The resulting PP samples usually contain regioirregular enchainments in the range of 0.3–1.0 mol%. The end groups in the polymer chain are typical of saturated propyl groups and 2-methyl-prop-1-enyl(vinylidene) groups, owing to the chain transfer by intramolecular β-H elimination. Additional saturated end-groups, such as *iso*-butyl and unsaturated but-2-enyl, are also observed because of the chain transfer to $AlMe_3$ and β-H elimination, respectively, at a last inserted 2,1 unit.[10]

One major drawback of *rac*-C_2-symmetric *ansa*-metallocene catalysts is that either during the synthesis of the precursors or by subsequent epimerization the *meso*-form with C_s-symmetry can also be obtained. The active sites of catalytic species formed from *meso*-C_s-symmetric precursors are obviously nonchirotopic, and cannot exert any stereocontrol on the chain propagation. As a result, some atactic PP is invariably obtained.[11]

C_{2v}-Symmetric Metallocenes

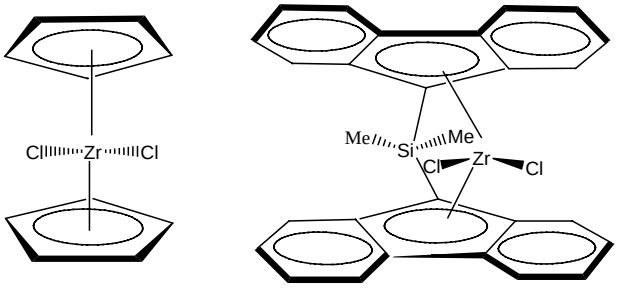
Two cyclopentadienyl-sandwiched Cp_2ZrX_2/MAO complexes (Cp = cyclopentadienyl; X = halogen or alkyl) with C_{2v}-symmetry form the earliest metallocene system that has been used for ethylene homopolymerization with remarkably high activity. The application in propylene polymerization is less useful. They produce PP with low activity and low molecular weight.[12] Unexpectedly, the Cp_2TiPh_2/MAO system can be used for the synthesis of predominately i-PP below room temperature. The stereochemical structure of the resulting polymer indicates a chain-end-controlled model in the polymerization. Bridged C_{2v}-symmetric metallocenes, such as $Me_2Si(9\text{-Flu})_2ZrCl_2$ (Flu = fluorenyl), provide convenient access to high molecular weight atactic PP, which performs like an elastomer.[13] The structure of two typical C_{2v}-symmetric metallocenes is shown in Scheme 3.

By means of ^{13}C and ^1H NMR, mainly propyl and 2-methyl-prop-1-enyl (vinylidene) end groups are detected in the polymers prepared by Cp_2MtX_2 (Mt = Zr, or Ti) catalyst. This indicates that the predominant monomer insertion is 1,2-insertion and that β-H elimination from the last inserted 1,2 unit is the major chain transfer pathway.[14] In PPs prepared with related catalyst systems $(Cp^*)_2ZrX_2$/MAO ($Cp^* = \eta^5$-pentamethylcyclopentadienyl), *iso*-butyl and prop-1-enyl (vinyl) groups are found to be the major end groups, which suggests that chain transfer consists of predominant β-methyl elimination.[15]

Bridged C_s-Symmetric Metallocenes

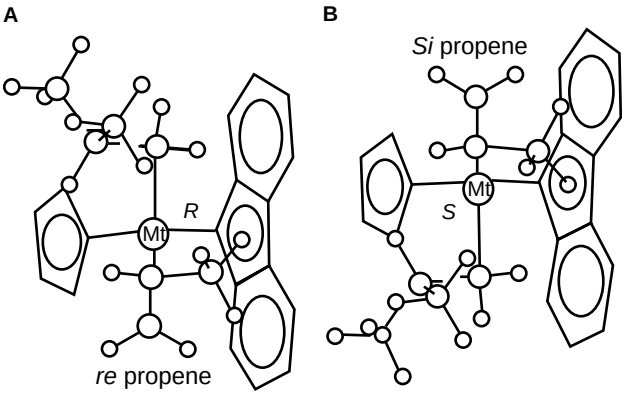
The first catalyst in producing highly s-PP is C_s-symmetric $Me_2C(Cp)(9\text{-Flu})ZrCl_2$ (Flu = fluorenyl), as illustrated in Scheme 4.[16] Although s-PP polymers in the experimental measurements always show lower melting points (T_m) than the corresponding i-PP polymers, the theoretical prediction of a fully s-PP will have T_m of 214°C, notably higher than that of i-PP (186°C).[17] It is a scientifically challenging and industrially important to develop new metallocene catalysts in order to prepare s-PP polymers with high syndiotacticity.

The invention of C_s-symmetric metallocenes has marked a major turning point in understanding the stereocontrol mechanism of metallocene catalysis. Scheme 5 shows the computer models of the cationic



Cp_2ZrCl_2 $Me_2Si(9\text{-}Flu)_2ZrCl_2$

Scheme 3



Scheme 5

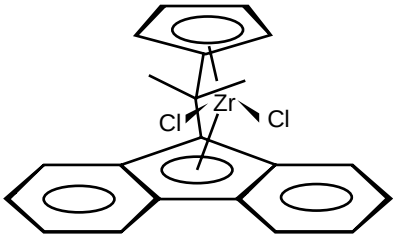
catalytic species $[Me_2C(Cp)(9\text{-}Flu)Mt(iso\text{-}butyl)]^+$ (Mt = Zr) with an η^2-coordinated propylene molecule.[18] The mutual arrangements of the first C–C bond of the *iso*-butyl group (simulating a growing PP chain) and of the monomer are the ones that minimize the nonbonded interactions at the 1,2-insertion step. According to the chain migratory polymerization mechanism, situations (1) and (2) (as given below) alternate regularly during chain propagation. In two successive insertion steps opposite propylene enantiofaces are inserted, therefore s-PP results. The presence of isolated insertion errors, showing rrrrmmrrrr stereodefects, indicates a site control mechanism.

At low polymerization temperatures with liquid propylene, $Me_2C(Cp)(9\text{-}Flu)ZrCl_2/MAO$ catalyst system can produce s-PP with a very high stereoregularity [(rrrr) > 0.95] and a melting point close to those of highly i-PP ($T_m > 150°C$).[19] Generally, C_s-symmetric metallocene catalysts are highly regioselective and no regioerrors are found in the typical s-PP.[20] The end groups are predominantly propyls and 2-methylprop-1-enyls (vinylidenes). At lower monomer concentration, small amounts of *iso*-butyls are found as a result of the chain transfer to $AlMe_3$.

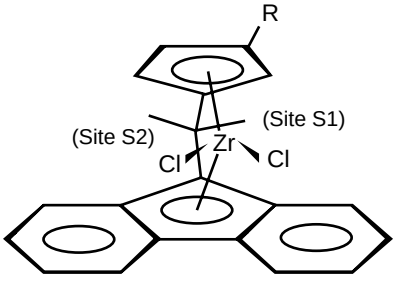
Bridged C_1-Symmetric Metallocenes

C_1-symmetric metallocenes are complexes lacking any symmetry, which can be divided into two categories: 1) those with one (substituted or nonsubstituted) cyclopentadienyl ligand having two homotopic faces (type I) and 2) those with two asymmetric cyclopentadienyls (type II), as illustrated in Scheme 6.

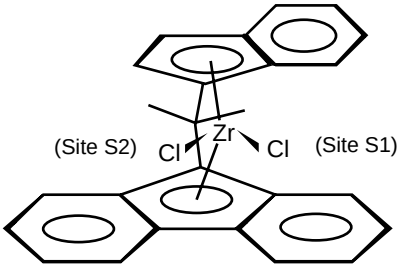
C_1-symmetric metallocenes present a synthetic advantage over C_2-symmetric ones in terms of their application for isospecific polymerization of propylene. As mentioned previously, a problem associated with the synthesis of *ansa*-C_2-symmetric metallocenes is that they are almost invariably generated along with their *meso*-isomers, which are difficult to remove from the catalyst mixture and often produce undesirable low molecular weight atactic PP with certain polymerization activity. The synthesis of pure C_2-symmetric catalysts usually requires multiple purification steps with low yields.[21,22] In contrast, a *meso*-form does not exist



Scheme 4



Type I



Type II

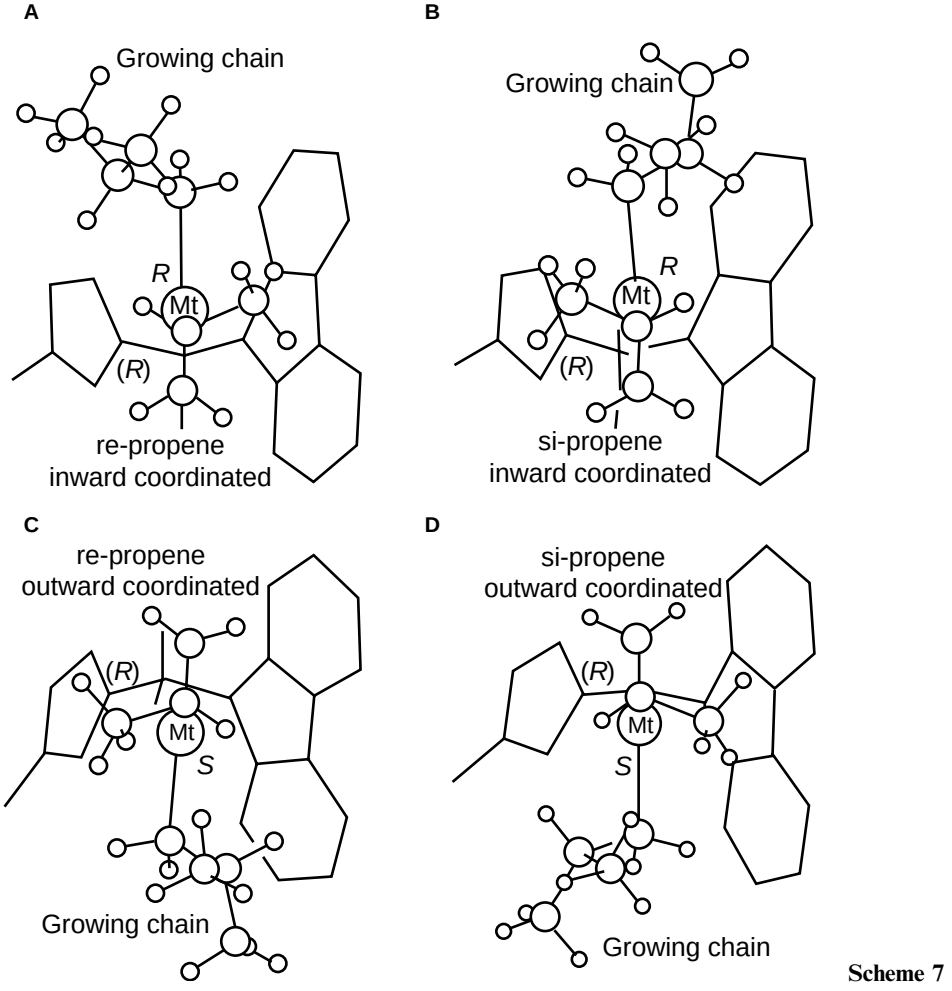
Scheme 6

in C_1-symmetric system, therefore the synthesis of ligand and catalyst is simple.

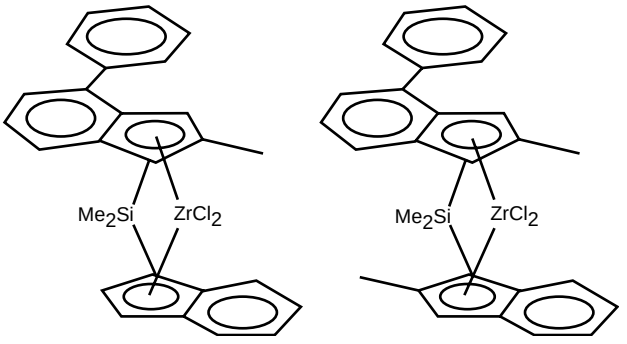
The common feature of C_1-symmetric metallocenes is that their two coordination sites are diastereotopic. On the size basis of the substitution on the cyclopentadienyl ligand, C_1-symmetric catalysts can vary in stereoselectivity to form PP that is hemi-isospecific (amorphous hi-PP) to partially isospecific (amorphous or low-crystallinity PP) to isospecific (i-PP with high T_m and high crystallinity).

The steroselectivity of C_1-symmetric metallocenes in propylene polymerization can be predicted based on rationalization of the ligand structure. In case of a typical type I metallocene, Me_2C(3-Me-Cp)(9-Flu)$ZrCl_2$, a computer model of the cationic catalytic species with growing polymer chain simulated by an *iso*-butyl group is shown in Scheme 7. Clearly, the model is enantioselective when the propylene molecule is inward coordinated, because structure A with a *re*-coordinated propylene is favored compared to structure B with a *si*-coordinated propylene. This is due to repulsive interactions between the growing chain and the fluorenyl ligand in structure B. On the contrary, the model is nonenantioselective when the growing chain is σ-bonded in the inward coordination position, because structures C and D are equally hampered by repulsive interactions of the growing chain, either with the 9-Flu ligand (structure C) or with the methyl group of the 3-MeCp ligand (structure D). According to a regular chain migration insertion mechanism, the insertions are alternately enantioselective and nanenantioselective. Therefore, the model is hemi-isospecific.[23] In fact, PPs with almost ideal hemi-isotactic structure can be obtained with Me_2C(3-Me-Cp)(9-Flu)$ZrCl_2$/MAO under conditions of chain migratory propagation (relatively low temperature and high propylene concentration).[24]

The stereoselectivity, however, strongly depends on the structure of the ligand. In particular, catalysts of type I with a bulky R substituent (e.g., R = *t*-butyl or trimethylsilyl), as well as those of type II, are predominantly isotactic selective.[25,26] The presence of *t*-butyl group or phenyl ring does not permit the growing chain to be located in the inward position. Particularly, in the absence of the monomer molecule, probably occurring at the end of each insertion step,



Scheme 7



Scheme 8

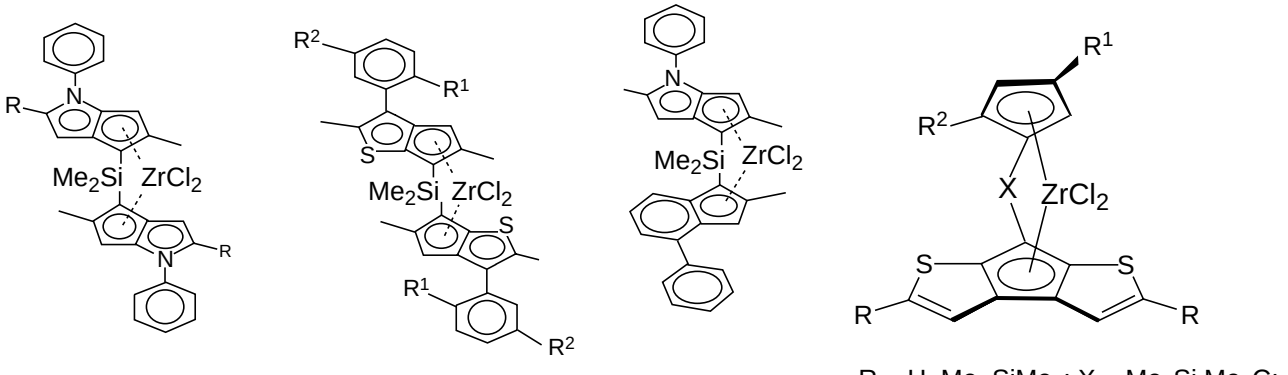
the steric stress of the ligand skeleton could force the growing chain to skip back to the less crowded outward position. Thus, insertion always occurs with the same relative disposition of the monomer and of the growing chain, and the model turns out to be isospecific. Experimental results show that Me_2C(3-*t*-Bu-Cp)(9-Flu)$ZrCl_2$/MAO produces i-PP with relatively high mmmm pentad contents from 77.5% at 60°C in liquid monomer to 87.8% at 50°C and pressure of 2 bar.[27,28] Spaleck reported the remarkable performance of C_1-symmetric systems, illustrated in Scheme 8, which combine the indenyl substitution of two different C_2-symmetric zirconocenes. These catalysts provide both high stereoregularity and high molecular weights. For example, Me_2Si(Ind)(2-Me-4-Ph-Ind)$ZrCl_2$ gives i-PP with mm = 96%, 2,1 = 0.4%, T_m = 155°C, and M_w = 530,000, at the relatively high polymerization temperature of 70°C.

Recently, Ewen et al. have designed C_2-, C_s-, and C_1-symmetric catalysts bearing heterocycle-condensed Cp ligands, as illustrated in Scheme 9, which add electronic effects to the stereocontrol.[29,30] The complexes, containing isopropylidene-bridged cyclopentadienyl and cyclopentyl thiophene ligands, show activity comparable to those of fluorenyl analogs, and obey the same symmetry rules for PP tacticity vs. catalyst symmetry. Such catalysts can produce i-PP with even higher melting temperature (161°C) and molecular weight ($M_w > 1$ million g/mol). However, when dithienocyclopentadiene is applied to substitute fluorenyl, the catalytic properties suffer greatly. Although low amounts of MAO are used to activate the metallocenes, only PPs with low isotacticity and melting point are produced.[31] Dialkoxyl substituted C_1-symmetric metallocene complexes, such as *rac*-[1-(5,6-dialkoxy-2-methyl-1-η^5-indenyl)-2-(9-η^5-fluorenyl)ethane]zirconium dichloride activated with triisobutylaluminum and $Ph_3C[B(C_6F_5)_4]$, also show few advantages compared with their counterparts without heteroatom substitutes in terms of catalytic activity, isotactity, molecular weight, and melting temperature of the products.

It should be noted that C_1-symmetric metallocenes show a stereoselectivity increase with elevated polymerization temperature and lowered monomer concentration, a behavior opposite to that displayed by the C_2-symmetric metallocenes.[32] The regioregularity of PP samples prepared with most C_1-symmetric metallocene catalysts is fairly high. The predominant monomer insertion mode is 1,2. Isolated 2,1 and/or 3,1 units can be observed with <0.5 mol%.

Metallocenes with Oscillating Structure

In unbridged metallocenes, like Cp_2MtX_2 or Ind_2MtX_2, the η^5-coordinated aromatic rings rotate freely even at very low temperatures. However, the rotation may become hindered in the presence of a bulky substituent, and the rate of rotation "oscillating" may be dependent on the temperature. Of special interest are (2-Ar-Ind)$_2$$MtX_2$ complexes (with Mt = Zr or Hf, and Ar = phenyl or a substituted



R = H or Me

aromatic moiety), which give rise to an equilibrium between two rotational isomers: one with quasi-C_2-symmetry (*rac*-like form, structure a) and the other with quasi-C_s-symmetry (*meso*-like form, structure b), as illustrated in Scheme 10.[33]

Polypropylenes prepared by (2-Ar-Ind)$_2$MtX$_2$/MAO catalysts contain both isotactic and atactic sequences, although with a complicated structure revealed by studies of solvent fractionation. These polymers perform as thermoplastic elastomers, involving atactic sequences imparting a moderately elastic response and isotactic sequences acting as physical cross-links.[34] The study on the regioregularity shows the predominant 1,2 propylene insertion with low amounts of detectable 2,1 insertion (0.2–0.3 mol%) only in a predominately isotactic environment.[35] This indicates that not only the stereoselectivity, but also the regioselectivity of the *rac*-like and *meso*-like forms of oscillating catalysts resemble that of the corresponding bridged bis-indenyl complexes.

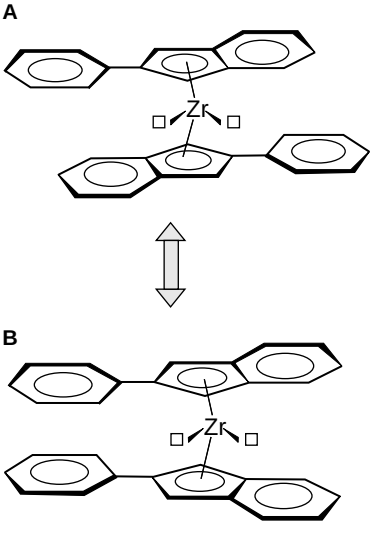
Bridged Half-Metallocenes

Many bridged and unbridged half-metallocenes have interesting catalytic behaviors. For example, CpTiCl$_3$/MAO is a highly active catalyst for syndiotactic polymerization of styrene.[36,37] However, such a catalyst cannot perform specific polymerization of propylene. Also, important half-metallocenes are constrained by the geometry of catalysts with the general formula Me$_2$Si(Me$_4$Cp)(NR)MtX$_2$(Mt = Ti or Zr, R = alkyl, X = halogen or alkyl), as illustrated in Scheme 11. This is well known as Dow ''Insite'' catalyst.[38] The absence of a second Cp ring and the short bridge results in a very open environment of the transition metal, allowing easier insertion of bulky monomers compared with bis-Cp systems. This special feature endows such catalysts with excellence performance in the copolymerizations of ethylene with higher α-olefins and even with styrene. In the case of propylene polymerization with such catalysts, the resulting atactic polymers are of poor regioregularity (with up to 5 mol% of 2,1 insertions).[39]

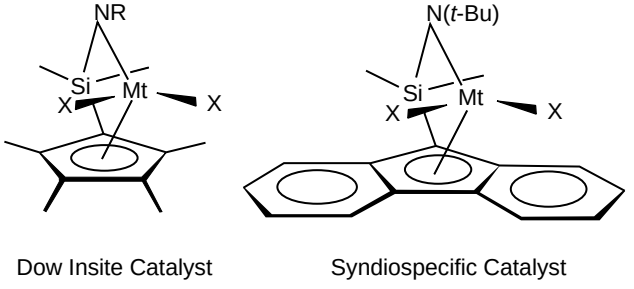
With the replacement of Cp by a 9-fluorenyl moiety, the metallocene promotes syndiotactic polymerization of propylene under site control. Syndiotactic PP with (rrrr) as high as 0.77 was obtained with Me$_2$Si(9-Flu)(N-*t*-Bu)ZrCl$_2$/MAO catalyst.[40] The stereoselectivity is due to the (pseudo)C_s-symmetry of the catalytic complex, and the stereocontrol mechanism is analog to that for the C_s-symmetric *ansa*-metallocenes.

Cocatalysts

Cocatalysts play an important role in the single-site polymerization of olefins. The relationship between the structure of cocatalysts and their activation in the metal-catalyzed olefin polymerization has been reviewed recently.[41] Methylaluminoxane is the most widely used cocatalyst, because it is able to activate a large number of metallocenes and other soluble transition complexes. It is usually synthesized by controlled hydrolysis of trimethylaluminum (TEA). The techniques for the preparation of MAO have been reviewed by Reddy and Sivaram.[42] It is generally believed that MAO consists of oligomers involving many [–O–Al(CH$_3$)–] units with the molecular weight of 1000–1500 g/mol. However, the precise chemical structure and composition of MAO are still not clear. A three-dimensional cage structure with four coordinate aluminum centers, resembling a half-open dodecahedron, was proposed by researchers.[43,44] The cage can seize an anion from the metallocene to form a stable AlX_4^- anion because of the delocalization of the electron over the whole cage. The utilities of MAO mainly include alkylation of halogenated metallocene complexes, serving as scavengers for moisture or other



Scheme 10 *(View this art in color at www.dekker.com.)*



Scheme 11

impurities, and stabilization of active species. Usually, a large excess of MAO (Al/Mt = 1000–50,000) is required to reach desirable activity. This is a major drawback of using MAO as a cocatalyst. In addition, conventional MAO has very low solubility in aliphatic solvents, as well as poor storage stability in solution. Therefore, commercial modified methylaluminoxane (MMAO) is prepared by controlled hydrolysis of a mixture consisting of TEA and triisobutylaluminum. This MMAO exhibits improved solution storage stability and solubility, and can be produced at a lower cost while providing good polymerization efficiency.

The other important cocatalyst is perfluoroaryl boranes, such as $B(C_6H_5)_3$, and highly Lewis acidic $B(C_6F_5)_3$, $NR_3H^+B(C_6F_5)_4^-$, and $Ph_3C^+B(C_6F_5)_4^-$, which can serve as substituents for MAO in combination with metallocene dialkyls.[45,46] A relatively small amount of boranes (borane/Mt = 1 : 1) is needed to form an effective catalyst for olefin polymerization. Unfortunately, this catalyst is rather sensitive to moisture and other impurities, and the stability of the resulting metallocene complexes is much lower than that formed with MAO. Usually, alklyaluminum (such as triisobutylaluminum) is added to the systems to scavenge the impurities and to stabilize the complexes.

Supported Metallocene Catalysts

As discussed, homogenous metallocene catalysts show special characteristics, such as a single active site, extremely high catalytic activity, capability of incorporating a high content of monomer, a narrow molecular weight distribution, and control of stereoregularity. However, the products prepared from homogenous metallocenes exhibit relatively poor apparent properties, compared with those from heterogenous Ziegler–Natta catalysts. They show irregular particle shape and low bulk density and contain a large amount of fine powder. Because such problems are the major concerns for the industrial application in slurry or gas-phase polymerization, immobilization of single-site metallocene on certain supports may improve the morphology of the final products and adaptation to the industrial process. Supported catalysts also show additional advantages in cost reduction due to lower amounts of MAO required and in giving products with higher molecular weight, higher melting temperature, and better stereoregularity. The carriers include inorganic supports, such as silica, Al_2O_3, $MgCl_2$, clay, zeolite, $CaCO_3$, and organic polymers, such as porous powdered high-density PE (HDPE), i-PP, nylon granules, and copolymer of styrene and divinylbenzene.[47–53] One of the great breakthroughs in heterogenous metallocene catalysts was made by investigators at Mitsubishi.[54] Acidic clays are formed by reacting $AlR_3$with clay, such as montmorillonite, hectorite, and mica, before contacting with metallocenes to form active metallocenes/AlR_3 complexes supported on clay. Overall, the AlR_3-treated clay minerals serve as both activators and carriers. The resulting catalysts show high activity comparable to those with MAO as cocatalyst, giving PE (co)polymers improved morphology and molecular weight distribution. This system has also been commercialized for propylene polymerization to form highly i-PP.

SYNTHESIS OF FUNCTIONAL POLYOLEFINS

The tunable metallocene catalyst with a well-defined polymerization mechanism provides distinctive advantages in the preparation of new polymers with well-controlled molecular structures, especially functional polyolefins that are very difficult to prepare by other methods.[55,56] Since the discovery of HDPE and i-PP about half a century ago, functionalization of polyolefin has been a scientifically challenging and industrially important area. The constant interest, despite lack of effective functionalization chemistry, is due to the strong desire to improve polyolefin's poor interactive properties. The hydrophobicity and low surface energy of polyolefin has limited its applications, especially in the areas of coating, blends, and composites, in which adhesion, comparability, dispersion, and paintability are paramount.

Polyolefin Containing Pendent Functional Groups

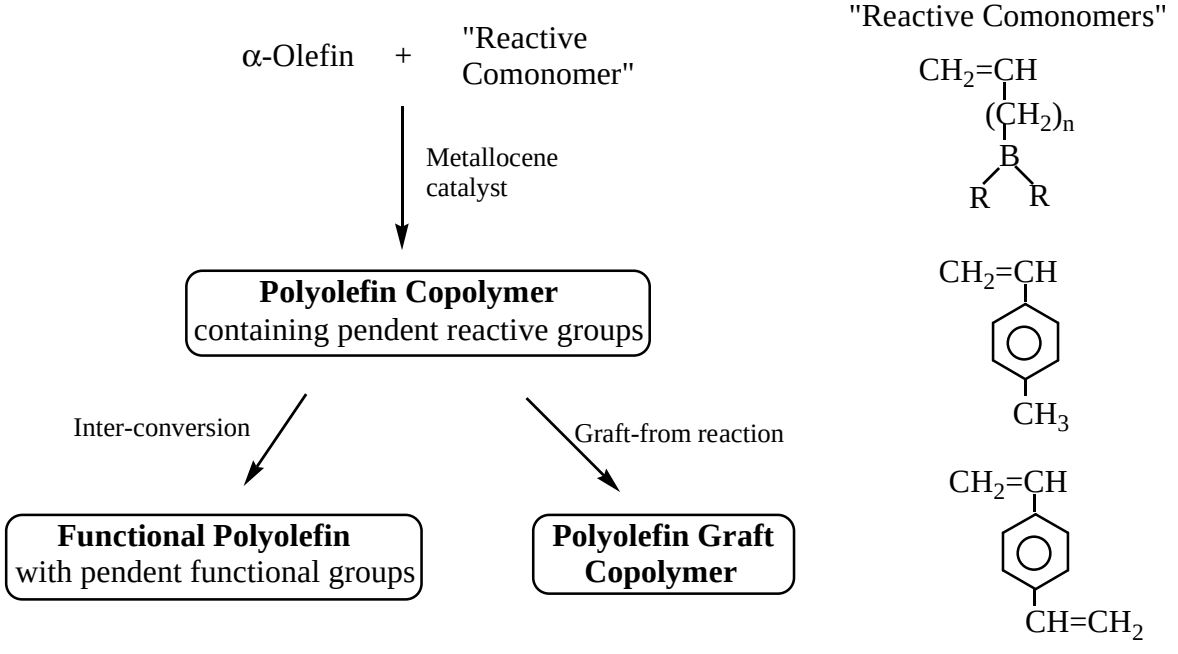
In the past decade, our group at Penn State has been focusing on a functionalization approach by the combination of metallocene catalysts and reactive comonomers. The chemistry takes the advantage of metallocene catalyst with a tunable single active site to prepare polyolefin copolymers with narrow molecular weight and composition distributions, high catalyst activities, and predictable tacticities and copolymer compositions.

As illustrated in Scheme 12, the metallocene-mediated copolymerization of α-olefin and reactive comonomer forms a copolymer containing several pendent reactive groups, and then serves as an ''intermediate'' for the transformation to functional polyolefins by various reaction mechanisms. In addition to the metallocene catalyst for effective copolymerization, the key factor in this approach is the design of a comonomer containing a reactive group that can simultaneously fulfill the following requirements. First, the reactive group must be stable to metallocene catalysts and soluble in hydrocarbon polymerization media.

Second, the reactive monomer should have good copolymerization reactivity with α-olefins. Third, the reactive group must be facile in the subsequent interconversion reaction to form polar groups under mild reaction conditions. It is particularly effective if the reactive group can serve as an initiator (with sufficient stability) of the polymerization of functional monomers. In other words, each incorporated reactive group can produce a functional polymer chain containing hundreds of functional groups. With the metallocene technology, the choice of reactive comonomers has dramatically increased.

Three reactive comonomers, including borane monomers, *p*-methylstyrene (*p*-MS), and divinylbenzene, have been incorporated in polyolefin copolymers with a broad compositional range and narrow molecular weight and composition distributions.[57–69] The resulting pendent reactive sites, i.e., borane, benzylic protons, and styrene units, located along the polyolefin backbone, are versatile in the subsequent transformation reactions, both in functionalization and graft reactions.[70–73] The transformation reactions occur selectively at the reactive sites. In other words, the concentration of functional groups is basically proportional to the concentration of the reactive sites, and the resulting functional polyolefin has a well-defined molecular structure.

One example is shown in Scheme 13, involving direct metallocene copolymerization of α-olefin and borane comonomer that is completely stable with the catalytic site, and can be effectively incorporated into polyolefin. The solubility of borane monomers and polymers in the reaction media (hexane and toluene) during metallocene polymerization is essential to ensure the optimum reaction condition for high polymer. In turn, the formed polyolefin contains reactive borane groups that can be selectively interconverted to the desirable functional groups (such as OH, NH_2, and halides) under mild reaction conditions.[55] This conversion can also be accomplished during the melt process (reactive extrusion). In addition, the borane side groups in polyolefin can then be selectively oxidized at the aliphatic C–B group for graft-form polymerization. The formed peroxyborane (B–O–O–C) initiates a controlled radical polymerization in the presence of free-radical-polymerizable monomers, such as methacrylates, vinyl acetate, acrylonitrile, etc., at ambient temperature. This controlled radical polymerization process minimizes the undesirable chain transfer reaction and termination (coupling and disproportional) reaction between the two growing chain ends, which result in the formation of homopolymers and cross-linked material. In most cases, the resulting graft copolymers are completely soluble and processible. The graft length (PMMA side chain) is controlled by the MMA concentration and reaction time. Some interesting graft polymers—including PE-*g*-PVA, PE-*g*-PMMA, PP-*g*-PMMA, PP-*g*-PMA, PP-*g*-PVA, and EP-*g*-PMMA—have been synthesized with controllable compositions and molecular microstructures.[56]



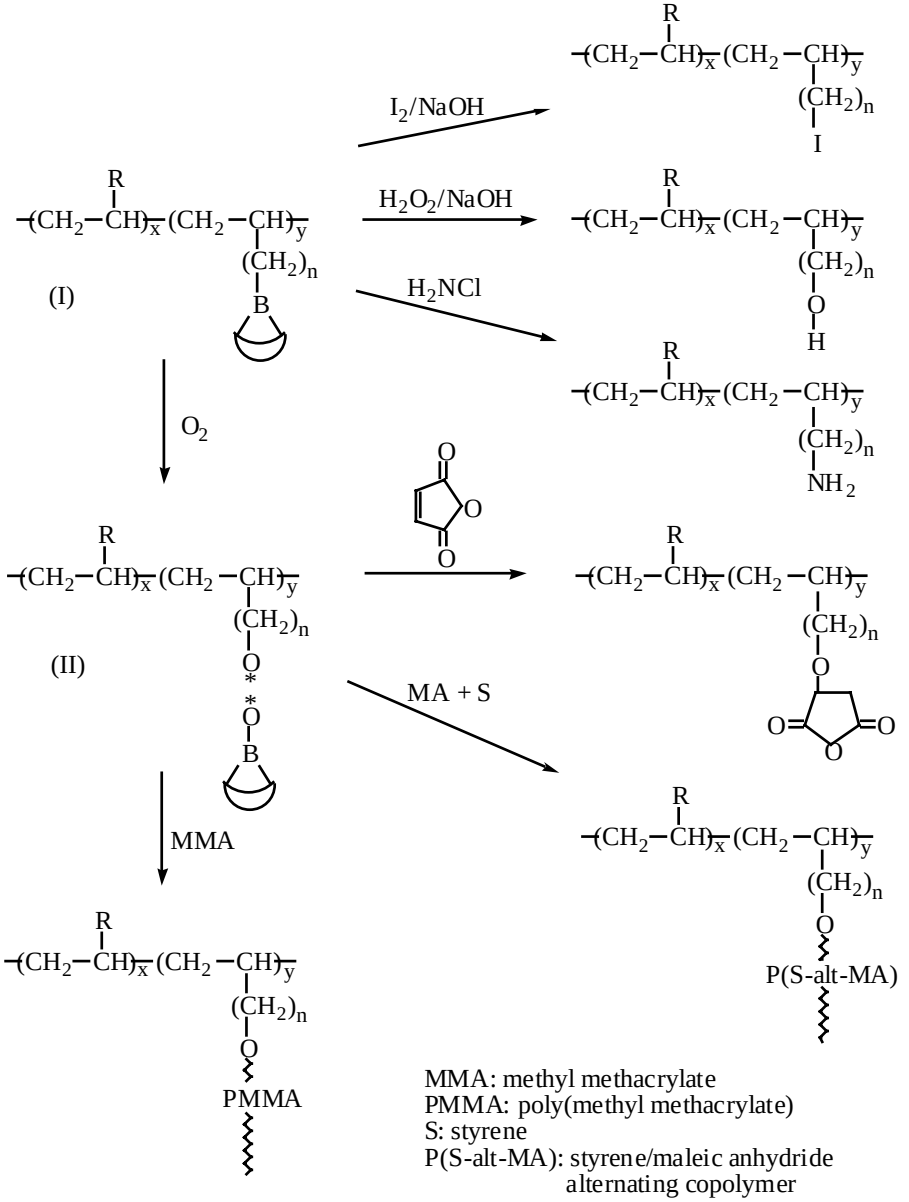
Scheme 12

Polyolefin Containing a Chain-End Functional Group

The chain-end functionalized polymer is a very attractive material that possesses an unperturbed polymer chain with desirable physical properties (such as melting temperature, crystallinity, glass transition temperature, melt flow, etc.) that are almost the same as those of the pure polymer.[74] Nevertheless, the terminal reactive group at the polymer chain end has good mobility and can provide a reactive site for many applications. This includes adhesion to the substrates, reactive blending, and formation of block copolymers.

The in situ chain transfer reaction by far is the most convenient and effective method for introducing a functional group to the polymer chain end.[56] With the combination of a well-defined metallocene reaction mechanism and suitable chain transfer agent (CT), it is possible to have a chain transfer reaction taking place with little change in the polymerization rate. Each polymer chain produced has a terminal functional group (the residue of the CT). Usually, the polymer's molecular weight is reversibly proportional to the CT/monomer ratio.

Several interesting CTs have been studied in the past decades with the major objective of introducing functional (polar) groups at the polyolefin chain end. In the past, aluminum-alkyl and zinc-alkyl were reported to act as coinitiator and CT in heterogenous Ziegler–Natta polymerization.[75] Recently, two hydride CTs, i.e., silane and borane containing Si–H and B–H moieties, respectively, have been successfully applied



MMA: methyl methacrylate
PMMA: poly(methyl methacrylate)
S: styrene
P(S-alt-MA): styrene/maleic anhydride alternating copolymer

Scheme 13

in metallocene-mediated polymerization.[76–79] The chemistry is very general and applicable to most α-olefins and their mixtures. The resulting silane and borane terminated polyolefins, having relatively well-defined molecular structures, were used as intermediates in the preparation of more elaborate polymer structures. It is intriguing that the versatility of metallocene catalysis also allows the chain transfer reaction to extend to styrenic and allylic molecules, which usually serve as monomers.[80–84] The new route allows the preparation of chain end functional PP containing a terminal functional group, such as OH and NH_2, in one-pot polymerization process.

One example is illustrated in Scheme 14, which involves the combination of styrenic molecule (St-X) and hydrogen as the CT during metallocene-mediated propylene polymerization. Ironically, the research stemmed from a failure in the copolymerization of propylene and *p*-MS using *rac*-$SiMe_2$[2-Me-4-Ph(Ind)]$_2$ $ZrCl_2$/MAO complex. The catalyst was deactivated after 2,1-insertion of *p*-MS unit as a result of steric jamming, which forms a propagating site (III) with unfavorable 1,2-insertion of propylene (k_p) and lack of *p*-MS homopolymerization (k_{22} reaction). However, the sluggish propagating chain end (III) allows the reaction with hydrogen, which not only recovers the catalytic site (I) but also produces PP polymer with a terminal styrenic group (IV). The regenerated catalytic site (I) reinitiates the polymerization of propylene and continues the polymerization cycles. In other words, the ideal chain transfer reaction will not significantly affect the rate of polymerization, but will reduce the molecular weight of the resulting polymer. The molecular weight of chain-end functionalized PP will be linearly proportional to the molar ratio of [propylene]/[St-X], and independent of the [propylene]/[hydrogen] ration.

Table 2 summarizes a systematic study of propylene polymerization by using a *rac*-Me_2Si[2-Me-4-Ph(Ind)]$_2$ $ZrCl_2$/MAO catalyst in the presence of *p*-MS/hydrogen, which results in *p*-MS terminated PP (PP-t-*p*-MS).[81] The in situ chain transfer reaction is evidenced by its comparison with the control reactions that were carried out under similar reaction conditions—without hydrogen and/or *p*-MS. A small amount of *p*-MS (control 2) effectively stops the polymerization of propylene. The introduction of hydrogen restores the catalyst activity, as shown in run 4, which exhibits about 85% of the catalyst activity of control 1 (without CTs). Hydrogen is clearly needed to complete the chain transfer cycle during the polymerization. Comparing runs 4, 8, and 11 by altering the *p*-MS concentration, the higher the concentration of the *p*-MS the lower the molecular weight of the resulting

[a]Reaction conditions: 50 ml toluene, propylene (100 psi), [Zr] = 1.25×10^{-6} mol/L, [MAO]/[Zr] = 3000, temperature = 30°C, time = 15 min.

polymer. A polymer with very low molecular weight (couple of thousands) is obtained, and the molecular weight distribution is generally narrow, consistent with the well-defined single-site polymerization processes. The catalyst activity was also proportionally depressed with the concentration of *p*-MS, reflecting the competitive coordination at metallocene active sites between monomer and CTs. Three comparative reaction sets (runs 1–4, 5–8, and 9–11) were conducted under the same reaction conditions except for varying the hydrogen pressure. The change of hydrogen concentration does not significantly affect the polymer molecular weight and molecular weight distribution, but has a profound effect on the catalyst activity. Therefore, hydrogen does not engage in the initial chain transfer reaction, but rather assists in the completion of the reaction cycle. A sufficient quantity of hydrogen, proportional to the *p*-MS concentration, is needed to maintain high catalyst activity and *p*-MS conversion.

It is desirable to directly prepare PP with a desirable terminal functional group, such as Cl, OH, and NH_2. In other words, the ideal reaction is a one-pot in situ polymerization process, and no chain-end functionalization would be needed after the polymerization reaction. Three functional St-X molecules were investigated (83), including *p*-chlorostyrene (St-Cl), silane-protected *p*-vinylphenol (St-OSi), and silane-protected *p*-ethylaminostyrene (St-NSi_2), as illustrated in Scheme 14.[83] No external protection agent is needed for St-Cl in metallocene/MAO systems. However, both the OH and the NH_2 groups are very sensitive to the metallocene cationic site. The silane groups not only provide effective protection for both the OH and the NH_2 functional groups during the metallocene catalysis, but also can be completely deprotected by aqueous HCl solution during the sample workup procedure. The overall reaction benefits, especially, from the very small quantity of the CT needed in the preparation of high polymers. Therefore, the additional protection–deprotection step causes almost no change in the polymerization conditions and procedures. The polymer molecular weight is linearly proportional to the molar ratio of [propylene]/[St-X] in all three, St-Cl/H_2, St-OSi/H_2, and St-NSi_2/H_2, cases.[83] The degree of polymerization (X_n) follows a simple comparative equation $X_n = k_p[\text{olefin}]/k_{tr}[p\text{-MS}]$ with a chain transfer constant k_{tr}/k_p of 1/21 for St-Cl/H_2, 1/48 for St-OSi/H_2, and 1/34 for St-NSi_2/H_2, respectively.

CONCLUSIONS

This entry discusses metallocene catalysts and polymerization, which can be classified into several

categories based on ligand geometries, including C_{2v}-, C_2-, C_s-, and C_1-symmetry, oscillating structure, and bridged half-metallocenes, and the resulting polyolefins. The important features in metallocene-mediated α-olefin polymerization that have been stimulating the rapid development of this technology for commercialization include: 1) a tunable single catalytic site to produce a well-defined polymer with extremely high catalyst activity and predictable microstructure (i.e., tacticity, molecular weight, terminal group, etc.); 2) excellent ability of incorporating higher α-olefins and cycloolefins; 3) production of polyolefin copolymers with narrow molecular weight and composition distributions; and 4) a well-controlled polymerization mechanism allowing the incorporation of reactive (functional) groups in polyolefins. With the appropriate choice of metallocene catalysts and reactive comonomers and CTs, a broad range of functional polyolefins have been prepared with well-controlled molecular structures, containing functional groups (OH, NH_2, etc.) in the side chains and/or at the chain end, narrow molecular weight distribution ($M_w/M_n \sim 2$), and predictable composition and molecular weight.

Microelectronics Fabrication

Edmund G. Seebauer
Charlotte T. M. Kwok
Department of Chemical and Biomolecular Engineering, University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

Chemical engineering can be defined as the study and practice of transforming substances at a large scale for the tangible improvement of the human condition. Such transformations are executed to produce other useful substances or energy, and lie at the heart of vast segments of the chemical, petroleum, and pharmaceutical industries. It is often less well recognized that chemical engineering principles form the core of most aspects of microelectronic fabrication. The microchip that emerges from a fabrication plant bears little resemblance to a tank car full of a petrochemical, yet the fabrication plant and the refinery–factory complex that generate these two kinds of products are in fact related to each other closely. Both facilities represent large-capitalization enterprises incorporating large sets of unit operations, with optimal production depending upon an understanding of phenomena on length scales ranging from the molecular to the factory level. This entry seeks to highlight how chemical engineering principles play a central role in microelectronic device fabrication.

HISTORICAL PERSPECTIVE

From modest beginnings in the middle of the last century (Table 1), microelectronic devices have come in just a few decades, to pervade nearly all aspects of modern life. This enormous change stems not only from the invention of new kinds of devices as outlined in Table 1 and materials listed in Table 2, but also from the steep power-law increase in speed and performance of integrated circuits (ICs). The simplest and most widely known metric for this improvement is commonly referred to as ''Moore's Law.''[1] This ''law'' represents a correlation originally articulated by Intel's former chief executive Gordon Moore in 1965, and states that device performance doubles roughly every 18 months. Fig. 1 shows this correlation graphically; it has been obeyed for approximately four decades. Some social commentators have suggested that this vast improvement in technology has led to improved macroeconomic performance and that the corresponding ''information revolution'' has manifestly advanced the human prospect.[2] Whether these claims are true should be the subject of another discussion. It is clear, however, that the giddy whirl of better hardware and frillier software has required consumers and businesses to upgrade their computer systems regularly, with substantial attendant costs.

Chemical engineers have played a central role in this rapid advance, particularly during the past 15 years or so. Employment statistics drive home this point. A typical new fab constructed by Intel employs about 30% chemical engineers, while the corresponding number for IBM is about 25%. These percentages equal or exceed those for any other discipline. However, their contributions remian sometimes hidden. This fact illustrates the point. Armytage had made:[3] ''The artistry of a bridge-builder is obvious to the naked eye, but the activities of the chemical engineer are not, until the products are bottled, batched or baled. Both profoundly affect the progress of mankind.''

CHEMICAL ENGINEERING AT MANY LENGTH SCALES

In a commodity chemical plant, chemical engineers have recognized for nearly a century how issues of chemistry and transport arise at length scales ranging from the factory level down to the molecular level. Such issues also pervade microelectronic fabrication as described in the following sections.

The Factory Level

A fabrication plant (or ''fab'') typically operates at 20,000 wafer starts per month or more, with each wafer taking several weeks to wend its way through the entire process sequence of over 400 individual steps. A typical fab now costs roughly US$2–3 billion to build and requires 2–3 years to complete. Fab-siting decisions rely on sophisticated and quantitative models[a] that

[a]An example is the Jupiter software from Abbie Gregg, Inc., a start-up consulting firm. See www.abbiegregg.com.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007859

Table 1 Major events in microelectronic device development

Year	Event
~1925	Vacuum tubes dominate complex circuits
~1940	First commercial sources developed for high-purity Si and Ge
1947	First transistor built (point-contact form) by Bardeen, Brattain, and Shockley of Bell Telephone Labs
1952	Junction transistor developed to avoid reliability problems with point-contact transistor
1954	First Si-based solar cell
1958	IMPATT diode invented for microwave generation; forerunner of wireless communication phones
1959	Jack Kilby files patent for first integrated circuit
1960	Invention of ruby laser, the forerunner of all solid-state lasers
1960s–1970s	MIS (metal–insulator–semiconductor) development leads to greatly reduced power consumption and miniaturization
1980s	1 μm design rule reached. GaAs circuits developed
1990s	0.18 μm design rule reached. GaAs and Si–Ge wireless devices become widespread

systematically consider factors such as government incentives, cost of land and electrical power, and proximity to universities and business partners. Crucial factors of specifically chemical nature include environmental regulations regarding gas emissions and access to water supplies for both intake and discharge.

Design of the main building itself depends upon issues of both chemistry and transport. For example, piping and equipment for chemical handling typically occupy one- quarter of the entire floor space, and need constrained optimization to minimize the required footprint while keeping incompatible chemicals stowed apart from each other. Poisonous gases such as arsine (AsH_3) and pyrophoric gases such as silane (SiH_4) have to be stored for easy access to contractors who specialize in changing large cylinders of these materials. The gases must then be piped to their place of use while keeping added contamination below parts-per-billion. Transport issues involved in such distribution are nontrivial. Many pieces of fabrication equipment (typically called ''tools'') require environment-controlled airspace, especially to minimize contamination from particulates. Particulate removal and clean air handling is clearly a problem of separations and transport. Elimination of mechanical vibration is also crucial for some tools, particularly in lithography.

Fab operation resembles a commodity chemical factory regarding the need for careful scheduling and debottlenecking. Yield levels typically exceed 90% for virtually all tools; hence major productivity and profitability improvements must originate more from optimization of the overall process flow rather than of individual unit operations.[4] In fact, a typical tool is often in production only about 30% of the time, with the balance falling prey to testing and tuning, set up, scheduled and unscheduled maintenance, and unscheduled shutdowns. The shutdowns include cancelled orders, late delivery of materials, turnover of trained operators, and software failures. Manufacturing execution systems that coordinate data management at the factory level are used to aid with these tasks.[b] Advanced systems include scheduling use of consumable items like wafers and chemicals to avoid shortages while minimizing inventory to avoid space and shelf life problems.

The complexity and expense of fab construction and operation have led to the development of detailed models for the cost-of-ownership of tools and usage of consumables. These models often call for the subcontracting of services to specialized firms. Such services include front-end processes such as silicidation and ion implantation, and back-end processes such as assembly, electrical test, and packaging. Foundry manufacturers such as Taiwan Semiconductor Manufacturing Corporation (TSMC) and Singapore's Chartered Semiconductor Manufacturing represent successful examples of this trend.

The Unit Operation Level

An overall process flow for making an integrated circuit typically consists of several hundred individual steps. A greatly simplified process flow for making an integrated circuit is seen in Fig. 2. The flow was drawn with Si-based IC fabrication in mind, but most of the major steps apply to nearly any microelectronic process. Steps before the creation of metal interconnect structures are commonly termed ''front-end,'' while subsequent ones are called ''back-end.'' Most process

Table 2 Common materials for semiconductor devices

Material	Advantages	Uses
Si	Easily forms a high-quality oxide and simple resistive metal contact	Most widely used semiconductor for ICs.
GaAs	Better optical properties than Si Higher electron mobility for fast devices Ga can be partially replaced with Al ($Al_xGa_{1-x}As$) for tunable light emission	Dominates high-performance optical and wireless devices
Ge	Can be alloyed with Si (Si_xGe_{1-x}) for specialized devices	Si_xGe_{1-x} quantum wells, heterojunction bipolar transistors, microwave devices
InP	Can be alloyed with GaAs ($In_xGa_{1-x}As_yP_{1-y}$) to emit light with wavelength that depends upon stoichiometry	Widespread use in light sources for fiber-optic communications at 1.3 μm Some microwave devices, radiation-hard solar cells
GaN	Emits blue light	Blue lasers and light emitting diodes
InSb, $Hg_xCd_{1-x}Te$	Emits and absorbs light far into the infrared	Infrared detectors, night vision

steps fall into just a few categories that chemical engineers would consider to be "unit operations."[5] Tools for accomplishing these unit operations can be staged sequentially in a process flow, or sometimes in a "cluster" form as shown in Fig. 3, wherein several separate unit operations are carried out using a single piece of apparatus. Irrespective of whether tools are arranged individually or in clusters, chemical engineering treatments focus on classical unit-operation concerns of optimizing and controlling temperatures, pressures, concentrations, reaction times, and the like.

Various schemes can be used for classifying the unit operations. Initial wafer fabrication falls into a class by itself. However, once device creation begins, the operations can be classified into five general categories: deposition, lithography, etching, doping, and cleaning. Deposition, etching, and cleaning share a common feature of reactions occuring at a solid interface, often with an intervening solid or fluid boundary layer that inhibits diffusion of reactants and products. Such effects are shown schematically in Fig. 4. In deposition, the net effect of the diffusion–reaction is to leave material behind on the substrate. In etching, portions of the substrate itself are removed, but in cleaning only contaminants are removed leaving the substrate intact.

Wafer fabrication

Electronic device fabrication requires a substrate, which is typically a highly purified slice of single-crystal semiconductor. For optoelectronic applications, the substrate could be GaAs, InP, or some other semiconductor; but for most integrated circuits and many Si–Ge wireless applications, the wafer is made of Si.

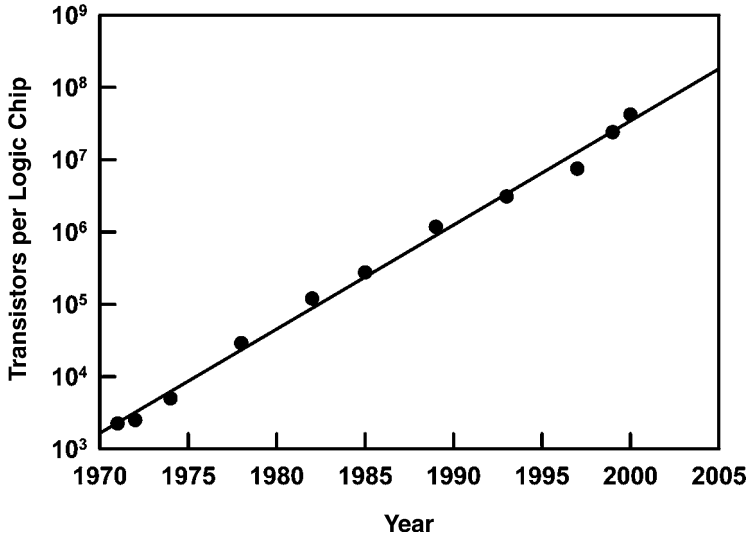

Fig. 1 A graphical representation of Moore's law for the past several decades.

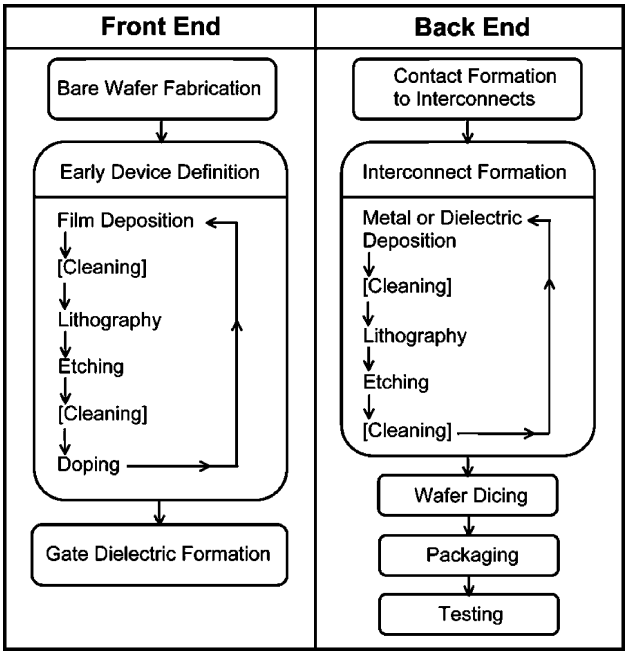

Fig. 2 A simplified process flow for making an integrated circuit. Most unit operations fall into one of the five categories: deposition, lithography, etching, doping and cleaning.

Fig. 5 shows a process sequence for the initial stages of making electronic-grade Si. The unit operations in this sequence resemble those typical of conventional chemical processing, and include furnaces, fluidized bed reactors, and distillation columns. The product semiconductor emerging from this process must however be purified further than what distillation allows, and must also be converted into single-crystal form. Invariably, the latter process involves melting the semiconductor again and crystallizing it slowly under carefully controlled conditions. Various methods exist for this purpose, including Bridgeman, floating zone, and Czochralski techniques. The Czochralski technique is favored for Si and GaAs, because crystallization occurs with no contact between the growing solid and the walls of the melt container, thereby resulting in very little defect production in the solid. The melt solidifies into a boule that is slowly pulled from the liquid as heat is continually withdrawn. Boule diameters capable of yielding Si wafers up to 300 mm across are now a routine practice. Modeling the heat transfer, impurity segregation into the liquid, and defect formation in the solid has now reached a high degree of sophistication.[6] After crystal pulling from the melt is complete, the boule is sliced into wafers that are polished and chemically cleaned in readiness for device fabrication.

Deposition

Deposition represents the primary means by which new layers are introduced onto the wafer substrate for subsequent feature delineation by lithographic patterning and etching.

Physical vapor deposition (PVD) is used most often for metals, especially where ultrahigh purity is needed in the grown film and perfect crystallinity is not crucially important. The method employs either evaporation or ion sputtering to vaporize a source material in high vacuum. The vaporized gas travels directly to the substrate without gas collisions and deposits there. Chemical reactions are minimal (leading to a material of very high purity), and transport involves line-of-sight ballistic motion. This motion leads to shadowing effects that yield poor conformality in the coverage of

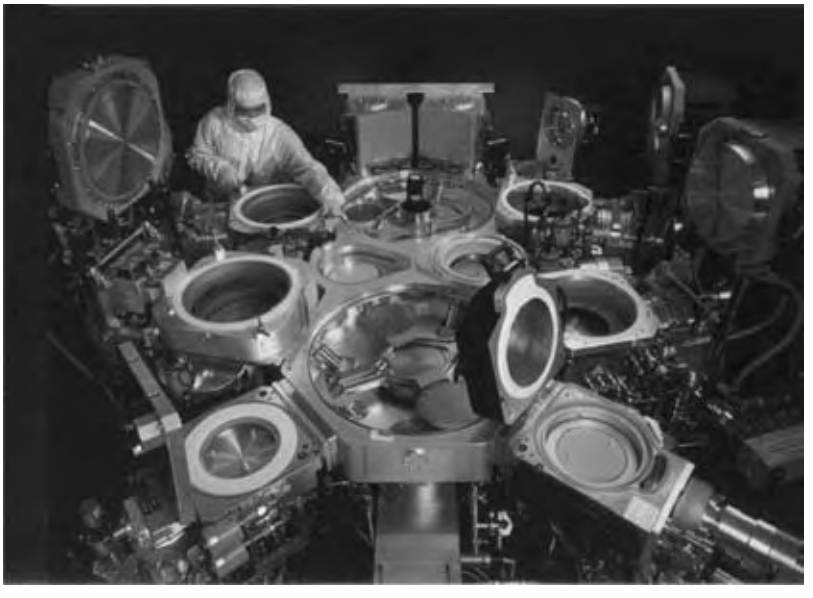

Fig. 3 Cluster tool (''Endura Classic'' from Applied Materials, Inc.) for accomplishing metal deposition on 200 mm diameter wafers. The various individual tools for unit operations surround a central handler (lower center) that transfers wafers among them. Fig. 4 Elementary molecular steps common to many deposition, etching, and cleaning processes.

recessed regions of the surface (e.g., trenches). Rotating the wafer during deposition mitigates some of these effects, as does heating the wafer to promote lateral transport by surface diffusion.

Spin casting is a liquid-based form of PVD that works at atmospheric pressure, finding use for polymers and other nonvolatile materials. These applications appear mainly in lithography and is discussed in the next section.

Chemical vapor deposition (CVD) finds its primary use in semiconductors and insulators, especially where epitaxial growth is required. (Epitaxy is the growth of a single-crystal film with a fixed orientation with respect to the crystal structure of the underlying substrate.) It employs reactive gas-phase precursors that decompose over the hot substrate, leaving solid behind. Fig. 6 shows an example of a tool commonly used for epitaxial deposition. Because of the surface reactions involved, films can sometimes be grown selectively on some regions of the substrate versus others. An example is the epitaxial growth of Si on Si using disilane, in which growth on wafer regions covered with SiO_2 is completely suppressed.[7] PVD is incapable of such selectivity. Moreover, the chemical reactions permit the growth of compounds such as GaAs with exact stoichiometry—a feat PVD cannot match. CVD often affords greater conformality as well. However, in typical applications where pressures range from millitorr to atmospheric, reactions and diffusion in the gaseous overlayer complicate the predictive modeling of CVD growth rate and thickness uniformity. Other potential CVD reactions suffer from a lack of reactive precursor gases. Sparking a plasma during growth can help to solve this problem by introducing additional reaction pathways. However, selectivity is often lost, the films suffer more contamination, and there is a possibility of ion-induced damage.

Atomic layer deposition (ALD) is a variant of CVD that relies upon the alternate exposure of a substrate to different precursor gases, with each gas being adsorbed to saturation. Between each adsorption step, the reactor is either purged with an inert gas or pumped down, so that several surface reactions take place during different stages of the cycle. Most ALD processes employed today include reactions that liberate gaseous products upon exposure to each of the precursor gases. This incarnation has been termed ''reaction sequence ALD,''[8] and should be distinguished from ''chemisorption saturated ALD,'' in which exposure to one of the precursors leads merely to chemisorbed layer, with no gaseous product produced. The reaction sequence version of ALD has clear advantages over CVD and PVD as films become increasingly thin. These advantages include exceptional thickness control, conformality, interface sharpness.

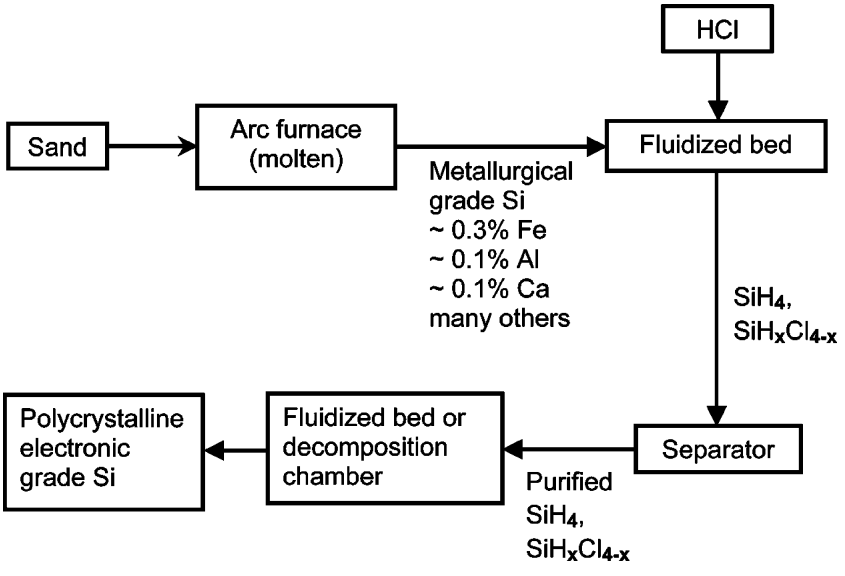

Fig. 5 Schematic process flow for making electronic-grade silicon.

Fig. 6 Deposition system used for epitaxial CVD. Heating in this case is accomplished by banks of lamps (e.g., upper right). (Photo courtesy of Applied Materials Inc.) *(View this art in color at www.dekker.com.)*

Electrodeposition is a liquid-phase analog of plasma-enhanced CVD, used especially in the formation of copper interconnects. This method employs electrochemical voltages instead of surface temperature to control the growth characteristics. It is however more difficult to model and predict than CVD, because of solvation effects and the relative dearth of experimental methods to examine individual elementary steps in the key reactions.[9]

The deposition processes discussed so far typically operate such that all the material required for the growing film comes from the overlying gas or liquid phase. Other deposition reactions involve reaction (and therefore consumption) of the underlying substrate itself. Examples of such deposition processes include thermal oxidation, nitridation, or silicidation of silicon, which can be accomplished by exposing a silicon wafer at high temperature to oxygen, ammonia, or titanium tetrachloride, respectively, to form silicon dioxide, silicon nitride, or titanium disilicide. Solid-phase diffusion and reaction processes are involved in each case.

Lithography

Individual microelectronic devices consist of numerous layers of carefully patterned thin films. Patterning depends upon the ability to define and ''draw'' a two-dimensional pattern on a wafer substrate. Currently, this ability depends on photolithography by optical projection, in which a polymer ''resist'' film is deposited on the wafer and subsequently exposed to ultraviolet light through a mask to render the illuminated areas either more or less susceptible to the action of a solvent. Use of this solvent selectively removes either the illuminated or unilluminated polymer (depending upon whether the resist is ''positive'' or ''negative,'' respectively), leaving regions of bare wafer available for further processing.

Limitations on photolithography originate primarily from image aberrations and diffraction effects introduced by the optical projection system. Image aberrations can be reduced to a considerable extent by using ''stepper'' technology, in which successive small portions of the whole substrate wafer are exposed in sequence using a small-field lens system together with a mechanical stepper motor. However, diffraction problems can be ultimately solved only by using shorter wavelengths of light to expose the resist. Pulsed excimer lasers that emit deep in the ultraviolet region have found extensive use for this purpose: for example, KrF lasers with output at 248 nm.

The deposition, exposure, and removal of resists involve quite a few issues of chemistry and transport[10] that benefit from the chemical engineering perspective. For example, resists are typically deposited by a spin-on process, in which the polymer is dissolved in a solvent and poured onto a rapidly spinning wafer. With the addition of suitable viscosity thinners and careful choice of spinning speed, this mixture spreads uniformly over the wafer with simultaneous evaporation of the solvent. Detailed modeling of the simultaneous flow and evaporation presents a nontrivial transport problem. Chemical issues make their appearance during optical exposure. Positive resists contain

roughly 20% of a photosensitizer such as naphthoquinone diazide, which absorbs light and decomposes to render the resist more soluble. By contrast, negative resists contain only 2–3% of a photosensitive agent such as a quinone or an azo compound that crosslinks to the resin matrix and renders the resist less soluble. The ever-shorter UV wavelengths needed to achieve high spatial resolution have an increasing tendency to pass through resists without stimulating such chemistries, so that the differential solubility between the exposed and the unexposed regions decreases. Chemical issues also appear during resist removal, both during pattern formation and subsequent stripping of all resists after the pattern has been defined. The issues typically revolve around reagent disposal; processes based upon organic solvents or oxidizing acids present more problems in this regard than dry plasma processes based upon oxygen, for example. However, dry processing with energetic ions typically induces undesired wafer damage in the surface region that needs to be avoided.

Etching

After lithography is used to deposit resist in a patterned way, the wafer must be exposed to some sort of etching to emblazon the pattern into the underlying substrate. Other forms of etching seek to remove gross debris left over from previous processing steps. Such debris could include photoresist that needs to be stripped off after a pattern-defining etch, or metal left over from a solid-phase silicidation reaction with silicon.

Wet etching appears mostly in applications where high spatial resolution is not critical. The process employs an aqueous acid or some other chemically reactive solution. The chemical specificity of liquid reagents is often exquisite, permitting the etching of one solid to the complete exclusion of others. However, in most cases the etching reaction is isotropic, meaning that the sidewalls of a trench disappear at the same rate as the bottom as shown in Fig. 7. Also, the etching reaction cannot be stopped instantaneously; an ill-defined period of time is needed to rinse the solution from the surface (including within trenches). Thus, controllability is too poor for fine features.

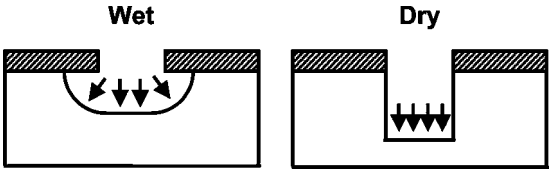

Fig. 7 Isotropic etching characteristic of wet etching (left) yields undercutting, leading to poor aspect ratios. Anisotropic etching characteristic of reactive ion etching (right) gives higher aspect ratios.

Etching of SiO_2 is almost always done with aqueous HF, because the solution is very selective against etching any underlying Si. However addition of HNO_3 to aqueous HF makes a fine etchant for Si; the nitric acid oxidizes the Si to SiO_2, which is immediately removed by HF. For elemental metals, some form of electrochemical oxidation usually operates to dissolve the metal. Both aqueous acids and bases can serve this function, although acids find greater use because they do not attack SiO_2 elsewhere on the wafer the way bases do.

"Dry" or plasma etching operates via the action of ions and/or free radicals on the surface. Plasma etching can be run in several modes, depending upon the relative balance that is sought between the effects of ions and free radicals. At one extreme lies ion milling, in which an inert-gas plasma is run at low pressures and high bias voltages (>300 V) with respect to the wafer. In this case, material removal takes place by physical erosion only. Although both the rate and the degree of anisotropy are high, chemical specificity is low and the substrate usually suffers considerable ion-induced damage. At the other extreme lies a free radical plasma, which employs halogen-containing gases at very low bias voltages (<70 V). In this case, material removal takes place almost entirely by chemical reactions. The chemical specificity is high and substrate damage is avoided, but the rate and anisotropy are low. Between these two extremes is reactive ion etching (RIE), wherein both ion sputtering and chemical reaction play a role. The plasma runs with a gas capable of producing reactive radicals of Cl, F, or O, and operates at intermediate bias voltages typically between 7 V and 300 V. The combination of moderate rate, anisotropy, chemical selectivity, and damage levels makes this mode the most common one for dry etching. Careful tuning of the bias voltage, pressure, and type of source gas offers extensive opportunities for optimizing these metrics of process performance.[11] Process controllability and reproducibility is good because the reaction stops as soon as the power to the plasma is shut off. This controllability, together with the considerable anisotropy (Fig. 7) offered by RIE, gives this method overwhelming advantages over wet etching for fine-feature patterning.

Chemical mechanical polishing (CMP) represents a specialized type of all-wafer etching meant to clean, smoothen, and planarize the entire wafer in preparation for subsequent lithographic steps. Modeling of CMP is complex[12] because both mechanical abrasion and chemical reaction are involved.

Doping

Doping intentionally introduces impurities into the semiconductor substrate to control its electronic

properties such as conductivity. Atoms of the dopant often have a valence similar to but not the same as those in the host lattice. For example, Si and Ge have valences of four and are typically doped with elements having valences of three (boron) or five (arsenic). GaAs comprises elements of valence three and five, and can be doped with Si having valence four.[13]

When deposited-thin films must be doped uniformly (as in the fabrication of many optoelectronic devices), it is common practice to use a CVD process wherein small amounts of a precursor gas containing the dopant are added to the reacting mixture. For example, Si-doped GaAs can be made using $(C_2H_5)_3Ga$ and AsH_3 with a little SiH_4 added.

However, often the substrate itself must be doped. If the doped region needs to be fairly thick and device fabrication has not reached stages where extended annealing at high temperatures could be damaging, then thermal solid-state diffusion processes can be employed. Several such methods exist, but they all involve forming a layer of dopant oxide (e.g., B_2O_3 or As_2O_3 on Si) on top of the semiconductor and then heating to temperatures that are appreciable fractions of the wafer melting temperature. The oxide then releases dopant atoms into the substrate, which diffuse in.

In more critical applications involving pn junction formation, the diffusion profiles afforded by thermal diffusion are too broad and deep to be useful. It is then preferable to introduce dopants into the substrate bulk by implantation of energetic ions. With ions having energies of only a few hundred electron volts, pn junctions can be made that are as shallow as 15–20 nm. A postimplant annealing step is then required to remove crystal defects and move the dopant onto lattice sites where it can become electrically active. However, the residual crystal defects mediate extraordinarily fast diffusion of dopants, particularly in the case of boron,[14] which tends to make the pn junction significantly deeper than originally intended. The precise temperature trajectory of the annealing exerts an enormous influence on this ''transient enhanced diffusion'' and therefore on the shape of the diffused profile. Current experimental and modeling efforts focus on the optimization of this trajectory through lamp-based rapid thermal processing (RTP), in which heating rates of 400°C/sec or more can be reached.[15]

Cleaning

Wafer cleaning can take several forms;[16] but most commonly it involves using aqueous liquids to remove small quantities of chemical residues and particulates left over from previous processing steps. For example, care must be taken to avoid leaving unreacted metal atoms on a silicon surface, because these atoms can diffuse into the silicon and adversely affect its electronic characteristics. Halogens such as chlorine must be scrupulously removed from the vicinity of chip-level interconnects or wire connections within a device package to inhibit corrosion of the elemental metals located there. Residual native oxides and organic species must be removed before epitaxial growth to ensure a high-quality interface. In all these cases, particulates that adhere to the wafer surface must be removed to avoid interfering with subsequent lithographic steps.

In some cases, simple rinsing with deionized, particulate-free water suffices. More commonly, however, removal of residues requires some form of chemical action. The reagents are then acids such as HCl or HNO_3 (for transition metals), HF (for SiO_2), or oxidants based on H_2O_2 (for organics). Regardless of the cleaning solution used, exposure to the liquid phase can be performed in either semibatch mode via spraying or batch mode by dipping in successive baths.

The Molecular Level

Good modeling of the chemistry and transport governing tool behavior almost always involves the use of reaction and diffusion rate expressions with appropriate parameters. As the forms of these expressions together with their parameters are manifestations of molecular phenomena, even phenomenological modeling often demands at least some recourse to a molecular view. As device dimensions have decreased progressively, such a view has become correspondingly more important.

As an example, Fig. 4 shows elementary steps common to most deposition, etching, and cleaning processes. First, a reactive molecule must approach the interface of interest, often diffusing through a fluid boundary layer. Sometimes a solid diffusion layer is also present. Upon reaching the interface, the molecule may then pass through some or all the following elementary chemical steps: adsorption, surface diffusion, surface reaction, and desorption. Product molecules also usually need to desorb, diffusing back through any solid or fluid boundary layers back into the bulk fluid.

As another example, atomic clustering and dopant motion during annealing after ion implantation can be modeled by a complex set of reaction–diffusion equations.[17] Determination of appropriate rate parameters requires an assessment of the importance of surface space charge on the motion of charged bulk interstitials and of transport aided by photogenerated carrier recombination. Such an assessment plays a key role in determining optimal temperature trajectories for RTP in postimplant annealing.

Environmental, Safety, and Health Issues

Semiconductor processing has witnessed ever-increasing attention to environmental, safety, and health (ES&H) issues. Chemical engineers play a central role in solving these problems.

Environmental issues show up throughout a processing sequence and usually involve the need to dispose of large quantities of hazardous reagents cost-effectively. For example, photoresist removal has often been accomplished with strong liquid oxidants such as H_2SO_4–H_2O_2 mixtures. However, new methods based on aqueous ozone are being developed,[18] as disposal of large quantities of acid can be avoided. Wafer cleaning employs very large quantities of water, and the effluent typically contains trace amounts of dissolved metals and other undesirable species. Separation processes are required before the effluent can be released back into the environment.

Safety concerns are near the top of the list of concerns in both fab and tool design. The gases typically used as reagents or produced as products in chemical vapor deposition, etching, and doping are exceptionally poisonous (e.g., AsH_3 and B_2H_6), corrosive (e.g., HCl and HF), flammable (e.g., organic solvents), or pyrophoric (e.g., SiH_4). Fab designs must ensure that liquid acids and bases are stored well apart from each other and that cylinders of poisonous gases be changed well away from where primary fab activity is located. Tool designs require provision for automatic shutdown and proper venting in case of power loss, operator error, or other malfunction.

Health issues arise, especially with respect to long-term exposure to low levels of these chemicals. The need for employees to work in a clean-room environment while wearing unwieldy ''bunny suits'' to reduce particulate contamination and protect against chemical exposure can also present problems with physical and mental stress, especially given the intense time pressures associated with fabs that run around the clock.

EMERGING PROCESSING CHALLENGES

Forecasting the future is always uncertain business, but the Si-based fabrication industry may be unique in the depth, breadth, and sophistication it uses to forecast developments and plan research and investments accordingly. Such forecasting germinated in the United States during the mid-1980s in response to intense competitive pressures from overseas, especially from Japan. In the face of relentlessly shrinking market share, especially in the equipment manufacturing business, the Semiconductor Industry Association (SIA), comprising virtually all major US integrated circuit manufacturers, began to recognize clearly the benefits of joint research and development in a technology base that was ''precompetitive,'' meaning common and fundamental to the engineering that member companies needed to do. Among the creations of the SIA was the National Technology Roadmap for Semiconductors (NTRS), which was produced by a broad-based committee of industry experts to define precompetitive areas of technology and to project how that technology would need to develop to keep the industry on its profitable Moore's Law trajectory.

During the 1990s, the NTRS received updates at roughly three-year intervals and became an exquisitely detailed document that defined the needs and pace of development for everything—from lithographic techniques to shallow junction design. While the industry largely managed to keep up with the aggressive milestones set down by the various roadmaps, it became clear by the end of the decade that certain technical problems would likely become so large and difficult that more than a national effort would be needed. Thus, representatives from major corporations in the Far East and Europe were consulted for the 1999 version of the roadmap, which accordingly became the ITRS, with ''I'' standing for ''international.''[19]

The ''Wall''

Even though the 2002 ITRS is still quite aggressive in projecting Moore's law trajectory, many experts believe that this trajectory is approaching the end of its nearly long run. Cost and technical limitations imposed by device and material physics will end rapid power-law device scaling. Many experts believe these problems will converge concurrently quite soon, erecting what many call simply ''the Wall.'' Although some industry observers have been predicting the end of Moore's law for decades, there are several reasons to believe that forecast may soon prove accurate.

Staggering costs of new fabs

The staggering capital costs and substantial lead times for building new fabs are causing the microelectronics industry to resemble the commodity chemical industry, with boom–bust cycles of production capacity and profitability. This behavior has been particularly evident in the production of dynamic random access memory (DRAM) devices. This segment of the industry was plagued in the late 1990s by overcapacity and marginal profitability, leading to extensive consolidation. Early in that decade, there were four significant DRAM manufacturers in the United States. By the end of the decade there remained only one (Micron Technologies). Economic turmoil in Pacific Rim countries exacerbated the problem in the late 1990s, but the ingredients for

the transformation of a specialty-product business into a commodity business were already in place. Consolidation has been steadily taking place in the microprocessor unit business as well. The 1998 sale of Digital Equipment's microprocessor manufacturing operations represents one such example.

Finding a cost-effective lithography

Optical lithography has provided the mainstay of pattern delineation on wafers for many years. In the early days of fabrication when device dimensions were much larger than a wavelength of UV light, lithography was relatively straightforward to accomplish. However, with current critical dimensions for commodity devices dropping below 0.1 μm, which is below the wavelength of light sources suitable for production, much more advanced projection methods like phase shifting are needed.[20] Reducing the wavelength also helps. The industry has recently relied upon XeCl excimer lasers with $\lambda = 308$ nm. Transition is taking place to KrF ($\lambda = 248$ nm) and may eventually move to ArF[21] ($\lambda = 193$ nm) or F_2[22] ($\lambda = 157$ nm). However, resists with suitable chemistry and photoactivity become progressively more difficult to make at shorter wavelengths.[23] This problem, coupled with the lack of practical light sources below 157 nm, will probably terminate the continued scaling of conventional UV-based lithography. Over the years, the industry has worked extensively on alternative techniques, such as electron-based SCALPEL[24] and X-ray lithography.[25] However, such techniques have generally foundered against the shoals of cost-effectiveness in a large-scale production environment.[26]

Interconnect delays

As individual devices get closer together on a chip, the spacing between the metal interconnects linking them together decreases correspondingly. Elementary electromagnetic principles then dictate that the capacitance C between the wires, which varies inversely with separation, must also increase. Thinner interconnects also lead to an increase in resistance R. Thus, even though the interconnects get shorter, the propagation delay (governed by $R \times C$) stops decreasing when device scaling reaches a certain point, and actually increases beyond that point. Fig. 8 shows this effect graphically.[27] Even with clever device layout on the chip, such physics eventually halts progress in improving clock speeds. This problem can be avoided to some extent by using metals with lower R. Indeed, for this reason the industry is moving from aluminum-based interconnects to copper.[28] Moreover, the capacitance can be reduced by using insulators with low dielectric constant k to separate the interconnects. The industry currently employs dielectrics

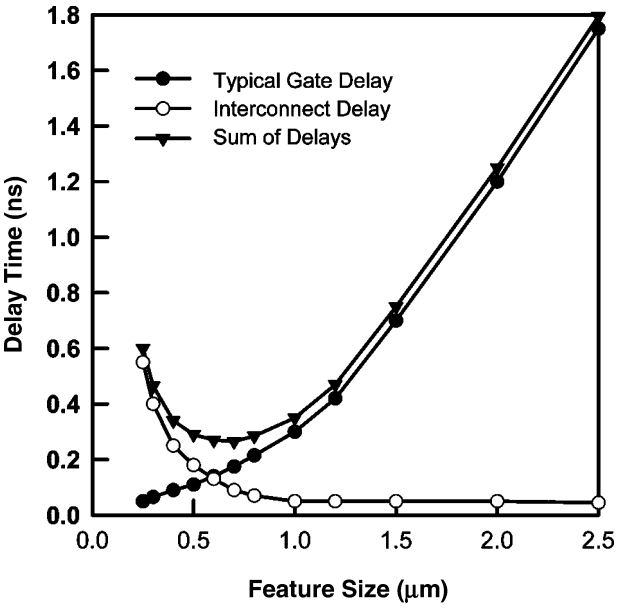

Fig. 8 Gate and interconnect delay versus feature size. Interconnect delay is shown for repeater spacings of 3000 μm. (Some data adapted from Ref.[29].)

based on SiO_2 ($k = 4$) and is actively investigating fluorocarbon polymers, aerogels, and other "low-k dielectrics" as replacements.[29] However, these measures are expensive to implement and represent stopgaps at best. Copper has about the lowest resistance available for a practical interconnect material, and k lower than unity is impossible. At this point entirely new paradigms like optical interconnects, are needed.

Problems with gate/capacitor dielectric materials

As device dimensions scale down, additional physical limitations arise because of fundamental aspects of the properties of the constituent materials. For example, central to both the field-effect transistors and capacitors that form the backbone of most complementary metal oxide semiconductor (CMOS) logic and dynamic memory devices is a thin film of dielectric material to prevent the flow of direct current between key components. In a transistor, this material lies sandwiched between the gate and the underlying channel between the source and drain. In a capacitor, this material is between the two electrodes. In both cases, nitrogen-doped amorphous SiO_2 is typically used, with thicknesses down to 2 nm.[30] While field effects in transistors and capacitance in capacitors rise as this distance increases, ways are needed to suppress current leakage to provide the requisite dc electrical isolation. Much work has focused on leakage mechanisms involving defects caused by strain, contamination, and injected charge.[31] However, this problem has been largely solved, so that below about 4 nm, the significant electrical conductivity because of

quantum mechanical tunneling poses an absolute limit on the ability of SiO_2 to provide isolation. A solution must be found to the tunneling problem—one that is universally recognized to require an insulator with a higher dielectric constant k. The search for ''high-k dielectrics'' (as opposed to the low-k dielectrics of the previous section) has proceeded for about the last decade. Much research has focused on materials such as Ta_2O_5 ($k = 20$–50), various ferroelectrics such as $Ba_xSr_{1-x}TiO_3$ ($k \approx 100$–400),[32] and more recently, oxides and silicates of metals from Group IVA of the periodic table. Examples include ZrO_2, HfO_2, $ZrSiO_4$, $HfSiO_4$, and $HfSi_xO_y$,[33] with the first two oxides receiving most attention in recent years. Ta_2O_5 has been developed sufficiently to find current use in production (for memory devices, but not transistor gates). $Ba_xSr_{1-x}TiO_3$ suffers from severe reliability problems. The Group IVA materials show more promise, but still require development to solve difficulties not only with current leakage and interfacial properties but also with process integration issues such as patterning and etching. Though are some reasons to believe that a suitable replacement for SiO_2 does not exist,[34] there is very recent evidence that the key problems can be solved.[35]

CONCLUSIONS

Current microelectronic processing involves working around fundamental constraints imposed by cost and physics. However, working in the presence of constraints is fundamental to chemical engineering: improved devices and processes are developed through optimization of all kinds. In other words, the industry must continue to learn how to squeeze most out of what Mother Nature permits. In device fabrication, where rates of transport and physical/chemical transformation govern, chemical engineering principles are needed more than ever.

Microfabrication

Chung-Chiun Liu
Electronics Design Center and Department of Chemical Engineering, Case Western Reserve University, Cleveland, Ohio, U.S.A.

INTRODUCTION

Microfabrication is a mature silicon-based manufacturing processing. It is effective to produce miniature size, geometrically well-defined, highly reproducible structures. While microfabrication processes are used extensively in microelectronic industries, it is interesting to know that these processes are intimately related to chemical engineering sciences. For instance, most of these microfabrication processes are batch processing, and the principles of transport phenomena and reaction kinetics are applied broadly in these microfabrication processes. There are excellent books describing the microfabrication processing in detail.[1,2]

Microfabrication processes consist of many different procedures, and four major processes will be discussed here:

- Lithographic reduction
- Oxidation
- Thick and thin film metallization
- Photoresist patterning and chemical wet etching

LITHOGRAPHIC REDUCTION

Historically, lithography is a stone-writing or stone-rubbing technique. In this process, an image or picture is first carved onto a flat-surface stone. The stone is then properly treated with chemicals resulting in the image and nonimage areas of the stone. Subsequently, ink is applied onto the carved stone surface, and an image receptive material, such as paper, is placed over the stone. By rubbing the paper over the stone, the image on the carved stone will then be transferred onto the paper. In microelectronic processing, lithographic technique is used to translate a designed pattern onto a substrate through the use of a mask. This translation is often a reduction of the original sizes.

The most commonly used lithographic technique is photolithography. It combines the photographic reduction capability and the lithographic pattern translation through a mask. Photolithography is relatively simple, but it is limited to minimum size reduction. Nevertheless, it can be used to produce geometrically well-defined microstructures with a high degree of reproducibility. Photolithography involves three major tasks: 1) photographic reduction; 2) mask fabrication; and 3) optical printing.

Photographic reduction starts with a design, which is generally produced using a computer-aided design (CAD) software package. The design can be any type of device that can be an integrated circuit, a sensor, or others. Consequently, the structure of this device may be multilayer. This will require more than a single mask, and in this case, proper alignment for the layers is critical. The original design of the device can be transferred onto a rubylith, then the design should be photographically reduced onto a special plate for the mask.

The mask is an integral part of the lithographic technology as well as for the patterning process. In IC processing, it is further defined as reticles and masks. A reticle is considered to contain a designed pattern that can be stepped and repeated over an entire substrate. A mask is viewed to be able to expose the designed pattern over the entire substrate at once. Obviously, the resolution and definition of a reticle or a mask are critical to the final definition of a microstructure. The polarity of a reticle or a mask can be either a dark field or a light field. Fig. 1 shows an example of the light field and a dark field of a mask. Obviously, the light parts of a mask permit the light, ultraviolet light, to penetrate through whereas the dark portions would not allow any light to go through. This will directly influence the results of photoresist patterning.

Using the patterned mask, the transformation of the design of the device to the substrate can be accomplished by optical printing techniques. There are three general optical photographic techniques, and they are contact printing, proximity printing, and projection printing. Each of these printing techniques has its own merits and limitations. In contact printing, the mask is in direct contact to the surface of the substrate or the surface of the material layer, such as photoresist or others, which covers the surface of the substrate. In this configuration, the image of the device can be translated directly to the surface of the substrate without any optical distortion. Because the mask is directly touching the surface layer of the substrate, damage, such as scratching on the mask, often occurs after a limited number of usages. This may not be acceptable economically.

In the proximity printing, a gap space is placed between the mask and the surface layer of the substrate.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007861

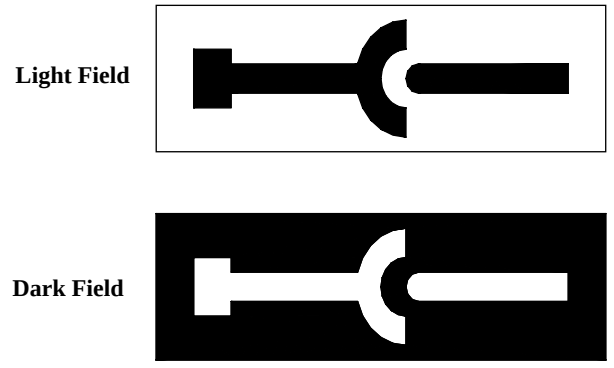

Fig. 1 The light field and dark field polarities of a typical mask.

There is no direct contact between the mask and the surface layer, minimizing the damage due to direct contacting. Because there is a gap space between the mask and the surface layer of the substrate, there is a distortion between the pattern on the mask and its translation onto the surface layer of the substrate. As expected, an increase in the gap space will degrade the resolution of the patterned image significantly.

Projection printing involves a much more complicated optical system. Optical lenses and mirrors are used to focus the pattern on the mask onto the substrate surface. There are several types of projection printing, including projection scanners, reduction step-and-repeat projection aligners, and nonreduction step-and-repeat aligners. Each type of the projection printing has its own merits and limitations. In general, the feature of step-and-repeat in projection printing is very useful to reproduce the image of a device accurately on the substrate surface, resulting in producing highly reproducible geometric structures.

The merits, advantages, and limitations of each optical printing technique have been discussed elsewhere.[3] For the microelectronic industry, as the demand of smaller device size increases, advancement in lithographic techniques is needed. This advancement includes the x-ray, electron-beam, and ion-beam lithographics. As the names of these lithographic techniques imply, various high-energy sources for the optical printing are used to enhance the resolution of the device structure. There is continuous development in lithographic technology including scanning, probe, and atomic force microscopic lithography, three-dimensional lithography and the so-called ''soft'' lithography. The description of these techniques is beyond the scope of this article.

OXIDATION

Silicon is a semiconductive material. When silicon is used as the substrate for the fabrication of IC and devices, the surface of the silicon substrate needs to form an insulation layer on which the IC and devices can be fabricated. This insulation layer can be silicon dioxide, silicon nitride, or other materials, and silicon dioxide is, however, the most commonly used insulation layer. Silicon dioxide is stable and tenacious and is well suited as the foundation layer for the construction of IC and devices. The formation of the SiO_2 layer on the silicon substrate can be accomplished by various means, and thermal oxidation is probably the preferred approach. The thickness of the oxide layer varies depending on the application, and a thickness range of 50–10,000 Å SiO_2 formed by thermal oxidation is commonly used.

The basic mechanism for the formation of SiO_2 on the silicon surface is well understood. The seminal work by Deal and Grove provided a mathematical model that describes the growth kinetics of the SiO_2 layer.[4] In this model, the oxidation process progresses as the diffusion of an oxidant takes place at the interface of Si/SiO_2. The oxidant can be oxygen in a dry oxidation process and H_2O molecule in a wet oxidation process. Because the oxidation reaction takes place at the Si/SiO_2 interface, the continuous growth of the oxide film is a moving boundary transport phenomena. Also, as the oxide layer grows, silicon will be consumed by the oxidation process. Based on the relative density and molecular weights of Si and SiO_2, the amount of silicon consumed is 44% of the final oxide thickness.[2,4] This implies that for an oxide layer of 10,000 Å, 4400 Å of the Si will be consumed.[2,4]

Thermal oxidation of silicon can be achieved under dry or wet oxidation condition. In dry oxidation, oxygen is the oxidant whereas in wet oxidation, water molecule is the oxidant. Thermal oxidation is often carried out at elevated temperatures, such as 600–1250°C. The oxide growth rate is generally faster in wet oxidation compared to dry oxidation. Also, the growth rate of the oxide depends on the crystallographic orientation of the silicon, that is, the linear oxidation rate of silicon qualitatively is [110] > [111] > z[100]. However, crossover in growth rate is possible; for instance, the oxide growth rate at 700–1000°C, [111] > [110], but not at 1100°C.

As in all microfabrication processes, the cleanliness of the substrate is very critical for the silicon oxidation process. As discussed above, the crystalline orientation will influence the oxidation rate of silicon dioxide. There are other operational parameters that will affect the oxidation rate of silicon. This includes the dopants in silicon, the trace amount of water, the concentration of Cl-bearing species, the temperature control, and its profile. Extensive assessment of each parameter on the growth rate and the quality of the SiO_2 layer on silicon can be found in microfabrication related literature elsewhere.[1,2]

There are other insulating materials that can be used instead of silicon dioxide. Silicon nitride, alumina, and aluminum nitride are a few that are often used. The selection of a proper insulation layer is based on the specific needs and the properties of selected materials.

THICK AND THIN FILM METALLIZATION

Deposition or formation of a metallic film is an important aspect in microfabrication. For traditional IC and electronic devices, metal films such as aluminum or copper film provide the electrical contact and connection from the device to external circuitry or equipment. In this circumstance, the line width and its electrical continuity are of interest. With the advancement of using microfabricated devices in chemical and biological application, formation of metallic films, such as gold, platinum, and others, becomes necessary. The formation of this metal film can be accomplished by thick or thin film techniques.

Thick film technology has been used extensively in the microelectronic industry, particularly in the manufacturing of hybrid circuit boards. Basically, thick film technology is a silk-screening printing process.[5] In general, the process involves a screen with the designed pattern, an ink or paste containing the desired component, and a mechanical squeegee. The screen has different mesh sizes and its selection is based on the properties of the ink or paste, such as particle size, viscosity, and others. The thick film ink or paste usually contains three components, the desired film material, such as gold, platinum, or others, a binding compound, and a solvent. For the formation of a metallic film, such as gold, platinum, and others, particles of the metal are used. These particles are then mixed with a binding compound, or the binder, into a solvent. The binder is often an inorganic compound, such as glass, and it serves to bind the metallic particles onto the surface of the substrate. However, organic binders, such as polyethylene oxide, are also used. The solvent is the vehicle to produce a homogenous mixture for the silk-screen printing. It is essential that the prepared ink or paste is homogenous in nature to obtain a uniform thick film. The printed thick films are not limited to metallic film; insulation materials, carbon, and other nonmetallic films can also be silk-screened using appropriate inks and pastes.

The thick film printing sequence involves first transferring the design onto a screen, then placing the thick film ink over the screen, and then using a squeegee to spread the ink over the screen. In this process, the ink or paste will go through the opening of the mask, forming the planned structure onto the substrate. Fig. 2 shows a typical sequence of the thick film processing. In this process, the thickness of the thick film in a single passage of the squeegee is approximately 5–30 μm. This thickness is controlled by the pressure applied by the squeegee, the gap space set between the screen and the substrate, and the properties of the ink or paste, such as viscosity and composition. After printing, the substrate is placed in an oven at a relatively low temperature, i.e., approximately 70–80°C, to remove the solvent. Then, the substrate is put inside a high-temperature furnace to carry out the binding process. For commercially available thick film inks or pastes, information for the heating temperature and the heating profile is readily accessible.

One of the attractive features of the thick film process is that the capital investment for thick film printing is relatively low. Basically, it involves a thick film printer, an oven, and a furnace. One of the notable commercial successes of using thick film techniques is the manufacture of glucose strips for diabetic patient management. The strip involves thick film printing and is cost-effective, making the disposable strip a reality.

However, one must also recognize the limitation of thick film printing techniques. For example, the minimum line width in thick film printing is in the order of 20–50 μm. Also, the reproducibility of the thick film printing is about ±10%. Therefore, the user of thick film printing technique needs to recognize its limitation.

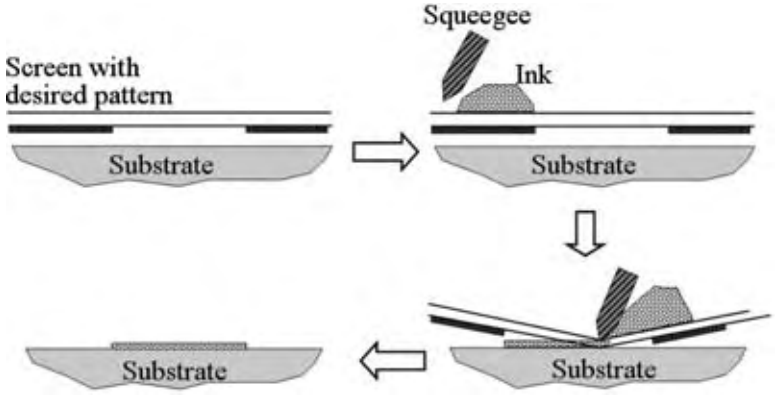

Fig. 2 Typical sequence of a thick film printing processing.

For the formation of a metallic film in addition to thick film silk-screen technique, thin film metallization is another means for the film deposition. Deposition of thin film can be accomplished by either physical or chemical means, and thin film technology has been extensively used in the microelectronics industry. Physical means is basically a vapor deposition, and there are various methods to carry out physical vapor deposition. In general, the process involves the following: 1) the planned deposited metal is physically converted into vapor phase and 2) the metallic vapor is transported at reduced pressure and condensed onto the surface of the substrate. Physical vapor deposition includes thermal evaporation, electronic beam assisted evaporation, ion-beam and plasma sputtering method, and others. The physical depositions follow the steps described above. In essence, the metal is converted into molecules in the vapor phase and then condensed onto the substrate. Consequently, the deposition is based on molecules and is uniform and very smooth.

Thermal evaporation involves an application of heat to evaporate the film material. This heating and thin film deposition process is carried out in a high-vacuum environment. In the vacuum environment, the vaporization temperature of the material becomes lower, and the vaporized molecules will strike on the substrate surface instead of collision with other molecules according to Knudsen's mean free path. Thermal evaporation has been extensively used in the microelectronics industry. The advantages of thermal evaporation include a high deposition rate and relatively low damage of the substrate because of the low energy of the impinging metal molecules. However, thermal evaporation also has its limitation. For instance, it is very difficult to deposit an alloy film with predetermined composition. In situ cleaning is important for thin film deposition, because a cleaned surface enhances the quality of the film deposited.

Electron beam assisted deposition involves the application of a stream of electrons to evaporate the source material of the deposited film. The electron beam power can be established at a very high value. This tends to enhance the deposition rate. However, the high-energy beam may cause damage on the surface of the substrate.

Deposition of thin film by ion beam and plasma sputtering are very similar, in principle, to electron beam assisted evaporation, with the difference in the energy source applied. Details of each of these physical vapor deposition methods can be found elsewhere.[6]

In addition to physical vapor deposition, thin film can also be formed using chemical vapor deposition (CVD). In general, a CVD involves a gaseous reactant containing the deposited component, and another reactant, often a reducing reagent, in the gaseous phase. Inside the deposition chamber, a reaction involving the gaseous reactants takes place leading to the formation of a nonvolatile solid film on the surface of the substrate.

In CVD, the process involves steps in sequence. This includes the transportation of gaseous molecules from the bulk to the reaction sites, a surface reaction, and the transportation of the by-products into the bulk. Similar to a heterogenous chemical reaction, the slowest step in the process is the rate-limiting step.

Chemical vapor deposition includes various systems, and they are low-pressure CVD (LPCVD), atmospheric pressure CVD (APCVD), plasma enhanced CVD (PECVD), and others. Each type of CVD system has its own advantages and limitations. For instance, in LPCVD, the reactor is usually operated at $\sim$1 torr. Under this condition, the diffusivity of the gaseous species increases significantly compared to that under atmospheric pressure. Consequently, this increase in transport of the gaseous species to the reaction sites and the by-products from the reaction sites in LPCVD will not become the rate-limiting steps. This leads to the surface reaction step to be the rate limiting one.

Atmospheric pressure CVD was first used for CVD in the microelectronics industry. The reactor for APCVD is, in general, relatively simple. However, as compared to LPCVD, APCVD can be mass-transport rate limited. Most of the APCVD used are for low-temperature oxide deposition and epitaxy.

Both LPCVD and APCVD are defined by the pressure regime. There is another type of CVD that is defined by the energy input to heat the reactive surface of the substrate. This heating can be accomplished by resistant, radiofrequency induction, glow discharge (plasma), and photon heating. Each one has its merits and limitations. When radiant heating is involved, both the substrate and the reactor wall will become hot, and the reactor is defined as hot-wall reactor. On the other hand, when the heating is directly on the substrate, the reactor wall does not become hot, and the reactor is defined as cold-wall reactor. It can be appreciated that the geometry of the reactor of CVD is horizontal or vertical or in another form and the control of gaseous flow rate will affect the performance of the CVD process directly.

Deposition of a metallic film onto the silicon dioxide surface requires a good adhesion between the two layers. An enhancement of the adhesion can be accomplished by first depositing a very thin layer of titanium or chromium, 50–100 Å in thickness, then the desired metallic film.

PHOTORESIST PATTERNING AND CHEMICAL WET ETCHING

In microfabrication, photoresist patterning is an important aspect of the definition of microstructures. In this processing, a layer of the photoresist material

is spin-coated onto the surface of the substrate. The coated photoresist layer is then exposed to radiation, which can be ultraviolet light, electrons, or x-rays. This exposure is usually through a mask that defines the pattern and the area to be radiated. After the radiation and in the subsequent development step, the photoresist layer yields the pattern based on the area where the photoresist remains or is removed. Photoresist generally consists of a base resin, a sensitizer, and a solvent, and the solvent serves as the vehicle to form a homogenous mixture for uniform coating. The basic resin is normally a polymer. There are two groups of photoresist, the positive and the negative photoresists. When radiated, the photochemical reaction of a positive photoresist will weaken the exposed polymer, resulting in rupturing or scissoring of the main and side polymer chains. Consequently, the exposed polymer becomes soluble in the developing solution and can be removed from the surface of the substrate. On the other hand, under radiation, the exposed part of a negative photoresist tends to cross-link forming a polymer layer insoluble in the developing solution.

Poly(methylmethacrylate) is a well-known single component positive photoresist, whereas a diazoquinone ester and a phenolic novolak resin is a two component positive photoresist. As anticipated, radiation will render the scission or rupture the main and side chain of the polymer making it soluble in an alkaline ''developing'' solution. Hydroxide solutions such as KOH and tetramethylammonium hydroxide are commonly used as the developer for positive photoresist.

Bis(aryl)azide rubber resist is a common negative photoresist. In a photoreaction, the evolution of nitrogen from the acylazide produces a highly reactive intermediate, nitrene. Through a series of reactions the nitrene intermediate leads to the formation of polymer by cross-linking the resin. The unreacted negative photoresist can then be dissolved in organic solvent, and xylene is commonly used.

Positive and negative photoresists have their own advantages and disadvantages. General consideration of the photoresists includes its adhesion on the substrate, the minimum feature size permitted, the resistance to chemicals, the cost, and others. Most of the commercially available photoresists provide information about the properties and the suitable developers of the photoresists.

After the photoresist layer is spin-coated onto a substrate, before it is exposed to radiation and further development, a soft-bake step often takes place. In this soft-bake step, the photoresist-coated substrate is placed inside a low-temperature oven to be baked at a temperature range approximately 90–100°C for a few minutes to about 30 min. This soft-bake procedure intends to remove the solvent from the photoresist, enhance the adhesion to the substrate, and release the internal stress of the photoresist film. In essence, the soft-bake step intends to provide a photoresist film that will perform well in the following radiation exposure and development process.

It should be recognized now that the mask making, the selection of the polarity, and the relation of the photoresist are intimately related.

The development of the photoresist on a substrate leads to the defining of the actual pattern on the substrate. The material for the actual pattern can be a thin metal film, silicon dioxide, or others. To release this pattern wet chemical etching is used. Obviously, the chemical used in the etching will attack neither the photoresist nor the material that is covered by the photoresist. Chemical etching, also referred to as wet etching, is generally isotropic. Thus, it has limitations in defining features of size less than 3 μm in width. However, wet etching remains an important processing step when the feature size of similar width is more than 3 μm. Wet etching for a specific material requires a specific chemical solvent. This solvent, the etchant, is capable of dissolving and removing the film layer, but not the masking or the substrate material. Wet etching is also a chemical reaction in series. It involves the transport of the etchant to the reacting surface, a surface reaction, and the transport of the products from the etching process to the bulk solution. As anticipated, the slowest step in the process is the rate limiting one.

Silicon, either single crystal or polycrystalline, can be wet etched in a mixture of nitric acid and hydrofluoric acid. This etching reaction is based on the nitric acid reaction with silicon forming silicon dioxide that is then dissolved by hydrofluoric acid. Different compositions of the HNO_3 and HF mixtures yield different etching rates. Both water and acetic acid have been used for the silicon etching mixture. The etching rate of silicon is also related to the crystalline structure of the silicon plane. This orientation etching is termed anisotropic etching. It is well recognized that etching at a <111> plane will create a V-shaped profile with an angle of 54.7°. For etching processes that are independent of the crystalline orientation, bulk micromachining techniques, such as reactive ion etching and plasma etching, can be used. These processes are well established and are described extensively in three-dimensional bulk micromachining literature.

Wet chemical etching is also a commonly used process to pattern the metallic film structure. In these cases, a suitable solvent for the metallic film is used to dissolve or etch away the exposed area of the metallic film. This wet etching technique has been used for various metallic films, such as gold, copper, aluminum, and others. However, there are cases where chemical etching of the metal can be difficult. For instance, the etching of the platinum film is not easy because of the required etchant for the platinum film. One of the patterning processes to overcome the potential

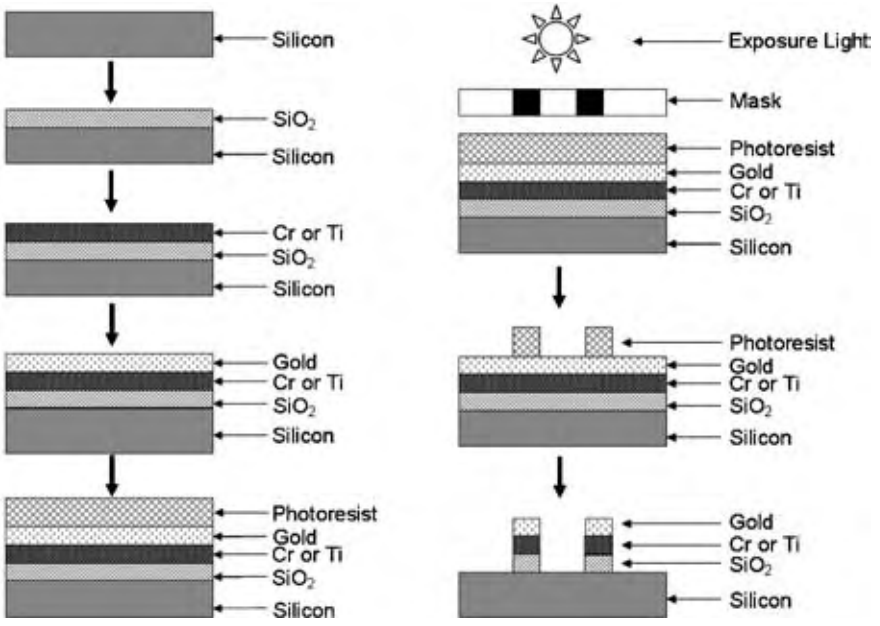

Fig. 3 Processing steps for the deposition and patterning of a thin film metal structure. (The thicknesses of the metal layers are not proportionally scaled.)

problems in wet etching is the lift-off technique. Lift-off is considered to be a technique for forming a pattern on a substrate surface by an additive process as opposed to the removal (or subtractive) process in the etching process.[1–3] In the lift-off process, the photoresist layer is first spin-coated and patterned on the surface of the substrate using lithographic and mask-based optical printing techniques. However, the photoresist is inverse-patterned in this lift-off process. The film, metallic or otherwise, to be patterned is then deposited over the inverse-patterned photoresist layer as well as the open area in the pattern. The substrate is then placed into a solvent that will dissolve or remove the photoresist. Consequently, any film material deposited on top of the photoresist will be lifted off leaving the patterned portion where the film material is deposited, on the surface of the substrate. As anticipated, there are advantages and disadvantages in the lift-off process in patterning. The choice of a proper process in patterning, as in other microfabrication processes, depends on the needs, the materials selected, and the required dimensions, and available facilities. Fig. 3 shows a typical thin film metallization processing sequence. This processing sequence summarizes the various steps in the thin film microfabrication.

CONCLUSIONS

In conclusion, silicon-based microfabrication processes prove to be effective in producing miniature size, highly reproducible microstructures at modest manufacturing cost. This provides opportunities for the development of microsensors for chemical processing control, microreactors, and microfluidics, and many other unique applications. The combination of the chemical engineering fundamentals, transport phenomenon and reaction kinetics, and the microfabrication technology provides an excellent opportunity and technical challenge in numerous research and development endeavors in the years to come.

Microgravity Processing of Materials

Robert Naumann
University of Alabama, Huntsville, Alabama, U.S.A.

INTRODUCTION

Why study materials science in space? Given the high cost of getting to and from low Earth orbit, the actual manufacture of most materials in space on a commercial basis seems unlikely. A principal justification for carrying out materials science experiments in space is the use of the virtual absence of the effects of gravity as a tool to obtain a more fundamental understanding of the processing of materials with the objective of being able to develop improved processing strategies for use on Earth.

Much of what goes on in a multicomponent melt is affected by gravity, but some of the more subtle interfacial effects are not. Yet these interfacial effects, which are poorly understood because they are masked by gravitational effects, can play important roles in many terrestrial processes. Using microgravity as a tool to sort out the nongravitational from the gravitational effects may add to our understanding of how these interfacial processes operate, which is needed to control their effects.

With the computational capability that exists today, it is possible in theory to model a complete solidification process in a complex mold, taking into account the heat and mass flow, culminating in the prediction of the microstructure of the final casting at critical places. However, to do this, the basic laws or theories governing the development of the microstructure must be known along with accurate values for the thermophysical properties of the constituents. Establishing the physical basis and workable models for the solidification process has, over the last half-century, transformed metallurgy from an industrial art, based on empiricism, to a more exact science. However, because of the complicating effects of convection, many of these theories or models in use today are based on the assumption of no convective flows. It is understood that many of these models do not apply exactly, but they are assumed to be basically correct and attempts are then made to "fix them up" by adding the effects of convection. However, most of these theories and models have never been tested in the absence of convection, so various subtleties may have been overlooked. The ability to experiment in microgravity provides opportunities to test some of these theories and models to make sure they are valid or at least to define the limits of their validity. This entry reviews some of the significant experiments that were performed during the Spacelab series of flights involving NASA, the European Space Agency (ESA), and the National Space Development Agency of Japan (NASDA). The types of experiments can be logically categorized under the topics of Alloy Solidification, Measurement of Thermophysical Properties, Undercooling Experiments, and Crystal Growth Experiments. Readers are encouraged to refer to the citations for more details about these experiments and their findings.

ALLOY SOLIDIFICATION

When one attempts to solidify a multicomponent system from the melt, difficulties arise. The solute atoms generally do not fit into the lattice as easily as the host atoms forming the matrix, and segregation results. The melt containing the rejected atoms will have a different density from the bulk liquid, resulting in solutally driven convection that causes the final solid to have a nonuniform composition on a macroscopic scale (macrosegregation). If a single crystal with uniform composition is required, a thermal gradient of sufficient magnitude must be applied to stabilize the solidification front or it will break down from plane front to cellular or dendritic growth. In most industrial processes that do not require single crystals, no attempt is made to stabilize the interface against breakdown, so the resulting dendrites form the microstructure of the casting. Therefore, it is important to understand how the structure of these dendrites depends on the processing conditions.

The microstructure will coarsen with time at high temperatures, meaning the grains or other microstructural features will grow larger, which alters the mechanical properties. Any particles intentionally or unintentionally dispersed in the melt will generally have a different density and will tend to either sink or float. Particle behavior is also affected by the interfacial energy between their surface and the melt, which determines if they are engulfed by an advancing solidification front or pushed ahead of it.

The alloy solidification experiments that have been performed on Spacelab missions generally fall into four categories: 1) interfacial stability; 2) evolution

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039235

of the microstructure during and after solidification; 3) Liquid phase sintering; and 4) particle/solidification interactions.

Interfacial Stability

As solidification progresses in a binary or multicomponent system, the rejected solute builds up in front of the solidification interface, which has the effect of lowering the freezing temperature at the interface because some of the component with the higher freezing temperature has already been removed. However, the bulk melt away from the solidification interface has the original composition, which has a higher freezing point. Therefore, the freezing point of the melt rises from the lower value at the growth front to the higher value of the bulk melt. Unless the imposed thermal field in front of the solidification interface is everywhere higher than the local freezing point of this melt, the melt is said to be constitutionally undercooled (or supercooled), which can lead to an interfacial instability. If a small fluctuation displaces a portion of the growth interface ahead and it finds the local freezing point to be lower than the local temperature, it will continue to advance. Thus the interface will break down, first into a cellular pattern if the constitutional undercooling is small, or into long finger-like projections if the undercooling is larger. The sides of these projections will also break down to form secondary arms, which in turn can break down to from tertiary arms. The resulting structure resembles a fir tree, hence the term ''dendrite.'' Where single crystals of uniform composition are required, the interface can be stabilized by applying a sufficient thermal gradient at the growth interface to keep the local temperature above the local freezing point and prevent interfacial breakdown.

A simple constitutional supercooling criterion (known as the CS criterion), which predicts the ratio of the gradient required to stabilize the interface moving at a particular growth velocity for a given solidification system, was developed by Rutter and Chalmers in 1953.[1] In 1964, Mullins and Sekerka[2] developed a more rigorous theory based on a stability analysis that included the liquid–solid interfacial energy, which can provide a stabilizing effect on the interface. Like most theories concerning solidification phenomena, it was necessary to assume no convection to simplify these analyses.

A unique and highly sophisticated apparatus for studying details of the solidification process was developed by Favier and co-workers at the French Centre d'Etude Nucléaire, Grenoble (CENG), under a cooperative program between NASA and the French Centre National d'Etudes Spatiales (CNES) or National Space Agency and the French Commissariat á l'Energie Atomique (CEA) or Atomic Energy Commission. The official name is Materials for the Study of Interesting Phenomena of Solidification on Earth and in Orbit or MESPHISTO. The middle of a sample is melted using two furnaces. One solidification front is kept stationary while the other is moved back and forth to create a solidification front that can be moved at different velocities. By measuring the differential Seebeck voltage between the stationary and moving interfaces, the kinetic undercooling can be determined as a function of growth velocity. At the freezing point, a solid will remain in equilibrium with its melt indefinitely. This kinetic undercooling is the driving force for continued solidification. The kinetic undercooling will be small for plane front solidification, but since additional interfacial energy must be provided as the plane front begins to break down, the kinetic undercooling must get larger. Thus, the transition from plane front solidification to cellular growth can be observed as a change in the Seebeck voltage, and the critical growth velocity where the plane front interface begins to break down can be determined accurately. The MEPHISTO instrument, flown on four Spacelab missions, provided the first opportunities to perform a critical test of the Mullins–Sekerka theory as well as to explore other important phenomena involved in the solidification process.

Favier used the USMP-1 opportunity to explore the interfacial breakdown in Bi-doped Sn, which, like most metals, solidifies as a plane front with little kinetic undercooling. His U.S. co-investigator, Abbaschian, investigated interfacial stability on the other side of the phase diagram; i.e., Sn-doped Bi, which solidifies with a faceted interface. The purpose was to test the extension of the Mullins–Sekerka stability criterion to include the effects of anisotropy, which acts to stabilize the interface against breakdown into cellular and dendritic growth.[3,4]

Microstructure Evolution

The strength and other properties of an alloy depend on its microstructure, which is characterized by the size, orientation, and composition of the grains and other features that make up the solid. One of the main tasks of a materials scientist is to design solidification processes to produce the microstructure that will give the material the desired properties. To accomplish this it is necessary to understand how this microstructure develops as a function of processing parameters.

Dendrite formation

Since the microstructure and hence the mechanical properties of the casting are largely controlled by the

structure of the dendrites, it becomes important to know how dendrite growth depends on processing parameters so that the desired microstructure can be engineered.

Glicksman and co-workers carried out a series of precisely controlled dendritic growth experiments on three Spacelab missions using succinonitrile, which solidifies body-centered cubic, and pivalic acid, which solidifies face-centered cubic. Both systems have unusually low entropies of fusion, more typical of metals than of organics and are widely used as transparent metal analogs. One of the governing factors in the growth of these thermal dendrites is the heat flow from the dendrite to the surrounding melt. Ivantsov[5] obtained an exact solution to the conductive heat flow problem for a parabolic shaped dendrite, which relates the product of growth rate and tip radius to the undercooling. However, from this simple analysis, there seems to be no fundamental relationship between the tip radius R and the growth velocity V.

The question becomes, how does nature select a unique operating state? Experimental observations of dendrite solidification in pure systems suggest that VR^2 is either a constant for a specific material, or a weakly varying function of the undercooling. A large body of terrestrial data has been taken on several systems, but convection effects, especially in the crucial region of low undercoolings where the growth rate is comparable to the convective flow velocities, have not been able to provide an adequate test of the selection rules governing this process (Fig. 1). The establishment of such relationships was the motivation behind this set of flight experiments.[6,7]

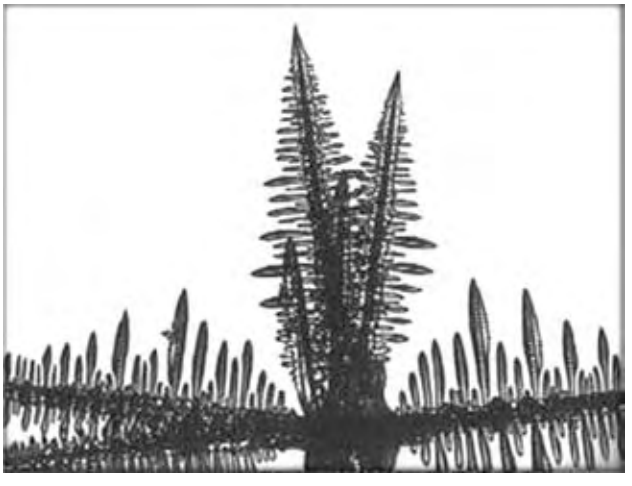

Fig. 1 Thermal dendrites grown in a microgravity experiment as part of the Isothermal Dendrite Growth Experiments (IDGE) carried out by the Renasslear Polytechnic Institute team headed by Glicksman. (Taken from the IDGE home page on http://www.rpi.edu/locker/56/000756/.)

Coarsening

Since the yield strength of a metal is inversely proportional to the square root of the average grain size, coarsening is of major importance in the evolution of the microstructure of alloys. This is particularly true in precipitation or dispersion hardened alloys because the added strength provided by the dispersed phase declines rapidly if the particles grow past a critical size. Coarsening is driven by the excess interfacial energy in a finely dispersed material, which could be reduced if fewer larger particles were present. The melting point of a small particle is lower than that of a larger particle of the same composition because of its excess surface energy (Gibbs-Thompson effect), so the smaller particles dissolve to feed the growth of larger particles in a melt. Coarsening also occurs in fully solidified systems through solid state diffusion.

This process was first recognized by Ostwald[8] and is known as Ostwald ripening. The mathematical details were worked out independently by Lifshitz and Slyozov[9] and by Wagner[10] and is known as the LSW theory. However, this theory is based on a mean field approximation and is restricted to low volume fraction systems. Voorhees and coworkers extended the LSW theory to finite volume fraction systems and conducted a series of flight experiments designed to test this and similar theories.[11–13]

Liquid Phase Sintering

Liquid phase sintering (LPS) is a widely used process for forming composites containing refractory particles such as tungsten, rhenium, or various carbides in a metal matrix. Sintered products include cutting tools, bearings, contact points, and other irregularly shaped parts where it is desirable to combine extreme hardness with the toughness and thermal or electrical conduction of the metal matrix. The refractory particles are combined with the metal matrix powder and isostatically pressed and heated to above the melting point of the matrix phase. If proper attention is paid to the wettability of the refractory particles, the molten host metal will infiltrate between the grains of the solid particles and envelop them. There are some obvious gravity effects because of the large difference in densities often encountered between particle and host phase. Consequently, these effects restrict the process to large volume fractions of the solid phase since the solid particles will essentially have to support themselves during the process. Even under these circumstances, there are differences in the particle size and morphology between the top and bottom of the specimen due to the gravity-imposed hydrostatic pressure.

German and co-workers conducted liquid phase sintering experiments during three Spacelab missions using W particles in a Fe–Ni matrix with the amount of W ranging from 78–98 wt% W in 5 wt% increments. The major results from this series of experiments are universal models for coarsening, slumping and distortion, and grain agglomeration.[14,15]

Particle/Solidification Front Interactions

Small ceramic particles are sometimes added to metals to block the motion of dislocations (dispersion hardening) or for flux pinning in type II superconductors. In the preparation of composite materials, it is important to know how such particles interact with the solidification front. If the particle is not wetted by the melt, intermolecular forces at the advancing solidification will tend to repel the particle. These forces are pitted against inertia and drag forces that tend to engulf the particle. There have been a number of attempts to model this process. It is generally accepted that for a particular system there is a critical velocity below which the particle will be pushed ahead of the solidification front, and above which it will be engulfed by the advancing solid. Buoyancy and convective flows complicate the picture in normal gravity and it is important to be able to separate these effects from the more fundamental interactions that take place at the solidification front. As a result, a variety of experiments were conducted on Spacelab missions to develop a better understanding of particle-solidification front interactions.

A theory developed by Shangguan, Ahuja, and Stefanescu to predict the critical velocity was validated for the case of zirconia particles being pushed by Al on a later Spacelab mission.[16,17]

MEASUREMENT OF THERMOPHYSICAL PROPERTIES

Not much is known about the thermophysical properties of liquid metals, especially the transport properties such as chemical and thermal diffusivities. The existing data are sparse and the scatter makes it difficult to make an accurate determination of the temperature dependency of these properties. This situation was the motivation for Froberg's experiment on Spacelab-1 in which he measured the temperature dependence of the self-diffusion of Sn from 240°C to 1250°C. He found that the diffusion coefficients were 30–50% lower than the accepted values and seemed to follow a T^2 dependence as opposed to the Arrhenius behavior observed in solid state diffusion.[18] These results prompted a number of experiments in subsequent missions designed to measure diffusion coefficients of liquid metals. Some of these experiments found a power law dependence on temperature, with the exponent varying around 2 for different materials, while others found a better fit with an Arrhenius model. However, all of the microgravity experiments consistently measured diffusion coefficients that were 30–50% lower than the accepted values, suggesting that all existing transport data for liquid metals may be contaminated by unwanted convection.[19–21] A recent analysis demonstrated the difficulty of eliminating convective transport in such measurements in normal gravity.[22]

UNDERCOOLING EXPERIMENTS

A space electromagnetic levitation facility designated as TEMPUS (Tiegelfreies Elektromagnetisches Prozessieren Unter Schwerelosigkeit) was developed by the Institute for Space Simulation, Cologne, Germany. It uses a quadrapole coil for sample positioning and a dipole coil for sample heating. Since only very small positioning forces are required in a microgravity environment, electromagnetically driven flows from positioning can be minimized. The sample chamber can be evacuated, or backfilled with an inert gas to reduce evaporation of samples with high vapor pressure. A team of U.S. and German investigators, using some innovative noncontact instrumentation was able, for the first time, to measure a variety of thermophysical properties including surface tension, viscosity, thermal conductivity, and enthalpy in the undercooled state of a number of alloys that are candidates for metallic glasses.[23–26] Other phenomena such as quasicrystal formation and dynamic nucleation were also explored and ferromagnetic magnetic ordering was in the liquid state of $Co_{80}Pd_{20}$ when it was cooled below its Curie temperature.[27,28]

CRYSTAL GROWTH EXPERIMENTS

Growth from the Melt

Macrosegregation has always been a problem in the growth of alloy-type multicomponent single crystals from the melt. Even in systems that are not subject to thermosolutal convection and can be stabilized by vertical Bridgman growth by placing hot over cold, radial thermal gradients can drive convective flows that result in radial as well as axial compositional inhomogeneities. A number of early flight experiments attempted to avoid this problem by growing such

crystals in microgravity under the assumption that by reducing the effects of gravity by some six orders of magnitude, the resulting residual convective flows would produce negligible compositional redistribution.[29] After these early experiments failed to produce the desired results, a serious analysis was undertaken of the effects of small convective flows. It was shown that a transverse quasi-steady acceleration of less than 1μg was sufficient to cause significant macrosegregation and that it would be necessary to align the thermal gradient along the residual acceleration vector to provide a small stabilizing force if unwanted solute redistribution is to be avoided.[30] The residual acceleration in the Spacelab was primarily due to gravity gradient effects, which occur when the experiment is some distance from the center of mass of the spacecraft. Beginning with the first United States Material Laboratory (USML-1) mission in 1992, all subsequent low-gravity emphasis Spacelab missions were flown with the orientation of the Space Shuttle controlled to provide a definable nearly constant residual acceleration vector during at least a portion of the mission.[31,32]

Larson designed an experiment to investigate how gravity might influence the formation of defects during the growth of $Cd_{0.95}Zn_{0.05}Te$ on the USML-1 mission. A headspace was left in the growth ampoule to accommodate thermal expansion. There was an unanticipated 0.5 μg lateral acceleration from the venting on the Space Shuttle that had the fortuitous effect of nudging the melt against one wall of the growth ampoule and leaving the opposite side of the melt free of wall contact. The space-grown crystal was found to have a dislocation density $\sim 100\times$ lower than the control sample grown in the same furnace under normal gravity. The X-ray rocking curve at full-width half-maximum, (an indication of structural perfection) was reduced by a factor of 2.[32] Larson attributed these improvements in crystal quality due to lack of strain from the virtual absence of hydrostatic pressure and minimum wall contact and adhesion, resulting in very low stress being exerted on the crystal during growth and postsolidification cooling.

Larson repeated this experiment on USML-2 using a novel ampoule design that would minimize wall contact with the sample. A second sample had a spring-plunger system that forced the sample to fill the ampoule, thereby assuring wall contact. Postflight analysis confirmed the lack of strain effects seen previously and found that twin formation was virtually absent in the region grown without wall contact; whereas, the sample in the spring-loaded ampoule was highly strained at the exterior and heavily twinned.[33,34] This set of experiments dramatically showed how wall effects can influence defect formation in crystals grown from the melt.

A number of crystals were grown in microgravity using the floating zone process. The low Bond number (ratio of hydrostatic forces to capillary forces) allows much larger zones than are possible in normal gravity. Surface tension-drive convection (Marangoni flows) was found to produce time-dependent flows resulting in dopant striations.[35] It was found that coating the sample with thin oxide films could eliminate such flows[36] and silicon, gallium arsenide, and other compound semiconductors were grown with low dislocation densities.[37,38]

Solution Growth

Growth of small molecule crystals

Lal developed a novel method for growing crystals from aqueous solution by extracting heat through the crystal using a cooled sting.[39] This method was used on the International Microgravity Laboratory (IML) missions to grow triglycene sulfate (TGS), a pyroelectric material used for detection of far infrared radiation. A smooth transition from seed to new growth was seen without the veil of dislocations (''ghost of the seed'') that usually surround the seed crystal during growth on the ground. The TGS crystal grown on the IML-2 mission was examined with high resolution monochromatic synchrotron X-radiation diffraction imaging using the National Synchrotron Light source at the Brookhaven National Laboratory. The X-ray topographic images indicated an extraordinary crystal quality.[40] The only inclusions were due to the incorporation of polystyrene particles intentionally inserted in the growth solution to study the fluid motion in low-g. The detectivity (D^*) of the space-grown crystal was found to be significantly higher than the seed crystal, and the loss tangent was reduced from 0.12–0.18 for the seed to 0.007 for the space-grown material.[41]

Growth of biomolecular crystals

A large number of proteins and other biomolecular crystals have been grown in space. The first Shuttle flight after the Challenger accident (STS-26) yielded crystals of 4 different proteins that were shown to have better diffraction resolution than the best crystals of these proteins that had ever been grown on Earth.[42] This feat was even more remarkable, considering that the crystals produced in only a handful of space experiments were compared with the best crystals of these particular proteins that had been grown in

thousands of experiments by the world's most qualified researchers whose professional success depends heavily on obtaining the molecular structure from the X-ray diffraction data from such crystals. These results formed the impetus for the major effort in the growth of biomolecular crystals for structural analysis by X-ray crystallography that was sponsored by NASA and ESA.

Not all space-grown biomolecular crystals were superior to those grown on Earth, but there were a number of cases of larger crystals, improved diffraction resolution, and lower mosasicity to merit a serious study among theorists to investigate how gravity effects influence the perfection of such crystals.[43] When a crystal grows on Earth, the nutrient next to the growth interface is depleted and the less dense solvent rises, bringing more solute to the growth site. Since growth kinetics are slow for most biomolecular crystals, the convective flows always bring nutrient to the crystal faster than it can be incorporated into the lattice. Thus, the growth in normal gravity is generally kinetics limited. In space, the solute must diffuse in from the surrounding region, which greatly reduces the transport to the growing crystal. One of the arguments for why protein crystals grow better in microgravity is that diffusion-limited growth slows the rate

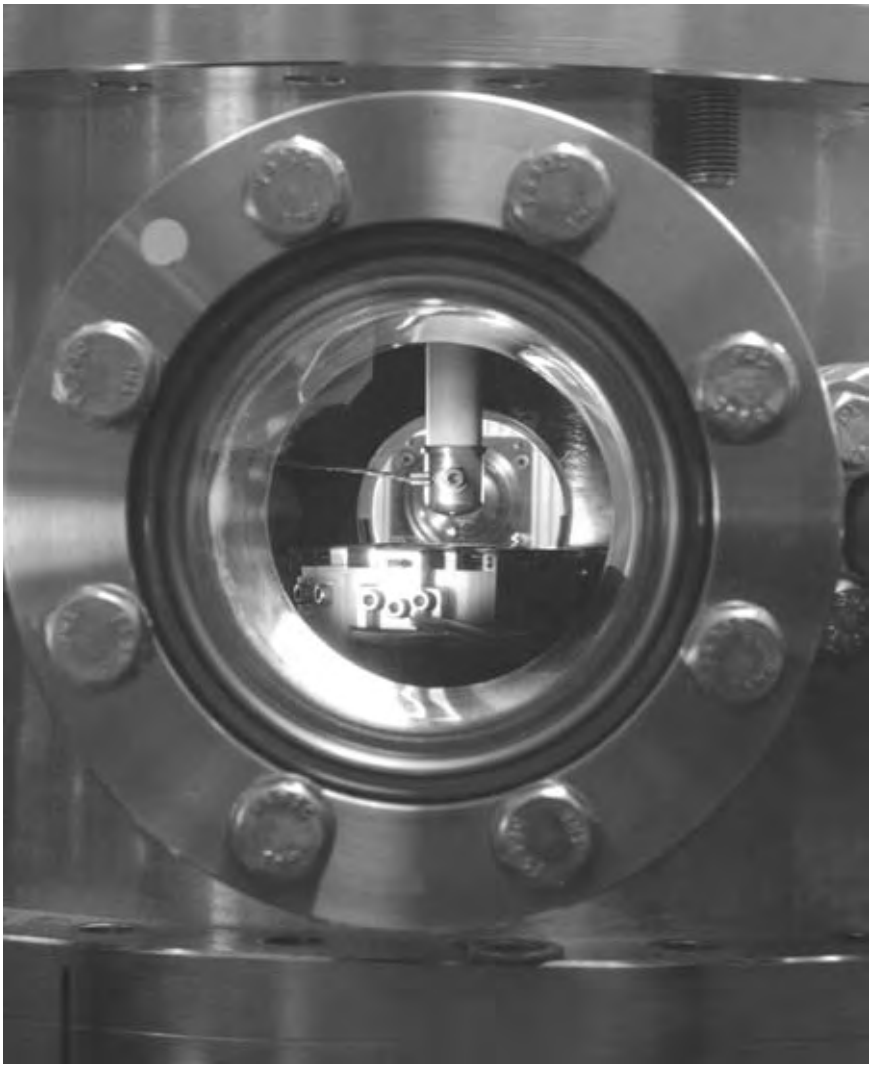

Fig. 2 A specimen levitated in the MSFC electrostatic levitator facility. A version of this device has recently been installed in the MUCAT sector of the beamline at the Advanced Photon Source for realtime studies of solidification of high temperature materials. Thermophysical properties measurements made on $Zr_{57}Nb_5Ni1_{2.6}Al_{10}Cu_{15.4}$ and $Ti_{34}Zr_{11}Al_{7.5}Cu_{47}Ni_8$ in the undercooled state helped William Johnson at Liquidmetal Technology design metal glass-forming systems with cooling rates slow enough to form in bulk quantities. Dr. Rick Weber, Containerless Processing, Inc., also used the MSFC electrostatic levitator to develop a new class of laser host glasses consisting of rare earth oxides and alumina. (Photo courtesy of NASA.) *(View this art in color at www.dekker.com.)*

at which nutrient is transported to the growing crystal so that growth becomes transport limited rather than kinetics limited. This gives surface kinetics a chance to go to equilibrium, allowing the admolecules to reach a configuration that minimizes the surface free energy and thus produce greater order in the lattice. Also, the diffusion field surrounding the growing crystal can act as a molecular weight filter that tends to exclude foreign impurities with higher molecular weights or oligomers of the growth molecules.[44]

APPLICATIONS

Space experiments have validated many of the theories and models that form the basis of our knowledge of alloy solidification and have begun to demonstrate the range of their applicability. Several lessons learned from materials experiments in space have been put to practice.

One of the more important ''real world'' problems has to do with attempts to dispersion harden superalloy single crystal gas turbine blades by incorporating very small (submicron) oxide particles during the growth process to increase their creep resistance. A uniform dispersion can be achieved by powder metallurgical techniques, which can then be densified by hot isostatic pressing (HIP). However, when the blade is melted so that it can be directionally solidified into a single crystal, the particles tend to agglomerate and are not uniformly incorporated into the superalloy matrix. The solidification velocities required to achieve plane front solidification are generally below the critical velocity for engulfment of such small particles. At higher solidification rates, the particles tend to be pushed laterally by the dendrites and wind up being clumped together, trapped in the last-to-freeze interdendritic fluid. This problem prompted several flight experiments by industrial firms trying to sort out gravitational effects from nongravitational effects that remain as barriers to developing this process.[45,46]

Much of the computational fluid dynamics modeling that was developed to analyze the effects of residual accelerations on solidification have been adopted along with magnetic damping to help control unwanted solute redistribution from convective flows in processes used on Earth. Researchers at NASA/MSFC picked up on the idea of using detached growth to minimize crystal defects. By carefully balancing the pressure in the growth ampoule against capillarity forces, they have been able to grow $Ge_{1-x}Si_x$ with minimal wall contact in the laboratory.[47]

Structural biologists, who must crystallize complex biomacromolecules to obtain structural information from X-ray diffraction, have learned to mimic growth in microgravity by growing such crystals in X-ray capillaries. Capillaries with inside diameters of 200–300 μm restrict flows to the same order of those in microgravity and crystals can be grown under diffusion-limited conditions.[48]

Given the realization that the few existing data on transport properties of liquid metals may be in serious error, care must be taken in using such data to design processes where these properties become critical and efforts must be made to refine the available data. The pioneering work that was done using the TEMPUS electromagnetic levitator on the 1997 Material Science Laboratory (MSL-1R) mission demonstrated the usefulness of being able to levitate a small sample quiescently. The desire to continue such experiments on the ground led to the development of the electrostatic levitator (ESL), now in operation at the NASA Marshall Space Flight Center (Fig. 2). The ESL is restricted to much smaller particles than can be levitated in microgravity and the types of data that can be extracted are somewhat limited, but data obtained from the ELS combined with the TEMPUS have been used to develop a new class of laser host glasses,[49] a commercial line of bulk metallic glasses, (Fig. 3)[50] and have provided new insight into the nucleation of metals from the melt.[51]

CONCLUSIONS

The rational behind some of the more significant materials processing experiments that have been carried out in space and their results have been presented along with a few key references that describe the experiments and their results in much more detail than could be presented here. The list of experiments and the publications that have resulted from them are by no means exhaustive. More detailed results from the U.S. experiments can be obtained from the Mission Science Review reports available from the Marshall Space Flight Center, Huntsville, AL. The European results are available in the EEA (Erasmus Experiment Archive) http://spaceflight.esa.int/eea/.

INTRODUCTION

Microreactors are chemical reactors with characteristic length scales ranging from the order of one to hundreds of micrometers. Such small length scales give microreactors many unique and potentially very useful properties. Fluid flow is nearly always laminar in microreactors, and timescales for heat and mass transfer become very short. Because smaller amounts of chemicals, typically on the order of microliters, are required for microreactors, hazardous and even explosive materials may be used at much less risk, opening up new reaction pathways. The small size of microreactors also makes them ideal for portable applications such as in micropower generation. The nature of microfabrication technology also is such that microreactors can be cheaply mass produced. Presently, microreactors are used mainly in research laboratories. However, projections suggest that the microreactors will soon be used in consumer products and in devices for medical laboratories.

WHAT ARE MICROREACTORS AND WHY ARE THEY USEFUL?

Microreactors are chemical reactors that are much smaller than typical industrial scale reactors, on the order of 1000 times smaller than the smallest reactors that were used for large-scale chemical production in the 1990s. Generally, they have a volume of $10\,cm^3$ or less and characteristic length scales on the order of 1 mm or less. Presently, microreactors are used mainly in research laboratories. However, projections suggest that the microreactors will soon be used in consumer products and in devices for medical laboratories.

Historically, the use of microreactors dates back to the 1940s when they were developed to measure kinetics of catalytic reactions.[1–5] One of the key early findings was Denbigh's 1965 observation that if a reactor were made small enough, temperature and concentration gradients with the reactor would be negligible, so that "differential" (i.e., gradientless) behavior would be observed.[6] This allowed much more accurate kinetic measurement to be made. Indeed, small differential reactors for research purposes are still sold today.

More recently, interest has been growing in the use of microreactors for consumer products, devices for medical laboratories, and for small-scale chemical production. For example, Fig. 1 shows a picture of Casio's proposed microreactor to power a laptop computer. This microreactor would produce hydrogen from methanol, then feed the hydrogen into a fuel cell to power the laptop.[7] The device is expected to have a lifetime 10 times that of lithium batteries. Another application for which microreactors have shown great promise is in amplification of DNA molecules by the polymerase chain reaction (PCR) method. The process requires three steps, each done at a different temperature, which are repeated to produce the desired amount of DNA. The speed of the process is generally limited by the speed of the thermal cycles. The rapid heat transfer that can be achieved in microreactors makes them ideal for this process, dramatically increasing the speed of the thermal cycles relative to conventional-scale devices. A schematic of a PCR device developed by Manz et al. is shown in Fig. 2.[8] These are just two of the many case studies demonstrating applications where microreactors, provide significant advantages of conventional systems.

To date, microreactors have not yet appeared in consumer products or for other large-scale uses. Thus, while microreactors have significant potential, it is unclear when, or if, that potential will be realized.

Generally, the main advantages of microreactors are

- Small size
- Rapid heat and mass transfer
- Ability to be mass produced

The size is critical to the use of microreactors in portable devices, such as many electronics goods. Microreactors could also be made small enough and be easy enough to mass produce so that they could be used in consumer products. Another advantage of the small size is that lesser amounts of chemicals must be used. This is highly desirable in dealing with chemicals that present significant environmental,

health, and/or safety risks or with materials that have a high cost or are difficult to obtain, as is the case with many biological materials or some pharmaceuticals, for example.[74,75] One particular application calls for the production and use on the spot of metastable compounds. For example, phosgene is an intermediate in the production of isocyanides, but it is very toxic. Jensen et al. found that they could make the phosgene in a microreactor and use it immediately in a subsequent reaction.[9] This approach avoids the need for large-scale storage and/or transport of phosgene, thus substantially increasing the safety of the process.

Another advantage of microreactors is that the heat and mass transfer rates are enhanced owing to short characteristic length scales. With regard to thermal management, this allows for more uniform heating throughout a reaction volume, more efficient heat removal, and better temperature control than is typically possible in macroscale systems. Heat transfer coefficients up to 25,000 $W/m^2/K$ have been reported in microreactors as compared to 2500 $W/m^2/K$ in conventional scale reactors. Extremely endothermic, exothermic, or even potentially explosive reactions can thus be safely and efficiently controlled in microreactors, opening up opportunities for new chemistries not feasible in conventional reactors. Short diffusion times allow for highly efficient mixing even under the laminar flow conditions that are characteristic of most microreactors.

High surface area to volume ratios are another distinctive feature of microscale reaction systems. Interfacial areas per unit volume in falling film microreactors have been reported to be as high as 25000 m^2/m^3. By comparison, interfacial areas in bubble columns are typically of the order of 1–200 m^2/m^3. As a consequence, surface effects that are often neglected in the macroscale become dominant. This makes a tremendous difference in gas–liquid reactions, where mass transfer from the gas to the liquid often limits the rate.

Microfabrication technology used to manufacture microreactors also introduces many advantages, most notably the ability to rapidly and cheaply mass-produce devices. The low cost of microfabricated devices makes it possible for these devices to be disposable, a characteristic desirable for many medical applications. Rapid scale-up of production by operating many microreactors in parallel can also be accomplished. Microfabrication also presents the opportunity for complete systems in a single monolithic device or systems on a chip as microreactors are incorporated with chemical sensors and analysis devices, microseparation systems, microfluidic components, and/or microelectronics.

CHARACTERISTICS OF MICROREACTORS

Scale

In discussing microreaction systems, it is helpful to first distinguish the characteristic size of a microreactor in comparison with conventional scale reactors. Two different definitions of the term microreactor are commonly used in the literature. The first defines any reactor that is an order of magnitude or more smaller than its conventional scale counterpart as a microreactor. For example, an industrial reforming reactor might be 10,000–100,000 L in volume. Using this first definition, a 1 L reforming reactor could be considered a microreactor. This definition is not very useful as it includes reactors of virtually any scale. A second, more precise and useful definition is that a microreactor is a reaction system with microscale characteristic length scales, on the order of 1–100 μm, or at most on the order of millimeters. This length scale typically refers not to the system as a whole, but rather to the length scale of the reaction vessel or fluid flow channels, or to the volume scale of materials handled by the microreaction system.[10] The volumes of reactants and products dealt with are typically on the order of microliters or less. We will adopt the latter definition here and call a microreactor, any reactor where the critical dimensions for fluid flow are about a millimeter or less. This definition is more useful than the first as transport processes are quite different at these critical device dimensions. Generally, the flow is laminar, heat and mass transfer is rapid, and wall interactions become more important when device sizes are millimeters or less. Thus, millimeter and microscale devices are fundamentally different from devices with a larger scale.

Fluid Mechanics in Microreactors

The small characteristic length scales found in microreactors significantly affect flow behavior in these systems and, consequently, their design and performance. In the section that follows, we will give an overview of some of the important characteristics of fluid mechanics at the microscale. The reader is referred to one of the many texts or review articles on microfluidics for a more thorough discussion of the topic.[10–14,73]

Flow regime

As a general rule, continuum mechanical descriptions of fluid flow still apply in devices with microscale critical dimensions.[10] Also, owing to the small characteristic length scales involved, the Reynolds number ($Re = uL/v$, where u is the characteristic flow velocity, L is the characteristic length scale, and v is the kinematic viscosity of the fluid) is very small, in the order of 10 or less, resulting in laminar flow.[10] Exceptions to both of these general rules, though not commonly encountered, can and do occur. For example, continuum mechanics do not apply to very diffuse gas flows where the mean free path becomes large when compared to the characteristic length scale for the flow ($Kn > 10^{-1}$, where Kn is the Knudsen number) or for very high shear rates in liquid flows. For length scales at the higher end of the microrange (on the order of hundreds of micrometers to millimeters), especially for very high flow rates, turbulent flow can be achieved.[10]

Fig. 3 illustrates the flow of two streams of dye inserted into a microfluidic channel.[15] Note that the

Fig. 3 Illustration of laminar flow in a microfluidic channel. (From Ref.[15].) *(View this art in color at www.dekker.com.)*

two dyes stay on their own side of the channel as mixing occurs only due to diffusion. Such a flow pattern is characteristic of laminar flow, and significantly impacts the design of microreactors when mixing of two or more materials is required, as discussed in the section on ''Mixing.''

Gas flows

Gas flows in microreactors are well described using the kinetic theory of gases. Two dimensionless groups of particular interest for gas flows are the Mach number and the Knudsen number. The Mach number, $Ma = u/c_s$, where u is the characteristic velocity of the flow and c_s is the speed of sound, gives a measure of the compressibility of the flow. If $Ma < 0.3$, which is common in microscale systems, the flow is considered to be incompressible. Exceptions to this condition occur when the walls of the system are heated leading to large changes in the density of the gas or when self-heating of the gas occurs due to viscous dissipation as might happen in very long, thin channels.[10] The Knudsen number provides a measure of how rarified the flow is. As previously mentioned, at high Kn ($Kn > 0.1$), continuum mechanics break down as the flow transitions into the free molecular regime. For smaller Knudsen numbers, as typically observed in microscale systems, the magnitude of the Kn determines the boundary conditions applied to the Navier–Stokes equations. For $Kn < 10^{-3}$, a no-slip boundary condition applies, while for $10^{-3} < Kn < 10^{-1}$, a slip boundary condition applies.[10]

Liquid flows

Liquid flow behavior is far more complex and not nearly as well understood as gas flow, especially in microscale. Generally, when the dimensions of a flow channel are 10 μm or more, the fluid behavior is simple and laminar. However, as the channel dimensions shrink below 1 μm new processes start to occur.[10] The presence of the wall can affect the phase behavior of the fluid causing colloidal behavior. Numerous and thus far unexplained deviations from classical laminar flow behavior have been observed. At very high strain rates, deviations from Newtonian behavior are observed in fluids that are Newtonian in macroscale systems.[16] Liquid viscosities have been observed to increase, decrease, and remain constant in microfluidic devices as compared to viscosities in larger systems.[10] Deviations from the no-slip boundary condition have been observed to occur at high shear rates.[17] One important deviation from no-slip conditions occurs at moving contact lines, such as when capillary forces pull a liquid into a hydrophilic channel. The point at which the gas, liquid, and solid phases move along the channel wall is in violation of the no-slip boundary condition. Ho and Tai review discrepancies between classical Stokes flow theory and observations of flow in microchannels.[11] No adequate theory is yet available to explain these deviations from classical behavior.[18]

Two-phase flow

Two-phase flow can also be utilized in microreactors. Fig. 4 shows a flow map for two-phase flow on the microscale.[19] Note that two phase flow is much simpler in a microreactor than is typical in a macroscale reactor. Only two-flow regimes are important: slug flow and annular-dry flow; complex turbulent conditions have not been observed. At low gas and liquid flow rates, the flow regime is slug–annular, in which small slugs of gas are present in the centers of the channels. With increasing gas flow, the flow regime changes to annular, in which the gas pockets become continuous streams in the centers of the channels, while the liquid streams are confined to the edges. At high liquid flow rates, dispersed flow is attained.

