada. Arsenosugars contain a dimethylarsenic moiety and these sugars also appear in creatures that graze on seaweed. Not all arsenosugars have been identified, but some of the species are illustrated in Scheme 2.

Tin appears in seafood as butylated tin compounds and as methyltin compounds in leachate from plastics. Tributyltin was used for many years to control barnacles and other marine growths on the hulls of ships. These organisms attached to the ships increase the drag on the ships and make them less energy efficient. Tributyltin leaches from the paint into the surrounding waters and can reach levels of concern in confined areas, such as harbors. Filter feeding organisms, such as oysters and mussels, as well as detritus feeders accumulate butyltin compounds and these compounds appear to have estrogenic effects. International food and health organizations have proposed standards between 0.25 and 1.6 μg/K of the body weight for the human population. Although there is not much clinical evidence, researchers suspect that organotins have an adverse effect upon the immune system. Methyltins appear as stabilizers in a wide variety of plastics. But there appears to be no strong evidence to suggest that they migrate readily into food and water that are in contact with plastics, which has been heat-stabilized with organotin compounds. There is evidence that inorganic tin is methylated in the environment.

CONCLUSIONS

Trace elements have huge impacts in many aspects of processing. Trace elements' effects upon crystallization, whether in alloys or in commodity chemicals, are of enormous significance in forming the final product. Our understanding of the effects of trace elements will develop further as the techniques for their determination improve.

Concern about the form in which trace elements appear in food or water will lead to increased demands for techniques that will determine the concentrations of the traces of species of elements. In this discussion, it is clear that the toxicities of different chemical species in which elements can be found vary widely. Although we may feel that the water we drink and the food we eat are well characterized, we should also know that our knowledge of trace elements and their impact at these minuscule concentrations is relatively recent. To protect human and animal health adequately, this area of development will continue to gain importance.



Scheme 2 Arsenosugars found in seaweed and in animals that consume seaweed.

The impact of trace elements in a variety of scenarios shows that we need to remain vigilant about their impact on materials that are processed and used in commerce. The anticipation of ''cradle to grave'' management of materials may provoke increasingly stringent regulations for the disposal of wastes. The effects of trace elements in foods will grow in importance not only from a nutritional perspective but also from a security perspective and the consequences of new regulations upon monitoring and regulation. Although trace elemental concentrations are important, speciation of elements will continue to grow in significance.

Transmission Electron Microscopy for Materials Science

Rolf Erni
Nigel D. Browning
Department of Chemical Engineering and Materials Science, University of California Davis, Lawrence Berkeley National Laboratory, Berkeley, California, U.S.A.

INTRODUCTION

Transmission electron microscopy (TEM) comprises a complete repertoire of imaging, diffraction, and analysis techniques. The combination of direct imaging as well as local structural and chemical analyses makes TEM a powerful tool to study materials down to the atomic level. TEM is used to characterize the microstructure of materials, the constitution of phases and nanoparticles, the local arrangement of atoms, and particularly to study crystal defects such as grain boundaries, dislocations, precipitates, and their impact on the physical properties of the solid. The increasing need to study materials on the atomic scale, which is primarily given by the scaling down of electronic devices, the optimization of catalysts, the development of nanostructures, and also by the goal to obtain a basic understanding of physical and mechanical properties of solids, can in many cases be met by selectively applying one or a combination of experimental TEM techniques.

In a transmission electron microscope, a highly coherent electron beam passes through a thin sample. The electron beam interacts with the sample and is transferred to the specimen's exit plane. The electron wave at the exit plane is magnified in order to form an image or alternatively a diffraction pattern of the sample.

A brief depiction of a transmission electron microscope is provided first. A short section about electron scattering qualitatively describes what types of electron–atom interactions are relevant for TEM. The most common experimental techniques are then explained consecutively. Diffraction mode including nanodiffraction and convergent beam electron diffraction (CBED) are explained first. Direct imaging techniques, such as bright-field (BF) and dark-field (DF) imaging, as well as high-resolution transmission electron microscopy (HRTEM) are dealt with in the following section. The third part of the experimental techniques is about scanning transmission electron microscopy (STEM) and Z-contrast imaging. Finally, analytical methods such as energy-dispersive X-ray spectroscopy (EDS), electron energy-loss spectroscopy (EELS), and energy-filtered imaging are discussed.

MICROSCOPE SETUP

Starting at the top of a microscope column (Fig. 1), two types of electron sources are common, thermionic sources, i.e., W and LaB_6 cathodes, and field-emission guns (FEG). Compared to thermionic sources, field-emission sources show higher brightness as well as coherence and a smaller energy spread,[1] which significantly increases the information limit of the microscope. Below the electron source, the emitted electrons are accelerated. The acceleration voltage U of a microscope defines the primary energy of the electrons and hence the wavelength of the electron radiation. Most microscopes used in materials science are operated between 100 and 400 kV corresponding to an electron wavelength λ between 3.7 and 1.6 pm, which is given by

$$\lambda = 4\pi^2 h \sqrt{2m_e eU\left(1 + \frac{eU}{2m_e c^2}\right)} \quad (1)$$

where h is Planck's constant, e is the elementary charge, m_e is the rest mass of the electron and c is the speed of light in vacuum.

The optical part of the microscope starts below the accelerator. The magnetic electron lenses can be divided into three main lens systems: condenser, objective, and projector lens system (Fig. 1). The condenser lens system, including C1 and C2 aperture, is used to form the illuminating electron beam in front of the objective lens. The objective lens, which focuses the electron beam to the specimen plane, consists of two parts, termed pole pieces. The sample is located between these pole pieces. The objective aperture, mainly used for BF and DF imaging, is in the back focal plane of the objective lens. The selected area aperture, used for selected area diffraction (SAD), is in the first image plane below the objective lens. A stack of projector lenses magnifies the electron wave below the sample. Depending on its setting, either an image or a diffraction pattern is formed on the fluorescence screen or the recording medium. State-of-the-art microscopes are equipped with charge coupled device cameras;[2] however, imaging plates and more frequently films are also used.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030635

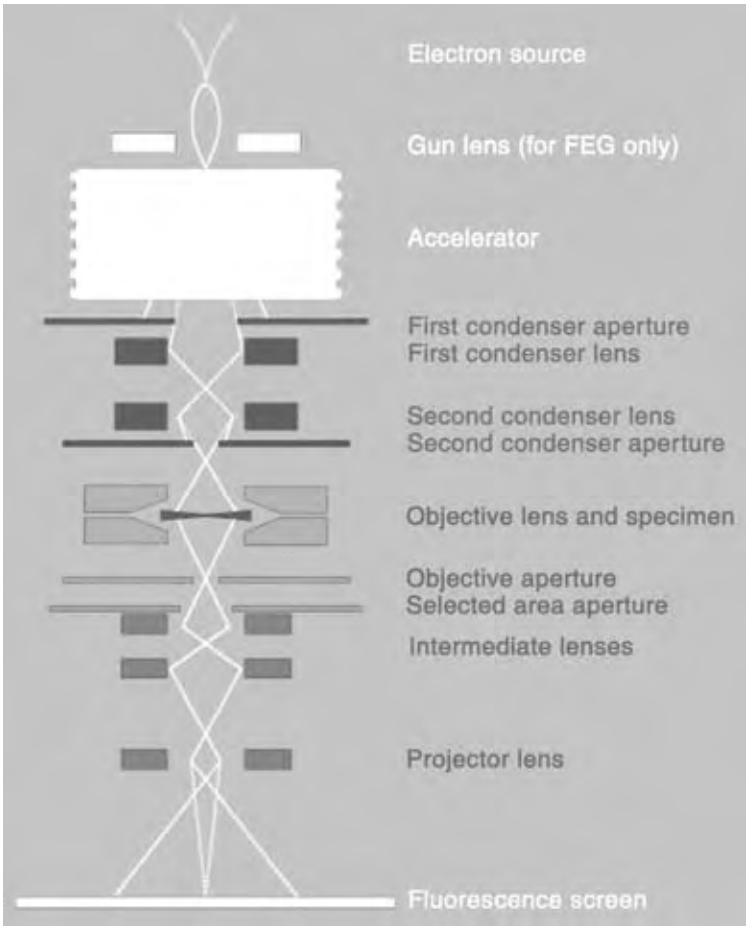

Fig. 1 Microscope setup. The electron beam is indicated as a green line. The projector lens forms either an image (solid line) or a diffraction pattern (dashed line) on the screen. *(View this art in color at www.dekker.com.)*

The resolution in TEM is limited by lens aberrations. In contrast to optical microscopy, where by serially ordering concave and convex lenses, aberrations can be compensated and hence the wavelength of the radiation is resolution limiting; in TEM lens aberrations cannot be compensated since concave electron lenses are not feasible.[3] The objective lens is the crucial part for image defining the microscope's resolution. The quality of the objective lens is described by the constants of spherical C_S(~0.5–3 mm) and chromatic aberration C_C (~1–2 mm). Recently, microscopes equipped with complex correctors for the spherical aberration have become available.[4]

ELECTRON–ATOM INTERACTIONS

Two types of electron–atom interactions have to be considered: elastic and inelastic interactions (Fig. 2). Generally, the interaction between electrons and matter is strong. Thin samples have, thus, to be prepared in order to make them electron transparent.[5] An electron-transparent foil has a thickness between 10 and ~200 nm and for perforated samples, a wedge-shaped thickness profile is typical.

Elastic Interaction

Elastic scattering is a result of the electrostatic interaction between the incident electrons and the atoms in the sample. Electrons elastically scattered on passing through the sample are used to form an image or a diffraction pattern. Elastic scattering of an electron by an atom is described by the elastic scattering factor f_e. The scattering factor is a function of the scattering angle θ, which in the Mott formula is written as:[6]

$$f_e(\theta) = \frac{\gamma m_e e^2}{128\pi^5 h^2 \varepsilon_o} \frac{\lambda^2}{\sin^2\theta}[Z - f_x(\theta)] \quad (2)$$

where γ is the relativistic factor, ε_o is the permittivity of free space, and Z is the atomic number of the element. The function $f_x(\theta)$, whose Fourier transform describes the distribution of the electrons surrounding the nucleus, corresponds to the X-ray scattering factor.[6] Eq. (2) can be interpreted as follows: the momentum of an incident electron is affected by the electrostatic potential of the nucleus, described by the term Z, and by the electrostatic potential of the electrons surrounding the nucleus, described by $f_x(\theta)$. Including the prefactor, each of these terms shows a different θ-dependence. For small and

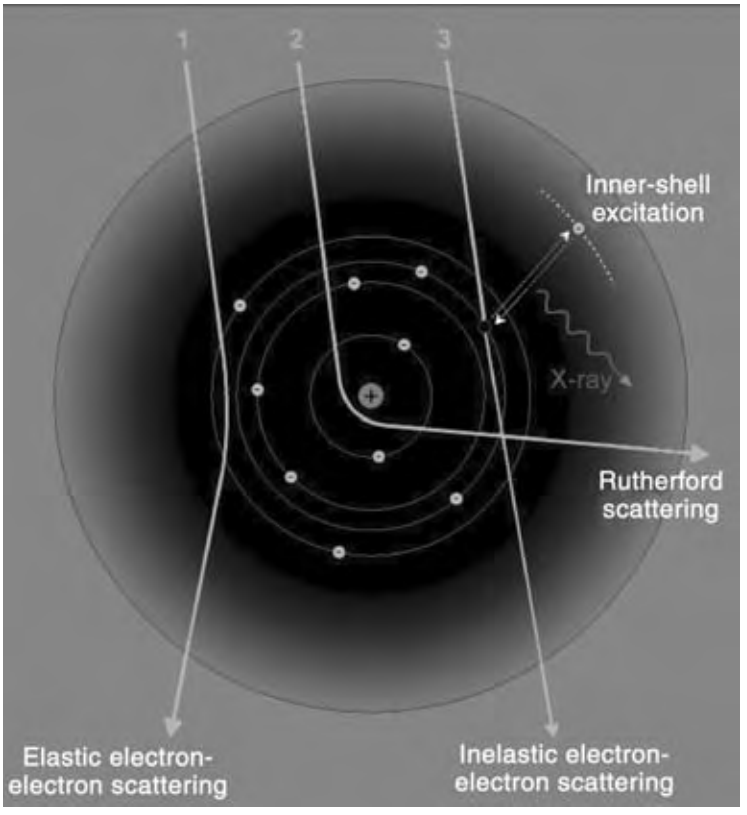

Fig. 2 Electron–atom interactions. (A) Elastic electron–electron interaction dominates the scattering intensity at low and medium scattering angles; (B) Rutherford scattering at the nucleus causes high-angle scattering; and (C) electrons can excite atom-bonded electrons from the ground state to higher unoccupied states or to the vacuum level, element specific X-rays are produced when the excited electron returns to the ground state. *(View this art in color at www.dekker.com.)*

medium scattering angles, scattering is dominated by electron–electron interactions (Fig. 2). However, since $f_x(\theta)$ rapidly decreases with increasing scattering angle, elastic scattering at the nucleus, i.e., Rutherford scattering, becomes important at large scattering angles (Fig. 2). With Eq. (2) and the first Born approximation, the elastic differential scattering cross-section of an atom is given by:

$$\frac{d\sigma_e}{d\Omega}(\theta) = |f_e(\theta)|^2 \quad (3)$$

where Ω is the solid angle and σ_e is the total elastic scattering cross-section. Compared to elastic X-ray $\left(f_x^2 \approx 10^{-26}\right)$ and neutron $(b^2 \approx 10^{-28})$ scattering, the total elastic scattering cross-section for electron scattering is large ($\sigma_e \approx 10^{-19}$). The probability that an electron is scattered more than once has to be taken into account by considering dynamical diffraction.[6]

Inelastic Interaction

Electrons also interact inelastically with the sample. Incident electrons can excite plasmons and phonons, and atom-bonded electrons can be excited from the ground state to higher unoccupied electron states.[7] In the de-excitation process, i.e., when the excited electron returns to the unoccupied core state (Fig. 2), element-specific X-rays are produced which are analyzed by EDS.

Inelastic interactions with atom-bonded, inner-shell electrons cause element-specific electron energy losses. The collective excitation of outer-shell electrons gives rise to energy losses corresponding to the plasmon energy of the solid.[7] The electron energy distribution below the sample can be measured by EELS. Phonon scattering, referred to as quasi-elastic scattering, causes a very small relative energy change (~25 meV). The electron energy distribution is hardly affected by phonon scattering. However, the change of the electron momentum caused by phonon scattering is observable, particularly as thermal diffuse scattering (TDS) in diffraction pattern.[8]

Radiation Damage

Inelastic and elastic interactions between the incident electrons and the sample can cause radiation damage. By elastic interactions, electrons can transfer a certain amount of kinetic energy to a nucleus.[9] The maximum energy that can be transferred, called maximum recoil energy, depends on the primary electron energy and the atomic weight of the element. If the maximum recoil energy exceeds the minimum energy required for displacing an atom, radiation damage, i.e., the creation of point defects, likely occurs.[10] By inelastic

electron–electron and elastic electron–nucleus interactions, electrons deposit energy to the sample. As an additional damage mechanism, the sample can be heated and even be destroyed by the amount of energy transferred to the sample.

ELECTRON DIFFRACTION

In diffraction mode, the projector lens system is adjusted in order to image the electron wave located at the back focal plane of the objective lens. What is seen on the screen is the intensity of this electron wave, which for coherent elastic scattering is called an electron diffraction pattern.

Diffraction Spots, Bragg's Law, and the Reciprocal Lattice

For crystalline samples under plane-wave illumination, a diffraction pattern is observed as a spot pattern. The individual spots depend on the crystal orientation, its structure factor, and obey Bragg's law. Bragg's law states that the difference between the scattered $\mathbf{k}$ and the incident $\mathbf{k}_0$ wave vector is equal to a vector $\mathbf{g}$ of the reciprocal lattice:[6]

$$\mathbf{k} - \mathbf{k}_0 = \mathbf{g} \tag{4}$$

For elastic scattering, the absolute value of the scattered and the incident electron wave vector are equal, given by the reciprocal value of the wavelength, $|\mathbf{k}| = |\mathbf{k}_0| = 1/\lambda$. The angle between scattered and incident wave vector is the scattering angle θ and the vector $\mathbf{q}$, given by

$$\mathbf{q} = \mathbf{k} - \mathbf{k}_0 \tag{5}$$

is the scattering vector. For elastic scattering in a crystal and according to Bragg's law (Eq. 4), only scattering vectors corresponding to reciprocal lattice vectors are allowed, $\mathbf{q} = \mathbf{g}$. The reciprocal lattice is related to the crystal lattice; a general reciprocal lattice vector $\mathbf{g}$ can be written as the sum of primitive vectors, $\mathbf{g} = h\mathbf{g}_1 + k\mathbf{g}_2 + l\mathbf{g}_3$, where h, k and l are independent integers termed Miller indices.[11] The set of primitive reciprocal lattice vectors defines the reciprocal lattice obeying the condition $\mathbf{g}_i \cdot \mathbf{a}_j = \delta_{ij}$, where $\mathbf{a}_j$ is a primitive crystal lattice vector and δ_{ij} is the Kronecker delta symbol ($\delta_{ij} = 0$ for $i \neq j$ and $\delta_{ij} = 1$ for $i = j$).

Ewald Construction

The general relation for elastic scattering in Eq. (5) can be visualized by using the concept of the Ewald sphere.[11] The incident wave vector points in beam direction to the origin of the reciprocal lattice, i.e., $hkl = \{0\,0\,0\}$. For elastic scattering, the set of scattered wave vectors $\mathbf{k}$ form a sphere surrounding the source point of $\mathbf{k}_0$ (Fig. 3). The points of intersection of Ewald sphere and reciprocal lattice form the set of allowed scattering vectors obeying Bragg's law, $\mathbf{q} = \mathbf{g}$. These points are observed as diffraction spots. The orientation of the crystal, its reciprocal lattice and the size of the Ewald sphere define which spots appear in the diffraction pattern. Tilting a sample under an invariant illumination means to rotate the reciprocal lattice around the origin of the reciprocal lattice, whereas the Ewald sphere remains unaltered.

Two points have to be considered when using the Ewald construction for electron diffraction in TEM. First, for the electron wavelength (~2 pm) is much smaller than a typical lattice spacing (~0.4 nm), the radius of the Ewald sphere is much larger than the spacing between nearby reciprocal lattice points, $|\mathbf{k}| \square |\mathbf{g_i}|$. For small and medium scattering angles, the curvature of the Ewald sphere is almost negligible. Second, the reciprocal lattice "points" of a thin foil are elongated perpendicularly to the foil plane and form rods.

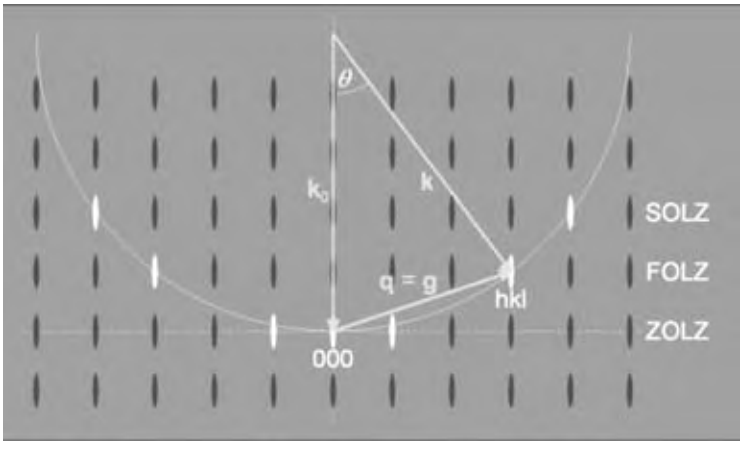

Fig. 3 Ewald construction. The white half-circle indicates the Ewald sphere in two dimensions. The points of intersection between the reciprocal lattice rods and the Ewald sphere form the set of reciprocal lattice points (bright) which obey Bragg's law and appear as diffraction spots in the diffraction pattern. Zero-, first- and second-order Laue zone are indicated. For electron diffraction in TEM, the ratio between the radius of the Ewald sphere and the reciprocal lattice unit is larger than visualized in the figure. *(View this art in color at www.dekker.com.)*

This circumstance is called shape effect.[1] The rods themselves are modulated according to the interference function.[6] What is seen in an electron diffraction pattern are the points of intersection between Ewald sphere, which approaches a plane, and the reciprocal lattice rods (Fig. 3). For small and medium scattering angles, an electron diffraction pattern basically corresponds to one plane of reciprocal space normal to the incident wave vector. This plane containing the origin of the reciprocal lattice is called zero-order Laue zone (ZOLZ). At large scattering angles, the curvature of the Ewald sphere causes the appearance of contributions of higher-order Laue zones (HOLZ).

Kikuchi Lines

Besides diffraction spots, which are caused by coherent elastic scattering, a diffraction pattern also contains contributions of incoherently scattered electrons. Quasi-elastic phonon scattering for instance, which is incoherent scattering, causes TDS, which with increasing sample thickness becomes apparent as a diffuse background. Combined incoherent and coherent elastic scattering gives rise to faint lines. These Kikuchi lines appear in pairs consisting of a deficient and an excess line.[12] Particularly for thicker samples, they can even dominate the contrast features of an electron diffraction pattern. Similar to diffraction spots, Kikuchi lines reflect the symmetry of the crystal.

Selected Area Diffraction

Diffraction spots reveal the symmetry and the spacing of the reciprocal lattice. Since both of them are directly related to the crystal lattice, diffraction patterns recorded for different crystal orientations can be used to determine crystal symmetry and lattice parameters. In order to see sharp diffraction spots, the sample has to be illuminated by a plane wave. A plane-wave illumination warrants that only one incident wave vector $\mathbf{k}_0$ goes into the elastic scattering relation, $\mathbf{k} - \mathbf{k}_0 = \mathbf{q}$. A plane-wave illumination, however, means that the entire sample is uniformly illuminated. The information contained in such a diffraction pattern is not localizable.

For a local analysis of the crystal structure, i.e., for the study of individual grains or selected phases, a selected area aperture can be inserted. Only the sample area selected by the aperture contributes to the diffraction pattern (Fig. 1). A plane-wave illumination, i.e., the appearance of sharp diffraction spots, can thus be maintained (Fig. 4). This technique is called SAD.[13] The smallest area that can be selected is about 0.5 μm given by the smallest selected area aperture.

Convergent Beam Illumination

In case a diffraction pattern of a smaller area is required, which is frequently the case when nanoscale

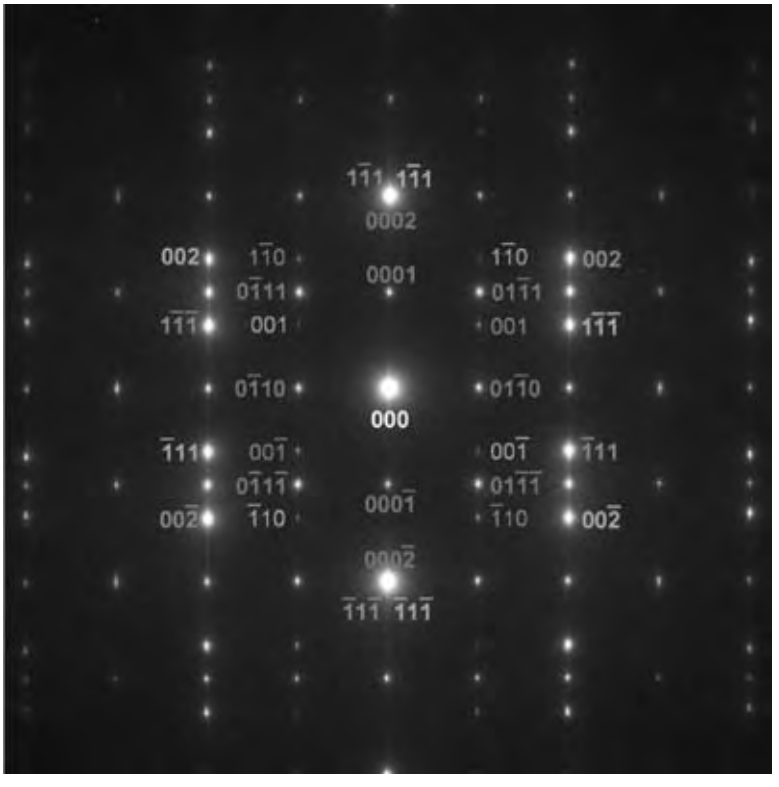

Fig. 4 Selected area diffraction. SAD pattern of uniaxially aligned lamellar γ/α_2 titanium aluminide consisting of hexagonal α_2-Ti_3Al lamellae with $D0_{19}$ structure and tetragonal (slightly distorted cubic) γ-TiAl lamellae with $L1_0$ structure. γ-TiAl is present in two twin variants causing two sets of reflections (green, blue). The spots labeled in red are caused by α_2-Ti_3Al. Main reflections are labeled in bold font, superstructure reflections of the tetragonal phases are in normal font. The interfaces between the individual lamellae are fully coherent which causes the overlap of certain diffraction spots. Incident beam direction for the tetragonal phases is {1 1 0}, for the hexagonal phase {1 1 0}. The streaks in y-direction are caused by the lamellar structure of the material. (*View this art in color at www.dekker.com.*)

materials are studied, a convergent beam is formed, which is focused to a small area. The area illuminated by a convergent beam is in the nanometer range. For a convergent beam, a continuous set of incident wave vectors $\mathbf{k}_0$, each forming an independent Ewald sphere, has to be considered. A convergent beam illumination thus results in the appearance of diffraction disks. Due to the appearance of HOLZ lines (Kikuchi lines of higher-order Laue zones), a convergent beam diffraction pattern contains information, which cannot be accessed by SAD. From CBED, lattice parameters, point and space groups, local lattice strains, and the sample thickness can precisely be measured.[14]

For FEG transmission electron microscopes, it is possible to demagnify the electron beam to a subnanometer electron probe. The diameter of the electron probe determines the sample area contributing to the (nano-) diffraction pattern. Electron nanodiffraction (END) makes possible the recording of a diffraction pattern from areas smaller than 1 nm.[15] Therefore, END is the appropriate technique to study the structure of nanoparticles, as for instance nanotubes and quantum dots. Although a nanoprobe is a convergent beam, the convergence angle is usually smaller than in CBED. As will be shown, END is fundamental for STEM.

IMAGING

Transmission electron microscopy images show a projection of the sample in beam direction. The three-dimensional information is projected to a two-dimensional intensity map. Direct imaging techniques are commonly divided into three groups: 1) conventional imaging covering BF and DF imaging techniques; 2) high-resolution imaging; and 3) STEM, which will be dealt with in the next section.

Electrons passing through a crystalline sample are elastically scattered according to Bragg's law. At the focal plane of the objective lens and of any other lens in the projector lens system, the angular distribution of the diffracted beams is observed. This angular distribution is studied when doing electron diffraction. At the corresponding planes where these beams interfere, an image is formed. An image is thus formed by the interference of Bragg-diffracted beams, however, each diffracted beam contains part of the full image information and can be used to form an individual image. This is the fundamental idea behind TEM imaging.

Diffraction Contrast and Mass-Thickness Contrast

Though each diffracted beam contains part of the full image information, the information contained in the individual beams differs. Defects as for instance dislocations, precipitates, and grain boundaries may locally change the diffraction conditions. Owing to distortions, the Bragg condition may locally be breached and a certain diffracted beam will not be excited from a particular area. Forming an image using this beam would result in low intensity for the area the beam is not excited. This type of contrast is termed diffraction contrast. Additionally, due to the presence of phases consisting of different elements and/or thickness changes, the attenuation of the forward scattered beam (i.e., the $\{0\ 0\ 0\}$ reflection) may locally vary. This position-dependent attenuation of the forward scattered beam gives rise to mass-thickness contrast. If an image is formed with the forward scattered beam only, areas containing heavy elements and thicker areas will show lower intensity.

Diffraction and mass-thickness contrast are both caused by an intensity change of a diffracted beam over the field of view. Since the intensity, specifically the amplitude, of a beam causes these types of image contrast, diffraction and mass-thickness contrast are referred to as amplitude contrast.[1]

Although this concrete explanation of the amplitude contrast is appropriate for a basic understanding, it does not account for all image features. It is based on the kinematical approach to explain electron diffraction. In the kinematical approach, an electron can be scattered once and once it is scattered it will not change its momentum. For very thin samples of light elements, this approximation is sometimes justifiable.

Dynamical Diffraction

Due to the strong Coulomb interaction between electrons and atoms, electron diffraction is generally treated by dynamical diffraction. In the dynamical approach,[6] an electron can be scattered more than once. As a consequence of multiple scattering, the forward scattered beam exchanges its intensity with the diffracted beams and each diffracted beam exchanges its intensity with any other diffracted beam. The intensity of a diffracted beam is thus not a smooth function of the specimen thickness; it is strongly modulated and the modulation period, which is termed extinction distance, depends on the elements in the sample as well as on the particular reflection. For heavy elements, the extinction distance is generally shorter, whereas for light elements, it is larger. Typical extinction distances are in the range of 10–$\sim$200 nm.[16]

Conventional Imaging

Conventional imaging is usually performed at low or medium magnification. Though the interference of all

Bragg diffracted beams forms an image, it is often of low contrast. In order to make use of the amplitude contrast, a single diffracted beam can be selected to form an image. By inserting an objective aperture at the back focal plane of the objective lens (Fig. 1) and selecting one particular beam, an image dominated by amplitude contrast can be formed. This is done by switching to diffraction mode, centering the aperture on the reflection, and switching back to imaging mode. Using the forward scattered beam, which for thin samples has the strongest intensity, is called BF imaging. Forming an image with any other beam, the imaging technique is called DFimaging. Bright-Field and Dark-Field images are in a qualitative way complementary; what is bright in the BF image appears with low intensity in the DF image and vice versa. The complementary application of BF and DF imaging is frequently used to locate (ordered) phases, which show certain (super)structure reflections the bulk material does not show. By choosing a reflection characteristic for a certain phase, the phase that causes the reflection will appear with high intensity and can clearly be located (Fig. 5).

Because the intensity of a diffracted beam is modulated as a function of the crystal thickness, using one diffracted beam to form an image results for a wedge-shaped sample in alternating bright and dark lines (Fig. 6A). The spacing of these thickness contours, depends on the angle of the wedge and the extinction distance of the selected beam.

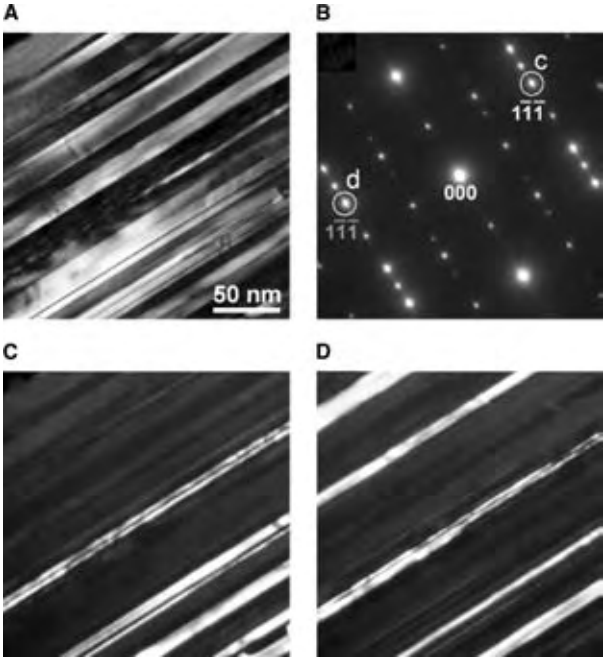

Fig. 5 Bright-field and dark-field imaging: (A) BF image of lamellar γ/α_2 titanium aluminide; (B) corresponding SAD pattern (see Fig. 4); (C) and (D) DF images of the reflections marked in (B). Each of these reflections is characteristic for one twin variant of tetragonal γ-TiAl appearing with high intensity in the corresponding DF image. *(View this art in color at www.dekker.com.)*

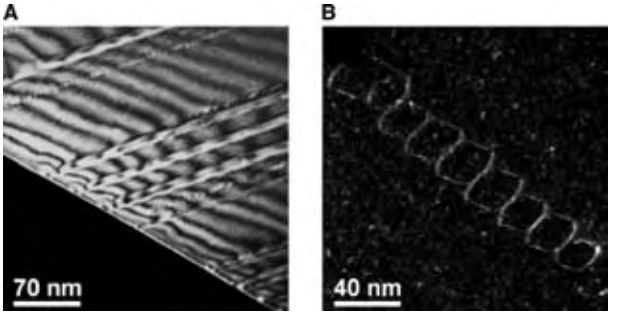

Fig. 6 Weak-beam DF imaging. Weak-beam DF images of: (A) lamellar titanium aluminide showing thickness contours and (B) a spiral dislocation in Al-3 at% Ag, the white speckling is caused by silver-rich Guinier–Preston zones. *(View this art in color at www.dekker.com.)*

Weak-beam DF imaging is an imaging technique which is based on a special diffraction condition, i.e., a two-beam case; besides the forward scattered beam, only one Bragg-diffracted beam is excited which is used to form an image.[1] Because weak-beam DF imaging is highly sensitive to the local diffraction conditions, defects as for instance dislocations can be imaged with high contrast (Fig. 6B).

High-Resolution Imaging

High-resolution transmission electron microscopy can be understood as a general information-transfer process. The incident electron wave, which for HRTEM is ideally a plane wave with its wave vector parallel to a zone axis of the crystal, is diffracted by the crystal and transferred to the exit plane of the specimen. The electron wave at the exit plane contains the structure information of the illuminated specimen area in both the phase and the amplitude.. This exit-plane wave is transferred, however affected by the objective lens, to the recording device. To describe this information transfer in the microscope, it is advantageous to work in Fourier space with the spatial frequency of the electron wave as the relevant variable. For a crystal, the frequency spectrum of the exit-plane wave is dominated by a few discrete values, which are given by the most strongly excited Bloch states,[17] respectively, by the Bragg-diffracted beams.

An ideal information transfer is described by a constant, frequency-independent transfer function with a value of one. A transmission electron microscope is a nonideal information channel, the individual spatial frequencies of the exit-plane wave are differently affected by the transfer and interfere. The complex

transfer process, which is a function of the defocus, lens aberrations, and the degree of coherency, is described by the transmission cross coefficient.[18,19] Both amplitude and phase of the exit-plane wave are transferred, however they are being mixed up. What is finally seen in a high-resolution micrograph (Fig. 7) is dominated by the phase of the exit-plane wave. Therefore, HRTEM is known as phase-contrast imaging. It is the imaginary part of the transmission cross coefficient, called transfer function, which is crucial for the imaging process (Fig. 8).

Due to the highly coherent imaging process in HRTEM, images can be recorded over a certain defocus range; there is not a well-defined value in which the sample is in focus. However, because the ideal case of a plane wave illumination is usually not met, the convergence angle of the incident beam and additionally the energy spread of the electron source constrict the coherency. Owing to this partial coherence, the transfer function is damped at high spatial frequencies (Fig. 8).

Optimizing the transfer function of a microscope means approaching the ideal case of a frequency-independent transfer, i.e., a constant phase shift over a large spatial frequency range. Working at Scherzer condition,[20] which gives a criterion for an optimum defocus $\Delta f_{\text{Scherzer}}$ balancing the effect of spherical aberration C_S against defocus Δf:

$$\Delta f_{\text{Scherzer}} = -\sqrt{\frac{4}{3} C_S \lambda} \tag{6}$$

results in a broad low-pass with almost constant (negative) value. The phase of the diffracted beams is similarly shifted up to a maximum spatial frequency where the transfer function becomes zero (Fig. 8). This first zero-crossing at Scherzer condition defines the microscope's point-resolution:

$$\rho_S = 0.65 \sqrt[4]{C_S \lambda^3} \tag{7}$$

As a consequence of the higher coherence in FEG electron microscopes, information beyond the point resolution significantly contributes to the image. In addition to the point resolution, it is adequate to define an information limit. The information limit corresponds to the highest spatial frequency, which contributes to the coherent imaging process. For FEG electron microscopes, there is a pronounced gap between point resolution and information limit (Fig. 8). However, owing to the strongly oscillating behavior of the transfer function, the information beyond the point resolution is not directly interpretable and suffers from image delocalization. Image delocalization means that image details are displaced from their true locations in the specimen and blurred over a certain area. Image delocalization depends on the defocus and the spatial frequency. In addition to the Scherzer condition, there is another criterion, called Lichte defocus Δf_{Lichte}, which minimizes the overall image delocalization up to a maximum spatial frequency $k_{\max}$.[21]

$$\Delta f_{\text{Lichte}} = -\frac{3}{4} C_S (k_{\max} \lambda)^2 \tag{8}$$

Although image delocalization is minimized when working at Lichte defocus, it is still present and has to be considered when analyzing high-resolution micrographs of FEG microscopes. Numerical methods, such as reconstruction of the exit-plane wave by analyzing focal series of HRTEM micrographs, are used to access the full information up to the information limit.[22]

There are different criteria to optimize the transfer function in HRTEM; the two cited are: Scherzer defocus for a nearly frequency-independent phase shift and Lichte defocus for minimizing image delocalization. The highly coherent imaging process, particularly in the case of FEG microscopes, causing image delocalization and focus-dependent contrast reversal[1] complicates a direct image interpretation. What is seen in a HRTEM micrograph strongly depends on the transfer function, i.e., on the experimental conditions, and therefore, has to be considered thoroughly.

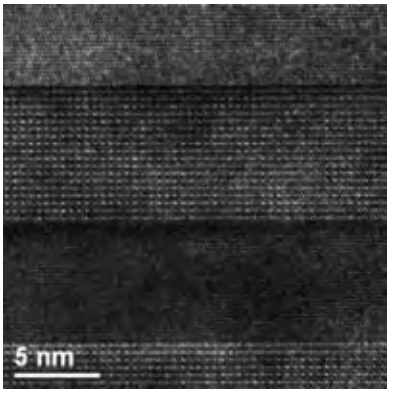

Fig. 7 High-resolution transmission electron microscopy. HRTEM micrograph of lamellar γ/α_2 titanium aluminide. From top to bottom, first twin variant of tetragonal γ-TiAl, hexagonal α_2-Ti_3Al, second twin variant of γ-TiAl and again α_2-Ti_3Al. Incident beam direction for the tetragonal phases is {1 1 0}, for the hexagonal phase {1 1 0}. *(View this art in color at www.dekker.com.)*

SCANNING TRANSMISSION ELECTRON MICROSCOPY

Imaging Process

The incremental way an image is acquired in STEM is fundamentally different from the single-shot imaging

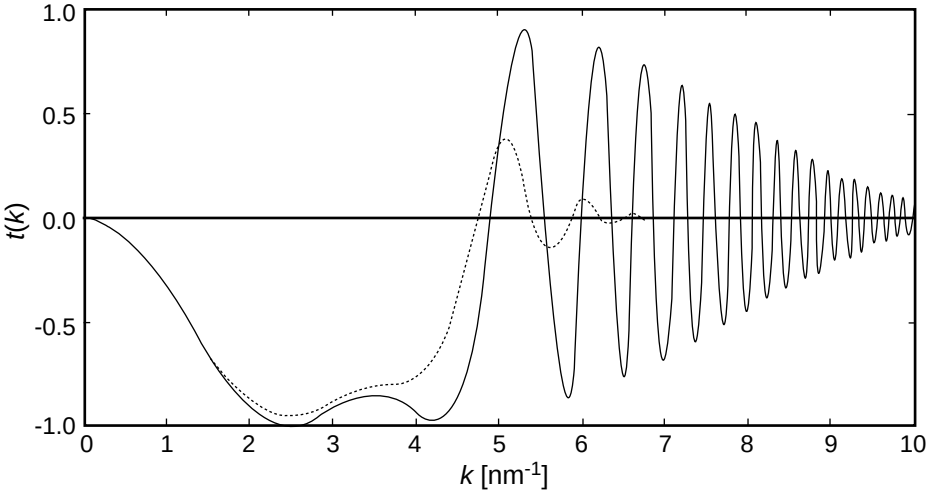

Fig. 8 Transfer function. The microscope transfer function $t(k)$ as a function of the spatial frequency k calculated for Scherzer conditions at 300 kV. Dashed line, microscope equipped with a thermionic source (LaB_6) and C_S = 1.3 mm; full line, FEG microscope, C_S = 1.2 mm.

process in normal transmission mode. In scanning mode, the electron beam is demagnified in the condenser lens system to a small, convergent electron probe (~1–2 Å), which is scanned across the sample. At each scan position, the electron probe is locally scattered on passing through the sample. The microscope is in diffraction mode; i.e., each scan position produces a nanodiffraction pattern of overlapping diffraction disks. On scanning the electron probe, the position of the diffraction pattern remains invariant. Scan detectors, which measure the electron current of a part of its diffraction pattern for each scan position, are either located below the retractable screen or can be inserted above it. Transmitted electrons are detected as a function of the electron-probe position and the scattering angle. The electron current measured for a single scan position reflects the integral intensity of a part of its diffraction pattern. This value is finally represented as the corresponding pixel intensity in the STEM image.

Scan detectors are distinguished according to the scattering-angle in whose range electrons are being detected. Bright-field detectors measure the forward scattered beam, annular dark-field detectors measure the integral intensity of low-order diffracted beams, and high-angle annular dark-field (HAADF) detectors collect electrons scattered to high angles over a large scattering angle range (Fig. 9).

Z-Contrast Imaging

According to the principle of reciprocity,[23] TEM and STEM mode are equivalent in a qualitative way. For instance, what is observed in a HRTEM image is similar to what is seen in a high-resolution BF STEM image. From the principle of reciprocity also follows that a large electron source in TEM mode is equivalent to the use of a large STEM detector that integrates the intensity over a large scattering angle range. A large, although fictitious electron source implies loss of (spatial) coherence and therefore, by using a large electron detector in STEM incoherently formed images can be recorded. This is realized when doing HAADF STEM (Fig. 9). The large HAADF detector area significantly reduces the coherence of the imaging process. Both TDS and the convergence of the electron beam reduce the coherence even further.[24] Contrast reversal and delocalization, caused by the coherent imaging process in (HR)TEM, are therefore absent when doing HAADF STEM. The incoherent nature of HAADF STEM allows for a direct, unambiguous image interpretation. Additionally, since the HAADF detector measures electrons scattered to high angles, Rutherford scattering (i.e., the Z-contribution in Eq. (2) dominates. The signal recorded approaches a Z^2 behavior, where Z is the atomic number of an element. HAADF STEM, also referred to as Z-contrast imaging,[25] is thus a chemical-sensitive imaging technique (Fig. 10).

Spatial Resolution

The spatial resolution in STEM mode is given by the size, i.e., the full width at half maximum (FWHM), of the electron probe, which depends on the electron wavelength, the convergence angle, the defocus, and the constant of spherical aberration C_S of the objective lens. The optimum probe size can be set according to Scherzer incoherent conditions,[20] where the optimum values for defocus $\Delta f_{S,inc}$ and semi-convergence angle $\alpha_{S,inc}$ are given by:

$$\Delta f_{S,inc} = -\sqrt{C_S \lambda} \quad \text{and} \quad \alpha_{S,inc} = \sqrt[4]{\frac{4\lambda}{C_S}}. \tag{9}$$

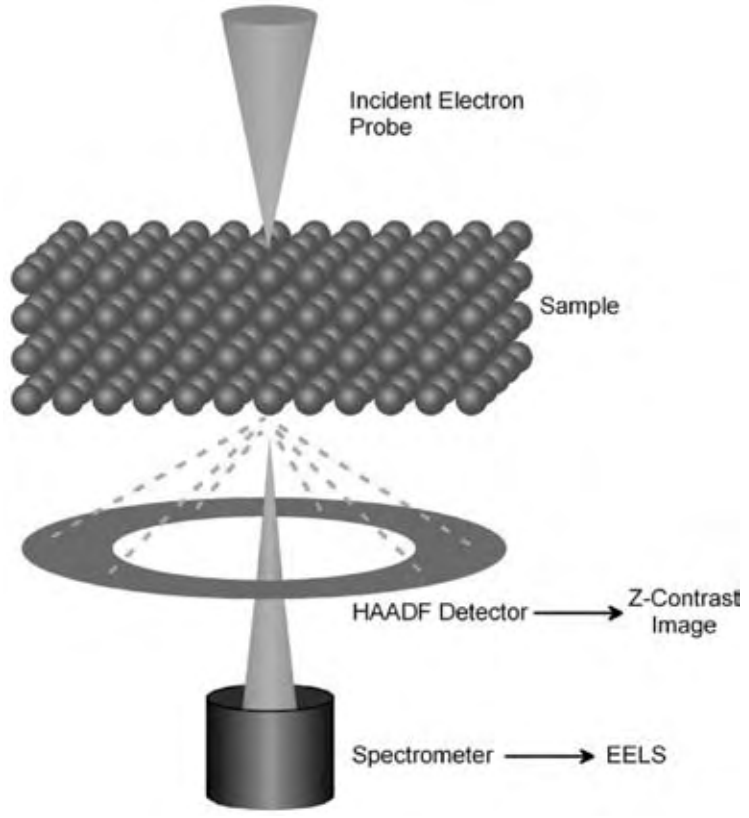

Fig. 9 Z-contrast imaging and EELS. The electron probe is scanned across the sample. For each scan position, the HAADF detector collects the high-angle scattering intensity. The intensity of one scan-position is represented as the corresponding pixel intensity in the STEM image. The forward scattered beam is not affected by the detector and can be used for EELS. *(View this art in color at www.dekker.com.)*

The electron probe size (FWHM), specifically the spatial resolution, the becomes:

$$\rho_{\mathrm{STEM}} = 0.43\sqrt[4]{C_{\mathrm{S}}\lambda^3} \tag{10}$$

For a well-aligned electron probe, which can be done by observing the electron Ronchigram of an amorphous specimen area,[26] atomic resolution STEM images are feasible for FEG microscopes (Fig. 10).

ANALYTICAL TECHNIQUES

The most common analytical techniques used in (S)TEM are EDS and EELS. The combination of STEM and EDS and/or EELS can be used to analyze the specimen locally; when stopping the scan process, the electron probe can be positioned at the point of interest.

EDS analyzes element characteristic X-rays caused by inelastic electron–atom interactions. It is mainly used to measure the composition of the sample. The spatial

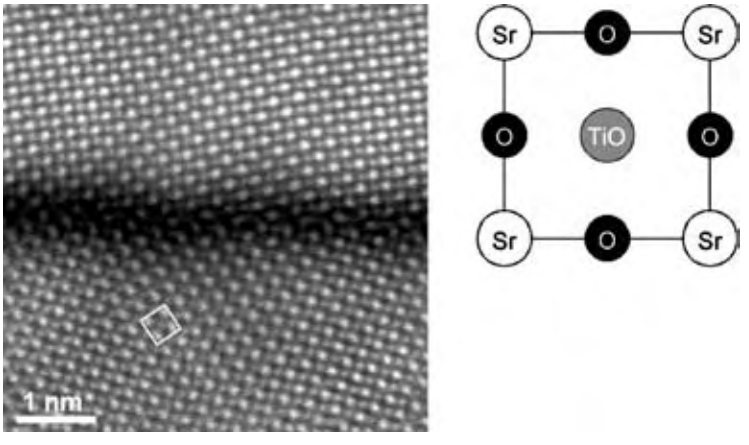

Fig. 10 High-resolution Z-contrast imaging. Z-contrast image of a grain boundary in $SrTiO_3$ (perovskite structure) recorded in {0 0 1} direction. One of the unit cells framed in the micrograph is illustrated on the left, the Sr columns (bright) are at the corner of the unit cell, in the center there is a TiO column. The pure oxygen columns, black in the model, are not observable in the Z-contrast image. The atomic number (Z) contrast is apparent; with increasing atomic number (Z) of the elements, the intensity increases. *(View this art in color at www.dekker.com.)*

resolution of EDS carried out in scanning transmission mode is given by the excited material volume, which in projection is in the nanometer range. EDS lacks the possibility to detect light elements,[1] i.e., elements of atomic numbers smaller than about six.

EELS measures the electron energy distribution below the sample. Two types of spectrometer are common, Ω-spectrometers and post-column energy filters.[7] Ω-spectrometers, located between objective lens and screen, are advantageous when analyzing angle-dependent inelastic scattering in diffraction pattern. As an independent add-on, post-column filters are mounted below the microscope column. Post-column filters use a magnetic prism, which deflects the electron trajectories as a function of their energy. The use of a post-column spectrometer is particularly advantageous when doing Z-contrast imaging in combination with EELS (Fig. 9). The forward scattered beam, which is not affected by the HAADF detector, can be analyzed in the spectrometer with a spatial resolution down to the atomic level.[27]

A typical EEL spectrum consists of the zero-loss peak, caused by elastically and quasi-elastically scattered electrons, plasmon-loss peaks, a downward-sloping background and element-specific ionization edges superimposed on this background.[7] The characteristic ionization edges can be used for a chemical analysis with the advantage compared to EDS that light elements down to He can be detected.[7] Due to the better energy-resolution in EELS (<1 eV) compared to EDS (~100 eV), EELS provides additional information. By studying the fine structure of ionization edges, information about chemical bonds and oxidation states of atoms, as well as the electronic structure of the material can be accessed.

Energy-filtered transmission electron microscopy (EFTEM) combines the analytical capability with imaging. Instead of forming an image with the entire electron distribution, an energy-slit can be inserted in an EEL spectrometer. The energy slit selects electrons with a defined energy loss, which are used to form an image. When positioning the energy slit on the zero-loss peak, images are filtered from inelastic contributions. The energy-slit can also be positioned on element-specific ionization edges. Performing an appropriate background correction, the distribution of an element can be mapped quickly.[28]

CONCLUSIONS

Transmission electron microscopy is an essential tool to study materials and their defects down to the atomic scale. Atomic resolution is feasible in HRTEM as well as in STEM mode, however the real strength of TEM is the combination of different imaging, diffraction, and analysis techniques all able to be performed in a single microscope.

The performance of (scanning) transmission electron microscopes is being steadily improved. Combined STEM/TEM microscopes equipped with correctors for the spherical aberration (already available), and in the near future also for the chromatic aberration (will), improve the spatial resolution in HRTEM. Aberration correctors for the electron probe forming optical part, allow for sub-Å electron probes when working in scanning transmission mode.[29] The improved spatial resolution in HRTEM and STEM is advantageous in studying materials of small lattice spacing containing light elements. However, increasing the spatial resolution is particularly of importance to make (S)TEM a more quantitative tool in materials science. Reconstructed electron exit-plane waves[22] and HRTEM micrographs[4] can be quantitatively analyzed providing information about the composition of individual atomic columns. The combination of sub-Å resolution Z-contrast imaging and EELS[27] is being used for instance to measure the chemical composition of dislocation cores and the intrinsic bonding states related to point defects. Electron tomography[30] on an atomic scale will fill the general lack of (S) TEM, which basically provides projected, two-dimensional information. Microscopes already available equipped with a monochromator allow for sub-100 meV energy-resolution in EELS. The experimentally accessed fine structure of ionization edges can directly be compared with electronic structure calculations. Valence EELS with a monochromated electron beam is used to study band gaps and inter- and intraband transitions locally. Not only are the microscopes being improved, but the repertoire of experimental techniques, not fully covered in this article (but see for example Refs.[1,13]) and the implementation of different techniques in one microscope, are being developed further as well.

ACKNOWLEDGMENTS

We would like to thank Prof. Dr. G. Kostorz, Institute of Applied Physics, ETH Zürich (Switzerland), for providing the titanium aluminide sample and for permitting the use of the corresponding figures in this article. INTRODUCTION

Tubular reactors are commonly used in laboratory, pilot plant, and commercial-scale operations. Because of their versatility, they are used for heterogeneous reactions as well as homogeneous reactions. They can be run with cocurrent or counter-current flow patterns. They can be run in isothermal or adiabatic modes and can be used alone, in series, or in parallel. Tubular reactors can be empty, packed with inert materials for mixing, or packed with catalyst for improved reactions. It is often the process that will dictate the design of the reactor, as discussed in this entry.

BACKGROUND

Definition

A tubular reactor is a device for conducting chemical transformations of reactants to one or more desired products. Typical products that may be generated with this device include organic or inorganic chemicals, petroleum-derived products, biological materials, and polymers. In the simplest embodiment, a homogenous fluid containing a reactant is introduced into one end of a cylindrical tube at a constant flow rate, where it undergoes a chemical transformation as it is transported through the tube by convection until the product is removed from the other end (Fig. 1). The local rate of reaction of a species, which corresponds to a given position measured relative to the tube inlet, will generally vary with both concentration and temperature. Under ideal conditions, the following three phenomena characterize the reactor hydrodynamics: 1) no fluid mixing occurs in the axial coordinate, i.e., in the direction of fluid flow; 2) complete mixing occurs in the radial direction; and 3) the fluid velocity is uniform across the reactor cross-section.

Application Areas

Commercial-scale tubular reactors are primarily used in the manufacture of petroleum-based products, bulk chemicals, fine and specialty chemicals, pharmaceuticals, and polymers and in environmental remediation. The types of reactions that may be conducted can occur either in the presence or in the absence of a catalyst and may involve more than one phase, such as gaseous phase, liquid phase, and solid phase. When a catalyst is used, it may generally exist as either a soluble organometallic complex or a solid heterogeneous catalyst. The catalyst either can follow the motion of a continuous phase or may be fixed in a place on either an active or an inert support. Examples of reactions that can be realized in tubular reactors include partial and total oxidation, hydrogenation, oxidative or nonoxidative dehydrogenation, hydroformylation, carbonylation, oxidative carbonylation, and polymerization. Tubular reactor types that are used in the above applications include single and multistage adiabatic fixed-bed reactors with either unidirectional or reverse flow, single or multitubular fixed-bed reactors, pipeline reactors, and other special-purpose tubular-type contactors. The scope of applications for these and various other reaction classes has been summarized.[1–3] Several other reviews and the references cited therein provide details of more recent work from both chemistry and process perspectives.[4–8]

Modes of Operation

Tubular reactors can be operated using various modes. These modes also serve to distinguish between various tubular reactor types. The number and type of phases that are present and whether or not a catalyst is used are the criteria for distinguishing between these various modes. The complexity of operation and prediction of reactor performance generally increases when more than one phase is present and when either soluble

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007998

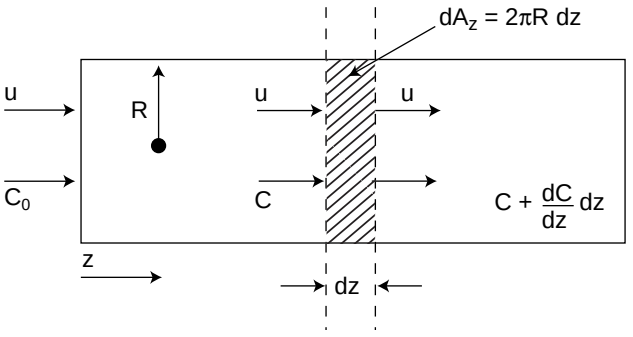

Fig. 1 The ideal tubular reactor.

homogeneous catalysts or solid-phase heterogeneous catalysts promote the reactions.

Homogeneous-phase mode

The simplest mode of operation occurs when the reaction mixture consists of a single phase (i.e., gas, liquid, or solid) during its sojourn through the tubular reactor environment and a catalytic material is not utilized to effect the reaction. The reactor is then referred to as a ''homogenous-phase noncatalytic'' tubular reactor. Some examples of reactions that are realized in this mode are the thermal cracking of hydrocarbons, the noncatalytic combustion of fuels, liquid-phase acid–base reactions, and ethylene polymerization.[9,10] These reactions are typically driven by the formation or the induced generation of one or more radicals that result in a sequence of either elementary or nonelementary steps. The empty tube may also be filled with inert packing to promote radial fluid mixing and heat transfer. Typical inert packings that might be used are illustrated in Fig. 2A–C. In Fig. 2A, nearly all of the commercially available randomly dumped packings are shown in a variety of materials of construction. Those constructed of plastic might find application in liquid-phase reactions where the expected upper temperature limit would not exceed the safe operating temperature of the material. In Fig. 2B, a subset that would be suitable for higher temperature operation, as they are constructed of either metal or ceramic, is shown. In Fig. 2C, several motionless mixers that could be inserted into a pipe or tube are shown. The mixers are designed to promote fluid mixing and heat transfer without the use of moving parts, such as motor-driven agitators. For multiphase mixtures, the mixers are intended to generate local turbulence and interfacial area between the various phases.

When the reaction mixture remains as a single phase, but a catalyst is used to accelerate the reaction, then the reactor is referred to as a ''homogenous-phase catalytic tubular reactor.'' One common application occurs when the reactant is a liquid mixture in which a soluble catalytic material is added to accelerate the conversion of the reactants into the desired product. Esterification reactions in which an alcohol is reacted with a carboxylic acid in the presence of an inorganic acid, such as sulfuric acid, are well-known examples. Pure or multicomponent mixtures of gases can also be used as reactants, and these may react at the active sites of a catalytic material that is deposited on the walls of the reactor tube. The tube can also be filled with a stationary heterogeneous catalyst in the form of a sphere, extrudate, tablet, hollow cylinder, or any other shape (Fig. 3) to form a randomly filled packed bed. Structured packing that has a well-defined geometrical representation, but with surfaces that are washed-coated with a heterogeneous catalyst can also be utilized (Fig. 4). The catalyst may also assume the form of a finely divided powder that is fluidized by either a moving gas phase or a liquid phase,[11] such as those used in fluidized catalytic cracking of crude oil[12] or olefin polymerization.[13] Examples of reactions that use heterogeneous catalysts are quite numerous and include gas-phase hydrogenation, partial oxidation, ammoxidation, catalytic cracking, and emission control chemistries.

Heterogeneous-phase mode

The other distinct mode of operation for a tubular reactor occurs in applications where more than one phase is present in the reaction mixture, e.g., gas and liquid reactants. The products from the reaction can be gases, liquids, or solids where the latter can exist as crystalline or amorphous materials. Either aqueous or organic-based solvents are sometimes included in the reaction medium to control the concentrations of reaction species, to provide increased thermal capacity for highly exothermic systems, or to alter solubility properties for subsequent catalyst recovery or product separations and recovery. This type of reaction is often termed a ''multiphase'' reaction, owing to the presence of multiple interacting phases in the reaction environment. In most practical applications of this mode, either a soluble organometallic complex or a solid heterogeneous catalyst is utilized to transform the reactants into the desired product or products.

When a soluble catalyst is used, the multiphase mixture can be contacted in an open empty tube, and mixing of the various phases occurs through an interaction that is induced by local fluid dynamical phenomena. Alternatively, the tube may be filled with inert packing in an attempt to increase radial mixing for improved multiphase contacting and to promote heat transfer between the fluid and the reactor walls. The inert packing may be either randomly dumped into the tube or inserted in the form of the structured variety as illustrated in Figs. 2 and 4, respectively.

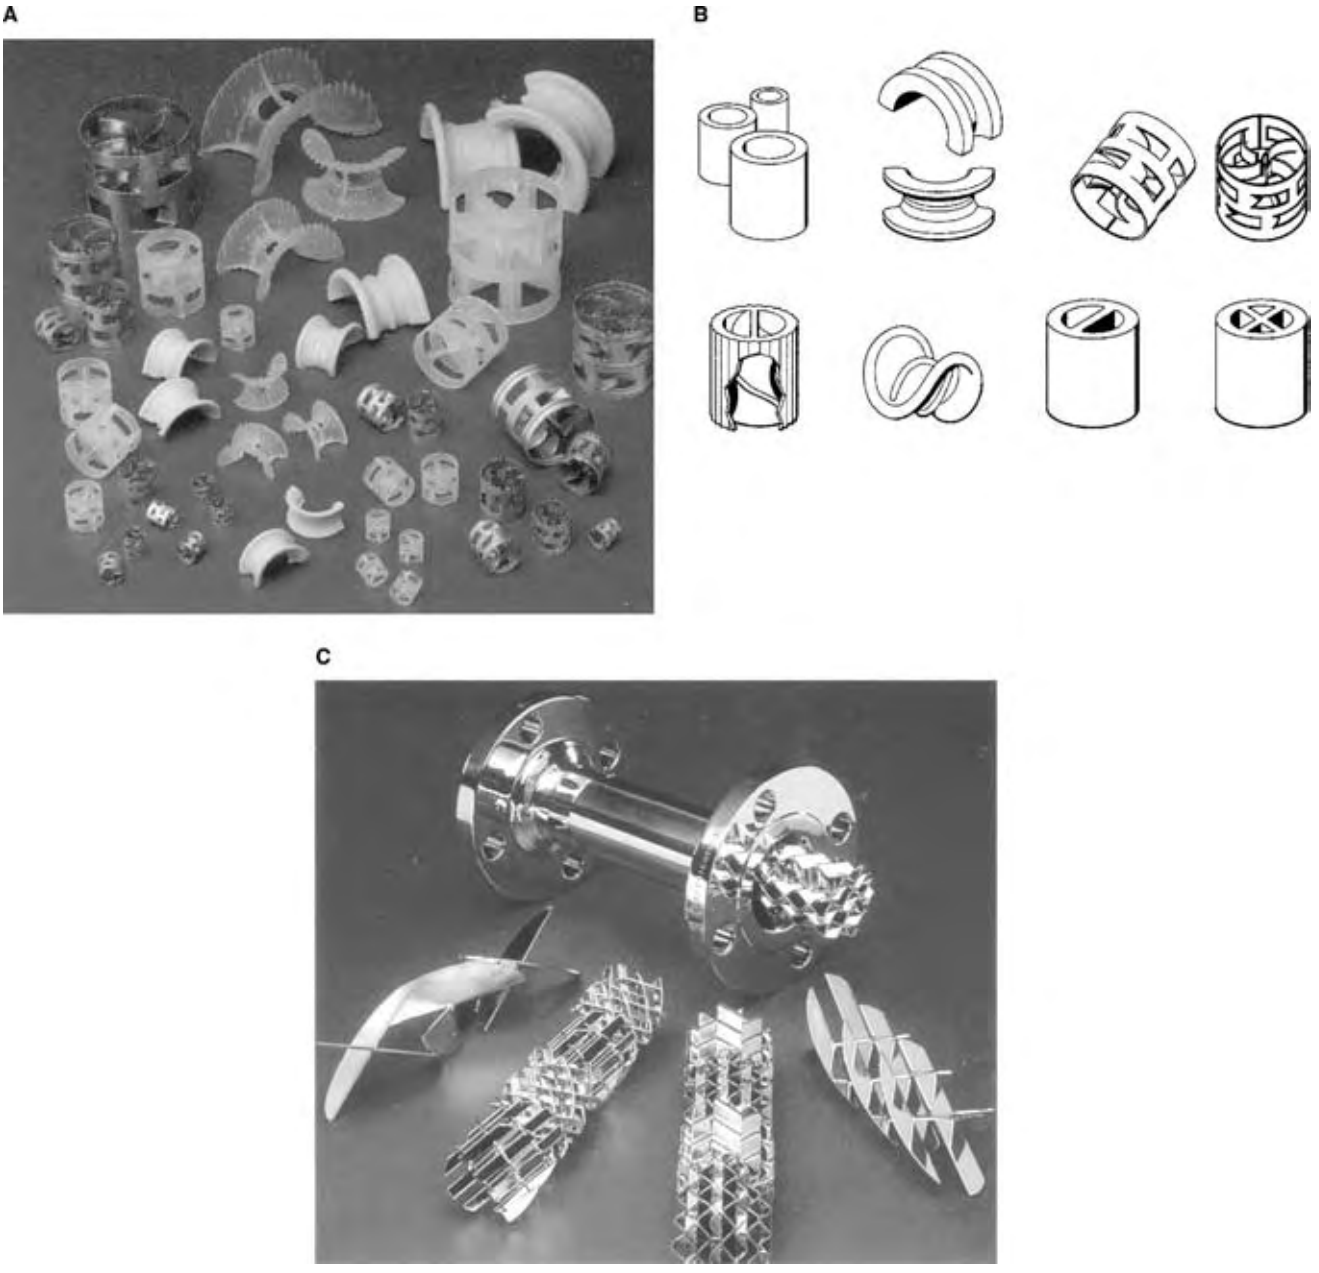

Fig. 2 Examples of randomly dumped inert packings for tubular reactors. (A) Packings for tubular reactors constructed from plastics, metals, and ceramics; (B) packings for tubular reactors constructed from metals and ceramics for higher temperature applications; and (C) inline motionless mixers constructed of metal.

For example, in one version of the Wacker process used for the oxidation of ethylene to acetaldehyde with soluble palladium–copper complexes, a tubular reactor containing ceramic rings is used to promote gas–liquid contacting and to impart a gas–liquid flow pattern that approaches ideal tubular reactor behavior.

Multiphase reactions that occur in the presence of a heterogeneous catalyst can be realized using a variety of tubular reactor types that can be classified according to the state of motion of the catalyst. When the catalyst remains stationary inside the tube and has the shape of a larger particle, such as those illustrated in Fig. 3, then the reactor is generally called a ''heterogeneous-phase fixed catalytic tubular reactor'' or ''multiphase fixed-bed reactor.''

Gas and liquid reactants can be contacted in fixed-bed tubular reactors according to one of several possible so-called ''gas–liquid contacting patterns.'' The three most commonly used contacting patterns are illustrated in Fig. 5. These include trickle-bed reactors (TBRs) with either downward cocurrent (Fig. 5A) or counter-current (Fig. 5B) gas–liquid flow,

Fig. 3 Heterogeneous catalyst shapes.

and packed bubble column reactors with cocurrent upward gas–liquid flow (Fig. 5C). Within this classification, TBRs are the most commonly used reactor in commercial operations as this contacting mode allows various flow regimes to be generated. This reactor is also the most flexible with respect to accommodating variations in liquid and gas flow rates that may be encountered in a manufacturing environment subject to pressure drop constraints. Counter-current flow operation of a TBR with a downflow of gas and an upflow of liquid provides the opportunity for selective removal or stripping of volatile byproducts from the liquid phase that may act as catalyst inhibitors. An example for this is the removal of H_2S and other light sulfur-containing compounds in hydrodesulfurization processes that can otherwise inhibit the local heterogeneous reaction rate. Counter-current gas–liquid contacting can also lead to a larger net driving force for local gas–liquid mass transfer for chemistries where the reaction rate is limited by the gaseous reactant and this species exists as a dilute component in the gaseous feed. Most importantly, with proper catalyst selection, counter-current operation provides the opportunity for in situ separation via catalytic or reactive distillation.[14–22] Upflow packed bubble column reactors (Fig. 5C), or the so-called ''packed bubble-flow reactors,'' are used when it is desirable to ensure a complete external wetting of the catalyst and to achieve the highest possible liquid holdups. The latter condition is desirable for reactions where control of thermal effects may be an issue, owing to the higher heat capacity of the liquid and the cooling effect associated with simultaneous vaporization and condensation.

A variation of the heterogeneous-phase mode occurs when the catalyst is used in the form of a powder so that it more or less follows the motion of the liquid phase. The catalyst powder usually has an irregular shape with a mean diameter ranging from 10 to 400 μm depending upon the particular application, with 50 μm being typical of most operations. Multiphase tubular reactors that use these powdered catalysts are called ''heterogeneous-phase slurry catalytic tubular reactors'' or ''multiphase slurry reactors.'' The more common mode of operation is one where the multiphase contacting between the reactants and powdered catalyst occurs in either a mechanically agitated vessel or a bubble column reactor where the latter has a length-to-diameter aspect ratio from

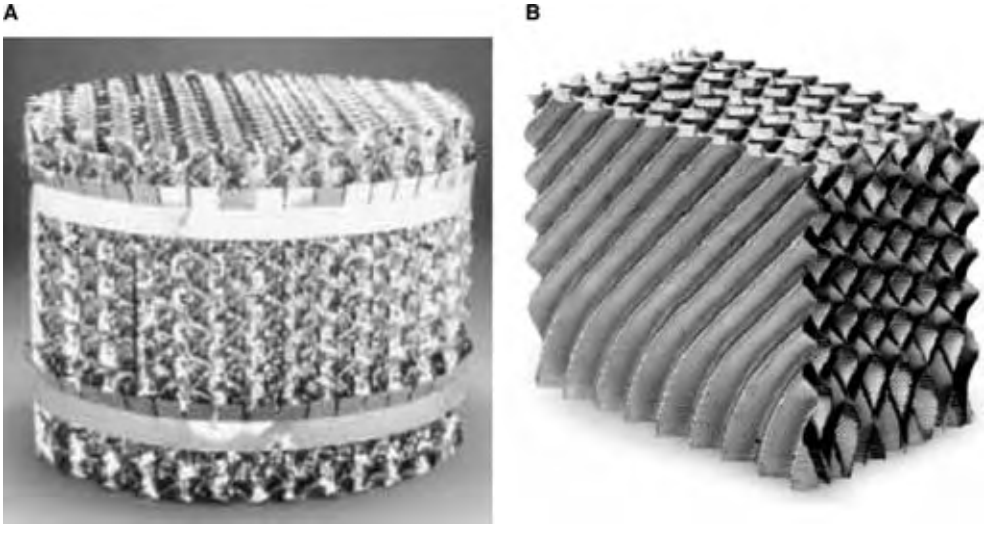

Fig. 4 Structured catalyst packings; A) Metal-Max structured packing and B) Montz-Pak type M structured packing.

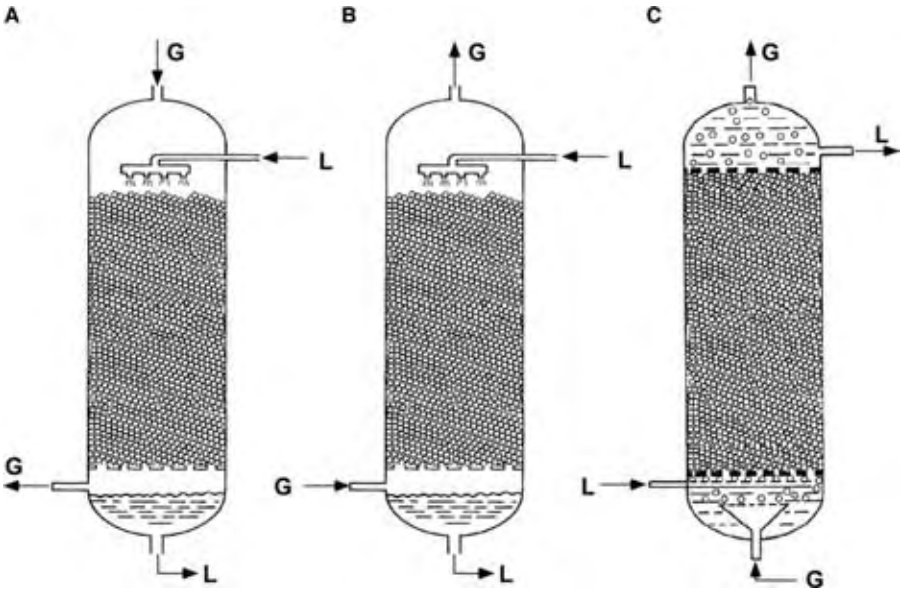

Fig. 5 Fixed-bed reactors with gas–liquid flow. (A) Trickle-bed reactor with cocurrent downflow; (B) trickle-bed reactor with counter-current flow; and (C) packed bubble-flow reactor with cocurrent upflow.

5 to 20. However, other applications exist where the multiphase reactants and powdered catalyst are contacted in tubes with narrower diameter, as part of an attempt to approach the flow pattern of an ideal tubular reactor. In some cases, various types of internals, such as sieve trays, may be added to alter the mixing characteristics of the various reacting phases.

REACTOR DESCRIPTIONS AND PROCESS APPLICATIONS

Introduction

The objective of this section is to provide a brief overview of selected chemistries and processes that are based upon various tubular reactor designs to illustrate more practical aspects. As the partial oxidation process is a key manufacturing technology that utilizes various tubular reactor designs, most of the emphasis will be placed here. The extension of the same concepts to other chemistries, such as hydrogenation reactions, is based upon similar principles.

The least complex class of reactors used for gas-phase catalytic oxidation reactions is adiabatic fixed-bed reactor. The number of processes that employ adiabatic reactors for oxidation processes is somewhat limited. The single-stage or single-bed adiabatic fixed-bed reactor has the simplest design. Also included in the adiabatic reactor class is the multistage design, even though heat is exchanged between adjacent stages. Finally, the most recently developed reactor type in the adiabatic class is the reverse-flow reactor. This reactor has been mainly used in the former Soviet Union to oxidize SO_2 to SO_3.

Unlike catalytic reactors that have heat exchange within the reactor, the distinguishing feature of the adiabatic reactor is that the heat generated by an exothermic reaction goes unchecked. The resulting steady-state temperature profile is a monotonically increasing function of distance from the reactor inlet. The temperature rise asymptotically approaches the adiabatic temperature rise. Temperatures can exceed the adiabatic temperature rise in the unsteady-state adiabatic reverse-flow reactor, which is described here. Because of the potential severity of the heat effects, oxidation reactions carried out in adiabatic reactors form a special subclass. Not only must the catalyst tolerate a temperature rise of several hundreds of degrees, but also that the high temperature must not negatively impact the desired product selectivity. If these two requirements are met, then the designer can take advantage of the high rate of reaction at the high temperature without significant penalty. Moreover, the relative simplicity of the adiabatic reactors, when compared with their cooled counterparts, can be exploited in design, scale-up, and operation.

Commercial manufacturing operations for various inorganic or organic chemicals that are used as chemical intermediates, monomers, or final products are often based upon partial oxidation processes using air, enriched air, or pure oxygen. The reactions upon which these processes are based are conducted in either the liquid phase or the vapor phase, using homogenous or heterogeneous catalysts. The key factors that determine the phase in which the reaction is conducted include the reactant volatility, thermal stability of the reactants and products, specific reaction rate, space–time yield, process safety, and process economics. Examples of inorganic chemicals that are produced using vapor-phase

partial oxidation include nitric acid, sulfuric acid, and hydrogen cyanide. The oxychlorination of HCl is also an example for vapor-phase partial oxidation process. Typical organic chemicals that are commercially manufactured using vapor-phase oxidation processes include ethylene oxide, acrolein, acrylic acid, methacrolein, methacrylic acid, maleic anhydride (MAN), and phthalic anhydride. Ammoxidation reactions, which occur when a mixture of air and ammonia reacts with a hydrocarbon to form a nitrile, are related to these as many of the catalysts used for oxidation are also utilized for this application. A summary of process aspects for selected chemistries is included in the next few sections.

Single-Stage Adiabatic Fixed-Bed Reactors

Description

A typical single-stage adiabatic reactor is shown in Fig. 6. Significant pressure drop can be created as packed bed length increases, the particle size is reduced, or the flow rate is increased. To minimize the pressure drop, a variety of other reactor designs for single-stage adiabatic reactors have been implemented as shown in Fig. 7. These include the simple catalyst bed,[23] the disk or shallow-bed reactor,[23,24] and the radial-flow reactor.[24] The shallow-bed reactor is used in fast reactions where complete conversion can be achieved in a very short contact time. The shallow-bed affords minimal pressure drop, although flow distribution can be an imposing problem.[24] The radial-flow reactor is used to reduce pressure drop as well.

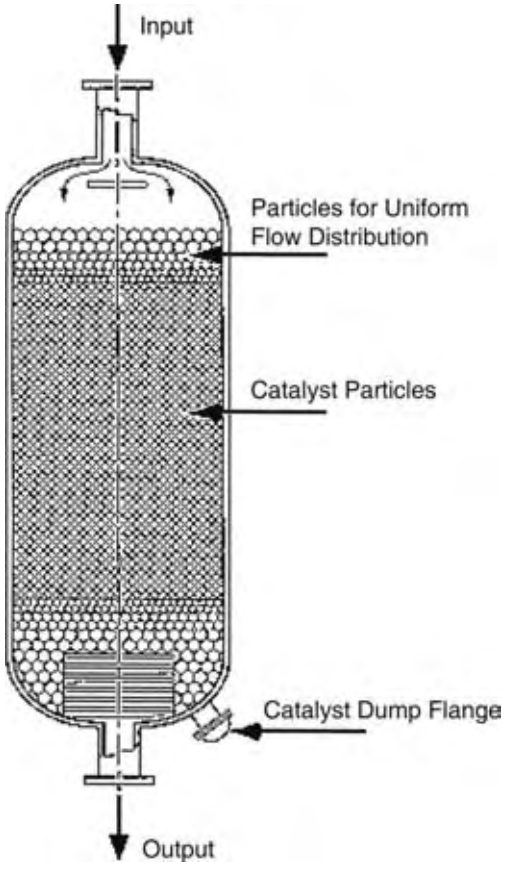

Fig. 6 Typical adiabatic catalytic fixed-bed reactor.

Single-stage adiabatic reactor commercial processes

The oxidation of ammonia to nitric oxide over Pt/Rh is the key step in the manufacture of nitric acid and is realized using a single-stage adiabatic reactor. The partial oxidation of methane to synthesis gas using a millisecond contact-time reactor has not been demonstrated on a commercial scale, but is an interesting example of a novel reactor operating design concept.[25] It is an attractive alternative to the conventional methane steam-reforming route to synthesis gas.

Nitric Acid Process. Nitric acid (HNO_3) is produced by the absorption of nitrogen dioxide (NO_2) in water. The primary route for the manufacture of NO_2 is based on the series oxidation of both ammonia and NO using a feed gas containing excess oxygen. A schematic of a typical high-pressure nitric acid plant is shown in Fig. 8.[26] The oxidation of ammonia is carried out in a reactor containing a Pt/Rh gauze at temperatures between 850°C and 950°C. The following two overall reactions occur:

$$NH_3 + 1.25O_2 \rightarrow NO + 1.5H_2O + 226\ kJ \quad (1)$$

$$NH_3 + 0.75O_2 \rightarrow 0.5N_2 + 1.5H_2O + 317\ kJ \quad (2)$$

Ammonia oxidation can also form nitrous oxide (N_2O) in small amounts. The desired NO producing reaction [Eq. (1)] is extremely fast as the contact time is about 1 msec and is limited by gas–solid mass transfer. For this reason, both the gas linear velocity and flow uniformity are critical issues. The yield to NO is an increasing function of temperature and a slightly decreasing function of total pressure. The NO yield is 98% at atmospheric pressure and 50°C, while it is 96% at 8 atm and 900°C. The loss of precious metal catalyst is an important consideration at higher temperatures.

The high-pressure process reaction operates at 110 psig and offers reduced equipment size at the expense of slightly lower NO selectivity. In the split-pressure process, the ammonia conversion is carried out at an intermediate pressure of about 30 psig, while the water absorption is carried out at higher pressure. The NO that is formed in the ammonia converter

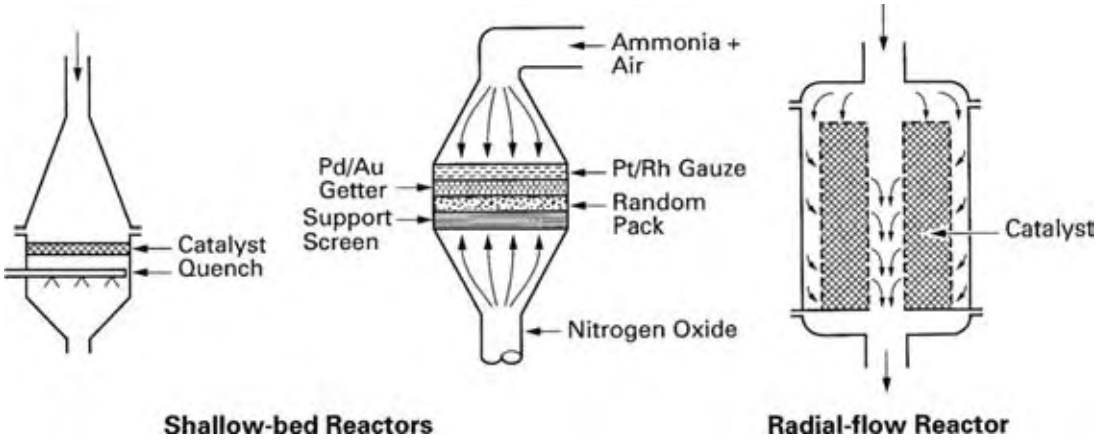

Fig. 7 Three single-stage adiabatic fixed-bed reactor types.

oxidizes further into NO_2:

$$NO + 0.5O_2 \rightarrow NO_2 + 57\ kJ \quad (3)$$

This reversible exothermic reaction is thermodynamically favored at low temperature. Finally, the resulting mixture of NO and NO_2 passes through a condenser and then a cooled absorption column to produce HNO_3. During the reaction between NO_2 and water, NO is formed, which is reoxidized into NO_2.

Multistage Adiabatic Fixed-Bed Reactors

Description

There are two classes of reaction systems for which the single-stage adiabatic reactor is incapable of satisfying the demands that can be placed upon reactant conversion and selectivity. The first class is reversible exothermic reactions. Multiple stages with interstage cooling are required for these reactions to achieve an acceptable conversion level with a reasonable reactor volume. The classical oxidation example is that of SO_2 to SO_3, which is described in more detail below. The second class is the partial oxidation of hydrocarbons in which the desired product selectivity is significantly sensitive to both temperature and the oxygen concentration. More specifically, yield losses to carbon oxides, which result from sequential or parallel side reactions, undermine the goal of achieving high product selectivity at a reasonable hydrocarbon conversion per pass. Most hydrocarbon partial oxidation reactions have this feature. Two illustrative commercial processes include the silver-catalyzed oxidation of methanol to formaldehyde and the catalytic oxidation of monomethylformamide to methyl isocyanate.

Multistage adiabatic reactor commercial processes

Important commercial reactions that are carried out in multistage adiabatic reactors include: 1) the oxidation of SO_2 to SO_3 over a vanadium pentoxide catalyst, which is the key step in sulfuric acid manufacture, and 2) the silver-catalyzed oxidation of methanol to

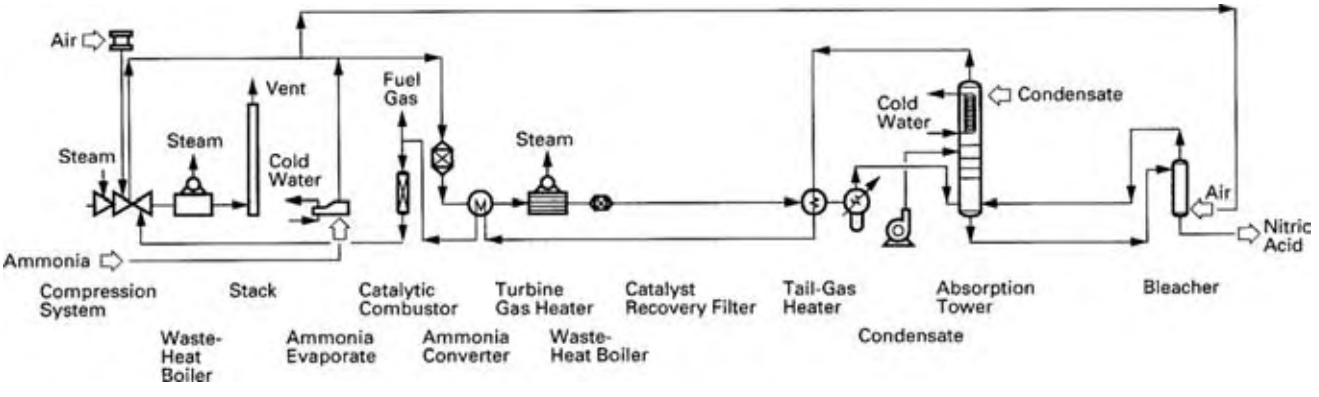

Fig. 8 High-pressure ammonia oxidation process. (From Ref.[26].)

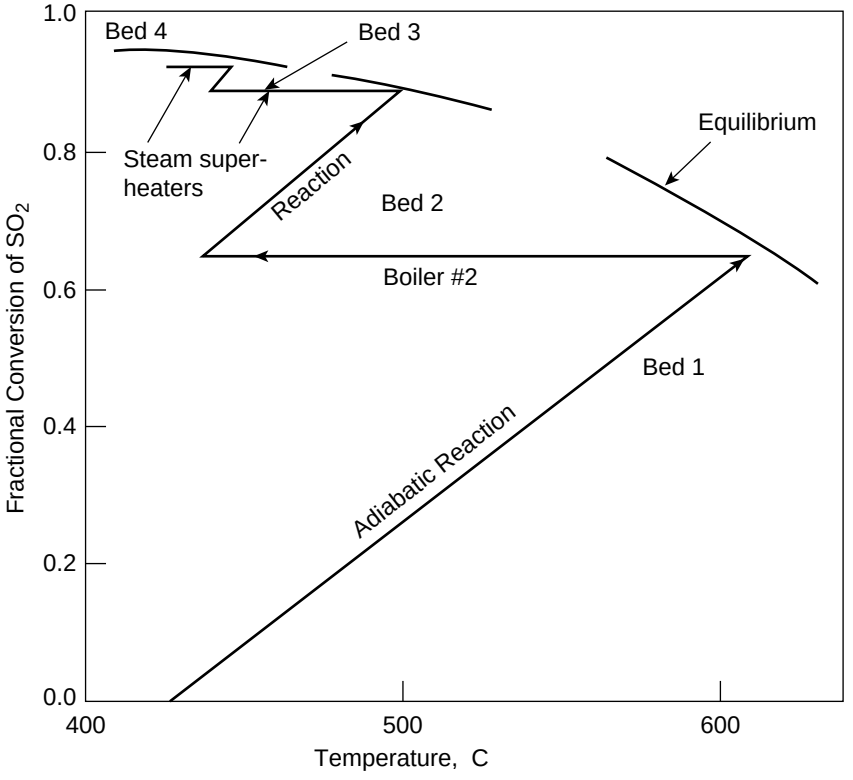

Fig. 9 Typical conversion vs. temperature profile for SO_2 oxidation in a multistage reactor system.

formaldehyde. A summary of the key process aspects for oxidation of SO_2 to SO_3 is given here.

Sulfur Dioxide to Sulfur Trioxide Process. The manufacture of sulfuric acid involves the oxidation of elemental sulfur to SO_2, followed by the catalytic oxidation of SO_2 to SO_3 over vanadium pentoxide. The next step involves the absorption of SO_3 with water to form H_2SO_4. The SO_2 oxidation reaction to SO_3 and the subsequent absorption of SO_3 to form H_2SO_4 are described by the following two reactions:

$$SO_2 + 0.5O_2 \rightarrow SO_3 \quad (4)$$

$$SO_3 + H_2O \rightarrow H_2SO_4 \quad (5)$$

A key attribute of the oxidation of SO_2 to SO_3 is that it is both exothermic and reversible. As shown in the conversion vs. temperature plot in Fig. 9, low temperature

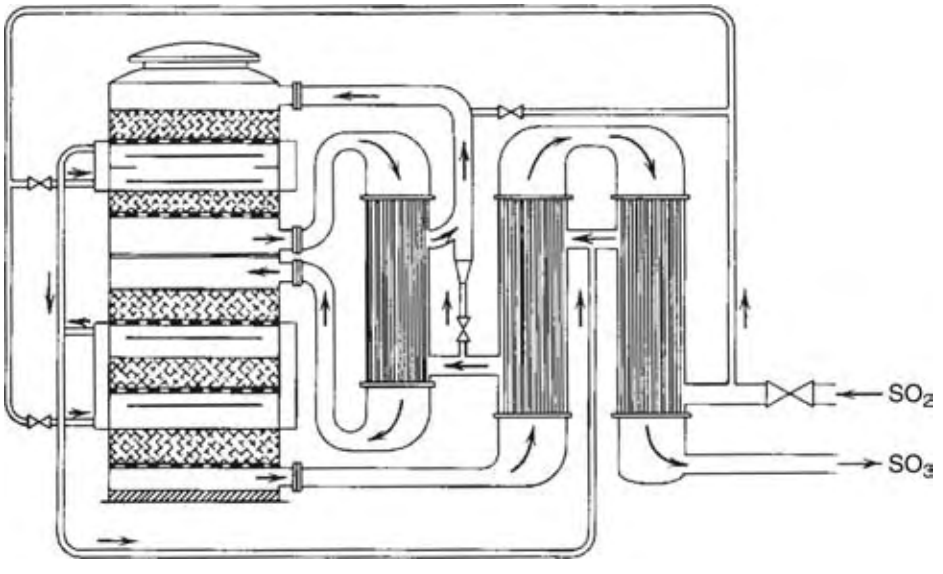

Fig. 10 Multibed adiabatic reactor for SO_3 synthesis. (From Ref.[27].)

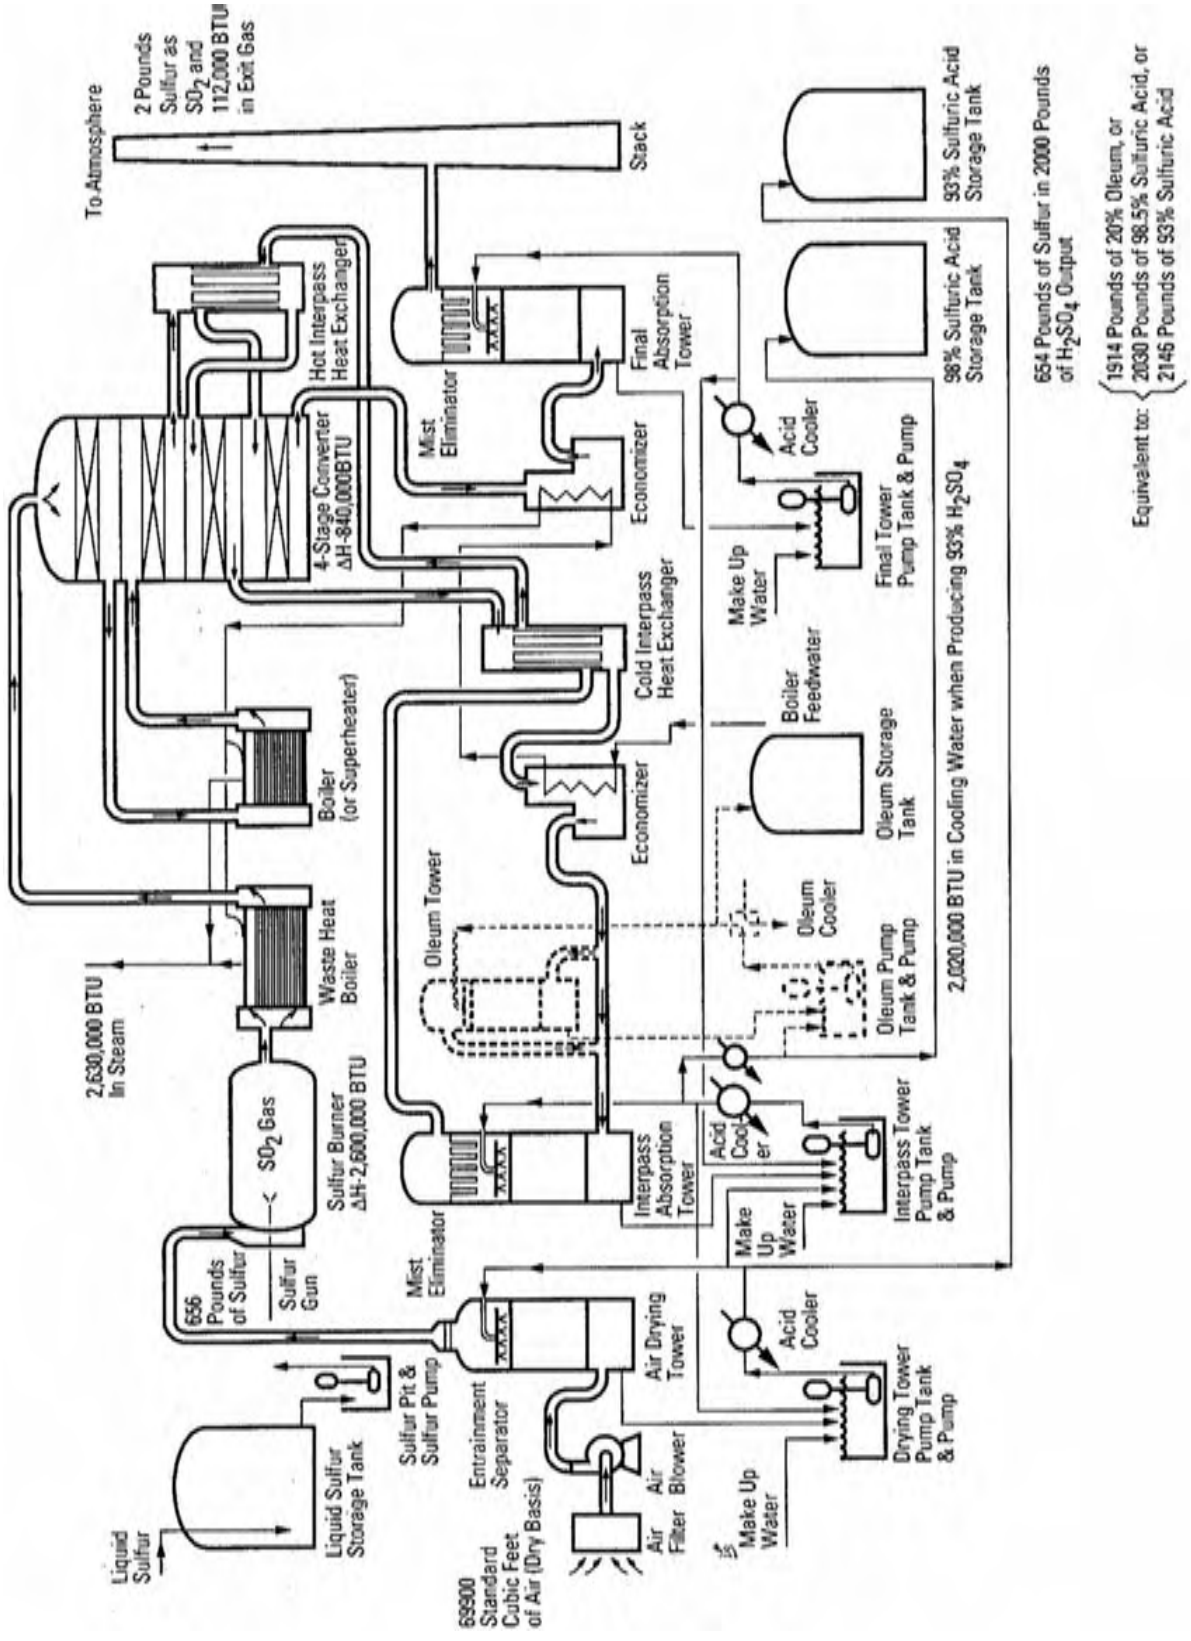

Fig. 11 Process flow sheet for a sulfuric acid process. (From Ref.[28].)

favors equilibrium. This is problematic because the rate of reaction is an increasing function of temperature. For this reason, the reaction is carried out in a multistage adiabatic reactor. In the first stage, a large fraction of the SO_2 conversion is carried out. A high temperature is desirable in the first reactor stage because the feed is free of the reaction product SO_3, which allows the exploitation of the beneficial kinetic effect of a higher temperature. The reactor temperature, which increases linearly with conversion, becomes sufficiently high in the first bed so that the reaction mixture must be cooled to confront the equilibrium constraint. In practice, several stages are employed. Interstage cooling can be accomplished with heat exchangers or by using the so-called "cold shots" of air.

Fig. 10 shows a typical SO_2 multistage reactor system manufactured by Zieren-Chemiebau.[27] This particular design has feed–effluent heat exchangers and cold-shot interstage cooling.

More elaborate multistage reactors have been developed as a result of environmental pressures to reduce sulfur emissions in sulfuric acid plants. One such process is shown in Fig. 11.[28] The final stage of the reactor in this process is fed with a stream in which a fraction of the SO_3 product has been recovered. This enables the final stage to push the SO_2 conversion closer to completion.

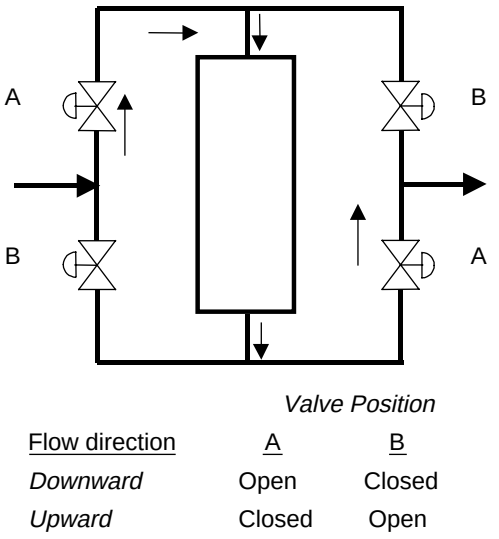

Fig. 12 Schematic of the reverse-flow reactor.

Reverse-Flow Adiabatic Fixed-Bed Reactors

Description

The reverse-flowreactor is a novel reactor design that was originally conceived by Boreskov and Matros[29,30]

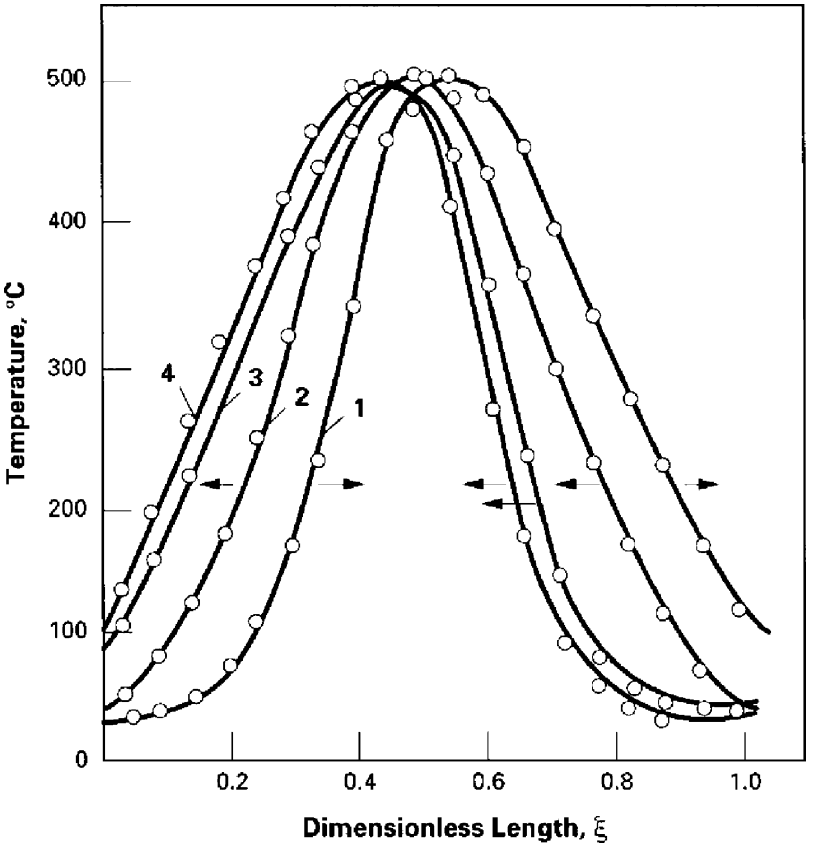

Fig. 13 Measured temperature profiles during SO_2 oxidation in a reverse-flow reactors. (From Ref.[29].)

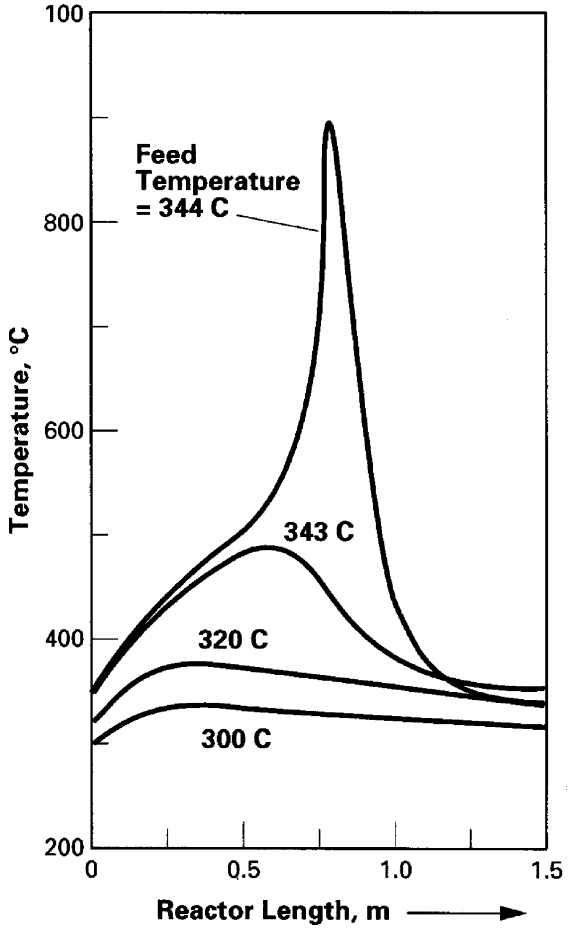

Fig. 14 Effect of reactor feed temperature on predicted temperature profiles for a gas-phase tubular reactor. (From Ref.[24].)

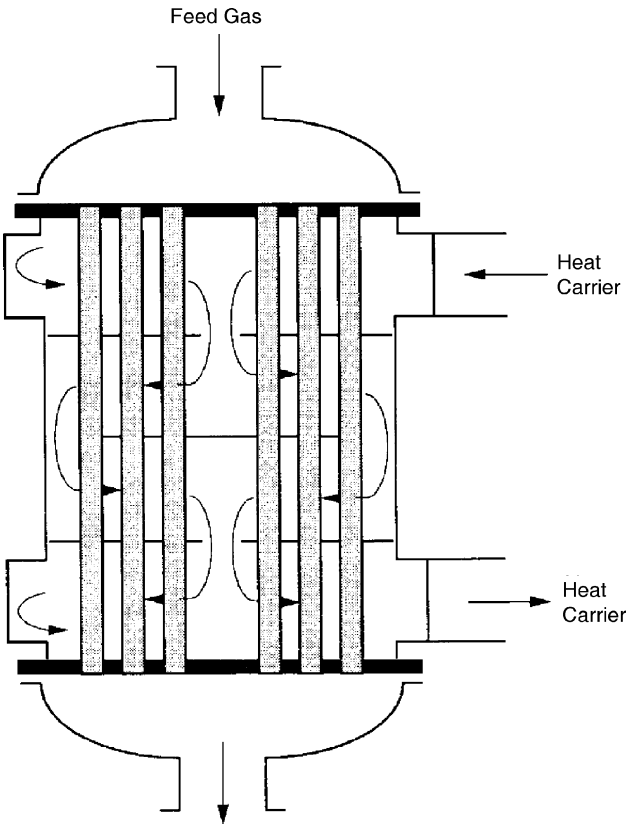

Fig. 15 Simplified schematic of a fixed-bed multitubular reactor.

and Matros et al.[31] As shown in Fig. 12, it is a standard adiabatic fixed-bed reactor, in which the feed gas enters through the opposing ends of the reactor in a deliberate periodic fashion. The main idea is to utilize the exothermic heat of reaction as efficiently as possible within the catalyst bed itself.

Operation of the reactor for pollutant abatement has been described as follows:[32,33] "After a sufficient portion of the packing has been heated to temperatures higher than the ignition temperature, the burner can be turned off. Thereafter, cold polluted air enters into the packing, where the hot bed heats the air so that catalytic oxidation takes place. The introduction of cold air leads to a progressive cooling of the inlet portion of the bed; and, as a result, to a continuous displacement of the temperature front, a so-termed migrating combustion zone. Without further action, the temperature front would move out of the reactor after a certain time, thereafter, the reaction would be extinguished. To prevent extinction, the direction of flow through the fixed bed is periodically reversed with the help of valves. As a result, the portion of packing that has cooled down is heated up again by the combustion zone moving in the opposite direction. Hence, the two end regions of the packing act as regenerative heat exchangers. After a considerable number of flow reversals, a periodically steady state is established in the fixed bed in which, in one-half period, the zone of reaction moves a distance upward, whereas, in the next half period, the zone moves the same distance downward."

The ability to capture the hot spot within the bed by flow reversal relies on the large difference in the characteristic time for convective mass (flow) and conductive energy transport. Flow switching can be easily accomplished, as this occurs on a time-scale that is much shorter than the characteristic time of transit of a creeping hot spot to traverse the length of the reactor.

Reverse-flow adiabatic reactor commercial processes

The reverse-flow reactor can be used to carry out the complete combustion of pollutants contained in air streams and to carry out reversible exothermic reactions. For the former application, the efficient exchange of

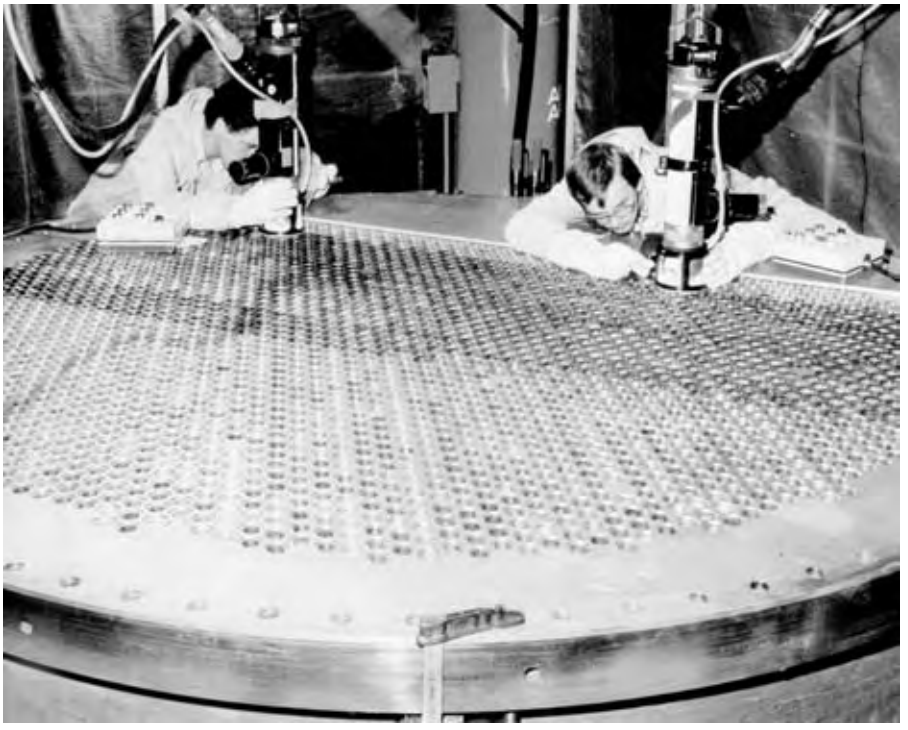

Fig. 16 Multitubular reactor tube sheet.

energy enables the complete combustion of pollutants in small concentrations in air streams with low feed temperature. For the latter application, the pseudosteady-state temperature profile that is established within the bed is close to the optimal profile for achieving high conversion in an equilibrium-limited situation. It is this application that has relevance for oxidation to produce useful chemical intermediates or final products.