Mass Transport

Reduced length scales also have a major impact on mass transfer in microreactors. The timescale for diffusion, τ, scales as the square of the length scale and can be expressed as $\tau = L^2/D$ where L is the characteristic length and D the diffusion coefficient. Typical diffusion coefficients are 10^0–10^{-2} cm^2/sec in gases and 10^{-4} to 10^{-6} cm^2/sec in liquids. As length scales decrease in microreaction systems, very short timescales for diffusion can be achieved leading to substantially enhanced mass transfer rates. This has particular importance with regard to mixing in microreactors. Mixing can be crucial to reactor performance, and is

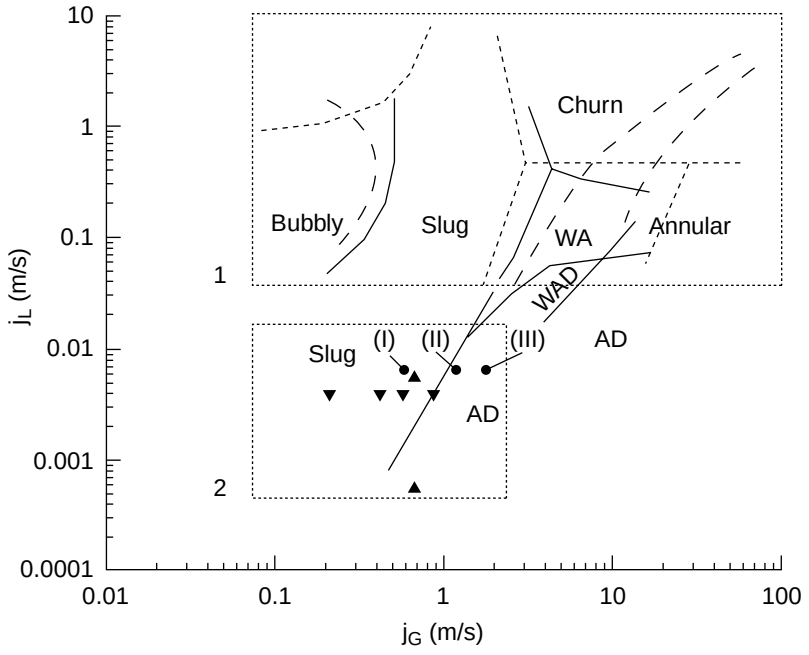

Fig. 4 Gas–liquid flow regime map in microchannels. Flow regimes are annular, churn, wavy annular (WA), wavy annular-dry (WAD), slug, bubbly, and annular-dry (AD) flows. (From Ref.[19].)

often the limiting factor in determining conversion. In conventional macroscale systems, mixing is usually achieved by the introduction of turbulence to the system. Because flow in microchemical systems is nearly always laminar, microscale mixing technologies must rely on the diffusion to achieve mixing. The typical approach taken in mixing in microreactors and other microfluidic systems is to reduce the diffusion length scale. Various micromixer designs will be discussed in the section on ''Mixing.''

Significant mass transfer advantages can be achieved in two-phase flows in microreactors.[20] Slug–annular flows provide contact areas of $\sim 1500\,m^2/m^3$ while dispersed flows provide contact areas of $\sim 16{,}000\,m^2/m^3$ in microreactors.[20] By way of comparison, bubble tower contact areas are ~ 1–$200\,m^2/m^3$. Thus, there is much more area for mass transfer in a two-phase microreactor than in a bubble column, or other two-phase mixer in addition to having a shorter characteristic length for diffusion. This effect is particularly important in gas–liquid reactions where the rate of mass transfer from the gas to the liquid limits the reaction rate. For the hydrogenation of cyclohexene to cyclohexane in this type of reactor, the mass transfer rate constant, $K_L a$, was found to be in the range 3–7 sec^{-1}, which is two orders of magnitude higher than that of conventional reactors.[20]

Despite the small dimensions, conventional models for dispersion have been applied to microreactors. Since flow is laminar, a Taylor–Aris or shear-induced dispersion model generally describes dispersion.[21–25] Beard has applied the Taylor–Aris dispersion model to correlate diffusion rates in a T-sensor with rectangular microchannels.[23–25]

Beard's derivation was for a rectangular channel of height W (y dimension) much less than the width S (x dimension), flow in the z direction, and a nonreactive solute of concentration c. The z component of laminar fluid velocity is approximated to be parabolic and is given by

$$\nu_z(y) = \frac{6\overline{V}}{W^2}\left(y^2 - Wy\right)$$

where $\overline{V}$ is the mean velocity. Owing to the high aspect ratio of the channel, variations of velocity in the x direction were neglected. The two dimensional advection–diffusion equation derived by Beard is given by

$$\frac{\partial c}{\partial t} = D_0\frac{\partial^2 c}{\partial x^2} + \left(D_0 + \frac{33}{560}\frac{\overline{V}^2 W^2}{D_0}\right)\frac{\partial^2 c}{\partial z^2} - \overline{V}\frac{\partial c}{\partial z}$$

where D_0 is the molecular diffusion coefficient, and the effective dispersion coefficient is given by

$$\widetilde{D} = \frac{33}{560}\frac{\overline{V}^2 W^2}{D_0}$$

Ghosal has also examined electrophoretic flow in microchannels using a Taylor–Aris dispersion model.[26] In both of the above cases Taylor–Aris models were reported to work well. On the other hand,[67] Ni, Seebauer and Masel found that at high flow rates over

porous reactor surface the Taylor–Aris model did not work as well, presumably because the wall roughness induced secondary flows.

Heat Transfer

Analogous to the enhancement of diffusion in microreactors is the enhancement of heat transfer at small length scales and high relative surface areas. Heat transfer coefficients as high as $25{,}000\,W/m^2/K$ have been reported in micro heat exchangers. This compares to $2500\,W/m^2/K$ in a conventional scale heat exchanger. Surface areas per unit volume are typically on the order of $10{,}000\,m^2/m^3$ in microheat exchangers, compared to $1–500\,m^2/m^3$ in conventional scale reactors. The net effect is that heat transfer is much more rapid on the microscale than on the conventional scale. Heat generated in a microreactor can be rapidly dispersed. The small scale also makes it much easier to control reaction temperatures uniformly throughout the reaction volume using external heating or cooling systems. As a result, microreactors are very attractive for both highly exothermic and highly endothermic reactions, where hot or cold spots can create problems, such as thermal quenching, thermal activation of undesired side reactions, or explosions.

Convective heat loss to the environment can be much more significant in microreactors than in conventional systems because of their high surface to volume ratios. A consequence of this is that insulation generally enhances heat loss rather than mitigating it. The critical radius of a tube below which the use of an outer insulation layer will increase heat losses is given by the ratio of the thermal conductivity of the insulation layer (k) and the heat transfer coefficient at the interface between the insulation and the ambient (h_0), $r_{critical} = k/h_0$. For most commonly used materials and ambient air, this critical radius is on the order of 1 mm.[27]

There are several examples where rapid heat transfer in microreactors has been utilized to perform highly exothermic reactions that would not be viable in conventional reactors. Localized hot spots occurring in conventional reactors to directly fluorinate aromatics can lead to undesired side reactions, including the formation of fluorine radicals and nonselective free-radical side reactions. Jenson et al. have run direct fluorination reactions of aromatics in microreactors, taking advantage of the rapid heat transport in the microreaction system to operate under very aggressive reaction conditions (up to 10 vol.% fluorine).[19] Highly exothermic nitration reactions of aromatics have also been widely studied in microreactors.[28,29] At high temperatures, hydrogen cyanide can hydrolyze to ammonia. Hessel et al. were able to produce hydrogen cyanide isothermally in a microreactor via the Andrussow route and avoid this undesired side reaction.[30] Another example is the production of the antibiotic ciprofloxacin which requires a complex 20–30-step synthesis to avoid explosions in conventional reactors. CPC Systems have recently patented a synthesis process utilizing a microreactor to produce ciprofloxacin via a five-step synthesis, where the first step is a highly exothermic and potentially explosive cycloaddition.[31]

Surface Reactions

As length scales are reduced, the surface area to volume ratio increases dramatically. For example, consider a cylinder of 1 cm in length. For a radius of 1 cm, the surface area to volume ratio is $2\,cm^{-1}$. For a radius of 100 μm, the surface area to volume ratio is $200\,cm^{-1}$. This high surface area to volume ratio inherent in microscale systems has many consequences. Among these are the increased importance of surface reactions and surface tension.

The relatively high surface of microreactors can be taken advantage of to enhance surface-catalyzed reactions. For example, Langer et al. have utilized reactive polymer coatings in microreactors to produce various biomolecules and to perform bioassays, as illustrated in Fig. 5.[32,33] The addition of monoliths or posts to the microreactor design can be utilized to further increase surface area for catalytic reactions. Sadykov et al. report the use of Pt-based catalyst wash coated onto monolithic supports in a microreactor for the selective production of propylene by propane oxidative dehydrogenation.[34] As shown in Fig. 6, Masel et al. utilize alumina surfaces that have been anodized to further enhance surface areas of catalytic supports in microreactors allowing very high conversions and production rates to be achieved in the reforming of ammonia to hydrogen.[35,36]

Surface Tension

Surface tension forces are proportional to the contact area between two immiscible phases and decrease linearly with the length scale. Other forces, however, tend to decrease with higher powers of the length scale. For example, inertial forces decrease proportionally to the cube of the length scale. Consequently, the relative importance of surface tension is magnified at small length scales. One result of surface tension is that it can be extremely difficult to force liquids into channels made of materials not wetted by that liquid. Similarly, it can be a challenge to get liquids out of small channels that are wetted by the liquid. While surface tension can create some engineering difficulties in microreactors, it can also be harnessed. In continuous-flow systems, the use of capillaries is an effective way

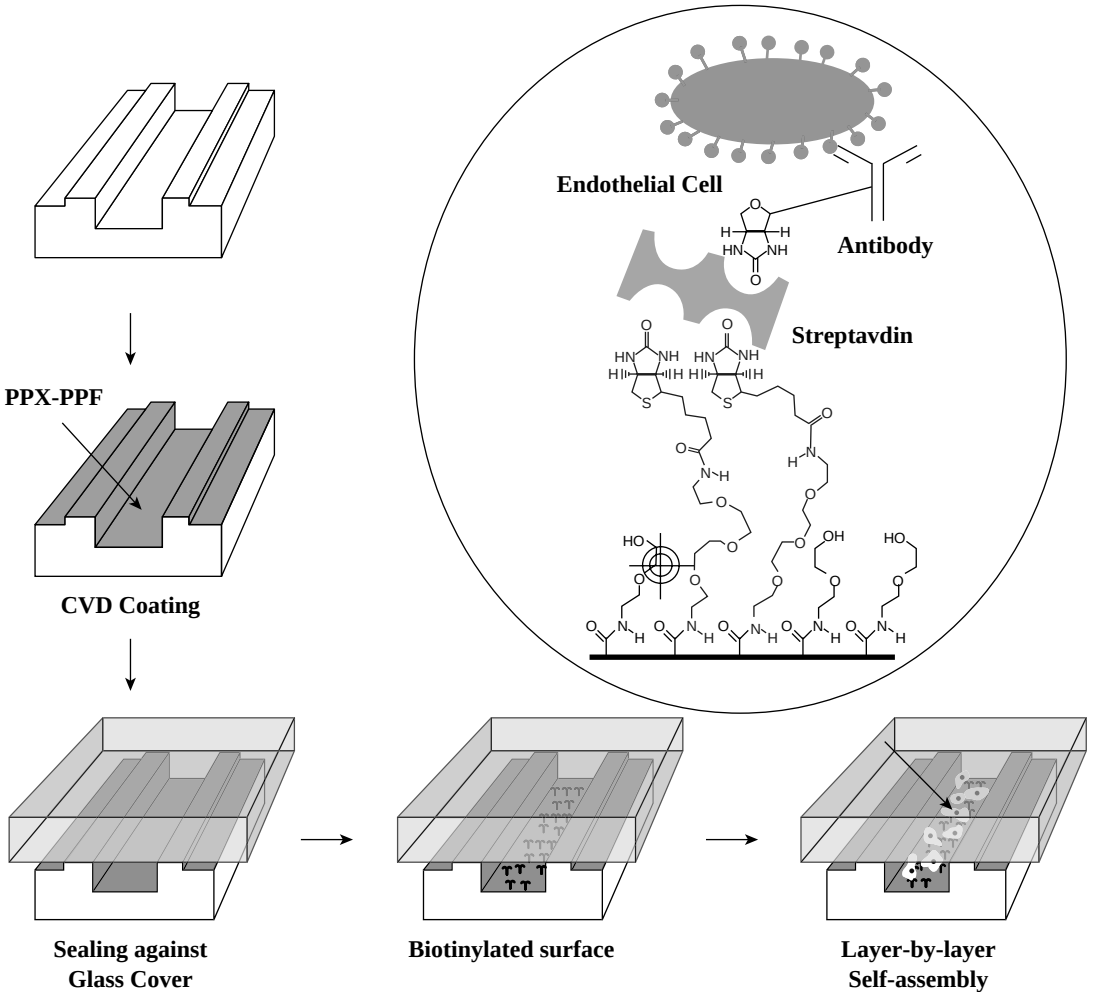

Fig. 5 Schematic representation of the surface modification steps used by Langer et al. to produce a biologically active surface in a microreactor. Biotin-labeled human anti-α_5-integrin (HAI) was bound to modified PDMS and used to study cell surface receptor activity. (From Ref.[33].) *(View this art in color at www.dekker.com.)*

of separating liquids from gases.[37] By controlling surface tension gradients, movement and mixing of liquid droplets can be achieved without the use of pumps and valves. Several approaches have been used to control surface tension gradients, including electrowetting or electrocapillarity, thermocapillarity, electrochemical processes, and light.[38–41]

Short Residence Time

Another consequence of the small length scales in microreactors is that very short residence times are commonly achieved creating engineering challenges to be overcome or major advantages depending on the application. If the residence time approaches the kinetic reaction timescale, conversions can become unacceptably low necessitating device designs that maximize residence times or enhance reaction rates. For example, in microcombustion systems, the kinetic reaction timescale is of the order of 0.01–0.1 msec for hydrocarbon–air reactions. In this case, the short residence time can lead to unacceptably low conversions. One obvious approach to overcoming this problem is to increase the reactor size and, consequently, the residence time. Other approaches to enhancing conversion such as premixing of the reactants, incorporation of catalytic materials into the reactor, or external heating of the reactor can be used to mitigate the problems posed by the short residence times and allow device size to remain small.[42,43] Short residence times achievable in microreactors can in some case be an advantage rather than a problem. For example, unstable or metastable intermediates can be produced and transferred quickly to a subsequent process.[10] Similarly, hazardous materials can be produced at the point of use.

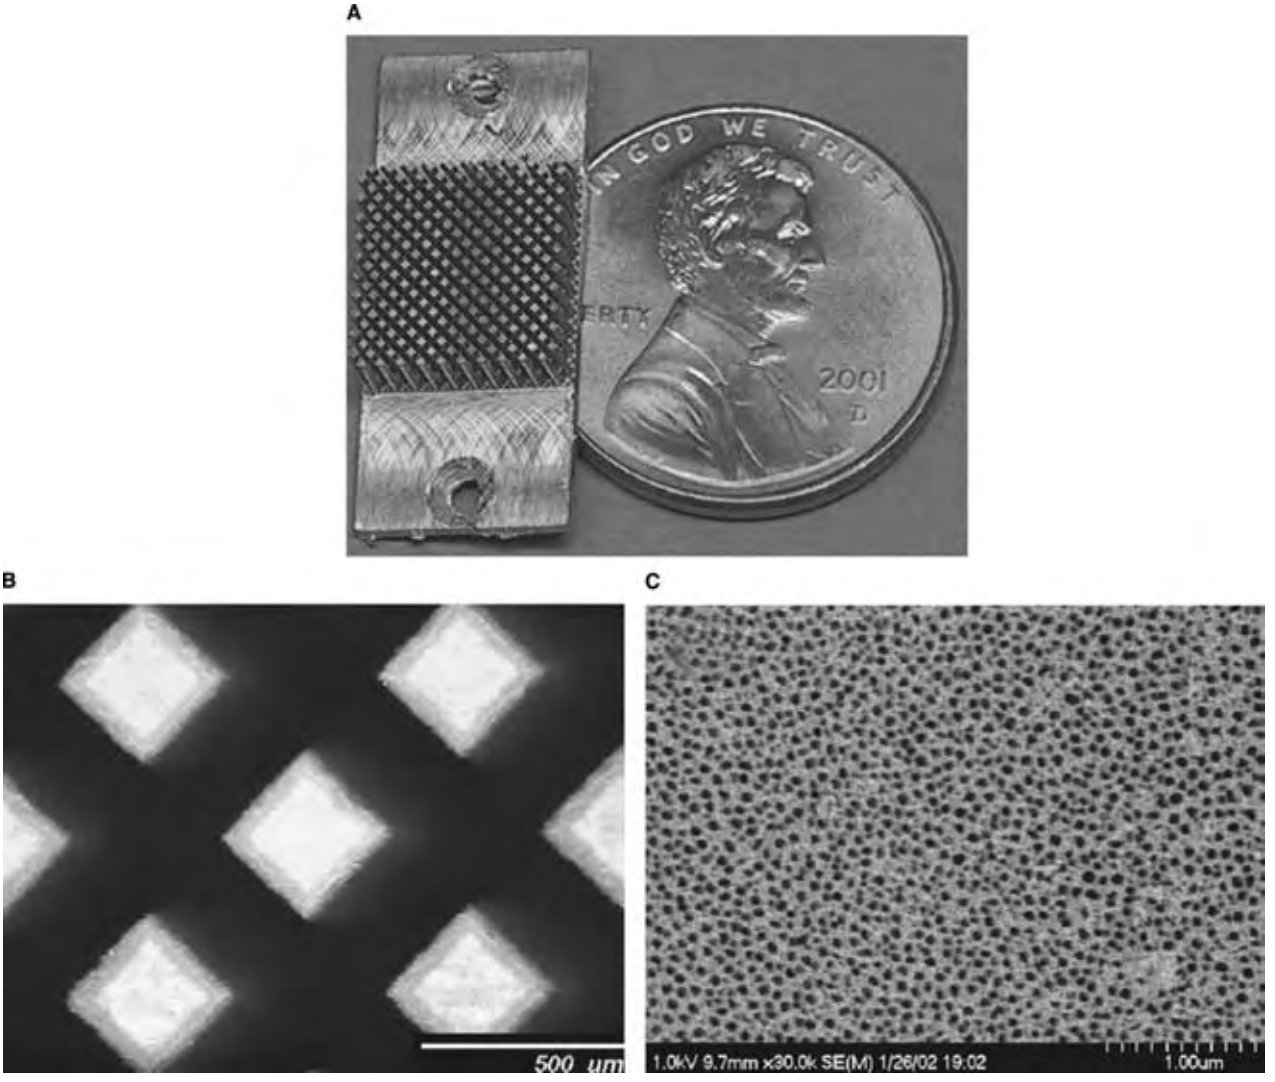

Fig. 6 (A) Anodized alumina, posted microreactor used for reforming of ammonia to hydrogen. (B) Optical microscope image of the microreactor posts. (C) Scanning electron microscopy image of a microreactor postsurface illustrating the porosity of the anodized surface. *(View this art in color at www.dekker.com.)*

This generates opportunities to use new reaction pathways not feasible in conventional macroscale reactors. For example, Sadykov et al.[34] utilize rapid thermal quenching in conjunction with short residence times in a microreactor to suppress undesired side reactions in propylene production by the oxidative dehydrogenation of propane.

PRINCIPLES OF MICROREACTION ENGINEERING

Design of Microreactors

Fluid movement

For fluid movement to occur, there must be a driving force for that movement. In many cases, flow in the microreactor system is driven by external, macroscale pumps, flow controllers, etc. Often, however, it is desirable to control fluid flow within the microscale system. A wide array of designs for micromechanical pumps and valves have been described in the microfluidics literature for just that purpose.[10]

In addition to conventional pressure driven flow, electrokinetic flow is also a commonly used means of transporting liquids in microfluidic devices. One type of electrokinetic flow, electroosmotic flow, relies on the presence of an electrical double layer at the solid–liquid interface. A negatively charged surface in a flow channel will attract cationic species from the fluid to form an electrical double layer at the surface. Application of an external voltage can pull those cationic species through the flow channel inducing bulk flow. The electroosmotic flow velocity can be described

by the Helmholtz–Smoluchowski equation:

$$u_{EOF} = \mu_{EOF}E = \frac{\varepsilon\zeta E}{\eta}$$

where u_{EOF} is the electroosmotic flow velocity, μ_{EOF} is the electrophoretic mobility, E is the electric field strength, ε is the dielectric constant of the fluid, and ζ is the zeta potential of the flow channel wall.[10] Velocity profiles in electroosmotic flow tend to be very flat. Significant flow velocities, as high as 5 cm/min, can be achieved with electroosmotic flow.[10]

Mixing

In conventional reactors and fluid systems, mixing is typically achieved by introducing eddies to the system. Eddies can be created in the wake of a ball moving through the fluid, by introducing fluid to the reactor through a jet, with a stirrer, or with any of a number of other approaches. These approaches are not viable in the microscale because of the large fluid volumes required and the fact that Reynolds numbers in the microscale are so low. Micromixer designs seek to enhance diffusional mixing by decreasing the characteristic diffusion length. In addition to achieving fast mixing times, it is also desirable to minimize the device area of the micromixer and to design it such that it can be integrated easily into the larger microchemical system. Several designs for microscale mixers have been developed, which can be divided into two classes, passive and active. They will be briefly described in the next two sections. More extensive discussion of micromixer design are given in the Refs.[10,44,68–72].

Passive Mixing. Passive or static mixing technologies are typically simple in that they involve no moving parts. Probably, the most common types of micromixing devices are lamination micromixers, of which there are two main types, parallel and sequential. In parallel micromixers, inlet streams are split into substreams, which are then joined into a mixed stream as laminae, in the simplest case, two fluids to be mixed are joined in a ''T'' or ''Y'' pattern. An example of a ''T'' micromixer is shown in Fig. 7. Splitting into multiple fluid streams can further enhance mixing. Another approach to enhanced mixing is to introduce a throttle design by reducing the size of the inlet, illustrated in a ''Y'' mixer in Fig. 8.[10,45] This reduces the timescale for diffusion at the throttled inlet. Johnson, Ross, and Locascio reported enhanced mixing when small wells were etched into the combined flow channel just past the confluence of two streams in a T mixer.[46] Another strategy used to enhance mixing in lamination micromixers is sequential switching. The flows of the fluids are alternately turned on and off. Sequential lamination micromixers, illustrated in Fig. 9, provide more rapid mixing by resplitting and then recombining the mixed fluid streams several times in sequence. One downside to these micromixers is that a more complicated structure is required. Injection or microplume mixers operate in a similar manner. In these micromixers, one fluid stream is split into many, which are then injected into a second fluid stream. By increasing the contact surface between the two fluids, the mixing path and therefore the mixing time is decreased. Application of these mixing technologies can be used for single-phase or multiphase mixing.

Another mixing strategy involves utilizing posts within a reaction chamber in a checkerboard pattern, as shown in Fig. 6.[47] In such an arrangement, characteristic diffusion lengths are decreased in the areas between the posts and between the post and the wall.[47] When this strategy is employed, the posts are commonly used as catalyst supports. The posts mix the streams further and provide a high surface area for gas–liquid contacting, while also having a lower pressure drop than a packed-bed reactor with a

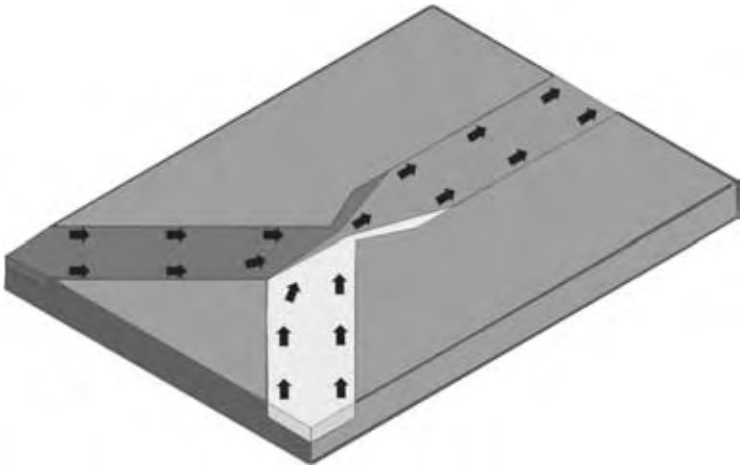

Fig. 8 A "Y" micromixer with throttling at the confluence of the impinging streams to enhance mixing. *(View this art in color at www.dekker.com.)*

comparable catalyst surface area. The uniformity of arrangement also allows for precise control of flow characteristics and minimization of channeling.

Active Mixing. Because they employ moving parts, active micromixers are inherently more complicated than their passive counterparts. Active or dynamic mixing technologies utilize actuators to agitate a fluid and thus cause mixing. A variety of different types of actuators have been employed to induce fluid mixing. Ultrasonic mixers, for example, utilize acoustic actuators.[48,49] Micromechanical pumps have also been utilized to drive fluid into a mixing chamber from the opposite direction in chaotic advection mixers.[50,51] Other active mixing technologies include magneto hydrodynamic and electrokinetic micromixers.[52,53]

Thermal management

One of the chief advantages of microreactors is the rapid heat transfer achievable at such small length scales. Consequently, microreactors are used in many applications where thermal management is critical. Many approaches for thermal management have been used in conjunction with microreactors. One widely examined method is the use of microheat exchangers. In design, microheat exchangers resemble their conventional counterparts. As in conventional heat exchangers, the thermal conductivity of the heat transfer fluid and the heat exchanger material as well as the flow configuration (cross-flow, countercurrent flow, etc.) are important design parameters.[54] Decreased length scales magnify the importance of material selection in microheat exchangers, as axial heat conduction in the walls of the heat exchanger is enhanced.[54–56] Contrary to intuition, materials with high heat conductivities reduce heat transfer efficiency when axial heat conduction becomes important. As thermal conductivities approach zero, the insulating effect of the material reduces heat transfer efficiency. Optimal heat conductivities are of the same order of magnitude as glass and other ceramics.[55]

Another approach to thermal management is ohmic heating.[57] This can be done by incorporating

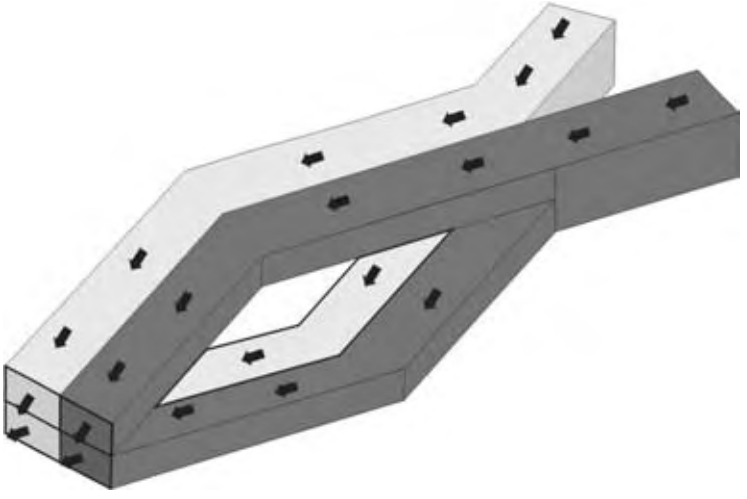

Fig. 9 A sequential lamination micromixer. *(View this art in color at www.dekker.com.)*

opposing electrodes to resistively dissipate electrical power as heat through a conductive medium.[57] Incorporation of a simple resistor into the reactor design can also be used.[27]

For high-temperature systems, radiative heat loss can be very significant. In conventional systems, reflective shields or radiation mirrors and low-emissivity material are commonly used to mitigate radiative heat loss. It is expected that similar approaches would be effective in microreactors as well.[27]

Fired heaters are often used to generate high temperatures in large-scale reactors. However, combustion is much more difficult on the microscale than on the conventional scale. Under normal conditions, flames will not propagate in small, confined spaces. The two dominant mechanisms of flame quenching, thermal and radical quenching, are surface phenomena, which are magnified in small devices. Flame arrestors employ a wire mesh to capture free radicals to terminate combustion reactions and quench flames, taking advantage of the high surface area and small gaps in the mesh. Masel et al. have demonstrated microburners with stable flames in combustion channels as small as 100 μm as illustrated in Fig. 10.

There are two primary challenges in fabricating microburners, surface free-radical quenching of the combustion reaction and thermal quenching due to the rapid heat transfer that occurs in small devices. Radical quenching is a heterogenous kinetic process whereby highly reactive radical intermediates undergo termination reactions at the wall. The removal of these radicals, crucial to the propagation of homogenous catalytic cycles in the combustion mechanism, quenches the flame. In microburners, thermal quenching of confined flames occurs when heat generated by the combustion process fails to keep pace with the heat loss to the walls. The walls effectively act as an enthalpy sink for the homogenous-combustion zone, lowering the near-wall temperature and retarding the kinetic mechanisms, further reducing heat generation and leading to flame extinction. Thermal quenching is less dominant when the surfaces are at higher temperatures but does act to reduce the reaction rates of the homogenous reactions. Both quenching mechanisms act to reduce the reaction rates of the homogenous reactions. To overcome both thermal and radical quenching, materials of construction with low thermal conductivities and relatively inert surfaces are generally chosen. This usually restricts material choices to insulative oxides, such as silicon dioxide and alumina. Thermal management schemes, such as the use of excess enthalpy (via a Swiss roll burner design) and cutting edge aerogel insulation, are also employed to maintain high device temperatures. While the ionic surface electronic structure of ideal insulating oxides

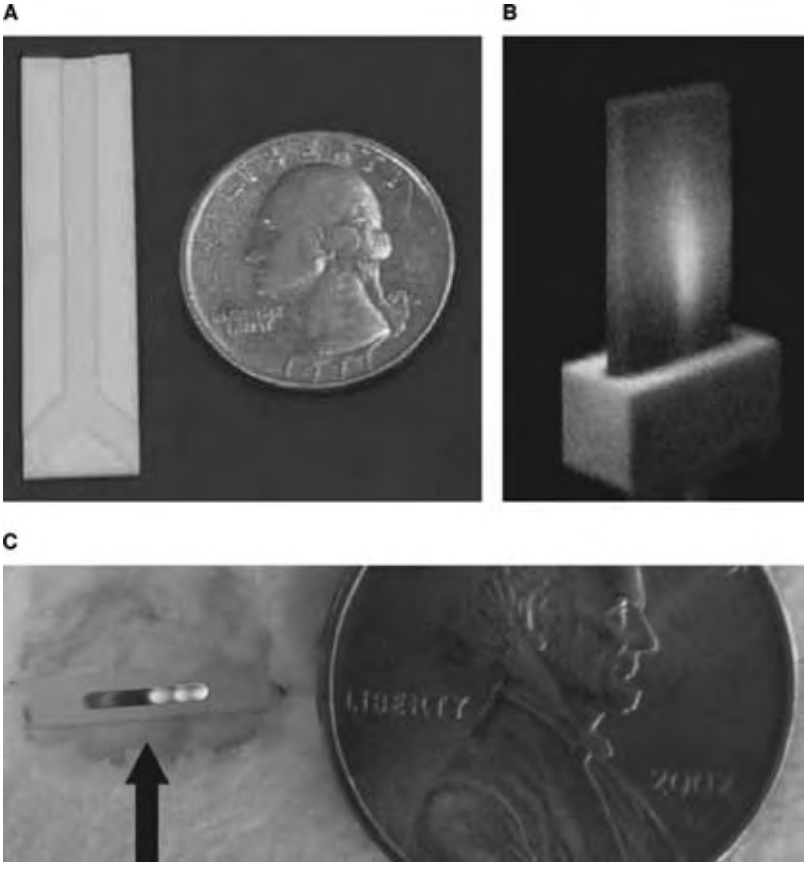

Fig. 10 Illustration of a microburner developed by Masel et al.: (A) cross section of alumina burner; (B) microburner operation; and (C) flame cells observed from top of microreactor. *(View this art in color at www.dekker.com.)*

generally renders them inert to heterogenous reactions, defects, impurities, and grain boundaries are present in reality. These surface features are active sites for radical quenching via radical recombination. Surface preparation to reduce the reactivity of the oxide surfaces, such as chemical cleaning and etching and thermal annealing, can be performed to reduce the occurrences and effects of these surface features. Another technique used to maintain high-temperature walls and to prevent radical quenching is using catalytic materials of construction, such as platinum. The heterogenous combustion, although not as reactive and exothermic as homogenous combustion can stabilize small gap combustion processes.

CASE STUDIES

Microreactors have been applied to many diverse applications and will doubtless be applied to many new reaction engineering problems in the future. Below are some specific examples of the uses of microreactors that illustrate some of the advantages of these systems. The applications described below clearly indicate the broad array of reaction engineering problems to which microreactors can be applied.

Hydrogen Production for Portable Electronics

One application of microreactors that is likely to appear in commercial devices soon is in the generation of hydrogen for portable-power generation. The power needs of portable electronic devices increase every year. Advances in battery technology have not kept pace with the growing needs. Thus, a power gap is developing, where portable devices can be built, but are not powered. One alternative is to use a fuel cell to generate the power. There are several designs including a direct fuel cell, and indirect fuel cell systems, where a hydrocarbon fuel is first reformed to form hydrogen, then the hydrogen is oxidized in a fuel cell to produce electricity. Such a design has been proposed by Casio to power laptop computers, as shown in Fig. 1. In response to this, many research efforts have focused on the use of microreactors to reform other fuels into hydrogen for use in microfuel cells. The small size and weight of microreactors makes them ideal for this application where portability is critical.

Masel et al. describe the synthesis and properties of a ruthenium-impregnated anodic aluminum catalyst in microreactors for the production of hydrogen from an ammonia feed, as illustrated in Fig. 6.[35,36] The catalyst structure was synthesized using microelectric discharge machining to create a series of posts on an aluminum substrate.[35,36]

The posts were anodized to yield a 60 μm covering of anodic alumina with an average surface area of $16\,m^2/g$ and an average pore size of 50 nm.[35,36] Ruthenium metal was dispersed on the alumina using conventional wet impregnation.[35,36] The enhanced surface area for the microreactor allows very high conversions and hydrogen production rates to be achieved relative to the reactor size.[35,36] A $0.9\,cm \times 0.9\,cm$ reactor containing 250 posts decomposed anhydrous ammonia at 650°C to yield 10 sccm of hydrogen at 95% conversion, while a similar channel design produced 200 sccm of hydrogen in one volume less than $1\,cm^3$.[35,36] A somewhat different approach is reported by Jensen et al. utilizing two suspended, thin-walled

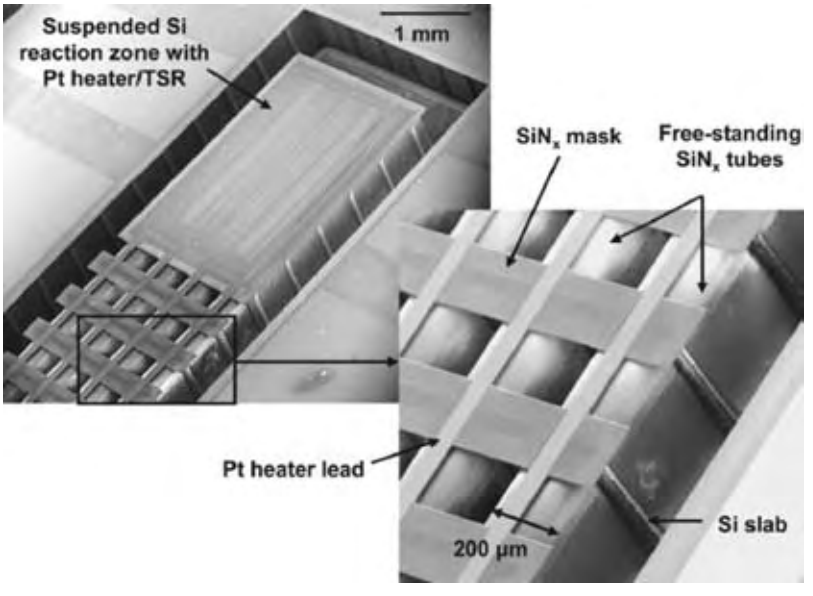

Fig. 11 Scanning electron microscopy photos of microreactor produced by Jensen et al. for reforming of ammonia showing four free-standing SiN_x tubes, a suspended Si reaction zone with integrated thin-film platinum heater and temperature sensing resistor (TSR), and Si slabs wrapped around the four tubes. (From Ref.[27].)

(2 μm) silicon nitride tubes in a ''U'' shape, as illustrated in Fig. 11.[27] The inlet and outlet ends of the U-shaped tubes are-fixed in a silicon substrate, while the remainder of the tube is kept floating to help thermally isolate it from the rest of the system and the floating end of the tubes are encased in silicon to enhance heat transfer between the tubes. The U shape allows flexibility for thermal expansion. Wash-coating was utilized to coat the channels with catalyst. Butane combustion was performed in one of the two tubes. Heat produced from this reaction was utilized to enhance ammonia reforming in the second tube. Yet another approach is described by Holladay et al. and is shown in Fig. 12.[58,59,76]A proprietary catalyst on a monolithic support was utilized to perform steam microreforming in an integrated system that included an external combustion heater, fuel vaporizer/preheater, reheater, heat exchanger, and CO filtering unit.[58,59]

Polymerase Chain Reaction

The PCR is another case with a huge potential market. The PCR method is commonly used to create copies of specific fragments of DNA. First, the individual strands of DNA are unwound and separated by heating to 90–96°C. Then, the DNA is cooled to 50–60°C so that primers can bind to the DNA. The primers allow the duplication process to start at a specific point on the DNA. Finally, the temperature is raised to 72°C and *Taq*-polymerase is used to grow two strands of DNA for the original single strand. Generally, the cycle is repeated perhaps 30 times to produce a factor of 2^{30} increase in DNA concentration.

In a conventional scale device, each cycle takes 5–10 min, for a total time of 150–300 min. However, it is possible to do more rapid thermal cycling in a microscale device owing due to the short length scales for heat transfer, thus reducing the analysis time. A schematic of such a device reported by Manz et al. is shown in Fig. 2. It utilizes flow channel repeatedly passing through three different temperature controlled zones on the chip to perform the required thermal cycling. Their device was able to perform 20 cycles in times ranging from 90 sec to 18.7 min depending on the flow rate through the system.[8] A different design is reported by Ramsey et al. (Fig. 13) which utilized an on-chip Peltier heater/cooler to perform the thermal cycling.[60] Electrophoretic sizing and detection is also performed on the same chip. Total analysis time, including 10 thermal cycles, was less than 20 min.[60]

Phosgene Production

Phosgene production in a packed-bed microreactor is a case study that illustrates the potential of the safety advantages of microreactors.[9] Commonly used as an intermediate in the production of isocyanates, which in turn are used in the manufacturing of pharmaceuticals, pesticides, and polyurethanes, phosgene is also extremely hazardous requiring specialized facilities for storage, and handling, and is subject to a variety of transportation restrictions. Microreactors present a convenient method for the production of phosgene at the point of use, minimizing the risks associated with large-scale storage and/or transport of phosgene. Operation of an array

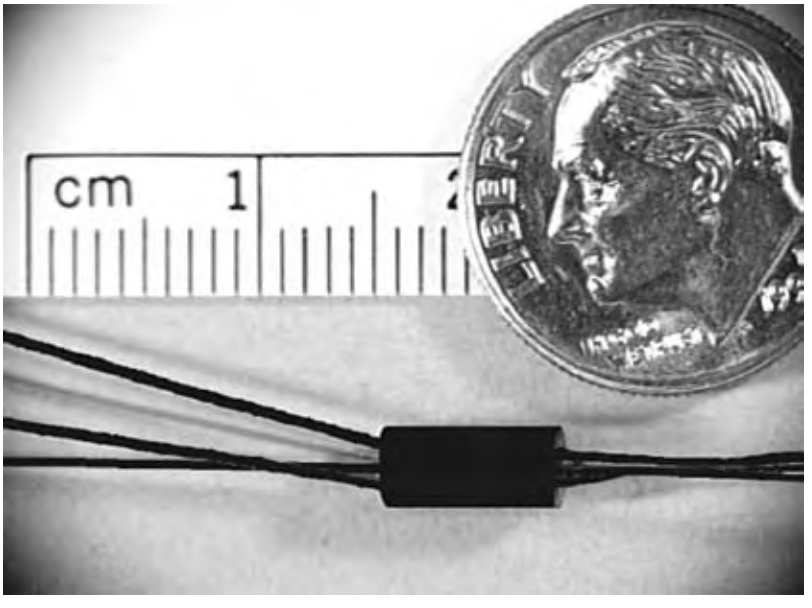

Fig. 12 An integrated fuel processing system from Holladay et al. (From Ref.[58].)

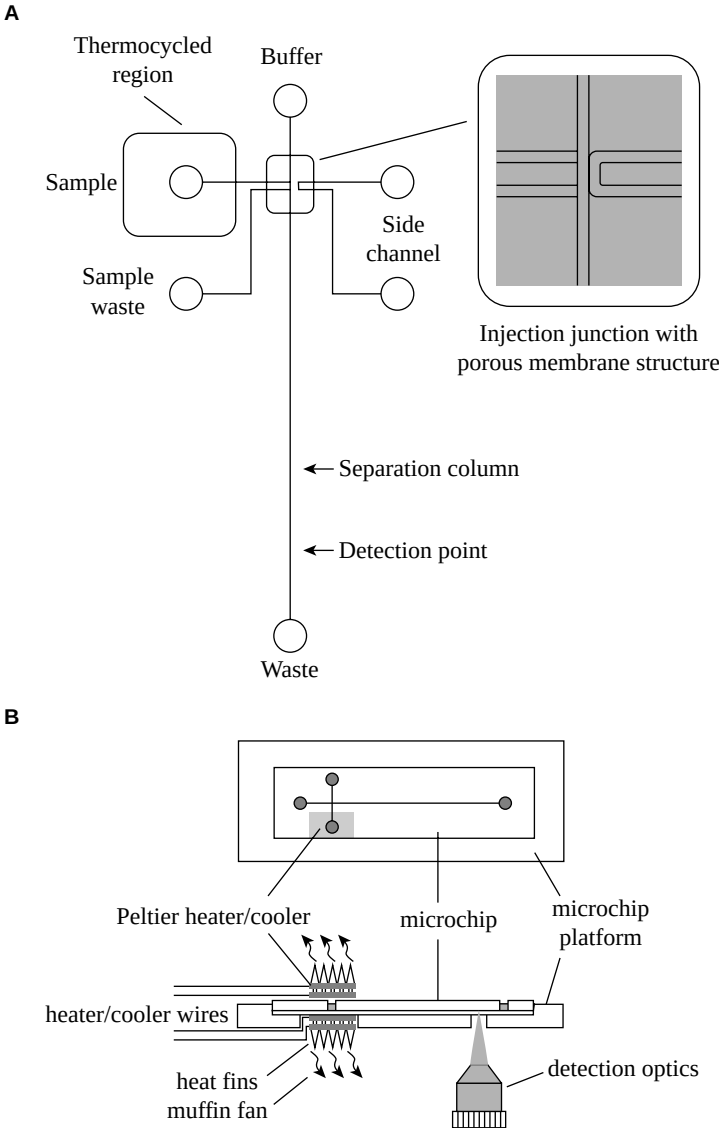

Fig. 13 Ploymerare chain reactor system on a chip reported by Ramsey et al. (A) Layout of chip. (B) On-chip Peltier heater/cooler for thermal cycling of PCR process. (From Ref.[60].)

of such reactors can allow significant production rates to be achieved. The failure of any one of these reactors, however, would only result in a minute chemical release, which mitigated the safety hazard.

The reactor described by Jensen et al. (Fig. 14) consists of a reaction channel 20 mm long, 300 μm deep, and 625 μm wide etched in single-crystal silicon and capped with Pyrex. A thick silicon dioxide coating protects the channels from being etched by chlorine used to produce phosgene. The reactor is loaded with catalyst by pulling a vacuum from the outlet of the reactor and feeding catalyst particles through feed channels perpendicular to the main reaction channel. A series of posts with 25 mm gaps at the outlet is used to keep the catalyst particles from escaping the reactor. Inlet flow is split among several streams to form a parallel micromixer at the inlet. Activated carbon particles between 53 and 73 μm in diameter with a surface area of $850\,m^2/g$ were used as catalyst.

The phosgene formation reaction is moderately exothermic ($\Delta H = -26$ kcal/mol). Despite this, Jensen et al. observed no temperature increase in the reactor when flows were switched from bypassing the reactor to going through the reactor owing to the high thermal conductivity of the silicon reactor and the short length scale for thermal conduction in the microreactor. No undesired side-product formation was observed either, presumably because hot spots, common in conventional reactors, were suppressed as a result of the rapid heat transport. Complete conversion was achieved in this system and significant production rates demonstrated. A 10-channel microreaction system like the one described by Jensen et al. could produce 11 g/hr. Greater production could of course be achieved by adding more reaction channels.

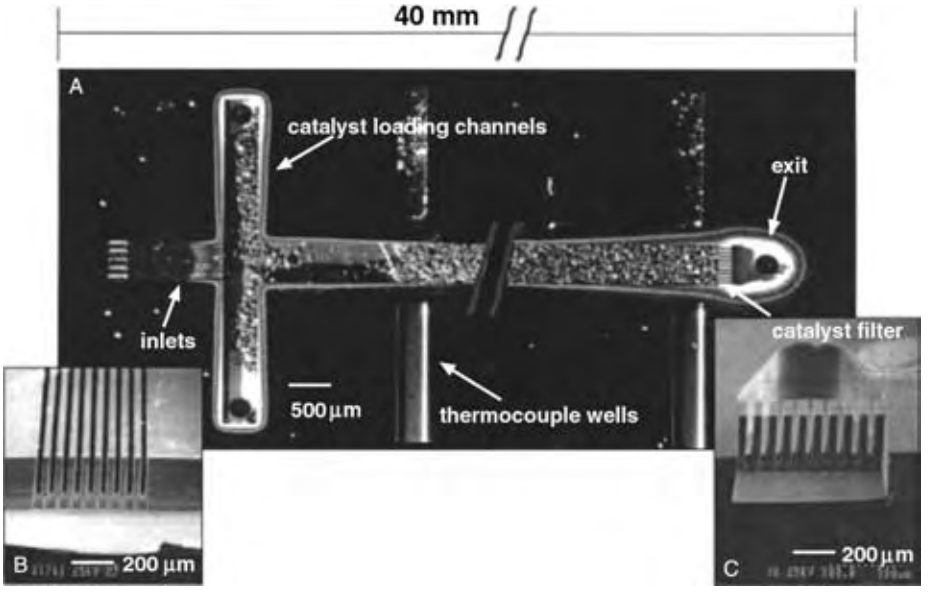

Fig. 14 A packed-bed microreactor used for phosgene production by Jensen et al.: (A) top view; (B) interleaved inlets; (C) catalyst filter. (From Ref.[9].)

Production of *N*-methoxycarbonyl-L-*tert*-leucine

Researchers at Johnson and Johnson have reported the use of microreactors in the drug development process.[61] They utilized a commercially available CYTOS benchtop system, shown in Fig. 15, to examine several reactions. One such reaction was the highly exothermic reaction to form *N*-methoxycarbonyl-L-*tert*-leucine by the addition of methylchloroformate to L-*tert* leucine. Such highly exothermic reactions present safety hazards in large-scale systems. Utilizing the CYTOS system, they were able to perform this reaction in the laboratory and achieved 91% yield.[61]

Photochemical Oxidation of Terpene

Short length scales combined with the use of optically transparent materials allow photoactivated reactions to be performed with much greater ease in microreactors than in conventional reactors. One illustration of these advantages is seen in terpene oxidation by singlet oxygen.[62] To efficiently carry out this reaction, illumination of the entire volume of the reactor with uniform light intensity and wavelength is desired. Complications in conventional reactors include the high absorptivity of the photosensitizers often used and excessive heating of the reactor by the light source. With microreactors,

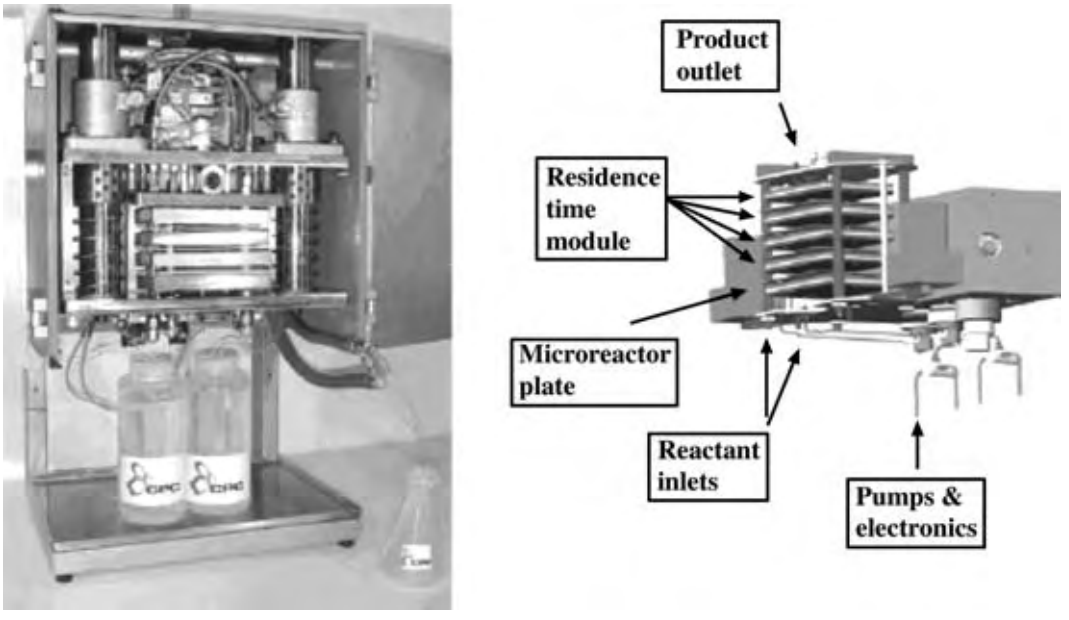

Fig. 15 CYTOS benchtop continuous microreactor system. (From Ref.[61].) *(View this art in color at www.dekker.com.)*

the pathlength for the light is greatly reduced, introducing several advantages. A lower-intensity light source can be used to fully and more uniformly illuminate the reagents, reducing not only the energy used for illumination, but also the undesired excess heating that creates problems with larger light sources.

MATERIALS AND FABRICATION

Nearly any material that can be used in conventional reactors can also be used to fabricate microreactors. Silicon is one of the most widely used materials for microreactors, primarily owing to the fact that microfabrication technology for silicon, borrowed largely from the microelectronics industry, is well developed and there is a large established knowledge base for these processes. Silicon micromachining can be accomplished through a wet etching procedure, such as in aqueous KOH, ethylene diamine pyrocatechol, tetramethyl ammonium hydroxide, or N_2H_4, or through a dry etching procedure, such as deep reactive ion etch, most commonly performed in a SF_6 plasma. A wide array of processes are available for creating structures and coatings from other materials on silicon substrates such as chemical vapor deposition, physical vapor deposition, and electrodeposition.

An inherent advantage of silicon microfabrication techniques is that numerous devices can be rapidly and cheaply produced. This presents the opportunity to develop disposable systems which would be valuable for many chemical analysis and medical applications or to operate many devices in parallel to scale-up production from microreaction systems. The large knowledge base for these processes due to their long history of use in the microelectronics industry also presents a major advantage. A major drawback to silicon microfabrication is the high cost of much of the associated equipment.

Microreactor material choices are by no means limited to silicon and other electronic materials as a wide array of microfabrication technologies for other materials have also been developed. Processes such as soft lithography (63), micromolding (64), and microstereolithography (10) have been utilized to fabricate microreactors from polymeric materials.[10,63,64] Electrodischarge machining has also been used to manufacture microreaction systems from metals and other conductive materials.[65] As can be seen, the choice of materials is generally not by the availability of microfabrication technologies for the material.

Often complex microchemical and microelectromechanical systems have components made in more than one substrate that must be bonded together to form the complete system. These systems also must be packaged to be used commercially. Bonding processes between silicon, glasses, polymers, ceramics, and metals are, hence, of great importance for producing practical microchemical systems. One of the most widely used bonding technologies in microfabrication is anodic bonding in which glass and silicon wafers are held together at temperatures around 400°C under an electric field. Many materials, including glasses and some polymers, can be bonded together thermally. Adhesives and eutectics are also approaches commonly used in bonding materials in microfabrication.

As can be seen, there are a broad array of microfabrication techniques available for many diverse materials. A thorough treatment of microfabrication technology is well beyond the scope of this work. For a more detailed treatment, the reader is referred to Madou's text on the subject.[66]

CONCLUSIONS

Microreaction engineering is a rapidly expanding field. As shown here, microreactors have significant inherent advantages for many applications. Because of their small size, they offer great opportunities for portable applications. Additionally, microreactors provide environmental, health, and safety advantages owing to the small amount of chemicals used and the ability to produce chemicals at the point of use, among other things. The greatest benefits of microreactors result from the enhanced heat and mass transport at short length scales.

The uses to which microreactors have been applied are diverse and cover many fields. Examples cited here include organic synthesis, combustion, reforming, and immunoassay applications. These are only a small sample of the applications to which microreactors have been applied and without doubt an even smaller sample of the future applications of these unique reaction systems.

INTRODUCTION

Fuel cell research has intensified in the past few years. In stationary and mobile applications, fuel cells are attractive for their potential high efficiency and low or no emissions.[1] With increasing number of people using laptop computers and other handheld electronic devices, the desire for longer operating time than what current battery technology provides has sparked interest in 10–100 W_e fuel cells.[2] But perhaps some of the most innovative works on fuel cells have been research dedicated to applying silicon fabrication techniques to fuel cell technology, and creating low power microscale fuel cells applicable to microelectromechanical systems (MEMS), microsensors, cell phones, PDAs, and other low power (0.001–5 W_e) applications. In this small power range, fuel cells offer the decoupling of the energy converter from the energy storage, which may enable longer operating times and instant or near-instant charging.[3] To date, most of the microscale fuel cells being developed are based on proton exchange membrane fuel cell (PEMFC) or direct methanol fuel cell (DMFC) technology. The following section discusses the requirements and considerations that need to be addressed in the development of microscale fuel cells, as well as some proposed designs and fabrication strategies.

FUEL CELL SYSTEM CONSIDERATIONS

There are many issues that need to be addressed for the making of a successful system: fuel cell design, oxidant and fuel delivery, thermal management, and power conditioning. These issues are not independent, because the performance, or lack thereof, of one affects the others. To be successful, all of these components need to be integrated and optimized to work together.

Fuel Cell Design

Fuel cell design needs to include strategies to enable high electrical conductivity of the current collectors and electrodes, high ionic conductivity in the electrolyte and electrodes, appropriate catalysts, and high fuel utilization. High electrical conductivity is required between the catalyst and the current collectors and between the current collectors and external loads. However, the cathode and the anode of a particular cell should be electrically insulated from each other. This is done by the electrolyte membrane separator.[4]

On the other hand, there must be good ionic conductivity between the electrodes and the catalyst surface. For most polymeric membranes, ionic conductivity is strongly dependent on the state of hydration of the membrane.[5] For example, the anode can dry out, thereby seriously hindering the performance. As the anode dries out, localized hot spots can form, which can irreversibly damage the fuel cell. At the other extreme, during high current operation, water produced at the cathode can condense and form a thin layer that blocks oxygen from the catalyst surface.[6] Thus, excess water must be removed from the cathode, while keeping the anode appropriately humidified. There are four modes of water transport in the stack: water produced electrochemically through applied load, that produced because of crossover, water crossover because of proton conduction, and that through simple permeation. Water loss and management in fuel cells are of greater importance as the size decreases. Various water management approaches have been proposed.[7,8] Strategies to manage water include humidifying the fuel and/or oxidant, using an active air blower to provide the oxidant, and removing any excess water.[6]

Water clogging issues in DMFC are similar to those in PEMFC. At high current density, clogging is more severe, especially at low stoichiometric ratio of oxygen, with the problem becoming more exacerbated for cells downstream from the air inlet. Controlling the pressure drop in the cathode flow field was found to be critical for water management. Higher temperatures also increase water transport across the membranes, thus creating water management issues. Higher airflows were needed at high temperature to support higher current density. For DMFCs, this was probably because of high methanol crossover at low current density. Hence, for low power density operation, it appears that unless crossover can be minimized, it is preferable to operate at a low temperature (20°C) in a DMFC system.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120019081

Electrocatalyst selection and design are the key aspects of PEM fuel cells. The most popular catalyst is platinum for the anode and the cathode in pure hydrogen cells. For direct methanol fuel cells and for hydrogen cells with carbon monoxide present, a platinum/ruthenium alloy is used.

Fuel utilization plays an important role in determining system efficiency. Obviously, it is desirable to use as much fuel as possible; however, when nearly all of it is used, fuel delivery to the electrode becomes increasingly difficult. This is because of the diffusional mass-transport limitations restricting the rate of transport of the unused fuel to the active catalyst sites. A significant drop in the current density occurs in the depleted region. This is more significant in direct methanol fuel cells than in hydrogen dead ended fuel cells because of the rapid diffusion of hydrogen. Therefore, in most cases, when operating on methanol the drop in the cell potential prohibits operating the cell to full fuel utilization, and the methanol fuel must either be recycled or expelled.[6] As methanol has a high toxicity, expelling it to the environment is generally not desired, leaving recycling as the preferred option.[6]

Fuel and Oxidant Delivery

The fuel cell does not contain its own fuel; therefore fuel storage and delivery system are very important to a successful system. One of the first questions that needs to be addressed is whether the fuel cell will operate on hydrogen, reformed fuel, or direct methanol. Another important question is whether the system will be active or passive with regard to the oxidant.

Hydrogen can be stored as a gas or a liquid, and in metal hydrides, chemical hydrides, and carbon storage material.[6] If hydrogen is stored as a gas, it requires high pressures and often a large volume, which negates one of the key advantages of a hydrogen fuel cell—high power density per unit volume.[6] Metal hydrides can safely store hydrogen and, depending on the media, it has an acceptable energy density.[9] However, the specific energy is very poor and the materials tend to be expensive.[9] Because hydrogen in all these cases is stored at pressure, this simplifies the fuel supply issue for the fuel cell. It can be supplied passively, requiring no pumps, with only a latching valve to turn the supply on and off.

Using a direct methanol system may improve the energy density of the power supply and make fuel storage easier, though at the cost of increased complexity within the fuel cell. The open circuit of the DMFC decreases with the concentration of methanol feed to the anode owing to methanol crossover and leads to lower performance at low current density because of methanol oxidation at the cathode. However, at a high current density, higher methanol concentration gives better performance owing to lower concentration polarization. Hence, a methanol tolerant cathode would significantly improve the fuel cell performance. Membranes that minimize methanol crossover would also be beneficial. Therefore, to successfully use a DMFC, methanol concentration must be tightly controlled. This requires a pump and a mixer, which add to the complexity to the system, and using passive (wicking) techniques to provide methanol at a low rate so that it has a chance of reacting before the concentrations get too high or by decreasing methanol crossover by tailoring the membrane properties.

Several methods have been used to determine methanol transport through perfluorosulfonic acid membranes. Verdrugge[10] measured methanol diffusivity of Nafion equilibrated with sulfuric acid at room temperature using radioactive tracers and estimated the effective diffusion coefficient to be $1.15 \times 10^{-5}\,cm^2/sec$ at 25°C for Nafion 117. Kauranen and Skou[11] measured time responses of anodic peak currents on two working electrodes and estimated that the permeability of methanol for Nafion 117 at 60°C was $4.9 \times 10^{-6}\,cm^2/s$, and the activation energy was 12 kJ/mol. Narayanan et al.[12] measured the methanol crossover rates by estimating the carbon dioxide content of the cathode exit stream. The crossover rate decreased with increasing current density because of an increased utilization of methanol at high current densities. Increasing the membrane thickness from 5 to 14 mils caused the crossover to reduce by 40–50%. Heinzel et al.[13] described a technique to measure methanol transport through Nafion membranes. Methanol was completely electro-oxidized on the opposite electrode at high electrode potential. Both the diffusion coefficient and the methanol concentration were determined from the measured transient current density following a potential step. Corrections for electro-osmotic drag were found necessary even for low methanol concentrations. The results agreed well with NMR measurements.

A number of organizations are involved in developing membranes with lower methanol permeability. At Giner Inc., Nafion membrane was impregnated with cross-linked polystyrene.[14] Other approaches include electrochemically polymerizing a cation edge film on the cathode to limit methanol diffusion to the cathode,[15] imbibing Nafion 117 with concentrated H_3PO_4,[16] and using membranes based on tin mordenite.[17] Ma, Cheng, and Zhao sputtered a thin layer of Pt/Pd–Ag/Pt on Nafion membrane to reduce methanol crossover.[18] This membrane reduced methanol crossover and gave higher performance than a Nafion membrane cell, with performance increasing with coating thickness up to 1 μm.

The most complicated way to provide fuel to a microscale fuel cell is the use of reforming technology to process a hydrocarbon into a hydrogen rich stream,

which is fed to the fuel cell. This process typically requires the use of multiple reactors and operates at higher temperatures (200–300°C for methanol processing[19] and >600°C for other hydrocarbon fuels[20]). Reforming of hydrocarbons theoretically enables higher energy densities to be achieved. The fuel cell operating on reformate hydrogen is often smaller, requires lower platinum loadings, and is more efficient than a direct methanol fuel cell. The disadvantages include increased thermal management requirements, more unit operations to control, and the need for liquid and air pumps.

Thermal Management

At maximum power, a typical fuel cell operating on hydrogen is only 50% efficient. This translates into 1 W of thermal power that needs to be dissipated for every watt of electricity produced.[21,22] A battery typically operates at an efficiency of 80% or more. Therefore, the use of a fuel cell can increase the thermal load in an electronic device by 60–100%.[21,22] The fuel cell efficiency can be improved by operating the stack at a higher voltage. However, this requires oversizing the stack, which increases the mass and the volume of the power supply, and also, perhaps more significantly, increased cost.

Thermal management has been achieved by passive convection cooling, active air cooling, or liquid cooling. The simplest cooling technique is to design the stack that is able to dissipate the generated heat using natural convection. This design eliminates the need for temperature monitoring, active cooling elements that require parasitic power to operate, and also increased controls.[21] The disadvantages of this approach are increased size because of large cooling plates and heat sinks, and also thermal gradients that may develop in the fuel cell, limiting the size and power of the fuel cell.[21] In addition, space limitations and high ambient temperatures may limit the effectiveness of natural convection cooling.[23] The active air cooling technique uses a blower or a fan to cool the stack. Special cooling plates are again used. These plates are often smaller than those used for natural convection, but are typically larger than those used in liquid cooled systems. The final approach is liquid cooling. This is generally used in larger applications (>1 kW) where large amounts of heat are produced.[23] Liquid cooling stacks are typically more compact and have smaller thermal gradients, enabling high power densities. The disadvantages are the need for a radiator to cool the liquid and the increased complexity of the system.[23] Depending on the power output of the microscale fuel cell, natural convection cooling and active air cooling are typically used.[21,23]

Power Conditioning and Load Handling

Microscale fuel cells are being developed to power a wide range of portable electronic goods. The input voltages and duty cycles will vary from application to application. Fuel cell based power supply must be able to provide the appropriate voltage (1V, 3V, 12V, etc. depending on the device) and also respond to sudden changes in power demand even from a ''cold start.'' The fuel cell voltage is typically achieved by increasing the number of cells in the stack until the desired voltage is attained or by using a DC to DC converter to step up or step down the fuel cell stack voltage. Load handling is a more difficult challenge. Under mild conditions, this may not be a problem; however, under extreme cold startup, this may be a significant challenge.[6,22] In addition, membrane hydration may also be required if the system is dry.[6,22] The change in demand is especially significant for direct methanol systems where control of the methanol concentration is required. For example, a sudden decrease in power demand may flood the system with methanol, thus significantly increasing crossover and its problems, whereas a sudden increase in power demand will starve the system. In either case, the fuel cell may not be able to respond to the demand.[6,22]

The two most common strategies to handle load changes are to oversize the fuel cell and to include a battery in the system to handle peak loads.[6,22] There has been significant development in microscale batteries that can be integrated into the smaller systems (see for example Refs.[24–26]), while more conventional batteries can be used in the ''larger'' systems.[6,22] The most extreme example of this hybrid technology is the battery handling all loads with the fuel cell trickle charging the battery. This setup lengthens the battery's life and enables the load handling during transients; however, it can only be used when the duty cycle has periods of low power that enable the fuel cell to completely or significantly charge the battery.[6,22]

FABRICATION

To build an efficient, high-quality microscale fuel cell, microfabrication techniques need to be combined with appropriate materials such as Nafion based membrane electrode assemblies (MEAs). These techniques must be able to produce three-dimensional structures, allow reactant and product flow into and out of the device, process appropriate materials, and should be of low cost. Fortunately, traditional thin film techniques can be modified for microscale fuel cell fabrication, while maintaining their advantages of surface preparation, sensor integration, and finishing or packaging. In addition, other techniques are also available and are discussed in the following sections.

Membrane Electrode Assembly Fabrication

Some common ways of fabricating the MEA for microscale fuel cells include hot pressing the membrane onto preformed electrodes or hot pressing a complete MEA onto a substrate, screen printing a membrane onto a substrate and depositing the electrodes on either side, and using spin deposition to deposit the membrane followed by electrode deposition.

In the hot pressing technique, the membrane is often pretreated prior to use. The exact pretreatment depends upon the membrane used, but the pretreatment of Nafion 112 is used as an example here. The pretreatment of Nafion 112 often consists of a four-step sequential boiling process.[27,28] The treatment was as follows: 3% H_2O_2, deionized water, 0.5 M H_2SO_4, and final deionized water. The membrane was placed in each boiling solution for 1 hr.[27,28] The membrane can then be hot pressed onto a substrate or onto cathode and anode electrodes (such as catalysts loaded onto a supported carbon paper).[27,28] Typical hot press conditions are a temperature of 135°C and a pressure of 30 MPa.[27,28]

Screen printing membranes onto a substrate is another way of forming the fuel cell. Wainright et al.[29] have developed a procedure, which begins with a typical 5% Nafion solution. This is modified to increase its viscosity to print a well-defined film.[29] The modification consists of adding higher boiling solvents, such as dimethyl sulfoxide (DMSO) or ethylene glycol, and then concentrating the solution. Using this solution, the films are cast and the solvent is then removed under vacuum at approximately 80°C.[29] They were able to cast 25 μm thick free standing films from 10 to 15 wt.% solutions.[29] Once cast, the electrodes are deposited on the films by printing a slurry of C/Pt particles (e.g., 40 wt.% Pt on XC-72 from Etek Inc.).[29] Other ways of forming the electrodes include deposition of the films onto preformed electrode substrate, vapor or sputter deposition techniques, and spray coating with an air brush.[30]

A third common way of depositing ion conducting membranes is to use a spin coating technique.[31] The specifics of this technique will depend on the viscosity of the solution to be deposited and the thickness of the desired layer. Morse et al.[31] used the following process to form their electrolyte membranes. They first formed a catalyst layer by electron beam deposition of 5 nm of Pt onto a prepared substrate. They used a perfluorinated sulfonic acid polymer in a 5 wt.% of a 950 weight equivalent solution. It was deposited over the catalyst using a pipette and spun at 500 rpm for 30 sec.[31] After baking at 120°C for 30 min, another electrode layer was deposited by electron beam deposition of 5 nm of Pt.[31]

Microfabrication

This section briefly reviews the material selection and some common microfabrication techniques.

Materials

The materials used in fuel cell construction must be chemically compatible, have appropriate thermal properties, and be structurally sound. In Table 1 are listed the advantages and disadvantages of some common materials used in microfabrication. There are three general categories of materials: metals, silicon (which includes materials containing silicon or those that are processed with semiconductor fabrication techniques), and low-temperature cofired ceramics (LTCC).[32,33] The material selection process is complicated by the fabrication process, as it may alter the material properties. Although microscale devices have the potential to be manufactured using high-volume techniques, the design, material, and fabrication selections must take cost into account to avoid developing a laboratory curiosity rather than a commercially viable device.[34]

Fabrication techniques

Popular microfabrication methods include lithographie, galvanoformung, abformtechnik (LIGA), wet and dry etching processes, micromachining, lamination, and soft lithography. An overview of these techniques is given here and specifics can be found in the references.

Table 1 Microreactor material and benefits and drawbacks

Substrate	Benefits	Drawbacks
Metal	Standard fabrication techniques; durable; low to modest costs; no clean room required	Poor compatibility with ceramics and glass
Silicon	Well-characterized silicon fabrication techniques; high precision; low cost	Fragile; requires a clean room
LTCC	Flexible fabrication; refractory and durable; low cost; no clean room required	Nonstandard fabrication; sealing

(From Refs.[32,33].)

Lithographie, Galvanoformung, Abformtechnik (LIGA). The LIGA technique, developed by researchers in Germany, with Forschnungszentrum Karlsruhe and the Institute for Microtechnology Mainz (IMM) being the primary drivers, combines deep lithography, electroplating, and molding[34,35] using three general steps. Pattern transfer using a serial beam writing process or mask into a photoresist or a special photosensitive epoxy, such as SU8, deposited on an electrically conductive substrate is the first step.[34] After removal of the undesired material (e.g., the developed mask), electroplating is used to form a relief structure on the exposed substrate. To complete the second step, the resist or epoxy is removed leaving the metallic structure. In some applications, this structure may be the final product; however, usually it is used as a master tool for a replication process (such as injection molding, casting, or embossing), which is the final step.[34,35]

Wet and Dry Etching Processes. The most common processes in microfabrication are the wet and dry etching processes. Liquid etch solutions (such as potassium hydroxide for silicon) are used to remove unwanted material from the substrate anisotropically in a wet etch. Dry etching uses plasmas or reactive plasmas and may be anisotropic or isotropic, depending on the source.[34] The procedures, fluids, temperatures, and times are material- and pattern dependent. One form of dry etching that is increasingly being used is deep reactive ion etching (DRIE).[35] Because wet etching is an anisotropic process, it has strong restrictions on the geometries that can be made. Isotropic dry etching enables a wider variety of geometries but is more limited in the materials that can be etched. The initial step in the process is pattern transfer into a photoresist or other protective layer. The unprotected substrate areas are etched using either technique. Next, the protective layer is removed.[34]

Micromachining. There are three main techniques in micromachining: milling, laser radiation, and electrodischarge machining. These processes typically do not need the initial deposition of a resist, an epoxy, or other protective layers. The equipment tends to be less expensive and has lower maintenance costs compared with that used in LIGA and wet/dry etching. Though not required, computer control is usually used. The milling technique includes traditional milling, turning, and grinding, but with ultraprecision machines to produce small features.[34,35] The feature sizes are not as small as of those constructed from LIGA and other fabrication processes; however, almost any material can be used. As the name implies, the laser radiation uses lasers to remove material or, in some situations, to build up material.[34] This technique removes the material by melting, evaporation, decomposition, photoablation, or a combination of these. Some development involves building structures by photochemically crosslinking inorganic compounds or powder solidification by laser sintering. Both processes can be used to make devices to critical dimensions of approximately 10 μm; however, the surfaces tend to be rough, which may cause problems in some cases.[34] Electrodischarge machining (EDM), also called microelectrodischarge machining, removes material by small sparks in a dielectric fluid, such as deionized water or oil, between the work piece and an electrode. This technique is limited to electrically conductive work pieces. The main disadvantages of this type of machining are the relatively rough surfaces, limitations in miniaturization to the size of the electrodes and spark, and relatively long machining times, which may limit the technology to prototyping and manufacture of mold inserts.[34]

Lamination. Lamination processes are typically done by stacking several sheets with different patterns and then braze or bond them together. In typical MEMS-based approaches, DRIE is used to pattern silicon or other substrates. The substrates are then stacked and bonded together using silicon bonding methods. Another approach, used by researchers at the Pacific Northwest National Laboratory (PNNL), is the fabrication of thin metal laminates using stamping, embossing, or processes described previously.[35] After stacking, these laminates are brazed or diffusion bonded into a single block.[35–37] Lamination is also particularly well suited for fabricating ceramic devices. Ceramic tapes in the ''green state'' are cut, molded, laser cut, etc. to the desired pattern. The layers are stacked and then cured in high-temperature furnaces, bonding them into a single structure.[35]

Soft Lithography. Soft lithography refers to a collection of techniques originally developed by Xia and Whitesides.[37] They typically involve pattern transfer, often by stamping, using an elastomer such as poly (dimethylsiloxane). This technique has been combined with other polymers, electroplating techniques, or molding of ceramics to make low-cost fast prototyping of devices.[35,37]

MICROSCALE FUEL CELL DESIGNS

In designing a microscale fuel cell, there are several considerations that need to be accounted for. These include the following: is the fuel cell to be completely active or passive? will it operate at room temperature or elevated temperatures? will the fuel be at atmospheric pressure or elevated pressure? will external humidification be required? and finally, will the fabrication techniques

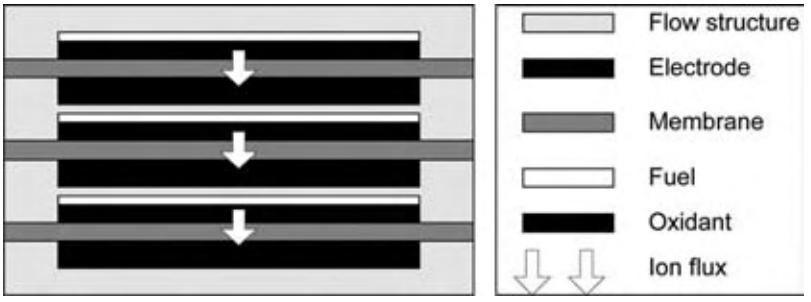

Fig. 1 Conventional bipolar plate configuration. (From Ref.[3].)

be compatible with the materials selected?[29] Several designs are reviewed here: a conventional bipolar plate configuration, a banded configuration, a ''flip-flop'' design, a monolithic configuration, and a mixed reactant configuration.

Conventional Bipolar Design

One way to make a microfuel cell is to size down conventional stacks. In this design (Fig. 1), the MEA, gas diffusion layer (GDL), if used, and bipolar plates are made thinner and smaller in area to make the microfuel cell. This design has the advantages of being able to achieve high voltages and one that most conventional fuel cell manufacturers prefer. For microscale fuel cells, this is a difficult design to manufacture, as it requires a large number of components and is very difficult to manifold.[27,28]

Banded Fuel Cell Configuration

In the banded fuel cell design, the cells are in a side-by-side planar array (Fig. 2). Higher voltages are achieved by overlapping adjacent cell electrodes. For example, the anode of one cell crosses the electrolyte to become the cathode of the adjacent cell.[27,28,38,39] These crossmembrane connections can be made by the use of edge-tabs or by routing breaches through the membrane.[3] This configuration enables very compact designs that show promise of improved volumetric packaging compared with conventional bipolar stacks in microscale fuel cells or other low power designs.[38] Other advantages of this design include relatively easy packaging and simpler manifolding of the fuel and oxidant. Major limitations are the crossmembrane interconnections. Interconnections by edge-tabs limit design flexibility and may require longer conductive lengths, which could increase the resistive losses in the cell. However, edge-tabs also offer the possibility of connecting the cells in parallel and/or serial configurations that would enable a wide range of voltages and currents to be fabricated.[29] For microscale cells, these losses may be minimized, but could still affect the cell performance.[3] If the interconnections are made by breaching the membrane, then the problem is sealing, especially when a polymer membrane that swells is employed.[3]

''Flip-Flop'' Fuel Cell Configuration

The ''flip-flop'' fuel cell design was developed to eliminate the need for crossmembrane interconnection of the electrodes that is apparent in the banded design. In this configuration, the anode and the cathode of adjacent cells are still electrically connected, but the connection no longer needs to cross the electrolyte membrane, as the anode and the cathode of adjacent cells are on the same side of the electrolyte membrane (Fig. 3).[3,27,28] The benefits of such a design include a fully continuous electrolyte membrane, all interconnects being on the same level so that all the electrodes are on the same side, and its conductor paths may have a lower resistance because this design does not require electronically conductive paths to the perimeter.[3,27,28] The disadvantage is the increased difficulty in sealing and in gas manifolding

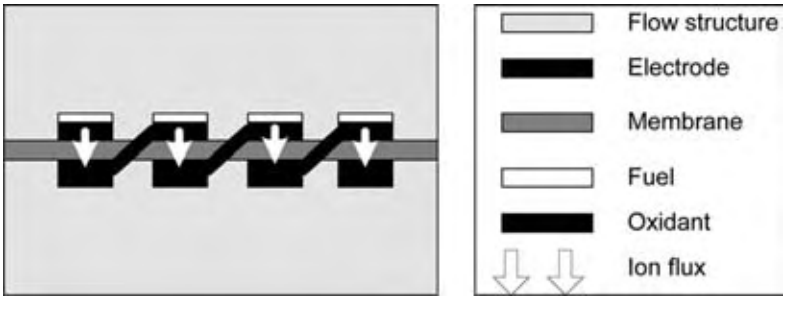

Fig. 2 Banded fuel cell configuration. (From Ref.[3].)

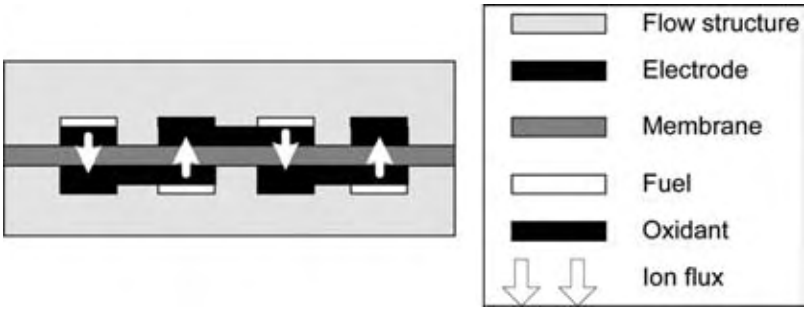

Fig. 3 ''Flip-flop'' fuel cell configuration. (From Ref.[3].)

because of the requirement of the reactant chambers to alternate between fuel and oxidant.[3,27,28]

Lee et al.[3] fabricated a four-cell assembly banded fuel cell as follows. On a 100 mm diameter silicon substrate (500 μm thick), the flow chambers were etched 200 μm deep and square flow distribution pillars (100 μm × 100 μm) were arranged in a rectangular array 100 μm apart. Cross channels were etched on different planar levels of the wafer to provide appropriate gas routing for the fuel and oxidant. These routes were in a checkerboard design. The etchant gas was SF_6 (130 sccm, 36 mT) and intermittent passivation with C_4F_8 (85 sccm, 18 mT) in an STS Multiplex ICP Deep Reactive Ion Etcher with an inductively coupled plasma at 13.56 MHz, coil rf power 600 W, and electrode rf power 120 W. After the etch was complete, a thermal oxide was grown on the wafer in a tube furnace. Electrically conductive regions were made by first depositing 15 nm of chromium (as adhesion promoter) followed by 100 nm of gold by electron beam evaporation. The prepared flow channels were then pressed onto MEAs by supplementary backing plates to interface gas fittings. Silicone gaskets were used to seal the substrates and backing plates together. Hand-tightened fasteners were used to supply the pressure. The cells were tested with compressed hydrogen and oxygen and were able to provide over 40 mW/cm^2 of power.[3]

Monolithic Fuel Cell Configuration

The monolithic design has been called an ''unfolded fuel cell'' with the anode and cathode on the same substrate.[6] The cathode and the anode of a particular cell are adjacent with each other in a coplanar configuration. Multiple cells are fabricated next to each other such that the cathode and the anode of adjacent cells are adjoining (Fig. 4). Advantages of this design include the ability to fabricate all the fuel cell components on the same structure, improved humidification control because the top structure is the moisture sensitive electrolyte membrane, very small separations between cathode and anode are now possible, and the cathode and anode electrodes can be sized differently enhancing the surface area of the limiting electrode to improve the cell's performance.[6] The main disadvantages of this design are the lower power density because the area is increased by 50% compared with a stacked design, the current distribution is not uniform, and also large metal lines are required to pull out the current.[6]

Mixed Fuel and Oxidant Fuel Cell Configuration

The mixed fuel and oxidant fuel cell design is similar to the monolithic fuel cell configuration except that there is only one reactant flow channel for both the fuel and the oxidant (Fig. 5).[6,40,41] Two approaches to this fuel cell configuration include the use of very selective catalysts for the electrodes so that the catalyst that reacts the fuel is significantly less active in the reaction of the oxidant and vice versa.[6,40] A second strategy is to have the component that is more active be consumed on the near side of the electrolyte membrane separator.

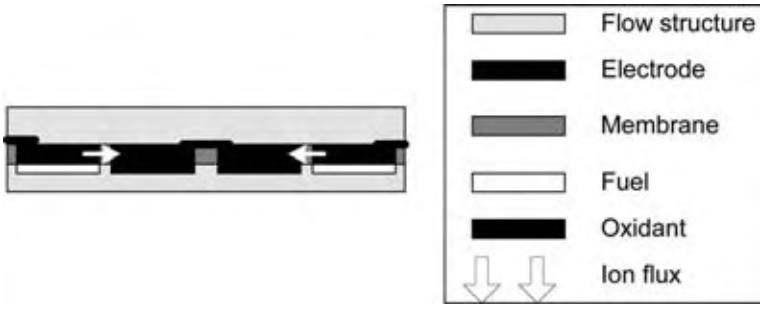

Fig. 4 Monolithic fuel cell configuration. Note: the two end electrodes are electronically connected.[3,6]

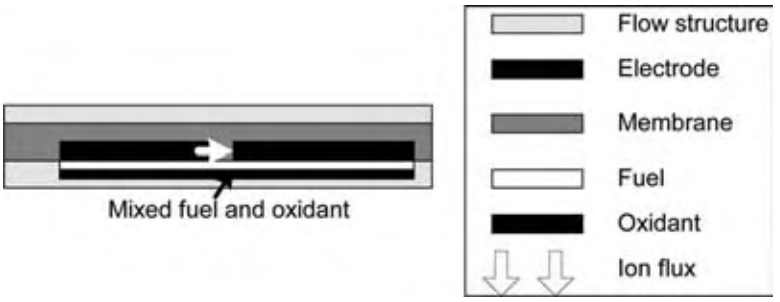

Fig. 5 Mixed fuel and oxidant fuel cell configuration. (From Ref.[3].)

The less active reactant is then free to diffuse to the other electrode and react.[6,41] The advantage of these designs is simple design. The main disadvantages are poor kinetic performance of the electrodes in the first strategy and operating the fuel cell with a mixed potential for the second.[6]

MINIATURE DMFC

There have been significant works in the development of direct methanol fuel cells at JPL,[12,42,43] University of Newcastle,[44] Korea Institute of Science and Technology,[45] Los Alamos National Laboratory,[13] and other institutions. The performance of the DMFC is highly dependent on methanol crossover, catalyst loading, and methanol concentration. At high temperature and high methanol concentration, the kinetics for methanol oxidation is highly enhanced and methanol crossover is also increased under these conditions. Methanol crossover has been extensively studied.[13,46,47] It has been found that high temperature increases methanol crossover, while high current density decreases crossover. Hence, at low current density and high temperature, the crossover current density was high, thus lowering the cathode potential. High methanol concentration increased crossover, while it improved kinetics at the anode. The effect of crossover on the cathode was shown to be $\sim$70 mV. Hence, the use of a membrane that would minimize crossover, along with the use of high catalytic activity at the anode, was identified as an effective means for preventing crossover and increasing cell performance.

The minimum goal for commercialization of DMFC is 250–300 mW/cm^2 for transportation and 30–40 mW/cm^2 for portable applications operating on methanol and air.[48] Siemens obtained 20 mW/cm^2 with pressurized methanol and oxygen, but the single cell was not durable. The University of Newcastle used liquid and vapor feed systems with low loading electrodes containing 2.5 mg/cm^2. A power density of 0.2 W/cm^2 was achieved at 98°C with pressurized oxygen and 2 M methanol solution, while pressurized air gave a power density of 60 mW/cm^2. JPL/Giner measured a cell voltage of 0.47 V at 400 mA/cm^2 in oxygen, while the cell voltage was 0.38 V in air. Electrodes with low Pt loading of 0.5 mg/cm^2 gave 150 mW/cm^2 at 95°C. Using a thinner Nafion 112 membrane, LANL developed DMFCs that had a cell voltage of 0.57 V at 400 mW/cm^2. High temperature and pressure were used to enhance electrode kinetics to counter methanol crossover.

Kho et al.[45] developed miniature DMFCs that operate under passive feed conditions. The effect of methanol concentration, membrane thickness, and amount of catalyst loading on the performance of air-breathing DMFCs was determined. Maximum power density was obtained for methanol concentration in the 4–5 M range. This was much higher than optimum methanol concentration in the active feed regime. At $>$6 M methanol, there was a sharp drop in performance. Higher concentration is needed to increase the transport rate of methanol. Thinner membranes gave better performance than thicker membranes, thus showing that proton conductance is more important than methanol crossover for the investigated range of membrane thickness. The cell performance increased with catalyst loading up to 6 mg/cm^2. This indicated that excess catalyst could result in providing a mass-transport barrier to methanol and oxygen. Under active methanol feed conditions, 2 M methanol concentration gave better results than 4 M because of lower crossover. The fuel cell was monopolar with six cells with an active area of 4.5 cm^2 per cell, with the electrodes of same polarity on the same surface of the polymer membrane. Other companies that have developed miniature DMFCs are Poylfuel, Samsung Advanced Institute of Technology, Casio, MTI, Toshiba, and NEC.

CONCLUSIONS

Typically, power source design has lagged behind the requirements of the portable electronic goods industry. As the demand for portable electronic devices increases and as those devices increase their power and energy

requirements, there will be a need for advanced power supplies with large power and energy density. There is significant developmental effort in the area of microscale fuel cells. Development has been focused primarily on hydrogen and more recently on direct methanol fuel cells. For low power applications, DMFCs appear to be very attractive, if methanol crossover through the membrane is reduced or cathode catalyst tolerance to methanol oxidation is increased. If a cost-effective and efficient hydrogen storage design can be obtained, PEM fuel cells show great promise. Many researchers are developing designs that enable the use of high-volume fabrication similar to that of the semiconductor industry in the hope of developing an inexpensive device. Various stack designs are available for the optimization of power or energy density.

INTRODUCTION

DuPont's Surlyns, which are semicrystalline poly(ethylene-*ran*-methacrylic acid) (EMAA) copolymers neutralized with various cations, were developed in the 1960s. They have ever since been used as coatings and adhesives, in food packaging, and other fields. The Surlyns are the first example of a then-new class of polymeric materials, so-called ionomers, that is, uncharged polymers with a small fraction of ionic groups. These can be neutralized with a variety of counterions, and the presence of these neutralized acid groups significantly influences the physical properties of ionomers. For example, the impact strength and melt viscosity of ionomers depend not only on the type of neutralizing cation, but also on the neutralization level. This is advantageous because by simply changing a cation or the neutralization level of an ionomer, one can tune the properties for a desired application. It is now generally accepted that the neutralized acid groups and the cations form larger structures, so-called ionic or ion-rich aggregates, within a predominantly hydrophobic matrix. These ionic structures act as physical cross-links between polymer chains and largely control the ionomer properties, particularly if there is no crystallization of the main polymer chain.

Despite the relative simplicity of most ionomers, questions about them remain. One of the key questions is how structure and dynamics on different length scales connect. Specifically, how does the metal coordination to the neutralized acid groups (which is on an angstrom level) correlate with the size, shape, and distribution of the ion-rich aggregates in the hydrophobic matrix (which is on a nanometer length scale)? Furthermore, how does the microscopic structure control the macroscopic properties like melt viscosity or elastic modulus?

Because the micro- and mesoscopic behavior of an ionomer governs its macroscopic properties, understanding these phenomena is the key to new and improved ionomers. Much research has thus been directed at investigating ionomers at different length scales. We will here present approaches to study ionomers on the intermediate mesoscopic (i.e., nanometer) length scale and show how one can obtain information about processing effects on ionomer morphology. The focus of this entry is on ionomer microscopy, which has recently been established as a complementary technique to, for example, x-ray scattering or IR spectroscopy for the investigation of ionomers. For a comprehensive treatment of ionomers, in particular their micro- and macroscopic properties and their chemistry, the reader should refer to the current literature.

IONOMER CHEMISTRY

We will briefly introduce some important ionomers (see Fig. 1), but for a thorough treatment of ionomer chemistry, see, e.g., Refs.[1,2]. The simplest classification of ionomers is semicrystalline vs. amorphous ionomers. The prototypical semicrystalline ionomer is EMAA (Surlyn, DuPont) neutralized with various cations. Also from DuPont, Nafion is a perfluorinated polyethylene with sulfonic acid or sulfonate groups on short side chains. Other commercial ionomers like Aciplex (Asahi Chemical Company), Flemion (Asahi Glass Company), and Neosepta (Tokuyama) are structurally similar to Nafion. For a recent review on Nafion see Mauritz and Moore.[3]

Arguably the most important amorphous ionomer is sulfonated polystyrene (SPS). Other ionomers include poly(styrene-*ran*-methacrylic acid) (SMAA), polyurethanes, siloxanes, butadiene-based elastomers, ethylene-propylene-diene terpolymers, acrylates and methacrylates, polyphosphoesters, polyimides, and many others.[1,2]

The most important ionic groups are carboxylates and sulfonates, but other groups like ammonium have also been reported.[4] Special classes of ionomers are zwitterionic ionomers, which contain both cationic and anionic groups, as well as ionomers with regular architectures like block ionomers, mono- or telechelic ionomers, star ionomers, or ionenes, which have regularly spaced ionic groups.[1,2]

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007825

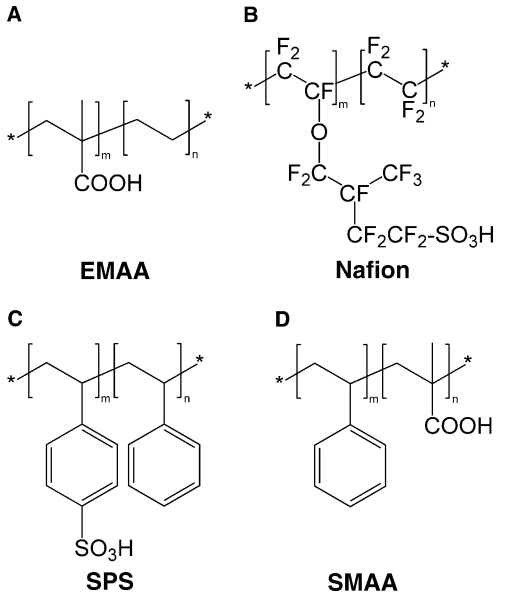

Fig. 1 Important ionomers: (A) poly(ethylene-*co*-methacrylic acid), the free acid form of Surlyn, (B) Nafion, (C) SPS, and (D) poly(styrene-*co*-methacrylic acid). For the sake of simplicity, all polymers are shown in the acid form. In the ionomers, the acids are partly or fully neutralized with cations such as Na^+, NH_4^+, or Zn^{2+}.

LOCAL ENVIRONMENT OF THE NEUTRALIZING ION

As stated above, the ionic groups act as physical cross-links between polymer chains; cross-linking is thus a phenomenon that occurs on an angstrom length scale. Ionomer structure and processing effects at this level have mainly been probed with solid-state nuclear magnetic resonance (SSNMR), Fourier transform infrared spectroscopy (FTIR), and extended x-ray absorption fine structure spectroscopy (EXAFS). Most of these experiments yield information about the local structure around the neutralizing cation (generally a metal). For example, ^{23}Na-SSNMR experiments by O'Connell et al. found a narrow peak at 7 ppm and a broad peak at ca. 20 ppm in the spectra of Na-SPS.[5] The authors interpret these peaks as being due to isolated and aggregated Na^+, respectively, where the breadth of the latter signal is caused by an overlap of the signals from dimers, trimers, etc. coexisting in the aggregates. Similar observations have recently been made by Moore and coworkers in Na-neutralized poly(butylene terephthalate) ionomers.[6]

Solid-state NMR also allows for the study of sample preparation effects on the local cation environment. Na-SPS with 1.7% styrene sulfonate groups cast from dimethyl formamide or tetrahydrofuran (THF)/water mixtures shows more aggregated ions, i.e., a more intense peak at ~20 ppm, than ionomers cast from less polar THF or THF/EtOH mixtures.[7] Humidification and subsequent drying also result in more Na^+ in the aggregates than before; however, annealing Na-SPS above the PS glass transition temperature leads to more ions in the polymer matrix. This process is partly reversible and can be controlled by adjusting the processing conditions.[8] In contrast to Na-SPS, ^{23}Na-SSNMR spectra of Na-EMAA only exhibit one broad signal at ~12 ppm, which is independent of the thermal history of the sample.[9] This implies that processing affects Na-SPS much stronger than Na-EMAA.

Extended x-ray absorption fine structure spectroscopy shows that in Zn-EMAA the oxygen atoms around Zn^{2+} form well-defined oxygen shells.[10] In Na-EMAA the environment around Na^+ is much less ordered, in particular at high neutralization levels.[11] This is in principle supported by the results of Kuwabara and Horii,[5] because the broad peak in ^{23}Na-SSNMR spectra of Na-EMAA can be attributed to dimers, trimers, etc. in the aggregates, similar to the suggestion by O'Connell et al. for Na-SPS.[9] Extended x-ray absorption fine structure spectroscopy has also shown that ionic aggregates may contain a significant amount of nonionic material (see, e.g., a new study by Grady and coworkers).[12]

Of particular interest with regard to processing is a study investigating the local cation environment of Zn-EMAA at high pressure.[13] The coordination geometry around Zn^{2+} depends on the applied pressure P: under vacuum (at $P = 0$), IR detects bands at 1624 and 1538 cm^{-1} that were ascribed to hexacoordinated Zn-carboxylates. Increasing P intensifies a band at 1585 cm^{-1}, which was assigned to a tetracoordinated Zn-carboxylate. A remarkable feature of this pressure-induced coordination change is that even atmospheric pressure significantly changes the coordination. Furthermore, if the pressure is applied below the melting temperature of the crystalline polyethylene backbone, the coordination change depends on the temperature. These results clearly show that temperature and pressure will have a drastic impact on the ionic structure on an angstrom length scale, which will in turn influence the macroscopic properties of the material.

X-RAY SCATTERING OF IONOMERS

Rather than probing very short-ranged features and interactions, many authors describe the structure and processing effects in ionomers as a function of the entire ionic aggregate, i.e., on a mesoscopic (nanometer length) scale. The morphology of the ionic aggregates has mainly been investigated with small-angle x-ray scattering (SAXS). Typical ionomer SAXS patterns show a broad scattering peak in the region from ca. 0.5 to 4 nm^{-1} and a low-angle upturn near the

beam stop. Different models have been proposed as to how the scattering peak shape and position relate to the size, shape, and spatial distribution of the ionic aggregates.[14–19] The low-angle upturn was explained as the result of parasitic scattering, remaining neutralizing agent, or other impurities.[17,20,21] However, already in 1987, Galambos et al. have suggested that the upturn is due to the presence of metal ions in the neutralized acid groups.[22] Eisenberg et al. have also suggested an inhomogenous distribution of so-called multiplets, i.e., very small, ion-containing entities, as the source for the upturn.[19]

Anomalous SAXS and ultra-SAXS further support the claim that both the scattering peak and the low-angle upturn are due to the neutralizing cations in the ionomers and not to impurities or artifacts.[23–27] Wu et al., Ding et al., and Li et al. suggest various kinds of long-range heterogeneities, for example, a nonrandom distribution of unaggregated ionic groups in the matrix, as the source of the low-angle upturn.[25–27] They also suggest sample preparation by compression molding, nonequilibrium structures arising from short annealing time, or compositional variations in the SPS as possible sources of the upturn. Register and Cooper assign the upturn to the microphase-separated structure of ion-rich aggregates, amorphous matrix, and crystalline matrix, where applicable.[28,29]

This chapter clearly shows that although scattering and spectroscopy are powerful methods, they have limitations in terms of the selection and applicability of the models used for data interpretation. For example, many of the suggested causes for the low-angle upturn in ionomer SAXS patterns are plausible, but they cannot be verified independently. Microscopy, however, can in certain cases provide a model-free assessment of ionomer morphology, which in turn will confirm or rule out the applicability of a certain model. In the remainder of the text we will thus focus on microscopy of ionomers.

MICROSCOPY OF IONOMERS

Imaging methods can yield valuable information about ionomer morphology, because imaging provides a

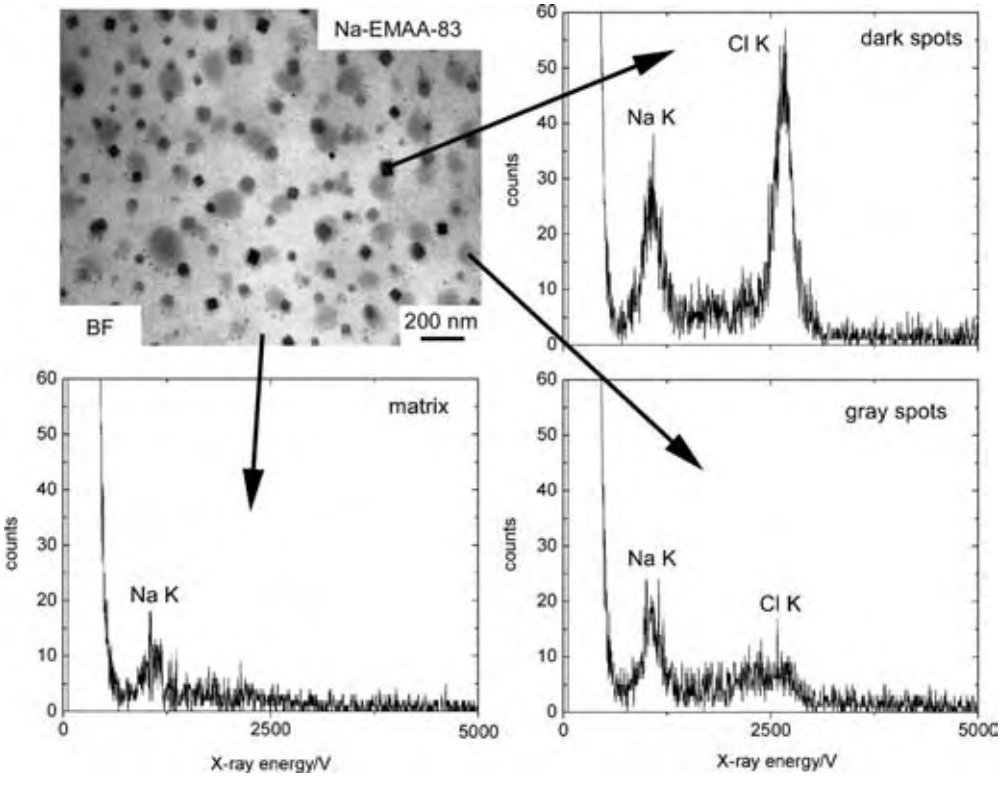

Fig. 2 Bright field STEM image of Na-EMAA neutralized to 83% and exposed to a warm and humid environment for about 5 days. The image shows a light background (the presumed matrix), gray spots, and dark rectangular features. By placing the electron beam on either one of these features it is possible to acquire energy dispersive x-ray spectra, which carry information about the chemical composition of the respective feature. The x-ray spectra acquired on a light gray, a dark gray, and a black feature show that the presumed matrix does contain some Na. However, this does have to be treated with care as stray electrons may also cause signals from adjacent areas. In any case, the dark gray and, in particular, also the black features do contain Na and Cl. These results thus indicate that aging of ionomers can include the formation of metal chloride nanoparticles on exposure to a certain environment. Unfortunately, the mechanism of the precipitation is not clear to date.

model-independent determination of the presence, size, size distribution, shape, shape variation, and spatial distribution of the ionic aggregates. Early transmission electron microscopy (TEM) experiments have, however, been inconclusive: stained solvent-cast ionomer films produce artifacts in the TEM but no reliable data.[30] Stained microtomed samples do not show features that can be assigned to either an ionic aggregate or a region without aggregates (matrix). It was thus concluded that either the ionic aggregates must be smaller than 2–3 nm in diameter, because otherwise they should be visible in the TEM, or that they are much more diffuse than expected. This would lead to a rather nondescript contrast variation in the images.

The same paper also reports the formation of MCl (M = Na, K, Cs) nanocrystals upon exposure of M-EMAA ionomers to chloroform. Interestingly, using scanning TEM (STEM) and energy dispersive x-ray spectroscopy, Winey and coworkers have observed the same phenomenon on thin sections of Na-EMAA exposed to the humid conditions of a Philadelphia summer for a few days (see Fig. 2). These results clearly show that aging effects in ionomers can be observed and identified on a nanometer scale with the appropriate electron microscopy technique.

Porat et al. have used sulfur mapping and zero loss imaging to investigate Nafion.[31] They report S-rich (and hence $-SO_3^-$ rich) domains of about 5 nm in diameter. Some of the S-rich domains appear to have a ring-like shape. This is intriguing because recently, Winey and coworkers observed similar, so-called vesicular, aggregates in Zn-SPS.[32] The shape observed by Porat et al. could thus be interpreted as evidence for vesicular aggregates in Nafion.[31] Electron diffraction also shows that Nafion crystallizes in a structure very similar to polyethylene, which is unlike the crystal structure of polytetrafluoroethylene, the Nafion base polymer. Unfortunately, this interesting publication has never been followed up.

The authors are only aware of one other study where conventional TEM was used to image ion-rich domains in ionomers. Huang et al. observe features interpreted as ion-rich domains in negatively stained poly(dimethyl siloxane) ionomers with pendant quaternary ammonium groups neutralized with chloride anions (Fig. 3).[4] Here, one does, however, have to

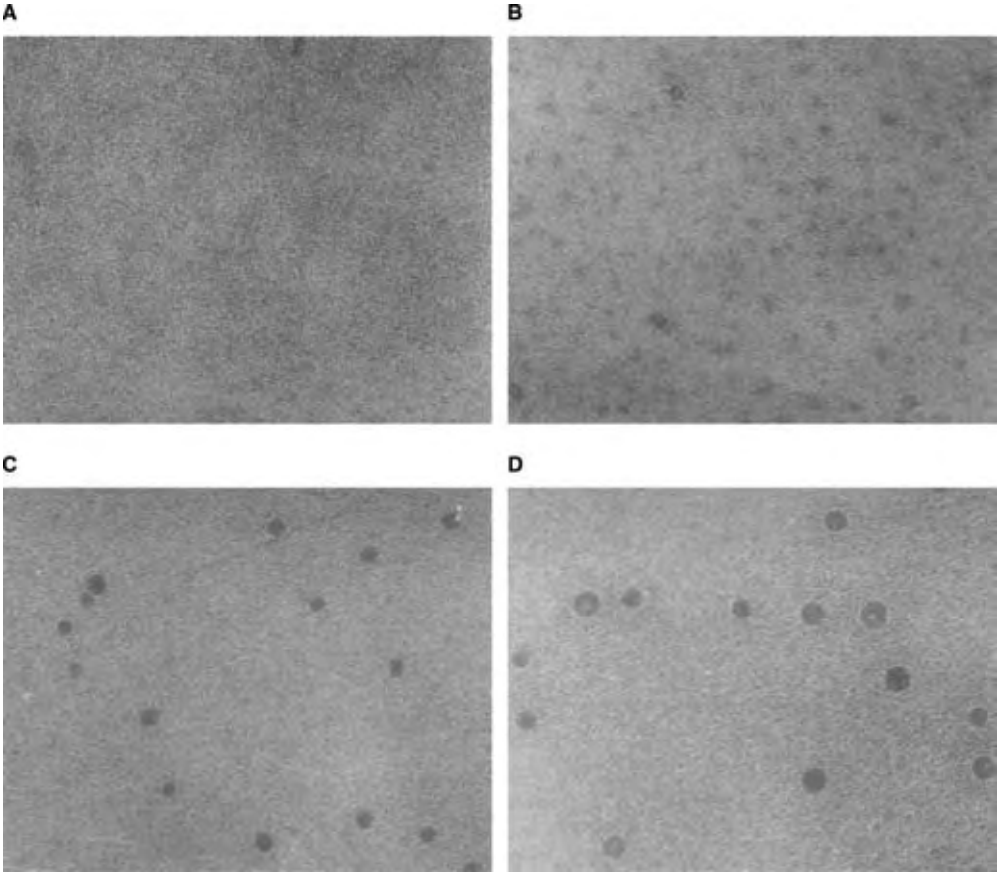

Fig. 3 Transmission electron micrographs of poly(dimethyl siloxane) ionomers with different contents of the ionic γ-(benzyl dimethylamino)propylmethylsiloxy unit: (A) 1.3 mol%, (B) 2.3 mol%, (C) 4.1 mol%, and (D) 10.0 mol%. Some aggregates may have a vesicular structure. (Reprinted with permission from Ref.[4]. Copyright 2004 Wiley–VCH.)

ask how staining affects the morphology of the polymer; also the authors do not elaborate about the shape of the claimed ionic aggregates. This is unfortunate because some of them appear to be vesicular rather than spherical. They thus represent an interesting deviation from models of ionic aggregation, possibly similar to the TEM results by Porat et al. or more recent studies by Winey and coworkers (see below).[31]

Using STEM rather than conventional TEM, Winey and coworkers have successfully imaged ionic aggregates in various ionomers. Scanning TEM has the advantage over TEM that here contrast scales approximately with the atomic number squared, Z^2.[33] This means that STEM provides a powerful tool for imaging high-Z elements like Zn in a low-Z matrix like C. This is exactly what is required for the investigation of ionomer morphology if one is interested in the size, shape, and distribution of ion-rich domains in ionomers.

Scanning TEM shows that semicrystalline Zn-EMAA neutralized between 17% and 78% contains nearly monodisperse spherical aggregates randomly distributed in the polymer matrix (Fig. 4).[34,35] The aggregates in both as-extruded and recrystallized Zn-EMAA are spherical. The diameter of the aggregates is ca. 2 nm, independent of the neutralization level; it increases slightly upon recrystallization. This is more pronounced at higher neutralization levels (see Fig. 5). Finally, at 17% neutralization the ionic aggregates are widely separated relative to the polymer chains, which is not the case at higher neutralization levels. Similar to Grady et al.[12] the authors suggest that the ionic aggregates include segments from the nonionic polymer backbone and that the aggregate morphology is primarily the result of ionic interactions in the system.[34,35]

These results thus support the Yarusso-Cooper model, where it was suggested that in any ionomer,

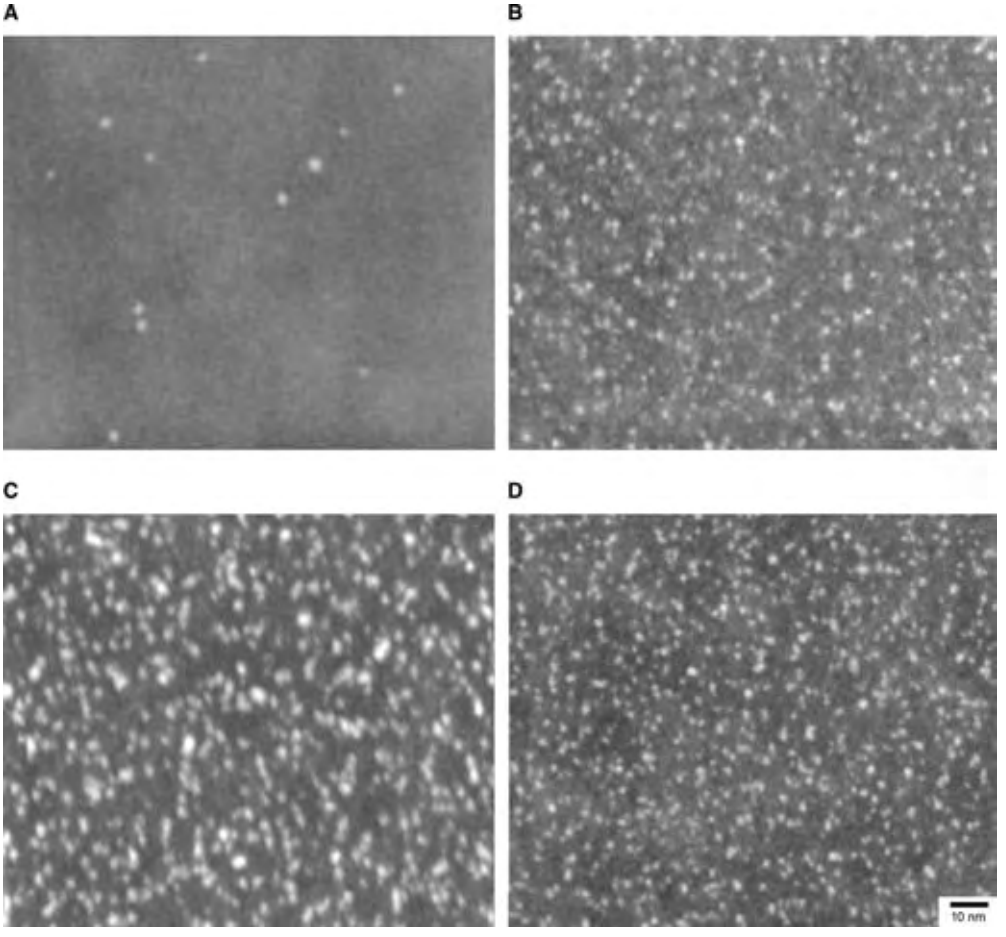

Fig. 4 Annular dark field STEM images of as-extruded EMAA neutralized to various extents with Zn^{2+}: (A) 17%, (B) 29%, (C) 55%, and (D) 78%. Here, bright regions correspond to higher average atomic number and hence to Zn-rich ionic aggregates. Nearly spherical ionic aggregates of ca. 2.1 nm are present at all neutralization levels, though the areal number density of aggregates increases substantially between 17% and 29% neutralization. (Reprinted with permission from Ref.[34]. Copyright 2004 American Chemical Society.)

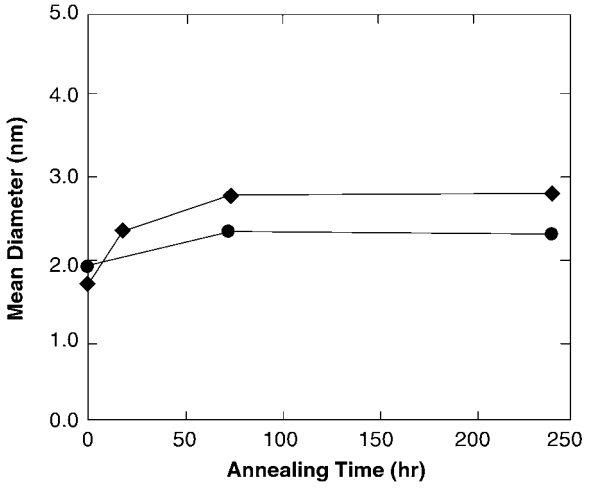

Fig. 5 Effect of thermal history on aggregate size in Zn-EMAA: the mean diameter for Zn-EMAA neutralized to 29% (circles) and 78% (diamonds) with Zn^{2+} increases slightly with annealing time. (Reprinted with permission from Ref.[34]. Copyright 2004 American Chemical Society.)

the ion-rich domains are only a few nanometers in diameter and are randomly dispersed in a hydrophobic matrix.[17] It is furthermore similar to the Eisenberg–Hird–Moore model, where spherical aggregates of ionic groups were postulated.[19] However, a significant deviation from the models was found at low neutralization levels, where only a few aggregates were observed.

It came as a major surprise when STEM images of amorphous Zn-SPS revealed a macrophase-separated morphology at the micrometer size scale (Fig. 6). In lightly neutralized ionomers, only some regions contain detectable aggregates.[32,36] Furthermore, a new aggregate morphology was observed: vesicular aggregates coexist with the expected spherical domains (Fig. 7). The spherical aggregates have diameters from 4 to 10 nm, whereas vesicular aggregates have diameters from 9 to 55 nm and an aggregate wall thickness of about 3 nm. Lightly neutralized ionomers exhibit only spherical aggregates, whereas higher neutralization levels exhibit both aggregate types. These ionic aggregates thus contradict previous interpretations of SAXS data with respect to size, size dispersity, shape, and spatial distribution, but they clearly demonstrate the need for a technique that is able to assess ionomer morphologies without the need to infer structures from a model. These results further raise the question whether the features observed by Porat et al. in Nafion are not actually vesicular aggregates.[31] If indeed they are, one may have to reassess existing Nafion morphological models.

Similar to Zn-SPS, Cs-neutralized poly(styrene-*ran*-methacrylic acid) (Cs-SMAA) ionomers exhibit Cs-rich vesicular aggregates that are randomly distributed in a

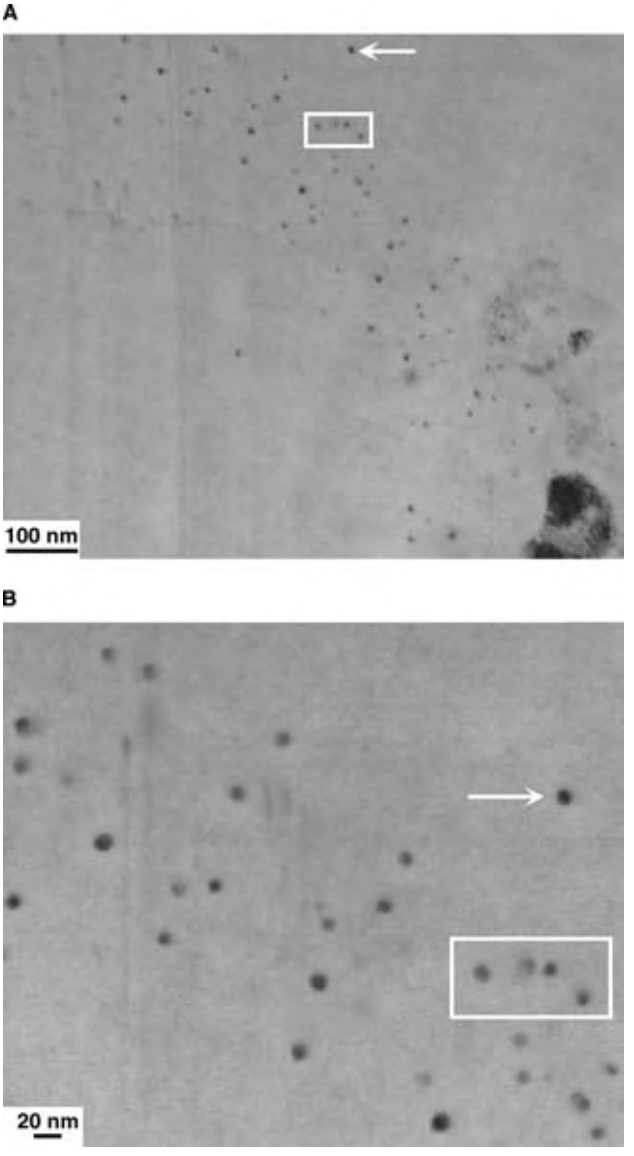

Fig. 6 Bright field STEM images showing the shape homogeneity and spatial heterogeneity in Zn-SPS neutralized to 25%. (A) Macrophase separation of ionic aggregates. Aggregates are only observed in a ca. 200 nm band across the field of view. (B) The Zn-rich aggregates indicated by the box and arrow in (A) are shown at higher magnification. Only uniform and spherical aggregates exist at 25% neutralization. (Reprinted with permission from Ref.[32]. Copyright 2004 Wiley–VCH.)

polystyrene-rich matrix.[37] Here, the aggregates are typically 5–20 nm in diameter and have a shell thickness of ca. 3 nm. The vesicular aggregates are invariant to annealing and their dimensions and number density remain unchanged. The aggregate diameters and shell thickness are independent of the copolymer concentration and the rate of neutralizing agent addition during solution neutralization. Like Zn-SPS, Cs-SMAA is thus quite resistant to various treatments.

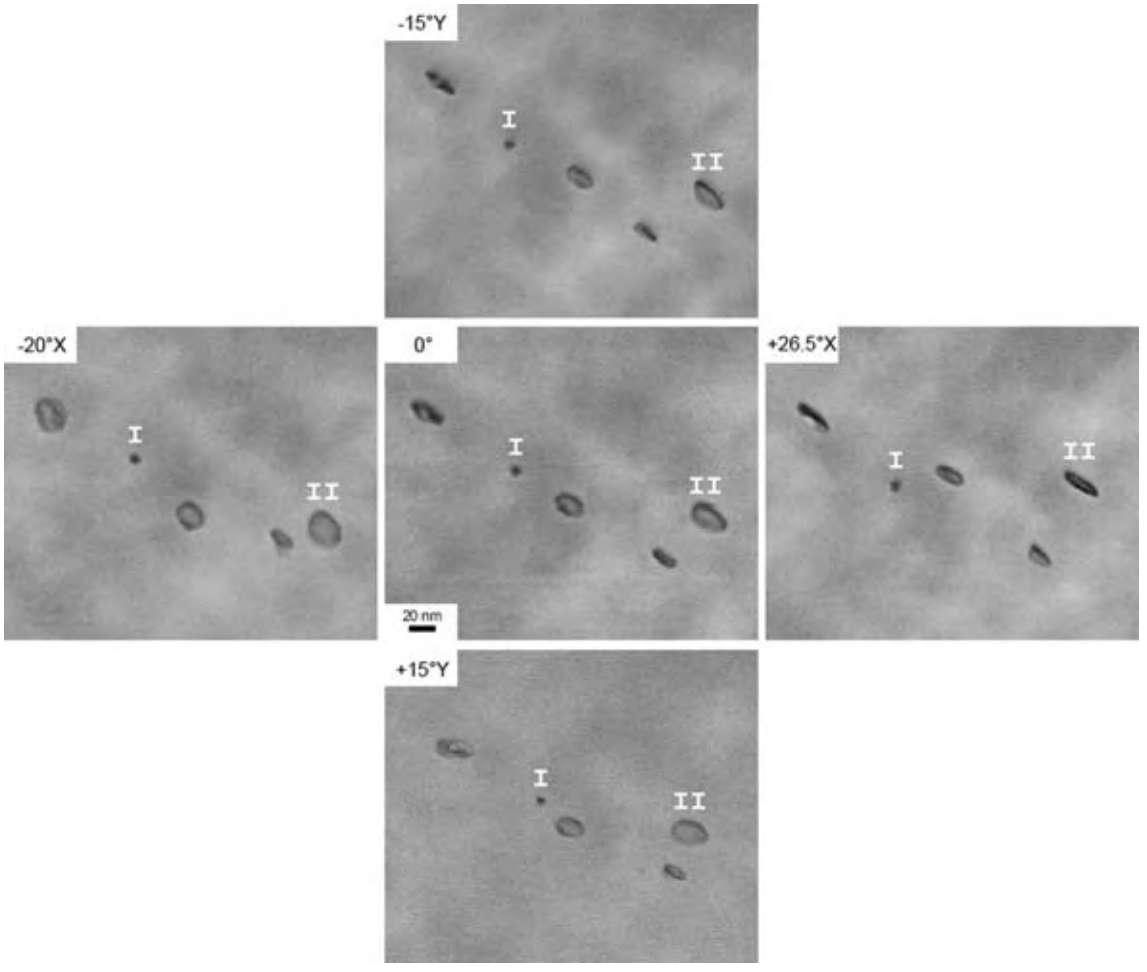

Fig. 7 Bright field STEM images showing the shape heterogeneity in SPS neutralized to 100% with Zn. The double-tilt series shows multiple projections of the Zn-rich aggregates to determine the aggregate shape. The horizontal and vertical sets of images were collected after rotating the sample about the *x* and *y* axes, respectively, by the amounts indicated in the figure relative to the untilted central image. The index I refers to a spherical aggregate; II refers to vesicular aggregates with a wall thickness of about 3 nm. (Reprinted with permission from Ref.[32]. Copyright 2004 Wiley–VCH.)

Also similar to Zn-SPS, Na-EMAA does exhibit macrophase separation after annealing at 60°C (Fig. 8).[38] Recrystallized Na-EMAA has a macrophase-separated structure where three phases with distinct boundaries coexist: no aggregates are observed in the so-called phase I, phase II shows rather small spherical aggregates with diameters of ca. 2–15 nm, and phase III exhibits large, approximately spherical aggregates with diameters from ca. 20 to 160 nm and rather diffuse boundaries. In contrast, the original, as-extruded Na-EMAA does not show any features on the STEM length scale. Like the findings discussed above, this study shows that thermal history has a significant impact on ionomer morphology on a nanometer length scale. Also, it is interesting to compare the results from ^{23}Na-SSNMR with the STEM results: NMR suggests that thermal treatments do not have a measurable impact on the aggregation in Na-EMAA, but STEM shows that on a nanometer length scale, processing drastically affects the morphology.[9,38]

Na- and Zn-EMAA blown films exhibit the same characteristics as the bulk material, that is, the blowup process does nothing to the morphology of Zn-EMAA but Na-EMAA does change with blow conditions similar to bulk Na-EMAA (N. M. Benetatos and K. I. Winey, in preparation).

Finally, two Al-neutralized copolyimides from (4,4'-hexafluoroisopropylidene) diphthalic anhydride, (4,4'-hexafluoroisopropylidene) dianiline, and 3,5-diaminobenzoic acid exhibit a variety of aggregate shapes and sizes that have not been previously observed or even postulated.[39] Scanning TEM shows Al-rich aggregates in both copolymers, but the aggregate size and shape distributions in the ionomer with a high ionic fraction are much more heterogenous than in the ionomer with a lower ionic fraction. This is despite

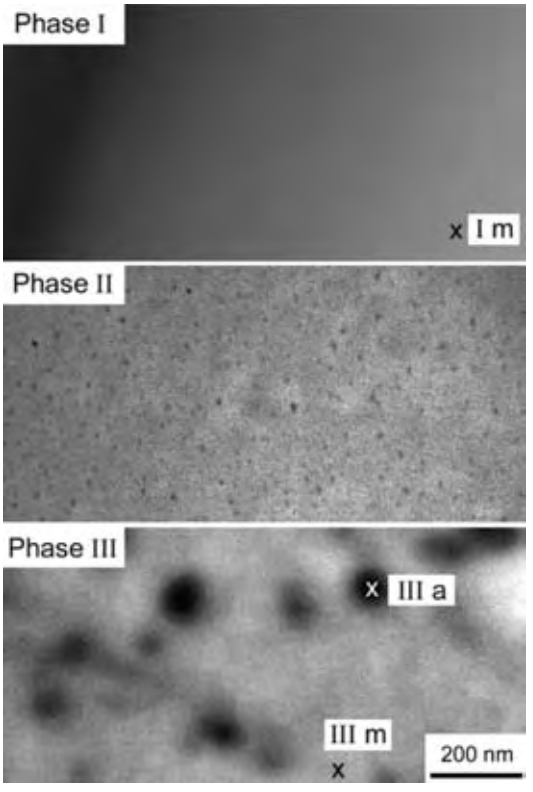

Fig. 8 Bright field STEM images of Na-EMAA showing three distinct phases. Phase I is featureless on the STEM length scale, phase II contains small spherical aggregates, and phase III contains large spherical aggregates. The designations ''a'' and ''m'' denote the locations of energy dispersive x-ray spectra taken of the aggregates and the matrix, respectively (data not shown, see Ref.[38]). (Reprinted with permission from Ref.[38]. Copyright 2004 American Chemical Society.)

the fact that the SAXS patterns of the two samples are identical. The former ionomer contains spherical aggregates ranging from ca. 5 to 25 nm in diameter, chain-like features, vesicular aggregates, and long, stripe-like aggregates with a length of up to 1000 nm. The latter ionomer contains only a few roughly spherical aggregates. Large fractions of both ionomers do not exhibit visible aggregates on the STEM length scale; this is again similar to several of the polymers described above.

At this point, it has to be noted that the analysis of STEM data is not straightforward. Similar to AFM, where the images are a convolution of the tip shape and size and the actual feature size and shape, the shape and size of the beam in the STEM will lead to convoluted images. Kirkmeyer et al.[40] have recently shown that STEM image deconvolution provides additional useful information about the ionic aggregates (Fig. 9). The deconvoluted images are sharper than the original and exhibit decreased noise levels. This simplifies detection of the aggregates and measurement of their size and shape in comparison with the original image. Both raw and deconvoluted images of spherical ionic aggregates in Zn-SMAA suggest that the electron density varies smoothly from the edge to the center of the aggregates. Line scans across single aggregates in deconvoluted STEM images suggest that the three-dimensional density distribution of these aggregates resembles a radially symmetric Gaussian distribution and not a uniformly dense sphere. This issue is currently addressed by N. M. Benetatos and K. I. Winey (personal communication).

What is not known, however, is whether image deconvolution can eliminate beam spreading as a contributor to the line scan shape. One would expect that beam spreading from a dense array of sources like the aggregates would obscure features beyond the resolution capabilities of the microscope. In this instance, deconvolution would provide only a modicum of aid in image interpretation. The authors of this entry however believe that beam spreading is a minimal contributor to the image.

Another significant issue is how STEM-observed ionic aggregates and SAXS-proposed multiplets are related, if at all. One possibility is that the aggregates and multiplets are actually the same features, but the measurement techniques skew the data. An example of this is related to the line scans detailed above. If the aggregates/multiplets are in fact Gaussian spheres, then a SAXS hard sphere data fit would interpret the features as smaller than they are, while a STEM direct measurement at the periphery of the features would interpret them as larger. Another possibility is a two-tiered morphology, each one accessible by only one technique. The 2–3 nm features observed in STEM would scatter near the beamstop in SAXS, while the <1 nm features from the SAXS data fits would not generate enough contrast to be observed in STEM. In this instance, the aggregates could be responsible for the low-angle upturn in SAXS. However, to the authors' knowledge, this issue is to date unresolved.

Besides (S)TEM, atomic force microscopy (AFM) has also been used to image ionomers. Chomakova-Haefke et al. report that dry Nafion has a disordered network structure, which reorganizes into parallel fibrils upon swelling.[41] No substantial changes in the fibril dimensions are found in the swollen state. This was interpreted as an indication that swelling occurs at the supramolecular level but this interpretation was not elaborated further. Also in Nafion, Lehmani et al. found spherical grains of ca. 11 nm in diameter surrounded by ca. 5 nm thick regions.[42] The authors speculate that the 5 nm features may correspond to some type of ionic aggregate, but both studies have remained inconclusive as to what the features really represent.

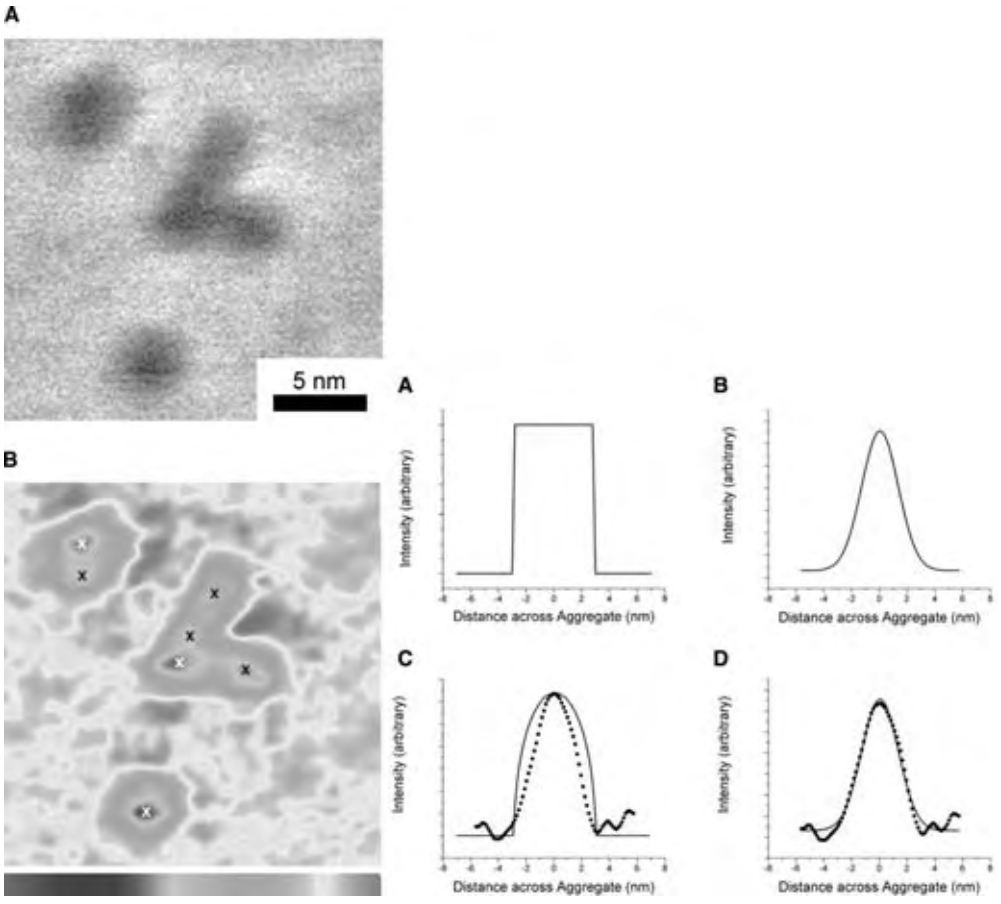

Fig. 9 Left: High-magnification images of the Zn-SMAA ionomer morphology: (A) grayscale raw STEM image and (B) grayscale image model. The images show both the decrease in the noise level and the multiple brightness maxima in various ionic aggregates, indicating an overlap of ionic aggregates in the projection. Each ''x'' indicates a brightness maximum. Right: (A) Line scan through the center of a three-dimensional solid sphere, (B) line scan through the center of a three-dimensional Gaussian sphere, (C) intensity profile across a projected ionic aggregate in Zn-SMAA (∗) and the best-fit curve of the intensity profile across a projected three-dimensional solid sphere (–), and (D) intensity profile across a projected ionic aggregate in Zn-SMAA (∗) and the best-fit curve of the intensity profile across a projected three-dimensional Gaussian sphere (–). Furthermore, using tapping mode AFM, Hill et al. have found features called ''bundles of micelles'' in Nafion thin films on silicon.[43] The films show no dewetting even above the glass transition temperature, but high-ionic-strength solutions like 20 wt% $NaHSO_4$ destroy the aggregates and lead to dewetting.

Scanning tunnelling microscopy, scanning electrochemical microscopy, and AFM-surface potential measurements have also been used to investigate Nafion films. Scanning electrochemical microscopy reveals a domain-like structure containing circular features ca. 1-2 nm in diameter made up of a conductive center (presumed to be ion-rich regions) surrounded by a much less conductive zone.[44] Atomic force microscopy surface potential measurements detect features that were interpreted as ion channels in Nafion membranes. The size of the claimed ion channels was 40–100 nm and several tens of the presumed channels were observed in a 10 × 10 μm region.[45]

James et al. have studied Nafion membranes in different states of hydration using an AFM with an environmental chamber to control the humidity (Fig. 10).[46,47] Tapping mode was used to identify the hydrophobic and hydrophilic regions of Nafion. As a main finding the authors report that the number of the supposed ionic domains decreases while the average size increases with increasing humidity. Similarly, Umeda and coworkers have shown that as-prepared Nafion films have an irregular surface morphology with features of ca. 10–30 μm. Upon exposure to methanol vapor the surface became relatively flat.[49,50] These studies provide an important piece of information for the fuel cell community, because the results are obtained from ''active'' material and not, like in

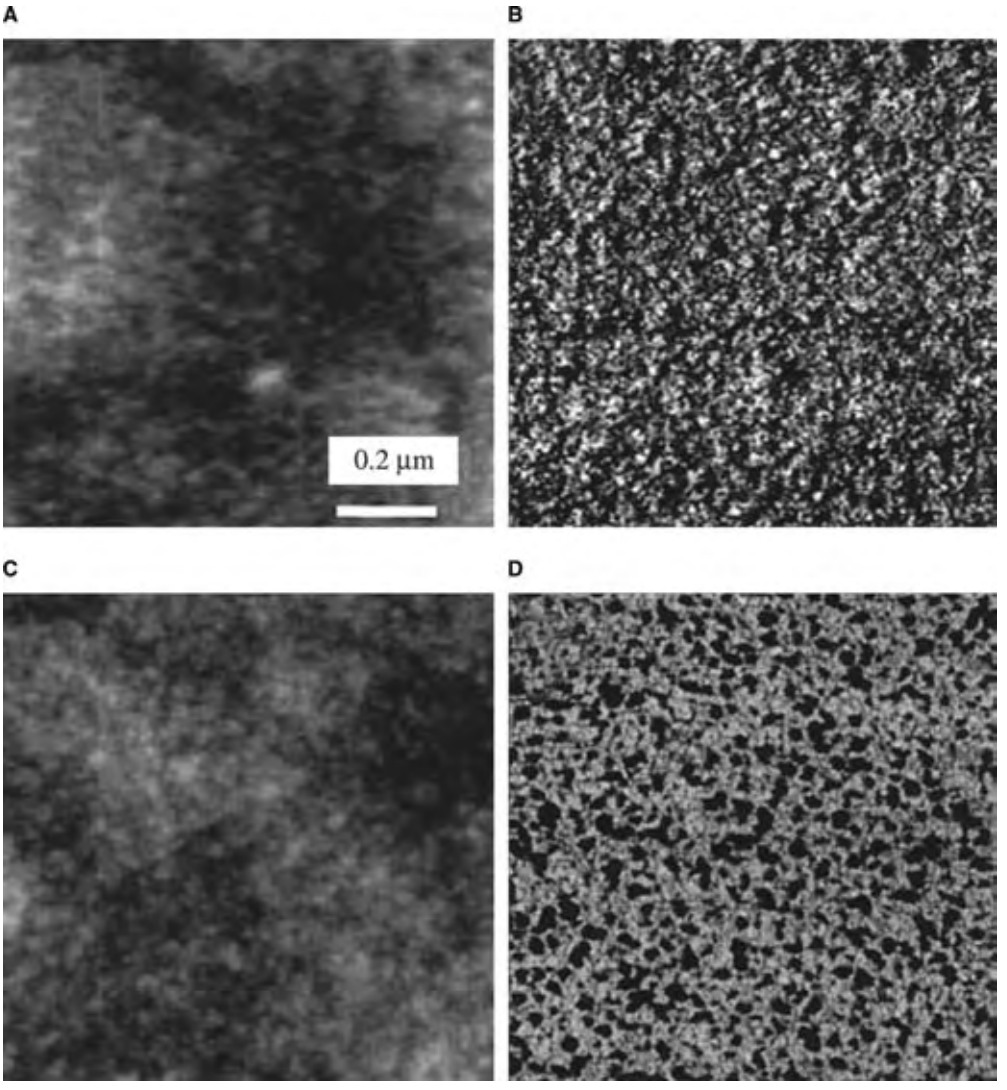

Fig. 10 Tapping mode AFM images of Nafion 115. (A) One-micrometer topography image of Nafion 115 free acid (protonated polymer) imaged under ambient conditions. (B) The corresponding phase image. (C) One-micrometer image of Nafion 115 neutralized with Cs imaged under ambient conditions. (D) The corresponding phase image. The images exhibit a marked difference in the phase contrast between the two ion forms: the phase range is significantly larger in the Cs^+ ion, 60° as opposed to 10° for the H^+ form.[48] There is no significant difference in the topography images; therefore topographic coupling is not responsible for the change in phase contrast. These images thus demonstrate that phase imaging can indeed yield some information about aggregation in ionomers. (Reprinted with permission from Ref.[48]. Copyright 2004 American Chemical Society.)

(S)TEM, from dry, thin sections of an ionomer. They also demonstrate, however, that ionomer physics is far from understood. For example, it is not clear yet how the different features and dimensions observed in AFM connect to one another or to the results obtained from other studies.

Much like James et al., Sauer and coworkers use tapping mode AFM technique to detect ionic aggregates in Zn-EMAA and Nafion.[46,47,51,52] Zn-EMAA exhibits crystalline polyethylene lamellae and noncrystalline regions. Operating the AFM under special low oscillation amplitude gave images that were interpreted by the authors as showing ion-rich regions and individual ionic domains. The diameter of the claimed individual domains was ca. 2 nm, similar to results obtained from STEM.[34] Further experiments showed that the lamellar morphology and perfection are controlled by chain mobility in the melt, which depends on acid level, neutralization level, and counterion. Nafion contains individual fluorocarbon crystallites separated by a matrix containing features interpreted as the ionic domains. While no particularly surprising structures were thus revealed in these studies of either Zn-EMAA or Nafion, it would be interesting to investigate the effects of thermal treatment on Na-EMAA or polymers where unexpected morphologies have

been observed in STEM to determine whether or not the same features are observed with the AFM.

Using scanning electron microscopy (SEM) with x-ray microanalysis rather than (S)TEM or AFM, Schulze et al. and Tierney and Register have investigated the elemental distribution of Nafion and EMAA ionomers, respectively, on a micrometer length scale.[53,54] Schulze et al. showed that the Na counterion in Nafion/polytetrafluoroethylene (PTFE) membranes in fuel cells are closely associated with the sulfonate anion and that PTFE does not take up Na during the solution neutralization of Nafion.[53] Tierney and Register have measured ion-hopping times by allowing a finite slab of one ionomer to diffuse into a matrix of a second ionomer. The distribution of metal cations was measured via x-ray line profiling in the SEM and it was shown that in Mg/Ca, Mg/Li, Na/Ca, and Na/Li diffusion couples the diffusion coefficient follows inversely with melt viscosity.[54]

Before concluding it must be clearly stated that when using a microscope it is of utmost importance to realize its limitations. One of the major issuess in AFM and STEM (at the high resolutions and magnifications required for ionomer work) is drift: if a feature is only a few nanometers in diameter, great care has to be taken to ensure that the sample does not move during the measurement. Even drift of 1 or 2 nm can dramatically affect the outcome. Furthermore, James et al. have pointed out that tapping-mode phase imaging is a very useful tool for identifying and mapping regions of different properties regardless of their topographical nature but that the interpretation of the AFM data is not trivial.[48] Both STEM and AFM do of course also have limitations as far as the atomic resolution of the ion-rich aggregates is concerned. They are thus not suited for the elucidation of the atomic arrangements in, e.g., ion-rich domains. Their power lies in the capability to provide an independent view of ionomers, which can validate existing models of ionomer morphology and thus contribute to a better understanding of the physics of ionomers.

CONCLUSIONS

This article shows that microscopy of ionomers is a powerful complementary technique to various spectroscopic and macroscopic techniques like EXAFS and rheology for the investigation of ionomers. If precautions are taken and data are carefully analyzed, microscopy can thus add valuable insights to results from other studies. Because of this, microscopy of ionomers is not only of interest for the scientist trying to understand the physics behind ionomer properties and behavior, but also for the engineer attempting to improve or adapt an existing or new ionomer for a desired application.

ACKNOWLEDGMENTS

The authors thank Prof. K. I. Winey for her support and many discussions during their tenure in the Winey group at the University of Pennsylvania. We also thank R. M. Walters, K. E. Sohn, N. Zhou, and in particular, J. Tam, N. M. Benetatos, Prof. R. J. Composto, and Prof. Y. E. Elabd for help in the laboratory and many useful discussions. Prof. J.-S. Kim is acknowledged for useful suggestions during manuscript preparation. Dr. D. M. Yates is acknowledged for help with the STEM and Prof. D. B. Williams for very insightful discussions on the technology of STEM. The writing of this entry was supported by the Swiss National Science Foundation and International Flavors and Fragrances (IFF). While at UPenn, A. T. was funded by the Petroleum Research Fund of the American Chemical Society (ACS).

Microwave Processing of Ceramics

Eldon D. Case
Chemical Engineering and Materials Science Department, Michigan State University, East Lansing, Michigan, U.S.A.

INTRODUCTION

Microwave processing of ceramics may be categorized in many ways, but two helpful schemes are: i) high-temperature processing and ii) low- or intermediate-temperature processing. For ceramics, high-temperature processing includes sintering and joining of ceramics.

Of course, microwaves are used for a variety of low-temperature processing applications. For materials other than ceramics, low-temperature applications of microwave heating include drying wood, preparing food, and synthesizing polymeric materials. For ceramics, low-temperature microwave applications include drying, binder burnout, and the synthesis of oxide and nonoxide ceramic powders.[1] In addition, microwave heating can be used to fabricate ceramic coatings or perform rapid thermal annealing over a range of temperatures.

In general, ceramic microstructure (grain size and porosity) is of central importance in processing, as many of the mechanical, thermal, electronic, and optical properties of ceramics are closely linked with their microstructure.[2] Microwave heating allows one to engineer microstructures and/or optimize processing times in ways that are not available via conventional radiant energy processing. This applies not only to microwave sintering and joining but also to microwave-assisted powder synthesis, drying, and fabrication of coatings. The apparent advantages of microwave processing stem from the volumetric heating and the inverse temperature profiles available from microwave heating. In addition, microwave heating (especially for high-temperature processing) can result in energy savings compared with conventional radiant heating.

MICROWAVE HEATING OF CERAMICS

In the 1950s, engineers working at Raytheon discovered that microwave radiation could be used to heat materials.[3] By the 1960s, scientists and engineers were performing the first microwave sintering studies on ceramic powders. While a number of the earlier experiments were done with 2.45 GHz radiation with magnetron tube power supplies, high power, high frequency gyrotron microwave sources were developed as part of the nuclear weapons research programs in a number of countries.[3] These gyrotron millimeter wave sources have subsequently been used to sinter and to join a variety of ceramic materials. Since the 1990s, the use of microwave heating to dry ceramics, synthesize ceramic powders, and in the fabrication of ceramic coatings has increased steadily.

POWER DISSIPATED BY THE MICROWAVE FIELD

Parameters Governing Microwave Power Absorption

The mechanisms by which microwave energy is absorbed by the entire processing system (the microwave applicator, the specimens, and the thermal insulation) are crucial to understand the microwave processing of ceramic materials. The microwave energy absorbed per unit time per unit volume, p_{abs} (the powder density), can be related to dielectric properties of the material and to the applied electromagnetic field:[4,5]

$$p_{abs} = 2\pi f \varepsilon_r' \tan\delta \langle E^2 \rangle = 2\pi f \varepsilon_r'' \langle E^2 \rangle \quad (1a)$$

where f is the frequency of the incident microwave field, ε_r' the relative dielectric constant of the material, $\tan\delta$ the loss tangent of the dielectric material, $\langle E^2 \rangle$ the time-average of the square of the local electric field, E, ε_r'' the dielectric loss constant ($= \varepsilon_r' \tan\delta$).

The dissipation of microwave power by ceramics is a function of the material properties ε_r' and ε_r'', which are the real (storage) and imaginary (loss) parts of the dielectric constant, respectively. In addition to the frequency dependence of p_{abs} [Eq. (1a)], ε_r' and ε_r'' are themselves functions of the microwave frequency, the ambient temperature, T, as well as material properties, including a number of microstructural and chemical variables. Thus, to emphasize the range of parameters that impact the local power dissipation, we define the following symbols: M denotes the microstructural variables, especially volume fraction porosity (VFP), as well as the size, shape, and the distribution of size

Encyclopedia of Chemical Processing DOI: 10.1081/-E-ECHP-120030627

and shape of pores; C_D denotes defect chemistry, chemistry of atomic-scale defects, especially in terms of concentration and chemical species, the effects of point defects such as vacancies and interstitial atoms.

Using the position vector $\vec{r}$ to indicate the spatial dependence of the material properties, the dependence of ε_r', ε_r'', and tan δ on microwave frequency and temperature as well as on the material's microstructure and chemistry can be denoted symbolically as $\varepsilon_r' \{f, T, M(\vec{r}), C_D(\vec{r})\}$, $\varepsilon_r'' \{f, T, M(\vec{r}), C_D(\vec{r})\}$, tan $\delta\{f, T, M(\vec{r}), C_D(\vec{r})\}$, respectively. To further emphasize the dependence of p_{abs} on a potpourri of physical variables, Eq. (1a) can be rewritten as

$$p_{abs} = 2\pi f \varepsilon_r'\{f, T, M(\vec{r}), C_D(\vec{r})\} \tan \delta\{f, T, M(\vec{r}), \times C_D(\vec{r})\}\langle E^2 \rangle \quad (1b)$$

Examples of the dependence of ε_r', ε_r'', and tan δ on temperature, frequency, and impurity level are given in Figs. 1–3. For a microwave frequency of about 3.5–4.0 GHz, the temperature dependence of ε_r' for three aluminas of differing purity (the purities are 99.5%, 99%, and 90–95% alumina for the topmost, middle, and bottom curves, respectively) is shown in Fig. 1.[6] Fig. 2 shows the dramatic temperature dependence of tan δ for the same three aluminas, with the onset of the rapid rise in tan δ occurring at increasingly lower temperatures as the concentration of impurities increases. Fig. 3 demonstrates the sensitivity of ε_r'' to changes in frequency for magnesium oxide at seven different temperatures from 25°C to 1200°C.[6]

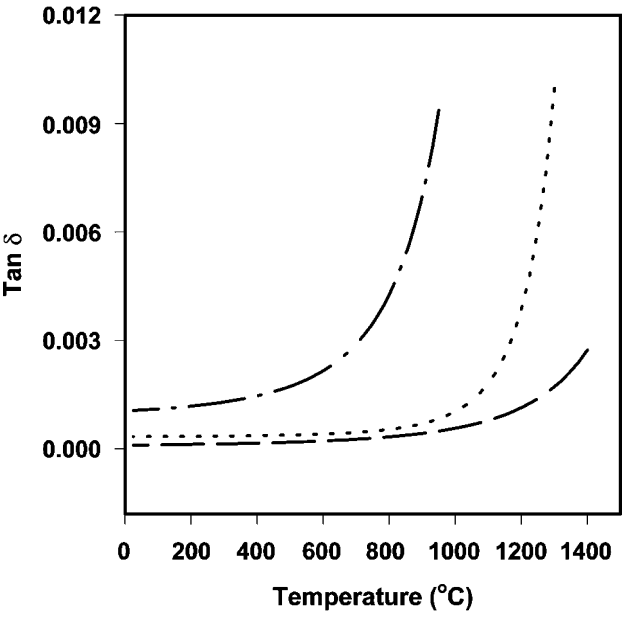

Fig. 2 The temperature dependence of tan δ for polycrystalline alumina with the following purities: 99.5% (bottom curve), 99% (middle curve), and 90–95% (topmost curve). (From Ref.[6].)

As can be seen from Eq. (1b), the magnitude of ε_r'' or tan δ indicates how easily a material absorbs the microwave energy that is subsequently converted into heat energy. At room temperature, most ceramics are "low loss" and thus not heated readily by

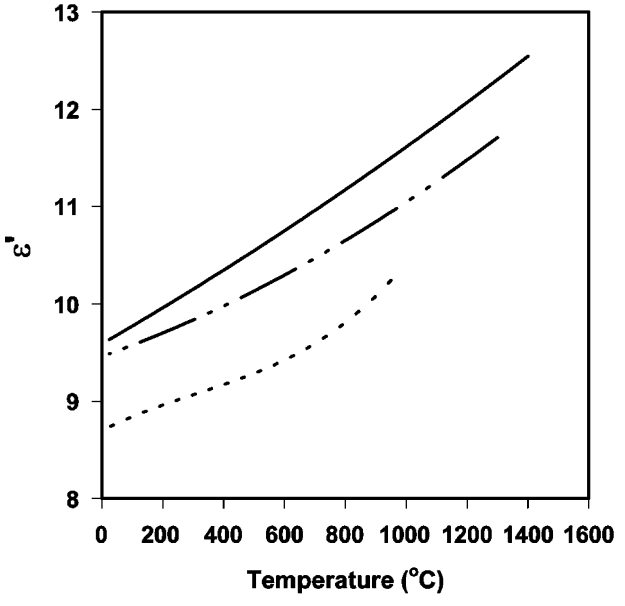

Fig. 1 The temperature dependence of ε_r' for polycrystalline alumina with the following purities: 99.5% (topmost curve), 99% (middle curve), and 90–95% (bottom curve). (From Ref.[6].)

microwaves, with tan δ values of roughly 10^{-3} to 10^{-4} for microwave frequencies. In contrast, ceramic susceptor materials (such as SiC) are lossy dielectrics at room temperature with tan δ values of about 10^{-1} to 1 at microwave frequencies. However, for most ceramics, tan δ and ε_r'' rise rapidly for temperatures above roughly 600–1000°C; hence, most ceramics readily couple with microwaves at elevated temperature.[1,6]

For high-temperature microwave processing of ceramics, the use of refractory specimen enclosures (caskets) is a natural consequence of the temperature dependence of ε_r'' or tan δ. Refractory caskets typically: 1) are fabricated from susceptor materials or 2) include susceptor materials that are placed inside the refractory casket, near the dielectric specimens. At low temperatures, the susceptor materials within the casket absorb microwave energy, heating the casket. The heated casket then radiatively heats the low loss ceramic specimens contained within it. However, as the processing temperature increases, the specimen's dielectric loss also increases (as in Fig. 2) until the specimen also couples directly with the microwave energy. This combination of radiative and direct microwave heating is termed "hybrid heating" and is often used in sintering, joining, and etching of ceramics.

In addition to the conversion of microwave power into heat, the dielectric constants also determine the manner in which microwave radiation penetrates a ceramic. Low loss ceramics are relatively transparent to microwave radiation, while electrically conductive materials reflect microwave radiation (Fig. 4).

Partitioning of Power Within the Cavity

Several power dissipation mechanisms are involved in heating a dielectric using microwave radiation. For an extended body such as a specimen or the refractory casket, p_{abs} is the local microwave power absorption. P_C and P_S give more global measure of the power dissipation in a dielectric, the spatial averages of the power density in the dielectric body. For the casket, p_{absc} is integrated over the casket volume, V_C, to give[4,5]

$$P_C = \int_{V_C} p_{absc}\, dV \tag{2a}$$

Likewise, the power dissipated in the specimen, P_S, is given by p_{abss} integrated over the specimen volume, V_S, to give[4,5]

$$P_S = \int_{V_S} p_{abss}\, dV \tag{2b}$$

The total microwave power, P_T, absorbed by the entire processing system is[4,5]

$$P_T = P_I - P_R = P_W + P_C + P_S \tag{3}$$

where P_I is the microwave input power, P_R the reflected microwave power, P_W the power dissipated by the cavity wall, P_C the power absorbed by the casket, and P_S the power absorbed by the specimen.

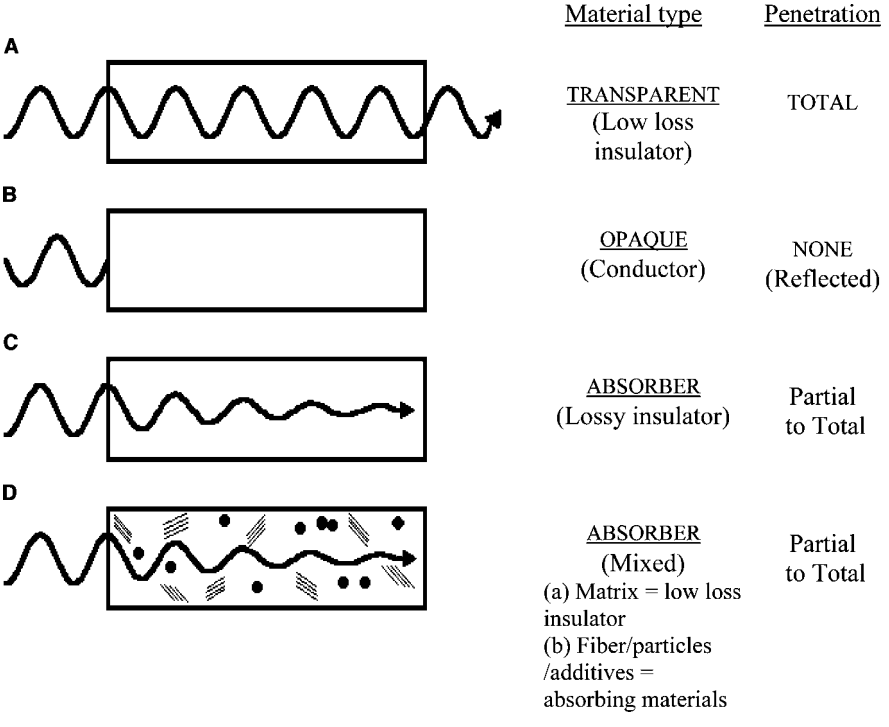

Fig. 4 Schematic diagram showing the nature of reflection and absorption from (A) low loss dielectric, (B) metallic, (C) monolithic high loss dielectric, and (D) a composite or particulate ceramic with high dielectric loss. (From Sutton, W.H. Microwave processing of ceramic materials. Am. Ceram. Soc. Bull. **1989**, *68*, 376–386, Fig. 2, page 377. In a microwave cavity loaded with a lossy dielectric material (such as a ceramic), the power is absorbed mainly by the casket (specimen enclosure) and the specimen. The losses in the cavity wall can typically be ignored[7] such that Eq. (3) can be written as

$$P_T = P_I - P_R = P_C + P_S \quad (4)$$

The discussion above has several implications. During high-temperature heating, the power is dissipated mainly by the refractory casket and the specimens. Also, refractory specimen enclosures (caskets) can allow the high-temperature microwave heating of ceramics that have low losses at room temperature. In addition, for microwave heating of caskets and specimens alike, the dependence of the power dissipation upon material properties [Eq. (1b)] complicates the modeling of the microwave heating process.

Analytical and Numerical Modeling of Microwave Heating

The temperature fields induced by microwave heating can be modeled via the simultaneous solution of Maxwell's equations (for the electromagnetic component of the problem) and the heat equation. The modeling is very challenging, in part because the dielectric constants ε_r' and ε_r'' are functions of temperature and the microwave frequency as well as of the microstructural and chemical details of the ceramic [Eq. (1b)]. Also, the thermal conductivity, k (which is needed for the heat transfer calculations), typically is a function of temperature as well as of microstructural variables such as porosity.[2]

A consequence of the complex interplay of the dielectric and thermal properties with the imposed microwave field is that both Maxwell's equations and the Fourier heat equation are mathematically nonlinear (i.e., they are in general nonlinear partial differential equations). Although analytical solutions have been proposed under particular assumptions,[8] most often microwave heating is modeled numerically via methods such as finite difference time domain (FDTD) techniques.[9] Both the analytical and the numerical solutions presume that the numerical values of the dielectric constants and the thermal conductivity are known over the temperature, microstructural, and chemical composition range of interest, but it is rare in practice to have such complete databases on the pertinent material properties.

As an example of the property changes induced by microwave processing, in the sintering process a porous ceramic powder compact evolves toward a dense body during heat treatment at elevated temperatures. During densification, changes in ε_r', ε_r'', and k can be large in amplitude and complex in nature. The lack of data on ε_r', ε_r'', and k can then result in large discrepancies between the predicted and the actual temperature fields during microwave processing. Moreover, even if the temperature field within the ceramic body is fully specified, it still can be extremely difficult to map the temperature–time values into the microstructural evolution (densification and/or grain growth, for example) experienced by a particular ceramic powder compact.

MICROWAVE CASKETS (SUSCEPTORS AND THERMAL INSULATORS)

For high-temperature microwave ceramic processing, the refractory specimen enclosure (the casket) serves as both i) a thermal insulator and ii) a microwave susceptor. The susceptor allows the microwave energy to couple with the material at high temperature. The thermal insulation diminishes the dissipation of thermal energy. On occasion, the caskets are referred to as "susceptors," which does not fully depict the dual role of the specimen enclosure or "casket" as both a thermal insulator and a microwave susceptor (absorber).

In general, there are two basic strategies in casket construction: one is to incorporate separate thermally insulating and susceptor materials and the other is to include materials that can serve both functions. The casket may consist of a number of substructures, reflecting its dual role. The outer part of the casket often is either a prismatic box or a cylinder composed of ceramic insulating material. Within the outer insulating shell of the casket are the specimens and a "setter" material that supports the specimens during densification or joining. Some casket designs position microwave susceptor materials and/or additional thermal insulation between the outer shell and the specimens (Fig. 5). Prior to discussing particular casket configurations, it is of interest to consider particular examples of insulating and susceptor materials used in microwave processing.

The susceptor materials used in high-temperature processing include zirconia, boron nitride, graphite, carbon black, sodium-beta alumina, zinc oxide, and silicon carbide. While each of these susceptor materials has relatively high dielectric losses at room temperature, silicon carbide is also refractory with a relatively good resistance to oxidation at temperatures up to roughly 1500°C.[10]

Ceramics used for thermal insulation of microwave caskets include alumina, aluminosilicates, mullite, and fused silica, each of which is relatively "transparent" to microwave radiation and thus have low dielectric loss at room temperature. The insulating materials included in the casket are typically in the form of ceramic fibers, fiberboard, or a granular bed of ceramic

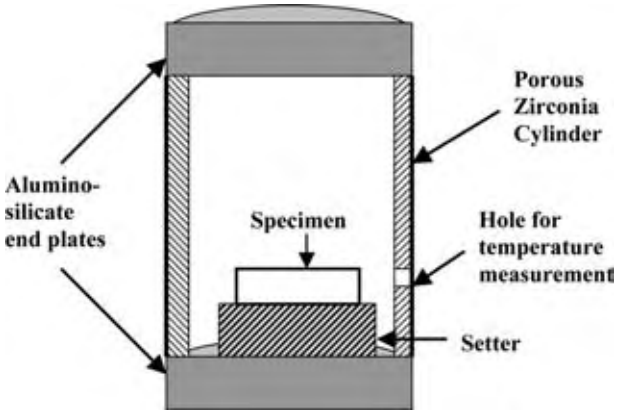

Fig. 5 A cross-sectional schematic view of the type of casket shown in Fig. 6. The casket is sectioned along a plane coincident with the casket's cylinder axis and shows the specimen setter and the specimen.

particles where the material's high porosity not only boosts the material's insulating capabilities but also tends to inhibit thermal shock damage in the insulator. (Rapid heating and cooling induces thermal gradients that can in turn generate mechanical stress and cracking. Such damage is referred as thermal shock damage.) In particular, ceramic fiberboard material offers some structural stability compared with powders or entirely fibrous materials. Fiberboard also is commercially available in sheets or hollow cylinders that are easily cut to the needed dimensions for caskets. For example, zirconia and/or aluminosilicate fiberboard has been used widely as microwave casket materials during joining and sintering operations at temperatures as high as 1600–1650°C.[4]

Although zirconia and aluminosilicate fiberboard insulation materials are quite versatile, hot spots tend to form in them during microwave processing, with the hot spots becoming increasingly prevalent in the temperature range of 1500–1650°C.[4,11] Such local hotspots are a manifestation of the "thermal runaway" phenomenon that may occur in both specimens and casket materials. As a material's temperature is raised, its dielectric loss, ε_r'', typically increases. Increasing ε_r'' then induces an increase in the local power absorption per unit volume (p_{abs}), which leads to further increases in the material's local temperature. Hot spots can result from inhomogeneities in either the material's dielectric loss and/or the electromagnetic field distribution and can lead to local melting.

In Fig. 6, the refractory casket is composed of a hollow, porous fiberboard zirconia cylinder. The zirconia cylinder is capped on both ends with porous endplates cut from a flat aluminosilicate fiberboard. In this case, the zirconia cylinder serves as both a susceptor and a thermal insulator. The processing temperature is measured via a circular hole in the cylindrical wall of the casket, which allows one to site an optical pyrometer on the specimen during heating (Figs. 5 and 6).

As an alternative, the casket may include separate insulator and susceptor materials. For example, in some caskets, a circular array of solid cylindrical SiC susceptor elements is embedded in porous ceramic insulation surrounding the specimen.[10] Instead of an array of rods, susceptors consisting of open tubes or crucibles also have been used.[10] Extremely high microwave sintering temperatures (>2100°C) have been achieved using a multistage casket consisting of i) a BN crucible enclosing the specimen, ii) a granular bed of BN particle/zirconia fibers outside the BN crucible, and iii) an outer layer of an alumina fiberboard.[12]

In addition to thermal runaway, microwave processing encounters the typical problems associated with high-temperature processing materials. For example, at elevated temperatures, local melting can occur because of eutectic reactions between materials. Solid-state diffusion or vapor phase transport between the specimen and the setter can contaminate the specimen. Another type of problem encountered during high-temperature processing is that fibrous and fiberboard materials tend to densify (and hence shrink and crack) if held at elevated temperatures for extended lengths of time. This may limit the useful lifetime of ceramic fiberboard casket elements to perhaps between 5 and 20 heating cycles.

HIGH-TEMPERATURE PROCESSING OF CERAMICS

Energy Savings

Microwave heating can offer significant energy savings compared with conventional heating,[1] especially for the high-temperature densification or joining of ceramics. For conventional radiant heating, significant thermal energy losses occur from the furnace walls. In contrast, for microwave heating the cavity walls

are relatively cool, as little microwave energy is absorbed directly by the cavity walls when lossy dielectrics such as ceramics are heated. A useful gauge of the energy cost is the energy consumed per unit time per unit mass of a processed ceramic. For example, the microwave sintering of alumina at 1600°C consumes about 4 kWh/kg, while conventional sintering consumes roughly 60 kWh/kg. Similarly, microwave sintering consumes roughly 3 kWh/kg during the 2 hr needed to densify a silicon nitride specimen, while for the same specimen conventional heating would consume roughly 20 kWh/kg for each hour of the 12 hr processing cycle.[1]

Microwave Sintering

During the 1980s and 1990s, much of the effort in microwave processing of ceramics focused on sintering. During that time, there also was a growing interest in ceramic/ceramic joining using microwave energy.

Microwave sintering has been successful with many different ceramics, including oxides such as alumina, zirconia, and hydroxyapatite (HAP) as well as nonoxides such as silicon nitride, silicon carbide, and titanium diboride.[10] The time–temperature history of the processing cycle (Fig. 7) varies with the details of the material and the furnace. For conventional heating, the sintering hold time, T_{hold}, is often several hours or more (Fig. 7). For microwave sintering, T_{hold} is typically 10–20 min or less and T_{hold} may approach zero to minimize grain growth.[3]

The primary interest in microwave sintering of ceramics has been in the promise of ''microstructural engineering'' of particular materials. For example, microwave sintering of SrO- and MgO-doped $LaGaO_3$ rapidly produces (within 10 min) a dense polycrystalline body with a more uniform microstructure than is obtained via conventional sintering,[13] with microwave heated specimens having a 4 μm average grain size. In contrast, the smallest mean grain size that the same researchers were able to achieve via conventional sintering was 10 μm.[13]

In general, covalently bonded materials are difficult to sinter because of their inherently low value of self-diffusivity. However, using microwave heating, silicon nitride with 20 wt.% yttria-doped zirconia has been sintered at 1400°C in a nitrogen atmosphere at a pressure 0.1 MPa. In contrast, via a conventionally heated hot isostatic press, a sintering temperature of 1850°C and a nitrogen pressure of about 180 MPa were required to densify the same silicon nitride/zirconia composition as completely as was achieved by microwave heating at 1400°C.[3]

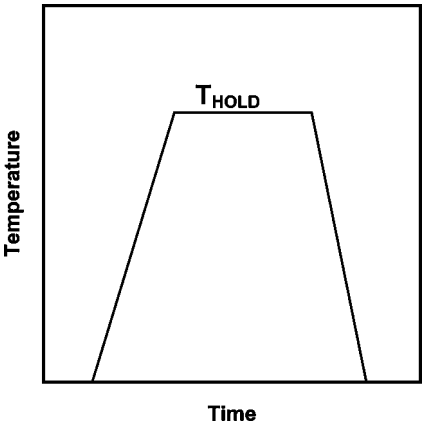

Fig. 7 A schematic of the time–temperature history of the processing cycle. Typically for conventional heating, the time at T_{hold}, the sintering or joining temperature, is in the order of 1 hr to several hours. For microwave processing, the time at temperature T_{hold} is 1020 min or less.

Ceramic/Ceramic Joining

Joining of dissimilar ceramics provides the synergistic advantages of combining materials with differing mechanical, thermal, electrical, or magnetic properties. In addition, ceramic/ceramic joining can create internal channels in ceramics by joining subcomponents with surface channels,[14] thus transforming the surface channels into bulk-penetrating conduits for cooling fluids, fuels, biochemical fluids, or medicine. Ceramics have been joined using both conventional and microwave processing,[15] but as is the case for sintering of ceramics, microwave joining may provide a means of joining at lower temperatures and in shorter times than is possible for conventional processing.

Successful ceramic/ceramic joints between both similar and dissimilar ceramic materials have been achieved both i) by layering materials in the green state, then firing,[16] and ii) by joining fully dense materials (Fig. 8).[17–19] In some instances, microwave

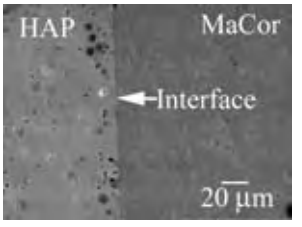

Fig. 8 A scanning electron microscope micrograph of microwave-joined MaCor™ and hydroxyapatite, joined at 1020°C for 20 min in a single-mode 2.45 GHz microwave cavity. (MaCor is a mica-platelet reinforced glass ceramic and HAP is a bioceramic material.) (From Ref.[19]. Reprinted with permission of The American Ceramic Society, www.ceramics.org. Copyright 2003. All rights reserved.)

joining can enhance the performance of the joint, compared with the joining by conventional heating. For example, for ceramic/ceramic joints formed in polycrystalline MgF_2 (an infrared window material), joined specimens exhibited a loss of transmittance because of a conventionally formed joint, while joints formed at the same temperature by microwave heating showed essentially no loss in transmittance because of the presence of the joint.[20]

Thermal Etching

Grain boundary grooving (also called thermal etching) occurs during the high-temperature treatment of polycrystalline ceramics by either conventional or microwave heating.[21] The grooves, which represent a balance between grain boundary and surface energies, form along grain boundaries via mass diffusion. Grain boundary etching is of considerable practical importance in terms of grain size measurement. (The surfaces of sintered specimens are polished and then etched to reveal grain boundaries, which allows one to determine both grain size and grain shape.) In the last 10–15 years, thermal grooving has supplanted chemical etching as perhaps the most commonly used method to facilitate grain size measurement in both ceramics and metals, because thermal etching is typically easier to control and yields more uniform results than chemical etching.

An accelerated rate of grain boundary grooving (thermal etching) has been observed in alumina ceramics (Fig. 9), where the etching rate was especially enhanced as the level of impurities increased.[21] The microwave enhancement of the grain boundary etching

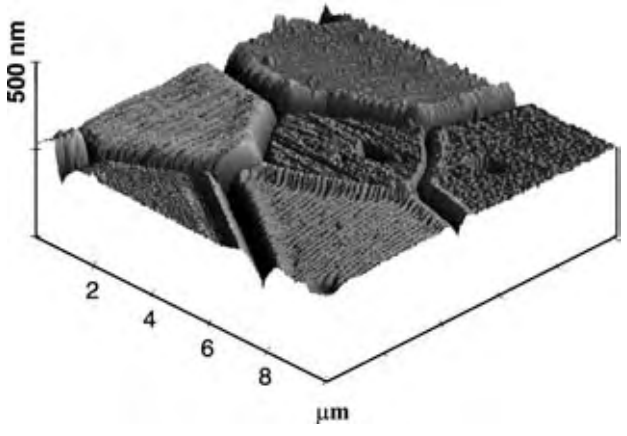

Fig. 9 An atomic force microscope (AFM) image of a polycrystalline alumina specimen that has been polished and then thermally etched by heating for 1 hr at 1527°C in a 2.45 GHz resonant cavity microwave. (From Ref.[21]. Reprinted with permission of EDP Sciences, P.A. de Courtaboeuf, Les Ulis Cedex, France.)

of polycrystalline ceramics is of practical interest, as grain boundary etching is a typical and reliable method of determining the grain size (GS). For both research and development of ceramic materials and quality control for production of ceramic materials, grain size measurements are crucial because a number of mechanical, thermal, and electrical properties of ceramics are functions of grain size.[2]

LOW AND INTERMEDIATE TEMPERATURE PROCESSING OF CERAMICS

Microwave-Assisted Synthesis of Ceramic Powders

While microwave heating has been used to accelerate chemical synthesis in a variety of organic systems, microwave-assisted ceramic powder production also has been done successfully for a number of years.[22] Since the early 1990s, a wide range of ceramic oxides and ferrites have been synthesized using microwave energy,[22,23] along with selected carbides, nitrides, and chalcogenides.[24]

Microwave heating can accelerate chemical reactions in liquids via dielectric heating, reducing the time required to fabricate a given ceramic powder by a factor of 10 or more.[22] It also offers the significant benefits of reducing the particle size and enhancing powder uniformity compared with powder synthesis via conventional heating. In addition, microwave-assisted synthesis of ceramic powders can typically be done at relatively low temperatures with low microwave power. As a consequence, ceramic powder synthesis often can be performed using domestic 2.45 GHz multimode microwave ovens, which tend to be relatively simple, inexpensive, robust, and easily adapted to a variety of uses.

A key aspect of the uniformity of the temperature field in both low- and high-temperature processing is the nature of the thermal gradients within the material. Consider the temperature distributions within a flat ceramic slab of thickness L (Fig. 10). For microwave heating (top curve in Fig. 10), the temperature is relatively uniform within the bulk, with a drop in temperature near the specimen surface owing to heat losses. In contrast, for conventional heating from the specimen surfaces (bottom curve in Fig. 10), the temperature is highest at the surface and lowest near the specimen's midplane.

Microwave-assisted synthesis using a copper acetate and sodium hydroxide solution with an ethanol solvent has produced quasispherical CuO nanoparticles with most particles ranging from about 3 to 5 nm and a mean grain size of roughly 4 nm.[25] In general, it is not easy to fabricate ceramic nanoparticles, in part because it is difficult to achieve the uniform thermal

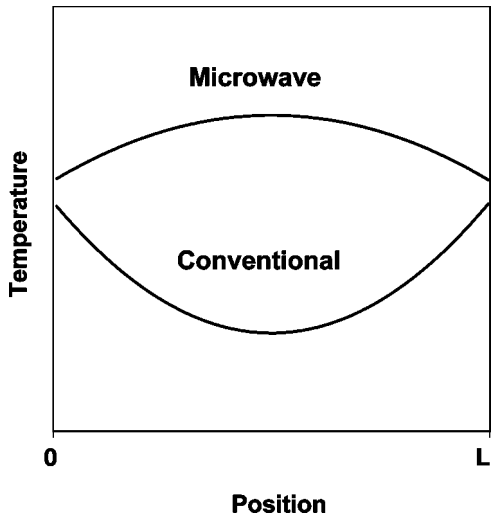

Fig. 10 Schematic of temperature distributions in a flat ceramic slab of thickness L for volumetric microwave heating (top curve) and conventional heating from the slab surfaces (bottom curve). For conventional heating, the finite value of thermal conductivity, k, gives the highest temperatures near the specimen surface and the lowest temperature along the specimen's midplane. Conversely, for microwave heating the heating is more uniform, with decreasing temperature near the slab surface because of heat losses from the surfaces.

environment needed for nanoparticles to nucleate and grow. Fortunately, microwave energy couples well with polar solvents resulting in uniform heating of the solution that in turn promotes the uniform reactant concentration and temperature fields required to synthesize ceramic nanoparticles.[25]

At a temperature of about 80°C, heating using a 2.45 GHz 650 W kitchen microwave oven produced spherical, submicron zirconia powders from zirconyl chloride precursor solutions.[26] A significant link between stirring, microwave heating, and the consequent powder size distributions was noted. For conventional heating, stirring affects the particle size distribution. Without stirring the particle size distribution is broad, while stirring during heating increases the uniformity of both the reactant concentration and the temperature field within the solution, and thus stirring gives a narrower particle size distribution. However, a disadvantage of stirring is that it leads to a shear-induced particle agglomeration.[26] For microwave heating, stirring is not necessary to obtain a uniform temperature field. Microwave heating produces simultaneous nucleation throughout the solution, yielding uniform size distribution without the stirring-induced particle agglomeration.[26]

Suboxide SnO is a candidate anode material for lithium-ion secondary batteries.[26] For the battery to function properly, it is critical that the material remains as the suboxide SnO rather than being oxidized to SnO_2. During conventional SnO processing, the solution is heated (aged) for more than 1 wk to reduce the oxidation rate, then crystallization is induced by further heat treatment (at roughly 75–95°C). In contrast, microwave synthesis of SnO can be completed in roughly 4 min using intermittent or pulsed heating consisting of 1 min long heating intervals interleaved with zero power intervals when the material is allowed to cool.[27] After the powder synthesis is complete, the powders can also be dried by microwave heating, enabling the entire process to be completed in about 15 min, thus avoiding the weeklong aging time.

In addition to the reduced processing time, the physical properties of microwave-fabricated SnO powders can be significantly different than conventionally prepared SnO powders. While microwave heating gives crystalline SnO, conventional heating yields amorphous SnO. In addition, microwave heating enhances the crystallization rate but does not that of oxidation. The microwave acceleration of SnO crystallization rates may be an athermal effect that may be linked to the coupling of microwave energy with atomic reactive sites.[27]

Ceramic Coatings on Powders, Fibers, and Substrates

Ceramic coatings on fibers and powders have a variety of uses. For example, porous ceramic coatings on nanoscale metallic or ceramic particles can improve the catalytic properties of a powder.[28,29] Also, the carbon fibers used as reinforcement in metallic matrices can be coated with a thin ceramic film (such as SiC or TiN) to reduce the rate of interdiffusion that may occur between the matrix materials and the fibers, and enhance the wetting of the fiber surface by metals.[29]

As is the case with ceramic sintering, joining, and powder synthesis, microwave-assisted fabrication of ceramic coatings can offer unique benefits. To expose the material surfaces for reaction with a gas phase, fibers[29] or powder particles[28] may be suspended by the flow of gas in the fluidized bed. In addition to the flow of the fluidizing gas, low frequency mechanical vibrations (for example, 10–15 Hz) may be applied to the container to reduce the tendency for the powders or fibers to sinter together to form clumps.[28] As the powder size decreases, the powder's sinterability increases. While vibration may not be necessary for particles as large as, say, 50 μm, it may be beneficial for powder particles that are a few microns in diameter.[28]

Careful control of the microwave-assisted reactions can produce nanometer-thick coatings.[28,29] For example, during the microwave-assisted fabrication of ceramic coatings on metallic powders, the microwave power may be switched on and off to produce a pulsed

microwave input signal with a pulse duration in the order of a few seconds and a pulse repetition rate of roughly 0.1–0.5 Hz. Pulsing the input power helps to thermally quench the outer surface of the particle to avoid the initiation of a self-propagating high-temperature synthesis (SHS) reaction that (for susceptible materials) would otherwise consume the entire particle rather than limiting the reaction to a thin outer film.[28] For metals, the skin depth for microwave radiation is in the order of a fraction of a micron, and this limited volume of microwave-induced heating also assists in limiting the formation of the ceramic coating to a thin film on the metal particle surface.

Microwave-assisted fabrication of ceramic coatings on fibers and powders can be done at intermediate temperatures. For example, at temperatures of about 800–900°C, carbon fibers have been coated with thin TiN layers using a microwave plasma-assisted fluidized bed with the precursor vapor ($TiCl_4$ in this case) being introduced into the reactor by the fluidizing gas.[29]

In addition to depositing thin coatings on the surfaces of powders and fibers, microwave energy can aid in processing thin, protective films on planar electronic substrates. Submicron thick boron carbon nitride (BCN) thin films have been successfully deposited on Si(1 0 0) substrates using plasma-assisted pulsed laser processing at temperatures lower than 80°C.[30] A pulsed Nd/YAG laser first ablated the surface of a boron carbide target in a nitrogen environment, then a microwave-induced low-energy, low-temperature nitrogen plasma was used to ''pin'' the BCN film onto the silicon substrates. The quality of the plasma deposited films was enhanced compared with that of boron carbide films deposited in vacuum, namely the plasma-assisted deposition process gave a lower oxygen concentration than films grown by conventional heating in vacuum.[30]

Microwave Drying of Granular Ceramics, Sol–Gel Precursors, and Cement

Microwave energy already has proven to be very advantageous for the rapid drying of granular food materials, grains, and pharmaceuticals, where the microwave-assisted drying rates are up to six times faster than those for conventional heating.[31] While conventional drying of particles in a fluidized bed relies on heat transfer via convection from the circulating drying gas to the wet surfaces of the particles, microwave heating rapidly achieves relatively uniform temperatures throughout the fluidized bed volume by the direct coupling of microwave energy to either water or other microwave-absorbing (polar) liquids.[31]

Fluidized bed drying is potentially important in the immobilization of high-level liquid radioactive waste (HLLW) materials. For example, sol–gel derived ceramic microspheres with diameters of 20–50 μm and porosities of about 40–50% are currently used to immobilize HLLW.[31] Efficient drying of the HLLW is related to the good coupling between microwave radiation and water in the porous ceramic microspheres. In particular, for a pilot-scale drying operation of 10 kg batches of ceramic microspheres, the microwave energy consumed per kilogram of moisture removed was about 6.6 J/kg for a moisture loading of 0.10 kg moisture/kg powder, while for a moisture loading of 0.20, the microwave energy consumed per kilogram of moisture decreased to about 5.5 J/kg.[31] Thus, the microwave energy consumed per kilogram of water removed decreased as the moisture content increased, such that microwave drying can become even more efficient as the moisture content increases.

Microwave radiation has also been used to accelerate the curing of cement paste and mortar. For Portland cement mortar, microwave heating at temperatures between 40°C and 60°C can shorten the curing time by up to a factor of 3 while maintaining the long-term strength of the mortar.[32] However, microwave curing at 80°C and above can decrease the strength of the mortar. In fact, if the curing temperatures extend above ≈90°C, then steam generated in the specimen bulk can generate cracks in the cement.[32] The results for the acceleration of curing were roughly similar for Portland cement paste and for mortars blended with pozzolanic materials including silica fume, blast furnace slag, and fly ash.

Another ceramic processing technique that involves drying as a key step is that of the sol–gel production of ceramic powders. Sol–gel precursors consist of small particles weakly bound together, permeated with networks of fine, interconnected pores.[33] These pores typically are filled with either an alcohol-based or a water-based liquid. Microwave heating has been successfully applied to dry sol–gel precursors.[34]

ATHERMAL EFFECTS

Athermal (or alternatively, nonthermal) effects in microwave processing have been a subject of long-standing controversy. With respect to microwave processing, ''thermal'' effects involve the direct conversion of microwave energy to heat, yielding a particular temperature field in the body. The thermal energy in turn stimulates the standard thermally activated processes associated with chemical reactions and mass diffusion. If only thermal effects are present, then given a particular temperature field, the effects on sintering rate or microstructural development are identical, regardless of whether the agent producing the given thermal field

is a microwave or conventional heating. A crucial point is that the temperature distribution produced in the microwave can be fundamentally different than the temperature distribution created by thermal heating, as microwave heating of ceramics can lead to the volumetric, selective, and/or rapid heating effects. Thus if solely thermal effects are present, then these effects only modify the temperature distribution within the body, based on the details of how the microwave energy is absorbed within the body according to its dielectric properties [Eq. (1b)].

However, there have been a number of reports of athermal effects in processing ceramic materials, where the sintering rate or the microstructure evolution (grain size and/or porosity) resulting from microwave heating differed from that obtained by a conventional heat treatment at the same temperature. Thus, athermal effects refer to mechanisms that operate in addition to the conventional thermal effects and may be a function of, for example, the electric field intensity or the frequency.

Modeling of possible microwave-induced athermal effects has been done in terms of a ''ponderomotive effect,'' which is enhanced by the tangential component of the electric field at grain boundaries.[1] The ponderomotive force is likely enhanced during sintering by the geometry of the small interparticle neck regions between the particles.[1] Nevertheless, sintering theory and practice specify that the interparticle necks are only small during the initial stages of sintering,[2] implying that the ponderomotive force may be of lesser importance during the intermediate and final stages of sintering.

CONCLUSIONS

The rapid, volumetric heating provided by microwave energy has a number of potential benefits. The resulting inverse temperature distribution (Fig. 10) promotes rapid and efficient drying of granular ceramics, sol–gels, and concrete. The uniform heating of polar liquids means that microwave heating can produce ceramic nanopowders with narrower grain size distributions and smaller mean particle sizes than are achievable by conventional heating. Moreover, the ability to precisely control the frequency and repetition rate of the microwave energy aids in depositing nanometer-thick ceramic coatings on particles, fibers, and planar substrates.

Microwave sintering, joining, and thermal etching are three high-temperature processes for which there have been claims that microwave energy can densify, join, or etch at lower temperatures and/or shorter times than are required to produce the same results by conventional heating. Regardless of the presence of athermal microwave effects, the temperature distributions achieved via microwave heating are different than those resulting from conventional heating, so that differences are to be expected between the results obtained from conventional and microwave heating. Also, especially with respect to high-temperature processes, microwave heating provides energy savings, in part because microwave heating avoids the substantial furnace-wall losses that are omnipresent in conventional radiant heating.

Microwave processing of ceramics will likely expand in scope in the future. The processes of slip casting and tape casting are additional examples that involve controlled drying of granular ceramics and are thus areas of potential application for microwave drying. In addition, large microwave ovens of the type now used to dry lumber may be used to speed up the drying of preformed concrete structures. The rapid development of microwave-assisted ceramic powder synthesis will likely continue in the future, encompassing an even greater scope of oxide and nonoxide powder production. The deposition of nanometer-scale ceramic coatings on fibers, powder particles, and substrates will also expand and diversify in the future.

INTRODUCTION

In developing a complex reaction for scale-up, or to improve yield, the mixing issues that must be considered are: 1) will mixing affect the reaction beyond the requirement to blend the reagents; 2) how are these mixing requirements evaluated; and 3) what mixing equipment design will optimize yield and selectivity? This chapter provides guidelines for addressing these questions. The same concepts can be applied to several other processes involving rapid mixing controlled steps that are not usually thought of as kinetically controlled, e.g., crystallization, precipitation, and physicochemical steps, such as surface and dispersion stability. Understanding the impact of mixing on these processes can improve yields by as much as 20% and reduce by-product formation, and can mean the difference between a successful product and one that fails on scale-up.

MIXING-SENSITIVE REACTIONS

Mixing can be a rate limiting mechanism in chemical reactions, reducing the rate of fast reactions and changing the rate, yield, and product distribution for complex reactions. Both homogeneous and heterogeneous reaction systems can be affected. This issue was first identified by Danckwerts and Levenspiel.[1,2] Since that time, the field has advanced significantly, moving well beyond the concept of residence time distribution to the modeling of local mixing rates and time varying concentration fields. Recent comprehensive treatments are given in Refs.[3,4].

Mixing effects in chemical reactions must be formulated in terms of local mixing rates or local mixing times. The easily formulated global blend time seldom has an effect, while the time constants based on local conditions in the reactor, such as local mixing time or local mass transfer rate can be very important. When the rates of reaction, local mixing, and mass transfer approach one another, mixing will affect the outcome of the process. Reactions cannot take place until the reagents are mixed locally to the molecular level. Thus, the processes of mixing/blending and chemical reaction operate in series initially, and then in parallel. When the chemical reaction is slow with a half-life of several minutes, and the mixing takes place quickly, say within seconds, then the mixing is essentially completed before a significant chemical reaction takes place. There is no effect of mixing on the slow chemical reaction and ideal reactor analysis can be used. The mixing requirement is satisfied by the blending of the reagents. When the chemical reaction is fast, however, the local mixing rate can be the rate-determining step.

Mixing effects can change the apparent kinetics of the reaction so that the measured kinetics is limited by the rate of mixing rather than by the rate of reaction. This problem is so pervasive that the rate of mixing for fast reactions is often mistaken for the rate of a chemical reaction. For a very fast chemical reaction, for example, an acid–base neutralization with a half-life of 0.001 sec, the rate of the chemical reaction depends on the rate of the mixing, which is much slower. If the reaction rate was measured, the result would be the mixing rate and not the molecular chemical reaction rate. The result is the ''apparent'' reaction rate.

When reactions are fast relative to the mixing rate, not only are the apparent reaction rates affected but the whole time and temperature history of the reaction mechanism is also affected, yielding different selectivities and yields, depending on the intensity of the mixing. This often leads to a scale-up/scale-down problem, where yields of the desirable products in a plant-scale reactor are not as good as those in a small-scale reactor in the laboratory or the pilot plant. If the yield drops from the pilot-scale to the plant-scale reactor when all other important variables (temperature, pressure, and composition) have been held constant, then there is a mixing problem. Fast

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030914

chemical reactions where the mixing rate and the reaction rates are intertwined may be either homogeneous (single phase) or heterogeneous (multiphase). Typical examples of such reactions can be azo-couplings, esterification, nitrations, sulfonations, and aminations.[5] In either case, local mixing rates provide important information for successful scale-up.

Time Scales and Local Mixing Rates

The competition between reaction and mixing is given by the Damkoehler number (*Da*), which is the ratio between the reaction rate and the local mixing rate, or conversely, the ratio of the characteristic local mixing time τ_M and the reaction time τ_R:

$$Da = \tau_M/\tau_R \quad (1)$$

A smaller *Da* indicates less effect of mixing. Larger *Da* indicates that mixing will be a concern. Local mixing rates and mass transfer rates can be accurately estimated for many common reactor configurations of both homogeneous and heterogeneous reactions. These estimates are combined with an estimate of the reaction rate to identify the conditions under which mixing effects may be critical to the course of a reaction. Care should be taken in estimating the characteristic time constant for a reaction. Many reactions consist of a series of steps and some of the initial ones may be mixing-controlled even though the overall reaction time is long. Classical examples of mixing-controlled reactions are the competitive-consecutive and competitive-parallel schemes, where the desired reaction is fast and an undesired side reaction is much slower, but fast enough to be of the order of the local mixing time.

Reaction Schemes of the Greatest Interest

Mixing effects on product distribution are of importance in multiple reactions because the impact of product distribution on design and economics can be profound. In such reactions, the desired product is one of two or more possible products. Economics is directly affected by the yield of the desired product and both design and economics are affected by downstream separation requirements.

Mixing effects may be significant for two major types of complex reaction:

1. Competitive-consecutive
   a. $A + B \rightarrow R$
   b. $R + B \rightarrow S$
2. Competitive-parallel
   a. $A + B \rightarrow R$
   b. $A + C \rightarrow U$

Fig. 1 illustrates the mixing problem for the competitive-consecutive case. R is the desired product and S is the undesired overreaction product. During the time from when the reactants are first contacted to when they are completely mixed on the molecular scale, reaction of A with B to form the desired product R occurs along with the undesired reaction of R with B to form S. When A and B are well mixed at the molecular scale, mainly R is formed, but when there is a boundary between A and B, a significant amount of undesired S appears. Competitive-parallel reactions can be subject to similar mixing effects where the first reaction is the desired one and the second is a simultaneous decomposition of A to form the undesired U. While these two reaction systems have received the most attention, the course of any reaction that is

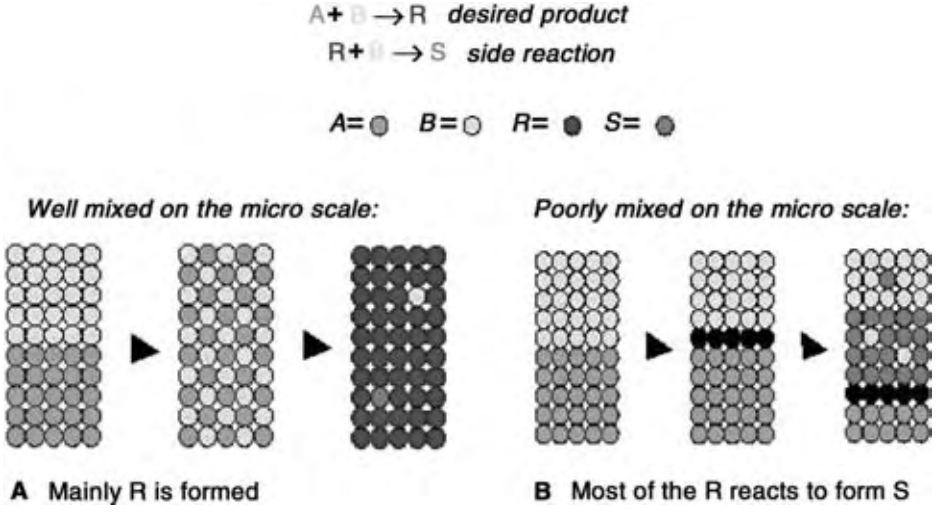

Fig. 1 Diffusion and chemical reaction at an A–B mixing surface. In this competitive-consecutive reaction the first reaction, which forms the desired product (R), is fast and the consecutive reaction step forming the undesired by-product (S) is slower. Local mixing conditions at the molecular scale determine the amount of undesired by-product (S) formed. *(View this art in color at www.dekker.com.)*

influenced by concentration has the potential to be influenced by mixing. The effect can be on the reaction rate and the product distribution or both.

In the ideal semibatch, consecutive-competitive case, reagent B is added to a tank containing A and is instantaneously mixed to the molecular level with the vessel contents. The objective is to determine how mixing conditions can affect the yield of the desired product. The maximum selectivity for the desired product R is a function of the rate constants k_{R1} and k_{R2}, the overall molar charge ratio of A to B, and the degree of conversion of A. The degree of conversion of A can depend on the charge ratio and the residence time. The discussion that follows is limited to the case of an equimolar charge ratio of A to B, and sufficient residence time for all of the B to react. The maximum selectivity for R in the absence of mixing effects then becomes a function only of k_{R1}/k_{R2} and the molar charge ratio. If we now fix k_{R1}/k_{R2} and the molar charge ratio, the selectivity is fixed, as are the yield and the degree of conversion of A.

The term "expected (ideal) yield," Y_{exp}, is used to denote the yield that would be obtained for a competitive-consecutive reaction under conditions of perfect mixing and complete conversion of the limiting reactant, as presented in Eq. (2):

$$Y_{exp} = R/A_0 = 1/(1 - \kappa)[(A/A_0)^{\kappa} - (A/A_0)] \quad (2)$$

where $\kappa = k_{R2}/k_{R1}$ and R and A denote molar concentrations. This equation applies to both batch and semibatch operations provided both the reaction rates depend on B in the same way (e.g., second order), B is added to A in the semibatch case, and B is completely consumed. The relationship between the magnitude of the secondary reaction rate constant and the yield is illustrated in Fig. 2, where the mixing *Da*, based on k_{R2}, is plotted against X_S, the yield of unwanted product based on the consumption of B. This is one minus the yield. This relationship was developed by Bourne using X_S to represent the amount of S formed where $X_S = 2S/(2S + R)$ and k_{R2} represents the undesired reaction kinetics.[6] The figure shows that mixing effects of homogenous reactions can only reduce yield below the expected (ideal) level as calculated by Eq. (2). The primary concern is the magnitude of the yield reduction attributable to deviation from instantaneous, perfect mixing to the molecular scale.

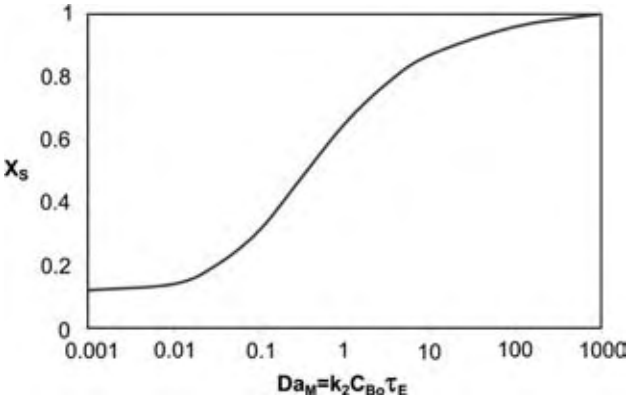

Fig. 2 By-product selectivity, X_s, as a function of *Da* based on k_2. This data from Bourne show the increased by-product formation with increasing mixing time based on the engulfment model, τ_E. As the reaction rate for the second reaction, k_2C_B, increases, the mixing time must decrease to maintain yield. (From Ref.[6].) *(View this art in color at www.dekker.com.)*

Relating Mixing and Reaction Time Scales: The Mixing *Da*

Here, we consider the characteristic local mixing time. The final phase of mixing during which chemical reactions can occur and before complete molecular homogeneity is achieved is the molecular diffusion controlled mixing of the smallest eddies in the turbulence energy dissipation spectrum. The smallest eddy size can vary over several orders of magnitude from $\sim$1 μm in intense jet mixing to $>$ 100 μm in stirred tanks with low-shear impellers. The time and length scales of turbulence and small-scale diffusion are discussed by Brodkey and Kresta.[4]

The magnitude of yield reduction because of imperfect mixing is determined by the following factors: 1) Local mixing time, a measure of the time from initial contact of the reactants to final homogeneity on a molecular scale at a given point. Any overreaction of R to S must occur during this time. 2) Chemical kinetics as given by the absolute values of the rate constants, k_{R1} and k_{R2}. 3) The *Da*, the ratio of rates of the first or the second reaction and the local mixing rate. The characteristic reaction time of interest is the one that produces the undesirable product. Other faster reactions are blending controlled. The reaction time constant consists of a reaction rate and a concentration. The concentration to be used is that of the feed, not the well-mixed concentration in the reactor. The reaction of interest takes place before dilution.

There are several mixing or blending times that can be measured and observed in an agitated vessel. The bulk blend time is the time it takes to reach a uniform concentration throughout the vessel. The local mixing time is a measure of how fast the material at a given point loses its identity. The local mixing time varies with position, while the bulk blending time is a characteristic of the whole tank. Bulk blending time is limited by the slowest rate of mixing in the vessel and varies

with the tank geometry. Local mixing times depend on the local turbulence.

Blend time

Although local mixing time is more relevant to yield effects of mixing-controlled reactions, blend times provide a rapid initial comparison of mixing and reaction time constants. If the reaction is slower than the blend time, mixing will not be an issue. The blend time is defined as the time required for the spatial variation of average concentration to drop to 5% of the original variation after a pulse disturbance to the vessel. Multiple probes must be used to obtain an accurate result. Typically, conductivity probes and salt-water pulses are used to make the measurements of blend time.[7,8] The Grenville correlations for blend times are extensively used for design and scale-up. They are dependent on the Reynolds number range as follows:

$$N\tau_B = 5.2(T/D)^2 \Big/ N_p^{1/3} \quad \text{for } N_p^{1/3}\,\mathrm{Re} > 6400 \tag{3}$$

$$N\tau_B = 3.35 \times 10^4 (T/D)^2 \Big/ \left(\mathrm{Re}N_p^{2/3}\right) \quad \text{for } 500 < N_p^{1/3}\mathrm{Re} < 6400 \tag{4}$$

Vessel blend times are typically 2 sec in a 1 L vessel and 20 sec in a 20,000 L vessel for low-viscosity liquids. If the blend time is small compared to the time constants of all key reactions, then there will be no mixing effects.

Local mixing time scales

In dealing with mixing effects on a reaction, two topics are of interest. The first is the rate of addition of the feed stream. The second is its rate of disappearance or the inverse local mixing time. For low-viscosity liquids, very rapid mixing times—with local mixing time constants, τ_M, as short as 0.01 sec—are easily obtained in liter-sized reactors, but because of mechanical limitations local mixing times of the order of 0.1 sec or longer often occur in reactors of 10,000 L or more. The rate of addition with the local mixing time determines the amount of the undesirable product that can be formed. There are many formulations for these two effects. The discussion of local mixing timescales must begin with a definition of the turbulent scales that underlie many mixing-time formulations. These scales are developed, as previously referenced, by Brodkey and Kresta.

Micromixing analysis considers the smallest scales of mixing, where the striations in the smallest turbulent eddies are dissipated by molecular diffusion. It is assumed that the amount added and the rates of addition are very small and that the scale of interest is set by the local turbulence. The earliest approach was to assume that the added material did not mix at the molecular scale until the Kolmogoroff scale was reached and the subsequent mixing took place by molecular diffusion. This is a good concept for moderate-viscosity turbulent systems and, with striation thickness replacing eddy size, can be used in fully laminar mixing systems. This molecular diffusion concept has been replaced by the engulfment model, τ_E, which is a more realistic way of treating the breakup of the added reactant as its scale is reduced by turbulence in low-viscosity systems:

$$\tau_E = 17\left(\frac{\nu}{\varepsilon}\right)^{1/2} \tag{5}$$

The differences in the approaches are small. Both include local energy dissipation and the viscosity. The molecular diffusivity is only important when the viscosity is high. In mechanically agitated tanks the local energy dissipation can vary by two to three orders of magnitude so that local mixing rates also vary dramatically. This provides a strong incentive to feed in the region of highest turbulence, close to the impeller. Local values of the dissipation, ε, are given by Patterson et al.[4] Alternate reactor configurations, where the dissipation is more uniform and can often be more tightly controlled, are increasingly in use in the chemical process industries. These include static mixers, impinging jet mixheads, and, in the more specialized field of reactive extrusion, twin screw extruders with kneading blocks.[9–11]

Mesomixing is used to describe a set of phenomena between macromixing, or blend time, which involves the whole vessel, and local micromixing at the smallest eddy scales. Thoma looked at the time of addition in semibatch operation and observed that when the addition time was very short there was an additional undesirable selectivity change.[12–14] High rates of addition overwhelm the local ability to take the material away by micromixing. The scales of mixing then penetrate into the larger eddy sizes in the inertial convective range of turbulence. This delays the molecular scale mixing. They called this phenomenon mesomixing. Mesomixing may be visualized as the mixing rate at the scale of the feed plume. Several models for mesomixing are discussed in Ref.[3]. This is an area of rapid development and change.

Summary: *Da*

Given the reaction time and the local mixing time one can calculate *Da* and use Fig. 2 for an estimate of yield and selectivity. Fig. 2, however, is based on the

assumption that the local mixing time is constant as the fed reactant moves away from the inlet position. In fact, there is a wide distribution of values of local mixing time constants in any mixing equipment and the entering material moves through many different zones of varying energy dissipation. The distribution of energy dissipation in a reactor is thus very important. This explains the interest in laser Doppler anemometry and computational fluid dynamics for the modeling of stirred tanks, and in static mixers and impinging jet mixheads as alternate reactor geometries.

This distribution of energy dissipation complicates any mathematical analysis immensely. It also explains why many modelers have gone to zone model analyses to more accurately predict the path of the reactants. In such models the vessel is divided into a number of zones of different energy intensities where the local mixing is allowed to vary. An example of such a model developed is given in Ref.[15]. Other examples of contributions in this area are discussed in Refs.[16,17].

In the absence of a full mathematical model of mixing and reaction kinetics, but given good estimates of the reaction and mixing rates, reactor design focuses on the following:

1. Determining and/or predicting which reactions are mixing sensitive.
2. Guidelines to minimize yield loss in mixing-sensitive reactions on scale-up from bench-scale to industrial reactors.

The homogeneous reaction case is considered first. All of the mixing concepts for homogeneous reactions will also apply to heterogeneous reactions, but with the added complication of multiphase mass transfer.

REACTOR DESIGN FOR MIXING-SENSITIVE HOMOGENOUS REACTIONS

The *Da* is extremely useful for initial evaluation of reaction conditions under which mixing effects must be considered. The reaction rate constant of the undesired reaction, k_{R2}, can vary over several orders of magnitude. When experimental data are not available but the class of reaction is known, the magnitude of k_{R2} can be estimated within two orders of magnitude or less. The mixing rate in vessels should not vary by more than two orders of magnitude. With these bracketed values, upper and lower limits on *Da* can be readily estimated and used as a first measure of mixing sensitivity as follows:[6]

$Da < 0.001$—Reaction is much slower than mixing and the selectivity is determined by chemical kinetics alone.

$Da > 1000$—Reaction is much faster than mixing and the selectivity can approach the asymptotic limit for minimum yield.

$0.001 < Da < 1000$—Reaction and mixing rates compete and both micromixing and chemical kinetics must be considered.

These concepts can be used to implement a developmental protocol for a new chemical reaction.[4]

Once the reaction is established, three key factors must be addressed for successful development and scale-up of homogenous reactions: 1) the effect of concentration on yield for competitive-consecutive reactions; 2) the effect of feed rate or addition time on yield; and 3) feed pipe backmixing.

Effect of Concentration

The rates of a reaction are determined by rate constants, concentrations of reactants, and temperature. At a given temperature, the rate of a second-order reaction depends on the product of the rate constant and the concentrations of the reactants. The concentration at which the chemical reaction becomes faster than the mixing is the critical concentration at which conversion and yield will be affected by mixing. It must be emphasized that the relative reaction rate at a point in the reactor is proportional to the product of the rate constant and the local concentration. It is recommended that bench and pilot data for mixing-sensitive reactions can be obtained at the same concentrations as they are to be used in the commercial plant. This eliminates concentration as a concern in scale-up.

Effect of Feed Point

One of the most important concepts from micromixing theory is the importance of addition position for selectivity in competitive-consecutive homogeneous reactions. It has been shown that there is a wide range of turbulent energy dissipation rates in a stirred tank.[4] The effect of position on mixing selectivity has been shown by a number of researchers and several methods have been used to demonstrate this effect. Nienow and Inoue give a set of examples using a small tank and the semibatch barium sulfate method of Villermaux to demonstrate the importance of feed position, as shown in Fig. 3.[18] The conversion to undesired by-product varies from 83% to 0.6%, depending on the feed location. Many other experimental measurements of yield and selectivity as a function of feed location have borne out this result.[16,19–23]

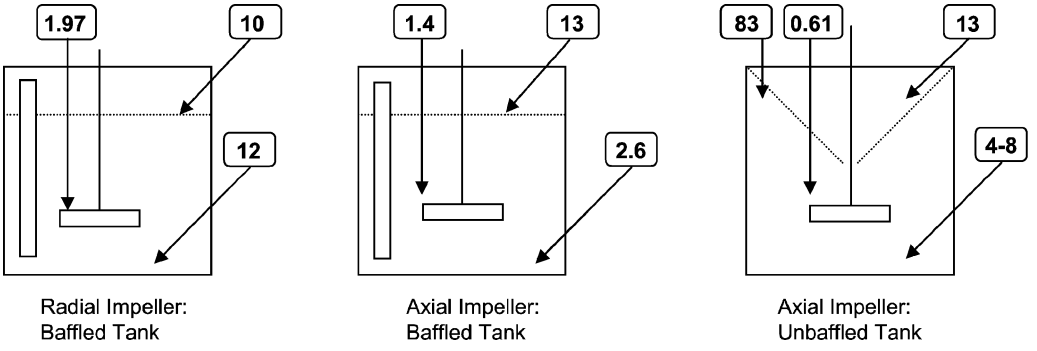

Fig. 3 Impact of different feed positions on the precipitation of barium sulfate. The selectivity to by-product as a percent of reactant is shown for feed into zones of high and low turbulent energy dissipation. The impeller speed and reactant addition time were held constant. More by-product is formed at feed points where the local mixing is slow.

Effect of Feed Injection Velocity

The importance of feed rate on yield for a mixing-sensitive reaction was demonstrated in Ref.[24]. The addition time in a semibatch reaction is often increased on scale-up because of heat transfer limitations. In the case of a mixing-sensitive reaction, the time of addition is increased on scale-up to compensate for the increase in blend time and to maintain the expected molar ratio at the feed point. The minimum feed time to achieve the expected yield is, therefore, scale dependent. Feed times that are too short will result in mesomixing conditions and reduced yield.

At feed times greater than the minimum, the yield becomes independent of feed time. The minimum feed time is a function primarily of the rate constant of the primary reaction and the mixing intensity at the point of feed introduction.

When feed velocities are low, backmixing into reactor feed pipes can lower yield by causing a slower overall mixing rate of the reactants. Jo et al. have shown that feed pipe backmixing can have a significant effect on yield, and they developed recommendations for V_f/V_{tip}, the feed pipe exit velocity divided by the impeller blade tip velocity.[25] Their results for turbulent flow in the feed pipe are summarized in Table 1. For laminar flow in the feed pipe, $V_f/V_{tip,min}$ was always lower than for turbulent flow. A good rule of thumb for turbulent flow is to design for $V_f/V_{tip} > 0.5$ except for Case 1, where $V_f/V_{tip} > 2$ is necessary.

Simple Guidelines for Scale-Up of Mixing-Sensitive Homogenous Reactions

Laboratory studies of mixing-sensitive homogenous reactions have been done by many investigators using the four reactions that are known as the ''Bourne Reactions.''[3] These studies and others fleshed out the previous theoretical predictions and established the mixing characteristics of stirred vessels in various configurations, as well as several types of in-line mixers. For fast reactions having timescales of seconds and tens of seconds, the concepts of micromixing and mesomixing can be reduced to a set of the following simple guidelines:

- Always add the ingredients to the point of highest turbulence. Avoid adding to the surface, a point of low turbulence.
- Scale up and scale down based on constant power per unit volume or mass. Even then there can be a loss of yield or by-product selectivity on scale-up.
- Consider using smaller reactors with higher energy dissipation rates such as in-line mixers in recirculation loops.
- Consider diluting the incoming reagents.
- Question the size of the reactor.
- If experiments show a possibility of mixing-sensitive reactions and the rate of addition is important, consider multiple point injections. The feed time will have to be increased in large-scale equipment.

MIXING AND TRANSPORT EFFECTS IN HETEROGENOUS CHEMICAL REACTORS

When chemical reactors have more than one phase, the problem increases in complexity because the reaction and mass transfer processes interact and another time constant is introduced. The interaction is governed by the relative rates of the reaction and mass transfer. In some cases, chemical reactions are mass transfer rate controlled (very fast chemical reactions) and in others, they are reaction kinetics controlled (very slow chemical reactions); however, in reality very few reactions strictly fit this classification. Thorough discussions of this problem are given in Refs.[26–28]. Classifications of the relative contributions of mass transfer and reaction kinetics in heterogeneous systems

Table 1 Recommended minimum V_f/V_{tip} for selected geometries for turbulent feed pipe conditions

Case	Impeller	Feed position	D/T	G/D	$V_f/V_{tip,min}$
1	6BD[a]	Radial/midplane[b]	0.53	0.1	1.9
2	6BD[a]	Above/near shaft[c]	0.53	0.55	0.25
3	HE-3[d]	Radial/midplane[b]	0.53	0.1	0.1
4	HE-3[d]	Above/near shaft[c]	0.53	0.55	0.15

[a]Six-blade disk turbine.
[b]Injection radially inward toward the impeller at its midplane at a distance G/D.
[c]Injection downward into the impeller at about $D/4$ from the centerline of the impeller shaft and G/D above the impeller midplane.
[d]High-efficiency three-blade down pumping turbine.

are outlined in Refs.[2,29]. These can be useful in an initial evaluation of reaction systems.

Homogenous reactions are more amenable to quantitative analysis and can, therefore, be developed more completely, as discussed earlier. The same local considerations apply for heterogeneous reactions, where the expected molar ratios between reactants cannot be maintained. In heterogeneous reactions, mass transfer limitations at phase boundaries, as well as local mixing limitations may affect the local concentration and reaction.

Homogeneous vs. Heterogeneous Selectivity

For simple reactions overall reaction rates may be affected and usually decrease, but yield is unaffected given equal degrees of conversion. For complex reactions, the selectivity may decrease but may also increase under certain circumstances. Significant selectivity effects can occur in heterogeneous systems at far lower absolute reaction rates because the mass transfer limitations can be very severe. These effects can be subjected to considerable magnification on scale-up to plant operations. This can be thought of as changing the k_{R2}/k_{R1} ratio, as measured by independent determination of the rate constants, to an apparent value caused by mass transfer limitations. Heterogeneous systems can also sometimes be manipulated to achieve improved yields, when compared to a homogenous system with the same reactions. There can be a great advantage to running under heterogeneous conditions or in some cases to deliberately creating a heterogeneous system for the purpose of improving selectivity.

The course of reactions is determined by events at the molecular scale, whether or not the reactive molecules are in the liquid, solid, or gas phase when they enter the reaction zone. As in the case of homogeneous reactions, the course of a complex reaction will be determined by local molar ratios and chemical kinetics. The degree of deviation from expected kinetic behavior is determined by the reaction rate relative to the rates of mass transfer and mixing. Possible mixing interactions in the films around heterogeneous phases, including dissolving solids, gasses, and liquid–liquid dispersions, are shown for illustration in Fig. 4. Differences in selectivity between the same reaction run under homogeneous and heterogeneous conditions are illustrated in the example below.

Competitive-Consecutive Reaction Example: Solid–Liquid Compared with Homogenous[4,30]

This example compares a reaction run using reagent addition as a dissolving solid and the same reagent added in solution. The two reactions were run in the

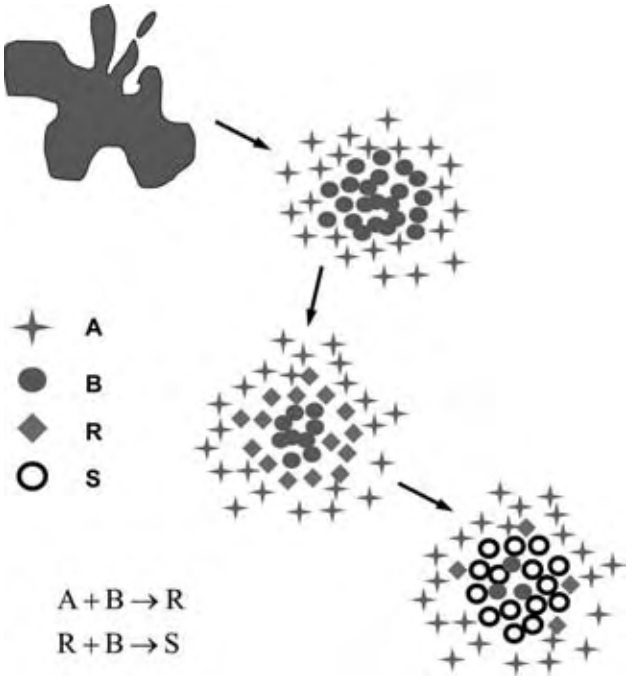

Fig. 4 Simultaneous mass transfer and reaction in the films around solid particles, gas bubbles, and liquid drops. For a heterogeneous competitive-consecutive reaction, mass transfer rates, reaction rates, and mixing rates can play a role. *(View this art in color at www.dekker.com.)*

same pilot-plant equipment with the same mixing conditions. The data for the product distribution in this consecutive–competitive reaction system allow direct comparison of product distributions obtained under homogenous and heterogeneous conditions. The reaction is a classical competitive-consecutive bromination to mono- and dibromo-substituted products, where the mono-substituted product is the desired product. Dibromo formation represents a yield loss both in this step and in the reaction steps to follow. The reaction is run in the semibatch mode in all cases. The dissolving reagent is *N*-bromo succinimide (NBS) and the reaction solvent is acetone. The pilot-plant conditions are shown in Table 2. The NBS is added over a 6-hr period because the reaction is highly exothermic. The actual reaction rate is not known but the addition requires 6 hr for heat removal. The impeller is a six-blade Rushton turbine.

Results from powder addition of NBS were satisfactory in the laboratory but in the pilot-plant, an increase in dibromo from 2% (Laboratory) to 8% (pilot-plant) was observed. This is an unacceptable increase in overreaction to dibromo. The apparent rate constant ratio, k_{R2}/k_{R1} for the two scales can be calculated from the product distributions [Eq. (1)]. This apparent ratio increased from 0.02 to 0.08 results in a decrease in selectivity.

Mixing effects in the film around the dissolving NBS are the obvious reason—the reaction rate is fast enough to allow significant reaction in the film before the dissolved NBS can be mixed to the molecular level. This indicates that the mass transfer rate is slower than the reaction rate. Possible solutions include: 1) reduce the particle size of the NBS by milling to reduce dissolution time and 2) eliminate mass transfer limitations by predissolving NBS in the reaction solvent and running as a homogeneous reaction. The latter option was run in the laboratory and was shown to reduce dibromo below that obtained with a powder addition ($< 1\%$). The same reduction was achieved in the pilot plant. In this example, the homogeneous reaction environment is more selective than the film around a dissolving reagent for a consecutive reaction.

Table 2 Pilot-plant conditions for bromination with NBS

Variable	Pilot-plant condition
Vessel volume (m^3)	0.75
Vessel diameter, T (m)	1
Impeller diameter, D (m)	0.4
Impeller speed, N (rpm)	175
Reaction volume H/T	0.5
Power/volume (W/m^3)	117
Local power (W/m^3) at point of solution addition	1170

Heterogeneous Reactions with Parallel Homogenous Reactions

The yield and selectivity of heterogeneous reactions can also be affected by mass transfer in extending the time for completion of a reaction during which a parallel reaction—possibly decomposition of A, B, or R—can be occurring in the bulk phase as well as in the films around the dispersed phase (or in the dispersed phase for liquid–liquid reactions). This problem can develop when the desired reaction rate can only be achieved at a temperature at which the starting materials, or any intermediate, or the product can react or decompose during the reaction time. This reaction time can be longer than expected on scale-up if the mass transfer rates do not duplicate those in the laboratory or in piloting. Shorter overall reaction times can also be realized on scale-up when mass transfer rates are increased by improved mixing, e.g., for liquid–liquid or gas–liquid dispersion. Reasons for slower mass transfer and extended reaction time for each type of contact are as follows:

Gas–liquid: Lower overall mass transfer rate because of insufficient gas dispersion–holdup and surface area.

Solid–liquid: Slower dissolution time because of variation in reagent particle size and mass transfer.

Liquid–liquid: Larger dispersed phase drop size and higher coalescence rates than expected.

All these factors are mixing dependent and can contribute to scale-up problems if mass transfer rates are not successfully reproduced.

Simple Guidelines for Scale-Up of Mixing-Sensitive Heterogeneous Reactions

The complex interaction between mass transfer and reaction kinetics requires determination of mixing sensitivity for virtually all heterogeneous reactions for which competitive and/or consecutive reactions are possible to be sure of successful scale-up. This requirement is prompted by issues of both: 1) overall reaction completion time and 2) undesired reactions in the films around the discontinuous phase(s). The following set of guidelines may be useful in evaluating mixing sensitivity and for scale-up.

Determine reaction by-product formation and true kinetics in the laboratory by running under dilute homogeneous conditions if possible.

Extend time of reaction beyond that required for completion of the primary reaction to determine whether or not the mass transfer rate must be duplicated on scale-up to prevent simultaneous homogeneous by-product formation and/or continuing consecutive reactions.

For solid–liquid reactions, determine whether the particle size or addition time affects yield. On scale-up provide sufficient power for off-bottom suspension.

For gas–liquid reactions, determine whether the gas–liquid mass transfer rate (a function of sparging and mixing) affects addition time and yield. On scale-up provide sufficient power and gas sparging to maintain interfacial surface area.

For liquid–liquid reactions, determine whether the drop-size distribution and/or additional time affects yield. On scale-up provide sufficient power and shear to generate the required drop-size distribution.

CONCLUSIONS

When local mixing rates are slower than the rate of reaction, but it is not feasible to perform complete reactor simulations, scale-up based on local mixing conditions is essential. For stirred reactors with multiple reactions where mixing affects the yield, the simplest approach is to hold the power per unit volume constant. This will only work if the feed locations are in the most turbulent location and strict geometric similarity is maintained. A more precise scale-up criterion is to hold the rate of turbulent energy dissipation per unit mass in the region of most intense mixing constant, and to feed at this location. This is particularly useful while feeding into the impeller stream of a stirred vessel. For geometrically similar mixing vessels, the local turbulence energy dissipation rate per unit mass is generally proportional to the overall power per unit volume, so the two criteria are essentially the same. In some cases, equal selectivity cannot be achieved on scale-up, even to a pilot-scale vessel. In this case, an in-line mixer may be considered. Results such as this are controlled by the local intensity of turbulence and the associated mixing field.

Molecular Bioengineering

Sundararajan V. Madihally
School of Chemical Engineering, Oklahoma State University, Stillwater, Oklahoma, U.S.A.

INTRODUCTION

Molecular bioengineering encompasses a broad area in which engineering principles are used to address problems at a molecular level, i.e., at the fundamental level of building blocks of life such as amino acids, proteins, carbohydrates, fatty acids, RNA, DNA, and their combinations. Although molecular bioengineering is still in its infancy, it is grounded on a solid scientific foundation attributed to the efforts of many disciplines. For example, the field of molecular biology provides ample information on the molecular events and their implications in health and disease. Significant advances in deciphering the human genome, culturing human embryonic stem cells (ESCs), and discovering the ''plastic'' nature of adult stem cells have opened a new window of opportunity for developing cellular therapies and also for generating functionally replaceable devices and/or tissue parts. Furthermore, advances in proteomic and genomic technologies have generated a driving force in high throughput screening and discovery of regulatory factors operating at the level of building blocks. Biochemistry provides a better understanding of the receptor–ligand interactions and enzyme–inhibitor interactions that have been studied using various experiments and modeling techniques. However, these concepts are not completely utilized to engineer efficient products and do not have related function and pathology to genomic sequence in biology and medicine.

The focus of molecular bioengineering is to utilize these interdisciplinary technologies to develop novel tools such as biosensors, efficient therapeutic molecules, and genetically modified products; design and develop efficient data analysis and data sharing techniques for a large pool of information typically obtained by proteomic and genomic technologies. Evaluating regulatory events that lead to a disease state in conjunction with biochemical alterations can lead to development of a highly efficient therapeutic molecule or development of a tool that can be used to diagnose a disease with high precision at the initial stages of the disease. Significant improvements in computational tools and information technologies have already played a greater role with the emergence of bioinformatics. To understand the output results, one has to develop sophisticated statistical tools that can help establish the network of information involved in the regulatory pathways controlling the activity of living organisms. In this entry, an overview of molecular bioengineering areas where significant activity and advancement have occurred is described by grouping them into four major categories as shown in Fig. 1. The first two categories are less defined and both engineering and fundamental sciences have to make simultaneous progress. On the other hand, the last two categories have a better understanding from the fundamental science perspective, but significant progress in engineering is still required.

TISSUE ENGINEERING

Tissue engineering has given promise for generating functionally replaceable tissue parts. The technology is based on using biodegradable porous scaffolds to guide and support the ingrowth of cells during tissue regeneration either at the site of grafting or in vitro. Here, the importance of biomimicry using molecular bioengineering is discussed.

Scaffolds are used with and without prior cell-seeded configurations based on the tissue to be replaced. In many applications where functionality of a tissue is critical to the survival of a patient, developing tissues outside the body or colonization of cells prior to transplantation is the preferred modus operandi. For example, the cardiovascular system poses unique challenges, as porous leaky materials cannot be grafted without cell colonization. Also, the absence of cellular components typically leads to blood clotting and overgrowth of cells that clog blood flow and lead to the subsequent failure of the graft. Another example is the liver cells, which are the metabolic hub of the body. If the liver has to be replaced, the replaced tissue should have the ability to provide the critical functions. To colonize the scaffolds, various molecular events have to be carefully programmed to regulate cellular bioactivity such as adhesion, spreading, migration, proliferation, and functionality. In addition, one has to identify an immunocompatible cell source in a quantity sufficient to support the functional load of the system. One practice is to retrieve autologous cells from a patient, grow them in vitro using tissue culture techniques, and transplant the cell-seeded scaffold back

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120027001

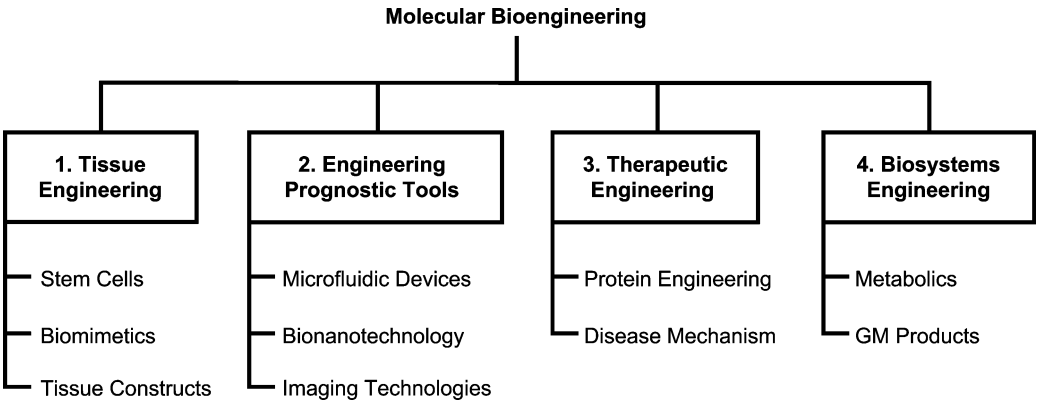

Fig. 1 Categories in molecular bioengineering.

to the patient. This procedure is restricted by the time taken in developing a graft and complications associated with the pathogenesis of a disease state. If allogeneic cells are isolated from a donor, the donor should be immunocompatible so that the graft rejection problem is abated. Hence, restrictions that limit the availability of transplantable donor tissue/organs also limit cell sources.

Stem cells

An alternative approach to broaden the availability of immunocompatible cells is to use stem cells that have the potential to differentiate into various cell types and also can be genetically manipulated because of their inherent self-renewal property. Thus, one could hope for the availability of functionally replaceable tissues ''off the shelf.''[1] Efficacy of using stem cells has been clinically proven beneficial in treating a variety of blood-related disorders. Furthermore, ''plasticity'' of stem cells has also been demonstrated in various animal models, suggesting that stem cells from one tissue type can be converted into cells of other tissues as well; for example, when bone marrow cells were transplanted into liver-injured animals, these cells restored the liver by differentiating into liver cells.[2] However, there is a need to engineer in vitro systems that can provide various microenvironments conducive to drive stem cells to defined cell types and then colonize them to generate needed tissue parts.

Exploiting the plasticity of stem cells in tissue regeneration will be the focus of many researchers in the coming years, as more concepts on the required elements and signaling mechanism(s) that regulate differentiation and proliferation of a variety of cell types are being understood. One of the activities that a number of investigators have focused on is evaluating the role of various soluble factors on the regulation of lineage development in culture systems. However, in addition to numerous soluble factors, dynamic interaction between stem cells and other cell types present in the microenvironment, membrane-bound factors, and polymeric matrix components that surround the stem cells directly regulate the process of differentiation and proliferation. Thus to recreate the microenvironment, coculturing stem cells with other cell types or incorporating molecules that significantly influence the cellular events into an artificial matrix has been the strategy. For example, an approach to incorporate bioregulatory activity is to use matrix molecules such as collagen (a protein) and glycosaminoglycans (GAGs, a polysaccharide) in scaffolds.[3] The latter are involved in diverse regulatory functions that include altering the bioactivity of mitogenic factor, colocalizing factors within a microenvironment (e.g., compartmentalization of the bone marrow microenvironment[4]) and directly regulating cell proliferation and differentiation (e.g., CD34 + cells).[5] Also, collagen/GAG-based skin equivalents are already in clinical use[6,7] and are under investigation in various tissue engineering applications. In addition, many other matrix elements such as fibronectin, vitronectin, laminin, fibrinogen, and denatured collagen are involved in orchestrating the dynamic events of cellular differentiation and proliferation and have to be carefully integrated into the matrix to program the differentiation and proliferation of stem cells so that transplantable tissues can be regenerated.

Biomimetics

While using individual components such as GAGs or collagen, a bigger engineering challenge is to process these materials into the required architecture without compromising their bioregulatory function. For example, an approach in using GAGs is to form an ionic complex with positively charged polymers, as ionically immobilized GAGs retain their bioactivity.[5,8] However, the ionic interactions are unstable and pH dependent, and the initial high content of GAGs can dissociate rapidly from the surface. To incorporate

bioregulation of other matrix elements, grafting a small peptide arginine–glycine–aspartic (RGD) acid onto polymers is an approach taken by many investigators.[9] Using RGD is based on the understanding that the majority of communication across the cell wall takes place via integrins, a family of transmembrane receptors, which communicate with many matrix elements through the RGD binding domain.[10] Nevertheless, availability of new molecules with specific biofunctions and ability to tailor their bioresponses to specific medical or biotechnological needs via protein engineering have added another driving force to biomaterials research.[11] The wide variety of ways by which such biomolecules and cells can be combined with polymeric biomaterials provides tremendous opportunities for tissue regeneration. Development of polymers that possess the capabilities of regulating the differentiation of stem cells to required mature cell types, new artificial biomimetic systems by exact placement of functional groups on polymer backbones, crosslinked structures, or macromolecular assemblies are the things to come.

Tissue constructs

Apart from replacing tissues in the body, developing tissue constructs outside the body will significantly help understand the progression of a pathological condition that is not clearly understood thus far. For example, development of solid tumors is aided by the growth of new blood vessels in a given location in a human body.[12] Although the signaling mechanism regulating the morphogenesis of endothelial cells that line the inner wall of blood vessels is an intensely investigated research area, the reason for the growth of new vessels is yet to be clearly understood. This is fundamentally limited by the lack of sensitive diagnostic tools that can detect the sprouting of new vessels in the body during the onset of a pathological condition in addition to the absence of reliable in vitro model systems. For example, routinely used magnetic resonance imaging and computer tomography techniques have 100–500 μm resolution, which is insufficient to carefully detect the initial stages of microvessels inside the body. On the contrary, confocal microscopy has a 0.1 μm resolution and can only be used in few-millimeters-thick samples. However, the sample size and the sample preparatory steps limit the usage of confocal microscopy in clinical applications. Needless to say, developing a reliable in vitro model that mimics various microenvironments will significantly help understand the molecular events that lead to sprouting of new vessels and the formation of solid tumors. Apart from solid tumors, understanding new blood vessel formation will also help comprehend its unequivocal role in a variety of patho/physiological processes including embryogenesis,[13] normal tissue development and function, atherosclerosis, diabetes, wound healing, and tissue engineering. Furthermore, developed tissue constructs can be used for toxicology studies and to test the effect of pathogens, i.e., as real time sensors for detecting biological agents. This would be highly effective in preventing infection altogether or alerting persons at risk about the need for immediate medical attention during bioterrorist attack and allergy seasons.

Engineering Prognostic Tools

Microfluidic devices

The microfabrication technology developed to create microelectronic devices has been adapted to create sophisticated, miniaturized analytical devices. Development of capabilities to miniaturize analytical devices and components offers a number of potential benefits including the ability to reduce sample sizes, development of low cost devices disposable after single-use devices, and improved device portability. Further, careful engineering of these devices will allow a wide variety of separations, chemical reactions, and detection steps that can also be carried out in an integrated fashion. Extensive work has been done on producing such micro-analytical systems on silicon or glass substrates using processes commonly employed in electronic chip manufacturing. A number of devices are currently under development for use in various laboratory techniques including bioseparations, microdialysis, and mass spectroscopy. Advances in the development of lab-on-chip devices shrink, and potentially simplify, laboratory tests like DNA analysis,[14] antigen detection and high-throughput genotyping.

Apart from developing miniature analytical tools, microfabrication technology can be utilized to develop portable biosensors or programmed drug delivery devices and also to understand the cell–cell or cell material interactions, which are useful for tissue engineering applications. While developing biosensors, one could utilize the cell-specific responses to obtain information for both pharmaceutical and chemical safety, and drug efficacy profiles in vitro as a screening tool.[15] Throughout their life cycle within specific tissues and organs, various cell types respond to a variety of chemical and physical signals by several means, i.e., either producing specific proteins or specific free radicals. Some of these events have been recreated using in vitro cell culture technique and molecular events are extensively cataloged for a few cell types. Knowing the desired output, a specific cell type is selected and cultured on microfabricated substrate to a desired pattern. In the case of electroanalytical

measurements and biosensing, electrode and biosensor devices can be miniaturized down to a cell-size scale and can be positioned directly at the vicinity of the cell surface, where cellular signaling substances are captured before they diffuse. Although quantitatively the signal is very small, it is enhanced through either circuit amplifiers or catalytic reactions on the biosensor.

Microfabrication technique can also be utilized, in conjunction with tissue engineering, to spatially control cell distribution in a cell culture, which can be used to understand the cell shape dynamics, cell division, and cell–cell interactions.[16] This information will be of significant use while engineering new materials for tissue regeneration and to develop biosensors of high sensitivity.

Bionanotechnology

The possibility of synthesizing nanoparticles, i.e., particles in the size range of 2–6 nm, is of considerable interest because of their unique size-dependent properties. Also, the particle size is dimensionally similar to that of biological macromolecules (e.g., nucleic acids and proteins).[17] These similarities could allow major advances in medical diagnostics, targeted therapeutics, molecular biology, and cell biology. Nanoparticles are among the first nanoscale materials to be directly useful in biology. Colloidal semiconductor nanocrystals called ''quantum dots'' (QDs) are the most attractive particles in biomedicine. They are generally composed of atoms of elements from groups II to VI or III to V of the periodic table. A normally used QD is zinc sulfide-capped cadmium selenide (CdSe-ZnS). Their size range of 2–10 nm or 10–50 atoms, often referred to as a size less than the Bohr radius in physics, leads to a quantum confinement effect dictated by the rules of quantum mechanics. This effect endows QDs with unique optical and electronic properties such as: a) exceptional photochemical stability; b) high photobleaching threshold; c) continuous absorption profiles; and d) readily tunable emission properties (from the UV to the IR), which allows simultaneous excitation of several particle sizes at a single wavelength; size-tunable narrow spectral line widths. For example, in comparison with commonly used organic dye rhodamine, the QD luminescent label is 20 times brighter, 100 times stable against photobleaching, and one-third as wide in spectral line width. In addition, the large surface-area-to-volume ratios of QDs make them appealing for the design of targeted molecular probes.

Imaging technologies

Targeted molecular probes are very useful for diagnostic purposes or as drug delivery systems and antigen/antibody immunoassays. Present imaging technologies rely mostly on nonspecific macroscopic physiological or metabolic changes that differentiate pathological tissues from normal tissue rather than identifying specific molecular events responsible for disease.

Specificity in targeting could be obtained by conjugating the surface with small molecules, such as receptor ligands or enzyme substrates, or higher-molecular-weight affinity ligands, such as monoclonal antibodies or recombinant proteins. While using these particles, the main concern is the fate of these particles when administered into the body. All foreign particles once injected into the bloodstream are detected by the immune surveillance system, which leads to adsorption of biological elements, especially circulating plasma proteins. This process is known as opsonization and is critical in dictating the fate of the injected particles. Normally opsonization renders the particles recognizable to the body′s major defense system, i.e., recognizable to the immune cells as a foreign material, and eliminates the particle. However, if the particles are large in size, then they are typically removed by the liver. Knowing immune surveillance mechanism(s), suitable surface modifications can be attempted to render the particles to remain in the blood circulation for a longer time or be directed to sites of interest. For example, uncoated poly(lactide-co-glycolide) (PLGA) particles are cleared rapidly, while particles coated with a block copolymer of polylactide-poly(ethylene glycol) (PLA-PEG) remained in the blood stream for a longer period of time.[18] This is attributed to rendered surface hydrophilicity and sterical stabilization of the particle. Recently, targeting specific tissues have been accomplished by tagging specific peptides to QDs and imaging the tissue;[19] because QDs are endowed with optical properties, the targeted tissue can be probed with increased sensitivity and for an extended period of time. Although producing stable QD-biomolecule complexes with clearly defined characteristics has been a challenge, advances in molecular engineering will allow the development of these targeted QDs of various diseases, and will potentially revolutionize medical treatment.

Therapeutic Engineering

Protein engineering

Evaluating molecular mechanisms is critical to understand the onset of a disease state. However, developing an effective and efficient therapy with minimum side effects using these concepts is more important. A classic example for this scenario is the understanding of diabetes type I (insulin-dependent diabetes). The fact that it is caused by the abnormal secretion of

insulin has been known for many years. Although significant improvement in insulin therapy has been made, it is still far from mimicking the physiological secretory profile of pancreatic β-cells. Many years of knowledge on the fate of insulin in the body, such as the need for dissociation of the insulin hexamer for insulin absorption and interaction with its receptor, has resulted in biosynthetic insulin (rapid-acting, intermediate-acting, and long-acting), produced by recombinant DNA techniques. However, the pharmacokinetic profiles of biosynthetic insulin do not adequately reproduce the physiological postprandial insulin response. This has led to the development of molecular analogs with slight modifications that prevent the spontaneous polymerization underlying delayed absorption.[20] Lispro is one such rapidly absorbed and short-acting insulin analog in which the amino acids at positions 28 (lysine) and 29 (proline) of the B chain are interchanged and has recently gained more attention. In the years to come, one could imagine having a controlled delivery device that could regulate the insulin dosage by sensing the level of glucose in the blood stream.[21] This concept not only decreases the number of doses a patient has to take but also improves the efficacy and alleviates the problem of overdosing. Also, administering insulin in other pathological states could prove beneficial because of its involvement in diverse biological processes such as fatty acid metabolism, protein synthesis, and protein degradation.[22]

Apart from insulin, engineering proteins has also advanced the antibody-based therapeutic approach, based on the cascade of interactions that lead to a disease state. Antibodies bind to antigens such as proteins, glycoproteins, phospholipids, and glycolipids with highest specificity, and one has to consider the half-life of circulation of antibodies. The factors affecting the antibody stability have to be carefully assessed so that novel molecules can be engineered without altering their target-recognition specificity. In this regard, a number of antibodies have been conjugated with high molecular weight PEG, which result in antibodies that have significant improvement in their half-life while still retaining their molecular recognition. Recent developments in engineering chimeric (containing components from two species) and humanized antibodies as well as antibody fragments and bispecific (two specificities that can direct the effector cells to a required target site) antibodies have rejuvenated the antibody-based technologies. Even more excitingly, approaches to utilize bioreactors and genetically modified lower eukaryotic organisms, plants, and milk from animals have provided alternative strategies for large-scale production of antibodies, overcoming many earlier clinical concerns. These developments have given new impetus in developing targeted immunotherapies for the treatment of asthma, autoimmune diseases, infection and inflammation, cancer, transplantation, poisoning, substance abuse, and other diseases. Antibody engineering has begun to show concrete success in its long-term efforts to develop targeted immunotherapies. Advances in phage display antibody libraries can now help to define novel gene function and the measurement of abnormal protein expression in pathological states.

Disease mechanism

Molecular events leading to many other pathological states are yet to be clearly understood. For example, more than seven decades ago, Cuthbertson[23] reported that severe trauma results in a generalized hypercatabolic state characteristically marked by severe skeletal muscle loss; recently, similar muscle losses have been observed in cancer and AIDS patients. Protein loss could not be explained by disuse alone; moreover, effects were observed at sites distal from the locus of injury. The net catabolic effect is attributed to imbalanced protein synthesis vs. degradation. Sustained loss of proteins is termed as ''muscle wasting'' and results in diminished muscle strength, with secondary complications including prolonged mechanical respiration, increased risk of pneumonia, poor wound healing, long-term hospitalization, and extended rehabilitation. Apart from muscle wasting, severe trauma also leads to depressed immune responses and multiorgan dysfunction syndrome, which together constitute the major cause of morbidity and mortality in post-traumatic patients. Based on our current understanding of mechanisms underlying muscle wasting and immune function, therapies to block proteolysis and/or augment immunity (e.g., cytokines) have been attempted. However, these have been largely ineffective, suggesting a need for better understanding of the pathways mediating the dysfunctional hypercatabolic state.[24] The underlying mechanisms also remain incompletely understood because of technical problems associated with whole muscle preparations and the lack of clinical data to support the mechanistic hypotheses. Thus, there is a need for models or in vitro tissue engineered constructs that mimic the pathological states. Recent advances in proteomics and genomics will significantly help in the understanding of the cascade of molecular events leading to a pathological state and subsequent development of target-based therapies.

Biosystems Engineering

Using the concepts of microbiology and plant biology, engineering micro-organisms and food crops has made substantial progress.

Metabolic engineering

Utilizing the biochemical understanding of metabolic pathways of prokaryotic and eukaryotic cells, pharmaceutical molecules such as aromatic amino acids that are difficult to process through the traditional chemical processing techniques can be synthesized.[25] For centuries, this concept has been utilized in the fermentation process to produce simpler ethanol from the various less-expensive, renewable carbon sources. Recent developments in metabolic engineering have shown that other molecules can be produced by diverting the competing reactions at the genetic level, i.e., by engineering the genetic sequence to increase selectivity of a biochemical reaction based on the required product.[26] In addition, producing secondary metabolites or small molecules important for pharmaceutical and materials applications is also possible.

For commercial feasibility, factors other than the metabolic pathways affecting the yield of the product synthesized by micro-organisms have to be analyzed. The higher sensitivity of the engineered cells to changes in environmental factors can cause cell death and decrease productivity. Thus, cells have to be made more robust to perturbations in environmental factors. Also, supplements used to grow the cells can become very expensive and hence the process has to be extended to include cost-effective substrates. Thus, apart from extending the process to cost-effective substrates, cells have to be made more robust to perturbations in environmental factors. Furthermore, efforts focusing on engineering cells by random selection methods have failed where genes are introduced based on conclusions derived in the absence of quantitative analysis of pathways or enzyme-dependent reactions carrying out various functions related to cell growth and product formation. Thus, to make a systematic approach to target selection for the improvement of productivity, methods of modeling the metabolic pathways using reaction kinetics and material balances are gaining more attention; if a genetic manipulation is made, how does it affect substrate utilization and, importantly, the selectivity of the required product. However, in any given scenario, completing the material balance is a challenging task because of the possibility of multiple product formation. With the emergence of proteomics and genomics, metabolic engineering is poised to succeed in the coming years and will play a significant role in the bioprocess industry.

Bioconversion can be thought of as an upstream integration of metabolic engineering, i.e., use micro-organisms to degrade renewable resources and then use the formed glucose or other substrates to synthesize required pharmaceutical products. Cellulose is a major building block of various crops. The potential for using cellulosic materials in bioconversions is well recognized, as the enzymatic hydrolysis provides an environmentally friendly means of depolymerizing cellulose. However, the high cost associated with the enzyme and also the very low yield obtained remains a major problem. A number of pretreatment strategies such as acid treatment, steaming, or peroxide treatment are being investigated to reduce the cost and also to increase the yield and is an upcoming area.

Genetically modified (GM) products

Another area in biosystems engineering focuses on developing crops, particularly fruit and vegetables, which are more resistant to handling or to infections. Pectin, the components constituting the skin of many fruits and vegetables, play a key role in plant physiology and plant pathology. The degree of methylation of these polysaccharides has been correlated with the extensibility of the cell walls.[27] Nevertheless, pectins are the first line of defense against infectious agents and also a target for genetic engineering to improve the shelf life of the crop. Thus, significant research has been focused on understanding how plant pathogens invade a fruit or a vegetable such as melons, apples, tomatoes, soybean, and maize so that one could develop a strategy that can prevent the invasion, thus leading to increased productivity. In the realm of plant–pathogen interactions, the interaction between plant polygalacturonase-inhibiting proteins (PGIPs) and pathogene-derived polygalacturonases (PG) is of significant interest as part of the plant's defense system, as it plays an important role in the prevention of the pathogenic micro-organism penetration in addition to pectic substance metabolism. Because the resistance of plant tissues to infection frequently correlates with PGIP expression and its inhibitory action on fungal PG, PGIP is a candidate for genetic engineering to obtain transgenic plants resistant to fungal infection or to impart extended shelf life to fruits. Further, PGIP is responsible for the specificity of cell–cell interactions during pollination or inoculation by fungi nonpathogenic for a particular plant. It is localized in plant cell walls and is encoded by a gene family whose expression is stimulated by injury or fungal infection.

To better understand the interactions, models describing the PG–PGIP interaction have to be developed that can be used to engineer better products.[28] However, the presence of a number of isoforms of the two interacting species and the alterations in the growth and development of fruits and vegetables have to be included in the models. Furthermore, with several classes of hydrolytic enzymes, the interaction of the enzyme with a specific inhibitor-protein results in a complex of two proteins that is inactive or of greatly depressed activity. Models can provide a better quantitative method to estimate the inhibitor-protein

activities and also generate the information on the important stage-specific alterations in the expression of inhibitor-proteins during growth and development. This could lead to minimal genetic manipulation of only the dominant inhibitory factors while engineering new products or to a better understanding of the process of evolution.

CONCLUSIONS

In summary, the emerging field of molecular bioengineering spans a wide spectrum of applications and will greatly expand the scope to tackle challenges in molecular medicine. A number of concepts will show significant progress in the coming years. Further advances in materials processing and micromachining will accelerate the development of more sophisticated diagnostic tools and therapies, such as imaging and antibody targeted chemotherapy.

Molecular Modeling for Nonequilibrium Chemical Processes

M

Dionisios G. Vlachos
Department of Chemical Engineering and Center for Catalytic Science and Technology, University of Delaware, Newark, Delaware, U.S.A.

INTRODUCTION

Applied computational quantum chemistry, such as density functional theory (DFT), and molecular modeling, including molecular dynamics (MD) and Monte Carlo (MC) techniques, have become essential tools for science and engineering research. Molecular modeling has its roots in Newton's laws of motion and the Metropolis stochastic evolution of phase space. Yet, it is only the advances in computational power coupled with novel algorithmic and theoretical developments (e.g., the Gibbs ensemble, the histogram reweighting MC with finite-size scaling for critical exponent determination, the Swendsen–Wang algorithm, etc.) since the early 1980s that have rendered molecular modeling an indispensable tool in computing ''equilibrium structure'' of bulk matter, small clusters, and interfaces. Examples of its applications include liquid and solid reconstruction, protein folding, crystallization, adhesion of macromolecules (e.g., biopolymers) on surfaces, phase diagrams of adsorbed layers, and segregation in alloys.[1–4] The introduction of molecular modeling for nonequilibrium systems entailing transport and/or chemistry has naturally been slower (selected application examples in chemical engineering are given in Ref.[5]). For example, the first report of MC simulation of surface kinetics appeared in Ref.[6], but it was the work of Ziff et al.[7] a few years later that actually ''ignited'' the scientific community. Monte Carlo methods were introduced earlier to study epitaxial growth of films, such as the growth modes and the transition to rough crystals (an overview of earlier work is given in Refs.[8,9]).

The delay in using molecular modeling in chemical process industry stems from many challenges, including the inherent complexity of nonequilibrium processes, the lack of a rigorous nonequilibrium statistical mechanics theory, the lack of experimental techniques with nanometer spatial and short temporal resolution that can be confronted with molecular models, and the inherent multiscale complexity of industrial processes. Despite these obstacles, molecular modeling is nowadays clearly an integral part of multiscale and nanoscience research,[10–12] as it can handle complex many-body systems and provide the ''exact'' numerical solution for a given input. Molecular models provide unprecedented insights into complex problems, such as reaction mechanisms[13] and diffusion paths.[14] In addition, they are already assisting design of new materials and catalysts, e.g., Refs.[15,16]. Their integration into macroscopic scale models creates a new multiscale-modeling paradigm by enabling for the first time design of materials and processes with atomic resolution.[17] This article describes major uses of molecular modeling, focusing briefly on MD and mainly on kinetic MC (KMC) methods, and presents examples from the author's group on heterogeneous catalysis and microporous materials.

MOLECULAR DYNAMICS SIMULATION

Molecular dynamics is a true first principles dynamic molecular model. It simply solves the equations of motion. Given an intermolecular potential, MD provides the exact spatial and temporal evolution of the system. The stiffness caused by fast vibrations compared with slow molecular relaxations demands relatively small time steps and challenges current simulations.[3,4] As an example, the time scale associated with vibrations is a fraction of a picosecond, whereas those associated with diffusion or reaction may easily be in the seconds to hours range depending on the activation energy. Consequently, MD on a single processor is usually limited to short time and length scales (e.g., pico- to nanoseconds and 1–2 nm).

Molecular dynamics has been successful in revealing preferred adsorption sites within microporous materials; diffusion paths in microporous materials and on single crystals, e.g., Refs.[14,18]; calculation of sticking coefficients of small adsorbates, e.g., Ref.[19], etc. It is in the calculation of dynamics though, such as sticking coefficients and diffusion paths, where the real merit of MD lies. It works well when there is no large activation barrier compared to the thermal energy, i.e., a fluid-like behavior. The small reachable scales have limited direct comparison of MD simulation results with data from most-far-from-equilibrium systems,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120026492

such as heterogeneous catalysts and transport through microporous membranes. Use of MD data into the phenomenological Stefan–Maxwell equations has been one approach in reaching larger length and time scales for microporous materials.[20,21] For large activation energies, alternative molecular modeling tools, including transition state theory and reaction coordinate search along with statistical mechanics, have been invoked.[17,18,22] The spatiotemporal dynamics of largely activated processes can be modeled using KMC, which is discussed next. The hierarchy of multiscale tools is large to fully describe here, though a recent review attempts to do this.[23]

MONTE CARLO METHODS FOR PROCESSES WITH TRANSPORT OR CHEMISTRY

Monte Carlo is a stochastic method that in many cases circumvents, at least in part, the time/length problem of MD. The introduction of the Metropolis MC algorithm in 1953[24] established a computational statistical mechanics framework for computing equilibrium solutions. For equilibrium structure determination, MC is often preferred to MD. On the other hand, MD is preferred for dynamics and when collective behavior dominates. Starting from a description of the physical system in terms of a Hamiltonian, MC solves stochastically an underlying master equation using pseudorandom numbers by constructing the probability with which the various states of the system have to be weighted according to a Markov process.

It is often stated that MC methods lack real time and results are usually reported in MC events or steps. While this is immaterial as far as equilibrium is concerned, following real dynamics is essential for comparison to solutions of partial differential equations and/or experimental data. It turns out that MC simulations follow the stochastic dynamics of a master equation, and with appropriate parameterization of the transition probabilities per unit time, they provide continuous time information as well. For example, Gillespie has laid down the time foundations of MC for chemical reactions in a spatially homogeneous system.[25,26] His approach is easily extendable to arbitrarily complex computational systems when individual events have a prescribed transition probability per unit time,[27] and is often referred to as the *kinetic Monte Carlo or dynamic Monte Carlo* (*DMC*) method. The microscopic processes along with their corresponding transition probabilities per unit time can be obtained via either experiments such as field emission or fast scanning tunneling microscopy[28,29] or shorter time scale DFT/MD simulations discussed earlier. The creation of a database/lookup table of transition probabilities emerges as a powerful modeling approach in computational materials science and reaction arenas.[30,31]

The extension of Gillespie's algorithm to spatially distributed systems is straightforward. A lattice is used to represent binding sites of adsorbates, which correspond to local minima of the potential energy surface. The discrete nature of KMC coupled with possible separation of time scales of various processes could render KMC inefficient. The work of Bortz et al. on the *n-fold or continuous time MC* (*CTMC*) method[32] can lead to computational speedup of the KMC method, which, however, has been underutilized most probably because of its difficult implementation. This method classifies all atoms in a finite number of classes according to their transition probability. Probabilities are computed a priori and each event is successful, in contrast to the Metropolis method (and other null event algorithms) whose fraction of unsuccessful (null) events increases drastically at low temperatures and for stiff problems.[27,33] In conjunction with efficient search within a class and dynamic variation of atom coordinates,[34] the CPU time can be practically independent of lattice size.[27] After each event, the time is incremented by a continuous amount.

PARAMETERIZATION OF MOLECULAR MODELS

The input to a microscopic MD or MC simulation is an intermolecular potential, whereas that to a KMC simulation is the microscopic mechanisms along with their corresponding transition probabilities per unit time. This input is obviously critical for the success of molecular simulation. Trial and error is often involved when determining the parameters of this input. As an example, in the case of MD, a functional form of the intermolecular potential is initially assumed; MD simulations are carried out with a guessed set of parameters of the potential to compute an ensemble average property that is subsequently compared with that of a corresponding experiment. An iterative approach must then be employed whereby a different set of parameters is assumed, and MD simulations are repeated to improve the agreement with the data. This process is tedious and time consuming, and may lead to a poor parameterization because of multiple local minima. Determining the parameters of molecular models is actually an optimization problem. It differs somewhat from reverse engineering, discussed next, in that forward molecular simulations are performed, and the potential form in MD or the paths in KMC are assumed to be correct (only the parameters are unknown).

A goal in parameterization of any model is to carry out a minimum number of simulations while maximizing the information content of these simulations. Extensive literature exists on optimum design of experiments that meets this objective.[35,36] The overall idea is based on a surface response methodology where one carries out a limited number of appropriately chosen molecular simulations to develop an empirical, low degree polynomial as a function of important parameters; this polynomial is subsequently used to determine the parameters so that simulation results are in close agreement with experimental data. Rigorous determination of parameters follows by minimizing an objective (cost) function that describes the difference between experimental data and simulation predictions. The approach can be further accelerated via hierarchical multiscale modeling: the corresponding mean field model is first parameterized to zoom in the correct range of parameter space (a mean field model assumes a spatially homogeneous system and ignores correlations and thermal fluctuations[37]). With the parameters of the mean field model as an initial guess, training of the parameters of the molecular model follows. The hierarchical approach is systematic, and has recently been demonstrated in the case of surface reactions (CO oxidation on Pt) and zeolites for KMC simulation.[38,39] Next a brief introduction to zeolites is given followed by an example of such parameterization.

Zeolites

Zeolites are crystalline aluminosilicate solid materials consisting of networks with pores of molecular dimensions. Because of the periodicity of the solid network and the nanometer size of the pores, zeolites have an unprecedented resolution (atomic size and shape selectivity) in a number of industrial applications, including catalysis, adsorption, and ion exchange. Currently, zeolites are also being explored as hosts for growth of nanowires, quantum dots, and sensors.

An example of molecular model parameterization: Benzene in NaX zeolite

NaX is a Faujasite type zeolite used industrially as a cracking catalyst. Its structure is depicted in the inset of Fig. 1. Benzene in NaX zeolite has been modeled extensively[18] and found to bind strongly in a facially coordinated orientation above four Na cations (S_{II} sites) and weakly in four sites near Na(III′) cations (W sites).

Figs. 1 and 2 depict the result of hierarchical training of a KMC model of benzene in the NaX lattice by simultaneously fitting self-diffusivity data at different loadings θ (number of benzene molecules per cage) and adsorption isotherms, respectively.[39] The optimized

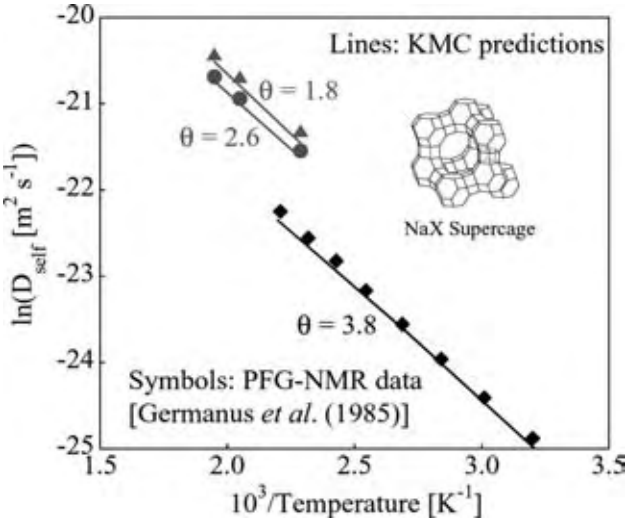

Fig. 1 Comparison of experimental and simulated self-diffusivities of benzene in NaX zeolite (supercage depicted in inset) vs. inverse temperature for three loadings, θ, indicated. *(View this art in color at www.dekker.com.)*

model behaves well even under extrapolation. Finally, the optimized parameters of the mean field and of KMC model differ by less than a factor of 2, underscoring the possibility for hierarchical multiscale modeling.

MOLECULAR MODELING AS A PREDICTIVE TOOL

Molecular modeling provides an unprecedented level of understanding. For most engineering applications,

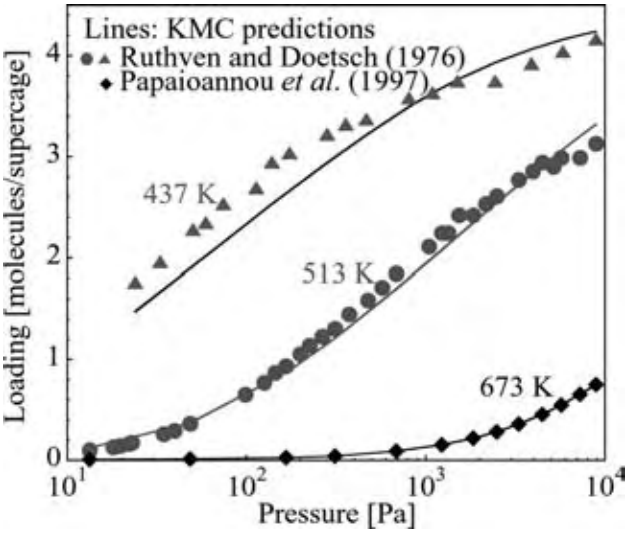

Fig. 2 Comparison of experimental and simulated isotherms of benzene in NaX zeolite vs. pressure for three temperatures indicated. *(View this art in color at www.dekker.com.)*

a spatially averaged quantity, e.g., a reaction rate or a flux, suffices, and this can easily be computed using molecular simulation output. However, this is not always a strict means for validating a molecular model (spatiotemporal data are a much more stringent requirement). Next we present two illustrative examples where KMC is used to make predictions and further discuss the validation issue.

Thin Zeolitic Microporous Membranes

Most technologies of microporous materials involve many simultaneous microscopic mechanisms (e.g., adsorption, desorption, migration, reaction, etc.) of molecular species. In particular, zeolites grown as oriented thin films or as membranes have received attention for their potential applications in high-resolution gas separations. Such systems are characterized by adsorption and desorption at the membrane boundaries and diffusion through the membrane interior. Armed with a KMC model trained with adsorption and diffusion data under equilibrium for the NaX zeolite/benzene system, the permeation for such membranes can be predicted (see inset in Fig. 3 for a schematic of the membrane). Fig. 3 shows an example of benzene loading profiles through a relatively thin membrane predicted via direct KMC. As expected, the strong adsorption sites (S_{II}) are nearly saturated whereas the weak adsorption sites (W) are nearly empty. Interesting nonmonotonic loading profile on W sites, shown in Fig. 3, arises mainly because of the difference in the density of benzene inside and outside the membrane.

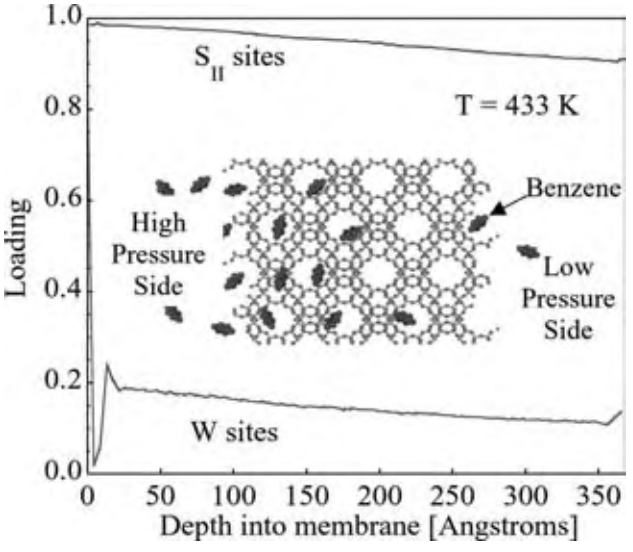

Fig. 3 One-dimensional loading profiles of benzene across a NaX zeolitic, single crystal membrane. The loading is the spatial average over planes perpendicular to the main diffusion direction (three-dimensional simulations are conducted; periodic boundary conditions are employed in the transverse direction and Robin at the membrane interfaces exposed to the high- and low-pressure sides). The inset shows a schematic of the membrane. *(View this art in color at www.dekker.com.)*

Simulations, such as the ones shown here, provide insights into loading profiles, which currently do not exist experimentally. At the same time, concentration profiles are a fingerprint of the diffusion mechanism[40] and could be used as an out-of-equilibrium test for stricter validation of a molecular model. Furthermore, molecular simulations enable one to predict flux and selectivity through membranes. These are spatiotemporal average quantities that can be compared to permeation experiments (such experiments are routinely conducted in several laboratories). More importantly, such simulations could be employed to understand how the microstructure and orientation of zeolite films affect separation properties and how important defects, e.g., grain boundaries, are for membrane performance. Such questions are presently unanswered. Yet, substantial improvements are possible if one were able to know what microstructures are best and subsequently how to make them.[41] Answers to such questions could provide insights into fabrication of systems with improved performance. Currently, real zeolitic membranes are polycrystalline and much thicker (1–30 μm) than the state-of-the-art simulated ones, and thus, comparison of KMC simulation to experiments is still infeasible. The above issues highlight the lack of strict out-of-equilibrium validation of molecular models and the limitation of KMC to reach realistic scales of experimental relevance.

Spatiotemporal Patterns on Catalyst Surfaces: The H_2/O_2 Reaction on Pt

Agreement of a spatially averaged quantity, such as a reaction rate and a temperature-programmed desorption spectrum, is often insufficient to test whether the underlying mechanisms and input in a molecular model are correct. Ideally, validation of molecular simulation predictions demands spatiotemporal data over a multitude of length and time scales. Unfortunately, such data are rarely available (see the membrane application example earlier). However, advances in scanning probe techniques start rendering such comparisons feasible.

We illustrate the above point with an example from the hydrogen oxidation on a single Pt(1 1 1) crystal. This system was recently studied experimentally by Ertl, Wintterlin, and coworkers, and motivated simulation because the corresponding continuum diffusion-reaction model was unable to capture some experimental features. Their experiments entailed predosing the

catalyst with oxygen and subsequently exposing the crystal to a hydrogen background.[42] Under certain conditions, a circular-looking wave propagates across the surface that is believed to emanate from an initial water cluster. The wave has a ring consisting of hydroxyl (OH), and as it travels outward into the pre-adsorbed oxygen pool, leaves behind mainly water.

Results from KMC simulations carried out with a detailed chemistry model were reported in Ref.[43]. The KMC simulation is able to capture qualitative experimental features without parameter adjustment. However, simulated length scales are slightly short, and finite-size effects probably affect the longer time evolution. Furthermore, the time scales predicted were longer than the experimental ones (dispersive NEXAFS data show that the difference in time scales is probably smaller[44]).

Sensitivity analysis (SA) could be an invaluable tool for understanding microscopic mechanisms, which unfortunately has been underutilized in molecular simulation in part because of its cost and the lack of system approach of the molecular simulation community.[23] We provide an SA illustration for the wave propagation problem. We have found that an increase in the diffusion coefficient of water leads to a reduction of predicted time scales, bringing simulation and experimental time scales closer. However, when one does not account for adsorbate–adsorbate interactions in diffusion, the increase of water diffusivity destroys the pattern, as shown in Fig. 4 (left panel). It is found that water–water and water–oxygen intermolecular forces via hydrogen bonding play a significant role in stabilizing the front and controlling time scales (Fig. 4, right panel). These simulations appear to be the first comparison of KMC with spatially distributed experimental data. More importantly, it appears possible to reveal the role of various molecular scale interactions in mesoscopic pattern formation.

REVERSE ENGINEERING USING MONTE CARLO METHODS

Recent advances in experimental techniques at the nanoscale and in high throughput experimentation (HTE) provide either information with unprecedented spatiotemporal resolution or massive data. Extraction of information from such data is also an optimization problem that is often referred to as ''reverse engineering.'' Here one bypasses the question of which are the actual kinetics giving rise to the experimental structures, i.e., how do these structures form and whether they are metastable or not, and simply focuses on determining these structures from data. Therefore, forward nonequilibrium KMC simulation is not carried out. Instead, MC is merely used as an efficient global minimum search (optimization) method [note that the term reverse MC (RMC) is also often employed] to determine structures consistent with experimental data.

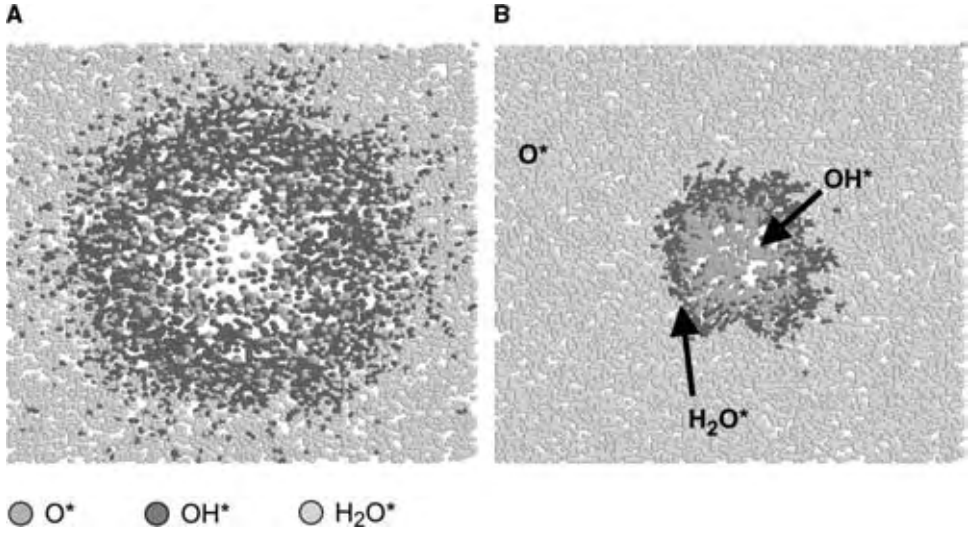

Fig. 4 Effect of intermolecular forces on wave propagation in the H_2/O_2 reaction on a single Pt crystal. The red dots represent OH, the gray adsorbed O, and the yellow water. For Fickian diffusion of water, i.e., in the absence of intermolecular forces, the wave propagates faster as the water diffusivity increases. However, the wave becomes ''diffuse'' (left graph) and eventually is lost (not shown) as realistic time scales are reached by increasing the diffusivity (A). Even weak attractive interactions between water molecules and between water and oxygen (e.g., 0.05 kcal/mol), owing to H bonding, are sufficient to keep the front sharp (right graph), even for the fast diffusivity used in the left simulation, so that the front is reminiscent of experimental data (B). *(View this art in color at www.dekker.com.)*

The overall idea of reverse engineering is simple. A ''cost'' function is formulated that represents the distance between experimental data and simulated results (this task parallels the molecular model parameterization discussed above). Multiple experimental points and multiple types of data can be added to the cost function. This is an important, highly recommended strategy because different types of experiments are usually sensitive to different parameters. Simultaneous use of multiple types of data constrains the system, resulting in a smaller subset of possible solutions. Given a cost function, one attempts random displacement of atoms or molecules in the system, which are accepted or rejected according to the Metropolis criterion.[24] According to the Metropolis criterion, the system can climb uphill in energy (in this case the cost function mimics the potential energy, and temperature has really no physical meaning). However, large barriers separating minima may prohibit the reach of global minimum in reasonable computational times.

The introduction of simulated annealing[45] has provided one of the best global optimization techniques and has become a widespread research tool. By slowly lowering the temperature from an initially high value, the system passes through quasiequilibrium states, and in principle the global minimum is obtained at low temperatures. Although this is undoubtedly a better approach compared with a single temperature MC simulation, possible large barriers still yield no guarantee that the global minimum is obtained. When the global minimum is desired, it is advisable that multiple runs starting from different initial configurations be exploited. Recent advances in tempering MC techniques provide an alternative approach.[46] A comparison of the efficiency of different MC search algorithms for HTE is given in Ref.[47]. Reverse engineering examples embody reconstruction of microporous carbon materials, nanoparticles of zeolites, porous media used as adsorption columns and fixed bed reactors, and design of libraries of materials, among many others.[47,48] Next we provide an example of reconstruction.

Structure Determination of Zeolite Nanoparticles in Hydrothermal Synthesis of Silicalite-1

One of the best-known zeolites is ZSM-5 whose lattice (MFI) is depicted in Fig. 5A. Its purely siliceous form is known as silicalite-1. Reverse engineering is used to determine the structure of silica nanoparticles formed during hydrothermal synthesis of silicalite-1 prior to any detectable crystallization of MFI zeolite particles. These nanoparticles have been detected prior to crystallization with scattering techniques and are believed

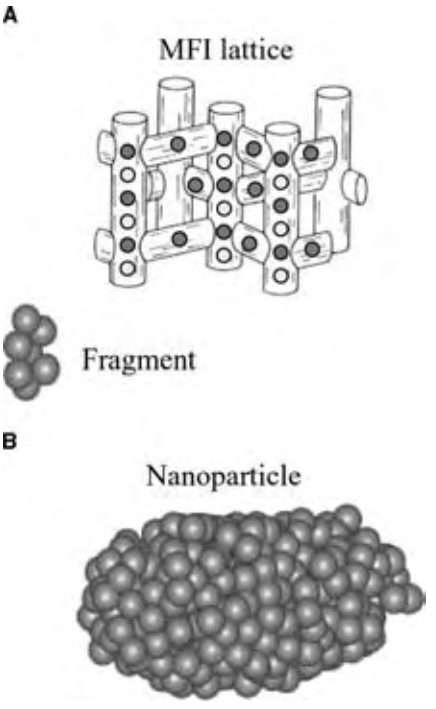

Fig. 5 Schematic of MFI lattice (A) and structure of siliceous nanoparticle determined by simultaneously fitting NMR and SANS data using simulated annealing (B). Small clusters (fragments) are often found to better fit the data. Each sphere in B represents a SiO unit. *(View this art in color at www.dekker.com.)*

to be the building growth units of zeolites.[49] Their size is usually in the order of 3–4 nm. Because of their apparent role in crystal growth of zeolites, an understanding of their structure is important.[50]

To determine the shape and structure of these nanoparticles, in situ ^{29}Si-NMR data have been obtained that reveal the local Si connectivity. Here Q^n ($n = 0, \ldots, 4$) denotes the coordination of a Si atom obtained from NMR, i.e., n is the number of Si atoms connected via an O bridge to a central Si atom. Knowledge of Q^n alone is insufficient to probe the long-range order, such as the size and shape of nanoparticles. In situ SANS data can provide information about the particle size, through the pair distance distribution function (PDDF). Using both NMR and SANS data within simulated annealing, possible structures have been computed (in preparation). Fig. 6 depicts how the simulated annealing works in this example, starting from a completely random distribution of ~400 SiO units. At high temperatures short-range order is built, manifested by the formation of small clusters (not shown), and the objective function decreases because the NMR data are fitted. Once a lower temperature is reached, longer-range order forms via an apparent Ostwald ripening type of mechanism, and the SANS

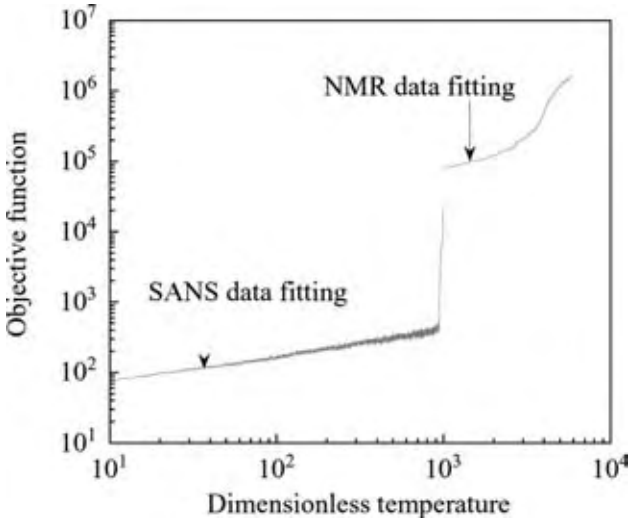

Fig. 6 Reduction of cost function with reducing temperature in simulated annealing calculations when determining the structure of siliceous nanoparticles by fitting NMR and SANS data. Short-range order occurs at higher temperatures and long-range order at lower temperatures. *(View this art in color at www.dekker.com.)*

data are fitted. An example of a possible structure is given in Fig. 5B (note that many structures can fit the experimental data). Fig. 7 and Table 1 show how well the PDDF/SANS and NMR data are captured, respectively. An important conclusion is that these nanoparticles are amorphous, elongated ellipsoids at

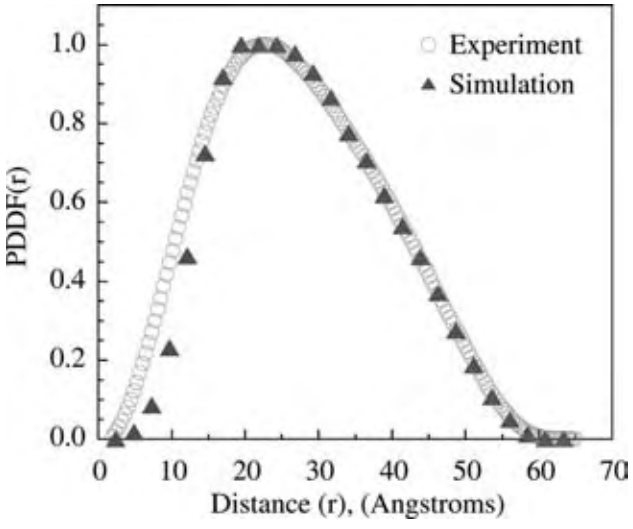

Fig. 7 Experimental and simulated PDDF of siliceous nanoparticles. The experimental PDDF is obtained via Fourier transform of SANS data and the simulated one from determining the nanoparticle structure (reverse engineering). The PDDF is fitted simultaneously with NMR data (see Table 1). *(View this art in color at www.dekker.com.)*

Table 1 Comparison of experimental NMR data and modeling results from determined structure of nanoparticles (see Fig. 5B for estimated structure)

room temperature that do not possess three-member rings. This information is important in building growth models.

EXTENSIONS OF MOLECULAR MODELING TO LARGER SCALES

Molecular models can considerably impact the chemical process industry. Obviously, numerous problems fall beyond the realm of conventional molecular simulation (see the example above on zeolitic membranes). Examples include dynamics of protein folding, diffusion through microporous membranes and human cells, formation of quantum dots in heteroepitaxial growth of semiconductors, and pattern formation on catalyst surfaces.

Currently, coarse graining of conventional molecular models, including MD, Brownian dynamics, and MC methods, to larger scales (often termed mesoscales) is pursued very actively. Most attempts of coarse graining are empirical in nature. One approach entails coarse graining in time of MD and KMC[51,52] to partially overcome the time scale gap. In the case of spatially varying systems, the system, e.g., a peptide, a polymer molecule, or a catalyst surface, coarse graining in space is carried out by discretization into coarse cells (also termed as interacting sites or lumps), each containing a number of actual atoms or microscopic sites (see Fig. 8). The united atom approach, where the atomistic view of carbon and hydrogen in a methyl or a methylene is replaced with a single sphere, is a widespread example of such coarse graining. Recent models though go beyond the united atom approach and combine a number of methylene (and possibly other) groups into a single lump. Lumping alone is obviously not sufficient for coarse-graining. Coarse-grained rules, such as potentials and transition probabilities, must also be derived. Currently these are fitted or reverse engineered so that the coarse simulation provides an accurate description of some microscopic simulation property, such as the pair distribution function (see for example Ref. [53]). Such spatial coarse graining can result in tremendous CPU savings because of removing degrees of freedom, i.e., fast relaxations, and

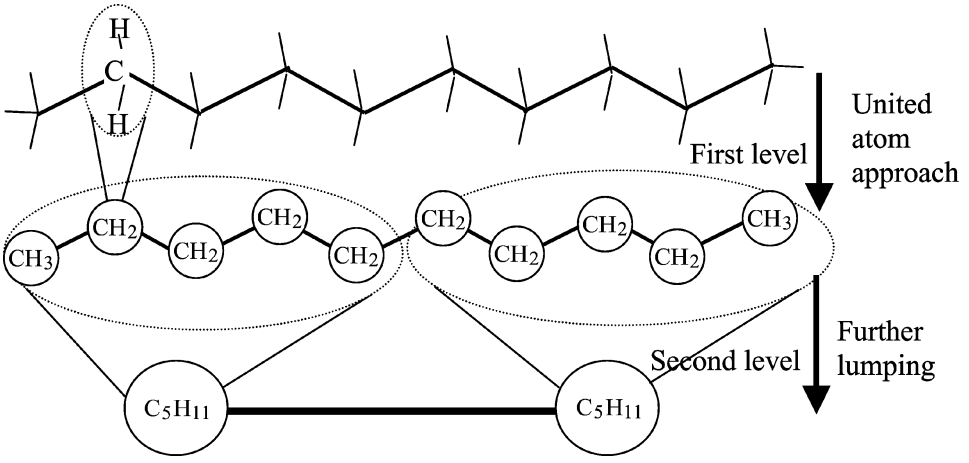

Fig. 8 Schematic of coarse graining of an *n*-decane molecule. In the first level, the united atom approach lumps hydrogen and carbons into methyl and methylene groups (spheres). In the second level, lumping of five groups into two supergroups (lumps or coarse cells) is depicted.

by reducing potential function evaluations (see grains in CPU in MD[53] and KMC[54,55]).

Several problems need to be overcome to render mesoscopic modeling an integral part of chemical process industry. One is the selection of the best size of coarse cells. Another is that the coarse rules are condition specific, i.e., they depend on density, temperature, etc. As a result, the coarse parameters need to be re-estimated for every new set of conditions. This is time consuming and tedious. These problems stem from the fact that first attempts of coarse graining are empirical in nature and lack a mathematical foundation that determines the factors controlling errors in coarse graining. Recent theoretical work on coarse graining of KMC[54–56] evidenced great promise to overcome the aforementioned problems. Here one derives from the microscopic mechanisms and rules, through nonequilibrium statistical mechanics, the coarse rules without fitting them to microscopic simulation results. As a result, reparameterization of the coarse rules is unnecessary. Furthermore, error estimates can be developed to guide optimum selection of coarse cell size. Also, microscopic cells can be used wherever there is a ''high activity,'' such as a chemical reaction, whereas coarse cells could be used far from such activity. These developments are at research level stages and it will take some time before they become an integral part of the chemical process industry.

CONCLUSIONS

Molecular modeling for nonequilibrium processes, such as heterogeneous catalysis and growth of advanced materials, is a relatively new tool in the chemical process industry. The advent of algorithms and advances in computer power on the one hand, and the development of coarse graining and multiscale techniques more generally on the other offer great promise for overcoming current limitations of molecular simulation and transform it into a design, predictive tool.

Molecular Self-Assembly

Yoon Seob Lee
James F. Rathman
Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, Ohio, U.S.A.

INTRODUCTION

Molecular self-assembly is the process in which molecules or molecular aggregates spontaneously organize into two- or three-dimensional supramolecular architectural objects. The formations of micelles and liquid crystalline phases in solutions containing surfactant molecules are common examples; however, in general, self-assembly phenomena are not limited to molecular-scale building blocks. Self-assembly is observed in processes on diverse length scales, from the atomic to the macroscale. Examples include amphiphilic polymers, such as block copolymers and dendrimers, and colloidal spheres and nanoparticles. The forces involved in self-assembly are weaker than the much stronger forces in covalent bonds. The organization of a self-assembled structure is maintained by a balance of weaker intermolecular forces. These forces include hydrogen bonding, coulombic interaction, coordination bonding, and van der Waals interactions. For example, self-assembly of amphiphilic molecules in water involves both hydrophobic forces, which tend to promote aggregation, and hydrophilic interactions, which favor the dispersion of molecules. Thermodynamically, self-assembly is in many cases similar to a phase transition with an important difference: the equilibrium size of the condensed phase may be finite. As the majority of self-assembly processes involve nanometer-sized entities, external effects such as capillary force, electric field, magnetic field, and flow can be strong and effective factors for controlling the self-organization.

Biological systems provide numerous examples of self-assembled objects. Owing to the relatively weak interactions involved, a self-assembled structure is much more sensitive and responsive to its environment than a more rigid structure held together by covalent bonds. Unlike processes involving simple surfactants, polymers, and nanoparticles, self-assembly processes in biological systems are usually directional and functional and often lead to the formation of extremely complex structures. For example, the three-dimensional structure adopted by a protein in solution is critical to the protein's function, and this structure is determined by both strong (covalent) and weak interactions. Thanks to the weaker interactions, the protein can respond dynamically to changes in its environment.

The wide spectrum of self-assembly phenomena can be categorized in various ways. In this entry, we discuss the similarities and the differences between two- and three-dimensional systems. The last section of this entry describes recent and possible future applications of self-assembly processes, mainly related to advanced materials, environmental issues, biotechnology, and nanotechnology. Emulsions, microemulsions, and foams are examples of important and common applications in which self-assembly plays a key role. These have a wide variety of industry applications from cosmetics, foods, detergents, oil recovery, drug formulation/delivery, petroleum refining, and mining. As these are the subjects of other topics in this encyclopedia, they are not covered here.

SELF-ASSEMBLY IN BULK (THREE-DIMENSIONAL SELF-ASSEMBLY)

Surfactant Self-Assembly and Micelles

Surfactants (short for surface active agents) are molecules that contain hydrophobic and hydrophilic groups within the same molecule.[1] A typical surfactant contains a hydrophilic ''head'' group and a hydrophobic ''tail'' group. Head groups can be cationic, anionic, nonionic, and zwitterionic.[2] Hydrocarbon tail groups can consist of one, two, or three saturated or nonsaturated chains. Surfactants with two head groups that are connected covalently through a linker (usually another hydrocarbon chain) are called Gemini surfactants.[3] Cationic and anionic surfactants are salts such as quaternary ammoniums and sulfates or sulfonates, respectively. Common nonionic surfactants include long chain derivatives of ethylene glycol head groups. Most zwitterionic surfactants have biological origins such as phospholipids.

In Fig. 1, the typical self-assembly process of surfactant molecules in aqueous solution to form aggregates called micelles is illustrated. At very low concentrations, the solution is a simple dispersion of individual

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007870

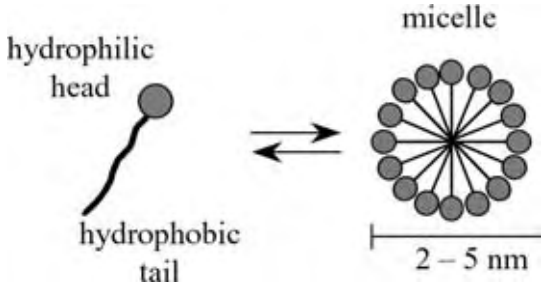

Fig. 1 Schematic of molecular self-assembly process of surfactant molecules. *(View this art in color at www.dekker.com.)*

surfactant molecules. Micellization begins at a concentration called the critical micelle concentration (cmc). Below the cmc, the hydrocarbon chains of surfactant monomers are encapsulated by the clusters of water molecules; the diffusion rate of molecules in this ''iceberg structure'' surrounding the hydrocarbon tails is approximately 1000 times slower than that of free water molecules.[1] Aggregation of surfactant monomers into micelles results in a release of the bound water because of favorable attractive interactions between surfactant tails. This phenomenon is called the ''hydrophobic effect'' and is the main driving force for micellization and many other self-assembly processes. Note that in a micelle the hydrophilic head groups remain exposed to the aqueous solution. When the head groups are ionic or dipoles, there is a net electrostatic repulsion between head groups. The equilibrium size and the shape of a micelle depend on the balance between the attractive and the repulsive forces. Any internal or external factor that affects this force balance can consequently change the micelle sizes and shapes. Such effects include the molecular structures of surfactants, surfactant concentration, solution pH, temperature, pressure, and the types and concentrations of counterions. Micellar diameters are typically in the range of 2–5 nm, primarily depending on the length of hydrocarbon chains. Micelles are dynamic objects—covalent bonding plays no role in this process. There is a continuous exchange of surfactant molecules between the monomer and micelle ''phases'' on a time scale of $\sim 10^{-5}$ sec. The micelle as a whole also may break up and reform, a relatively slow process that occurs on a time scale of 10^{-3} sec.

In Fig. 2, a variety of micelle structures are shown. Typical shapes of micelles are spherical, rod-like, and worm-like. At high concentrations of surfactant or at high concentrations of counterions, liquid crystals are usually formed. Hexagonal, cubic, and lamellar are common liquid crystal phases that occupy much of a

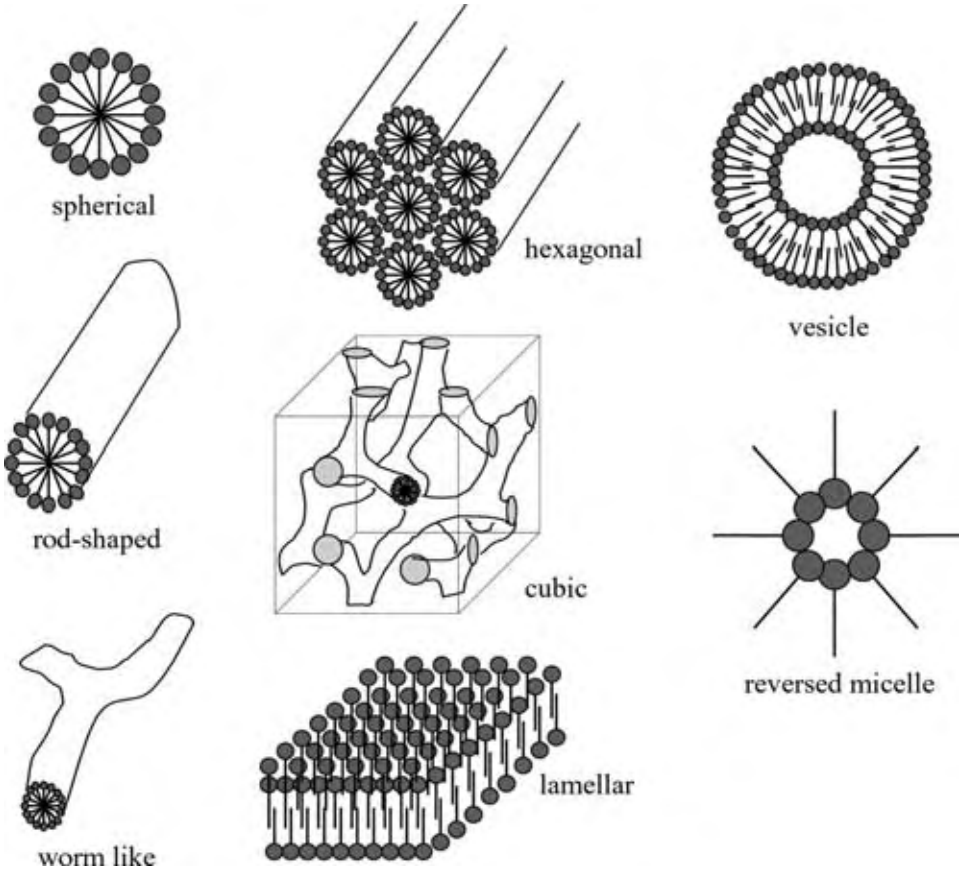

Fig. 2 Schematics of a variety of micelle structures. *(View this art in color at www.dekker.com.)*

typical phase diagram. Only three space groups are known for cubic structures of surfactant liquid crystals: *Ia*3*d*, *Pm*3*n*, and *Im*3*m*. Depending on the components and conditions, there can also be intermediate phases of liquid crystals, but usually only in a very narrow range of concentrations. These include orthorhombic, rhombohedral, and tetragonal phases. Because their structures and properties are strikingly similar to those of the biological membranes, vesicles are widely being applied as models for the study of biological cells.[4] Lipids having two hydrocarbon chains are typical amphiphiles that form vesicles (liposomes). Mixed systems of anionic and cationic surfactants at relatively low concentration may form vesicles too. When the medium consists of a binary or ternary aqueous mixture with organic solvents, their dielectric constant strongly affects the micellization, and reverse micelles can be formed at low water content. In a reverse micelle, the hydrophilic head groups are oriented inward, surrounding a small core of water molecules, while the hydrocarbon chains are oriented outward toward the oil-like solvent. Hexagonal and cubic liquid crystals have their reverse micelle-like counterparts in a media rich in the oil-like component.[5] Phase transitions between all these micelle structures including liquid crystals are possible through first order transitions.

The molecular packing parameter is a useful concept for understanding how the structure of an individual surfactant molecule influences the type of aggregate that will form by self-assembly. As illustrated in Fig. 3, the packing parameter (N_s) is simply the ratio of the volume of the hydrophobic tail to the product of the tail length and the effective head group area. Owing to the many factors that influence self-assembly, the packing parameter is an overly simplistic concept; for example, the effective head group area is often difficult to estimate because of hydration and electrostatic interactions. Despite these limitations, this dimensionless parameter does in many cases provide at least a qualitative understanding. Low values of N_s favor structures with positive curvature such as normal micelles; intermediate values favor surfaces with no net curvature, such as bilayers and cubic structures; and high values result in negative curvature.

Self-Assembly of Amphiphilic Polymers

The basic principles and driving forces for the self-assembly of polymers (polymer micellization) are the same as for the micellization of surfactant molecules. Dendrimers, and di- and tri-block copolymers are the typical amphiphilic polymers that form polymer micelles. For block copolymers, polypropylene or polybutylene segments compose the micelle cores, while polyethylene segments are the micelle corona that is exposed to water. Depending on the length of the polymer chains, micellization can occur either by intramolecular folding or by intermolecular aggregation. Polymer micelles have shapes analogous to surfactant micelles including liquid crystals, but the sizes are usually larger than their surfactant counterparts because of their molecular characteristics.[6] There are also intermicellar and intramicellar exchange processes in polymer micelles, but the diffusion rate is much slower than that of the surfactant micelles. Neutron scattering is an excellent tool to study polymer micelles, especially through contrast matching techniques.

Biological Self-Assembly

Many essential life activities are strongly controlled and regulated by self-assembly processes.[7] In addition

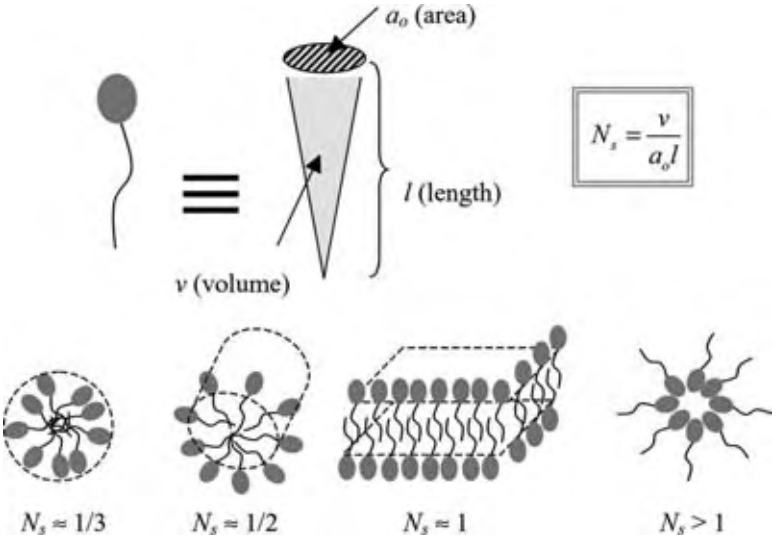

Fig. 3 Molecular packing parameter. *(View this art in color at www.dekker.com.)*

to the hydrophobic and electrostatic forces that are major players in the self-assembly of surfactants and polymers, the formation of self-assembled biological structures also often involves hydrogen bonding, π–π stacking, and coordination bonding. Covalent bonding, often involving disulfide bonds, may also be an important part of the self-assembly process.[8] These rather strong forces not only provide additional driving forces for biological self-assembly, but in many cases act as ''functional forces'' as well (Fig. 4).[9,10] As a result, biological self-assembly processes are directional (DNA, RNA, tobacco mosaic virus), functional (proteins, molecular motor), nearly irreversible (streptavidin–avidin complexation), molecular recognizing (antibody–antigen), and highly selective (enzymes and membranes). A variety of vital life activities such as cell–cell interaction, intercellular aggregation, activation of the cytoskeleton, transport through plasma membranes, cell fusion and lysis, focal adhesion, roles of collagen and fibronectin, and movement of certain cells on solid surface are largely because of biological self-assembly, which can be understood as the hierarchical evolution of self-assembly in nature.[11] Owing to its diversity and complexity, biological self-assembly is more difficult to characterize than surfactant and polymer self-assemblies.

Meso-/Macroscale Self-Assembly

Self-assembly is not limited to molecular-scale building blocks. It is possible in much larger entities, usually aided by external forces such as capillary effects, electric and magnetic fields, and shear and elongational flows. These approaches rely on the careful design and modification of surface chemistry of the building block objects. For example, assembly of solid objects on the millimeter-to-centimeter size into an amazing level of hierarchy and architectural variety using lateral capillary forces has been demonstrated.[12]

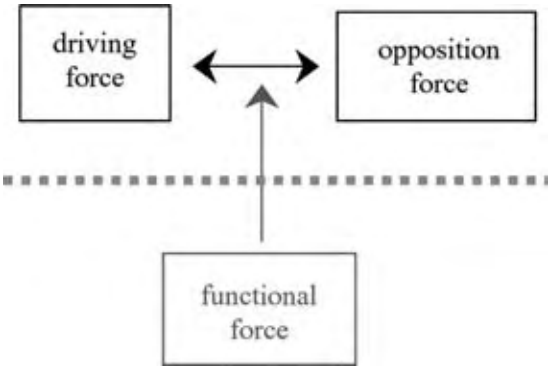

Fig. 4 Process of molecular self-assembly in biological systems. *(View this art in color at www.dekker.com.)*

Assembly and directional orientation of liquid crystals of 5CB (4-cyano-4′-pentylbiphenyl) under magnetic field provide another example of this category of self-assembly.[13]

SELF-ASSEMBLY AT INTERFACE (TWO-DIMENSIONAL SELF-ASSEMBLY)

Some of the most interesting examples of self-assembly arise at the interfacial region between two bulk phases. Surfactant molecules, for example, tend to concentrate at interfaces, and self-assembly can give rise to intricate patterns and structures.

Surface Micelles at Liquid–Solid Interface

Just as surfactants in bulk solution aggregate to form three-dimensional structures such as micelles, those adsorbed at an interface may self-assemble to form two-dimensional structures. In the past decade, the long-debated existence of ''surface micelles'' at liquid–solid interfaces has been conclusively proven, in large part thanks to the development of new imaging techniques such as high-resolution atomic force microscopy (AFM).[14] In Fig. 5, side views of two types of possible surface micelles at solid surfaces formed in solution are presented: hemimicelle and semimicelle. Hydrophobic and electrostatic forces largely govern the formation of these surface micelles and determine their sizes (diameter). As this micellization is believed to proceed after adsorption (physisorption) of amphiphilic monomers onto the solid surfaces from solution, solid surface properties such as hydrophobicity, lateral defects, and epitaxy strongly affect the final geometry of surface micelles. Hemimicelles are usually formed on hydrophobic solid surfaces, while semimicelles are formed on hydrophilic solid surfaces. Lateral dimension and length are in many cases affected by surface epitaxy. Typical factors governing bulk micellization such as monomer concentration, solution pH, type and concentration of counterions, temperature, and pressure are still important during this two-dimensional micellization. Bulk micelles have the capacity to solubilize nonpolar oil-like solutes inside

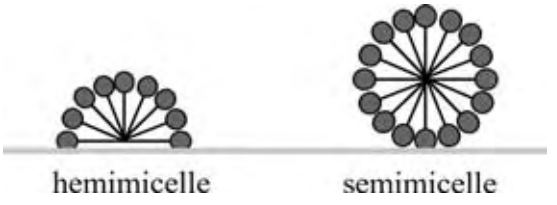

Fig. 5 Schematic side views of two typical admicelles at solid surfaces. *(View this art in color at www.dekker.com.)*

the micelles in a process called ''micellar solubilization.'' Analogous to this bulk micellar solubilization, both hemimicelle and semimicelle are capable of solubilizing nonpolar solutes inside their core region (coadsorption, adsolubilization, or surface solubilization).[15] Lateral dimensions of both hemimicelle and semimicelle are either a rod-like linear or a worm-like curved geometry. Both geometries are always highly parallel to each other and are believed to be governed by surface epitaxy. As the formation of surface micelles begins with the physisorption of monomers, there is always a monomer exchange process between surface micelles and monomer and micelles in bulk solution.

Bilayer structures may also form at solid surfaces instead of surface micelles. Whether or not they are intermediate phases for surface micelles or true stable thermodynamic phases is currently not known. As in bulk micelles, the phase transition that proceeds gradually by the change of micelle surface curvature seems to be possible in surface micelles also.

Surface Micelles at Gas–Liquid Interface

In Fig. 6, the top and side views of surface micelles at an air–liquid interface are illustrated. First proposed by Langmuir in the 1930s and debated very extensively in the literature, the existence of this equilibrium surface micelle has only recently been proven by both experimental data and theory.[16] Thermodynamic energetics and molecular packing for three-dimensional self-assembly in bulk can be directly extended to this two-dimensional system. For surface micelles, the critical micellar area (cma) is now analogous to the cmc for characterizing the onset of micelle. Both surfactants and amphiphilic polymers can form these surface micelles, with the number of aggregation molecules ranging from 10 to 1000. Structural transitions, as in bulk micelles, are possible, such as from circular-to-rod and liquid crystal-like structures, and even reverse micelles, as the surface curvature (or molecular packing geometry) is increased. The exchanging process between monomer and micelle, and intermicellar diffusion is also important, but there is no experimental report in this area to date.