Sulfur Dioxide to Sulfur Trioxide Process. In Fig. 13, representative temperature profiles within a bed of vanadium oxide particles during flow reversal for SO_2 oxidation to SO_3 are shown.[29] Profile 1 was measured during flow from left to right through the bed just before the flow reversal. Profiles 2–4 were measured after the flow reversal during flow from right to left. The latter three were measured at various time intervals to show how

Fig. 17 Multitubular reactor used for the air oxidation of *o*-xylene to phthalic anhydride.

they migrate down the bed after the flow reversal. The profiles reveal the very large temperature rise that can be sustained (approximately 400°C) compared with the adiabatic temperature rise (approximately 70–80°C) for the 1.7% SO_2 mixture in air.

Multitubular Fixed-Bed Reactors

Description

Owing to their thermodynamic behavior, almost all partial oxidation reactions require more precise temperature control than that provided by the staged adiabatic reactor. The selectivity of the desired product usually decreases with an increase in temperature beyond a certain practical limit. This behavior suggests that the activation energy of the desired reaction is less than the activation energies for the remaining nonselective reactions. In such cases, ineffective temperature control can lead to hot spots and a subsequent loss in the desired product selectivity. An illustration of the importance of thermal energy management in this type of reactor is provided in Fig. 14. Here, temperature profiles in a gas-phase catalytic fixed-bed reactor, as predicted from a detailed mathematical model for a single reaction, are compared using various feed temperatures.[24] Increasing the feed temperature by 1°C, i.e., from 343°C to 344°C, causes the maximum temperature to increase from 480°C to approximately 900°C. The implications of such sensitive behavior in terms of process operations, process control, and mechanical engineering are obvious.

A simplified schematic of a typical multitubular reactor design is shown in Fig. 15. The mechanical design generally parallels that used for multipass heat exchangers except that the scale is often significantly larger. It consists of a bank of parallel tubes whose nominal inside diameter typically varies from 25 to 40 mm. The tubes are usually laid out on a triangular pitch on a tube sheet where the pitch distance typically varies from 1.5 to 3 tube diameters. A typical tube sheet for a smaller multitubular reactor is shown in Fig. 16. The tube bundle, which is welded on both ends into the tube sheet, is contained inside in a shell through which a suitable heat transfer fluid is circulated. Typical heat transfer fluids include water, pressurized steam, molten salts, and commercially available oils. The multitubular arrangement provides sufficient heat transfer area and reduces the effective radial heat transfer distance by the use of inside tube diameter to particle aspect ratios that are in the order of 2–5. A commercial-scale reactor design used for the manufacture of phthalic anhydride is shown in Fig. 17. Multiple reactors of this type are often operated in parallel when a single large-scale reactor cannot meet the required plant process design rate.

Some of the key attributes of the multitubular fixed-bed reactor are provided in Table 1. The corresponding attributes of the fluidized-bed reactor, which is an alternative reactor type for carrying out oxidation reactions, are also included for comparison.

Multitubular fixed-bed reactor commercial processes

Multitubular reactors are mainly used in gas-phase partial oxidation processes, such as the air oxidation of light olefins, paraffins, and aromatics. Examples of chemistries where these reactors are used include the partial oxidation of methanol to formaldehyde, ethylene to ethylene oxide, ethylene and acetic acid to vinyl acetate, propylene to acrolein and acrylic acid, butane to maleic anhydride, isobutylene to methacrolein and methacrylic acid, and *o*-xylene to phthalic anhydride. An overview of the multitubular reactor process for the partial oxidation of *n*-butane to maleic anhydride is given here.

Table 1 Fixed-bed. vs. fluidized-bed reactors for selective hydrocarbon oxidation reactions

Parameter	Fixed-bed reactor	Fluidized-bed reactor
Hydrocarbon concentration	Below flammability limit	Flammable region possible
Oxygen concentration	Large excess	Near stoichiometric
Temperature control	Hot spot	Nearly isothermal
Catalyst effectiveness	Poor to average	Good
Catalyst attrition	Minimal	Possible problem
Catalyst charging	Complex	Straightforward
Catalyst cost	Least expensive	More expensive
Gas flow pattern	Approaches plug-flow	Flow-regime dependent
Solid flow pattern	Fixed	Flow-regime dependent
Design and scale-up	Well-established	System-dependent
Capital investment	Expensive	Less expensive

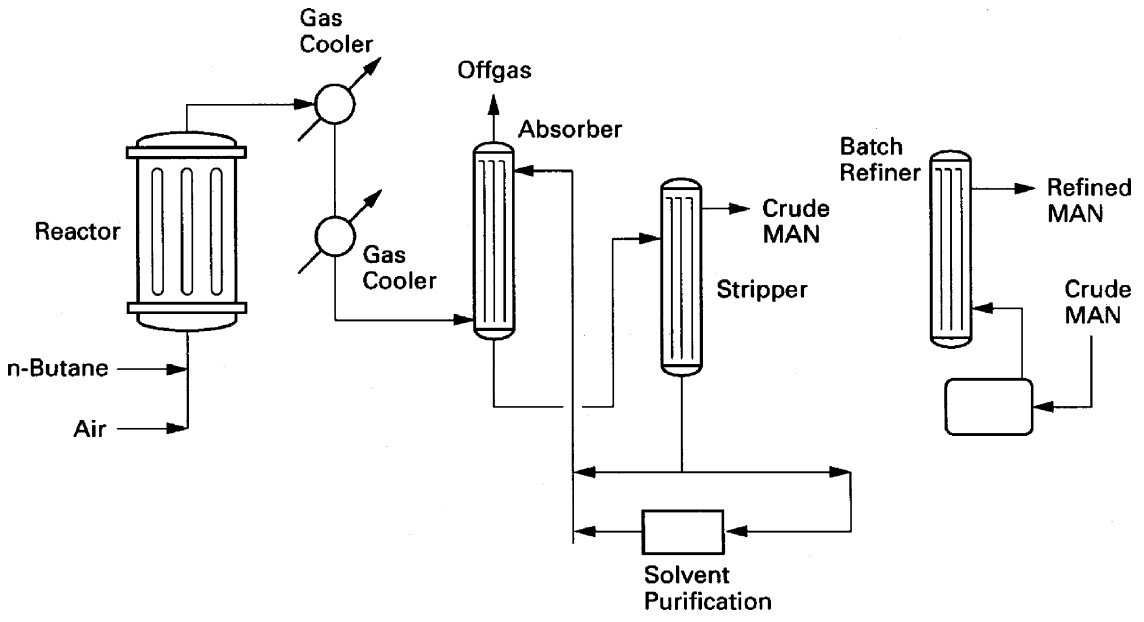

Fig. 18 Process flowsheet for *n*-butane oxidation to maleic anhydride using multitubular reactors. (From Refs.[35,36].)

Butane to Maleic Anhydride Process. Maleic anhydride is an unsaturated diacid that is used in the manufacture of several key products.[34] The chemistry, applications, and process technology of MAN have been described in several comprehensive reviews.[35,36] The greatest use of MAN is in the formation of unsaturated polyester resins. The polymeric resin is formed from the reaction between MAN, ethylene glycol, and a vinyl monomer. The production of MAN is carried out in most of the existing processes by a selective oxidation of *n*-butane over a vanadium–phosphorus oxide (VPO) catalyst. The main selective and nonselective reactions that occur are

$$C_4H_{10} + 3.5O_2 \rightarrow C_4H_2O_3 + 4H_2O + 1236\ \text{kJ} \quad (6)$$

$$C_4H_{10} + 6.5O_2 \rightarrow 4CO_2 + 5H_2O + 2656\ \text{kJ} \quad (7)$$

$$C_4H_{10} + 4.5O_2 \rightarrow 4CO + 5H_2O + 1521\ \text{kJ} \quad (8)$$

The ability to achieve a 60% to 75% yield of MAN at 80% to 90% butane conversion is remarkable given the complexity of the selective reaction, because it involves the abstraction of fourteen hydrogen atoms, the incorporation of three oxygen atoms, and ring closure. Moreover, the selective and nonselective reactions are quite exothermic.

A schematic of the Huntsman fixed-bed MAN process is shown in Fig. 18.[35,36] The process consists of a fixed-bed multitubular reactor, energy recovery units, a MAN absorber/stripper section, and a refinery section. As in other processes discussed in this section, thousands of tubes are used in the fixed-bed reactor to decrease undesirable radial temperature gradients.

Recent advances in fixed-bed-based MAN processes include the development of reactors that can operate in the flammable regime and of the total butane recycle processes that can give overall process yields between 65% and 75%. The ability to safely use butane feed compositions that are above the lower flammability limit of approximately 1.8% in air can translate into increased production rate of MAN, which has obvious advantages from a process economics perspective.

CONCLUSIONS

Tubular reactors have been reviewed from the perspective of various reactor types and selected process applications. The tubular reactor configuration is generally used to contact one or more fluid phases so that high reactant conversion and product selectivity can be achieved in a single pass or by several reactors operating in a series or parallel arrangement. The reactor is generally characterized by a geometry whose length-to-diameter aspect ratio is chosen so that the flow pattern of the fluid, in the case of single-phase operation, approaches ideal plug-flow. The counterpart to the tubular reactor is the continuous-flow stirred-tank reactor whose ideal flow pattern approaches perfect back mixing. Tubular reactors are also widely used for reactions involving multiple flowing phases in the presence of a stationary or moving catalyst, in which case the flow patterns of the individual phases

and the interaction of these phases with the catalyst must be considered as part of reactor engineering issues. Tubular reactors that are used to conduct gas–solid-catalyzed reactions or reactions involving gases and liquids over fixed beds of catalyst always involve complex engineering issues from the perspective of mechanical design, heat transfer, mass transfer, and fluid mechanics. For this reason, each application must be treated on a case-by-case basis, where the interactions between reaction kinetics, transport effects, hydrodynamics, mixing, and heat transfer are accounted for through the use of appropriate reaction engineering models. The engineering science associated with tubular reactor design is well developed for homogeneous single-phase systems, but the heterogeneous systems still have various challenges that are the subject of active research. Use of advanced modeling techniques, such as computational fluid dynamics, along with new flow visualization experimental tools, is generating new insights into both the local and macroscopic phenomena. Tubular reactor design is expected to be more reliable, as these new tools gain more validation.

Twin-Screw Extrusion

Paul Andersen
Coperion Corporation, Ramsey, New Jersey, U.S.A.

INTRODUCTION

The term ''Twin-screw Extrusion'' encompasses a wide range of material process applications. Likewise, these applications are not all processed on a single type or configuration of twin-screw extruder, but utilize a variety of twin-screw equipment design concepts. For example, a vinyl profile such as might be used for a window casement, or a wood fiber composite decking board, can be directly extruded from a premix formula using a conical counter-rotating twin-screw extruder.[1] Wood fiber composites are also compounded and extruded as deck and other profiles from parallel counter-rotating fully intermeshing twin-screws, as well as co-rotating intermeshing twin-screws with a single-screw discharge.[2,3] Many breakfast cereals are cooked and extruded from co-rotating units.[4] Additionally, thermoplastic polyurethane is polymerized and compounded, solvent is devolatilized from polymerization products, and water is removed from the washed recycled polymers on the co-rotating twin-screw.[5–7] Also, highly filled products such as detergents, ceramics, fertilizer, nanocomposites (both masterbatch and full recipe formulations), polymer magnets, and propellants (explosives) are compounded on the co-rotating machine.[8–11] The above examples are in addition to the more traditional mixing/compounding operations for producing filled and reinforced plastics, color and additive masterbatch, blends and alloys, thermoplastic vulcanizates (TPV), powder coating, toner, adhesives, sealants, and curable rubber.[12–19] The long list of processes already noted only scratches the surface of the possible applications for a twin-screw extruder. Unfortunately, there is a tendency to treat the various twin-screw geometries as one general category. This is very misleading. Each type of twin-screw extruder has a very distinct operating principle (mechanism) and set of process applications where it is successfully implemented. There are also many cross-over applications. This entry will review the various types of commercial co-rotating and counter-rotating twin-screw extruder systems and define the operating principles and processing characteristics of each type. Wherever possible, process examples will be included for illustration.

EXTRUSION BASICS

Before going into details of the different machine geometries and operating mechanisms, it is useful to look at the common features. Each contains a motor, coupling, gearbox, process section, and shaping device, such as a strand or profile die (Fig. 1). This die is either directly coupled to the end of the process section or an intermediate pressure generation unit such as a single-screw extruder. The process section is built up from modular components (both barrels and screw elements). The only notable exception is the counter rotating profile extruder (both parallel and conical) that normally has a single piece barrel and a solid screw. The process section for a typical compounding line can normally be broken down into unit operations that would include:

- Introduction of the feed material
- Solids conveying
- Melting (softening, phase transformation)
- Mixing (dispersive, distributive)
- Additive incorporation
- Degassing/devolatilization
- Discharge pressurization
- Discharge shaping.

TYPES OF TWIN-SCREW OPERATING MECHANISMS

There are several basic design characteristics that provide differentiation among twin-screw extruders. The two most obvious are co-rotating vs. counter-rotating, and intermeshing vs. partial and non-intermeshing. Parallel vs. conical shafts is also a variable, but there is really only one type of conical machine, that is, a counter-rotating, fully intermeshing design.

Fig. 2 shows the cross-section and profile of both the counter and co-rotating intermeshing geometry. The counter rotating design has a closed chamber in the intermesh. Therefore this system is crosswise and lengthwise closed (i.e., there is no path for material transfer from chamber to chamber either along the screw axis or from screw to screw). Consequently, material is force conveyed down the barrel in ''C'' shaped sections. This segregated forced transport translates into good conveying and pressure build up characteristics, but reduced longitudinal mixing (residence time distribution). The co-rotating system has an open intermesh area. Therefore, material is transferred from screw to screw, but each time with a down channel offset with respect to the starting point.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007999

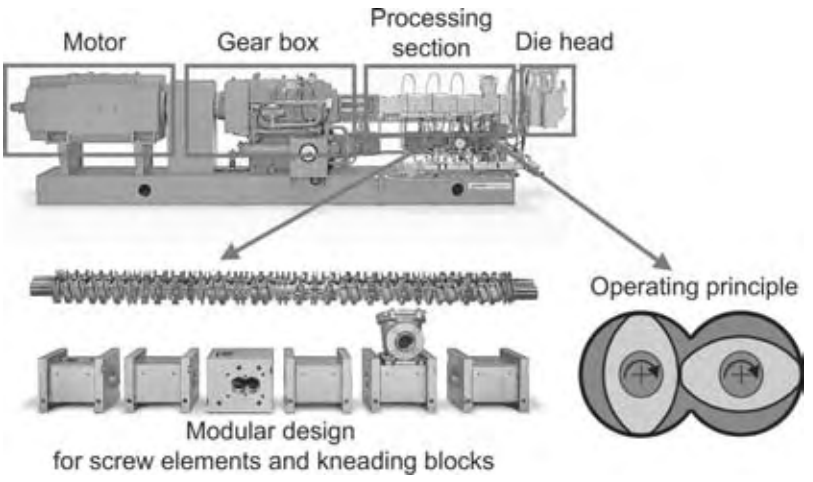

Fig. 1 Basic layout and main components of the twin-screw extruder with drive power available from 10 kw to 12 Mega-watts and rates from 5 kg/hr to 75 tons/hr. (Courtesy of Coperion Corporation.) *(View this art in color at www.dekker.com.)*

This means that there is a continuous path along the screw axis from inlet to discharge. However, there is no path for material to flow from channel to channel along a single- screw shaft for screw bushings, but there is one for kneading blocks and other special elements. Therefore, the co-rotating fully intermeshing geometry is lengthwise open, but depending on screw profile (screw elements vs. kneading blocks) it is either crosswise closed or open. Compared to the counter rotating geometry this flow mechanism has reduced conveying characteristics, reduced pressure build up capabilities, but good longitudinal mixing. Non-intermeshing counter-rotating systems are always open lengthwise and crosswise and therefore have good distributive mixing or homogenization characteristics, but an extremely poor pumping efficiency.

CO-ROTATING FULLY INTERMESHING SYSTEMS

Geometry

The main degrees of freedom in twin-screw extruder design are geometry (cross-section profile of screw pair), power (torque capacity) and speed (rpm). The essential geometry of any co-rotating twin-screw extruder is defined by two key parameters: 1) centerline distance [a] between the shafts, and 2) outer diameter to inner (root) diameter ratio [OD/ID], see Fig. 3. For a fixed centerline, the OD/ID ratio defines the free volume of the extruder.

The co-rotating twin-screw extruder is commercially available with both 2- and 3-lobe cross-section geometry

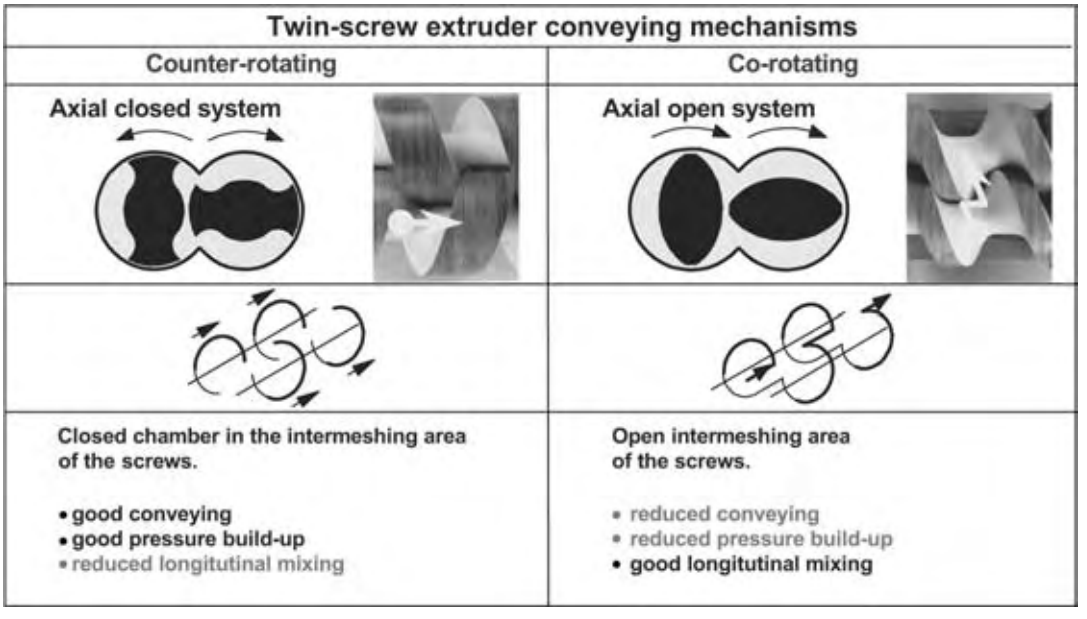

Fig. 2 Comparison of twin-screw conveying mechanisms. (Courtesy of Coperion Corporation.) *(View this art in color at www.dekker.com.)*

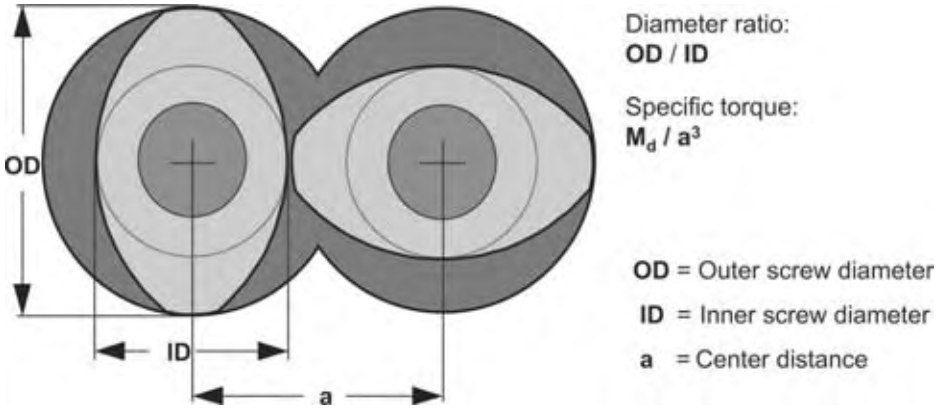

Fig. 3 Characteristic dimensions of an intermeshing twin-screw extruder. (Courtesy of Coperion Corporation.) *(View this art in color at www.dekker.com.)*

(Fig. 4). Geometry constraints limit the 3-lobe design to a more shallow channel depth (lower OD/ID ratio) than 2-lobe units with identical centerline distances. This means that the 3-lobe machine can have a greater shaft diameter for power transmission, impose higher average shear rates on material, but have substantially less free volume. In practice, because of the low free volume relative to the available power, the 3-lobe extruder is often volume, i.e., rate, limited for many mixing tasks.

Within the geometric constraints for self-wiping, the OD/ID ratio can be specified to impart a specific average shear rate, define a free volume, or determine allowable shaft diameter (power transmission). While a 2-lobe machine could be designed to have a low OD/ID ratio, as in the 3-lobe unit, this would not be very sensible. The purpose of creating a 2-lobe unit is to have a machine that would be less likely to be volume limited, but still have the power transmission

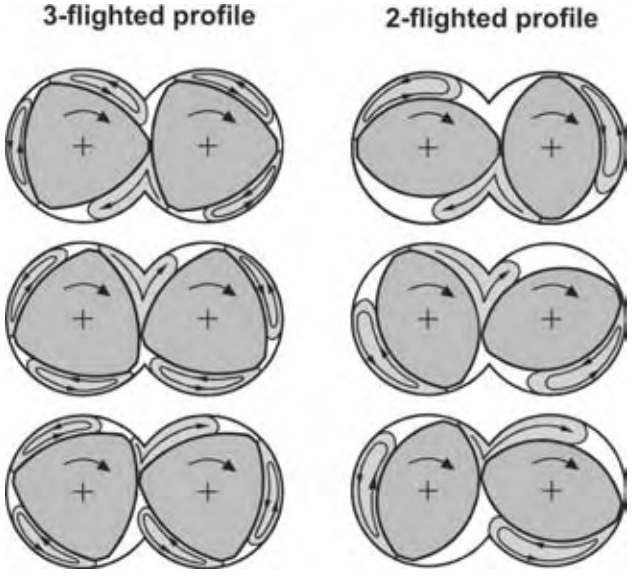

Fig. 4 Self-wiping in the two and three lobed co-rotating twin-screw extruders. (Courtesy of Coperion Corporation.) *(View this art in color at www.dekker.com.)*

capacity necessary to accomplish the desired mixing tasks. The greater the OD/ID ratio, the lower the average shear rate, the higher the unit free volume, and the thinner the shaft available for power transmission. Therefore, the appropriate balance required between power transmission and available free volume must be determined. Fig. 5 shows the progression of available power and volume for five co-rotating twin-screw extruders with the same centerline distance. The OD/ID ratio increases from 1.22 to 1.80 (greater volume) and the specific torque [power/volume ratio expressed as torque capacity/centerline distance cubed (M/a^3)] more than triples. (The allowable power transmission increases for the 1.55 OD/ID unit with thinner shafts as a result of a shaft/element geometry interface improvement. The energy is transferred through 24 splines as opposed to one or two keys). All five machines can be used for similar processing tasks, however, the screw configuration and operating conditions would be different, and the resulting rate typically would be lower for the machines with the smaller OD/ID ratio.

As the power transmission capacity of the extruder gearbox has increased, the ability to process at higher rpm has kept pace. While at the beginning of the 1990s typical processing speeds were between 300 and 600 rpm, today, these same materials are processed at up to 1200 rpm and greater.[20,21]

Elements

Material transport in intermeshing, co-rotating twin-screw extruders is generally dependent on drag flow. The screws pick up the material as they rotate and, where the two screws meet, a complete transfer of the material from one screw to the other takes place, see Fig, 4. The tip of one screw wipes the flanks and roots of the other screw, resulting in a self-wiping action. As the material is transferred from one screw to the other, the direction of material flow is changed and new material surfaces are created with each screw revolution.

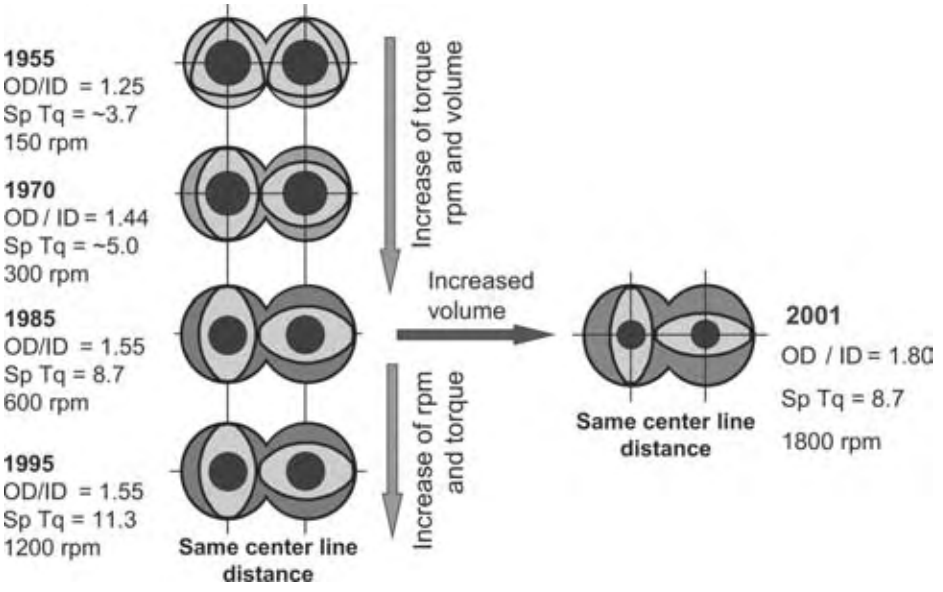

Fig. 5 Development of cross-section, torque and rpm. (Courtesy of Coperion Corporation.) *(View this art in color at www.dekker.com.)*

Screw Bushings

Standard screw bushings are constructed with pitches ranging from approximately 1/2D to 2.0D, where D is the machine diameter, see Fig. 6. High pitch elements might typically be used in feed or devolatilization areas of the extruder. Narrow pitch is used in areas where compaction of material and 100% fill is desired, such as before kneading blocks or seals, or between unit operations (i.e., feeding and vacuum devolatilization). Up to approximately 2.5D, increasing element pitch results in a decrease in residence time and degree of fill, a more narrow residence time distribution, increased drag flow capacity, but also increased sensitivity to pressure flow. That is, as the pitch of an element is increased, drag flow conveys material in the down-channel direction at a faster rate. However, if there is a restrictive force placed in the flow path, the higher pitch element is less effective in building up the pressure necessary to push material past the restriction.

Reverse pitch elements are used to generate back-pressure and therefore create sections of 100% fill that, for example, can be used to separate unit operations, or totally fill a mixing section.

Kneading Blocks and Special Elements

The basic building blocks for mixing in the co-rotating, intermeshing type twin-screw extruder are kneading blocks and special mixing bushings. Special bushings include slotted elements, toothed mixing elements, and blister rings, or the self-wiping equivalent element. Standard conveying type screw bushings are also used in certain circumstances.

Just as screw bushings are characterized by pitch (i.e., flight angle), kneading blocks can be characterized

Fig. 6 Examples of screw bushings (top) and kneading blocks (bottom). (Courtesy of Coperion Corporation.) *(View this art in color at www.dekker.com.)*

by individual disc length (width) and stagger angle between successive discs, see Fig. 7. Kneading blocks introduce both a distributive and dispersive mixing component into the system. The relative intensity of each component depends upon disc length as well as stagger angle. For constant stagger angle, increasing the disc width leads to an increase in the dispersive mixing component per unit mixing length, but at the expense of distributing mixing (stream splitting). In other words, as a disc gets wider, it can trap particles more easily in the high shear region, but there are fewer discs per unit length to distribute them. For a constant disc width, the greater the stagger angle the more back mixing and the higher the residence time distribution. Finally, just as there are reverse pitch elements, there are reverse stagger kneading blocks. As with reverse pitch elements, reverse kneading blocks are used to create backpressure. They are however, less restrictive than the reverse pitch elements.

Toothed/gear type elements are the most commonly used of the special mixing elements. The number of teeth around the circumference, as well as the tooth angle, defines them. The former contributes to stream splitting for generation of interfacial surface and the latter, conveying capacity. The main function of these elements is to provide the maximum amount of distributive mixing (little if any dispersive mixing) with minimal energy input.

COUNTER-ROTATING FULLY INTERMESHING

There are three functional variants of the counter-rotating intermeshing extruder, low speed, slow speed, and medium speed. The ''low'' rpm profile extruder is closest in design concept to the screw pump from which all the counter-rotating intermeshing extruders originate. The function of this extruder is to take a premixed powder formulation, melt it with minimal energy introduction, and build pressure to force the melt through some sort of shaping device, such as a profile die. These machines are generally about 25 l/d and have a single feed location. There are a number of different screw concepts. In one variant, the screw consists of thin flight elements at the feed throat for feed intake and initial transport down-channel.[22] The flight width of these elements takes up only a small percentage of the channel width on the opposite screw. The screw then transitions to wide flight elements that take up the entire channel width of the opposite screw. This effectively cuts off any transfer of material from one screw channel to the other, both in the cross-channel and down-channel direction. It also reduces the free volume in the screw channel. This causes the material to be compressed. Thus, as the screw rotates, the material particles push and rub against each other. This interaction causes heat generation, deformation, and eventual melt formation. However, due to the constraints on melt flow, mixing, especially dispersive mixing, is limited. A second screw variant[22] would be to have only fully conjugated screws in the extruder. In this configuration, the pitch along the length of the machine is decreased to implement compression and therefore induce material to melt. Unless the channels are full, the material is not compressed as it is conveyed downstream. Therefore, these machines are typically flood fed. Starve feeding causes the point at which there is sufficient compression to melt the material to move further downstream. Because of the fully conjugated screws, another limitation is screw speed and, therefore, rate for a given machine diameter. Typical speeds for one of these units is 25–50 rpm. This is limited because of the mechanical separation forces between the screw resulting from calendaring effect when material passes between the screw. As rpm is increased, the separation forces also rise causing the screw shafts to rub against the barrel wall.

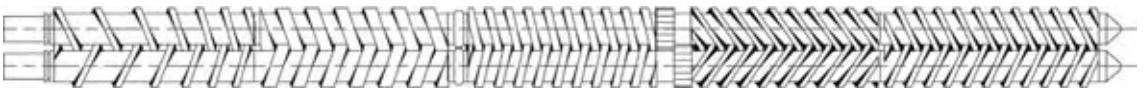

Fig. 8 Traditional compounding counter-rotating screw geometry. (Courtesy of Leistritz Corporation.)

There are exceptions to the above design concept. Most notable is the ''Woodtruder'' that has an l/d up to 40 for some designs. The wood fiber is starve fed into barrel one and molten polymer is introduced downstream by a side arm extruder.[2]

The second variant is a compounding extruder.[23] This unit uses the basic design described above but opens up the intermesh clearances a little and adds mixing elements at various locations along the length of the machine, see Fig. 8. This allows a significant fraction of the material to flow through the high shear ''calendar'' gap that exists between the screws, but still maintains closed pumping chambers. There are several types of conveying elements (all based on mono lobe geometry) and two basic mixing element designs. The conveying elements consist of nonconjugated narrow flight units, fully conjugated units of various pitch and flight width, and transition units. The mixing elements are: 1) intermeshing shearing or blister rings for dispersive mixing; and 2) blister rings with slots cut in the axial direction for more distributive mixing. As a compounding unit, this machine is composed of modular components and can be constructed with downstream feed locations and vent zones. It can also have an l/d up to 60, although a more typical value is between 30 and 40. A significant number of these machines have been sold into the color masterbatch market where high shear is typically required for good pigment dispersion. Since they also have good pressure generation capabilities, they can also be used in profile applications where additional melt mixing is required. The typical maximum speed for these machines is 150 or so rpm.

Recently, a more open geometry that maintains good dispersive mixing characteristics, but permits material to pass between the elements at reduced separation force, has been developed.[23] This allows the machine to be run at much higher speeds of up to 600 rpm. The new mixing element geometry consists of long ''lobal'' elements that mesh together like gear teeth and squeeze material between them, see Fig. 9. This action provides dispersive mixing. The elements can have almost any number of lobes. The more lobes, the greater the number of squeezing actions per revolution. A typical element would have six lobes. Lobal elements can also have slots for distributive mixing cut across the lobes. Additionally, there are also distributive mixing elements composed of circumferential rows of axially offset teeth that wipe past each other in the intermesh zone.

CONICAL COUNTER-ROTATING FULLY INTERMESHING

Conical twins are mostly used in profile extrusion applications. The operating mechanism of these extruders is based on the same positive displacement screw pump conveying principle as is used in low rpm parallel counter-rotating fully intermeshing extruders. As a result, they display a low energy melting mechanism and good pressure generation capability while maintaining

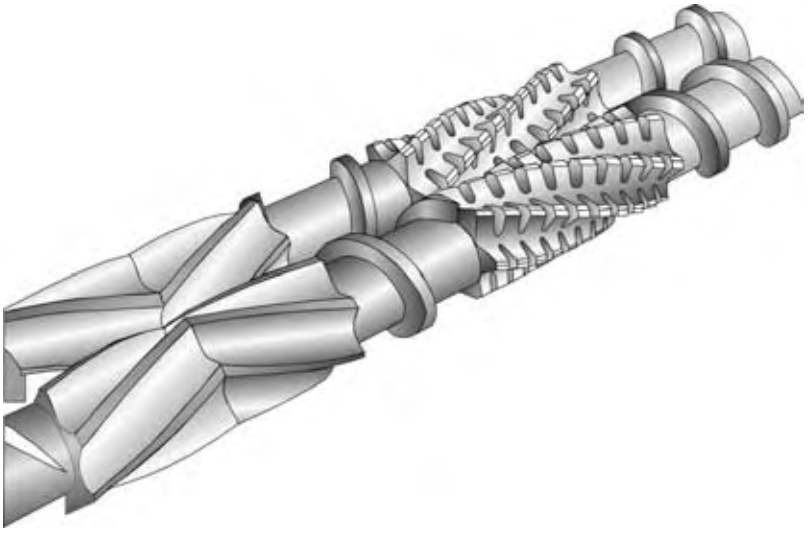

Fig. 9 ''Lobal'' mixing elements. (Courtesy of Leistritz Corporation.)

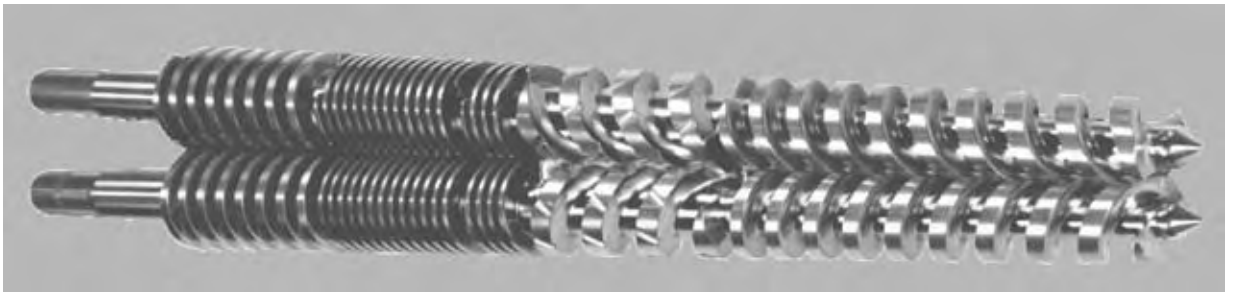

Fig. 10 Screw profile for Conical Twin-screw. (Courtesy of Cincinnati Milacron.) *(View this art in color at www.dekker.com.)*

uniform material flow. This is ideal for heat and shear sensitive materials such as PVC. The unit melts, blends, degasses, and builds up pressure to force the PVC through the die with a minimal temperature rise.

The machine typically has an l/d in the low 20s. The screws are tapered from the inlet to the discharge. A typical ratio of inlet to outlet diameter is two.[24] The screw is a one-piece construction. It is generally divided into five zones: feed, initial compression, compression melting, venting, and metering discharge, see Fig. 10. The feedstock is most often a powder preblend of all ingredients. It is generally flood fed into the large diameter feed opening, then conveyed downstream. To improve the rate for more difficult feedstocks, a crammer can be utilized.[1] As the material is transported down the machine length, the reduction in screw pitch and barrel diameter compress the powder and put it under increasing pressure. Compression, material circulation in the ''C'' shaped chamber that generates frictional heat, and heat transfer from both the barrel and the cored screw introduces enough energy to melt the material. Even as the material melts, the circulation within the chamber is not sufficient to impart any significant mixing of the material. This is why the feedstock is generally premixed powder that only needs to be fused together. However, in some configurations a compression mixing section is used to promote melting and dispersive mixing.[1] Once the material is melted, it enters a vent zone for removal of trapped air, moisture, and other volatiles. As with all other intermeshing extruders, in the vent zone the screw pitch is increased to achieve a partially filled section. Finally, the material is metered and discharged through a profile die.

COUNTER-ROTATING NON-INTERMESHING TWIN-SCREW

In the most simplistic view, the counter-rotating non-intermeshing twin-screw extruder could be viewed as two tangential single-screws sitting side by side in a barrel with an open apex area between them, see Fig. 10. Unlike intermeshing twin-screws, the non-intermeshing extruder can use variation in channel depth as an operating variable, as in a single-screw extruder. The feed and vent sections have deeper screw channels and for pressure generation the channel depth is reduced. Also, in some designs, one shaft is extended to serve as a discharge screw.[25] Unlike the single-screw, the non-intermeshing counter-rotating twin-screw has very good distributive mixing characteristics. This is due to material reorientation that occurs in the apex as the material flow from each screw converges and is transferred from one screw to the other.[26]

Just as in other twin-screw extruders, mixing is accomplished or enhanced by incorporation of special screw elements, see Fig. 11. Dispersive mixing is introduced by placing blister rings in the screw configuration. These elements are typically 1.5D long. Blister rings have two effects that must be balanced. First, the greater the diameter of the ring, the more shear energy is introduced to help disperse particles or agglomerates. However, the larger diameter causes a greater backpressure that must be overcome by the conveying action of the upstream screw configuration. For increased distributive mixing, a reverse pitch element is used. This restricts material flow, increases residence time, and residence time distribution, which in turn increases distributive mixing.

Screws can be placed in the barrel so that the flight tips match. That is, the two flight tips are across from each other in the apex. The other configuration is to have them staggered, typically 180°. When the tips are matched, then the conveying forces of the two screws are working together to drag the material forward, thus minimizing the amount of material that slips backward. If the screws are staggered, then the material has an easier path to avoid being conveyed or dragged forward.

Since the screws do not intermesh, the non-intermeshing extruder is not subjected to some of the same mechanical tolerance constraints as the other twin-screw extruders. This enables the non-intermeshing machine to be built to an almost unlimited l/d ratio. A 72 to 1 l/d unit was used for a number of devolitalization experiments.[27] The enhanced length capability provides a mechanism for the increased internal volume.

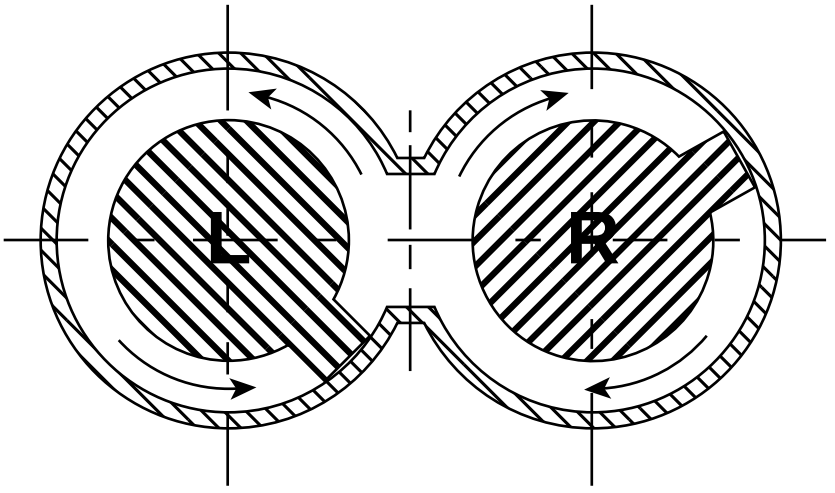

Fig. 11 Crosssection of counter-rotating non-intermeshing extruder. (Courtesy of the Polymer Processing Institute.)

Combine this with the fact that, for the same diameter, a non-intermeshing geometry has approximately 25% greater internal free volume per unit length than an intermeshing unit. This means that material in the non-intermeshing machine can have a significant residence time. This is beneficial for reactive extrusion, dewatering, and devolitalization processes. However, the lack of self-wiping of one screw against the other creates the potential for stagnation zones that can allow material to degrade and potentially slough off to give black specks. Running the extruder screws at a high fill ratio and with proper screw configuration will minimize this potential problem.

COMPARISON BETWEEN CO-ROTATING AND COUNTER-ROTATING OPERATION

The obvious difference between the co- and counter-rotating extruder is that in the co-rotating geometry both screws rotate in the same direction, either clockwise or counter clockwise. In the counter-rotating geometry, they rotate in opposite directions. In addition to geometry, this simple difference impacts the way the two screws interact.

Apex and Intermesh Region

For the counter-rotating systems, the screws in the intermesh area roll-off one another. They both have the same angular velocity at the horizontal axis where the two shafts meet, but a different circumferential speed. The screw flight tip has a larger diameter than the screw root into which it nests. Therefore, the flight tip rolls passed the screw root in a calendering type action. Co-rotating screws, however, do not roll-off one another. In contrast to the rolling motion of the counter-rotating screws, a scraping movement takes place, where one crest edge wipes a screw flank tangentially with equally high relative velocity.

The open area in the apex region between the two screws is significantly different. In the fully intermeshing counter-rotating system, the two screws effectively interlock in the intermesh. This means that no material transfer from one screw to the other takes place and, therefore, the distributive mixing efficiency is greatly reduced. Co-rotating screws form V-shaped apex areas, with 4–5 times more volume. Material can therefore transfer from one screw to the other. This results in a renewal of material layers and surfaces and a better degree of distributive mixing.

Self-Wiping Fully Intermeshing Screws

Self-wiping screws are desirable, and frequently necessary, to prevent material from adhering to the screw root and subsequently degrading. Both counter-rotating and co-rotating fully intermeshing screws are self-wiping. However, self-wiping is achieved in different ways in each system.

In counter-rotating screws, the roll-off process between the screw crest and screw root and between the screw flanks creates a calendar effect. The shear velocity available to wipe the boundary layers is proportionately lower due to the small relative velocity between the surfaces.

In co-rotating screws, one crest edge wipes the flanks of the other screw with a tangentially oriented, constant relative velocity. Because of the higher relative velocity in co-rotating screws, there is a sufficiently high shear velocity to wipe the boundary layers. Consequently, a more efficient and uniform self-wiping action is achieved with the co-rotating screws.

Allowable Operational Speeds and Their Effect on Wear

In counter-rotating screws, the rolling motion of the screws and the resultant calendar effect produces

pressure between the surfaces. This pressure tries to push the shafts apart. The parting forces on the two shafts can cause considerable wear. Since the wear of the screws increased proportionally to the relative velocity of the shafts, it becomes obvious that the intermeshing, self-wiping, counter-rotating machines should operate at relatively low rpm.[23] However, the newer ''lobal'' geometry with greater gaps between the screws, gives up some of the pumping characteristics of the traditional design but can turn at up to 600 rpm.

In co-rotating screws, there is no calendaring effect between the crest and the flank of the screw. The screws are suspended in the plastic melt and, since there is no tendency to push them apart, there is considerably less wear. Therefore, co-rotating machines can be operated at much higher screw speeds with greater throughputs. For example, a 58 mm co-rotating, self-wiping, twin-screw extruder running at 1200 rpm can process 2000 plus lbs/hr of glass filled nylon.[20]

UNIT OPERATIONS—COMPOUNDING

The primary application of twin-screw extruders is profile extrusion and compounding. As indicated, profile extrusion is normally limited to melting of a preblended feedstock. Compounding is significantly more complicated and involves additional unit operations. Additionally, co-rotating machines are the primary geometry used in compounding applications.[23] Therefore, most of the comments in the following sections are related to this geometry.

Feeding

Twin-screw extruders (with the exception of most counter-rotating profile extruders) are designed to be starve fed. Therefore, throughput is independent of screw speed. This permits the processor to control residence time, degree of fill, and specific energy input (kw/kg).

Feeding locations are not limited to the first barrel section. Depending on the feedstock or recipe, feed streams, either solid or liquid, may be introduced at a number of locations along the process section. The only general exception is the conical and parallel counter-rotating twin-screw for profile extrusion. As mentioned previously, this extruder geometry does not lend itself to good mixing. Therefore, all ingredients are generally preblended and introduced at a single feed location.

Upstream Feeding

In compounding operations, the feedstock introduced at the first barrel section is usually a polymeric solid. The form is typically pellets, flake, or powder. Most pellets and flake are easy to feed since they have a high bulk density, their individual dimensions are sufficiently small with respect to extruder channel depth, and they do not lubricate the screw and thus impede the drag flow mechanism. Standard profile screw elements with a pitch of 1–2D are appropriate.

In situations where the particle size is large with respect to the channel depth ($>1/2\,h$), the material has a lower bulk density, or absolute maximum feed capacity is needed, special elements with increased volume are useful. The self-wiping profile of the pushing flight (and sometimes the trailing flight) has been transformed into a square channel profile. This modification accomplishes two functions. First, it directs more force acting on the material to be in the down-channel direction. Second, it creates up to 40% additional free volume in the element.

Powders that tend to fluidize, especially those such as silica which have a very low initial bulk density, are significantly more difficult to feed than pellets or flakes. The first step to successful feeding depends upon eliminating (or at least minimizing) fluidization, and controlling the separation of already entrained air, prior to material entering the extruder. In general, the vertical drop should be as short as possible. Also, direct the feed to the down-turning section of the screw. This is the apex region for the counter-rotating machine and the barrel wall for the co-rotating extruder. Ideally the screw configuration should be designed to allow air to travel down channel for removal through a vent section rather than be trapped and forced to flow countercurrent and back out the feed throat. However, in order to be effective, a plastification zone typically must be backed up by a restrictive element. This element then blocks the air from traveling downstream. In this case, special elements such as increased volume (undercut) or single flight (SF) elements play an important role in feed introduction. The choice of either increased volume or SF elements depends upon the amount and degree of air separation required. For a relatively low amount of air, the undercut element again provides a greater free volume and a more open path for air to flow backwards. However, as more air is forced back to the feed throat, the material fluidizes and the undercut elements lose their effectiveness. Under these circumstances the SF should be considered. Unlike the undercut element, which has greater free volume, the SF has approximately 15% lower free volume per unit length than a standard element. The SF elements do not allow air to flow easily in a countercurrent direction and, therefore, force it to flow past the restriction in the plastification section. These elements function in this manner as a result of the severe flow restrictions through the apex caused by the wide crest. These crests create a positive

displacement flow greater than in any other co-rotating twin-screw element.

Downstream Feeding

In many compounding operations it is necessary to split the feed streams. This may be required in order to: 1) achieve disperse phase size of an impact modifier; 2) retain aspect ratio of reinforcing fiber filler; or 3) obtain high level of loading for either low bulk density filler or incompatible low viscosity additives.

The most efficient way to add solids in a downstream location is to use a twin-screw side feeder. The twin-screw side feeder is normally a co-rotating device with high OD/ID ratio ($\sim$1.8). It has several advantages over single-screw side or top feeders. First, the twin-screw has better solids conveying characteristics, since a twin-screw device does not totally rely on drag flow. The twin-screw also has a wider longitudinal as well as a larger total cross-sectional discharge opening than a single-screw side feeder, and therefore provides lower pressure and more uniform feed introduction. Typically there is a vent above the side feed opening in the barrel. This permits entrained air to escape. For very low bulk density material containing significant air, the vent opening is moved one barrel upstream to avoid material particles getting entrained in the air as it exits the extruder. By having the air travel upstream before discharge, requires it to travel a path around the screw channel. This disrupts the air flow and causes the solid to disengage.

Liquid additives are mostly added downstream of the plastification section because they tend to lubricate the pellets or cause powders to agglomerate in the feed throat. If a significant amount of liquid is to be incorporated, it can be added at several locations. The most effective method for low viscosity liquid incorporation is to inject into a fully filled distributive mixing section. This requires a pressure injection valve and positive displacement pump. For small amounts of compatible liquid, non-pressurized injection into a low degree of fill area of the screw configuration may also be acceptable.

Plastification Mechanisms

Plastification of polymeric material requires energy to be transferred from an outside source into the material. In the twin-screw extruder, this energy transfer occurs through both mechanical and thermal mechanisms. However, as the extruder gets larger, the surface to volume ratio decreases significantly. Therefore, mechanical energy transfer is the dominant mechanism for plastification.

Thermal Heat Transfer

Normally, thermal energy is introduced through electric heaters surrounding the barrel or heat transfer medium that is pumped through barrel bores. As mentioned previously, smaller extruders can introduce a greater percentage of energy through heat transfer. Conversely, they can also loose a higher percentage of heat through heat transfer. If too much heat is lost in this manner, then on scale up to a production unit, the same percentage of heat cannot be removed. This will result in a higher discharge temperature. It is therefore very important that laboratory or development extruders run as close to adiabatic conditions as possible.

Mechanical Heat Transfer

In most cases, the majority of energy required for plastification comes from the mechanical input of the screw configuration. In counter-rotating intermeshing systems, material is compressed and deformed by reduction of screw pitch. In co-rotating systems, kneading blocks are the primary tool used to accomplish this task. The amount of mechanical energy introduced depends upon not only the number of kneading blocks, but also the configuration within the plastification zone, the screw rpm, and throughput rate. Specific mechanical energy (Sme), the energy introduced per pound or kilo of product, increases with rpm, especially when the plastification section is backed-up with a restrictive screw element. A second restrictive element further increases Sme.

Mixing Mechanisms

Mixing requirements for polymer compounding can be divided into two basic disciplines—dispersive and distributive. Dispersive mixing breaks down a particle into smaller units, while distributive mixing homogenizes the spatial relationship of the particles (whether dispersed or not).

The basic building blocks for mixing in the co-rotating twin-screw are kneading blocks and special mixing bushings. These special elements include toothed mixing units and blister rings, both standard geometry and self-wiping.

It is not surprising that the mixing element selection for distributive and dispersive blending processes is different. The distributive mixing profile uses narrow kneading blocks to maximize the number of flow divisions per machine length.

In dispersive mixing, wide disc kneading blocks are used to increase shear stress applied to the material. These elements are typically backed up with a restrictive

kneading block or screw bushing to increase the degree of fill as well as residence time. The number of restrictive elements that can be used is limited due to the resulting temperature buildup and potential material degradation. Therefore, in order to transmit increased stress to the material, a number of shorter mixing sections (1–2D long) are often more efficient than one long mixing section as this permits elastic materials to relax in the conveying sections between the mixing areas.

For very low viscosity products, introduce sufficient energy for dispersive or distributive mixing by adjusting the feed sequence, such that only a small portion of the solvent or dilution oil is added in the upstream part of the twin-screw extruder and therefore high mechanical stress transfer can be achieved. The remainder of the diluent is introduced in the latter sections of the machine.

Devolitalization/Degassing

In compounding lines, devolatilization typically involves removal of entrained air, moisture contained in the incoming feedstock, or byproducts from any reaction between recipe components. The amounts are generally less than 1% or 2% and typically less than 1%. Therefore, the staged vacuum set-ups and stripping techniques used in devolatilization processes where 10% to 60% volatile must be removed, are not necessary. However, even in compounding, devolatilization is a critical step, because while it is necessary to remove these volatile, it serves as a location for the potential introduction of contamination. The screw configuration in the vent area is typically comprised of screw bushing with a pitch of between 1 and 2D. This design permits sufficient residence time at a lower degree of fill to remove volatiles while maintaining the polymer within the bounds of the screw flight.

Discharge

Material is discharged from most twin-screw compounding operations as pellets or specialized forms, such as sheets, tubes, ropes, or other more complicated profiles. In order to push material through these dies, the machine must generate the appropriate pressure. This can range from 200 psi or less for strand dies, and up to 5000 or so psi for sheet and other profile dies. When the discharge pressure exceeds 2000 psi, or precise product gauge control is critical, a single-screw extruder or melt gear pump is typically used to generate the pressure in the co-rotating twin-screw. In large-scale polyolefin pelletizing operations, rates can be dramatically increased by integrating a gear pump into the system.[28] Also, fiber spinning and sheet extrusion operations typically use a gear pump at the end of the machine. For fully intermeshing counter-rotating machines, no device for discharge assistance is required.