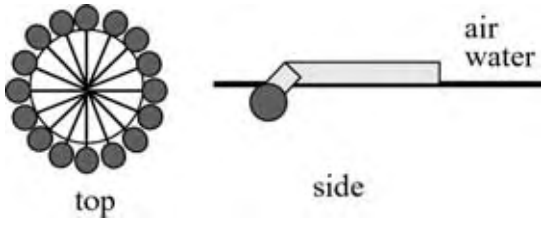

Fig. 6 Illustration of top and side views of surface micelle at air–liquid interface. *(View this art in color at www.dekker.com.)*

Langmuir Monolayers and Langmuir–Blodgett (LB) Films

In Fig. 7, the typical process for the formation of Langmuir monolayers and LB films is presented. When a Langmuir monolayer is transferred to a solid substrate at an angle other than vertical it is called Langmuir–Schafer deposition, and the deposited film is an LS film. There are no experimental and theoretical reports so far as to whether the concept of molecular packing (that was successfully applied to hemimicelles, semimicelles, and surface micelles) can be extended to these systems. The surface pressure–area isotherm is an excellent tool to follow this self-assembly event at a molecular level. At low surface pressure, the gas-like phase or ''liquid extended'' phase of amphiphilic monomers is dominant. As the surface pressure is increased, the gas-like phase is equilibrated with microsized domains called ''liquid condensed'' phase. The formation of this domain is caused by the competition between dipole moment and line tension. At high surface pressure, a tightly packed ''solid'' phase is formed. Technically, LB or LS films can be obtained at any stage of this phase transition of Langmuir monolayer, but the act of the meniscus at the point of solid–liquid–gas interface and the interaction between Langmuir monolayer and substrate often create defects such as stripe patterns, holes, and deformations of domains. This is indeed a mechanical assembly of amphiphiles (mainly insoluble or nearly insoluble) at air–liquid interface rather than a purely spontaneous thermodynamic self-assembly such as surfactant or polymer micelles. Hydrophobic and electrostatic interactions are important for the formation of domains or phases, but they are not major driving forces for the assembly. Molecular geometry of amphiphiles highly affects the size and shape of the domains, the stability of monolayers and films, and overall phase transitions. Usual parameters such as solution (subphase in this case) pH, temperature, and counterions in subphase are also strong factors for the phase formation and transitions. Surface tension and spreading are also important colloidal factors for the assembly of Langmuir and LB films.[17] Dynamic processes, such as self-diffusion or tumbling of monomers in the monolayer or film, and molecular orientation such as vertical molecular tilting or lateral positioning, are currently under intensive study.

Self-Assembled Monolayers (SAMs)

In Fig. 8, the typical structure of a SAM on a solid surface is shown. The driving force for the formation of SAMs is either coordination bonding or covalent bonding. Amphiphiles or even short chain hydrocarbons

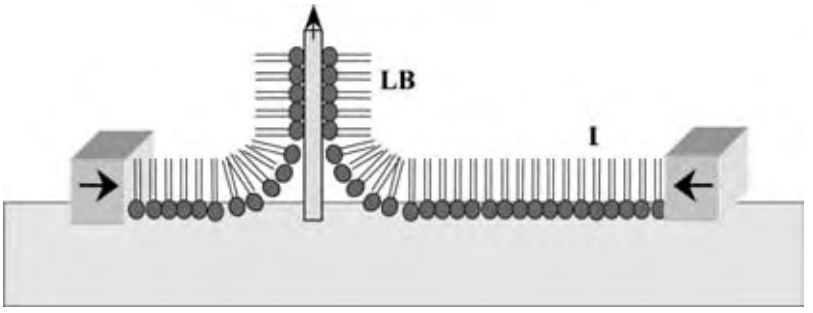

Fig. 7 Schematic for the formation of Langmuir monolayer (L) and LB film. *(View this art in color at www.dekker.com.)*

with functional (usually terminal) groups such as thiol, phosphonoic, or silane can form SAMs on a variety of solid surfaces such as gold, silver, platinum, copper, mica, silica, etc. Molecular packing is governed by hydrophobic effects, molecular structures, and surface epitaxy. Electrostatic interaction is usually not a major factor in this assembly. In a variety of media such as aqueous solution, gas, or supercritical fluid, SAMs are formed spontaneously. They show an excellent stability upon the exposure to air owing to the strong bonding between organics and substrates.[18] Domain formation and phase transitions observed in Langmuir monolayers and LB films are rarely observed in SAMs for this reason. Even though the bonding is rather strong between the monomer and solid substrate, there is an exchange process between the monomer and SAM upon the immersion of the SAM in solution.

Layer-by-Layer Self-Assembly

Alternating deposition of organic polyelectrolytes with multiple cationic and anionic charges can create well-defined nanometer-sized multilayers on solid surfaces. Electrostatic interaction is the major player for this type of self-assembly. Hydrophobic forces and molecular structure largely determine the film thickness and physical properties, but are not the major driving forces. Unlike SAMs, which often cannot be successfully formed on curved surfaces owing to the packing constraint (too loose packing on the end region of the chain that is exposed to air), assembly through layer-by-layer approach can be successfully performed on highly curved surfaces, even on surfaces of colloidal particles.[19] The flexibility of polymer chains should be carefully considered in this process. This assembly process is somewhat mechanical, in a sense that it requires constant repetition of immersion and drying. The result is highly organized well-defined self-assembled multilayers of polymeric polyelectrolytes through a very simple process. This cannot be obtained through LB or SAM techniques. Detailed structural study, diffusion issues, and exchange process are under investigation.

CURRENT AND FUTURE APPLICATIONS

Biomineralization and Biomimetic Materials

The structural variety and the morphological variety of biominerals such as aragonite and calcite are used in nature to achieve diverse functionality and amazing mechanical properties. Understanding the process by which these materials are formed will therefore provide excellent insight into the development of new synthetic materials.[20] The key to biomineralization, the process in which these materials are produced in nature, is the cooperative self-assembly between inorganic constituents and self-assembled bio-organics such as proteins, enzymes, and membrane lipids. These self-assembled structures act as templates on which the polymerization of reactive inorganics takes place to form the final structured solid material. Biominerals can be formed through nonselective random polymerization or selective growth on specific sites on bio-organics. An important characteristic of this process is that the self-assembly usually proceeds multistepwise, making the final structures highly hierarchical.[21] Mimicking the biomineralization process in the laboratory is believed to be a very promising and efficient route toward the discovery of new materials with excellent mechanical (high volume-to-weight ratio), chemical (functional sites), and magnetic properties. Diatoms, animal bone, abalone shell, spider silk, and eggshell are among the many examples of complex materials produced in nature by biomineralization.

Advanced Materials

Examples of advanced materials include highly porous materials, such as zeolites and mesoporous materials, and multifunctional materials such as magnetorheological fluids and optomagnetic multilayered films. Methods in which organic self-assembled aggregates served as the guide or removable template for the synthesis of meso- and macroporous materials are prime examples of the utilization of self-assembly in this field of research.[22] This process can be considered as the analogy of biomineralization, in the sense that the cooperative self-assembly process is strongly involved between the inorganic constituents and the organic self-aggregates, and the entire process proceeds in a multistepwise manner. There is no selective assembly involved. The mesoporous materials have well-controlled pore sizes and shapes between two and a couple of hundred nanometers and high inner surface areas of $1000\,m^2/g$ or even higher. These remarkable physical properties are tunable through the manipulation of the self-assembly processes. Pore sizes are directly determined by the size of micelles, which is the function of the length of the monomers. Three-dimensional pore arrangement in hexagonal, cubic, or lamellar is the result of respective formation of liquid crystals of organic–inorganic composites. Often phase transitions between mesophases are observed, which is the result of the change of charge matching and packing geometry of micelles. Modification of the inner surface of mesopores for the secondary functionality such as selective binding and separation of heavy metals from wasted water can be accomplished using SAMs. Multilayering is another key in the field of advanced materials. Examples include the preparation of multifunctional materials, nanosized devices, biological sensors, drug delivery systems, and biomimetic systems for the study of biological systems. For this task, LB film techniques and layer-by-layer self-assembly provide facile and economic routes with molecular level precision. In combination with molecular recognition and directional properties of biological self-assembly, this approach can provide powerful structural diversity and control.

Nanoscience and Nanotechnology

The core concept of this fast growing new field is the ability to manipulate/assemble nanometer-scale building blocks into integrated systems.[23] Self-organizing phenomena and nanoscale events share the same working length scale of 1 nm–1 μm and are driven by the same major forces of formation, primarily weak intermolecular forces. This provides the foundation of the so-called ''bottom-up'' construction of nanoscale supramolecular architecture. The variety of above-mentioned classes of self-assemblies can provide a rich spectrum of tools to achieve this goal. Understanding and manipulation of self-assembly processes and self-aggregates in general represent the ability to assemble/link molecular or colloidal level entities together with high precision. Biological self-assembly can bring direction, selectivity, and hierarchy to this. Compared with ''top-down'' approaches that rely on creating features by ''chiseling'' bulk raw materials into nanosized architectures, the bottom-up approach can be used to create features with dimensions smaller than what can be attained by top-down methods such as lithography or microprinting. Another suggested advantage of the bottom-up approach is that it can possibly be designed to have built-in error-checking process.[24] Some of the details include synthesis and nanofabrication of nanosized material such as nanoparticles, nanocrystals, and colloidal particles, nanoelectronics, bioelectronics, molecular switches, hybridization of noncomparable materials such as bioinorganic, and biometal for multifunctional materials, and processing of functional organics such as conducting polymers or conjugate oligomers.[25] The key point of course is how to improve upon the precision that is currently available by top-down techniques. This requires a thorough understanding of the interplay between various types of colloidal forces, the exact role of each force, the interaction with the surrounding environment, and, most importantly, a facile way to control them in a mass scale.

Biological Issues and Biotechnology

In mature, self-assembly plays a key role in a huge array of nanoscale events such as protein folding/defolding, gene expression, RNA transfer, and functions of cell membrane. Understanding the delicate balance between driving and opposition forces, role of functional forces, molecular and structural origin of these forces, and changes of these forces by the surrounding factors are vital to understand biological systems. Self-assembled monolayers such as SAMs and Langmuir monolayers provide useful model systems for the study of biological membranes.[26] Similarly, liposomes and amphiphilic vesicles provide highly simplistic but useful models of biological cells. These systems provide a wide variety of site-specific functionality and domain- or phase-orientated issues that can be easily reproduced and tested in vitro.

Biotechnology deals with the engineering of biological systems. Development of target drug delivery vehicles, functional biomaterials that can be comparable with both biosystems and solid materials, such as inorganics or metals, and cell cultivation for the large-scale

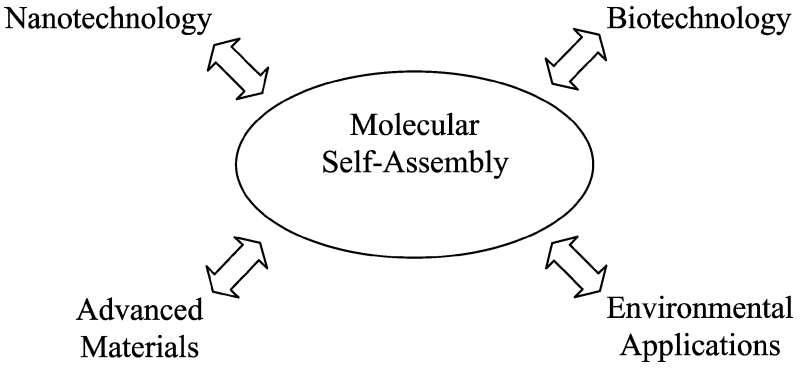

Fig. 9 Diagram of bottom-up self-assembly approach to nanotechnology, biotechnology, advanced materials, and environmental issues.

and effective production of molecular drugs are among many possible excellent examples.[27] Issues related to molecular self-assembly again are inevitably involved with these subjects, often because of effects resulting from weak intermolecular forces and molecular packing.

Environmental Issues

Two basic approaches for a better environment are minimal use of potential pollutants and effective removal of pollutants. Surfactant or polymer micelles have been demonstrated to effectively catalyze many types of reactions in aqueous solution involving organic reactants that are only sparingly soluble. Environmentally toxic materials that are insoluble or have limited solubility in water are solubilized and reacted inside micelles. Systems such as this that are macroscopically homogeneous but microscopically heterogeneous can be used as alternate solvents to minimize the use of organic solvent in industry processes. High loading, subsequent changes of micellar phases, and separation of desired product after the reaction are the issues for major research in this regard. The second approach can include microfiltration using micellar membrane systems, soil remediation using colloidal materials such as mesoporous materials and nanoparticles (for example, bimetallic nanoparticles), and sonochemical removal of pollutants. Micellar solubilization, counterion binding, and interfacial self-assembly are among the key concepts in addition to the self-assembly process itself.[28]

CONCLUSIONS

The spontaneous formation of structures by self-assembly relies on a delicate balance of relatively weak intermolecular forces such as the hydrophobic force, electrostatic and van der Waals interactions, and hydrogen bonding. Building blocks for self-assembly can range from small atoms to much larger macroscale objects. A wide variety of two- and three-dimensional architectures are possible; common examples include micelles, liquid crystals, tertiary protein structure, cell membranes, monolayers, multilayers, vesicles, and liposomes. Self-assembled structures are responsive to their environment; hence, factors such as temperature, pressure, solution pH, and additives strongly affect the self-assembly process. External factors such as capillary force, flow, magnetic field, and electric field can also be used to control the self-assembly process.

Self-assembly plays a key role in many areas (Fig. 9). Using self-aggregates as templates has proven to be an extremely powerful approach for developing novel materials, especially mesoporous particles and films for use as catalysts, catalyst supports, sorbents, and molecular sieves. Biological systems offer many examples of highly complex process in which intricate structures formed by self-assembly play a key role. Understanding these systems will help drive the development of next-generation materials.

Ken D. Shimizu
Department of Chemistry and Biochemistry, University of South Carolina, Columbia, South Carolina, U.S.A.

INTRODUCTION

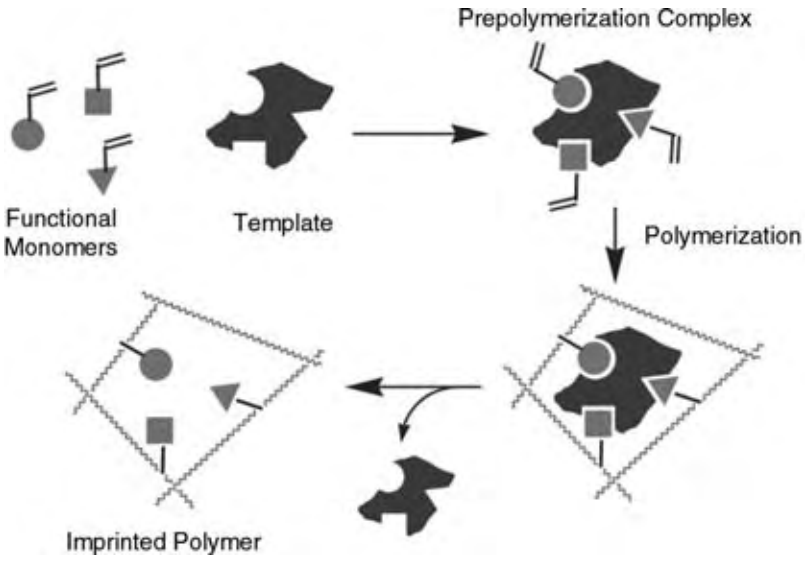
Molecularly imprinted polymers (MIPs) are polymers formed in the presence of a template molecule. Removal of the template from the polymer matrix creates complementary binding sites with affinity and selectivity for the template molecule. Molecularly imprinted polymers are attractive materials capable of molecular recognition owing to their versatility, ease of preparation, and robust physical and chemical properties. Over the past 30 years, MIPs have been developed as stationary phases in chromatography, heterogeneous catalysts in organic synthesis, and sensors for a wide array of biologically relevant compounds. This review seeks to highlight the accomplishments of these materials over this period of time, which has led to their rise in popularity and their potential in commercial applications. We begin by describing the primary approaches to preparing MIPs, and then discuss their success in various applications. We conclude with an eye to the future and suggest where the imprinting field may be heading.

BACKGROUND

Molecular recognition is an important feature of all essential biological processes. For example, enzymes and monoclonal antibodies are able to identify a specific substrate in the presence of many other structurally similar entities and then carry out their catalytic and immune response functions. The study of the recognition properties of these systems has led to insight into the mechanisms of binding and the subsequent rational design of many pharmaceuticals and chemosensors. Both biological and synthetic receptors have been intensely studied as the focus of research groups but each presents a unique set of challenges.[1–4] Biological recognition systems, such as enzymes and antibodies, have a fairly narrow range of chemical, thermal, and physical stability, which limits their ''shelf life'' and ultimately, their utility in commercial applications. They also typically, require time-consuming preparation from biological sources and the necessity to sacrifice animals. Synthetic molecular receptors, on the other hand, are more chemically and thermally stable and can, in principle, be prepared in large quantities. However, synthetic molecular receptors typically have much lower selectivity and binding affinities when compared to their biological counterparts, and they also require lengthy multistep syntheses.

Since the early 1970s, an alternative route to easily-tailored recognition materials has attracted considerable interest in the form of MIPs.[5,6] Molecularly imprinted polymers are synthetic polymers that contain shape-specific binding cavities that are lined with complementary functional groups, mimicking the recognition properties of biological systems.[7,8] These materials are versatile and easy to prepare. A generalized imprinting scheme is shown below (Scheme 1). First, a template or ''guest'' molecule is chosen and is linked to functional monomer(s) via either covalent or noncovalent bonds to form a prepolymerization complex. The prepolymerization complex is then preserved by polymerization into a highly cross-linked polymer matrix, when rigid cavities are formed that are complementary in size and shape to the template. Upon removal of the template molecule, the polymer is ready to be used as a recognition material for the host molecule. Imprinted polymers have many attractive characteristics, such as the ability to be prepared and utilized in organic solvents. They retain their recognition properties when stored dry for long periods of time and are thermally stable up to 125°C. Molecularly imprinted polymers are readily accessible in large quantities as they can be formed in a single step from commercially available starting materials. Finally, the recognition properties of imprinted polymers can be easily tailored to new substrates simply by carrying out the polymerization using the appropriate template molecule. This combination of attributes is complementary to the molecular receptors produced by immunological and organic synthesis. For example, MIPs can be made using highly toxic or hydrolytically

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120041040

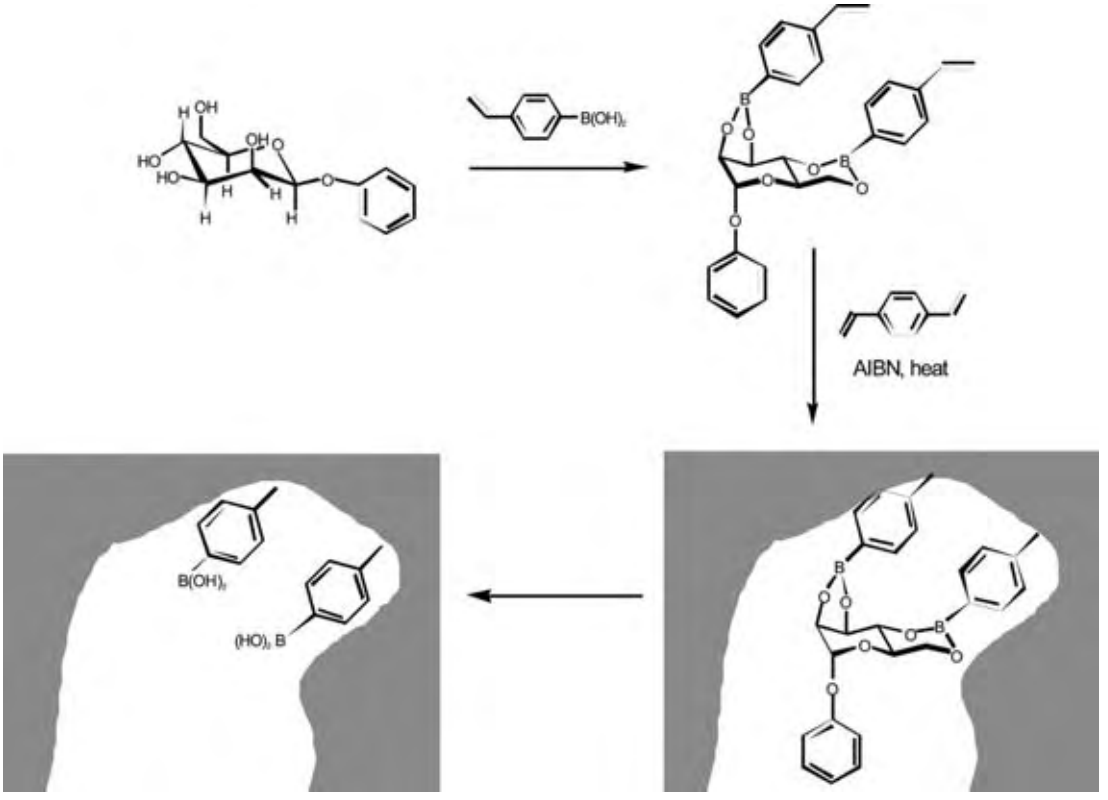


Scheme 1 The imprinting process begins with the selection of a template molecule and complementary functional monomer(s). *(View this art in color at www.dekker.com.)*

unstable templates, such as nerve toxins, pesticides, or short peptides for which antibodies cannot be directly elicited. The molecular imprinting process is also more efficient than the preparation of most synthetic or biological receptors.

The first forays into molecular imprinting took place in the 1940s when Frank Dickey, a student of Linus Pauling, prepared silica gels in the presence of organic dyes, such as methyl orange and found that these gels showed improved adsorption of the dyes as compared to a control gel.[9] Although these results were promising, it was not until the early 1970s that Gunter Wulff began conducting research that served as the impetus for the current generation of molecularly imprinted materials. Initial efforts by Wulff et al. focused on the difficult problem of carbohydrate recognition using boronic acid monomers that form covalent boronate linkages with 1,2-diols. Although the boronate ester is a covalent linkage, it is reversible and can be cleaved under hydrolytic conditions (Scheme 2). This covalent imprinting approach yields a homogeneous population of binding sites with a high affinity for the template, which could even resolve enantiomers when the polymer was used as the stationary phase in liquid chromatography. For example, when phenyl-α-mannopyranoside was selected as the template and (4-vinyl)-phenylboronic acid was used as the monomer, the resulting MIP could discriminate D- and L-enantiomers with baseline separation and separation factors up to 4.56.[10] The enantioselectivity of the imprinted polymer provided verification that the imprinting process produced template selective binding cavities. The constituent monomers are achiral and, therefore, the enantioselectivity of the imprinted polymer can only arise from the imprinting process. Polymers made without template did not show any enantioselectivity when measured under similar conditions.

While the covalent imprinting approach proved successful, it was limited to templates that could form labile covalent bonds to a functional monomer, such as boronic esters, imines, ketals, and disulfides. In the 1980s, a new noncovalent imprinting approach was introduced by Klaus Mosbach. The noncovalent imprinting approach quickly became the preferred approach owing to the ease of synthesis and the ability to tailor the materials to accommodate a wide range of template molecules. The key feature of the approach was the in situ formation of the prepolymerization complexes via self-assembly of the template and functional monomers using reversible noncovalent interactions, such as hydrogen bonding, electrostatic interactions, solvaphobic, and π–π interactions. This simplifies the imprinting procedure into a more versatile one-pot process (Scheme 3). The self-assembled prepolymerization complex is formed by simply combining the component template and functional monomer(s) and then is polymerized into a highly cross-linked polymer matrix. The reversibility of the template–functional monomer interactions in the prepolymerization complex allowed a common set of functional monomers and cross-linkers to be used with many different template molecules. The most common pair of functional monomer and cross-linking agent is methacrylic acid (MAA) and ethylene glycol dimethacrylate (EDMA). This copolymer system has been used to imprint amino acids, pharmaceuticals, and herbicides. An additional advantage of the noncovalent imprinting approach is that interactions of the imprinted binding cavity with the template molecule are also noncovalent interactions. This allows for much faster binding kinetics, which is important for

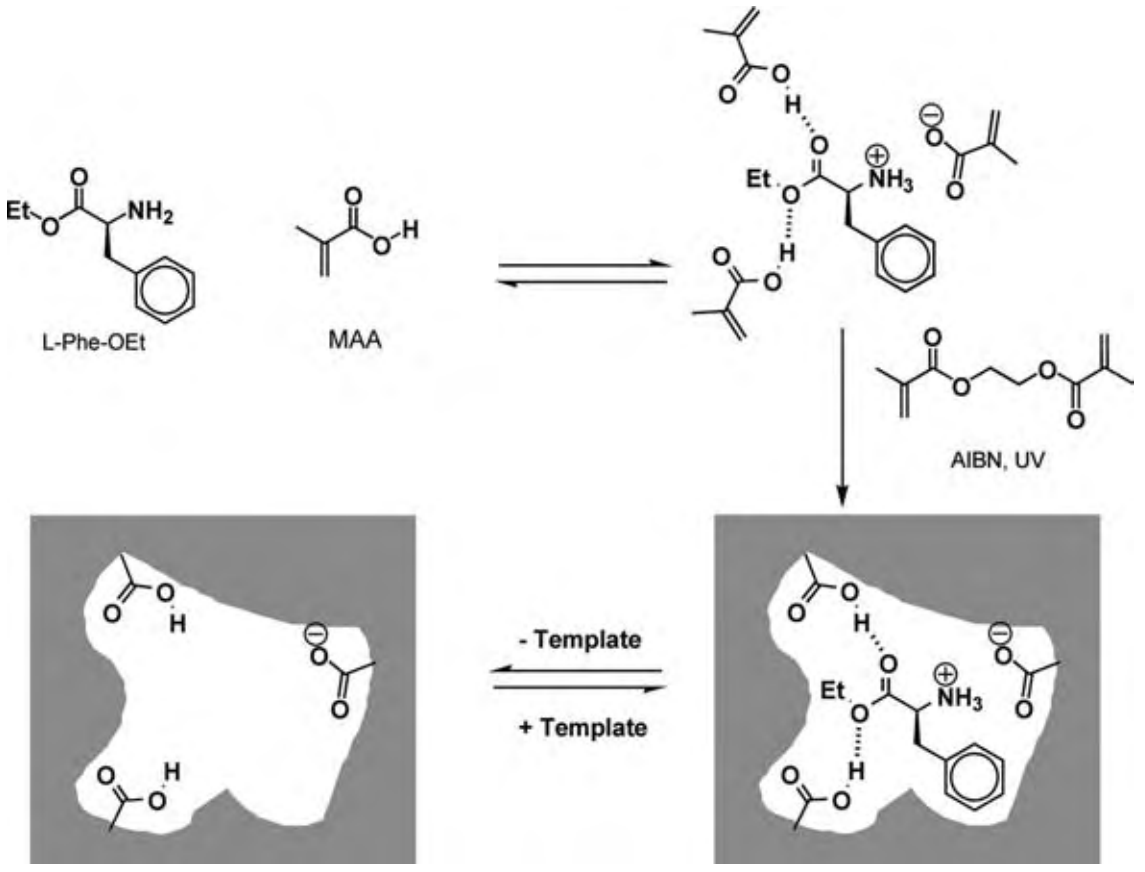


Scheme 2 Covalent imprinting of α-phenyl-D-mannopyranoside in a DVB/4-vinylphenylboronic acid matrix, via the formation of covalent boronic ester linkages between the 4-vinylphenylboronic acid and the carbohydrate. *(View this art in color at www.dekker.com.)*

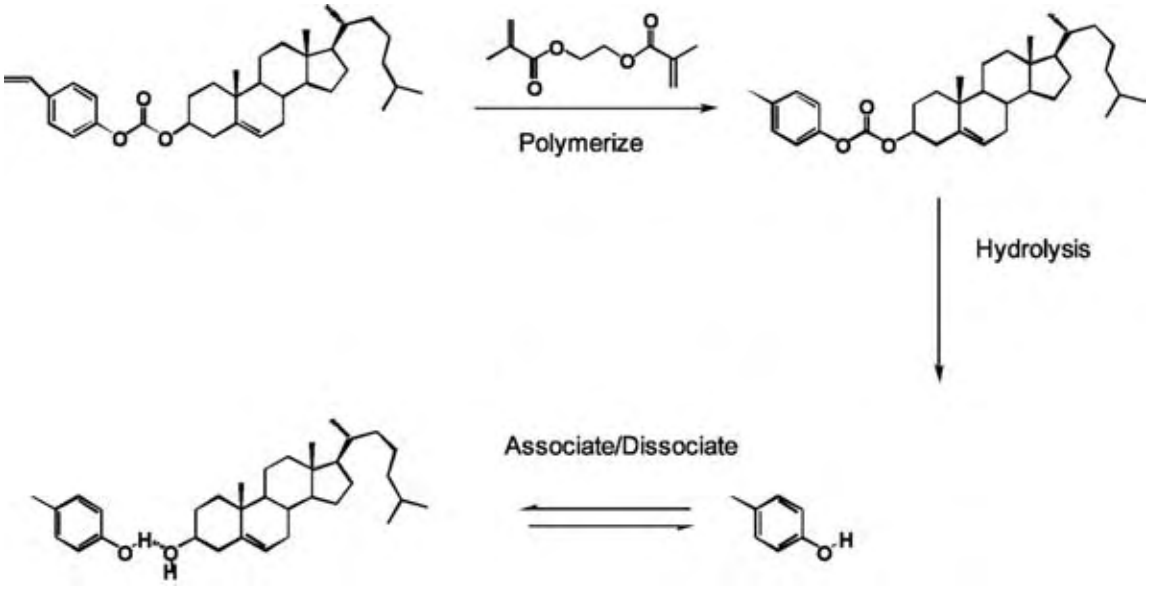
chromatographic and sensing applications. One disadvantage of the noncovalent imprinting approach is binding site heterogeneity arising from the dynamic nature of the noncovalent prepolymerization complex. Noncovalently imprinted polymers contain a range of binding sites that vary from low affinity to high affinity.[11,12] Unfortunately, the binding site distribution is heavily weighted toward the low-affinity selectivity binding sites. The MIPs prepared by the covalent approach tend to have a more homogeneous binding distribution that does not extend out as far into the high-affinity region.

More recently, hybrid-imprinting strategies have been developed that seek to combine the advantages of covalent and noncovalent imprinting methodologies. The hybrid imprinting methods attempt to form the prepolymerization complex in a stoichiometric fashion like the covalent imprinting approach, while still producing an imprinted polymer that forms noncovalent interactions with the template molecule. For example, the sacrificial spacer approach developed by Whitcombe et al. uses covalent bonds to connect the monomers and template like the covalent approach. However, hydrolysis of the template unmasks hydrogen-bonding functionality that forms noncovalent interactions to rebind the guest. A specific example of Whitcombe's sacrificial spacer imprinting method is outlined in Scheme 4. A cholesterol containing prepolymerization complex was prepared using (4-vinyl)-phenyl carbonate ester. Polymerization with EDMA followed by hydrolysis of the template from the polymer matrix yielded a phenol moiety positioned in a complementarily shaped binding cavity that could bind cholesterol through noncovalent hydrogen bonding interactions.[13] This polymer was able to discriminate among cholesterol analogs, such as epicholesterol and cholesterol acetate.

Another hybrid imprinting method is to use functional monomers that form particularly strong noncovalent interactions with the template. The ''stoichiometric'' noncovalent imprinting approach retains the synthetic efficiency ''one pot'' imprinting procedure of the noncovalent approach but also produces MIPs with a more homogeneous distribution of high-affinity, high-selectivity binding sites like the covalent approach. One moiety that has been used is the amidine group, which can form both strong hydrogen bonds and electrostatic interactions with carboxylic acids, phosphonates, and phosphoric esters. Sellergren used MAA to bind the pneumonia drug pentamidine



Scheme 3 Noncovalent imprinting of L-phenylalanine methyl ester in a methacrylic acid (MAA)/ethyleneglycol dimethacrylate (EDMA) polymer matrix. *(View this art in color at www.dekker.com.)*



Scheme 4 A hybrid method of imprinting by Whitcombe et al. uses stoichiometric amounts of monomer and template during polymerization and then relies on noncovalent interactions during the rebinding phase.

and Wulff used the amidine moiety in a monomer to resolve two enantiomers of *N*-(4-carboxybenzoyl)-phenylglycine with separation factors up to 2.8.[14]

COMPOSITION AND PREPARATION OF MIPs

One of the most attractive features of the imprinting process is the ease with which new MIPs can be prepared for and tailored to specific applications. This is particularly the case for the noncovalent imprinting approach. In most cases, MIPs can be synthesized and processed within a few days using readily available starting materials. First, a functional monomer must be selected that forms reversible interactions with the chosen template molecule. The most common functional monomers, such as acrylic acids and vinylpyridines, are inexpensive, commercially available, and readily polymerized by free radical polymerization.[15] Although the imprinting mechanism is not restricted to free radical polymerization of vinyl monomers, radical polymerizations are the most common method of preparation of MIPs because of their high yields in a range of solvents and tolerance to many acidic and basic functional groups that are used in the imprinting process.

The second variable is the cross-linking agent, which serves as a solid support for the functional monomer, ensuring the proper distance and orientation of the functional groups around the template molecule. The cross-linking agent also provides shape selectivity by forming a rigid cavity around the template. These cavities must remain intact during polymerization and subsequent extraction of the template from the matrix for selective binding properties to be observed. Common cross-linking agents are EDMA, divinylbenzene (DVB), and the bisacrylamides (Fig. 1). Wulff systematically examined the influence of the cross-linker on the selectivity of the resulting imprinted polymer. A high percentage of cross-linking agent, typically 80%, was required for the matrix to maintain the integrity of the binding cavity after cleavage of the template.

The final component in the polymerization mixture is the solvent. Although the choice of solvent is often overlooked, it can have dramatic consequences on the surface area, properties of the materials, and binding affinity and selectivity of the resulting MIP. The solvent must dissolve the template, monomers, and cross-linker without disrupting the stability of the prepolymerization complex. Common solvents include acetonitrile, chloroform, and toluene. The solvent also acts as a porogen, creating ''macropores'' within the imprinted polymer so that the template can be efficiently removed from the cross-linked matrix and can also access the binding sites during the rebinding process. Imprinted polymers are typically macroporous monoliths with high surface areas of 100–600 m^2/g. Near theta solvents in which short polymer chains are soluble but longer polymer chains are insoluble are particularly effective in yielding highly macroporous morphology because of phase separation during polymerization.

Other variables in the imprinting process are stoichiometry and temperature, which are particularly important in the cases of noncovalent imprinted polymers. Lower temperatures and higher functional monomer to template ratios stabilize noncovalent prepolymerization complexes, resulting in noncovalent MIPs with higher capacities and selectivities. The imprinting process can be carried out at lower temperatures by either UV initiated radical polymerizations or by using azo-based radical initiators.

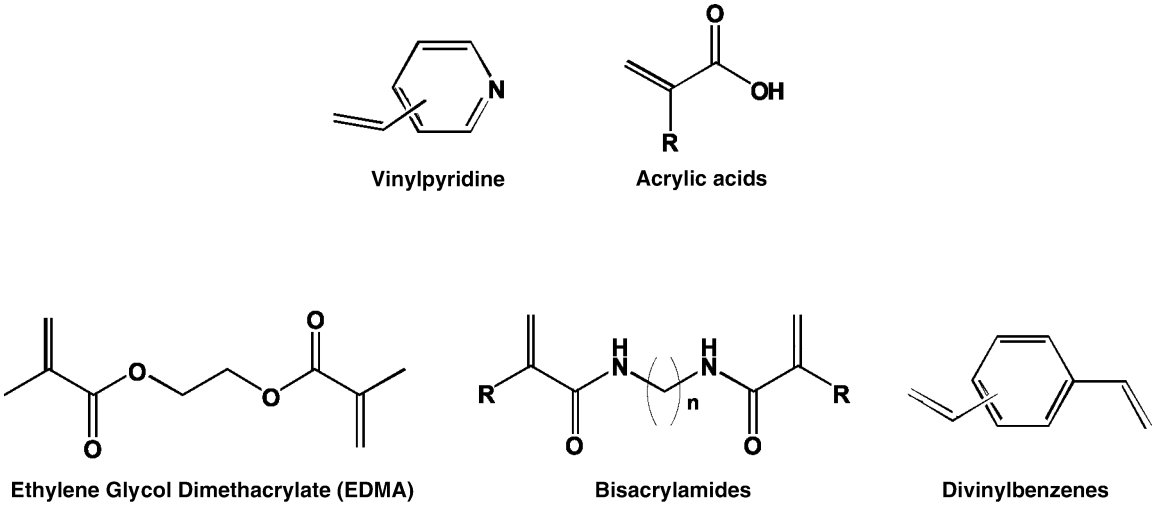


Fig. 1 Common functional monomers (top) and cross-linking agents utilized in noncovalent imprinting.

Once the imprinted polymer has been synthesized, the template must be washed out of the matrix. In most cases, greater than 80% of the template can be effectively removed by Soxhlet extraction. This is sufficient for most applications, and the recovered template can be reused, which is important if the template molecule is particularly valuable. However, a small amount of template usually remains in the highest affinity sites and slowly leaches out over time, which can interfere with sensing applications at very low concentrations (nM). These issues can be circumvented by selecting applications for MIPs that are carried out at micromolar (μM) or higher concentrations or by indirectly monitoring binding of the analyte by radioligand or fluorescently labeled analyte assays.

POLYMER MORPHOLOGIES

As the imprinting field moves toward commercial applications, the need to conveniently and efficiently produce the polymers in different formats is becoming increasingly important. In this section, the primary methods utilized for the preparation of MIPs and their relative merits for various applications will be presented.

By far the most popular approach for preparing MIPs is bulk polymerization. In this strategy, the template, monomer, cross-linker, and initiator are combined in a suitable porogenic solvent and irradiated or heated until a sufficient degree of polymerization has taken place. The macroporous monolith is then ground and sieved to achieve a narrow size distribution of particles. Polymers synthesized in this way are used in chromatography, solid phase extractions, and binding assays.[16] Grinding the polymer does not destroy or alter the binding sites. However, it does enhance the accessibility of the binding sites, which is important for chromatographic applications. The polymer monoliths can also be used directly, which eliminates the grinding and sieving steps that contribute to lower yields. Molecularly imprinted polymer monoliths have been synthesized in chromatography columns and have shown similar levels of affinity and selectivity.

For chromatographic applications, monodisperse spherical MIP particles are preferable to the irregularly shaped MIP particles formed by grinding and sieving the polymer monoliths. Consequently, some researchers have developed methods that produce spherical MIP particles through precipitation polymerization and emulsion polymerization.[17] Monodisperse MIP microspheres were prepared by Mosbach et al. under similar conditions to the MIP monolith preparation but under significantly more dilute precipitation polymerization conditions.[18] The MIP microspheres grew to 1–3 μm diameter with a narrow size distribution. These imprinted microspheres can then be packed more efficiently into chromatography columns or into solid-phase extraction (SPE) cartridges than the particles prepared by bulk polymerization techniques. Larger spherical imprinted polymer particles can be prepared by modification of preformed latex particles either by reswelling with a secondary polymerization mixture or by coating a spherical core particle with an imprinted polymer shell.

Imprinted thin films or membranes have also been prepared for applications in chromatography, sensing, and SPE and can be either freestanding or supported on a solid substrate. The MIP films have been synthesized by bulk thin film polymerization, surface initiated polymerization, and phase inversion precipitation of a preformed linear polymer. For example, Rotello and Penelle et al. fabricated a polychlorinated aromatic quartz crystal microbalance (QCM) sensor by bulk thin polymerization with a hexachlorobenzene imprinted thin film directly on to gold surface. The issues of adherence of the polymer film to the gold substrate and the film integrity on drying were resolved by the choice of a more flexible 1,5-bis(2-acetylaminoacryloyloxy)pentane cross-linker. Sellegren et al. have synthesized MIP thin film stability by preparation of MIPs via surface initiated polymerization. Azo-based radical initiators were anchored to silica surfaces to develop new high surface area MIP stationary phases.[19] Kobayashi et al. have developed a unique preparation of MIP thin films by precipitation of linear polymers in the presence of templating agents. For example, Nylon-6 and L-glutamine dissolved in formic acid were cast onto a solid substrate to a thickness of 100 μm.[20] Rinsing the film with water leads to a phase inversion, yielding a macroporous film with enantioselective recognition properties. The imprinted Nylon-6 membranes formed by this inversion polymerization have been used as the recognition element in a QCM sensor and as a filtration membrane.

APPLICATIONS OF MIPs

The most common application for MIPs has been as stationary phases in chromatographic or SPE formats. The stability of MIPs to a wide range of solvents, temperatures, and pressures makes them particularly well suited to be stationary phases in high-performance liquid chromatography (HPLC) and capillary electrophoresis. Some of the most impressive studies using MIPs are reports of MIP systems that preferentially bind a single enantiomer over its antipode, such as amino acids and drugs. One of the key advantages of MIP-based stationary phases, in comparison to general enantioselective stationary phases, is that there is a logical order of elution of enantiomers. The imprinted

enantiomer is more strongly retained and typically elutes as a broader peak after the nonimprinted enantiomer. The known order of elution is useful in identifying the respective enantiomers in analytical applications. Mosbach et al., for example, successfully separated a racemic mixture ($\alpha = 2.9$) of the β-blocker timolol, using an HPLC column packed with an *s*-timolol imprinted polymer (Fig. 2).[21] Mosbach et al. also developed stationary phases based on MIP imprinted with a short peptide and observed separation factors as high as $\alpha = 17.8$, which exceeds that of commercial chiral stationary phases.[22]

Solid-phase extraction is a widely used method for cleanup and preconcentration of a solution containing a mixture of analytes. The SPE sorbents preferentially bind a specific analyte while allowing the other analytes to pass through. A solvent capable of disrupting the polymer–analyte interactions is then introduced to wash off the desired analyte. The concentrated and purified analyte is then quantified by a secondary method, such as gas or liquid chromatography. An attractive feature of this imprinting application is that the polymer need only work in ''on'' or ''off'' mode, either strongly adsorbing the template or releasing the analyte in contrast to the chromatographic mode where the MIP column must also exhibit good resolution to be effective. Theodoridis, for example, recently demonstrated the selective extraction of caffeine from beverages and spiked plasma using an SPE cartridge loaded with an MIP.[23] Zhu et al. recovered 96% of the herbicide metsulfuron-methyl in spiked river water using an MIP-SPE cartridge. The stability of MIP-based SPEs was also demonstrated as the SPE was shown to be reusable for up to 200 sorption studies.[24] In another study, an MIP imprinted with 4-nonylphenol showed selectivity for the template over 11 related phenolic pollutants.[25] These successes of MIPs in SPE technology have led to the establishment of MIP Technologies, Lund, Sweden (www.miptechnologies.se). MIP Technologies' MIP4SPE-Triazine10 cartridge was tailored, using the imprinting process, to selectively adsorb triazine and triazine metabolites from environmental samples. MIP Technologies have also developed other MIP-based sorbents for clenbuterol, nicotine metabolites, and riboflavin and are working toward others for steroids, peptides, and nicotine.

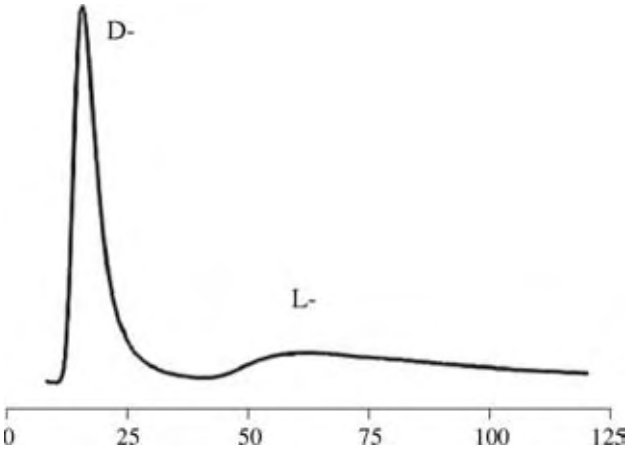

Fig. 2 Elution profile of a racemic mixture of *t*-BOC-D-tyrosine (first peak) and *t*-BOC-L-tyrosine (second peak) on a molecularly imprinted polymer made using *t*-BOC-L-tyrosine as template and *N,O*-bismethacryloyl ethanolamine as the only monomer. HPLC conditions: particle size 45–63 μm; mobile-phase: 99/1, acetonitrile/acetic acid; flow rate 0.1 mL/min; injected volume 5 μl of a 2.0 mM racemic solution; detection at $\lambda = 270$ nm. (Courtesy of David Spivak, Lousiana State University.) *(View this art in color at www.dekker.com.)*

The MIPs have also been utilized as heterogeneous catalysts.[26] The strategy is analogous to work on catalytic antibodies. The MIPs are imprinted with transition state analogs, and then the imprinted polymers tested for their ability to effect rate and selectivity enhancements. Beach and Shea, for example, prepared an MIP capable of catalyzing the dehydrohalogenation of 4-fluoro-4-(*p*-nitrophenyl)butan-2-one.[27] Sellergren and Shea have developed an MIP that mimics enzyme action by hydrolyzing a protected phenylalanine ester.[28] To date, MIP catalysts have produced only modest rate enhancements. The future of catalytic applications for MIPs will depend on the ability to form binding sites that bind the transition state of the reaction with higher affinity or include catalytic functionality. One interesting development along these lines is transition metal containing MIP catalysts.[29] For example, Severin has prepared MIPs containing ruthenium arene complexes that showed enhanced regioselectivity in the catalytic reduction of 4-acetylbenzophenone.

The MIPs have also been utilized as the recognition elements in pseudoimmunoassays.[30–32] In this approach, MIPs are substituted for antibodies to quantify the amount of analyte in a biological sample, such as blood plasma. Most MIP immunoassays are competitive binding studies in which a radio- or fluorescent-labeled analyte is added to a mixture of the MIP and unlabeled analyte. After equilibrium is reached, some fraction of the labeled species is bound to the polymer surface and thus can be separated from the supernatant. The supernatant is then analyzed via scintillation or fluorescence techniques to determine the concentration of the original unlabeled analyte. Mosbach et al. have demonstrated that MIP-based immunoassays can rival the selectivity of antibody-based assays.[33] Imprinted polymers for the opioid receptor ligands enkephalin and morphine were prepared and showed submicromolar (μM) level selectivity in a radioligand competition assay in aqueous buffers. The analysis

by Andersson et al. of *S*-propranolol in human plasma and urine using an MIP assay demonstrated remarkable accuracy and low cross-reactivity with structurally similar analogs.[34] With propranolol, nanomolar selectivity has been demonstrated using an MIP assay. The MIP assays have also been developed for the demanding application of measuring enantiomeric excess (ee).[35] An L-phenylalanine anilide (L-PAA) imprinted polymer was equilibrated with PAA solutions of varying ee. After equilibration, the concentrations of PAA remaining in solution could be correlated to the ee of the original solutions with a standard error of only $\pm 5\%$ ee. Although MIPs have shown comparable selectivity to antibodies at low concentrations, MIPs more typically show high degrees of cross-reactivity and low selectivity. Greene et al. have addressed this issue by grouping a number of different MIPs together into an MIP sensor array.[36] Six aryl amine analytes, which included structurally similar analytes, such as ephedrine and psuedoephedrine, were classified with 94% accuracy, using the MIP array assay.

Sensors based on MIPs have also been developed in which the MIP is the recognition element of the sensor, often replacing a polymer thin film or antibody. The MIPs lack signaling functionality and thus the primary difficulty is coupling a singling element to the MIP binding site. Molecularly imprinted polymers containing fluorophores and electrochemically active monomers have been prepared. For example, MIPs synthesized from conductive polymers, such as polypyrrole and polyanaline by electrochemical polymerization have been tested and shown to be able to sense the presence of the template molecule.[37] Alternatively, MIPs can be prepared on signaling surfaces, such as an electrode or a gold QCM or surface plasmon resonance surface. For example, Shoji et al. prepared an MIP-based sensor for atrazine by polymerization on the surface of a gold electrode and measuring the reduction potential of atrazine vs. a Ag/AgCl electrode.[38] The sensor showed good sensitivity for atrazine over other triazines. Kroger et al. developed a sensor for 2,4 dichlorophenoxyacetic acid, and Marx et al. coated glassy carbon electrodes with sol–gel MIP matrices to sense parathion in aqueous solutions.[39]

FUTURE APPLICATIONS FOR MIPs

The MIPs are particularly versatile materials, especially as the number and types of templates that have been successfully imprinted increase. For example, imprinted polymers have been prepared using metal ions as templates.[40] Potential applications for these polymeric ionophores include the remediation of toxic metals from the environment, recognition elements for ion sensors for medical diagnostics, catalysis, and chromatography.[29] Other potential applications for MIPs have been as drugs. Researchers from Geltex Pharmaceuticals reported the use of MIPs as cholesterol lowering drugs. An imprinted version of the commercial cholesterol sequestering polymeric drug, colesevelam–HCl, was prepared and shown to have higher capacity and affinity for bile acids than the non-imprinted polymer. The imprinted colesevelam–HCl was synthesized by cross-linking poly(allylammoniumchloride) with epichlorohydrin in the presence of sodium cholate as a templating agent. The non-imprinted polymer had a capacity for bile acids in deionized water of 1.30 mmol/g, and the imprinted polymer had a capacity of 1.97 mmol/g. Other medical applications for MIPs include MIP hydrogels for timed and triggered drug release.

Another limitation of imprinted polymers is the size of the template. Most template molecules are small molecules of less than 20–30 Å in length.[41] Larger templates become physically entrapped in the highly cross-linked matrix and cannot be removed from their binding sites. Thus, important biological macromolecules and structures, such as DNA, proteins, viruses, and cells cannot be imprinted by traditional methods. However, new surface imprinting methods are being developed, which should greatly increase the scope and utility of imprinted materials. For example, Ratner et al. have imprinted proteins using cellulose films.[42] The proteins are first coated with disaccharides. Then, a glow-discharge plasma deposition covalently links the disaccharides into a polymer film around the proteins. A number of different proteins were imprinted by this method including immunoglobulin G, ribonuclease, and streptavidin. The protein-imprinted films could be patterned into a microarray using microcontact printing, opening up the possibility of biomedical applications. Nusslein et al. have imprinted even larger biological structures, specifically bacteria, using a polymer film on the surface of a QCM. The imprinted polymer film displayed recognition abilities for the shape and surface functionality of the imprinted bacteria. The cell-selective QCM was able to differentiate gram-positive and gram-negative cells, cell aggregates, and cell shapes.

CONCLUSIONS

The MIPs have already shown great potential in a wide range of applications requiring molecular recognition elements. The MIPs can replace synthetic molecular receptors or antibodies in many applications and can function with similar levels of affinity and selectivity. The MIPs have the advantage that they can be tailored to recognize an ever-increasing pool of templates including chiral amines, carbohydrates, proteins, and

bacteria. With improvements in the imprinting process and the development of new imprinted polymer morphologies and formats, MIPs will find new applications in catalysis, separation materials, pharmaceuticals, medical devices, and sensors.

INTRODUCTION

Fuel cells are electrochemical power generators that convert chemical energy of a fuel such as hydrogen directly into electricity. Power generation through fuel cells is considered to be a new option for future energy production. Fuel cells have several advantages relative to other power generation technologies, such as: 1) very high efficiency levels for conversion of fuels into electricity; 2) low emissions of NO_x, CO_x, and other airborne pollutants, which contribute to air quality problems; 3) an inherently modular construction, minimum siting requirements, flexibility in fuel sources, and stable response to load changes; and 4) the power plant efficiencies are independent of power plant size. Unlike the other conventional energy sources, the high-temperature combustion processes are absent in fuel cells. The fuel cells are highly efficient and convert the fuel into electricity without flame or smoke and are more ecofriendly. Fuel cells are commonly classified according to the operating temperature and electrolyte employed. There are five different types of fuel cells under development, namely, alkaline fuel cell (AFC), polymer electrolyte membrane fuel cell (PEMFC), phosphoric acid fuel cell (PAFC), molten carbonate fuel cell (MCFC), and solid oxide fuel cell (SOFC). The AFC, PEMFC, and PAFC are categorized under low-temperature fuel cells, which operate in the temperature range between 50°C and 200°C. The MCFC and SOFC are placed under the high-temperature fuel cells category, which operate at 650°C and 700–1000°C, respectively. Only recently have efforts been focused on the development of direct methanol fuel cell (DMFC) as centralized power packs for stationary applications after the success of the PEMFC technology.

The MCFC technology is under consideration for on-site power generation source because of its high efficiency and ability to utilize a variety of fuel sources such as hydrogen, natural gas, and other hydrogen-rich hydrocarbons. Theoretically, a single cell can deliver an open circuit voltage of around 1.02 V. An optimized cell can deliver a current density of 150 mA/cm^2 at 0.70 V. The state-of-the-art MCFC utilizes Ni-10 wt% Cr anode, lithiated nickel oxide cathode, and $(Li_2 + K_2)CO_3$ embedded in $LiAlO_2$ is served as electrolyte. Normally, the cell is operated at 650°C at which the electrolytes are in molten stage favoring the hydrogen oxidation and oxygen reduction reactions at the anode and cathode, respectively. The efficiency of MCFC is as high as 50% because of its high operating temperature. The electrodes and the electrolyte structures are prepared by different methods and tape casting process is the most widely accepted method for preparing these components. The typical thickness for the anode is in the range of 0.5–1.0 mm while the same for the cathode is in the range between 0.5 and 1.5 mm. The thickness of the $LiAlO_2$ electrolyte retention matrix ranges between 0.75 and 1.0 mm. Pure nickel was the choice of anode material during the early stages of MCFC development but it has now been replaced by Ni–Cr alloy. Lithiated nickel oxide has been the choice of cathode material. Alternate materials such as $LiCoO_2$, $LiFeO_2$, and Co-coated nickel are being considered as potential cathodes because they show good stability at the cathode operating conditions. Lithium aluminate has been continuously used as an electrolyte retention material because of its high stability in molten carbonate and ability to transport carbonate ions from cathode to anode. This material also has minimum resistance and effectively separates the electrodes with minimum gas crossover. Because of its high corrosion resistance stainless steel is served as both cathode current collector and bipolar plate. Different coatings have been applied on these materials to improve its corrosion resistance especially at the cathode side. The ideal MCFC technology would employ either direct internal reforming (DIR) or indirect internal reforming (IIR) concept, wherein the fuel source can be processed to produce the hydrogen fuel.

MOLTEN CARBONATE FUEL CELL

Molten carbonate fuel cells have been termed as the "second-generation fuel cell" as they have lagged

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039322

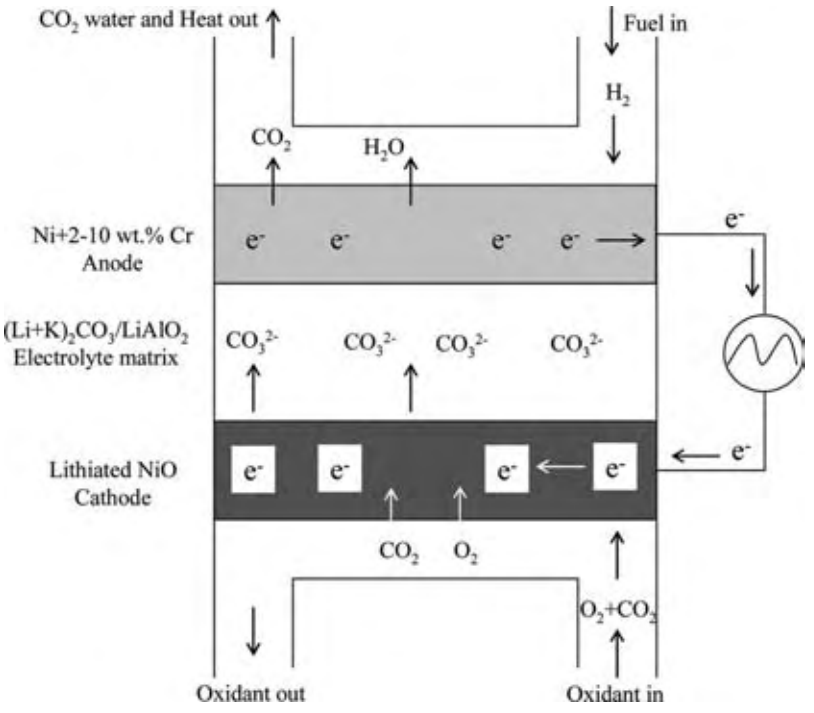

Fig. 1 Schematic representation of molten carbonate fuel cell operation.

behind in developmental efforts when compared to other types of fuel cells.[1–5] Molten carbonate fuel cells consist of nickel anode, nickel oxide cathode, and lithium aluminate as an electrolyte retention matrix. The electrolyte is a mixture of potassium and lithium carbonates. The cell operates at a nominal temperature of 650°C, where the carbonates are in the liquid phase. The molten carbonate is immobilized within a porous ceramic matrix, which takes the form of a planar tile. Electrodes are located above and below the tile to make up a single fuel cell, which can easily be assembled into a stack to produce a useful output voltage.[6]

The electrodes are flat. The anode is composed of porous sintered nickel along with additives, which inhibit the loss of surface area during operation. The anode is in direct contact with the electrolyte matrix. The cathode is a porous nickel oxide, which is initially fabricated in the form of a porous sintered nickel and is subsequently oxidized during the cell operation.

The electrolyte tile is formed from $LiAlO_2$ either by hot pressing or by tape casting methods and filled with $Li_2CO_3 + K_2CO_3$ (62/38 mol% eutectic). A schematic of MCFC is shown in Fig. 1. During the cell operation, the following electrochemical reactions take place at the electrodes.

Anode reaction:

$$H_2 + CO_3^{2-} \rightarrow H_2O + CO_2 + 2e^- \quad (1)$$

The CO_2 produced is transferred to the cathode chamber, where it is reduced along with O_2 to form CO_3^{2-} ion.

Cathode reaction:

$$\tfrac{1}{2}O_2 + CO_2 + 2e^- \rightarrow CO_3^{2-} \quad (2)$$

The carbonate ion takes part in the electrode reactions and the melt remains constant in composition by a continuous transfer of CO_3^{2-} ion from the cathode to the anode.

The overall reaction is:

$$H_2 + \tfrac{1}{2}O_2 \rightarrow H_2O \quad (3)$$

If carbonaceous fuels are used, the CO present in the anode gas chamber oxidizes to CO_2:

$$CO + CO_3^{2-} \rightarrow 2CO_2 + 2e^- \quad (4)$$

Thus, the presence of CO_2 or CO in the fuel stream is not detrimental to the fuel cell performance. The materials currently used for each of the cell components are summarized in Table 1. These components are typically fabricated individually and assembled into alternating layers to form a stack.

THERMODYNAMICS OF MCFC REACTIONS

The overall cell reaction occurring in MCFC can be written as:

$$H_2(g) + \tfrac{1}{2}O_2(g) + CO_{2(\text{cathode})} \rightarrow H_2O + CO_{2(\text{anode})} \quad (5)$$

Table 1 Typical characteristics of the electrode and matrix materials in MCFC

Characteristics	Anode	Cathode	Matrix
Material	Nickel	Lithiated nickel oxide (5 wt%)	$LiAlO_2$
Stabilizer	Chromium	—	—
Reinforcement material	Nickel	Stainless steel mesh	Al_2O_3 and ZrO_2 fibers
Porosity (%)	50–70	70–80	70–75
Mean pore diameter (μm)	3–4	10–15	7–10
BET surface area (m^2/g)	0.1–1.0	0.1–0.5	1.0–20
Thickness (mm)	0.5–1.0	0.5–1.5	0.75–1.0
Other additives	Al_2O_3, MgO, $LiAlO_2$, $LiMoO_2$, $LiCrO_2$, Li_2ZrO_3	Perovskites, Ag, $LaSrNiO_3$	$LiAlO_2$ fiber
Alternate materials	Ni–Al alloy, Ni–Cr alloy, Li_2TiO_3, Cu–Ni alloy	$LiCoO_2$, $Li_2Mn_2O_3$, $LaSrGaO_3$	$SrTiO_3$
Fabrication technique	Compaction, sintering, hot pressing, slurry casting, tape casting	Compaction, sintering, hot pressing, slurry casting, tape casting	Hot pressing, hot rolling, plasma spraying, paper making, tape casting

The reversible voltage for this reaction is given by the equation:

$$E = E^0 + \frac{RT}{2F} \ln \frac{[pH_2][pO_2]^{1/2}}{[pH_2O]} + \frac{RT}{nF} \times \ln \frac{[pCO_2]_{(cathode)}}{[pCO_2]_{(anode)}} \quad (6)$$

When the partial pressure of CO_2 is identical in both compartments and the electrolyte is invariant, the cell voltage depends only on the partial pressures of H_2, O_2, and H_2O. The theoretical reversible voltage E^0 at 650°C calculated by using Eq. (6) is 1.019 V with a theoretical efficiency of $\Delta G/\Delta H$ equal to 79.45%.[7,8] The CO_2 produced at the anode compartment is recycled to the cathode for the continuous formation of CO_3^{2-} ions.

ADVANTAGES OF MCFC

The MCFC because of its high operating temperature has higher efficiency (>50%) and faster electrode kinetics than any other fuel cell system.[9,10] At 650°C, almost a theoretical reversible potential is established at the interface with low electrode overpotentials, which does not require any noble metal catalysts. The CO does not poison the anode, because in the MCFC it is oxidized at the anode interface.

The MCFC operating temperature is also suitable for internal reforming of hydrocarbon fuels such as methane. The heat required for the reforming reaction can be supplied directly from the heat generated in the fuel cell, which minimizes the need for stack cooling devices. These advantages resulted in the development of MCFC stack technology with integrated reformers. The high-grade waste heat can also be used to generate more power by utilizing a steam turbine (bottoming cycle). The MCFC has an efficiency of 50% or above. However, with the addition of the bottoming cycle, the efficiency increases up to 60%. The overall combined heat and power (CHP) efficiency of an MCFC system will probably exceed 60%. This high efficiency and low heat/power ratio make the MCFC ideal for CHP or co-generation.

HISTORY OF MCFC

Bauer (1921) developed the first high-temperature MCFC based on a molten $(Na/K)_2CO_3$ electrolyte, immobilized in a MgO matrix.[4] The MCFC in its present form was developed by G. H. J. Broers in 1951. Small laboratory cells were constructed using a non-sintered MgO + molten carbonate "paste electrolyte." The durability of these cells was tested up to 6 mo. Common features of today's cells and the early Broers' cells are the nickel-based electrodes with planar and bipolar construction and the alkali carbonate electrolyte in inert matrix filler. The basic operating principles are still the same and the cell is represented below.

$$\underset{\text{(Nickel oxide)}}{Air(O_2) + CO_2, Cathode(+)/\gamma} - \underset{\text{(Matrix/electrolyte)}}{LiAlO_2} + \underset{\text{(Ni-based alloy)}}{M_xCO_3/anode(-), fuel(H_2)}$$

Major technological breakthroughs have been made in the electrode materials, electrolyte composition, and fabrication technologies. Argonne National Laboratory (ANL), U.S.A., and Institute of Gas Technology (IGT), U.S.A., are the pioneers in optimizing electrolyte, engineering, and component fabrication. The IGT optimized the parameters for the cell stack and has done modeling optimization studies in collaboration with Physical Sciences Inc. Several theoretical models have been derived for the molten carbonate fuel cathode.[11–21] First principles based theoretical models for MCFC cathode can be divided into the thin film model and the agglomerate model.[11,12] Wilemski assumed that the MCFC cathode could be described as a cylindrical pore covered with a thin film of electrolyte.[11] Gases flowing through the pore dissolve at the surface of the film and diffuse to the surface of the pore and react there. While the model gives good agreement with experimental data, it requires knowledge of the pore diameter, length, and film thickness. Further, the entire description of the electrode is limited and cannot be used for cathode design analysis or two-dimensional simulations. The more common and popular approach for describing the MCFC cathode is the agglomerate model proposed by Yuh and Selman.[12] In this approach, the electrode is assumed to consist of cylindrical agglomerates completely flooded with electrolyte. Gaseous species move through straight cylindrical channels of macropores. A three-phase homogenous model and a full cell model have been developed at the University of South Carolina, U.S.A.[22,23]

Government Industries Research Institute, Osaka (GIRIO), Japan, conducted basic research on MCFC components during the past two decades. Currently, Fuel Cell Energy (FCE), U.S.A., MTU Friedrichshafen, Ansaldo, Italy, and Ishikawajima-Harima Heavy Industries, Japan, are actively pursuing the commercialization of MCFCs.[24]

CELL COMPONENTS

Table 2 provides a chronology of MCFC component technology development.[25] In the early 1960s precious metals such as Pt and Ag were used as anode and cathode, respectively. Continued research in this field resulted in the use of nickel and lithiated nickel as anode and cathode. Until the mid-1970s, there was no significant change in the development of electrodes and the electrolyte matrix. A major development in the 1980s was the evolution in the fabrication of electrolyte structures. The developments in cell components for MCFCs have been reviewed by Maru and co-workers, Petri and Benjamin, and Selman.[26–29] Over the past 30 yr, the performance of single cells has improved from about 10 to $>150\,mW/cm^2$. During the 1980s, major improvements were made in both the performance and the endurance of MCFC stacks. Several MCFC stack developers have produced cell stacks with cell areas up to $1\,m^2$. Recently, FCE, U.S.A., has tested a stack consisting of nearly 300 cells with effective area of $\sim 9000\,cm^2$ delivering >250 kW power. ERC, U.S.A., also tested a stack with $246 \times 5600\,cm^2$ cells and $253 \times 7800\,cm^2$ cells producing 125 and 253 kW, respectively. M-C Power, U.S.A., has tested a stack with $250 \times 1\,m^2$ cells producing 250 kW.[25]

OPTIMIZATION OF MOLTEN CARBONATE FUEL CELL TECHNOLOGY

Attempts were made in recent years related to the development of the component for MCFC. These

Table 2 Evolution of MCFC component technology

Component	ca. 1965	ca. 1975	Current status
Anode	Pt, Pd, or Ni	Ni-10 Cr	Ni–Cr/Ni–Al/Ni–Al–Cr 3–6 μm pore size 45–70% initial porosity 0.20–1.5 mm thickness 0.1–1 m^2/g
Cathode	Ag_2O or lithiated NiO	Lithiated NiO	Lithiated NiO–MgO 7–15 μm pore size 70–80% initial porosity 60–65% after lithiation and oxidation 0.5–1 mm thickness 0.5 m^2/g
Electrolyte support	MgO	Mixture of α-, β-, and γ-LiAlO2 10–20 m^2/g 1.8 mm thickness	γ-LiAlO2, α-LiAlO2 0.1–12 m^2/g 0.5–1 mm thickness
Carbonate electrolyte (mol%)	52 Li-48 Na 43.5 Li-31.5 Na-25 K"paste"	62 Li-38 K hot press "tile" 1.8 mm thickness	62 Li-38 K 60 Li-40 Na 51 Li-48 Na tape casting 0.5–1 mm thickness

Table 3 Issues in MCFC technology

Component	Issues	Results
Electrolyte	Loss due to volatilization	Decrease in the conductivity
	Loss due to filling inside the electrodes	Increase in the resistivity of the layer
	Loss due to reaction with the separator plate	Decrease in the cell voltage Increase in the polarization of electrodes
Matrix	Particle growth	Changes in the microstructure
	Stability and crack formation	Increase in the ionic resistivity
	Dissolution of γ-$LiAlO_2$ in the electrolyte	Decrease in the cell voltage
	Phase transformation from γ to α variety	Decrease in the cell life
Anode	Anode sintering	Change in the pore structure, gas leak through the edges, poor strength
	Anode deformation and creep	Forms a BBP layer
	Extent of electrolyte filling	Increase in the polarization due to increase in the area of the electrode
Cathode	Cathode stability	Cathode shrinkage
	Electrocatalytic activity	Changes in the microstructure
	Cathode dissolution	Deformations at the separator ribs
	Extent of electrolyte filling	Changes in the electrocatalytic activity Increase in the polarization due to increase in the electronic resistivity of the electrode
Separator plates	Corrosion due to reaction with the electrolyte	Decrease in the cell voltage Increase in the resistivity between cells due to increase in polarization

studies are summarized in Table 3.[30] Besides the fact, that the present approaches function properly in full-size cells at atmospheric pressure, research was carried out in addressing alternate cathode materials and electrolytes, performance improvement, life extension beyond the commercialization goal of 5 yr, and cost reduction.[31] These studies provide updated information on the promising materials for electrodes, the electrolyte matrix, and the capability of the cell to tolerate trace contaminants in the fuel supply.

ANODE

The following anode properties were recognized to be of fundamental importance with respect to cell performance: 1) electronic conductivity; 2) electrocatalytic activity; 3) thermodynamic stability; 4) chemical inertness; 5) moderate cost; 6) interconnected porosity; and 7) ease of fabrication.

ANODE PERFORMANCE

Table 1 presents the anode performance characteristics. Efficient fuel cell operation requires that the electrodes must have sufficient electrolytes to maintain the electrode/electrolyte reactant gas interface necessary for the electrochemical reaction to occur. The electrode performance of MCFC depends on the number of pores occupied by the electrolyte. This requires careful control of the overall porosity and the pore size distribution within the electrode structure.[32–36]

The MCFC anodes are made from a porous sintered nickel with a thickness of 0.8–1.0 mm and a porosity of 55–70% with a mean pore diameter of 5 μm.[1] This porosity range provides adequate interconnected pores for mass transport of gaseous reactants and adequate surface area for the anodic electrocatalytic reactions. Because the anode kinetics is faster than that of the cathode, less active surface area is sufficient for the anodic process. Partial flooding of the comparatively thick anode is therefore acceptable at the anode interface.

In MCFC, the three-phase contact, i.e., the contact between the catalyst, electrolyte, and the reacting gas is accomplished by balancing the capillary pressures, which establishes the electrolyte interfacial boundaries in the porous electrodes.[25] Theoretically, the relation between the pores in the cell components is given by the equation:

$$\frac{\gamma_c \cos\theta_c}{D_c} = \frac{\gamma_e \cos\theta_e}{D_e} = \frac{\gamma_a \cos\theta_a}{D_a} \quad (7)$$

where γ is the interfacial surface tension (dynes/cm), θ is the contact angle of the electrolyte, D is the pore diameter (μm), and the subscripts a, c, and e refer to the anode, cathode, and electrolyte matrix, respectively. An optimized electrolyte distribution could be achieved by appropriate coordination of the pore diameters at the anode and cathode with that of the electrolyte retention matrix. This pore size arrangement allows the electrolyte retention matrix to remain completely filled with molten carbonate electrolyte, while the porous electrodes are partially filled, depending on their pore size distribution. Trials have been made to control the electrolyte occupation at the anode.[35] The MCFC anode pores are smaller than the gas-filled (large) pores of the cathode. Ideally, a dual pore structure electrode can be employed, the microporous side containing the molten liquid electrolyte and the macroporous side containing the fuel gas. The matrix should have a pore size that is smaller than that of both the electrodes, so that it is always filled with the electrolyte.

BUBBLE PRESSURE BARRIER

The ideal function of the porous structure in the electrode is to maintain the equilibrium between the gas and electrolyte within these pores of the anode. The fine pore layer of the anode can also be used as an electrolyte reservoir, which prevents gas leakage through the electrolyte.

Alternatively, an additional layer constructed by using fine nickel powder, $LiAlO_2$, and NiO is positioned between the anode and the electrolyte and filled with molten carbonate electrolyte. The purpose of this additional layer is to prevent gas crossover from one electrode to the other if cracks develop in the electrolyte structure. This bubble barrier layer serves as a reinforcement of the electrolyte matrix. This bubble pressure barrier (BPB) can be fabricated as an integral part of the anode structure. Typically, the pores of this barrier layer are smaller than the anode pores and provide ionic transport through the cell.[25]

Various materials have been evaluated for use as anodes in MCFC.[26,37] There are many methods reported in the literature for the preparation of porous sintered nickel structures with adequate porosity and pore size distribution. The oldest method is the gravity sintering method.[38,39] Improvements have been made by incorporating a BPB layer to control the wetting properties of the anode.[40] Organic binders were used during the cold rolling stage, which was removed during the sintering process.[41] Composite coating method was employed to deposit Raney alloys into the nickel matrix.[42]

From the point of view of larger-scale fabrication of MCFCs, these processes for preparing the electrodes may not be efficient. To prepare larger-area electrodes, slurry/slip casting and tape casting methods were adopted as an improvement on the aqueous slurry process.[26,34,43] Aqueous tape casting method employs polyvinyl alcohol or methylcellulose as binder. To obtain fast curing green electrode sheets, a nonaqueous process has also been reported.[44,45] To provide better contact with the electrolyte substrates, preparation of combined tapes by a nonaqueous process and in-cell sintering procedures were adopted.[46,47]

Pure nickel tends to sinter at the fuel cell operating conditions, resulting in loss of surface area and pore growth. Additives have been used to control the sintering. For example, the addition of Cr_2O_3 to nickel has been shown to effectively prevent anode sintering, by the formation of submicrometer $LiCrO_2$ on the nickel surface. Additions of Co, Cr, and Cu metals to nickel powder have also been tried and a Ni-10% Cr alloy has become the standard anode.[25]

The anode structure is also susceptible to deformation (creep) under compressive load during normal stack operation (i.e., shrinkage of anode thickness under load). Anode creep results in decreased porosity, increased contact resistance, and leaks. To stabilize the anode structure, addition of oxides such as Al_2O_3, $LiAlO_2$ and ZrO_2 has been reported in the literature. The oxide dispersion strengthened anodes have demonstrated encouraging results toward minimizing the creep. The kinetics of the anode reaction was not affected. Recent reports indicated that addition of Al, Cu, and Ti also shows encouraging results in retarding the anode creep.[30]

The anode is stabilized by using mixed powders of Ni–Cr, Ni–Al, or refractory oxides and sintered at 900–1100°C under a reducing atmosphere to provide a creep resistant anode structure.[43,48] The function of the additives is to reduce the loss of porosity during sintering and develop creep resistant materials. The creep is referred to as the shrinkage in thickness and change in shape. The sintering resistance is increased by the additives, which are usually metals or oxides of metals.

The sintering of the anodes can be minimized by stabilizing the anode with Al/Cr.[49] The addition of aluminum and chromium inhibits porous Cu–Ni anodes from being sintered because of the formation of aluminum oxide and chromium oxide on their surfaces.[50] Addition of Cr or Cr_2O_3 prevents the anode sintering by formation of submicrometer size $LiCrO_2$ on the nickel surface. Ni alloy with 10 wt% Cr has become the standard anode.[51] Heat treatment after impregnation caused a decomposition of the metal salts and resulted in finely dispersed oxide particles on the surface of the sintered electrodes. This stabilization method effected lower porosity changes of the anode in MCFC operating condition. Also, addition of ceramic oxides such as $LiAlO_2$ stabilized the anode structure. Ni powder with 20% $LiAlO_2$ resulted in stabilization of the electrode

exposed to further compaction by sintering and retained the initial porosity.

CATHODE

The primary challenge in commercialization of MCFC remains in the proper selection of materials for the cathode. The life expectancy of the electrode structure is aimed toward 40,000 hr for successful commercialization of MCFC.[52] The following cathode properties were recognized as of fundamental importance with respect to the cell performance: 1) high electronic conductivity at 650°C ($\sigma > 1$ S/cm); 2) low chemical reactivity and solubility in the electrolyte; 3) thermodynamic stability at 650°C in carbonate electrolyte at different partial pressures of O_2/CO_2 mixtures; 4) high electrocatalytic activity for the oxygen reduction reaction; and 5) suitability for the fabrication of porous electrodes.[26]

The most widely used cathode material is nickel oxide doped with 3 atomic percent (at%) of Li to provide the required electrical conductivity and electrocatalytic activity. The cathode structures were fabricated by sintering either metallic nickel or nickel oxide into 0.4 mm-thick porous plaque. In situ oxidation results in electrochemically conducting ceramic $Li_xNi_{1-x}O$, where x is in the range of 0.022–0.04. At 650°C, the resistivity of the lithiated nickel oxide is about 0.20 Ω cm. Typical cathodes have a porosity of 55% and a mean pore size of about 10 μm. They usually develop a bimodal pore distribution. The small pores are flooded with electrolyte, thereby providing an extended reaction surface and ionic conduction. The larger pores facilitate mass transport in the gaseous phase. Because the lithiated nickel oxide is completely wetted with CO_3^{2-} electrolyte, the agglomerates are covered with a thin film of electrolyte. Gases diffuse through the film to react at the electrode. Thus, it is important to avoid flooding of the entire electrode. The cathode performance is sensitive to the thickness of the electrode and the degree of filling of pores with the electrolyte. Ohmic losses in both the liquid and solid phases increase as the cathode thickness increases. Diffusion losses in the gas phase also increase with cathode thickness. On the other hand, activation and liquid phase diffusion losses decrease as the cathode thickness increases. The optimum value was identified at a thickness of 0.5 mm, when the total losses are at a minimum.[25]

ISSUES IN CATHODE DEVELOPMENT—NiO DISSOLUTION

The major problem identified during testing of MCFC for long durations exceeding 1000 hr of operation is the dissolution of NiO cathodes and accumulation of Ni nodules in the matrix toward the anode. These phenomena result in a cell shorting. There is an excellent review in the literature that extensively covers this problem.[53] NiO dissolves in molten carbonate electrolyte (62–75 mol% Li^+) slowly to about 10–15 ppm according to:

$$NiO + CO_2 \longrightarrow Ni^{2+} + CO_3^{2-} \quad (8)$$

The NiO solubility increases with increasing temperature, pCO_2, and cation fraction Li^+.[54] The dissolved Ni^{2+} ions diffuse through the electrolyte toward the anode, where it is reduced and precipitated as metallic nickel. This causes a sink for the Ni^{2+} ions, which facilitates further NiO dissolution. The lifetime of MCFC is significantly reduced by the slow dissolution of nickel oxide cathode and precipitation of Ni ions in the matrix.

ALTERNATE CATHODE MATERIALS

To solve the problems associated with the instability of state-of-the-art NiO cathodes, research has been focused on the development of new stable cathode materials to replace NiO. Currently, perovskite types of compounds and mixed metal oxides such as $LiFeO_2$ and $LiCoO_2$ have been evaluated as cathode materials.[55–67]

Preliminary work on alternate $LiFeO_2$ cathodes showed better chemical stability under the cathode environment and a lower dissolution rate.[25] However, because of slower kinetics, the catalytic activity of this material for oxygen reduction is very poor when compared to the state-of-the-art NiO cathode. Because $LiFeO_2$ shows better performance than NiO under pressurized operation it is still under consideration to be used as a cathode material.[25]

NiO doped with 5 mol% Li showed only 43 mV overpotential and higher performance at 160 mA/cm^2 compared to the state-of-the-art NiO cathode.[25] Performance improvements were suggested with Co-doped $LiFeO_2$ and Ni–Fe–Co ternary alloys.[26,68] NiO coated with CoO or $LiCoO_2$ or mixed oxides such as $LiFe_{0.5}Co_{0.5}O_2$ and mixture of $LiFeCoNiO_2$ electrodes have also been suggested as cathodes for MCFC.[69–71] Also, lithium (Li) content was found to affect the solubility of either prelithiated NiO or prelithiated cobaltite.[72]

Other materials such as Ni–Ti alloys, cerium incorporated NiO, lanthanum impregnated NiO, electroless cobalt encapsulated NiO, cobalt-doped lithium nickel oxides, and $La_{0.8}Sr_{0.2}CoO_3$ coated NiO were also suggested as alternate cathode materials.[73–78] The electrochemical cell shown in Fig. 2 made of

alumina tubes was used for the evaluation of different cathode materials under cathode operating conditions.

ELECTROLYTE

The MCFC electrolyte structure is referred to as a ''tile'' or ''matrix.'' It consists of a mixture of alkali carbonates supported within a porous support (matrix) made from finely divided $LiAlO_2$ or ceramic particles, by capillary action.[79] It contains about 45% by volume of the molten carbonate electrolyte, in most cases an eutectic mixture of 62 mol% Li_2CO_3 + 38 mol% K_2CO_3 (m.p. 487°C). Binary and ternary electrolyte compositions have also been investigated.[80] Typical compositions are 52 mol% Li_2CO_3 + 48 mol% Na_2CO_3 (m.p. 500°C) and 43.5 mol% Li_2CO_3 + 31.5 mol% Na_2CO_3 + 25 mol% K_2CO_3 (m.p. 397°C). Electrolyte compositions may be varied within the ternary system to tailor properties such as ionic conductivity, melting point, vapor pressure, gas solubility, surface tension, coefficient of thermal expansion, and corrosivity.

Electrolyte optimization is a key to MCFC lifetime.[30] The electrolyte composition affects the cell performance via: 1) tile resistance, which depends on the ionic conductivity, and 2) the polarization of the electrodes. The latter depends primarily on the electrode kinetics and gas solubility in the electrolyte.

High Li^+ and Na^+ ion contents in the melt result in higher electrical conductance of the electrolyte, while high K^+ content promotes the gas solubility.[79] The conductance measurements with various binary and ternary systems indicate that the ternaries of Li, Na, and K carbonates can also be successfully used as alternate electrolytes.[81] Typical conductance values of various electrolytes are as follows:[82]

62 mol% Li_2CO_3 + 38 mol% K_2CO_3	2.513 S/cm
52 mol% Li_2CO_3 + 48 mol% K_2CO_3	3.53 S/cm
60 mol% Na_2CO_3 + 40 mol% K_2CO_3	2.351 S/cm

Addition of Na^+ lowers the melting point of the eutectic, which is advantageous because of the fact that it lowers the vapor pressure and the expansion coefficient. Li_2CO_3/Na_2CO_3 eutectic electrolyte is expected as a new candidate electrolyte for MCFC, because it offers higher ionic conductivity and lower NiO cathode dissolution rate than the Li_2CO_3/K_2CO_3 eutectic electrolyte.[83] It was found that Li/Na electrolyte has the following superiority over Li/K:[84–88] 1) high ionic conductivity; 2) low volatility; 3) low solubility of the electrode materials; 4) no electrolyte segregation as observed with Li/K electrolyte; 5) no phase change and no particle growth of $LiAlO_2$; 6) no degradation of the cell components; 7) low kinetics at low pO_2; 8) small power density enhancement; and 9) good performance at high pressures. Addition of Ba/Ca salts lowers the melting point and increases the life stability. However, the O_2 solubility and the electrode kinetics is lower in Li/Na when compared with that in Li/K.[89]

The cell containing $(Li_{0.75}Cs_{0.25})CO_3$ electrolyte has higher cell voltage and lower cathode and anode overpotentials and it shows smaller dependence on operating temperature.[90] Li/Na/Ba/Ca electrolytes ranging from 3% to 5% Ba/Ca have shown stable and long-term performance.[91] Addition of alkaline

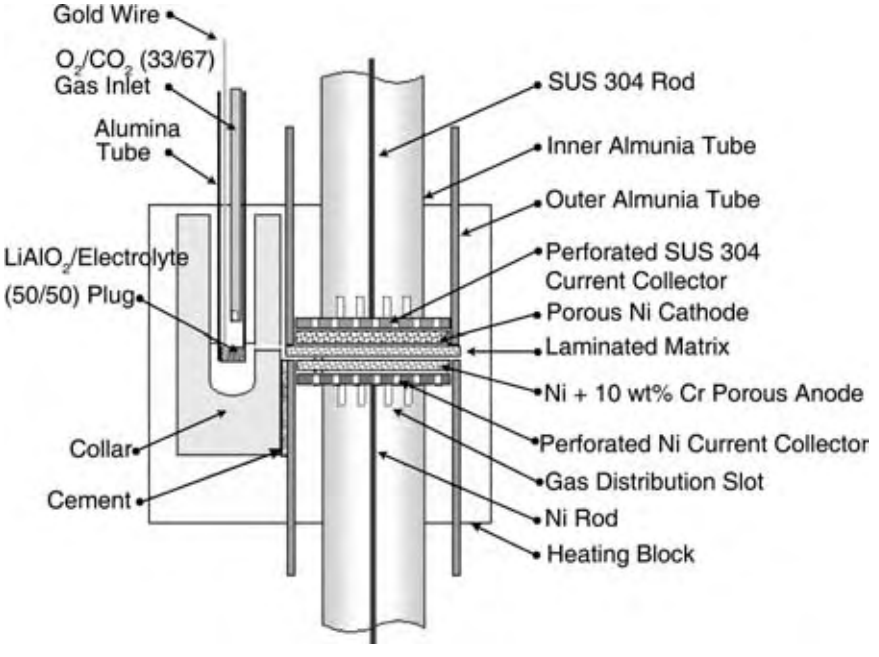

Fig. 2 Electrochemical cell used for the evaluation of MCFC cathode materials. *(View this art in color at www.dekker.com.)*

earth carbonates such as $SrCO_3$, $BaCO_3$, and $CaCO_3$ to the MCFC electrolyte increases the cathode stability and the cell performance.[92]

ELECTROLYTE RETENTION MATRIX

The electrolyte matrix provides: 1) transport of CO_3^{2-} ions from the cathode to the anode within its pore structure with a minimum resistance, and 2) separation between the fuel and oxidant gases with a minimum crossover through the voids. The matrix should satisfy the following requirements: 1) the matrix material must be chemically inert against molten carbonates, adjacent cell components, and reactant gases, and must be morphologically stable; 2) the matrix material must be of minimum crystallite size, consistent with stability; and 3) the matrix must be porous having appropriate pore size distribution. Typically, the pore size distribution should be in the range of 0.1–0.5 μm to control the distribution of CO_3^{2-} ion. The electrolyte retention matrix material should be electronically insulating and should not dissolve in the molten alkali carbonate melt.[93] It should possess porosity of more than 40%, which will enable complete flooding by the electrolyte.

The strength of the matrix and the electrolyte structure depends on the relative amount of carbonate and $LiAlO_2$. At low carbonate contents, the structure is rigid. Currently, 40 wt% of $LiAlO_2$ and 60 wt% carbonate mixtures are used to form the matrix. At the fuel cell operating temperature, the electrolyte structure is a thick paste, which provides gas seals (called the wet seal) at the edges of the cell.

To satisfy these requirements, the matrices are made of MgO, Al_2O_3, and $LiAlO_2$. The allotropic form γ-$LiAlO_2$ was found to be thermally stable and hence widely used. The status of MCFC matrix materials and their characteristics are summarized in Table 1.

Three allotropic forms of $LiAlO_2$ (α, β, and γ) have been reported.[94] Both α and β-$LiAlO_2$ undergo an irreversible transformation to γ-$LiAlO_2$ in the presence of Li_2CO_3/K_2CO_3 (62/38 mol%) at high temperatures. The phase changes are accompanied by a change in particle morphology and a decrease in surface area. Therefore, γ-$LiAlO_2$ appears to be the most desirable crystalline form for MCFC applications. The size, the shape, and the distribution of particles of $LiAlO_2$ control the carbonate retention, mechanical properties, and effective ionic conductivity of the electrolyte structures. A matrix with a narrow pore size distribution with a small mean pore size (<0.2 μm) can be attained from this powder and is considered quite acceptable. The most effective shape for $LiAlO_2$ particles appears to be fibers of submicrometer diameter.

$LiAlO_2$ powders have been prepared by using three different methods. The solid-state high-temperature reaction was developed at ANL, U.S.A.[95,96] This method involves the reaction between γ-Al_2O_3 and Li_2CO_3 at 600°C for 10 hr, leading to the formation of α-$LiAlO_2$, which was homogenized and subjected to further high-temperature treatment at 1000°C when it is converted into γ-$LiAlO_2$. The following reaction sequences are reported.[95,96]

$$\gamma\text{-}Al_2O_3 + Li_2CO_3 \xrightarrow{10\,hr,\ 600^\circ C} \alpha\text{-}LiAlO_2 \quad (9)$$

$$\alpha\text{-}LiAlO_2 \xrightarrow{24\,hr,\ 1000^\circ C} \gamma\text{-}LiAlO_2 \quad (10)$$

The α-$LiAlO_2$ thus obtained was generally of very high surface area (57–69 m^2/g), which reduces to a low-surface-area (0.4–10 m^2/g) γ-$LiAlO_2$ after the heat treatment. General Electric (GE) reported two procedures, namely aqueous slurry process and chloride synthesis routes.[4]

ALTERNATE MATERIALS

Strontium titanate ($SrTiO_3$) is recommended as an alternate material for MCFC matrix and GE has carried out extensive studies with $SrTiO_3$ tiles.[4,97] It was reported that $SrTiO_3$ reacted with Li_2CO_3 to form Li_2TiO_3 and $SrCO_3$. This reaction is inhibited by the addition of $SrCO_3$ to the carbonate melt, resulting in lowering the melting point of the melt. Unfortunately, no further studies were done either to characterize this material or to identify a more suitable matrix material than $LiAlO_2$ for MCFC.[98]

Other alternate materials such as Ga_2O_3, In_2O_3, SnO_2, PbO, Bi_2O_3, Ti_2O_3, and lithium double oxides such as $LiGaO_2$, $LiSnO_2$, and Li_2SnO_3 and zirconia were also reported in the literature.[99,100] All these materials showed a very poor performance. Thus, currently γ-$LiAlO_2$ is continuously used as matrix material for MCFC application.

ELECTROLYTE RETENTION MATRIX PREPARATION

Several researchers have reviewed the state-of-the-art and advances in MCFC matrix technology from time to time.[83,96,101] Simple, cost-effective, and scalable techniques were demonstrated for the preparation of γ-$LiAlO_2$ and to fabricate electrolyte retention matrices.[102,103] Hot pressing of the support material and electrolyte mixture at a temperature 5–10°C below the melting point of the carbonate phase was the standard method of fabrication of a carbonate fuel cell matrix (tile) in the 1980s.[104–106] Typically, tiles were hot pressed at 5000 psi and contained more than

50 vol% of the electrolyte. They were relatively thick with thickness varying from 1.8 to 2.5 mm.

Because of the inherent functional and manufacturing problems with the hot pressed tiles, alternate fabrication procedures like hot rolling, cold pressing, and sintering followed by impregnation were adopted.[107–109] Other methods such as cold pressing followed by sintering and low-pressure compression molding were also reported to produce crack-free electrolyte matrix support.[108,109] Tiles of large sizes are very difficult for production by these techniques. The major drawback of this process is that the tiles were characterized by 1) poor uniformity of microstructure; 2) low porosity; and 3) high IR drop.

Alternate methods such as vacuum casting, cold and hot roll milling flow cast technique, and paper making were adopted for the fabrication of electrolyte tile.[110–115] Electrophoretic deposition offers fabrication of very thin electrolyte layers (0.25–0.50 mm).[116] The process involved dispersion of very finely divided ceramic powder in an organic liquid and deposition onto an electrode under a d.c. electric field. This technique has also been proved to be less promising because of poor adhesion to the electrodes, matrix cracking, and lack of reproducibility. Although both the technique and the deposited product were initially well suited for MCFC applications, structural fracture resulted during impregnation with the alkali carbonate electrolyte.

TAPE CASTING TECHNIQUE

The tape casting process, which is utilized widely in the electronics industry, has been adopted by many MCFC developers.[117,118] The tape casting process was originally introduced for matrix fabrication, because of its suitability for low-cost processing of very thin structures with large areas.[101] The tape casting process was demonstrated to be advantageous by IGT, Energy Research Corporation (ERC), and United Technologies Corporation (UTC).[38,119] This process involves dispersing the ceramic powder in an organic vehicle (solvent) along with binders, plasticizers, and additives to yield proper slip rheology. As presented in Fig. 3, a typical tape casting process begins by dispersing the dried ceramic powders in solvents containing a dissolved organic deflocculant.

Although the basic formulation of the tape casting slurry and the tape casting process variables is known, optimization of these variables is desired. The current activities are focused to improve the performance of the carbonate fuel cell matrix manufactured by the tape casting method. The crack propagation was arrested by the use of Al_2O_3 or $LiAlO_2$ fibers. Various additives such as submicrometer size $LiAlO_2$ or ceramic fiber have been reported for reinforcement to avoid matrix cracking.[120,121]

MATRIX STABILITY

It is important to improve the endurance and the reliability of the electrolyte plate for the commercialization of MCFC. The electrolyte loss from the matrix plate increases the cell resistance and deteriorates the cell voltage. The formation of cracks in the electrolyte plate causes a gas cross-leakage between the fuel gas and the oxidizer gas. The pore structure of the matrix plate must be stable and fine to support liquid electrolyte under MCFC operation. It is necessary to prevent the formation of cracks in electrolyte plates during thermal cycling. Because of the immediate and large

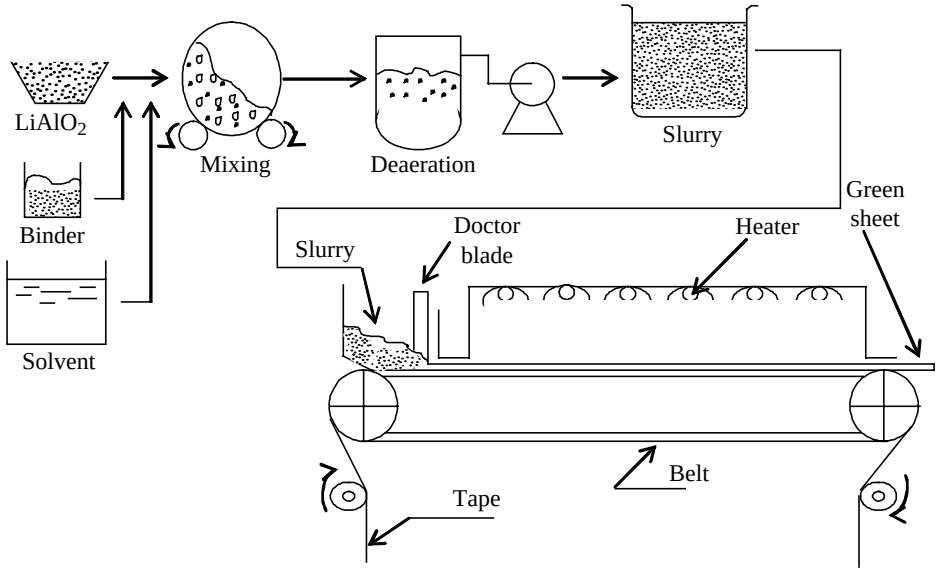

Fig. 3 Tape casting process—a schematic.

performance loss associated with gas crossover, resistance to thermal cycling is considered a major critical issue for stack lifetime. The stability of electrolyte plate has been improved by using advanced $LiAlO_2$ powder and its durability by the addition of the ceramic fiber.[122,123]

ELECTROLYTE RETENTION CAPACITY

To prolong the life of MCFC, the amount of electrolyte in the matrix must be maintained at an appropriate level over long-term operation. The growth of particles of $LiAlO_2$ as an electrolyte retention material in molten carbonates leads to a decrease in the electrolyte retention ability. These phenomena result in a decrease of the fuel cell performance. It was found that zirconia powder added to lithium aluminate keeps the electrolyte retention ability constant for over 7000 hr in Li/Na carbonates and $pCO_2 = 0.1$.[124]

ELECTROLYTE LOSS AND MANAGEMENT

The causes that trigger the electrolyte loss from the cell packages are vaporization and reaction of the electrolyte with the metallic components.[25] Corrosion of cell metallic parts consumes Li^+ ions. Li^+-rich compositions tend to have a very good performance. Carbonate creepage, i.e., migration of electrolyte from one end of the stack to the other through the external manifolds, gaskets, etc. is another cause. Engineering solutions are aimed to solve this with a proper stack design and by manifold concept.

Electrolyte loss by volatilization is a continuous phenomenon. This can be overcome by using Na^+ containing electrolyte. Also, use of thicker electrodes can store more electrolytes in it. The effect of matrix thickness and cathode pCO_2 on cell shorting has also been discussed.[125] The relationship between cell life and matrix thickness is not linear. Cells employing thick matrix have longer life. On the other hand, the resistance of the thick matrix is high.[26] It is important to determine the matrix thickness in consideration of the cell life and performance. Also, the use of corrosion resistant materials in cathode development will reduce the carbonate loss. There is a tendency for the electrolyte to migrate from the positive end of the stack to the negative end of the stack. This may cause the end cells to perform poorly compared to the central cells. The electrolyte loss is through the gasket used to couple the external manifolds to the cell stack. The standard gasket material is porous and provides a conduit for electrolyte transfer. Stacks with internal manifolding do not require a gasket and may not experience this problem.[25]

CURRENT COLLECTORS AND BIPOLAR PLATES

Austenitic stainless steels like 310S, 316, or 316L are typically used for the construction of cathode and anode current collectors and bipolar separator plates.[126–128] Corrosion of these steel components is a major lifetime-limiting factor in MCFC. The corrosion behavior of stainless steel components in molten carbonate conditions has been studied extensively during the past decade. Research is being aimed at increasing the corrosion resistance of these components by altering the alloy composition or by surface modification techniques.[126,129–132]

The corrosion resistance of stainless steels and nickel-based alloys in aqueous solutions can often be increased by addition of chromium or aluminum.[133–135] Chromium protects the base metal from corrosion by forming an oxide layer at the surface. Chromium is also considered to be an important alloying metal for steels in MCFC applications. Chromium containing stainless steel, however, leads to the induced loss of electrolyte. Previous studies done to characterize the corrosion behavior of chromium in MCFC conditions have shown the formation of several lithium chromium oxides by reaction with the electrolyte.[133] This corrosion process also results in increased ohmic loss because of the formation of scales on the steel. Aluminum additions similarly have a positive effect on corrosion resistance.[134,135] However, corrosion scales formed in aluminum containing alloys show low conductivity leading to a significant ohmic polarization loss.

Nickel electrocladding is popularly used as a surface modification technique to reduce corrosion on the anode side of the bipolar plate. However, nickel electroplated parts do undergo corrosion. Also, nickel cladding does not offer good barrier protection to the diffusion of oxygen. Alloying, or coating with aluminum or alumina, is often reported to improve corrosion resistance. Aluminum coating typically gives lifetime protection in the wet-seal area.[135] However, the high electrical resistance of an Al_2O_3 or $LiAlO_2$ scale is not acceptable in the active area.

The nature of the corrosion scale is very important in deciding the corrosion resistance of the component. Surface modification or alloying alters the composition and complexity of the corrosion scales, which prevents further corrosion and outward diffusion of alloy components. Vossen et al. have shown the complex scale formation in the case of stainless steel and nickel-based alloys in comparison to pure metals.[133,136–142] These scales are understood to cause transport problems to the outward diffusion of alloy components and thereby decrease the dissolution of the steel components. Therefore, any improvement to the corrosion resistant properties of the current collector has to come by way

of novel coatings, which possess the ability to alter the corrosion scale structure of the alloy component. By using this approach, the barrier properties of the corrosion scale to the oxygen diffusion can be improved. Also, the coating should restrict the outward diffusion of steel components, a common problem associated with Ni coating.

Nickel containing scales exhibit higher conductivity because of the presence of trivalent nickel ions, which introduce vacancies in the lattice of the scale.[136] Therefore, nickel-based coating can lead to superior conductivity and good protection provided that it is alloyed properly with corrosion resistant elements. Cobalt has a lower solubility in molten carbonate and electroless Co has been successfully used for a variety of corrosion-resistant applications.[82,143] Electroless plating of Ni–Co gives rise to deposition of uniform layers of nanostructured material, which would result in better protection of the substrate.

INTERNAL REFORMING

The MCFC operates at sufficient high temperatures to allow natural gas to be reformed within the fuel cell stack itself. This involves addition of a reforming catalyst in the fuel gas passages adjacent to the anode, where the reforming reaction takes place.[144] This concept is called DIR step.[25] A direct fuel cell (DFC) is a unique type that employs the DIR concept for MCFC (IRMCFC), eliminating the need for an external reformer and the associated heat transfer loop. Heat and steam are supplied directly by the electrochemical reaction and this reaction drives the reforming reaction to completion by removing the hydrogen as it is formed. The water gas shift reaction:

$$CO + H_2O \longrightarrow CO_2 + H_2 \qquad (11)$$

also occurs, i.e., reaction of the carbon monoxide with steam to produce additional hydrogen. In this way an external reformer is not needed. Other advantages claimed for the IRMCFC are greater system simplicity, multifuel capacity, increased reliability, which can lead to a 30% cost reduction. Fuel to electricity conversion efficiencies greater than 60% can be achieved. But the major disadvantage is that the catalyst can become deactivated in the presence of carbonate, which migrates out of the cell.[25]

In another alternative, in IIR mode, the reforming reaction takes place in a separate catalyst compartment located in close thermal contact with the cell. This method allows the heat from the fuel cell to be used for the reforming reaction, but there is no hydrogen removal or steam production to help move the reaction forward. Indirect reforming therefore is not as efficient as direct reforming but it does have the advantage that the catalyst is less likely to become deactivated.[25] A combination of both methods of internal reforming may give optimum cell characteristics for the longest cell life.

In the direct internal reforming MCFC (DIR-MCFC) system, the direct reformation of fuel at the anode can give fuel saving of 20%, resulting in 12% improvement in fuel cell electrical efficiency. The schematic representation of the IIR and DIR concepts is shown in Fig. 4.

Simple molecules such as methanol can be directly fed to a carbonate fuel cell anode. Hydrocarbon molecules, such as methane, can be reformed in situ with the help of a catalyst.

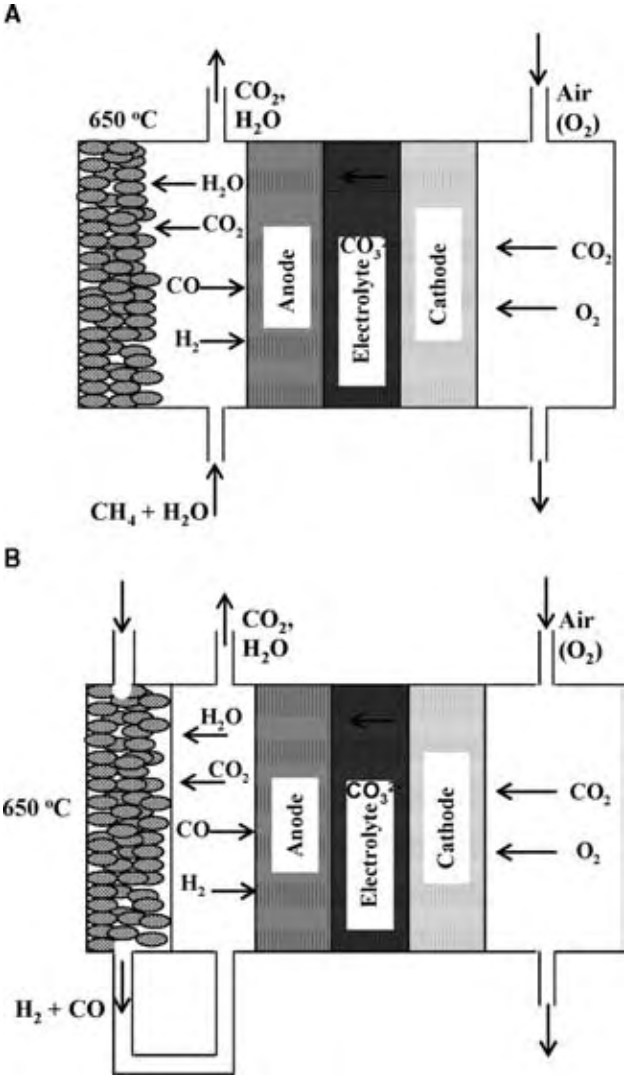

Fig. 4 Schematic representation of (A) direct internal reforming (DIR) and (B) indirect internal reforming (IIR) MCFC concepts.

The reformation reaction is:

$$CH_4 + H_2O \longrightarrow CO + 3H_2$$
$$H_{650^\circ C} = +53.87\,\text{kcal/mol} \quad (12)$$

The H_2 thus formed then reacts in the cell as:

$$H_2 + \frac{1}{2}O_2 \longrightarrow H_2O(g)$$
$$H_{690^\circ C} = -59.26\,\text{kcal/mol} \quad (13)$$

The reforming reaction is endothermic, whereas the overall cell reaction is exothermic. It is estimated that for typical operating parameters, approximately 60% of the heat produced by the fuel cell can be consumed for the reforming reaction.[144]

Different nickel-based catalysts on ceramic supports have been extensively investigated as internal reforming catalysts. Ni/MgO or Ni supported or Al_2O_3 provide sufficient catalytic activity for the steam reformation reaction.[145] It possesses the stability and converts about 85% CH_4 to H_2 at 650°C. But it is deactivated by the alkali metal cations of the electrolyte. No thorough study has been made on the suitability of available catalysts besides nickel. Ni–cermet anodes are suggested as alternatives. Nickel catalyst supported with γ-$LiAlO_2$ was also used to study the steam reforming of methane in internally reformed MCFC.[146,147]

Catalyst support such as Co/Al_2O_3 and Rh/Al_2O_3 were used for the production of hydrogen from ethanol for internal reforming MCFC application.[148] Research is also focused on the use of nickel catalyst supported on $MgO–TiO_2$ composite oxide with varying ratio of Mg to Ti.[149]

CONCLUSIONS

The MCFC is a promising power generating source because of its unique characteristics such as high fuel efficiency and ability to use various carbonaceous fuels. Although Ni-10 wt% Cr is used in the state-of-the-art MCFC as anode, it needs to be improved in terms of better creep and sintering resistance. In spite of the development in the alternate cathode material research, lithiated nickel oxide has been the choice of cathode material in the kilowatt-level MCFC stacks developed by many companies. Continuous research in the development of stable electrolyte retention matrix, identification of suitable molten carbonate electrolyte composition, and additives to the electrolyte will be a significant milestone. Also, research in the area of current collector/bipolar plate to overcome the corrosion problem will lead to the MCFC technology hitting the commercial market in the near future.

Multiphase Mixing and Solid–Liquid Mixing in Agitated Reactors

INTRODUCTION

Multiphase reactions can be significantly affected by how well mixed the system is and how intimately dispersed the phases are. The reason for this is easy to explain, but more difficult to quantify: although the course of any reaction is determined exclusively by the *local* concentrations of the reactants and the intrinsic reaction kinetic rates, in any real reactive system, the local reactant concentrations depend not only on how fast the reactants are depleted by the reaction, but also on how fast they are locally replenished from the bulk of the phases in which they initially reside. The latter phenomenon is directly related to the existence of a mass transfer step (in series with the reaction step), which determines the rate at which the reactants in different phases are brought in contact with each other. In many cases, especially if the rate of reaction is "fast" with respect to the mass transfer rate, the latter mechanism can become controlling over the former, and the overall reaction process is dominated by mass transfer and, hence, multiphase mixing.

BACKGROUND

Mixing has no impact on the intrinsic reaction kinetics, but it has a controlling effect on the temporal variation in species concentration and the mass transfer rate. This can be shown by examining the typical convective mass transfer rate equation:

$$\dot{m} = k_L A(C_{\text{interface}} - C_{\text{bulk}}) = k_L a_v V_L \Delta C \qquad (1)$$

All the variables on the right-hand side of this equation are directly affected by mixing. More specifically, the mixing effects generated by the mechanical energy introduced into the reactor impact the overall mass transfer rate $\dot{m}$ by affecting the following variables:

1. State of dispersion or suspension of the dispersed phase, i.e., *degree of macroscopic homogeneity* of the dispersed phase throughout the continuous phase. This variable affects mainly the volume of the liquid that is *effectively* available for the reaction. Depending on the intensity of mixing, such a volume can be equal to, or smaller than, the liquid volume in the reactor, V_L. The local concentration gradient ΔC is also affected by the degree of homogeneity, in that poor mixing can lead to variations in the bulk concentration, C_{bulk}, from location to location within the reactor.
2. Specific interfacial area, a_v, and overall interfacial area, A, available for mass transfer.
3. Mass transfer coefficient at the interface (k_L).

The first variable refers to how well interdispersed the phases are in different portions of the reactors. In most cases, mixing affects this variable by determining the major flow patterns existing in the reactor under a specific operating regime. For example, the loading regime in a stirred liquid sparged with a gas is defined as the condition at which the impeller can disperse the gas throughout the upper part of a vessel only (but not necessarily in the portion below the impeller). Obviously, if one phase, i.e., the gas in this example, is dispersed only in a portion of the liquid in the reactor, the liquid volume available for mass transfer will be reduced and C_{bulk} will vary from location to location within the vessel at any given time. Similar remarks can be made for liquid–liquid dispersions, and especially solids–liquid suspensions, where it is critical to ensure that the solids are in the "just-suspended" regime, thus fully exposing their entire

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030574

surface to the liquid, if mass transfer effects are to be minimized.

The second variable, the interfacial area, is also greatly affected by mixing, especially in those systems, such as liquid–liquid and gas–liquid dispersions, where mixing effects produce a breakup of the dispersed phase into smaller ''elements'' (bubbles or droplets): the smaller these elements, the larger the interfacial area. Finally, the turbulent mixing produced by agitation has a well-known effect on the third variable, the interfacial mass transfer coefficient, by reducing the thickness of the boundary layer around a dispersed phase: the greater the local turbulent intensity, the thinner the boundary layer and the higher the mass transfer coefficient.

In summary, mixing controls every aspect of mass transfer. Hence, mixing, through mass transfer, is a key factor in the mass balances for the reactants, strongly affecting the local concentration of the reactants and, ultimately, the overall reaction process, especially if the reaction kinetic rates are comparable to, or faster than, the mass transfer rates.

It should also be stressed that the mass transfer is affected by scale, whereas the intrinsic reaction kinetics is not. To make matters worse, small reactors are typically much better mixers than large reactors, implying that many mixing phenomena are negatively impacted by scale and may manifest themselves only at large scales. Therefore, failure to analyze the multiphase mixing aspects of a reaction process may result in undesired results on scale-up, such as reduced yield of a desired product, or partial dispersion, and, hence, reduced utilization of a suspended solid catalyst.

Computational fluid dynamics (CFD) has been used in recent years to predict the flow, mixing, and reaction characteristics of single and multiphase systems, including a variety of complex mixing-reactive systems.[1–5] Although the majority of these applications have described processes occurring in single-phase systems, CFD is being currently used to study more complex multiphase systems, and it is expected to be even more extensively used in the future for such applications.

The remainder of this entry as well as the other two entries in this encyclopedia entitled ''Liquid–Liquid Mixing in Agitated Reactors'' and ''Gas–Liquid Mixing in Agitated Reactors'' deal exclusively with systems in which a liquid is the continuous phase and a second dispersed system is introduced as a finely divided solid (solid–liquid mixing), an immiscible liquid (liquid–liquid mixing), or a sparged gas (gas–liquid mixing). Most of the discussion is focused on multiphase reactors whose content is mechanically stirred by an impeller operating under turbulent regime. Each system is analyzed independently, but the impact of mixing on the three main variables listed above, i.e., degree of dispersion, a_v (and A), and k_L, is examined in a similar fashion in each case.

POWER DISSIPATED BY IMPELLERS IN AGITATED VESSELS

In general, increasing the mixedness of a system (e.g., by increasing the agitation speed) has a beneficial effect on all the above-mentioned variables responsible for mass transfer, and, hence, on the overall mass transfer rate. However, a higher rate of mechanical energy dissipation (power) is typically required to achieve such an increased level of mixedness. Power dissipation has a significant impact on all the variables controlling mass transfer. Therefore, before proceeding any further, it is important to distinguish among different types or impellers and determine their mixing or hydrodynamic characteristics.

Impellers come in a variety of shapes and forms. They are commonly classified as either radial impellers, producing a main radial flow perpendicular to the shaft (as shown in Fig. 1), or axial impellers, generating a flow mainly oriented parallel to the shaft (as shown in Fig. 2).[6] More recently, hydrofoil (or fluidfoil) impellers have been developed, typically producing strong axial flow and low shear (as shown in Fig. 3).[6] Radial impellers typically dissipate more power as turbulent shear than axial and hydrofoil impellers, because of the significant shear which they generate. Consequently, they are used in those applications in which new surface area must be created, and high mass transfer rates are required (e.g., gas–liquid and liquid–liquid applications). Axial and hydrofoil impellers are more common when high flow and low shear are demanded (e.g., solids suspension), although they may have other applications as well (e.g., fermentation). Close-clearance impellers (such as rotor–stator homogenizers) are a separate class of impellers finding applications in higher-viscosity fluids, or where very high shear is required (e.g., liquid–liquid emulsification).[6]

The power dissipated by an impeller rotating in a homogenous, single-phase liquid in a baffled vessel is a function of the type of impeller, the flow regime in which the impeller operates (laminar vs. turbulent), which is, in turn, a function of the impeller Reynolds number, $Re = \rho_L N D^2/\mu$, and a number of geometric ratios. For an agitated vessel, the impeller power dissipation, P, and the power dissipation per unit liquid mass, ε, can be calculated, respectively, from:

$$P = N_p \rho_L N^3 D^5 \tag{2}$$

and

$$\varepsilon = \varepsilon_{avg} = \frac{P}{\rho_L V_L} \tag{3}$$

where the impeller power number, N_p, is available, for selected impellers in selected system geometries (from Fig. 4).[6] For sufficiently high Re, the flow is turbulent

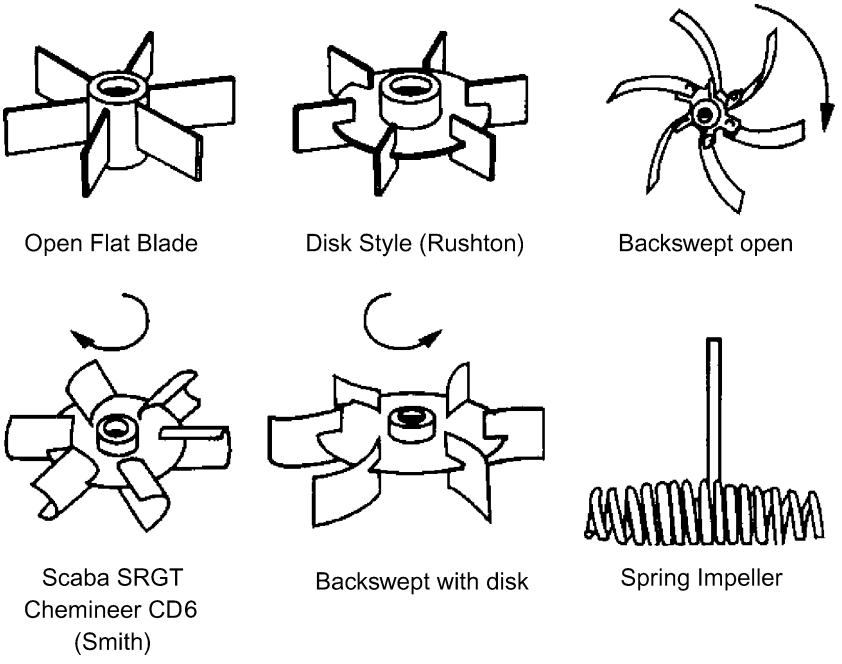

Fig. 1 Radial flow impellers. (From Ref.[6].)

and the power number becomes a constant, which depends only on the type and geometry of the impeller–vessel configuration. For example, for a standard Rushton turbine in a baffled standard impeller–vessel configuration ($H/T = 1$; $C/T = 1/3$; and $D/T = 1/3$) $N_p = 5$. Additional N_p values for different types of impellers are provided below, in the next two entries, and elsewhere.[7–13] The power numbers for multiple impellers mounted on the same shaft are also available.[11,14–16]

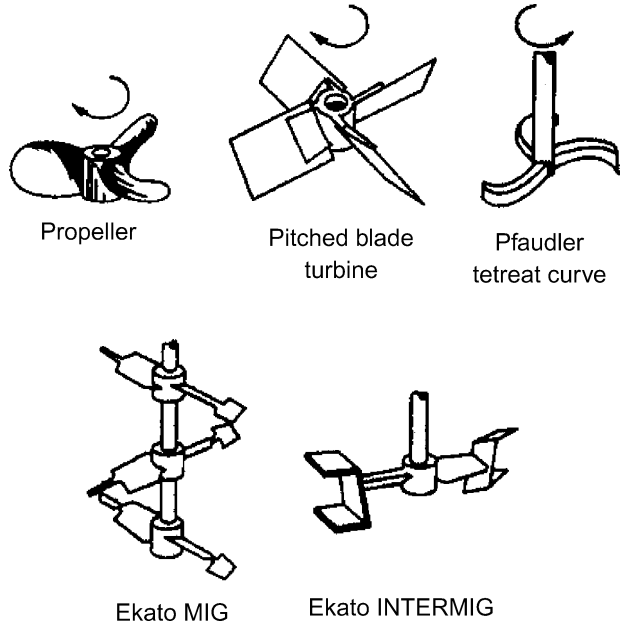

Fig. 2 Axial flow impellers. (From Ref.[6].)

MIXING IN SOLID–LIQUID AGITATED REACTORS

Solid–liquid reactors contain a two-phase mixture of the continuous liquid phase and finely divided, small, solid particles resulting from the addition or formation of solids. Typical operations involving solid–liquid mixing include dissolution and leaching, crystallization, precipitation, adsorption, desorption, ion exchange, solid catalyzed reaction, and suspension polymerization. All these unit operations involve solid–liquid mass transfer. The objectives of solid–liquid mixing operations are to promote suspension of solids, resuspension of settled solids, incorporation of floating solids, dispersion of solid aggregates, or control of particle size from the action of fluid shear as well as any abrasion due to particle–particle, particle–wall, and particle–impeller impacts, and mass transfer at the solid–liquid interface.[7]

Selection and Configuration of Solid–Liquid Equipment

Solids suspension is usually carried out in mechanically agitated vessels with or without draft tubes, as shown in Figs. 5 and 6.[7] Dished heads (ASME dished, elliptical, or torispherical heads) are preferred. A single impeller is usually sufficient for off-bottom solids suspension in vessels with dished heads and $H/T < 1.3$. Dual impellers are recommended for vessels with $1.3 < H/T < 2.5$, which are used for uniform suspension of fast-settling solids. Three or more impellers

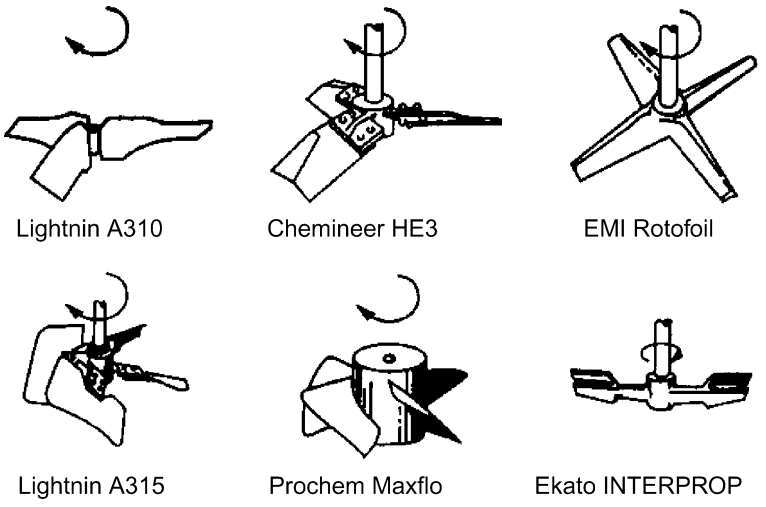

Fig. 3 Hydrofoil impellers. (From Ref.[6].)

may be required if $H/T > 2.5$. A vessel with such a high aspect ratio is a poor choice for solid suspension.

Baffles are essential for solids suspension operations involving solids that are heavier than the liquid. They convert the swirling motion into top-down or axial fluid motion, which helps to lift and suspend the solids.

In steel or alloy vessels, the recommended baffle design for suspension of settling solids is four, flat-blade baffles, each baffle with a width, B, equal to $T/12$, and a wall clearance of at least $T/72$. The baffles should extend to the lower end of the straight section of the cylindrical vessel, at the intersection of the cylindrical section with the bottom dish head. In glass-lined equipment, the recommended baffles are either fin or beaver tail types.[7] A minimum of two baffles is recommended. These baffles are generally less effective than the standard four flat-blade baffle design.

Solids suspension and solids distribution are primarily governed by the bulk or convective flows in the vessel. Axial impellers and hydrofoil impellers (e.g., Lightnin A-310, A-320; Chemineer HE-3, APV LE-20, Ekato Viscoprop) whose discharge is axially directed are more efficient than others in achieving solids suspension. The recommended impeller speed should be higher than N_{js} (defined below). For multi-process batch reactors, mixers equipped with variable speed drives permit the mixer to be operated at different impeller speeds to accommodate the different mixing needs of the various steps in the process.

Typical values for the impeller clearance off the vessel bottom are $T/4$ for hydrofoil impellers and $T/3$ for pitched-blade turbines. Hydrofoil impellers may be a poor choice when solid suspension is accompanied by other mixing duties, such as liquid–liquid dispersion or gas dispersion. For such cases, a multiple impeller system consisting of a high-efficiency impeller in combination with a 45° pitched-blade impeller should be evaluated. Small pitched blade impellers with a

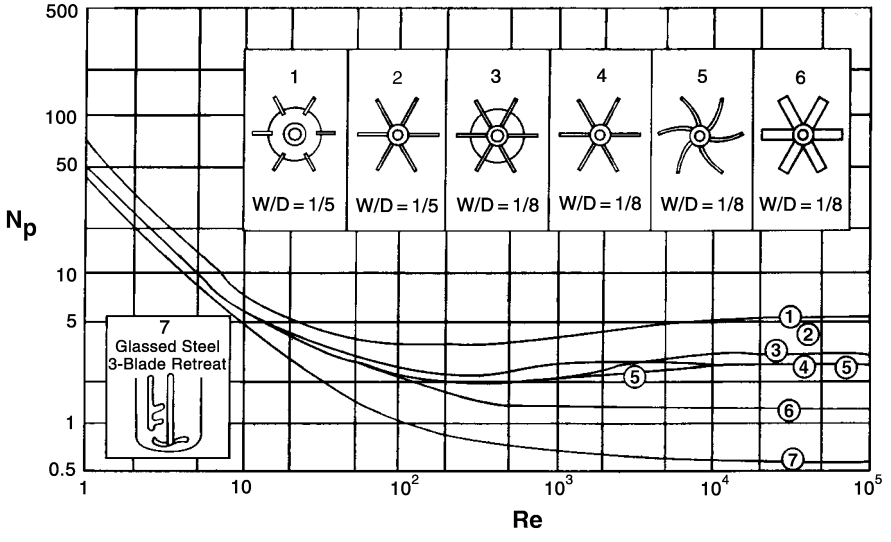

Fig. 4 Power number, N_p, vs. impeller Reynolds number, Re, for seven different impellers. (From Ref.[6].)

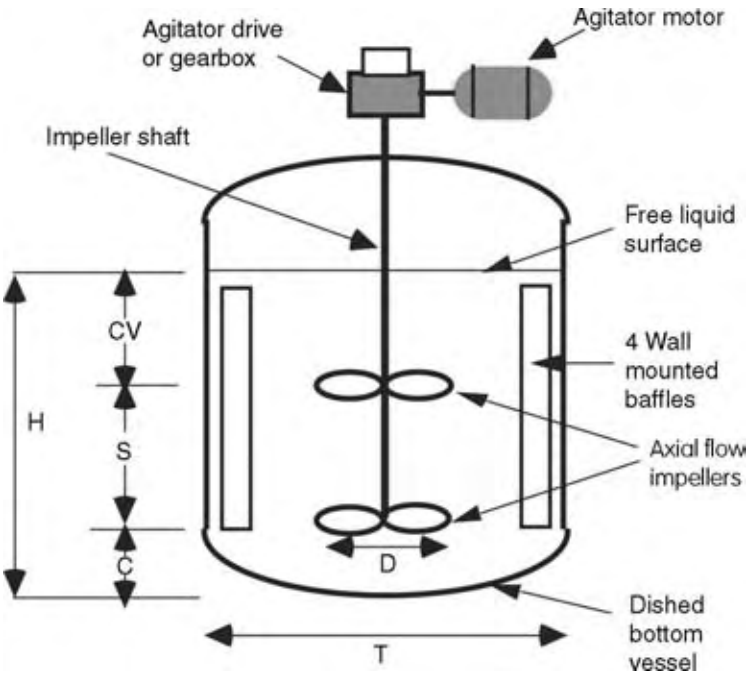

Fig. 5 Schematic representation of a typical mechanically agitated vessel. (From Ref.[7].)

diameter $D < T/2.5$, located near the vessel base ($C < T/4$) are appropriate for solid suspension, and also aid in the discharge of the solids during slurry transfer. If the impeller is located very close to the tank bottom, a four-bladed flat-blade impeller is more appropriate than a pitched-blade turbine.

Nozzles for solids addition should be provided with gratings or screens to keep large solid chunks or foreign matter from entering the vessels. Bottom nozzles should be as short as practical and be installed with flush-bottom valves to prevent the solids from collecting and plugging the nozzle.[7]

Settling Velocity and Solid Suspension

A dense solid particle placed in a quiescent fluid will accelerate to a steady-state settling velocity (free- or still-fluid settling velocity). Equations to calculate the settling velocity are given elsewhere.[17] In an agitated

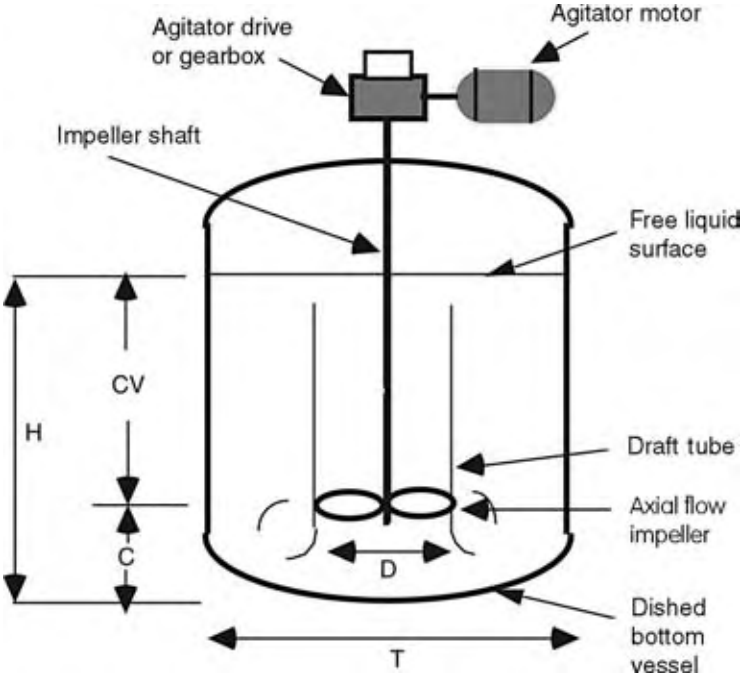

Fig. 6 Schematic representation of a mechanically agitated vessel with a draft tube. (From Ref.[7].)

Table 1 Impact of desired result on mixer design (power and speed depend on mixing criteria and settling velocity)

		Power ratio at settling velocity (ft/min)		
Suspension criteria	**Speed ratio**	**16–60 (Difficult)**	**4–8 (Moderate)**	**0.1–0.16 (Easy)**
On-bottom motion	1	1	1	1
Complete off-bottom suspension	1.7	5	3	2
Total uniformity	2.9	25	9	4

(From Ref.[19].)

solid suspension, the particle settling velocity is always less than the free-settling velocities because of the complex turbulent hydrodynamic field and solid–solid interactions.[18]

The magnitude of the free-settling velocity has proven useful in characterizing solid suspension problems into easy, moderate, or difficult categories, as reported in Table 1.[19]

Hydrodynamics of Solid Suspension and Distribution

Solid suspension requires the input of mechanical energy into the fluid–solid system by some mode of agitation. The input energy creates a turbulent flow field in which solid particles are lifted from the vessel base and subsequently dispersed and distributed throughout the liquid. Solids lifting from the vessel base is achieved by a combination of the drag and the lift forces of the moving fluid on the solid particles and the bursts of turbulent eddies originating from the bulk flow in the vessel (Fig. 7).[7,20,21]

The distribution and magnitude of the mean fluid velocities and large anisotropic turbulent eddies generated by a given agitator determine to what degree the solid suspension may be achieved. Thus, different agitator designs may achieve different degrees of suspensions at similar energy input. For any given impeller, the degree of suspension will vary with D/T as well as C/T, at constant power input.

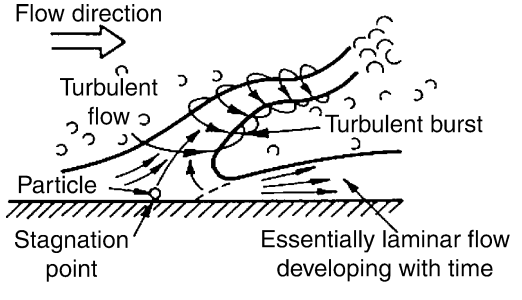

Fig. 7 Sudden pickup of solids by turbulent burst. (From Refs.[7,20].)

Solids Suspension and Distribution Regimes

In agitated vessels, the degree of solid suspension, or solid suspension regime, is generally classified into the following three levels (Fig. 8).[7]

- *On-Bottom Motion or Partial Suspension Regime*: This state is characterized by the complete motion of all particles around the bottom of the vessel. It excludes the formation of fillets, i.e., loose aggregations of particles in corners or other parts of the vessel bottom. As the particles are in constant contact with the base of the vessel and with one another, not all the particle surface area is available for chemical reaction, mass, or heat transfer.
- *Off-Bottom or Complete Suspension* (*Just-Suspended*) *Regime*: This state is characterized by the complete off-bottom motion of all particles with no particle remaining on the base of the vessel for more than 1–2 sec (Zwietering criterion).[22] Under this condition, the total surface area of the particles is exposed to the fluid for chemical reaction, mass or heat transfer. The just-suspended regime refers to the minimum agitation conditions at which all particles attain complete suspension.
- *Nearly Uniform Suspension Regime*: This is the state of suspension at which particle concentration and particle size distribution are roughly uniform throughout the vessel. Any further increase in agitation speed or power does not appreciably enhance the solids distribution in the fluid. A coefficient of variation of the solid concentration of about 0.05 (i.e., a uniformity of 95%) is often considered adequate for most process applications. In practice, a concentration gradient as a function of vertical position will always exist.[23] Complete uniformity is theoretically unattainable and impractical to achieve because a thin clear fluid layer always exists at the air–liquid interface, as the axial lift velocity, and, hence, the particle concentration approaches zero near the liquid surface. Nearly uniform suspension is often the desired process result for operations where a representative sample of solids is required or a uniform concentration of solids must

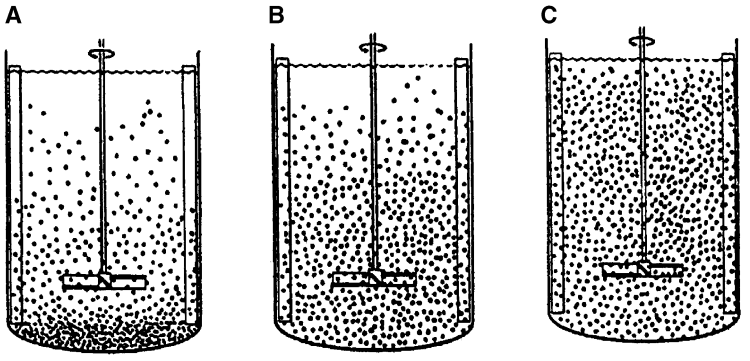

Fig. 8 Degrees of suspension. (A) Partial suspension: some solids rest on the bottom of the tank for short periods, a useful condition only for dissolution of very soluble solids. (B) Complete suspension: all solids are off the bottom of the vessel, minimum desired condition for most solid–liquid systems. (C) Nearly uniform suspension: solids suspended uniformly throughout the vessel, required condition for crystallization, solid-catalyzed reaction. (From Ref.[7].)

be achieved. For example, in crystallization, nonuniform solids concentration may lead to unacceptably high local supersaturation levels and subsequent nonuniformity in crystal growth. Similarly, feeding of filters and reactors from batch feed tanks requires nominal complete uniformity.

Calculation of the Just-Suspended Impeller Speed, N_{JS}, in Solid–Liquid Suspensions

The attainment of the solids just-suspended regime is essential to ensure that all solids are suspended off the tank bottom, thus ensuring that their surface area is fully exposed to the fluid. Therefore, the ability to determine or predict the minimum impeller speed, N_{js}, for the just-suspended state is a critical step in any solid–liquid mixing operation. Techniques for measuring N_{js} are discussed elsewhere.[24,25] In addition, N_{js} has been the subject of significant studies and correlations are available to predict it.[21] The most widely used equation for the determination of N_{js} is the Zwietering equation:[22]

$$Re_{js}^{0.1} Fr_{js}^{0.45} \left(\frac{D}{d_p}\right)^{0.2} X^{-0.13} = S \tag{4}$$

which is often rewritten as

$$N_{js} = S\nu^{0.1} \left[\frac{g(\rho_S - \rho_L)}{\rho_L}\right]^{0.45} \frac{d_p^{0.2}}{D^{0.85}} X^{0.13} \tag{5}$$

With the exception of the density difference, the influence of fluid and particle properties on N_{js} is not significant, as indicated by the small exponents on the kinematic viscosity, ν, the particle diameter, d_p, and the percent solids-to-liquid mass ratio, X ($100 \times m_S/m_L$). Obviously, this correlation fails as $X \rightarrow 0$, because N_{js} can never be zero. This error is handled practically by using $X = 5$ for solids concentrations smaller that 5%. The density difference is the property having the largest influence on N_{js}. Its exponent reflects the effect of the terminal settling velocity of the particles. The exponent on the impeller diameter, D, represents the effect of scale. Note that an exponent of -0.67 on D would imply a scaling rule based on power per unit volume [as it can be derived from Eqs. (2) and (3)].

The effects of the geometry of the impeller, vessel, and its internals are incorporated into the S parameter. Values of S are listed in Table 2[26] for a variety of impellers. The S value varies with D/T, and C/T. Zwietering provided plots of S as a function of D/T and C/T.[22] More recently, Armenante and Uehara Nagamine and Armenante, Uehara Nagamine, and Susanto have sought simple mathematical expressions to describe the effects of geometry (D/T and C/T) on S.[25,27] Their results, reported in Table 3, are yet to be validated with data from large-scale tests and for vessels with dished bottoms. N_{js} is 10–20% lower in dished-bottomed vessels than in flat-bottomed vessels.[28,26] Solids suspension is impractical with conical bottoms.

When the power number of the impellers is taken into account, it becomes clear that axial-flow impellers (e.g., Lightnin A-310, Chemineer HE-3) are able to achieve the just-suspended state at a lower power input than other impellers, such as pitched-blade or disk turbines. The resulting axial flow developed by high-efficiency impellers is higher at the vessel base, per unit of power expended, than that for radial flow impellers. These impellers are also more effective at higher clearances from the vessel base, i.e., larger C/T values.

The use of multiple impellers usually has a negligible impact on N_{js}, as solid suspension is dominated by the hydrodynamics at the bottom of the vessel, which is primarily affected by the lowest impeller.[29]

Chowdhury has pointed out regions of interest where Zwietering's correlation is not as reliable.[30] They include: 1) solids loading below 2% (v/v); 2) high d_p/T values; and 3) high solids loading (>15%, v/v).

Table 2 Value of the S parameter for solid suspension in dished-bottomed vessels

Impeller geometry and location	S value
A-310 ($T/2.4$)	
C = $T/4$	6.9

$C = T/8$	4.1

The first term in parentheses refers to the value of the impeller diameter, D; the second is the impeller blade width, B.
(From Ref.[26].)

Cloud Height and Solid Distribution in Stirred Tanks

In solid suspensions, there is a distinct level to which most of the solids are lifted within the fluid even at speeds above N_{js}. The distance from the bottom of the vessel to this level is called the cloud height (H_{cloud}). The liquid below this height is solid rich, while above it there is only an occasional visit by a few small solids.

Recently, Bittorf and Kresta have successfully correlated the cloud height data of Bujalski et al. and Hicks, Myers, and Bakker with the following equation for purely axial impellers:[31–33]

$$H_{cloud} = \frac{N}{N_{js}}\left[0.84 - 1.05\frac{C}{T} + 0.7\frac{(D/T)^2}{1 - (D/T)^2}\right] \tag{6}$$

This equation is appropriate for $0.154 < D/T < 0.52$ and for solids with a terminal settling velocity less than 0.143 m/sec. The correlations produced by Magelli et al. can be used to predict the solid distribution as a function of the position along the vertical axis.[23]

Power Dissipation in Solid–Liquid Stirred Reactors

The power dissipated by the impeller in solid–liquid dispersions can be calculated from an equation similar to Eq. (2), i.e.,

$$P = N_p\bar{\rho}D^5N^3 \tag{7}$$

where the average density of the solid–liquid mixture is now given by

$$\bar{\rho} = \phi\rho_S + (1 - \phi)\rho_L \tag{8}$$

Such a value for the average density is only approximately correct for power calculations (although it is appropriate in most cases), as the solids fraction in the impeller region may differ from ϕ depending on N, i.e., on the solids suspension state.

The volumetric solids faction ϕ is related to X as follows

$$\phi = \frac{(X/100)\rho_L}{\rho_S + (X/100)\rho_L} \tag{9}$$

Interfacial Area in Solid–Liquid Suspensions

The surface area of a given mass of solids is strictly determined by the size and geometry of the particles,

Table 3 Correlations for the S parameter for solid suspension in flat-bottomed vessels

Impeller type	Correlation for S	Source
Dis turbine ($C/T < 1/6$)	$S = \left[0.99(T/D)^{1.40}\exp(2.18(C_b/T))\right]$	Armenante and Uehara Nagamine[25]
Dis turbine ($C/T > 1/5$)	$S = \left[2.10(T/D)^{1.18}\exp(0.24(C_b/T))\right]$	Armenante, Uehara Nagamine and Susanto[27]
6-Blade flat-blade turbine ($C/T < 1/5$)	$S = \left[1.43(T/D)^{1.20}\exp(1.95(C_b/T))\right]$	Armenante and Uehara Nagamine[25]
6-Blade flat-blade turbine ($C/T > 1/4$)	$S = \left[1.78(T/D)^{1.16}\exp(1.77(C_b/T))\right]$	Armenante, Uehara Nagamine and Susanto[27]
6-Blade 45°C pitched-blade turbine ($C/T < 1/4$)	$S = \left[2.28(T/D)^{0.83}\exp(0.65(C_b/T))\right]$	Armenante and Uehara Nagamine[25]
Chemineer HE-3 ($C/T < 1/4$)	$S = \left[3.49(T/D)^{0.79}\exp(0.66(C_b/T))\right]$	Armenante and Uehara Nagamine[25]

and cannot be altered by mixing. However, the solids interfacial area available for effective mass transfer with the liquid depends strongly on the solids suspension state. If the solids are accumulated at the vessel bottom their surface will not be fully exposed to the liquid, and most of the liquid in the vessel will not be brought in effective contact with the solids. This is clearly shown in Fig. 9.[7,34–36] Increasing N when $N < N_{js}$ produces a dramatic increase in the mass transfer rate primarily because the particles' exposed area in Eq. (1) increases with N as more particles become fully suspended. Increasing N beyond N_{js} produces only a moderate increase in the mass transfer rate, as the interfacial area, A, now corresponds to the effective solids surface area, and the mass transfer rate increases solely because k_L increases with P (and hence N), as quantified in the next section. This constitutes an additional reason why solid–liquid operations should always be conducted at an agitation speed $\geq N_{js}$.

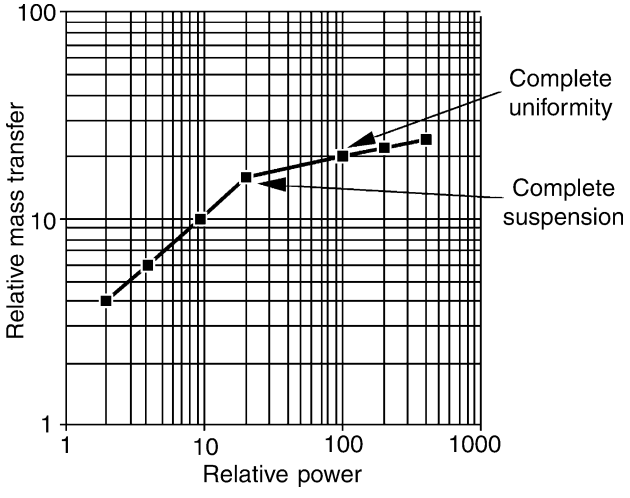

Fig. 9 Relative mass transfer as a function of impeller power. The mass transfer increases sharply up to the point of complete suspension, and at a much lower rate to nearly complete uniformity. (From Ref.[7].)

When $N > N_{js}$, the surface area of the particles, now fully exposed to the liquid, is given by

$$A = a_v V_L = \frac{6\phi}{\psi d_{32pe}} V_L \tag{10}$$

implying that

$$a_v = \frac{6\phi}{\psi d_{32pe}} \tag{11}$$

where ψ is the particle sphericity factor (i.e., the ratio of surface area of a sphere having the same volume as the particle to the surface area of the particle), and d_{32pe} is the Sauter mean equivalent diameter[17]

$$d_{32pe} = \frac{\sum_{i=1}^{i=m} n_i d_{pe\,i}^3}{\sum_{i=1}^{i=m} n_i d_{pe\,i}^2} \tag{12}$$

The equivalent particle diameter, d_{pe} is the diameter of a sphere of equal volume as the particle.

Mass Transfer Coefficient in Solid–Liquid Suspensions

In reactive solid–liquid systems, the process can be dominated by one or more of the following mechanisms: 1) external (extraparticle) mass transfer; 2) internal (intraparticle) mass transfer; or 3) chemical reaction (at the surface, below the surface, or in the liquid). The agitation speed only affects the interfacial area available for mass transfer (if $N < N_{js}$, as described above), and the external mass transfer coefficient

k_L (in all cases). Only processes in which the external mass transfer is partially or completely rate controlling are affected by the agitation speed. Experimentally, this phenomenon can be observed by varying the agitator speed and determining the effect on the overall reaction process rate. If the reaction conversion is affected by N, mass transfer plays a role.

The mass transfer coefficient to a single solid spherical particle immersed in a liquid flowing with velocity v_{SL} past the particle can be calculated from:

$$Sh_{SL} = 2 + 0.6Re_{SL}^{0.5}Sc^{0.33} \tag{13}$$

where the solid–liquid Sherwood number for a single sphere, $Sh_{SL} = k_{SL}(d_p/D_L)$ is a function of the solid–liquid Re, $Re_{SL} = \rho_L \nu_{SL}(d_p/\mu)$.[37] Eq. (13) is of limited use in mixing vessels, where the particle–liquid slip velocity v_{SL} cannot be easily calculated. Instead, the following approach can be used. In any turbulent system, the Kolmogoroff's microscale, λ_K, defines the size of the smallest eddy in the stirred vessel:

$$\lambda_K = \left(\frac{\nu^3}{\varepsilon}\right)^{1/4} \tag{14}$$

Armenante and Kirwan have defined as macroparticles and microparticles solid particles having diameters larger or smaller than λ_K, respectively.[38] Then, the overall particle–liquid mass transfer coefficient for fully suspended macroparticles is given by:[39,40]

$$Sh = 2 + 0.47Re_p^{0.62}Sc^{0.36}(D/T)^{0.17} \quad (\text{for } d_p > \lambda_K) \tag{15}$$

while the following equation applies to microparticles:[38]

$$Sh = 2 + 0.52Re_p^{0.52}Sc^{1/3} \quad (\text{for } d_p < \lambda_K) \tag{16}$$

In these equations, $Sh = k_L d_p/D_L$, and the particle Re for the turbulent system, Re_p, is defined as

$$Re_p = \left(\frac{d_p}{\lambda_K}\right)^{4/3} = \frac{d_p^{4/3}\varepsilon^{1/3}}{\nu} \tag{17}$$

Although Eqs. (15) and (16) were obtained for single-size particles, it is reasonable to assume that they apply to multisized particle dispersions also, in which case d_p should be replaced with d_{32pe}. The effect of agitation on solid–liquid mass transfer can be predicted from these equations. For example, for macroparticles it is:

$$Sh = \frac{k_L d_p}{D_L} \propto Re_p^{0.62} = \left(\frac{d_p^{4/3}\varepsilon^{1/3}}{\nu}\right)^{0.62}$$
$$\Rightarrow k_L \propto \varepsilon^{0.21} = \left(\frac{P}{\rho_L V_L}\right)^{0.21} \propto P^{0.21} \propto N^{0.62} \tag{18}$$

These results show that k_L in solid–liquid systems increases only modestly with power dissipation. For example, a 20% increase in N increases P by 73%, but k_L by only 12%. In conclusion, at agitation speeds below N_{js}, $k_L a_v$ increases significantly with N (as shown in Fig. 9), primarily because the solids' exposed surface area increases with N, as more particles become suspended.[7] Above N_{js}, the value of $a_v = A/V_L$ is constant and k_L increases only modestly with N [Eqs. (15), (16), and (18)]. In many cases, operating slightly above N_{js} is economically optimal.

CONCLUSIONS

Multiphase mixing is a critical element in the analysis of any multiphase reactor system. Multiphase mixing phenomena involving solid–liquid, liquid–liquid, and gas–liquid present not only significant differences, especially in terms of equipment and operation, but also many similarities. Each of these multiphase systems should be analyzed to determine the optimal equipment configuration and operating conditions required to generate an adequate dispersion of the dispersed phase in the continuous phase, a high interfacial area, and a high mass transfer coefficient. Quantitative information of this kind combined with knowledge on the effect of operating variables will result in the ability to predict, estimate, or conduct precisely aimed experiments to determine the rate of multiphase mass transfer for the reactants. Such knowledge will in turn be essential to determine the relative importance of mass transfer vis-à-vis the reaction kinetics in the overall reaction process, thus enabling the designer to predict the behavior of the system, especially during scale-up.

NOMENCLATURE

A	Interfacial area between phases (m^2)
a_v	Interfacial area per unit volume of liquid (m^2/m^3)
B	Baffle width (m)
C	Impeller clearance off the vessel bottom, measured from impeller centerline to vessel bottom (m)

C_b Impeller clearance measured from bottom of the impeller to vessel bottom (m)
ΔC Concentration driving force for mass transfer (mol/m^3)
C_{bulk} Concentration of dissolved component or reactant in bulk liquid (mol/m^3)
$C_{interface}$ Concentration of dissolved component or reactant in liquid at interface between dispersed and continuous phases (mol/m^3)
d_p Particle diameter (m)
d_{pe} Particle equivalent diameter, i.e., diameter of a sphere of equal volume as the particle (m)
d_{32} Sauter mean diameter $= \sum_{i=1}^{i=m} n_i d_i^3 / \sum_{i=1}^{i=m} n_i d_i^2$ (m)
d_{32pe} Sauter mean equivalent diameter $= \sum_{i=1}^{i=m} n_i d_{pe\,i}^3 / \sum_{i=1}^{i=m} n_i d_{pe\,i}^2$ (m)
D Impeller diameter (m)
D_L Diffusivity of dissolved component or reactant in liquid (m^2/sec)
g Gravitational acceleration (m/sec^2)
H Height of liquid in vessel (m)

V_L Volume of liquid in vessel (m^3)
W Width of an impeller blade (m)
X Mass ratio of suspended solids to liquid

Greek Symbols

ε Energy dissipation rate (or power draw) per mass of mixture (W/kg)
ε_{avg} Average energy dissipation rate (or power draw) per mass of mixture (W/kg)
ϕ Volume fraction of dispersed phase, i.e., ratio of volume of dispersed phase total volume of dispersion (–)
λ_K Kolmogoroff microscale of turbulence (m)
ψ Particle sphericity factor, i.e., ratio of surface area of a sphere of same volume as the particle to surface area of particle (–)
μ Viscosity (Pa sec)
ν Kinematic viscosity (m^2/sec)
ρ_L Density of liquid (kg/m^3)
ρ_S Density of solid phase (kg/m^3)
$\bar{\rho}$ Average density of mixture (kg/m^3)

Dimensionless Groups

Fr Impeller Froude number $= N^2 D/g$
Fr_{js} Modified impeller Froude number at N_{js} for solid–liquid suspensions $[\rho_L/(\rho_S - \rho_L)]\, N_{js}^2 D/g$
N_p Power number $= P/(\rho_L N^3 D^5)$
Re Impeller Reynolds number $= \rho N D^2/\mu$
Re_{js} Impeller Reynolds number at N_{js} for solid–liquid suspensions $= N_{js} D^2/\nu$
Re_p Particle Reynolds number in a turbulent system $= \left(d_p^{4/3}\varepsilon^{1/3}\right)\Big/\nu$
Sc Schmidt number $= \mu/(\rho_L D_L)$
Sh Sherwood number $= k_L d_p/D_L$
Sh_{SL} Sherwood number for a single sphere $= k_{SL} d_p/D_L$

Multiphase Reactors

Stanley M. Barnett
University of Rhode Island, Kingston, Rhode Island, U.S.A.

INTRODUCTION

Multiphase reactors are very common in the chemical, petroleum, food, mining, pharmaceutical, and semiconductor industries. They are also prominent in many civilian processes. The production of drinking water can consist of several multiphase reactors and separators, removing soluble salts, organic matter, live organisms, and insoluble material. Our waste treatment systems usually have an activated sludge reactor in which air is forced into the solid–liquid waste stream. In the past, when untreated wastes fouled potential drinking water, people produced beer as a method of purification using a multiphase reactor in a procedure called fermentation.

Antibiotics are produced by a three-phase process: Air is sparged into a vessel or tank to supply oxygen, keep the producing cells suspended in a liquid broth, and mix the contents of the vessel. Coal liquefaction is another three-phase process with hydrogen as the gas phase, coal as the solid phase. Fuel cells, a key component of distributed energy systems, are three- or more-phase reactors depending on the type of fuel cell: solid oxide, molten carbonate, phosphoric acid, or proton exchange membrane. They can be catalytic electrochemical reactors with membranes and multiple solid phases. Genetic engineering requires many multiphase reactor systems. Enzymatic peptide synthesis is a multiphase reaction. Sample applications are summarized in Table 1. With such diversity, this entry will focus on a few key types with some new applications. The reactors can be divided into just a few broad categories. These are column contactors with one phase fixed, fluidized or transported, stirred-tank reactors with at least one phase kept distributed by agitation, film reactors, membrane reactors, and large diameter tank reactors, including open top tanks and ponds. The goals for each reactor design are usually identical, maximize conversion of the reactants and yield of product. Cost minimization, energy efficiency, and conforming to space or weight constraints are additional requirements. In some situations, extra care is needed to avoid contamination of the environment or the product. The differing reactor designs optimize heat and mass transfer, usually limiting factors controlling conversion and yield. For example, by passing or channeling of a reactant must be minimized. Flow patterns can be used to generate sufficient turbulence to ensure intimate contact of a reactant or catalyst. Alternately, agitation might be minimized to ensure that shear sensitive organisms live long enough to produce the desired product(s).

Governing equations are the continuity equation, the chemical reactions and their thermodynamic relationships, and the heat, mass, and momentum equations. Elastic behavior of an expanding bed of particles sometimes must be included. These equations can be many and complex because we are dealing with both multiphase and multicomponent systems. Correlations are often in terms of phase-based dimensionless groups such as Reynolds numbers, Froude numbers, and Weber numbers.

MULTIPHASE BIOREACTORS FOR BIOTECHNOLOGY AND ENVIRONMENTAL APPLICATIONS

Activated Sludge Process

The objective of an activated sludge process is to remove soluble and insoluble organics from municipal or industrial wastewaters and convert the reactants into a microbial suspension. Traditionally, the tank is narrow and long enough to provide 6–8 hr of contact between the fluid and air, usually blown in through diffusers (see Fig. 1A). The narrow flow paths are the first step above a simple pond. On a more sophisticated level, the long, narrow tank with diffusers is replaced by a cylindrical tank with an agitator, designed to beat air into the fluid as well as mix the tank contents (see Fig. 1B). Recycle streams allow for stabilization of the reactor by returning live microorganisms to the process. An important design parameter is power input per unit volume, which controls the aeration efficiency.

For certain industrial applications, a biofilm reactor is preferred. In one type a rotating drum becomes coated with the waste stream as it moves through a tank of the wastes. As the drum surface moves from below the liquid level to above, the attached wet film becomes exposed to air (see Fig. 1C). Alternately, the waste liquid stream can be poured onto a bed of

Table 1 Multiphase reactors: some examples

Reactor types	Applications
Gas–liquid	Absorbers
	Gas phase olefin polymerization
Gas–solid	Fluidized beds
	Trash incinerators
	Catalytic crackers
	Coal gasification
	Reformers
	Ore processing
Liquid–liquid	Enzyme reactions
	Bulk polymerization-casting
	Solution polymerization
Liquid–solid	Ion exchange
	Electrode reactions (including plating)
	Enzyme reactions peptide synthesis
	Liquid phase olefin polymerization
	Cheese making
	High-fructose corn sweeteners
Three-phase:	Hydrogenation
gas–liquid–solid	Fermenters
	Airlift
	Stirred tank
	Enzyme production
	Alcohol
	Fuel cells
	Electrolysis of water
	Trickle bed filters
	Coal liquefaction
	Wastewater treatment
Liquid–liquid–solid	Emulsion polymerization
	Suspension polymerization
	Enzyme reactions
	Detergents
	Proteolysis

particles—stones, crushed glass, or commercial packing to allow intimate contact between the liquid and upflowing air stream. The key is the improved mass transfer of oxygen from the air stream into a thin film of the wastewater because of the turbulence created by liquid falling from one packing particle or tray to another, without the energy input required for the aerator–agitator of the tanks. There can be an environmental problem if volatile organic chemicals are released into the atmosphere, instead of being converted by the treatment system.

Stirred Tank Reactors and Fermenters

The waste treatment systems described above can also be used to grow algae as a protein-rich product found in foods as nutritional supplements. A pond, or shallow tank similar to that in Fig. 1(A), provides the large surface area/volume ratio required for photosynthetic processes.

In the pharmaceutical industry, the reactors are closed to maintain aseptic conditions, and agitation and aeration are provided as needed. The classic example is the Monod chemostat, often found in laboratories. A representative chemostat, fermentation vessel, or bioreactor, is shown in Fig. 2 with an air sparger, agitator, and feed or exit streams. The continuous flow system is usually replaced by a batch process for production in the pharmaceutical and biotechnology industries. The general relationships for a constant volume system are developed in terms of cell concentration (X), often the component of interest, and substrate concentration (S), such as a sugar or oxygen,

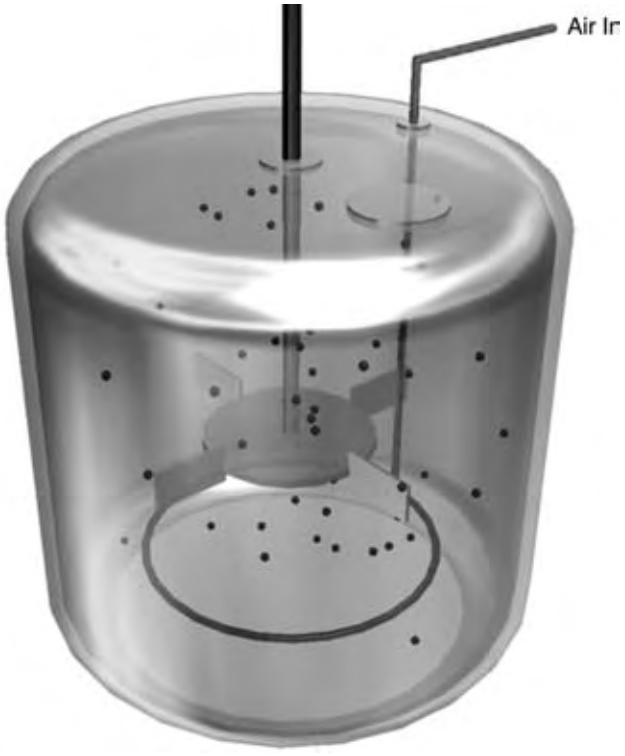

Fig. 2 Stirred tank reactor. *(View this art in color at www.dekker.com.)*

the contributing component.[1] Simple rate equations for cells and substrate are:

$$dX/Xdt = \mu = \mu_{max}S/(K_s + S)$$

and

$$dS/dt = -\mu_{max}SX/Y_{X/S}(K_s + S)$$

Here, μ is the specific growth rate, K_s the Monod coefficient, and $Y_{X/S}$ the yield of cells per unit of substrate. After the integration and use of initial substrate (S_0) and cell (X_0) concentrations the following results were obtained:

$$(X_0 + Y_{X/S}(S_0 + K_s))\ln[(X_0 + Y_{X/S}(S_0 - S))/X_0] - K_sY_{X/S}\ln(S/S_0) = \mu_{max}(X_0 + Y_{X/S}S_0)t$$

These equations can be easily adjusted to reaction conditions, for example, replacing S with light intensity for photosynthetic reactions.[2] A hybrid reactor, consisting of suspended biomass, as above, plus particles coated with biofilm, can be evaluated by segregating the two systems for separate analysis and then adding the two contributions.

S, substrate or reactant concentration, is often controlled by factors such as agitation. Mass transfer of a reactant such as oxygen is correlated with power input per unit volume. Power input to a multiphase stirred vessel is complex. Most commonly used correlations in the literature are valid over a narrow range of conditions. Power must be total power, which includes mechanical power input plus that from bubble expansion or other multiphase issues. The total power number correlates well over a broad operating region with impeller liquid pumping and gas Froude numbers plus various geometric ratios, each to the 0.25 power.[3]

Stirred tank reactors are also common in the chemical and plastics industry. Multiphase processes include emulsion and suspension polymerization plus bulk polymerization of high-impact polystyrene.

Oscillatory Flow Reactors

These are tubular reactors with intensified mixing due to built-in eddy creating and shedding devices. These devices might be baffles coupled with positive displacement devices capable of creating oscillatory flow patterns. Both macro- and micromixing are enhanced, although Reynolds numbers are typically about 50. Because mixing control can be independently achieved by means of amplitude and frequency of oscillation, the mixing effect is decoupled from the flow rate.[4,5] This reactor is an active area of research.

Membrane Reactors

Nano- and ultrafiltration membranes will retain biological catalysts, such as enzymes, which are in the 10,000–100,00 molecular weight range. Larger particles, such as whole cells, can be retained by microfilters. Membrane materials can be in the form of flat sheets as in a filter press type operation or in the spiral wound format. They can also be formed as tubes for a shell and tube arrangement. Or they can be set up as rotating cylinders. The feed stream usually flows tangentially across the surface, helping to minimize cake buildup on the membrane surface. The permeate exits perpendicular to the membrane surface. Membrane pore size or molecular weight cutoff is chosen on the basis of whether we want the substrate and product to be retained or passed through the membrane. Membranes can also be hydrophilic or hydrophobic.

An example is the production of glycerol and fatty acids from plant oils, such as olive oil, catalyzed by the enzyme lipase. The oil flows on the feed side, exiting with the fatty acid product in the concentrate stream shown to the right of the membrane in Fig. 3.

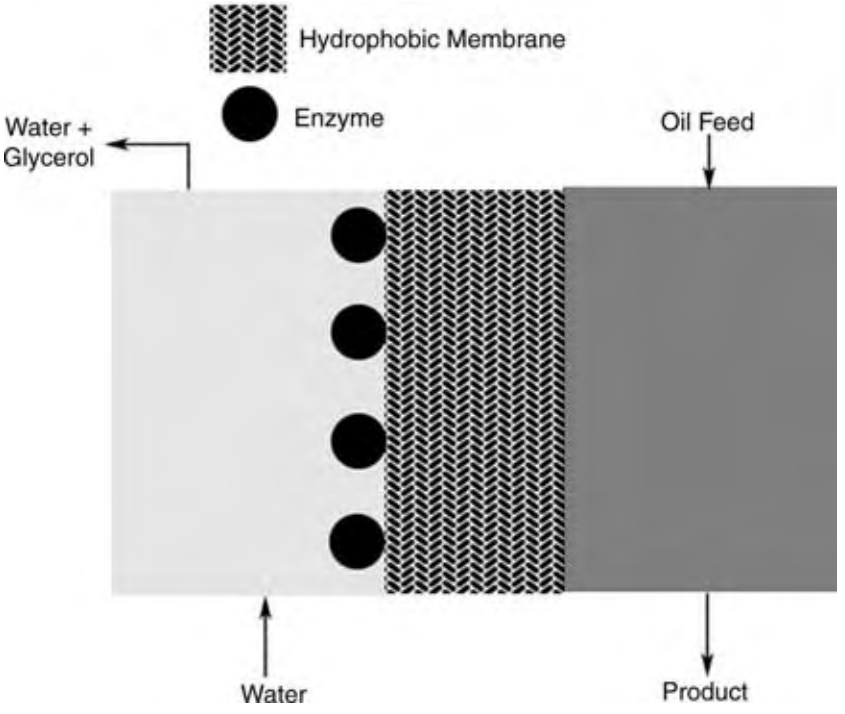

Fig. 3 Multiphase membrane reactor.

The lipase, shown as black circles in Fig. 3, can be attached to the hydrophobic membrane or allowed to wet the membrane surface, taking advantage of the surface-active properties of the enzymes. The hydrophobic oil can also wet the membrane pores and contact the lipase. The glycerol produced by the reaction is water-soluble and moves into the aqueous permeate stream on the left side of the membrane. The undissociated acid returns to the oil stream.[6]

MULTIPHASE REACTORS IN THE ENERGY AND CHEMICAL INDUSTRIES

Packed Bed Reactors

The standard, when one considers multiphase reactors, has become more complex over the years. Most can be classified as reactions over heterogenous catalysts. The catalytic activity occurs in one phase, the solid phase, while transport of the reactants occurs in a gas or liquid phase, or both. A common example is the catalytic converter for automobile exhaust gas. The key steps for a packed bed reactor are:

1. Bulk movement of reactants to the catalyst particle.
2. Mass transfer from the gas or liquid phase to the surface of the catalyst.
3. Diffusion of the reactants from the catalyst surface to the internal pore surface.
4. Adsorption of key molecules onto the catalyst site.
5. Reaction proceeds.
6. Desorption of product from the catalyst site.
7. Pore diffusion to the outer surface of the particle.
8. Interphase transport into the liquid and gaseous phases.

Equations can be written for each step, but it is easier to determine the rate controlling step(s) and focus on just that section of a complex process. In Fig. 4, the cartoon on the right provides a view of the reactant entering and product leaving a catalyst particle.

For industrial reactors, the effectiveness factor (η) is used to provide a measure of the actual reaction rate, as affected by operating conditions, in comparison to the intrinsic reaction kinetics.[7] Assuming that the trickle bed reactor shown in Fig. 4 is operated so that interphase transport of one of the reactants, steps 2 or 8 above, is controlling,

$$\eta = \frac{k_l a \tanh\left(L\sqrt{k/D_a}\right)}{k_l a L\sqrt{k/D_a} + k \tanh\left(L\sqrt{k/D_a}\right)}$$

The rate for this first-order reaction is $-\eta k c_a$, where, k is the reaction rate constant, c_a the concentration of the limiting reactant, L the pore length, k_l the mass

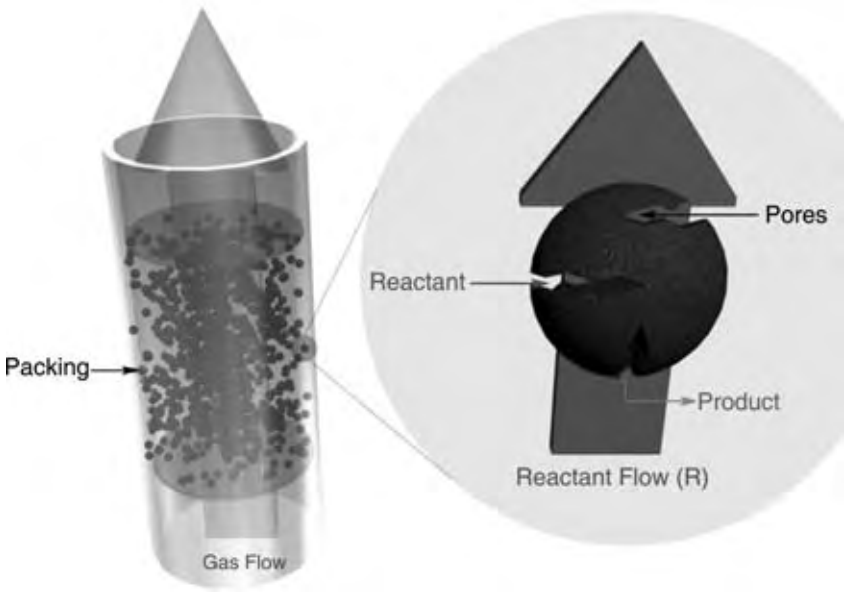

Fig. 4 Packed bed reactor regions. *(View this art in color at www.dekker.com.)*

transfer coefficient, a the specific surface area, and D_a the diffusivity of the limiting substance.

This rate can be added to the global rate equation. Here, ε is the porosity and u_s the superficial velocity.

$$u_s \frac{\partial c_a}{\partial z} = D_a \left(\frac{1}{r} \frac{\partial c_a}{\partial r} + \frac{\partial^2 c_a}{\partial r^2} \right) + \varepsilon \eta c_a$$

A related energy–balance relationship will provide temperature profiles.

Pressure drop is determined using the Ergun equation:

$$\frac{-\Delta P}{L} + \rho_f g = \frac{E_1 \mu_f (1 - \varepsilon)^2 U}{D_p^2 \varepsilon^3} + \frac{E_2 \rho_f (1 - \varepsilon) U^2}{D_p \varepsilon^3}$$

The Es are constants best determined by experiment, ε porosity, ρ_f fluid density, U superficial velocity, and D_p particle diameter.[8]

Two-phase flow through a packed bed, gas–solid flow, for example, requires modification of the Ergun equation. The change includes accounting for mixture density and viscosity. Particle-bed interaction factors must also be considered.[9]

Reforming

To provide hydrogen for fuel cells, various fuels can be used as a feedstock. Currently, methane is the source of choice for hydrogen. Fuel cells are accompanied by a reactor called a reformer, in which the methane is reacted with steam over a supported nickel catalyst at temperatures above 500°C. This is a gas–solid packed bed type reactor.

Hydrocarbon Hydrocracking

A hydrocracker is a three-phase operation. The gas phase supplies hydrogen, the liquid phase supplies the heavy hydrocarbons, and the catalyst is the solid phase. This unit can be operated as a trickle bed reactor, with gas and liquid phases fed in at the top. Products, removed from the bottom, are in both the gas and the liquid phases. The key steps and analysis are similar to the packed bed reactor above. Pressure drop and holdup can be determined from the Ergun equation and gas and liquid phase Reynolds numbers. Relationships for transitions to pulsating and other flows can also be developed.[8]

A hydrocracker can also be run with both liquid and gas fed from the bottom and the solids kept in suspension by drag forces of the fluids. This reactor is a fluidized bed reactor explained below.

Coal Liquefaction

A related reactor is that for coal liquefaction, which can be carried out in a three-phase slurry bubble column (see Fig. 5). Hydrogen can be supplied at the bottom of a column of downcoming product—oil. The solid coal reactant is blended with the product or carrier oil and fed at the top. The generic process depicted in Fig. 5 is a generalization of the liquefaction reactor in the Exxon Donor Solvent Process. As the gas flow rate increases, the bubbles change from uniformly small to chaotic. In the H–coal process, both the gas and a coal–oil slurry are fed from the bottom in an ebullating-bed reactor. Catalyst solids are fed from the top. This reactor operates as an expanded

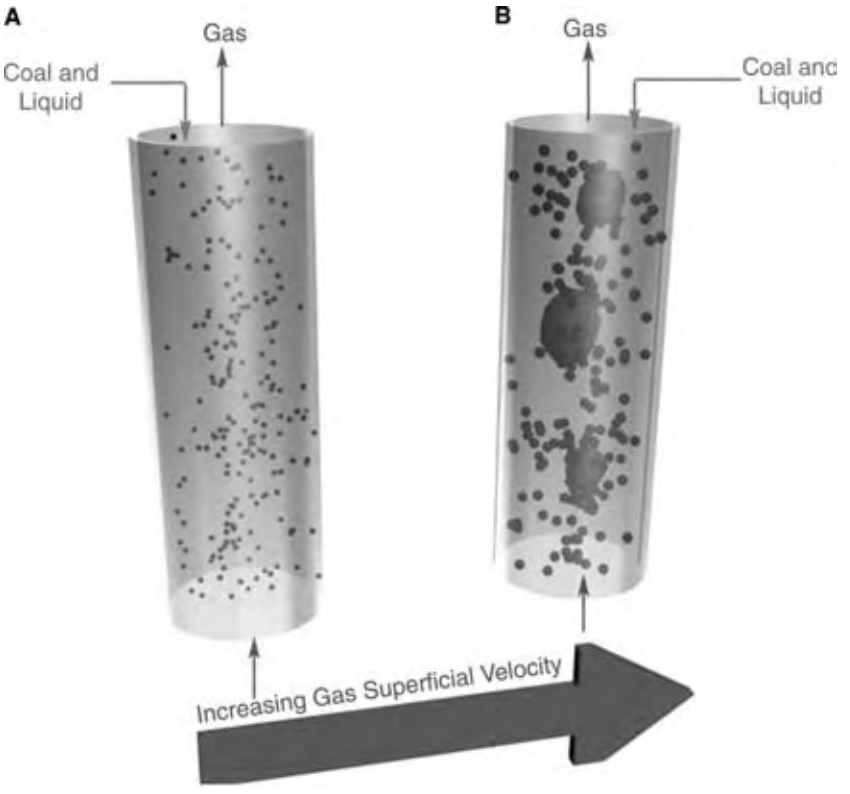

Fig. 5 Coal liquefaction column. *(View this art in color at www.dekker.com.)*

bed type fluidized bed reactor. The products of these reactors are further processed using other multiphase reactors. The solvent-refined coal process (SRC) is related.[10] Coal gasification, Fisher–Tropsch syntheses, and methods of impurity removal, such as desulfurization, are also in three-phase columns.

Understanding three-phase flow dynamics is necessary for design of these reactors. A major aid is the classification scheme of Fan, depending on stream direction and degree of fluidization, expanded bed or transported bed. For example, a continuous liquid phase reactor, with gas and liquid inlets at the bottom and solids at the bottom, is classified as Mode E-I-a-1 if it operates as an expanded bed and Mode T-I-a-1 if all phases are flowing together, called transport.

Slurry bubble columns, with liquid and solid countercurrent to the gas stream, Mode E-1-a-2 or liquid batch Mode E-111-a, demonstrate three flow patterns: the homogenous bubble regime (see Fig. 5A), the larger coalesced bubble or churn flow regime (Fig. 5B), and the huge bubble or slugging regime. Gas bubble size depends on gas and liquid velocities and holdups. Predicting gas holdup is a complex function of flow velocities, solids loading, and Newtonian or non-Newtonian fluid behavior.[11,12]

For gas holdup, bypassing and the effect of solids loading are important issues. Gas holdup increases with solids loading at low solids level, peaks and then decreases with solids content. Gas holdup also increases with superficial gas velocity. Liquid holdup is a function of superficial flow rate and solid particle size. Important dimensionless groups are the liquid and gas Froude numbers, the liquid Reynolds number, and the Weber number. The transitions from channel flow to slugging flow, or to plug flow or homogenous distribution flow are needed design factors.[13]

Dispersed phase holdups, usually gas and solids, have traditionally been determined by differential pressure tranducers, conductivity measurements, photography, particle counters, and volume changes. Ultrasonic techniques have also been used.[14] Liquid flow is complex, with up and down patterns. Local liquid velocities tend to be higher than predicted by energy balances. Circulation cells occur, increasing residence time distributions. Solids suspension depends on passing a critical fluid velocity, about two to four times the particle terminal velocity. Solids loading and equipment design are important variables.[10,15]

Three-Phase Air Lift Reactors

This annular reactor operates with bubbles of gas causing the liquid phase to rise in the central section of the reactor (see Fig. 6). As the gas leaves in the separator or reversal zone at the top of the center column, the heavier liquid falls in the annular downcomer, and is lifted again in the bottom flow-reversing

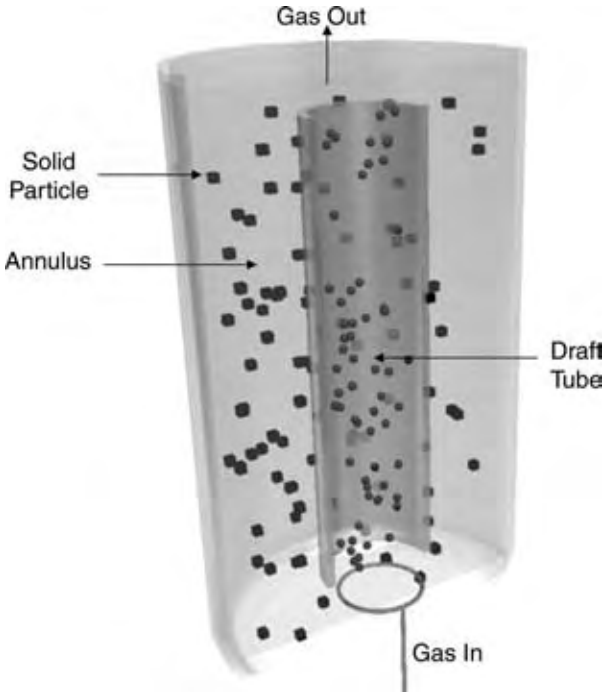

Fig. 6 Annular reactor. *(View this art in color at www.dekker.com.)*

zone by the gas distribution system. The solids circulate with the liquid. This reactor and variations are also used as fermenters, for immobilized cell reactors and for catalytic hydrogenation. Modeling is accomplished by separately evaluating the riser, downcomer, and two transition zones and then combining the modules.[16] This type of reactor has also been used with microbubbles to gain interfacial area.

Fluidized Beds

Instead of a fixed bed reactor, the solid particles, catalyst or reactant, can be moving or fluidized. Normally, the entire solid particle bed is lifted by the upflowing gas stream (see Fig. 7). The minimum superficial fluidizing velocity (U_{mf}), considered a property of the solid particles, can be estimated from:

$$U_{mf} = 0.0009(g\Delta\rho)^{0.934} d_w^{1.8}/\mu^{0.87}\rho_f 0.006$$

Here, g is the gravitational acceleration, ρ_f the density of the gas, ρ_s the density of a particle, $\Delta\rho = \rho_s - \rho_f$, and μ is the gas viscosity. The d_w is calculated as an inverse weighted average from a sieve analysis. Entrainment increases with gas velocity and viscosity, vessel diameter, and particle attrition. It decreases with increasing freeboard height and particle density.[17] Pressure drop is nearly constant across the fluidization region. Clusters of particles can be a problem, but an issue appears to be defining a cluster, by size or effect on reactor hydrodynamics and erosion.[18]

Once U_{mf} is reached, various operating regions are encountered. At first, the bed expands, and then a bubbling/slugging region ensues. The desired turbulent region follows and as gas velocity increases beyond the particle terminal settling velocity, a circulating bed is feasible. At a still higher gas velocity, the solids can be conveyed.[19]

High temperatures have been found to effect particle–particle interaction, beyond the changes in fluid properties such as density and viscosity. Particle classification can change.[20]

Applications include coal and trash combustion, coal and biomass gasification, and chemical, including polymer, synthesis. Both particles and the fluidizing gas stream change properties during the process. Coal is converted to ash, carbon dioxide, and carbon monoxide. The coal particle can also become fragmented. Coal and steam can yield hydrogen and carbon monoxide.

In a spouted bed version of a fluidized reactor, gas enters from a nozzle located at the bottom of the reactor, solids flow in from the sides, or annulus, and are carried up again forming a spout. At the top of the spout, the solids move to the annulus and return to the bottom of the spout.

Using a hybrid arrangement, a fermentation vessel can also be based on fluidized bed technology. The solid phase consists of particles surrounded by an organism-rich biofilm. It is kept in suspension by a flowing liquid medium saturated with air or, both the gas and liquid enter the bottom of the column as separate streams and both help suspend the solids.[21]

Fuel Cells

A growing application of multiphase reactors is for fuel cells. There are many types but they have certain characteristics in common. The basic construction of the fuel cell, as shown in Fig. 8, is that of cathode–electrolyte–anode connected to a load, such as an electric motor. Oxygen is fed to the cathode and hydrogen to the anode. The electrode structure is porous so that gas can enter from one side and the electrolyte from the other. In an acid electrolyte, as in the phosphoric acid fuel cell, the hydrogen ionizes, releasing electrons. The hydrogen ions move across the electrolyte from anode to cathode. At the cathode, they react with oxygen to form water. In an alkaline electrolyte, as is found in the potassium hydroxide fuel cell, the oxygen at the cathode reacts with water in the electrolyte and electrons returning from the load circuit, to form hydroxyl ions. In this situation, it is

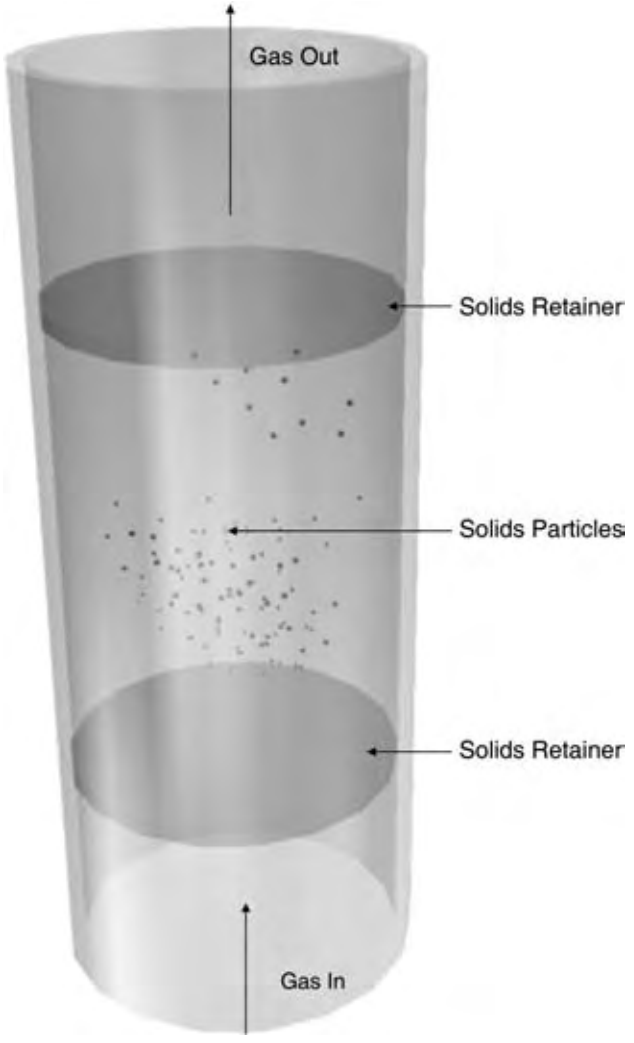

Fig. 7 Fluidized bed reactor. *(View this art in color at www.dekker.com.)*

the hydroxyl ions that move across the electrolyte to the anode to react with hydrogen to form water and release electrons to drive the load. For both types of cells, the anodes and cathodes are usually carbon with a dispersed platinum catalyst. The fuel cell is thus a gas, liquid, multisolid reactor producing energy. Key variables used to compare systems are power density (power produced/unit volume) and specific power (power/mass). To replace the internal combustion engine in automobiles, the goal for power density is bettering 1 kW/L.

For transportation applications, such as automobiles and buses, the liquid electrolyte is replaced with a solid electrolyte-polytetrafluoroethylene containing pendent sulfonated fluoroethylene groups. Water is absorbed onto the sulfonated side chains, hydrogen ions are weakly attracted and are able to move from site to site, creating a weak acid. With an electrode structure consisting of a carbon-supported platinum catalyst, the result is a gas–solid–solid–solid–solid system that can operate at no more than 80°C.

A high-temperature fuel cell capable of operating in the 800–1100°C range, is the solid oxide fuel cell. The high temperatures allow for increased energy efficiencies due to easily recoverable heat. The electrolyte is zirconia doped with small amounts of yttria and other components. The anode can be a zirconia cermet, the metal is nickel. Instead of hydroxyl ions moving from cathode to anode as above, oxygen ions are transported across the electrolyte moving from one vacant oxygen site to another across the crystal structure. This cell is another example of a gas–multisolid phase system.[22]

Hydrogen by Electrolysis

One source of hydrogen for the hydrogen economy is electrolysis of water. Hydrogen is evolved at the cathode. Focusing on the hydrogen generating region, the cathode and the electrolyte between the membrane separator and cathode, the cathode reaction that can occur is:[23]

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^-$$

The key equations are the conservation and momentum equations with a buoyancy term and an added term for interphase friction (F). The latter is given by:

$$F = 0.75 C_d \rho_L \alpha_L \alpha_g |u_L - u_G| d_b$$

C_d, the drag coefficient, is a function of the Reynolds number (Re) and the Weber number (We), both based on the bubble diameter (d_b) and slip velocity ($|u_L - u_G|$).[24,25] An equation can be added for transport across the gas–liquid interface. Ionic species diffusion must be accounted for by the Nernst equation with the current density from Faraday's law, equations for conservation of current and ionic species, and the diffusivities modified by the gas fraction. Solving for all equations with appropriate boundary conditions indicates electrolyte velocity to be the controlling variable for hydrogen production.[23]

Microfluidic Channel Reactors

Recently, researchers have been carrying out multiphase reactions in nanometer to micrometer sized channels in terms of diameter or height and width. In one example, hydrogenation of a liquid flowing over a solid catalyst immobilized on the wall is carried out

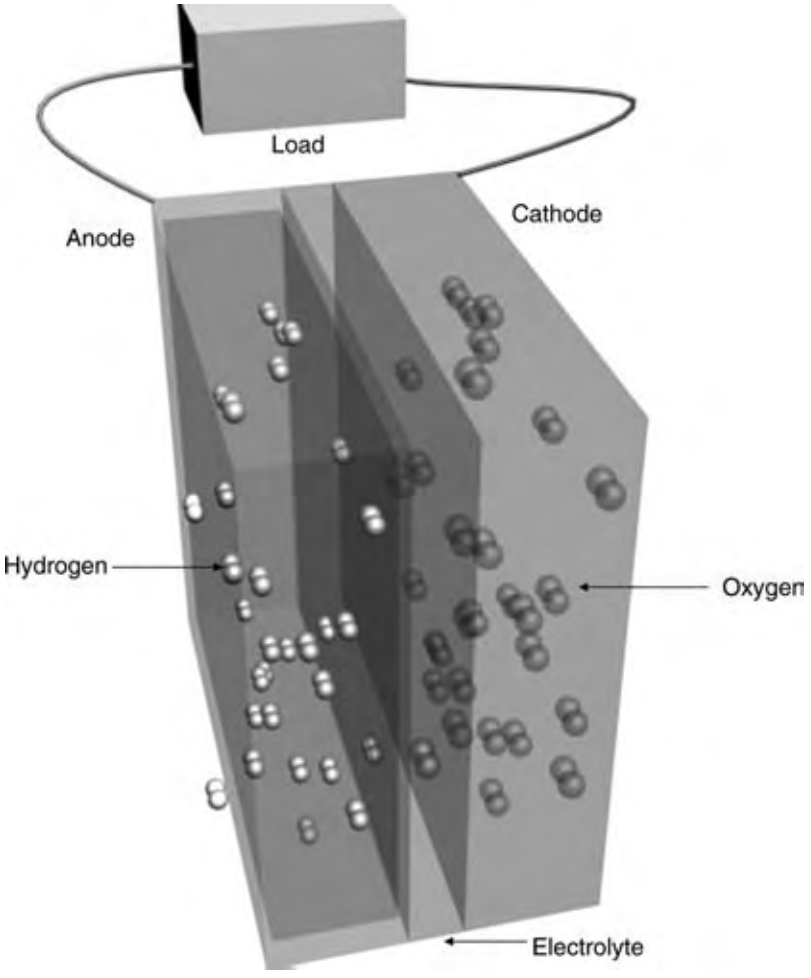

Fig. 8 Fuel cell. *(View this art in color at www.dekker.com.)*

by gaseous hydrogen flowing through the channel. The specific surface area (a) used to calculate the effectiveness factor for the packed bed reactor above is 100 times or more greater for a microreactor than for conventional reactors because of the large number of microchannels that can be placed in a given volume.[26] Wall effects, normally neglected in reactor flow calculations, must be considered in calculations for nanometer range channels. Current practical applications are focused on analysis: the lab-on-a-chip. The oscillatory flow reactor introduced above can utilize these narrow channels.

An application of microfluidic reactors is the development of a membraneless fuel cell. Two streams, one containing a fuel such as methanol, the other an oxygen-saturated acid or alkaline stream, are merged without mixing. The laminar flow pattern in the narrow channel helps to maintain separate streams without the use of membrane separators. Opposite walls function as the electrodes and are doped with catalyst. Ion exchange, protons for the acid system, takes place through the liquid–liquid interface. This is an example of a solid–liquid–liquid–solid multiphase reactor.[27]

CONCLUSIONS

Multiphase reactor types are highly varied. The simplest approach to analyzing and predicting their behavior is to focus on the rate limiting steps or segment the reactor and model each segment and its contributions separately. Correlations are invariably a function of phase-based Reynolds and Froude numbers. Fractional volumes and properties of the solids are factors. Where interfacial tension is an important factor, the Weber number can be added.

Because of energy, sustainability, and security issues, multiphase reactors will have an ever-increasing role in all the countries. Considerable effort is needed to better predict the very complex phenomena occurring in the many types of multiphase reactors.

Nanoimprint Technology and Its Applications

L. Jay Guo
Department of Electrical Engineering and Computer Science, The University of Michigan, Ann Arbor, Michigan, U.S.A.

INTRODUCTION

Nanoimprint is an emerging lithographic technology that promises high-throughput patterning of nanostructures. Based on the mechanical embossing principle, nanoimprint technique can achieve pattern resolutions beyond the limitations set by the light diffractions or beam scatterings that exist in other conventional techniques. The basic principles of nanoimprint and some of the recent progress in this field are reviewed in this entry. Nanoimprint not only can create resist patterns as in lithography, but can also imprint functional device structures in polymers. This property can be exploited in several potential applications in the area of electronics, photonics, microelectrical-mechanical system (MEMS)/BioMEMS, and biotechnology.

PRINCIPLES OF NANOIMPRINT

The ability to replicate patterns from micro- to nanoscale is of importance to the advance of micro- and nanotechnologies and the study of nanosciences. Critical issues that need to be considered in developing new lithography methodologies include resolution, reliability, speed, and overlay accuracy. Considerable industrial effort has been devoted to the leading-edge UV optical lithography, and the so-called next generation lithography (NGL) techniques by exposing resist material with energetic beams from Extreme UV, electron-beam, ion-beam, or x-ray sources. But a lot of issues are yet to be solved in deep ultra-violet (DUV) photolithography and various NGL methods, and the high costs of such equipments are prohibitive for many users.

In recent years, researchers have investigated a number of alternative and potentially low-cost techniques; most notably, microcontact printing (μCP), nanoimprint, atomic force microscope (AFM) lithography, and dip-pen lithography. Since mid-1990s, nanoimprint lithography (NIL)[1,2] has emerged as one of the most promising technologies for high-throughput nanoscale patterning. In this method and its successful variants such as the step-and-flash imprint lithography (S-FIL), pattern replication is done nontraditionally by mechanical deforming of the resist materials, which completely free itself from the resolution-limiting factors such as light diffraction and beam scattering that are often inherent with the more traditional approaches. Investigations by several researchers in the sub-50 nm regime indicate that imprint lithography resolution is only limited by the resolution of the mold or template fabrication process.

Imprinting-based lithography also presents many new challenges to researchers. Many critical issues need to be addressed for the further progress of this technology, such as its limitations in handling complex patterns with varied feature density, patterning over topographies, and pattern alignment, and defect and critical dimension (CD) control, to name an important few. There is also great demand in new material systems with properties more suitable for the imprint application, where off-the-shelf commercial polymers have become inadequate to satisfy the special requirement in nanoimprinting. In addition, new techniques are needed for many nontraditional microelectronics applications. The basic principle and component requirements for nanoimprinting and some of the recent development in the area of imprint technology and its various applications are reviewed in this entry. The readers are also referred to a recent book, *Alternative Lithography*,[3] which includes chapters dedicated to the discussion of various aspects of nanoimprint lithography written by several experts in the fields.

The principle of nanoimprint is quite simple. As shown in Fig. 1A, NIL uses a hard mold that contains nanoscale features defined on its surface to emboss into polymer material cast on the wafer substrate under controlled temperature and pressure, thereby creating thickness contrast in the polymer material, which can be further transferred through the resist layer via an O_2 plasma-based anisotropic etching process. Nanoimprint has the capability of patterning sub-10 nm features,[4] yet only entails simple equipment setup and easy processing. This is the key reason that NIL attracted wide attention within only a few years after its inception.

Most of the device fabrications require several lithography steps and precise overlay. A derivative of imprint lithography, S-FIL, provides an effective solution to address registration issues. It uses a transparent fused silica template, facilitating the viewing of alignment marks on the template and wafer simultaneously.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120027069

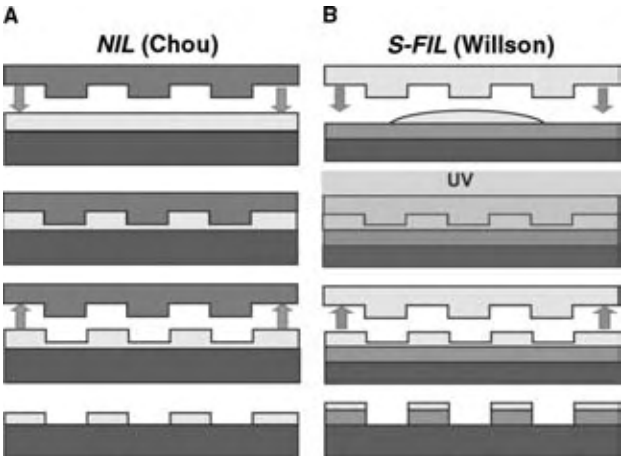

Fig. 1 Schematic of (A) nanoimprint lithography and (B) step-and-flash imprint lithography. *(View this art in color at www.dekker.com.)*

In addition, the imprint process is performed at low pressure and room temperature, minimizing magnification and distortion errors. In the S-FIL process, as illustrated in Fig. 1B, the substrate is first coated with an organic transfer layer; then a surface-treated, transparent template with surface relief patterns is brought close and aligned to the coated substrate. Once in proximity, a drop of low viscosity, photopolymerizable organosilicon solution is introduced into the gap between the template and the substrate. The organosilicon fluid spreads out and fills the gap by capillary action. Next the template is pressed against the substrate to close the gap, and the assembly is irradiated with UV light, which cures the photopolymer to make it a solidified and silicon-rich replica of the template. Significant efforts from both academia and industry have been put in S-FIL research and development,[5] template fabrication methods,[6,7] and defect analysis.[7,8] Because of its ability to pattern at room temperature and at low pressure, the template can be stepped to pattern the whole wafer area similar to that of a stepper lithography tool. These imprinting-based lithography technologies, especially S-FIL, are entering the competition of NGL methodologies for future semiconductor IC manufacturing, and are emerging as strong contenders. Recently the International Technology Roadmap for Semiconductors (ITRS) also announced the inclusion of NIL onto their roadmap as a candidate technology to begin production in 2013.

NANOIMPRINT MOLD

Material Selection and Mold Fabrication

Mold in nanoimprint technique plays the same role as photomask in photolithography. Both NIL and S-FIL utilize hard molds to replicate patterns, which distinguish themselves from the widely studied μCP technique that uses soft and flexible poly(dimethylsiloxane) (PDMS) stamp. The hard features on NIL molds and S-FIL templates can allow imprinting of features in polymer materials with resolutions below 10 nm, which is not possible to achieve by μCP using soft stamp. Hard molds have mostly been made in Si or SiO_2 for nanoimprint, while it is also possible to use metal as the mold material.

Considerations for selecting mold materials include hardness, compatibility with traditional microfabrication processing, and thermal expansion coefficient, to name an important few. Li has examined the relative hardness of various materials suitable for imprinting mold, including Si, SiO_2, SiC, silicon nitride, and sapphire. Taniguchi et al.[9,10] have investigated diamond as a potential mold material for NIL. On the other hand, works from many groups have shown that Si and SiO_2 have sufficient hardness and durability for the nanoimprint application. Thermal expansion coefficient is especially important in thermal NIL where a temperature over 100°C is typically required in the imprinting step. Thermal mismatch between the mold and the substrate could result in pattern distortions or stress build-up during the cooling cycle, which would affect the pattern fidelity. In this regard, Si mold and Si substrate make a very good pair for the NIL process.

Nanoscale protrusion features on the mold or template are typically fabricated by a combination of electron-beam lithography (EBL) and anisotropic reactive ion etching (RIE). When silica or glass wafer is used as the substrate, especially for S-FIL template, special considerations are required to eliminate or minimize the electron charging effect because of the insulator nature of the substrate. Two effective methods have been developed to fabricate S-FIL templates on standard photomask plate.[6,7] The first method uses a very thin (15 nm) layer of Cr as a hard mask, on top of which electron beam resist is coated and patterned by direct EBL writing. The thin Cr layer suppresses charging during electron-beam exposure of the template and minimizes the CD losses during the pattern transfer through the Cr by wet etching. Because the high etch selectivity of glass to Cr in a fluorine-based RIE process, a sub-20 nm Cr layer is also sufficient as a hard mask during the etching of the glass substrate. The second scheme incorporates a conductive and transparent layer of indium tin oxide (ITO) on the glass substrate, and charging is suppressed not only during EBL process of making the template, but also during final inspection stage, which greatly facilitates the template manufacturing.

Low Surface Energy Coating on Mold

One would normally imagine that the nanoscale protrusion features on the mold are a weak point in NIL.

But this is usually not the case. The reason is that in imprint lithography, mold durability is maintained by choosing the proper polymer resist layer thickness such that the mold protrusion will not contact the hard substrate directly. In other words, a thin viscous polymer fluid exists between the mold protrusions and the substrate surface and acts as a ''soft cushion,'' which effectively protects the nanofeatures on the mold. The trade-off of this is the existence of a residual resist layer that is present in the recessed regions, which has to be removed by a separate plasma etching step before pattern definition can be completed.

Mold used for imprint lithography typically has high density of nanoscale protrusion features on its surface, which effectively increases the total surface area that contacts the imprinted polymer, and therefore leading to a strong tendency of adhesion of imprinted polymer to the mold. This effect can be easily seen by the sticking of resist material on a mold without any special treatment. The solution to this problem is to apply a low surface tension coating to the mold to reduce its surface energy. This can be done by plasma deposition of fluoropolymers or by using a monolayer of perfluorosilane surfactant molecules. The latter technique is the most widely adopted method. Surfactant molecules, such as 1H,1H,2H,2H-perfluorodecyl-trichlorosilane (FDTS), can be deposited on mold surface either by liquid phase or by vapor phase through a silanization process (Fig. 2). Silanization of oxidized silicon with an $RSiCl_3$ precursor begins with the hydrolysis of the polar headgroup, which converts the Si–Cl bonds to Si–OH (silanol) groups. The generated silanol groups, which are strongly attracted to the hydrophilic surface of oxided silicon, condense and react with the hydroxyl group on the surface as well as with other monomer silanol groups to form networks of covalent siloxane bonds, Si–O–Si. Such covalent bonding makes the surfactant coating layer chemically and thermally stable. Vapor phase coating has shown to provide better imprint results for nanoscale features, because it avoids the difficulty of liquid wetting of the nanoscale trench features on the mold.[11]

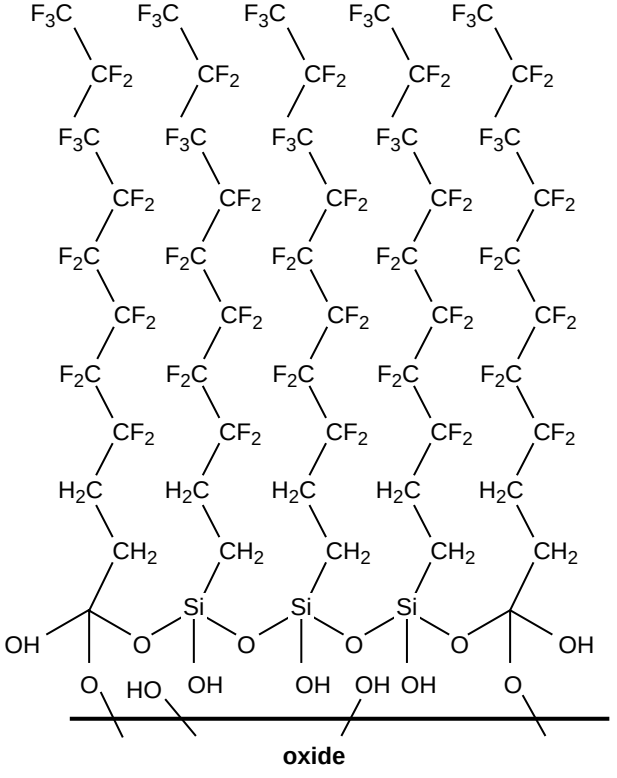

Fig. 2 Formation of a monolayer of FDTS molecules on SiO_2 to create a low-energy surface.

A more important issue in terms of mold durability is actually related to the wearing and stability of this surfactant coating layer. This could be a critical issue for the acceptance of imprint-based technology in industrial applications. A good coating could allow hundreds to thousands of imprints before it loses its effectiveness. We should point out that the durability issue of the surface coating on molds could be alleviated if the mold itself is made of a material that has low surface energy. For example, it has been demonstrated that amorphous fluoropolymers, such as Teflon AF ($T_g = 240°C$), can be used as an imprinting mold without any surface treatment. Mold fabrication can also be simplified by casting of the fluoropolymer solutions over a prefabricated template and drying off the solvent[12] or by direct molding or imprinting of this fluoropolymer at 350°C under a high pressure. A flexible film mold can be obtained using these methods, which can provide better conformal contact with the substrate to be patterned and reduce the pressure needed during the imprinting step.

NANOIMPRINT RESIST

Requirement for Nanoimprint

Because imprint lithography makes a conformal replica of the surface relief patterns by mechanical embossing, the resist materials used in imprinting should be deformable easily under an applied pressure. Step-and-flash imprint lithography uses a very effective solution by utilizing a liquid resist that can be cured and solidified by UV exposure. The viscosity of the initial monomer liquid is chosen to be lower than 4 cps to allow a very low-pressure printing. In NIL, typically a thermal plastic material is used as imprint resist, and a suitable imprint temperature is chosen to be 70–80°C above the material's glass transition temperature (T_g). This choice can be explained by considering the typical deformation behavior of thermal plastic polymer as a function of the temperature (Fig. 3). At a temperature

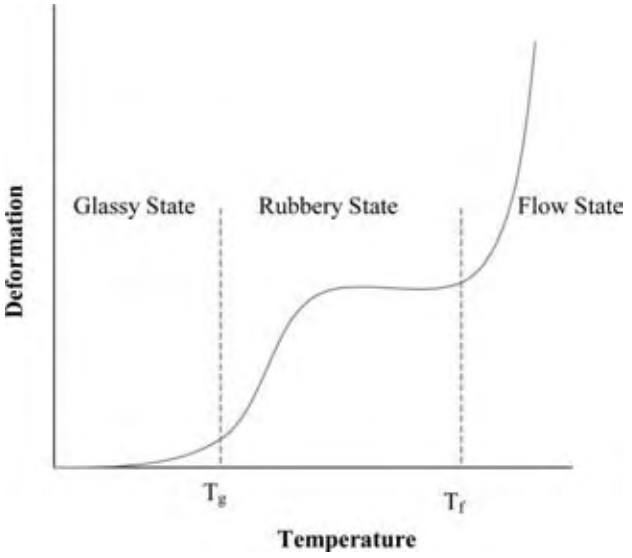

Fig. 3 Typical deformation behavior of thermal plastic polymers as a function of temperature. *(View this art in color at www.dekker.com.)*

below T_g, the major contribution to the deformation comes from the elongation of the atomic distance, and the deformation is ideal elastic. The Young's modulus for glassy polymers just below T_g is approximately constant over a wide range of polymers (3×10^9 Pa) and the magnitude of deformation is very small. Above T_g, the local motions of chain segments take place, and the modulus of the material drops by several orders of magnitude. However, the entire chains are still fixed by the temporary network of entanglements. A rubber–elastic plateau region exists beyond T_g, where relative large deformation may occur because of extension of chain segments fixed between entanglement points. The modulus stays relatively the same in the rubbery state and the deformation will recover after the release of force. Next is the rubbery flow region for linear amorphous polymers; but it does not occur for crosslinked polymers. Finally, with further increase in temperature, viscous liquid flow state is reached. In this regime the motion of entire chains takes place and the polymer flows by chain sliding. The modulus and viscosity are further reduced in this region and the deformation is irreversible, which makes it the right temperature range for NIL patterning. It is perceived that a good imprinting result can be acquired when imprinting temperature is set to be higher than the flow temperature (T_f) of the polymer. Empirically the optimal imprinting temperature is found 70–80°C above the T_g of the material used. In this temperature range, the viscosity of the polymer can be described by the following equation by Williams, Landel, and Ferry:

$$\log \eta(T) = \log \eta(T_g) - \frac{C_1(T - T_g)}{C_2 + (T - T_g)} \quad (1)$$

where the values for C_1 and C_2 are 17.44 and 51.6, respectively. This equation describes the effect of temperature on viscosity for a large number of polymers. Because T_g is the onset temperature for molecular motion in polymers, factors that increase the energy required for molecular motion also increase T_g; those that decrease the energy requirement lower T_g. These considerations can be exploited in choosing the desired T_g for the imprint resist. Therefore factors such as intermolecular forces, intrachain steric hindrance (e.g., branching or crosslinking) and bulky and stiff side groups can be used to increase T_g. While flexible bonds and flexible side groups can decrease T_g.

Often, it is desirable to do patterning at lower temperature for higher throughput and reducing the thermal expansion mismatch. From the above analysis, one can use materials that have a lower T_g as NIL resist. In Fig. 4A, the imprinted patterns in poly(benzyl methacrylate) ($M_w \sim 70{,}000$, $T_g = 54$°C) at temperature of 134°C are shown; and in Fig. 4B, the patterns imprinted in poly(cyclohexyl acrylate) ($M_w \sim 150{,}000$; $T_g = 19$°C) at 99°C are shown. In both cases, the imprinting temperatures were chosen to be $T_g + 80$°C °C and the applied pressure was 50 kg/cm^2, and very good pattern definition was obtained.

For typical thermal plastic, not only the viscosity has temperature dependence, but it also strongly depends on the polymer's molecular weight M_w, relative to the so-called critical molecular weight of a given polymer M_c. M_c can be interpreted as the molecular weight at which a temporary network of entanglements

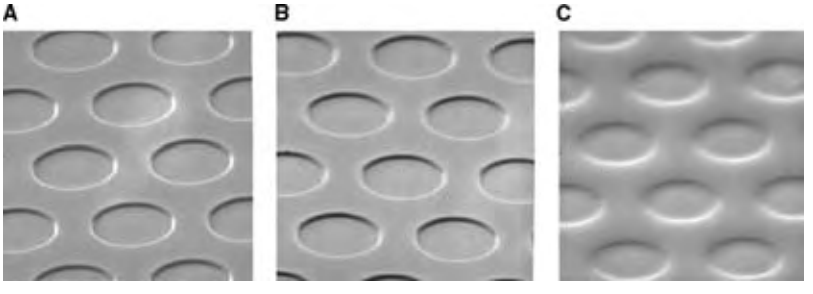

Fig. 4 SEM micrograph of patterns imprinted in (A) poly(benzyl methacrylate); (B) poly(cyclohexyl acrylate); and (C) relaxation of poly(cyclohexyl acrylate) patterns 10 days after the imprinting. *(View this art in color at www.dekker.com.)*

spans over macroscopic dimensions. Below M_c entanglements may be present, but their number is too small to lead to a sufficiently connected temporary network. Accordingly, the polymer melt resembles the flow properties of a low molecular weight compound, namely, the viscosity increases linearly with the molecular weight. Above M_c, the segment length between entanglements appears to be constant according to the experimental observation, and the viscosity shows a stronger dependence on M, as the number of entanglements per chain has to increase with M for a constant segment length.[3] If the Newtonian viscosity at critical molecular weight is denoted by η_c, the viscosity of a linear polymer in the flow state can be described by the following equations:

$$M_w < M_c, \text{ unentangled molecules}$$
$$M_w > M_c, \text{ entangled molecules}$$

In practice, low molecular weight polymers with $M < M_c$ can be imprinted at lower temperatures, lower pressures, or within shorter times. However, the absence of a network of entanglements may lead to more brittle behavior and could result in the fracture of the imprinted polymer features during the mold separation step. Therefore, the choice of both T_g and M_w is important in pattern structural stability. On the other hand, this property can also be exploited in deciding the structures to be obtained in using the reverse imprinting technique to pattern over topographies (see the section titled ''Nanoimprint Mold''). In addition, the stress build-up during the thermal cycling of the NIL process also affects the pattern integrity during mold separation, and Hirai et al. have investigated this problem in detail.[13] For more discussions on the material rheology issues related to nanoimprint, the readers are referred to chapters 3 and 4 in Ref.[3].

Another important criterion for a good NIL resist is that the imprinted pattern should maintain its mechanical integrity during mold–substrate separation as well any subsequent pattern transfer steps. Although low T_g material can be used for NIL for the sake of reducing processing temperature, the imprinted patterns are also unstable and tend to deform at temperatures close to the imprinting temperature. In Fig. 4C, the pattern relaxation at room temperature is shown, which was observed 10 days after the structures shown in Fig. 4B were imprinted (in this case the resist has a T_g of 19°C, less than room temperature). From this demonstration, it can be inferred that thermal curable or thermosetting polymers could be excellent resist systems for NIL because of the possibility of low-pressure imprinting and good mechanical integrity after crosslinking by thermal treatment. We recently developed a new, fast thermal curable liquid resist that can be imprinted under a low pressure with a very high precision and throughput. This system is based on the hydrosilylation chemistry of siloxane polymers shown in the following scheme. It consists of four basic chemical components: a vinyl terminated polydimethylsiloxane polymer, a silyl-hydride (Si-H) -based dimethylsiloxane crosslinker, a platinum catalyst, and an inhibitor. The high Si content in this polymer system guarantees that the resist has high etching resistance in RIE processes. (See below.)

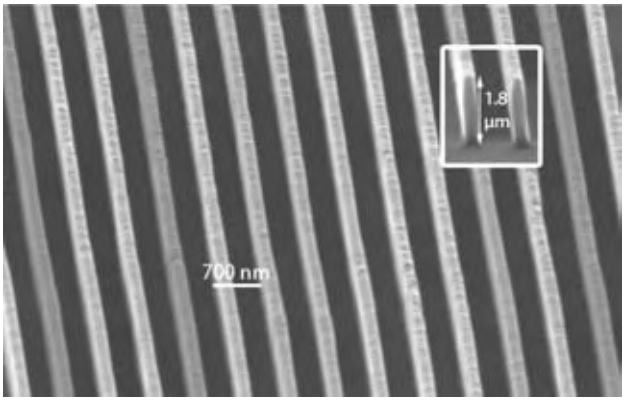

Fig. 5 SEM micrograph of an imprinted high-aspect ratio grating pattern with a 250 nm line width, and a 1.8 μm height using PDMS-based thermal curable liquid resist.

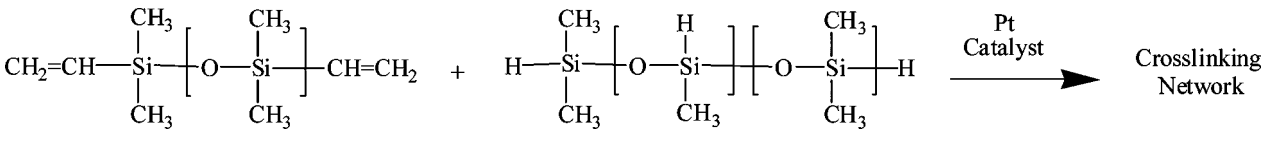
In nanoimprinting, the liquid resist is first spin-coated on a silicon wafer, followed by imprinting with pressures in the range 30–100 psi at room temperature, and crosslinking after being heated above 80°C within a minute. Because of the low surface tension of the patterned film ($\gamma = 19.8$ dyne/cm at 20°C), the mold separation is quite easy even for high aspect ratio features and the imprinted resist surface is very smooth (Fig. 5). Importantly, the mold separation does not require cooling to room temperature, thereby increasing the process throughput.



DEVELOPING BETTER RESIST MATERIALS FOR NANOIMPRINT LITHOGRAPHY

The rapid development of this technique in recent years has also stimulated the research for new materials that are better suited as nanoimprint resists. Because imprint lithography makes a conformal replica of the surface relief patterns by mechanical embossing, the resist materials used in imprinting need to be deformable easily under an applied pressure. The most commonly used materials in the original NIL scheme are thermal plastic polymers, which soften significantly when heated above their glass transition temperatures. Many commercial thermal plastic materials, e.g., poly(methyl methacrylate) (PMMA) and polystyrene (PS), have been used as NIL resists.[2,4,14] Obviously, these materials are not optimized at all for the special requirement in NIL process. One critical requirement for candidate polymers used in imprinting-based lithography is that it should provide excellent mold releasing properties during the demolding process, while at the same should not compromise its adhesion to the substrate. Commercially available polymer materials can hardly satisfy these seemingly contradictory requirements. Although the mold surface is normally treated with low surface energy surfactant, when imprinting high-density or high aspect ratio patterns, the imprinted polymer tends to adhere to the mold, creating pattern defects that are intolerable for many device applications. Block copolymer materials that have dual surface properties by microphase segregation can be exploited to solve this problem. In addition, higher dry etching resistance is highly desirable if the imprinted polymer pattern is to be used as a dry etching mask for further pattern transfer. Recently we exploited the use of siloxane copolymers as NIL resist, such as polystyrene-*b*-poly(dimethyl siloxane) (PS-PDMS) block copolymer. The presence of PDMS imparts the copolymers with many properties that are favorable for NIL, e.g., low surface energy for easy mold release and high Si content for chemical etch resistances—in particular, extremely low etch rates (comparable to SiO_2) in oxygen plasma, to which organic polymers are quite susceptible. In addition, the copolymers are thermoplastic and can be thermally deformed reversibly. An imprinted grating pattern with 250 nm line width is shown in Fig. 6.

On the other hand, the high temperature and pressure required for the nanoimprinting of thermal plastic materials limit the throughput and the application scope of the NIL technique. In addition, the thermal expansion mismatch between the mold and the substrate frequently incurred often presents an obstacle for pattern alignment over large substrates. Although various means have been attempted to make the thermoplastics imprintable at a temperature close to room temperature, including dissolving the polymer into its monomer or solvent[15] using PDMS stamp for solvent evaporation,[14] the success has been very limited.

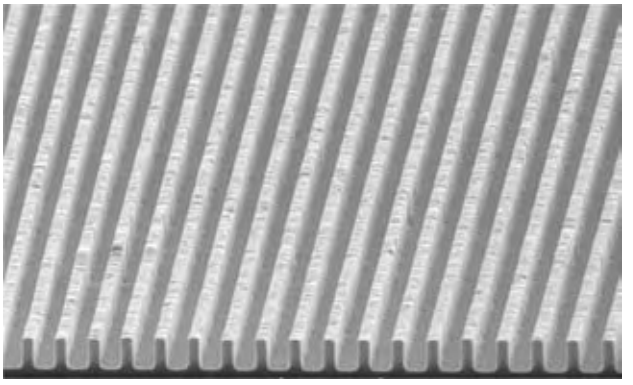


Fig. 6 SEM micrograph of 250 nm line width patterns imprinted in PS-PDMS diblock copolymer.

A very attractive method for achieving room-temperature and low-pressure imprinting is to utilize a liquid precursor that can be cured and solidified by heating or UV light. Comparably, UV-curable material system is preferred to thermal curing system because the heating and cooling cycle of the latter can slow down the process throughput. The most widely used UV-curing formulations are based on free radical polymerization of acrylic and methacrylic monomers because of their high reactivity, as in S-FIL.[4] However, such material systems suffer from oxygen sensitivity issue: oxygen scavenges free radical species and thus inhibits polymerization process at the resist surface, making the process prone to defect generation. Besides, the acrylate-based UV-imprint resist has a large shrinkage upon curing ($\sim$10%), which not only affects the faithful pattern definition but also tends to cause delamination of the resist film from certain substrates, especially metals and plastics.

As a result, a number of critical issues have to be resolved before this potentially powerful technique can be exploited for any industrial-scale nanopatterning. First, it is preferable that the imprinting resist precursor is in liquid state and can be spin-coated on the substrate to allow low-pressure and high-throughput processing. Second, the shrinkage of the resist after crosslinking must be very small to ensure the fidelity of pattern transfer and to prevent possible film delamination. Third, a resist with a good dry etching resistance is highly desirable as it allows the resist to be used directly as a hard mask in RIE process to transfer the patterns into the underlying substrate (Fig. 7). We developed a new UV-curable epoxysilicone material based on cationic crosslinking of cycloaliphatic epoxies. This resist combines a number of aforementioned desired features for nanoimprinting.[16] Because cationic polymerization is not prone to oxygen

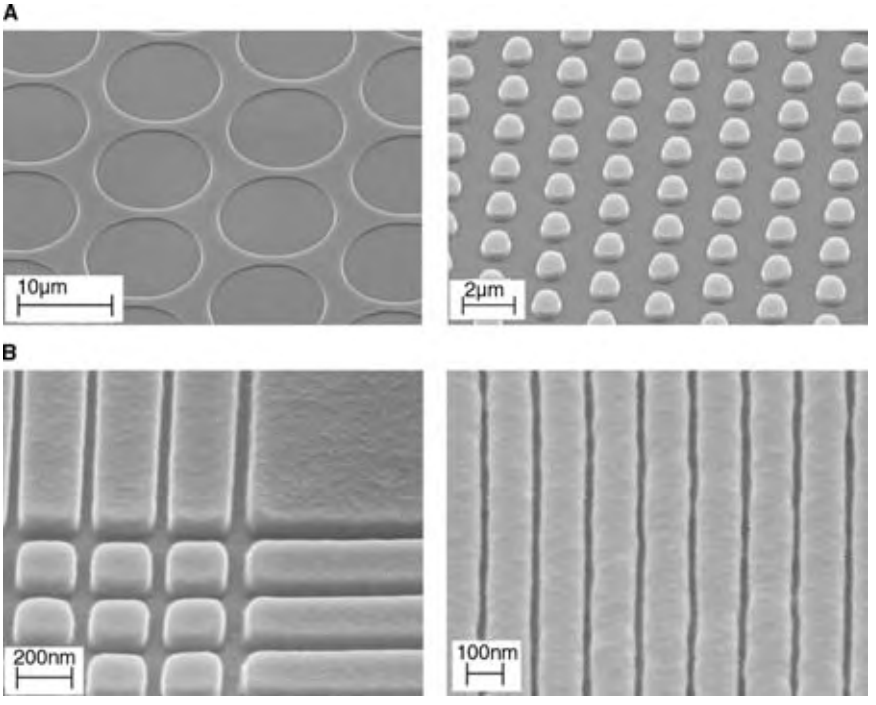

Fig. 7 SEM micrographs of imprinted and UV-cured resist patterns: (A) 20 μm diameter recessed patterns (left) and 1 μm diameter protruded patterns (right) and (B) sub-100 nm trench patterns (left) and 20 nm trenches (right).

inhibition as compared to the free radical polymerization of the acrylate monomers, fewer defects are expected. The resist exhibits very good dry etching resistance because of high silicon content. Furthermore, its very low shrinkage after curing, only a fraction of that of the acrylate system, allows a reliable patterning. In addition, with a suitable undercoating polymer, a very uniform liquid precursor can be formed simply by spin-coating, which also allows other processes such as lift-off to be easily performed.

The novel liquid nanoimprint resist consists of a silicone-diepoxy monomer, a silicone crosslinking agent, and a photoacid generator. The epoxysilicone materials were prepared via hydrosilylation of 4-vinyl-1-cyclohexane 1,2-epoxide with the corresponding SiH-functional silicone intermediates in the presence of a platinum catalyst and purified by vacuum distillation. A typical liquid resist formulation comprises 94 wt.% diepoxy monomer, 5 wt.% crosslinkers, and 1 wt.% PAG. Organic solvents, such as propylene glycol monomethyl ether acetate (PGMEA), can be used to adjust the viscosity of the resist so that film thickness from 1 μm down to sub-50 nm can be readily obtained. With a suitable under-coating layer, such as baked PMMA or SU-8 resist, stable and uniform liquid thin films can be formed on Si or other substrate.

With such a UV-curable nanoimprint resist, both micro- and nanoscale patterns can be easily achieved at room temperature and at a pressure of less than 0.1 MPa by using a conventional contact exposure tool. In Fig. 7A, recessed hole pattern of 20 μm in diameter and protruded pillar pattern of 1 μm in diameter after imprinting and curing is shown, and in Fig. 7B, various nanoscale patterns are shown. These results demonstrate that patterns as small as 20 nm (limited by the feature resolution on the current mold) can be easily achieved by conventional contact aligner using this new resist material.

OTHER IMPRINT-BASED PATTERNING TECHNIQUES

Combined Nanoimprint and Photolithography

Although NIL has proved to be very successful in nanopatterning, especially in replicating periodic nanoscale features with uniform sizes, it still has several limitations as a flexible lithographic technique. A general lithographic technique should be capable of producing both large and small features in various combinations and distributions—a typical requirement in micro- and nanofabrication processes. In NIL, protrusion features on the mold physically deform and displace the polymer. Larger features on the mold must displace more polymer material over larger distances. Thus, patterns with large features are much more difficult to imprint than nanopatterns. Moreover, NIL pattern defects or even failures in the form of incomplete pattern transfer can occur because of the high viscosity of the polymer melt and the mold pattern complexity.

The aforementioned defect generations are related to the mold pattern itself and are inherent in NIL process. To solve those problems, we developed a technique

that integrates photolithography into NIL to take advantages of both techniques while compensating each other's limitations.[17] The schematic of such a combined-nanoimprint-and-photolithography (CNP) technique is shown in Fig. 8. A hybrid mask concept is introduced in this process (Fig. 8A), which is made of UV transparent material, and acts both as a NIL mold and as a photolithography mask. Protrusions are made on the mold for imprinting nanoscale features, while metal pads are embedded into the mold serving as light mask for photolithography to replicate large patterns. Fabrication details of such hybrid mold can be found in Ref.[17]. The resist used in this method can be either negative tone photoresists or UV-curable materials.

The processing steps of CNP are very simple. The hybrid mold is first imprinted into the resist layer by pressure, then the whole mold–substrate assembly is exposed by UV radiation (Fig. 8B). After the hybrid mold and the substrate are separated (Fig. 8C), the substrate is immersed in a developer solution to remove the unexposed resist that are blocked by the metal pads (Fig. 8D). After developing, both large-scale and nanoscale patterns are created in the polymer resist in one step. The effectiveness of this new technique was demonstrated by using a negative tone photoresist SU-8.

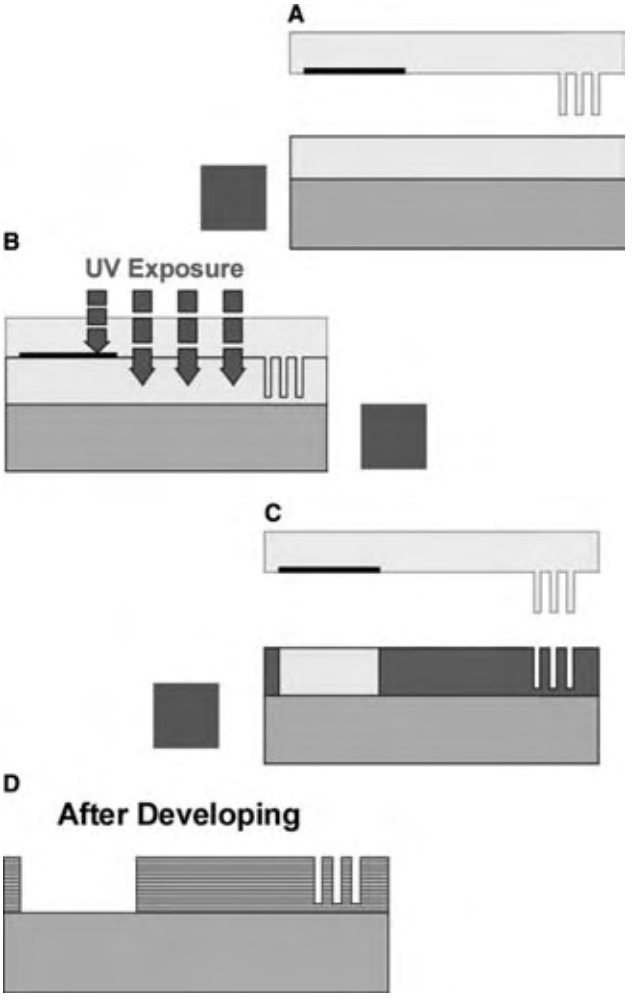

Fig. 8 Schematic of the CNP technique using a hybrid mold. *(View this art in color at www.dekker.com.)*

There are many advantages of the CNP method by using the new hybrid mask concept. First, it enables one-step lithography of arbitrary patterns containing both large-scale and nanoscale structures, which is often required in functional device fabrications. Second, because there are only nanoscale mold protrusion features on the hybrid mold, it allows low imprinting pressure to be used as only very small amount of polymer needs to be displaced. Third, by forming the large patterns as a photomask (i.e., making them as metal pads), it reduces the complexity of the relief pattern on the hybrid mask-mold. This simplifies residual layer thickness distribution, which can ease the step for residue removal significantly. Finally, the throughput could also improve because, in NIL, imprinting nanoscale features can be a very fast process, while establishing a quasi-equilibrium distribution of residual polymers when imprinting large patterns could take significant time. The last point can be quantified using a simple model by considering the squeezed flow of a Newtonian fluid between plates that have a radius R and a gap distance of d. Such a structure can approximate the process where a mold protrusion with size R is imprinted into a resist of thickness d on a substrate. One can obtain a simple solution that expresses the pressure (P) in terms of these dimensions and to the speed of imprinting ($\mathrm{d}h/\mathrm{d}t$) and fluid viscosity h. Numerical simulation based on finite difference method using nonsteady-state Navier–Stokes equation has also given such relationship for simple periodic mold features.[18] Integrating this equation can give the time required to reduce the thickness of the fluidic layer by half (i.e., to imprint half way through the feature height). This simple model says that under the sample pressure the imprinting time scales as quadratic function of the pattern size. Therefore, the time required for imprinting large size pattern will be significantly longer than that for nanopatterns.

Reverse-Nanoimprint Technique

This technique was developed to address the issue of patterning on topographies and on flexible substrate (Fig. 9). Nanoimprint lithography has a great advantage in that it can directly imprint device structures in polymer materials[19] (sometimes in single step) and create patterned features using polymers with certain desirable physical or chemical functionalities.[20–22] But NIL patterning is typically carried out at a temperature 70–80°C above the glass transition

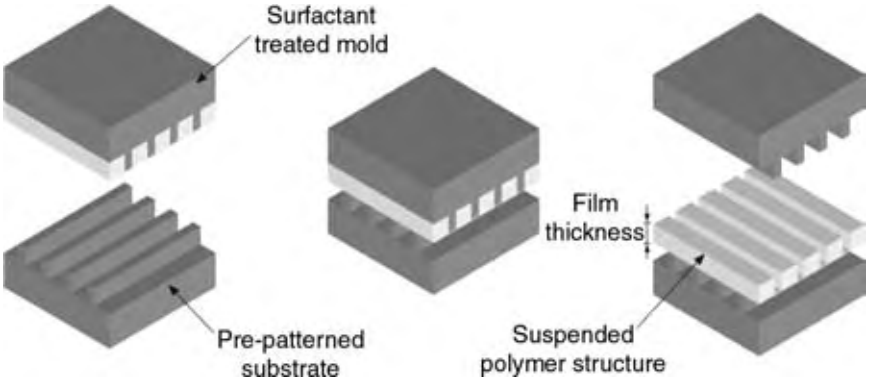

Fig. 9 Schematics of reverse-imprinting polymer nanostructures over topography. *(View this art in color at www.dekker.com.)*

temperature (T_g) of the polymer material to ensure that the polymer has a sufficiently reduced viscosity that can be imprinted at reasonable pressure. For micro- and nanoscale patterning, especially when directly patterning functional polymers, it is often desirable to operate at lower temperature and with reduced pressure. This is required not only in certain applications or limited by certain substrate characteristics, but also if the mold and substrate are made from different materials with mismatch in thermal expansion coefficients, higher temperature will create more stress during the NIL thermal cycle, and could present problem for mask–sample alignment. To target these problems, room temperature NIL has been previously demonstrated by using spin-on-glass or hydrogen silsequioxane (HSQ) as imprint resist material,[23,24] but the pressure needed was very high because of the very high modulus and viscosity of such inorganic material.

It was developed based on the following consideration. If a polymer film is spin-coated onto a mold, the polymer will fill up the trench regions of the surface relief patterns. This means that a replica of the mold pattern is formed in the polymer film simply by spin-coating. Now if this film can be transferred from the mold to a substrate, patterned structures are obtained (Fig. 10A). In Fig. 10B, the imprinted 350 nm line-spacing PMMA grating obtained by reverse imprint process that was done at a temperature of 105°C, i.e., at the T_g of PMMA, is shown. The key to the successful film transfer lies in the fact that the mold has a lower surface energy than that of the substrate, so the polymer film has better adhesion to the substrate and therefore can be detached from the mold.

Because in reverse imprinting coating of polymer resist on the substrate is not required, it is therefore possible to use this technique to transfer patterns onto substrates that are not suitable for spin-coating or have surface topographies. We have demonstrated that this technique can be applied to flexible substrates and substrates that already have other fabricated features (e.g., nonflat surface or prepatterned surface) to create nanoscale patterns (Figs. 11A and 11B).[25] The ability to pattern over topography has solved a long-standing problem in imprint-based lithography. Previous efforts to solve this problem often involve multilayer resist approaches with a thick polymer planarization layer on top of the nonflat substrate.[26] Those approaches not only require complex processes with multiple steps, but also entail deep etching steps to etch through the thick planarization layer, which often degrades the resolution and fidelity of the pattern. But reverse-imprint solved this problem very effectively. In Fig. 12A, the reverse-imprinted polycarbonate grating

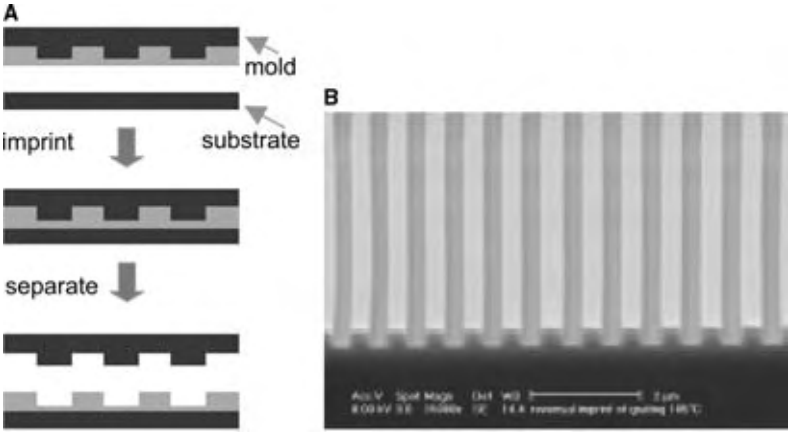

Fig. 10 (A) Schematic of reverse nanoimprint, and (B) SEM of reverse imprinted PMMA gratings with 350 nm line width/spacing. *(View this art in color at www.dekker.com.)*

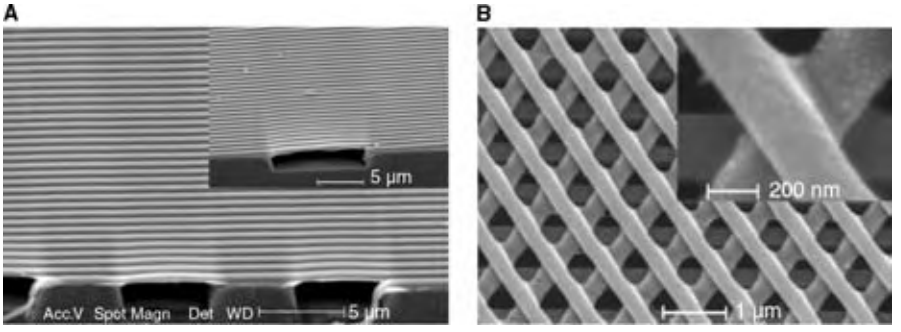

Fig. 11 Imprinting of 700 nm period grating on topographies: (A) PC pattern imprinted across 5 μm gaps and 10 μm gaps as shown in the inset. (B) PMMA pattern imprinted on the protruded surfaces for line spacing of greater than 3 μm.[25]

structure is shown that is suspended over etched features on Si substrate.

The reverse-imprinting technique can potentially offer a simple method to fabricate three-dimensional (3D) polymer nanostructures. Such 3D structure can be achieved by simply repeating the process and building up the structure in a layer-by-layer fashion. An example of imprinted three-layer nanostructure, using three different polymers with progressively lower T_g, is shown in Fig. 12B.[24] Note that this approach can also allow a single polymer material to be used for all layers if the material can be thermal or UV cured.

There are many potential applications of such 3D polymer nanostructures. Multilayered structure with varied grating periods can be used as size-controlled filters in microfluidics to select and separate particles of different sizes. Another potential application is to fabricate periodic 3D polymer structures and infiltrate the polymer template with high refractive index inorganic materials to create 3D photonic crystal materials (Fig. 12). Not only the dimensions of such structure can be designed and controlled but also it is straightforward to form defect waveguide and resonator structures that are useful for many photonic device applications, by simply removing rows on the mold. This example only serves as an illustration of a potential application of 3D printing method—we should not undermine the challenge of stringent pattern alignment required in this particular application.

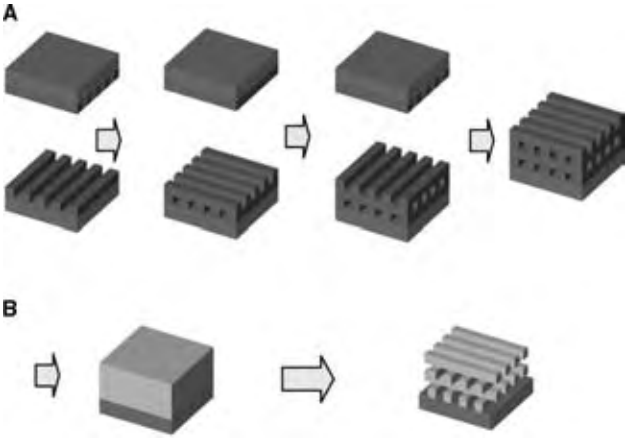

Fig. 12 Schematic of (A) building 3D polymer nanostructures by using reverse-imprint; thermal plastic or photosensitive material is spin-coated on the mold for pattern transfer and (B) infiltrate the 3D periodic structure with other materials, such as inorganic materials that have high refractive index; then remove the polymer template layer to create a 3D pattern of the infiltrated material that is complementary to the original polymer resist pattern. *(View this art in color at www.dekker.com.)*

CONCLUSIONS

Nanoimprint technique has, for the first time, enabled parallel nanoscale processing capability with simple equipment setup. The simplicity of this method has made it appealing to researchers in various fields. New techniques based on the concept of mechanical printing or embossing are appearing very rapidly. New variations of the technique aimed at different applications have also been developed at a fast pace. More and more researchers are attracted by these nonconventional patterning technologies because of their scalability, low-cost and potential new applications. It is certain that advances in new materials for imprinting will fuel the development in this field.

The simplicity and high resolution provided by this technique have also found numerous applications in electronics such as hybrid plastic electronics,[27] organic TFTs and electronics,[28,29] and nanoelectronic devices in Si;[30,31] in photonics such as organic lasers, high-resolution OLED pixels,[32] diffractive optical elements,[33] waveguide polarizers,[34] and active[20] and nonlinear optical polymer nanostructures;[21] in magnetic devices like high-density quantized magnetic disks[35] and patterned magnetic media;[36] as well as in biological applications such as manipulating DNA in nanofluidic channels[37,38] and nanoscale protein patterning.[39] Because of its fast development in the past decade and its potential for sub-100 nm lithography, MIT's Technology Review listed NIL as one of 10 emerging technologies that are likely to change the world.[40]

ACKNOWLEDGMENTS

The author would like to thank all the graduate students, postdoctoral fellows, and other colleagues at the University of Michigan who have contributed to the work described here: Dr. Xing Cheng, Dr. Li-Rong Bao, Dr. Xu-Dong Huang, Dr. Tan Li, Philip Choi, Wayne Fung, Professor Stella W. Pang, and Professor Albert F. Yee; and special thanks to Dr. Peng-Fei Fu at Dow Corning Corporation for his collaboration and contribution to some of the work described in this entry.

INTRODUCTION

Industrial interest in nanomaterials derives from the novel properties they exhibit. These are defined for this entry as materials having engineered discrete particulate domains with diameters in the range of 1 nm to a few hundred nanometers. These domains may appear in many forms, such as dispersions of nanoparticles in a liquid, on surfaces, or embedded in a continuous matrix. The unique properties of nanomaterials are a consequence of the small size and extremely large interfacial areas. In this regime, dramatic variations in the chemical and physical properties of a material may be effected. Representative examples of size-critical properties, enabling new industrial applications, reviewed in this entry include surface and interfacial, catalytic, optical, and mechanical.

NANOPARTICLES IN SURFACE AND INTERFACIAL PHENOMENA

Small particles have been known for years to stabilize dispersions, foams, and emulsions.[1] Two prominent theories have been put forth to explain this phenomenon. One is based on the ''surface activity'' of the particles, while the other is based on viscosity control of the continuous phase.

The first theory claims that the particles are ''surface active but, unlike surfactants, are not amphiphilic.''[2] Partially modified particles preferentially partition the interface between the two phases, with the key physical characteristic for stabilization being the contact angle of the individual particle with the interface. Particles having a 90° contact angle (approximately equal amounts of hydrophobic and hydrophilic character) with the interface will create the most stable emulsions. The particles used in these studies are nanometer sized (~10–30 nm), but this is the primary particle size. The particles are actually agglomerated and are typically several hundred nanometers in size. This distinction is important for Eq. (1), which is used to support the proposed mechanism:

$$E = \pi r^2 \gamma_{\alpha,\beta}(1 \pm \cos\theta)^2 \quad (1)$$

where E is the energy required to remove a particle from the interface between the two liquid phases, r the radius (in meters) of the particle, $\gamma_{\alpha,\beta}$ the interfacial tension between the two phases, and θ the contact angle the particle makes with the interface.

This implies that the larger the particle (up to where gravity becomes a factor), the more stable the emulsion. It is also implicit that a particle with a too high (or too low) contact angle or of too small size should not be held at the interface and would be located in the bulk. This theory concludes that particles bound to the interface will stabilize systems, while those that are not bound to the interface cannot be used for stabilization.

Proponents readily admit that there is no significant reduction in surface tension when the particles are incorporated into the fluids. No arguments are proposed as to how the particles are bound to the surface. Their presence cannot be detected by surface tension measurements.

There is little applicability of this mechanism to stabilization by small particles. For instance, using the values exemplified earlier, the energy required to remove a particle with a diameter of 200 nm (approximate actual size of the particles in the above study) and a contact angle of 150° from a water/toluene interface (interfacial tension = 0.036 N/m) is 4927 kT, while a 5 nm particle in the same system has a binding energy of 3 kT. Therefore, a 200 nm particle will be ''irreversibly'' bound to the interface, while a 5 nm particle should not be held at the interface and if stabilization occurs, it must take place by a different mechanism.

An alternative theory based on results using unmodified, nanometer-sized, individual silica particles in an aqueous system was proposed almost 15 years ago.[3] Using reflected light microinterferometry, it was determined that the nanoparticles formed ordered structures inside the thin liquid films located between the dispersed phase regimes. This mechanism relies on

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008059

purely physical effects for stabilization, not on thermodynamic/surface tension phenomena. To briefly summarize this work, the diagram in Fig. 1 will be useful.

The large circles represent a dispersed phase (bubbles, droplets, or solids), while the small ones represent surface modified nanoparticles (SMNs) dispersed in the continuous phase that can be found between dispersed phase domains. The diagram on the left illustrates that the SMNs must be dispersed in the continuous phase. If they are not well dispersed or are agglomerated, they will not work as efficiently.

In the next diagram, the thin liquid film located between the dispersed phase regimes begins to drain and the discontinuous phase regimes begin to approach each other. When this happens, the SMNs are forced into the restricted volume of the thinning film, resulting in an ordered structure. The SMNs begin acting as steric barriers to coalescence or flocculation. As this ordering takes place, a localized concentration of the SMNs occurs—the liquid drains faster than the SMNs. This results in a very concentrated dispersion in the localized environment between domains. As with any concentrated dispersion, the viscosity in this region (only) increases. With the viscosity increasing in the region between domains, drainage is slowed and the system is further stabilized.

In the third diagram, the local concentration increases and the SMNs actually create well-ordered layers between the dispersed phase regimes while the liquid continues to drain. The SMNs cannot get out of the way fast enough, which is more commonly known as ''depletion flocculation.''[4]

Depletion flocculation occurs when two particles approach each other to within a distance that is smaller than the particle size so that no other particle can fit into the space between them. The osmotic pressures between the particles and in the rest of the dispersion are not balanced, and this pressure difference pushes the two particles toward each other. This leads to a further increase in viscosity and stability.

Finally, in the last diagram, drainage cannot be completely halted and layers of SMNs will eventually drain away. This stepwise draining is attributed to the existence of an osmotic pressure gradient—SMNs leave the film and ''vacancies'' appear in their place. The higher chemical potential of the SMNs causes the SMNs to slowly diffuse to the meniscus, leaving behind vacancies. The vacancies reach an equilibrium concentration that can only be increased by the further removal of SMNs from the film. This is known as the diffusive osmotic model.[5]

These diagrams demonstrate that the SMNs should be well dispersed in the continuous phase, monodisperse, and small in size. This can be visualized if one assumes that the SMNs in the diagrams are 5 nm particles. Thus, there would be four layers of particles between the dispersed phase regions. If one replaces the 5 nm particles with 20 nm particles, then a single 20 nm particle will essentially take up the same space (linearly) as four 5 nm particles. Replacing the 5 nm particles with 20 nm particles makes the path to coalesce or flocculation less tortuous. Also, at equal weights of particles, there are fewer 20 nm particles than 5 nm particles. It is well known that the viscosity

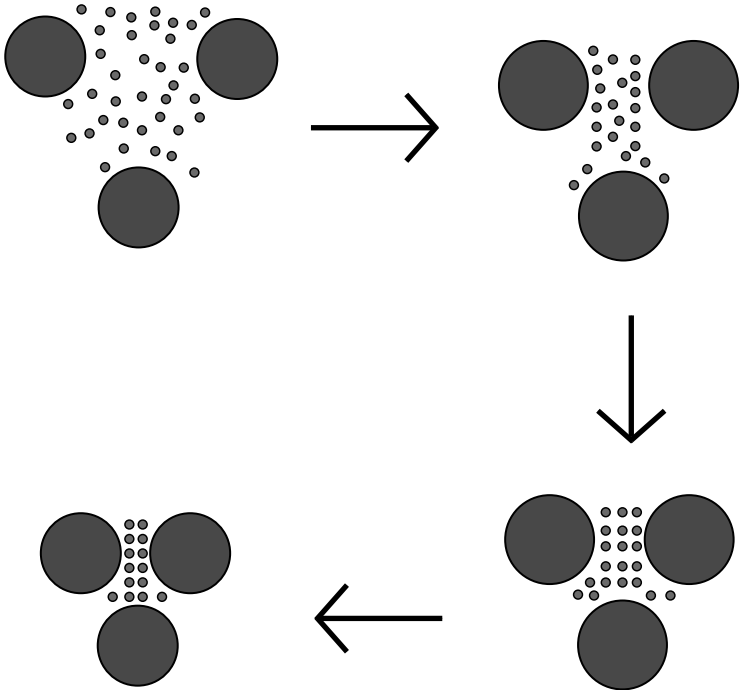

Fig. 1 Proposed stabilization mechanism. *(View this art in color at www.dekker.com.)*

of a dispersion of smaller particles will increase faster with an increase in solid content than that of a dispersion of larger particles, leading to a more stabilized system.[6] Therefore, with everything else being equal, smaller particles should stabilize better.

There are limitations on the size. As has been estimated by theoretical calculations, for spherical particles, ~4 nm will be the approximate minimum size that should stabilize an emulsion or foam. This represents the smallest particle that will not be enveloped by the amplitude of surface corrugations.[3]

Work was conducted in emulsion stabilization using only nanoparticles. It was surprising to find that these emulsions were stable for months (sometimes years) without high shear mixing. Particles with the same surface modification would stabilize a water-in-oil system and a fluorocarbon-in-oil system. This is nearly unheard of in emulsion science. Typically for a surfactant to be useful, it must be located at the interface between two phases, meaning that it must have a limited amount of solubility in both phases. Because water and fluorochemicals are vastly different in their chemical potentials, it is unlikely that a single surfactant would stabilize both types of systems. Fig. 2 shows optical micrographs of these multiple emulsions. On the left is one of the more interesting ''micelle'' shapes. On the right is the actual breaking of one of the emulsion droplets.

This led to the inclusion of two types of particles into the emulsions and the formation of multiple emulsions. For example, hydrophobically modified particles were dispersed in toluene, while hydrophilically modified particles were dispersed in water. Emulsification of this system produced water-in-toluene-in-water or toluene-in-water-in-toluene multiple emulsions. Formulations of one type over the other were achieved by changing the water/toluene ratio or hydrophobic/hydrophilic particle ratio. Fluorocarbon-in-toluene-in-water multiple emulsions were made by adding a fluorochemical fluid. Fig. 3 is an optical micrograph of a multiple emulsion containing Fluorinert® FC75 in toluene in water.

These multiple emulsions could be made by simple mixing, without any special order of addition of the ingredients. In fact, all three liquid components (the particles were previously dispersed in the respective phases) in the FC-in-toluene-in-water system were combined and emulsified simply by mixing. It is well understood that multiple emulsions are extremely process dependent and are nearly a black art. The ability to create these emulsions with minimal processing is a vast improvement over the current art.[7]

Dispersion stabilization with nanoparticles is also known. A recent example of a dispersion stabilized by nanoparticles was published by Tohver et al.[8] This group used zirconia particles to stabilize an aqueous colloidal system of larger silica particles. The dispersion was stabilized by electrostatic stabilization and thus is essentially applicable only to aqueous systems. Surface modification of the particles changes the stabilization mechanism to steric stabilization, and dispersions in both aqueous and nonaqueous systems have been demonstrated.

Foam, emulsion, and dispersion stabilization can be accomplished with organic molecules. With the proper chemistry, organic molecules also exhibit stabilization capabilities. Because many of these molecules are hydrophobic to begin with, further hydrophobic modification only makes them more compatible with the solvent, resulting in very few, if any, lyophobic/lyophilic regions that would cause them to partition the interface.

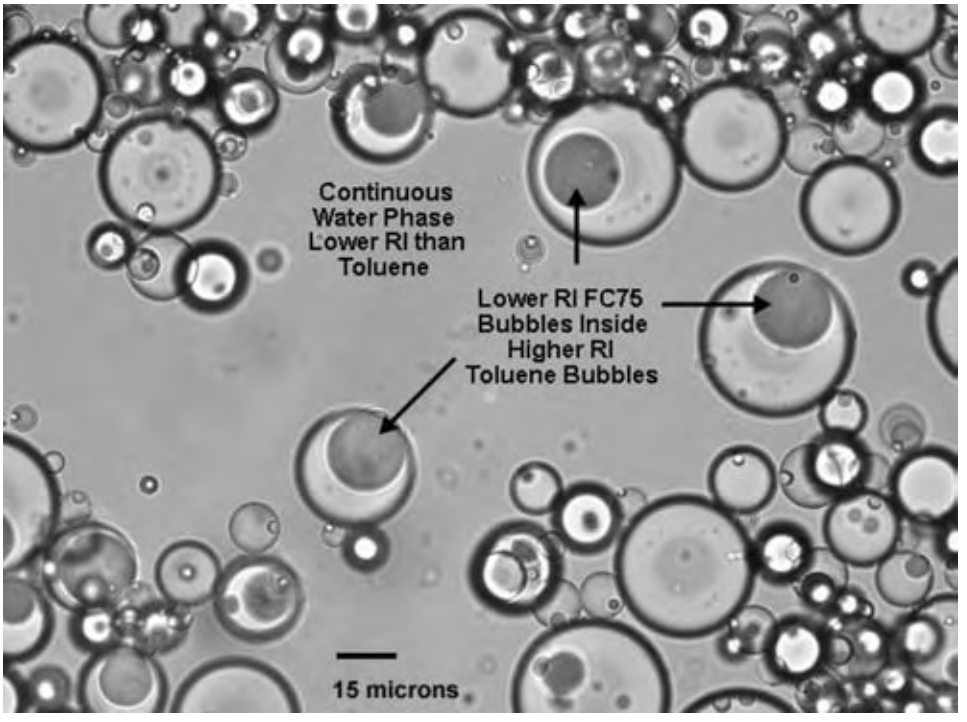

Fig. 3 An optical micrograph of fluorocarbon-in-toluene-in-water emulsion stabilized with nanoparticles.

GOLD NANOPARTICLE CATALYSTS

The science of metal nanoparticles has had a significant impact on commerce and industry, most prominently through the chemical transformations of hydrocarbons that lead to fuels and petrochemicals. Additionally, the physics of small metal particles has been fascinating for a long time. A problem considered in latter times has centered on quantum size effects: how electronic, and perhaps chemical, properties change as the particle size is reduced in three (nanoclusters), two (nanowires), or one (rafts or islands) dimensions. Gold nanoparticles are singled out in this entry because clusters and particles formed from main group and d-block elements comprise too vast a field. The majority of work on gold nanoparticles has been done in the past two decades. This smaller subfield replicates the puzzles and surprises presented by metal nanoparticles in general. Because it is so new, there are many technological opportunities to be explored and many fundamental questions remain to be answered. Gold nanoparticles are at a frontier in catalytic chemistry today.

The surface chemistry of bulk gold is limited in scope compared with its lighter congeners copper and silver, and to elements of the transition series. Oxygen absorption is strong but occurs rapidly only at $>500^{\circ}C$.[9,10] Chemisorptive properties are weak although of some importance in electrochemistry. Gold has long been known to catalyze the oxidation of CO to CO_2; the discovery that this reaction proceeds rapidly at ambient temperature on small gold particles was a breakthrough. Catalysis by or on gold nanoparticles has since developed rapidly, and this[11] as well as CO oxidation[12] has been recently reviewed. Broad topics discussed here include a) preparation and characterization of gold nanoparticle catalysts; b) the nature of the active site(s) and the mechanism of CO oxidation; and c) other processes catalyzed by gold nanoparticles.

Catalyst Syntheses and Characterization

Gold catalysts are made through two general methods that differ in terms of the principles involved, the materials produced, and the level of their understanding that has been achieved. In both, a solid support is used to stabilize the particles against sintering and to provide them in a form that is convenient to use.

Chemical methods

The first method involves chemical reduction of Au(III), usually as the hydrated H_3O^+ salt of $AuCl_4^-$. A preformed support may be impregnated with this "$HAuCl_4$" and then treated with a reducing agent. Alternatively, when the pH of a mixture of $HAuCl_4$ and various metal ions is raised, gold hydroxide and metal hydroxide coprecipitate. Drying, calcination, and reduction of this mixture provide Au(0) supported upon a metal oxide. Suitable reducing agents include H_2, BH_4^-, citrate, and ascorbate. Permutations of

support materials and reaction conditions are myriad. Some systematic studies are available,[13–18] but a real understanding of the role of processing variables has not been achieved. Supports can be carbon, metal oxides, or mesoporous oxides such as zeolites. Oxides can be categorized as reducible (TiO_2, Fe_2O_3, CeO_2) or not (ZrO_2, SiO_2, Al_2O_3).

Chemical vapor deposition (CVD) has been used to prepare nanoparticle catalysts, although the technology is quite expensive. Dimethylgold acetylacetonate absorbs on supports such as MgO. Decomposition at $>100°C$ produces an efficient CO oxidation catalyst. X-ray absorption near edge (XANES) and extended X-ray absorption fine structure spectroscopies (EXAFS) showed that, under steady-state CO oxidation conditions, the catalyst contained Au(0) in the form of (on average) Au_6 clusters and also additional gold as Au(I).[19–21]

Preformed gold clusters, obtained by the reduction of $(Ph_3P)AuCl$ followed by treatment with O_2 to remove capping ligands and then with H_2, have been used as catalysts.[22]

Usually, these catalysts are characterized in terms of their efficiency in some test reaction, usually CO oxidation, under arbitrary conditions (O_2 and CO concentrations, humidity, flow rates, and catalyst time on stream) that would be difficult to reproduce in another laboratory. Characterization on any length scale, from molecular to morphological, is extremely difficult. In many cases, it is uncertain whether all the reactants and by-products have been removed from the catalyst surface. It is reported that chlorides poison the active sites.[23] This raises the question of a role for gold ions, and these, rather than Au(0), are reported to be the active sites in the water-gas shift reaction.[24]

Transmission electron microscopy (TEM) and scanning tunneling microscopy (STM) have been used to visualize small particles.[25–27] Catalysts can contain large amounts of large particles and crystalline bulk gold. One study of Au/Al_2O_3, prepared by sputtering, found that some gold was unaccounted for in the mass balance and in size regime below TEM resolution limits ($\sim$1 nm).[28] It is not clear whether all the catalytically active gold has (or can be) viewed by microscopy. Gold particles <2 nm in size have structureless absorption, and larger ones show a surface plasmon peak in the visible.[29,30] Colors of gold catalysts thus can provide a crude, qualitative measure of gold aggregation. On MgO, they vary from light blue to blue, purple, and then pink with increasing particle size.[11] Individual characterization techniques have different limitations. For example, in x-ray photoelectron spectroscopy (ESCA) and TEM, a sample prepared (and used) under ambient conditions is studied under high vacuum conditions. In ESCA, photoelectrons can cause spurious reduction of cationic gold.

Incisive characterization of gold nanoparticle catalysts, however prepared, faces formidable obstacles. The root cause is this: virtually all experimental probes average over or ''see'' all (or almost all) of the gold in the sample. But it is not clear whether all the gold is responsible for all the catalytic activity. The effect of a small fraction of the total gold can be greatly amplified in catalysis. The same problem exists with particles and clusters of other metals. However, for gold, the effect on activity of particle size is extremely large, going from high at <10 nm diameter to zero for the bulk-like metal. In contrast, Ru and Pt are active under all degrees of dispersion (allowing for scaling for surface area).

Sputtering methods

This process is conducted under vacuum and deposition is line-of-sight. It is expensive and best suited to planar surfaces having relatively small areas. Impediments to commercial applications are aids to fundamental research. Catalysts can be prepared, studied, and tested under UHV conditions and in the absence of chemical contaminants. Most of our detailed understanding of gold nanoparticle catalysts comes from work on sputter-coated model catalysts.

Basic studies

It is difficult to deduce what gold particle morphologies arise from heterogeneous chemical reduction of $HAuCl_4$. Understanding of the model catalysts is much easier. In brief, a) nucleation of gold clusters occurs at surface defects that act as traps; b) on Al_2O_3, there are two kinds of traps at <0.8 and >1.6 eV; c) the defect density is ca. 3×10^{12} sites per cm^2 (10^{-3} monolayer); and d) when the clusters grow to >600 atoms, they leave the traps. This can explain the bimodal size distribution of the clusters.[31] Atomistic definition of these traps is needed.

Fundamental studies of metal nanoparticle growth on oxide surfaces indicate that, on a larger length scale, particles tend to collect at dislocations and grain boundaries,[32–34] and mobility on rough surfaces is lower than on smooth ones.[35] There is a significant size dependence,[36] and oxygen can enhance lateral diffusion.[37] Many theoretical studies have explored stability–size–geometry relationships in small gold clusters.[38–40] There are ''magic numbers'': Au_{20} in T_d form is particularly stable.[41] Metal–support interactions (which need to be explored further) and relativistic effects[42] tend to stabilize flat 2-D structures over polyhedral 3-D ones.

Ionized gold clusters generated in the gas phase can be mass sorted, deposited with low kinetic energy onto oxide surfaces, and then charge neutralized. For Au_n

($n > 2$) on MgO, Au_8 was found to be the smallest cluster that catalyzed CO oxidation and then only on defect-rich surfaces. Adsorption is accompanied by partial electron transfer into the cluster from surface defects (possibly oxygen vacancies). This may play a key role in enhancing catalytic activity. On Au_8, CO is a weakly bound η^1 ligand.[43,44] Oxidation by small gold clusters has been studied experimentally[45] and theoretically.[46,47] Interestingly, in the gas phase, only Au_n^- ($n \leq 20$, $\neq 16$ and even) reacts with O_2 to form $Au_n(O_2)^-$.

Scanning tunneling microscopy studies of gold nanoparticles on TiO_2 suggested that clusters may have unusual catalytic properties as one cluster dimension becomes smaller than three atomic spacings. Two-atom thick clusters show maximum activity for catalytic CO oxidation at diameters 2.5–3.0 nm. A metal-to-nonmetal transition occurs as cluster size decreases below 3.5 nm in diameter and 1 nm in height (ca. 300 atoms).[48,49] These results raise fundamental questions about the electronic nature of gold nanoparticles, particularly when they are small and thin. Also, O_2 is reported to bind more strongly to ultrathin Au islands than to thick ones.[50] Two-dimensional Au islands are thermodynamically less stable than three-dimensional aggregates and sintering occurs on annealing or in the presence of O_2.

A different view of CO oxidation comes from computational studies of extended Au(1 1 1). Steps and kinks play a critical role in reducing the activation energy for O_2 dissociation.[51] The enhanced activity of thin islands may be related to step density (geometric effects) rather than to quantum size effects.[52] The literature suggests a key role for such defects. Gold is an effective catalyst because it can bind CO and O_2 but weakly enough so that subsequent processes have achievable activation barriers.

Hydrogenation

Use of gold nanoparticles as hydrogenation catalysts is a recent development.[53] In hydrogenation of acrolein using Au/ZnO, edge sites effected reduction of carbonyl groups, whereas reduction of the C=C bonds occurred on facial sites.[54] Thiophene doping of supported gold increased the rate of carbonyl hydrogenation of crotonaldehyde,[55] a remarkable example of promotion of gold by sulfur.

Silane chemistry

Alkylsilanes, $RSiH_3$, are absorbed on gold with loss of hydrogen to form monolayers of RSi≡moieties.[56] Reaction of $RSiH_3$ with water is catalyzed by gold nanoparticles. Products include siloxane nanowires, filaments, and tubes.[57] These results indicate that gold nanoparticles have considerable potential in the synthesis of novel materials and in developing new chemistry of p-block hydrides.

Other applications

Gold nanoparticles have been used to catalyze the liquid-phase oxidation of *vic*-diols, e.g., ethylene glycol to glycolic acid.[58] This may presage an extensive liquid-phase catalytic chemistry. In the gas phase, $Au_n(OH)^-$ clusters form adducts with O_2.[59] Propylene oxide is formed over Au/TiO_2 from a mixture of propylene, H_2, and O_2. Very small gold particles tend instead to form propane.[60–63] Numerous other applications will surely soon be published.

NANOPHASE GLASS-CERAMICS

Nanophase glass-ceramics are an important class of materials that incorporate a nanoscale, particulate phase in a continuous matrix. These nanoscale grains are formed by controlled nucleation and growth from a precursor glass during a separate heat-treatment step that follows higher-temperature forming. A nanophase microstructure can impart unique optical and mechanical properties to glass-ceramic materials, as demonstrated through some commercially important examples.

Glass-ceramic materials were invented in the 1950s at Corning Glass Works by S. Donald Stookey[64] who discovered that when small amounts (e.g., <5 wt.%) of nucleating agents (e.g., TiO_2, ZrO_2) were added to certain glass-forming compositions, a separate heat-treatment step after forming could generate highly crystalline bodies. The devitrified materials displayed superior mechanical and thermal properties, including exceptional thermal shock resistance and strength. Glass-ceramic materials with many-fold increases in strength, as well as elimination of thermal expansion, as compared with their parent glasses, can be engineered. Through development efforts at Corning, Schott, Nippon Electric Glass, and IBM, among others, glass-ceramic materials have found useful application in cookware, cooktops, dental restorations, electronic packaging substrates, building materials, and machined structural components. Commercial glass-ceramics are sold under such trade names as MACOR®, DICOR®, Vitronit™, Corning Ware®, Vision®, Neoceram®, CERAN®, EMPRESS®, and others.[65]

Although a complete treatment is beyond the scope of this entry, it is worth considering the source of improved mechanical properties of glass-ceramic materials over simple glass materials. There are many aspects of mechanical performance that combine to define the utility of a material, including numerous

modes of strength and fracture toughness, as well as surface hardness and thermomechanical attributes. At the same time, the variety of glass-ceramic compositions has become enormous in the past half century. Accordingly, there is no way to efficiently capture the full breadth of what is known about the development of mechanical properties of glass-ceramic materials in general. However, there are some dominant themes that have emerged. Glass-ceramic materials, as brittle solids, display superior strength mainly by virtue of improved abrasion resistance and flaw tolerance, which develop when crystalline grains form regions with some inherently superior properties. However, those grains also frequently serve to create unique localized stress conditions for crack suppression and barriers for crack deflection in the microstructure. More detailed analyses of specific materials systems can follow numerous lines of explanation that include considerations of such factors as differences in thermal expansion coefficient, anisotropy in thermal expansion, and chemical substitution effects. Glass-ceramic materials, as composite materials, develop properties that depend on their different constituent phases as well as interactions between them. An example is the elimination or reversal of thermal expansion of some glass-ceramics that results from the crystallization of low or net-negative thermal expansion phases in a higher net-positive thermal expansion residual glass matrix. Finally, effects of grain size on strength of ceramics, mainly the effect that decreasing grain size almost always leads to higher strength, are manifest in glass-ceramics as well. Thus, it is not uncommon to observe eventual reductions in strength when glass-ceramics are heat treated to increase the grain size.

Recently, glass-ceramic materials with exceptionally fine-scale microstructures have been reported at an increasing rate. In most of the original work by Stookey, crystal sizes in the range of 0.1–20 μm were reported. Although such materials have great utility in a wide range of applications, certain advantages can be realized when the crystal size is further reduced to the nanoscale (<100 nm). Primarily, with a nanoscale crystal size, one can access advantageous combinations of high mechanical performance and improved optical transparency for many compositions. As mentioned, glass-ceramic materials in general are characterized by much higher strength, fracture toughness, and thermal shock resistance than their glass counterparts. However, glass-ceramics take on even more value when their optical properties can be tailored for certain applications. The rapid growth in the use of glass ceramic materials in cooktops, following a migration from opaque β-spodumene to transparent β-quartz glass-ceramics, is an example. In the latter case, optical transparency is achieved mainly through index of refraction matching and low birefringence for the crystalline phase, although a small crystal size of around 100 nm is achieved.

A good example where a unique combination of mechanical and optical properties has been achieved in a nanophase glass-ceramic material relates to high index of refraction beads or microspheres. 3M has recently patented transparent nanophase glass-ceramic microspheres that include comparatively large amounts of ZrO_2 and TiO_2, with index of refraction values that can exceed 2.0.[66–68] The materials are particularly useful as exposed lens elements in durable retroreflective pavement markings. Without index matching between the crystal grains and the surrounding glass phase, within the microspheres, these materials rely on ultrafine crystal size for transparency. Useful beads comprise crystal grains, with a size usually smaller than 20 nm. Other new nanophase glass-ceramic materials from 3M have been reported with ternary rare-earth-oxide-Al_2O_3–ZrO_2 compositions.[69] The glasses are formed with near-eutectic compositions, and can be devitrified with nanoscale grain structure and exceptional mechanical properties, including very high hardness. At the same time, optical transparency is preserved.

There are other examples of glass-ceramic materials that are crystallized to develop a particular property, but crystallized specifically with nanoscale grain structure to preserve optical transparency. Transparent oxyfluoride glass-ceramics with exceptional optical frequency upconversion were first reported by researchers at Sumita Optical Glass and NTT Opto-Electronics Laboratories in 1993.[70] Since that time, research at Corning and elsewhere has further proven the potential utility of the materials, which comprise a nanoscale dispersion of doped lead or rare earth fluoride crystals in an aluminosilicate matrix.[71] The nanophase glass-ceramics are preferred to competing materials, like simple glasses and single crystals. Nanophase glass-ceramics offer the outstanding fluorescence properties of an active rare earth doped fluoride, with their low phonon coupling losses, together with mechanical and chemical durability of an aluminosilicate glass, which derives from the residual matrix after devitrification.

Nanophase glass-ceramics, being nanocomposite materials, offer the potential to achieve unique combinations of properties that have not been demonstrated in other materials systems. Most significantly, small feature sizes in the multiphase microstructures can lead to optical transparency. At the same time, an interaction between phases, or a functional phase itself, can impart additional properties, such as high strength. Just as glass-ceramics in general have experienced extensive technical development and commercial application since their invention half a century ago, the advancement and the use of nanophase glass-ceramics

in particular can be expected to grow substantially over the coming years.

CONCLUSIONS

The capability to controllably engineer discrete nanoscale particulate domains in a material is a powerful tool for accessing new and unique material properties that enable innovative industrial applications. It is expected that research and development work on nanomaterials will continue to increase and numerous new applications will be identified.

Nanoporous Dielectric Materials

Jorge A. Lubguban
Shubhra Gangopadhyay
University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

A solid, liquid, or gas that exhibits poor conductivity of electricity is generally considered as dielectric material. Examples of such material include porcelain, mica, glass, plastics, and metal oxides, which have a wide range of dielectric constants (k). The dielectric constant relates to the capacitance enhancement over that of a vacuum. In microelectronics, dielectric materials are simply called dielectrics. They are used as insulation between metal interconnect and as passivation layers. The insulation capability of a material is determined by its breakdown strength. Low dielectric constant materials have a high breakdown strength and the ability to withstand intense electrostatic field. Nanoporous dielectric materials are related to microelectronics and are material candidates for future dielectrics. The semiconductor industry needs to continuously improve performance and speed in ultra-large-scale integration devices has motivated researchers to look into nanoporous dielectrics as a replacement of the standard SiO_2 material.

HISTORY OF DIELECTRIC MATERIALS

Since the invention of integrated circuits (ICs) in 1959, the progress of this technology has been extremely fast paced.[1] Advances in device fabrication, such as lithography, etching, and film deposition, in over four decades have brought extraordinary increases in IC complexity together with tremendous improvement in chip performance. The main factor driving this complexity and improved performance is the ability to scale down device dimensions into the microscopic regime. This can be illustrated by the continued shrinking of the transistor gate lengths from 7 μm to submicrometer levels today, facilitating the decrease in gate delays to negligible levels as well as the increase in transistor density. The number of transistors in a single microprocessor chip if plotted as a function of time from 1970 to 2000 traces a semilog behavior and follows a trend that roughly doubles the number of transistors every 18 mo.[1] The regular doubling of transistors is known as Moore's law. Fig. 1 illustrates Moore's law for IC.[1] It shows an exponential increase in the transistors per chip as a function of time for different generations of microprocessors. Advanced semiconductor chips are estimated to have more than 0.5 billion transistors and require over 10,000 m of wiring distributed over six to eight levels.[2]

As devices are continually scaled down to satisfy the ever-increasing demand for speed, it is recognized that device physics will not be the first limiting factor for performance improvement.[3] The main hindrance lies in the back end of the line (BEOL), which consists of metal interconnect and dielectric materials. The metal lines are responsible for transmitting electrical current and distributing clock signals that control the timing and synchronize the operation, whereas the dielectric materials are used as insulation. As feature size (generally the metal oxide semiconductor field effect transistor channel length) decreases below 0.1 μm, the BEOL interconnect resistance–capacitance (RC) delay, power dissipation, and cross-talk noise increase significantly.[4] The RC delay is given by the following equation:

$$\mathrm{RC}_{\mathrm{delay}} = 2\rho\varepsilon_0 k\left[(4L^2/P_{\mathrm{m}}^2) + (L^2/T^2)\right] \quad (1)$$

where ρ = interconnect resistivity, ε = permittivity free space, k = dielectric constant of insulator, L = total line length, P_{m} = metal pitch, and T = metal thickness. The power consumption, P, is given by:[3]

$$P = \alpha C f V^2 \quad (2)$$

where α = wire activity, C = capacitance, f = frequency, and V = voltage. With the increase in L and f and decrease in T and P_{m}, both $\mathrm{RC}_{\mathrm{delay}}$ and P increase. To address these issues, alternative materials must be used for BEOL. The standard for BEOL materials (Al and SiO_2) needs to be replaced with low-resistivity metal and low-dielectric constant materials. The successful implementation of Cu as replacement for Al has resulted in a decrease in $\mathrm{RC}_{\mathrm{delay}}$ by as much as 37% because of the lower resistivity of Cu. Fluorinated silicon dioxide films with k value from 3.2 to 3.6 have been successfully integrated at the 180 nm node replacing SiO_2 dielectric with $k = 4.0$.[5] Organosilicates with dielectric constant of 2.6–2.8 deposited by current chemical vapor deposition (CVD) tool have also been introduced and developed with Cu technology.[6]

Dielectric materials with even lower k values are needed for future generation IC devices. The International Technology Roadmap for Semiconductors projecting the overall technology requirements since 1994 suggested that for technology nodes of less than 65 nm, materials with $k < 2.1$ are needed. As a limited number of fully dense materials satisfy $k < 2.5$, researchers have focused on the preparation of porous films. The ability to tailor the degree of porosity, size, and shape of pores offers versatility and extendability from one generation to the next, which makes porous films attractive candidates. Fig. 2 shows the dielectric constant for methylsilsesquioxane (MSSQ) (discussed later) film vs. the pore volume fraction, V, as obtained from Bruggeman-effective-medium approximation. The figure shows that we can decrease the dielectric constant by tailoring V.

NANOPOROUS DIELECTRICS DEFINITIONS

The most common characteristic of a porous material is its gas–solid interphases.[7] Historically speaking, porous materials are defined in terms of their adsorption properties.[8] The pore sizes of the materials are frequently characterized from their gas adsorption isotherm, i.e., the amount of gas adsorbed by the material at a fixed temperature as a function of pressure.[9] The International Union for Pure and Applied Chemistry (IUPAC) has proposed to classify porous materials in terms of these isotherms. Nanoporous materials

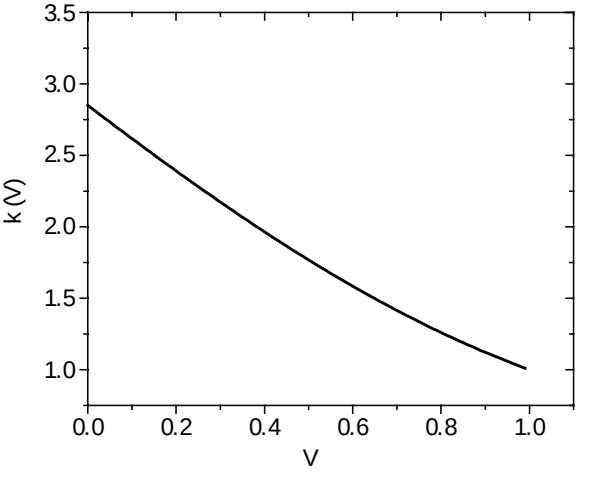

Fig. 2 Bruggeman effective medium approximation of a two-component film of a PMSSQ ($k = 2.85$) and air ($k = 1$).

pertain to those with pore sizes in the nanometer range of 1–1000 nm. However, for practical semiconductor applications pore sizes of interest must be significantly smaller than current feature sizes. The IUPAC defines pore diameters as follows: micropores as having 0–2 nm-diameter pores; mesopores as having 2–50 nm-diameter pores; and macropores as having greater than 50 nm-diameter pores.[10] Pores can be classified as closed or interconnected. Further classifications are in terms of network material, which can be inorganic or organic, and also in terms of being ordered or disordered.[7] Nanoporous materials can be characterized by gas adsorption methods, mercury porosimetry, small-angle x-ray scattering (SAXS), small-angle neutron scattering, positron annihilation lifetime spectroscopy, and electron microscopy methods like scanning electron microscopy, and transmission electron microscopy (TEM).[3,8,11]

PREPARATION OF NANOPOROUS DIELECTRIC MATERIALS

Thin film dielectrics are usually deposited using chemical vapor deposition (CVD). A variation of CVD utilizing a plasma discharge is called plasma-enhanced CVD (PECVD) and is the standard in IC fabrication for the deposition of dielectric films. Plasma-enhanced CVD involves the formation of a solid film in a substrate surface from volatile precursors (vapor or gas) in a plasma discharge. The precursors are chosen to contain the constituent elements of the final film and chemical reactions in the gas phase are encouraged. They are condensed in a substrate that is heated or cooled. It will be shown later that porosity can be introduced in the PECVD films. Spin coating is another preparation technique and a popular choice in future nanoporous dielectric materials. In spin coating, a solution (in soluble form or ''sol'') is prepared containing the material constituents of the final film mixed with a compatible solvent. The succeeding important steps are spinning, baking, and curing. Typical rotational speeds are 2000–6000 rpm. The bake step, typically below 200°C, expels the solvents and the final step called cure, done typically above 200°C, hardens the film via cross-linking or polymerization. The final thickness of the film depends on the fluid viscosity and density, rotation speed, rate of evaporation, and other factors. The initial amount of solution has little effect on the final thickness. Both CVD and spin-coating methods produced films with good planarization and gap fill properties.

REQUIREMENTS FOR DIELECTRIC MATERIALS

The most important requirement for future dielectric material is low dielectric constant. However, this is hardly the main requirement. Researchers have routinely shown films with k-values lower than 2.0 but these are not feasible from the point of view of manufacturing. The International Technology Roadmap for Semiconductors, which assessed the overall technology requirements for future microelectronic devices, has projected that no manufacturable dielectric with $k < 2.4$ will be found until 2007.[12] The main challenge lies in the integration of these films, which undergo harsh conditions in IC fabrication. Table 1 enumerates important properties of candidate materials.[13] The candidate material should not only satisfy these requirements, but also must have versatility and extendability for a future generation of nodes to be cost-effective.[4]

Table 1 Property requirements of low-dielectric-constant interlayer-dielectric materials

Electrical	Chemical	Mechanical	Thermal
k, Anisotropy	Chemical resistance	Thickness uniformity	High thermal stability
Low dissipation	Etch selectivity	Good adhesion	Low coefficient of thermal expansion
Low leakage current	Low moisture	Low stress	
Low charge trapping	Absorption	High hardness	Low thermal shrinkage
High electric-field strength	Low solubility in H_2O Low gas permeability	Low shrinkage Crack resistance	Low thermal weight loss High thermal conductivity
High reliability	High purity No metal corrosion Long storage life Environmentally safe	High tensile modulus	

(From Ref.[13].)

FACTORS AFFECTING THE DIELECTRIC CONSTANT

The dielectric constant of a material depends primarily on its polarizability and, hence, strongly depends on density. The three types of polarization that contribute to the dielectric constant are electronic, ionic, and orientational polarizations and are given by the Debye equation[3]

$$\frac{\varepsilon_r - 1}{\varepsilon_r + 2} = \frac{N}{3\varepsilon_0}\left(\alpha_e + \alpha_d + \frac{\mu^2}{3kT}\right) \quad (3)$$

where α_e is the electronic polarization, α_d is the ionic polarization, and $\mu^2/3kT$ is the permanent dipole contribution.

To obtain low k, these three polarizations are kept as low as possible. An obvious way to have low polarizations is reduction of the density of the material (N). The lower density will decrease the number of polarizable species in the films and thus results in a lower dielectric constant. This is done by incorporating low molecular weight molecules, space occupying molecules, inherently open structures, and, more significantly, introducing porosity. This entry presents an overview of nanoporous dielectric materials. This overview is not exhaustive because new materials are being developed as this entry is written.

NANOPOROUS DIELECTRIC MATERIALS AND PORE GENERATION METHODS

Nanoporous dielectric materials in microelectronics are inorganic, organic, or hybrids. Silsesquioxane (SSQ)-based, silica-based, and organic polymers are well studied. There are many dense materials that exhibit molecular porosity because of their inherent open structure and also because of incorporation of space occupying structures like methyl groups that provide steric hindrance. These materials will be mentioned here as they are a popular matrix host for the introduction of porosity. Maex et al. have classified two routes for fabrication of nanoporous materials as constitutive and subtractive.[3] In subtractive route, less stable materials from a stable matrix are removed selectively by different processes to produce a porous material. This is an effective method in producing porous materials with tunable porosities. Examples of constitutive porous materials are CVD and spin-coating organosilicate films. In these, methyl structures provide steric hindrance and open structures creating molecular-level porosities. The addition of sacrificial material or porogen (pore generator) in a film matrix is the most widely used technique in subtractive pore generation. Basically, it relies on incorporation of a thermally degradable material within a thermally stable matrix. The sacrificial material is removed usually by thermal degradation and volatilization to produce a porous structure. There are other techniques that will be shown later to remove the sacrificial material. One can use inorganic, organic, and hybrid materials in this approach. The availability of pore generators with different morphologies and the ability to vary the precursor ratios provide versatility and control not only the pore size and pore distribution but also the pore shape of the film.

BLOCK COPOLYMERS

A block copolymer is composed of chemically distinct and mutually incompatible homopolymer segments, and is covalently joined at the ends. It can be synthesized through different chemical pathways, typically, anionic polymerization. This type of polymerization is initiated by nucleophilic addition to two double bonds of the monomer. In the case of linear AB block copolymer synthesis, a nucleophile or a carbanion can originate from an organometallic species such as alkyl lithium or Grignard reagents (initiators). The carbanion now reacts with another monomer molecule on sequential monomer addition and at this point an appropriate terminating agent is added. To fabricate a nanoporous material, a thermally degradable polymer block is used with another block that is thermally stable to act as the matrix. The polymers are mixed with a casting solvent and spin coated to a substrate. The precursors form block copolymers and undergo self-assembly, where the thermally degradable block is surrounded by the thermally stable block by manipulating precursor ratios. The film is then annealed at higher temperatures, but below the glass transition temperature (T_g) of the matrix, to volatilize the thermally degradable block producing a nanoporous dielectric. Matrix polymers must have good dielectric properties and a higher T_g when compared with the decomposition temperature of the sacrificial polymer. Suitable matrix polymers enumerated by Hedrick et al. include polyimides, poly(phenylguinoxalines), poly(benzoxazoles), poly(benzimidazoles), poly(triazoles), poly(oxadiazoles), and poly(benzothiazoles).[14] For the thermally decomposable oligomers, poly(propylene oxide), poly(methylmetharcrylate), and aliphatic polycarbonates like poly(propylene carbonate) and poly(ethylene carbonate) can be used.[14] Common organic casting solvents include tetrachloroethane, *N*-methylpyrrolidone or γ-butyrolactone. An illustration scheme for producing nanopores via block copolymers is shown in Fig. 3 where poly(propyleneglycol) (PPG)–polyimide–PPG triblocks are used as building blocks

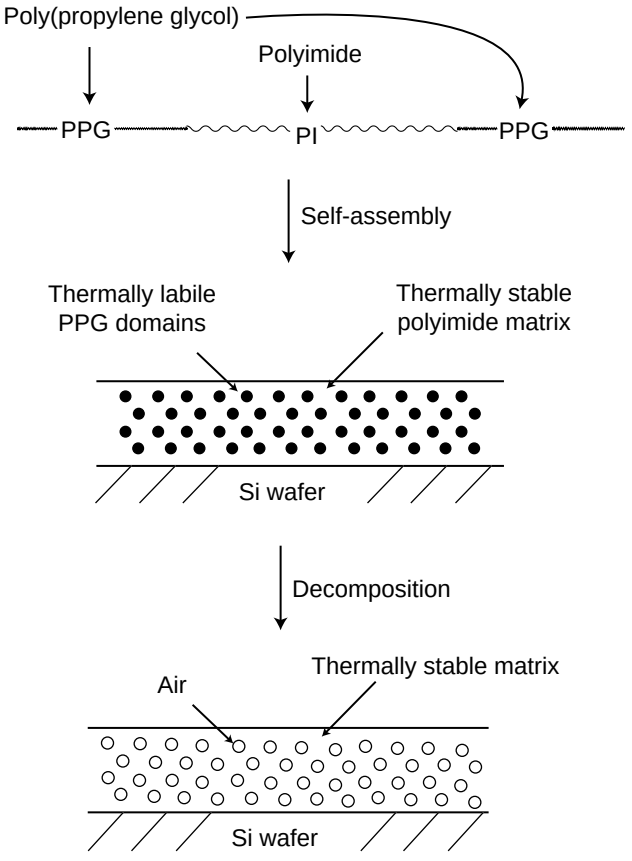

Fig. 3 Schematic representation of the self-assembly of block copolymers to give porous dielectric materials. (From Ref.[15].)

for self-assembly.[15] The weight percent of the polyimide matrix is increased relative to PPG to form nanoscopic domains of PPG surrounded by polyimides. The PPG is then removed by thermal decomposition and volatilization at a temperature below the glass transition (T_g) of the polyimide to prevent collapse of matrix. This process leaves behind pores (typically 5–10 nm), which take the morphology of the sacrificial block.[16] This successful approach has drawbacks because of the low inherent T_g of the matrix polymer, low hardness, and non-cross-linking of the organic matrix, which is prone to collapse. This approach has been extended to inorganic–organic hybrid materials.

SOLVENT AS POROGEN APPROACH

Another variation of sacrificial material technique to produce porous materials with less than 30 nm pore diameter and less than 10 μm thickness is using a high-boiling point solvent as the templating material.[17,18] This solvent is mixed with a low-boiling point solvent and then used as solvents for the polymer material that acts as the host matrix in the final film. Typically, the low-boiling point solvent has a volatilization temperature of less than 100°C and the high-boiling point solvent, a temperature greater than 150°C. After spin casting, the film is partially dried to expel a large amount of low-boiling point solvent. The film is then put into contact with a chemical, which is miscible to the high-boiling point solvent but immiscible to the polymer to induce nonsolvent phase separation in a process called phase inversion. The film is then annealed to completely remove the solvents and toughen the matrix producing a porous material. Cross-linking of the polymer matrix before or after phase inversion may be done by ultra violet or chemical processes. O'Neill et al. provided polymer precursors, such as poly(arylene ethers), polyimides, poly(phenyl quinoxalines), substituted poly(*p*-phenylenes), poly(benzobisoxazoles) polybenzimidazoles, polytriazoles, and mixtures thereof.[18] The low-boiling point solvents includes tetrahydrofuran, acetone, 1,4-dioxane, 1,3-dioxolane, ethyl acetate, methyl ethyl ketone, cyclohexanone, cyclopentanone, and mixtures thereof. The high-boiling point solvent can be selected from dimethylformamide, dimethylacetamide, *N*-methyl pyrrolidone, ethylene carbonate, propylene carbonate, glycerol and derivatives, naphthalene and substituted versions, acetic acid anyhydride, propionic acid and propionic acid anyhydride, dimethyl sulfone, benzophenone, diphenyl sulfone, sulfolane, phenol, *m*-cresol, dimethyl sulfoxide, diphenyl ether, terphenyl, cyclohexanone, cyclopentanone, and mixtures thereof.[2] The nonsolvent (immiscible to the polymer matrix) for the polymers can be selected from the group consisting of water, methanol, ethanol, isopropanol, toluene, hexane, xylene, cyclohexane, butanol, cyclopentane, octane, and mixtures of these solvents.[18]

NANOPOROUS SILICA VIA SOL–GEL TECHNIQUE

Silica in the form of thin films as well as oxide monoliths, fibers, and powders can be prepared from sol–gel method. In contrast with the fabrication of conventional inorganic glasses at much higher melting temperature, sol–gel processing is performed at low temperatures to produce oxide materials with desirable hardness, optical transparency, chemical durability, tailored porosity, and thermal resistance.[9] The sol–gel method involves formation of a colloidal suspension (sol) and gelation to form a network in a continuous liquid phase (gel). One starts with an aqueous solution containing oxides or alkoxides, mutual solvent, and catalyst. Usually an external catalyst is added like mineral acids and ammonia as well as acetic acid, KOH, amines, KF, and HF for rapid and

complete hydrolysis. The most widely used alkoxides are tetramethoxysilane (TMOS) and tetraethoxysilane (TEOS), because they readily react with water. However, other alkoxides like aluminates, titanates, and borates are also used. Alkoxides and water are not miscible, hence we use a mutual solvent like alcohol. The general reactions involved in sol–gel are hydrolysis and condensation. If an alkoxide precursor is used, a general scheme to produce silica can be written as:[7]

$$Si(OR)_4 \xrightarrow{H_2O} [Si(OH)_4] \longrightarrow SiO_2 \quad (4)$$

The hydrolysis reaction replaces the alkoxide groups (OR) with hydroxyl groups, after which condensation reactions involving the silanol groups (Si–OH) occur to produce siloxane bonds (Si–O–Si). The condensation reactions form a soluble high molecular weight polysilicate (a sol) and these polysilicates link together to form a three-dimensional network, whose pores are filled with solvent molecules (a gel).[9] If the liquid in the gel is removed without collapsing the structure, a highly porous and extremely low-density material can be obtained. Thin films can be produced by spin-coating or dip-coating the sol in a substrate. The spin coating is divided into four stages: deposition, spin-up, spin-off, and evaporation.[19] Gel aging and drying after the spin-coating step are the two most critical steps in sol–gel thin film processing. Drying usually involves shrinkage, implying reduction in pore volume and pore sizes and possible pore collapse. Shrinkage during drying must not occur to prevent cracking, pullout, adhesive loss, and delamination in the patterned substrate. Generally, the film must gel first before drying to prevent collapse. There are two routes of drying: if the film is dried by solvent evaporation, it is called xerogel and if dried supercritically, it is called aerogel. The final stage of sol–gel processing is heat treatment. The organics and adsorbed solvents burn off at temperatures of about 400°C. Fig. 4 is a simple illustration of sol–gel silica formation in thin films.

The porosity of the film can be tailored during initial stages and other processing conditions. The initial factors include pH (acid- or base-catalyzed), temperature of reaction, reagent concentrations, and H_2O/Si molar ratio. The processing conditions that affect the porosity are aging, temperature, and time of drying.[20] For example, silica xerogels processed under acidic conditions display characteristics of microporous materials, while those processed under basic conditions display mesoporous characteristics. Silica materials with porosity of 2–80 nm with a variety of pore shapes can be obtained by sol–gel method.[21] The acceptance of this technology is hampered by elaborate processing conditions and the hydrophilic nature of the pores, which leads to increased dielectric constants.[21]

NANOPOROUS SILICA VIA SURFACTANT-TEMPLATING APPROACH

The semiconductor industry has recognized the potential of silica mesophases for use as dielectrics, because it is built on the idea of true templating.[22] Here, the final pore size and geometry of the material are a direct resemblance of the initial surfactant array size and shape. In the fabrication of these bulk materials, the pore geometry can be controlled primarily by the concentration of surfactant in the solution as shown in Fig. 5 and also by the processing conditions.[22] The pore size is controlled by the length of surfactant, addition of auxiliary organics, choice of solvent, template removal method, aging conditions, processing conditions, and postfunctionalization of the isolated porous material.[22] However, there is difficulty in controlling the film formation process of this material. The basic process that will be presented here is based on fabrication of bulk material. It is recognized that film formation is different and the mechanism is complex and not yet well understood.

This technique uses surfactant as organic templates for the inorganic network to build on. The surfactants are molecules with a hydrophilic head group and a hydrophobic tail. They can aggregate into micelles with different supramolecular structures like spherical, cylindrical, hexagonal closed-packed liquid crystal, and cubic bicontinuous shapes depending on its concentration in the solution. The fabrication of mesoporous silica is a three-step process that includes synthesis, drying, and template removal. In film formation, a solution is made, spin-coated into a substrate, and then dried after which the template is removed. The synthesis of mesoporous silica requires a silica source, surfactant, water, and catalyst. The silica source acts as the inorganic network and conforms to the template, because it is precondensed initially. The reaction

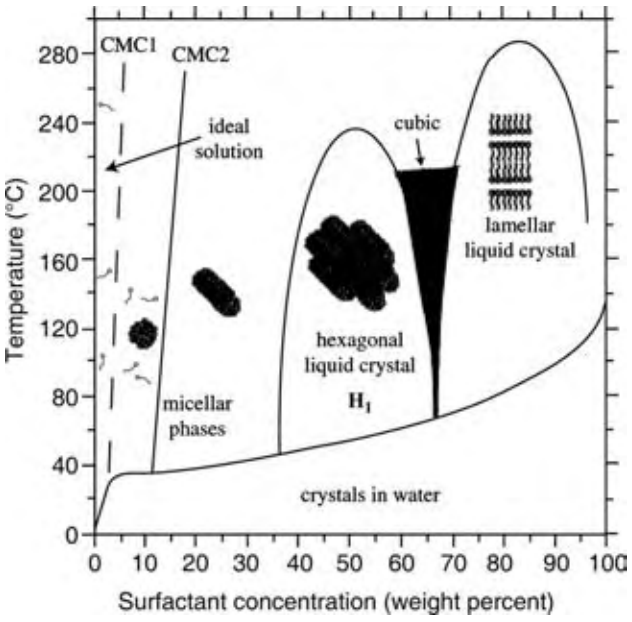

Fig. 5 Schematic phase diagram for C_{16} TMABr in water. CMC1 is increased to a higher concentration. (From Ref.[22].)

between the network and templating materials is via electrostatic, van der Waals, and hydrogen bonding interactions. Examples of nonmolecular silica sources are fumed silicas, precipitated silicas, or water glass, whereas molecular silica sources are alkoxysilanes, such as TEOS or TMOS. There are varieties of surfactants with different sizes, shapes, functionalities, and charges. Examples include sulfates, sulfonates, phosphates, carbolyxic acid, alkyllammonium salts, gemini surfactant, cetylethypiperidinium, and bichain salts, primary amines, poly(oxyethylene oxides), and octaethylene glycol monohexadecyl ether.[23–27] Surfactant concentrations can be as low as 0.5 wt% and typically 15–30 wt%. After synthesis, the films are dried to polymerize the inorganic silica and remove the solvents. There are several methods to remove the template and these are solvent extraction, calcination, oxygen plasma treatment, and supercritical extraction.[22] Acidic ethanol has been used to extract the organic template. Chen, Li, and Davis also reportedly removed 100% of the organic material in MCM-41 using HCl at 70°C for about 30 hr.[28] Pure ethanol has also been used, but extraction is only 85%.[29] Calcination of MCM-41 has been done in flowing N_2, O_2, and air at 540°C.[30,31] In spin coating, a preferential evaporation of the solvent increases the surfactant and silica concentrations in the film and the surfactant start to self-assemble into micelles, while the silica begins to vitrify around the supramolecular structures.[32] The self-assembly during the formation of the film is a complex process governed by the interactions at the interphases between organic and inorganic phases in the films.[33] The self-assembly and silica formation mechanisms are said to occur simultaneously during the removal of alcohol from the thermodynamic equilibrium.[34]

ORGANOSILICATES, SSQs-BASED MATERIALS, AND THEIR INORGANIC–ORGANIC HYBRIDS

One type of material that is being developed for low-k applications is organosilicate film.[35–37] Basically, the structure of this material is composed of a silicon–oxygen backbone with methyl (CH_3) incorporation. The methyl groups make a robust structure leading to a less dense film and may result in a lower k. For PECVD organosilicate films, deposition is done using either SiH_4/hydrocarbon gas mixtures or liquid sources. Published reports using liquid sources as deposition precursors show films with low k, good gap-filling capability, and high thermal stability. In the study conducted by A. Nara and H. Itoh, tetramethylsilane [$Si(CH_3)_4$ (TMS)] was used as a liquid precursor with O_2 gas and the result is a film having a value of k below 3.0 after annealing at 500°C.[36] Uchida et al. produced a OH-free organic silica using tetra-isocyanate-silane, $Si(NCO)_4$; di-methyl silyl di-*iso*-cyanate silane, $(CH_3)_2Si(NCO)_4$; tri-methyl amine, $N(CH_3)_3$; and di-methyl ethyl amine, $N(CH_3)_2C_2H_5$.[38] Siloxane-based materials also discussed below are chemically stable against thermal decomposition and moisture absorption. One such material utilized as a precursor for PECVD is hexamethyldisiloxane [$(CH_3)_3SiOSi(CH_3)_3$], which can be mixed with O_2, CF_4, and toluene ($C_6H_5CH_3$).[39,40] The result is a film with a low dielectric constant and the value decreased with annealing and/or addition of flourine. Precursors like tetravinyltetramethylcyclotetrasiloxane [TVTMCTS (ATMI)] have been investigated by this group. The structure of the liquid is a cyclic Si–O with methyl and vinyl groups attached to Si. Some organosilicates (OSG) precursors enumerated by Laxman include methylsilane, $(CH_3)SiH_3$; dimethylsilane, $(CH_3)_2SiH_2$; trimethylsilane, $(CH_3)_3SiH$; TMS, $(CH_3)_4Si$; dimethyldimethoxysilane; and 1,3,5,7,-tetramethyltetrasiloxane.[39]

Some OSG films by PECVD available from several manufacturers are as follows:[41] 1) Applied Materials (Santa Clara, CA) —Black diamond I and II, $k = 2.4$–3.1; 2) Novellus Systems (San Jose, CA)—CORAL, $k = 2.2$–2.8; 3) Trikon Technologies (Newport, U.K.)—Flowfill CVD, $k = 2.8$; 4) ISMT PECVD solutions, $k = 2.2$; and 5) ASM International (ASMI, Bilthoven, Netherlands), $k = 2.7$.

For spin coating films:[41] 1) Dow Chemicals (Midland, MI)—SiLK, $k = 2.65$, Dow Corning (Midland, MI)—Fox HSQ, $k = 2.9$, XLK porous HSQ,

$k = 2.0$; 2) JSR—MSQ, $k = 2.7$, porous film, $k = 2.0$–2.2; 3) Air Products—MesoELK, $k = 2.2$; and 4) Honeywell Electronics materials (Sunnyvale, CA)—Nanoglass, $k = 2.0$.

Silsesquioxane refers to structures with an empirical formula of $RSiO_{3/2}$ where R is H or any alkyl, aryl, arylene, or organofunctional derivatives of alkyl, aryl, or arylene groups. There are different structures of SSQ and these are random, ladder, and cage structures, as shown in Fig. 6.[42] The ladder and cage structures are preferable because of the inherently open structure. This material is hydrophobic because of the methyl end groups, which are nonpolar. The fully cured SSQs have many good qualities for application to interlayer dielectric (ILD)-like excellent thermal stability greater than 400°C, k value equal to 2.85, low dielectric loss, good electrical properties, low moisture absorption, etc. Two SSQs that are used in microelectronics are hydrogen silsesquioxane (HSQ) and methylsilsesquioxane (MSSQ). Hydrogen silsesquioxane has H as the termination element with a dielectric constant of 3.0–3.2 and MSSQ has CH_3 end group with $k = 2.8$.[3]

To obtain an even lower k, porosity is introduced to MSSQ by incorporating preformed organic materials by "reactive blending."[43,44] This also utilizes the concept of sacrificial-porogen technique. It is an improvement of block copolymer, because silica-based matrix materials are used. Its advantages are compatibility with current fabrication processes and the ability to withstand rigorous requirements of the semiconductor industry. The process is to develop an inorganic–organic, nanophase-separated, hybrid material and subsequent removal of the organic material by thermolysis to produce nanoporous film. To form nanoscopic domains, preformed macromolecular porogens with controlled structure and architecture are used. The organic macromolecule must be tailored to have strong reactive sites capable of bonding to the silicate matrix, and hence, the concept of reactive blending. This chemical bonding and other matrix–template interactions like hydrogen bonding will significantly prevent the mobility of the organic phase until the polymer mobility is restricted by matrix vitrification. It also prevents macromolecule aggregation and hence, avoids macrophase separation. Thus, the sacrificial polymer must be chosen to have several end groups. The matrix must have low molecular weight and a lot of functional groups to have a low dielectric constant. The inorganic–organic precursors are dissolved in a common solvent, spin-coated, and then prebaked to remove the solvent. The inorganic–organic hybrid undergoes another annealing stage, where the matrix vitrifies without decomposition of the organic phase. Then, the sacrificial organic material is removed by thermal decomposition and volatilization, whereby the matrix further cross-links. Fig. 7 shows a schematic diagram of this technique.