CONCLUSIONS

There is a wide range of process applications for twin-screw extrusion. The two most prolific are profile extrusion and compounding. The former utilizes traditional counter-rotating geometry with either parallel or conical screws. The majority of compounding applications are run on co-rotating fully intermeshing extruders. The other twin-screw machine types, while not as widely used, each have specific areas where they are the preferred geometry. For a more detailed analysis of the operating mechanisms of the various geometries please see Refs.[29–33].

Use of Lipases to Isolate Polyunsaturated and Oxygenated Fatty Acids and Form Value-Added Ester Products

Douglas G. Hayes
Department Biosystems Engineering and Environmental Science, University of Tennessee, Knoxville, Tennessee, U.S.A.

INTRODUCTION

Polyunsaturated and oxygenated fatty acids, obtained from triacylglycerols (TAG) of several different plant and animal species, are valuable materials feedstock for value-added products in a variety of industries: food, pharmaceutical, cosmetics, and paints and coatings. The acyl species, their chemical structure, and their most abundant sources are summarized in Table 1. In contrast to inexpensive C_{16} and C_{18} saturated and Δ9-unsaturated acyl groups, such as palmitic (16:0), stearic (18:0), oleic (18:1-9c), linoleic (18:2-9c, 12c), and α-linolenic acid (ALA; 18:3-9c, 12c,15c), recovered from the oil of soybean and other common sources, and C_4–C_{16} saturates from palm oil and milk fat, polyunsaturated and oxygenated acids are derived from less common sources, and particularly for polyunsaturated fatty acid (PUFA), are typically present at only 20–40% purity.

Although common C_4–C_{18} acyl groups are readily isolated and modified by chemical means, PUFA and oxygenated fatty acids are susceptible to degradation at their double bonds and oxygenated groups, respectively. Biocatalytic means of isolation and modification provide mild operating conditions (low temperature and pressure, near-neutral pH, and the absence of toxic materials such as catalysts and harmful solvents), which will prevent degradation and promote an environmentally-friendly workplace.[1,2] The positional, substrate, and regioselectivity of lipases will lead to a narrower product distribution compared to chemical methods. The higher selling costs of PUFA and oxygenated fatty acid-derived products will help offset the high materials costs of enzymes, in contrast to common C_{16} and C_{18} acyl groups and their esters. This entry will briefly review the applications of PUFA and oxygenated fatty acids and the biocatalytic properties of lipases in a broad sense, discuss the lipase-mediated isolation of PUFA and oxygenated free fatty acids (FFA), and review lipase-catalyzed synthesis of PUFA and hydroxy FFA-enriched ester products and their applications.

APPLICATIONS OF POLYUNSATURATED AND OXYGENATED FATTY ACIDS

Δ4–Δ6 PUFA such as docosahexaenoic (DHA), eicosapentaenoic (EPA), arichidonic (AA), and γ-linolenic (GLA) and their derivatives are gaining popularity as food additives, or ''nutraceuticals,'' due to the many medical and nutritional benefits they present.[3] (DHA, EPA, and ALA are frequently grouped together in application-oriented discussions as ''n-3'' fatty acids, since each contains a double bond located three positions away from the terminal carbon atom on the acyl chain and provide similar medical benefits.) For instance, a literature search on patents involving DHA and AA from the year 1999 to the present resulted in 1014 and 878 hits, respectively. Of great benefit to world population suffering from an epidemic of obesity, a diet rich in PUFA is known to decrease blood TAG levels, blood pressure, and low density lipoprotein (or ''bad'') cholesterol. They also have many applications relating to brain and nervous system development in infants, treatment of arthritis and osteoporosis, and possess anti-inflammatory properties. In addition to the applications listed above, AA dietary supplements have been reported to increase muscle mass and reduce intravenous hemorrhaging in premature infants. AA, DHA, EPA, GLA, and ALA possess *cis* double bonds in positions whereby they can serve as oxidation substrates for the enzyme lipoxygenase to produce hydroperoxides, which are valuable precursors of prostaglandins, leukotrienes, and flavor ingredients: ketones, alcohols, and aldehydes, and are chiral synthons for combinatorial libraries employed in drug discovery. Although not technically a PUFA, petroselinic acid (18:1-6c) is listed in this category because it possesses a double bond positioned at C_6, and shares many of the same nutritional and medical applications as DHA and EPA. Petroselinic acid is employed as a cosmetic ingredient for hair growth and skin rehydration products. Conjugated linoleic acids, CLAs, lipids that occur naturally in milk fat and beef tallow are becoming increasingly popular materials with applications similar to those

Table 1 Polyunsaturated and oxygenated free fatty acyl species

FFA product	Chemical structure	Sources
Arachidonic (AA)	20:4-5c, 8c, 11c, 14c	Single-cell oils (25%)
Crepenynic	18:1-9c, 12-yne	*Crepis alpine* oil
Docosahexaenoic (DHA)	22:6-4c, 7c, 10c, 13c, 16c, 19c	Fish oils; single-cell oils (5–20%)
Eicosapenaenoic (EPA)	20:5-5c, 8c, 11c, 14c, 17c	Fish oils; single-cell oils (5–20%)
γ-Linolenic (GLA)	18:3-6c, 9c, 12c	Blackcurrant (*Ribes nigrum*, 15–20%) borage (*Borago officinalis*, 20–25%), or evening primrose (*Oenothera biennis*, 8–14%) oil
Petroselinic	18:1-6c	Coriander (*Coriandrum sativum*) oil (15.3%)
Conjugated linoleic acids (CLAs)	18:2-9c, 11t; 18:2-10t, 12c	Milk fat; beef tallow; modification of ricinoleic acid; free radical isomerization of α-linolenic acid (equimolar mixture of two CLA isomers)
	20:1-5c, 22:2-5c,13c	Meadowfoam (*limnanthes alba*) oil (83.5%)
	20:3-5c, 11c, 14c, 20:4-5c, 11c, 14c, 17c	*Biota orientalis* oil (15.6%)
Dimorphecolic	S-18:2-10t, 12t,OH-9	*Dimorphotheca pluvialis* oil (61.8%)
Lesquerolic and auricolic	R-22:1-11c, OH-14, R-22:2-11c, 17c OH-14	*Lesquerella fendleri* oil (57%)
Ricinoleic	R-18:1-9c, OH-14	Castor (*Ricinus comminus*) oil (90%)
Vernolic	18:1-9c,-epoxy-12,13c	*Vernonia galamensis* (77–81%) or *Euphorbia lagascae* (60-65%) oil

listed above for DHA, with additional employment in the treatment of diabetes.[4] An equimolar mixture of the CLAs 18:2-9c, 11t and 18:2-10t, 12c are synthesized from free radical isomerization of ALA.[4] Long-chain PUFA from meadowfoam and *Biota orientalis* oils (Table 1) have applications as oleochemicals, surfactants, and cosmetics; *B. orientalis* PUFA may have activity in lipid metabolism. Crepenynic acid has received attention as a chemical feedstock, including for use in paints and coatings, due to its unique carbon–carbon triple bond.

The second category, hydroxy- and epoxy-containing acyl groups (and their esters), have numerous applications as chemical feedstocks in lubricants, paints and coatings, food and cosmetics emulsifiers, nylon synthesis, laxatives, disinfectants, etc.[5,6] The utility of ricinoleic acid and its derivatives, for instance, the most commonly recognized member of this category, has existed for at least a century, demonstrated by US patents issued nearly 100 years ago, and 577 patents issued between the years 1990 and 2004.

LIPASES

Lipases play the specific role of forming and hydrolyzing ester bonds involving long-chain carboxylic, or fatty, acids (Fig. 1).[7] Lipase-catalyzed hydrolysis, or ''lipolysis,'' typically occurs at liquid–liquid or liquid–solid interfaces, while esterification and acyl exchange (reactions 2 and 3–5 of Fig. 1, respectively) are catalyzed by solid-phase lipase dispersed in low-water, nonaqueous, media.[8] Lipases possess regio-, stereo-, and substrate selectivity to control the product distribution.[9] For instance, many lipases are strongly regioselective toward primary hydroxyl groups, allowing them to utilize the 1- and 3- position of glycerol as substrate but not the 2-position. Lipases which fit this description are categorized as ''1,3-regioselective'' while those that do not are ''random.'' The strong stereoselectivity of lipases has made them common tools in the separation of racemic acid or alcohol mixtures in the pharmaceutical industry. The fatty acyl substrate selectivity of lipases is based on chain length and the position, type (*cis* or *trans*), and number of double bonds. For instance, lipases discriminate against substrates with double bonds near the carbonyl terminus, such as the Δ4–Δ6 PUFA. *Geotrichum candidum* lipase has unique substrate selectivity, with a strong preference toward Δ9 acyl groups, such as oleic, linoleic, and α-linolenic acids. There are several lipases commercially available which possess high activity and thermo-, storage, and operational stability resulting from enhanced knowledge of the fundamental

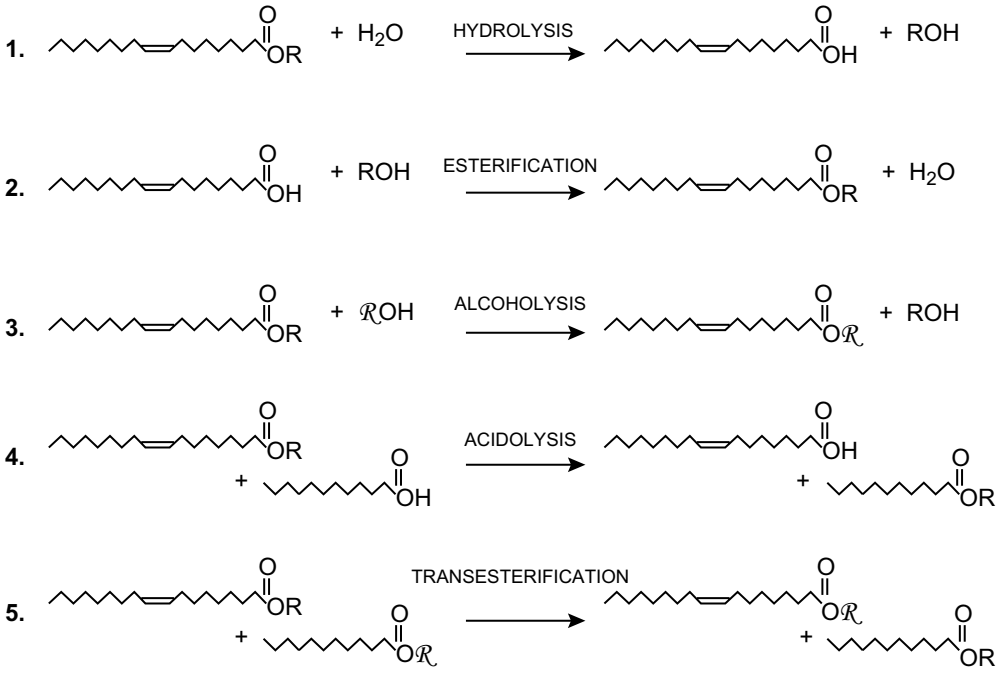

Fig. 1 Reactions catalyzed by lipases. (From Ref.[6].)

biochemistry of lipases, isolation of lipases from extremophiles, expression of lipase genes in recombinant hosts, directed evolution, and enhanced immobilization technology (e.g., Novozyme™, Lipozyme RM IM™, and Lipozyme TL IM, immobilized *Candida antarctica*, *Rhizomucor miehei*, and *Thermomyces lauginosus* lipases, respectively, from Novozymes, Inc., Franklinton, North Carolina, U.S.A.).[7]

ACYL MIGRATION PLAGUES 1,3-POSITIONAL SELECTIVITY OF LIPASES

1,3-Selective lipases are particularly useful for lipolysis of TAG that possess acyl groups of interest only in the 1- and 3-glycerol positions and for forming ''structured'' TAG, both of which are discussed later. However, acyl migration, a non-enzymatic intramolecular acyl exchange within monoacyl- and diacyl-glycerol, or MAG and DAG, respectively, greatly reduces the anticipated yield and purity. Specifically, the following two reactions occur:

$$\text{I.}\quad 2-MAG \rightleftharpoons 1-(3-)MAG$$

$$\text{II.}\quad 1,2-DAG \rightleftharpoons 1,2-(2,3-)DAG$$

Reviewed elsewhere,[10] acyl migration is frequently catalyzed by electrostatically charged materials in the reaction medium or enzyme preparation. Its occurrence increases with the water content of the reaction medium and temperature. Although acyl migration is difficult to prevent, its extent is significantly lessened when the residence time of the reaction medium in the presence of the biocatalyst is minimized.

THE IMPORTANCE OF LIPID SEPARATIONS IN ENZYMATIC PROCESSES

High yield of PUFA incorporation can only occur when the acyl donor is highly enriched in PUFA due to the relatively poor selectivity of all lipases toward Δ4–Δ6 FFA, with *Pseudomonas* sp. and *C. antarctica* lipase being the least discriminatory. Thus, when synthesizing structured or PUFA-enriched TAG from raw sources such as seed or fish oil or lard, one must employ a PUFA source that is highly pure in order to achieve a high yield. Thus, lipid separation steps are a very important component of the overall process. The most commonly employed lipid separation steps integrated with biocatalysis are listed in Table 2. Molecular distillation is perhaps the most common and rapid of the separation methods, but can degrade double bonds and involves a high energy cost.

Saponification is the preferred choice for isolation of FFA from esters, but must be employed in a buffered solution when applied to hydroxy fatty acyl mixtures. Crystallization and precipitation can be slow

Table 2 Separation methods that accompany lipase-catalyzed reactions

Method	Selectivity	Application with enzyme reactions
Short-path molecular distillation	Separates molecules by their molecular weight	Fractionation of MAG, DAG, TAG, and fatty acid esters from lipolysate or reaction medium
Saponification	Removes FFA from esters	Downstream removal of FFA
Crystallization and precipitation	Fractionates based on melting point	In situ removal of long-chain and hydroxy FFA and polyol monoesters
Urea inclusion compounds	Fractionation of polyunsaturates from saturates	Downstream processing of lipase-catalyzed PUFA-enriched FFA
High performance and low pressure liquid chromatography (adsorption)	Separation of lipid classes, separation of lipids by molecular weight and degree of unsaturation	Impractical for most preparative or large-scale processes
Solvent extraction (''countercurrent distribution'')	Separation of neutral lipid classes and PUFA from saturated FFA	Readily scaled up, but poorly selective

processes that require high-energy costs due to the low temperatures and process time required; thus, they are impractical for large-scale processes. Exceptions to this rule may be the isolation of MAG, polyol monoesters, and long-chain saturated and hydroxy FFA and their derivatives, which have melting point temperatures slightly below ambient (10–20°C). A cold trap can be implemented into the bioreactor design for continuous isolation of MAG, thermodynamically driving the desired reaction in the forward direction.

Chromatographic methods provide the greatest selectivity among the methods listed in Table 2; however, chromatography is very difficult to adapt to large-scale processing and is quite expensive. Solvent extraction, a technique that isolates FFA by their degree of saturation and/or the presence or absence of hydroxy groups, is poorly selective. It was employed frequently in the 1940s–1960s in the form of multistage, countercurrent, contacting equipment (known as ''countercurrent distribution'') before its replacement by chromatographic techniques for analytical and preparative scale applications. Urea inclusion compounds (UICs) have also been employed for over 50 years to separate lipids primarily by the degree of saturation.[11] UICs represent a process that has a high selectivity (greater than solvent extraction but less than molecular distillation or chromatography), can be readily scaled up, and involves much lower energy costs.[11] UIC-based fractionation is complementary to lipase-catalyzed selective esterification to purify PUFA.[11] Moreover, lipase-catalyzed esterification of an FFA mixture will remove common Δ9-unsaturated C_{18} FFA and UIC-based fractionation will remove saturated and monounsaturated FFA, resulting in a PUFA-enriched FFA product.[11]

ISOLATION OF FFA BY LIPOLYSIS

Traditionally, FFA are isolated from a degummed and bleached seed oil by the Colgate–Emery process, which employs steam at high pressure and temperature (typically 250°C and 5 MPa) to cleave the TAG ester bonds. The high temperature of this process is known to degrade PUFA and oxygenated FFA. In addition, the Colgate–Emery process consumes a large amount of energy, about 800 kJ of energy per kg of oil. Although lipolysis may serve as a low-cost and environmentally safe alternative to the Colgate–Emery process for FFA isolation, its widespread use in the oleochemical industry is blocked by the high material costs of enzymes. Lipolysis will have a greater impact upon PUFA and oxygenated FFA isolation due to the susceptibility of double bonds, epoxy, and hydroxyl groups to degradative side-reactions and the higher selling costs of PUFA-related products.

Partial isolation of PUFA with Δ4–Δ6 unsaturation occurs during lipolysis due to the inability of lipases to rapidly utilize TAG that contain PUFA groups.[12] Moreover, the PUFA are recovered from the MAG, DAG, and TAG molecules of the reaction mixture, while common acyl groups are preferentially released, then removed from the glycerides by saponification. (Alternatively, TAG are subjected to alcoholysis, reaction 3 of Fig. 1. The ester products are removed from the MAG/DAG/TAG by short-path molecular distillation. Since lipolysis and alcoholysis yield similar degrees of purification, selection between the two is based on economic considerations.) *C. rugosa* lipase has been employed in most instances for selective lipolysis. Due to the inability of many lipases to hydrolyze TAG with 2 or 3 Δ4–Δ6 PUFA groups, glyceride

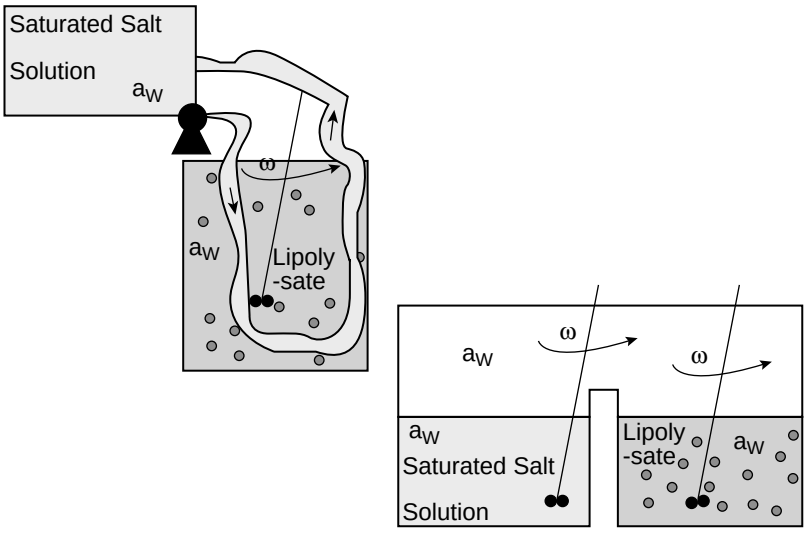

Fig. 2 Bioreactor configurations for lipolysis that employ saturated salt solutions of high water activity to maintain water saturation. *(View this art in color at www.dekker.com.)*

products contain PUFA at only moderately high concentrations (~40–75%) and yield (60–90%). The purity and yield are not strongly affected by reaction medium type nor by addition of fresh lipase during the time course of reaction. *Pseudomonas* sp. lipases generally produced the highest degree of lipolysis (79% or greater), but exhibited a much lower degree of discrimination against PUFA acyl groups than most other lipases.

1,3-Selective lipolysis is employed to isolate the hydroxy FFA listed in Table 1 because, unlike "random" lipolysis, poly(hydroxy acid) byproduct formation cannot be catalyzed. The employment of 1,3-selective lipases is particularly beneficial for recovery of lesquerolic and dimorphecolic acids from lesquerella and dimorphotheca oils, respectively, because the hydroxyl acyl groups are located solely in the 1- and 3-glycerol positions within TAG. Lipolysis of lesquerella oil by Lipozyme RM IM occurred at 66.7% yield and produced lesquerolic and auricolic FFA at a combined purity of 80% among the FFA.[13] A greater extent of lipolysis resulted in a greater yield at the cost of lower purity due to the occurrence of acyl migration.[13] FFA enriched in hydroxyl, epoxy, and long-chain ($>C_{20}$) cannot be isolated by a simple saponification procedure; the alkali extractant must be buffered at pH 10. Alternatively, hydroxy FFA-rich products are isolated by crystallization through use of cold trap placed on-line in a continuous-mode bioreactor.[14]

When designing a bioreactor for lipolysis for preparative scale or larger, the use of immobilized lipases is essential to facilitate reusability and recovery of the biocatalyst from the reaction medium. The major issue to decide is the relative amounts of water and TAG, and the means of contacting the two poorly miscible liquids. The most common approach, to employ rapid stirring, resulting in either water-in-oil or oil-in-water emulsions, provides a high degree of interfacial area, but promotes poor dispersion of the immobilized biocatalyst and hinders rapid separation of liquid phases and the immobilized lipase. Microemulsions, nanometer-sized dispersions formed by the addition of a surfactant and alkane, provide excellent interfacial area and interfacial mass transport but are not recommended because of the occurrence of product inhibition and the very difficult separation of the water and oil phases due to the surfactant. Two approaches are recommended as alternatives to the employment of emulsions. The first is to operate with a water-saturated oil phase, with saturation maintained by the use of a compartmentally separated saturated salt solution (Fig. 2). The principle which drives water transport from the saturated salt solution to the lipophilic reaction solution is the thermodynamic requirement of equal water activity (i.e., chemical potential) for all phases. Hence, water consumed by the reaction will be replenished by the saturated salt solution. The water content of the lipolysate will increase during the course of reaction for a given water activity due to the formation of FFA, a surface-active agent. A salt which yields a high water activity, such as NaCl, should be employed. Two configurations are presented in Fig. 2, one where a saturated salt solution is circulated through the lipolysate through semi-permeable tubing of hydrophobic material. The second configuration employs a common vapor head space between the saturated salt solution and the reservoir. The second alternative to emulsion-based systems is to employ membrane bioreactors, in which the membrane compartmentalizes the water and oil phases. Both flat membrane and hollow microfiber configurations have been employed.[15] Membrane bioreactors allow for continuous-mode operation and the continuous removal of glycerol, the latter of which will

thermodynamically drive hydrolysis over its reverse reaction, esterification. However, the barrier to mass transport presented by the membrane and the low activity of lipases immobilized to the membrane surface lessen enthusiasm for this approach. A nitrogen-rich, oxygen-poor reactor head space is recommended for all lipolytic reactions that produce PUFA or hydroxy FFA to reduce oxidative degradation.

ISOLATION OF PUFA VIA LIPASE-CATALYZED SELECTIVE ESTERIFICATION

In contrast to lipolysis, the use of selective lipase-catalyzed esterification (reaction 2 of Fig. 1) in conjunction with a purification method is very successful for isolating PUFA.[16] Due to the discrimination most lipases possess against Δ4–Δ6 FFA (particularly from *Rhizopus* sp., *G. candidum*, *Candida rugosa*, and *Chromobacterium viscosum*), acyl groups such as the C18 Δ9s are rapidly esterified, while the Δ4–Δ6 PUFA are esterified much more slowly. As a first step, FFA are derived from a TAG source, for instance, by employing lipolysis. Next, selective esterification is operated in a stirred batch reactor containing the FFA source, an acyl acceptor (in stoichiometric excess), lipase, and perhaps a solvent. The acyl acceptor chain length (n-C_{12} reported optimal[17]), substrate ratio, temperature, water activity level, biocatalyst type and concentration, and extent of reaction are variables that should be optimized by the user in preliminary small-scale batch reactions.[18] Optimal conditions represent a position on the hyperbolic plot of purity versus yield that is dictated by economic factors. The time course of reaction is monitored so that the reaction can be stopped upon reaching the optimal extent of reaction by removal of the lipase via filtration or sedimentation. Saponification is then employed to isolate the PUFA-rich FFA from the reaction mixture. As an alternative to saponification, FFA, esters, and unreacted alcohol can be fractionated by short-path molecular distillation if long-chain acyl acceptors are used. An additional cycle of lipase-catalyzed selective esterification applied to the recovered PUFA-enriched FFA fraction will improve the purity of PUFA at the expense of reduced yield. For PUFA isolation from FFA mixtures derived from their natural sources (Table 1), typical purities and yields are 73–95% and 60–90%, respectively. To improve the PUFA purity, urea inclusion compounds (UICs) are frequently employed, as discussed above. Lipase-catalyzed alcoholysis (reaction 3 of Fig. 1) or hydrolysis of fatty acid methyl or ethyl ester mixtures is equally effective in discriminating against Δ4–Δ6 acyl groups. Assuming that the acyl acceptor substrate and acceptor group in the ester substrate in a selective alcoholysis reaction are significantly different in chain length, Δ4–Δ6 polyunsaturated fatty acyl-rich esters can be isolated by short-path molecular distillation. Lipase-catalyzed esterification to isolate PUFA has been scaled up to the 1–10 kg level.[18]

Lipase-selective esterification has recently helped fractionate PUFA species present in the same mixture. Fish oil-derived FFA was esterified with glycerol using Lipozyme IM in solvent-free media to fractionate DHA and EPA.[19] The unesterified FFA contained 78% DHA and only 3% EPA, with a 79% recovery of DHA; the esters contained the majority of the EPA and the other acyl groups, with a 91% recovery of EPA.[19] Lipases have also successfully fractionated the two most abundant species of CLAs: 18:2-9c,11t and 18:2-10t,12c from an equimolar mixture derived from acid-catalyzed isomerization of ALA.[20]

STRUCTURED AND PUFA-ENRICHED TAG

Structured TAG are defined as TAG molecules that contain mixtures of short- (C_1–C_4), medium- (C_6–C_{12}), and long- (C_{14} or higher) chain acyl groups, with a given acyl group types frequently being confined to either the 1-(3-) or 2-position on the glycerol backbone.[21] (TAG rich in medium chain acyl groups are clinical pharmaceuticals for patients with lipid absorption or digestion disorders and high- and rapid-energy sources for athletes since medium chain acyl groups are readily metabolized via the portal vein and generally are not stored in adipose cells for long-term use.) Structured TAG have many applications as nutraceuticals. Commercial examples include Salatrim™ from Danisco Cultor (dietary agents consisting of TAG with at least one long-chain saturate, e.g., 18:0, and one short-chain acyl group), Caprenin™ and Caprucin™ from Procter and Gamble, dietary agents containing C_8, C_{10}, and behenic (22:0), or erucic (22:1-13) acyl groups, respectively, Captex™ 810-D from Abitec, Columbus, Ohio, U.S.A. (cosmetic agents containing TAG enriched in C_8, C_{10}, and 18:2 acyl groups), and Structolipid™ from Fresenius-Kabi AB, Sweden (parenteral nutrients formed by random interesterification of coconut and soybean oils). All of these products contain TAG with random distribution of the named acyl groups among the three acylglycerol positions.

The employment of 1,3-selective lipases leads to structured TAG where specific acyl groups are confined to either the 1-(3-) or 2-acylglycerol position. One of the earliest examples is cocoa butter substitute formed by 1,3-selective lipase-catalyzed acidolysis (reaction 1 of Fig. 3) of palm oil midfraction by palmitic acid (resulting in the replacement of 1-, 3-dipalmityl, 2-oleyl TAG by 1-(3-) palmityl, 2-oleyl, 3- (1-) steryl TAG and 1-, 3-disteryl, 2-oleyl TAG, both of which are abundant in cocoa butter). The product

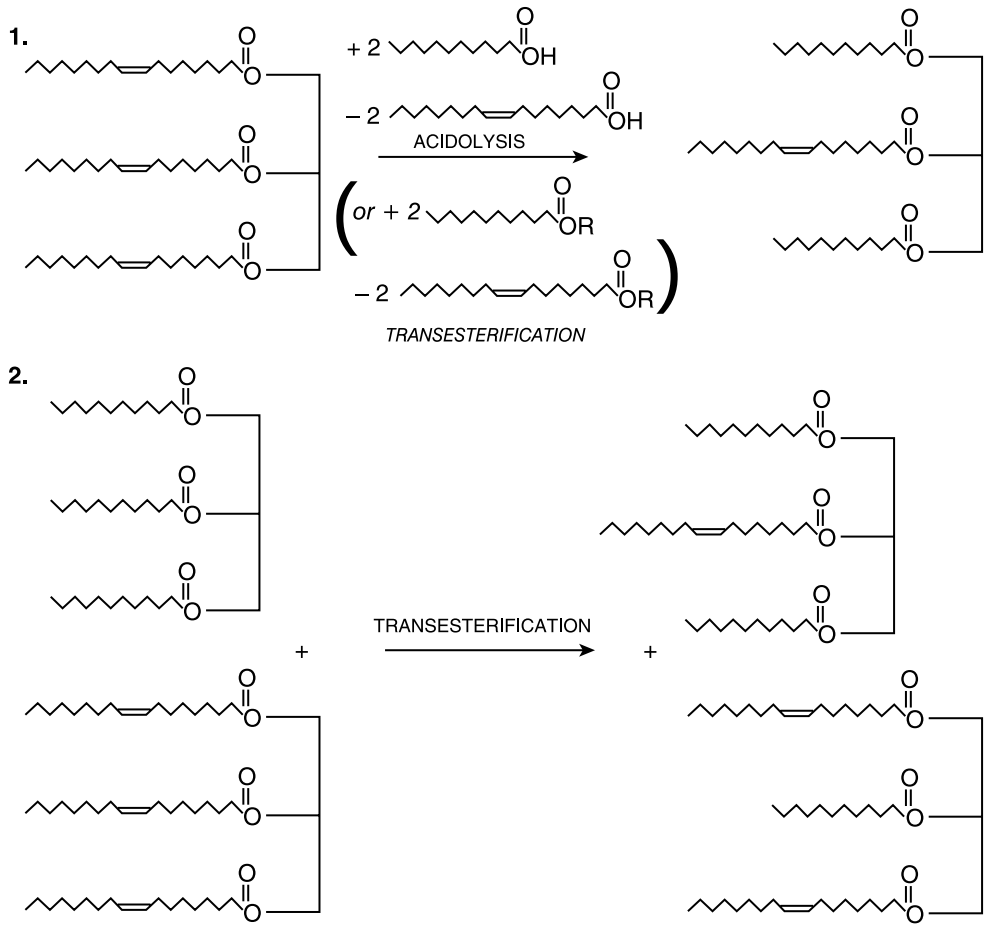

Fig. 3 Reactions catalyzed by 1,3-selective lipases to synthesize structured TAG. (From Ref.[6].)

Bohenin™, consisting mostly of 1,3-behenyl, 2-oleyl TAG, is synthesized using lipases by Fuji Oil, Osaka, Japan, as a cocoa butter improver. A second product area is human milk fat substitute for use in formula for both prematurely born and full-term infants. Mammalian milk frequently contains TAG possessing a palmitic acyl group at the 2-position. The commercial product Betapol™ from Loders Croklaan, Wormerveer, Netherlands, a TAG product enriched in 1,3-dioleyl, 2-palmityl TAG, recently received the rating ''generally regarded as safe (GRAS)'' by the US Food and Drug Administration (FDA). Betapol™, the first commercial product employing lipases to create structured TAG, improves the absorption of dietary fat and calcium by infants, and reduces constipation. Infant formula that contains PUFA-acyl groups at the 1- and 3-acylglycerol position is suggested to enhance brain and nervous system development.[22] Positioning of PUFA groups in the outer acylglycerol positions allows for proper digestion by infants, since only the 2-position acyl group is strongly absorbed in vivo.[22] This fact suggests that structured TAG containing PUFA at the 2-position and medium-chain acyl groups at the 1- and 3-positions may be a useful nutraceutical, providing the benefits described above for Salatrim™, Caprenin™, and Caprucin™, with the added benefit of an essential FFA being adsorbed by the body. Such a structured TAG has been suggested as a nutrition source for patients with pancreatic deficiencies. However, a problem recently discovered for structured TAG prepared by 1,3-selective lipases is the product's relatively low oxidative stability.[23]

Synthesis of a structured TAG with PUFA confined to either the 1-(3-) or 2-position requires 1,3-selective lipases to interesterify a TAG using FFA or fatty acid esters (reaction 1), or to transesterify two different populations of TAG molecules (Fig. 3). Alternatively, a two-step approach can be employed, where a TAG is first subjected to 1,3-selective lipolysis, resulting in 2-MAG that is carefully isolated, then crystallized, to prevent acyl migration.[24] The second step is 1,3-selective esterification of the 2-MAG.[24] Such an approach results in a 72–85% yield and >95%

purity.[24] In addition, the acidolysis of a medium acyl chain-rich TAG by PUFA-rich FFA was enhanced by use of a membrane bioreactor in which the released medium-chain FFA were selectively removed by their permeation through the membrane.[25] To enrich a common TAG mixture in PUFA, either 1,3- selective or ''random'' lipases are employed to catalyze interesterification using PUFA-enriched FFA (acidolysis, reaction 4 of Fig. 1) or fatty acid methyl or ethyl ester (transesterification, reaction 5 of Fig. 1). PUFA-enriched MAG/DAG/TAG, produced via selective lipolysis (discussed above), can replace the TAG substrate, resulting in a TAG highly enriched in PUFA. An alternative approach to produce PUFA-enriched TAG is direct esterification between glycerol and PUFA-rich acyl groups.

When conducting interesterification for structured and PUFA-enriched TAG synthesis, the three main goals are high activity, low occurrence of hydrolysis (resulting in DAG and perhaps MAG), and, for structured lipid synthesis, low occurrence of acyl migration, because this reaction will lead to formation of TAG with undesired structure. One must optimize reaction parameters: residence time, reaction temperature, and fatty acyl donor-to-TAG substrate ratio, to arrive at a desired position between the two extremes of high percent interesterification and low degrees of acyl migration and hydrolysis.[26] An optimal water activity also exists: suboptimal water content reduces biocatalytic activity, while high water content leads to increased hydrolysis and acyl migration.[26] A continuous-mode packed bed bioreactor is recommended because it lowers residence time of reaction mixture in the presence of immobilized lipase, which leads to reduced acyl migration.[26]

PUFA AND HYDROXY ACYL-RICH *MAG*, *DAG*, AND POLYOL ESTERS

MAG are well-known biodegradable and biocompatible emulsifiers in the foods, dairy, cosmetics (e.g., in toothpastes), and pharmaceutical industries.[27–29] 1-(3-) MAG are easily modified chemically to produce MAG sulfates, cosmetic surfactants which yield low irritability. As discussed above, 2-MAG are feedstock for the lipase-catalyzed synthesis of structured lipids. Approval of MAG as GRAS was recently granted by the FDA. DAG are cocoa butter additives that reduce the extent of crystallization or ''blooming.'' Isomerically pure DAG are possible feedstocks for the synthesis of glycerylphospholipids, glycolipids, and pharmaceuticals.[29] Current industrial methods to produce MAG and DAG (e.g., glycerolysis directed by a heterogeneous catalyst) involve high temperatures (~180–220°C or 30–160°C if a high vacuum pressure of 200–400 Pa is applied) that may produce byproducts that promote off-flavors, -odors, or -colors, and a broad product distribution containing various MAG, DAG, and TAG species.[27,29] Molecular distillation must be applied to remove the impurities, which increases operating costs and can result in further chemical degradation. Therefore, enzymatic preparation of MAG and DAG may gain further interest if energy costs continue to increase and will be of particular interest for products that contain degradation-susceptible PUFA and oxygenated acyl groups. PUFA-enriched MAG (and polyol monoesters, discussed below) are food emulsifiers that provide essential FFA nutrients. Hydroxy acyl-rich MAG are waxy materials employed in lipsticks.

Lipase-catalyzed synthesis has been employed to synthesize FFA partial and poly-esters of glycols such as ethylene and propylene glycol, neopentanol, trimethylolpropane, and polyglycerol as a low-cost and low-temperature alternative to chemical processing for applications as biodegradable and biocompatible lubricants and emulsifiers in the food and cosmetics industry. Saccharide acyl acceptors (e.g., fructose, glycols, sucrose, xylose, maltose, and trehalose) have received the most attention of the polyols due to the narrow product distribution provided by regioselective lipases.[30] For instance, 1,3-selective lipase-catalyzed esterification of 1,2-propanediol results in only the 1-monoester. The substrate ratio, water activity, and reaction medium polarity can also be selected to control the relative proportion of mono- and di-esters. As a second example, lipases esterify only the primary OH groups of sucrose, at the 6, 6′ and 1′ positions, with the three hydroxyls listed in the order of preference by lipases. Chemical synthesis of sucrose esters requires temperatures above 100°C and results in a broad product distribution.

Lipases catalyze MAG (or polyol ester) synthesis via esterification or glycerolysis (alcoholysis) in nonaqueous media (Fig. 4). The challenge to overcome when conducting lipase-catalyzed reactions is the poor miscibility of glycerol (or polyol) and the acyl donor-rich lipophilic phase. The employment of polar solvents (e.g., *tert*-butanol, acetone, and, recently, room temperature ionic liquids) increases miscibility and the product distribution in favor of mono- rather than di- or poly-esters, but decreases the catalytic rates because of the partitioning away of essential water molecules from lipase to the solvent. Other approaches include the use of polyhydric alcohol complexation agents such as phenylboronic acid, the use of protective groups such as isopropylidene (which for glycerol covalently blocks access to two of its three hydroxyls, resulting in regioisomerically pure 1-(3-) MAG), water-in-oil microemulsions, and the suspension of silica gel saturated with glycerol in the reaction medium,

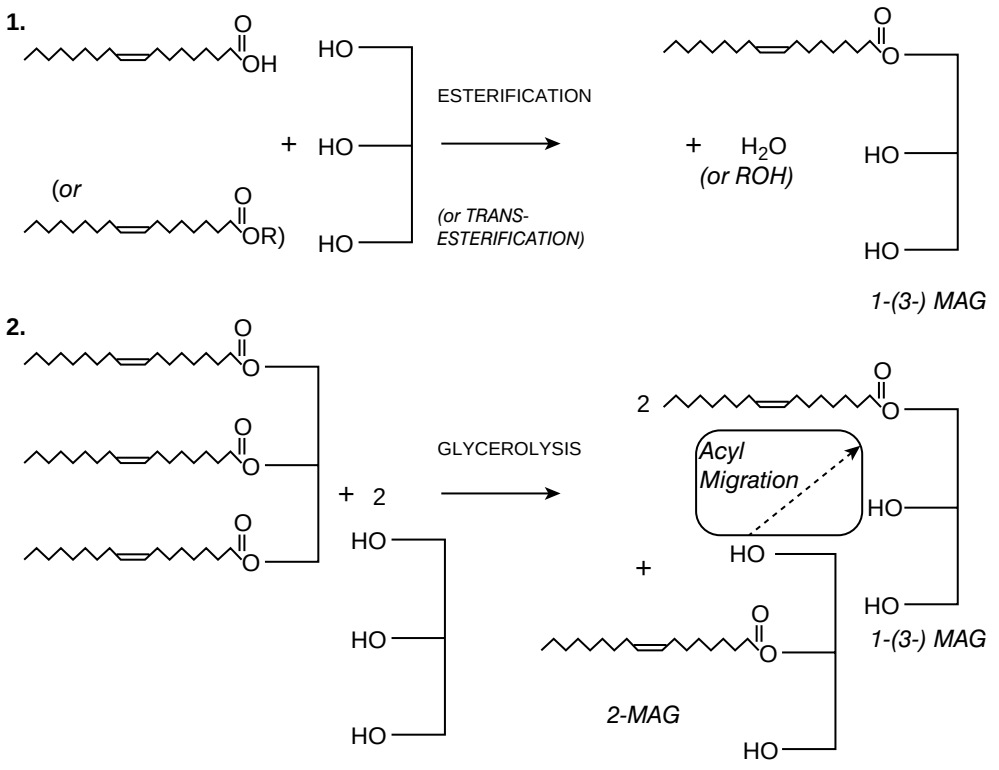

Fig. 4 Reactions catalyzed by 1,3-selective lipases to synthesize monoacylglycerol (MAG). (From Ref.[6].)

all of which are impractical for large-scale manufacturing. Of note, glycosides (saccharide alkyl ethers) can be readily formed by chemical and enzymatic means (glucosidases) to solve the problem of poor substrate miscibility for saccharides. *Penicillium camembertii* lipase-catalyzed esterification will produce MAG and DAG, but not TAG due to its unique substrate selectivity.

POLY (HYDROXY FATTY ACID) ESTERS

Random lipases are known to catalyze the formation of poly(hydroxy) fatty acids, primarily ricinoleic acid and its product via hydrogenation, 12-hydroxystearic acid; however, polymerization also occurs readily by chemical processing.[31] The value of lipase-catalyzed processing is the ability of 1,3-selective lipases to permit esterification of the free carboxyl moiety without cleavage of the ester bonds that join together the hydroxyacyl monomeric units. Esterification improved the physical properties of poly(hydroxy acids) as lubricant materials, evidenced by their reduced viscosity change with temperature, i.e., increased viscosity index.[31] Monoesters of polyglycerol and poly(ricinoleic acid) are well known emulsifiers for the food industry. Star polymers have been synthesized recently from polyol and poly(ricinoleic acid), e.g., pentaerythritol-poly(ricinoleic acid) tetraester, using lipases in nonaqueous media. Such materials have very good lubricant properties and may have utility as drug delivery vehicles.[32]

STERYL ESTERS

Lipases have also been employed to isolate tocopherols and sterols, important antioxidants from ''deodorizer distillate,'' a by-product formed during the deodorization step of seed oil purification, by hydrolyzing MAG and DAG in the ''distillate,'' and by esterifying sterols into sterol esters.[33] The latter serves as antioxidant in non-polar food products such as margarine (e.g., Benacol™ from the Raisio Group, Finland and ''Take Control''™ from Unilever, Englewood Cliffs, New Jersey, U.S.A.). PUFA-sterol esters would provide the benefits of essential fatty acid intake and antioxidant protection.

PEROXIDATED FFA

Peroxy fatty acids, R-COOOH, formed from the esterification of FFA or alcoholysis of fatty acid methyl or

ethyl esters with hydrogen peroxide, H_2O_2, are oxidants employed in the chemical industry for epoxidation of double bonds, conducting Baeyer-Villiger oxidation reactions, and hydroxylation of aromatic rings and amines. Traditionally, this reaction occurs via catalysis using a strong acid; however, for long-chain and unsaturated FFA, harsh operating conditions (strong acids and high temperature) are required and by-products frequently occur. Thus, biocatalysis may be a safer alternative.[34] Lipase-catalyzed peroxidation of PUFA yields epoxy FFA, of potential use for paints, coatings, and disinfection agents (sporicides).[34] Epoxy FFA occur due to the isomerization, or ''self-epoxidation'' of peroxy FFA. For instance, peroxidation of ALA results in peroxy-ALA, which isomerizes, or ''self-epoxidizes,'' into a mixture of 9,10-epoxy, 12,13-epoxy, and 15,16-epoxy FFA. Lipase-catalyzed peroxidation typically results in a 70–90% yield of epoxy-FFA.[34] Hydroxy and peroxy acids are also formed from the chemical rearrangement of hydroperoxides, a class of lipid products formed via lipoxygenase-catalyzed oxidation of PUFA,[35] a topic that is beyond the scope of this entry.

Although enzymes are very susceptible to denaturation by H_2O_2, Novozyme^{TM} appears to be reasonably stable. To reduce denaturation, fed-batch addition of 30–60% aqueous H_2O_2 to the pure FFA or alkyl ester is employed. Typical solvents used for this reaction are toluene and dichloromethane.

CONCLUSIONS

The employment of lipases to isolate polyunsaturated and oxygenated FFA and transform them into ester products will expand in the near future, especially for purifying PUFA and synthesizing structured TAG. Biocatalytic modification will become more competitive with chemical processing if energy costs continue to rise. Advances in lipase bioreactor design and process scale-up technology will be an area of focus in future research, including the implementation of reactive separations. Along the same lines, multistep processing schemes composed of biocatalytic and separation steps to convert raw lipid feedstock into products of interest such as structured TAG, have improved in their sophistication during the past five years, with the trend expected to continue, particularly with regard to the integration of reaction and separation steps. Bioreactor design will also be developed for multiple enzyme systems, for instance, the combination of random lipases and lipoxygenases to transform TAG into hydroperoxides. Another example may be a multistage bioreactor where random lipases hydrolyze PUFA-enriched TAG in an upstream stage, and 1,3-selective lipases catalyze the acidolysis of a tripalmitin feed stream with the PUFA-enriched FFA transported from the upstream portion of the process in a downstream stage, resulting in an infant formula nutraceutical.

Although acyl migration and hydrolysis side reactions cannot be prevented in manufacturing TAG, future bioreactor designs will facilitate the programming of operational parameters such as water activity, solvent system polarity, and temperature to improve yield and recovery. The ability to program the water activity and other parameters effectively will require improved capabilities in kinetic modeling and means of in situ control and rapid measurement of substrate and product concentration. The in situ measurement of water activity is being developed.[36] It is highly desired that a lipase be produced that will be less discriminatory against Δ4–Δ6 and long-chain saturated FFA to improve the rate and extent of PUFA acyl incorporation into ester products. Advancements in directed evolution, extremophile discovery and screening, and recombinant DNA technology will lead to more active and stable lipases that possess narrower substrate selectivity.

In conclusion, although a mature field, lipase-catalyzed lipid modifications will require further improvement along the lines given in the preceding paragraphs for the further use of PUFA and hydroxy acyl material as chemical and biological intermediates. Although alternate technologies (lipid purification, chemical modification, transgenic plants,[37] and microbial bioconversions[38]) will improve, the selectivity of lipase-based processing will continue to make it a viable choice as unit operation in a lipid ''biorefinery'' as a substitute for petrochemical-based processes.

Vapor–Liquid–Solid Synthesis of Nanowires

Brian A. Korgel
Tobias Hanrath
Forrest M. Davidson, III
The University of Texas, Austin, Texas, U.S.A.

INTRODUCTION

Fundamental aspects of vapor–liquid–solid (VLS) semiconductor nanowire growth are presented here. The synthesis of VLS semiconductor has been extended to different reaction media and pathways from the early chemical vapor deposition (CVD) approach, including solution–liquid–solid (SLS) and supercritical fluid–liquid–solid (SFLS), laser-catalyzed growth, and vapor–liquid–solid-epitaxy. The properties of nanowires grown by these VLS embodiments are compared. In this entry, VLS growth of nanowire heterostructures and oriented and hyperbranched arrays is examined. In addition, surface passivation and functionalization are assessed, and the importance of these techniques in the progress toward VLS produced nanowire devices is detailed.

BACKGROUND

Semiconductor nanowires are ultrahigh aspect ratio (>1000) crystals that are micrometers in length and <50 nm in diameter. Because of their nanometer diameter and high aspect ratio, they exhibit unique size-dependent optical, electronic, and mechanical properties. When the nanowire diameter is smaller than the Bohr exciton diameter, quantum confinement occurs, changing the optical and electronic properties of the semiconductor. These properties might be exploited in new optical sensor, light-emitting diode, or field effect transistor (FET) applications. Semiconductor nanowires are also extremely flexible, unlike bulk ceramics, bending and flexing like polymers, giving them the ability to combine and interface with plastic substrates and organic electronic materials for flexible display and computing applications. Their very high surface area-to-volume ratios make their properties very sensitive to surface chemistry and to subtle changes in the environment, which may be exploited in high sensitivity sensor applications. Recently, new synthetic approaches for varying the composition—either along the length of the nanowire or radially in the form of core/shell structures—have been developed, which adds another degree of freedom for materials property design. This capability is particularly important for electronic applications, such as computing architectures that require controlled doping, such as p–n–p type heterostructures, and metal–insulator–semiconductor (MIS) devices. Aside from having an immense technological potential, semiconductor nanowires provide a model materials system for experimental studies of fundamental quantum mechanical concepts.

The VLS Growth Mechanism

In the 1960s, Wagner proposed the VLS growth mechanism for crystalline silicon whiskers.[1] In the literature, crystalline wires with diameters exceeding 100 nm have generally been referred to as "whiskers," whereas wires with diameters <100 nm have been called "nanowires." Noncrystalline wires are generally called "fibers." And a "wire" typically has an aspect ratio of at least 100. Since its initial proposal, VLS growth has been observed in a broad range of crystallization environments, including liquids and supercritical solvents—VLS growth is even believed to be responsible for the formation of Fe whiskers on the surface of lunar rock samples.[2]

Wagner, in his early work, formed single crystal Si whiskers by CVD of SiI_2 or $SiCl_4$ on Si(1 1 1) substrates in the presence of metal impurities, such as gold (Au). In VLS growth, the metal impurity promotes whisker crystallization through the formation of a liquid metal : Si alloy droplet. Instead of depositing epitaxially on the underlying substrate, Si adsorbs to the surface of the metal impurity and dissolves into it. An example of the binary equilibrium phase diagram for Au–Si is shown in Fig. 1A. It exhibits a low-temperature liquid eutectic (~360°C), which is lower than the typical CVD temperatures in the range of 500–800°C. Therefore, as Si deposits on the substrate surface, it dissolves into the Au metal "seed" until reaching supersaturation when it nucleates and recrystallizes from the particle surface in the form of a whisker. Under the appropriate deposition conditions, sidewall growth on the whisker surface will occur at a slower rate when compared with the rate of crystallization from the metal seed particle.

Au forms a relatively low-temperature eutectic with many different semiconductors, including Ge and GaAs and, therefore, has been used extensively to seed the growth of many different semiconductor whiskers. However, there is nothing unique about the properties of Au for VLS growth, and high-quality crystalline semiconductor whiskers have been grown using many different metals as seeds, including Ag, Cu, Ni, Pd, and Pt.[1] The only requirement for VLS growth is that the deposition temperature should be greater than the metal : semiconductor eutectic.

In Fig. 1B, the VLS process is illustrated. At reaction temperatures exceeding the eutectic, Si vapor dissolves in the Au seed to form a liquid alloy droplet. As more gaseous Si dissolves in the alloy, the droplet becomes supersaturated, and Si crystallizes on the droplet surface. The shape of the droplet interface and the surface tension difference between the liquid alloy and the solid semiconductor promote crystallization in one direction. In many cases, the liquid alloy droplet displaces off the surface and ''rides'' on the top of the vertically growing whisker—crystallization continues to occur at the liquid–solid interface as the metal seed is continuously fed with Si from the gas phase.

For high-quality whiskers with a consistent diameter along their lengths, the CVD deposition parameters must be optimized to minimize sidewall deposition and to promote relatively rapid whisker growth. The deposition conditions must be at sufficiently high temperature and precursor concentration to feed sufficient semiconductor to the liquid metal : semiconductor seeds to maintain consistent whisker growth. Fluctuations in semiconductor concentration, or temperature, lead to defects in the whisker, such as changes in the growth direction, bends in the wire, or even the formation of an amorphous phase. The semiconductor feed rate, however, must be slow enough to limit unwanted sidewall deposition on the surface of the whisker, which leads to polycrystallinity and large variations in diameter along the whisker length. The ''nutrient'' concentration must sustain steady whisker growth, while not inducing sidewall deposition or homogeneous nucleation on the substrate.

Crystallographic characterization has revealed that nearly all Si whiskers produced by Au-seeded VLS by CVD are oriented with their long axes in the $\langle 1\,1\,1\rangle$ direction. Some whiskers are observed to be oriented with their long axes extended in the $\langle 2\,1\,1\rangle$ or $\langle 1\,1\,0\rangle$ axis. This observation is somewhat unexpected, as the rate of epitaxial Si deposition on monolithic substrates by CVD occurs much faster on $\{2\,1\,1\}$ and $\{1\,1\,0\}$ surfaces than on $\{1\,1\,1\}$ surfaces. The preferential $\langle 1\,1\,1\rangle$ growth direction of Au-seeded Si whiskers is believed to relate to the formation of an energetically favorable flat $\{1\,1\,1\}$ interface with the liquid alloy seed droplet.

Measurements of whisker crystallization rates by VLS have revealed that the linear growth rate is proportional to the whisker diameter, with larger fibers growing faster than smaller ones.[3] The observed diameter-dependence has been attributed to differences in seed saturation concentration resulting from the curved interface of the seeds. The Gibbs–Thomson equation provides the relationship between the sphere diameter, d, and the chemical potential difference between the nutrient phase (e.g., molecular Si in the vapor) and the liquid alloy droplet $\Delta\mu$:

$$\Delta\mu = \Delta\mu_0 - (4\Omega\gamma_{\mathrm{SF-L}})\left(\frac{1}{d}\right) \quad (1)$$

where $\Delta\mu_0$ is the chemical potential difference at a flat interface, $\gamma_{\mathrm{SF\text{-}L}}$ the surface energy of the vapor–liquid alloy interface, and Ω the atomic volume of the liquid alloy.

As the smaller seed particles have a higher solubility, the seed supersaturation, or the Si chemical potential between that dissolved in the liquid droplet and

adsorbed to the solid crystal, is lower. In fact, Eq. (1) predicts a lower size limit for the seed when VLS growth becomes thermodynamically unfavorable. Recent experiments measuring Si/Ge[4] and Si[5] nanowire growth rates as a function of seed diameter have verified slower growth from small seeds (vide infra).

In early VLS whisker growth studies, there was no attempt to control the liquid alloy droplet size. Consequently, whisker diameters were large, ranging from 100 nm to 0.2 mm. The smallest whisker diameters that could be produced were limited by the minimum stable liquid droplet diameter (~100 nm). In 2000, researchers began to apply size-selected nanometer-size colloidal metal particles as seeds to promote semiconductor nanowire growth.[6,7]

Solution-Phase Nanowire Growth

Nearly 30 years after the discovery and development of VLS whisker growth, the drive toward nanoscale miniaturization of electronic devices and the development of ''bottom-up'' nanocircuit assembly, in which integrated devices are ''self-assembled'' from prefabricated nanocrystal building blocks, pushed research on alternative synthetic strategies for nanometer-scale semiconductor crystals. In 1993, two years after the discovery of single-wall carbon nanotubes, Heath and LeGoues reported the synthesis of highly anisotropic crystalline Ge nanowires with diameters ranging from 7 to 30 nm and lengths up to 10 μm.[8] Their synthesis involved the solvothermal reduction of $GeCl_4$ and phenyl-$GeCl_3$ by Na metal in hexane at 275°C and 100 atm. Although the authors did not attribute nanowire formation to a VLS growth mechanism, most likely liquid Na clusters formed in the reaction ''soup'' promoted anisotropic nanowire crystallization. Interestingly, the Na-seeded Ge nanowires exhibited a ⟨1 1 0⟩ growth direction with a high density of ⟨1 1 1⟩ twins extending parallel to the wire axis, qualitatively different than the ⟨1 1 1⟩ oriented Si and Ge whiskers produced by VLS from Au seeds. The yield of Ge nanowires from this synthesis was relatively low, only ~10–20%, which may have been because of a low reaction yield of Ge in these solution conditions, or the very low Ge : Na ratio used (~1 : 10) in the synthesis—typical semiconductor : metal ratios in most current syntheses range from 10 : 1 to 1000 : 1.

A couple of years later, Buhro and coworkers observed polycrystalline InP, InAs, and GaAs nanowire formations in hydrocarbon solvents from organometallic precursors at relatively low temperatures of ~200°C—well below the Au : Si eutectic temperature.[9] The nanowires had diameters ranging from 10 to 150 nm and their formation was attributed to a VLS-like growth mechanism. The organometallic precursors they used were similar to those used for CVD growth of III–V semiconductor thin films, such as tri-*tert*-butylindane (or gallane) and tri-*tert*-butylphosphine (or arsine). Solution-phase syntheses are limited by the solvent boiling point (~350°C for trioctylphosphine oxide), compared with the typical CVD synthesis temperatures of 500–800°C. At the low temperatures in the solution, reactions of tri-*tert*-butyl precursors are plagued by the incomplete elimination of the alkyl ligand from the Group III precursor, resulting in reaction products composed primarily of organometallic oligomers instead of the crystalline semiconductor material. To promote the reaction at these low temperatures, Buhro and coworkers added small amounts (~10%) of protic reagents, such as methanol, thiophenol, or diethylamine, to catalytically assist the elimination of the alkyl ligands from the Group III and V precursors and to successfully generate the III–V semiconductors at low temperatures (≤200°C).[9] It is well known that the In and Ga precursors decompose to metallic In and Ga at relatively low temperatures—in the range at which these reactions are carried out. Therefore, during the reaction, the III–V semiconductor is produced, but Group III precursor decomposition can also produce Ga or In metal. Both Ga and In have low melting points and form very low-temperature eutectics with GaAs, InAs, GaP, and InP. Therefore, in the reaction, metallic In (or Ga) forms and drives the crystallization of the III–V semiconductors at the relatively low temperature of ~200°C. Because precursor decomposition occurred in solution as opposed to the vapor phase, this metal-seeded semiconductor nanowire growth mechanism was termed ''solution–liquid–solid'' growth.

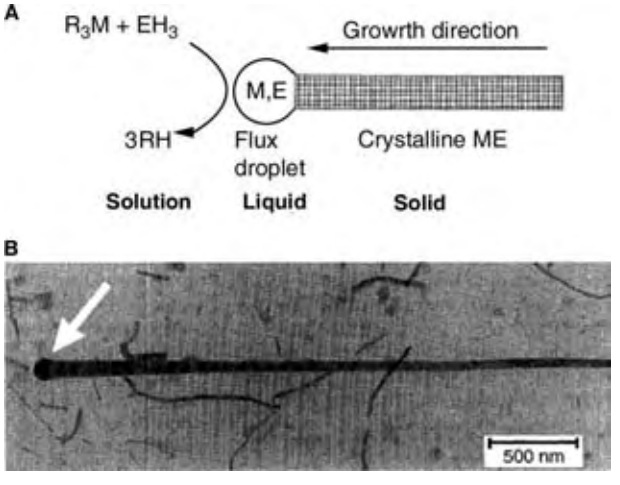

Fig. 2 (A) Schematic of SLS growth mechanism. M and E are elements of the composite semiconductor material. (B) TEM image of an InP whisker. The white arrow points at the In flux particle at the whisker's tip. (From Ref.[9].)

The SLS process was illustrated in Fig. 2A—Ga metal evolves as a reaction byproduct and serves as the metal seed to crystallize the semiconductor nanowire. In Fig. 2B, a transmission electron microscope (TEM) image of an InP nanowire crystallized from liquid In (mp = 157°C) droplets is shown. Note the metal droplet at the end of the nanowire (white arrow in Fig. 2B). The TEM image reveals a tapered nanowire shape with the nanowire diameter decreasing with increasing distance from the seed particle. This tapered shape indicates that the In particle at the tip of the growing InP nanowire grows larger as the nanowire grows. Increasing In accumulates in the seed metal tip over the course of the reaction. The SLS process was later applied to other compound semiconductor nanowires. However, it has been found nearly impossible to limit the size distribution of the metal seeds that are generated in situ during wire growth and that the polydisperse seeds that grow during nanowire elongation give rise to polycrystalline nanowires with diameters that vary by at least one order of magnitude in the sample.

CVD Nanowire Growth

In the gas phase, Westwater et al. narrowed the Si whisker diameter into the nanometer-size range by VLS growth by decomposing SiH_4 over a Si substrate coated with a very thin (0.6 nm) Au film.[10] The nanometer thickness of the thin Au film limited the nanowire diameter to the nanoscale. Their comprehensive survey of critical synthesis parameters, including Si partial pressure and temperature, showed that Si nanowires could be grown with diameters as narrow as 10 nm and successfully demonstrated that CVD–VLS could produce crystalline semiconductor whiskers with nanoscale diameter. However, the small diameter nanowires produced in their studies were of relatively poor quality, because it was found that narrow diameter (~20 nm) wires could only be produced at low Si partial pressure (1 Torr) and low temperature (440°C). The low-temperature slow growth conditions gave nanowires a high density of kinks and crystallographic defects. Si nanowires grown under low Si partial pressure (0.01 Torr) and high temperature (600°C) were much higher quality single crystal nanowires with limited crystallographic defects; however, the nanowires produced under these conditions were very large with diameters of approximately 120 nm. Despite some of the apparent remaining challenges in producing high-quality nanometer diameter Si nanowires by CVD–VLS, Westwater and coworkers revealed the potential to grow nanowires on selected areas of a substrate, as they lithographically patterned the gold films to selectively grow nanowires in desired regions. These studies provided a glimpse into the possibility of integrating VLS nanowire growth into standard Si complementary metal-oxide semiconductor (CMOS) electronics processing.

Using CVD–VLS, Kamins et al. grew Si nanowires from solid $TiSi_2$ seed islands on a Si substrate.[11] Ti-containing seed islands were formed on the substrate via CVD of $TiCl_4$ in a hydrogen atmosphere at 640°C, and in select cases a 920°C thermal anneal was used to form $TiSi_2$ islands. These islands were employed as nucleation sites for Si nanowires, which were subsequently grown by introducing either SiH_4 or $SiCl_2H_2$ at growth temperatures ranging between 640°C and 920°C. At low-growth temperatures (640°C), a small number of long crystalline nanowires formed with the majority of the reaction product consisting of short wires with multiple crystallographic defects. At high temperatures (920°C), the quality of the nanowires, in terms of crystallinity, was better, but significant homogeneous Si particle nucleation and film deposition on the substrate occurred, along with substantial sidewall Si growth on the radial nanowire surface. Nanowires produced in the higher temperature were very large with diameters in the ~100 nm range.

By comparing the nanowire growth when using $SiCl_2H_2$ and more reactive SiH_4, Kamins et al. identified the importance of the reaction chemistry on the quality of the nanowires. At higher temperature, Si decomposition on the substrate is very fast (the diffusion-limited deposition regime), and it is nearly impossible to control Si deposition on the substrate and on the sidewalls of the nanowires. At lower temperature, the decomposition of the Si precursor on the substrate is relatively slow (the surface reaction limited regime), and Si deposition is nearly eliminated on the substrate. Ti catalyzes the decomposition of the Si precursor and helps to promote selective nanowire growth. The rate of nanowire growth at lower temperature, however, was relatively slow and it was difficult to achieve high-quality single crystal Si nanowires. Wang and Dai later also showed that the balance between substrate nucleation and deposition and metal-seeded nanowire formation relates to the precursor reactivity. They showed that H_2 could be added to suppress the GeH_4 decomposition rate in the Au nanocrystal-seeded Ge nanowire synthesis by CVD–VLS.[12] This ''additive'' prevented sidewall growth and deposition on the substrate to give much higher quality narrow diameter nanowires. They were also able to grow Ge nanowires at very low temperatures, ~275°C, which helped to limit unwanted substrate and sidewall deposition. This is also the strategy used in the metal nanocrystal-seeded growth of single-wall carbon nanotubes by CVD—a precursor is identified that is reactive enough to produce tubes, but unreactive on the bare substrate.

The work of both Kamins et al. and Dai et al. revealed the importance of the nanocrystal seed in

promoting crystallization and its potential role in the reaction kinetics. $TiSi_2$-nucleated Si nanowire growth was actually observed at temperatures more than 600°C below the lowest Ti–Si eutectic, indicating that metal-assisted nanowire growth can occur from solid nanometer-size seed particles by a vapor–solid–solid (VSS) mechanism.[11] Nanowire growth from solid seed particles is made possible by sufficiently rapid diffusion of the nutrient material (Si) either through the solid seed particle or along its surface. Mathur et al. have reported VSS growth of Ge nanowires from polished Fe substrates at 385°C—approximately 500°C below the lowest temperature eutectic in the Fe : Ge phase diagram.[13] For binary semiconductors such as GaAs, CVD nanowire growth can proceed at temperatures below the eutectic by a VSS pathway if there is preferential solubility of the Group III metal in the seed, as is the case for Ga and gold. For example, Samuelson and coworkers combined nanoscale spatially resolved elemental characterization with in situ heating experiments on Au-nucleated GaAs nanowires to show that the seed particle contained only Ga and Au and remained solid during nanowire growth, implying that nutrient delivery proceeds by both solid (for Ga) and surface (for As) diffusion.[14] It is possible, however, to have VLS nanowire growth at temperatures below the metal : semiconductor eutectic on the phase diagram as a result of melting point depression in nanometer-size particles. For example, Wang and Dai attributed their Au particle-assisted VLS-CVD growth of Ge nanowires at 275–80°C below the Au : Ge eutectic—to such a melting point reduction in nanoscale seed particles.[12]

A significant advance in metal-nucleated semiconductor nanowire synthesis was made by Morales and Lieber by combining VLS growth with nanometer-size aerosol metal seeds generated by laser ablation.[15] In the initial conception of this laser-catalyzed growth (LCG) process, a pulsed-laser ablated a $Si_{0.9}Fe_{0.1}$ target at 1200°C to generate nanometer-size $Si_{1-x}Fe_x$ liquid clusters (see Fig. 3A). These supersaturated clusters underwent phase separation to precipitate Si nanowires with diameters ranging from 6 to 20 nm and lengths up to 30 μm (Fig. 3B). Similar to previous reports of VLS grown Si nanowires, the LCG approach yielded Si nanowires grown in the ⟨1 1 1⟩ crystallographic direction. Expanding upon this approach, Duan and Lieber demonstrated LCG synthesis of essentially all main group elemental and binary semiconductor materials.[16] For example, Figs. 3C and

3D show SEM and HRTEM images of an ensemble of GaP nanowires and a $GaAs_{0.6}P_{0.4}$nanowire oriented along the $\langle 1\,1\,1 \rangle$ axis. In Fig. 3E, a CdSe nanowire with $\langle 1\,1\,0 \rangle$ growth direction as an example of a Group II–VI compound semiconductor is shown. These studies highlight the generality of metal-seeded semiconductor nanowire growth to virtually any semiconductor, provided the appropriate precursors, seed metal, and reaction temperatures can be identified.

Supercritical Fluid Solution Growth

Although the seed particle sizes in LCG and SLS growth are in the nanometer-size range, the particle size distribution cannot be controlled, as the in situ generation of seed particles leads to broad log–normal size distributions and affords little control of the nanowire diameter in the preparation. These limitations have been addressed in two general ways by research groups: 1) by depositing size-selected colloidal metal nanocrystals onto substrates to seed CVD–VLS nanowire and 2) by performing SLS-type nanowire growth in solution by feeding in prefabricated size-selected metal seed particles. One limitation of the SLS approach is the relatively narrow temperature range available for nanowire growth. Squalene boils at about 400°C, which is about the maximum allowable temperature for SLS growth. One way to increase the temperature range available for SLS growth is to use pressurized solvents, in particular organic solvents heated and pressurized above their critical point—supercritical fluids. In 2000, we demonstrated the use of size-selected organic monolayer stabilized Au nanocrystals to seed Si nanowire synthesis in hexane.[6] To achieve the necessary high-temperature growth conditions in solution, we pressurized the solvent well above its critical pressure, which enabled temperatures between 350°C and 650°C to be reached. In this temperature range, organosilanes, such as diphenylsilane can be used as a Si precursor, decomposing to Si. For example, diphenylsilane and Au nanocrystals have been used to grow high-quality crystalline Si nanowires in hexane at ~450°C with diameters as small as 4 nm in diameter. This SFLS approach was later extended to other semiconductors, including Ge,[17] GaAs,[18] and GaP,[19] and has been scaled up to a continuous flow reactor configuration capable of producing a gram of crystalline nanowires in a single reaction.[17]

In addition to providing a potentially technologically important synthetic route to semiconductor nanowires capable of meeting the high throughput and high-quality needs to meet the potential future technological demands for semiconductor nanowire applications, SFLS synthesis also provides a good experimental testbed for studying the fundamental interplay between kinetic and thermodynamic factors that underlie VLS growth. A wide range of semiconductor

precursor molecules can be studied in solution, as limitations of volatility are not an issue. For example, Korgel and coworkers conducted a systematic study of various organosilane precursors and found that phenylsilanes produce high-quality nanowires with high product yield, while alkylsilanes decompose much too slowly at 450°C to yield nanowires. These studies provide important information that might be applied in CVD processes, which have been particularly prone to unwanted sidewall deposition because of very fast precursor decomposition. Highly reactive trisilane, on the other hand, degrades too rapidly and overwhelms the Au-mediated nanowire crystallization with homogeneous nucleation and colloidal growth of amorphous Si particles.[20] The SEM image in Fig. 4E shows the high quality and large quantities (in Fig. 4G) of Ge nanowires produced by SFLS. The TEM image shows a Ge nanowire.

Also, SFLS has been applied to the synthesis of binary semiconductors, such as GaAs and GaP; however, the development of the synthesis has proven to be relatively challenging. Unlike in the gas-phase, there is very little we know about precursor decomposition rates in high-temperature supercritical fluids, which creates challenges because high-quality nanowire synthesis requires precursor decomposition kinetics that are balanced to ensure that materials with the appropriate stoichiometry are produced. The growth of Au nanocrystal-nucleated GaP nanowires via the SFLS approach using a stoichiometric ratio of tri-*tert*-butylgallium and *tris*-(trimethylsilyl) phosphine can result in excess Ga metal that accumulates at the tips of growing nanowires, which can under some conditions supplant Au as the metal catalyst.[19] In another conception of the SFLS process, Au nanocrystals were molecularly tethered to the Si substrate inside the reactor. The combination of this technique with the continuous flow SFLS reactor enabled the elucidation of the influence of critical synthesis parameters, including reactor pressure, temperature, residence time, precursor concentration, and precursor choice on the nanowire growth kinetics and morphology.[21]

Nanowire Growth Seeds

The use of size-selected Au nanocrystals has been employed extensively by many researchers to control the size of VLS-grown nanowires (Fig. 5A).[6,7,12,14,17,18,21,27] For CVD–VLS nanowire growth, colloidal particles are first size-selected in solution and then drop cast or spun cast onto the substrate prior to nanowire deposition. Nanowire diameter control is very important, as the optical, electronic, and mechanical properties of nanowire depend on the nanowire diameter. The histograms shown in Fig. 5B illustrate that the nanowire diameter

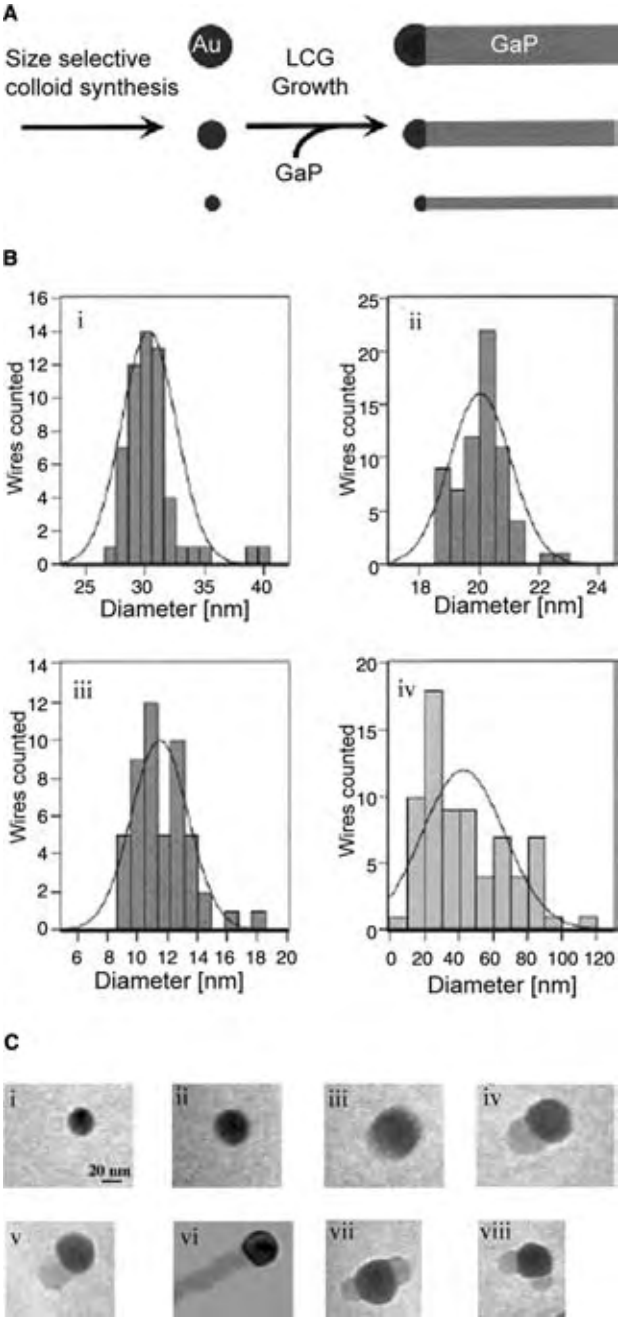

Fig. 5 (A) Schematic illustrating control of nanowire diameter distribution through use of Au nanocrystal seeds with different diameter distributions. (B) Diameter distribution histograms of GaP nanowires nucleated by: i) 28.2 nm, ii) 18.5 nm, iii) 8.4 nm diameter average sized Au seed nanocrystal, and iv) the broad diameter distribution obtained with LCG growth. (From Ref.[7].) (C) In situ TEM images of Au-nucleated Ge nanowire growth: i) solid Au nanocrystal at 500°C, ii) initial alloying at 800°C, iii) liquid Au/Ge alloy, iv) nucleation of Ge nanocrystal on the alloy surface, v) Ge nanocrystal elongates with further condensation, vi) eventually forms a wire, vii and viii) two nucleation events from a single alloy droplet. (From Ref.[23].)

corresponds reasonably well to the diameter distribution of the size-selected Au seed nanocrystals.

Although still under investigation, the nanowire growth direction also appears to be influenced by the seed particle diameter. Lieber and coworkers found that the growth direction of Au-seeded Si nanowires depended on the nanowire diameter.[22] Small Si nanowires with diameters ranging from 3 to 10 nm appeared to favor the ⟨1 1 0⟩ growth direction; whereas, larger nanowires in the diameter range of 10–20 nm favored the ⟨2 1 1⟩ growth direction, and even larger nanowires (20–30 nm) favored the characteristic ⟨1 1 1⟩ growth direction observed in Si whiskers. Lieber correlated the Si nanowire growth direction with the appearance of a flat {1 1 1} Si/Au interface, which gave rise to a V-shaped Au/Si interface in smaller diameter ⟨1 1 0⟩-oriented nanowires. Ge nanowires developed through SFLS exhibit predominantly ⟨1 1 0⟩ oriented growth, which appears to relate to crystallographic faceting of the nanowire nucleus and hexagonal sidewall faceting along the length of the nanowires as opposed to the Au/Ge interface.[28] From Au nanocrystals on a TEM grid, Wu and Yang made real-time TEM observations of VLS Ge nanowire from resistively vaporizing Ge (800–900°C).[23] As shown in Fig. 5C, these in situ imaging experiments captured the VLS growth process, including the liquefaction of the solid Au seed particle upon alloy formation and the emergence of the Ge crystal.

Au has been the most widely used metal to seed semiconductor nanowire growth because of the general availability of relatively size monodisperse nanocrystals, their chemical inertness, and the relatively low-temperature eutectic formed with a broad range of semiconductor materials. Unfortunately, Au is generally unacceptable in Si microelectronics, as it forms deep traps in Si that seriously degrade device performance. Other metals, such as Fe, Ni, Co, and Ti, are more compatible with Si electronics but exhibit significantly higher eutectic temperatures. Several researchers have explored the use of these alternate metals as replacements for Au seed nanocrystals.[11,13,24] For example, Korgel and coworkers recently exploited the catalytic properties of colloidal Ni nanocrystals to direct the growth of Si nanowires by SFLS.[24]

Complex Structure Nanowires

In a further extension of LCG growth, Lieber and coworkers[25] and Yang and coworkers[4] independently demonstrated the preparation of nanowires with structurally complex radial or axial heterostructures. Radial or core-shell heterostructure nanowires were formed by depositing layers on a core nanowire (Fig. 6A).[25] Using this approach, homoepitaxial growth of B-doped Si shells on intrinsic Si and heteroepitaxial

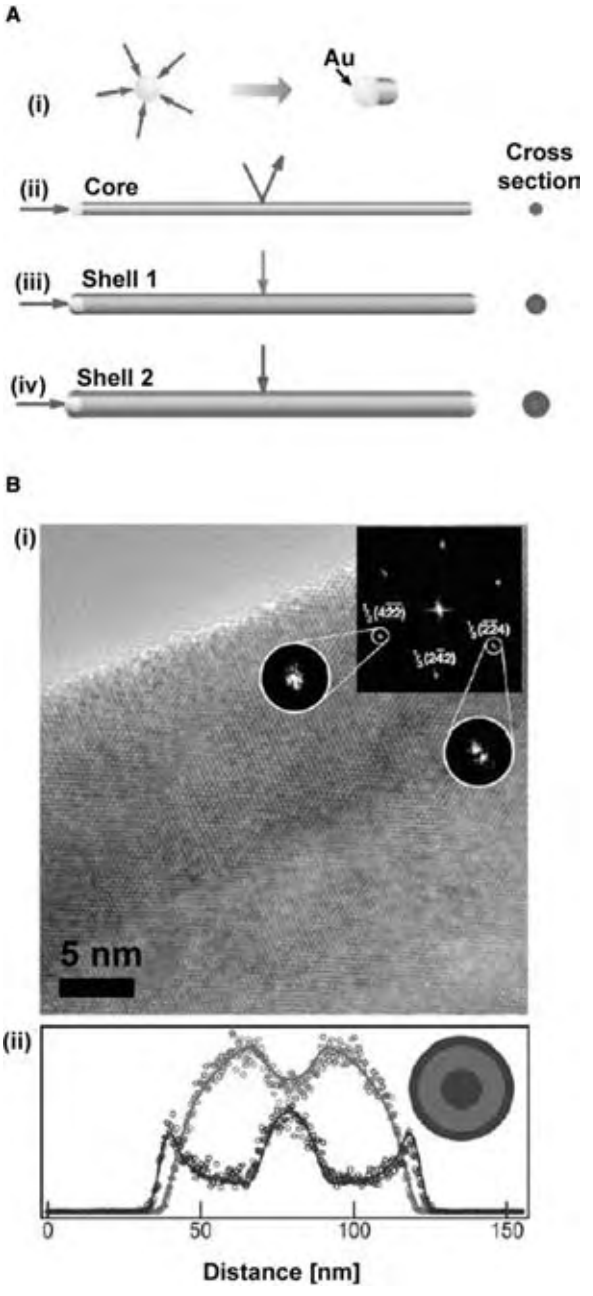

Fig. 6 (A) Schematic illustration of core-shell nanowire synthesis: i) gaseous reactants (red) catalytically decompose on the surface of a gold nanocrystal leading to nucleation and nanowire growth, ii) one-dimensional growth is maintained as reactant decomposition on the gold catalyst is strongly preferred, iii) synthetic conditions are altered to induce homogeneous reactant decomposition on the nanowire surface, and iv) multiple shells are grown by repeated modulation of reactants. (B) i) HRTEM image of Si–Ge–Si core shell nanowire showing the epitaxial interface, and ii) cross-sectional elemental mapping of a double shell structure with an intrinsic silicon core (diameter, 20 nm) intrinsic germanium inner shell (thickness 30 nm) and p-type silicon outer shell (4 nm); silicon is blue circles and germanium is red circles. (From Ref.[25].) *(View this art in color at www.dekker.com.)*

growth of Ge–Si, Si—Ge, and Ge–Si–Ge core shell structures was demonstrated. The TEM image and compositional profile shown in Fig. 6B illustrates the well-defined heteroepitaxial Ge–Si interface between the core and the shell structures. Heterostructure nanowires hold great potential for nanowire based electronic devices, as the multistep synthesis allows controlled modulation of the electrical properties of the core or the shell materials.[29]

Nanowire heterostructures with axially modulated compositions were achieved by switching the laser to ablate a different material target or through alternating the vapor phase molecular precursor being fed into a CVD reactor.[4] Both Group III–V and Si/SiGe SiGe heterostructure ''superlattice'' nanowires have been produced, as shown in Fig. 7A. By using well-defined switching intervals, Yang and coworkers measured the nanowire growth rate and verified its relation to the nanowire diameter as governed by the Gibbs–Thompson equation. The nanowires are especially intriguing for optoelectronic applications. For example, it has been shown that by modulating dopant fluxes it is possible to create an InP p–n heterojunction for use as the active component in polarized nano-LEDs.[30]

In another conception of nanowire heterostructures with axially modulated composition, Lieber and coworkers generated nanowires with lithographically defined segments of alternating metallic NiSi and semiconducting Si.[31] Ni was thermally evaporated on lithographically defined segments of a Si nanowire on a substrate. A thermal anneal diffused Ni into the Si nanowire to form the silicide NiSi, resulting in single nanowire NiSi/Si heterostructures with well-defined segments as shown in Figs. 7A and 7D. Heterostructures such as these modulate electrical properties along the nanowire length, enabling the fabrication of electrical devices with multiple source and drain electrodes defined on a single nanowire. The structural complexity of individual nanowires can also be increased, as branched and hyperbranched nanowires have been generated, as shown in Fig. 8A.[26] Secondary and tertiary branches were epitaxially grown from a central nanowire by decorating the nanowire surface with additional Au seed nanocrystals and repeating the VLS growth process. Multistep modification of VLS

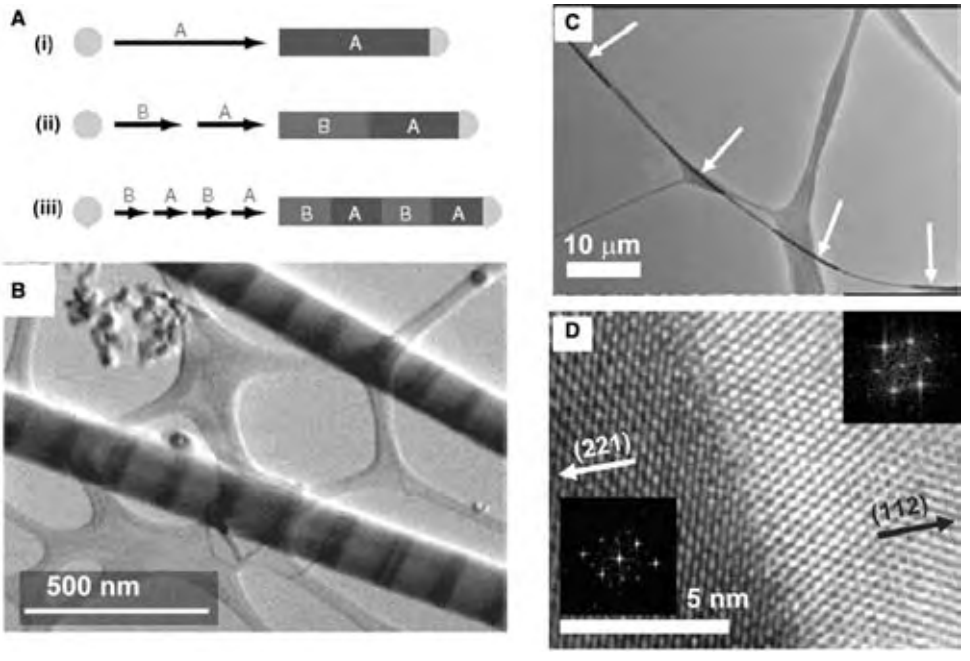

Fig. 7 (A) Synthesis of axial nanowire heterostructures: i) Au nanocrystal catalyst nucleates and directs one-dimensional semiconductor nanowire (blue) growth with the catalyst remaining at the terminus of the nanowire, ii) upon completion of the first growth step, a different material (red) can be grown from the end of the nanowire, and iii) repetition of steps i) and ii) leads to a compositional superlattice within a single nanowire. processes can provide significant control over the structural and chemical complexity of the nanowires (Fig. 8B).

Integrating Nanowire Synthesis with Existing Microelectronics

The vast majority of proposed technological applications of semiconductor nanowires require multiscale integration with existing microelectronic platforms, and research efforts have been intensively directed at making nanowire syntheses compatible with conventional microelectronic processes. Some efforts have been directed at reducing nanowire growth temperatures.[12,27] Other efforts have focused on lithographic patterning for the directed deposit of nanowires.[12,32] Recently, epitaxial nanowire growth has been demonstrated, with

nanowire crystallographic orientation matching the substrate orientation.[32,33] Si nanowires grown via vapor–liquid–solid-epitaxy (VLSE) preferred $\langle 1\,1\,1 \rangle$ growth axes, growing vertically on Si(1 1 1) substrates and along four equivalent $\langle 1\,1\,1 \rangle$ directions oriented 54.7° relative to the surface normal when grown on a Si(1 0 0) substrate[33] (Figs. 9A–C). In a related work, Williams and coworkers later demonstrated the epitaxial VLS growth of high density Si nanowire arrays between two vertical sidewall surfaces, as seen in Figs. 9D and 9E[34].

Nanowire Surface Chemistry

The enormous surface to volume ratio of the nanowires profoundly impacts the nanowire properties, making it imperative to control the surface chemistry. Several chemical routes have been explored for passivating or functionalizing nanowire surfaces.[35,36] Hanrath and Korgel reported a comprehensive investigation of Ge nanowire surface chemistry modification including oxidation, sulfidation, hydride and chloride termination, and organic monolayer passivation (Figs. 4A–D).[35] By combining SFLS synthesis with thermally initiated hydrogermylation reactions, organic monolayers were covalently attached to the nanowire surfaces (Fig. 4D). Monolayer-passivated nanowires exhibit improved dispersibility in solvents—an important requirement for many nanowire device fabrication processes—and enhanced chemical stability.[37] Electron transport was also found to be particularly sensitive to the surface chemistry,[38,39] a characteristic that several researchers have exploited to create high sensitivity environmental sensors. For example, nanowires with antibody-decorated surfaces exhibited conductivity changes that were sensitive to the presence of influenza or adenovirus, enabling the detection of single binding/unbinding events.[40]

Controlling the crystallographic growth direction is a highly desirable synthetic goal for a broad range of technological applications because of the anisotropy of fundamental properties, particularly the electron mobility and bandgap. In addition to size, shape, and composition, control over the nanowire growth direction offers another parameter that can be tuned to adjust the nanomaterial properties. In 2004, Yang

and coworkers reached a new milestone in semiconductor nanowire synthesis when they combined the VLSE process with careful selection of a lattice matching substrate to achieve control over the crystallographic orientation of GaN nanowire arrays.[32] Their experiments showed that wurtzite GaN nanowires epitaxially grown on (1 0 0) γ-$LiAlO_2$ substrates exhibited triangular cross-sections and a [1 1 0] crystallographic growth axis (Figs. 10B and 10D). Similar epitaxial growth on (1 1 1) MgO substrates, which exhibits good epitaxial match to GaN(0 0 1), resulted in [0 0 1] oriented GaN nanowires with hexagonal cross-sections (Figs. 10C and 10E).

CONCLUSIONS

The progress in the field of semiconductor nanowires over the past decade has been rapid. The field has evolved to a point where relatively complex, both structurally and chemically, functional nanomaterials with control over the size, shape, composition, surface chemistry, and crystallographic orientation can be produced. These synthetic advances have enabled nanowires to be integrated into a broad range of prototype devices including logic gates, data storage devices, optoelectronic devices, nanowire lasers, and chemical and biological sensors.

Water Gas Shift Reaction

Wolfgang Ruettinger
Oleg Ilinich
Engelhard Corporation, Iselin, New Jersey, U.S.A.

INTRODUCTION

Water gas shift (WGS) refers to the reaction of carbon monoxide with steam to yield carbon dioxide and hydrogen:

$$CO + H_2O \leftrightarrow CO_2 + H_2$$
$$\Delta H = -41.1 \text{ kJ/mol}$$

It is a mildly exothermic reaction, with an adiabatic temperature rise of 8–10°C per percent (wet gas) CO converted to CO_2 and H_2. It was first used industrially at the beginning of the 20th century in hydrogen production via coal gasification, as a part of ammonia synthesis by the Haber-Bosch process.[1,2] Water gas ($CO + H_2$) was produced by blowing steam over hot coal via an endothermic reaction $C + H_2O \rightarrow CO + H_2$. To maintain high temperature of the coal (above approximately 1000°C), steam was periodically cut off and air was blown through the bed of coal, producing carbon monoxide via the exothermic reaction $2C + O_2 \rightarrow 2CO$. Therefore, the gas mixture exiting the water gas converter contained CO and hydrogen plus small amounts of nitrogen and CO_2. Carbon monoxide was catalytically shifted to produce more hydrogen. Residual CO was removed by absorption in copper liquor, CO_2 was removed by caustic scrubbing, and the resulting hydrogen/nitrogen mixture was used in ammonia synthesis. Most hydrogen plants today consist of hydrodesulfurization (HDS) units and zinc oxide beds for feed purification, followed by steam reformers (SRs) and WGS reactors.

A catalyst consisting of iron oxide stabilized by chromium oxide was used in the shift reaction and was patented by Bosch and Wild in 1914.[3] This catalyst is largely unchanged and is still in use in industry as the high temperature shift (HTS) catalyst. Since the 1960s, copper-based low temperature shift (LTS) catalysts have been introduced in order to reduce the CO content of reformate to <0.5%. They are primarily important in the ammonia industry, where a high hydrogen yield is economically important.[4] Additionally it enables CO clean-up by the methanation reaction to protect the Fe-based ammonia synthesis catalyst from CO poisoning. If properly used, CO concentrations as low as 0.1% are possible in the resulting reformate. The WGS reaction is primarily used today in hydrogen and synthesis gas production for production of ammonia and methanol. Besides the large industrial production of hydrogen and synthesis gas, small-scale hydrogen production for fuel cells, hydrogen filling stations, as well as on-site hydrogen generation, is becoming a field of growing interest.[5] New catalysts have been developed for these applications, and we will describe some of the recent development later in this chapter.

These catalysts have to fulfil new safety requirements as they may be operated in the consumer's home, and also will experience a very different duty cycle than industrial catalysts. Another field that has attracted interest is sulfur tolerant shift catalysts. Catalysts have been developed for high sulfur concentrations in the feed gas since the 1960s,[6,7] but have not found large-scale application up to the present. The fact is that most ammonia, methanol, and hydrogen plants are based on natural gas or naphtha feedstocks, which have relatively low content of sulfur-containing compounds, and therefore do not require these more expensive catalysts. HDS is typically used to reduce sulfur levels in the feed gas to ppm to ppb levels to protect the steam reforming and downstream catalysts.

THERMODYNAMICS

The water gas shift reaction is a mildly exothermic reversible reaction, and CO conversion is limited by the thermodynamic equilibrium (see Fig. 1).

$$K_p = \exp\{(4577.8K/T) - 4.22\}$$
$$K_p = \{p(CO_2) * p(H_2)\}/\{p(CO) * p(H_2O)\}$$

The equilibrium constant K_p (see equations above) decreases with increasing temperature. Thus, low temperatures favor product formation in the WGS reaction. The equilibrium can also be shifted towards the right by increasing the steam concentration or removing a product from the reaction mixture (i.e., hydrogen through a hydrogen permeable membrane).

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008007

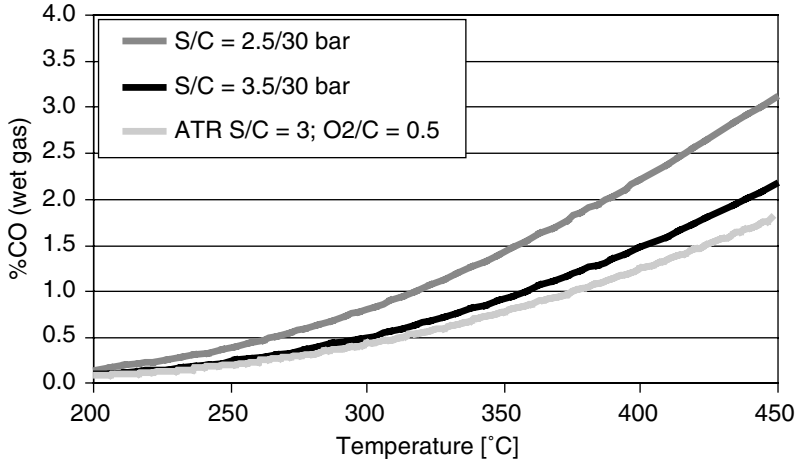

Fig. 1 WGS equilibrium curves for different reformates.

Pressure does not influence the equilibrium constant, since the same number of moles and therefore the same volume of gases exist on both side of the reaction equation.

Industrially, the shift reaction is run in adiabatic reactors.[7] Thus, there exists the dilemma of slow catalyst kinetics where the equilibrium is favorable (low temperature) and fast catalyst kinetics where the equilibrium is unfavorable (high temperature). This problem is solved by operating the reaction in one to three sequential reactors with inter-stage cooling and subsequently lower inlet temperatures.

Let us examine how the gas composition influences the WGS equilibrium CO concentration. If the feed gas comes from a steam reformer (SR) where methane and water react producing CO and hydrogen,

$$CH_4 + H_2O \leftrightarrow CO + 3H_2$$

the SR equilibrium CO concentrations are dependent on the steam to carbon ratio and pressure at which the reformer is run as well as the hydrocarbon feedstock. Some typical SR gas compositions are shown in Table 1 and the equilibrium gas composition for the WGS reaction is shown in Fig. 1.

The other methods of gas generation involve catalytic partial oxidation (CPO)

$$CH_4 + \tfrac{1}{2}O_2 \rightarrow CO + 2H_2$$

and autothermal reforming (a combination of CPO and SR). The CO concentration achievable using autothermal reforming (ATR) reformate as the feed gas are lower than with SR reformate, but the gas is diluted with ~25% nitrogen. The CO concentration in CPO feed gas can be as high as 50% and care has to be taken not to exceed the upper temperature limit of the catalyst due to the exotherm of the WGS reaction.

CATALYSTS, KINETICS, MECHANISMS, AND OPERATING WINDOWS

This section gives a brief overview of HTS and low temperature shift (LTS) catalyst formulations, their use in the water gas shift processes, as well as the reaction mechanisms and kinetics (Fig. 2).

Table 1 Typical reformate gas compositions of steam reformate and ATR reformate

Component	S/C = 2.5, 1 bar, 700°C exit temperature	S/C = 2.5, 30 bar, 850°C exit temperature	S/C = 3.5, 30 bar, 850°C exit temperature	S/C = 2.5, 30 bar, 850°C exit temperature
Feed gas	CH_4	CH_4	CH_4	Naphtha
CO	12.1	9	7.35	10.9
CO_2	5.9	5.3	5.7	7.5
H_2	60	48	44.85	43.3
CH_4	0.25	6.2	3.35	5.2
N_2	—	—	—	—
H_2O	21.75	31.5	38.75	33.1

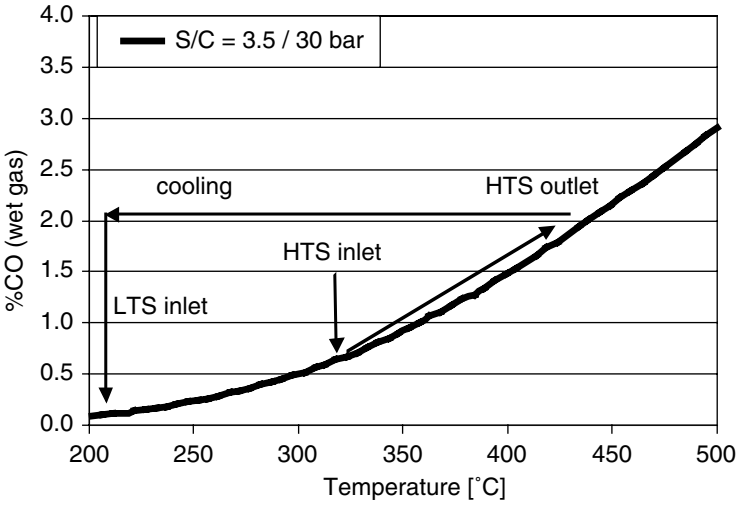

Fig. 2 Typical operating regime of HTS and LTS catalysts.

High Temperature Shift Catalysts

The first stage of the WGS process is HTS which operates at relatively high inlet temperatures, typically in the range of approximately 320–360°C.[6,7] These temperatures are dictated by the activities and selectivities of iron-chrome (or *ferrochrome*) catalysts that are being used in the HTS stage. In 90 years that have passed since its first use, the catalyst compositions and manufacturing procedures have gone through numerous changes to adopt the catalysts to new feedstocks (natural gas has now largely replaced coal) and process requirements (e.g., faster startup; high pressure), and to improve their activity.

HTS Catalyst Formulation

The HTS catalysts are typically produced by precipitation of aqueous solution of iron sulfate and chromium sulfate with sodium carbonate or sodium hydroxide, followed by careful washing to remove essentially all of the residual sulfate. Washing is an important step in the catalyst manufacture, since the residual sulfate converts into hydrogen sulfide when the catalyst is reduced during the process startup, and hydrogen sulfide is a poison to the LTS catalyst located downstream of the HTS bed.[8]

Addition of chromium is essential for stabilizing the catalyst activity over long periods of time on stream, which typically averages several years of continuous operation.[7,9] Chromium was reported to retard sintering of iron oxides in the catalyst under HTS reaction conditions, thus minimizing the loss of catalytically active surface.

Subsequent steps of the catalyst manufacture involve drying, calcining, and tabletting. Typically, tablets are 5–10 mm in diameter. Diffusion limitations to the reaction rate occur in the larger pellets increasingly above 350°C. However, larger pellets have superior strength. Therefore, the choice of the pellet size can be very important. After calcinations, the catalyst consists of approximately 90–95% Fe_2O_3 and 5–10% chromium oxides, which is predominantly Cr_2O_3 with some CrO_3 also present. The dominant phase in the freshly calcined catalyst is a solid solution of Cr^{3+} in α-Fe_2O_3 (hematite).[10] Cr^{+6} in the catalyst is undesirable because it represents a serious health hazard as a carcinogen. Besides, CrO_3 is water soluble and can leach out of the catalyst, e.g., if the WGS process steam condenses over the oxidized catalyst. In addition, reduction of CrO_3 to Cr_2O_3 is highly exothermic and can lead to overheating of the catalyst and activity loss due to sintering of the active phase. Therefore, the calcination step has to be carefully controlled to minimize the amount of Cr^{+6} in the catalyst.

The iron-chrome catalyst was improved by addition of Cu to increase activity and selectivity (by suppressing CH_4 generation).[8,11,12] The possible elimination of Cr from Fe-based WGS catalysts has also been addressed.[13] However, Fe–Cr catalysts have been used for a long time and a change of catalyst by industry will inevitably be slow.

Reduction of Iron-Chrome Catalyst in HTS Process

To become active, this catalyst needs to be reduced. The reduction converts α-Fe_2O_3 (hematite) into Fe_3O_4 (magnetite), which is the catalytically active phase, and CrO_3 reduces to Cr_2O_3. The reduction is typically performed during the HTS reactor startup, and it should be carefully controlled because of a significant heat release resulting from the exothermic

nature of the reactions involved, which may damage the catalyst:

$$3Fe_2O_3 + H_2 \rightarrow 2Fe_3O_4 + H_2O \quad \Delta H = -9.6\,kJ/mol$$

$$3Fe_2O_3 + CO \rightarrow 2Fe_3O_4 + CO_2 \quad \Delta H = -50.7\,kJ/mol$$

$$2CrO_3 + 3H_2 \rightarrow Cr_2O_3 + 3H_2O \quad \Delta H = -697.9\,kJ/mol$$

$$2CrO_3 + 3CO \rightarrow Cr_2O_3 + 3CO_2 \quad \Delta H = -821.3\,kJ/mol$$

Besides, over-reduction with formation of FeO and metallic iron should be avoided since these phases are not catalytically active in WGS and they catalyze undesired side reactions (i.e., methanation and CO disproportionation). Therefore, the reduction is always conducted in the presence of steam and with relatively low concentrations of the reductants in the process gas. Steam acts as a mild oxidant, thereby stabilizing the magnetite phase.

Fe–Cr HTS Catalyst Kinetics

The mechanism and kinetics of the WGS reaction over Fe–Cr catalysts have been the subject of numerous publications.[7,10,14–16] Despite intense investigations, still there is no full agreement as to the reaction mechanism. The two competing approaches are a redox (regenerative) mechanism first proposed by Kulkova and Temkin[17] as early as 1949 which presumes reduction of an oxide center (O) by a CO molecule yielding CO_2 and a vacant surface center (*), followed by reoxidation of the vacant center by water that produces hydrogen and regenerates the oxide center for the catalytic cycle.

$$CO + (O) \rightarrow CO_2 + (^*)$$
$$H_2O + (^*) \rightarrow H_2 + (O)$$

The alternative approach implies that adsorbed CO reacts with a surface hydroxyl group to yield a surface bound formate species.[18] The formate then decomposes in the presence of steam to CO_2 and H_2.

$$H_2O \rightarrow OH(ads) + H(ads)$$
$$CO(ads) + OH(ads) \rightarrow COOH(ads)$$
$$COOH(ads) \rightarrow CO_2 + H(ads)$$
$$2H(ads) \rightarrow H_2$$

The published evidence is overwhelmingly supportive of the redox mechanism,[6,7,19–22] although some authors still favor the adsorptive (associative) mechanism.[10,18] The existing discrepancy in conclusions probably results from differences in the experimental conditions employed in different studies such as temperatures, concentrations, and nature of catalysts.

The earliest kinetic equation published in the open literature was the one suggested by Kulkova and Temkin.[17] It was based on the hypothesis of the redox mechanism, with reduction of the oxide center (O) by a CO molecule being the rate-controlling step:

$$r = k_+P_{CO}(P_{H_2O}/P_{H_2})^{1/2} - k\_P_{CO_2}(P_{H_2}/P_{H_2O})^{1/2}$$

where r is the reaction rate, k_+ and k_- are rate constants for forward and reverse reactions, respectively, and P_i is the partial pressure of a given reactant.

A more accurate kinetic equation covering a broader range of process variables was later proposed by Shchibrya et al.[23] This equation was based on the same hypothesis of a redox mechanism but without rate-controlling steps.

In later years, a number of equations were suggested by different authors. A comprehensive analysis of kinetic equations published before 1980 can be found in Ref.[10] An alternative to the fundamental equations based on mechanistic concepts, e.g., proposed in Refs.[17,24], is an empirical equation of the following power-law type:

$$r = k(P_{CO})^a(P_{H_2O})^b(P_{CO_2})^c(P_{H_2})^d(1 - \beta),$$

where k is the rate constant, P_i is the partial pressure of a given reactant, a, b, c, d are the exponents, $\beta = P_{CO2}P_{H2}/K P_{CO} P_{H2O}$, and K is the WGS equilibrium constant.

The equations of the latter type, with the exponents determined under a sufficiently broad range of the process parameters, are good practical tools for describing the WGS process.

Low Temperature Shift Catalysts

The second stage in WGS processes is LTS, which was introduced in the industry in the 1960s and is now widely used in hydrogen plants. Rapid success of the LTS process was due to the use of copper-based catalysts that are more active at lower temperatures than iron-chrome HTS catalysts and therefore enable low equilibrium CO concentrations in the gas exiting the reactor, which increases the yield of the hydrogen production process.

Although copper-based catalysts have long been known to have good WGS activities, sensitivity of those catalysts to poisons that were present in the coal-derived gas precluded them from being employed industrially. It is only due to a massive change from coal gasification to hydrocarbon steam reforming which produces much purer synthesis gas, that copper-based catalysts entered the scene of WGS processes. Since

then, these catalysts have gone through significant improvements that have made them much more active and robust. However, the thermal stability of the LTS catalysts is still inferior to the HTS catalyst. This is why an HTS catalyst is needed. If the steam reformate containing approximately 10% CO enters an LTS catalyst, the WGS reaction exotherm would bring the exit temperature to unacceptable levels.

LTS Catalyst Formulations

The first industrially used LTS catalyst consisted of copper and zinc oxides,[7] and these components are still present in the catalysts that operate in today's plants. The latest formulations of LTS catalyst are significantly more active than their predecessor and have a much longer operating life. This progress was achieved by introducing additional components in the catalyst to stabilize small crystallites of copper (the active component) from sintering under the process conditions. In earlier versions of LTS catalysts an additional component was chromium,[23,25] later replaced by aluminum since Cu–Zn–Al oxide system has shown better stability. Today copper-zinc-alumina-based catalysts are widely used in the LTS stage of hydrogen plants. They are typically made from aqueous solutions of corresponding nitrates via continuous precipitation by sodium hydroxide, sodium carbonate, or ammonium bicarbonate under controlled pH.[6] The other operations in the catalyst manufacture include washing of the precipitate to remove sodium, followed by drying, calcination, and tabletting. Optimum content of copper oxide in the final Cu-Zn–Al catalyst is about one third of the total weight, while the amounts of zinc and aluminum oxides in different commercial catalysts vary. Thus, the catalysts produced by ICI were reported to have 53–34% ZnO and 15-33% Al_2O_3.[7] The pellet size varies by 3–8 mm in different commercial catalysts. Since the reaction is pore diffusion limited under most reaction conditions, the size and shape of the particles is optimized to give maximum surface area while still having the required strength and pressure drop.

Reduction of Copper-Based Catalysts in LTS process

Copper-based LTS catalysts are supplied to customers in their oxide form. Analogous to the iron-chrome HTS catalysts, LTS catalysts have to be activated by reduction prior to their use:

$$CuO + H_2 \rightarrow Cu + H_2O \qquad \Delta H = -80.8\ \text{kJ/mol}$$

Reduction of the catalysts can be a lengthy procedure for which experienced plant operators are needed.[7,8] For conventional LTS catalysts, adiabatic temperature rise resulting from the above reaction can be as high as 500–600°C. Such extreme temperatures are unacceptable for the LTS section primarily because of the catalyst sintering which occurs above approximately 260°C.[7] Therefore the reduction is always carried out using low concentrations of hydrogen and/or CO in inert gas such as nitrogen or natural gas, while carefully monitoring the catalyst bed temperatures and consumption of the reducing agent(s). The use of steam in the reducing gas is known to cause sintering of the copper crystallites decreasing the activity and shortening the catalyst lifetime. To achieve optimal performance of the catalyst, the reduction should be conducted in dry gas, and care should be taken not to exceed 260°C in the bed.