IBM has prepared a number of architecturally defined star-like, dendrimeric, and hyperbranched polycaprolactones from functionalized core molecules as porogen macromolecules.[44] Short linear chains of polycaprolactone are attached to the chain ends of the starting dendrimers like dendritic polyesters derived from 2,2-bis(hydroxymethyl)propionate. The degree of polymerization of the linear blocks could be accurately controlled simply by varying the ratio of ε-caprolactone to the dendrimer. The number of branches could be varied from 6 to 48 by controlling the size or generation number of the dendrimer. The precondensed SSQ and the porogen are usually dissolved in a common solvent, such as propylene glycol monomethylether acetate (PM-acetate) and then spin coated. The matrix resin vitrifies at temperatures above 150°C, whereas the porogen start to decompose from 300°C. As stated above, it is important that the matrix stiffens first before decomposition and volatilization of

the porogen. The amount of various components was varied to generate different porosities with decreasing k from 2.7 to 1.65, as the amount of dendrimers was increased from 0 to 40 wt%.[15] Rajagopalan et al. have shown removal of PPG pore generator in an MSSQ matrix via an alternative route to annealing, which is supercritical CO_2 ($SCCO_2$).[45] Here, the porogens are extracted from the matrix by the ability of $SCCO_2$ to penetrate the packed matrix structure, dissolve the porogens, and remove it from the matrix via depressurization. The extraction was found to be also effective in the production of inorganic–organic hybrid nanoporous material. Fig. 8 shows TEM micrographs of two porous films with open- and closed-pore morphologies processed by $SCCO_2$.[45] The pore distribution of these $SCCO_2$ processed films was shown in Fig. 9 and compared with the thermal removal of the porogens.

NANOPOROUS PLASMA-ENHANCED CVD FILMS VIA ANNEALING AND SUPERCRITICAL CO_2 TREATMENTS

Plasma-enhanced CVD has been the standard for dielectric depositions. Extending its use provides obvious advantage in terms of manufacturing costs. Researchers have shown that nanoporous PECVD films can be obtained by postdeposition treatments. In this method, a composite/dual-phased film consisting of a thermally stable matrix like silicon dioxide or silicon carbide and a less stable material like CH_x is prepared by PECVD.[46–48] In some cases, a non-cross-linked low -molecular weight CF species is incorporated in low-density organosilicate films. Postdeposition treatments of the films like annealing and alternatively applying supercritical CO_2 remove the less-stable materials (CH_x and CF) leaving behind a film with voids/pores and hence, a nanoporous structure.[46–49] The porosity can be tailored by the amount of CH_x or CF incorporation by adjusting precursor ratios and deposition conditions. Grill and Patel have prepared a dual-phased material of SiCOH by PECVD of tetramethylcyclotetrasiloxane (TMCTS) mixed with an organic precursor for the source of CH_x.[47] The TMCTS acts as the host matrix, whereas the organic precursor is the material to be removed. The films were annealed after deposition at 400°C to remove the sacrificial organic material. The results show that the dielectric constant decreases from 2.8 for the nonporous material to 2.05 for the nanoporous material. Measurements of positron annihilation

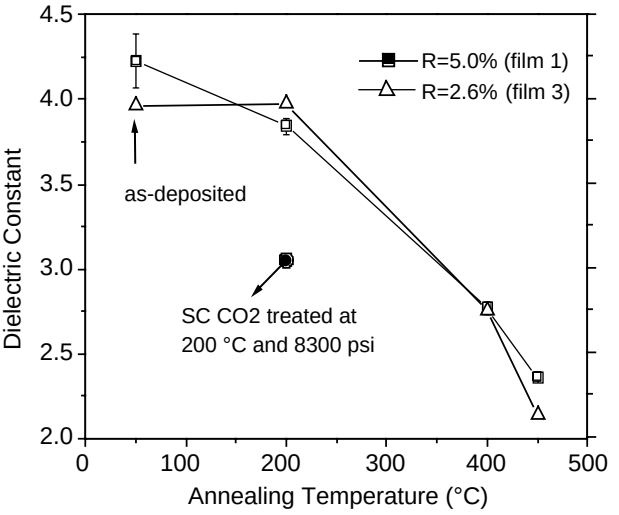

Fig. 11 Effect annealing temperature and $SCCO_2$ treatments on the dielectric constant of Films 1 and 3. *R* stands for gas flow ratio given by $\{[C_4H_{12}Si]/[(C_4H_{12}Si) + (CH_4)]\} \times 100\%$.

spectroscopy and ellipsometric porosimetry show that the annealed films show porosities up to 30–39% for films with *k*-values of 2.05. The pore sizes were measured to be less than 5 nm. A similar strategy is developed by Lahlouh et al.[48] where a-SiC : H films with lots of less stable CH_x and other species were deposited from a diethylsilane liquid precursor and CH_4. The films were deposited at the low radiofrequency power and deposition temperature to deposit a less stable material. The films were then annealed from 200°C to 450°C and also treated with $SCCO_2$ at 200°C. Results show that CH_x, species like the OH group, SiH_n, and C=O were removed by the treatments, possibly leaving voids/pores as shown in Fig. 10. The dielectric constant of the films decreased from 4.2 to 2.1 after 450°C annealing. $SCCO_2$ treatments at 200°C show a more effective extraction of the less stable species. The results are shown in Fig. 11. Lubguban et al. have deposited a nanocomposite film from TVTMCTS and C_4F_8 via PECVD.[49] It was shown that a pure CF film can be removed totally by $SCCO_2$ and pure TVTMCTS film cannot be removed. These facts are used to create a nanocomposite film with stable and less stable parts. The result is a film with a open and stable structure of TVTMCTS with a C : F species that can be removed via supercritical CO_2. Measurements of dielectric constants show decreases to about 10–14%.

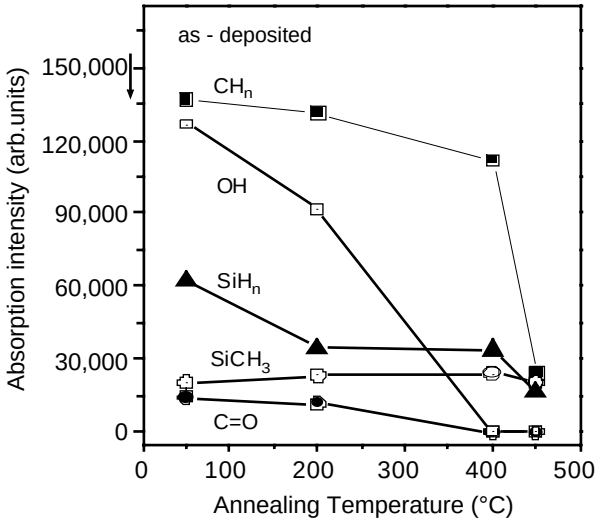

Fig. 10 Effect of the different annealing temperatures on the concentration of C–H_n, –OH, Si–H, Si–CH_3, and C=O bonds in the films.

CONCLUSIONS

In this review, nanoporous dielectric materials have been presented. The preparation techniques, methods of pore generation, and materials classification were discussed. Inorganic, organic, and hybrid films were also discussed. The nanoporous dielectric films were classified by preparation method, which includes block copolymer, solvent as porogen approach, surfactant templating, and sol–gel approach. This is still a very active field of research because no one film has satisfied all the stringent requirements in semiconductor device processing.

Nanostructured Materials

Vikrant N. Urade
Hugh W. Hillhouse
Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Profound changes may occur in the electronic properties of materials as their characteristic length scale is reduced to the nanoscale. These changes affect the optical properties, mechanical response, adsorption behavior, and catalytic properties of the material. The possibility of manipulating the structure of materials at the nanometer length scale to alter these properties has opened up an array of opportunities for the materials science, chemistry, and the engineering communities. Synergistic efforts by researchers in these areas have led to the discovery of a large number of new nanostructured materials. Many of these materials have promising applications in heterogeneous catalysts, molecular-sieve adsorbents, sensors, hydrogen and methane storage materials, solar energy conversion, thermoelectric devices, and magnetic data storage. However, in many cases, these properties are sensitively dependent on the processing conditions.

Because of the explosion in new materials, we introduce a nomenclature scheme to help clarify the field. In general, we define a nanomaterial as any material with a characteristic length scale that is less than 100 nm. This characteristic length scale may be the overall size of the sample (such as a 10 nm diameter particle), or it may be an internal length scale over which the structure varies. The realm of nanomaterials may then be divided into four subcategories depending on the dimensionality of the material (Fig. 1). Thus we reserve the term ''nanostructured materials'' for the materials that are macroscopic in three dimensions but contain internal structure, on the nanometer length scale, of less than 100 nm but greater than 1 nm (this excludes normal crystal structures such as fcc, rocksalt, zinc blende, etc.). This classification thus encompasses an array of materials including zeolites, self-assembled inorganic materials such as mesoporous metal oxides, and self-assembled block-copolymers. If the material is porous and has pores of diameter less than 100 nm, then we classify the material as nanoporous. Historically, porous materials have been classified by the IUPAC as being microporous if the pore dimensions are below 2 nm, mesoporous if they are between 2 and 50 nm, and macroporous if the pore dimensions exceed 50 nm. While the choice of the term ''microporous'' for a material with pores less than 2 nm is unfortunate, this terminology is still heavily used.

There have been many breakthroughs in the synthesis of nanostructured materials in the last 10–15 years, including the synthesis of large pore zeolites with pores larger than 1 nm,[1,2] the discovery of surfactant templated mesoporous materials by the scientists at Mobil,[3] the extension of this templating method to nonsilica systems including transition metal oxides, metals, and carbons,[4–6] and the synthesis of nanoporous metal organic frameworks (MOFs).[7] This entry focuses on the synthesis strategies and the mechanisms involved in the synthesis of nanostructured materials and the processing parameters that are vital for the successful synthesis of these nanostructures. Special emphasis is placed on the synthesis of materials that are closer to applications and are therefore of more immediate technological importance to the process engineer. Further, within the branch of nanostructured materials, materials may be further categorized depending on the synthesis procedures, as illustrated in Fig. 1. This entry also focuses on templated nanostructured materials assembled by the bottom-up approach.

GENERAL STRATEGIES TO SYNTHESIZE NANOSTRUCTURED MATERIALS FROM THE BOTTOM-UP APPROACH

Nanostructured materials can be synthesized from the so-called ''top down'' or ''bottom-up'' approach. In the first approach, features at the micron (or submicron) length scale are created on a substrate by masking and exposing selected regions of a radiation sensitive layer (typically a polymeric photoresist) to a UV source. This exposure is followed by various chemical treatments and mechanical steps to obtain the desired spatial pattern on a substrate. However, the feature sizes that can be obtained with this approach are limited to the length scale of the wavelength of the radiation employed. If features at the nanometer scale are desired, one must start from the bottom (i.e., use individual molecules or clusters) and assemble templates that will impart the nanostructure to the desired material.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018074

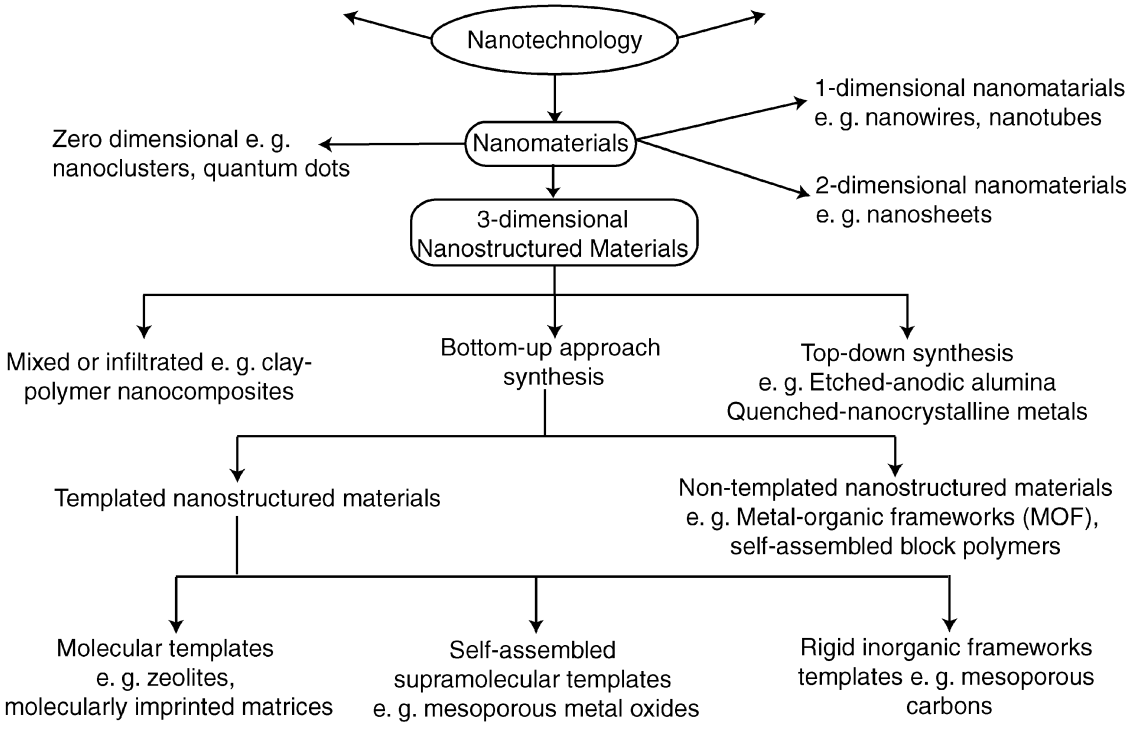

Fig. 1 A schematic illustrating various classes of nanostructured materials based on the synthesis strategies.

Templating Route to Synthesize Nanostructured Materials

The general strategy for the synthesis of nanostructured materials involves the use of templates, which can be ionic, molecular, or supramolecular structures and act as molds. These molds guide the formation of the structure and leave behind porosity when removed by suitable means (if desired). The templating approach allows control over the size and the shape of the resulting pores. In a typical synthesis of a nanoporous metal oxide material, a suitable template molecule (typically an amphiphile) is added to the synthesis mixture. The synthesis mixture contains inorganic precursors that are capable of interacting with the template molecule either via electrostatic or entropic pathways to create an ordered nanostructured assembly of the template and the inorganic material. The composition of the mixture is adjusted such that the desired material self-assembles and phase separates from the mixture. At this stage, the template molecule is occluded in the inorganic framework, directing the nanoscale structure. The removal of the template creates ordered voids in the inorganic framework, whose size and topology are determined by the template used. Template removal is essential for applications of these materials as catalyst supports, adsorbents, or molecular sieves. The inorganic framework must be structurally rigid and capable of supporting itself in the absence of the template.

Types of Templates

Depending on the size and the shape of the pore system desired, the nature of template molecules also varies. Microporous materials are typically synthesized using individual molecules or ions as templates. In this case, these molecules may not constitute the entire template, but may be combined with solvent or water molecules to form the templating species. When larger pore sizes are desired, the templates are supramolecular assemblies of surfactants arranged in various configurations depending on the synthesis parameters. It is also possible to use other porous inorganic materials as templates and create new porous materials inside them. These templates are termed as ''rigid templates,'' as opposed to ''soft'' surfactant templates, which are labile and undergo phase transition in the solution. The words ''endotemplating'' and ''exotemplating'' are also used to indicate the use of surfactant micelles and inorganic porous solids as templates, respectively.

USE OF SINGLE MOLECULES AS TEMPLATES TO SYNTHESIZE MICROPOROUS MATERIALS

The use of single molecules or ions as templates results in materials with the smallest pore sizes (typically less than 1 nm), and hence they are called microporous according to the IUPAC definitions. Most microporous materials synthesized to date are zeolites.

Zeolites are a subclass of microporous materials in which the crystalline inorganic framework is composed of four-coordinated species interconnected by two-coordinated species. Traditionally these materials are aluminosilicates; however, many different compositions have been synthesized.[8] The templates used in the synthesis of microporous materials are typically small ionic or neutral molecular species. The function of the template in the synthesis of microporous materials is little understood, and there are at least four different modes by which an additive can operate in a zeolite synthesis:[9] a) It may act as a space filler occupying the voids in the structure, thereby energetically stabilizing less dense inorganic framework; b) the additive may control the equilibria in the synthesis mixture, such as solution pH or complexation equilibria; c) it may preorganize the solution species to favor the nucleation of a specific structure; d) it may act as a true template determining the size and the shape of the voids in the structure.

Noncrystalline microporous materials may also be synthesized by a technique called molecular imprinting. In this process, a molecular template, called a ''print molecule,'' is used to direct the arrangement of functional monomers around the template, which can then be fixed by chemical polymerization with a crosslinking monomer. This results in the formation of a rigid matrix with the template embedded in it. The removal of the template exposes the functional sites, which can specifically recognize the print molecule or molecules similar to it. This technique can be effectively used to synthesize catalytic and enzymatic hosts having specific interactions with a particular kind of molecule and can be used for separations as well. For a review of molecular imprinting, the reader is referred to Refs.[10–12].

USE OF SELF-ASSEMBLED ARRAYS OF MOLECULES AS TEMPLATES FOR MESOPOROUS MATERIALS

The pore sizes obtained using molecular or ionic templates are restricted because of the small sizes of the templates used (typically less than 15 Å), restricting the accessibility of the internal surface to small molecules. Hence, a great deal of effort has been devoted to the synthesis of materials having pore sizes larger than those in zeolites. In the last decade, progress toward this goal has been made following the discovery of surfactant templated silica by the scientists at Mobil.[3] A variety of materials (silica and nonsilica oxides, carbons, metals, chalcogenides, phosphates, borates, and sulfides) have been synthesized in highly ordered forms having extremely high surface areas ($>1000\,m^2/g$) and narrow pore size distributions, with the pore size tunable all the way from 2 to 30 nm by varying the size of the surfactant and the synthesis conditions. These materials, with pore diameters between 2 and 50 nm, are called mesoporous or mesostructured materials, depending on whether the template has been removed or not. The most well known of these materials is the Mobil family of mesoporous materials (M41S), including a two-dimensional hexagonal mesoporous silica (MCM-41) and a cubic phase mesoporous silica (MCM-48).

The templates used in the synthesis of mesostructured and mesoporous materials can be classified into two categories: The first class of templates includes ''soft'' templates, which are ordered arrays of self-assembled surfactant micelles, similar to the ones used by the researchers at Mobil. Alternately, mesoporous materials can themselves be used as templates to synthesize new mesostructured materials, and such templates can be termed as ''rigid'' templates. In the following sections, we focus on the use of supramolecular assemblies of surfactants as well as on the use of rigid templates as the templates for the synthesis of mesostructured materials.

Self-Assembled Surfactant Templates

Surfactants are amphiphiles and as such have both hydrophilic and hydrophobic portions. If the contrast in the hydrophobicity of the hydrophilic and hydrophobic moieties is strong, then above a certain concentration (critical micelle concentration, cmc) these molecules may self-assemble in solution to form aggregates called micelles. If the concentration is increased further, the micelles may themselves self-assemble into a tertiary structure and form a lyotropic liquid crystalline phase to minimize the free energy of the system. There are three important parameters that characterize the self-assembly process of the surfactant: cmc, aggregation number, and molecular packing factor. Below the cmc, surfactant molecules predominantly exist as monomers in solution. The cmc is experimentally identified as the concentration at which added surfactant starts to enter into an aggregate.[13] The aggregation number is the dominant number of monomeric units in an aggregate. The geometry and the topology of the assembly are affected by the aggregation number, the geometry of the surfactant molecule, concentration of the surfactant, temperature, and the presence of other species in solution. For the effect of the aggregation number on the microstructure of some block copolymers that are commonly used as templating agents, the reader is referred to Ref.[14]. The effect of surfactant geometry can be qualitatively, and in many cases quantitatively, described by making use of the concept of molecular packing factor, g.

Surfactant molecules aggregate into different shapes in solution (spherical, cylindrical, lamellar, spherical bilayer, vesicular, etc.), which result in minimum interaction between the hydrophobic moieties of the surfactant and the polar solvent. The concept of molecular packing factor is useful in visualizing and qualitatively predicting the geometry of the micelles from the known geometry of individual surfactant molecules. Israelachvili et al.[15] proposed the concept of molecular packing parameter and demonstrated how the size and the shape of the aggregate at equilibrium can be predicted from a combination of molecular packing considerations and general thermodynamic principles. The molecular packing factor is defined as:

$$g = \frac{V_0}{a l_0}$$

where V_0 is the volume of the surfactant tail, l_0 the critical length of the tail (not the actual length of a fully extended tail), and a the effective area of the head group at the surface of the micelle. Thus, low values of g result in structures of high curvature, while a value of $g = 1$ has no net curvature. Table 1 summarizes the range of values of the packing factor for which various structures are obtained. The key point to keep in mind is that solution conditions can drastically affect the effective area of the head group. For instance, highly charged metal oxide ions can effectively screen the charge of adjacent head groups, reducing their effective area, and thus increase the packing parameter.

Use of Functional Dendrimers for the Self-Assembly of Nanobuilding Blocks

Chemically well-defined inorganic clusters (often termed as ''nanobuilding blocks'') can be assembled into an ordered array using dendrimers capped with functional groups that can chemically bond with the inorganic clusters. Various metal oxo-based hybrid materials, including Ti- and Ce-based gels, have been synthesized using this synthetic strategy.[16,17]

Table 1 Molecular packing factor values corresponding to various micellar structures

Packing factor, g	Structure obtained
1/3	Spherical
1/2	Infinite cylinders
1	Planar bilayers

Between $g = 1/3$ and $g = 1/2$ or between $g = 1/2$ and $g = 1$, complex phenomena such as formation of aggregates of lower or higher symmetry or phase separation may occur.

Synthesis Strategies

Self-assembled mesostructured materials are typically synthesized from dilute solutions of inorganic precursors and surfactant molecules wherein the self-assembly process occurs through electrostatic and entropic interactions and is a cooperative one. However, in some cases, mesostructured materials are synthesized at much higher surfactant concentrations such that a liquid crystalline phase actually pre-exists in solution, and the inorganic precursor is preferentially accommodated in the hydrophilic domains. This approach, called ''true liquid crystal templating'' (TLCT, route II in Fig. 2), was used by Attard et al. for the synthesis of mesoporous silica, metals, and alloys.[18,19] In addition, there have been several novel synthesis routes developed that utilize inorganic precursors with covalently bonded hydrophobic ligands or take advantage of specific solution interactions such as hydrogen bonding.

Cooperative self-assembly

After the addition of the inorganic precursor, cooperative assembly between the surfactant and the inorganic precursor takes place, leading to the formation of the mesostructure. This approach is similar to the one used by the Mobil scientists and is also the most commonly used one for the synthesis of nonsilica systems, where the control of precursor reactivity demands lower concentrations of the inorganic precursors and hence of the surfactant. In Fig. 2, the formation of a mesostructure by this approach is illustrated (route I).

To help explain this mechanism of the self-assembly process, Stucky and coworkers[20,21] proposed a very useful concept of charge density matching. This concept refers simply to the fact that electroneutrality is maintained locally at the interfaces. At the isoelectric point (IEP) of the inorganic material, the inorganic framework is charge neutral. When the pH is below the IEP, the framework carries a positive charge, and when it is greater, it is negatively charged. The electrostatic interactions between the charged inorganic moieties (I^- or I^+ depending on pH) and the surfactant head groups (S^+ and S^- depending on the type of surfactant, cationic or anionic) lead to the formation of a hybrid interface. The interaction can be direct (S^+I^- or S^-I^+) if the surfactant head groups and inorganic moieties carry opposite charges or they can be mediated by counterions associated with the surfactant ($S^+H^-I^+$ or $S^-H^+I^-$). The shape of the resultant hybrid structure is determined by the balance of charge density between the inorganic moieties and the surfactant head groups. If the charge density of the inorganic framework is reduced, the average head group area of the surfactant assembly increases and the packing

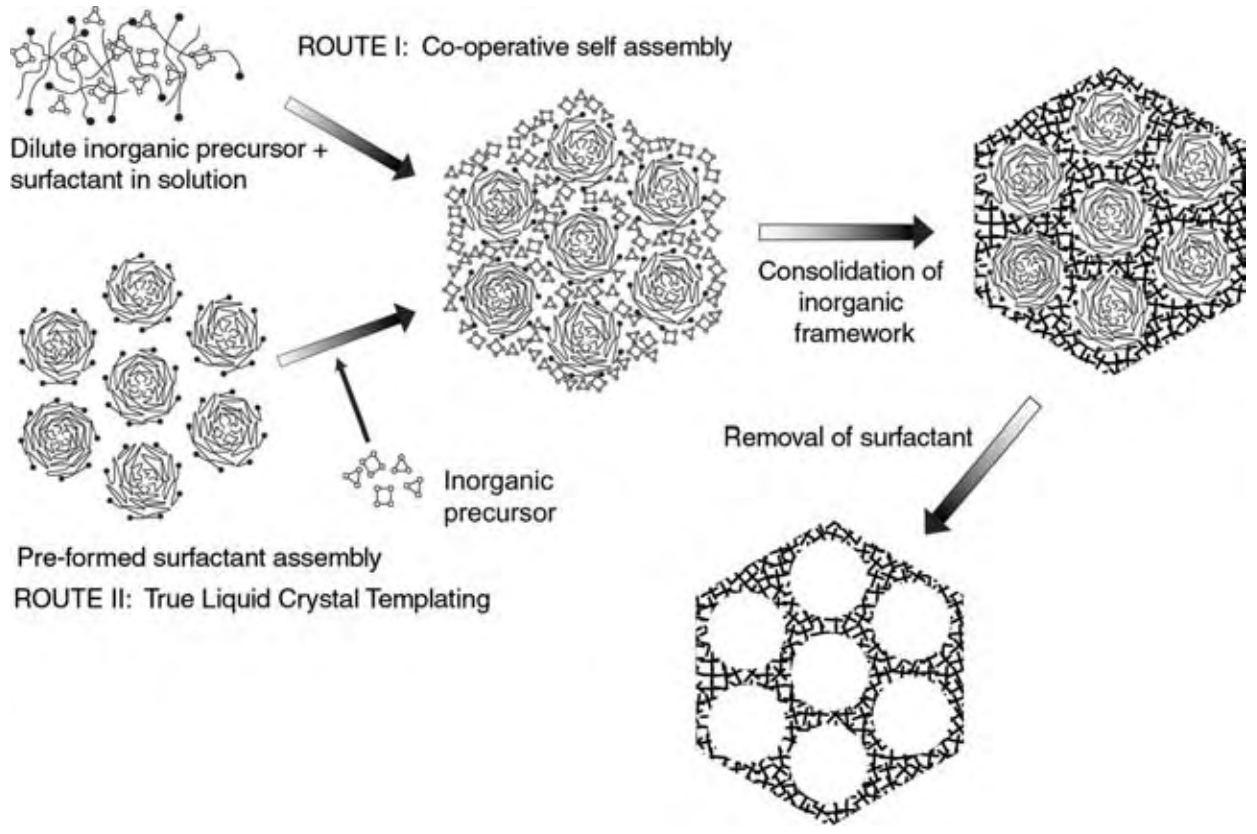

Fig. 2 A schematic illustrating various routes used to synthesize mesostructured materials. Route I: A cooperative self-assembly route relying on the interaction between the surfactant molecules and the inorganic precursors. Route II: TLCT route. The inorganic framework condenses around preformed surfactant micelles in this case.

factor g decreases, resulting in the formation of more curved structures.

In addition to using charged surfactants, Tanev and Pinnavaia[22] synthesized mesoporous silica by utilizing the hydrogen bonding interactions between the head group of an alkyl amine surfactant (S^0) and the hydroxylated silica precursor, tetra ethyl ortho silicate (I^0). The bonding between the amine head group and the hydroxylated inorganic precursor occurs through the exchange of the lone pair of electrons on nitrogen (Fig. 3). This work led to a very useful development reported by Zhao et al.[23] in which nonionic amphiphilic triblock-copolymers were used as templates. These commercially available templates are quite robust in the synthesis of mesoporous materials and produce thicker walled materials than the cationic surfactants. One unique feature of the triblock-copolymer templated materials is that many structures have micropores in the walls that interconnect the mesoporosity.

Ligand-assisted templating

As opposed to the liquid crystal or electrostatic templating mechanisms, which rely on coulombic, van der Waals, or hydrogen bonding interactions between the surfactant molecules and the inorganic species, Antonelli et al.[24] proposed a ligand assisted templating mechanism, which relies on the formation of a covalent bond between the surfactant head group and the inorganic moieties. The amine surfactants were pretreated with metal alkoxides in the absence of water to form metal-ligated surfactants. Addition of water, which acts as both a solvent and a reactant, to the alkoxide–surfactant solution initiates the self-assembly and alkoxide hydrolysis–condensation. The reaction scheme following this route is given in Fig. 4.

Processing of Mesostructured Materials: Effect of Synthesis Parameters

The formation of self-assembled materials is governed by a number of experimental parameters: the choice of inorganic precursors and surfactants, the inorganic to surfactant ratio, amount of water and other solvents used, pH during synthesis, additives, reaction time and temperature, treatments used to stiffen the inorganic framework, and treatments to remove surfactant and obtain porosity, all decide the final ordering, porosity and surface area. It is well known that successful

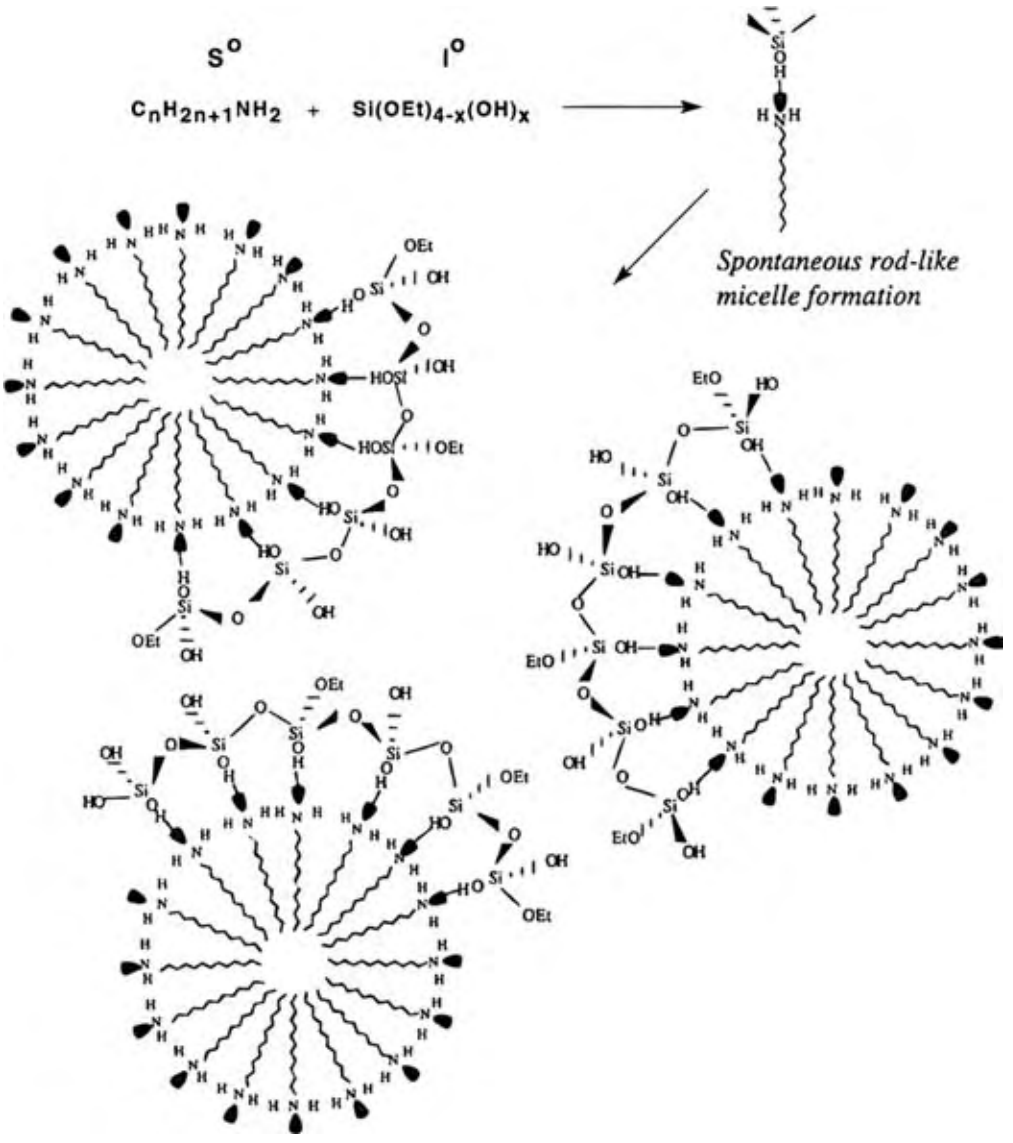

Fig. 3 The neutral templating route proposed by Pinnavaia et al. The electron lone pairs indicated by the shaded lobes on the surfactant head groups participate in the hydrogen bonding process with the framework silanol (Si–OH) groups. (From Ref.[22].)

synthesis depends on tuning the rates of the reactions that lead to the formation of inorganic framework with that of the self-assembly of the surfactant micelles.

Control of reactivity of inorganic precursor

Silica is the most extensively studied system among the self-assembled materials. Commonly used precursors in the synthesis of silica are tetraalkyl orthosilicates ($Si(OR)_4$). However, in nonsilica systems, including transition metal oxides or chalcogenides, the precursors are typically very reactive, and hence some means must be devised to control the reactivity of these precursors to avoid outright precipitation of solids having no mesostructure. The ways to control the reactivity of the inorganic precursors are summarized here. These are specific mostly to metal oxide systems, as they are the most extensively studied single class of mesostructured materials and are well characterized.

Addition of Complexing Agents. Complexation of metallic centers in the precursors by various chelating agents such as acetylacetone, ethylene glycol, and triethanolamine allows the control of the hydrolysis and condensation reactions of the inorganic precursors in the synthesis of metal oxides. Alternately, surfactants with a complexing ability can also be used.

Synthesis Under Low pH Conditions. The reactivity of transition metal alkoxides $M(OR)_n$ can be controlled

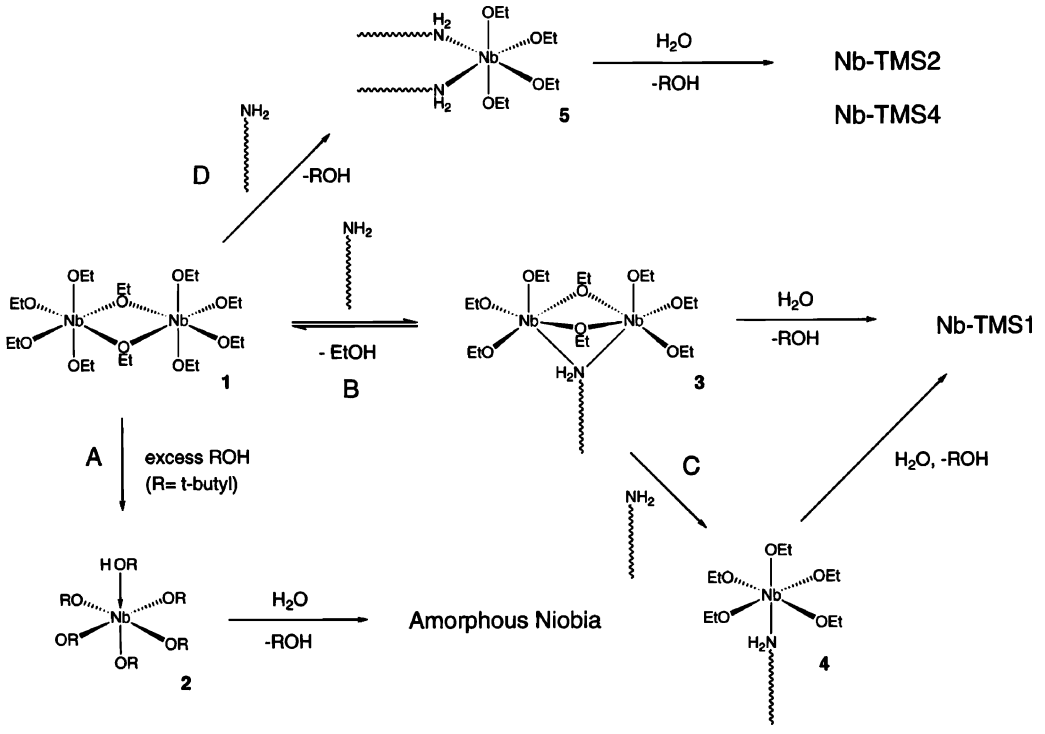

Fig. 4 Ligand assisted templating mechanism for the synthesis of niobium oxide. The amine surfactant forms covalent bonds with the niobium (V) ethoxide, resulting in the formation of a hybrid interface. Upon exposure to water, the system organizes into various structures such as bidimensional hexagonal (Nb-TMS1), three-dimensional hexagonal (Nb-TMS2), lamellar (Nb-TMS4), or a cubic phase. (Nb-TMS3 is not shown in the figure.) (From Ref.[24].)

by carrying out syntheses at very low pH. The protonation of M–OH groups by the excess H^+ ions in the solution, as well as increased rates of the depolymerization reaction, leads to the formation of small hydrophilic inorganic species almost all uncondensed, which can interact better with the polar head group of the surfactant.

Use of Mixed Precursors. When the framework of mesostructured materials consists of mixed materials (mixed metal oxides) or materials that require more than one inorganic precursors (e.g., metal phosphates require metal and phosphorous precursors), it is necessary that the inorganic precursors interact with each other more strongly than with molecules of the same species (strength of interactions should vary as $I_1I_2 > I_1I_1, I_2I_2$, where I_1 and I_2 represent two different inorganic precursors). Hence, the difference in the acidity/basicity of the precursors should be maximum to maximize the interaction between them. Tian et al.[25] reported a variety of metal phosphates, borates, and mixed metal oxides using this approach.

Use of Nonaqueous Solvents and Addition of Limited Quantities of Water. Use of limited quantities of water in nonaqueous solvents allows the control of the degree of hydrolysis of the transition metal oxide precursors. The resultant hydrolyzed, polar species can have a better interaction with the polar head group of the surfactant, resulting in the formation of ordered structures. Soler-illia et al. reported a ''modulation of hybrid interface'' approach,[26] which relies on the addition of controlled quantities of water to the solution of the inorganic precursor and a nonionic surfactant in an organic solvent to obtain ordered mesostructures.

Use of Dilute Solutions. The reactivity of the inorganic precursors can also be controlled by using low concentrations to lower the reaction rates. Consequent evaporation of solvent results in the formation of organized structure. This approach, introduced by Brinker et al.[27] and termed as ''evaporation induced self-assembly.'' (EISA), allows the formation of powders, films, gels, and monoliths.

Use of Nanoparticles. Instead of using reactive precursors that undergo reactions converting them to the final inorganic material, nanometer sized particles of final inorganic materials can themselves be used as the precursors. These particles will be inert, in that they will not interact with each other, but their interaction with the surfactants will allow formation of ordered mesostructure.

Surfactant to inorganic precursor ratio

The type of mesostructure obtained depends strongly on the surfactant to inorganic ratio. In fact, there is a close correlation between the surfactant to solvent ratio in the phase diagram of a surfactant and the surfactant to inorganic ratio in the mesostructured materials obtained. Alberius et al. demonstrated this correlation by the so-called ''general predictive synthesis'' approach.[28] They used the phase diagrams of the water-surfactant system to guide the synthesis of mesoporous silica and titania films. There was a very close correlation between the values of the volume fraction of the surfactant over which different phases are obtained in the water-surfactant system and in the silica-surfactant and titania-surfactant systems.

Effect of additives

Additives can have multifold effects on the structure of mesoporous materials: they can affect the structure at the nanometer level, i.e., change the phase obtained, or they can act at the micrometer level, changing the morphology of the resultant materials. The morphology control is discussed separately. When they are acting at the nanometer level, the additives can modulate the rate of the hydrolysis and condensation reactions associated with the inorganic precursors and hence change the range of variables over which ordered materials can be obtained. For example, Kim et al. obtained highly ordered silica mesostructures over a diverse range of pH by controlling the relative rates of hydrolysis and condensation of the silica species through the use of fluoride ions and tetramethyl orthosilicate (TMOS) as the inorganic precursor.[29]

Ionic additives can accumulate at the surfactant–inorganic interface and modulate the interfacial curvature, thereby changing the value of ''a,'' the effective head group area per surfactant molecule. This can change the structure of surfactant micelles and hence the structure of the mesophase obtained. The addition of salts to solution can also lower the critical micelle concentration, thus broadening the synthesis domain in surfactant concentration, as well as increase the range of surfactants that can be used in producing ordered mesostructures. The salt addition can also affect the radius of the micelles and hence the unit cell parameter and porosity of the inorganic material obtained after surfactant removal.[30]

The dramatic effect of salt addition on the mesostructure was demonstrated by Che et al.[31]. Starting with solutions with the same surfactant: inorganic ratio and working under the same synthesis condition, and by varying only the type of acid used (H_2SO_4, HCl, HBr, and HNO_3), the authors obtained a three-dimensional hexagonal structure with H_2SO_4 ($P6_3/mmc$ space group), a two-dimensional hexagonal with HBr ($p6m$), a bicontinuous cubic with HNO_3 ($Ia3d$), and a cubic ($Pm3n$) with HCl. (For an introduction to the space group nomenclature, which is quite common among the zeolite and mesoporous materials community to describe the crystal structures, the reader is referred to Ref.[32]. Various ''International Tables for Crystallography'' also constitute a useful and handy reference.) This modulation of structure was explained in terms of the adsorption strength of the acid anions on the head groups of the surfactant micelles. The acid anions are more or less hydrated in the surfactant solution. Less strongly hydrated ions have, in general, smaller ionic radii and bind more closely and strongly on the head group of the surfactant. The small anions contribute to the partial reduction in the electrostatic repulsion between the charged surfactant head groups and the decrease in the effective area of surfactant, ''a,'' thereby resulting in a significant increase in the g value. Ionic radii decrease in the following order: $\frac{1}{2}SO_4^{2-} > Cl^- > Br^- > NO_3^-$. Hence, H_2SO_4 leads to the formation of the 3D hexagonal $P6_3/mmc$ mesophase with a smaller g parameter and HNO_3 favors the formation of the $Ia3d$ mesophase with a larger g parameter. Liu et al.[33] found that the addition of organosiloxane or small organic molecules like benzene and its alkyl derivatives to the synthesis mixture containing TEOS, as silica source, and nonionic block-polymeric surfactants results in the formation of cubic bicontinuous $Ia3d$ phase at room temperature under acidic conditions. Previous reports of the synthesis of this phase were limited to alkaline media and high temperature synthesis.

Effect of environmental variables

Relative Humidity (RH) of Atmosphere. Relative humidity is an extremely important parameter for the synthesis of thin films from solution by dip or spin coating. The dynamics of evaporation is highly dependent on the RH of the atmosphere. The importance of controlling the RH was demonstrated by Cagnol et al.[34]. Starting with a solution with a fixed composition, different mesostructures were obtained just by changing the RH of the atmosphere. Structures with higher curvature and lower values of the packing factor g, such as cubic structures, require higher values of RH. More water is retained in the films at higher RH and hence the flexibility of inorganic framework, where the water is mainly located, is enhanced. The inorganic framework, therefore, can conform to the more curved interface resulting in the formation of cubic structure. At lower values of RH, on the other hand, structures requiring less curvature (such as

2D hexagonal mesostructure) are obtained. It was also demonstrated that the final structure is formed through a series of intermediate structures, the sequence of which depends on the relative humidity. It is also possible to change the structure after the dip coating by changing the relative humidity.

Organic Solvent Environment. The partial pressure of the organic solvent in the atmosphere has effects similar to that of water. The organic solvent generally has high volatility and evaporates faster. At high concentrations of the solvent, though, a high quantity of solvent is maintained in the films and the films remain low in viscosity, paving way for phase transitions.[35] Gallis and Landry studied the transformation processes leading to the formation of MCM-48 from MCM-41 and found that the presence of ethanol at the interface was necessary for the phase transition.[36] The authors theorized that hydrolysis of TEOS leads to the production of ethanol in the vicinity of the organic–inorganic interface. Upon heating, ethanol was driven further into the organic region, increasing the surfactant packing parameter and causing the system to transform from MCM-41 into MCM-48.

Strategies for Stabilization of the Inorganic Framework and Removal of the Template

Most of the applications of surfactant templated materials depend on the porosity of the inorganic framework; hence removal of the template is necessary. However, the inorganic framework must be strong enough to retain its fidelity even in the absence of the template. This is particularly important for the synthesis of materials with reactive precursors, as the strategies to control the precursor reactivity result in a framework that has a lower degree of polymerization and, hence, lower structural stability. This necessitates post-treatment of the mesostructured materials to enhance the polymerization of the inorganic framework and removal of template without destroying the mesostructure. The strategies employed to achieve this end are summarized here.

Thermal Treatments to Consolidate the Inorganic Framework. The surfactants are usually removed by heating the organic–inorganic hybrids to temperatures high enough to oxidize the template. Thermal treatment of the hybrids at a temperature that is lower than that required for template removal but high enough to enhance the rate of condensation will lead to consolidation of the inorganic framework in the presence of the template; this will enhance the stability of the inorganic framework for subsequent template removal at higher temperatures.

Mild Template Removal. Instead of using strong thermal treatments to remove the templates, mild template removal techniques, e.g., by refluxing in a solvent that can dissolve the template, use of UV irradiation, or use of mild oxidants, can also be used for template removal without structural collapse.

Doping with Foreign Atoms to Reduce the Size of Crystallites. In the case of transition metal oxides, calcination of the mesostructures is accompanied by crystallization of the inorganic framework. The size of the crystallites formed in the inorganic framework walls grows as the temperature increases, and it has been shown that when the size of these crystallites becomes comparable to the wall thickness, the structure collapses. Doping of the inorganic walls by heteroatoms prevents the growth of the crystallites, and, therefore, retains the structural integrity of the inorganic framework after template removal.

Aging Under Mild Conditions. Longer duration of aging, if it is permitted by the synthesis parameters, leads to a higher degree of condensation, and, therefore, stronger inorganic walls.

Treatment with Vapors of the Inorganic Precursor. The density of the inorganic walls can be increased post-synthesis by subjecting the material to an environment saturated with the vapors of the inorganic precursor. The vapors infiltrate into the wall of the structure, and fill any defects and microporous voids in the framework, which would otherwise lead to the collapse of the structure on template removal. The denser walls that result from the vapor treatment have much higher structural strength than those of untreated materials.

Morphology Control of Mesostructured Materials

The control of morphology of the materials at a macroscopic level is essential from an application point of view. Various morphologies of mesostructured materials, especially silica and nonsilica mesoporous oxides, have been obtained, such as free standing and supported thin films, spheres, fibers, and monoliths, using a combination of sol–gel chemistry and emulsion chemistry. Syntheses in acidic solutions afford better control over the morphology of the materials. Addition of a cosolvent immiscible with the solvent used for synthesis also leads to the formation of different morphologies of the resultant materials. Completely different morphologies are observed on the oil side and the water side of the resultant emulsion.[37] Morphology can also be affected by the synthesis temperature; polymerization at low temperatures leads to the formation of faceted single

crystals under thermodynamically controlled conditions. For a complete discussion of the control of morphology of mesostructured materials, the reader is referred to a review by Zhao et al.[38].

USE OF RIGID TEMPLATES

Rigid vs. Nonrigid Templates

Although very versatile and well researched, the surfactant templating route has some disadvantages. Surfactants are labile molecules and undergo thermal degradation typically at temperatures lower than ~350 °C. Most transition metal oxides undergo amorphous to crystalline transition at a temperature higher than this, which is responsible for the destruction of mesostructure, as discussed earlier. Most applications of the metal oxides, on the other hand, depend on the crystallinity of the wall. This necessitates the use of rigid templates. It has also been demonstrated that the use of mesoporous carbons as rigid templates for the synthesis of mesoporous metal oxides results in the formation of mesostructures that are otherwise not obtained with surfactant templates. A complete infiltration of inorganic precursors into the mesopores of the template is necessary to obtain dense wall with as little volume shrinkage as possible.

Materials Synthesized

The first ordered mesoporous materials synthesized using rigid templates were carbons. Ryoo et al. reported the synthesis of highly ordered cubic mesoporous carbons (termed CMK-1) using MCM-48 silica as the template[6] (and references therein). As a general route for the preparation of mesoporous carbons, the silica template is infiltrated with a solution of carbon precursor or an organic compound. This is followed by pyrolysis, in which the carbon precursor is converted to carbon. The silica template is then removed by treating with HF or NaOH. Mesoporous carbon materials typically have very high surface areas (1500–1800 m^2/g). But the carbon prepared using MCM-41 as a template (which has a 2D hexagonal structure) collapses upon the template removal to yield disordered microporous structure with high surface area. The reason behind this is explained in Fig. 5. It is necessary that when the silica template is 2D hexagonal, there should be some micropores connecting the mesopores to each other. Otherwise, the resultant carbon nanorods are disconnected and they collapse upon one another after template removal. When large pore 2D hexagonal silica, SBA-15, having micropores in the wall was used as template, the synthesized mesoporous carbon, termed CMK-3, was a true replica of the silica structure.

Tian et al. demonstrated the use of microwave digested silica as a template for the synthesis of a variety of metal oxides having crystalline structures in the form of nanowires and nanospheres.[39] The use of microwaves instead of the usual high temperature calcination to remove the surfactant from the silica during its synthesis leaves behind a large number of surface silanol groups (Si–OH). This leads to better hydrophilic affinity interactions with the inorganic precursors resulting in higher loading of the pores.

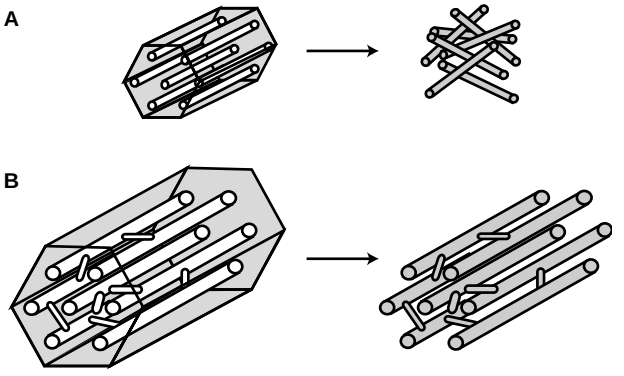

Fig. 5 A schematic illustrating the necessity of an interconnected pore system for the formation of mesoporous carbon. When MCM-41 (A), which does not have interconnections, was used as template, the structure collapsed upon calcination. The use of large pore interconnected SBA-15 (B) led to a stable, highly ordered material. (Adapted from Ref.[6].)

CONCLUSIONS

Phenomenal progress has been made in the synthesis of nanostructured materials in the last decade. A deeper understanding of the formation mechanisms has been established and it is now possible to synthesize these materials in a reproducible way. Modification of the properties of these materials should now pave the way for the use of these materials for conventional applications (catalysis, separation, adsorption, etc.) and for novel applications in the fields of solar energy conversion, electronics, hydrogen generation, etc.

INTRODUCTION

Nanotribology is the study of friction, lubrication, and wear at nanometer scales. Trends in device miniaturization, coatings for protection from wear in extreme environments, and lubricant technology motivate the development of improved materials and structure–property relations. Because engineering surfaces are innately rough and contact is made via a multiplicity of micro- and nano-sized contacts, measuring material properties and lubricant performance at this scale is critical, especially as classical descriptions of material behavior fail. This entry discusses efforts to measure and predict friction and material deformation at the nanoscale, leading to the development of improved structural materials for tribological applications.

MOTIVATION FOR NANOTRIBOLOGY

Tribology, the study of friction and wear, is of immense importance to the transportation and process industries. Over $100 billion in capital is lost each year because of wear-related reduced functionality of machines and devices.[1] Except in cases where transmitting mechanical forces between surfaces is desirable (such as traction in sneakers, automotive brakes, and fingertips), tribology is substantially focused on reducing friction as a means of improving mechanical longevity. However, mathematical relationships between friction and wear remain elusive, even for the simplest surfaces, because of the complex interplay of chemical reactions, mechanical deformation, heat conduction, and lubrication phenomena that occur during sliding. Thus, the key need of tribology is the development of constitutive relationships that link surface physicochemical and mechanical characteristics to energy dissipation and material deformation.

The development of instrumentation capable of studying and manipulating matter on a molecular scale has ushered in new opportunities to explore surfaces in relative motion (Fig. 1).[2] The field of nanotribology has emerged from the belief that a more fundamental understanding of the physics of interacting surfaces on the nanometer scale will yield new design methodologies of larger (micrometers and up) systems. Technologically, nanotribology is driven by trends in device miniaturization, composite coating development for extreme wear environments, nanofluidics and nanorheology for bioseparations, and lubrication research, and data storage technology, and by the need to meet increasingly stringent environmental and technological challenges in the ''conventional'' lubricant industry. Fundamental scientific issues need to be addressed as well, including the origins of friction and modes of energy dissipation, and how materials well described at the macro level respond differently when probed at nanometer scales. For example, fluids such as vegetable oil that exhibit only viscous behavior under bulk conditions behave viscoelastically when confined to molecular dimensions.

Earlier books and reviews have provided considerable detail on specific aspects of nanotribology.[3–11] Some are written from the lay person's perspective, and provide a historical account of tribology leading to specific research efforts in the field.[3–5] Others are compilations of the state-of-the-art contributions in various fundamental and applied aspects of nanotribology.[6–11] The intention here is to provide a brief overview of the purpose and progress of nanotribology in developing a more complete understanding of the behavior of sliding interfaces. The first two sections explore the atomic and molecular origins of static and kinetic friction, the third focuses on differences of the response of fluids to molecular confinement, the fourth focuses on new nanoindentation methods and insight gained on the deformation of materials at the nanoscale. The relevance of the research from a practical viewpoint of materials and systems development is highlighted.

MOLECULAR-LEVEL EXPLANATION OF MACROSCOPIC FRICTION ''LAWS''

Despite the ubiquitous presence of friction, most people study friction for no more than one or two

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120039301

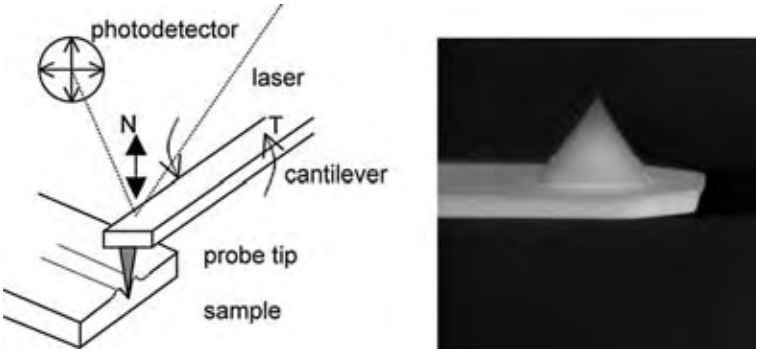

Fig. 1 Schematic of the AFM cantilever and cantilever tip micrograph. Cantilever bending normal to the surface is used to calculate a normal force (N) and torsional motion is used to calculate the frictional force (T). Cantilever deflections are detected by a photodetector.

lectures in a basic physics class. Classical ''rules'' are taught that are based on everyday observations and a host of experimental data. To summarize:

1. Frictional forces do not depend on an ''apparent'' area of contact, but rather the ''true'' area of contact between the opposing asperities (Fig. 2).
2. Frictional forces are proportional to normal load (known as Amontons' laws). This has been explained by the increase in true contact area between the surfaces as the load increases.
3. The force required to begin sliding an object from rest (static friction) is generally greater than the force required to sustain motion (kinetic friction).
4. The kinetic friction force is independent of sliding velocity (Coulomb's law).

Surprisingly, these rules apply to a wide range of paired surfaces, irrespective of roughness, hardness, or the presence of a lubricant.

Today, many undergraduate physics textbooks describe friction in terms of the work required to separate adhesive microcontacts formed during sliding. As the load increases, the true contact area increases, resulting in a larger resistance to motion. This intuitively simple picture explains the load dependence of friction (1 and 2 above), but does not provide insight into the origins of friction, mechanisms of friction energy dissipation, and the differences between static and kinetic friction. Despite embellishment, models based on a purely classical description of surfaces cannot explain the commonly observed friction rules. Thus, considerable theoretical models, molecular dynamics (MD), computer simulations, and nanoscale experimentation are converging on the mechanisms of energy dissipation, origins of static friction, and the velocity independence of friction. These efforts are briefly described.

Proportionality of Friction and Load

For surfaces that deform plastically, the contact area A is proportional to the applied load. A single elastic contact deforms as $A^{2/3}$ as load increases, and would not be expected to follow this rule.[12] However, when considering an exponential surface height distribution, which leads to a multiplicity of elastic asperity contacts, a linearity between load and contact area is recovered. Using instrumentation developed in the last 15 yr, notably the atomic force microscope (AFM) and surface forces apparatus (SFA), researchers have explored the universality of friction–load proportionality over a much wider range of dimensions and surface characteristics. Indeed, SFA experiments have shown friction–load proportionality between atomically smooth mica surfaces in dry air over square micrometers of contact area. A contact mechanics expression for elastic contacts that incorporates the effects of adhesion was used. Similarly, AFM experiments of

a single-asperity contact between two highly stiff materials showed a friction–load proportionality. Surprisingly, these nanotribological investigations have validated the applicability of Amontons' laws to nanometer dimensions.[13] Further, they clearly demonstrate the presence of friction in the absence of wear through studies of well-characterized surfaces, and demonstrate the significant role that adhesion plays in the generation of friction.

The Origin of Static Friction

Atomically flat, weakly interacting surfaces are predicted to exhibit no friction. In this limit, no asperities block motion, and the atoms of one surface cannot incite movement of atoms on the opposing surface. Thus, no relaxation of the surfaces to local energy minima occurs, and no energy is required to initiate sliding (Fig. 3). In practice, these conditions are difficult to achieve, so simulations have explored the effect of atomic impurities on static friction. In MD simulations, both the motions of the surface impurity molecules and the atoms that compose the surface are considered explicitly. The friction is obtained from an atomistically applied damping constant required to keep the system isothermal. Through these computations, a static co-efficient of friction has been predicted in the case of deformable surfaces under compression.[14] Upon cessation of sliding, the atoms at the interface move swiftly to a low energy state and require a finite force to initiate motion. During sliding, the atoms are not given an opportunity to reach a low energy state. Thus, the force required to initiate motion is larger than that required to continue motion. In the case of atomic impurities, the relaxation of the interface generally occurs on time scales too rapid for experimental verification. However, using an SFA to confine liquid films of oligomers to molecular thicknesses, an increase in the stress required to initiate motion as a function of elapsed time was demonstrated.[15] This provides strong evidence that static friction arises from interfacial relaxation processes.

Velocity-Independent Friction

Of all the classical friction rules, this is perhaps the most complex one to elucidate. In contrast to most everyday observations, many theories and simulations generally predict a viscous response where the friction is proportional to, rather than independent of, sliding velocity.[9] In fact, quartz crystal microgravimetry (QCM) experiments also show a velocity-dependent friction.[5] Quartz crystal microgravimetry is able to measure the degree of slippage of condensed gas films on a rapidly oscillating and resonating metal surface (Fig. 4). Through resonant frequency and amplitude changes, the slippage of a layer of condensed krypton was found to be dependent on QCM oscillation amplitude. (That is, the friction seen in this system is velocity dependent, in contrast with rule 4.) In lubricated systems, velocity independence may be partially explained by the shear thinning of the lubricant, in which the viscosity of the fluid decreases as shear rate is increased. Further, wall slip can occur, resulting in a momentary reduction in friction. However, the occurrence of velocity independence in dry systems has not been explained, including those conducted at a nanometer scale using AFM. Thus, a more universal explanation for this friction behavior is needed, and provides impetus for future research in this area.

NATURE OF FRICTION

The focus of this discussion so far has been on research that compares macroscopically observed friction

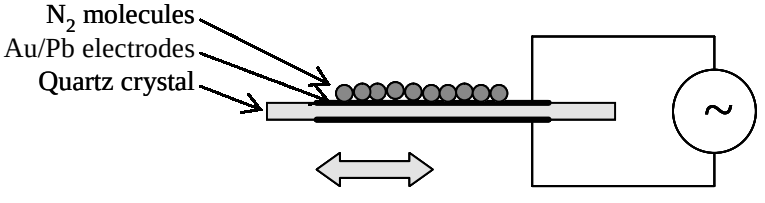

Fig. 4 Schematic of the QCM experiment with Pb-coated electrodes. *(View this art in color at www.dekker.com.)*

phenomena to that found at nanometer scales. No wear has been allowed in most simulations, or is desired in nanoscale experiments, and all frictional energy was dissipated in the form of heat. Because wear is a primary concern of tribological research, the modes by which energy is dissipated are of significant interest. From a materials design perspective, it is desirable to have the energy dissipated in the form of heat, rather than in the form of viscoelastic or plastic deformation, which results in permanent damage. The focus of this entry is on exploring the mechanisms by which energy is dissipated and the connections between friction, atomic, and molecular structure.

Phononic and Electronic Energy Dissipation

Energy transfer away from a sliding contact occurs through a number of means. Lattice vibrations can be excited through localized variations in relative velocity caused by asperity contact.[5,9] A ''wave'' of atoms vibrating in concert, termed a phonon, can be transmitted through the solid. These atomic vibrations may be absorbed at grain boundaries, resulting in atomic dislocations at the boundary. With sufficient accumulation of energy, the material may fracture and be removed from the surface. Energy may also be dissipated via surface exchange of electric charge. A classic experiment is to charge a balloon by rubbing it against hair. This electronic friction can be modeled as charges and dipoles moving through a ''viscous'' medium. Coulombic interactions between dissimilar surfaces can also generate resistance to motion even with noncontacting surfaces, although these forces are generally small. To experimentally distinguish between phononic and electronic contributions to the friction, Dayo, Alnasrallah, and Krim performed QCM experiments of monolayers of nitrogen on lead under ultrahigh vacuum (UHV) conditions (Fig. 4).[16] As the system temperature cools to below the superconducting temperature of lead, the electronic contribution to friction will disappear, allowing a calculation of the relative contributions of phononic and electronic friction to be measured. While other experimental evidence suggested that both phononic and electronic contributions to friction existed, these marked the first nanotribological studies that could determine the relative magnitude of these effects.

Commensurate and Incommensurate Surfaces

The term ''commensurate'' is applied to opposing surfaces that possess the same lattice spacing and orientation, as though the surfaces had been generated by cleaving a single crystal (Fig. 5). While commensurate surfaces do not typically appear in tribology, they assist in elucidating the origins of friction and modes of energy dissipation: Given the above discussion on phonon transport and slip at grain boundaries, it follows that friction would be sensitive to lattice orientation. Indeed, theory and simulations predict a significant dependence of friction on the commensurate nature of the interface.[5]

Numerous tribological studies have measured the friction anisotropy that results as a function of changing lattice orientation on both elastic and plastic contacts.[17] Under elastic deformation conditions, both adhesion and friction have been shown to be highly dependent on slight changes in orientation in SFA studies of atomically flat mica surfaces. The friction and adhesion anisotropies persisted even when the surfaces were separated by four molecular layers of liquid. Using AFM, friction anisotropy and lattice-directed sliding have been measured between diamond surfaces and between MoO_3 nanocrystals and single-crystal MoS_2, respectively.

In contrast, for plastically deformed surfaces, friction anisotropy appears to be primarily attributable to the movement of atomic slip planes within the bulk of the metal, and not to commensurability at the sliding interface. Early experiments using diamond surfaces showed that friction anisotropy disappeared at low loads where no plastic deformation was evidenced.

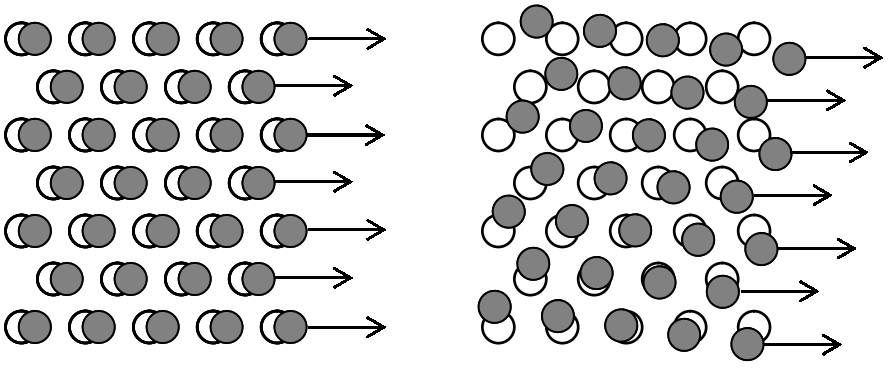

Fig. 5 Atomic configurations representing a commensurate surface (on the left) and incommensurate surface (on the right). Sliding friction is predicted and experimentally shown to be different between these cases.

Friction anisotropy has also been seen between clean and monolayer-coated metal (100) single crystals in UHV, and persists when the surface is covered with as much as 20–40 monolayers of octane, beyond which no anisotropy is detectable.[17]

Energy Dissipation in Polymers

Many of the above nanotribology theories, computer simulations, and experiments have focused on surfaces composed of covalently or metallically bonded atoms. Polymers are distinguished on the basis of their covalently bonded backbone, but entangled macromolecular structure. Relaxation times for polymers can extend from seconds to days, and lend themselves nicely to nanotribology studies of time-dependent behavior. Current nanotribology experiments on polymers using the AFM have found that the dependence of friction co-efficients on sliding speed can be traced to polymer segment motion.[18] When the sliding time is comparable to the relaxation times associated with the movement of polymer functional groups, the friction is maximized. This behavior has been seen in several polymers, including poly(vinyl alcohol), poly (vinyl acetate), poly(ethylene terephthalate), and polystyrene thin films. Further, because of the inherently fast response time of the cantilever compared to macroscopic load cells, the AFM can acquire ''instantaneous'' frictional forces on a nanometer scale. In a separate study, it has been suggested that the distribution of friction forces is reflective of glass-like and rubber-like relaxations, again tying friction to the relaxation behavior of the polymer.

NANORHEOLOGY

One central issue in the development of lubricants for tribological purposes is the shear behavior of molecules confined to small, thin layers. Conventional tribological experiments often use ill-defined surfaces, and more than one parameter change during measurement (viscous heating, surface roughness changes), making the interpretation of friction behavior on the basis of the shape of the molecule, functionality, and size difficult. One of the most remarkable nanotribological experiments performed using the SFA was the finding that simple molecules form a layered structure upon angstrom-level confinement between atomically smooth mica surfaces.[19] Simulations and models have followed that predict this behavior.[9] Alternating compressive and tensile forces were created as the mica surfaces were brought into close proximity, with a period that corresponded to the segment diameter of a methyl group. The oscillations in force decreased in magnitude using a linear chain having a pendant methyl group, which interrupts the layered structure. This provided an important clue as to the importance of molecular structure in the load carrying capacity of lubricant films. Subsequent SFA experimentation with perfluoroethers demonstrated that branched molecules produce thinning, more compression resistant films than linear chains, and that as molecular weight increases, the lubricant exhibited solid-like to liquid-like transitions with increasing strain.[20] Since then, the SFA has proven to be indispensable in investigating the effects of lubricant physicochemical properties such as friction, stick-slip, and nanorheology.

Stick-Slip Behavior

Under certain conditions, systems can exhibit an unsteady stick-slip motion. Technologically, stick-slip behavior is usually undesirable, causing mechanical shudder in power transmission equipment, for example, and it is difficult to predict and control. In essence, as the velocity decreases, an increasing friction force slows the system further, potentially bringing the system to rest. At this point, the applied tangential forces build up, ultimately reinitiating motion. From the preceding discussion of the origins of static friction, relaxations of lubricant and surface molecules can explain this velocity-dependent friction. However, theory, nanoscale simulations, and experimentation have shown that confined lubricant films can also undergo a solid-like–liquid-like phase transition.[21] This more abrupt behavior is temperature sensitive, but surprisingly load and speed independent. These findings suggest that friction may not always be ''smoothly'' dependent on the viscoelastic nature of a lubricant film, but may undergo sharp transitions attributable to confinement-dependent phase behavior.

End-Chain Functionality

Because of the importance that friction modifiers play in lubricant technology, the effect of varying chain-end chemical functionality on nanorheology of alkane chains has been studied.[22] Measurements of the dynamic shear stress revealed differences in solid-like and liquid-like behavior of the thin films depending on the strength of hydrogen bonding between end groups. Carboxylic acid groups have strong bonding and exhibit a more solid-like behavior than corresponding measurements with hydroxyl-terminated alkanes. Further, self-association between end groups affects film thickness. These results clearly establish links between nanorheological behavior and the behavior of lubricants in larger-scale applications.

Lubricity of Aqueous Systems

Water is a reasonable lubricant under low load conditions, but a poor one under higher loads. For this reason, considerable attention has recently been focused on aqueous systems in an effort to understand the mechanisms by which diarthrodial joints and other biological systems maintain such low-friction co-efficients. The large number of variables associated with the choices of surfactant or polymer type and conformation (whether native or synthetic, hydrated or polyelectrolytic, homopolymer, or diblock, tethered, or untethered) coupled with the variability in testing conditions creates an inherently complex experimental space. Currently, there is insufficient information to draw significant generalizations. However, experiments have shown that hydrated and electrolytic polymer-coated surfaces remain more fluid-like compared to nonaqueous systems, and that their ability to lubricate directly depends on hydration.[23] Clearly, nanotribological investigations of biolubrication will continue to be fruitful areas of research.

Effects of Density Fluctuations

The nature of thin films may also be influenced by rapid, thermally driven fluctuations in the local density of liquids. Heuberger, Zäch and Spencer performed force and refractive index measurements of hexane confined to nanometer thickness using fast spectral correlation spectroscopy, and observed the fluctuations in density.[24] This finding may help explain observations of high surface mobility, anomalously fast self-diffusion, and apparent solidification in liquid films.

NANOINDENTATION

In addition to the behavior of intervening lubricants, mechanical properties of material surfaces and solid thin films clearly affect tribological performance.[25] Recent advances have shown the capability to fabricate and control materials and structures on the scale of nanometers, which has spurred research both in tribological films for extreme environments and in the design of durable micro/nanodevices. Measuring mechanical properties on the nanoscale is essential, considering the strong size and structure dependence of both thick and ultrathin films, nanocomposites, nanowires, nanotubes, nanobeams, and nanoparticles.[26] Direct nanoindentation shows continuing promise for measuring hardness, elastic modulus, scratch resistance, film adhesion, fracture toughness, creep resistance, and fatigue of materials.[27] Further, nanoindention mimics micro- and nanoscale physical contact at the tribological interface of magnetic storage and MEMS/NEMS devices. Thus, the discussion here will focus on the recent developments in nanoindentation techniques, and on the use of nanoindentation to elucidate the mechanisms of solid deformation.

Nanoindentation Techniques

Recently developed nanoindention instruments can accurately measure loads as small as a nano-Newton and displacements of about an angstrom. Clearly, this depends on the indenting tip structure. The Berkovich triangular pyramidal diamond indenter is widely used for measuring hardness and elastic modulus at nanometer scales. Ideally, the indenter tip radius should be as small as possible, and has been fabricated to 20 nm dimensions using focus ion beam techniques. At a small indentation depth, friction between the indenter and the material being indented, which has been long ignored, needs to be considered in analyzing the load–displacement curve. Surface roughness greatly affects the hardness and elastic modulus measurement.

Hardness and elastic modulus measurements

A depth-sensing nanoindenter is capable of continuously measuring load and displacement throughout nanoindentation (Fig. 6). Experimentation has been focused on improving the accuracy of hardness and modulus measurements through concurrent measurements of contact area. Material pile-up around the indentation, unaccounted for in earlier analysis procedures, can now be measured via subsequent topographical imaging using an AFM (Fig. 7). Numerical and finite element analyses that consider pile-up effects have been used to extract more accurate mechanical property measurements from load–displacement curves. Versatile methodologies are still under development.

To measure the hardness and elastic modulus of thin films while avoiding the influence of the substrate, peak indentation depth cannot exceed about 30% of the film thickness.[25] Because commercial nanoindenters can make a minimum penetration depth of 10–15 nm, hardness and elastic modulus of films thinner than 30 nm cannot be measured. Clearly, new techniques for fabricating sharper indenters and new nanoindentation theories are needed to extend this technique. For film thicknesses less than 30 nm, nanoscratch tests are widely accepted to evaluate the mechanical properties (discussed later). Alternatively, assuming the hardness and elastic modulus of a film do not change with thickness, thicker films can be used.

A significant improvement in nanoindentation testing is continuous stiffness measurement (CSM).[27]

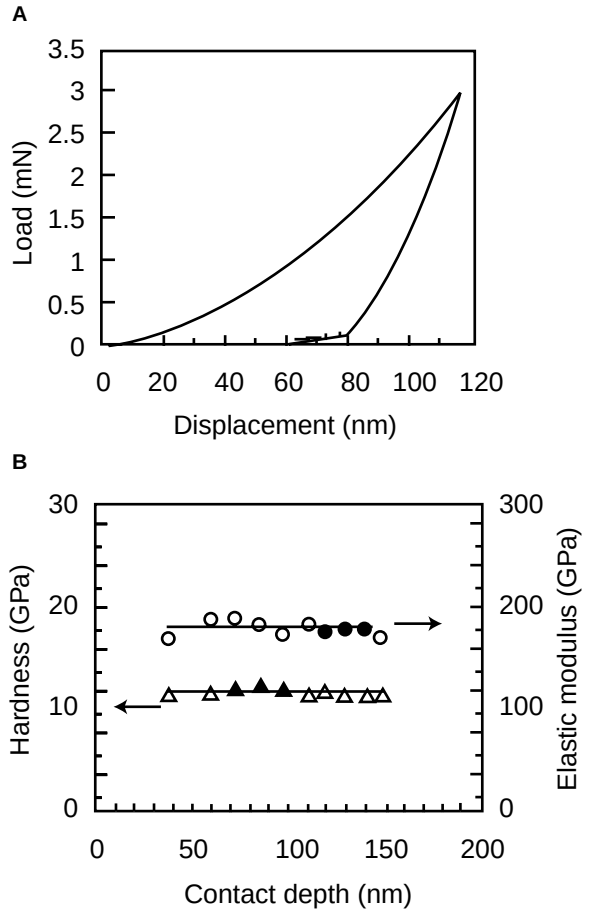

Fig. 6 (A) A representative load–displacement curve of an indentation made at 3 mN peak indentation load and (B) the hardness and elastic modulus as a function of indentation contact depth for the $Al_{74.6}Co_{16.9}Ni_{8.4}$ quasicrystal. (Li, X.; Zhang, L.; Gao, H. Micro/nanomechanical characterization of a single decagonal AlCoNi quasicrystal. J. Phys. D: Appl. Phys. **2004**, *37,* 753–757.)

During CSM, a smaller, oscillatory force is superimposed on a steady larger force. This enables CSM during loading. Without CSM, stiffness can only be measured from the unloading cycle, which requires a larger indentation depth to be obtained. Further, CSM allows mechanical properties to be obtained without the need for multiple, discrete unloading cycles, and avoids creep effects. Finally, the CSM can detect microstructural and mechanical property changes with indentation depth in nonuniform, multilayered materials.

For viscoelastic materials such as polymers and many biomaterials, recently developed nanoindentation dynamic mechanical analysis (DMA) techniques enable the study of dynamic response as a function of load amplitude and frequency. The DMA stiffness mapping technique offers the unique capability of mapping storage and loss moduli of the sample surface. This technique has proven to be very powerful in characterizing copolymers and composites.

Fracture toughness measurements

In general, a material with high strength and fracture toughness exhibits high wear resistance. Fracture toughness of a material is a measure of its resistance to the propagation of cracks, and can be measured via nanoindentation testing. Fracture toughness can be obtained by measuring the length of cracks generated radially from the corners of the indentation. However, several micrometers of indentation are needed for many brittle materials, which exceeds the thickness of many tribologically important thin films. Thus, the fracture toughness measurement of ultrathin films depends on the development of new indenter geometries.

Indenters that displace more volume with shallower indentations, such as the cube-corner indenter, generate stresses and strain concentrations sufficient to create radial cracks in thin films. Further, it has been experimentally proven that the fracture toughness measurement equation is applicable to the radial cracks by the cube-corner indenter.[25] Improvements to toughness measurements from nanoindentation beyond simple models could clearly be made by atomistic computer simulation of crack initiation and propagation, which are currently lacking. Indentation experiments capable of investigating fracture of nanometerthick films are ongoing.

As an alternative to indenter development, new nanoindentation methodologies for measuring the fracture toughness of ultrathin films (of the order of 100 nm thickness) have been recently developed. By measuring crack length via SEM/AFM and calculating the energy release in indentation-induced through-thickness cracking from steps in the loading curve, the fracture toughness can be obtained. Fracture toughness of thin films with thicknesses less than 100 nm has not yet been achieved.

Fatigue measurements

Recently, nanoscale fatigue damage has received much attention because frequent, high-magnitude impacts that occur at the interfaces of magnetic storage and MEMS/NEMS devices lead to fatal flaws.[28] Nanoindenters outfitted with CSM are ideally suited to simulate nanoscale fatigue damage through high-frequency repetitive surface impact. During fatigue tests, sharp decreases in contact stiffness or a sudden increase in indentation depth indicates specimen damage. Fatigue resistance as a function of both load and amplitude frequency has been studied for these thin films and nanostructures. The number of cycles to failure as a function of load, commonly obtained

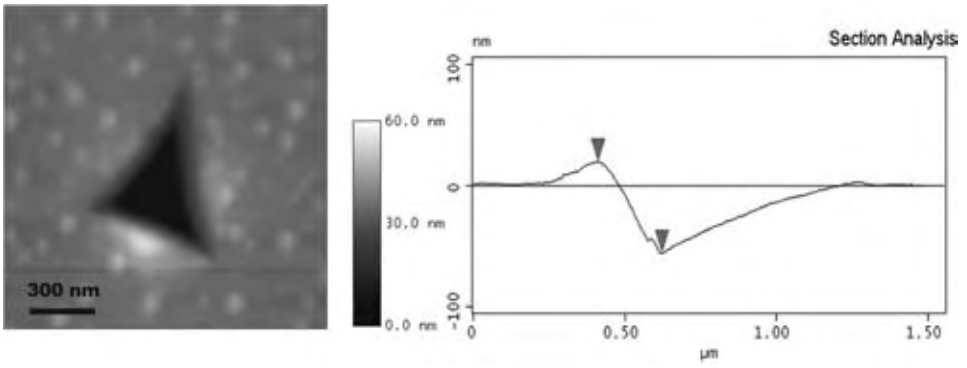

Fig. 7 Atomic force microscopy image and the cross section of the residual impression made at 3 mN. (Li, X.; Zhang, L.; Gao, H. Micro/nanomechanical characterization of a single decagonal AlCoNi quasicrystal. J. Phys. D: Appl. Phys. **2004**, *37,* 753–757).

in macroscale tribological durability testing, can be used to gage device or surface durability in a specific service.

Fatigue tests on nanoscale silicon beams used in constructing MEMS/NEMS devices, such as radio frequency switches, are of critical importance. Fatigue damage is the main failure mechanism of these devices. Silicon itself is a brittle material. No fatigue damage has been found in bulk silicon. Nanoscale fatigue tests on silicon nanobeams in ambient air have suggested that the failure of the beams arises from sequential fracturing of the oxide surface layer and oxidation of the underlying exposed silicon. More specifically, many film/substrate systems exhibit: 1) indentation-induced compression; followed by 2) delamination and buckling of the film from the substrate; and finally 3) a ring-like crack formation of the delaminated film.

Scratch and wear resistance measurements

Nanoscratch tests have been used to simulate the effect of third-body particulate wear debris on component surface scratching during use. The load at which the co-efficient of friction or friction force suddenly increases is identified as the critical load, and is used to evaluate scratch resistance and adhesion strength. The depth-sensing nanoindenter, usually equipped with a conical indenter, can elucidate the mode of failure, whether elastic/plastic deformation, cracking, or delamination.

Finally, wear tests can be realized by using a nanoindenter tip sliding against the sample surface at a constant load. Cyclically sliding against the samples surface is analogous to ball-on-flat wear tests. The indenter can detect the co-efficient of friction and wear depth in situ, offering a real-time study of wear mechanisms. The wear scar can then be imaged by the same tip. Debris particles, delamination, and buckling can be monitored. In summary, continuing advances in nanoindentation and related methods will accelerate materials development and durability testing for ultrathin films and microdevices.

Material Deformation Mechanisms

In the preceding section on energy dissipation mechanisms in solids, the origins of friction in the absence of material deformation have been studied. The focus here is to review the role nanoindentation experimentation has played in elucidating material deformations. Briefly, in the initial stages of deformation, many surfaces deform elastically. Surprisingly, this elastic deformation has been successfully modeled using classical theories of contact mechanics even at nanometer scales.[13] If the load is applied for sufficient durations, materials such as metals and polymers will creep, where the individual or collective diffusion of atoms or molecules will relax the stress.[29] Beyond a critical stress, the material will deform via crack propagation (in brittle materials) or via the nucleation and migration of atomic lattice dislocations (Fig. 8).[30,31] The brittle–ductile transition has been described through a balance between the energy associated with creating additional free surface and the energy required to create and move a dislocation.

"Pop-in" discontinuity

Upon exceeding a critical stress, ductile surfaces deform plastically. Often in nanoindentation experiments under controlled load, the indenter moves in a

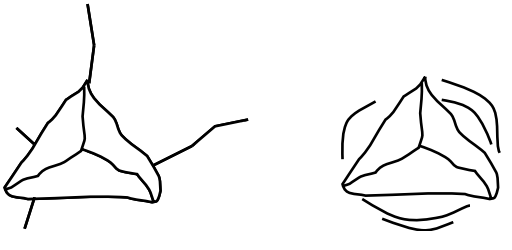

Fig. 8 Differences in response to indentation. The colored area is the indentation. In a brittle material, cracks form, whereas in a more ductile material, dislocation motion accommodates plastic deformation.

discontinuous, step-like fashion, analogous to an avalanche (Fig. 9). This ''pop-in'' effect has been shown to arise from one of the two mechanisms, breakthrough of the harder oxide overlayer that covers most metals exposed to air and nucleation and migration of crystal dislocations. To correlate nanoindentation pop-in events with atomic motion, recent MD simulations have shown a correlation between indenter motion and the formation of dislocation loops and cross-slip events. A central finding of these simulations is the importance of elucidating the relative roles of dislocation nucleation vs. dislocation migration. These simulations were performed on an oxide-free surface. Experimentally, the presence of an oxide has a dramatic effect on the critical load behavior. Electropolished tungsten exhibited an initial elastic deformation regime, followed by a staircase yielding phenomenon indicative of multiple pop-in events, whereas mechanically polished tungsten exhibited a steady plastic deformation with no initial elastic regime. Because both have equal oxide layers, the pop-in effect was attributed to dislocation nucleation. More recent nanoindentation studies have focused on silicon because of its use in MEMS fabrication, its crystallinity (which allows comparisons to simulations), and its unusual transition to a conductive phase under high loads.

Amorphous alloys

Because of their high strength and large elastic deformation, bulk metallic glasses are emerging as structural materials for MEMS and other devices. As the name suggests, these metal alloys have no inherent crystalline structure, and exhibit decidedly different indentation behavior from their crystalline counterparts. Plastic deformation is highly localized to shear bands, which propagate rapidly across a macroscopic specimen.[32] Recent nanoindentation studies show small, incremental discontinuities in response to load. Further, nanocrystallites form in shear bands during indentation attributable to flow dilation inside the bands and the radially enhanced atomic mobility within deforming shear bands.

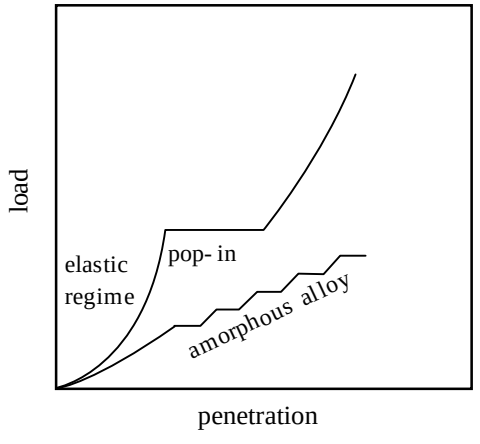

Fig. 9 Graphical representation of results from a nanoindentation experiment. For many solids, an elastic regime at low loads is followed by a discontinuous excursion. For amorphous alloys, a series of ''staircase'' deformations occur in response to shear banding.

Hard thin films

To increase the wear resistance of surfaces, silicon and metals are often coated with a hard nitride, carbide, boride, or oxide film.[33] Nanoindentation and fracture simulations have been used extensively to elucidate failure mechanisms of these typically more brittle surfaces, which include crack propagation and film delamination. Considerable attention has also focused on nanocomposite materials, which possess nanocrystalline inclusions in an otherwise amorphous matrix. The nanocrystalline component is sufficiently small to preclude the formation of stable dislocations, and thus provide a higher hardness.

CONCLUSIONS

Clearly, nanotribology has made significant progress in our understanding of the nature of friction, how friction is influenced by surface and lubricant structure, and how materials deform under specific loads. This has led to more complete explanations of macroscale behavior, such as the classical ''rules'' of friction and the nanoscale deformation mechanisms of metals, ceramics, thin films, and nanocomposites. Further, with the progress in synthesizing nanoscale materials, such as carbon and boron nitride nanotubes, the need to develop tools to probe mechanical properties at the nanoscale has never been greater. Despite these successes, several challenges remain:

1. Mathematical structure–property relations have yet to be developed that tie molecular level information to a prediction of friction and wear behavior. Current theories focus on idealized structures and interfacial interactions that are rarely realized in practice. Thus, statistical representations of the surface topography and interfacial forces need to be integrated with nanotribological measurements to develop more widely applicable and predictive tools.
2. Many of the instruments used in nanotribology experiments are limited in terms of the surfaces and materials used. The surface forces apparatus accommodates ''soft'' materials such as

lubricants, polymers, and surfactants, but the ''solid'' surfaces are limited primarily to mica. Atomic force microscopy studies typically use a silicon or silicon nitride probe tip. Replacing the sharp tip with a colloidal particle of arbitrary composition presents a promising new avenue for exploring specific interactions of a wider range of materials. Further, by replacing a sharp tip having a radius of curvature of 15–30 nm with a 3–10 μm spherical particle, the probe will more readily glide over surfaces rather than cut through them. This allows the study of a wider range of lubrication phenomena. An example is the recent study of the friction of cellulosic fibers, which show stick-slip behavior, dependence on load, and dependence on the presence of small amounts of high molecular weight polyelectrolytes.[34]

3. Fatiguing processes at a nanoscale have not been extensively studied. Processes leading to wear (material removal) are often initiated only after repeated loading and unloading. Because of the difficulties associated with characterizing subsurface material deformations or slight changes in atomic structure, current nanotribology research focuses primarily on either scratch testing, in which the surface is scored during first contact, or friction measurements made under no-wear conditions. An exception is Ref.[35] where fatigue-induced wear of mica was studied using AFM and modeled based on the friction energy dissipated and the number of sliding events. Their results represent one of the first efforts in relating friction to wear at the nanoscale. Nevertheless, long-term materials testing (hours to days) are impractical for these instruments; yet, the majority of macroscale tribological testing is of this nature.
4. The atomic and molecular structure of tribological surfaces and lubricants under shear plays a crucial role in tribology. Unfortunately, techniques to probe nanostructure spectroscopically or optically simultaneously with tribological probing are limited. This limits the ability to draw conclusive structure–property relations for all but the most idealized macroscopic surfaces, such as those described here.

These challenges present a host of opportunities in nanotribology and allied fields. Most of the advances discussed above were made within the last 15–20 yr, with a focus on the last ten. In this respect, nanotribology is by no means a mature field. With continued progress, further impact on our scientific and technological understanding of the nature of sliding surfaces and nanomechanics is expected.

Natural Gas Hydrates

P. R. Bishnoi
Matthew A. Clarke
Department of Chemical and Petroleum Engineering, University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

Gas hydrates are nonstoichiometric crystalline compounds that belong to a group of solids called clathrate. They are formed from mixtures of water and low molar mass gases at high pressures and low temperatures. Through hydrogen bonding, water molecules form a framework containing relatively large cavities, which can be occupied by certain gas molecules that get linked to the framework by van der Waals forces. The hydrate forming gases include light alkanes (methane to *n*-butane), carbon dioxide, hydrogen sulfide, nitrogen, and oxygen.

The first recorded observation of gas hydrates was made in 1823 when Humphrey Davy and Michael Faraday[1] bubbled chlorine gas through water. As the mixtures cooled, they noticed a solid material forming at temperatures above the normal freezing point of water. Throughout the remainder of the 19th century, much work was undertaken cataloging the various molecules that could form hydrates and the conditions at which each hydrate was stable.

The second phase of gas hydrates research began in the 1930s when Hammerschmidt[2] observed that gas hydrates were responsible for plugging natural gas pipelines. Following the discovery by Hammerschmidt,[2] Katz and coworkers[3,4] pioneered experimental investigations of the thermodynamics of gas hydrate formation for several natural gas systems. Also in this period, van der Waals and Platteeuw[5] developed the first thermodynamic model for the solid hydrate phase. This enabled development of computer-based predictive methods[6,7] to determine the incipient hydrate conditions. The 1960s saw another shift in gas hydrate research when natural gas hydrates (NGHs) (primarily composed of methane) were observed as a naturally occurring constituent of subsurface sediments in the giant gas fields of the Western Siberia basin.[8] In 1974, marine NGHs were directly observed when Soviet scientists discovered large hydrate nodules from the floor of the Black Sea. In recent years, there has also been speculation[9] that gas hydrates are present at the polar regions of Mars and on Europa. Interest in gas hydrates received additional impetus during the 1970s when rising energy costs and depletion of conventional hydrocarbon reserves pushed the search for new oil and gas into increasingly deeper offshore waters and arctic permafrost regions. Environmental concerns due to oil and gas activities in the cold waters of the arctic or deep offshore waters generated interest in understanding the impact of gas hydrate formation on the dynamics of gas/oil plumes. Exploitation of oil and gas from deep offshore waters also necessitated the development of kinetic inhibitors and flow modifiers for multiphase flow assurance in the offshore pipelines.

THE STRUCTURE AND PROPERTIES OF GAS HYDRATES

Gas hydrates constitute a class of solids in which small molecules occupy almost spherical holes in icelike lattices made up of hydrogen-bonded water molecules. This class of solids is known as clathrates. Technically speaking, clathrate compounds are characterized by the structural combinations of two substances that remain associated not through strong attractive forces, but because strong mutual binding of the molecules of one sort makes possible the firm enclosure of the other.

The Crystal Structure of Gas Hydrates

Gas hydrates can exist in one of four structures: structure I (sI),[10] structure II (sII),[11,12] structure H,[13] and a new, as of yet unnamed structure.[14]

All four structures contain the basic building block water cavity referred to as the 5^{12} cage. The notation 5^{12} indicates a crystal structure that contains 12 pentagonal faces. The 5^{12} cage can accommodate small guest molecules such as H_2S and CH_4.

In addition to the 5^{12} cage, there are two other commonly encountered cages: the $5^{12}6^2$ cage that can accommodate slightly larger molecules, such as CO_2 and C_2H_6 and the $5^{12}6^4$ cage that can accommodate even larger molecules such as propane and *n*-butane. The 5^{12} cage occurs in both sI and sII hydrates, the $5^{12}6^2$ cage is the large cage in the sI hydrate and the $5^{12}6^4$ cage is the large cage for the sII hydrate.

The sH hydrate is composed of the basic 5^{12} cage, as well as a $4^3 5^6 6^3$ cage and a $5^{12}6^8$ cage. The $4^3 5^6 6^3$ cage

Table 1 Geometry and occupying species of hydrate cavities

	Structure I	Structure II	Structure H
Cavity types	5^{12}, $5^{12}6^2$	5^{12}, $5^{12}6^4$	5^{12}, $4^35^66^3$, $5^{12}6^8$
Radius (Å)	3.91, 4.33	3.902, 4.683	3.91, 4.06, 5.71
Cages/unit cell	2, 6	16, 8	3, 2, 1
Co-ordination number	20, 24	20, 28	20, 20, 36
Crystal type	Cubic	Cubic	Hexagonal
Guest species	CH_4, C_2H_6, Xe, O_2, H_2S, CO_2	Ar, Kr, N_2, C_3H_8, *i*-C_4H_{10}, $(CH_2)_3O$	Butane[a], neopentane[a], benzene[a], cyclopentane[a], cyclohexane[a], cycloheptane[a], cyclo-octane[a], adamantane[a]

[a]Requires the presence of a ''helper'' molecule to stabilize the structure.
(From Refs.[10–13].)

contains three fairly strained square faces, six pentagonal faces, and three hexagonal faces. The $5^{12}6^8$ cage contains 12 pentagonal and 8 hexagonal faces. Structure H hydrates are double hydrates. Small guest molecules, such as xenon, methane, or hydrogen sulfide, occupy the two small cages of the sH hydrate while a larger molecule occupies the large sH cage. Structure I is a body centered cubic crystal, structure II is a diamond cubic crystal and structure H is a hexagonal crystal. Diagrams of the cages and the unit cell for structures I, II, and H are readily available.[10–13]

A comparison of the geometrical properties of structures I, II, and H is given in Table 1. The list of guest species contains some of the most common hydrate formers for each structure. Although both pure methane and pure ethane form structure I hydrates, it has recently been observed[15] that hydrates formed from mixtures of methane and ethane can actually form structure II.

The new, and currently unnamed, structure consists of alternating stacks of structure II and structure H hydrates. It has been synthesized by crystallizing choline hydroxide with tetra-*n*-propylammonium fluoride from aqueous solution.

Physical Properties of Gas Hydrates

In many respects, the acoustic, strength, thermal, and rheological properties of gas hydrates are similar to those of ice. However, there are a few properties, including the dielectric constant and the thermal conductivity, which differ significantly from that of ice. The vast majority of data available on the physical properties of gas hydrates is only for methane hydrates. Davidson[16] presented a comparison of the physical properties of hydrates with those of ice. Table 2 summarizes some of these properties.

A handful of researchers[17,18] have measured the hydration numbers (the ratio of the number of water molecules per molecule of hydrate former in a unit cell) for natural gas and methane and found that they lie between 5.9 and 8.2.

THERMODYNAMIC ASPECTS OF NGH FORMATION AND DECOMPOSITION

Phase Behavior of Hydrate Forming Systems

The phase behavior of NGHs has been extensively researched. The temperature, pressure, the composition of the gas, and the state of the aqueous solution determine the incipient conditions of gas hydrate formation. The most common method for representing phase behavior for gas hydrates is by a temperature versus pressure

Table 2 Comparison of ice and methane hydrate properties

Property	Ice	Methane hydrate
Dielectric constant at 273 K	94	58
Isothermal Young's modulus at 268 K (10^9 Pa)	9.5	8.4
Speed of longitudinal sound at 273 K		
Velocity (km/sec)	3.8	3.3
Transit time (μsec/ft)	80	92
Velocity ratio V_p/V_s at 272 K	1.88	1.95
Poisson's ratio	0.33	0.33
Bulk modulus (272 K)	8.8	5.6
Shear modulus (272 K)	3.9	2.4

(From Ref.[16].)

phase diagram. Makogan,[8] Berecz and Balla-Achs,[19] and Sloan[20] have many examples of phase diagrams for various hydrate forming systems. For a single gas, the Gibbs phase rule suggests that for the binary system of water and a hydrate former gas, there is only one degree of freedom for three phases to coexist in equilibrium. In other words, for a given temperature there is only one pressure for the equilibrium of three phases of solid hydrate, liquid water, and gas phases. For the single gas, the quadruple point has no degree of freedom.

For gases, such as methane, which are supercritical at hydrate forming temperatures, there is one quadruple point, as indicated by point Q1 in Fig. 1. At this point, ice, liquid water, gas and hydrate are in equilibrium. For gases that are subcritical at hydrate forming temperatures, such as ethane,[20,21] there are two quadruple points (Q1 and Q2 in Fig. 2). While Q1 lies at approximately the freezing point of water, Q2 is at approximately the intersection of the hydrate–water–gas three-phase equilibrium curve with the vapor pressure curve. At this latter point, liquid water, gas, hydrate, and liquid hydrate former are all in equilibrium. As seen in Fig. 2, the hydrate formation pressure increases sharply above this quadruple point.

Of particular interest to those in the natural gas industry is the phase diagram of hydrate systems in the presence of inhibitors. Fig. 3 shows the phase diagram for methane hydrates in the presence of methanol[22] and a NaCl and KCl mixture.[23] The solid line is the three-phase equilibrium curve for methane in pure water. As seen from Fig. 3, forming hydrates in the presence of either an alcohol[22] or salt[23] increases the pressure required for gas hydrate formation, at a given temperature.

The equilibrium behavior of structure H hydrates has only recently been studied.[24–27] Fig. 4 shows the incipient hydrate formation conditions of a mixture of methane, carbon dioxide, and neo-hexane, as measured by Servio et al.[27]

Formation of gas hydrates in porous media

Experimental data on gas hydrate formation in porous medium are very sparse. Ershov and Yakushev[28]

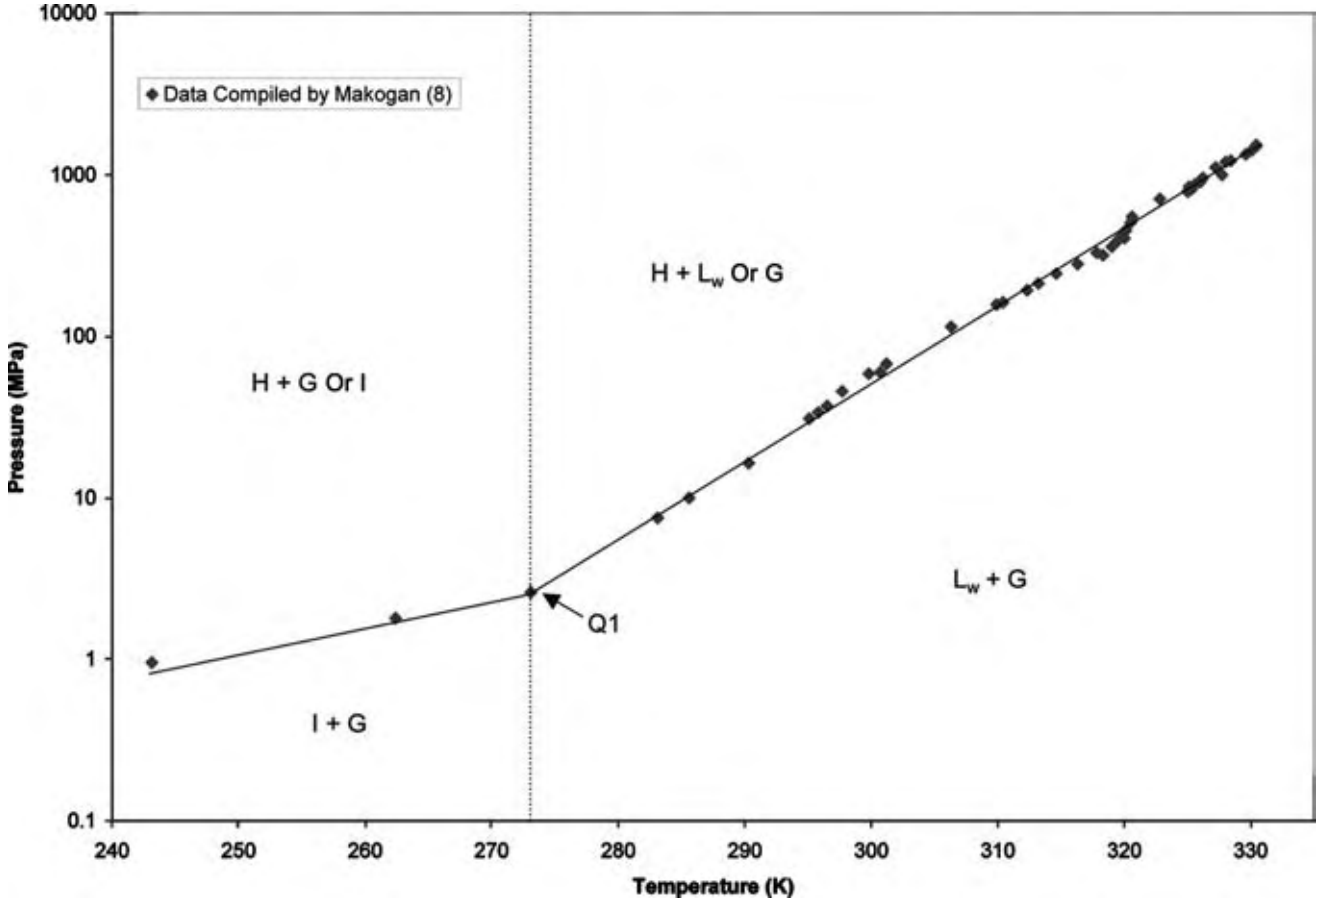

Fig. 1 Incipient hydrate forming conditions for pure methane. The solid line represents the three-phase equilibrium for either ice–hydrate–gas ($T < 273.15$ K), or liquid water–hydrate–gas ($T > 273.15$ K). *(View this art in color at www.dekker.com.)*

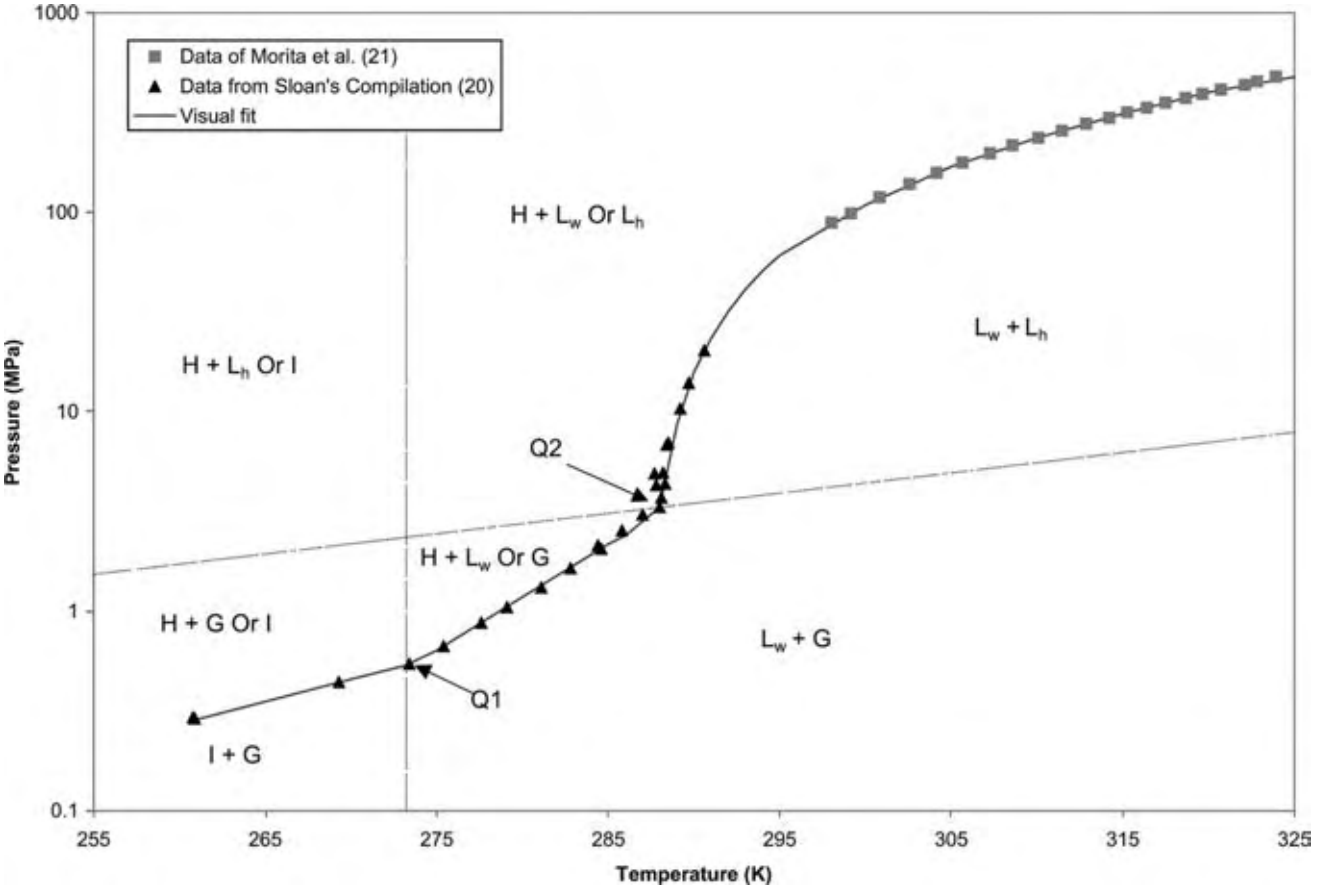

Fig. 2 Incipient hydrate forming conditions for pure ethane. The solid line represents the three-phase equilibrium for either ice-hydrate-gas ($T < 273.15\,\text{K}$), or liquid water–hydrate–gas ($273.15\,\text{K} < T < 288.1\,\text{K}$) or liquid water–hydrate–liquid ethane ($T > 288.1\,\text{K}$). *(View this art in color at www.dekker.com.)*

conducted experiments on rocks freezing by decomposing gas hydrates. Handa and Stupin[29] measured the dissociation characteristics of methane and propane in 70-Å-radius silica gel pores. In both cases, the equilibrium pressures were between 20 and 100% higher than those for hydrates in free water, as seen in Fig. 5. Ahmadi, Chuang, Smith[30] measured equilibrium pressures over a range of temperatures for dissociation to free gas and liquid water of various sI (methane, ethane, and carbon dioxide) hydrates and one sII (propane) hydrate confined in silica gel pores of nominal radii 3–7 nm. Each of these porous media contained a broad distribution of pore radii. The observed pressures again were higher than those in free water.

General Computational Procedures

Incipient point computations

At the three-phase equilibrium condition, the chemical potential (or fugacity) of water in the hydrate phase will be equal to those in the liquid solution (or ice phase, depending on the temperature) and in the gas phase. For computation, it is necessary to have a model to compute the chemical potential in each phase. For the vapor phase, an equation of state is most commonly used. The model of van der Waals and Platteeuw[5] is generally used to calculate the chemical potential (or fugacity) of water in the hydrate phase. The model is given by

$$\frac{\mu_{\text{w}}^{\text{MT}} - \mu_{\text{w}}^{\text{H}}}{RT_{\text{f}}} = \sum_{m=1}^{2} \nu_m \ln\left(1 + \sum_{j=1}^{\text{NH}} C_{mj} f_j\right) \qquad (1)$$

In Eq. (1), the Langmuir constant, C_{mj}, is normally computed from a Kihara potential function.[6]

For calculating the chemical potential of water in the liquid solution, or ice phase, Holder, Corbin, Papadopoulos[7] generated chemical potential, enthalpy, and heat capacity functions for gas hydrates at temperatures between 150 and 300 K and derived

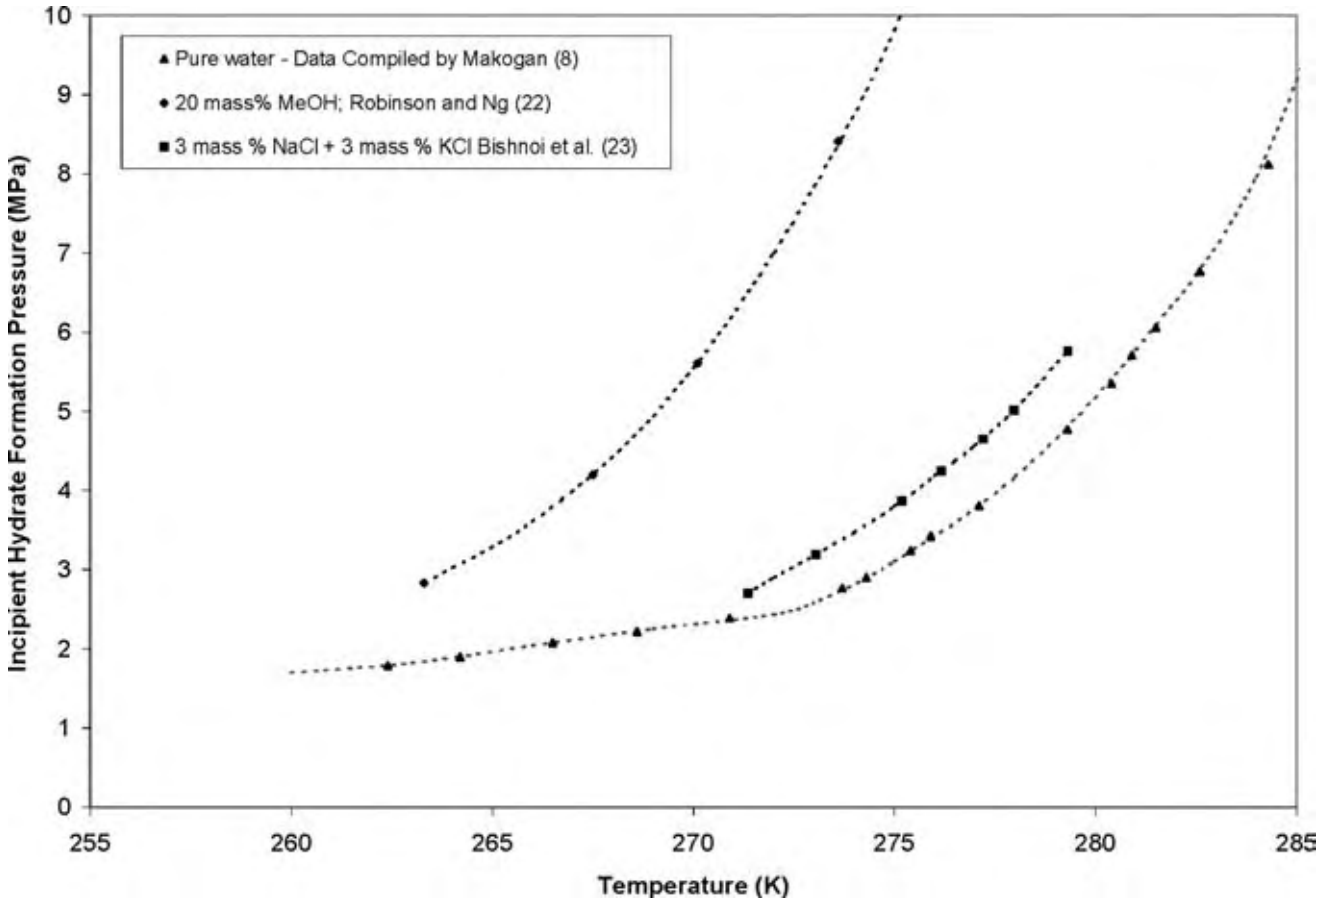

Fig. 3 Three-phase equilibrium curves showing incipient hydrate forming conditions for methane in the presence of various inhibitors. The dashed lines are visual fits of the experimental data. *(View this art in color at www.dekker.com.)*

the following relationship:

$$\frac{\mu_w^{MT} - \mu_w^{L}}{RT_f} = \frac{\Delta\mu_w^{o}}{RT_o} - \int_{T_o}^{T_f} \frac{\Delta h_w^{MT-L_o}}{RT^2} dT + \int_{P_o}^{P} \frac{\Delta v_w^{MT-L_o}}{RT_f} dP - \ln a_w \qquad (2)$$

At equilibrium, the right hand sides of Eqs (1) and (2) are equal. In Eq. (2), the activity of water may be calculated from either an equation of state or from a liquid solution model.

Englezos and Bishnoi[31] developed a model to predict the formation conditions of gas hydrates for sparingly soluble gases in solutions of aqueous electrolytes. More recently, Clarke and Bishnoi[32,33] proposed an equation of state for high-pressure aqueous systems, which may contain soluble gases, single or mixed electrolytes, and/or a second nonaqueous solvent. The equation of state was successfully used in conjunction with the model of van der Waals and Platteeuw[5] to calculate the formation conditions of hydrates formed from pure and mixed gases, in the presence of single salts, mixed salts, and salt/alcohol systems. An alternative approach to modeling hydrate formation in the presence of salts and alcohols was undertaken by Jager, Ballard, Sloan[34] who used the Bromley activity model to compute the activity of water.

Activity models have also been used to compute incipient hydrate conditions in the presence of polymers. Englezos and Hall[35] presented a predictive model for the calculation of the incipient hydrate formation conditions in a hydrocarbon–water–polymer system. The activity of water in the polymer–water solution is computed using the UNIFAC model.

In addition to salts, alcohols, and polymers, the presence of a porous medium will also have an inhibiting effect on the formation of gas hydrates. Clarke, Pooladi-Darvish, Bishnoi[36] derived the following expression for the activity of water in a pore of radius r, and used it along with the model of van der Waals and Platteeuw[5] to model the incipient conditions for

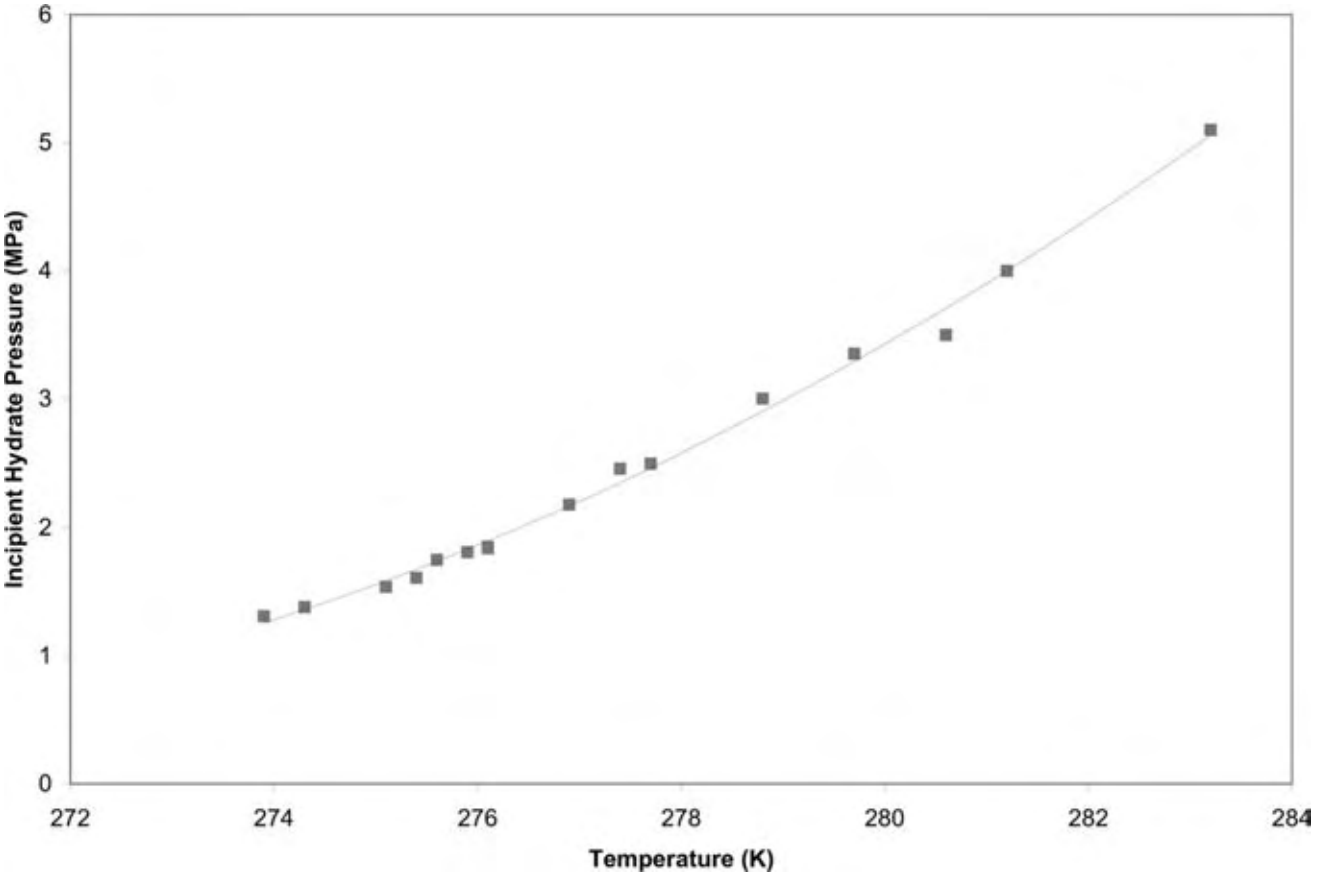

Fig. 4 Three-phase equilibrium curves showing incipient hydrate forming conditions for sH hydrates formed from a mixture of CH_4/CO_2/neo-hexane. methane and propane hydrate formation in 70-Å silica gel pores.

$$\ln a_w = \frac{-2\sigma v_l}{rRT_f}\cos\theta \quad (3)$$

This equation was used with Eqs. (1) and (2) to model the formation of methane and propane hydrates in 70-Å silica gel pores.

Phase fraction calculations

The calculations described in the earlier section gave the incipient point only. At the incipient point, the amount of hydrate formed is infinitesimally small. At conditions that depart from the incipient pressure and temperature, it is possible to estimate the phase fractions (or amounts) of hydrates that have formed. The pioneering work in this field was that of Bishnoi et al.,[37] in which solid phases of structure I and II gas hydrates were included in multiphase flash calculations. The multiphase equilibrium calculations are based on a Gibbs free energy minimization methodology developed by Gupta, Bishnoi, Kalogerakis[38] Recently, Ballard and Sloan[39,40] made minor modifications to the methodology of Gupta, Bishnoi, Kalogeratis[38] and reported calculations on the hydrate phase fractions for some systems.

KINETICS OF GAS HYDRATE FORMATION AND DECOMPOSITION

Hydrate Formation

The process of hydrate formation is a heterogeneous process having similarities with crystallization processes. The difference in the two processes is that in the hydrate formation the solute (hydrate former) is supplied from another fluid phase (gas or liquid) to the aqueous liquid phase where it combines with water and crystallizes as solid hydrate. Also, the process is generally conducted at high pressures. It is because of these factors that the kinetics of hydrate formation and decomposition has been studied by only a few researchers. The similarities lie in the fact that the

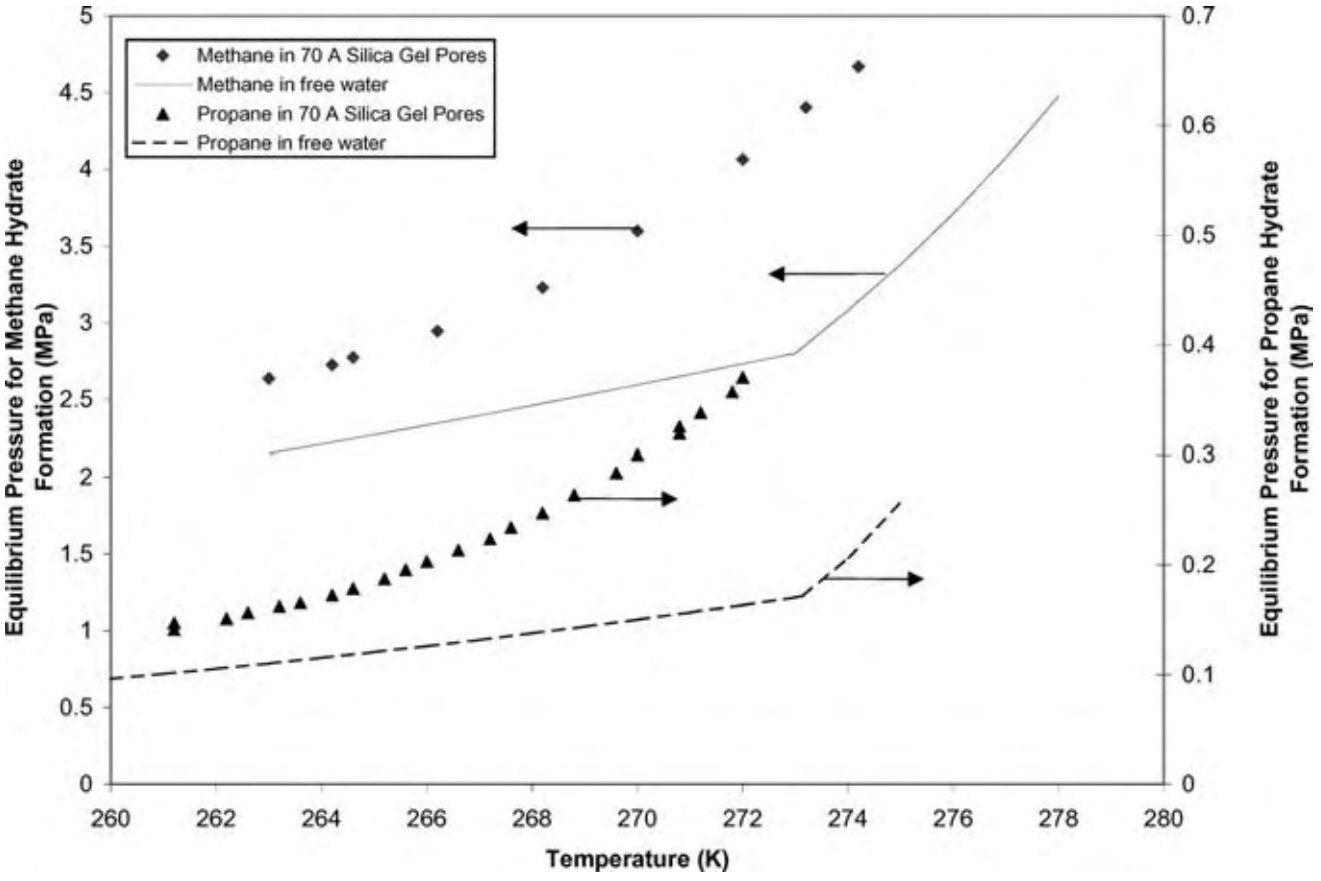

Fig. 5 Three-phase equilibrium curves showing incipient hydrate forming conditions for methane and propane hydrates formed in 70-Å silica gel pores. Points are the data from Handa and Stupin. (From Ref.[29].) *(View this art in color at www.dekker.com.)*

hydrate formation, like crystallization, consists of two different phenomena—nucleation and growth. A crystal nucleus that reaches the thermodynamically stable critical size grows to form crystals. The kinetics of hydrate formation thus requires studying these two different phenomena.

Nucleation

Experimental information on gas hydrate nucleation at a microscopic level is almost nonexistent or at best very limited. Most of the studies on the hydrate nucleation are based on a macroscopic approach. Although there are some differences, gas hydrate nucleation has similarities with salt crystal nucleation.[41] For the nucleation to occur, supersaturation of the aqueous solution with the hydrate former gas is required. The supersaturation is necessary to overcome the free energy barrier for creating a new surface of a solid hydrate nucleus. The degree of supersaturation or the driving force for nucleation may be defined in terms of difference in the chemical potential or the fugacity of a hydrate former in the solution and that at the equilibrium state. The state of supersaturation is a metastable state in which the nucleation processes consisting of the formation and breakage of gas–water clusters occur. These processes continue to eventually form critical size particles that are thermodynamically stable. Formation of the critical size particles leads to nucleation of the solid hydrate phase. The hydrate nucleation may occur in the liquid solution where a sufficient degree of supersaturation exists. For a non-stirred solution, the probability of reaching the desired supersaturation is highest at the gas (or liquid hydrate former) liquid (water) interface. For a well-stirred system the desired supersaturation may reach anywhere in the liquid solution. Englezos et al.[42] estimated the thermodynamic critical size of the hydrate nucleus, assuming primary homogeneous nucleation, to be of the order of 10^{-8} m.

Hydrate nucleation, like salt crystallization, is intrinsically a stochastic process.[43] For a deterministic process, a set of consistent input variables will produce a consistent reproducible result. Hydrate nucleation being a stochastic process will not produce a single set of outputs, but a broad statistical distribution of results owing to the presence of a probabilistic element

in the nucleation mechanism. Because the stochastic characteristics of a homogeneous nucleation event may be masked by heterogeneous influences, the intrinsic kinetics of hydrate nucleation processes is difficult, if not impossible, to measure. The heterogeneous influences may be due to active foreign bodies, surface effects, mechanical perturbations and agitation, thermal history of water, and thermal shocks. Experimentally, the random nature of the process may be dominated by these influences, producing a seemingly deterministic behavior that leads to repeatable experimental results. In addition to the heterogeneous influences, the degree of supersaturation, i.e., driving force and local supersaturation affect the rate of hydrate nucleation. Hydrate nucleation kinetics, in the macroscopic approach, has generally been studied experimentally by observing induction time, defined as the duration of the metastable (supersaturation) state. Modeling of experimental data on induction time is reported in the literature.[41,44] The parameters in such models are equipment dependent and hence cannot be used for other equipment and industrial applications.

Gas Hydrate Crystal Growth

Hydrate crystal growth, unlike hydrate nucleation, is not a stochastic process. Hence, the intrinsic kinetics of hydrate growth can be studied experimentally and modeled. The intrinsic rate constant obtained for this process can be independent of the equipment used for its determination, if determined carefully with proper experimental design, and thus can be used for industrial or other applications.

Experimental information on the kinetics of gas hydrate growth on molecular level is either nonexistent or at best extremely limited. Most of the studies on the hydrate formation kinetics are based on a macroscopic approach. Although hydrate growth is a heterogeneous process, a few researchers have studied and modeled hydrate growth by considering it a homogeneous process.[45,46] The first work to recognize and quantitatively account for the fact that the growth of gas hydrate particles is a heterogeneous crystallization process was that of Bishnoi and coworkers.[42] They formulated a macroscopic mechanistic model based upon crystallization and mass transfer theories. They experimentally studied the hydrate formation in bulk water using a semi-batch high-pressure stirred reactor by monitoring gas consumption during its dissolution in water and consumption for hydrate formation. The experiments were conducted so that the heat and mass transfer effects around a hydrate particle are eliminated. Thus, the measured rate constant is the intrinsic rate constant, which is not system dependent. The data, obtained after the appearance of hydrate nuclei, were analyzed to formulate the model. The studies were undertaken for hydrates of methane, ethane, and their mixtures. Recently, they completed a study on carbon dioxide hydrate formation by installing a particle size analyzer in the high-pressure reactor.[47] The rate model is formulated by considering the intrinsic step of hydrate growth as the ''reaction'' at the hydrate solid–liquid interface. The reaction is a combination of steps for the creation of water structure near the interface, the incorporation of guest (hydrate former) by adsorption in the lattice, and subsequent stabilization of the hydrate structure framework by hydrogen bonding and van der Waals forces. The intrinsic model for the rate of hydrate growth per particle is given by:

$$\left(\frac{dn_H}{dt}\right)_p = K^* A_p (f - f_{eq}) \tag{4}$$

where

$$\frac{1}{K^*} = \frac{1}{k_r} + \frac{1}{k_d} \tag{4a}$$

In the above model, the driving force is given by $(f - f_{eq})$, which is the difference between the fugacity of the dissolved gas and its three-phase equilibrium value. In Eq. (4a), k_r is the intrinsic rate constant for the hydrate particle growth reaction and k_d is the mass transfer coefficient around the particle. If the experiments are carried out under conditions such that heat and mass transfer resistances around the particle are eliminated, then $k_d \gg k_r$ and $K^* \approx k_r$. The intrinsic rate constants K^*, for methane, ethane, and carbon dioxide are reported in Table 3.

The heterogeneous nature of gas hydrate formation was also acknowledged by Herri, Gruy, Cournil,[48] who developed a new model of gas hydrate crystallization and an experimental technique that uses in situ turbidimetry measurements to study the crystallization of methane hydrate.[49]

A handful of studies have investigated the effects of additives, such as salts and surfactants, on the kinetics of hydrate formation.[50–52]

Gas Hydrate Decomposition

Hydrate crystal decomposition, like the hydrate growth, is a deterministic process. Hence, the process is amenable to study experimentally and modeling. Although some studies have been undertaken at the molecular level, most of them on the hydrate decomposition kinetics are based on a macroscopic approach. The hydrate decomposition is a heterogeneous process where liquid water and gas are released as the solid

Table 3 Intrinsic rate constants for hydrate formation for CH_4, C_2H_6, and CO_2 hydrates

Temperature (°C)	K^a for CH_4 (mol/m^2 s MPa)	K^a for C_2H_6 (mol/m^2 s MPa)	K^a for CO_2 (mol/m^2 s MPa)
1.0	0.65×10^{-5}	0.12×10^{-5}	6.42×10^{-3}
3.0	0.55×10^{-5}	0.11×10^{-5}	4.82×10^{-3}
4.0	—	—	3.21×10^{-3}
5.0	—	—	—
6.0	0.57×10^{-5}	0.13×10^{-5}	—
6.5	—	—	5.27×10^{-3}
9.0	0.58×10^{-5}	0.14×10^{-5}	—

[a]Rate constants for CH_4 and C_2H_6 are currently being re-evaluated using an in situ particle size analyzer.
(From Refs.[42,47].)

shrinks due to its decomposition. Bishnoi and coworkers[53–57] experimentally studied the hydrate decomposition in bulk water using a semibatch high-pressure stirred reactor by monitoring gas released during the decomposition. The experiments are conducted so that the heat and mass transfer effects around a hydrate particle are negligible. Thus, the measured rate constant is the intrinsic rate constant, which is not system dependent and thus, can be used for industrial or other applications.

In their earlier work,[53] the experiments were conducted without determining the particle size analysis in the water slurry in the reactor. Later, they installed a particle size analyzer externally to the reactor to obtain the data with the particle size analysis.[54–56] Recently, they installed a particle size analyzer in the high-pressure reactor for their experiments.[57]

To obtain the intrinsic rate constant from the data, Kim et al.[53] developed a mechanistic model given below:

$$\left(\frac{dn_H}{dt}\right)_p = -K_d A_p \left(f_{eq} - f_g^V\right) \quad (5)$$

The model is formulated on the premise that the decomposing hydrate particle is surrounded by a cloud of the product gas; hence the driving force for the decomposition process is expressed in terms of the fugacity difference given in Eq. (1). The process of decomposition possibly involves (1) destruction of the clathrate host (water) lattice at the surface of the particle, and (2) and desorption of the guest (hydrate former) molecules from the surface. The particle size distribution was incorporated in the calculations for the determination of the intrinsic rate constants.[54–57] The following Arrhenius type equation is used to represent the effect of temperature on the intrinsic rate constant:

$$K_d = K_d^o \exp\left(-\frac{\Delta E}{RT}\right) \quad (6)$$

The intrinsic rate constant, K_d^o, and activation energies, ΔE, for CH_4, C_2H_6, and CO_2 hydrate decomposition are given in Table 4. For the decomposition of hydrates formed from mixtures of methane and ethane, Clarke and Bishnoi[56] showed that the total rate of decomposition is equal to the sum of the decomposition rates of the individual species.

PRACTICAL ISSUES AND APPLICATIONS

Industrial Issues

It is of interest to avoid hydrate formation or modify its flow characteristics to circumvent the problem of plugging natural gas pipelines or process equipment. Interest in gas hydrate research also stems from the planned activities to exploit the huge natural deposits of gas hydrates as an energy resource.

Flow assurance

In many pipelines, the temperature and the pressure conditions that are encountered place the flowing fluid well within the hydrate stability envelope. Experts estimate that controlling and preventing hydrate formation, or ''flow assurance,'' costs industry more than $100 million per year.[58] The problem is extremely severe in off-shore pipelines. In fact, the replacement of hydrate plugged flow lines in deep water is estimated to cost roughly $1

Table 4 Intrinsic rate constants, K_d^o, and activation energies, ΔE, for methane, ethane, and CO_2 hydrate decomposition

Gas	K_d^o (mol m^{-2} Pa^{-1} sec^{-1})	ΔE (kJ/mol)
CH_4	3.6×10^4	81
C_2H_6	2.56×10^8	104
CO_2	1.83×10^8	103

(From Refs.[54,55,57].)

million per mile.[59] Conventional methods of preventing hydrate formation in pipelines are to process the petroleum fluids, typically by heating the fluid, water dew point control through moisture removal, or to inject thermodynamic inhibitors so that the operating conditions of the pipelines lie outside the hydrate stability envelopes. These may be called the ''hydrate avoidance'' methods. More recently, kinetic methods of delaying hydrate formation and hydrate flow modifiers have been developed. The methods, based on modifying the flow characteristics of hydrates seem to be gaining popularity with industry, especially for off-shore applications.

Of the above-mentioned techniques, thermodynamic inhibitors, which include alcohols, salts, and glycols, are by far the most prevalent. For example, adding methanol to a natural gas will shift the equilibrium conditions so that a higher pressure is required to form hydrates, at a given temperature, as illustrated for methane in Fig. 3. Methods for estimating the saturation water content of natural gases and amounts of methanol or glycol required to suppress hydrate formation are discussed by Katz,[3] Sloan,[20] and Campbell.[60] Current practice for the estimations is to use computer software based on phase equilibrium calculations.[61]

Kinetic inhibitors are typically water-soluble polymers or copolymers that delay hydrate nucleation and/or growth. An inhibitor molecule slows crystal growth by either adsorbing on to the growth sites on the crystal surface, or by fitting into the crystal lattice. Antiagglomerants are designed to specifically interact with the growing hydrate crystal surface. These inhibitors permit hydrates to form but inhibit agglomeration, deposition, and plugging.[62]

Natural gas recovery from hydrate deposits

Fig. 6 shows the worldwide distribution of the currently known hydrate deposits.[63] It can be seen that the majority of the deposits are located offshore, either in subduction zones, passive margins, or offshore hydrocarbon deposits. Methane hydrates can exist in oceanic sediment where the ocean is at least 300 m deep. In the permafrost regions, methane hydrate is present at depths between 150 and 2000 m below the surface. It is interesting to note from Fig. 6 that NGH deposits are distributed worldwide quite evenly unlike conventional oil and gas deposits.

On the Earth, the total amount of carbon sequestered in offshore and onshore hydrate deposits is believed to be larger than all other carbon sources combined. Fig. 7 shows the relative sizes of organic carbon reserves. Of the estimated 18,777 gigatons of carbon, 10,000 gigatons are believed to be in the hydrate form.[64]

Currently, the techniques to recover natural gas from in situ hydrate deposits are in their infancy. Possible techniques include dissociating the in situ hydrates by pressure reduction, heating, or solvent injection. Two test wells were drilled for characterization and production testing in the Mackenzie Delta region of Canada, by international efforts in 1998 and 2002. The results of the first test well have been reported.[65] The release of production test results from the second well is expected. On 25 August 2005 from the Geological Survey of Canada.[66]

Environmental Issues

Seafloor stability and global warming

As oil and gas exploration extends into progressively deeper waters, the potential hazard posed by gas hydrates to operations is gaining increasing recognition. Hazards can be considered as arising from two possible events: (1) the release of high-pressure gas trapped below the hydrate stability zone, or (2) the destabilization of in situ hydrates. A major issue is how gas hydrates alter the physical properties of sediment. The link between seafloor failure and gas

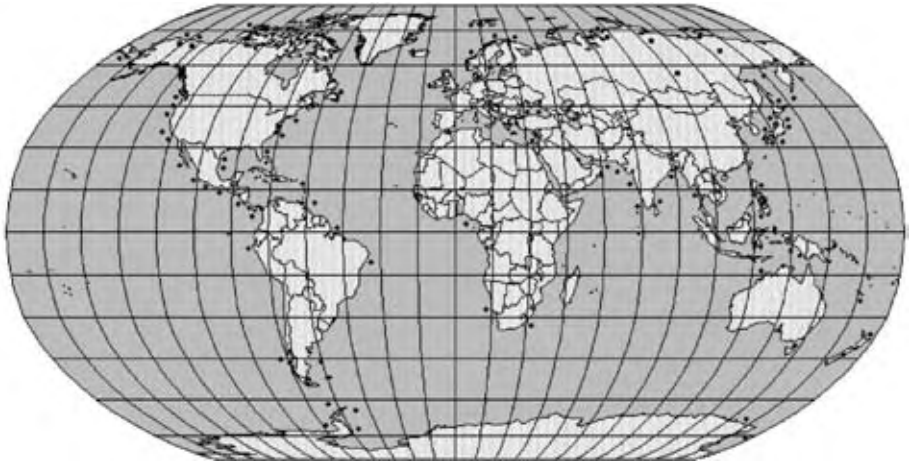

Fig. 6 Worldwide deposits of gas hydrates. Circles are offshore deposits and squares are onshore deposits. (From Ref.[63].) *(View this art in color at www.dekker.com.)*

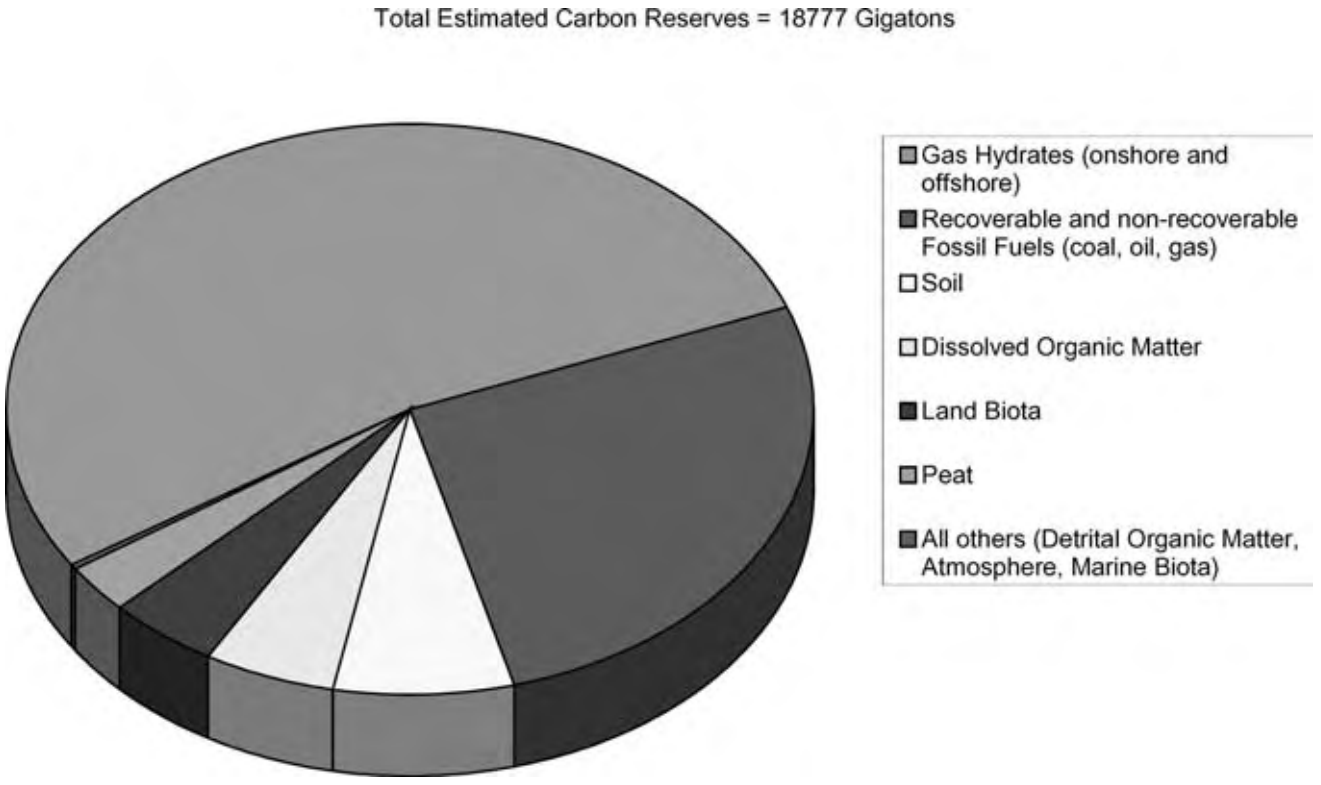

Fig. 7 Relative sizes of organic carbon reserves. (From Ref.[64].) *(View this art in color at www.dekker.com.)*

hydrate destabilization has been well established, especially with respect to the previous glacial–interglacial eustatic sea-level changes. Sea slope failure, as a result of gas hydrate decomposition, is considered to pose a significant hazard to underwater installations, pipelines, and cables, and, in extreme cases, to coastal populations through the generation of tsunamis.

As a greenhouse gas, methane is roughly 10 times more potent than CO_2. Over geologic time scales, there is evidence pointing to periodic, large releases of methane into the atmosphere. During formation of large polar ice sheets the sea level falls, thereby reducing the pressure on the ocean margin gas hydrates. It has been suggested that the shallower gas hydrate deposits became unstable and released methane into the atmosphere, which contributed to warming and the ending of the Ice Age.[67] On the other hand, the presence of increased amounts of CO_2 in the atmosphere due to human activities is likely to lead to global warming, which could increase surface temperatures. This, in turn, could release methane from hydrate deposits in ocean sediments or permafrost regions leading to further global warming.

Deep-water well blowouts

In the event of a deep-water well blowout, one of the environmental concerns is whether oil will surface and if so, where, when, and what will be the thickness of the oil slick. In the high-pressure and low-temperature conditions encountered in deep water, the gases are likely to form hydrates. As the density of hydrates is similar to that of oil, the conversion of gas into hydrates has a significant impact on the behavior of the jet/plume due to the alteration of the buoyancy. This phenomenon was first studied experimentally by Maini and Bishnoi,[68] later modeled by Topham,[69] and more recently by Chen and Yapa,[70] who also provide a summary of other important experimental work in this area. Chen and Yapa incorporated kinetic models of hydrate growth[42] and hydrate decomposition[53] in their plume model.

Applications of gas hydrates

Gas hydrates for natural gas storage

Natural gas could possibly be stored at low pressures and temperatures in the form of a hydrate. The relative density of gas in the hydrate lattice exceeds its liquid density. According to the calculations of Parent,[71] a natural gas with a volume of $4.42\,m^3$ at 15°C and atmospheric pressure only needs $0.028\,m^3$ volume for storage in the hydrate state. Thus, only 1/156 of the volume in the free state is needed. Rogers and Zhong[52] conducted a study on storing natural gas

in hydrate form in which they found that adding surfactants greatly increased the rate of hydrate formation in storage vessels.

Transportation of natural gas

Gudmundsson and Borrehaug[72] have presented results from a study to determine the feasibility of transporting natural gas in the frozen hydrate form. A NGH transportation chain comprises hydrate production, marine transport, and regasification elements. Even after a conservative economic analysis, it was found that the capital cost associated with an NGH chain will be 28% lower than the equivalent LNG chain. Takaoki et al.[73] found that the most suitable way to store hydrate for transportation was as small pellets.

Separation processes involving gas hydrates

Knox et al.[74] investigated using gas hydrates for the desalination of seawater. In this process, pure water is separated from its solution in a solid form by a reaction with certain agents to form a gas hydrate. The hydrate crystals are then separated from the brine, washed, and decomposed into propane gas and pure water.

Ngan and Englezos[75] formed propane hydrates in pulp mill effluents to recover water. Another application of gas hydrates in separations was seen in the study of Purwanto et al.,[76] which sought to investigate the concentration of coffee solutions through gas hydrate formation.

CONCLUSIONS

Since their discovery in the early 19th century, gas hydrates have gone from being merely a laboratory curiosity to a serious problem for the natural gas industry to potentially becoming the largest source of methane. The emerging gas hydrate technologies have the potential not only to provide a huge source of methane, but may also one day be a means for natural gas storage and transportation and for various separations. However, in order to shift to these processes from the conceptual stage to becoming commercially feasible, it is still necessary to further enhance current understandings of hydrate science and engineering.

NOMENCLATURE

a	Activity
A	Surface area
C	Langmuir constant
f	Fugacity
h	Enthalpy
K^*	Intrinsic rate constant for hydrate formation
K_d	Intrinsic rate constant for hydrate decomposition
n	Moles
NH	Number of hydrate formers
P	Pressure
r	Pore radius
R	Universal gas constant
T	Temperature
v	Molar volume

Greek Letters

μ	Chemical potential
ν	Number of cavities per water molecule
σ	Interfacial energy
θ	Wetting angle

Subscripts and Superscripts

eq	Three-phase equilibrium conditions
f	Hydrate formation conditions
g	Gas phase
H	Hydrate or in hydrate
L	Liquid solution or phase
MT	Empty lattice
o	Standard state
p	Particle
V	Vapor phase
w	Water

Natural Gas Utilization

Peter R. Pujadó
UOP LLC, Des Plaines, Illinois, U.S.A.

INTRODUCTION

Natural gas is a complex mixture of light hydrocarbons and some nonhydrocarbon materials. Methane (CH_4) is its major constituent, but natural gas may contain much heavier hydrocarbons, including pentanes or hexanes. This gives rise to terminology like ''wet gas'' for a natural gas that contains condensable hydrocarbons and ''dry gas'' for a natural gas that is essentially free of recoverable liquid hydrocarbons. Other components of natural gas include carbon dioxide (CO_2), nitrogen, hydrogen sulfide (H_2S), mercaptans (HS-R), helium, water, and other minor contaminants. The composition of the natural gas is often related to its provenance. ''Associated gas'' is natural gas that is recovered from an oil reservoir and, having been in contact with oil, tends to contain a larger proportion of hydrocarbons other than methane. On the other hand, natural gas that has not been in contact with oil, sometimes called ''nonassociated gas,'' tends to be leaner on hydrocarbons other than methane and often contains only small amounts of ethane and propane. ''Natural gas liquids'' are light hydrocarbons like ethane, propane, and butanes that can be recovered from natural gas by condensation.

BACKGROUND

Although natural gas has been known for thousands of years, sometimes as a subject of awe and worship, its first documented ''industrial'' use appears to have been by the Chinese who used it to evaporate salt brine in around the eighth century. It appears in the environment either as a result of gas seeps from underground coal mines or shallow oil reservoirs, or as swamp gas from the decomposition of organic compounds, and not insignificantly from the flatulence of animals, in particular cattle. All natural gas appears to be of organic origin, although some theories postulate the existence of abiotic gas reservoirs deep in the Earth's crust. Regardless of its source, the release of natural gas into the environment is of growing concern, as, because of the relative quantities, methane is potentially a more significant contributor to the ''greenhouse effect'' than CO_2.

In recent times, natural gas was first used domestically for lighting in Fredonia, New York, in around 1821. Later, in 1865, the Fredonia Gas, Light, and Waterworks Company became the first natural gas company in the U.S.A. The high calorific value of natural gas soon prompted its use as an industrial fuel for the steel and glass industry in Pittsburgh in the late nineteenth century, and its use has continued to expand ever since. The availability of natural gas in Europe has always been very limited and it has been only in relatively recent years that its use has expanded as a result of the discovery of oil and gas in the North Sea and the import of natural gas from Russia by pipeline and from North Africa and the Middle East by ship as liquefied natural gas (LNG). Eventually though, natural gas and liquefied petroleum gases (LPG; propane, butanes, or mixtures thereof) completely replaced the old ''town gas'' or ''water gas,'' a highly toxic mixture of carbon monoxide (CO), hydrogen, methane, and other hydrocarbons, which is obtained by blowing air and steam over red-hot coal, and which, despite its very low calorific value, for many years was the mainstay for domestic illumination in many European countries.