Cu-based LTS Catalysts Kinetics

Publications dealing with LTS over Cu-based catalysts offer even more conflicting opinions on the reaction mechanism than those considering Fe–Cr catalyzed HTS. Over the years, both redox and associative mechanisms have gained essentially equal support. When copper-based catalysts appeared on the industrial scene, the Cu-based LTS catalyst kinetics was found to obey equations similar to those proposed for HTS,[26] and initially that was the ground for conclusions about LTS occurring via redox mechanism. Further studies produced evidence both conflicting with this hypothesis[27] and supporting it.[22,28–31] It seems likely that depending on LTS process conditions and catalyst properties, the reaction can proceed either via associative or via redox mechanism.

SULFUR-TOLERANT WGS CATALYSTS

The use of Fe–Cr and especially Cu–Zn–Al WGS catalysts in present-day hydrogen plants is directly connected with moderate levels of sulfur-containing compounds in natural gas and naphtha that almost completely displaced coal as the feedstock. It is likely, however, that the incentives for the use of fossil fuels rich in sulfur can be revitalized in the future. If this scenario comes into play, sulfur-tolerant catalysts will be a must for WGS process. Such catalysts are already developed, but so far they have only found a limited use in some particular cases where feed gases with high concentrations of CO and sulfur compounds had to be converted. The best known of this type are cobalt-molybdenum compositions, which are usually supported over alumina and may be promoted with alkali

metals to increase their activity. These catalysts are completely sulfur tolerant; moreover, they have to be sulfided to show maximum activity. Sulfided cobalt-molybdenum catalysts are reported to operate between 230°C and 450°C. Good reviews on compositions and catalytic behavior of these catalysts can be found in the literature.[6,7,10]

NEW CATALYST DEVELOPMENTS FOR EMERGING APPLICATIONS

In recent years, the area of hydrogen production has seen the emergence of new trends stimulated by growing societal concern about environmental protection and efficient use of natural resources. In this aspect, hydrogen has solidly acquired the reputation of being the fuel of the future, with potential uses ranging from internal combustion engines to fuel cells. To meet these expectations, hydrogen fuel will have to become readily available to millions of customers, just like gasoline is at present. This goal requires some important changes to be implemented in the hydrogen industry. The major trend in those upcoming changes is that hydrogen has to be produced by converting fuels in numerous small-scale environmentally-benign and low-maintenance processes. This totally new approach requires new types of catalysts capable of withstanding frequent start–stops under harsh conditions when no special precautions common to the existing hydrogen plants will be available. Therefore new catalysts in particular must be much less prone to self-heating than the conventional WGS catalysts. In addition, the ''green'' image of the emerging applications implies that the new catalysts should be devoid of components harmful to humans and the environment. Development of such catalysts is briefly reviewed below.

Base Metal Catalysts

In developing water-gas shift catalysts for fuel cell applications, efforts have been primarily focused on the LTS rather than the HTS process, since the latter yields too high outlet CO concentration for subsequent CO clean-up steps. New base metal LTS catalysts have been developed specifically for the purpose of fuel processing for fuel cells.[32] These catalysts do not require special precautions during reduction of a fresh reactor charge, as well as during discharge of a spent catalyst. They are more resistant against frequent start–stops typical of fuel cell applications, where traditional Cu–Zn LTS catalysts deactivate because of water condensation on the catalyst or air exposure. However, their activity is somewhat inferior to that of the conventional Cu-Zn-Al catalysts.

Another type of LTS catalyst includes nitrides, carbides, and borides of Group VI and Group VIII metals, with molybdenum carbide apparently being the most active of this group.[33] Those are highly experimental catalysts and are not in production.

Precious Metal Catalysts

Precious metal-based (PM) catalysts have long been known to be active in WGS.[34] investigated catalytic properties of Pt, Ru, Pd, Os, and Ir supported over alumina, silica, and active carbon by running the WGS reaction at atmospheric pressure in the temperature range 270–380°C. They found that alumina-supported catalysts were the most active, with turnover frequencies of the metals at 300°C changing in the order $Ru > Pt > Os > Pd \approx Rh > Ir$.

In recent years, the interest toward PM catalysts has grown from essentially academic to much more practical, as a result of efforts to develop on-board fuel processors for cars. Operational conditions envisaged for such fuel processors preclude the existing Cu–Zn–Al catalysts from being applicable, while PM catalysts are believed to be a viable candidate. Platinum-based catalysts with a great variety of promoters, modifiers, and supports, as well as their preparation conditions seem to be most widely explored in research papers and patent applications. Pt supported on ceria containing support materials have been widely explored for the WGS reaction.[35–38]

In recent years, significant attention has also been given to gold-containing catalysts.[39,40] However, PM catalysts have not yet become an industrial reality, and different opinions regarding their viability have been expressed.[41,42] At present, these catalysts are still too expensive and their activity needs to be improved to assure good performance at low temperatures (~200°C). However, PM catalysts offer important advantages such as insensitivity to frequent start–stops, thermal stability, and operational safety. Besides, significant cost savings and environmental benefits can result from PM recycling.

Reaction Kinetics for Precious Metal Catalysts

Reaction orders and activation energies have been determined for Pt/ceria catalysts by several authors.[37,38,43] There is an agreement that the reaction order with respect to CO is approximately 0 at 200°C. Therefore high CO concentrations do not speed up the reaction for Pt-based catalysts at low temperature, as opposed to Cu-based catalysts which have approximately first-order kinetics. Activation energy estimates range from approximately 46 kJ/mol[37] to 80 kJ/mol.[34]

PRACTICAL ASPECTS

In industrial hydrogen and synthesis gas production, the WGS reaction is used to:

1. Adjust the CO/H_2 ratio for the specific purpose of the synthesis gas (methanol production, Fischer-Tropsch synthesis)
2. Increase the hydrogen yield of the process (i.e., ammonia synthesis; refinery hydrogen production)
3. Reduce the CO concentration to a level amenable to clean-up by preferential oxidation catalysts (fuel cell applications).

Water gas shift converters in industry are largely unchanged from their original design: adiabatic fixed bed reactors with particulate catalysts. There are only two kinds of these reactors in use in industry today: HTS and LTS. They differ in the operating temperatures and catalysts which they use. Two reactors are needed to convert the majority of CO, because of the equilibrium limitations of the process (see previous section). The inlet temperature of the HTS reactor is typically around 320°C. The outlet temperature rises to about 400–450°C because of the reaction exotherm. The gases are cooled to about 200°C before entering the LTS reactor, where the final 2–3% CO is partially converted to CO_2 and H_2.

HTS Reactors

The HTS reactor converts the majority of CO (from about 12% for SR plants to 45% for partial oxidation and coal gasification plants) to CO_2 and H_2 and experiences the majority of the 100–400°C exotherm associated with CO conversion. This conversion can be done in one step (for SR gas) or two to three steps with addition of quench water or inter-cooling (for high CO content gas, i.e., partial oxidation or coal gasification) because of the associated exotherm of CO conversion.[8] Inlet HTS temperatures are typically kept in the range of approximately 320–360°C, which is the compromise determined by such criteria as the catalyst activity, equilibrium outlet CO concentration, catalyst lifetime, reactor materials cost, etc. In particular, higher operating temperatures lead to a more rapid decrease in the catalyst activity due to sintering of magnetite (Fe_3O_4) crystallites, which accelerates with temperature. Typically, the lifetime of the iron-chrome HTS catalyst amounts to 3–5 years and depends on how the catalyst has been handled in a given plant. Aging of the catalyst requires the corresponding gradual increase of the reactor inlet temperature to compensate for the activity decrease. This increase has to be carefully controlled, since unnecessarily high temperature spikes can shorten the catalyst life. Despite all precautions, however, the exit CO concentration eventually gets to a too high level, which necessitates a replacement of the aged catalyst by a fresh charge.

The exit concentration depends on the inlet gas composition and temperature and usually lies between 1% and 4% (dry gas). The space velocity is kept between 500 hr^{-1} and 5000 hr^{-1}.

Poisoning of HTS Catalyst

The HTS catalysts in modern plants are fairly resistant against poisoning. The most common poison almost inevitably present in the feedstocks is sulfur. The iron-chrome catalysts are less sensitive to sulfur compared to the other catalysts used in hydrogen generation processes, such as steam reforming and LTS catalysts, therefore the levels of sulfur-containing compounds in the feed gas that are tolerant for those catalysts do not affect the activity of the HTS catalyst. Moreover, the HTS catalysts, even if sulfided with Fe_3O_4 being converted into FeS (this may occur in the coal-based processes where high concentrations of sulfur-containing compounds are common), still retain the WGS activity at about one half that of Fe_3O_4.[7] For this reason the iron-chrome HTS catalyst is a good choice in processes where high concentrations of sulfur-containing compounds in the feed gas can be anticipated. It also serves as a sulfur guard bed for the more expensive Cu-Zn catalyst.

Other known chemical poisons for the HTS catalyst are halides, although under normal operating conditions they are not present in the feed at an appreciable concentration. Decay in the catalytic activity was also observed with the feed gas which contained minor amounts of unsaturated hydrocarbons, oxygen, and nitric oxides.[7] Under the HTS conditions these compounds were converted into a heavy carbonaceous residue deposited on to the surface of the catalyst, blocking access of the reactants to the catalytic surface.

Commercial HTS catalysts are mechanically quite strong. However, in an industrial process environment, the HTS catalyst can suffer from mechanical factors that deteriorate its performance, such as steam condensation leading to a gradual disintegration of the catalyst pellets, and deposition of foreign components (e.g. particulate matter from corrosion of the process equipment). Increase in the pressure drop across the catalyst bed resulting from these factors is yet another factor determining the catalyst lifetime.

Discharge of HTS Catalyst

The HTS catalyst deactivated beyond an acceptable level has to be discharged from the reactor and

replaced by a fresh charge. Due to a highly exothermic reoxidation of the magnetite phase

$$2Fe_3O_4 + \tfrac{1}{2}O_2 \rightarrow 3Fe_2O_3$$
$$\Delta H = -232.2 \text{ kJ/mol}$$

which results in an adiabatic temperature rise of approximately 450°C, the reduced catalyst should not be exposed to air unless special measures are taken to avoid dangerous overheating. Thus, on the reactor cool down, the catalyst is usually kept under a reducing or inert atmosphere, then discharged under nitrogen and slowly oxidized by gradually admitting air into the catalyst storage vessel. Another procedure for safe catalyst discharge includes filling up the cooled reactor with water and removing the wet catalyst.

Sulfided catalyst must be handled with exceptional precautions, since oxidation of iron sulfide is extremely exothermic:

$$6\,FeS + 13\tfrac{1}{2}O_2 \rightarrow 2\,Fe_2(SO_4)_3 + Fe_2O_3$$
$$\Delta H = -5379 \text{ kJ/mol}$$

Therefore the sulfided catalyst initially needs to be steamed to convert the sulfide into magnetite.

Operation of LTS Catalyst

Temperature dependence of the equilibrium CO concentrations and sintering of copper crystallites (the active phase) at elevated temperatures dictate that the LTS stage be operated at the lowest possible temperature. It is common practice to keep the inlet temperature at least at about 20°C above the dew point of the feed gas, which can be as high as 180–200°C. If water condenses on the catalyst, it can lead to breakage of particles and deactivation of the catalyst.

The catalyst bed temperature increases in the direction of gas flow due to the WGS reaction exotherm. Typical temperature gradients in the bed are about 20–30°C. The lifetime and state of activity of the catalyst is conveniently monitored by the temperature profile through the adiabatic bed. As the reaction front moves through the bed when the catalyst ages, so does the temperature rise from the reaction (Fig. 3).

Poisoning of LTS Catalysts

The lifetime of the LTS catalysts in industrial processes is about 3–4 years. During this time, the catalyst slowly loses its activity due to inevitable sintering and poisoning of copper. To be able to compensate for deactivation and to operate the LTS stage for at least 3 years with required low outlet CO concentrations, the actual charge of LTS catalyst is always overestimated by a factor of about three or more, relative to the amount that would be needed if the activity did not decrease. Sulfur- and halide-containing compounds, the known poisons for copper-based LTS catalysts, gradually decrease the activity even if their concentrations in the feed are very low. The sensitivity to these substances for many years precluded copper-based catalysts from being used in industrial WGS processes. It is only with the massive transfer of hydrogen industry from coal gasification to steam reforming of natural gas and other hydrocarbons, which produces much cleaner gas, that copper-based LTS catalysts became a viable option. The effects of poisons on Cu-based LTS catalysts is described in detail in Refs.[7,8].

Another problem is the formation of methanol over the LTS catalyst. The methanol accumulates in the process condensate and in the gas entering the CO_2 removal system.[44] Therefore, emissions from the plant can become an environmental concern. Catalysts doped with Cs have been developed to address this problem.[44,45] These catalysts reduce the production of methanol by nearly 90%.

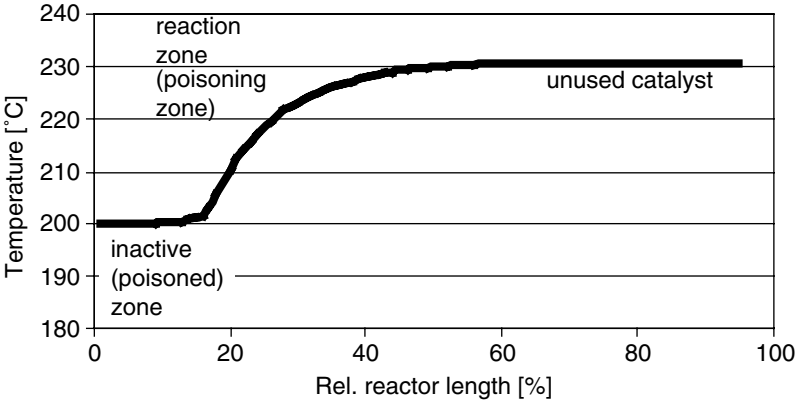

Fig. 3 Typical temperature profile through an LTS bed.

Table 2 Catalyst requirement for different H_2 generation applications

Catalyst properties	Industrial H_2 generation	Small scale H_2 generation
Cost	Very important	Important
Size (volume)	Important	Very important
Sensitivity to water condensation	Accommodated by process	Insensitivity required
Sulfur tolerance	Desired	Desired
Attrition resistance	Important	Important
Reduction requirements	Accommodated by process	Use of process gas
Air sensitivity	Accommodated by process	Insensitivity required

Discharge of LTS Catalyst

After several years of operation at the LTS stage, the CO level at the reactor exit begins to increase due to catalyst deactivation. This signals the need for the catalyst to be replaced and the plant shut down. Discharge of a spent catalyst from the reactor requires special precautions due to the strongly exothermic character of its reoxidation by air, which may generate an exotherm as high as 800–900°C, unless special measures are taken to moderate the temperature rise. Therefore, the common LTS catalyst discharge procedure includes purging the reactor with nitrogen, while cooling it down to below 50°C, followed by the discharge under nitrogen flow with immediate spraying of the catalyst with water to prevent rapid reoxidation. An alternate procedure for a safe catalyst discharge is analogous to the one employed for HTS catalysts and includes filling up the cooled reactor with water and removing the wet catalyst.

SIZE VERSUS COST—NEW CATALYSTS FOR ON-SITE H_2 GENERATION AND FUEL CELL REFORMERS

The industrial means of hydrogen production for methanol synthesis, ammonia synthesis, Fischer-Tropsch synthesis, and refinery hydrogen production have one thing in common: they are tightly controlled processes, run by trained plant operators in an industrial setting.[46] For the emerging applications in hydrogen production, such as fuel cells and small-scale hydrogen production, the operating conditions are different. Often, fuel processors and small hydrogen generators will be operated by inexperienced personnel.[5] Moreover, the typical "duty cycle" of operation for the catalyst is very different. For most industrial processes, this duty cycle consists of continuous steady-state operation with infrequent plant shutdowns. These planned shutdowns are tightly controlled by trained plant personnel and the catalyst is cautiously treated so that it retains its

Table 3 Limitation of WGS catalysts compared to new PM monoliths

	HTS catalyst (FeCr)	LTS catalyst (CuZn)	PM catalyst
Form	3–10 mm pellets	3–6 mm pellets	Monolith supported
Activity	Not active below ~350°C	High activity starting below 200°C	Highly active above 250–300°C
Thermal stability	Thermally stable to ~500°C	Loss of activity above ~260–280°C	Thermally stable to >400°C
Space velocity	<8,000 h^{-1}	<6,000 h^{-1}	>20,000 h^{-1}
Poisons	Low sensitivity to sulfur	Deactivates upon exposure to sulfur and halogens	Tolerant to some poisons
Other considerations	Self-heating material in the reduced state Cr(VI) can be present Inexpensive material Insensitive to sulfur; used to polish sulfur to very low levels	Needs to be carefully reduced Self-heating material in the active (i.e., reduced) state Deactivates by water condensation and air exposure Needs careful discharge from the reactor (self-heating catalyst) Reaction is diffusion limited	Insensitive to start-stop and air exposure No need for pre-reduction Kinetics limit usefulness of the catalyst below 250°C

activity after restart. Industrial startup/shutdown procedures may involve purging with nitrogen and preheating the catalyst bed before restart.

On the other hand, in fuel cell applications, the H_2 generator (reformer) is often tied to the demand for electricity or hot water and therefore operation at night is often not required. These systems may shut down daily (for home systems) or weekly (for small businesses). At night, there is no plant operator available to monitor the proper shutdown and startup conditions. Therefore the catalyst has to be able to withstand repeated water condensation, to ensure fast startup and to respond well to transient conditions due to changing hydrogen demand.

The size of catalytic reactors is a factor of minor importance compared to catalyst and process cost in the industrial environment. This changes as we look at potential future applications of hydrogen production: fuel cell reformers, hydrogen filling stations and on-site hydrogen generation. In some of these applications, size, simplicity, and durability are equally or even more important than minimal cost.

Table 2 compares requirements for the catalysts in industrial hydrogen generation with small-scale production of hydrogen. Table 3 compares the properties of Fe–Cr and Cu–Zn with new precious metal catalyst formulations on monolith supports. A clear match can be seen between the desired properties of catalysts for small-scale H_2 production and actual properties of precious metal catalysts.

CONCLUSIONS

Water gas shift catalysis has been practiced for 90 years in hydrogen and syngas production. High- and low-temperature WGS is run in industry in adiabatic reactors using Fe–Cr– and Cu-Zn-based formulations. The established catalysts have not changed dramatically in the last 40 years, but continue to improve marginally.

New applications for WGS catalysis are slowly emerging. These are small-scale hydrogen production and fuel cell reformers. For these new applications, a new generation of catalysts, including precious metal-based monolith catalysts, is being developed, since the traditional catalysts do not fit the application profile (duty cycle, size and safety requirements).

Sulfur-tolerant shift catalysts have been developed, but are not being used because of the development of other sulfur-sensitive technologies and their higher cost as compared to traditional catalysts.

INTRODUCTION

With the increasing world population and limited water resources, water reclamation is becoming increasingly important in providing and maintaining sustainable water supplies. Water reclamation may be defined as the treatment of wastewater to make it suitable for one or more beneficial uses. One of the most important water treatment technologies used in water reclamation is membrane technology. Therefore, this entry is focused on membrane technology and its use for water reclamation.

Membrane technology used in water reclamation includes five major membrane types: reverse osmosis, nanofiltration, ultrafiltration, microfiltration, and liquid membranes. These five types of membranes are discussed briefly, and examples of their applications in municipal and industrial wastewater reclamation is also described.

REVERSE OSMOSIS MEMBRANES

When two saline solutions are separated by a semipermeable membrane, water will pass through the membrane from the side with lower salt concentration to the side with higher salt concentration. This spontaneous passage of water is called osmosis. One of the most important examples of osmosis is transport of water through cell membranes. The driving force of the osmosis process is the gradient of the chemical potential across the membrane. The water passage across the membrane continues until the chemical potential of the water is equal on both sides. At equilibrium, the pressure difference between the two sides of the membrane is equal to the osmotic pressure difference. As a rule of thumb, every 100 mg/L of dissolved salts produces roughly 1 psi of osmotic pressure.

If a pressure higher than the osmotic pressure difference is applied to the side with high salt concentration, the water flow can be reversed. This process is termed reverse osmosis (RO), also known as hyperfiltration. This phenomenon makes the separation of water from saline solution possible. Fig. 1 provides a schematic drawing of the osmosis and reverse osmosis processes.

Reverse osmosis membrane is a semipermeable membrane, which is permeable to water but not to other species, such as dissolved salts. The observed salt rejection R of an RO membrane is defined as

$$R = 1 - c_p/c_f$$

where c_f is the solute concentration in the feed and c_p is the solute concentration in the permeate.

Reverse osmosis membranes are usually synthetic membranes and are made of polymers. Depending on their structures, RO membranes can be classified as either asymmetric or composite.

An asymmetric membrane has a very thin dense top layer (or skin) with a thickness of 0.1–0.5 μm. A porous sublayer with a thickness of approximately 50–150 μm supports the dense top layer. The thin dense skin facing the feed solution acts as the selective layer, allowing water passage but rejecting dissolved solids. The resistance to mass transfer across the membrane is also mainly determined by the thin top layer. In asymmetric membranes, the selective top layer and the porous support layer are made of the same polymer material. Asymmetric membranes can be obtained by phase inversion, a technique in which a polymer in solution is transformed in a controlled manner from a liquid into a solid form. The top skin layer and the porous support layer are formed in a single-step process.

In composite RO membranes, the selective top layer and the porous support layer are usually made of different polymeric materials. The selective top layer is formed on the porous support in a second step, typically by an interfacial polymerization reaction.[1] For example, a commercially available thin film composite RO membrane is made by coating a porous polysulfone support with a polyamide thin film formed by the interfacial reaction of *m*-phenylenediamine and 1,3,5-benzenetricarbonyl trichloride. Details regarding membrane structures can be found elsewhere in the

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016186

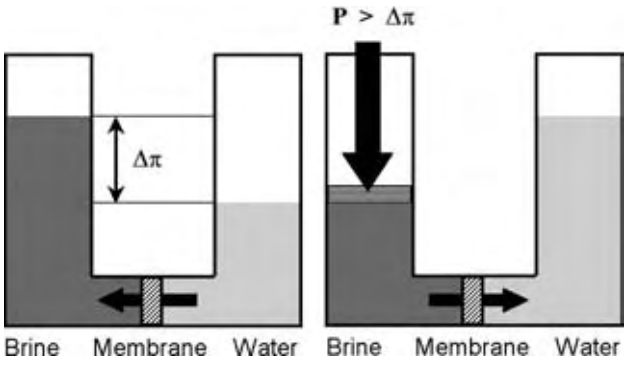

Fig. 1 Schematic of osmosis and reverse osmosis processes.

literature.[2–4] A schematic diagram of a thin film composite membrane is provided in Fig. 2.

Reverse osmosis membranes can be further classified according to their applications or processes as either seawater (SW) membranes or brackish water (BW) membranes. Seawater membranes are high-pressure membranes because seawater desalination is carried out at high feed pressure (5.5–10 MPa). Seawater membranes have very high salt rejection (>99.5% NaCl rejection) and moderate water flux. Brackish water membranes, on the other hand, are low-pressure membranes. The operating pressure of BW membranes is usually between 1.4 and 4.0 MPa. The inorganic salt rejection of BW membrane is approximately 95–99.5%, and the water flux is higher than that of SW membrane. When RO membranes have fixed charge groups (such as carboxylate anions), improved salt rejection can be obtained by means of Donnan exclusion. In principle, RO membrane is suitable for treatment of organic as well as aqueous solutions. However, problems with membrane stability under actual operation conditions make organic solvent applications very limited.

Among others, spiral-wound and hollow-fiber modules are two commonly available RO membrane products on the market. Currently, spiral-wound modules have approximately 80% of the total RO membrane market. Thin film composite membrane

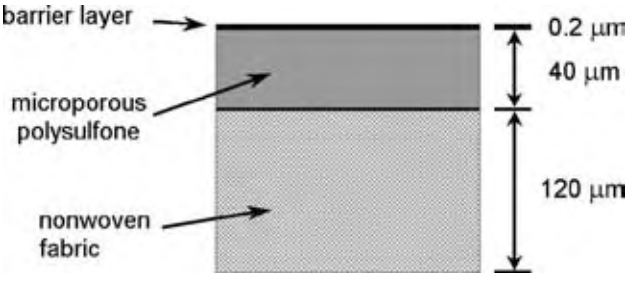

Fig. 2 Schematic diagram of a thin film composite membrane.

is usually sold in spiral-wound modules. Two flat membrane sheets are glued (sandwiched) together with a product spacer (permeate spacer) in between to form an envelope. The envelope is sealed on three sides with the fourth open side attached to a product tube. Many of these envelopes are then rolled around a product tube, with feed spacers between the facing membrane surfaces. Under pressure, the feed stream enters the module from one end and exits from the other end. The product water is collected from the center tube. Fig. 3 provides a cutaway view of a spiral-wound module.

Reverse osmosis membrane is widely used in seawater and brackish water desalination processes. Compared to traditional distillation, there is no energy-intensive phase change involved in membrane processes. Therefore, desalination with RO membrane is more energy efficient. In addition to the traditional desalination processes, RO membranes have also found wide application in industrial and municipal wastewater treatment, in pure water production for the electronic and pharmaceutical industries, and in the food industries.

Current RO membrane research is focused mainly on improving membrane performance and membrane resistance to fouling. Fouling is the deposition of components from the feed stream onto the membrane surface, which reduces membrane flux. Membrane fouling is a major obstacle for the efficient use of membrane technology. Membrane fouling can dramatically reduce process efficiency and, ultimately, also shorten membrane life. Methods to improve fouling resistance of membranes include chemical modifications of membranes and improvements in module design. The membrane surface can be modified to suit specific applications. For instance, making the membrane surface more hydrophilic will improve membrane biofouling characteristics; a smooth surface will reduce the tendency of particle deposition onto the membrane surface. Introducing surface charge is found to be helpful in certain types of applications. Because most colloidal particles, proteins, and cells are negatively charged in aqueous solution, one can expect that membrane with negative charges will be more fouling resistant.[5]

Another area of continuing interest and need is to provide RO membranes having high flux at low pressure, while maintaining high solute rejection characteristics.[6,7] The major advantages of using such membranes are low energy consumption and low equipment cost. Compared to the first generation of asymmetric cellulose acetate RO membranes operated at 3 to 4 MPa, current low-pressure RO membranes can be run at approximately 1 MPa. Research efforts to further enhance the permeation rate of RO membranes and reduce energy requirements are ongoing.[8–10]

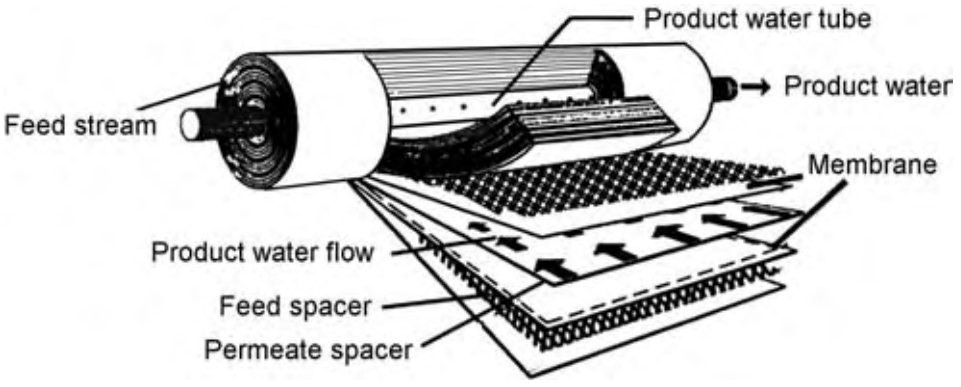

Fig. 3 Cutaway view of a spiral-wound membrane module.

NANOFILTRATION MEMBRANES

Nanofiltration (NF) membrane is a category of membrane between reverse osmosis and ultrafiltration (UF). An NF membrane can reject organic molecules with molecular weights (mol wt) in the range of 300 to 1000, a lower range that can be separated by UF. However, NF membranes typically have much higher flux than RO membranes at low pressures (0.5 MPa or lower), and they have lower rejection than RO membranes for neutral molecules below 150 mol wt and for monovalent inorganic salts.[11] For example, the NaCl rejection of most NF membranes is in the range of only 30–90%.

Most NF membranes have a large concentration of negatively charged groups, such as carboxylate ions, covalently bonded to their surfaces. These surface anions give NF membranes a high rejection for salts with multivalent anions, such as sulfates, carbonates, and phosphates. Nanofiltration membranes are commonly used as water softening membranes, because they can very effectively remove most hard water components, i.e., carbonates and sulfates of calcium and magnesium. NF membranes designed for this purpose are usually rated in terms of their $MgSO_4$ rejection, which is typically in the range of 95–99%.

Other applications of NF membrane include organics removal from surface water, radium removal from ground water, sulfate removal from seawater, and food and pharmaceutical applications such as concentration of dilute solutions and desalting of cheese whey.

Like RO membranes, many NF membranes are polyamide thin film composite membranes. These membranes can be prepared by interfacial reaction of piperazine with 1,3,5-benzenetricarbonyl trichloride and/or isophthaloyl dichloride, or by treating polyamide thin film composite RO membranes with compounds such as mineral acids, to increase their flux and lower their salt rejection.[2] A few ceramic NF membranes have also been developed. New methods to produce NF membrane are a subject of ongoing research, as exemplified by two recently reported methods: filling the pores of microfiltration (MF) membrane with cross-linked poly(4-vinylpyridinium) salts,[12] and grafting charged groups onto the surface of UF membrane.[13]

ULTRAFILTRATION AND MICROFILTRATION MEMBRANES

Ultrafiltration and microfiltration membranes are both porous membranes but with two different ranges of pore size. Microfiltration membranes are used to separate particles in the range of 0.02–10 μm. Ultrafiltration membranes are used to remove much smaller species, such as dissolved macromolecules and colloids with 1000–500,000 mol wt.

Ultrafiltration membranes have pore diameters in the range of 1–100 nm and separate primarily by size exclusion. In this process, a liquid containing dissolved or suspended matter is driven through the membrane by an applied pressure difference across the membrane, and any species larger than the pore size of the membrane is rejected (prevented from passing through the membrane). The observed rejection R of a species is given by

$$R = 1 - c_p/c_r$$

where c_p is the concentration of the species in the permeate liquid that passes through the membrane, and c_r is the concentration of the same species in the retentate stream, which remains on the feed side of the membrane.

The pore size of a UF membrane is described by its nominal molecular weight cutoff (MWCO), defined as the molecular weight of the smallest species for which the rejection is 90% or greater. Although the nominal

MWCO is a useful measure of a membrane's average pore size, it is only an approximate indication of how a UF membrane may perform in a given application. In reality, the rejection level for a solute molecule depends not only on its molecular weight, but also on its shape, its molecular orientation, and operating conditions such as feed pressure and solute concentration. To eliminate the effect of molecular orientation in MWCO measurement, spherical macromolecules such as globular proteins are recommended as test solutes. Although there is at present no generally accepted standardization of the procedure for MWCO measurement, the factors that affect the measurement have been reviewed in detail, and recommended operating conditions have been proposed.[14]

Two phenomena that complicate UF processes are concentration polarization and fouling. During filtration, the solution upstream of the membrane becomes enriched in the retained molecules or particles. At high permeation flux rates, mixing and diffusion in the upstream liquid might not be rapid enough to maintain uniform concentration, resulting in a layer of highly concentrated solution next to the membrane. This effect is called concentration polarization, and it leads to lower flux and lower apparent rejection, because the effective solute concentration at the membrane surface is higher than that of the bulk solution. Fouling is the deposition of components from the feed stream onto the surface and in the pores of the membrane, which can cause total pore blockage or an effective reduction of pore diameter, and leads to lower flux and in some cases, increased rejection. Fouling can be partially reversed by membrane cleaning, but some fouling is also irreversible, eventually making membrane replacement necessary.

Although some inorganic membranes are available, most UF membranes are made of polymers. The earliest UF membranes were made of cellulose acetate, but today, the most widely used polymers are polysulfone and polyethersulfone, which are preferred because of their higher resistance to extremes of pH and temperature. Other polymers used include polyvinylidenefluoride, polyacrylonitrile, and polyamides.[15]

Most UF membranes are asymmetric, having a thin separating layer or ''skin layer'' with small pores on one side of the membrane, and a much thicker layer with larger pores below the membrane which provides structural support with minimum flow resistance. Asymmetric membranes are manufactured by wet phase inversion casting. In this process, a casting solution of a polymer in a water-miscible solvent is spread in a thin layer onto a flat surface and then immersed in water. The water causes extraction of solvent and precipitation of the polymer as a porous flat sheet. The skin layer is formed on the upper surface that was in direct contact with water, and the underlying porous structure has progressively larger pores with increasing distance from the skin layer. The skin layer pore size and MWCO are determined by the casting solution formulation (polymer concentration, type of solvent, and additives) and by the phase inversion casting process conditions.

Flat sheet UF membrane is usually manufactured with a polyester or polyolefin nonwoven fabric backing for added durability, and membrane sheets are rolled into spiral-wound membrane modules (see Fig. 3). Ultrafiltration membranes are also commonly manufactured as hollow membrane fibers and sold as modules containing bundles of fibers. Both spiral-wound and hollow fiber membrane modules are usually operated in crossflow filtration mode, wherein the feed liquid flows tangential to the surface of the membrane under pressure. The high tangential feed velocity helps to sweep particles away from the membrane surface and reduce concentration polarization and fouling. In crossflow filtration, only a portion of the feed passes through the membrane and the remaining liquid exits as a separate retentate stream, carrying rejected components away and out of the membrane module.

Microfiltration membranes are similar to UF membranes but have larger pores. Microfiltration membranes are used to separate particles in the range of 0.02–10 μm from liquid or gas streams. Commercial MF membranes are made from a wide variety of materials including polymers, metals, and ceramics. A wide variety of membrane module designs are available including tubular, spiral wound, pleated sheet, hollow fiber, and flat sheet designs. Some modules are best suited for crossflow filtration,[16] and others are designed for dead-end filtration.[17] In dead-end filtration, the feed liquid flows normal to the surface of the membrane, and retained particles build up with time as a cake layer on the membrane surface or within the pores of the membrane.

LIQUID MEMBRANES AND FACILITATED TRANSPORT MEMBRANES

Liquid membranes are ultra-thin films of water or an organic liquid that are stabilized by the presence of surfactant molecules and other additives. This film is placed between two miscible phases: one is a feed phase, and the other is a phase receiving the materials that are transferred from the feed phase through the membrane phase. This means that if the feed and the receiving phases are both aqueous, an organic liquid membrane will be needed, whereas if the feed and the receiving phases are organic, the liquid membrane will need to be aqueous. In commercial applications, liquid membranes are prepared via emulsion techniques as agglomerations of micrometer-sized droplets.

This emulsification technique aims to maximize membrane surface area. The internal phase of the droplets can be placed inside the pores of polymeric films, or inside hollow fibers.[18–21] The membrane phase can contain surfactants or no surfactants for easy coalescence. This aspect of the liquid membrane system will be discussed in more detail in the application section.

The transfer of materials through liquid membranes is based on two facilitated transport mechanisms. In the type 1 facilitation, the solute reacts with a reagent dissolved in the receiving phase, or the internal phase in an emulsion liquid membrane system. This reaction should be selected so that it produces a nonpermeating compound. The purpose is to effectively reduce the concentration of the solute to zero in the receiving phase, thereby facilitating the continuous transfer of the materials. The type 2 facilitation uses a complexing agent for the transferred compound in the membrane phase. The complexing agent reacts with the transferred compound inside the membrane phase to form a complex, which permeates through the membrane phase to the receiving phase, or the internal phase in an emulsion liquid membrane system. The transfer through the membrane phase is based on the concentration gradient of the complex molecules, and the decomplexation at the interface between the membrane and the receiving phase is based on a counter-diffusion of ions. The counter-diffusing ions from the receiving phase are usually either hydrogen ions or hydroxide ions from the acid or base materials placed in the receiving phase (Fig. 4). The facilitated transport will stop when the amount of the acid or base material is consumed.[21–23]

There have been several modified systems since the invention of liquid membranes, including a facilitated transport mechanism. One of them is to disperse the receiving solution in an organic membrane phase on one side of a porous hollow fiber.[24,25] Two plants to treat contaminated groundwater were built and operated based on this revised liquid membrane system. More discussion about this application is given below in the application section.

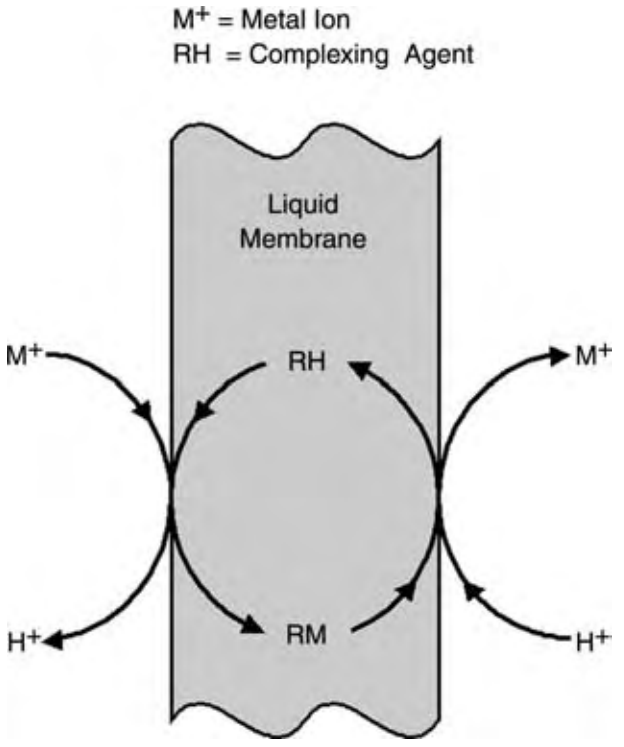

Fig. 4 Facilitated transport in a liquid membrane system with complexing agent in the membrane phase and acid in the receiving phase.

MEMBRANE PROCESSES FOR WATER RECLAMATION

With world population increase and scarcity of water sources, the key to providing a sustainable development of water resources is to carry out water reclamation. The concept of water reclamation is to treat wastewater from different sources to meet different water quality requirements of various water applications economically. USEPA provided guidelines for nonpotable water reuse,[26] which stated various conventional technologies commonly used in treating municipal wastewater such as primary and secondary treatment, and specified the water quality level required for various applications such as irrigation, industrial cooling processes, and groundwater recharge. As for industrial wastewater reuse, the American Institute of Chemical Engineers Center for Waste Reduction Technologies published a book[27] to provide guidelines for a systematic approach, which was summarized by Zinkus.[28]

With the advancement of membrane technologies and engineering in the integration of MF, UF, NF, and RO membrane systems, and possibly a liquid membrane system, wastewater reclamation can provide high quality water for underground water replenishment and direct household nonpotable use, and source water for ultra-pure water applications. Membrane technology provides several advantages over conventional treatment processes:

1. It is simpler to apply in treating a wide range of contaminants in wastewater effectively.
2. A membrane system occupies a smaller footprint. Efficient use of floor space is critical in meeting the future expansion needs of municipal wastewater treatment plants, which are typically located within densely populated areas.
3. Modular design of membrane treatment systems allows easier future expansion.
4. Less coagulation or flocculation chemicals are required in the treatment processes.

Membrane technology will play a major role in water treatment and wastewater reclamation, as indicated in *Desalination and Water Purification Technology Roadmap*,[29] and will require continued research and development in:

1. reducing the operational cost of membrane systems;
2. enhancing membrane fouling resistance to reduce membrane cleaning frequency; and
3. providing better on-line monitoring of membrane module and system integrity to ensure a 100% safety barrier in rejecting bacteria and viruses.

It should be noted that, in developing a membrane process for treating a specific type of wastewater efficiently and effectively, the Six Sigma quality management program was suggested to be incorporated in the development process.[30]

Municipal Wastewater Reclamation

In the Orange County Sanitary District of California, the wastewater treatment plant (Fig. 5) treats approximately 200 million gallons per day (MGD) of municipal wastewater through preliminary treatment (bar screens and grit processing to separate solid waste from wastewater), primary treatment (a physical/chemical treatment process to settle small solids), and secondary treatment (an aerobic bio-treatment process consisting of trickling filter and activated sludge plants to treat dissolved matter with activated sludge). Effluent from secondary treatment is discharged into the ocean. Because of excessive exploitation of underground water in this area, however, a barrier to prevent seawater intrusion was necessary. In 1976, Water Factory 21 was built to provide highly treated (purified) water as this water barrier. This treatment plant reclaimed 15 MGD of the secondary treatment effluent from Orange Country Sanitary District's wastewater plant by pretreatment (flocculation, recarbonation, and multi-media filtration), followed by division into two treatment processes: 6 MGD was purified by an RO membrane system, and 9 MGD was treated with activated carbon and disinfected with chlorine. This highly treated wastewater (with quality of potable water) was then blended with underground water before being injected into the ground as a water barrier for seawater intrusion prevention.

To provide a sustainable water resource in Orange County, a 100,000 acre-foot per year Ground Water Replenishment System (GWRS) was proposed[31] on the basis of the success of the Water Factory 21 project. Because of limitations in land space available to this treatment plant, a new pretreatment process using a membrane system (MF and UF system) was tried and approved by virtue of its superior performance, cost effectiveness, and smaller footprint than the conventional pretreatment process.[32] The first phase of GWRS, a 71,600 acre-foot wastewater reclamation project using a new integrated membrane process consisting of an MF system followed by an RO system, and last by a UV disinfection system, has been under construction since 2001.

Membrane technology also shows its potential in replacing the secondary activated sludge treatment step. Although using a membrane system as a replacement for sedimentation in the activated sludge process was tried in the late 1960s, current membrane bioreactor (MBR) systems provide more robust engineering design to overcome membrane fouling.[33] Compared to the conventional activated sludge process, the MBR provides complete solids removal, a significant disinfection capacity, high treatment rate, and high efficiency of organic and nutrient removal. Therefore, the MBR strengthens the future role of membrane systems in wastewater recycling and reuse applications. Currently, more than 500 commercial MBR systems are in operation worldwide.

Industrial Wastewater Reclamation

In addition to wastewater effluent treatment regulations as a driving force for industrial wastewater treatment, other factors such as water and wastewater management costs, operation costs, and recovery and recycle of processing chemicals play critical roles in determining industrial wastewater reclamation needs and treatment processes.

With 16 million tons/day of water usage, the paper and pulp industry in the USA generates enormous wastewater pollution problems.[34] Characteristics of wastewater from pulp and paper are high BOD and COD, and high suspended solids content. The industrial "end of pipe" abatement approach is to treat all wastewater together, using primary treatment to settle the solids and to biological processes such as activated sludge to reduce BOD and COD content. Industry has tried membrane technology to reclaim wastewater, thereby reducing water consumption and wastewater pollution. Without significant pretreatment of wastewater, however, traditional hollow fiber, spiral-wound, or tubular membrane modules would be fouled within a very short time. Nuortila-Jokinen[35] used shear enhanced membrane modules to overcome the membrane fouling problem, thereby allowing membrane processes to treat and reuse pulp mill effluent effectively. Shear enhanced membrane modules used a vibration or spinning force to produce 150,000 s^{-1}

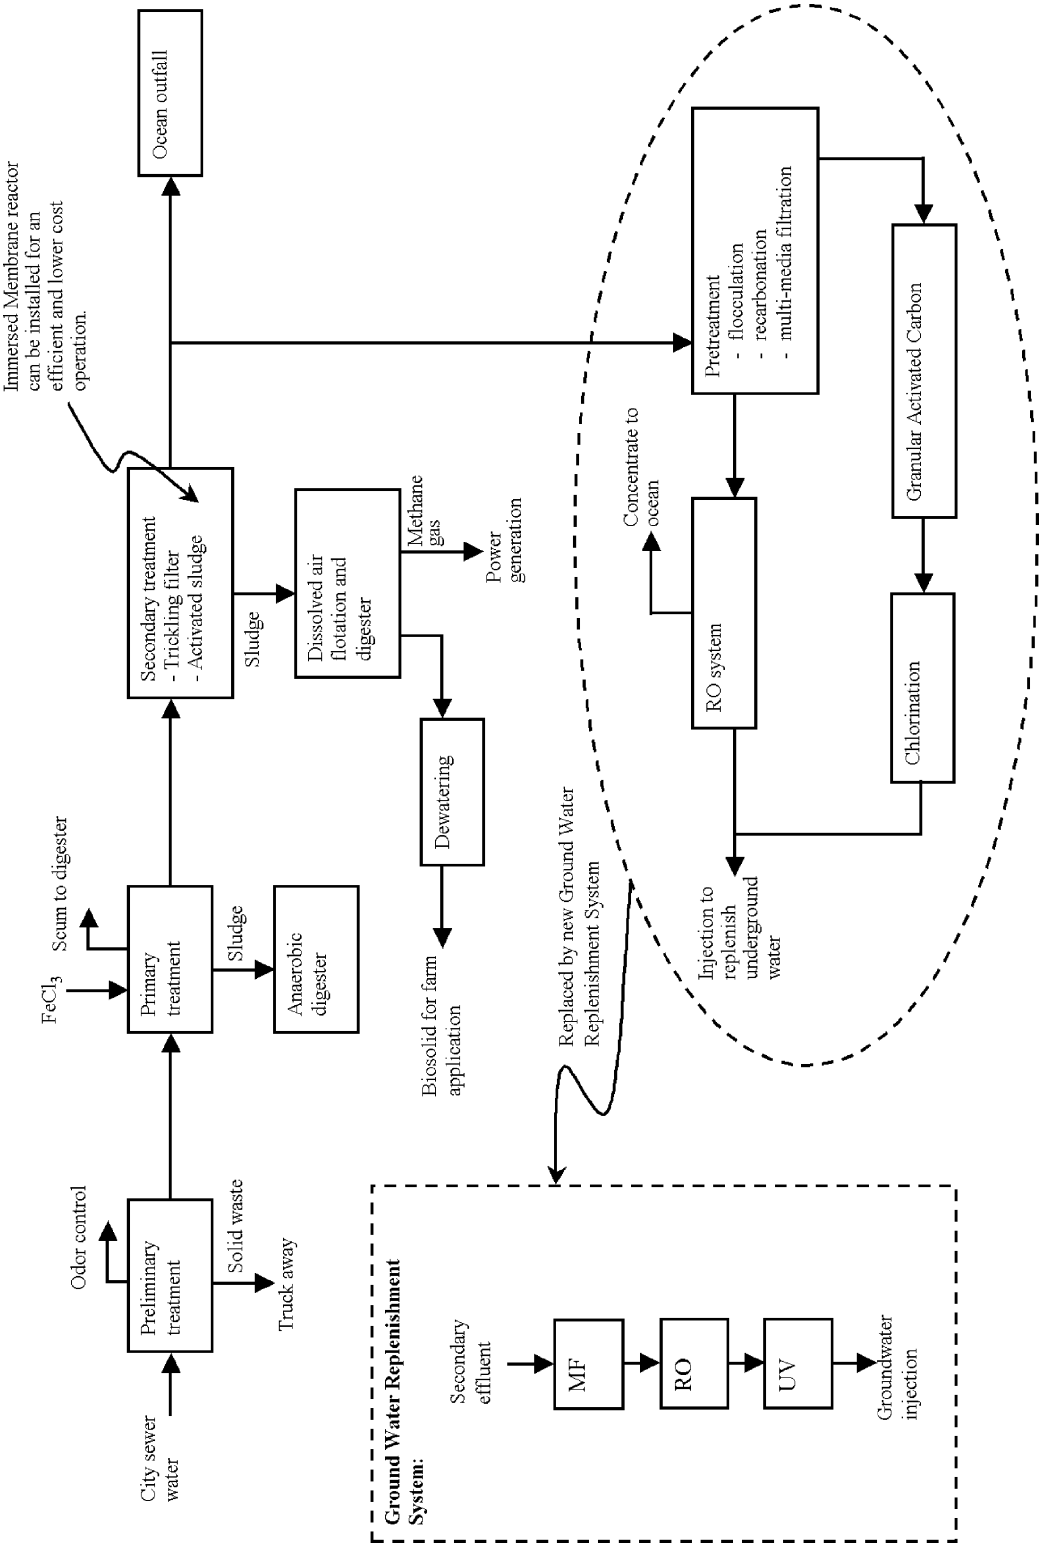

Fig. 5 An overall block diagram of the Orange County municipal wastewater treatment process and Water Factory 21 process.

shear rate at the membrane surface, which was three to five times the rate attainable in crossflow systems.[36] This dispersal force prevented foulants from plugging up the membrane surface and resulted in a significantly higher permeation rate and longer operation time between cleanings. Wagner[37] described the application of membranes for wastewater treatment in a paper manufacturing plant. Wastewater generated during the process of paper formation was rather white because of the high content of suspended solids. This white water from the paper mill was reclaimed by the use of a plate and frame UF filter. Wagner also noted that as more water was recycled in a pulp or paper mill, more salt built up. Salt concentration had to be reduced in order to decrease the possibility of corrosion in machinery and pipelines. Nanofiltration or RO membranes showed capability in significantly reducing salt content. Using UF membrane, fresh water consumption of the pulp and paper industry could generally be reduced by 50%, while NF or RO membrane could provide a further 50% reduction.

Two commercial size plants for groundwater treatment based on liquid membrane technology in general, and the supported liquid membrane using hollow fibers in particular, were built and operated in Baltimore, U.S.A.[20] Specifically, the purpose of the two plants is for hexavalent chromium cleanup. One plant went into commercial operation in March 1999 and the other approximately about a year later. The liquid membrane system in these two plants is able to reduce metal-ion concentration from 100–1000 ppm range to approximately 0.05 ppm and, meanwhile, produce a concentrated chromium solution, which is the spent strip solution, at approximately 20% Cr (VI). This concentration is suitable for sale for reuse.

Other commercialized major applications for liquid membranes are the recovery of zinc from rayon plant effluents,[38] the removal of phenol from industrial wastewater streams,[39] and the treatment of cyanide-containing wastewater from gold leaching solutions.[40,41] The process of extraction of uranium from phosphoric acid was successfully developed in a pilot plant and is waiting for commercial opportunity.[42]

Membrane technology also helped an aluminum can manufacturer (Fig. 6) treat processes wastewater to reduce ever-increasing fresh water and wastewater discharge fees.[43] Oily wastewater from the can forming process and other facilities processes was filtered by a UF unit. The UF permeate combined with can washing wastewater was further treated by an NF unit. Three RO units were used to purify the incoming municipal water and the NF permeates. Using such an integrated membrane system, this aluminum can manufacturer recovered approximately 88% of the process water.Cassano[44] reviewed the potential of using UF and NF in the treatment of aqueous solutions from leather processing industries. Water is used in almost every step during leather manufacturing processes. Through the application of various types of membranes, process water can be either recycled directly or used in other steps of leather manufacturing. Polysulfone spiral-wound UF modules with an MWCO of 20,000 could maintain the sulfide concentration during the unhairing steps, and NF element could concentrate the tanning solution for reuse instead of discharge into the wastewater treatment plant.

Semiconductor wafer production also consumes a large quantity of fresh water. The Philips San Antonio facility was producing 150 mm wafers and planned to move into 200 mm wafer production in early 2000. One task it encountered was the need to increase its supply of high purity water. Its project team evaluated several options, including expanding the fresh water supply and recycling waste wafer rinse water. The team

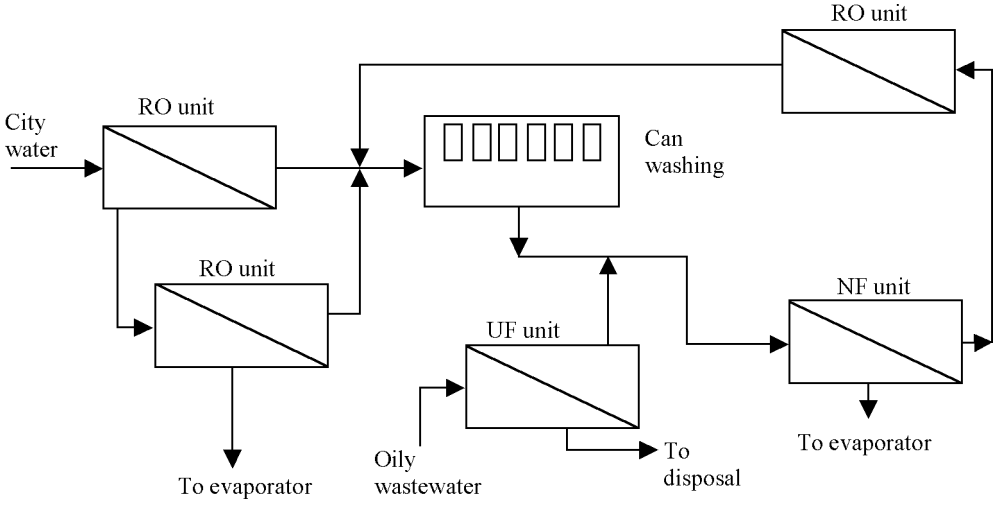

Fig. 6 Integrated membrane system used in a can manufacturing plant.

concluded that reclaiming and recycling the process wastewater would meet both the project's critical schedule milestones as well as its budget.[45] A 180 gpm double pass RO system was installed with weak acid cation resin as RO pretreatment and post-treatment. This system provided a maximum 87% recovery rate with 93% or better rejection of waste rinse water TOC.