Today, natural gas is the third most important fuel used worldwide, after oil and coal. Like all fossil fuels, the reserves of natural gas are far from being inexhaustible but, fortunately so far, newer fields and reserves have been identified at a faster rate than its consumption so that, overall, the proven reserves have been increasing. If the recovery of deep-ocean natural gas hydrates were to become feasible in the future, much larger reserves would be available. The uses of natural gas today can be summarized as:

1. Residential fuel.
2. Commercial fuel.
3. Industrial fuel.
4. Power generation fuel.
5. Transportation fuel.
6. Chemical feedstock.
   a. Direct chemical applications.
   b. Indirect chemical applications (through synthesis gas, or ''syn gas'').
7. Feedstock for liquid fuels (also through syn gas).

NATURAL GAS RESERVES

Because of their nature, encyclopedias are never comprehensive nor up to date, and this one is no exception. For the best overview of the reserves and production of natural gas and almost all other fuels it is best to consult the specialized literature. Two particularly valuable resources are the *Oil & Gas Journal* and the annual *BP Statistical Review of World Energy*, currently available in the internet at http://www.bp.com and also available in hard copy as far back as 1951. These and other publications from the International Energy Agency (IEA), the European Union, and other sources, provide a detailed, up-to-date picture of the energy balance for all fuels, on a country-by-country, and year-by-year basis.

At the end of 2004, the proved reserves of natural gas were 179.53 trillion (10^{12}) cubic meters (m^3). [Please refer to the appendix on units and unit conversions—in this writing we use the American and British definitions of billion (10^9) and trillion (10^{12}), which should not be confused with the European definitions, 10^{12} and 10^{18}, respectively. Also, unless noted otherwise, the volumetric amounts are expressed in terms of standard m^3, or scm, measured at 15°C and 1 atm or 1013 mbar]. In Table 1 the change in reserves over the past 20 years is illustrated:[1]

The increase in reserves is short of spectacular, but conservation has had nothing to do with it. Worldwide consumption increased from 2.04 trillion m^3 in 1992 to 2.54 trillion m^3 in 2002 and about 2.7 trillion m^3 in 2004. The main contributor to the growth in reserves has been the discovery of massive fields in the Russian Federation, from western Siberia all the way to Sakhalin island in the Far East, and the potential for future discoveries in Siberia, Kazakhstan, and surrounding areas. Iran, Qatar, Nigeria, the United Arab Emirates, and, to a lesser extent, Trinidad, Bolivia, Venezuela, Egypt, Australia, etc. have also been significant contributors to the growth in reserves. In contrast, the proved reserves in the U.S.A., Canada, and Mexico have decreased. The reserves/production (R/P) ratio for a given year provides an indication of the length of time that the remaining reserves would last if production were to continue at the same level as for that year. Typically, the R/P ratios are low for industrialized countries with a large appetite for fuel—for example, 9.6 for the U.S.A. at the end of 2002—and high for less developed areas. Not surprisingly, we are seeing a shift in the location of large gas-consuming industries from high-cost industrialized countries where natural gas may cost as much as $6.00 per million Btu to less developed areas where gas is abundant at the source and its cost may be as low as $0.50 per million Btu.

Figs. 1–7 are reproduced here from the *BP Statistical Review of World Energy 2005*, by permission from BP p.l.c.

Table 1 Worldwide natural gas reserves

Year end	Trillion (m^3)
1982	85.9
1992	138.3
2002	155.8
2004	179.5

FUEL PROPERTIES OF NATURAL GAS

Natural gas is a mixture of variable composition. Its properties, therefore, cannot be defined precisely. A typical range of compositions could be as given in Table 2.

Because natural gas may contain significant amounts of nonhydrocarbons, its calorific value will be a strong function of its composition. In fact, for transportation and fuel utilization, it is necessary to remove these nonhydrocarbons to the highest extent possible. Typically, natural gas is treated at the source, either for a single well or, more commonly, at a central point for several wells. The gas is desulfurized or sweetened to bring the hydrogen sulfide content down to a few ppm. Usually amines or other solvents are used for the removal of H_2S by absorption and stripping; elemental sulfur can then be recovered by using a Claus unit or similar. Depending on the system, CO_2 can also be removed or depleted by absorption/stripping; alternatively, it can be separated from natural gas using membranes (membranes have also been used for H_2S but to a lesser extent).

Typically, natural gas will also be dried to remove water vapor using a glycol system, a cryogenic unit, or molecular sieve adsorbents, and it may be treated for the removal of mercury, arsenic (often as arsine, AsH_3), or phosphorous (often as phosphine, PH_3). Various adsorption units are available for the removal of traces of these metals.

At the end what matters is to have a natural gas with a high calorific value. In Table 3, heating values for typical components in clean natural gas are provided:[2]

Although natural gas is usually priced in terms of its high heating value (HHV), most users only benefit from its low heating value (LHV), as the latent heat of water vapor condensation is seldom recovered in smaller applications. In Table 4, the heating value calculation for a hypothetical gas composition is illustrated.

Nitrogen and CO_2 dilute natural gas and lower its heating value. A ''good'' natural gas typically will have high heating values of about 1000 Btu/scf (pure methane has an HHV of 1009 Btu/scf). Commercially,

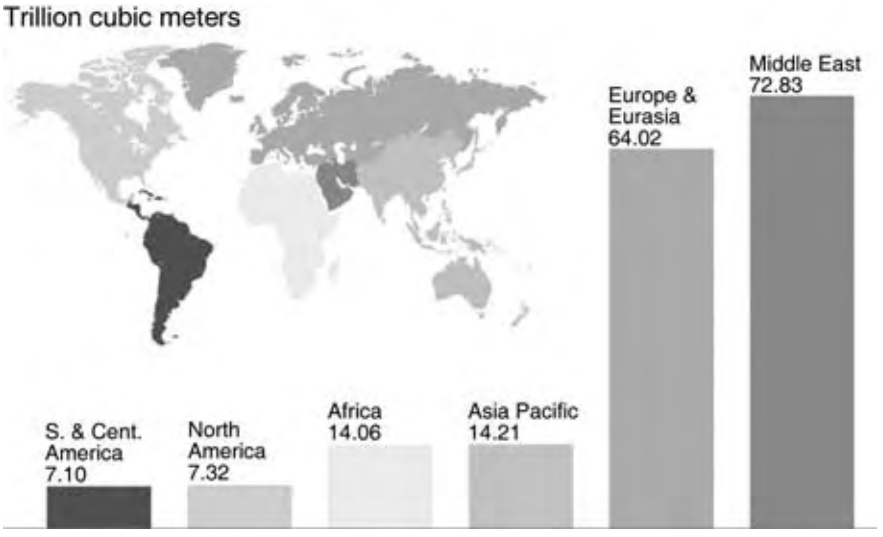

Fig. 1 Distribution of proved natural gas reserves (2004). (From Ref.[1].) *(View this art in color at www.dekker.com.)*

heating requirements are usually expressed in terms of millions of Btu (mm Btu). One mm Btu = 1.055 giga-Joules (GJ). Domestic gas consumption in the U.S.A. is often expressed in terms of ''therms.'' One therm = 10^5 Btu = 0.1 mm Btu.

The success of natural gas as a clean fuel has greatly increased its consumption in power plant applications. Natural gas fueled power plants are significantly less costly to build than coal fired or nuclear power plants. They are also easier to operate so that they lend themselves to ''peaking'' operations in which they are only brought on stream when required and may sit idle the rest of the time. In principle, natural gas fired power plants are also cheaper to operate, but the increased demand for natural gas has rapidly increased feedstock prices in the U.S.A. in recent years.

When facilities for shipping natural gas by pressurized pipelines are not available, the only feasible solution is to liquefy it in cryogenic installations and to ship it as LNG. Most LNG landing facilities are located in Japan, Korea, and in southern Europe. Although the facilities to land natural gas as LNG in the U.S.A. are currently very limited (one in the Gulf Coast and one in New England), it can be expected that others will be built as a result of the growing demand and diminishing domestic supply. While this entry does not address LNG or the shipping of natural gas in general, it must be realized that the natural gas requirements for LNG facilities that are commercially and economically viable can be formidable. A typical facility to handle 5 mm t/yr of LNG requires 22.2 mm scmd of natural gas, or about 222 billion scm

over a 30-year time span. Liquefaction, shipping, and revaporization costs are significant. Even with natural gas priced at source at not more than \$0.75 per mm Btu, the landed price is likely to exceed \$3.50 per mm Btu, before local distribution costs and profit margins.

NATURAL GAS AS TRANSPORTATION FUEL

In addition to its use as domestic and industrial fuel, natural gas is extensively used as a transportation fuel. In transportation applications, natural gas offers the advantages of being a clean burning fuel that can

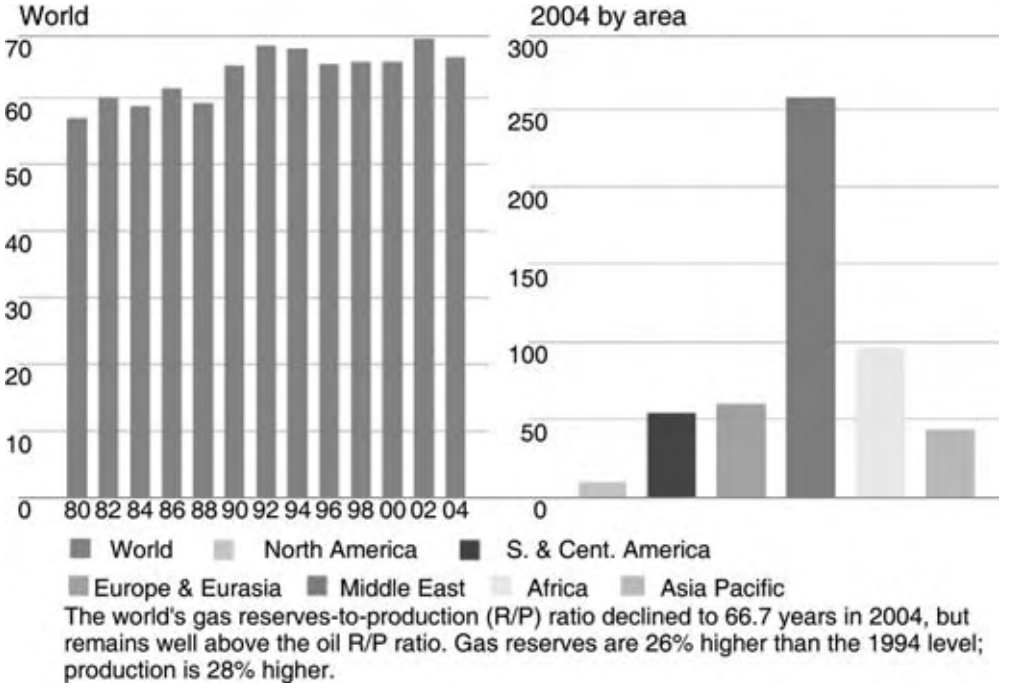

Fig. 4 Geographic reserve/production ratios of natural gas (2004). (From Ref.[1].) *(View this art in color at www.dekker.com.)*

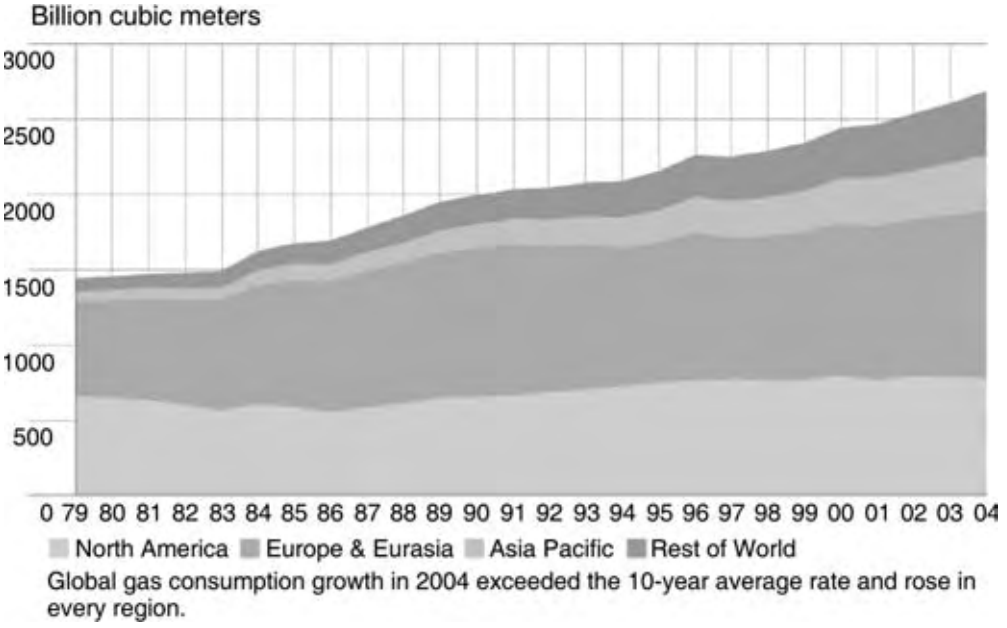

Fig. 5 Geographic consumption of natural gas (2004). (From Ref.[1].) *(View this art in color at www.dekker.com.)*

generate significantly reduced exhaust and greenhouse gas emissions than in comparable gasoline- or diesel-powered vehicles. In addition, because methane, the main ingredient of natural gas, has an exceptionally high octane number with $(R + M)/2 > 120$, it can be readily used in conventional gasoline-powered engines.

The main difficulty with natural gas is its storage requirements and limitations. As a gas, its energy capacity per unit volume is exceedingly low. Therefore, the conventional solution has been to raise its pressure to about 2400 psi or higher. Compressed natural gas (CNG) has a much higher energy content per unit volume and is of practical use in vehicular applications. While in the U.S.A. uses of CNG have been largely limited to municipal transit buses and fleet applications, in other countries, in particular New Zealand, CNG has gained wide acceptance as an automobile fuel. In Table 5, comparative values of the energy content of various fuels are provided.

Higher energy content of CNG can be obtained by storing it at even higher pressures. Pressures as high as 3500–5000 psig have been used, although there may be

Fig. 6 Per capita consumption of natural gas (2004). (From Ref.[1].) *(View this art in color at www.dekker.com.)*

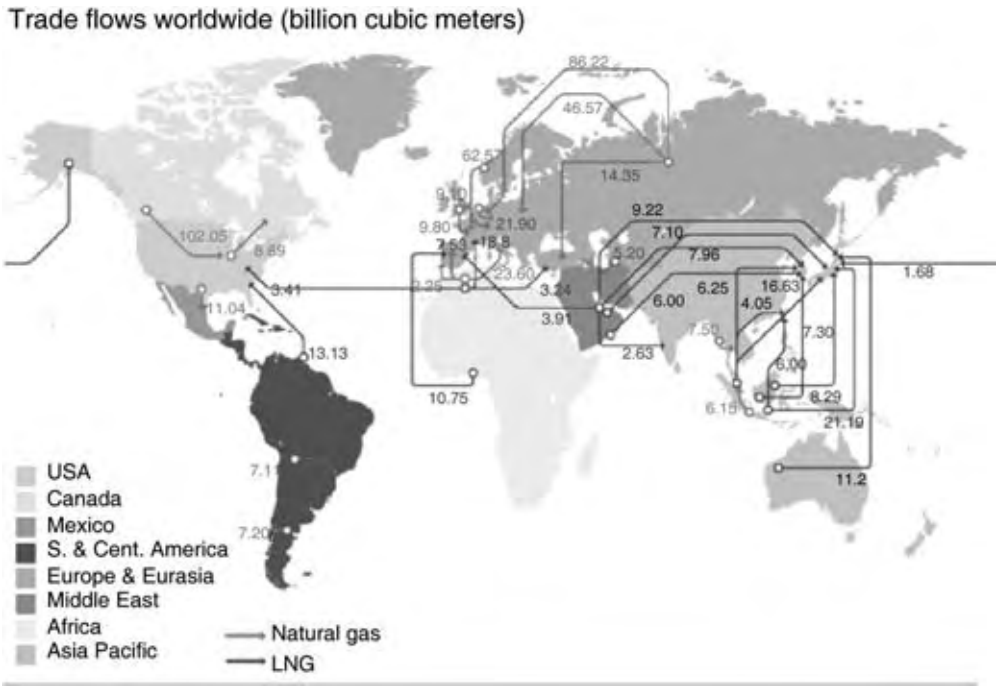

Fig. 7 Natural gas shipping and trade movements (2004). (From Ref.[1].) *(View this art in color at www.dekker.com.)*

some concerns as to the integrity of the storage tanks, principally in the event of an accident.

Clearly, CNG has a significant energy content, but still falls short of the energy contained in an equivalent volume of gasoline or diesel fuel. Typically, even with an expanded fuel tank volume made possible by its lower weight, the driving range of a CNG-powered vehicle is only about one-third to one-half that of the same vehicle with a gasoline-powered engine.

An alternative that has been proposed is to take advantage of the solubility of methane in hydrocarbons under medium to elevated pressures. Thus, by operating at pressures comparable to or lower than those used for CNG, it is possible to greatly increment the volumetric energy content by coupling the energy content of the solvent with that of the solute.

Data for methane/hydrocarbon mixtures are not well established. Some results can be generated through commercially available simulators like Aspen or Hysys but are somewhat questionable because of the nonidealities of these mixtures at elevated pressures. Also, the vapor–liquid equilibrium data currently available are very limited and mostly concern blends of methane with *n*-paraffins, which have very poor ignition characteristics in internal combustion engines.

With the above-mentioned uncertainties and limitations concerning the accuracy of commercial simulators, results obtained with Aspen, which can be used to at least directionally, illustrate the merits of using methane/diesel blends for a particular set of conditions with a diesel fuel at room temperature (70°F), are illustrated in Table 6.

Table 2 Typical composition ranges for natural gas

	Mol%
Hydrocarbons	
Methane	75–99
Ethane	1–15
Propane	1–10
n-Butane	<2
iso-Butane	<1
n-Pentane	<1
iso-Pentane	<1
Hexane and heavier	<1
Nonhydrocarbons	
Nitrogen	0–15
Carbon dioxide	0–30
Hydrogen sulfide	0–30
Helium	0–5

Table 3 Heating values of individual natural gas components

	MW	HHV (Btu/lb)	LHV (Btu/lb)
Nitrogen	28.014	0	0
CO_2	44.011	0	0
Hydrogen	2.016	60,958	51,571
Methane	16.043	23,861	21,502
Ethane	30.070	22,304	20,416
Propane	44.097	21,646	19,929

Table 4 Heating values calculation for a given natural gas composition

	Mol%	Wt.%	HHV (Btu/scf)	LHV (Btu/scf)
Nitrogen	2.00	3.17	0.00	0.00
CO_2	3.00	7.47	0.00	0.00
Hydrogen	1.00	0.11	3.24	2.74
Methane	90.00	81.66	907.87	818.11
Ethane	3.00	5.10	53.02	48.53
Propane	1.00	2.49	25.15	23.16
Average MW = 17.683			989.28	892.54

Thus, by using mixtures of natural gas with hydrocarbon fuels, we can maintain the volumetric energy density of the mixture at values close to those of the hydrocarbon while adding significant amounts of natural gas to the hydrocarbon fuel pool, thereby incrementing the total energy content by 10% or more, depending on the pressure.

While the above results reflect mixtures of methane with a standard diesel fuel, similar or even better effects can be observed with blends of methane with gasoline components. In Table 7, as an example, literature data on the solubility of methane in toluene at 300°F (solubilities are much higher at lower temperatures) are provided. This also illustrates the need to generate additional data for different hydrocarbons over a broad range of operating conditions, i.e., pressure and temperature.

Methane forms azeotropes with many hydrocarbons. For example, methane and *n*-butane at 32°F and 2660 psig form an azeotrope with 92.9 mol% methane. Azeotropes are ideal for fuel blend applications because the composition remains essentially constant as the fuel is being used and the tank is being emptied. Little has been done to date to identify the optimal temperature and pressure conditions for the formation of azeotropes for the various hydrocarbons and for commercial gasoline and diesel compositions.

DIRECT USES OF NATURAL GAS AS A CHEMICAL FEEDSTOCK

For the most part we refer to the direct use of methane (100% basis) as a chemical feedstock. The methane molecule is very inert in relation to other molecules, except when used as fuel with oxygen (air); however, there are a few applications involving the direct reaction of methane to chemical derivatives. The more characteristic applications are listed here:[4,5]

- Production of acetylene.
- Production of hydrogen cyanide (HCN).
- Production of chloromethanes.

Other applications have been proposed but as yet without success, like the direct coupling of methane to ethylene or the direct conversion of methane to methanol. Recently, some disclosures were made on the reaction of methane with alkanes to yield augmented alkanes.[6]

Production of Acetylene

Most acetylene is produced nowadays from methane and other light hydrocarbons. Methane is usually the preferred raw material. Although ethane, propane, and butane can also be used, the yield of acetylene declines with increasing molecular weight of the feedstock and,

Table 5 Typical heating values of various fuels

LHV	Btu/U.S. gallon
Gasoline	115,000+
Methanol	~60,000
Diesel	128,000+
Methane (atmospheric pressure)	120
CNG at 2400 psig	23,000

CNG (at 2400 psig)	23,000	23,000
Mixture	110,000	100,000

Table 7 Solubility of methane in toluene at 300°F

Pressure (psig)	Mol% methane
278.5	3.53
424.4	5.45
731.4	9.54
1441.4	19.49
2199.4	28.79
2924.4	38.58
3614.4	48.97

in any case, ethane, propane, and butane are better used in the production of olefins by steam cracking.

Production of acetylene from methane requires very high temperatures in the order of 1000–1500°C, very short residence times, and a very fast quench to prevent decomposition of the product.[5] Typically, methane can be heated by: a) contact with a very hot solid; b) in situ partial oxidation of the feedstock; or c) electric discharge or plasma processes. In a typical electric arc process (e.g., the Hüls process), the furnace may be a vertical tube with an injection chamber in which methane is fed tangentially to generate a rapidly rotating vortex that flows through an arc created between electrodes at some 7000 V. This has the advantage of making the temperature of the reactor more uniform and of assisting in the separation of soot particles. The reactor is cooled by water circulation. Because of the reduced dimensions of such reactors, high productivities can be obtained with a residence time of about 2 msec. The hot effluent gas is rapidly quenched by water or by injecting a hydrocarbon that can be thermally cracked to olefins, thus allowing for the dual production of acetylene and olefins.

Production of Hydrogen Cyanide

Although substantial amounts of hydrogen cyanide are produced and recovered as a byproduct from the manufacture of acrylonitrile by the ammoxidation of propylene, some hydrogen cyanide is also made on purpose from methane. Basically, two main approaches are available.[5]

The Andrussov process involves the ammoxidation of methane:

$$CH_4 + NH_3 + \frac{3}{2}O_2 \rightarrow HCN + 3H_2O$$
$$\Delta H^0_{298} \sim -480 \text{ kJ/mol}$$

The reaction is highly exothermic and uses volumetric flow ratios, air/CH_4/NH_3, of about 5/1/1. Whereas propylene ammoxidation proceeds at about 440°C, the ammoxidation of methane requires temperatures of about 1100–1200°C. Although HCN yields are high, in the order of about 80 mol%, the gaseous effluent is very dilute with only about 6–8 vol.% HCN, and it has to be rapidly quenched to about 400°C to avoid undesirable side reactions.

The Blausäure Methan Ammoniak (BMA) process of Degussa uses an endothermic amination reaction in the absence of oxygen:

$$CH_4 + NH_3 \rightarrow HCN + 3H_2$$
$$\Delta H^0_{298} \sim +250 \text{ kJ/mol}$$

The reaction takes place in sintered alumina tubes covered with platinum and heated externally to about 1200–1300°C. The HCN in the effluent may be as high as 20 vol.% and the molar yields may approach 85%.

Production of Chloromethanes

Because of its relatively poor selectivity to individual components, methane is not the preferred feedstock for the production of chloromethanes.[4] Methyl chloride, for example, is best obtained by the reaction of methanol with hydrogen chloride, and methylene dichloride can be obtained by the chlorination of methyl chloride. Methane is difficult to chlorinate. Because methyl chloride is easier to chlorinate than methane, a large excess of methane is required if a reasonable yield of methyl chloride is desired. For example, a mol ratio of 0.1/1 for chlorine to methane at about 450°C over a copper chloride catalyst will yield mostly methyl chloride:

$$CH_4 + Cl_2 \rightarrow CH_3Cl + HCl$$

As the chlorine-to-methane ratio increases, the higher chlorinated methanes are favored. At a chlorine-to-methane ratio of about 1.4/1, methylene dichloride is favored; at about 2.6/1, chloroform is mostly obtained; and at 3.4/1, the end-product is mostly carbon tetrachloride.

Methane chlorination reactions do not require the use of a catalyst, but UV light may be used to activate the molecules. Typical reaction temperatures are in the 350–400°C range.

Other Direct Applications of Natural Gas as a Chemical Feedstock

Oxidative methane coupling at high temperatures and very short residence times would hold great promise in the production of ethylene. As noted throughout, methane (natural gas) is abundantly available at relatively low cost, albeit in remote locations, and its

conversion to ethylene could be of significant commercial interest if and when such an approach can be fully developed. A similar direct approach has been proposed for the conversion of methane to methanol. However, all the results to date show very poor selectivities at moderate per-pass conversions or reasonable selectivities at very low methane conversions. At present, these direct applications can only be viewed as long-term exploratory research projects.

INDIRECT USES OF NATURAL GAS AS A CHEMICAL FEEDSTOCK

In reality, the largest direct use of natural gas as a chemical feedstock is in the production of syn gas, a mixture of hydrogen and carbon monoxide:

By steam reforming (endothermic)

$$CH_4 + H_2O \rightarrow CO + 3H_2$$
$$\Delta H_{298} \sim +49.27 \text{ kcal/mol}$$

where 1 kcal = 4.184 kJ.

By partial oxidation (exothermic)

$$CH_4 + \frac{1}{2}O_2 \rightarrow CO + 2H_2$$
$$\Delta H^0_{298} \sim -8.53 \text{ kcal/mol}$$

or by various combinations of the above (i.e., autothermal reactors, gas-heated reactors, etc.), as might be required to balance the endothermic reaction requirements of steam reforming with the exothermic heat generated by partial oxidation. It should be noted though that catalytic processes for the production of syn gas require deep desulfurization of the natural gas. Noncatalytic processes, like partial oxidation, do not require feed desulfurization and, thus, can easily accommodate heavier feedstocks all the way to refinery residues, but the product syn gas has to be desulfurized for most downstream applications.

Syn gas by itself has no direct commercial use. However, Syn gas, apart from its use in hydroformylation reactions, is the main intermediate in the production of:

- Hydrogen.
- Ammonia and urea.
- Carbon monoxide for carbonylation reactions.
- Methanol.
- Liquid fuels by the Fischer–Tropsch reaction mechanism.

Steam reforming provides the highest hydrogen yield and is preferred when hydrogen is the desired product, as for the production of ammonia or hydrogen for refinery uses (hydrotreating, hydrocracking, etc.). In these cases, the product syn gas invariably is made to undergo the shift reaction:

$$CO + H_2O \rightarrow CO_2 + H_2$$
$$\Delta H^0_{298} \sim -9.83 \text{ kcal/mol}$$

Thus, with steam reforming, it is possible to obtain an aggregate of 4 mol of hydrogen per mol of methane. This ratio is always lower when some form of partial oxidation is used, but that is less of a problem when methanol is desired as end-product (theoretical $H_2/CO = 2.0$) or for gas to liquids (GTL) in the production of hydrocarbon fuels ($H_2/CO \sim 2.0$).

$$2H_2 + CO \rightarrow -CH_2- + H_2O$$

Traditional steam reformers are limited to processing about 100 mm scfd of natural gas in a single train, equivalent to the production of about 3000 t/day methanol (1 scf = 0.02679 Nm^3, inclusive of the temperature correction; see the appendix). While this was regarded as a world-scale unit until recently, current methanol projects under construction are for 5000 t/day and projects are being announced for methanol capacities in excess of 15,000 t/day. Likewise, GTL projects have been announced for capacities well in excess of 100,000 barrels/day (bpsd) of liquids (1 oil barrel = 42 U.S. gallons = 159 L) or a feed stock requirement of almost 1000 mm scfd of natural gas. These applications require huge units for the generation of syn gas and, as a result, partial oxidation or autothermal schemes are often preferred.

METHANOL UTILIZATION

Traditional demand for methanol is fairly limited. Apart from its use as a solvent and as a feedstock for the production of formaldehyde and acetic acid, the use of methanol is not growing in demand significantly. Because of unrelated concerns with ground water contamination in the U.S.A. and a few other countries, MTBE (methyl *tert*-butyl ether), one of the fastest growing outlets for methanol in recent years, has slowed down to almost a halt. Currently, the principal momentum behind the renewed interest in methanol production resides in its application in nontraditional areas. These can be summarized as follows:

- Methanol to gasoline (MTG).
- Methanol to olefins (MTO), especially ethylene and propylene.
- Methanol to propylene (MTP).
- Methanol to dimethyl ether.

Dimethyl ether is being contemplated as a high-cetane, clean burning diesel fuel alternative, or as a substitute for methanol in the MTO or MTP reactions mentioned above.

In all these projects, economics plays a leading role. It is always necessary to secure the feedstock at a very low price (typically natural gas at not more than about \$0.75 per mscf), which is only available in remote locations (e.g., ''stranded'' natural gas) with low local demand. This can be translated into a cost of methanol production of about \$80 per tonne, or perhaps a maximum of about \$90 per tonne if allowances are made for shipping costs, etc. Considering that methanol has a fairly low heating value of only about 60,000 Btu per U.S. gallon (LHV) or about 21.1 GJ/t, these ''low'' methanol prices are not insignificant, as \$90 per tonne translates into about \$4.50 per mm Btu (~\$4.25 per giga-Joule). Not surprisingly, although an MTG unit was built and operated by Mobil near New Plymouth in the Northern Island of New Zealand, the production of gasoline (at fuel value) from methanol proved uneconomical and the unit was shut down.

Utilization of methanol or DME for petrochemical applications has a much better chance of succeeding, as there is a much higher value added in going from methanol to light olefins. Even when the markets are soft, ethylene and propylene command prices of at least about \$400 per tonne, and usually substantially more. Even on a pure fuel value basis, \$400 per tonne for ethylene would be equivalent to about \$8.00 per giga-Joule, or a very significant value-added markup.

A typical MTO unit for the production of about 1 milliont/yr of ethylene and propylene (say, about 500,000 t/yr each) requires about 2.7 million t/yr methanol or about 259 mm scfd (6.9 mm Nm^3/day) of natural gas, which, at \$0.75 per mm Btu, corresponds to a relatively modest annual feedstock expense of about \$65 million. This compares favorably with \$400 million/yr value for the olefin product (if priced at \$400 per tonne) or about \$750 million/yr for the end-product polyolefins (if priced at about \$750 per tonne).

Although the attractiveness of the projects is case specific as it depends on the plant capacity, unit location and local investment requirements, cost of the feed natural gas, scope of the project (whether only olefins or all the way to polyolefins), etc. on the average MTO or GTP (gas-to-polymers) projects provide returns on investment in the order of 20–25%.

Main licensors in this area are UOP LLC in the U.S.A. (together with Norsk Hydro in Norway) with MTO technology for the simultaneous production of ethylene and propylene at adjustable $C_2=/C_3=$ ratios between 0.6 and about 1.3 and Lurgi GmbH in Germany with MTP technology for the production of propylene. The former uses a microspheroidal catalyst based on a SAPO-34 molecular sieve catalyst contained in fluidized-bed reactors scalable up to about 1.5 mm t/yr of light olefins in a single train, depending on the product slate and the operating conditions. Lurgi appears to favor a modular approach with individual trains of three fixed-bed reactors in series using a modified HZSM-5 molecular sieve catalyst supplied by Süd-Chemie;[7] it is believed that each train can produce up to about 200,000 or 250,000 t/yr of propylene. Both processes use proprietary schemes to recover and reprocess heavier olefin byproducts in the $C_4=$ to $C_6=$ range.

At the time of writing this entry, one MTO unit for 800,000+ t/yr of ethylene-plus-propylene had been designed by UOP for Axinova (Eurochem Technologies Corporation Pte Ltd) to be located at the Lekki peninsula near Lagos, Nigeria.[8] ExxonMobil are also showing a high level of patent activity in this area and it is not unreasonable to expect that they may develop one or more commercial MTO projects too.

GAS TO LIQUIDS

Production of liquid hydrocarbons from syn gas makes use of the well-established Fischer–Tropsch technology using either the older Fe catalysts or the more modern Co catalysts. Originally commercialized in Germany toward the early part of the twentieth century and widely used during the World War II, it was further developed by Sasol in South Africa. All these earlier applications used syn gas derived from coal and made use of a variety of reactor types like the multitubular ARGE low-temperature (250°C) reactors first used by Sasol based on the German design or the Synthol high-temperature (350°C) fluidized-bed reactors for a lighter product slate or, more recently, ebullated bed or slurry phase reactors also at the lower-temperature conditions.[9] One of the goals in Fischer–Tropsch technologies is to control the product slate by controlling the degree of polymerization. In a very simplified form, Fischer–Tropsch reactions follow a Schulz–Flory equal-growth-probability polymerization mechanism of the form:

$$P_n = n(1 - \alpha)^2\alpha^{(n-1)}$$

where P_n is the probability (fractional molar concentration) of having a hydrocarbon with an n-long carbon chain in the product, and α is the degree of polymerization, and such that

$$\Sigma P_n = 1$$

In Figs. 8–10, the chain growth patterns that develop as a function of the degree of polymerization[10] are illustrated on the basis of the simplified mechanism shown above. Lower values of α yield lower molecular weight

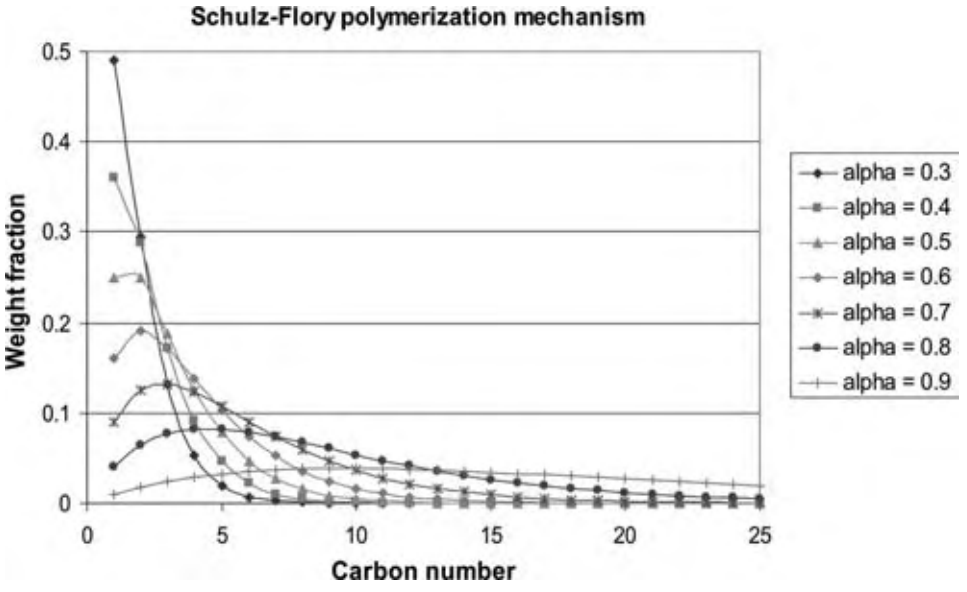

Fig. 8 Fischer–Tropsch chain growth mechanism (Schulz–Flory polymerization mechanism). *(View this art in color at www.dekker.com.)*

products, but unfortunately large amounts of methane also. Practical applications of Fischer–Tropsch usually require relatively high values for $\alpha(>0.8)$ that lead to the maximization of products in the diesel range (say, C_{12} to C_{18}) and also to the production of waxy materials. Often, a mild hydrocracking step is advisable to crack the heavier materials to more useful products, but Fischer–Tropsch can also be used advantageously for the production of waxes and lube oils as more valuable byproducts. Typically, about 80% of the product is in the diesel range while the remaining 20% is a paraffinic naphtha, which is ideal as steam cracker feedstock.

At present, the only operating Fischer–Tropsch-based units in the world are Sasol I, II, and III, all based on coal feedstocks, with an aggregate capacity of about 180,000 bpsd, the natural-gas-based PetroSA (Mossgas) unit, also in South Africa, with close to 35,000 bpsd capacity, and the Shell unit at Bintulu in Malaysia originally designed for 12,500 bpsd, but since revamped to about 15,000–16,000 bpsd. The PetroSA unit uses Synthol high-temperature reactors licensed from Sasol, while the Shell unit uses fixed-bed tubular reactors (Fig. 11).[11]

Many GTL projects have been announced around the world, some of the more credible ones include:

Sasol-Chevron	Escravos, Nigeria	34,000 bpsd
Shell	Ras Laffan, Qatar	140,000 bpsd
Conoco-Qatar Petroleum	Qatar	120,000 bpsd
ExxonMobil	Qatar	100,000 bpsd
Sasol-Qatar Petroleum	Qatar	34,000 bpsd

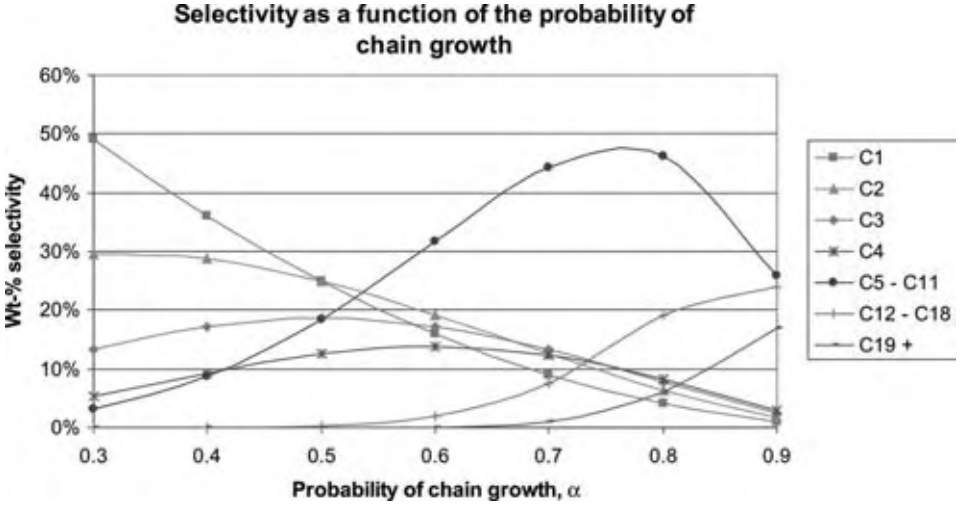

Fig. 9 Fischer–Tropsch chain growth mechanism (selectivity as a function of the probability of chain growth). *(View this art in color at www.dekker.com.)*

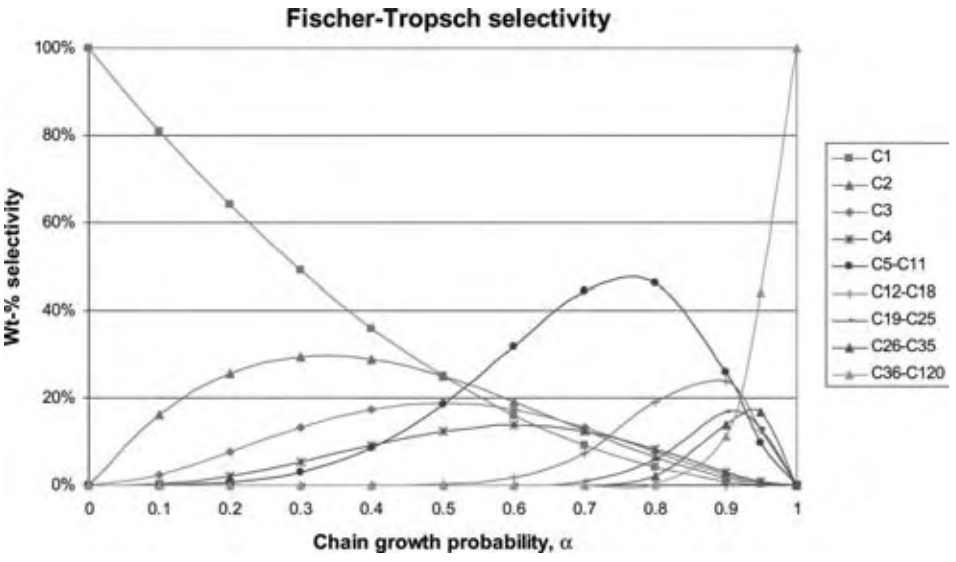

Fig. 10 Fischer–Tropsch chain growth mechanism (Fischer–Tropsch selectivity). *(View this art in color at www.dekker.com.)*

Other projects have also been announced in Iran, Australia, South America, etc. Iran and Bolivia, in particular, appear to be likely candidates for GTL facilities in the future.

Gas-to-liquid plants consume in the order of 9500 scf per barrel of product. Thus, a 100,000 bpsd unit will consume about 950 mm scfd (26.9 mm scmd) of natural gas. Therefore, over a typical project life of about 30 years (10,000 days), the cumulative consumption of natural gas will be 260 mm scm. Only very large natural gas fields can support such production rates. Obviously, Qatar, Iran, and some other countries with very large gas reserves are in a good position to satisfy the needs for such projects.

Although GTL can be advantageously used to add value to natural gas reserves in remote or less industrialized locations, the fact is that the return from GTL facilities is fairly modest, as basically they make

Fig. 11 Reactors at Shell's MDS unit, Bintulu, Malaysia. *(View this art in color at www.dekker.com.)*

fuels (naphtha, diesel, and middle distillates) out of another fuel (natural gas). Even when natural gas is only priced at low values of less than about \$0.75 per mm Btu, the typical rates or return for these facilities are in the order of 10–12% and depend greatly on the investment costs. Better returns can be expected for GTL units that recover more valuable fractions like waxes, synthetic lube oils, *alpha*-olefins, etc. Although older and smaller gas-based units like the Shell unit at Bintulu, Malaysia, were reported to require investments in excess of \$60,000 per daily barrel of installed capacity, more recent reports indicate that, at least for larger world-scale units, the investment costs may be in the order of \$23,000 per daily barrel of installed capacity. These numbers, however, may be taken with a certain degree of skepticism, as they often ignore the large investments for services and infrastructure at remote construction sites. The investment requirements for the 140,000 bpsd GTL unit that Shell is planning to build in Qatar have been disclosed[12] as being in the order of \$5 billion, or about \$36,000 per daily barrel of installed capacity.

CONCLUSIONS

The appetite for natural gas as an industrial fuel continues unabated and is only limited by the supplies available in the major industrialized countries, in particular in the U.S.A., which has led to significant increases in its pricing. Large reserves of natural gas at low cost exist in remote of less industrialized areas. This has led to the increase in the number of LNG facilities and also to the construction of facilities at such locations where natural gas can be advantageously exploited in new ventures for the manufacture of methanol and light olefins and for the conversion of natural gas into liquid fuels for transportation applications.

APPENDIX

Units and Equivalences

Volumetric gas rates are defined either at ''normal'' conditions (0°C and 1 atm or 1013 mbar of absolute pressure) or at ''standard'' conditions; in English units ''standard'' conditions are defined at 60°F (15.56°C) and 1013 mbar, while in metric units ''standard'' conditions are defined at 15°C and 1013 mbar. There is practically no difference between the two ''standard'' conditions, but care should be used not to confuse them with ''normal'' conditions. The abbreviations cf and cm are commonly used to denote ft^3 and m^3, respectively. Volumes defined at ''standard'' conditions are about 1.055 (=288.15/273.15) or 1.057 (=288.71/273.15) times the same volumes defined at ''normal'' conditions.

1 kmol of ideal gas at ''normal'' conditions occupies 22.414 N m^3 or 791.5 N ft^3.

1 kmol of ideal gas at ''standard'' (60°F) conditions occupies 23.690 scm or 836.6 scf.

1 lb mol = 0.4536 kmol.

INTRODUCTION

Flame retardancy of polymeric materials is an important field of science because of its beneficial societal impacts in preventing fire losses. It is also a broad and complex field of science, with many different routes available to provide fire safety with polymeric materials. In this entry, we discuss two classes of materials that impart fire safety. The first is nonhalogenated flame retardant additives derived from halogenated flame retardant feedstocks. The second is inherently low-flammability polymers. We discuss the advantages and disadvantages that these materials bring to flame retardancy in relation to current technology, as well as their flammability performance. Also presented are the chemical syntheses and processing of these materials. These materials are still new, and the larger use and application may not occur until new advances are made or new regulations mandate their use.

BACKGROUND

Fire safety is an all-encompassing need in modern society as the damage caused by fire results in significant loss. According to the National Fire Prevention Association, in 2002 there were 1,687,500 fires, resulting in $10.3 billion of property loss and 3,380 fire deaths in the U.S.A.[1] If one were able to collect data on fires worldwide, the degree of damage and number of fire deaths would be significantly larger, especially in developing or fast-growth countries. Worldwide, plastics and polymers make up a large amount of materials used in everyday life, and in many cases these plastics contribute significantly to fires when ignition sources are present. The plastics and polymers contribute to fires because many of them are inherently flammable owing to their chemical structure being based upon petrochemical feedstocks. Therefore, as plastics contribute to fire risk scenarios, efforts have been taken to provide flame retardancy to these materials. Flame retardancy can be provided to polymeric materials in a variety of ways, including flame retardant additives, the use of non- or low-flammable polymers, and engineering solutions that seek to keep flammable materials away from ignition or fire sources. The use of flame retardant additives is the most commonly used approach, followed by engineering solutions and then the use of inherently fire-safe polymers. The primary reason for this is economics, but other reasons include regulations and market demands. There are advantages and disadvantages to each flame retardant approach. Flame retardant additives have economical advantages and can be highly effective in multiple polymers. However, they can give an undesirable balance of properties to the final polymer formulation, as well as introducing recycling and environmental issues when the product containing that plastic has reached its end of use. In addition, additives can fail to provide fire performance beyond the product requirement test, should that product encounter a fire risk scenario outside of its original design. Engineering solutions can have some economic advantages and they can be easily implemented, but they also can be easily defeated, leading to catastrophic fire loss. Inherently low flammability or nonflammable polymers can withstand a variety of fire risks and provide some of the highest levels of fire safety, but they can be very expensive and/or fail to have the proper balance of properties because of their chemical structures. For the purposes of this entry, we focus on the use of flame retardant additives and non- or low-flammability polymers.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007768

The flame retardant additives market worldwide was $2 billion with a 3–3.5% growth rate per year as of 2002.[2] Despite the healthy growth of this additive industry, there are significant concerns that are causing changes in the flame retardant additive area. The main concern is focused on the perceived persistence, bioaccumulation, and toxicity (PBT) of these additives. As mentioned earlier, one of the drawbacks of additives is that they can leach out of the plastic, either during the lifetime of the final article or during end-of-use which includes landfill, recycling, or incineration. While there are no disagreements with the fact that flame retardants provide fire safety during the use of the product, and this safety performance has a clear environmental benefit in the prevention of fire,[3] the impact of the additive at the end the product's lifetime is causing concern with government regulators.

Halogenated flame retardants are the main class of flame retardants coming under regulatory scrutiny because of their perceived PBT. In some cases, extensive scientific studies have shown that some of the halogenated flame retardants have definite PBT characteristics, and these materials have been banned from further manufacture and use.[4–6] It should be noted, however, that other studies are inconclusive and the use/lifetime of some halogenated flame retardants is still in question. From a product lifetime point of view, many of the halogenated flame retardant additives have been in use for decades, some for over 50 years, and their effective service may be coming to an end simply because they are being replaced by less expensive or newer products perceived or shown to be more environmentally friendly in their life cycle analysis. Whether a product is environmentally friendly or not may be subjective. Careful data analysis is required to determine if a material is compatible with the environment.

The next major class of flame retardant additives that are nonhalogenated is the phosphorus-based flame retardants, but even these materials have some regulatory environmental concerns.[7,8] Other nonhalogenated flame retardants that are not phosphorus-based exist, including mineral fillers (i.e., $Al(OH)_3$, $Mg(OH)_2$),[9–11] expandable graphite,[12–15] melamine,[16,17] and polymer nanocomposites combined with other flame retardants.[18–26] Each of these materials has its own advantages and disadvantages, and effectiveness in one polymer system often does not translate into another system.

Inherently fire-safe polymers do not have any of the regulatory issues associated with additives because they can be recycled/incinerated with minimal issues. Today, some fire-safe polymers are in use where the product requirements demand them, and cost is not as large an issue as it is in the additive applications. These applications typically include mass transport (i.e., aircraft, subways, trains, buses, and maritime shipping) where fire risk must be addressed to prevent significant human or material losses. Currently, market forces and local regulations that perceive additive FR solutions as negative are beginning to embrace inherently fire-safe materials as the replacement technology.

To summarize, the field of flame retardancy for polymers is in a state of flux, and multiple new technologies and approaches are expected to arise in the coming decade. In this entry, we focus on some new technology from our laboratory, including nonhalogenated flame retardants synthesized from brominated starting materials, and inherently fire-safe and low-flammability polymers.

NEW NONHALOGENATED FR ADDITIVES

Before describing the new nonhalogenated FR additives, we must first explain how polymer combustion occurs and how various flame retardants work. Polymer combustion occurs when the polymer has undergone enough thermal degradation to volatize into flammable decomposition species, such as monomer and polymer fragments, which then combine with oxygen for combustion upon the application of an ignition source. Once combustion begins, the oxygen is consumed at the flame front, and heat from the flame radiates back down to the polymer, assisting in additional polymer thermal degradation, melting, and fuel pyrolysis. The process continues until the flame is extinguished or the fuel is completely consumed (Fig. 1).[27–29]

To provide flame retardancy to the polymer, there are three main mechanisms that a flame retardant can use, and the most effective flame retardants use two or all three mechanisms in concert. The first is by altering the gas phase or combustion chemistry. Additives that work by this mechanism are referred to as vapor phase flame retardants (see Fig. 1) during combustion. Halogenated and some phosphorus flame

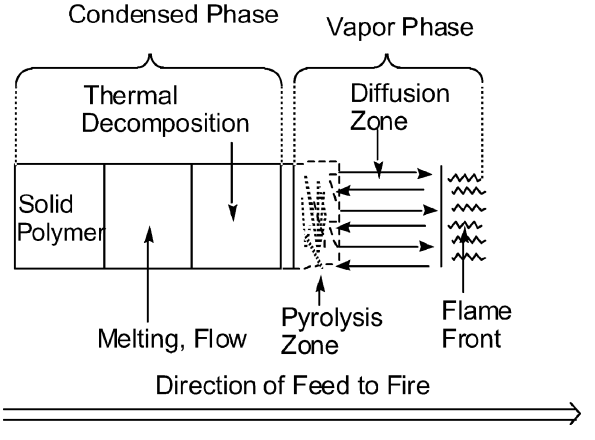

Fig. 1 The polymer combustion process in fires.

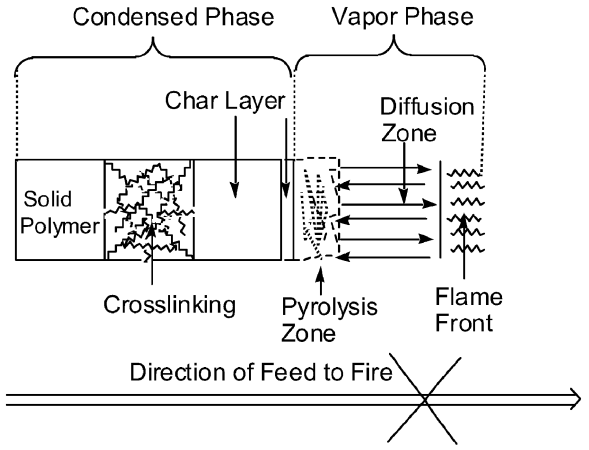

Fig. 2 Formation of a char layer extinguishes polymer fires.

retardants work by this route by reducing heat from combustion through the scavenging of reactive free radicals, in either a catalytic or a stoichiometric manner. The second is by cooling the system through endothermic decomposition. These materials are usually metal hydroxides or carbonates that release nonflammable gases, such as water or CO_2, which cool the polymer and dilute the total amount of fuel going to the flame front. The third mechanism by which flame retardancy is achieved is through crosslinking or char formation. There are a variety of flame retardants that rely on this mechanism through numerous chemical pathways. Char formation is a strictly condensed phase phenomenon. It works by preventing fuel release through the crosslinking of the polymer matrix or by inducing the formation of high thermal stability chemical bonds. The prevention of fuel release retards combustion, which in turn slows down the rate of flame growth and further polymer decomposition. Additionally, as char forms, it may become thermally stable enough to act as an insulator to prevent heat from being transmitted to nondecomposed polymer, thus extinguishing the flame and protecting the non-heat-exposed polymer (Fig. 2). There is an additional benefit to char formation in that it will keep the heat release rate of the polymer low during burning. This will lower the fire risk to other items near the burning polymer, as low heat release rates have much lower chances of propagating fire to nonflame retardant objects (Fig. 3).[30,31]

As mentioned earlier, brominated flame retardants are under regulatory scrutiny that may lead to their eventual abandonment as chemicals used in industry. The chemistry of bromination is well understood, and it can yield a variety of different products and structures. In light of this, brominated starting materials, in particular brominated flame retardants, could be a very useful route into new nonhalogenated flame retardants, and the C–Br bond is usually quite reactive to a variety of organic chemical reactions. Work in our laboratory focused on the use of brominated flame retardants as starting materials in flame retardant additive syntheses and their conversion to nonhalogenated FR derivatives.[32–34]

The first class of compounds, which were nonhalogenated and nonphosphorus containing in structure, was alkyne-functionalized materials made from brominated aromatic compounds via a Pd/Cu mediated crosscoupling reaction.[35,36] The brominated aromatics were all commercial flame retardants, some of which presented synthetic challenges because of their insolubility when highly brominated. For example, decabromodiphenyl ether (**1** where X = Br) is a commonly used flame retardant in a variety of applications.[37] However, it is highly insoluble in most organic solvents. It was found that as the reaction proceeded over time, the addition of each phenylalkyne group to the structure improved its solubility, leading to additional reaction and eventual conversion of a majority of the aromatic bromides (only 1–2 wt.% Br remained unreacted) to alkynes. Other materials, such as the tetrabromobisphenol A carbonate oligomers (**2** where X = Br), reacted with 100% Br conversion in less time, because of a combination of better solubility and carbonate functionality assisting the Pd/Cu reaction. The choice of amine base, palladium catalyst, and ratio of alkyne to bromide under reaction conditions does need to be optimized with each aryl halide

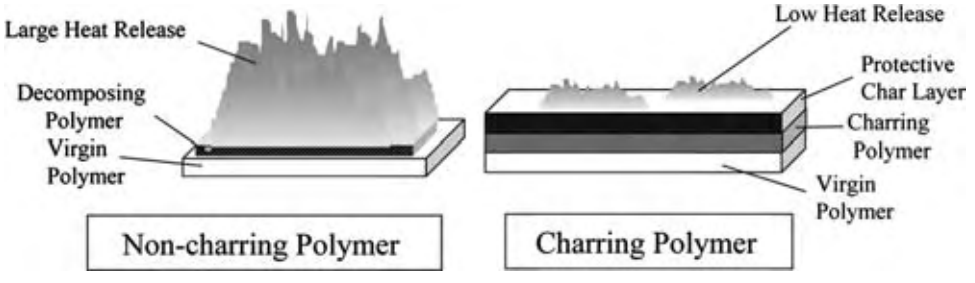

Fig. 3 Large heat release (left) leads to larger fires while low heat release because of char formation (right) retards fire propagation. (From Ref.[30].) *(View this art in color at www.dekker.com.)*

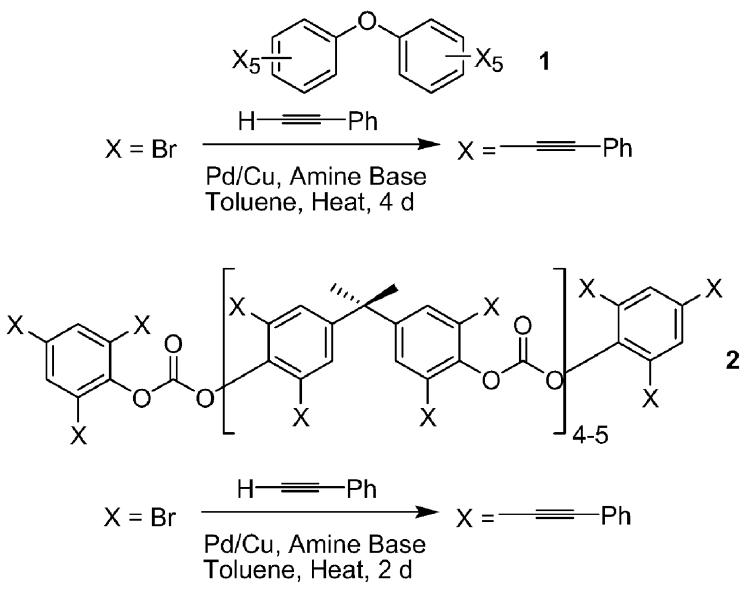

Fig. 4 Synthesis of alkyne-based flame retardants.

one considers for this type of reaction. A schematic of the alkyne-based flame retardants is shown in Fig. 4.

As mentioned earlier, phosphorus flame retardants are another class of commonly used materials, and they come in both halogenated and nonhalogenated versions. Just as alkyne-based flame retardants were made from halogenated materials, attempts were made to synthesize alkyne/phosphorus materials via the same Pd/Cu chemistry with phenylacetylene and an aryl bromide phosphate. However, it was found that the phosphate prevented the reaction from occurring; thus a different synthetic route was chosen that is far more versatile in producing derivative chemical structures. For the synthesis of existing phosphate flame

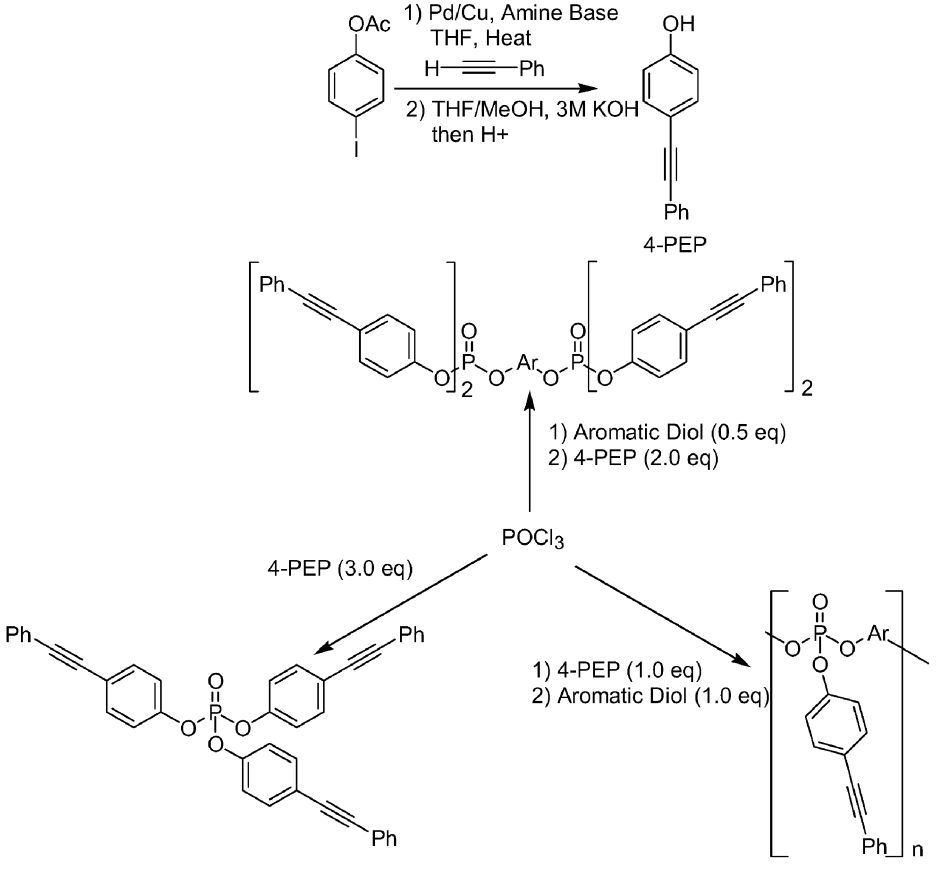

Fig. 5 Synthesis of phosphorus-based flame retardants.

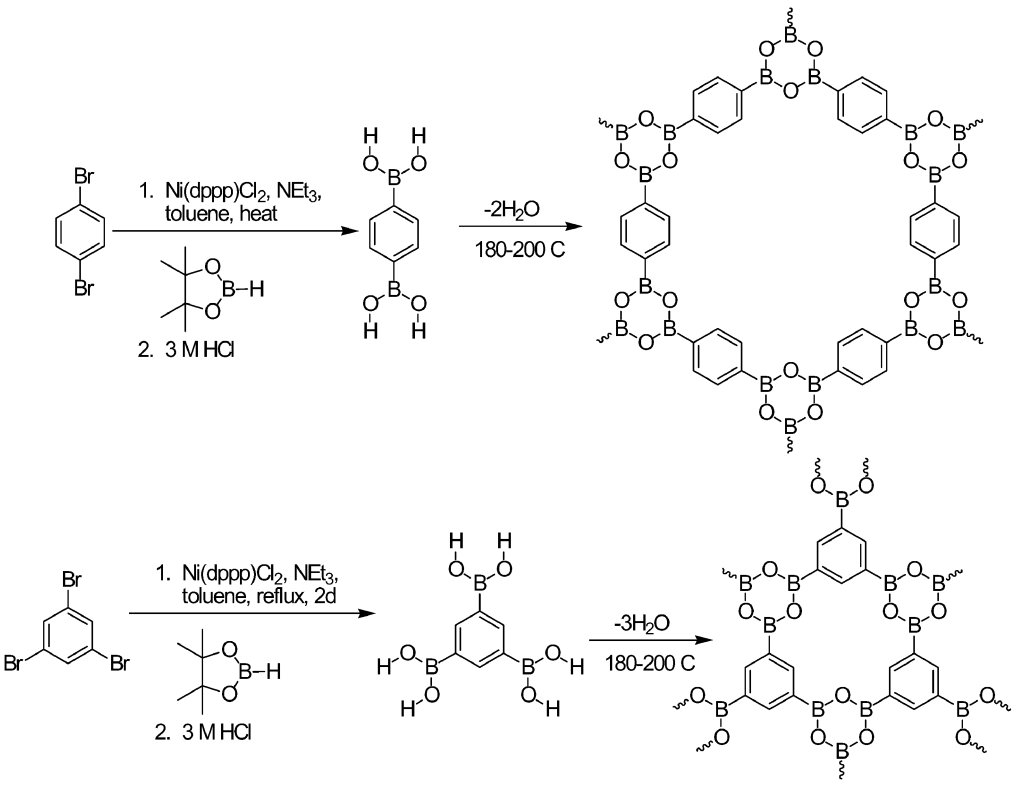

Fig. 6 Synthesis of aromatic boronic acid flame retardants, showing the dehydration process that can take place in formulated products when subjected to heat.

retardants, the primary starting material is phosphorus oxychloride ($POCl_3$), whereupon various alcohols and phenols are reacted to give the resulting phosphate. To synthesize alkyne/phosphorus materials, it is necessary to put the alkyne functional group on phenol before adding the phenol to $POCl_3$. The phenol (4-phenylethynyl phenol, or **4-PEP**) was synthesized from 4-iodophenyl acetate. The acetate group is important, as the phenol can inhibit the Pd/Cu reaction by preventing oxidative addition between the C–I bond. The iodide, rather than bromide, is essential for reaction, as the reactivity of 4-haloaryl acetates is quite low to Pd/Cu conditions, with chlorides being unreactive and bromides reacting only in low yields over long reaction times. There are some new generation catalysts and ligand combinations that permit these types of reactions to proceed with aryl chlorides;[38–43] however, at the time of our research, they were not available. Once the Pd/Cu-catalyzed reaction is complete and the phenylethynyl group has been added, the acetate can be removed with the use of base, followed by acid quench to give the phenol. This phenol can then be esterified with $POCl_3$, and by controlling the ratio of $POCl_3$ to phenol and 1,3-/1,4-aromatic diols (such as bisphenol A, hydroquinone, and resorcinol) along with the order of addition, a variety of diphosphate or polyphosphate structures can be obtained (Fig. 5).

While synthesis of these alkyne-based or phosphorus/alkyne materials can be accomplished, melt compounding the materials into a polymer to impart flame retardancy is not straightforward. Compound **1** (Fig. 4) and other 1,2-dialkynyl materials synthesized in our laboratory were found to have poor thermal stability above 200°C. More specifically, the alkyne groups began to react via Bergman cyclizations[44–47] to generate a variety of crosslinked highly aromatic species. Therefore, these materials would only be suitable in polymers that can be processed below 200°C, otherwise the alkyne groups would be nonfunctional under fire conditions and the alkyne crosslinking during polymer processing would result in polymer degradation. 1,3- and 1,4-Dialkyne materials have much higher thermal stability in that the alkyne groups do not begin crosslinking until 350–400°C.[48] These materials were compounded into a wide range of polymers, but the

$$H\bullet + HX \longrightarrow H_2 + X\bullet$$

$$HO\bullet + HX \longrightarrow X\bullet + H_2O$$

$$X = Cl \text{ or } Br$$

Fig. 7 Capping of radicals in the vapor phase with halogens.

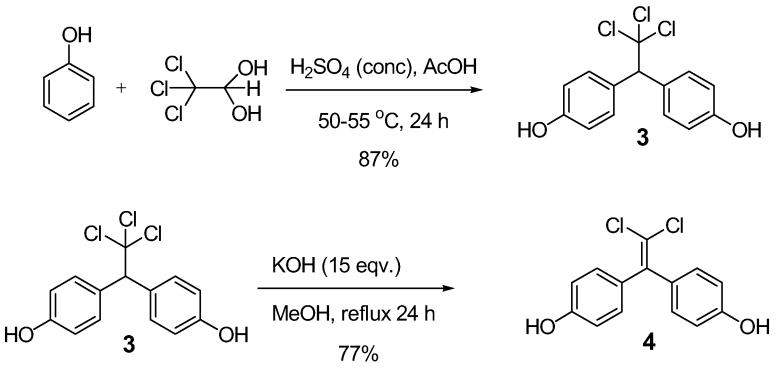

Fig. 8 The classical synthesis of bisphenol C (BPC).

flame retardancy they provided was limited. Although the presence of the alkyne provided a significant amount of char formation, thus preventing fuel from being volatilized and combusted, the heat generated during the crosslinking/char formation process overwhelmed any benefits because of charring. The phosphorus/alkyne materials were more effective because the phosphate structure is capable of crosslinking chemistry in some polymers and, when combined with the alkynes, gave good flame retardancy in polycarbonate.

The final category of flame retardants synthesized from brominated starting materials is the aromatic boronic acids. There are several ways to make aromatic boronic acids from brominated aromatics, including Grignard,[49–51] lithium–halogen exchange,[52] and catalytic routes.[53–57] Grignard and lithium–halogen exchange routes gave complex mixtures with impurities that could not easily be removed, and in some cases not all of the halogens were exchanged when more than one halogen per aromatic ring was present. We found that aromatic monoboronic acids were ineffective as flame retardants, but di- and triboronic acids were very effective at low loadings in polycarbonate and poly(acrylonitrile–butadiene–styrene) (ABS).[58] Catalytic routes to making di- and triboronic acids were the most useful, but optimization of the chemistry is still needed. The catalytic route found to be effective in producing boronic acids was the use of pinacol borane and a nickel(II) catalyst. The reaction works through an oxidative addition between the Ar–Br bond, followed by transmetallation with the pinacol borane, and finally reductive elimination to yield the aryl pinacol borate. Acid hydrolysis of the pinacol ester gave the final boronic acid (Fig. 6). Specifically, we synthesized two aromatic boronic acids: 1,4-benzene diboronic acid, and 1,3,5-benzene triboronic acid.

As mentioned with the alkyne additive above, melt compounding can affect the structure of the additive. If this material is compounded below 180°C, the boronic acid structure remains intact. However, if compounded above 180–200°C, the boronic acid loses water and condenses to form a boroxine network structure. Depending upon the boronic acid substitution, a variety of boroxine networks can be formed. We found that the boronic acids were ineffective as flame retardants in high-impact polystyrene, but were effective in ABS and polycarbonate. The latter two are compounded at temperatures above 200°C; therefore the active flame retardant species is the boroxine network. However, there is a limit to the effectiveness of the boroxine network as a flame retardant, as antagonistic flame performance is found at high loadings of boroxine in polycarbonate. Furthermore, the loss of water during melt compounding results in polycarbonate

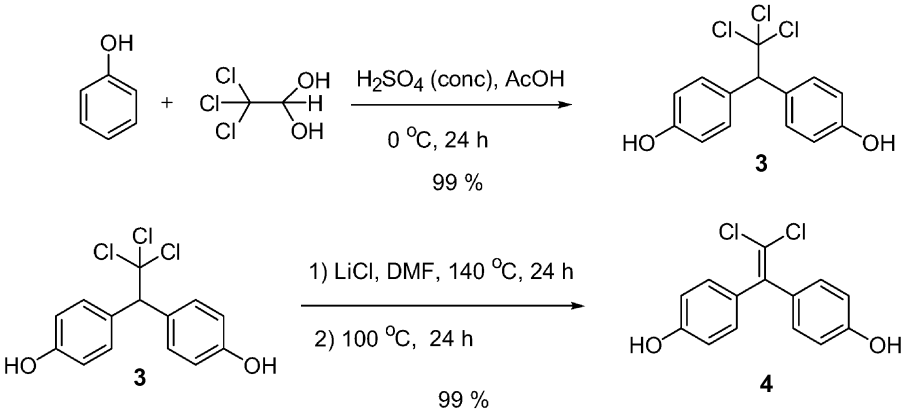

Fig. 9 The improved synthesis of BPC.

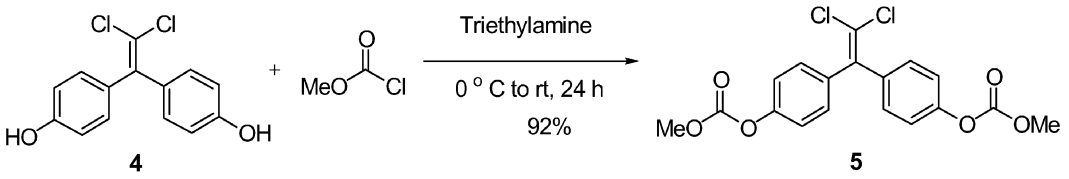

Fig. 10 Synthesis of the BPC bis(methylcarbonate) monomer from BPC.

molecular weight degradation by the hydrolysis of the carbonate groups. The loss in polycarbonate molecular weight results in higher flammability, rendering the flame retardant less effective during a fire. As removing all of the water from the boronic acid/boroxine network prior to compounding is difficult, there is a limit to the effective loading for this flame retardant additive. At 5 wt% loading in PC, UL-94 5V and V-0 ratings were achieved at the 3.2 mm sample thickness. In ABS, the limit does not exist, as the release of water will not affect ABS molecular weight during melt compounding. At high loadings of boronic acid/boroxine network, UL-94 V ratings were not achieved in ABS; however long burn times with no dripping (5–6 min to consume an entire burn bar) were observed. Presumably with an additional synergist this material would be more effective in ABS. The mechanism of flame retardancy for these materials is presumably a condensed phase mechanism, with the boroxine network assisting in char formation in PC and complexing with the nitrile groups in ABS to assist in char formation and antidrip behavior. The boroxine systems act antagonistically with additional halogenated flame retardants; as it appears, the formation of hydrogen halide, either Cl or Br, results in degradation of the char that the boroxine forms during a fire. There is still more to be learned about this class of materials, and additional studies should help to improve their performance and utility in a wider range of polymers.

NEW INHERENTLY NONFLAMMABLE POLYMERS

The chemical structure of a polymer determines its flammability, or to be more specific, the chemical structure of the polymer degradation product dictates the base flammability of the polymer. When a polymer breaks down there are several pathways by which the polymer can decompose or "unzip" to form high energy free radicals. In Fig 1, it is illustrated that a burning piece of plastic has two distinct phases: a vapor phase and a condensed phase. In the vapor phase, the combustion cycle can be stopped by physically diluting the flame with noncombustible gases and chemically reacting the high energy free radicals with halogens.[37] Obviously, materials that decompose to give flammable small molecules, such as ethylene from polyethylene, are highly flammable materials, whereas materials with nonflammable species (such as halogen) are inherently nonflammable, as they release species that inhibit the flame. Materials such as polyvinyl chloride (PVC) and polytetrafluoroethylene (PTFE) have very low flammability and nonflammability, respectively, because of their chemical structure and thermal degradation products.[59]

Halogenated flame retardants inhibit the flame efficiently by acting as a radical trap. The halogen radicals, chlorine and bromine in particular, catalytically stop the radical chain by reacting with the high energy free radicals, $HO^{\bullet}$ and $H^{\bullet}$, in the vapor phase to produce lower energy radical species that eventually lower the energy of the entire combustion cycle, thus extinguishing the flame once the free-radical pathway can no longer be sustained (Fig. 7).[37] The generation of H_2O from $HO^{\bullet}$ is a highly exothermic reaction in the chain branching step that should be mitigated to ensure efficient flame retardancy.

Bromine and chlorine are two reactive halogens that have worked well for flame retardant purposes. Organofluorine compounds have not been as effective as flame retardant additives because the carbon–fluorine bond energy is so high that other events dominate at temperatures where halogenated flame retardants operate.[60]

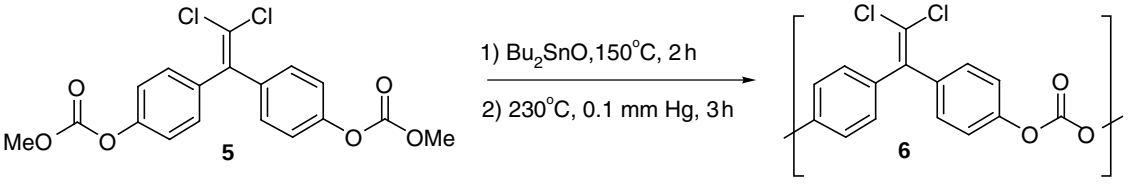

Fig. 11 Polymerization of BPC bis(methylcarbonate) **5** to polymer **6**.

Table 1 Pulsed combustion flow calorimetry (PCFC) data for the polycarbonates: Comparison of PCFC data for polymer **6** to that for BPA polycarbonate

Polymer	HR capacity	Total heat (kJ/g)	Char yields (%)
BPC**6** polycarbonate	29	3	50.1
BPA polycarbonate	359	16.3	21.7

Organofluorine compounds are used as extinguishing agents to put out high-intensity fires, such as aircraft fuel-pool fires, whereas polymer fires tend to have lower temperatures, and therefore materials with C–F bonds tend not to be effective flame retardant additives. Conversely, the iodine–carbon bond is so weak that it is easily cleaved by light and the released HI or I_2 is leached out of the plastic, making it unsuitable for many applications.[60] Halogenated flame retardants can work effectively by themselves, but there are cases where their action must be enhanced by the addition of a synergist to achieve the right balance of properties in the final product. The synergist acts to improve the activity of the additive in the polymer, thus lowering the amount of halogenated additive needed. One synergist, antimony oxide (Sb_2O_3), acts as a halogen shuttle bringing SbX_3 into the vapor phase.[37,60]

The goal of the polymer industry is the design of a low-cost flame retardant polymer that does not require additives yet still has favorable physical and mechanical properties. New flame-resistant engineering plastics that have been commercialized are used in specialty applications. These include polyaryl sulfone and polyetheretherketone (PEEK). These polymers work as heat-/flame-resistant polymers, but because of their high cost of production and poor processibility, their commercial use has been limited.

The monomer that we have used as a backbone for our work toward flame retardant polymers is commonly called bisphenol C (BPC) or 1,1-dichloro-2,2-bis(4-hydroxyphenyl) ethylene. As has been shown by many research groups, BPC can be used as a blendable additive in a commercial plastic or as part of a polymer backbone to effectively impart flame resistance to certain polymeric materials.[61–69] When thermally decomposed, BPC exothermically produces volatile products such as HCl and CO_2, and the unique structure formed upon thermal degradation leads to a very stable carbon structure (char).[70–72] It is this pyrolysis byproduct and the high char forming nature of BPC that give inherently low flammability and flame retardancy (Fig. 3) in these polymers and blends.

The thrust of our research has been to incorporate the BPC moiety into a polymer backbone that can impart flame retardancy without additives. The incorporation of this monomer into a thermoplastic has been approached in several ways including the following: nucleophilic aromatic polymerizations,[73] nucleophilic displacement under phase transfer conditions (PTC),[74] diene metathesis,[75–77] and vinyl addition polymerization.[78]

While halogenated flame retardants have PBT perceptions, halogenated polymers do not have this problem, provided that a polymer with halogen in the backbone does not degrade to give structures with PBT concerns. By incorporating the halogen into the polymer backbone, it is not readily available for bioaccumulation or environmental degradation. Also, these halogenated materials are more easily recycled,[79] as they do not degrade upon multiple regrind/remelts during plastic recycling, and do not lose flame retardant effectiveness, thus further decreasing the environmental impact of inherently nonflammable, halogenated polymers.

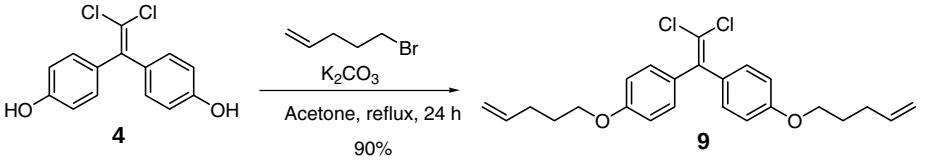

Fig. 13 Preparation of diether monomer **9** via alkylation of BPC **4**.

BISPHENOL C AND BPC POLYCARBONATE

As it was believed that bisphenolic compounds would have laxative properties, the original research on that class of compounds was done by Ex-Lax Inc.,[80] who pursued the development of BPC.[81] The synthesis of BPC was carried out by condensing phenol with chloral to produce 1,1,1-trichloro-2,2-bis(4-hydroxyphenyl) ethane (**3**) followed by a dehydrohalogenation to give the corresponding dehydrohalogenated compound BPC (**4**) (Fig. 8).[80]

A newer process for synthesizing BPC results in near quantitative yields (Fig. 9).[60] Several decolorizing and recrystallization steps are needed to obtain material that is suitable for condensation polymerizations, but overall this procedure requires less workup time and produces higher yields than the original protocols.[61–69] Compound **4** is now commercially available from Sigma–Aldrich.

The use of BPC as a flame retardant additive or polymer was not explored until General Electric (GE) examined its use in the late 1970s.[59,82] The flame-resistant properties of polycarbonate were improved by copolymerizing BPC with bisphenol A (BPA).[59,82] Phosgene gas is used in GE's process but because of the high toxicity of phosgene, we opted to use a non-phosgene-containing polymerization procedure for our small scale investigations.[53–55] In this new process to make carbonate monomers, BPC was transformed into the dicarbonate by condensation with methyl chloroformate to give BPC bis(methylcarbonate) (**5**) (Fig. 10).[83] Compound **5** was then polymerized into **6** using dibutyltin oxide as a catalyst, with high heat and vacuum to drive off CO_2 and MeOH (Fig. 11).[83]

Polymer **6** was tested in a pulsed combustion flow calorimetry (PCFC) apparatus (Table 1). The flame retardant properties of this polycarbonate were previously tested by GE, so no full scale flammability testing was pursued in our laboratory.[59] The PCFC is a small scale flammability testing instrument developed by the FAA for its fire-safe materials program.[84–87] This instrument measures the oxygen consumed by a sample exposed to rapid pyrolysis temperature profiles, thus measuring the heat release (HR) capacity as well as the total heat evolved from the sample. The instrument measures the inherent flammability of a polymeric material; the lower the HR capacity and total heat, the less flammable the material. The PCFC results obtained from the BPC polycarbonate show a much lower heat release capacity and also a much higher char yield, compared with traditional BPA polycarbonate, thereby underscoring the effectiveness of the BPC system.

BPC Polyarylethers

The inflexibility of most aromatic polymers is a problem because they do not melt and flow, making processing the polymers difficult. To make flexible polymers with reasonable melting points and glass transition temperatures, aliphatic and olefinic groups were added to the polymeric backbone. The problem in using these types of functional groups is that they

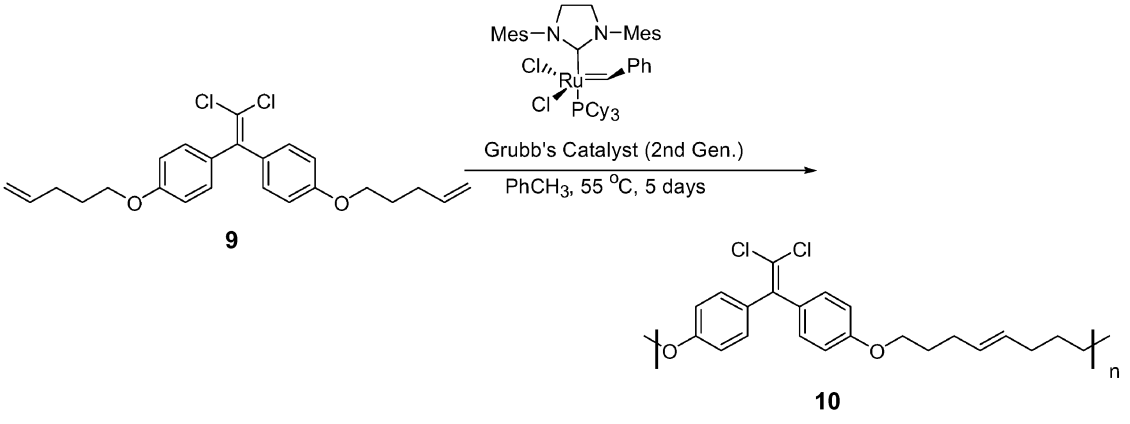

Fig. 14 Acyclic diene metathesis polymerization of **9** to give polymer **10**.

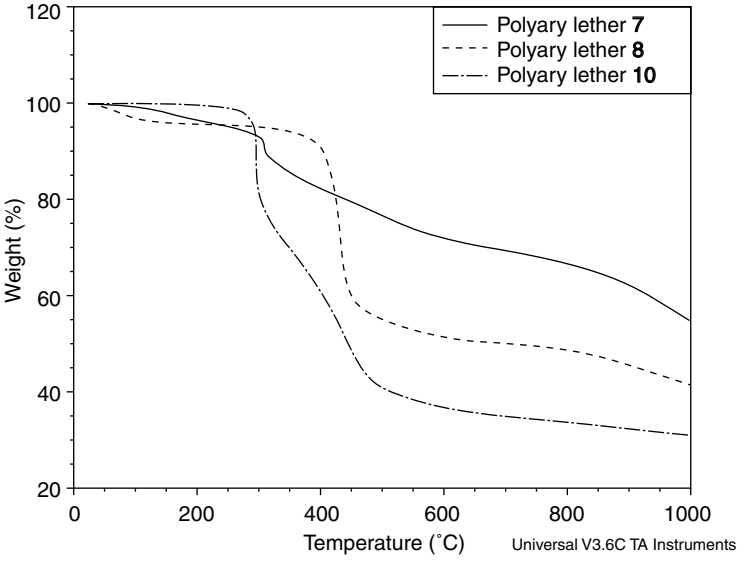

Fig. 15 Thermogravimetric (TG) analyses of polymers **7**, **8**, and **10** to determine weight loss on heating. Weight retention indicates some flame resistance.

might increase the amount of fuel for the fire, and therefore the flammability of the polymer. On the other hand, it is known in flame retardant chemistry that olefins can crosslink during the burning process and increase char formation.[69] In addition, Wagener describes some of his unsaturated polyethers as having a high degree of thermal stability as measured by thermogravimetric analyses.[88]

The first polymer with a flexible backbone was synthesized by a process known in the literature for making bisphenol A polyaryl ether under phase transfer catalysis conditions.[83] We used this procedure to couple BPC with 1,4-dichloro-2-butene (DCB) or 1,5-dibromopentane in *ortho*-dichlorobenzene (*o*-DCB) to yield polyethers **7** and **8** (Fig. 12).

The next approach for obtaining higher molecular weight polymers was to explore acyclic diene metathesis (ADMET) polymerizations.[75–77] The aim was to achieve higher molecular weight flame-resistant polymers. We modeled the reaction using aliphatic diene monomers such as 1,5-hexadiene and 1,9-decadiene under test conditions to optimize conditions before making BPC-derived products. At this point, we decided to functionalize the BPC with an olefin. Wagener has done considerable work on the influence of the neighboring group effect, and how it affects the ADMET reaction. These studies have concluded that atoms such as oxygen and sulfur act as Lewis bases, complexing with the metal (Ru) and hindering the metathesis reaction.[88] To circumvent this problem, three methylene spacer groups were incorporated into the monomer. This was achieved by condensing BPC with 5-bromo-1-pentene under basic conditions to yield monomer **9** (Fig. 13). After purification of this monomer by multiple recrystallizations from methanol, we polymerized **9** using ''second generation'' Grubb's catalyst[88] in toluene at 55°C with a positive flow of argon for 5 d to yield polyether **10** (Fig. 14).

The incorporation of the aliphatic (pentyl) and olefinic (butenyl and octenyl) functionalities in the present work has yielded processible polymers with a defined T_g. In addition, these materials are flame retardant with little to no additives being required (1 wt% PTFE was used as an antidrip additive) to pass vertical flammability tests, such as UL-94 V.

Polyarylether **7** was the first to be synthesized using PTC conditions. It is the most thermally stable of the three polymers. Comparisons of the TG analysis

Table 2 PCFC results for the polyarylethers (comparison of PCFC HR capacity, total heat, and char data for polymers **7**, **8**, and **10** to polyethylene and polystyrene)

Polymer	HR capacity (J/g K)	Total heat (kJ/g)	Char yields (%)
Polyarylether **7**	37	8	58
Polyarylether **8**	205	13	37
Polyarylether **10**	146	18	20
Polyethylene	1676	42	0
Polystyrene	927	39	0

Additive	First ignition[a] (s)	Observed dripping[b]	Second ignition[a] (s)	Observed dripping[b]	UL-94 rating
Polyarylether **7**, 1 wt.% PTFE	3, 0	No, no	0, 0	No, no	V-0
Polyarylether **8**, 1 wt.% PTFE	1, 6	No, no	3, 0	No, no	V-0
Polyarylether **10**, 1 wt.% PTFE	6, 0	No, no	0, 2	No, no	V-0

[a]Time to self-extinguishing after the first and second 10 s ignition in two sample runs.
[b]Molten sample did (yes) or did not (no) drip onto cotton patch underneath ignited bar during UL-94 test.

(Fig. 15) and PCFC data from the three polyarylethers show that **7** gives the highest char yields (58%) followed by **8** and **10** (Table 2). The thermal stability of the polymers is reduced with the incorporation of more aliphatic/olefinic groups, which results in a lower percentage of the char yields, which is apparent when you compare heat release capacity and char yields of polyarylethers **7** and **10.**

The PCFC total heat release data correlate well with the TG analysis char yields. Polyarylether **10** has a lower heat release capacity than polyarylether **8**, but also has a lower char yield. The thermal stability of these polymers can be attributed to the BPC structure; in addition, the olefin functionality in polyarylethers **7** and **10** might also give rise to its thermal resistance.[89] Almost half the polymer weight in **7, 8**, and **10** is retained; this indicates some flame resistance because we would have otherwise expected complete incineration (Fig. 15).

The flammability of the three polyarylethers **7, 8,** and **10** was measured using the UL-94 V test, and all three samples obtained a V-0 rating when mixed with 1 wt.% PTFE as an antidrip additive. It is important to note that the samples were tested without antidrip additive, and did not burn but dripped excessively, making characterization impossible. It was observed that while these polymers where subjected to prolonged exposure to the Bunsen burner flame, the fire never consumed them. The UL-94 sample results are shown in Table 3.

Asymmetric BPC Polymers

The incorporation of flexible linkers for making processible polymers, which are found in vinyl addition polymers, is not usually considered flame resistant and therefore is not generally a suitable option for

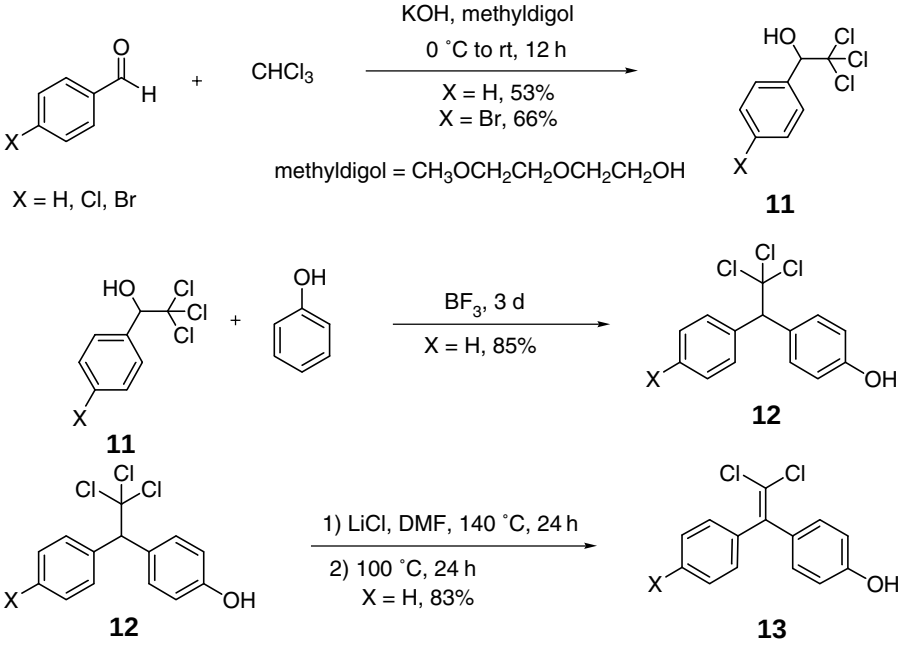

Fig. 16 Synthesis of asymmetric BPC **13**.

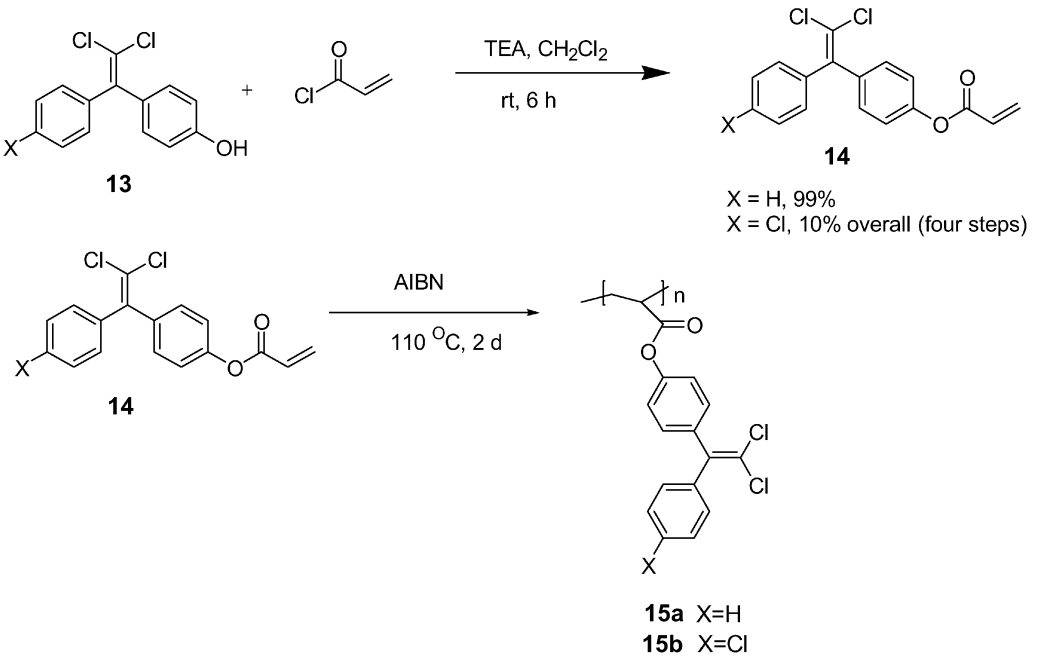

Fig. 17 Synthesis of asymmetric acrylate polymers **15a** and **15b**.

flame retardant polymers. However, because of the excellent flame retardant characteristics of BPC, we have made new asymmetric BPC (ABPC) monomers with an easily polymerized acrylate or styrene functional group. Acrylate polymers are known for their resistance to heat, sunlight, and weathering, which makes them excellent candidates for flame retardant polymers.[90] Styrene polymers are one of the most widely used plastics in the world having applications in markets such as those for building materials, packaging,

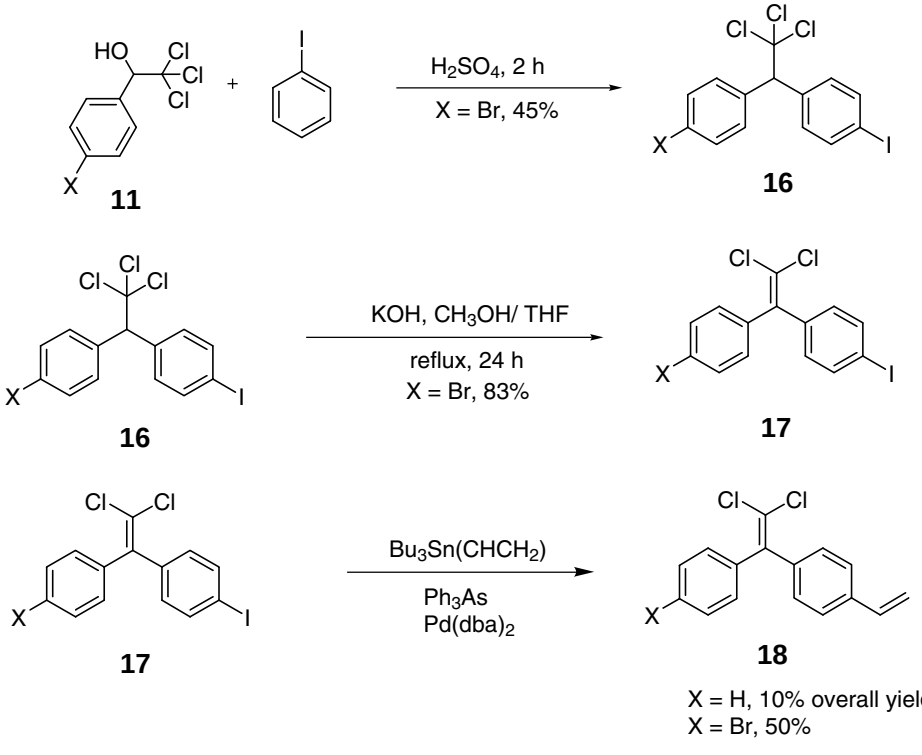

Fig. 18 Synthesis of asymmetric BPC styrene monomer **18**.

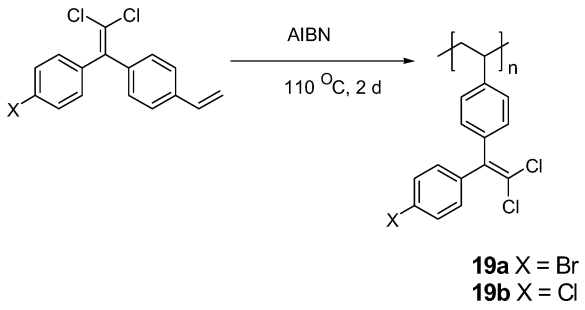

Fig. 19 Polymerization of BPC styrene monomers to give polymers **19a** and **19b**.

appliances, and automobiles, among others. By utilizing these two very important classes of polymers, it is possible to incorporate flame retardant properties into the most common plastics used today. Our approach to increasing the flame retardancy of vinyl polymers was to incorporate BPC as a pendant group of the vinyl backbone. As we will show, this work has produced a flame retardant polymer that can be easily melted and molded during processing. Such properties make the commercialization of the polymer more likely.

Acrylate BPC structures are made from inexpensive and readily available starting materials. The first step is to produce the trichloroethanol carbinol **11**. The carbinol is synthesized by slowly adding a solution of potassium hydroxide and methyldigol (diethylene glycol monomethylether) to a stirring solution of aromatic aldehyde (X can be H or Cl) and chloroform chilled at 0°C (Fig. 16).[91] The resulting carbinol **11** was purified by vacuum distillation and subsequently coupled with phenol in the presence of BF_3 gas over several days to yield **12**.[91] This process required several daily additions of BF_3 gas and mechanical stirring to mix the dark viscous product that was then purified by column chromatography. The dehydrohalogenation of **12** was completed using lithium chloride in DMF at 140°C for 24 hr, then slowly decreasing the heat to 100°C, to yield the asymmetric BPC analog **13** (Fig. 16).[92]

The final step to afford the acrylate monomer is the addition of acryloyl chloride to a solution of **13** and triethylamine in methylene chloride to produce the acrylate monomer **14** (Fig. 17). The acrylate polymer **15** was made by a bulk polymerization catalyzed by 2,2′-azobisisobutyronitrile (AIBN) at 110°C for 2 d (Fig. 17).

Styrene BPC polymers are made in much the same way; however, different attachment groups must be utilized to incorporate the styrene group onto the BPC molecule. Continuing on with the synthesis of **16**, sulfuric acid (H_2SO_4) was used to couple iodobenzene to make the asymmetric BPC analog as seen in Fig. 18.[93] The iodo-functionalized BPC compound was then dehydrohalogenated using potassium hydroxide and a methanol/THF mixture under reflux conditions to yield the BPC **17** (Fig. 18). The final step to afford the styrene BPC monomer (**18**) is to couple a vinyl group to the aryl iodide using Stille coupling procedures (Fig. 18).[94] The vinyl polymer **19** was polymerized under the same conditions as for **15** (Fig. 19).

The burn results for polymers **15** and **19** show that the polymers are inherently flame retardant with low base flammability (Table 4). The polymer dripped but did not ignite the cotton when it was subjected to the UL-94 flame test, and with the addition of 1 wt% PTFE, it did not drip. The PCFC results show that these polymers have a high heat release capacity when compared with the BPC carbonates and aryl ethers, but it is still significantly less than that of the base commodity polymers, such as polyethylene or polystyrene (Table 5).

CONCLUSIONS

In this entry, we have summarized recent work in the field of nonhalogenated flame retardant additives and

Table 4 UL-94 test for flammability—polyacrylates and polystyrenes

Compound tested	First ignition[a] (s)	Observed dripping[b]	Second ignition[a] (s)	Observed dripping[b]	UL-94 rating

Polyacrylate **15b**	224	10	11
Polystyrene **19a**	263	8	26
Polystyrene **19b**	320	16	20

inherently nonflammable polymers. Currently, none of the additives we developed are in commercial use because of cost issues associated with their production. However, process chemistry and economy of scale would greatly lower the cost for these additives if new regulations pushing to higher levels of fire safety, or nonhalogenated flame retardants, mandated their use. The inherently nonflammable polymers could be commercialized if there were sufficient market incentive. Because the BPC materials have very low flammability, their use may be mandated in high-performance applications, such as aircraft interiors and military/aerospace applications. The synthetic routes into these materials are not difficult, which indicates that the potential cost for these materials should be more than that of the existing commodity plastics, but not prohibitively expensive. The only potential concern with the synthetic approaches into BPC would be the use of chloral, which is an FDA regulated substance, and requires special licenses for its large scale commercial use.

To summarize the key findings of our work:

1. Alkyne, phosphorus/alkyne, and boronic acid flame retardant additives can be synthesized from brominated feedstocks via catalysis reactions.
   a. These additives are effective in providing flame retardancy in polycarbonate and require an additional synergist (currently unknown) to provide flame retardancy in other polymers.
2. BPC is a very versatile molecule that can be used to produce a variety of polymeric materials with inherently low levels of flammability, allowing them to be used with no additional flame retardant in some applications.
   a. Polycarbonates via transesterification with a tin catalyst.
   b. Polyarylethers via condensation or ADMET polymerizations.
   c. Vinyl polymers (acrylate or styrenic-like) via free-radical polymerizations.
3. The increasing market demand for higher fire safety and lower environmental impact will likely stimulate the commercial development of new flame retardant systems. These new systems may be additive or inherently polymer based, as described in this entry, and it may be that these materials are early analogs of future systems that someday will be in commercial use.

ACKNOWLEDGMENT

We thank the FAA, grant number 02-G-023, for funding this research.

INTRODUCTION

Nickel–cadmium (Ni–Cd) battery is one of the rechargeable battery systems produced on a large scale industrially. It is also one of the most mature and the widest employed rechargeable power sources in various industrial and consumer markets. At its peak, the annual production worldwide of the small-scale Ni–Cd batteries (cylindrical and prismatic) approached about 1.6 billion cells and over U.S.$2 billion in 1994 (R. Brodd, private communication).[1] This is mainly attributed to the various advantages of the Ni–Cd battery, such as its high discharge rate and high power density, long cycle life and long storage life, wide operational temperature range, etc. Ni–Cd batteries have been widely used in the transportation industry (power sources for trains, aircraft, and others), in the aerospace industry (power sources for rockets, satellites, and others), in the consumer market (portable power for cordless phone, cordless tools, toys and hobbies, portable electronic devices, portable lighting, and others), for standby power (uninterrupted power sources or UPS, emergency lighting, electronic backup, etc.), and in various military applications.[2–9] However, Ni–Cd batteries have some drawbacks: they are environmentally unfriendly (owing to the toxicity of cadmium), and have a relatively high self-discharge, memory effect in some cases, and relatively low energy density. Because of these disadvantages, the Ni–Cd battery has undergone a continuous decrease in its annual production volume in recent years, and in applications in selected fields it has been replaced by other more advanced battery systems such as nickel–metal hydride and Li-ion batteries. However, despite these drawbacks, the Ni–Cd battery remains a popular choice for various applications, and it still has a large production volume (about 1.16 billion cylindrical and prismatic cells and about U.S.$ 1.1 billion in 2001 and still holds a unique position in the field of rechargeable batteries (R. Brodd, private communication).[1]

The developmental history of the Ni–Cd battery can be traced back to the late 19th and early 20th centuries. The initial work was conducted by Jungner and others, who brought the ''alkaline electrolytes'' concept into the rechargeable battery field and introduced the ''pocket-plate'' Ni–Cd battery and its modifications.[2–8] The second milestone in the history of the Ni–Cd battery was the development of ''sintered-plate'' batteries, which was initially proposed by Pflider in 1928.[8] The application of sintered-plate electrodes resulted in a significantly improved battery energy density and a better rate capability. The disadvantages of the sintered-plate electrodes were the relatively higher fabrication cost and a possible memory effect during battery storage. A series of developments in the electrode structure of the Ni–Cd battery followed, to further improve the battery performance, which included the ''fiber-plate'' electrodes in the late 1970s and early 1980s, the ''pressed-plate'' or ''pasted'' electrodes, and more recently, the ''foam nickel'' electrodes, etc.[4–8] On the other hand, the cell structure of the Ni–Cd batteries underwent a development from the original vented cell structure to the sealed cell structures. Both structures of Ni–Cd batteries are in current production depending on the nature of the applications, and they represent two different concepts to overcome the problem of cell internal pressure buildup due to gas formation during the battery charge–discharge cycle. With the vented cell structure, the gas formed in the cell is removed via a ''physical-release'' mechanism by a specially designed gas valve on the cell container, while in the case of the sealed cell structure, the gas formed is removed via a ''chemical-combination'' mechanism by a special chemical reaction and special cell design. The sealed cell is a maintenance-free system and it can improve the battery cycle and the storage life. Therefore, it is very attractive for many applications, especially in the consumer market and for portable devices.

CELL COMPONENTS AND CELL CHEMISTRY

Cathode/Anode/Cell Reactions

The Ni–Cd cell consists of four base elements, that is, cathode, anode, separator, and electrolyte. Nickel

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007878

hydroxide ($Ni(OH)_2$) is the active material of the cathode at its discharge state. Among its various forms, beta-$Ni(OH)_2$ is believed to be the actual form undergoing a charge transfer reaction and it can be reversibly converted to nickel oxyhydroxide (NiOOH) as shown in Eq. (1) below:

$$Ni(OH)_2 + OH^- \underset{\text{discharge}}{\overset{\text{charge}}{=\!=\!=\!=\!=\!=\!=\!=}} NiOOH + H_2O + e^- \quad (1)$$

with an equilibrium potential $E^\circ = 0.49\,V$ vs. standard hydrogen electrode (SHE).

It has been established that the above cathode reaction is actually a proton transfer (or proton insertion/deinsertion) reaction between $Ni(OH)_2$ and NiOOH lattices. Eq. (1) can thus be rewritten as:

$$Ni(OH)_2 \underset{\text{discharge}}{\overset{\text{charge}}{=\!=\!=\!=\!=\!=\!=\!=}} NiOOH + H^+ + e^- \quad (2)$$

$Ni(OH)_2$ and NiOOH coexist in a single phase of a homogenous solid-state solution, and their relative concentration ratio in the solid solution varies with the state of charge (SOC) of the cell. Therefore, the cathode potential varies with the battery SOC governed by the Nernst equation. The temperature coefficient of the cathode reaction is about $-0.5\,mV/^\circ C$.

For the anode, cadmium hydroxide ($Cd(OH)_2$) is the active material at its discharge state. $Cd(OH)_2$ is reversibly converted to metallic Cd during the charging process, as shown in Eq. (3) below:

$$Cd(OH)_2 + 2e^- \underset{\text{discharge}}{\overset{\text{charge}}{=\!=\!=\!=\!=\!=\!=\!=}} Cd + 2OH^- \quad (3)$$

with an equilibrium potential, $E^\circ = -0.81\,V$ vs. SHE.

It should be noted that Eq. (3) is only a simplified reaction scheme for the anodic reaction. Actual anodic discharge reaction may take place via a ''dissolution–precipitation'' mechanism with soluble complex ions such as $Cd(OH)_3^-$, $Cd(OH)_4^{2-}$ as intermediates, as shown below:

$$Cd + 3OH^- \xrightarrow{\text{dissociation}} Cd(OH)_3^- + 2e^- \quad (4)$$

$$Cd(OH)_3^- \xrightarrow{\text{precipitation}} Cd(OH)_2 + OH^- \quad (5)$$

Unlike the cathode reaction, the anode reaction is not a homogenous single-phase reaction, but rather a two-phase [Cd and $Cd(OH)_2$] charge transfer reaction. Therefore, the anode potential is independent of its SOC. The anode reaction mechanism plays a significant role in impacting the reduction in battery capacity during its charge/discharge cycling. The temperature coefficient of the anode reaction is $-1.01\,mV/^\circ C$.

The overall cell reaction is thus shown as:

$$2Ni(OH)_2 + Cd(OH)_2 \underset{\text{discharge}}{\overset{\text{charge}}{=\!=\!=\!=\!=\!=\!=\!=}} 2NiOOH + Cd + 2H_2O \quad (6)$$

with cell voltage at the standard state $E_{cell} = 1.30\,V$.

Reactions in Overcharge and Overdischarge

In overcharge, the following reactions may take place at the cathode:

$$4OH^- \rightarrow 2H_2O + O_2 + 4e^- \quad (7)$$

at the anode:

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad (8)$$

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad (9)$$

In overdischarge, the following reaction may occur at the cathode:

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad (10)$$

The charging efficiency in the Ni–Cd battery is generally only about 80%. Part of the electrical energy during charging is consumed by side reactions, such as the water decomposition reaction. Although cadmium electrode has a high overpotential to hydrogen evolution reaction [Eq. (8)], which can be further suppressed by using excess anode, the O_2 evaluation at the cathode during charging is generally inevitable. Because the charging efficiency is lower than 100%, the Ni–Cd cell needs to be overcharged to a certain degree to attain the desired discharge capacity of the given cell.

Additives and Their Functions

Various additives are used for the Ni–Cd batteries to improve the battery performance. Additives are selected based on their special functions to improve the electrode structure and/or electrode chemical and electrochemical properties. For example, cadmium hydroxide $Cd(OH)_2$ is added to the cathode to prevent phase segregation and to help maintain a single phase of the solid solution during the transfer between $Ni(OH)_2$ and NiOOH in charge and discharge processes. Because $Cd(OH)_2$ is isomorphous with both $Ni(OH)_2$ and NiOOH, this structural functionality can improve the cycle life of the battery. Cd or CdO can increase the overpotential of oxygen evolution

reaction at the cathode and thus can suppress the gas evaluation and reduce the self-discharge rate because oxygen evaluation at the cathode is one of the major factors that causes cell self-discharge. Similar functions have been found with a number of metals, such as Zn, Li, Co, etc., which can also be used as cathode additives. On the other hand, metallic cadmium grain growth and the formation of large-size crystals may cause loss of battery capacity during the charge–discharge cycle; some materials having antiagglomorant function are used as anode additives. These include selected iron compounds, nickel, and selected organic polymers (such as PVA, cellulose, etc.), which can prevent Cd crystal growth, stabilize Cd structures, and thus minimize the loss of capacity during the charge–discharge cycle. Indium is a different type of anode additive and its basic function is to enhance the electrochemical activity of the anode-active material, $Cd(OH)_2$. Other selected compounds can be used as electrolyte additives; for example, a small amount of lithium hydroxide, LiOH, can be added into the electrolyte to improve the battery cycle life at elevated temperatures.

Electrolyte

The typical electrolyte of the Ni–Cd battery is the concentrated potassium hydroxide (KOH) aqueous solution (~30% by weight). This electrolyte solution provides high ionic conductivity and a wide temperature window of a liquid phase. In addition, both the cathodic and the anodic active materials have low solubility in this electrolyte. These properties make a substantial contribution to the performance of the Ni–Cd, especially the high rate, wide operational temperature range, long cycle life, and long shelf life.

Separator

The main function of the separator in a cell is to prevent direct contact between the cathode and the anode and thus avoid an internal electrical short circuit of the cell. In addition, a separator needs to provide a good pathway for the ion transport in the cell. Therefore, in addition to its good chemical and electrochemical stability in the cell's environment, a good separator should have a high degree of porosity and a good wettability with regard to the electrolyte used. In the case of the vented cell type of Ni–Cd batteries, a separator also functions as a gas barrier to prevent gases formed in the cell from passing from the cathode area to the anode area, or vice versa. The commonly employed separators in Ni–Cd batteries are nonwoven nylon and polyimide. A newly developed separator in recent years is polymer impregnated Zircar material, which shows an extremely high chemical stability in concentrated caustic solutions, and can thus further reduce the self-discharge rate and improve battery life. Zircar is a high-temperature fibrous ceramic material containing zirconia as a major component.

BATTERY CONSTRUCTION

Ni–Cd cells can be categorized into two major groups of batteries, vented and sealed, based on the cell construction.

Vented Ni–Cd Batteries

As mentioned, gas (oxygen) evaluation at the cathode takes place in the overcharge process, which results in a continuous accumulation of gases and a buildup of the internal pressure of the cell during its charge–discharge cycle. To resolve this problem, the vented cell structural concept was introduced into the Ni–Cd battery in its original form during its early development stage, and it has been widely employed in manufacturing Ni–Cd batteries since then. For the vented cell construction, the cell container is fabricated with an open space that is covered by a removable cap (vent cap). The main function of the cap is twofold: first, it serves as a check valve to release gases generated during cell overcharge (such as from water decomposition) and prevent the increase of the cell internal pressure and second, it serves as an inlet for replenishment of water to the electrolyte when water is consumed during cell usage.

For the vented Ni–Cd batteries, two types of electrode structures and configurations are used. One is the so-called pocket-plate electrode and the other is the sintered-plate electrode. In the case of the pocket plate, electrodes are made by pressing or feeding electrode composite materials (cathode: nickel hydroxide mixed with conductive materials, such as graphite, binder, and other selected additives; anode: cadmium hydroxide mixed with graphite, binder, and other selected additives) into flat pockets of preshaped perforated steel strips. The steel strips are plated with nickel to avoid iron contamination in the system. The pocket functions as a current collector and also provides mechanical support. The thickness of the pocket-plate electrode can be controlled according to the requirement of the battery discharge rate, and it is generally in the range of 1.5–5.0 mm. The pocket-plate Ni–Cd batteries have a number of advantages, such as the simplicity of the electrode fabrication process, its low cost, the good physical stability and reliability, the long storage life, etc. One of its main disadvantages is its relatively low energy density, which results largely

from the loose structure of the electrodes and the inefficient volume utilization of the cell.

The sintered-plate electrode was developed to successfully change the electrode structure from loose to compact. By this technology, electrodes can be made denser and thus thinner compared with pocket-plate electrodes. Accordingly, the energy density of the sintered-plate Ni–Cd battery is significantly higher than its pocket-plate counterpart (up to 50% higher). The sintered-plate electrode consists of two main components, that is, a sintered porous metal substrate (usually called ''plaque'') and the active material dispersively impregnated into the pores of the plaque. The plaque is usually made with a perforated (or woven screens) nickel or nickel-plated steel strip (or wire) substrate. This substrate is then coated with carbonyl nickel powder plus binder and pore former via either the ''wet coating'' (slurry coating) or the ''dry powder'' process. The coated substrate is then sintered in a reducing atmosphere at 800–1000°C for a controlled time duration to become a compact, highly porous plaque. The plaque obtained by this process usually has porosity up to 85% and its thickness can be controlled based on the requirements. The plaque has the dual function of both host of the active materials and current collector for the given electrode. The active materials (nickel hydroxide for the cathode and cadmium hydroxide for the anode) are dispersed and held in the pores of the plaque. This is usually accomplished by using an impregnation process. There are several methods of impregnation, including mechanical, chemical, and electrochemical. Chemical impregnation is the most typical and widely employed method in the industry. In this process, the plaque is first filled with aqueous nickel nitrate $Ni(NO_3)_2$ solution [or cadmium nitrate solution $Cd(NO_3)_2$ for anode], and then the $Ni(NO_3)_2$-filled plaque is soaked and polarized cathodically in a caustic NaOH solution, in which the corresponding metal hydroxide is precipitated in the pores of the plaque. This impregnation process can be repeated several times until the desired loading level is approached. For the electrochemical impregnation process, the plaque is soaked in an acidic aqueous or alcoholic solution of nickel nitrate, and it is then cathodically polarized in this solution, and nickel hydroxide is then formed on the plaque.

Unlike the pocket-plate electrodes, the sintered-plate electrodes do not need the addition of any conductive material (such as graphite) to create enough electronic conductivity of the electrode, because plaque itself provides this function. On the other hand, the sintered-plate electrodes do not need the addition of the binder material to the active material to create the structural integrity of the electrode, because the plaque itself provides this integrity in the first place. Having these structural advantages, the sintered-plate Ni–Cd batteries show substantially higher material utilization and a higher energy density than the pocket-plate Ni–Cd batteries. The sintered-plate Ni–Cd batteries have other advantages such as high physical reliability, high performance rate, good storage life, etc. One of the disadvantages of the sintered-plate Ni–Cd battery is its relatively higher manufacturing cost, which is associated with costly processes such as sintering and impregnating. Another major disadvantage of the sintered-plate Ni–Cd battery is its memory effect.

The memory effect is generally referred to as an apparent decrease in the discharge capacity and power with respect to a given discharge cutoff voltage (VOC) after repeated shallow discharge–charge cycles. The apparent discharge capacity and power decrease results from depression or decrease of the discharge voltage; in other words, the discharge capacity could remain the same if the discharge VOC decreases accordingly. Therefore, the memory effect can be more correctly described as the depression of discharge voltage. The memory effect usually is not observed in the pocket-plate Ni–Cd batteries but it occurs in the sintered-plate Ni–Cd batteries. Although the mechanism of the memory effect is not fully clarified, it is believed to be associated with the change in the anode structure. The morphological changes of the unused metallic cadmium in a shallow discharge may lead to an increase in cell resistance, R, and thus an increase in IR drop during discharge. This is one of the proposed mechanisms for the voltage depression (IR mechanism). A different mechanism for the memory effect is the formation of intermetallic alloys such as Ni_5Cd_2 in the anode during the overcharge. Intermetallic alloys may have a higher discharge potential compared with metallic cadmium, which leads to a decreased cell discharge voltage. The main source of nickel in the anode to form Ni–Cd alloys is the residual nickel hydroxide that is formed from Ni-plaque during the impregnation process. Thus, it is important to control the impregnation process in order to reduce the formation of nickel hydroxide. Or, one can either completely remove Ni substrates or eliminate the impregnation process in the anode fabrication. The employment of the ''plastic-bonded'' or pressed-plate electrodes is one of the new developments following the above idea. It is noticed that the memory effect is actually a reversible effect, which can be recovered totally by an electrical reconditioning process called the ''maintenance cycle.'' In this process, the cell is forced to undergo a complete discharge (e.g., short circuiting the cell) to use up all unused active materials of the charged state, and this is then followed by a complete charge/overcharge step. The capacity and power of the cell can usually be restored by this treatment.

Vented sintered-plate Ni–Cd batteries are usually designed with capacity-matched cathode and anode.

Under this condition, the oxygen evaluation on the cathode and the hydrogen evaluation on the anode may occur during overcharge. To minimize and avoid oxygen transferring from the cathode area to the anode area and recombining with hydrogen, the separator used should be O_2 impermeable. In addition, vented Ni–Cd batteries usually use excess amount of the electrolyte to form the flood cell.

As discussed above, the electrodes of Ni–Cd cells are categorized in pocket-plate electrodes and sintered-plate electrodes, both of which are widely employed in the Ni–Cd battery industry. On the other hand, several new structures of the electrode have been developed in recent decades. One is the so-called fiber-plate electrode developed in the late 1970s, in which a mat of nickel fibers or nickel-plated plastic fibers is used instead of the pocket of perforated nickel-plated steel strips in the pocket-plate structure. Compared with the pocket-plate electrode, the fiber-plate electrode has higher utilization of the electrode-active materials and higher energy density. The next development in this field was the introduction of plastic-bonded or pressed-plate or pasted electrodes, in which the electrode composite (active material, conductive material, and plastic binder) is mixed with a solvent to become a paste first and then the paste is extruded or rolled on a current collector of nickel-plated perforated steel. The advantages of the plastic-bonded electrode are its cost-effective processing, higher structural integrity, and compactness of the electrode, which improves the energy density. The plastic-bonded electrode is widely used for the fabrication of the anode of Ni–Cd batteries. A further new development in the mid-1980s was the introduction of the foam-nickel electrodes. A porous Ni-foam substrate is fabricated first by plating the nickel on a porous plastic material (such as polyurethane, etc.), which is made electrically conductive by a pretreatment step consisting of an electrode-less deposition, and then removing the plastic material by a pyrolysis treatment after Ni plating. The Ni-foam framework obtained possesses a high degree of porosity (e.g., 90–95% free volume) and a high surface area, which creates a large capacity for holding active material and provides an effective conductive pathway. This results in enhanced cell energy density. The Ni-foam electrode structure has been widely employed for the cathode of Ni–Cd batteries in both industrial and consumer products.

Sealed Ni–Cd Batteries

The use of the vented cell structure can prevent the buildup of internal pressure in the cell resulting from gas generation during overcharge. One of the disadvantages of the vented structure, however, is that the batteries need to be routinely maintained, e.g., by replenishing water in the electrolyte to compensate for water consumed during overcharge. The sealed Ni–Cd battery, a new generation of the cell construction, was developed to further resolve the gas generation problem. The mechanism of the sealed Ni–Cd cell is based on the following chemical reaction:

$$\tfrac{1}{2}O_2 + Cd + H_2O \rightarrow Cd(OH)_2 \qquad (11)$$

where the oxygen, generated on the cathode during overcharge, transfers to the anode area and reacts with cadmium to produce cadmium hydroxide, which is continuously converted to cadmium during charge. Through this recombination route, the oxygen formed can be ''consumed'' or ''eliminated'' continuously, thus avoiding the buildup of internal pressure in the cell. The cell can be completely sealed and becomes maintenance free. The sealed Ni–Cd batteries have the same cell chemistry as that of the vented ones, but have the following differences in terms of cell design:

1. The cell is designed with excess anode-active materials, so that the overcharge takes place only on the cathode, and oxygen gas will be generated on the cathode, but no hydrogen gas is formed on the anode.
2. The separator employed in the sealed cells is not a gas barrier, but rather an oxygen permeable membrane (such as nonwoven nylon, polypropylene, etc.).
3. The amount of electrolyte is limited, that is, the cell is of ''starved'' type rather than the ''flooded'' type for vented batteries. The starved electrolyte can facilitate the oxygen transfer process.

In addition to being maintenance free, the sealed Ni–Cd batteries provide many other advantages, such as long shelf life, long cycle life, good performance rate, good low-temperature performance, etc. The sealed Ni–Cd batteries have been widely employed in various industrial and consumer markets. In the field of portable power sources, the sealed Ni–Cd batteries are especially attractive for various portable electronic devices such as wireless phones, camcorders, PCs, etc., and for various consumer products such as toys, wireless tools, photography, etc. The sealed Ni–Cd batteries can be manufactured with different constructions. The cylindrical cell is the most common one and Fig. 1 shows its general structure.[9]

In this structure, one of the core elements is a round jellyroll, which consists of a cathode strip, an anode strip, and a separator strip between them. The jellyroll is inserted into a cylindrical-shaped Ni-plated steel can with adequate electrical connections. The controlled

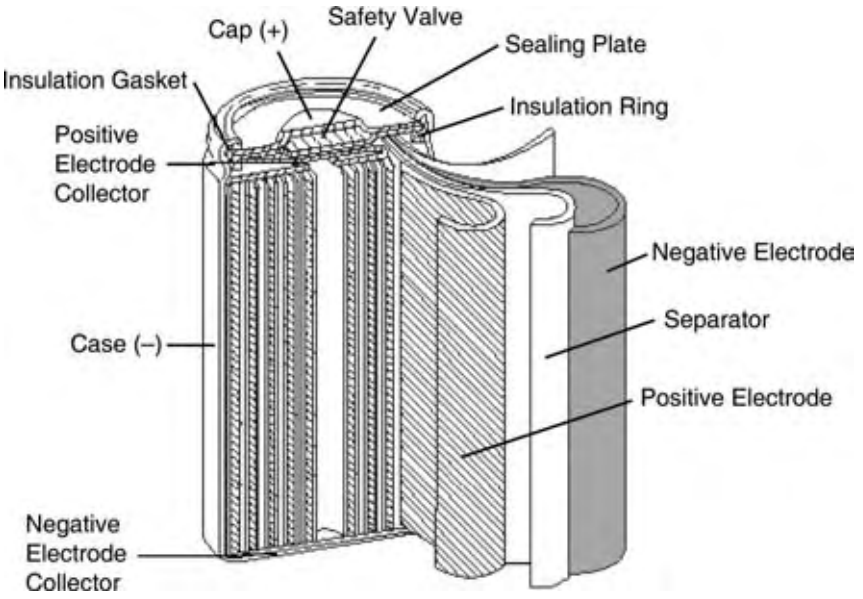

Fig. 1 Construction of the sealed Ni–Cd battery. (From Ref.[9].) *(View this art in color at www.dekker.com.)*

amount of electrolyte is then added into the can and the electrolyte is absorbed by the electrodes and the separator. The sealed Ni–Cd batteries can also be manufactured with other configurations, such as button cells, prismatic cells, and rectangular cells. Among them, button cells are usually used for applications of low capacity and low drain rate, while prismatic cells have more applications in portable and compact devices because of their structural advantage of enhancing volume efficiency by 20% with respect to the cylindrical structure.

OPERATION MODES

Charge Mode and Its Characteristics

The constant-current charge is the most commonly used charge mode for Ni–Cd batteries. Usually, a low or medium charge rate is recommended (e.g., a rate of a few tenths of coulombs rate) to avoid a fast increase in cell temperature during the charge. It is usually necessary to have a charge control circuit on the cell to control charge depth (ending charge), for which various parameters, such as charge time, cell temperature, and voltage change rate, can be selected as the charge controlling factors. Trickle and float charge are also used for Ni–Cd batteries in which the batteries are kept in a continuous charge step at a very low charge current (such as 0.02–0.05 C) to maintain them always in a fully charged state. Another charge mode is the constant voltage charge. In general, the charge efficiency in Ni–Cd batteries is significantly lower than 100% (typically about 70% for vented cells and about 80% for sealed cells) because of the side reactions occurring during the charge. Therefore, the overcharge is generally needed to obtain a full charge state. The charge efficiency is impacted by the charge rate and the charge temperature. For the sealed Ni–Cd batteries, the charge efficiency decreases with increasing charge temperature, which can be attributed to the decrease in potential for oxygen generation on the cathode. Although a higher charge rate leads to a higher charge efficiency, it is not recommended to use an overhigh charge rate because it could cause the buildup of internal pressure in the cell once the oxygen generation rate on the cathode is higher than the oxygen recombination rate on the anode. On the other hand, a high charge rate may cause an increase in cell temperature due to heat generated in the oxygen recombination reaction. Fig. 2 shows the typical charge characteristics of Ni–Cd batteries.

It is important to control the end point of the charge process for the constant-current charge mode. One method is to set up a predetermined VCO at which the charge process of constant current will be automatically terminated. Although this method is simple and effective, the selection of the VCO and the impact of temperature on the cell charge voltage must be considered. It has been found that the temperature effect of the charge voltage at constant-current conditions is $-4\,\mathrm{mV}/^{\circ}\mathrm{C}$. Owing to this effect, a VCO that is adequate at temperature T_1 may become too high if the cell temperature changes to T_2 ($T_2 > T_1$), which in turn may hurt the battery. To prevent this adverse effect, a temperature compensation element should be used. By using a temperature sensitive control unit to monitor cell temperature in situ, and with the function of the temperature compensation element installed in the battery case, charge process can be controlled

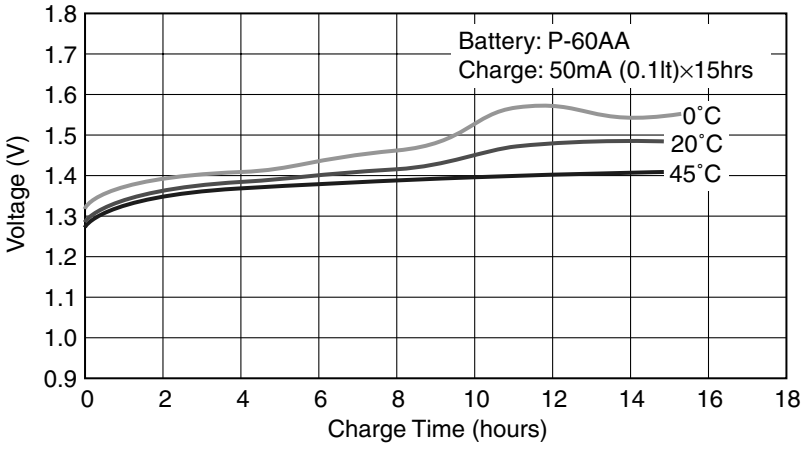

Fig. 2 The charge characteristics of Ni–Cd batteries. (From Ref.[9].) *(View this art in color at www.dekker.com.)*

adequately. Another commonly used charge control method is to use voltage change rate as a signal to terminate the charge, because the cell voltage undergoes a sharp rise when the charge approaches the end. This characteristic property can be used for controlling the charging process. It is noted that the ''end-of-charge'' voltage is higher for the vented Ni–Cd batteries than for the sealed Ni–Cd batteries; this is attributed to a higher overpotential for the gas evaluation reactions in the former, and a decreased overpotential for the latter due to depolarization of the anode once the oxygen recombination reaction takes place on it. Table 1 summarizes various charge systems of Ni–Cd batteries.[7]

Discharge Mode and Its Characteristics

The discharge mode of Ni–Cd batteries is dependent on their applications. The most common one is the constant-current discharge, in which the current can be changed from very low (e.g., in the case of button-batteries) to very large (e.g., for batteries for wireless tools). There are also other discharge modes, such as constant-resistance discharge, content-power discharge, etc.

BATTERY PERFORMANCE CHARACTERISTICS

Energy Density and Power Density

The energy density of Ni–Cd batteries is higher than for lead-acid batteries. Generally, the energy density of vented sintered-plate Ni–Cd cells ranges from 58 to 96 W hr/L and the specific energy ranges from 30 to 37 W hr/kg.[4] The value of the energy density varies with the cell structure and battery size. Ni–Cd batteries can be discharged at high rates and have a high power density. The typical power density of vented sintered-plate Ni–Cd cells ranges from 730 to 1250 W/L, and the specific power ranges from 330 to 460 W/kg.[4] In general, vented Ni–Cd batteries have higher power capability than the sealed ones.

Effect of Drain Rates on Discharge

Ni–Cd batteries have an open circuit voltage of about 1.35 V and an average close circuit voltage of about 1.20 V at normal discharge rates. The discharge capacity and the average voltage change depending on the discharge rate. Fig. 3A shows a family of typical discharge curves at various drain rates for sealed Ni–Cd batteries. As shown in the plot, the battery capacity decreases with increasing drain rates.

Effect of Temperature on Discharge

Ni–Cd batteries can be used at a wide range of temperatures (-40° to $+50^{\circ}$C). Fig. 3B shows a family of discharge curves at various temperatures for sealed Ni–Cd batteries. As shown in the plot, both capacity and average voltage decrease with decreasing temperatures. At –20°C, about 80% of the rated capacity can be obtained at 0.2 C rate.

Cycling Life

For Ni–Cd batteries, the cycling life is usually measured to the stage when the discharge capacity decreases to 80% of the rated capacity. Ni–Cd batteries generally have a cycling life of 500 cycles or more. The cycling life is even longer if the battery undergoes shallow discharge–charge cycling (low depth of discharge). The cycling life of the battery is also impacted by other factors such as charge mode and charge rate, discharge mode and discharge rate, battery operation temperature,

Table 1 General comparison of the various charge systems of Ni–Cd batteries

	Cycle (repeated) use				Standby use
Charge system	**Semiconstant current charge**	**Timer controlled charge**	**$-\Delta V$ cutoff charge**	**dT/dt cutoff charge**	**Trickle charge**
Operation VB: battery voltage Ich: charge current T: battery temperature					Features	Most typical charge system Simple and economical	More reliable than semiconstant current charge system Relatively simple and economical	Most popular	Charging circuit costs more than the others but overcharge can be avoided enabling longer life cycle than $-\Delta V$ charge method	Simple and economical Applicable to the equipment for continuous long charge

and others. Fig. 4 shows a typical cycling performance for a sealed Ni–Cd cell.

Self-Discharge and Shelf Life

The shelf life of Ni–Cd batteries is largely determined by the cell self-discharge rate. The mechanism of the self-discharge for Ni–Cd batteries includes the following reactions:

1. The decomposition of the charged cathode-active material NiOOH:

$$2\mathrm{NiOOH} + \mathrm{H_2O} \rightarrow 2\mathrm{Ni(OH)_2} + \tfrac{1}{2}\mathrm{O_2} \quad (12)$$

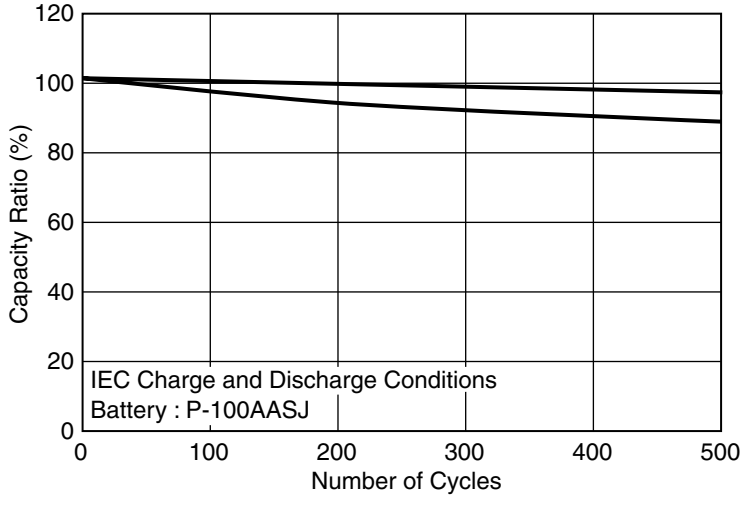

Fig. 4 Typical cycle life characteristics of Ni–Cd batteries. (From Ref.[9].)

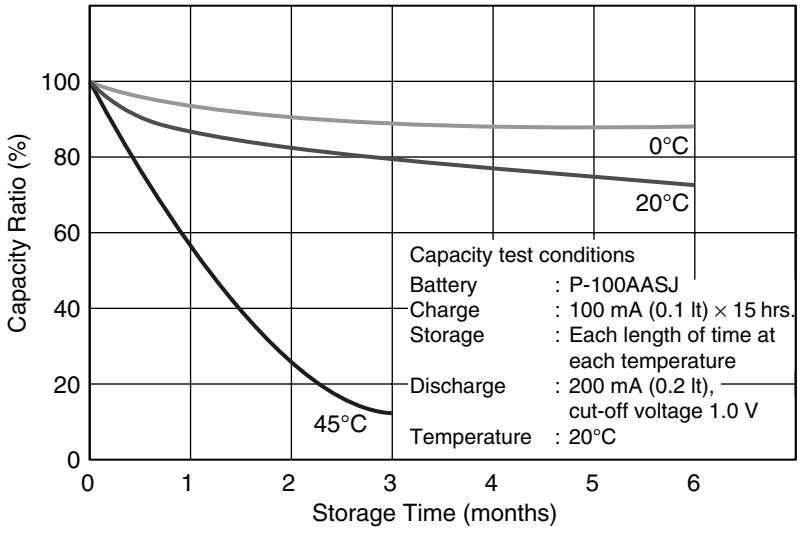

Fig. 5 Typical self-discharge characteristics of Ni–Cd batteries. (From Ref.[9].) *(View this art in color at www.dekker.com.)*

This decomposition reaction can be further enhanced by the O_2 recombination reaction at Cd anode, which in effect consumes part of the charged anode-active material (Cd).

2. Consumption of NiOOH and Cd (charged active materials) by residual inorganic impurities, mainly nitrate ions. The residual NO_3^- ions come from the electrode impregnation process; NO_3^- ions can react with Cd to form NO_2^- and NH_3. Both NO_2^- and NH_3 can, in turn, react with NiOOH. Therefore, both charged anode- and cathode-active compounds (Cd and NiOOH) can be gradually consumed by $NO_3^-/NO_2^-/NH_3$ shuttle reactions and this leads to capacity loss during the battery storage.
3. Consumption of NiOOH by organic impurities. Organic impurities are formed as a result of the decomposition of the separator materials in concentrated alkaline solutions. The organic impurities formed can react with NiOOH to cause capacity loss.

In general, the self-discharge rate increases with increasing temperature; accordingly, the shelf life of Ni–Cd batteries becomes shorter at high temperatures. Besides, several other factors such as electrode structure, process control during cell manufacturing, separator materials, etc. also affect the cell self-discharge rate and the shelf life. Fig. 5 shows the typical shelf life of sealed Ni–Cd cells at various temperatures.

CONCLUSIONS

The Ni–Cd battery is one of the important rechargeable batteries in both industrial and consumer markets. This battery system has special advantages in its high rate capability, high power density, and long cycle life, among others. Toxicity of cadmium is one of its major drawbacks, which has resulted in a gradual decrease in its production volume since the mid-1990s.

NMR in Chemical Processing

Sangrama K. Sahoo

INTRODUCTION

Nuclear magnetic resonance (NMR) spectroscopy since its discovery in the 1940s has become one of the most valuable characterization tools for chemical and biological substances. Purcell et al.[1] and Bloch et al.[2] independently discovered the NMR phenomenon in 1946 and shared a Nobel Prize in 1952 for their work. In the first two decades following its discovery, NMR was used for the measurement of magnetic shielding, electric field gradients, and coupling tensors in molecular physics and for the chemical structure determination of small molecules. However, with the implementation of Fourier transform methods[3] and diffusion phenomena,[4] NMR has become a popular characterization tool in chemistry, physics, biochemistry, materials science, and medicine.[5] Another breakthrough in the 1970s used the deliberate introduction of field gradients along the sample to image nuclear spin density, a technique now commonly known as magnetic resonance imaging (MRI).[6] These developments led to many important applications of NMR as evident from the award of Nobel Prizes in Chemistry to Professor Richard Ernst in 1991 and Professor Kurt Wüthrich in 2002 for their work in the development of NMR methodology and their biological applications.

Nuclear magnetic resonance spectroscopy offers engineers the opportunity to study the influence of process parameters on heterogeneities in the physical and chemical structure of materials. It was first used in chemical engineering as a noninvasive probe of structure and flow.[7] One advantage of NMR is its utility to probe all three forms of matter: solid, liquid, and gas. Although solution NMR was first used in chemical processing, developments in solid-state NMR and imaging in the 1980s provide additional analytical tools. It is possible to obtain qualitative and quantitative information on adsorption, transport, and reaction processes in situ by NMR spectroscopic and imaging techniques.[7] These data are utilized in modeling studies to develop theories for predicting the behavior of relevant processes. The temperature dependence of the NMR spectrum makes it a unique tool for analyzing molecular dynamics behavior and reaction kinetics.

Conventional one-dimensional NMR involves the collection of a spectrum with signal intensity plotted as a function of resonance frequency (in ppm). However, recent developments in NMR led to the use of multidimensional (2D- and 3D-) NMR. These nD spectra are usually displayed as contour maps where each of the axes of the spectrum contains information relating to spectral parameters such as chemical shift (δ), scalar coupling (J), and diffusion coefficient (D); correlations between these spectral parameters provide additional structural and dynamics information.[8] These studies can be performed on solid powders, gels, liquid crystalline solutions, supercritical fluids, liquids, and solutions. Before discussing the application of NMR in chemical processing, basic principles of NMR spectroscopy are discussed, followed by applications categorized by studies in solution, solid state, and imaging.

BASIC PRINCIPLES OF NMR

Nuclear magnetic resonance spectroscopy is a technique to study the perturbation of atomic nuclei in a static magnetic field (B_0) in the presence of a second oscillating magnetic field (in the radiofrequency range).[8–11] All atomic nuclei possess a characteristic known as nuclear spin (I). However, only those nuclei with nonzero spin are NMR active, undergoing precession when placed in a static magnetic field. The unique precession frequency, known as the ''Larmor frequency,'' for each nucleus is dependent on B_0 and is unique for each atom. The irradiation frequency ω_0 applied to induce the resonance condition must match the magnetic moment's precession and is related to B_0 and magnetogyric ratio, γ, of the nucleus by

$$\omega_0 = \gamma B_0$$

Nuclei with $I = 1/2$ have two energy states, $m = \pm 1/2$, with the nuclear moment, μ, aligned with (lower energy) or against the field (higher energy) (Fig. 1). Generally, nuclei with spin I populate $2I + 1$ energy levels. Every element in the periodic table has at least one NMR-active isotope; some of the common NMR-active nuclei and their properties

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120018073

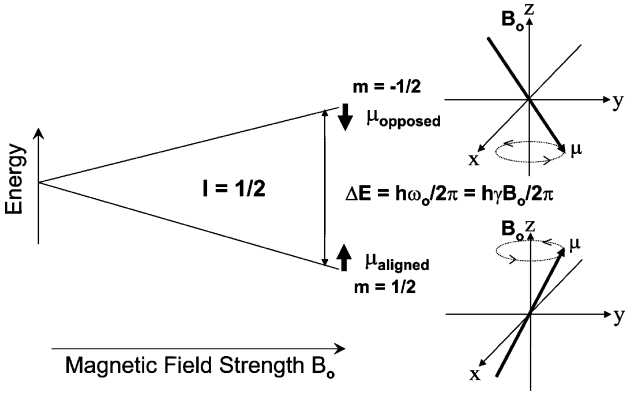

Fig. 1 Energy separation between nuclear spin states.

are given in Table 1. In a stationary (laboratory) reference frame at equilibrium, the spins are randomly oriented and precess on the surface of a cone (Fig. 2a). However, as there is a small excess of nuclei in the lower energy level, the average or net orientation of these magnetic moments is aligned along the magnetic fields and is represented by vector M_0. The intensity of the NMR signal is proportional to M_0. In an rf field, B_1, precessing at the Larmour frequency, this magnetization will rotate around an axis, which is the vector sum of $B_0 + B_1$ and will tip into the $x'y'$-plane. In a reference frame rotating about B_0 at a frequency ω_0, the nuclear moments B_1 appear stationary, and M_0 will precess about B_1 toward the y-axis (Fig. 2c). The external field (B_0) effectively disappears in the rotating frame and there is no apparent precession.

In pulsed NMR, a short rf pulse is applied to all spins at the Larmor frequency, creating a small B_1 field along the x-axis in the rotating frame and causing the nuclear spins to rotate toward the xy-plane as a coherent packet (Fig. 3). Typically, the pulse duration is such that M_0 flips into the y-axis where the decaying xy component of the magnetization can be detected as a time domain signal, commonly known as a free induction decay (FID). Each unique atom gives rise to a decaying cosine signal with its own characteristic frequency. The Fourier transformation of the time domain signal gives the characteristic frequency domain NMR spectrum.

After the perturbation, the net magnetization returns to equilibrium by two relaxation processes. The recovery of z-magnetization M_z to its equilibrium value, $M_z = M_0$, which depends on the rate of exchange of energy between the nuclei and the lattice, is called spin-lattice relaxation or longitudinal relaxation and is governed by the time constant T_1. The common method of determining T_1 is by inversion recovery.[10] Similarly, the recovery of M_{xy} to its equilibrium value $M_{xy} = 0$ is known as spin–spin or transverse relaxation, T_2. Spin-echo experiments are used for measuring T_2.[10] The line width of the resonance at half height is inversely proportional to T_2. The resonance line shape of dilute solutions is approximately Lorentzian, with a width at half-height, $\Delta\nu_{1/2}$, given by

$$\Delta\nu_{1/2} = \frac{1}{\pi T_2^*} = \frac{1}{\pi T_2} + \Delta\nu_{B_0\text{inhomo}}$$

For dilute solutions, T_2^* is large and the line width is narrow (on the order of Hz). As the solution viscosity increases, T_2 decreases and line width broadens (in solids, line widths are 10^2–10^4 Hz). For dilute solutions of small rapidly tumbling molecules $T_1 = T_2$; however, as the solution viscosity or the molecular weight increases, T_2 decreases whereas T_1 increases.

The magnetogyric ratio is different for each isotope; thus at a constant B_0, different isotopes resonate at different frequencies. For example, if $B_0 = 14\,\text{T}$, ^{1}H atoms resonate at 600 MHz and ^{13}C atoms resonate at 150 MHz. When atoms are placed in a static magnetic field, their electronic environments create small perturbations in the effective magnetic field sensed by nuclei in slightly different local environments. The

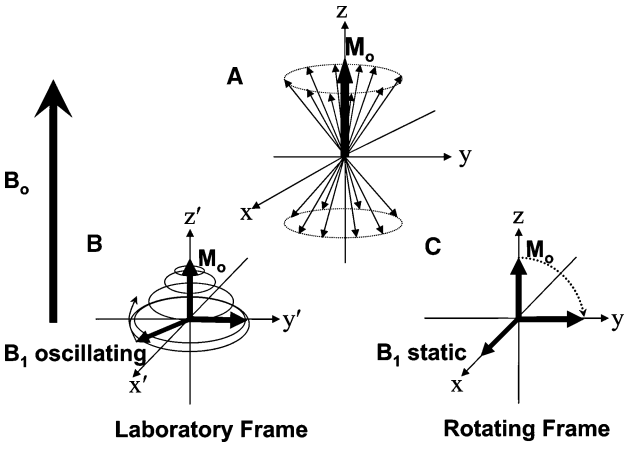

Fig. 2 (A) Macroscopic equilibrium magnetization M_0 from the vector sum of the individual nuclear moments μ; (B) magnetization interacting with B_1 rf field in the laboratory reference frame; and (C) magnetization interacting with B_1 field in the rotating reference frame.

magnetic field at the nucleus (B_{eff}) is therefore different from B_0 by a fraction σ,

$$B_{\text{eff}} = B_0(1 - \sigma)$$

where σ is known as the shielding constant. Depending on the direction of effective field, the shift in the resonance position might be deshielded (higher frequency) or shielded (lower frequency). This spread of resonance frequencies, which is proportional to B_0, is known as the chemical shift. To facilitate comparison of results from instruments with different B_0s, the chemical shifts are reported relative to the resonance frequency of a standard in field-independent units. The ^{1}H, ^{13}C, and ^{29}Si resonances of tetramethylsilane (TMS) are generally used for ^{1}H, ^{13}C, and ^{29}Si chemical shift reference standards, respectively. This chemical shift is reported in ppm and given the symbol δ, where

$$\delta = \frac{(\nu - \nu_{\text{ref}}) \times 10^6}{\nu_{\text{ref}}}$$

Structural information can be obtained from through-bond, scalar, or J coupling and through-space (nuclear Overhauser effect, NOE) magnetization transfer NMR experiments between pairs of protons.[11] Spin–spin (J) coupling is the through-bond interaction between the moments of two neighboring nonequivalent nuclei. If a nucleus is coupled to n equivalent nuclei, a multiplet is observed with approximate intensity ratios defined by polynomial coefficients of $(x + 1)^n$. The ^{1}H spectrum of 2-propanol in Fig. 4 serves as an example. Three groups of signals (multiplets) are present with relative areas 1 : 1 : 6 from the methine, hydroxyl, and methyl protons. The hydroxyl protons rapidly exchange between molecules, so coupling to them is not detected. The methyl proton is a 1 : 1 doublet from coupling to the methine proton; and the methine proton is a 1 : 6 : 15 : 20 : 15 : 6 : 1 septet from coupling to six equivalent methyl protons. The separation between peaks in both multiplets is 6 Hz because it is caused by the same interaction. An enormous amount of structural information can be obtained from such simple interpretation of ^{1}H NMR spectra.