CONCLUSIONS

Water reclamation, the treatment of wastewater to meet the water quality standards of various applications economically, is becoming increasingly important in view of the increasing world population and scarcity of fresh water sources. The major technology used for water reclamation is membrane technology. This entry gives an overview of the major membrane types used for water reclamation: reverse osmosis, nanofiltration, ultrafiltration, microfiltration, and liquid membranes. Applications of these membranes in municipal and industrial wastewater reclamation have been described.

Wide Band-Gap Electronics Materials

Mark A. Prelas
Krishnendu Saha
Nuclear Science and Engineering Institute, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

A wide band-gap material is a semiconductor that has a band-gap approximately greater than 2 eV. Some of the most prominent wide band-gap materials are GaP (2.26 eV), 3C–SiC (2.36 eV), 6H–SiC (3.0 eV), 4H–SiC (3.23 eV), GaN (3.2 eV), diamond (5.46 eV), AlN (6.2 eV), and BN (6.1–6.4 eV). These materials have applications in high-efficiency optoelectronic devices such as blue and UV light emitting diodes (LEDs) and lasers, as well as high-power, high-temperature, and high-frequency electronic devices. Electronic devices formed in wide band-gap materials operate at high temperatures without suffering from intrinsic conduction effects because of the wide energy band-gap. Some wide band-gap materials emit and detect short-wavelength light, which has applications in blue LEDs and nearly solar blind UV photodetectors. Wide band-gap materials, in general, have a high breakdown voltage, which allows them to withstand a voltage gradient much greater than that of Si or GaAs without undergoing avalanche breakdown. This property makes wide band-gap materials excellent for applications in very high-voltage, high-power devices such as diodes, power transistors, power thyristors, and surge suppressors, as well as high-power microwave devices. Because of their excellent thermal properties, devices made of wide band-gap materials can be placed close together, allowing a high device packing density for integrated circuits. Packing density is dependent on molecular size of the element in the chip and an example of packing density is a few million transistors in an area of 4 mm^2 with spacing between elements of approximately 1.5 μm. Diamond, for example, has the highest known thermal conductivity (five times larger than copper). Wide band-gap materials can operate at very high power levels and still dissipate even large amounts of excess heat. Many wide band-gap materials have a high electron drift velocity, which allows them to operate at high frequencies (RF and microwave). The electron drift velocity is the velocity of electrons in semiconductors under the influence of electric field. Wide band-gap materials have a high resistance to chemical attack, which allows them to be used in corrosive environments. Additionally, wide band-gap materials are resistant to radiation, which makes them ideal for devices that require radiation hardening, such as components for satellites and spacecraft.

BACKGROUND

Diamond

Diamond is discussed in Diamond and Diamond-Like Film Applications.

III–V Materials (Nitrides)

Wide band-gap materials have always been a subject of interest for electronic applications.[1] Light emitting diodes with blue and green light emitting capability have been in the market and ultraviolet and blue laser diodes , high-speed transistors, and ultraviolet photodetector technology have been demonstrated. The III–V materials (nitrides) especially stand out. The properties like high electron mobility, high current carrying capability, high thermal capability, high temperature operation, and high breakdown field are important attributes of III–V materials. Electron mobility and hole mobility are the measure of scattering of electron or holes in semiconductors. The first report of synthesizing a small GaN crystal was made by Johnston and Parsons in 1932.[2] Grimmeiss and Koelmans in 1959 performed luminescence studies.[3] In 1969, Maruska and Tietjen succeeded in growing the first single-crystal GaN on a sapphire substrate by hydride vapor phase epitaxy (HVPE).[4] This work was a major breakthrough because of the difficulty of growing large bulk GaN single crystals and because the available methods relied on heteroepitaxial growth. Heteroepitaxial growth is a method in which a thin layer of single-crystal material is deposited on a single-crystal substrate, the chemical composition of the depositing material being different from that of the substrate. Additionally, it was found that GaN has a direct-transition band structure with band-gap energy of about 3.39 eV, at room temperature. This caused an acceleration in research on GaN as seen in Fig. 1, period A, which lists the number of worldwide

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120025854

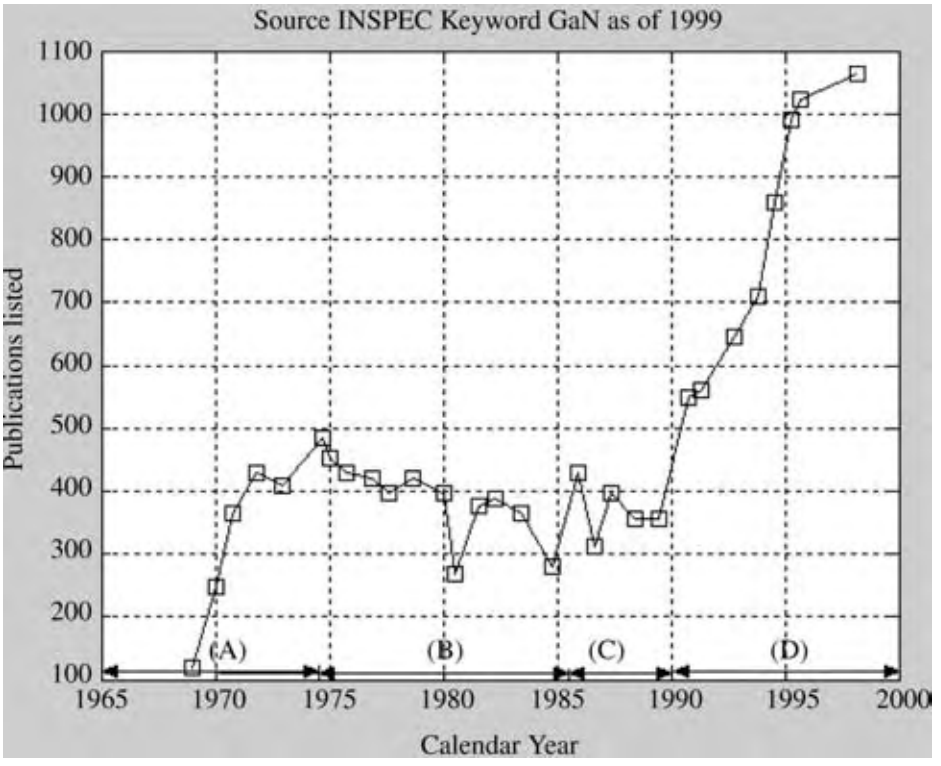

Fig. 1 Number of worldwide publications on nitrides over the years. (From Ref.[1].)

publications related to GaN in any given year. By 1971, Dingle et al. demonstrated optically pumped UV stimulated emission from a GaN crystal at 2 K.[5] The demonstration used Zn as a deep acceptor.

By changing doping of the Zn level, various colors can be produced and blue, green, yellow, or red can be emitted. The first blue LED using a metal–insulator–semiconductor structure was developed by Pankove et al. in 1971.[6] The basic studies of the physical properties of GaN crystals occurred in this period. Ejder reported energy dispersion of the refractive index of GaN in 1971.[7] Then, studies of luminescence including exciton recombination were reported by several researchers.[8,9] Through these studies some basic properties like positions of exciton ground state transition energies of GaN and the lowest band-gap of GaN were clarified. However, the crystalline quality of GaN in those days was not sufficient to characterize the intrinsic properties. Moreover, because of the high n-type background, p-type conduction was very difficult to obtain. N-Type is the lattice where there is an extra electron while p-type is where there is an one electron less in the lattice. Because of this limitation many researchers discontinued Group III nitride research and as a result, the number of publications gradually decreased during this period as seen in Fig. 1, period B. With the introduction of metalorganic vapor phase epitaxy, which is preferred compared to molecular beam epitaxy (MBE), dramatic improvement of crystalline quality of nitrides, was obtained. This caused a revolutionary breakthrough in period C, which resulted in extensive research from period C to period D.

AlN, GaN, InN, and their alloys are all wide band-gap semiconductors. They crystallize into both wurtzite and zincblende polytypes.[10] Wurtzite GaN, AlN, and InN have direct room temperature band-gaps of 3.4, 6.2, and 1.9 eV, respectively. In cubic form, GaN and InN have direct band-gaps while AlN has an indirect energy band-gap. Alloys of GaN with AlN and InN can form materials with a wide range of energy band-gaps. Group III nitrides span a continuous range of direct band-gap energies throughout much of the visible spectrum into the ultraviolet wavelength. Short-wavelength optoelectronic device application is one of the reasons for the increase in research papers after 1990. Group III nitride optoelectronic devices, like LEDs and lasers, can be fabricated for green, blue, and UV wavelengths. The LEDs have applications as elements for full color displays and also as elements for signal and illumination applications. Used as coherent sources they have applications in high-density optical read and write device. In the latter application, because of the fact that the diffraction limited optical storage density increases roughly quadratically as the probe laser wavelength is reduced, nitride based coherent sources at wavelengths down to UV are attracting attention. For optical storage applications these devices have shown storage and retrieval property of a large

number of images and large video files. Currently, optical storage devices use lasers made from InGaAlP heterostructures whose wavelengths are limited to about 550 nm. ZnSe alloys have recently been explored that operate in fringes of green and blue wavelength. These devices have a short lifetime probably owing to stacking faults, which is in the range of about $10^5/cm^2$. The potential short life of ZnSe because of mechanical instability is a significant concern. GaN and/or its alloys can overcome these problems because of longer lifetime and fill the green, blue, and UV regions of the spectrum. During the past several decades, lasers and LEDs have expanded in terms of both range of wavelengths and brightness. Introduction of a bright blue emitter paved the way for full color displays. The low power consumption of LEDs will allow full color display to extend battery life and reduce battery weight.

Both n- and p-type doping is possible in SiC and it has an excellent power amplification device performance. As a result it is a direct competitor of the nitrides in this application. Nitrides form direct band-gap heterostructures allowing the placing of carriers at the interface and carrier confinement. In addition, nitrides can form good ohmic contacts, which are imperative for power devices.

Many wide band-gap semiconductors are produced by epitaxial growth. A brief history of applications of these techniques is given below.[11] The first event of importance was the success of Al-ferov in 1969 in fabricating a continuous-wave laser diode that operated at room temperature by liquid phase epitaxy. For this, he received the Nobel Prize in physics in 2000 with two other scientists. Liquid phase epitaxy, which was proposed by Nelson, makes high-quality thin film semiconductors.[12] In III–V LPE, the compounds are grown from Group III metal solutions on a substrate. This produces highly stochiometric, thin, pure, and perfect films. The next important event in the history of III–V epitaxy is the invention of the high electron mobility transistor (HEMT) by Mimura et al., which was made by MBE.[13] They used the idea of modulation doping that was originally proposed by Dingle et al.[14] The growth technology of high-quality and ultrathin III–V films of about 10 nm thickness was required for the fabrication of HEMT. At that time, such films could be grown only by MBE. Almost at the same time, the technology of metal organic chemical vapor deposition (MOCVD) was developed and used for growing high-quality thin films. Without MBE and MOCVD, neither HEMT nor high-performance laser diodes such as quantum well (QW) and multi-quantum well (MQW) lasers could be made.

Recent successes in growing high-quality GaN and related compounds were achieved by Amano et al. by using a low-temperature buffer layer on sapphire in MOCVD.[15] The improvement in crystal quality realized made it possible to get p-type GaN. The success of p-GaN was a real breakthrough for making blue to ultraviolet lasers and LEDs.

PROPERTIES OF WIDE BAND-GAP MATERIALS

General Properties

The properties like high electron mobility, high current carrying capability, high thermal capability, high temperature operation, and high breakdown field) of wide band-gap materials are superior to silicon. The Keyes figure of merit (KFM) takes into account the power density dissipation for closely packed integrated circuits. High thermal conductivity is an important element for the KFM. The KFM is based on V_{sat} (electron saturation velocity), σ_t (thermal conductivity), and ε_r (dielectric constant). The relative value of the KFM is related to the speed of the transistor in the material as given below:

$$\text{KFM} = \sigma_t (V_{sat}/\varepsilon_r)^{0.5}$$

The higher the value of KFM, the higher will be the speed of the transistor (Table 1).

Table 1 Properties of some wide band-gap semiconductors

Material	Band-gap (eV)	σ_t (300 K) (W/cm)	ε_r	V_{sat} (cm/sec)	KFM ($W\,cm^{-1/2}sec^{-1/2}$)	Ratio to silicon
Si	1.1	1.5	11.8	1.0×10^7	13.8×10^2	1.0
GaN	3.5	1.5	9.5	2.5×10^7	24.3×10^2	1.76

(From NSM Archive, Http://www.ioffe.rssi.ru/SVA/NSM/Semicond/.)

The Johnson figure of merit (JFM) is used to compare materials for power microwave applications. Larger values indicate superior performance in microwave power applications. The higher the value, the higher will be the power capability. This figure of merit is the product of the breakdown voltage (V_b) and the electron saturation velocity (V_{sat}).

$$\text{JFM} = (V_b V_{sat})/2\pi$$

Wide band-gap materials have an excellent JFM, about two orders of magnitude higher than silicon, making them excellent candidates for high-power microwave electronics (Table 2).

Overall, the properties of wide band-gap materials have many advantages over Si, GaAs, and related semiconductor materials (Table 3). Wide band-gap materials have a much higher breakdown voltage and a higher thermal conductivity than silicon and related semiconductors. In addition when you compare the electron mobility (Si: 1450 $cm^2/V/sec$, GaAs: 8500 $cm^2/V/sec$) and hole mobility (Si: 450 $cm^2/V/sec$, GaAs: 400 $cm^2/V/sec$) of standard semiconductor materials to that of diamond (electron mobility: 2200 $cm^2/V/sec$, hole mobility: 2000 $cm^2/V/sec$), there are some very distinct advantages that come to light. The large band-gap difference makes these materials suitable for high-temperature electronics, power electronics, and radiation-hardened electronics.

The material properties of some individual wide band-gap materials are discussed below.

SPECIFIC MATERIAL PROPERTIES

GaP

Gallium phosphide is primarily used for the manufacture of red and green diodes. Its band structure is direct. Some properties of wide band-gap materials are given in Table 2.

GaP has a number of potential shallow-level donors (n-type dopant). These include sulfur (substituted for P-activation energy of 0.107 eV), selenium (substituted for P-activation energy of 0.105 eV), tellurium (substituted for P-activation energy of 0.093 eV), lithium (substituted for P-activation energy of 0.091 eV), germanium (substituted for Ga-activation energy of 0.204 eV), silicon (substituted for Ga-activation energy of 0.085 eV), tin (substituted for Ga-activation energy of 0.072 eV), and lithium (substituted for Ga-activation energy of 0.061 eV). Of these potential donors, typical commercial GaP wafers use sulfur (carrier concentration of $1.15 \times 10^{17}/cm^3$ and an electron mobility between 80 and 130 $cm^2/V/sec$) or tellurium (carrier concentration of $1.7 \times 10^{17}/cm^3$ and an electron mobility between 100 and 140 $cm^2/V/sec$). Wafer sizes are 50–80 mm.

GaP also has a number of potential shallow-level acceptors (p-type dopant). These include germanium (substituted for P-activation energy of 0.265 eV), carbon (substituted for P-activation energy of 0.0543 eV), silicon (substituted for P-activation energy of 0.210 eV), beryllium (substituted for Ga-activation energy of 0.0566 eV), cadmium (substituted for Ga-activation energy of 0.1022 eV), magnesium (substituted for Ga-activation energy of 0.0599 eV), and zinc (substituted for Ga-activation energy of 0.0697 eV). Of these potential acceptors, typical commercial GaP wafers use zinc (carrier concentration of $1.2 \times 10^{17}/cm^3$ and a hole mobility between 50 and 80 $cm^2/V/sec$). Wafer sizes are 50–80 mm.

3C–SiC

3C–SiC is the sole cubic polytype among the many SiC polytypes. It has the highest electron mobility of the SiC polytypes. Its band structure is indirect. Most of the commercial applications of SiC are with 4H–SiC and 6HSiC. 3C–SiC has a potential shallow-level donor (n-type dopant) with nitrogen (activation energy of 0.06–0.1 eV).

3C–SiC has several potential shallow-level acceptors (p-type dopant) with aluminum (activation energy of 0.26 eV), gallium (activation energy of 0.344 eV), and boron (activation energy 0.735 eV).

Table 2 Johnson figure of merit (JFM) of some wide band-gap semiconductors

Material	Band-gap (eV)	V_b(V/cm)	V_{sat}(cm/sec)	JFM (V/sec)	Ratio to silicon
Si	1.1	3×10^5	1.0×10^7	3×10^{12}	1.0

6H–SiC

6H–SiC is an indirect band-gap material that is produced commercially. 6H–SiC along with 4H–SiC is used for short-wavelength optoelectronic, high-temperature, radiation-resistant, and high-power/high-frequency electronic devices. High-quality SiC is grown commercially by companies, such as CREE Research Inc., of Raleigh, NC, by bulk growth methods (4H and 6H structures) as well as by chemical vapor deposition (CVD). A p–n structure in SiC can be achieved by various methods. Some of these methods are sublimation epitaxy, container-free liquid phase epitaxy, CVD, ion implantation of aluminum, and boron diffusion. Many of the problems, which plagued SiC in the past, have been overcome. The micropipe defect density has been reduced to less than one per square centimeter. The crystal size is now being produced in 3 in. production wafers and large by CREE.

6H–SiC has potential shallow-level donors (n-type dopant) with nitrogen (activation energy of 0.085–0.125 eV) and phosphorous (activation energy of 0.085 eV). 6H–SiC has several potential shallow-level acceptors (p-type dopant) with aluminum (activation energy of 0.239 eV), gallium (activation energy of 0.317 eV), beryllium (activation energy of 0.320 eV), and boron (activation energy of 0.31–0.38 eV).

4H–SiC

4H–SiC is an indirect band-gap material that is produced commercially. As stated previously, 4H–SiC along with 6H–SiC are used for short-wavelength optoelectronic, high-temperature, radiation-resistant, and high-power/high-frequency electronic devices.

4H–SiC has potential shallow-level donors (n-type dopant) with nitrogen (activation energy of 0.059–0.102 eV), titanium (activation energy of 0.13 eV), and chromium (activation energy of 0.15–0.18 eV). 4H–SiC has several potential shallow-level acceptors (p-type dopant) with aluminum (activation energy of 0.19 eV), gallium (activation energy of 0.267 eV), and boron (activation energy of 0.647 eV).

GaN

Gallium nitride is a direct band-gap material that is primarily used in green, blue, and UV LEDs and lasers, white-light sources, high-power RF and microwave sources, and high-temperature devices. Its band structure is direct. Some of the properties of gallium nitride are given in Table 3. GaN has been the extensively studied material for optoelectronic applications among all III–V nitrides. Blue LEDs and lasers made of GAN are obtained by overcoming constraints like doping and heteroepitaxial growth.[16,17] Gallium nitride (GaN) substrates are being grown by MOCVD, MBE, and HVPE. GaN is typically grown on sapphire (Al_2O_3), 6H–SiC, and ZnO. Most as-grown GaN (and InN) films exhibited high n-type conductivity because of native defects but p-type conductivity cannot be obtained.[16] p-Type GaN was achieved by doping with Mg, and GaN p–n homojunction and blue light emitting devices were demonstrated.[18,19] GaN LEDs are now being made commercially. The alloy of $Al_xGa_{1-x}N$ has also been developed for blue to UV emitters.[18,19] However, only films with a small amount of Al ($x \sim 0.1$ for p-type and $x < 0.4$) for n-type can be doped successfully.[18–20]

GaN has a number of potential shallow-level donors (n-type dopant). An N vacancy is believed to be the dominant donor. The activation energy of the N vacancy is still under debate. Of these potential donors, typical commercial GaN wafers are naturally a donor because of the N vacancy. Wafer sizes are about 50 mm.

Both magnesium and beryllium have been used to make p-type GaN; however, there is an unintentional incorporation of oxygen and silicon in the GaN growth process.[16,18,19]. p-Type materials are possible with beryllium or vanadium (in the Ga position with approximate activation energy of 0.236 eV), magnesium or vanadium (in the Ga position with approximate activation energy of 0.236 eV), and zinc or vanadium (in the Ga position with approximate activation energy of 0.232 eV). There are a number of deep-level acceptors.

ZnO

ZnO is a direct band-gap material that has gained interest for optoelectronic applications. It is an II–VI semiconductor, which gives it advantages in performance because II–VI semiconductors are not easily degraded through defects. ZnO is naturally an n-type material.[21] Its primary uses are for the polycrystalline form for piezoelectric transducers, varistors, phosphors, and transparent conducting films. Bulk crystals of ZnO have been fabricated by various methods including vapor phase growth, hydrothermal growth, and melt growth. Additionally, epitaxial growth of ZnO single-crystal films has been demonstrated by various techniques such as pulsed laser deposition, MBE, MOCVD, and HVPE.

Acceptor levels in ZnO can be created with hydrogen and potentially sulfur and nitrogen.[22,23] A p–n junction in ZnO has been formed.[24] Various light emitting structures have been formed using ZnO including LEDs, and a UV nanowire laser.[25,26]

Diamond

Diamond is an indirect band-gap material that is used in grinding, polishing, cutting, wear resistance, tribology, acoustics, optics, thermal management, and electronic applications (see section on Diamond and Diamond-Like Materials). It has been used in electronic applications as a heat sink for large-scale integrated circuits. Recently, an 81 GHz high-frequency diamond device was made by Nippon Telegraph and Telephone Corp. (NTT).[27] This promises to make possible amplification *e* in the millimeter-wave band from 30 to 300 GHz. In addition, efforts by the Japanese government to initiate a joint research project with industry in fiscal year 2003 to develop diamond-based semiconductors indicates the progress that has been made in diamond electronics over the last decade.[28] Diamond, because of its superior properties is envisioned as an advanced chip technology that could one day replace silicon as the base for superfast, high-voltage semiconductors. There are two keys to diamond technology, the most challenging is making electronic grade high-quality synthetic diamond single crystals. NTT will focus its technology on a proven means of fabricating millimeter electronic single crystals. Other breakthroughs may lead to a source of large single crystalline diamond. A company called Genesis is producing large high-quality HPHT diamond crystals that may lead to a source of diamond wafers for the electronic industry. A company called Apollo is producing gem quality single-crystal diamond that may be economical for the diamond electronics business.[29] The second is in the formation of complex device structures. A fundamental device, a p–n junction, was fabricated in 1997 using a method called field enhanced diffusion with optical activation the details of which are given in Ref.[30]. Field enhanced diffusion with optical activation lends itself well to the fabrication of complex integrated circuits.[31]

Donors for diamond are challenging. Lithium has been identified as a donor with an activation energy of 0.2 eV (searching did not reveal) using field enhanced diffusion with optical activation.[32] However, the lithium concentration was limited to about 5×10^{17} atoms/cm^3. Other methods of introducing lithium into the diamond, such as in situ doping or ion implantation, did not produce n-type material owing to the defects introduced by the method. When dopant atoms are introduced into the semiconductor layers during its growth, most commonly during epitaxial growth of semiconductor layer, it is called in situ doping. Field enhanced diffusion with optical activation is a low-energy method that maintains the quality of the crystal and thus is able to limit the formation of defects. Another method of creating n-type conductivity has been reported. In this process, deuterating boron-doped diamond in a plasma at about 550°C converts the material from p-type to n-type with conductivities as high as 2 S/cm at room temperature.[33] Nitrogen is also a donor but it is deep level with activation energies of 1.7 and 4 eV, which may be due to substitutional impurity, simple aggregates, or platelets. Phosphorus is a donor with reported activation energies between 0.84 and 1.16 eV. Sulfur is a donor that has received a great deal of attention recently. Dr. Matt West demonstrated that diamond doped by the field enhanced diffusion with optical activation method has activation energy of 0.9 eV.[34]

Boron is an acceptor in diamond with an activation energy of 0.37 eV. Natural type II b diamond is an example of a boron doped p-type diamond. There are many commercial sources of synthetic boron doped-diamond. Polycrystalline boron doped diamond films, made by CVD, have been made for electrode applications. High-pressure high-temperature diamonds with boron doping are also available.[35]

AlN

Aluminum nitride is direct band-gap material that has a very wide band-gap (6.2 eV). Also, it has a high thermal conductivity, high electrical resistivity, high acoustic velocity, high thermal stability, and high chemical resistance, and radiation stability. These properties make AlN suitable for UV optical devices, surface acoustic wave (SAW) devices, electrical insulators, or passive layers in microelectronics. Such a device can operate in a harsh environment with high temperatures and/or radiation. However, it is very difficult to dope AlN with impurities to make it to n- or p-type semiconductors. Also as grown AlN films do not show any n- or p-type characteristics. Although both n- and p-type doping of aluminum nitride have been reported as far back as 1967, almost no recent paper can be found that verifies these results.[36] Field enhanced diffusion with optical activation has been used for doping AlN and some promising results with magnesium as the p-type dopant and silicon as the n-type dopant.[37] Additional potential donors include C (Al), Ge (Al), and Se (N) while additional potential acceptors include Be (Al), C (N), Ca (Al), and Hg (Al).

BN

Despite the excellent properties of cubic boron nitride, it is a very difficult crystal to grow. Thus far the crystal size has been limited to micrometer-type size. Little is known about the ultimate potential of cubic boron nitride in electronics. Potential donors include Si with activation energy of 0.24 eV, C with activation energy of 0.28 eV, and sulfur with activation energy of

0.41 eV.[38] A potential acceptor is Be with activation energy of 0.19 eV.[39]

APPLICATIONS

There are many industries that utilize wide band-gap materials. The primary applications of wide band-gap materials are identified below.

Grinding and Polishing

Grinding and polishing is one of the oldest applications for wide band-gap materials primarily owing to the property of hardness that some of these materials possess (e.g., diamond). SiC and cubic boron nitride, in addition to diamond, have found a commercial market in grinding and polishing, primarily for ferromagnetic materials with high carbon solubility.[39,40]

Tool and Die

Because of the hardness of band-gap materials such as diamond, SiC, and boron nitride, wide band-gap materials have found applications in the tool and die industry.[40,41].Wide band-gap materials have been successfully used for coating field emission tips in SEM with results showing reduction in turn-on voltage by 100 V and more uniform emission during low-voltage operation.[42]

Electronics

One of the major markets for wide band-gap materials is in electronics. Specifically, they are suitable for and have been used for heat sinks (diamond), short wavelength optoelectronic devices (GaP, GaN, SiC), high-temperature electronics (SiC, GaN), radiation resistant devices, and high-power/high-frequency electronic devices (diamond, GaN, SiC).[40,43–45] Recent research showed that Mn-doped GaN can be used for spintronic applications.[46] Atomically flat technology developed by NASA for SiC and GaN WBG material can introduce a new dimension of application for WBG materials.

Heat Sinks

Because of diamond's exceptional heat conductivity (about five times that of copper), it has been used as a heat sink for large-scale integrated circuits.[40]

Insulators

Because of the high breakdown voltage, wide band-gap material can and have been used as electrical insulators. There has been a great deal of interest in pressed nanophase SiC and diamond powders as an electrical insulator for capacitors.

Semiconductors

All of the wide band-gap materials have potential applications as semiconductors, ranging from high-temperature, high-power, and high-radiation resistance applications to high-speed integrated circuits to high-frequency devices. Recent research has shown that wide band-gap materials like ilmenite-hematite (IH) can be used for low-voltage varistor application for space research.[47] Semiconductor technology based on wide band-gap material composites has been widely used for MEMS devices.[48]

Optoelectronic Devices

Wide band-gap semiconductors have been used for green, blue, and UV LEDs and lasers, and white-light sources.

CONCLUSIONS

As the wide band-gap electronic field matures, a wide variety of optoelectronic devices, high-temperature devices (for automotives, combustion chambers, smoke stacks, furnaces, etc.: 150°C to >600°C), radiation hardened devices (for satellites, nuclear power plants, etc.), high-power devices (high-voltage switching, power transistors, etc.), high-speed integrated circuits (LSI, CPU, etc.), and high-frequency devices (microwave amplification, communication, etc.) will be developed. Wide band-gap materials are positioned well to play an important role in the vibrant electronics industry over the next several decades.

Zeolite Membranes

INTRODUCTION

Zeolites and zeolite-type materials (hereafter referred to as zeolites for simplicity) are a class of crystalline oxides with uniform channels and cages ranging from 0.3 to 2 nm. Structurally, a zeolite consists of 3-dimensionally linked tetrahedra and each tetrahedron has one tetrahedrally coordinated atom (hereafter referred to as T-atom) (e.g., Si, Al, P, B, Ga, Ge, Zn, Be, etc.) at the center and four oxygen atoms at the corners. Each corner oxygen atom is shared by two neighboring tetrahedra. Depending on the T-atom, the zeolite framework can be charged or neutral. When the framework is charged, balancing ions are needed, and this is the origin of the ion exchange capability of zeolites. According to their structural symmetry and topology, zeolites are classified into different framework types. Each framework type is assigned a unique three-letter code (e.g., MFI) by the International Zeolite Association (IZA). These structure codes are generally from the zeolite names (e.g., MFI from Mobil Five) and do not follow any sort of established naming procedure. More than 150 framework types with numerous compositional variations have been verified and approved by the IZA.

Zeolite materials are used commercially as shape/size selective catalysts in the petrochemical and petroleum refining industry, and as molecular sieving separation media for gases and hydrocarbons. For both applications, zeolites are used in powder composite form such as pellets and granules. In this entry, we focus on zeolite membranes. We define zeolite membranes as a continuous phase of zeolite-based materials (pure zeolite or composite) that separate two spaces. Zeolite membranes are generally uniform thin films attached to a porous or a nonporous substrate. They can also be self-standing without a substrate. Note that we have included zeolite films and layers on nonporous substrate in this entry because we believe many of the synthesis strategies and applications reported for those nonporous substrates are easily transferred to a porous substrate to prepare a zeolite membrane.

In this entry, we briefly discuss the types of the zeolite membranes and then focus on new applications that have been demonstrated recently. New developments are also included and analyzed, which are followed by some concluding remarks and future directions.

TYPES OF ZEOLITE MEMBRANES

Polycrystalline Zeolite Membranes

Polycrystalline zeolite membranes consist of intergrown zeolite crystals with no apparent cracks or pinholes[1] (Fig. 1A). These films are composed of only zeolite (i.e., there are no non-zeolite components such as amorphous silica or polymer). They are normally supported on a substrate although free-standing films have also been synthesized.[2] Membranes can be prepared on different substrates such as silicon wafer, quartz, porous alumina, carbon, glass, stainless steel (SS), gold, etc. Polycrystalline films are primarily prepared by hydrothermal synthesis methods including in situ crystallization,[1] seeded growth,[3] and vapor transport,[4] and have potential use in all of the applications discussed in this entry.

Zeolite Matrix Composite Membrane

A zeolite matrix composite membrane is defined as a membrane in which zeolite crystals are imbedded in a solid matrix that is either inorganic (e.g., silica and carbon)[5–8] or organic (e.g., polymer)[9,10] (Fig. 1B). Inorganic matrix membranes are often supported, while organic polymer matrices are normally free-standing. The selection between an inorganic and an organic phase as the imbedding matrix strongly depends on the intended application. For example, an inorganic matrix is ideal for applications where thermal stability is required,[5] whereas an organic polymer matrix is the better choice when flexibility is desired.[9,10] These composite films are usually

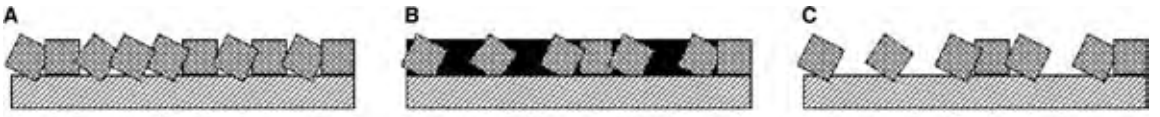

Fig. 1 Schematic of the three types of zeolite membranes: (A) a polycrystalline zeolite membrane; (B) a zeolite matrix composite membrane; and, (C) a zeolite crystal layer.

prepared by wash-coating, sol-gel processing, and polymer film casting.

Zeolite Crystal Layer

Another form of zeolite membranes is a zeolite crystal layer that consists of isolated crystals deposited on a solid substrate[11] (Fig. 1C). The substrate can be a variety of materials such as metal, ceramic, or silicon wafer. Crystal layers have to be supported. There has been exciting fundamental research carried out in this area, however, demonstrated applications have been limited to sensors. The organic linker approach appears very promising for the preparation of these types of membranes.[12]

APPLICATIONS OF ZEOLITE MEMBRANES

Zeolite membranes have been demonstrated for many applications. Applications such as separation membranes, membrane reactors, adsorption, and catalysis have been covered in several reviews.[13–16] In this entry, we focus on new applications including sensors, low-dielectric constant (low-k) films, corrosion resistant coatings, hydrophilic coatings, heat pumps, and thermoelectrics.

Sensors

Chemical sensors are important for industrial process control and environmental monitoring. They also find critical use in medical and defense applications. Two of the critical performance parameters of a sensor are selectivity and sensitivity. When integrated with an appropriate sensor platform (e.g., quartz crystal microbalance or electrochemical quartz crystal microbalance), a zeolite film can improve the selectivity and sensitivity of the sensor due to its ability to selectively adsorb a component out of a mixture. A large number of publications have appeared in this area, and an in-depth review on zeolite films for chemical sensor applications up to 1996 was provided as a section in a recent review by Bein.[11] Here, we highlight a recent development of selective chemical sensor based on continuous oriented zeolite films.

To achieve selective adsorption and quick response, the zeolite film is required to be continuous (i.e., free of non-zeolitic pores) and thin, and have proper orientation. For facile mass transport, a monocrystal film is also preferred because there are no grain boundaries in the mass transport direction, which have proved to decrease diffusion in zeolite by orders of magnitude. Strong adhesion between the zeolite film and the sensor surface is also critical for the durability of the sensor. Recently, a *b*-oriented continuous pure-silica-zeolite (PSZ) MFI monolayer film was successfully synthesized on SS and silicon wafers using a very facile direct in situ crystallization method.[17–19] As-synthesized *b*-oriented films have good continuity and thin monocrystal layer thickness. The thin film thickness and preferred crystal orientation can reach a fast adsorption and desorption equilibrium, which can thus increase the stability of the sensor. In addition, the superior adhesion of this film to the substrate ensures high durability. All these features make this type of film a better candidate as sensor coating to achieve higher selectivity, sensitivity, stability, and durability.[11] The molecular sieving property of this continuous *b*-oriented PSZ MFI monocrystal film was demonstrated in a zeolite modified electrode (ZME) configuration using redox molecules of different sizes (Fig. 2).[20] $Ru(NH_3)_6^{3+}$ (diameter $\sim$5.5 Å) was able to traverse the film, while $Co(phen)_3^{2+}$ (diameter $\sim$13.0 Å) was completely excluded. This film has excellent adhesion to the electrode and is stable in strong acidic conditions.

Low-k Dielectrics

Low-k (k for dielectric constant) dielectric materials have been identified as one of the most difficult challenges for interconnects in future generation integrated circuits (ICs). Many materials have been proposed, studied, or are under commercial development as potential candidates for low-k dielectrics. Among these materials, two major classes are dense organic polymers and porous inorganic based materials. It has been shown that some dense, organic polymers could easily have a k value between 2 and 3, but there are concerns about their low thermal stability and low heat conductivity. Also, due to their low mechanical strength, polymeric materials may have potential problems with the chemical and mechanical polishing (CMP) process.

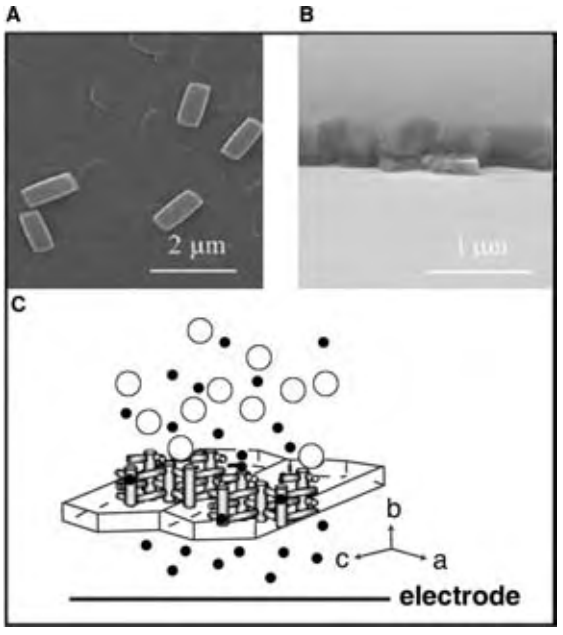

Fig. 2 (A) SEM top view of *b*-oriented pure-silica-zeolite (PSZ) MFI monocrystal-thick film; (B) cross-sectional view of the sample in (A) after slight polishing; (C) schematic illustration of molecular sieving in *b*-oriented PSZ MFI monocrystal-thick film. A distance was intentionally kept between the MFI film and the electrode so that the sieving behavior can be illustrated more clearly. (From Ref.[20].)

Current dielectric material is dense silica that has a k value of 4. Porous silica has a lower k because of the incorporation of air. Sol-gel silica and mesoporous silica have been studied as possible low-k materials. However, these materials have drawbacks such as low mechanical strength and low heat conductivity. Sol-gel silica also has randomly occurring large pores that can cause electrical breakdown. High mechanical strength is needed for the new low-k materials to be compatible with the CMP process.

Very recently, zeolites have been demonstrated to be a promising low-k material (Fig. 3). Zeolites have very uniform pores and their pore size falls into the micropore range (<2 nm), which is significantly smaller than the IC feature size. Therefore, the problem of electrical breakdown should be mitigated. Zeolites have a high heat conductivity and mechanical strength due to their dense crystalline structure.[5,21–25] Pure-silica-zeolite MFI membranes were first developed by in situ crystallization. These films had a k value of 2.7 and were highly hydrophobic. The elastic modulus was 30–40 GPa by nanoindentation using a membrane of 0.43 μm thick. This value is much higher than sol-gel silica or mesoporous silica films. Note that a modulus of 6 GPa is usually considered to be a threshold value for industrially viable low-k dielectrics.

Although the membranes formed by in situ crystallization are mechanically strong, the k value is still high. Also, the solution phase deposition is of concern to the semiconductor industry. Another method was recently developed, which is a simple spin-on process of zeolite nanoparticle suspension. The spin-on process is simple and preferred by the semiconductor manufacturers, and therefore represents a significant step toward the integration of zeolite materials into microelectronic devices. More recently, k values of PSZ MFI films can be lowered to 1.8 by incorporating extra mesopores from organic porogens.[22] The k value of the spin-on PSZ MFI films could be further reduced to 1.6 by using PSZ nanoparticle suspensions with high crystallinity.[23]

PSZs with low framework density (FD) and small pore opening windows are preferred for low-k applications.[25] By having lower FDs, the same k can be achieved with higher microporosity, which translates into better mechanical strength. We recently extended PSZ low-k materials from MFI (FD = 18.4) to MEL (FD = 17.4). We prepared MEL nanoparticle suspensions with high crystallinity (relative crystallinity ~70%). The k values obtained from these suspensions can be as low as 1.5. Organic-functionalized PSZ MFI low-k films are prepared.[25] With organic groups substituting hydroxyl groups, the films are less hydrophilic.

Corrosion-Resistant Coatings

Aluminum alloys are widely used in the aerospace industry because they are light and mechanically

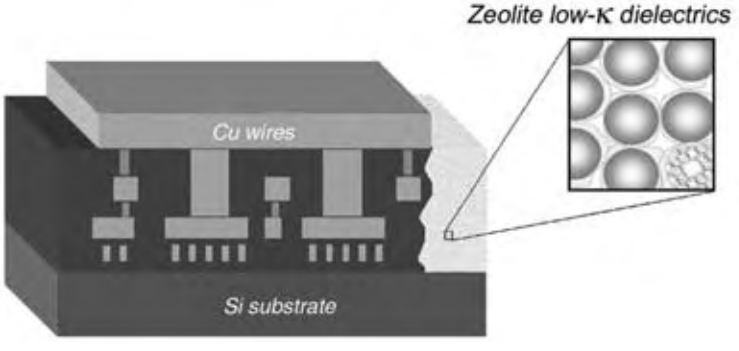

Fig. 3 Schematic illustration of spin-coated zeolite low-k membranes from a nanoparticle suspension as insulator in the interconnect of a microprocessor. *(View this art in color at www.dekker.com)*

strong. However, some of the aerospace aluminum alloys (e.g., 2024-T3) are very prone to corrosion. In order to combat corrosion of aluminum alloys, chromic acid anodization and chromate conversion have thus far proved most effective. Both processes, however, use and release hexavalent chromium, a proven human carcinogen, causing serious environmental and worker health and safety concerns. Thus, a chromium-free alternative with equivalent or superior corrosion performance has long been desired.

The idea of corrosion-resistant zeolite coatings may be counter intuitive, but is well supported by several well-known facts about zeolites. First, high-silica and pure-silica zeolites are thermally and chemically stable. For example, many high-silica zeolites are thermally stable up to 1000°C, and pure-silica zeolites are stable in all mineral acids except hydrofluoric acid. Thus, the framework of zeolites contains the needed corrosion resistance. Second, most of the high-silica zeolite syntheses use template molecules, and these molecules are eventually trapped inside the zeolite pores. Normally, for separation and catalysis applications, these molecules have to be removed by high temperature calcination. It was recognized very early on that as-synthesized zeolite membranes could be gas-tight if they were defect-free. This suggested that as-synthesized zeolite films could be corrosion resistant.

It has been recently shown that as-synthesized template-containing high-silica MFI coatings on aluminum alloys have superior corrosion resistance to chromate conversion coatings in strong acids, bases, as well as pitting aggressive media,[26] and the in situ crystallization coating deposition process can coat surfaces of complex shape and in confined spaces. In addition, the thermal and mechanical properties of the high-silica MFI coatings were shown to be satisfactory.[27] It was also shown that corrosion resistance is possible for all high-silica zeolite coatings such as MFI, BEA, and MTW,[28,29] and high-silica MFI coatings can be extended to other aluminum alloys such as 6061-T6.

Hydrophilic Coating

An environmental control system for a manned spacecraft typically includes a condenser for controlling cabin temperature and humidity. As the moisture-laden air is cooled in the small channels of the condenser, water normally condenses out as water droplets. In a microgravity environment, these water droplets tend to become entrained in the air stream and carried back into the cabin, failing to achieve water separation. In such an instance, the cabin air could become foggy. To effectively remove water from the air, heat exchanger surfaces could be coated with a hydrophilic zeolite coating[30] so that the condensation mode changes from drop-wise to film-wise (Fig. 4). The water film can then be removed by vacuum sipping.

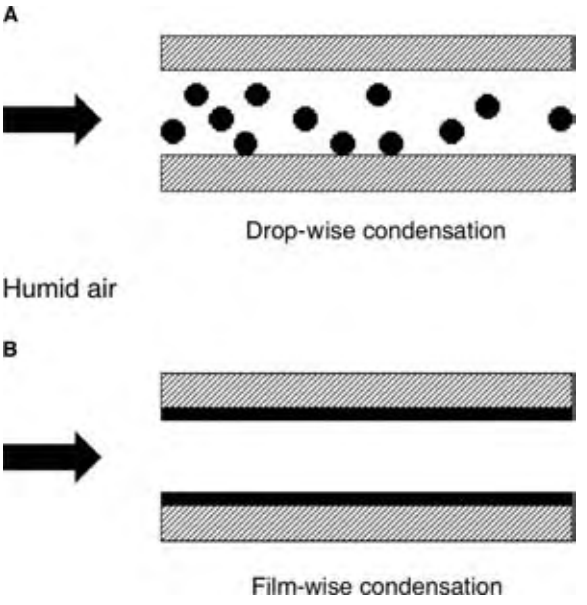

Fig. 4 Schematic illustration of the use of hydrophilic zeolite coating to change condensation mode from drop-wise without zeolite film (A) to film-wise with zeolite film (B).

In situ crystallization was used, and clearly preferred, as it can coat surfaces of complex shape and in confined spaces. In addition, it is a low temperature process (e.g., 165°C) and is compatible with most metal alloys. Another significant advantage for a zeolite coating is that an anti-microbial characteristic can be added readily through ion exchange of metal ions such as silver. Anti-microbial function is desirable for hydrophilic coatings as damp surfaces tend to grow bacteria and fungi. Furthermore, once depleted, the anti-microbial capability of zeolite coatings can easily be regenerated by another ion-exchange without the need of a potentially costly recoating. Hydrophilic membranes made from zeolite A (LTA) with a low silicon to aluminum ratio have been silver exchanged and are effective at killing a large number of cells over a short amount of time (Fig. 5).[31]

Heat Pump

It is well known that water adsorption in zeolites releases heat while water desorption absorbs heat. This phenomenon has been exploited for the design of a heat pump for cooling applications using waste heat or solar energy. Currently, zeolite pellets are used, and the heat and mass transfer are inefficient, leading to bulky pumps. Recently, there have been renewed interests in zeolite coating heat pumps.[32] A new in situ

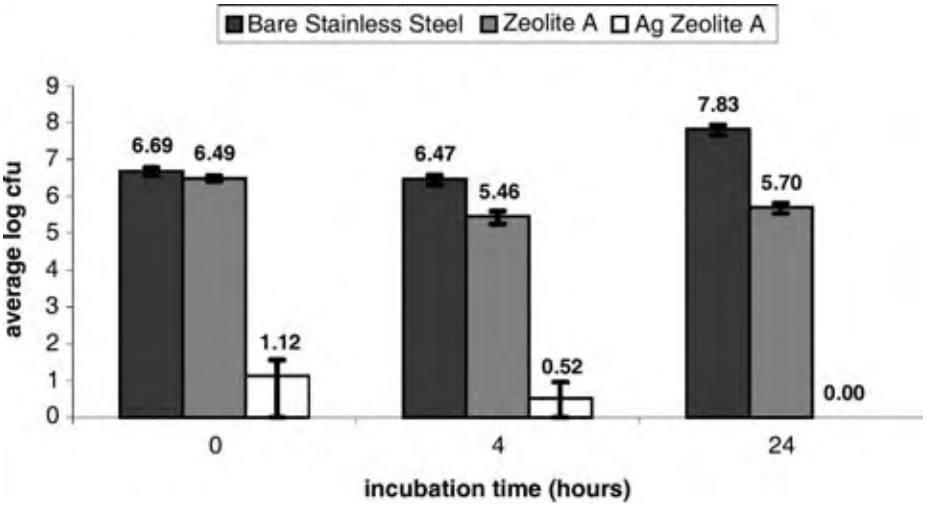

Fig. 5 Surviving colony forming units on bare stainless steel zeolite A coated stainless steel, and silver ion-exchanged zeolite A over a 24 hr incubation period. (From Ref.[31].)

crystallization method for zeolite coatings was developed which suppresses the reaction in the bulk and promotes it on the substrate by applying a temperature difference between the reaction mixture and the substrate. The substrate was heated directly, while the reaction mixture was kept at a lower temperature by means of a water bath. The method was tested for zeolite A coatings on SS plates from a clear aluminosilicate synthesis solution. Zeolite layer thickness and wall thickness of the heat exchanger tubes are essential to optimize the cycle durations. The optimum zeolite layer thickness was found to be 75–150 μm, depending on the wall thickness of the heat exchanger tubes, which led to almost a two-fold power increase from the adsorption heat pump.

Thermoelectrics

Thermoelectrics are all solid-state devices that can directly convert heat to electricity (power generation), or use electricity to pump heat from cold to hot (refrigeration), both without using any moving parts or hazardous compressed fluids. Although the phenomena was discovered in the early 19th century, it was only after the mid-20th century that technology brought practical applications for thermoelectric devices. Thermoelectric devices are lightweight and compact, and have extremely fast responses, and therefore are particularly useful for applications such as microelectronics and semiconductor lasers where conventional compression based cooling is very difficult or impossible. Applications of thermoelectric devices are presently limited because of their low efficiency. The efficiency of a thermoelectric device is usually characterized by a dimensionless figure-of-merit, ZT. Current thermoelectric materials have a ZT of 1. A thermoelectric cooler with a ZT of 1 operates at only 10% of Carnot efficiency, whereas a thermoelectric cooler with a ZT of 4 would achieve 30% of Carnot efficiency, which is comparable to the efficiency of a home refrigerator.

Very recently, theoretical calculations for isolated single nanowires predict over a ten-fold increase in the figure-of-merit. In order to realize these size-effects, wires must be synthesized with diameters less than the thermal de Broglie wavelength (typically less than 10 nm), which is smaller than what is currently accessible, by lithography techniques. Also, in order to transfer meaningful amounts of thermal energy, a practical device must consist of an array of a large number of nanowires in parallel. One way to potentially synthesize these nanowire arrays is to use the pores of microporous and mesoporous materials as a mold to template the diameter and orientation of wires of suitable thermoelectric materials. A recent review has been published discussing the relevant physics, from which a model was derived to assess the feasibility of using microporous and mesoporous frameworks in the fabrication of thermoelectric devices.[33] The model accounted for the possible deleterious effects of thermal conduction through the microporous or mesoporous framework and the presence of bulk thermoelectric material (that may result from defects in the microporous or mesoporous framework) in parallel with the wires on the thermoelectric figure-of-merit. Simulation results were reported for SBA-15, MCM-41, and zeolites VFI, LTL, and LTA embedded with Bi_2Te_3 nanowires. The results showed that the microporous zeolite frameworks may yield figures-of-merit much larger than one, while thermal conduction through most mesoporous frameworks reduces the figure-of-merit below the current level using traditional thermoelectric materials.

NEW DEVELOPMENTS

Proton Exchange Membranes for Fuel Cells

Direct methanol fuel cells (DMFCs) are potentially compact, high efficiency power sources for portable applications. One of the major problems of DMFCs is methanol crossover, meaning that methanol molecules can permeate through the Nafion® membrane from anode to cathode, where it is chemically oxidized. This reduces the fuel efficiency and also causes mixed potential on the cathode. It has been recently demonstrated that acid functionalized zeolite beta Nafion nanocomposite membranes can take advantage of the molecular sieving property and high proton conductivity of acid functionalized zeolite beta nanocrystals, and are shown to have higher proton conductivity and lower methanol crossover (e.g., <50%) than Nafion[10]

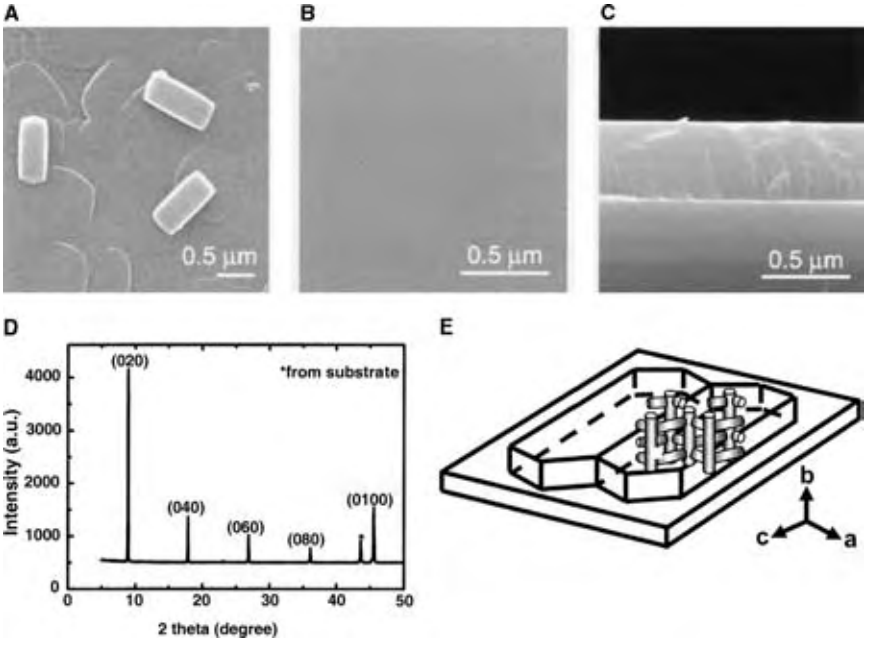

Fig. 7 (A, B, C) SEM micrographs of silicalite-1 films on silicon wafer by in-situ crystallization: (A) before polishing, top view; (B) after polishing, top view; (C) after polishing, cross sectional view; (D) XRD pattern of the silicalite-1 film showing that all the straight channels are vertical to the silicon substrate; (E) a schematic showing the orientation of the crystals vs. the substrate. (From Refs.[34–36].)

(Fig. 6). Polymer–zeolite nanocomposite membrane exploits the unique size of zeolite nanocrystals (e.g., adjustable diameter from 1580 nm) and has the potential to synergistically combine the advantages of polymers and zeolites while overcoming the shortcomings of both. Highly crystallized zeolite beta nanocrystals were hydrothermally synthesized with phenethyl organic functional groups. Sulfonic acid groups were then added to the phenethyl side chains with a concentrated sulfuric acid treatment. Acid functionalized zeolite beta nanocrystals were mixed with Nafion in suspension and cast into a membrane in a glass vessel. This nanocomposite membrane also has the potential to be able to operate at high temperatures (e.g., 150°C) for hydrogen proton exchange membrane (PEM) fuel cells.

Oriented Zeolite Films

Almost all applications for zeolite films could benefit from a preferred orientation. This is especially critical for zeolites with anisotropic pore systems. One particularly interesting *b*-oriented MFI film is shown in Fig. 7. It is a continuous monolayer film (0.4–0.5 μm thick) by in situ crystallization on metal substrates (SS and Al alloy)[34–36] or on silicon wafers.[19] Since MFI has straight channels in the *b*-direction, this film is extremely well suited for membrane applications.[38] It has been found that there is positive thermal expansion in the *a*- and *c*-directions and negative expansion in the *b*-direction; thus, a *b*-oriented MFI film helps to relieve thermal stress. The thinness is also important for relieving thermal stress. Also, because this is a monolayer film, it does not have any grain boundaries in the direction perpendicular to the substrate, leading to minimized resistance for mass transport. This film could also be useful for sensor, magnetic, optical, and thermoelectric applications as the template for nanowire arrays.

Patterned Zeolite Films

The ability to pattern zeolite films is critical for many of their potential applications, especially optical, magnetic, and electronic applications that have not been adequately explored so far. The first patterned zeolite film was achieved by using zeolite nanocrystals as building blocks combined with soft lithography[38] (Fig. 8). Convection-assisted assembly was also demonstrated for the generation of surface patterned zeolite films although the patterns are not very regular[6] (Fig. 8). Recently, using organic linkers, Yoon et al. have demonstrated that microcrystals can also be patterned and oriented. Although these films have very sophisticated patterns, they may find limited use as they are either not continuous or adhesion is not very strong. There is a critical need to fabricate patterned oriented continuous films on a variety of substrates. This was recently accomplished for *b*-oriented MFI monocrystal layer film on gold patterned silicon wafer by taking advantage of the fact that selective deposition can be achieved on Si over Au.[39]

Zeolite Nanocrystals as Building Blocks

Zeolite nanocrystals have been demonstrated to be versatile building blocks for constructing hierarchical porous structures.[40–42] The use of nanoparticles as building blocks allows mild processing conditions

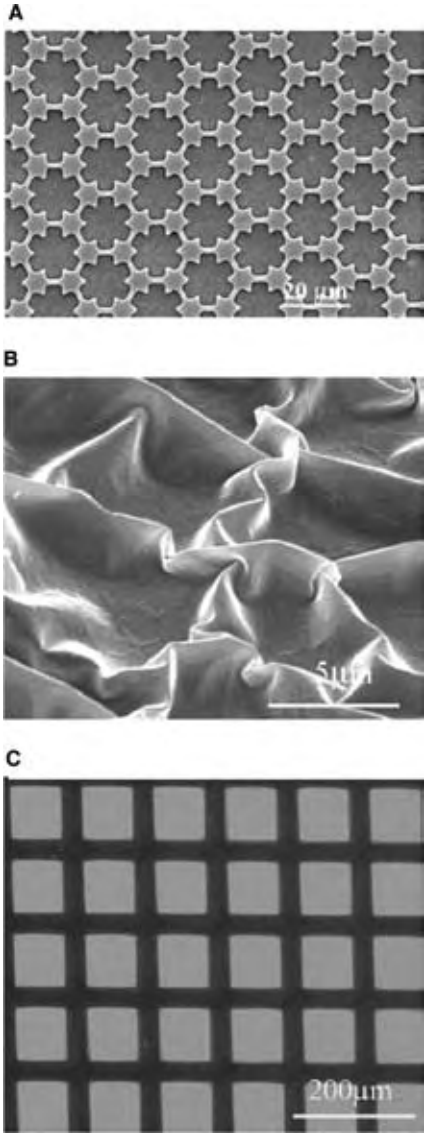

Fig. 8 Patterned zeolite films by using: (A) soft-lithography; (B) convection-assisted assembly of zeolite nanoparticles; and (C) selective deposition on Si on a wafer pre-patterned with gold. (From Refs.[6,38,39].)

and innovative strategies to be used that would have been difficult or impossible otherwise with the conventional hydrothermal synthesis methods such as in situ crystallization, seeded growth, and vapor phase transport. The fabrication of 3-D structures with designed shapes via gel-casting[42] and transparent zeolite films[40] (Fig. 9) are examples that clearly illustrate the utilities and versatility of this approach.

Specifically for the preparation of zeolite films, zeolite nanoparticles could be used directly to form zeolite films by self-assembly.[38] They could also be combined nicely with the seeded growth and vapor phase transport method to produce high quality polycrystalline zeolite films. There is clear evidence that small zeolite nanoparticles are preferred for producing compact continuous films.

Another important application for zeolite nanoparticles is the preparation of zeolite matrix composite films. Micrometer-sized crystals have long been used in these types of films, using techniques such as wash-coating and sol-gel processing. However, the use of nanoparticles in these films appears to offer many unparalleled advantages in terms of achievable film thickness, uniformity, and processability. The low-k dielectric films[21,22,43] and polymer-zeolite nanocomposite membranes[9,44] are two examples.

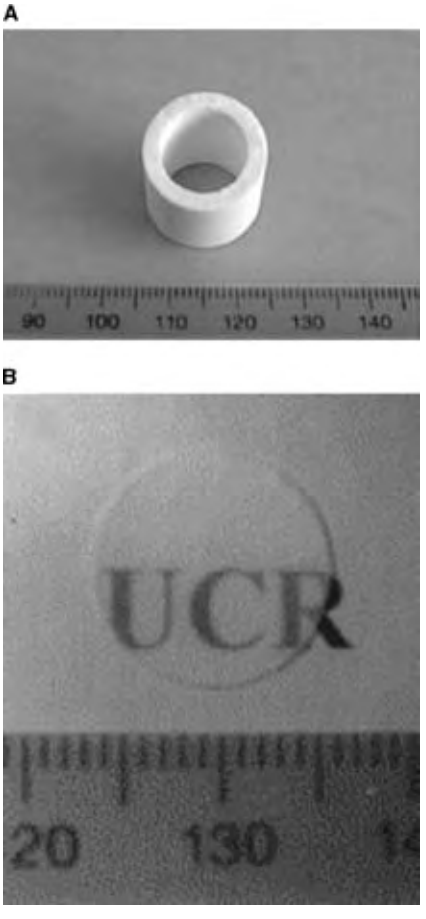

Fig. 9 Zeolite structures constructed by using zeolite nanocrystals as building blocks.. (From Refs.[40,42].)

Another interesting application is microreactors. Zeolite adsorbents and catalysts have been an important part for the conventional reaction-separation system. As the efforts to miniaturize the reactors evolve, using zeolite nanocrystals as building blocks could be an ideal way to introduce zeolites into these microreactor systems.

CONCLUSIONS

Since the first paper on ZME using large crystals,[45] the field of zeolite membranes has come a long way during the last decade from almost nonexistence in the early 1980s to a vibrant field. Many applications show promises and one commercial application has already been realized today (i.e., zeolite A membrane for water separation). The key to this success has been the persistent work of a large number of researchers around the world during the last 10 yrs. The single biggest driver behind this collective effort so far appears to be the potential application of zeolite membranes for separation and membrane reactors. However, non-conventional applications (i.e., non-separation and non-catalysis) are quickly being added and promise to offer even more exciting opportunities (e.g., zeolite low-k films and polymer–zeolite nanocomposite membranes for fuel cells). As shown in this entry, zeolite-based nanostructured membranes could take on several different configurations and be prepared by a number of synthesis methods. Current strategies for oriented membranes are highly specific for a particular zeolite or a particular orientation. More general methods for preparing oriented membranes are still critically needed. The use of nanoparticles as building blocks has broadened our capability significantly and will continue to bring exciting opportunities to the field. Although not covered in this entry, additional new applications such as optical, magnetic, and electric devices are being, and will continue to be explored. As the research of zeolite membranes draws more and more attention, novel applications will emerge.

Ziegler–Natta Catalysis

John C. Chadwick
Dutch Polymer Institute (DPI), Laboratory of Polymer Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

INTRODUCTION

Ziegler–Natta catalysts play a dominant role in polyolefins manufacture. More than 50 million tonnes per annum of polyethylene and polypropylene are now produced by means of Ziegler–Natta catalysis. Since the first discoveries, more than 50 years ago, many breakthroughs and innovations have been made in catalyst and process chemistry and technology, leading to ever more efficient manufacturing processes, and also to increasing control over polymer structure and properties.

This entry describes the development of successive generations of Ziegler–Natta catalysts and highlights the main factors determining catalyst activity, stereospecificity, and the relationship between catalyst type and polymer molecular weight, molecular weight distribution, and chain microstructure. Important mechanistic aspects of propylene polymerization using $MgCl_2$-supported Ziegler–Natta catalysis are outlined, and the current position of Ziegler–Natta catalysts in polyolefin production is considered in relation to developments in the area of homogeneous catalysis.

BACKGROUND

Ziegler–Natta catalysis stems from breakthrough discoveries made by Karl Ziegler and Giulio Natta in the early 1950s. In 1953, Ziegler and coworkers at the Max Planck Institute in Mülheim were investigating the ''Aufbau'' reaction in which triethylaluminum reacts with ethylene to give higher aluminum trialkyls.[1] Unexpectedly, one experiment led to the formation of 1-butene and it turned out that this dimerization reaction had been catalyzed by traces of nickel present as a contaminant in the reactor. Soon afterwards, a revolutionary breakthrough was achieved when combinations of transition metal compounds and aluminum alkyls were found which could polymerize ethylene under mild conditions, yielding high-density polyethylene. In 1954, Giulio Natta and coworkers at Milan Polytechnic were successful in polymerizing propylene with the Ziegler catalyst combination $TiCl_4$/$AlEt_3$ and in fractionating the resulting polymer to obtain and characterize isotactic polypropylene.[2] This demonstration of stereoregular polymerization led to an explosive growth of new olefin- and diene-based polymers, and Ziegler and Natta were jointly awarded the Nobel Prize for chemistry in 1963.

The first-generation Ziegler–Natta catalysts used in early manufacturing processes for polypropylene (PP) comprised $TiCl_3$ and cocrystallized $AlCl_3$, resulting from reduction of $TiCl_4$ with Al or an aluminum alkyl. At low Al/Ti ratios, this reaction yields titanium trichloride as a solid precipitate. The β-$TiCl_3$ formed can be converted to the γ form by heating.[3] The latter catalyst has much higher stereoregulating ability in propylene polymerization, while β-$TiCl_3$ is an effective catalyst for the production of cis-1,4-polyisoprene. The cocatalyst used in propylene polymerization was $AlEt_2Cl$ (DEAC). Catalyst activity was relatively low, giving polymer yields of around 1 kg PP/g cat., necessitating removal (de-ashing) of catalyst residues from the polymer. In many cases, extractive removal of atactic polymer was also required.

In the 1970s, an improved $TiCl_3$ catalyst for PP was developed by Solvay.[4] Catalyst preparation involved reduction of $TiCl_4$ using DEAC, followed by treatment with an ether and $TiCl_4$. The ether treatment results in the removal of $AlCl_3$ from $TiCl_3.nAlCl_3$, while treatment with $TiCl_4$ effects a phase transformation from β to δ-$TiCl_3$ at a relatively mild temperature ($<100°C$).[5] Using catalysts of this type, it was possible to obtain PP yields in the range 5–20 kg/g cat. in 1–4 hrs polymerization in liquid monomer.[6] Commercial implementation of second-generation catalysts was, however, overshadowed by the advent of third- and later-generation magnesium chloride-supported catalysts, described later in the sections entitled ''Ziegler–Natta Catalysts for Ethylene (Co) Polymerization'' and ''Ziegler–Natta Catalysts for Polypropylene.''

POLYMER CHAIN GROWTH

The essential characteristic of Ziegler–Natta catalysis is the polymerization of an olefin or diene, using a combination of a transition metal compound and a base metal alkyl cocatalyst, normally an aluminum alkyl. The function of the cocatalyst is to alkylate the transition metal, generating a transition metal–carbon

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008015

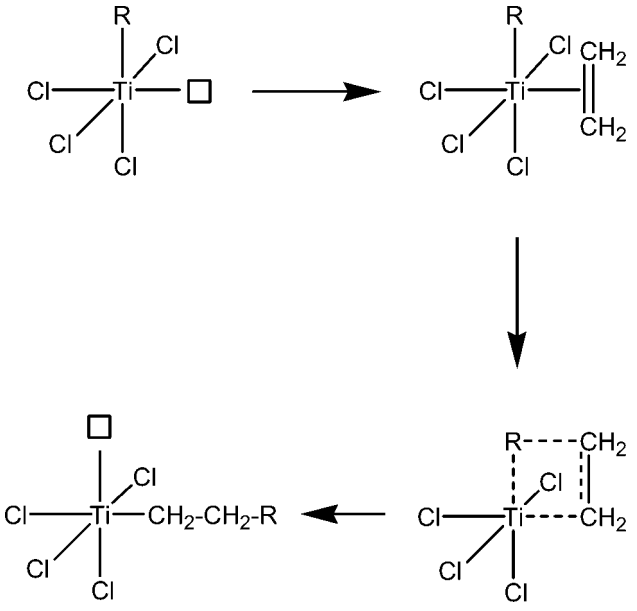

Fig. 1 Cossee–Arlman mechanism for polymerization.

bond. It is also essential that the active center contains a coordination vacancy. Chain propagation takes place via the Cossee–Arlman mechanism,[7] in which coordination of the olefin at the vacant coordination site is followed by chain migratory insertion into the metal carbon bond, as illustrated in Fig. 1.

Regulation of polyolefin molecular weight is effected by the use of hydrogen as the chain transfer agent. Chain transfer can also occur via β-hydrogen transfer from the growing chain to the transition metal or to monomer, and, to a lesser extent, via alkyl exchange with the cocatalyst.

In propylene polymerization using titanium chloride catalysts, chain propagation takes place via primary (1,2-) insertion of the monomer. For isospecific propagation, there must be only one coordination vacancy and the active site must be chiral. Corradini and coworkers have demonstrated that the asymmetric environment of the active site forces the growing chain to adopt a particular orientation so as to minimize steric interactions with (chlorine) ligands present on the catalyst surface.[8] This in turn leads to one particular prochiral face of the incoming monomer being preferred, as illustrated in Fig. 2, leading to isotactic polymer.

An elegant demonstration of the above mechanism has been provided by Zambelli et al.,[9] who showed that the first insertion of propylene into a Ti-CH_3 bond generated by chain transfer with Al alkyl using the system $TiCl_3/Al(CH_3)_3$ is *not* stereospecific, whereas the second insertion (i.e., into Ti-isobutyl) *is* stereospecific.

In contrast to the isospecific titanium-based catalysts, vanadium-based catalysts give predominantly syndiotactic polypropylene. At very low polymerization temperature (–78°C), living polymerization can be obtained using homogeneous catalysts obtained by the reaction of a vanadium compound (e.g. VCl_4 or a V(III) β-diketonate) with R_2AlCl.[10,11] With these catalysts, syndiospecific propagation occurs via secondary (2,1-) insertion of the monomer. The overall stereo- and regioregularity of the polymer is poor, comprising not only syndiotactic blocks resulting from secondary insertions, but also short, atactic blocks arising from sequences of primary insertions. This polymer has not been developed commercially, but vanadium catalysts are used in ethylene (co) polymerization, outlined in the section entitled "Ziegler–Natta Catalysts for Ethylene (Co) Polymerization" below. C_s-symmetric metallocene catalysts[12] have been developed for the production of syndiotactic polypropylene having significantly higher chain regularity.

POLYMER PARTICLE GROWTH

A very important feature of any heterogeneous catalyst used in slurry and gas-phase processes for polyolefin production is particle morphology. Typically, heterogeneous Ziegler–Natta catalysts have particle sizes in the range 10–100 μm. Each particle comprises of millions of primary crystallites with sizes of up to approximately 15 nm. On contacting the catalyst components, at the start of polymerization, cocatalyst and monomer diffuse through the catalyst particle and polymerization takes place on the surface of each primary crystallite within the particle. As solid crystalline polymer is formed, the primary crystallites are pushed outwards and apart as the particle grows, analogous to the expanding universe. The particle shape is retained, and this phenomenon is therefore referred to as replication (Fig. 3). Ideally, the catalyst particle should have spherical morphology and controllable porosity.

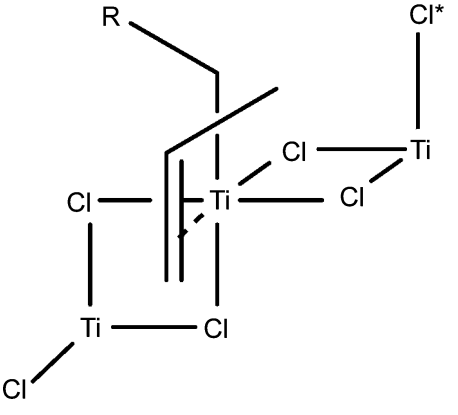

Fig. 2 Model for stereospecific polymerization of propylene. The orientation of the growing chain is influenced by the chlorine atom marked with an asterisk.

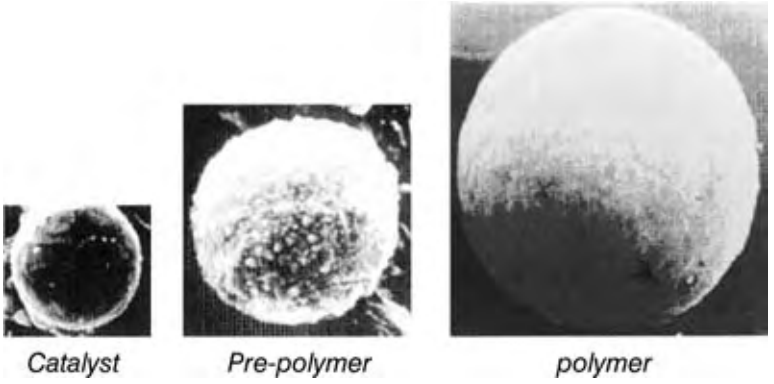

Fig. 3 ''Replication'' phenomenon during polymerization. *(View this art in color at www.dekker.com.)*

It is important that the mechanical strength of the catalyst is high enough to prevent disintegration, but low enough to allow progressive expansion as polymerization proceeds.[13]

Under appropriate polymerization conditions, polymer particles can be obtained with an internal morphology that can range from a compact to a porous structure.[14] In what is termed Reactor Granule Technology (RGT), porous polymer particles can be produced which can then function as a microreactor for the polymerization of other monomers within the solid matrix. A polypropylene skin encloses the second polymer phase, thereby preventing coalescence of particles in which the second phase is an amorphous, low-melting material. Reactor Granule Technology is able to provide products ranging from superstiff, high-fluidity PP homopolymers to stiff/impact or clear/impact heterophasic copolymers and supersoft alloys, produced using the *Catalloy* process.[13,15] The feasibility of producing heterophasic alloys containing up to 70% of elastomeric copolymers arises from the use of a controlled porosity catalyst and the ability to control the porosity of the growing polymer particle during the early stages of polymerization. Prepolymerization is applied to give the particles sufficient heat capacity to withstand injection into a gas-phase polymerization step.

Several models have been put forward to explain the mechanism of particle growth during polymerization.[16] One of the most popular models is the ''multigrain model,'' put forward by Ray et al.,[17] in which the monomer diffuses into the catalyst macroparticle and polymerises on the surface of the microparticles within, causing progressive expansion of the macroparticle as polymerization proceeds. An investigation by Kakugo et al.[18] of nascent polymer morphology obtained using a $TiCl_3$ catalyst, showed that the polymer particle comprised numerous globules, each of which contained some tens of much smaller primary particles. Recently, a model for particle growth with $MgCl_2$-supported catalysts has been proposed by Cecchin,[15,19] who has also provided evidence for polymer ''subglobule'' formation within the growing particle. Again, these subglobules originate from clusters of primary crystallites, but the crystallites themselves are pushed to the surface of each subglobule as the polymer forms. This model explains the fact that, in the preparation of heterophasic copolymers via propylene homopolymerization followed by ethylene/propylene copolymerization, the rubbery E/P copolymer is formed at the surface of the homopolymer subglobules, gradually filling up the pores within the particle. Evidence for drifting of catalyst microparticles to the surface of polymer (sub) globules has been provided by scanning electron microscopy studies of prepolymerized catalyst particles.[20]

ZIEGLER–NATTA CATALYSTS FOR ETHYLENE (CO) POLYMERIZATION

Ziegler–Natta catalysts are widely used in the production of high-density and linear low-density polyethylene (HDPE and LLDPE). More than half the world production of HDPE and over 90% of LLDPE is based on Ziegler–Natta catalysts, although increased use of metallocene and other single-site catalysts is expected throughout the next decade.

The most important titanium-based catalysts for HDPE and LLDPE are those comprising a titanium component on magnesium chloride or on a magnesium chloride-containing support. Towards the end of the 1960s, catalysts obtained by reaction of $TiCl_4$, or derivative thereof, with a magnesium compound such as Mg(OH)Cl, $Mg(OH)_2$, $Mg(OH)_2$, or $MgCl_2$, were found to give very high activity in ethylene polymerization, eliminating the need for deashing of the polymer.[13,21] The most effective support was found to be active magnesium chloride, prepared by comilling of $MgCl_2$ and titanium halides or by chlorination of organomagnesium compounds.[22] Numerous catalyst systems and methods of preparation have been

disclosed,[23] and the characteristics of magnesium chloride as a support for Ziegler–Natta catalysts are discussed in more depth later in the section entitled ''Ziegler–Natta Catalysts for Polypropylene''. Magnesium chloride can also be used in combination with a silica support, for example, by impregnation of the porous support with a solution of $MgCl_2$ and $TiCl_4$ in tetrahydrofuran.[24]

An important manufacturing process for HDPE which makes use of high-mileage catalysts is the cascade process, in which polymerization reactors in series are used to give reactor blends with improved properties for film and pipe applications.[25] Broad molecular weight distribution can be obtained by the use of different hydrogen concentrations in each reactor. In addition, the process can be designed to give low molecular weight homopolymer in the first reactor and a high molecular weight copolymer in the second. The high molecular weight copolymer chains function as tie molecules linking the crystalline, homopolymer domains, thereby leading to high stress crack resistance of the polymer. This process allows an ''inverse'' comonomer distribution to be obtained, in the sense that the comonomer is in the high molecular weight fraction, counteracting the general tendency of Ziegler–Natta catalysts to incorporate the comonomer mainly in the low molecular weight chains. The latter feature is an important consideration in Ziegler–Natta catalyst design for LLDPE, where the best catalysts are those that have relatively uniform active center distribution.

Vanadium catalysts have also been developed for polyethylene and ethylene-based copolymers, particularly ethylene-propylene-diene rubbers (EPDM). Homogeneous (soluble) vanadium catalysts produce relatively narrow molecular weight distribution polyethylene, whereas supported V catalysts give broad MWD.[26]

Ethylene polymerization, in contrast to the polymerization of propylene and other alpha-olefins, is often influenced by diffusion limitations, which occur if the monomer reactivity in polymerization is high, relative to diffusivity through the catalyst particle. This can result in the formation of an ''onion'' type internal particle morphology as polymerization first takes place at the external surface of the particle, particle growth occurring step by step as the monomer reaches the inner parts of the catalyst particle. This mechanism of particle growth is associated with a kinetic profile in which an initial induction period is followed by an acceleration period, after which, in the absence of chemical deactivation, a stationary rate is obtained. Ethylene polymerization activity can be increased by first carrying out a prepolymerization with propylene, which results in a significant lowering in the monomer diffusion barrier in the subsequent ethylene polymerization.[27]

ZIEGLER–NATTA CATALYSTS FOR POLYPROPYLENE

The manufacture of polypropylene (PP) is dominated by high-activity $MgCl_2$-supported Ziegler–Natta catalysts. The development and implementation of $MgCl_2$-supported catalysts in bulk (liquid monomer) and gas-phase processes has led to the advent of simple, low-cost (non-de-ashing, nonextracting) manufacturing processes for PP,[28] global production of which now exceeds 30 million tonnes per annum.

The basis for the development of the high-activity supported catalysts lay in the discovery in the late 1960s of ''activated'' $MgCl_2$ able to support $TiCl_4$ and give high catalyst activity, and the subsequent discovery in the mid-1970s of electron donors (Lewis bases) capable of increasing the stereospecificity of the catalyst so that (highly) isotactic polypropylene could be obtained.[21,22,29,30]

Catalyst Structure and Composition

In the early stages of $MgCl_2$-supported catalyst development, activated magnesium chloride was prepared by ball milling in the presence of ethyl benzoate, leading to the formation of very small ($\leq$3 nm thick) primary crystallites within each particle.[5] Nowadays, however, the activated support is prepared by chemical means, such as via complex formation of $MgCl_2$ and an alcohol, or by reaction of a magnesium alkyl, or alkoxide with a chlorinating agent or $TiCl_4$. Many of these approaches are also effective for the preparation of catalysts having controlled particle size and morphology. For example, the cooling of emulsions of molten $MgCl_2.n$EtOH in paraffin oil gives almost perfectly spherical supports, which are then converted into the catalysts.[28] A typical catalyst preparation involves reaction of the $MgCl_2.n$EtOH support with excess $TiCl_4$ in the presence of an ''internal'' electron donor.

High-activity Ziegler–Natta catalysts comprising $MgCl_2$, $TiCl_4$, and an internal donor, are typically used in combination with an aluminum alkyl cocatalyst such as $AlEt_3$ and an ''external'' electron donor added in polymerization. The first catalyst systems containing ethyl benzoate as internal donor were used in combination with a second aromatic ester such as methyl p-toluate as external donor.[30] These were followed by catalysts containing a diester (e.g., diisobutyl phthalate) as internal donor, used in combination with an alkoxysilane external donor of type $RR'Si(OMe)_2$ or $RSi(OMe)_3$.[31] The combination $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane represents the most widely used catalyst system in PP manufacture. The most effective alkoxysilane donors for high isospecificity are methoxysilanes containing

relatively bulky alkyl groups branched at the position alpha to the silicon atom,[32,33] such as cyclohexyl(methyl) dimethoxysilane and dicyclopentyldimethoxysilane.[34] Of these, the latter gives particularly high stereospecificity[35] and broader molecular weight distribution.[36]

The function of the internal donor in $MgCl_2$-supported catalysts is to stabilize the small primary crystallites of magnesium chloride formed in the catalyst preparation and to control the amount and distribution of $TiCl_4$ in the final catalyst. Activated magnesium chloride has a disordered structure comprising very small lamellae. Giannini[22] has indicated that, on preferential lateral cleavage surfaces, the magnesium atoms are coordinated with four or five chlorine atoms, as opposed to six chlorine atoms in the bulk of the crystal. These lateral cuts correspond to (110) and (100) faces of $MgCl_2$ (Fig. 4).

It has been proposed that bridged, dinuclear Ti_2Cl_8 species can coordinate to the (100) face of $MgCl_2$ and give rise to the formation of chiral, isospecific active species (Fig. 5), it being pointed out that Ti_2Cl_6 species formed by reduction on contact with $AlEt_3$ would resemble analogous species in $TiCl_3$ catalysts.[37] Accordingly, it has been suggested[28] that a possible function of the internal donor is preferential coordination on the more acidic (110) face of $MgCl_2$, such that this face is prevailingly occupied by donor and the (100) face is prevailingly occupied by Ti_2Cl_8 dimers.

Analytical studies[38] have indicated that a monoester internal donor such as ethyl benzoate is coordinated to $MgCl_2$ and not to $TiCl_4$. In the search for donors giving catalysts having improved performance, it was considered[39] that bidentate donors should be able to form strong chelating complexes with

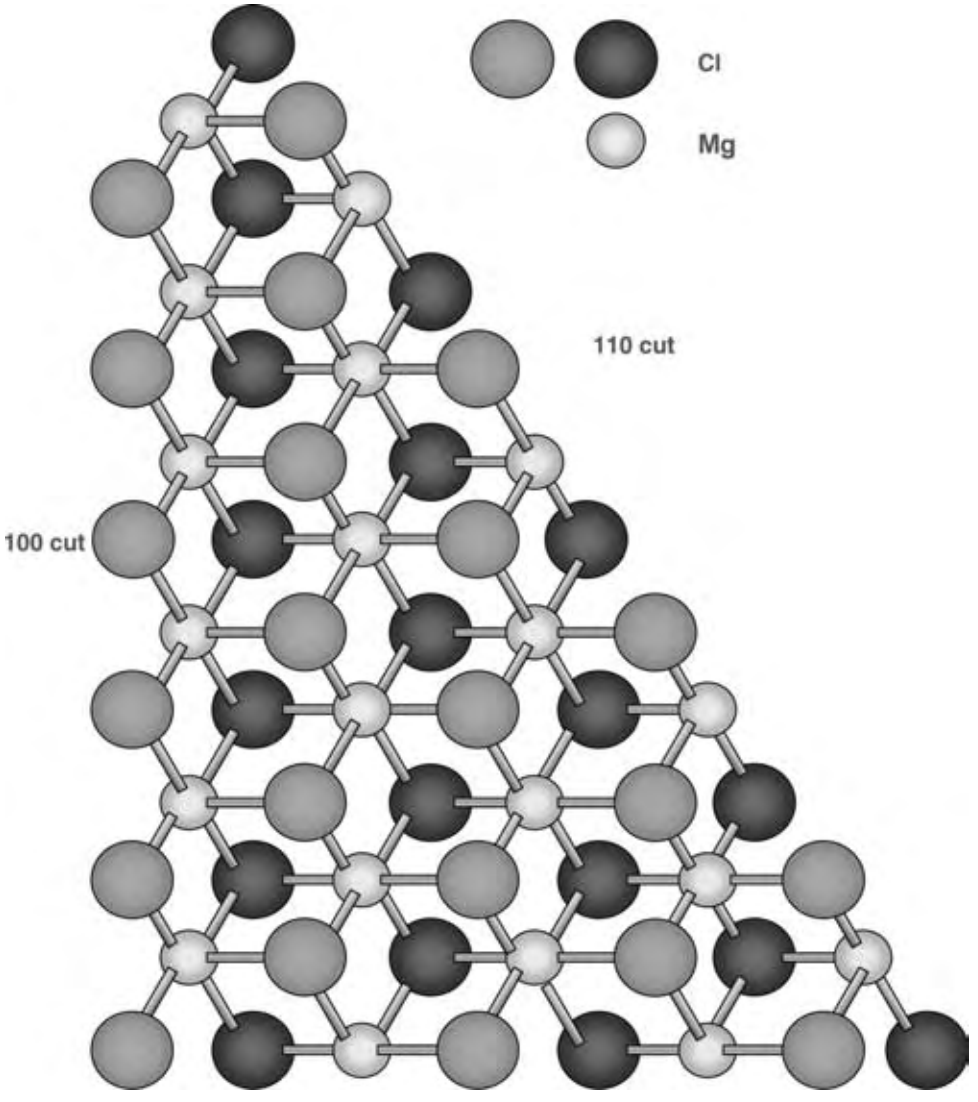

Fig. 4 Model of a $MgCl_2$ layer showing the (100) and (110) lateral cuts. (From Ref.[13].) *(View this art in color at www.dekker.com.)*

tetracoordinate Mg atoms on the (110) face of $MgCl_2$, or binuclear complexes with two pentacoordinate Mg atoms on the (100) face. This led to the development of the $MgCl_2/TiCl_4$/phthalate ester catalysts, used, as indicated above, in combination with an alkoxysilane as external donor. The requirement for an external donor when using catalysts containing a benzoate or phthalate ester is due to the fact that, when the catalyst is brought into contact with the cocatalyst, a large proportion of the internal donor is lost as a result of alkylation and/or complexation reactions, which, in the absence of an external donor, would lead to poor stereospecificity. When the external donor is present, contact of the catalyst components leads to replacement of the internal donor by the external donor. The most active and stereospecific systems were found to be those which allowed the highest incorporation of external donor,[40] the effectiveness of a catalyst system depending more on the combination of donors rather than on the individual internal or external donor.

More recently, research on $MgCl_2$-supported catalysts has led to systems not requiring the use of an external donor. This required the identification of bidentate internal donors, which not only had the right oxygen–oxygen distance for effective coordination with $MgCl_2$ but which, unlike phthalate esters, were not removed from the support on contact with $AlEt_3$. It was found[39,41–43] that certain 2,2-disubstituted-1,3-dimethoxypropanes met all these criteria. The best performance was obtained when bulky substituents in the 2-position resulted in the diether having a most probable conformation[44] with an oxygen–oxygen distance in the range 2.8–3.2 Å. Successive ''generations'' of high-activity $MgCl_2$-supported catalyst systems for polypropylene are summarised below:

$MgCl_2/TiCl_4$/ethyl benzoate – AlR_3 – aromatic ester

$MgCl_2/TiCl_4$/phthalate ester – AlR_3 – alkoxysilane

$MgCl_2/TiCl_4$/diether – AlR_3

Catalyst performance has improved considerably with each generation. The polypropylene yield obtained under typical polymerization conditions (liquid monomer, in the presence of hydrogen, 70°C, 1–2 hrs) has increased from 15–30 kg/g cat. for the third generation ethyl benzoate-containing catalysts to 30–80 kg/g cat. for the fourth generation phthalate-based catalysts. With the fifth generation catalysts containing a diether as internal donor, yields of 80–160 kg/g cat. can be achieved. These different catalysts also display different kinetic profiles in propylene polymerization. The catalysts containing a diether as internal donor exhibit very stable activities during polymerization. A low rate of catalyst decay during polymerization is also obtained with the catalyst system $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane, whereas the system $MgCl_2/TiCl_4$/ethyl benzoate–AlR_3–aromatic ester has a very high initial polymerization activity, but also a high decay rate, limiting the final polymer yield. The rapid decay in activity can, at least, partially be ascribed to the use of an ester as external as well as internal donor, the ester being able to react with titanium–hydrogen bonds formed in chain transfer with hydrogen, generating Ti–O bonds inactive for chain propagation.[45]

Most recently, a further family of $MgCl_2$-supported catalysts has been developed[15,46] in which the internal donor is a succinate rather than a phthalate ester. As is the case with the phthalate-based catalysts, an alkoxysilane is used as external donor. The essential difference between these catalysts is that the succinate-based systems produce polypropylene having much broader molecular weight distribution, discussed below in the section entitled ''Catalyst/Polymer Relationship.''

Mechanistic Aspects

It is well established that effective external donors not only increase the isotactic index of the polymer (the proportion of polymer insoluble in boiling heptane or in xylene at 25°C), but they can also increase in absolute terms the amount of isotactic polymer formed. This has been demonstrated by Kashiwa[47] for the catalyst system $MgCl_2/TiCl_4$–$AlEt_3$. An increase in the molecular

weight and stereoregularity of the isotactic fraction was also noted. Similar trends are apparent with catalyst systems of type $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane.[48] Kakugo[49] has used elution fractionation to demonstrate that the external donor not only decreases ''atactics'' formation, but also increases the degree of steric control at isospecific sites. This is also apparent from determination of the stereoregularity of the first insertion step in propylene polymerization.[50]

Recently, significant advances have been made in understanding the fundamental factors determining the performance of state-of-the-art $MgCl_2$-supported catalysts. Studies by Busico et al.[51] have shown that the chain irregularities in isotactic polypropylene prepared using Ziegler–Natta catalysts are not randomly distributed along the chain but are clustered. Therefore, the chain can contain, in addition to highly isotactic blocks, sequences which can be attributed to weakly isotactic (isotactoid) and to syndiotactic blocks. This implies that the active site can isomerise very rapidly (during the growth time of a single polymer chain, i.e., in less than a second) between three different propagating species. The same sequences are present, but in different amounts, in both the soluble and the insoluble fractions. The polymer can therefore be considered to have a stereoblock structure in which highly isotactic sequences alternate with defective isotactic (isotactoid) and syndiotactoid sequences. Fig. 6 illustrates a mechanistic model in which the relative contributions of these sequences can be related to site transformations involving the presence or absence of steric hindrance in the vicinity of the active species.

If it is considered that the steric hindrance in the vicinity of the active species can result from the presence of a donor molecule, and that the coordination of such a donor is reversible, the above model provides us with an explanation for the fact that strongly-coordinating, stereorigid donors typically give stereoregular polymers in which the highly isotactic sequences predominate. Several types of active species in which the presence of a donor in the vicinity of the active Ti atom is necessary for high isospecificity have been proposed,[52] although the exact structure of the active species is still by no means resolved. The model illustrated in Fig. 6 has also been used as a basis for quantum mechanical calculation of activation energies for primary (1,2-) and secondary (2,1-) insertion of the propene monomer into the growing chain.[53] The lowest energy insertion path, in accordance with the Corradini mechanism,[8] is the 1,2-insertion shown in Fig. 7(A). Of the paths for 2,1-insertion, illustrated in Figs. 7(B) and (C), the latter is prohibited by steric repulsion with the ligand (L1 of Fig. 6). However, a low stereoselectivity of 2,1-insertion with a donor-free catalyst[53] indicates the presence of active species in which the ligand is missing.

In PP production, hydrogen is used as chain transfer agent for polymer molecular weight control. Catalysts containing a diether donor show particularly high sensitivity to hydrogen, such that relatively little hydrogen is required for molecular weight control. This effect can be ascribed to chain transfer after the occasional 2,1- rather than the usual 1,2-insertion, a 2,1-insertion slowing down a subsequent monomer insertion and therefore increasing the probability of chain transfer.[54] Reactivation of ''dormant'' (2,1-inserted) species via chain transfer with hydrogen also explains the frequently observed activating effect of hydrogen in propylene polymerization, giving polymer yields which may be around three times those observed in the complete absence of hydrogen. These conclusions have been based on the ^{13}C NMR determination of the relative proportions of *i*-Bu and *n*-Bu terminated chains, resulting from chain transfer with hydrogen after primary and secondary insertion respectively:

$$TiCH_2CH(CH_3)[CH_2CH(CH_3)]_nPr + H_2 \rightarrow TiH + iBuCH(CH_3)[CH_2CH(CH_3)]_{n-1}Pr$$

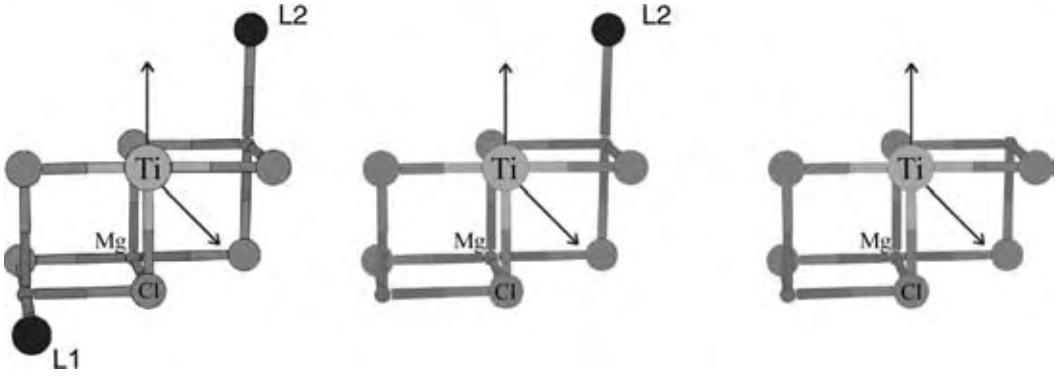

Fig. 6 Model of possible active species for highly isotactic, isotactoid and syndiotactic propagation. (From Ref.[53].) *(View this art in color at www.dekker.com.)*

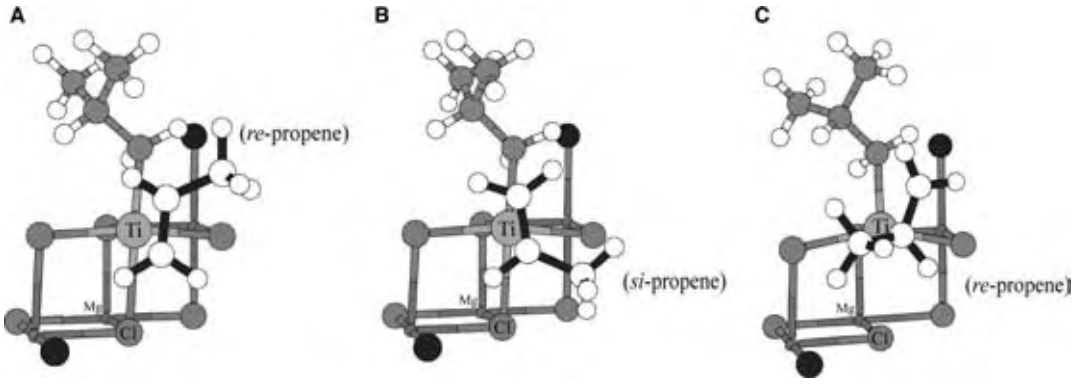

Fig. 7 Optimized geometries for (A): 1,2-insertion, and (B) and (C): 2,1-insertion of propylene. (From Ref.[53].) *(View this art in color at www.dekker.com.)*

$$TiCH(CH_3)CH_2[CH_2CH(CH_3)]_nPr + H_2 \rightarrow TiH + nBuCH(CH_3)[CH_2CH(CH_3)]_{n-1}Pr$$

Other studies have demonstrated that chain transfer is dependent not only on *regio-*, but also on *stereo-*selectivity.[35] This is in keeping with the tendency that, with catalyst systems of type $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane, the silanes which give the most stereoregular isotactic polymer also give relatively low hydrogen response. Effective chain transfer with hydrogen also appears to be dependent on the presence of species able to promote the dissociation of H_2 to atomic hydrogen, studies by Terano and coworkers[55] having shown that, under stopped-flow conditions, hydrogen is only effective as a chain transfer agent when catalyst and cocatalyst have been precontacted.

CATALYST/POLYMER RELATIONSHIP

By varying the catalyst composition, and in particular the nature of the electron donors (esters, silanes, diethers) present in the catalyst system, it is possible to control the polypropylene tacticity, molecular weight, and molecular weight distribution to produce a range of polymers having the processing and end-use properties required for very different applications. Ziegler–Natta catalysts typically give broader molecular weight distributions than are obtained with homogeneous (metallocene) catalysts. This is because Ziegler–Natta catalysts contain a range of different active centers, each center giving different relative rates of chain propagation and chain transfer. The proportion of Ti which is catalytically active in $MgCl_2$-supported catalyst systems for PP is relatively low, values reported by different groups ranging from 1% or less[56] to more than 20%.[57] The propagation rate constant, k_p, for isospecific active sites, is around an order of magnitude greater than for weakly-specific sites[56,57] and increases significantly in the presence of hydrogen,[58] in accordance with the reactivation of ''dormant'' (2,1-inserted) centers by chain transfer.

The donors present in the catalyst system play an active role in the formation or modification of isospecific sites, and the polymer molecular weight distribution depends on the relative contribution and hydrogen response (i.e., sensitivity to chain transfer with hydrogen) of each type of active site. The characteristics of different catalyst systems with regard to PP molecular weight distribution are as follows:[15]

Internal donor	*External donor*	M_w/M_n
Diether	–	5–5.5
Phthalate	Alkoxysilane	6.5–8
Succinate	Alkoxysilane	10–15

It can be seen that the diether-based catalysts give relatively narrow molecular weight distribution. A narrow molecular weight distribution, and relatively low molecular weight, is advantageous in fibre spinning applications. In contrast, extrusion of pipes and thick sheets requires high melt strength, and, therefore, relatively high molecular weight and broad molecular weight distribution. A broad molecular weight distribution, along with high isotactic stereoregularity, is also beneficial for high crystallinity and, therefore, high rigidity. The new succinate-based catalysts enable very broad MWD PP homopolymers to be produced in a single reactor and are also of interest for the production of heterophasic copolymers having an improved balance of stiffness and impact strength, taking into account that the incorporation of a rubbery (ethylene/propylene) copolymer phase into a PP homopolymer matrix increases impact strength, but, at the same time, leads to decreased stiffness.

The relatively narrow PP molecular weight distributions obtained using diether-based catalysts can be attributed to the fact that, in these systems, even the most highly stereospecific active sites are not totally regiospecific. A proportion of approximately one secondary insertion for every 2000 primary insertions at highly isospecific sites has been noted for the system $MgCl_2/TiCl_4$/diether–AlR_3.[54] The probability of chain transfer with hydrogen after a secondary insertion is such that this is sufficient to prevent the formation of very high molecular weight chains, taking into account that the highest molecular weight fraction of the polymer is formed by the active species having the highest isospecificity. The broader molecular weight distributions obtained with catalysts containing ester internal donors are likely to be due to the presence of (some) isospecific active sites having very high regiospecificity and, therefore, lower hydrogen sensitivity. Such results illustrate the profound effect of catalyst regio- and stereospecificity distribution on both molecular weight control and polymer MWD and properties.

POLYMERIZATION OF OTHER MONOMERS

In addition to their widespread use in the production of polyethylene and polypropylene, Ziegler–Natta catalysts play an important role in the production of poly-1-butene, and are also widely used in the manufacture of synthetic rubbers such as *cis*-1,4-polybutadiene and *cis*-1,4-polyisoprene, the synthetic equivalent of natural rubber. Titanium-, cobalt-, nickel- and neodymium-based Ziegler–Natta catalyst systems are used in the manufacture of butadiene rubber. Isoprene rubber is produced using β-$TiCl_3$[59] typically prepared by the reaction of approximately equimolar quantities of $TiCl_4$ and Al*i*Bu_3 in the presence of a small quantity of an ether. Recently, it has been shown that almost perfectly stereoregular *cis*-1,4-polyisoprene can be synthesized using lanthanide metallocene catalysts.[60]

Cis-1,4-polymerization of conjugated dienes requires the presence of two coordination vacancies on the transition metal atom, allowing bidentate coordination of the diene. β-$TiCl_3$ has a fiber-like structure in which the titanium atoms in the lattice are octahedrally coordinated to six chlorine atoms. The terminal titanium atoms are, however, incompletely coordinated and are linked to four or five chlorine atoms. Alkylation of the tetracoordinated titanium atoms will generate the double-vacancy species active in isoprene polymerization. Stereospecificity in diene polymerization can change dramatically if one of the coordination vacancies is blocked by a Lewis base. An interesting illustration of this[61] is the addition of an external donor in isoprene polymerization with $TiCl_4$–$AlEt_3$ or $MgCl_2/TiCl_4$–$AlEt_3$, which changes the catalyst stereospecificity to give mainly *trans*-1,4- rather than *cis*-1,4-polyisoprene. At the same time, a notable increase in isospecificity in propylene polymerization is observed.

$TiCl_3$-based and $MgCl_2$-supported catalysts have been developed for the production of poly-1-butene. With $TiCl_3$, the use of $AlEt_2I$ as cocatalyst was found to give higher isotacticity than $AlEt_2Cl$.[62] Much higher polymerization activity, as well as high isotacticity and broad molecular weight distribution, is obtained using $MgCl_2$-supported catalysts, for example, the catalyst system $MgCl_2/TiCl_4$/di-isobutyl phthalate–$AlEt_3$–alkoxysilane.[63]

Ziegler–Natta catalysts have also been developed for the polymerization of 4-methyl-1-pentene[64] and higher alpha-olefins. Polymerization activity decreases with increasing steric bulk of the monomer. For example, with the catalyst system $MgCl_2/TiCl_4$/ethyl benzoate–$AlEt_3$–ethyl benzoate, the relative activities in propylene, 1-butene, and 4-methyl-1-pentene polymerization were 100:80:15.[65] For catalyst systems of type $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane, the type of silane required is dependent on the steric bulk of the monomer. An active center having high stereospecificity in propylene polymerization may be too sterically hindered for effective polymerization of a bulkier monomer, propylene/1-butene copolymerization studies having shown[66] that the incorporation of 1-butene into the polymer chain decreases with increasing site stereospecificity. This phenomenon is also illustrated by the fact that nonbulky alkoxysilanes, such as Me_3SiOMe, are effective donors in 4-methyl-1-pentene polymerization,[67] whereas such donors are relatively ineffective in propylene polymerization.

FUTURE TRENDS IN ZIEGLER–NATTA CATALYSIS

Progress in (heterogeneous) Ziegler–Natta catalysis has continued unabated over the last 50 years, while the last 20 years have seen the advent of homogeneous (metallocene and other single-site) catalysts.[68] However, despite the enormous research effort and many advances made in the field of homogeneous catalysis, polyolefins manufacture is still dominated by Ziegler–Natta systems.

Homogeneous catalysts, in which each catalytic center is identical, give polymers having very narrow molecular weight and tacticity distribution and, in the case of copolymers, random comonomer incorporation. The latter feature is particularly important in polymers such as LLDPE, while a uniform stereo- or regiodefect distribution in PP can give improved optical and barrier properties. However, utilization of

these catalysts in slurry or gas-phase processes requires immobilization on a suitable support material.[69]

Inherently heterogeneous Ziegler–Natta catalysts have the advantage of excellent morphology control, while the nonuniform nature of the active species results in polymers having molecular weight distributions ranging from very broad to relatively narrow. For PP, this has opened the way to a range of polymers suitable for widely differing applicational areas. The most important variable determining the suitability of a catalyst for a particular application is the internal/external donor combination and continuing research in this area is highlighted by the recent development of succinate-based catalysts.[15,46] Very high activity, notably with diether-based catalysts, has already been achieved, but if the proportion of active centers in a typical Ziegler–Natta PP catalyst is taken to be less than 10% of the Ti present, it is clear that there is still considerable scope for further improvement.

There are many differences between Ziegler–Natta and metallocene catalysts, not the least of which is that in a $MgCl_2$-supported $TiCl_4$ catalyst the Ti centers are octahedral, whereas the metallocene complexes are tetrahedral. However, homogeneous single-site catalysts having octahedral geometry have now been developed. Complexes containing phenoxy-imine ligands have been developed that give exceptionally high activity in ethylene polymerization.[70] Other complexes, containing tetradentate ligands, have been found[71] to give isotactic poly(1-hexene) and the stereoselectivity of such C_2-symmetric complexes in propylene polymerization has been shown[72] to mimic the behavior of Ziegler–Natta catalysts, albeit with much lower activity. The accessibility of well-defined octahedral complexes for olefin polymerization therefore provides further mechanistic insight in Ziegler–Natta catalysis, and molecular modeling is playing an increasingly important role in defining the nature of the active species in both heterogeneous and homogeneous systems.[8]

CONCLUSIONS

Continual improvements in catalyst activity, selectivity, and particle morphology obtained with successive generations of Ziegler–Natta catalysts have paved the way to efficient polyolefin manufacturing processes and to ever-increasing control over polymer structure and properties. Different catalysts are required for different applications, and the characteristics of Ziegler–Natta catalysts for polypropylene are strongly dependent on the type of electron donor(s) used. Recent developments have led to new $MgCl_2/TiCl_4$/donor catalysts for polypropylene, with diether donors giving relatively narrow PP molecular weight distribution and succinate donors giving broad molecular weight distribution.

Ziegler–Natta catalysts are complex systems and the exact structure of the various active species is still by no means fully understood. Nevertheless, significant advances in basic understanding have recently been made with regard to the role of the electron donor and the effects of the stereo- and regiospecificity of monomer insertion on polymer chain growth and chain transfer. Recent developments in homogeneous (single-site) catalysis have provided further mechanistic insight, with molecular modeling playing an increasingly important role.

Polyolefins manufacture is still dominated by Ziegler–Natta catalysts, and this situation is likely to remain for some time, despite the many advances being made in the field of metallocene and related single-site catalysis. Ziegler–Natta and single-site catalysts can be regarded as complementary rather than competitive systems, which together provide the basis for a wide range of polymers with closely controlled molecular structure.

Volume 1

Encyclopedia of Chemical Processing

EDITED BY
Sunggyu Lee

about the book...

Collecting information of vital interest to chemical, polymer, electrical, mechanical, and civil engineers, as well as chemists and chemical researchers, this Encyclopedia supplies nearly 350 articles on current design, engineering, and manufacturing practices—offering expertly written articles on technologies at the forefront of the field to maximize and enhance the research and production phases of current and emerging chemical manufacturing practices and techniques.

A complete reconceptualization of the classic reference series—*the Encyclopedia of Chemical Processing and Design,* whose first volume published in 1976—this resource offers extensive A-Z treatment of the subject in five simultaneously published volumes...completely new material on the design of key unit operations involved with chemical processes; the design, unit operation, and integration of reactors and separation systems; process system peripherals such as pumps, valves, and controllers; analytical techniques and equipment; and pilot plant design and scale-up criteria...comprehensive indexing of all five volumes to appear in the backmatter of each tome...well-researched sections on automation, equipment, design and simulation, reliability and maintenance, separations technologies, and energy and environmental issues...authoritative contributions on chemical processing equipment, engineered systems, and laboratory apparatus currently utilized in the field... expert overviews on key engineering science topics in property predictions, measurements and analysis, novel materials and devices, and emerging chemical fields...and gold standard articles on the methods, practices, products, and standards recently influencing the chemical industries.

about the editor...

SUNGGYU LEE is the C.W. LaPierre Professor and Chairman of the Department of Chemical Engineering at the University of Missouri–Columbia. He is the author or coauthor of several books and over 400 archival publications. He received 20 U.S. patents in fields of chemical process technologies. A specialist in chemical reaction engineering and process analysis, and an active member of the American Institute of Chemical Engineers, Dr. Lee has designed more than 25 pilot, commercial, and demonstration plants, and advised companies such as B. F. Goodrich, Water Technologies Limited, and Northern Technology International. He received the B.S. (1974) and M.S. (1976) degrees in chemical engineering from Seoul National University, Korea, and the Ph.D. degree (1980) in chemical engineering from Case Western Reserve University, Cleveland, Ohio.