Commonly ^{1}H NMR is used, as its high γ and essentially 100% natural abundance, and its presence in the vast majority of chemical and biological molecules ensures broad applicability. However, the narrow ^{1}H chemical shift dispersion (12 ppm) is a drawback, because ^{1}H NMR resonances in complex structures often overlap (Fig. 5). The acquisition of a ^{1}H NMR spectrum is fairly simple and takes less than a minute; however, this is not true for other nuclei that have low sensitivity because of their low natural abundance and

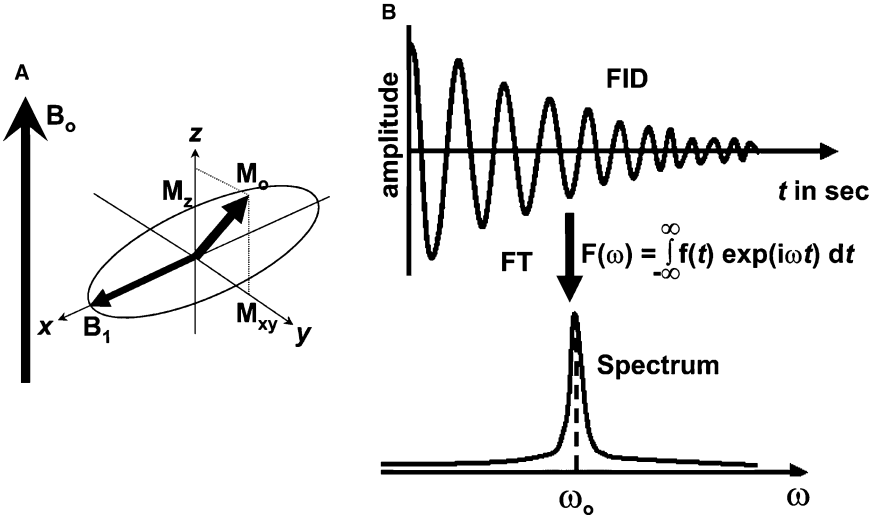

Fig. 3 (A) Interaction of M_0 with B_0 and B_1 fields; (B) time domain FID; and (C) frequency domain spectrum obtained from Fourier transformation of the FID.

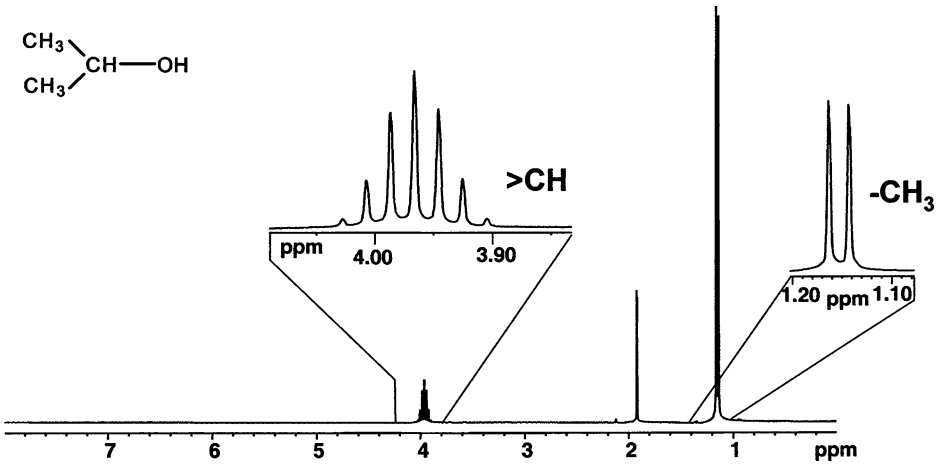

Fig. 4 ^{1}H NMR spectrum of 2-propanol showing splittings because of spin–spin coupling.

low γ. For example, the ^{13}C NMR signal is 100 times weaker than the ^{1}H NMR signal from the same number of atoms, as 99% of the carbons are ^{12}C with $I = 0$, and only 1% of the atoms are ^{13}C with $I = 1/2$. Furthermore, γ_C is only $1/4 \times \gamma_H$, resulting in an additional $(\gamma_H/\gamma_C)^{5/2}$ times, i.e., 32-fold, reduction in the ^{13}C NMR signal relative to that of ^{1}H (relative signal strengths for commonly observed isotopes are summarized in the last two columns of Table 1).

With the development of Fourier transform NMR, ^{13}C NMR spectroscopy has become a routine sensitive tool for characterizing organic and biological

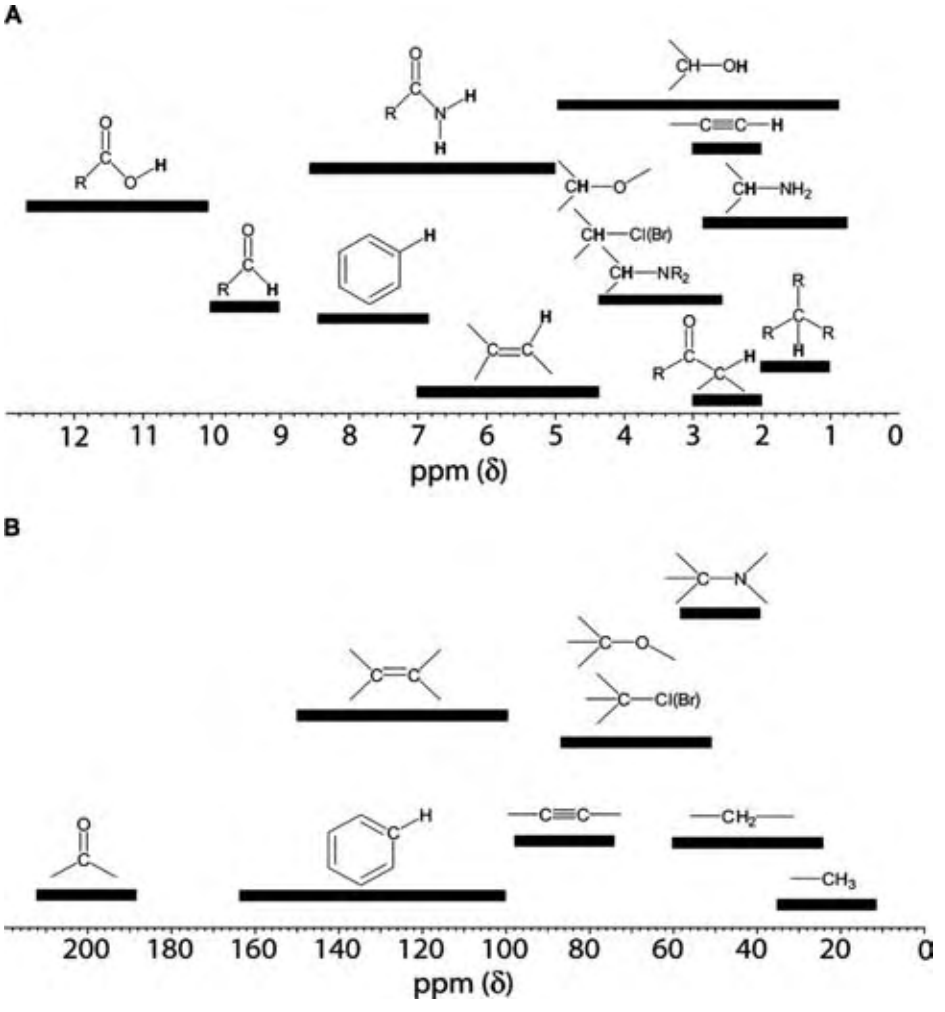

Fig. 5 Typical chemical shifts of (A) proton and (B) carbon resonances in organic compounds.

molecules. Advantages of ^{13}C NMR are its wide chemical shift range (250 ppm; Fig. 5), proton decoupling is used to remove J coupling so that each carbon produces a single resonance, the sensitivity of ^{13}C chemical shift to its chemical environment is such that carbons that differ by substituent four or five bonds away can be distinguished from each other.

Other commonly used nuclei are ^{15}N, ^{19}F, ^{29}Si, and ^{31}P. However, their use is limited in scope, as they are not always present. ^{19}F NMR is a very sensitive technique when fluorine is present, as ^{19}F has 100% natural abundance, $I = 1/2$ and γ_F is as large as γ_H providing 83% of the receptivity of ^{1}H NMR for the same number of atoms. ^{19}F NMR exhibits a large chemical shift range (several thousand ppm) and is highly sensitive to minute environmental changes.

The role of quantitative NMR in chemical processing is significant and has been studied in detail. The ratio of the areas under the NMR resonances is directly related to the relative number of atoms contributing to the resonances. This is a unique feature of NMR; in other forms of spectroscopy, absorption coefficients differ for different groups, and extensive calibrations are needed. Two factors complicate the efforts to perform quantitative analysis such as compositional analysis of mixtures NOE and different T_1s.

The NOE results in an enhancement of the ^{13}C signals when simultaneous ^{1}H decoupling is performed throughout the experiment. Under optimal conditions, signals are enhanced by threefold compared to the intensities obtained if the NOE is not present. Because the NOEs are not always full for all ^{13}C atoms, the signal intensity ratios might not accurately reflect the ratios of ^{13}C atoms. To eliminate this problem, spectra are obtained with a gated decoupling to suppress the NOE.[11] Also, for better quantitative results, it is beneficial to reduce the T_1s by introducing a paramagnetic relaxation reagent, such as Cr(acetylacetonate)$_3$. The loss of NOE can result in as much as a threefold loss in signal-to-noise ratio, requiring a ninefold increase in signal averaging time. However, when paramagnetic relaxation reagents are employed, it is common to observe a 10 to 100-fold reduction in the relaxation delay needed for quantitative analysis, more than compensating for the loss in sensitivity from the lack of NOE.

SOLUTION NMR

The majority of industrial applications of solution NMR spectroscopy are for quality control and routine analysis. Production line samples are usually taken and analyzed off-line. Many industrial NMR units are equipped with sample changers and probes capable of detecting more than one nucleus with automatic control of routine experiments, for high throughput operation. ^{1}H and ^{13}C NMR are common. For unambiguous resonance assignments, more complicated methods such as DEPT and 2D-NMR are performed. It is also possible to detect insensitive nuclei like ^{13}C through ^{1}H by 2D-correlation techniques like HMQC and HMBC. The development of pulsed field gradient (PFG) methods makes it possible to obtain artifact-free 2D and 3D spectra in a short time.

Common Industrial Applications

A common industrial application of NMR is the determination of functional groups in various natural products, synthetic chemicals, and drug molecules.[12] For example, the estimation of hydroxyl groups is performed by comparing ^{1}H NMR spectra with and without deuterium exchange of hydroxyl protons. This method is also useful in determining the contributions from configurational and conformational isomers as well as in the test of optical and enantiomeric purity, which has applications in pharmaceutical industries. Other functional groups such as aldehydes, ketones, and carboxylic acids can be easily identified by their unique ^{1}H and/or ^{13}C NMR spectra. Also, NMR is used in the analysis of vegetable oils and fats (which are predominantly triglycerides of C_{18} fatty acids) and in food processing industries. Another useful application of ^{1}H NMR is the determination of the degree of unsaturation in oils and fats, commonly known as iodine number.

The use of low-field NMR in quality control applications has increased because of the ease of operation and reliability of the data.[13] Most of the applications involve the measurement of T_2 and/or T_1 relaxation times, to yield quantitative information relating to the concentrations of individual components. The applications include the determination of viscosity and the measurement of moisture, fat, hydrogen, fluorine, and carbon contents.[14] One of the most common uses of this technique is the quantitative determination of the state of water in soils, foodstuffs, coals, and catalysts.[14]

Applications of NMR in process control, although not as popular as FT-IR and NIR, provide an alternative when the latter techniques fail. The advantages of low-field (10–60 MHz) low-resolution NMR in process control applications are its noninvasive nature and the lack of need for calibration procedures with feed or product, as it is tolerant to changes in process environment and feed quality. Process/quality control NMR applications are based on separation of the FID into separate responses from components with different T_2s (Fig. 6). Longer in-stream analysis times, high

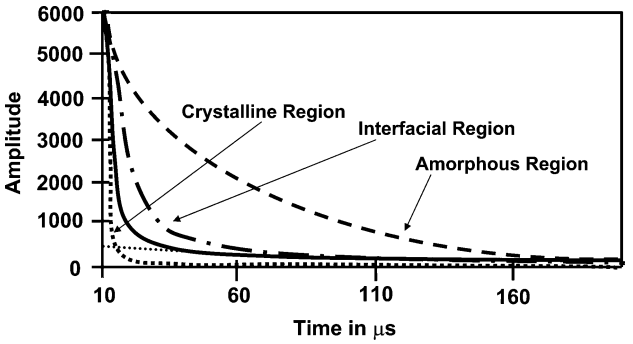

Fig. 6 A typical semicrystalline polypropylene FID (—) and its three distinct components from fast-decaying (crystalline ·····), medium-decaying (interfacial — . —), and slower-decaying (amorphous or atactic - - - - -) polymer domains.

accuracy, rapid measurement capabilities, and low instrument maintenance make process NMR useful for acid alkylation control, blending of petroleum fractions and crude oils, refinery feed optimization, base oil manufacturing, styrene–butadiene rubber, and ethylene–propylene copolymers.[14]

Although NMR is versatile in characterization of molecules and mixtures, often in industrial applications, it is utilized in combination with chromatographic techniques, such as LC-NMR in process control applications to improve efficiency.[15] Recent improvements in sensitivity, the design of flow cells, and rapid data acquisition make NMR a suitable detection system for HPLC.[15]

Polymer Processing

Solution NMR is widely used in polymer processing for the qualitative and quantitative analyses of tacticity, end-groups, degradation products, chain defects, and monomer sequence distribution.[16] A typical application is in the characterization of monomer sequence distribution by quantitative ^{13}C NMR spectroscopy.[17] For example, Fig. 7 shows a typical ^{13}C NMR spectrum of ethylene-co-1-butene.[18] From the relative peak areas, it is possible to determine the fractions of the two monomers, their reactivity ratios, the triad distribution, and the ''blockiness'' or ''randomness'' of the monomer distributions.[17] All of these structure factors play an important role in the polymer's physical and mechanical properties.

Nuclear magnetic resonance is also used to determine the tacticity of polypropylene and vinyl polymers.[19] For example, high-resolution ^{13}C NMR spectra show the variations in spectral patterns with varying tacticity of polypropylene (Fig. 8). Not only is it possible to distinguish between various stereo-regular polymers, but the higher resolution of ^{13}C NMR also makes it sensitive for measuring stereo-defects, regio-defects, and end-groups. The greatly increased spectral dispersion of solution state 2D- and 3D-NMR is increasingly being used to study complex polymer architectures.[20]

The use of NMR relaxation studies in the polymer solutions is well known for the study of polymer chain dynamics, polymer/polymer, polymer/solvent,

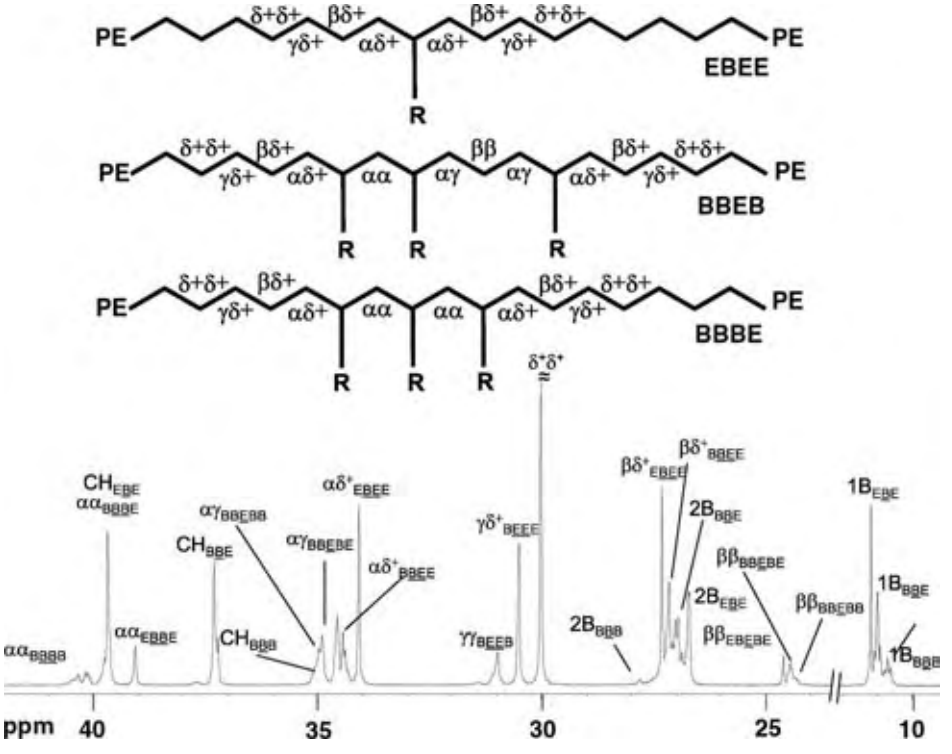

Fig. 7 Aliphatic region from the 188.6 MHz 1D ^{13}C NMR spectra of poly(ethylene-co-1-butene) containing 41% 1-butene. (From Ref.[18].)

polymer additive interactions, and phase transitions. T_1 and T_2 relaxation measurements of dilute solutions provide valuable information on energy barriers of intramolecular motional processes linked to bulk properties.[21]

Fuels and Lubricants

The use of NMR for the compositional analysis of crude oils and fractionated products is routine in industrial production. Common analyses include the determination of saturated and aromatic hydrocarbon content, average structural parameters such as the percentages of *n*-paraffins, *iso*-paraffins, cyclo-paraffins, mono-, di-, and polyaromatics. These data are used for the development of correlations between the compositions and their characteristics.[22,23] Spectral editing such as DEPT is routinely used for the unambiguous assignments of resonances in complex mixtures, and recent trends indicate the utility of 2D-correlation techniques for such purpose.[24] In addition, NMR is used to determine additive constituents in formulated oils and lubricants. For example, ^{31}P NMR is used to analyze the structure and decomposition pathways of additives like dialkyldiothiophosphates that are found in used crankcase and gear oils. Alcohols and oxygenates are added to gasoline as fuel extenders and to improve the octane rating. ^{1}H NMR of 60 MHz is used to monitor alcohols in fuels by quantifying the CH_3 singlet at 3.4 ppm, which is correlated to the methanol concentrations in gasoline. Similarly, the concentrations of oxygenates such as methyl *t*-butyl ether (MTBE) can be determined from the signal near 3 ppm (Fig. 9).[25]

Pharmaceutical Applications

Modern approaches in drug discovery rely on NMR-based screening techniques to investigate protein–ligand interactions. Parameters of NMR such as chemical shifts, relaxation, and diffusion are used to identify small ligand molecules and macromolecular targets.[26] The development of structure–activity relationships (SAR) using 2D-NMR of proteins has opened new avenues for the discovery and analysis of drugs.[27] This technique is based on the use of chemical shift changes to screen for low-affinity ligands, in combination with structural information to direct a

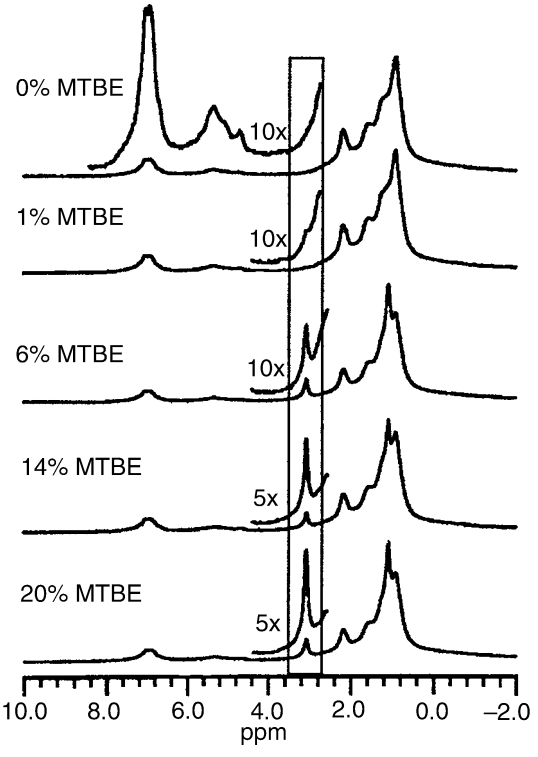

Fig. 9 ^{1}H NMR spectra at 42 MHz of various MTBE blends with regular and unleaded gasoline. The highlighted area shows signals from MTBE. (From Ref.[25].)

linked fragment approach for enhancing binding affinity. Another exciting area is high throughput screening for potential drug molecules or fragments using combinatorial techniques. The recent availability of high sensitivity cryogenic probes and flow methods makes it feasible for NMR to keep up with the requirements to screen more than 10,000 compounds per day. It is possible to prepare, characterize, and screen libraries of more than 200,000 compounds in less than a month.[26]

SOLID-STATE NMR

Solid-state NMR (SSNMR) is becoming an indispensable tool in the chemical and material processing industries because of its utility for studying structure characteristics such as internuclear distances, bond torsion angles, atomic orientations, spin diffusion, molecular dynamics, and exchange processes.[28] The most common SSNMR protocol is the use of magic-angle spinning (i.e., fast sample rotation about an axis oriented at 54.7° relative to the static magnetic field) to average chemical shift anisotropy, high power decoupling (to remove homonuclear and heteronuclear dipolar couplings), and crosspolarization (magnetization transfer from high γ nuclei, usually ^{1}H, to the observed low γ nuclei) to increase the sensitivity for detection of the low γ nuclei; the combined method is commonly referred to as CP/MAS NMR. For maximum enhancement by polarization transfer from nucleus I to nucleus S, the Hartmann–Hahn condition $\gamma_I B_{1I} = \gamma_S B_{1S}$ (where γ is magnetogyric ratio and B_1 is the rf field strength) must be satisfied. However, one of the limitations of the crosspolarization method is that it discriminates between protonated and nonprotonated nuclei, yielding nonquantitative information. For quantitative measurement, spectra obtained by CP method are compared with data from the time consuming Bloch Decay or single pulse excitation (SPE) NMR. To study the structure and dynamics of a variety of solids, SPE and CP/MAS NMR along with relaxation measurements such as T_1, T_2, and $T_{1\rho}$ are being used.

Although ^{1}H is the most commonly detected nucleus in solution NMR, this is not true in SSNMR. The strong homonuclear dipole–dipole interactions broaden the line widths of ^{1}H resonances, and fast magic-angle spinning (>40 kHz) is needed to produce spectra with the line narrowing needed to resolve signals of chemically distinct protons. Another method of line narrowing in solid-state ^{1}H NMR is the use of combined rotation and multipulse spectroscopy (CRAMPS) NMR, which is most often used for the analysis of solid substances in which MAS rate is not sufficient to narrow the lines of the proton resonances.

Polymer Processing

As it is difficult to find good solvents for many commercial polymers and there is a need to relate NMR properties directly to macroscopic properties such as crystallinity, adsorption, transport phenomena, blending, and determination of domain sizes, SSNMR is important in polymer processing.[29] The characterization of polymer morphology is important as the majority of the polymers are semicrystalline; thus SSNMR can be used for the analysis of both crystalline and amorphous phases, and exchange process between the two.[30] For example, ^{13}C CP/MAS NMR data of polypropylene can be correlated with its crystalline, interfacial/entangled, and amorphous components. It is also used for the analysis of crosslinked polymers that are generally not soluble. Another engineering-based application of SSNMR is ^{1}H and ^{13}C relaxation measurements of stimuli-responsive polymeric gels, which include superabsorbing polymers and hydrogels.[7]

Catalysis

Applications of SSNMR in catalysis include the study of zeolites and supported-metal catalysts. It has provided information on the structural changes of catalysts with changes in environment, and on interactions and reactions that occur on catalyst surfaces and in zeolite pores.[31] Most studies on zeolite structures are based on the application of SPE and CP/MAS NMR of ^{29}Si and ^{27}Al. The collection of NMR data with and without CP enhancement helps to assign the peaks in ^{29}Si NMR, as only peaks from ^{29}Si atoms having hydrogen neighbors are observed in the CP experiment, whereas the SPE experiment produces spectra from all ^{29}Si atoms (Fig. 10). ^{29}Si CP/MAS NMR was also used to study hydroxyl groups on catalyst surfaces and spillover phenomena. Multinuclear NMR can be used for the structural characterization of the coke species that deactivate catalysts. Multiple quantum NMR was used to study the distributions of adsorbed species within porous catalysts, and in situ NMR of adsorbed species is used to study mechanisms, acid site distribution, and porosity. Most of the studies focus on the state of sorbed reactants such as chloroform using ^{13}C NMR, or the state of catalyst architecture using ^{29}Si and ^{27}Al NMR.[31,32] In general, glass ampoules containing adsorbed catalyst are charged with reactants on a vacuum line, flame sealed, heated to high temperature for variable reaction times, and then quench cooled. This method has been used to identify the reactants, intermediates, and products at various stages of the methanol to gasoline (MTG) transformation (Fig. 11).[32]

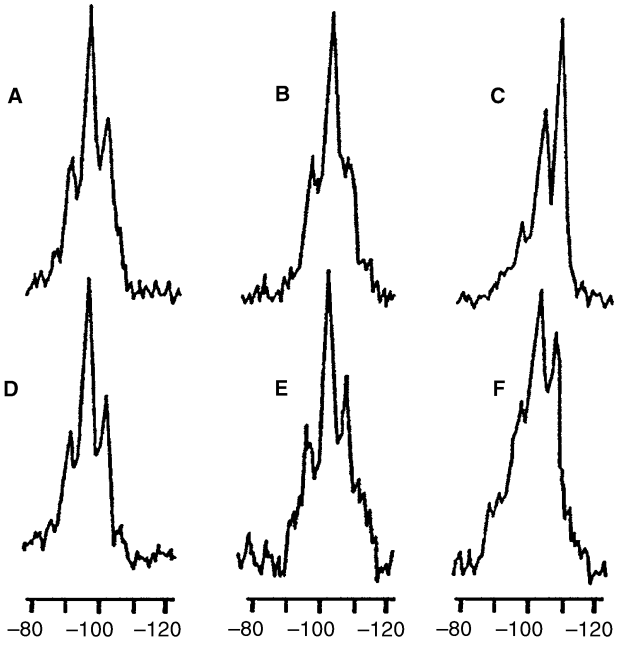

Fig. 10 ^{29}Si MAS NMR spectra of Y zeolites as synthesized (A and D) and dealuminated to varying degrees (B–F). Spectra were obtained without (A–C) and with (D–F) cross-polarization. (From Ref.[31].)

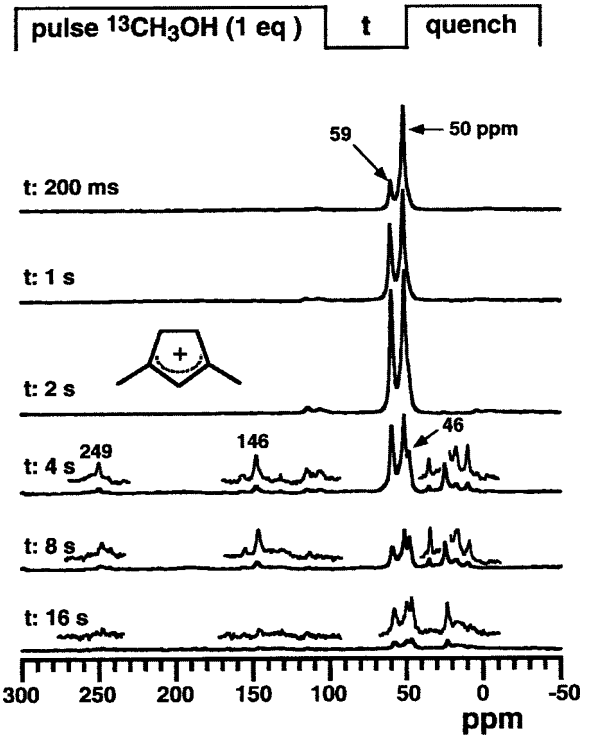

Fig. 11 ^{13}C MAS NMR spectra at 90.5 MHz from pulse-quench in situ studies of MTG chemistry on zeolite HZSM-5 at 643 K with He carrier gas flow and reaction times from 200 ms to 16 s are shown. ^{13}C signals of methanol (50 ppm), dimethyl ether (59 ppm), and cations (249, 146, and 46 ppm) are indicated. Spectra were measured at 298 K after a rapid thermal quench. (From Ref.[32].)

Pharmaceutical Applications

In the pharmaceutical industry, SSNMR is commonly used to study polymorphism, hydrogen bonding, crystal packing, and solid–solid interactions.[33] Shelf life or activity decay is often determined by the bioavailability of different polymorphs. Fig. 12 shows very different ^{13}C CP/MAS spectra from two polymorphs of an analgesic, flufenamic acid. It is also used for the study of inclusion complexes, drug–excipient interactions, or the effect of moisture on drug substances or formulations.

NMR IMAGING

Nuclear magnetic resonance imaging, commonly known as MRI, involves using magnetic field gradients to image nuclear spin density in one, two, and three dimensions with submillimeter resolution.[6] A noninvasive 3D volume image can be obtained by applying linear gradients that are varied in each of the *x*-, *y*-, and *z*-directions. The resultant spin–density image provides information regarding the concentration of given molecular species, relaxation characteristics of the sample, and local transport properties. The image construction is usually carried out by measuring the strength of ^{1}H NMR signal of mobile molecules (e.g., free H_2O in living organisms). Although proton imaging is most common, ^{19}F, hyperpolarized ^{129}Xe, ^{31}P,

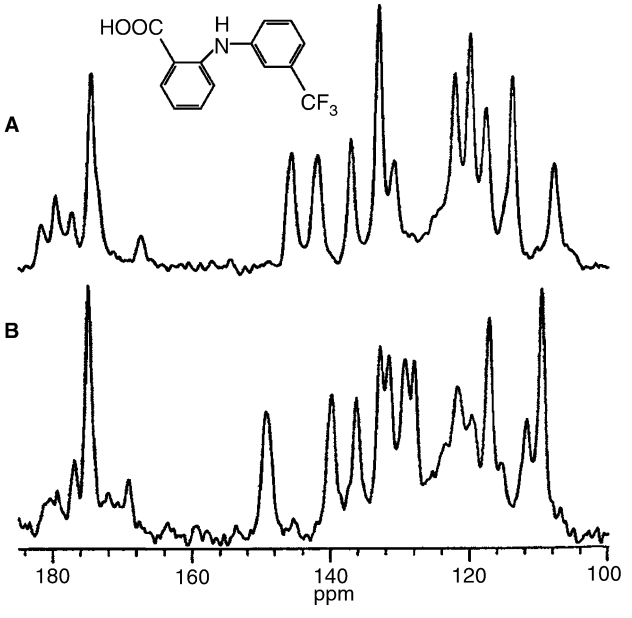

Fig. 12 ^{13}C CP/MAS NMR spectra of flufenamic acid polymorphs: A) Form III and B) Form I. (From Ref.[33].)

and other abundant nuclei can be used for constructing images of materials. These noninvasive imaging methods are used to study the nonequilibrium distribution of heat or strain, transport phenomena, and the progress of chemical reactions.[7]

Although clinical MRI has been ubiquitous for many years, only in recent years has the use of MRI grown in applications such as study of ceramic processing, catalysis, food processing, polymeric materials, and transport in reactors.[7,34] Normally, the size of objects studied is limited by the size of the magnet dimensions. One of the newer developments in this field is a mobile imaging instrument, the NMR MOUSE.[35] A mouse sized probe is moved along an object's surface, and spin density is measured in a stray field created by the mouse, making it possible to image large objects like tires.

One of the major focuses of the engineering research is the understanding of the spatial distribution of flow and diffusion. Nuclear magnetic resonance imaging has enormous untapped potential for noninvasively studying materials transport in reactions and in flowing systems. This method is used to study diffusion of fluids into the solid materials such as water migration into controlled drug release polymers, hydration of materials, and material porosity. It is also possible to investigate the pore and void structure of catalyst support pellets to evaluate the efficiency of liquid transport through these porous media. It has been used to study the influence of reactor design on catalytic processes and to study flow phenomena such as gas and liquid distributions during the trickle flow operation of fixed bed reactors.

Ceramic Processing

The nondestructive nature of MRI makes it ideal to study the microstructure at the various stages of ceramics processing. For example, T_2 contrast measurement is used to discriminate between crystalline, amorphous, and highly plasticized binder materials to measure binder distribution, damage during binder burnout, and slip-casting processing of ceramics. Unlike medical imaging, materials imaging is complicated by short T_2 relaxation times of binder materials, which are polymers such as poly(ethylene glycol), poly(vinyl alcohol), or crosslinked elastomers. These difficulties are overcome by using techniques such as homonuclear line narrowing, back-projection imaging, multiple quantum coherence, and magic-angle spinning.[36]

Polymer Processing

Nuclear magnetic resonance imaging is used extensively to characterize the structure and swelling properties of polymers.[37] It is ideal for studying material inhomogeneities such as filler clustering and air pockets, composite structures such as fiber reinforcements and cords in tires, the structure of vulcanized rubber, concentration and structural gradients as a function of crosslink density, swelling and diffusion characteristics, thermal and mechanical aging, and local stress and strain distributions. For example, Fig. 13a shows the MRI image of four layers of an elastomer differing only in their filler concentrations. The intensity of the image is readily quantified as shown by the scale on the side of the figure. The second layer from the right shows a defect that is approximately 0.2 mm in diameter. Fig. 13b shows another MRI image of a rigid polymer with a defect of a few tenths of a millimeter in diameter. Other novel applications include the study of polymerization kinetics[38] in which T_2 weighted images show the transition from ''liquid'' to ''solid'' during PMMA synthesis.

Transport in Reactors

The applications of NMR to study the transport processes within the reactors, filler cakes, and packed columns and for imaging of packing distribution and

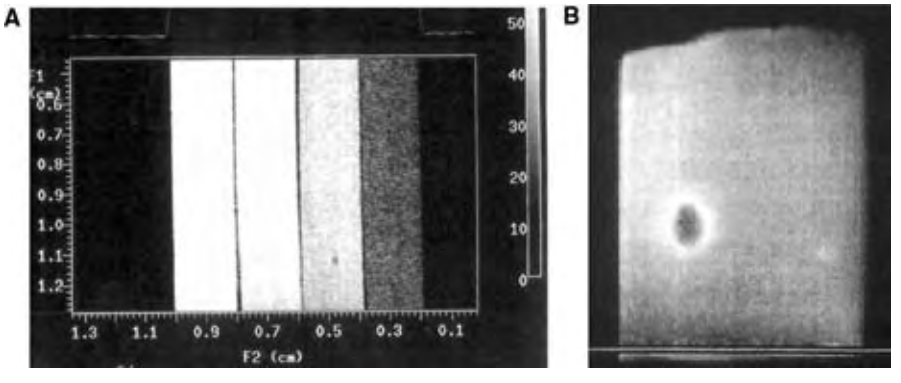

Fig. 13 (A) Cross section of MRI image (obtained at 9.4 T) of four layers of filled elastomer composite materials. Total data accumulation time was ca. 2 hr. (B) MRI image of defect in composite layer.

the fluid flow processes are of considerable interest in engineering research. Nuclear magnetic resonance imaging can be used to optimize the fabrication of preparative chromatographic columns, as relaxation measurement provides information on the mobility of the solvent in the stationary phase. ^{23}Na imaging was used to study real-time ion-exchange processes in a column.

CONCLUSIONS

Nuclear magnetic resonance spectroscopy has found application in all branches of science. Modern solution, solid-state, and imaging NMR techniques provide unique and detailed information on molecular structure, dynamics, morphology, and other interesting physical characteristics of various materials including polymers, pharmaceuticals, chemicals, and fossil fuels. Despite the expense, NMR is routinely used to monitor the characteristics of various commercial materials. When rapid, low-cost analyses of many samples are required, NMR techniques are often used in method development and as a primary standard for calibrating other low-cost spectroscopic instruments that might be used inline. With the availability of low-field, low-cost NMR instruments, the routine use of NMR is becoming popular in process/quality control applications. Expensive research grade instruments will continue to play an important role in designing production processes, in understanding the molecular basis for production problems so that they can be corrected, and in developing new process monitoring methodology.

NMR Spectroscopy of Polymers in Solution

Sangrama K. Sahoo
Peter L. Rinaldi
Department of Chemistry, The University of Akron, Akron, Ohio, U.S.A.

INTRODUCTION

In the past decades, nuclear magnetic resonance (NMR) spectroscopy has been used extensively to study various aspects of polymer chemistry and engineering. Fig. 1 shows the relationship among polymerization conditions, polymer structure, and the material's physical structure and end uses. Solution, solid state, and imaging NMR techniques contribute to understanding the physical and chemical aspects of the route from raw materials to final product.[1,2] Solution NMR provides information about all aspects of the polymerization reactions and the final structure of the synthesized polymer. This information can be correlated with the material's final properties and provide feedback to control the initial polymerization process so that the fraction of structures responsible for desirable properties can be controlled in a systematic way.

High-resolution ^{1}H and ^{13}C NMR, and recently, multidimensional methods have revealed the microstructures of complex polymers.[3] In particular, multidimensional (2D- and 3D-) NMR have proven to be useful techniques to identify small amounts of irregular structures in synthetic polymers. In this entry, specific topics to be covered include the use of solution NMR methods to study polymer stereochemistry/tacticity, monomer composition and sequence distribution, short-chain branches, and chain-end structure, as these parameters influence the material's mechanical, thermal, optical, and electrical properties.

NMR METHODOLOGY

One of the major differences between NMR characterization of synthetic polymers and other organic structures is that polymers contain the same repeat units, differing only by their sequence, stereochemistry, branching, blocking, or termination by end-groups. As a consequence, polymer NMR spectra contain huge signals from the main chain repeat units in the presence of much smaller signals, often representing the most interesting polymer structural features. Many synthetic polymers are soluble in organic solvents and can be made in large quantities; however, detection of signals from small numbers of these unique structures presents a challenge as the dynamic range of the NMR instrument places a limit on the detection range. However, modern pulsed Fourier transform NMR with high-field magnets, advanced electronics, fast computers, advanced experimental methodology, and new data processing methods has provided researchers with the capability of detecting minor structural components in polymers below 1 unit per 100,000 atoms.[3] Nuclear magnetic resonance has the advantage over other analytical techniques in that quantitation of structural components can be accomplished without using external calibrations. Reviews of polymer NMR characterization techniques are discussed in several classical monographs.[4–6]

Observable NMR spectral parameters such as chemical shift, spin–spin coupling, and peak intensities in simple 1D spectra allow one to obtain polymer composition, tacticity, sequence distribution, and mechanism of polymerization. However, the poor mobility of polymers often leads to high viscosity solutions and rapid T_2 relaxation, resulting in the poor spectral resolution. The viscosity can be decreased by dilution and high measurement temperature. Fortunately, many polymers possess segmental mobility, which facilitates the observation of high-resolution spectra with the line widths in the range of 1–10 Hz.

Most polymer characterization is accomplished with ^{1}H and ^{13}C NMR although ^{15}N, ^{19}F, ^{29}Si, and ^{31}P NMR are also routinely used. ^{1}H NMR is most commonly used because it is present in most chemical structures, has 100% natural abundance and a high gyromagnetic ratio, making it the most sensitive of all the NMR observable nuclei to detect. Moreover, because of its fast relaxation and the ability to extract information from spin–spin coupling constants, ^{1}H NMR is one of the most useful techniques for determining chemical structure. However, because of its small chemical shift range (only 10 ppm) and the complexity of each proton resonance, severe peak overlap occurs for ^{1}H atoms situated in similar chemical environments.

On the other hand, the ^{13}C nucleus has low natural abundance of only 1.1% and a gyromagnetic ratio one-fourth that of ^{1}H, making ^{13}C detection almost 6000 times more difficult than ^{1}H detection. The advantages

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120024576

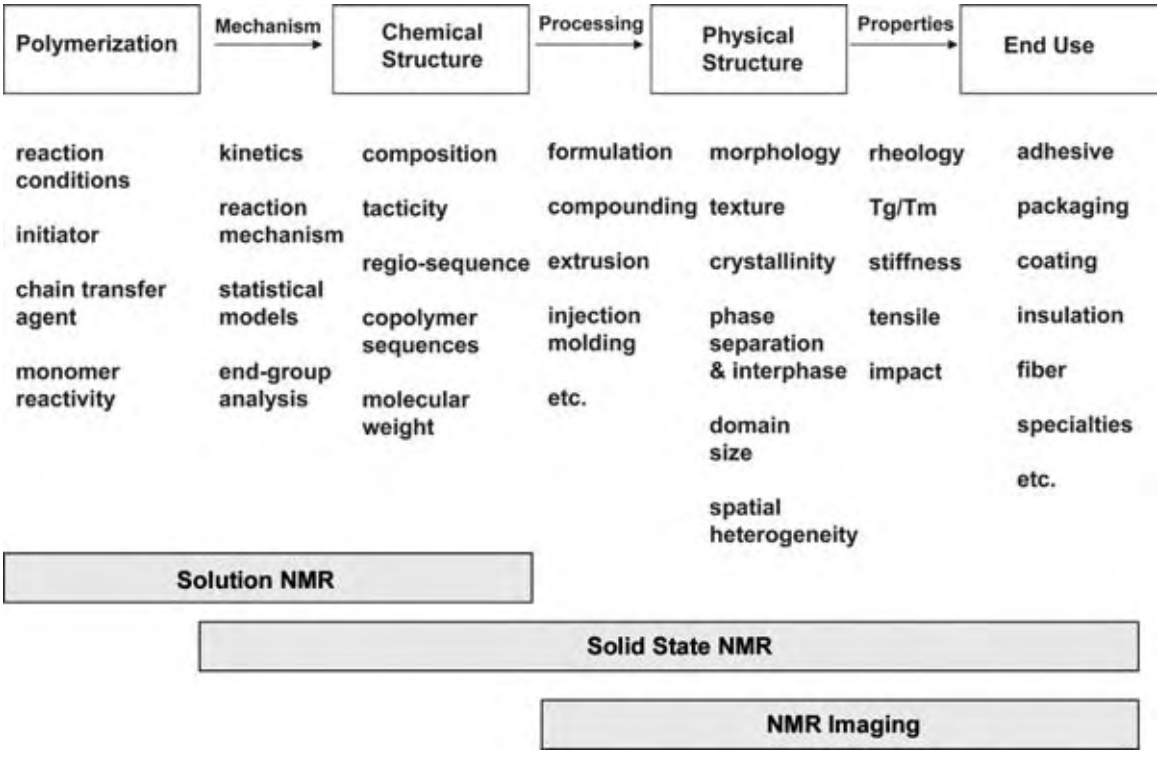

Fig. 1 Summary of polymer NMR studies. (From Ref.[1].) *(View this art in color at www.dekker.com.)*

of ^{13}C NMR are its large chemical shift range of 250 ppm, the sensitivity of its chemical shift to the small changes in its chemical environment, and that ^{13}C signals appear as single sharp lines. ^{13}C NMR is also insensitive to long-range effects, such as solvent effects and diamagnetic anisotropy of neighboring groups. Modern, high-field NMR instruments make ^{13}C NMR routine, despite its insensitivity.

The most fundamental step in NMR studies of polymer microstructures is the assignment of resonances to structural features of the polymer. This is accomplished by a variety of methods, including the use of low molecular weight model compounds, estimation of chemical shift by using empirical relationship, synthesis of polymers having known structures, isotopic enrichment, spectral simulation based on statistical models, NMR spectral editing, and multidimensional NMR.[4] The following section presents a brief overview of these methods of resonance assignments with some specific examples pertaining to ethylene-based polymers, as these are one of the most important groups of polymers that have been extensively characterized by NMR.

Model Compound Analysis

One of the first methods of analyzing polymer microstructure was to systematically study model compounds and to compare their spectra with those of the polymer to provide resonance assignments. The major drawbacks of this characterization method are the difficulty in obtaining suitable model compounds and the fact that the methodology is time consuming, and that prediction of chemical shifts can be ambiguous in the spectra of complex structures where many peaks fall in a narrow region.

When the polymerization mechanism is known, peak intensities in the spectra of polymers with different monomer compositions can be compared with calculated intensities based on various polymerization models [e.g., first order Bernoullian (B) or first order Markovian model]. For example, if polymerization mechanism of a vinyl monomer fits a Bernoullian model, then the fractions of triads will be given by:

$$P_{mm} = P_m^2 = (m)^2 \quad (1)$$

$$P_{rm/mr} = 2P_m(1 - P_m) = 2(r)(m) \quad (2)$$

$$P_{rr} = P_r^2 = (1 - P_m)^2 = (r)^2 \quad (3)$$

where P_m is the probability that a monomer will add in a meso (m) fashion to the end of the growing chain and P_{xx} is the final fractional probability of forming xx diad units in the polymer chain. Even when the statistical model for polymerization is not known, most resolvable

Table 1 A_l and corrective term S_l used in chemical shift calculation

		4° (2°)	−8.35

(From Ref.[7].)

resonances can be assigned based on qualitative comparisons of the signal intensity variations with varying polymer compositions.

The estimation of chemical shifts by examining the spectra of model compounds is not always feasible, and the prediction models fail to distinguish between two or more stereosequences as they cannot always be distinguished on the basis of intensity alone. To overcome these limitations, large numbers of organic compounds have been analyzed by NMR and their chemical shifts have been used to determine a set of empirical correlations that are used to determine the structure based on the polymer's NMR spectrum. The carbon chemical shifts of hydrocarbon-based polymers such as polyethylenes can be predicted by empirical additivity rules such as:

$$\delta_C = B + \sum_l A_l n_l + \sum_l S_l \qquad (4)$$

where δ_C is the calculated chemical shift, B the chemical shift of methane (−2.3 ppm), n_l the number of carbons at position l bonds away from the carbon of interest, A_l the additive shift because of carbon l, and S_l a term used to account for branching; the values of A_l and S_l are given in Table 1.[7] These empirical correlations are very useful for main chain resonance assignment and in many cases are valid for assignments of resonance of end-groups, branches, crosslinks, and regioisomers, which show distinctly different chemical shifts and *γ-gauche* effects. The *γ-gauche* effect along with the rotational isomeric state (RIS) model[8] has also helped in characterizing polyolefin tacticity.[9]

Isotopic Enrichment

Selective isotopic labeling overcomes ^{13}C NMRs insensitivity and permits reliable peak intensity measurements.[10] The enriched sample allows NMR to be performed on dilute solutions, reducing sample viscosity, with concomitant line narrowing. Selective spectral windows can be used to record the NMR spectrum without worrying about the folding of weak signals from unlabeled sites; hence, better resolutions can be achieved especially in 2D-NMR experiments. Selective labeling also facilitates the detection of weak resonances from chain-end structures, which give information on the polymerization initiation and termination mechanisms. The sensitivity enhancement achieved ameliorates the dynamic range limitations of NMR.

Statistical Modeling

Statistical models for the analysis of NMR data are used in two complementary approaches (Fig. 2): an analytical (model fitting) approach and a synthetic (computer simulation) approach.[11] In the analytical approach, assigned NMR resonance intensities are fit to expected intensities based on statistical models. In the synthetic approach, spectral intensities are first calculated using reaction probabilities predicted by theoretical models; these theoretical intensities are matched with those observed in the NMR spectrum. The calculation is based on theoretical probability expressions or Monte Carlo simulation. In an integrated approach, both methods are used for more complex systems.[12]

Simple propagation models discussed earlier fail to provide good fits when there is compositional heterogeneity in the polymer structure because of different comonomer reactivity ratios or deviations from the statistical combinations of comonomer placements on polymer chains. To overcome these drawbacks,

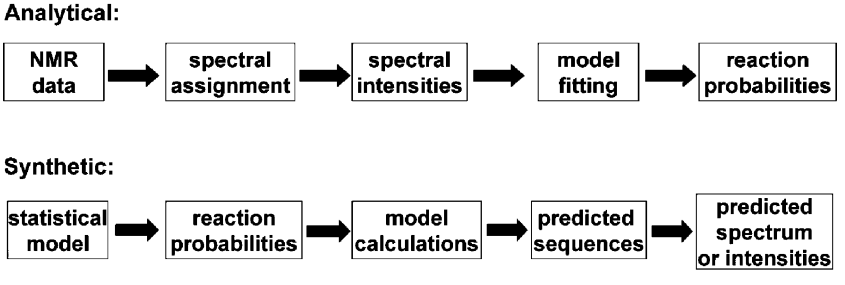

Fig. 2 Statistical models to analyze NMR data. (From Ref.[11].)

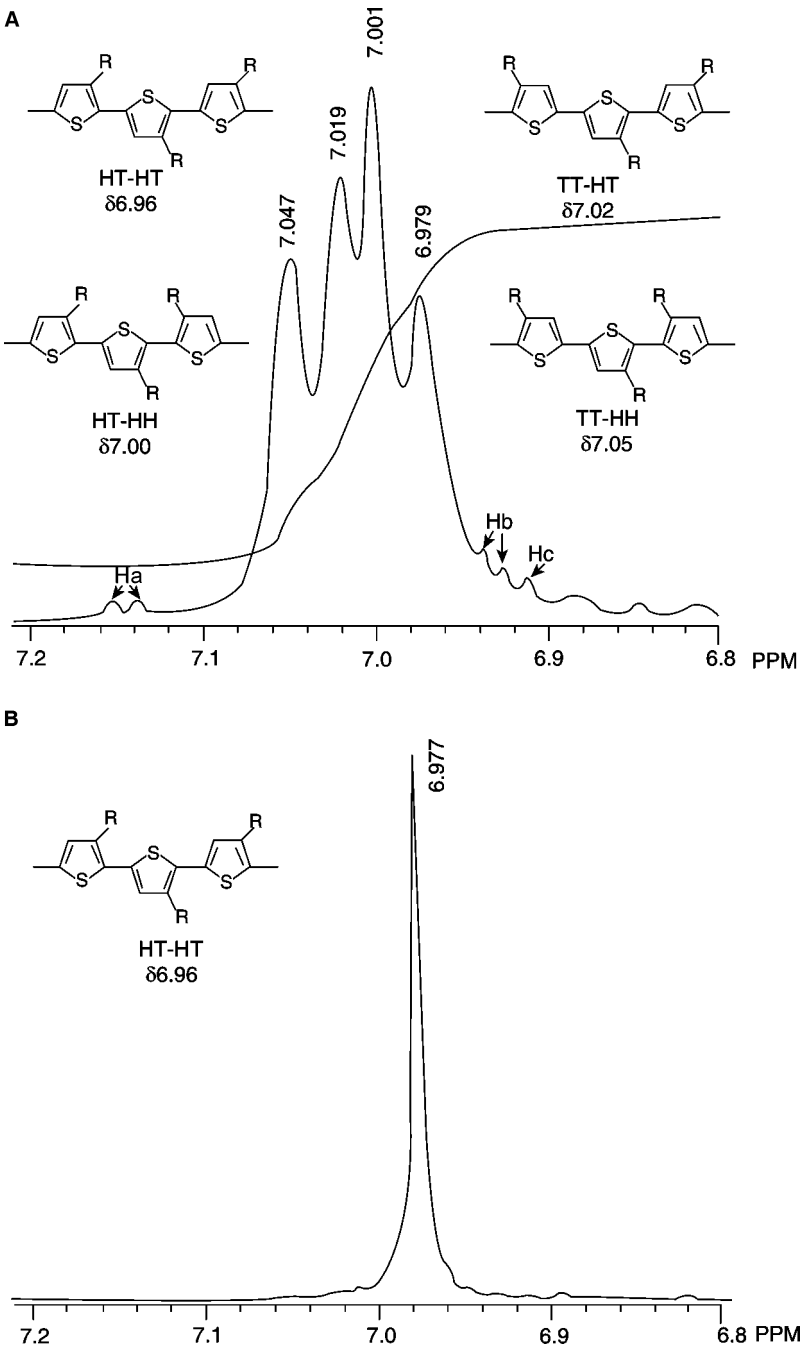

Fig. 3 Proton NMR spectra of (A) regioirregular and (B) regioregular poly(3-hexyl thiophene). (From Ref.[23].)

various models were proposed to specifically include the effects of compositional heterogeneity.[6] Models that are suitable for statistical, conversion, and process heterogeneities can be generalized as the perturbed Markovian model, perturbed enantiomorphic-site (E) model, perturbed model with exponentially modified Gaussian, and perturbed model applicable to any arbitrary chemical composition distribution.[12] For multicomponent heterogeneity, the bicatalytic-site model (involving a B component and an E component) is routinely used.

Multidimensional NMR

Recently, multidimensional NMR has become a standard technique for the assignment of polymer resonances and for characterization of polymer microstructure. Two-dimensional and three-dimensional NMR have been useful for identification of resonances from trace structures such as block junctions, chain-ends, or chain branches that are usually obscured in 1D-NMR spectra because of overlap with polymer backbone resonances. Complex spectral features are simplified

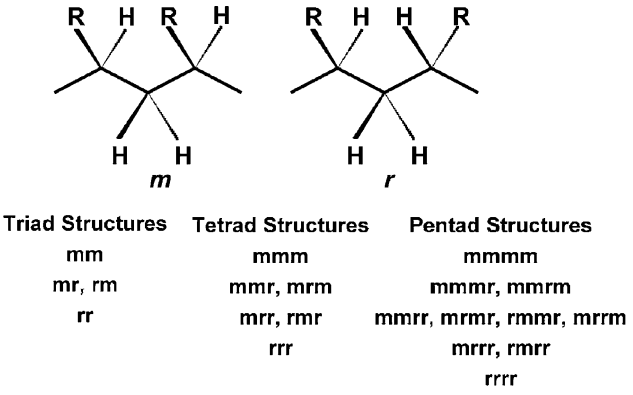

Fig. 4 Stereochemical arrangement of groups in a vinyl polymer.

by dispersion of the overlapping 1D-NMR resonances into additional frequency dimensions, and the correlations observed in multidimensional spectra provide atomic connectivity information, helping in identification of structures in complex polymers. There are many types of 2D-NMR experiments; however, the most commonly used methodologies for the polymer analysis depend upon combinations of homonuclear correlation experiments such as ^{1}H–^{1}H COSY and NOESY;[13] or heteronuclear ^{13}C–^{1}H HETCOR and COLOC, ^{1}H–^{13}C HMQC, HSQC, and HMBC;[14] or ^{13}C–^{13}C INADEQUATE experiments.[15]

The methodologies based on ^{1}H–^{1}H COSY and NOESY experiments are the most sensitive, as they rely on detection of high-sensitivity, abundant ^{1}H nuclei. COSY provides correlations among ^{1}H atoms that are *J*-coupled, while NOESY provides those among protons based on their separation in space. The drawback of using these homonuclear 2D methods is their complexity, as two coupled protons can produce many peaks in the 2D spectrum.

Two classes of heteronuclear correlation experiments are used to provide information about one-bond and two/three-bond carbon–hydrogen attachments. These experiments are 100-fold less sensitive, as they require detection of signals from 1% of the molecules containing ^{13}C. The earlier experiments such as ^{13}C–^{1}H HETCOR and COLOC involve ^{13}C detection; these have been superseded by more sensitive ^{1}H-detected HMQC, HSQC, and HMBC experiments, which provide ca. 30-fold sensitivity improvement over ^{13}C detection. Heteronuclear correlation experiments provide simpler spectra (a single peak is observed for each C–H attachment) and they take advantage of the much greater ^{13}C spectral dispersion.

Homonuclear ^{13}C–^{13}C INADEQUATE experiments are the most difficult and least frequently used. They require detection of ^{13}C–^{13}C fragments that are present in only $1/10^{4}$ molecules. When sufficient sample and instrument time is available, they provide unambiguous identification of a molecule's entire carbon skeleton and utilize the enormous ^{13}C chemical shift dispersion in both dimensions of the 2D spectrum.

Triple resonance 3D-NMR has been used to study polymers containing three NMR active nuclei,[16] and parallel methods for studying hydrocarbon-based polymers are now being used.[17] ^{1}H–^{13}C–X (X = ^{19}F, ^{29}Si, and ^{31}P) NMR correlation experiments help to simplify and unambiguously assign both main chain and chain-end resonances in a variety of fluoropolymers, polyorganosilanes, and phosphorus-containing polystyrenes.

The availability of pulsed field gradient (PFG)[18] techniques has had the most significant impact in terms of making it possible to perform 2D- and 3D-NMR experiments on polymer samples. These methods have taken the place of traditional radiofrequency phase cycling methods for coherence selection. By optimizing the use of the spectrometer's dynamic range, PFG techniques not only save time but also drastically reduce artifact noise.

Often it is impossible to resolve the signals from different molecular species in complex polymer mixtures by simple 1D- and 2D-NMR. However, development of diffusion-ordered spectroscopy (DOSY),[19] which employs PFGs, provides another method of separating the resonances of different polymer species. In DOSY experiments, the normal 1D spectrum is obtained in one dimension of the 2D spectrum and these spectra are dispersed in a second dimension based on the structure's diffusion coefficient. It is possible to resolve separate spectra of small monomer and large polymer molecules;

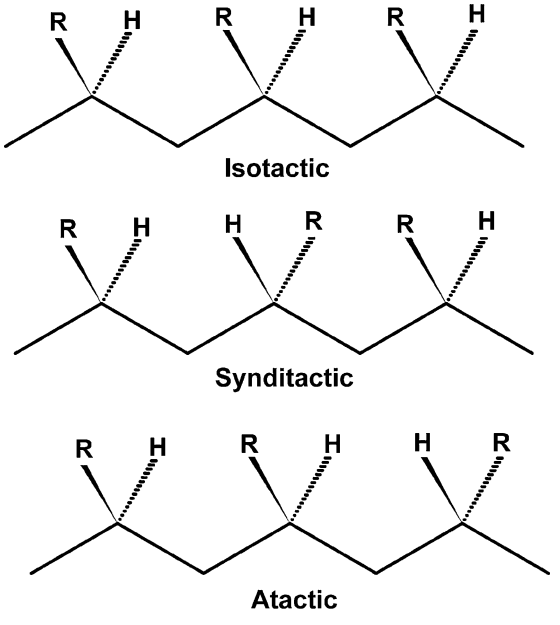

Fig. 5 Regular stereochemical arrangements found in vinyl polymers.

to produce a spectrum with dispersion based on molecular weight distribution of polymer molecules; and to distinguish between rapidly moving chain-ends and main-chain groups in the same polymer molecule.

Hyphenated NMR Techniques

Recent trends indicate an increased use of hyphenated NMR techniques, especially those involving NMR in combination with chromatographic methods such as HPLC, GPC, or SEC.[20] Online SEC- and GPC-NMR have found useful applications in the direct determination of molecular weight and molecular weight distribution.[21,22]

APPLICATIONS

Structural Isomerism

Three kinds of structural isomerism are observed in polymers: regioisomerism, stereoisomerism, and geometrical isomerism, depending on the polymerization mechanism. For example, with modern catalysts, structures contained in polyolefins can be controlled to determine stereoregularity, monomer sequence distribution, and branching. The relative amounts of these structures are directly related to the polymer's preparation conditions and end properties. Nuclear magnetic resonance provides the key link between the polymer's production/processing conditions and its characteristics.

Regioisomerism arises from head-to-tail (H-T), head-to-head (H-H) vs. tail-to-tail (T-T) addition of asymmetric monomer units. Regiodefects produce large changes in chemical shifts compared with the shifts of atoms in regioregular parts of the molecule. For example, in poly(2-hexylthiophene-2,5-diyl) distinct resonances from regioregular (HT-HT) and regioirregular (HT-HT, HT-HH, TT-HT, and HH-TT) polymers are observed in the aromatic region of the ^{1}H NMR spectrum shown in Fig. 3.[23] Moreover, 2D INADEQUATE NMR has been used to characterize regioregular and regioirregular polypropylenes[15] and to identify the resonances from H-H and/or T-T units. Once the resonances from these defect structures are reliably identified, their relative intensities can be used to determine the relative abundances of these structures.

Nuclear magnetic resonance has been extensively used to investigate stereoisomerism in polymers such as polypropylene, polyacrylates, vinyl polymers,

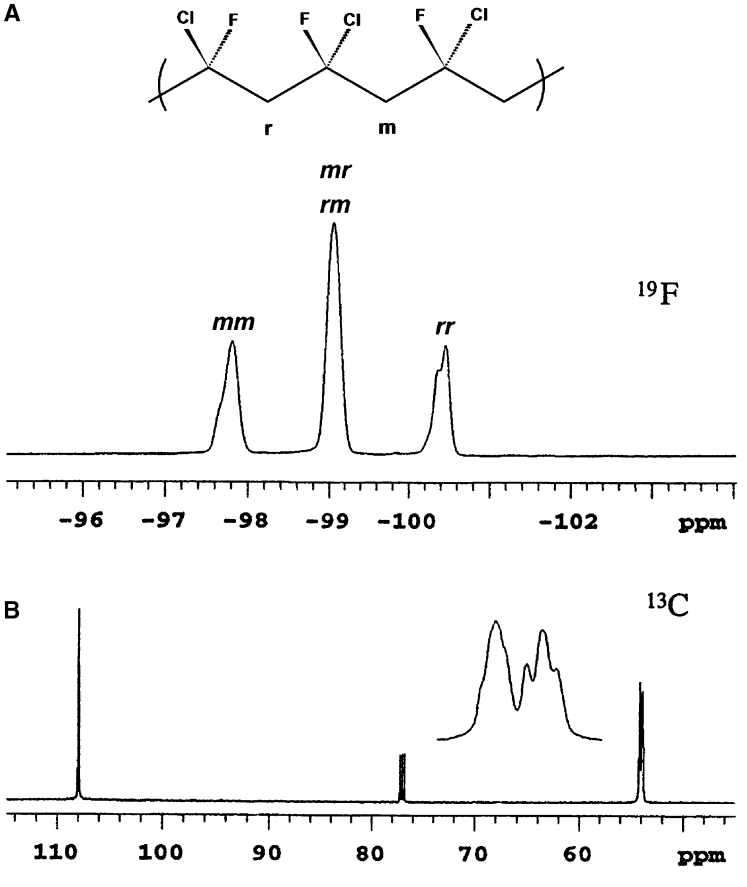

Fig. 6 NMR spectra of poly(1-chloro-1-fluoroethylene): (A) ^{19}F spectrum, (B) ^{13}C spectrum obtained with ^{1}H and ^{19}F decoupling. (From Ref.[24].)

ethylene/α-olefin copolymers, and a variety of other copolymers. Monosubstituted olefins when polymerized introduce stereogenic centers along the polymer's backbone. As most polymers are prepared in the racemic form, absolute stereochemistry is unimportant. However, the relative configurations of sites in neighboring monomer units are important in determining and understanding polymer structure–property relationships. The two possible relative configurations of stereogenic centers in consecutive monomer repeat units (diads) are meso (*m*) and racemic (*r*) (Fig. 4). If the polymer backbone is drawn in an all trans-planar conformation, as illustrated in top portion of Fig. 4, the *m* diad has R-substituents in adjoining monomer units on the same side, and the *r* structure has the R groups on opposite sides. The configurations of longer monomer stereosequences are defined by the relative configurations of their component diads.

A monosubstituted vinyl monomer yields polymers having three regioregular arrangements of configuration (Fig. 5), described by triad stereosequences. The isotactic structure has all R groups on the same side of the backbone (*mm*) the syndiotactic structure has R groups on alternate sides of the polymer's backbone (*rr*) and the heterotactic or atactic structure has R groups randomly oriented on either side of the polymer's backbone.

In the NMR spectra of polymers of monosubstituted ethylenes, resonance patterns from the atoms at branch sites and substituents bound to it are determined by the configuration at the α-carbon relative to those of the stereogenic centers on the adjacent monomer units.[5] The observed patterns will be those arising from the four possible triad sequences: *mm*, *mr*, *rm*, and *rr*. If the polymerization is random, four stereosequences are produced in equal amounts, *mr* and *rm* triad sequences are usually indistinguishable, and three resonances in a ratio of 1 : 2 : 1 are observed for *mm*, *mr*/*rm*, and *rr* triad stereosequences. The ^{19}F NMR spectrum of poly(1-chloro-1-fluoroethylene) (Fig. 6A) serves as an excellent illustration.[24] When the substituents have a large influence on shielding, or when the spectra are obtained at very high magnetic field, the chemical shift of a nucleus can be sensitive to the stereochemistry more than one monomer away. In these cases, the resonance patterns observed will be for higher *n*-ad (where n = odd integer) stereosequences. The unresolved fine structure in Fig. 6A arises from these remote stereosequence effects. When observing the CH_2 resonances of methylenes between stereogenic centers, chemical shifts are influenced by their relative configurations, resulting in two resonances from only two possible diad sequences, *m* and *r*. This pattern is clear in the ^{13}C NMR spectrum of poly (1-chloro-1-fluoroethylene) obtained with both ^{1}H and ^{19}F decoupling (Fig. 6B). Two groups of methylene ^{13}C resonances are observed near 54 ppm; the incompletely resolved splitting at 54 ppm arises because the

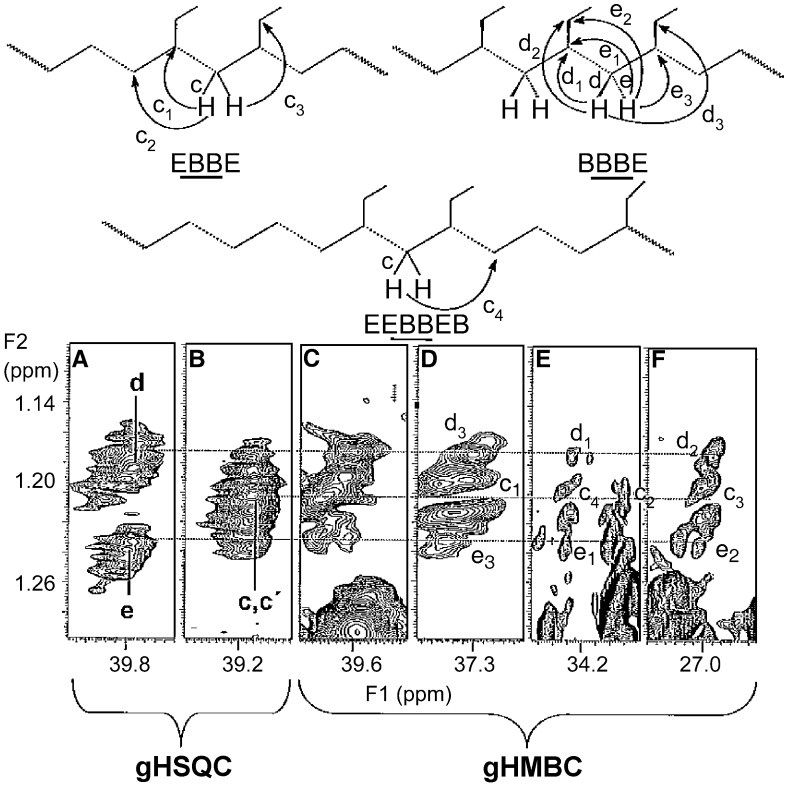

Fig. 7 Expansions from the gHSQC and gHMBC spectra of poly(ethylene-co-1-butene) in the αα proton chemical shift region: (A, B) gHSQC spectrum showing only the carbon chemical shift regions containing crosspeaks, (C–F) gHMBC spectrum showing only the carbon chemical shift regions containing crosspeaks. (From Ref.[14].)

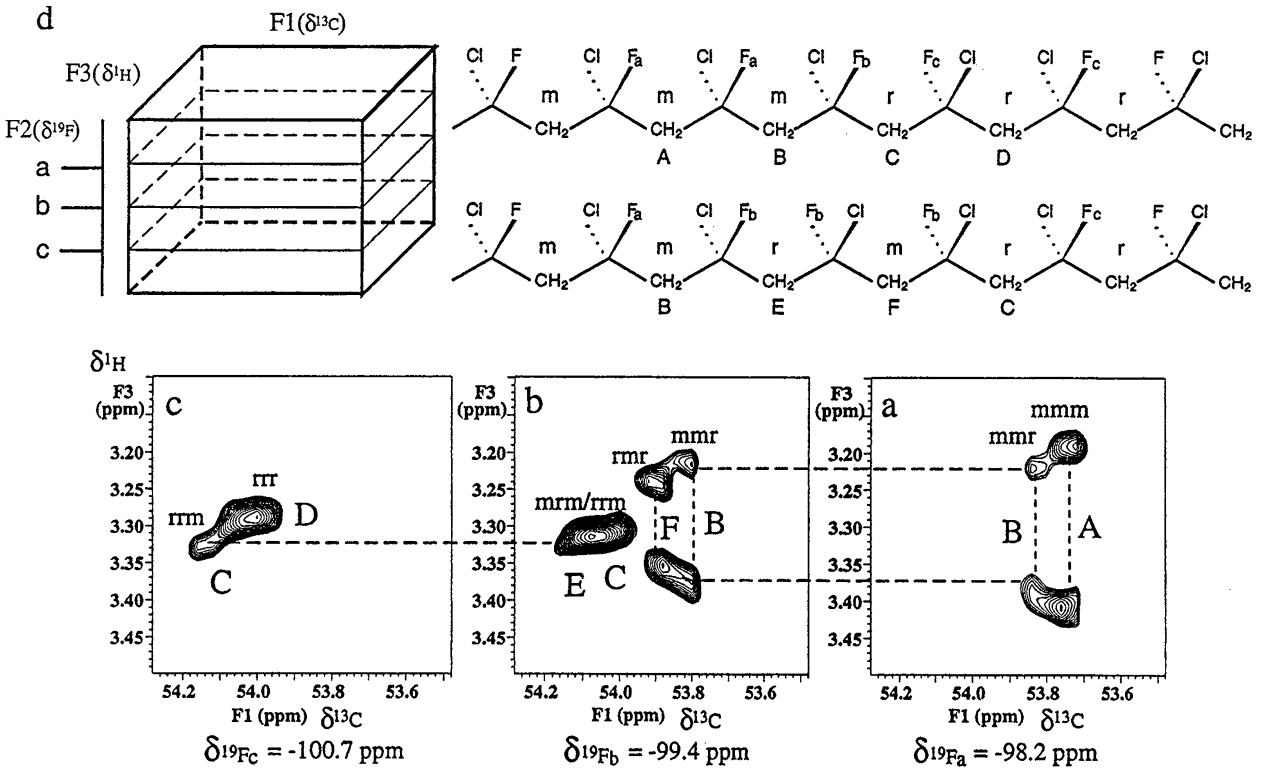

Fig. 8. 3D-HCF NMR spectrum of PCFE with $f1f3$ slices at different ^{19}F frequencies: (a) $f1f3$ slice at $\delta^{19}F = -98.2$ ppm; (b) $f1f3$ slice at $\delta^{19}F = -99.4$ ppm; (c) $f1f3$ slice at $\delta^{19}F = -100.7$ ppm; (d) schematic illustration of the 3D spectrum showing the relative positions of the slices. (From Ref.[24].)

methylene chemical shifts are sensitive to structure differences two monomer units away. Generally, the resonance patterns of symmetric groups between stereogenic centers are determined by the relative distributions of diad or higher n-ad (where n = even integer) stereosequences.

Although the patterns in Fig. 6 indicate the influence of remote stereosequence effects on the spectrum,

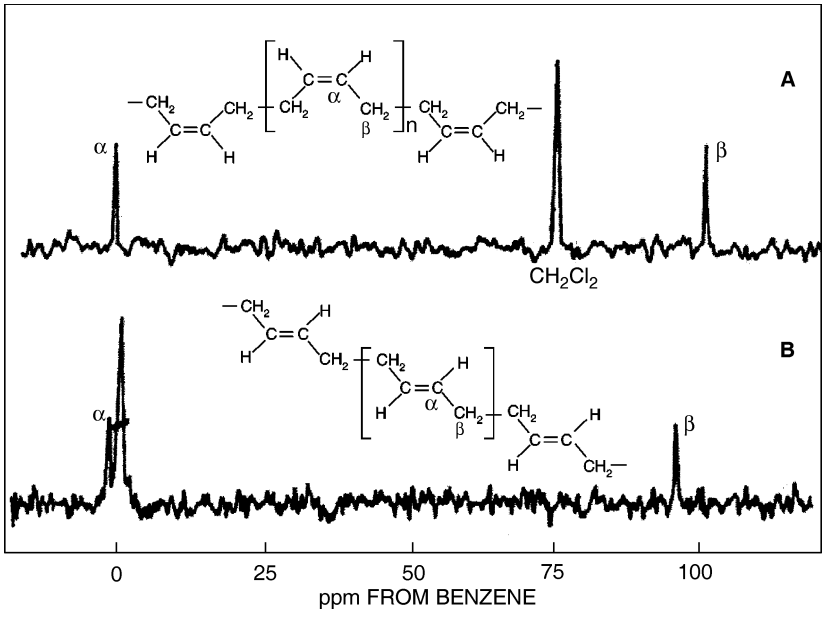

Fig. 9 ^{13}C NMR spectra of 15.08 MHz of (A) *cis*-1,4-polybutadiene and (B) *trans*-1,4-polybutadiene. (From Ref.[25].)

it is difficult to resolve resonances from higher *n*-ad sequences. By dispersing the resonances into two frequency dimensions using multidimensional NMR, it is routinely possible to resolve and assign resonances from stereosequence effects in polymers. One such example is seen in the HSQC and HMBC NMR spectra of poly(ethylene-co-1-butene), which shows the presence of *m* and *r* diads in sequences with two butene units (Fig. 7).[14] Additional detail can be resolved with the addition of more frequency dimensions. For example, from the $^{1}H/^{13}C/^{19}F$-triple resonance 3D-NMR spectrum of poly(1-chloro-1-fluoroethylene), six methylene and ten ^{19}F resonances are resolved from the possible tetrad and pentad stereo sequences, respectively (Fig. 8).[24]

Lastly, NMR is useful in identifying geometrical isomers when *cis*- and *trans*-double bonds are formed from polymerization of dienes such as butadiene. ^{1}H and ^{13}C 1D-NMR is commonly used to distinguish between these isomeric forms, as they have distinct chemical shift patterns as shown by the spectra of *cis*- and *trans*-polybutadiene in Fig. 9.[25]

Monomer Sequence Distribution

The examination of monomer sequence distributions by NMR is one of the most extensively used applications in materials science. When two (or more) dissimilar monomers A and B are copolymerized, a polymer is obtained with varying placements of A and B units along the backbone as shown in Fig. 10. It is important to know the relative distribution of monomer sequences, as these have an influence on the polymer's properties, and information about the distributions is valuable for studies of copolymerization mechanism. Initially, NMR was the only technique available to determine monomer sequences.

The monomer sequence is governed by the relative preference of monomer A to add to a growing polymer chain-end containing the same monomer P-A (where P is the rest of the polymer chain) or the comonomer B (in P-B) as illustrated in Fig. 11. This preference is described by reactivity ratios r_1 and r_2, the ratios of the rate constants for the addition of similar and dissimilar monomer units at the growing chain-end.

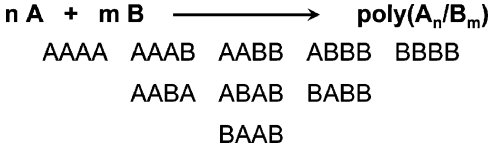

Fig. 10 Reaction of monomers A and B to form a copolymer, and the 10 possible tetrad monomer sequences.

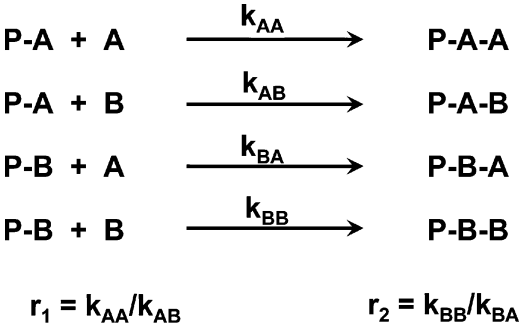

Fig. 11 Reactivity ratios (r_1 and r_2) for addition of monomer to a polymer chain-end containing similar or dissimilar monomer units.

The reactivity ratios can be calculated from the resonance intensities of different monomer sequences in the spectra of polymers obtained from termination of the polymerization at low monomer conversion (<10–20% to avoid complications from changes in monomer concentrations during the reaction).

Generally, the NMR analysis begins with comparison of the spectra of the corresponding homopolymers and a series of copolymers prepared by systematically varying the monomer compositions. Fig. 12C shows the C–F resonances from the ^{13}C NMR spectra

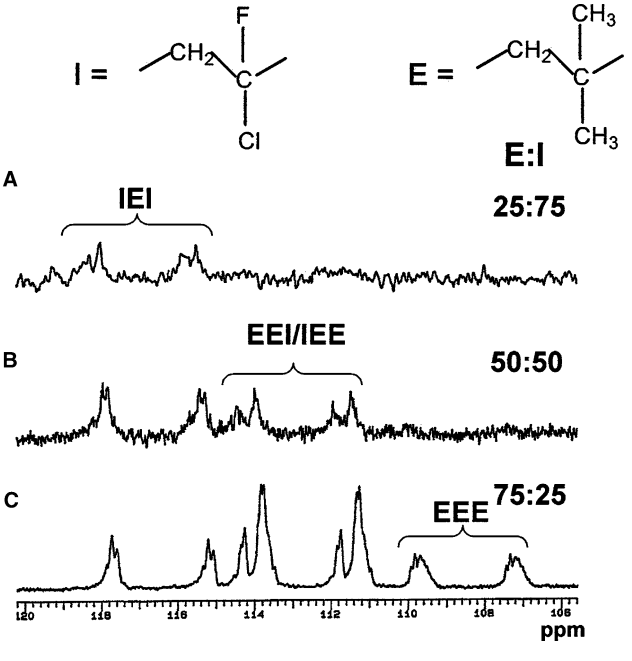

Fig. 12 Expansion of the C–F region from the ^{13}C NMR spectra of poly(1-choloro-1-fluoroethylene-co-isobutylene) obtained from different monomer feed ratios of 1-choloro-1-fluoroethylene (E) and isobutylene (I).

of copolymers prepared from different ratios of 1-chloro-1-fluoroethylene (E) and isobutylene (I). The spectra contain three groups of doublets with shift ranges of 107–110, 111–115, and 115–118 ppm. These groups of peaks arise from C–F carbons of E units centered in EEE, EEI/IEE, and IEI triads. The large doublet splitting results from one-bond C–F couplings. The additional fine structure is a result of stereosequence and longer-range monomer sequence effects.

Most copolymer analyses are carried out by fitting the calculated spectra to experimental ^{1}H and/or ^{13}C NMR spectra based on various propagation models.[26] More detailed information on the compositions of higher order (greater than tetrads) monomer sequences can be obtained only by combining the results from 1D- and 2D-NMR. Examples of these applications can be found in studies on poly(ethylene-co-1-alkene), poly(ethylene-co-alkyl acrylate), and poly(ethylene-co-vinyl monomer).[6,26]

Chain-End Analysis

Nuclear magnetic resonance is useful for determining the number and the structure of chain-ends. The structures of polymer chain-ends are usually relatively complex, producing many unique ^{13}C resonances. Identification of these resonances provides information about the regiospecificity, stereospecificity, the relative rates, and the mechanisms of initiation and termination reactions. In many cases, the unique chain-end structures are the primary reaction sites for degradation and further reactions in otherwise inert materials. Identification of only a single chain-end resonance permits calculation of the polymer's number average molecular weight (M_n). Most of the NMR analyses of chain-end structures rely upon chemical shift calculation and use of model compounds. A good example is presented in Fig. 13 showing 750 MHz ^{1}H NMR spectrum chain-end structures arising from initiation, chain transfer, and termination reactions of poly(methyl methacrylate) (PMMA) prepared with benzoylperoxide in toluene at 100°C;[27] resonances are observed corresponding to *m* and *r* chain-end diad sequences.

Multidimensional NMR combined with multiple resonance techniques can be used to remove most of the resonances from the spectrum and to selectively detect unique structures such as those found at chain-ends.[28] For example, the unique occurrence of

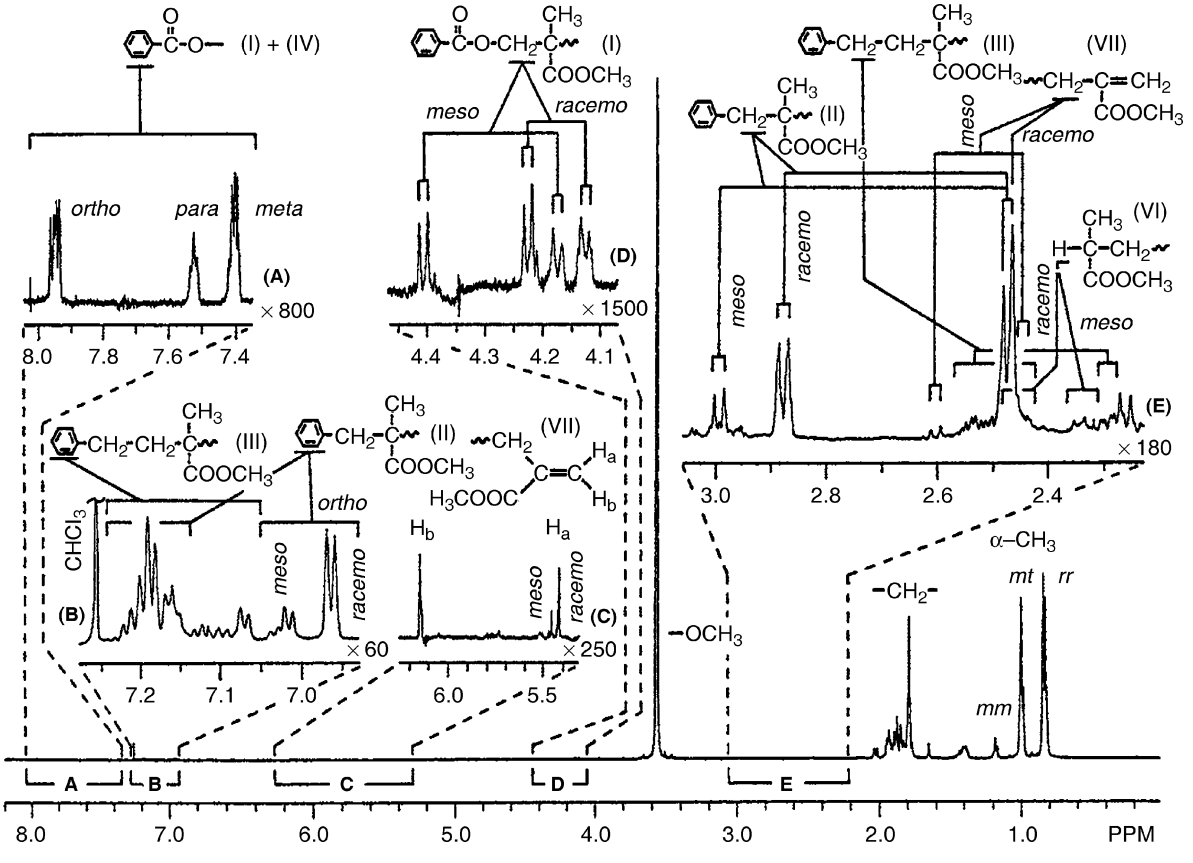

Fig. 13 ^{1}H NMR spectrum of 750 MHz of PMMA prepared with benzoyl peroxide in toluene at 100°C. (From Ref.[27].)

phosphorus (from initiator) at the end of polystyrene chains was exploited by using $^{1}H/^{13}C/^{31}P$ triple resonance multidimensional NMR to produce spectra containing only those resonances from CH_n groups directly bound to ^{31}P at the chain-ends.[28] In Fig. 14A, an HMQC spectrum shows the correlations from both main chain and chain-end structures, whereas a $^{1}H/^{13}C/^{31}P$ triple resonance 2D-NMR spectrum (Fig. 14B) shows only correlations from chain-end structures, simplifying the spectral assignment. The full 3D-NMR spectrum shows resolved resonances from eight different chain-end structures.

A quantitative comparison of end-group resonances with those of the rest of the polymer provides its number average molecular weight (M_n). The relationships between M_n and peak area are generally defined by

$$M_n = \frac{\sum_i (I_i \times m_i)}{I_{CE}} \quad (5)$$

where I_i is the intensity of a unique resonance from each repeat unit in the polymer, m_i the mass of repeat unit i, and I_{CE} the intensity of a chain-end resonance. When possible, the average of several resonances for each monomer unit and for the chain-end structure can provide a more reliable measure of M_n than that obtained from the integration of one peak for each structure fragment. The mobility of the chain-end atoms is usually significantly greater than the mobilities of the atoms in the polymer backbone, leading to

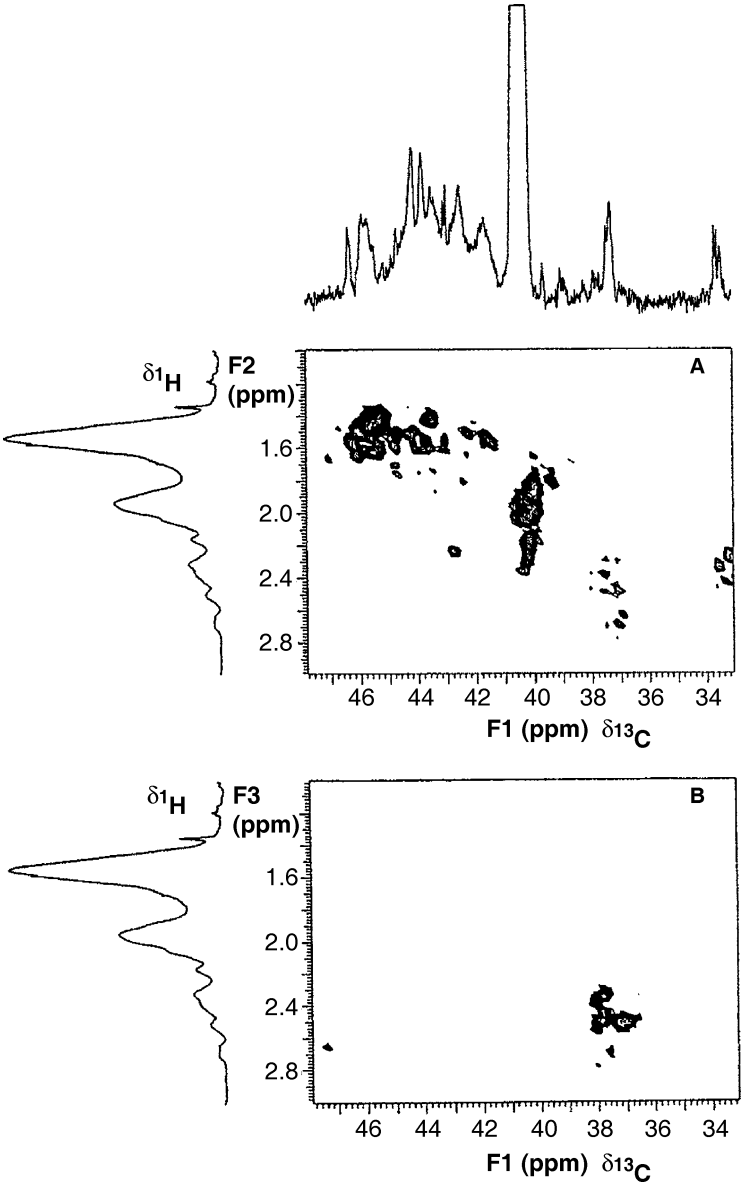

Fig. 14 (A) Aliphatic region from the 2D HMQC NMR spectrum of polystyrene (*Mn* Å 3000, %P Å 1.55) containing diphenylphosphinyl chain-ends, showing the 1D ^{1}H and ^{13}C spectra along the axes; (B) corresponding region from the projection of *f2f3* planes from the 3D PFG-$^{1}H^{13}C^{31}P$-NMR spectrum. (From Ref.[28].)

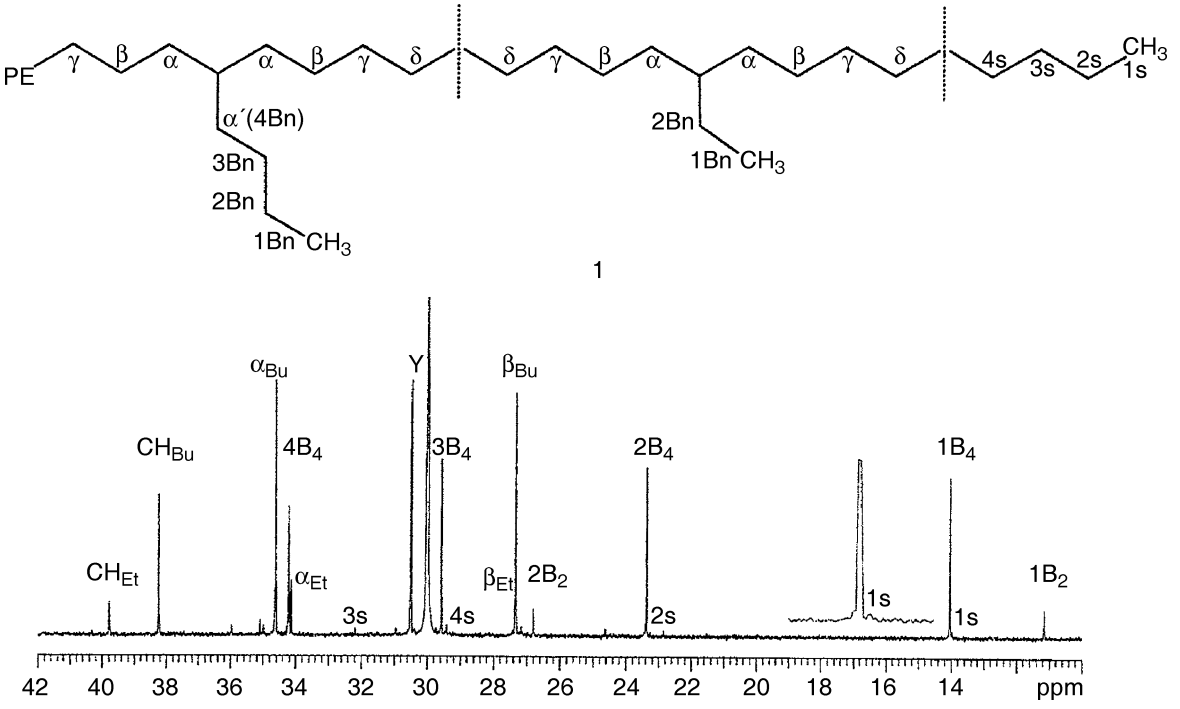

Fig. 15 ^{13}C NMR spectrum of 188.6 MHz of polyethylene containing ethyl and butyl branches. (From Ref.[31].)

significantly different T_1 relaxation times for the nuclei in the former. Consequently, errors from inadequate relaxation delays are greater than those introduced in determining monomer and stereosequence distribution, where the atoms in the main chain repeat units are likely to have similar T_1s. This is particularly true when the areas of methyl resonances are compared with polymer backbone resonances; relaxation delays governed by the longest T_1s must be used.

Branching Structures

The presence of a small number of defects in a polymer chain can have a large influence on a polymer's properties. Two important aspects of polymer chemistry involve detection and structure identification of chain branching and junctions between segments in block copolymers, as low levels of these structures can have a large effect on a polymer's crystallinity,

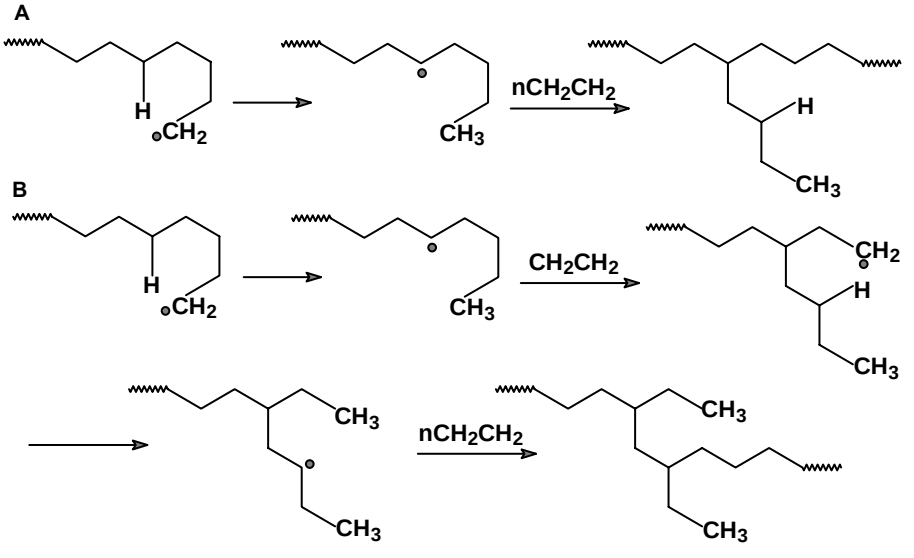

Fig. 16 Typical short-chain branching mechanisms for ethylene homopolymerization: (A) formation of a butyl branch; (B) formation of paired ethyl branches. (From Ref.[29].)

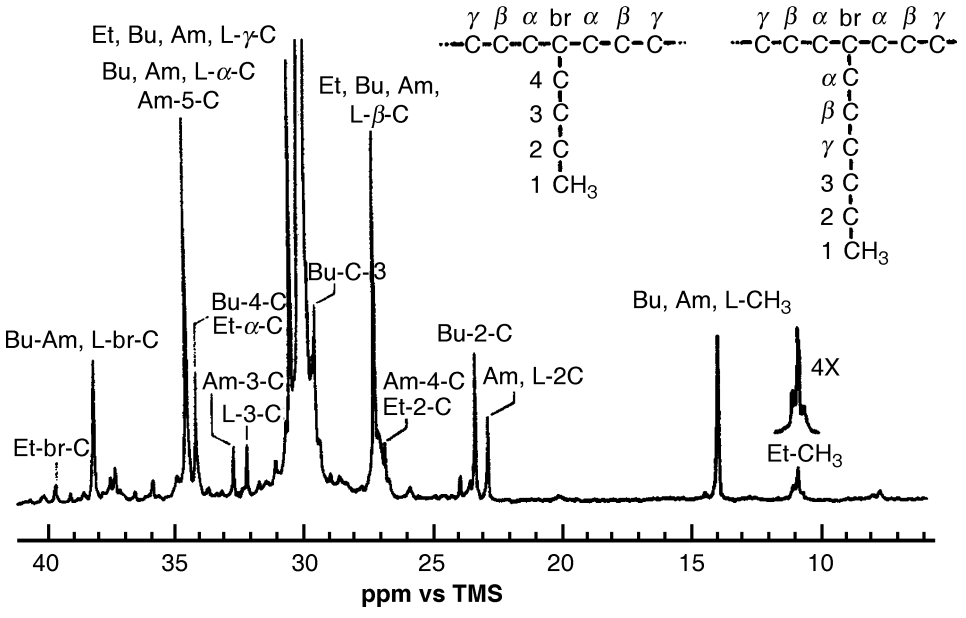

Fig. 17 ^{13}C NMR spectrum of 25 MHz of low-density polyethylene. (From Ref.[4].)

density, and thermal, rheological, and mechanical properties. As in the study of chain-end structures, branch points can be present in very low concentration and can be hard to detect. An excellent example is in the spectrum of polyethylene (Fig. 15), where branching arises from rearrangements and/or hydrogen migration during the polymerization[29,30] or by deliberate introduction of α-olefin comonomers.[26,31]

Fig. 15 shows a ^{13}C NMR spectrum of a polyethylene containing ethyl and butyl branches.[31] The peaks are labeled with the resonance assignments referring to the carbon labels on the structure. The intense peak at 30.0 ppm is from the major component, long sequences of methylene groups ($\delta^+\delta^+$ methylenes) and is plotted far off scale. Three additional sets of resonances are observed for the structures formed at chain-ends (ns), ethyl branches (CH_{Et}, nB_2, α_{Et}, β_{Et}), and butyl branches (CH_{Bu}, nB_4, α_{Bu}, β_{Bu}). In this case, the concentrations of branch structures are low, so that these structures are isolated from one another. Quantitative results are typically reported as the number of branches per 1000 carbons (or number of branches per 10,000 carbons) in the polymer. This can be calculated from the ratio of the integral from one peak of the branch

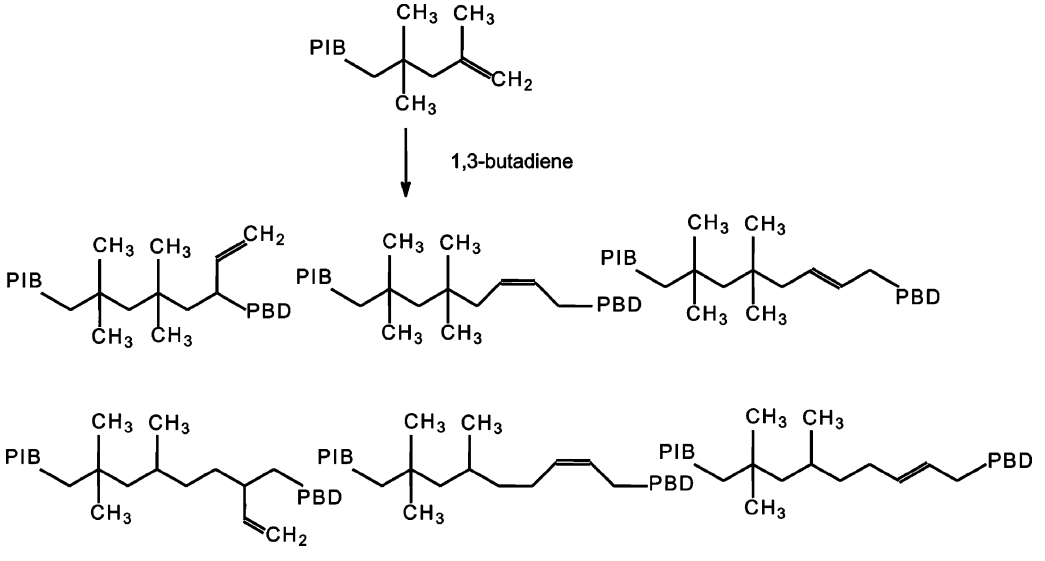

Fig. 18 Reaction of PIB chain-end to form PIB-*b*-PBD copolymer.

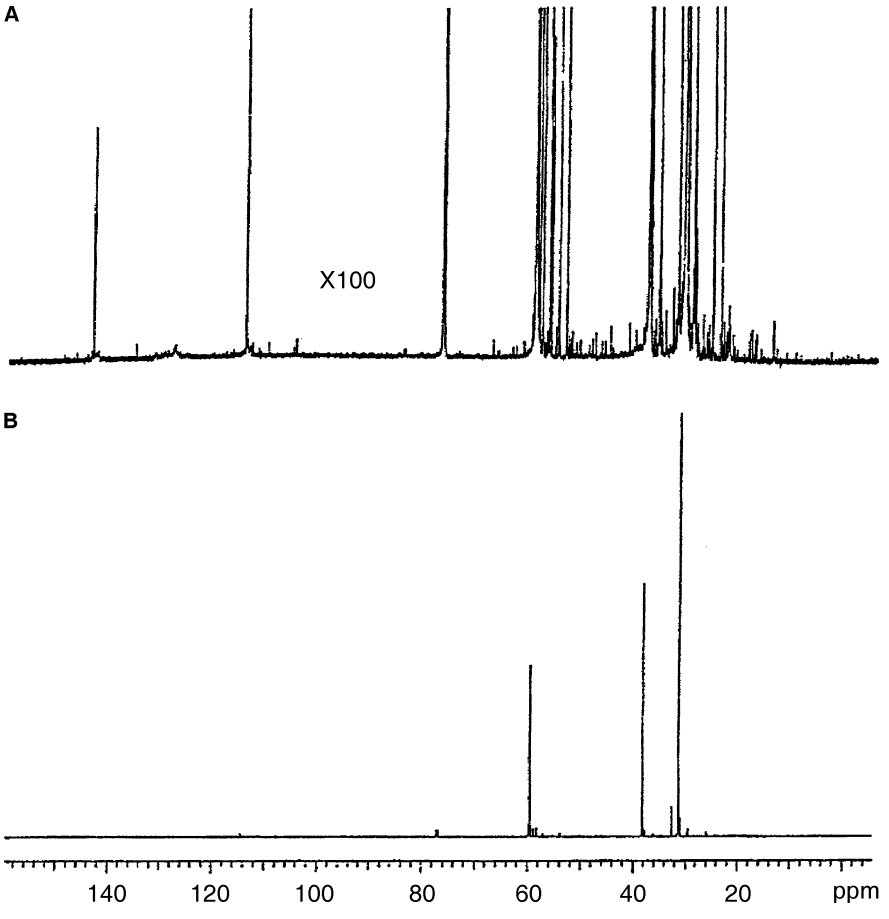

Fig. 19 ^{13}C NMR spectrum of 150 MHz of poly(isobutylene-*b*-butadiene): (A) normal plot and (B) plot of the same region with 100 × vertical amplification.

structure divided by the total integrated area of peaks from the polymer. For example, the number of ethyl branches (N_{Et}) per 1000 carbons is

$$N_{Et} \text{ per 1000 carbons} = \frac{1000 \times I_{CH_{Et}}}{\sum_i I_i} \quad (6)$$

where $I_{CH_{Et}}$ is the area under the signal from CH carbons of ethyl branches and the denominator indicates a summation of the areas of all the polymer's peaks.

McCord et al.[29,30] in a series of papers presented ^{13}C and 2D-NMR evidence for short-chain branch (SCB) forming reactions in the case of ethylene and α-olefin homo- and copolymerization. Backbiting (SCB formation) is a type of intramolecular chain transfer in which the growing radical chain-end curls back on itself to form a five-, six- or seven-membered ring intermediates, transferring the radical back along the chain by hydrogen atom abstraction to form short-chain (propyl, butyl, or amyl) branches (Fig. 16). Fig. 17 shows the ^{13}C NMR spectrum of polyethylene synthesized at 270°C indicating the presence of butyl and amyl branches. It was shown that with increasing reaction temperature, the concentration of branches increases.

Block Copolymers

Block copolymers made from monomers A and B contain long sequences of A units connected to long sequences of B units. To understand the block polymerization mechanism, it is useful to measure the number of structures at block junctions. The issues associated with the study of block copolymers are similar to those discussed earlier in relation to chain-end and branching analysis; the resonances from block junctions are small compared with those of the main chain peaks.

Data from poly(isobutylene-*b*-butadiene) (PIB-*b*-PBD) are an excellent illustration of the characterization of block junction structures.[32] This polymer is more complicated than most because the 1,3-butadiene monomers add to PIB at the PIB–PBD junction in one of three ways (illustrated in Fig. 18): by 1,2-addition to form vinyl (V) units, and by 1,4-addition to form *cis*-1,4-units (C) or *trans*-1,4-units (T). Six structures are possible for the block junction if one considers that addition of V, C, or T units occurs at either of two sites on the terminal isobutylene unit. Because additional butadiene units can add to form C, T, or V units in the second position from the block junction, the number of possible structures increases dramatically.

The ^{13}C NMR spectrum of PIB–PBD, shown in Fig. 19A, is dominated by the resonances of the PIB portion of the polymer. In the spectrum plotted with 100 × vertical expansion (Fig. 19B), a large number of weak signals are detected from the numerous chain-end and block junction structures. In the aliphatic region (10.0–60.0 ppm), the signals are so numerous that they appear to be noise. Resonance assignments obtained by chemical shift predictions or by comparison with the shifts of model compounds are ambiguous in this case, as many signals appear in a small region. Multidimensional NMR experiments were used to obtain unequivocal assignments before these peaks were used to obtain useful information about polymer's structure.

CONCLUSIONS

Nuclear magnetic resonance has become the premier technique for characterizing polymer structure dynamics and interactions in solution. Advances in multidimensional NMR and gradient spectroscopy along with labeling methods continue to enhance applications in the characterizing complex polymers. It is now routinely used in all aspects of fundamental and applied polymer work. Although the instrumentation is somewhat expensive, it is often the only way to obtain necessary analyses. In process monitoring and quality control environments requiring high sample volume and rapid throughput, NMR is used to obtain primary calibration standards for use with other less expensive and more rapid instrumental analysis techniques.

NO_x Removal

Mike Bradford
Rajiv Grover
Jacobs Engineering Group Inc., Houston, Texas, U.S.A.

INTRODUCTION

Nitrogen oxides (NO_x) are a combination of nitrogen oxide (NO) and nitrogen dioxide (NO_2). Nitrogen oxides can combine with volatile organic compounds (VOCs) to form ozone. For this reason, NO_x control has become a target of the environmental regulatory authorities. The minimization or reduction of NO_x is required because of ever-tightening regulations and permitting requirements.

The emission control requirements of the existing as well as future regulations require an understanding of the NO_x-emitting sources, pollution prevention opportunities, emission reduction technologies, costs of controls, and impacts on existing operations and plant safety. This entry discusses a number of aspects of NO_x control:

- NO_x reductions through process changes and/or pollution prevention activities
- ultra low NO_x burners (ULNB)
- burner-related NO_x reduction, such as flue gas recirculation (FGR)
- postcombustion NO_x control options, such as selective noncatalytic reduction (SNCR), selective catalytic reduction (SCR), and catalytic oxidation/scrubbing.

When evaluating these technologies, it should be kept in mind that in many cases, retrofitting the NO_x controls can have positive side benefits. In many instances, the installation of NO_x controls can result in better energy efficiency and in lower maintenance requirements.

TECHNOLOGY OVERVIEW

Table 1[1,2] lists various technologies available for NO_x reduction. It also lists the estimated percentage of reduction using each technology and the approximate ppmvd NO_x that can be achieved. The table is divided into two sections: one for fired heaters and the other for boilers, because NO_x generation is very different for the two types of systems.

FIRED HEATER NO_x REDUCTION

Process Modifications and/or Pollution Prevention NO_x Reduction

A number of process modifications and/or energy efficiency improvements can be made to reduce NO_x emissions.[1,2] Also, some of the standard NO_x reduction technologies have the additional benefit of improving energy efficiency. Possible process modifications include:

- Replacement of boilers with a cogeneration system.
- Replacement of inefficient heaters with more efficient heaters.
- Provision of a new convection section or upgradation of the existing one. These modifications can be used to preheat the process fluid, thereby improving the heater efficiency and decreasing the firing rate. The lower firing rate results in less NO_x generation, and reduction in operating cost could pay for the modification.

  It must be noted, however, that modification to the convection section is often required to provide the correct temperature for installation of an SCR. An increase in energy efficiency may be an additional benefit of installing an SCR.
- Upgradation of the heater controls to allow tighter control of the excess air. Tighter controls could be used to reduce the oxygen concentration in the flue gas. A reduction in the O_2 concentration in the flue gas from 6% to 2% reduces the firing rate by only few percentages. But this still has two advantages.

  i. The lower firing rate decreases the NO_x generation a little
  ii. Less NO_x is generated if the oxygen concentration is low. In general, a decrease in O_2 concentration from 6% to 2% reduces the NO_x generation by approximately 30%.

  Combining the above two benefits results in a NO_x reduction of a little over 30%.
- Sealing the heater can also reduce the O_2 concentration in the firebox and improve the heater

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007882

Table 1 Potential NO_x reduction technologies

Technology	Approximate reduction (%)	Approximate lbs/MM Btu	Approximate ppmv at 3% O_2
Fired heaters			
Process modifications/pollution prevention			
Standard burners	Base case	0.14	120
Low NO_x burners	60%	0.06	50
ULNB–first generation	80%	0.025–0.06	20–50
ULNB – current best demonstrated	90%	0.012–0.05	10–40
FGR	30%	(1)	(1)
Boilers			
Standard burners	Base case	0.25	200
ULNB–first generation (w/o FGR)	70%	0.08	65
ULNB–first generation (w/o FGR)	84%	0.04	35
ULNB – current best demonstrated (w FGR)	96%	0.01	8
FGR	55–90% (2)	(1)	(1)
Miscellaneous			
SNCR	40–90%	(1)	(1)
Catalytic scrubbing	70–90%	(1)	(1)
SCR	90–97% (3)	(1)	$\geq$5 ppmvd

Notes: (1) Final NO_x level depends on the starting point; (2) Depends on % of FGR and level of air preheat; (3) >90% reduction requires special attention to NH_3 distribution.

efficiency. Like the upgradation in controls, this can be an additional advantage of the installation of ULNB.

Ultra Low NO_x Burners

Burners have been undergoing a rapid state of development based on pressures to reduce NO_x formation and stages of development include:

- Standard burners that were designed more for fuel economy and maintenance ease than for NO_x control.
- Low NO_x burners (LNB) specifically designed for lower NO_x emissions. These burners typically utilized air staging to reduce NO_x.
- Ultra low NO_x burners that typically had a combination of air staging and fuel staging. The latest version of ULNB includes new, more experimental improvements.

Impacts on Standard Burner NO_x Generation

Nitrogen oxides are formed in fired systems in three ways:

- Thermal NO_x, formed because of local hot spots in the flame.
- Prompt NO_x, formed because of reactions at the fuel–oxygen interface.
- Fuel NO_x, resulting from the burning of fuels containing organic nitrogen. Some of the organic nitrogen is oxidized into NO_x. This type of NO_x formation tends to be negligible with natural gas and fuel gas firing.

Standard burners typically result in NO_x formation in the 0.12–0.14 lb/MM Btu (100–120 ppmv) for fired heaters and the 0.2–0.3 range for boilers. Factors that influence this number are:

- Excess air: the lower the excess air (%O_2), the lower the NO_x (Fig. 1).[3]
- Firebox temperature: high firebox temperatures result in higher NO_x formation (Fig. 2).[3]
- Air preheat: higher air preheat results in higher NO_x (Fig. 3).[3] Note: This figure only applies to standard burners. Air preheat does not have as great an effect on ULNB.

Ultra Low NO_x Burners for Fired Heaters

While this section discusses the ULNB used for fired heaters only, boiler burners are discussed in the subsequent section. These two types of fired units are discussed separately because of their different firing characteristics.

Currently, there are two recognized generations of ULNB. The first generation, under ideal conditions, has demonstrated NO_x levels as low as 0.025 lb/MM Btu.

Burners that have achieved NO_x levels as low as 0.012 lb/MM Btu are currently under development, but their performance is highly variable because it is

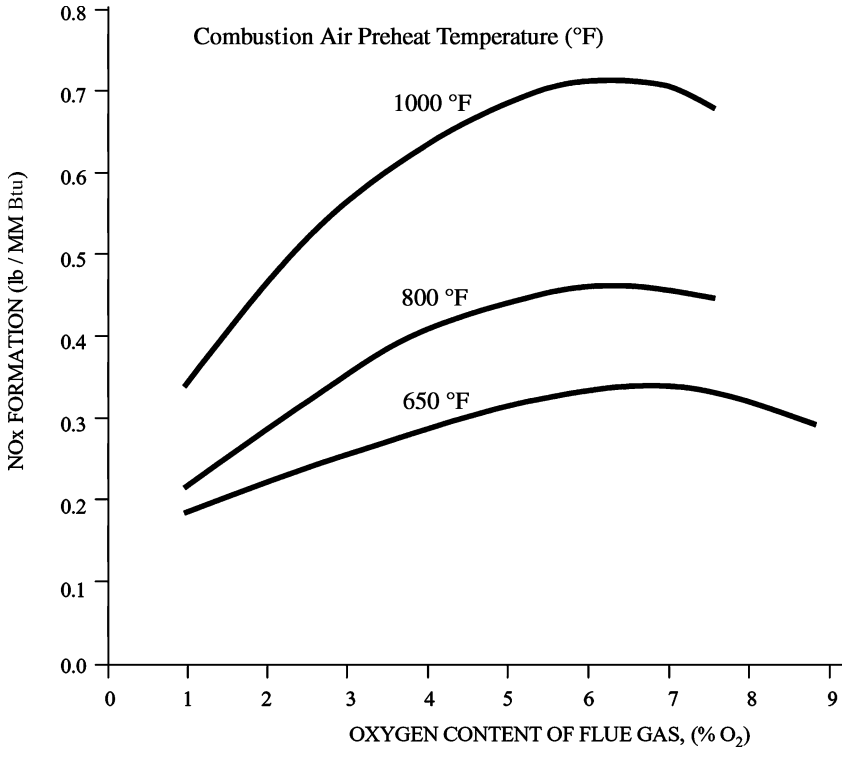

Fig. 1 Stack gas O_2 concentration vs. NO_x. (From Ref.[3].)

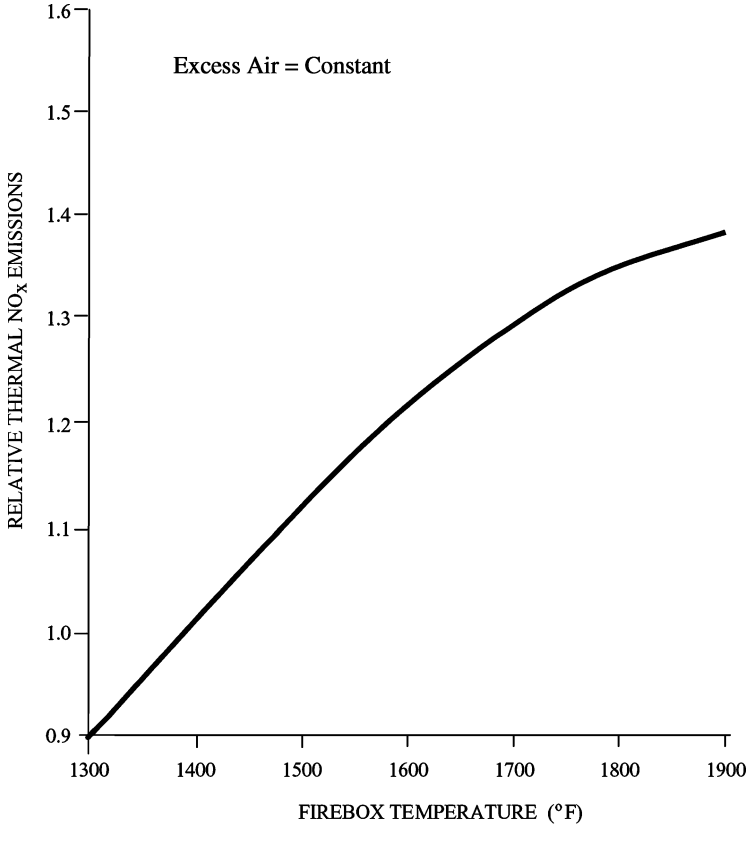

Fig. 2 Firebox temperature vs. NO_x formation. (From Ref.[3].)

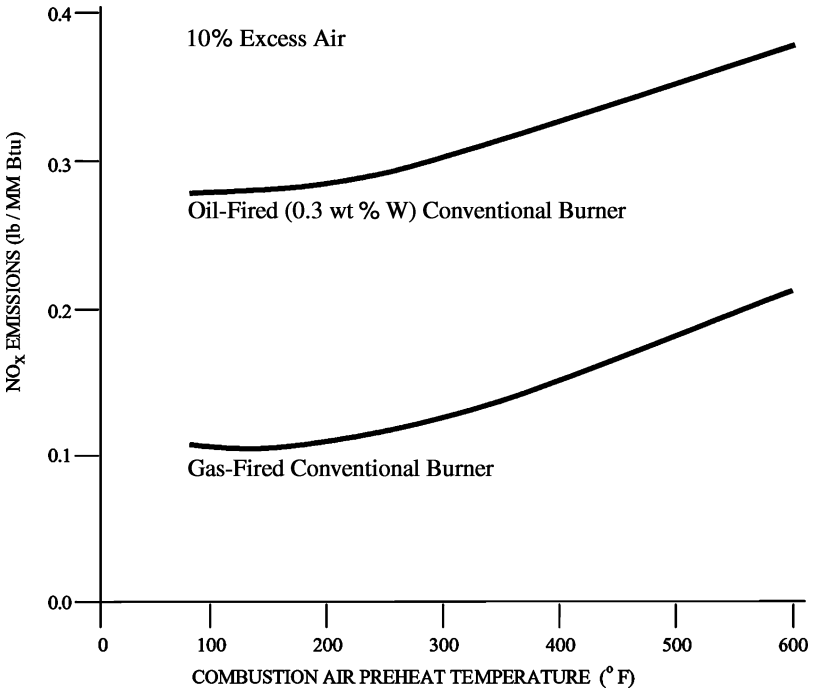

Fig. 3 Impact of air preheat on NO_x formation. (From Ref.[3].)

highly dependent on flux levels and flow patterns within the heaters.

Ultra low NO_x burner's performance

Burner performances are dependent on the following:

- No air leaks: Most of the ULNB use internal FGR to dilute the flame. Air leaks result in a high oxygen level in the flue gas that is recirculated and result in higher NO_x levels. Leaks into the furnace may need to be welded shut, and gaskets may need to be installed to stop air leaks around view ports.
- Firebox temperatures: Low NO_x guarantees are easier to obtain if firebox temperatures are low.
- Fuel gas: Fuel gas systems containing hydrogen cause problems with some burners, because hydrogen burns hot and also owing to swings in the hydrogen concentration. Some vendors derate their burners in fuel gas systems.

More advance control systems may be required to ensure the performance of the burners. Control modifications that may be required include:

- Installation of continuous emission monitoring systems (CEMS).
- Use of oxygen analyzers near the bridgewall and/or in the floor of the heater.
- Automatic controls on stack dampers. The stack damper is used to control the heater draft. This in turn approximately controls the O_2 concentration in the firebox.
- Automatic modulation of the burner inlet air registers. This is used in conjunction with the stack damper control. The stack damper controls the draft and the O_2 concentration in the firebox controls the inlet air registers.
- CO trim control. This has proven to be the optimum control scheme. An ''optical through-the-stack'' light beam is used to measure the CO. This CO control is used in place of oxygen control.
- Upgrades to the burner management system (BMS). This may be triggered by the above changes to the control systems.
- The installation of coalescers/filters to remove liquid and particulates from the fuel gas. The ULNB that depend on inducing internal FGR have small fuel tips. These fuel tips are very susceptible to plugging if the fuel gas is not clean.

Additional potential restrictions on the use of ULNB are:

- Size: The latest generation of ULNB is significantly larger than standard burners.
- Minimum spacing: ULNB depend on FGR, inside the firebox, quenching the flame temperature. Recent tests have demonstrated that if burner spacing is too tight, the flue gas cannot recirculate

inside the burner circle, and NO_x generation goes up.
- Computational fluid dynamics (CFD) computer modeling can be used to flag problem heaters.

Vendors are doing a tremendous amount of research to develop burners that will achieve very low NO_x levels. As this is an evolving technology, the odds are that the burners we install next year will be different from those we install this year.

Ultra Low NO_x Boiler Burners

Boilers are higher NO_x producers than fired heaters because the firebox temperatures are higher and they typically have air preheat systems. Firebox temperatures typically run in the 2100°F range, at full loads.

Historically, FGR has been used extensively to minimize boiler NO_x. The reasons that FGR have been used so extensively are:

- Historically, there has been no other way to achieve low NO_x levels because of the high firebox fluxes/firebox temperatures.
- Boilers normally are forced draft (FD) versus most fired heaters that are natural draft. It is cheaper to combine FGR with an FD system because the FD fan can be used to induce the flue gas and the plenums already exist to distribute the air.
- Boilers frequently have air preheat systems. The induced draft (ID) fans used for air preheat can be used to recirculate the flue gas.

In addition to FGR, LNB boiler burners have used air staging to minimize NO_x formation. ULNB boiler burners also use fuel staging and/or a combination of air and fuel staging.

A number of approaches to achieve the quenching effect of fuel gas recirculation can be used:

- The conventional FGR from the stack to the air-side of the burner
- Steam or water injection into the air-side of the burner
- Induced FGR from the stack into the fuel gas
- Steam injection into the fuel gas

Fig. 4 provides information on the impact of FGR on NO_x reduction. Boiler NO_x levels that have been achieved are:

- First generation ULNB

Without FGR	0.08 lb/MM Btu
With FGR	0.04
With FGR and water injection (air-side)	0.033

- Latest generation burners

Without FGR (natural gas)	0.04 lb/MM Btu
Without FGR (fuel gas)	0.03 (one installation)
With FGR (natural gas)	0.01
With induced FGR into the fuel gas (IFGR) and steam (fuel gas)	0.01 (low flux boiler)

Coalescers/filters may or may not be required to clean up the fuel gas. Burners that utilize FGR as the fuel gas have larger than normal fuel tips, and thus are less susceptible to plugging than standard burner

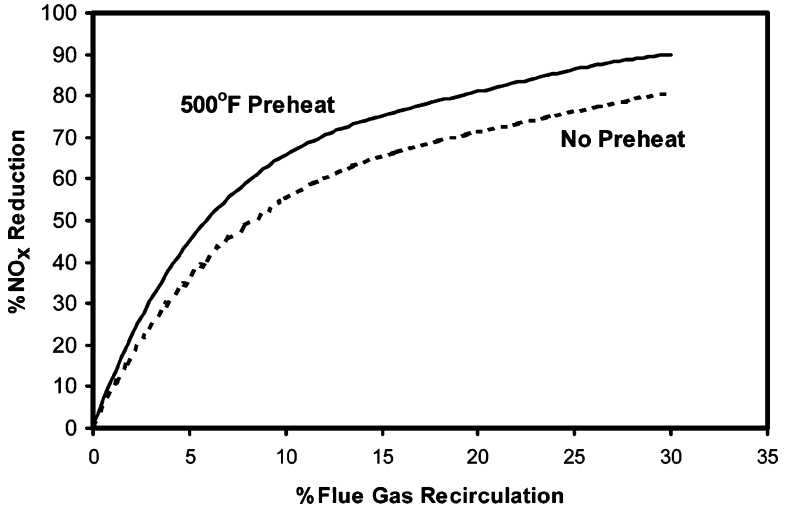

Fig. 4 Impact of FGR on NO_x reduction.

tips. In general, boiler burners do not depend on inducing FGR within the firebox, they do not have the small diameter burner tips that fired heater ULNB use. So, they also are no more susceptible to fouling than the standard burners.

Burner-Related NO_x Reduction

Conventional FGR

Historically, recirculation rates in the 15–20% neighborhood have been used, with NO_x reductions in the 40–55% range. The maximum stoichiometric recirculation possible is 40%. The latest regulations have been forcing recirculation close to 30% for NO_x reductions as high as 70%, but these systems require very tight control systems to maintain flame stability.

Fig. 4 shows the NO_x reduction that can be achieved for various FGR rates. It must be noted that

- FGR has a greater impact if the system has an air preheater.
- The greatest benefits are achieved with the first 5–10% FGR. Beyond 10%, the returns diminish. However, to achieve very low NO_x numbers, the vendors are pushing the systems all the way out to the 30% FGR range.
- The curves are for boilers only. Because of their high firebox temperatures, boilers tend to have high NO_x and benefit more from FGR. Estimates are that fired heaters can achieve a maximum of about 30% NO_x reduction from FGR.

FGR design details include:

- An FD system is required, which is one reason this technology has been more popular with boilers than with fired heaters. Boilers are typically FD while fired heaters are typically natural draft.
- An eductor in the FD air can be used on new installations to educt in the recirculated air. For retrofits, the FD fan may not have enough capacity for an eductor, so a recirculating fan may be required.
- The burners may need to be retrofitted with ''bussels'' for introduction of the recirculated air.

Alternates to the conventional FGR are the educting of flue gas into the fuel gas and/or steam injection into the fuel gas.

Advantages of FGR include:

- Being less expensive than an SCR.
- Perhaps the only way to achieve low NO_x on boilers, because of the high firebox temperatures and the potential impact from air preheat.
- Use in combination with ULNB to achieve very low NO_x concentrations, especially in boilers.
- Use in recirculating flue gas in the fuel gas to reduce the heat of combustion of the fuel. The reduced heat of combustion reduces the NO_x generation.

Disadvantages of FGR include:

- Higher investment and higher operating costs than the installation of ULNB.
- Need to increase the capacity of the FD fan.

Steam or Water Injection (Air-Side of Burner)

Steam or water injection into the air-side of the burner can be used to quench the flame. Unless free steam is available, water injection is more economical.

The disadvantage of water injection is that it introduces particulates into the flue gas from the dissolved salts in the water. These particulates can deposit on the tubes or result in an increase in particulate emissions from the boiler. Boiler feedwater has been used to minimize this, although it is not required by the burner vendors.

Fig. 5 provides information on NO_x reduction versus steam injection rates. Water injection can achieve the same NO_x reductions, but with lower injection rates.

IFGR

This technology was developed by one of the vendors based on observations that low-Btu fuel gases produce low NO_x. Inducing the flue gas into the fuel gas dilutes the fuel gas. This dilution has a greater impact than FGR into the air-side of the burner because it reduces both the flame temperature and localized hot spots. A general rule of thumb is that 15% IFGR will produce the same NO_x reduction as 30% FGR.

A fan is not required. Instead, an eductor in the fuel gas is used to educt the recirculated flue gas. Because of the higher fuel gas flow, larger fuel tips are required in the burner.

This can be a very economical technology, as long as extensive internal modifications are not required inside the boiler and the existing FD fan can handle the extra pressure drop.

Steam Injection into the Fuel Gas

This is the same principle as IFGR—the steam dilutes the fuel gas thus reducing both the flame temperature and the localized hot spots. Systems have used up to 8% steam injection (the steam injection rate is 8% of the total steam production from the boiler).

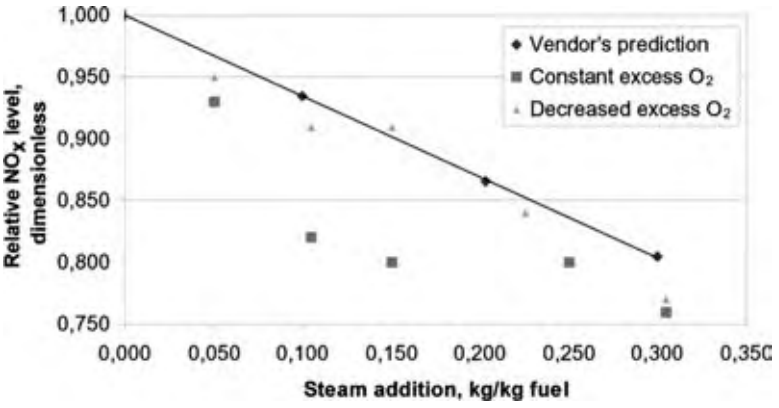

Fig. 5 NO_x reduction vs. steam injection to air-side of burner. *(View this art in color at www.dekker.com.)*

The main drawback of steam injection is the potentially high operating cost. If 8% steam injection is required, in general it would be more economical to install an ID fan and use FGR into the air-side—the higher investment would offset the operating cost.

An ideal application of steam injection would be in cases where the steam is normally not needed. For example, one plant normally does not require steam, but adds it when needed to offset NO_x production in other parts of the refinery. As the addition frequency is low, operating costs are low and there was no requirement for FGR fans.

SNCR

SNCR units can achieve approximately a 40% NO_x reduction without requiring the installation of an SCR. Combined with other technologies, SNCR can potentially produce low NO_x concentrations. A number of vendors license SNCR technologies.

SNCRs utilize the reducing capability of ammonia and urea to reduce NO_x to nitrogen. The requirements for good conversion include:

- Proper temperature. The reactions occur over a very narrow temperature range; however, additives can be used to extend the range.

Ammonia reaction	1600–2200°F (with versions down to 1400°F)
Urea reaction	1600–2000°F (with versions down to 1200°F)

- Good mixing. The ammonia is typically injected into holes drilled into the firebox. These injectors can be installed on-line.
- Adequate residence time.
- No impingement of the injected chemical against tubes.

The equations for the reaction of ammonia with NO_x are:

$$4NO + 4NH_3 + O_2 = 4N_2 + 6H_2O \quad (NH_3/NO = 1/1)$$

$$2NO + 4NH_3 + 2O_2 = 3N_2 + 6H_2O \quad (NH_3/NO = 2/1)$$

$$6NO_2 + 8NH_3 = 7N_2 + 12H_2O$$

For temperatures between 1600°F and 2200°F, the top and bottom equations dominate.

Most of the NO_x is NO (90–93% by volume); hence, the theoretical NH_3/NO_x ratio is about 1.03, plus the NH_3 slip.

The equation for the reaction of urea is:

$$CO(NH_2)_2 + 2NO + 1/2O_2 = 2N_2 + CO_2 + 2H_2O$$

Advantages of SNCR include:

- Lower capital investment than SCRs.
- Can be used in dirty/fouling services (particulates and/or high sulfur). However, any SO_3 can react with the NH_3 and form ammonium bisulfate precipitates (see the section on SCR technology).
- Can be combined with other technologies, such as catalytic scrubbing or partial burn regenerators, to achieve greater NO_x reduction.
- SNCR may be economical in conjunction with an SCR. The SNCR can be used to reduce the required size of the SCR by reducing the inlet NO_x concentration to the SCR.

Disadvantages of SNCR include:

- Operates only in a narrow temperature range.
- The residence time may not be long enough for the SNCR reaction to occur.

- High ammonia consumption/ammonia slip. An excess of 20–50% is required to achieve a 40% NO_x reduction. By comparison, SCRs require < 5% excess ammonia. Because of the higher ammonia slip, operating costs could be higher than SCRs.

SCRs

SCRs utilize the following equations for the reaction between ammonia and NO_x at high temperatures:

$$4NO + 4NH_3 + O_2 = 4N_2 + 6H_2O$$
$$2NO + 4NH_3 + 2O_2 = 3N_2 + 6H_2O$$
(minor at standard temperatures)
$$6NO_2 + 8NH_3 = 7N_2 + 12H_2O$$

This is basically the same reaction that occurs with SNCR. The difference is that the catalyst allows the reaction to proceed at lower temperatures.

The NO_x is primarily NO (90–93% by volume). So, the theoretical NH_3 required is approximately 1.03 NH_3/NO_x plus the slip. The slip is the unreacted NH_3 that exits the stack.

There are three basic types of SCR technology:

- Low temperature catalysts: These catalysts have the advantage of operating at lower temperatures, but are susceptible to sulfur and particulates.
- Medium temperature catalysts.
- High temperature catalysts: These tend to use zeolites.

In addition to the choices between the types of catalysts, the following are also required in designing SCR systems:

- Catalyst volume (space velocity) versus percent conversion. Modules can be mounted in series for greater conversion.
- Provisions for excess catalyst to allow long runs between unit turnarounds.
- Where does one locate the SCR in the flue gas train? There is some flexibility in operating temperature, but in general the higher the temperature, the lower the catalyst volume.
- Horizontal or vertical flow. Vertical flow is most common because it occupies less space. Vertical down flow is preferred in many applications because it allows particulates to drop through the catalyst.
- The design of any downstream heat recovery equipment. Any SO_3 in the flue gas will react with the NH_3 added in the SCR to form ammonium sulfate salts (ammonium sulfate and ammonium bisulfate). These salts form a solid at high temperatures and tend to precipitate on heat transfer surfaces. Note: phase diagrams are available that predict the solid dew points. A more detailed discussion of ammonium salt deposit concerns is included later in this section.

Advantages of SCRs include:

- A high percentage of NO_x removal. Recent systems achieve 80–97% reductions, depending on the design space velocity. The volume of catalyst used can be varied depending on the required percentage of reduction.
- Only approach technically feasible in applications that are difficult for burners.
- Less ammonia slip and a greater NO_x reduction than SNCRs.

Disadvantages of SCRs include:

- The temperature profile in the heat recovery train may not be optimal for the performance of the SCR system. This may require modifications to the heat recovery train and the installation of some type of temperature control.
- Sulfur can precipitate as ammonium bisulfate, thus fouling the catalyst.
- Sulfur can also precipitate as ammonium sulfate on downstream heat transfer surfaces. Any new heat recovery system must be designed to deal with this precipitation. Existing systems must be checked to make sure they can be cleaned without disrupting the process.
- Safety concerns for the storage and handling of ammonia. This can be minimized by using aqueous ammonia, but with an increase in operating cost.
- High capital investment.
- Higher operating costs than some of the other options.
- The increase in pressure drop could require a conversion to FD or the installation of ID fans.
- Low temperature units are particularly susceptible to fouling in high sulfur applications. Plus, some low temperature catalysts are susceptible to particulate plugging.

Low Temperature SCRs

A low temperature installation (GE Frame 3 Gas Turbine) is seen in Fig. 6.[4] A catalyst being loaded is shown in Fig. 7.[4]

Advantages of low temperature SCRs include:

- Can be operated at a lower temperature because it either has a higher surface area or a higher vanadium content for a higher activity

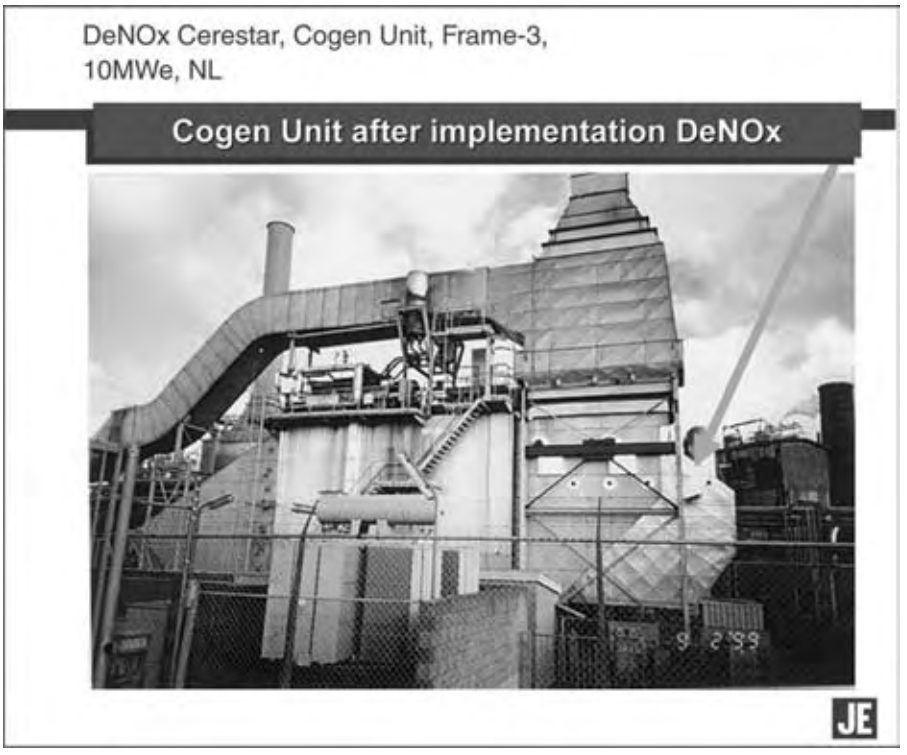

Fig. 6 A low temperature installation. (Courtesy of Cerestar.) *(View this art in color at www.dekker.com.)*

- Can be located at the end of the stack gas train, low temperature area. This minimizes the need to run ducting from a high temperature area and then return the flue gas to the stack gas train. This is its biggest advantage.
- Operating temperature range = 320–680°F (but is not likely to be economical above 500°F).
- Can be used in installations of firing natural gas and many installations of firing plant/refinery fuel gas.

Disadvantages of low temperature SCRs include:

- Susceptible to sulfur concentrations.
- Cost: higher catalyst volumes are required at the lower temperatures.

Low temperature sensitivity to sulfur include:

- The problem is operation below the freezing point of ammonium bisulfate. This results in deposition on the catalyst. At the end of this section is a phase-chart showing the deposition temperature of both ammonium sulfate and ammonium bisulfate, as a function of SO_3 and ammonia concentrations.
- The allowable sulfur level depends on the length of runs between turnarounds. SO_2 levels as high as 100 mg/m^3 can be tolerated with frequent turnarounds and the installation of excess catalyst. However, lower sulfur levels are required for turnaround frequencies of four or five years.

Approaches to minimizing the impacts of sulfur include:

- Increasing the temperature to stay above the dew point.
- Increasing catalyst volume to provide spare surface area for deposition. This has been used successfully in a refinery with an H_2S level in the fuel gas of 50 ppmv.
- Periodic operation at higher temperatures to desublime the deposited ammonium bisulfate. If possible, flow can be stopped to the convection section to raise temperatures. Alternately, duct burners could be installed for periodic operation.

Medium Temperature SCRs

Medium temperature catalysts operate in the 500–725°F temperature range. Three basic types of medium temperature SCRs are:

- Honeycomb units
- Corrugated designs
- Plate

A honeycomb catalyst is shown in Fig. 8. A corrugated unit is similar in design except that the walls are thinner, thus allowing more open area. A plate-type catalyst has long, rectangular openings between the plates.

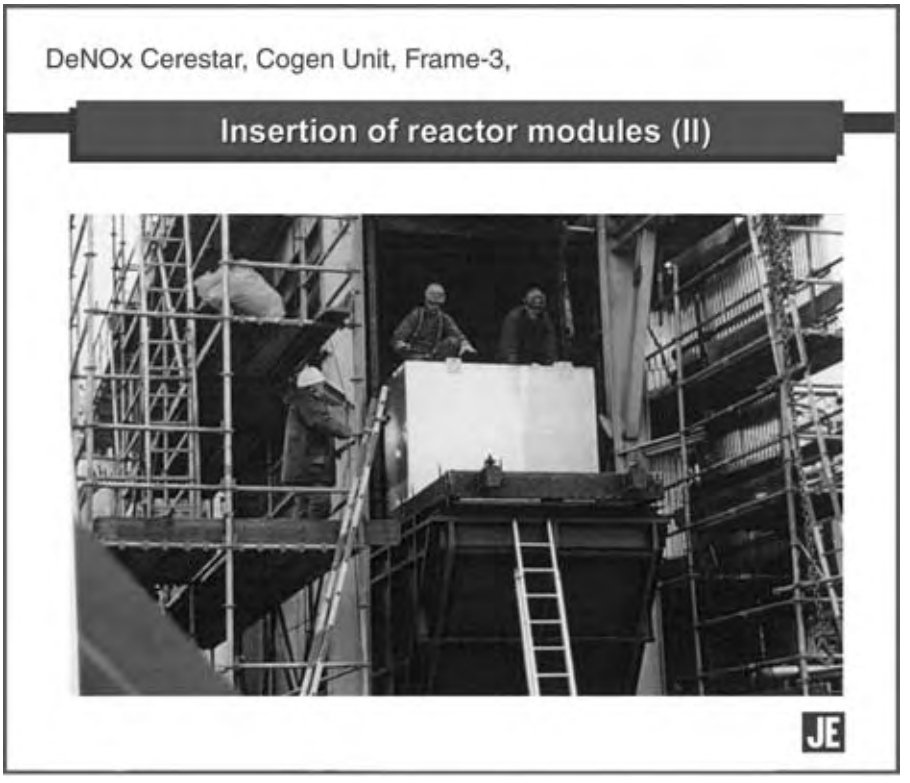

Fig. 7 A catalyst being loaded in a low temperature installation. (Courtesy of Cerestar.) *(View this art in color at www.dekker.com.)*

Advantages of medium temperature catalysts are:

- Honeycomb catalysts have been in use for a number of years.
- Can stand high sulfur and high particulate loadings. A soot blower can be provided for particulate control (the particulates are stirred up and flushed through the honeycomb).

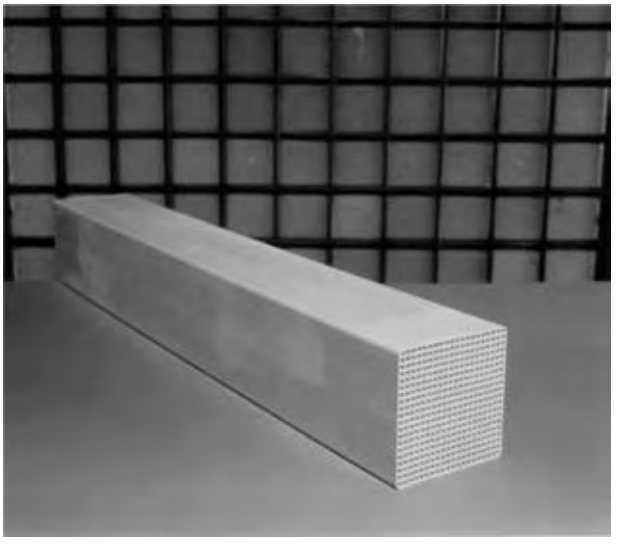

Fig. 8 Honey comb catalyst in front of module. *(View this art in color at www.dekker.com.)*

- Low-vanadium catalysts can be used that minimize the conversion of SO_2 into SO_3. This minimizes the precipitation of ammonium bisulfate on downstream heat recovery units. However, in general these low-vanadium catalysts are not economical because the catalyst volumes are larger (low-vanadium catalysts are less active).

Disadvantages of medium temperature catalysts are:

- The ideal temperature may not exist in the flue gas system. A typical operating temperature range is 550–725°F. This temperature range may not exist in all facilities, and may require modification of the heat recovery train.
- Increased pressure drop. Could require conversion to FD burners, or installation of an ID fan.
- Precipitation can still occur in the catalyst bed because of capillary action that raises the dew point of the ammonium salts. This is negligible for natural gas and refinery fuel gas fired systems but can be significant for applications with high sulfur in the fuel.

High-Temperature SCRs

High-temperature catalysts operate in the 650–1100°F temperature range. These are primarily zeolite based catalysts.

The advantages of high temperature catalysts are:

- Can be used in applications that have little or no heat recovery.
- Can stand periodic high-temperature upsets.
- Zeolite catalysts can be used for high sulfur applications. The reaction with zeolite catalysts occurs inside the molecular sieve body, rather than on the surface of a metal catalyst. This eliminates the sulfur poisoning of metallic catalysts and reduces the conversion of SO_2 into SO_3.

The main disadvantage of the high temperature catalyst is cost.

SCR Support Facilities

SCR systems require the following support facilities:

- Ammonia storage and vaporization facilities.
- An air compressor provides dilution air for the ammonia to aid injection and distribution. Air to ammonia ratio of approximately 20/1 is used to stay safely below the 15% LEL, for NH_3, and to provide enough volume for good NH_3 distribution.
- Control of the ammonia injection rate. As a minimum, the ammonia feed rate should be controlled by the exit NO_x concentration, possibly adjusted for the firing rate. For larger installations, those with varying NO_x concentrations or for those with a tight ammonia slip specification, an inlet NO_x analyzer or an ammonia analyzer could be used to reset the ammonia/feed ratio.
- Soot blowers may be required for services with high particulate loadings. Down flow designs can also help in flushing any solids through the system.
- The ammonia injection is typically through a distribution grid (AIG) located upstream of the reactor. This distribution is critical to the performance of the system and to minimize ammonia slip. For a high percent NO_x reduction, this distributor should be located as far upstream as possible to get very good mixing. The grid should be removable for on-stream cleaning if there are high concentrations of SO_3 in the flue gas.
- Turning vanes may be required to ensure distribution of the airflow across the catalyst. Computer modeling (CFD) or "cold flow" modeling may be required to ensure the proper air distribution and the proper design of the straightening vanes.

Precipitation of Ammonium Sulfate Salts

The ammonia added to the SCR can react with any SO_3 to form ammonium sulfate salts. These salts can precipitate at high temperatures to deactivate the SCR catalyst or to foul downstream heat transfer surfaces.

A portion of the SO_2 present in the flue gas is actually present as SO_3. The SO_2 is frequently either measured or calculated from sulfur in the fuel. The SO_3, as a percentage of the total SO_x, can vary depending on the source, but tends to range between 3% and 10% of the total SO_x.

- In addition to the SO_3 in the incoming flue gas, part of the SO_2 is converted into SO_3 by the SCR catalyst. This percent conversion can vary from less than 1–5%, depending on the operating temperature and the type of catalyst.

The temperature at which the ammonium sulfate salts start precipitating (dew point) is a function of both the ammonia and the SO_3 concentration.

Fig. 9 is taken from API 536 (as seen in Fig. 6). This figure can be used to determine the dew point of the mixtures in and out of the SCR.

Because of capillary action, the liquid in micropores of a catalyst has a lower vapor pressure than the free liquid. This means that ammonium salts have a higher

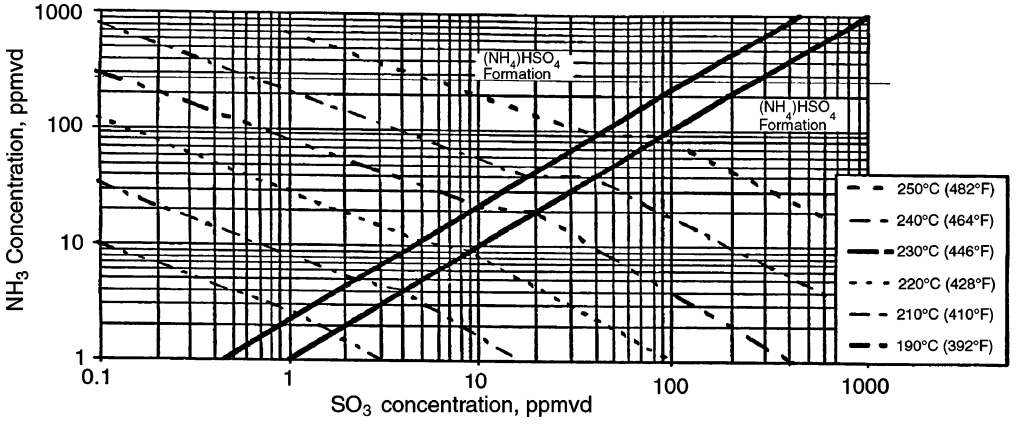

Fig. 9 Ammonium salt dew points 10% water. (Courtesy of API 536.)

dew point in the pores of the SCR catalyst than would be indicated by the curves above.

CATALYTIC SCRUBBING NO_X REDUCTION

NO_2 can easily be scrubbed with caustic solutions, but NO cannot be scrubbed. Most thermal NO_x is NO; so the NO_x in the vent from fired units cannot be scrubbed unless the NO is converted into NO_2. However, many nonfired processes generate NO_2 that can be scrubbed. A number of noncatalytic scrubbing systems have been installed on nitric acid plants and plants generating NO_2 in the process.

There are a number of methods to convert NO into NO_2 so that the NO_x can be scrubbed:

- Adding oxidizing additives to the scrubbing solution.
- Oxidizing the NO in the vapor stream upstream of the scrubber.

Additives to Scrubbing Solution

A number of vendors have proprietary technology for the catalytic oxidation of NO in scrubbing systems. These technologies use liquid-phase oxidizing agents to convert the NO into NO_2, or chelating agents to tie-up the NO in solution. However, the NO must first be dissolved in the scrubbing solution before it can react. So, a large number of theoretical stages are required to dissolve and then react with the NO.

Vapor Phase Oxidation Upstream of Scrubber

An alternate approach to catalytic scrubbing is the injection of ozone, chlorine, or hydrogen peroxide into the flue gas upstream of the scrubber. Ozone is the more powerful oxidizing agent, with chlorine just behind. Hydrogen peroxide is not always practical because of the long reaction times required.

Ozone injection can reportedly achieve up to a 95% NO_x reduction because the ozone reportedly converts both the NO and NO_2 into N_2O_5. N_2O_5 is more soluble in caustic solutions than NO or NO_2. Considerations for ozone injection include:

- The temperature must be low, below 300°F and ideally below 200°F, to minimize decomposition of the ozone.
- The large oxygen generation requirement. Ozone is generated from oxygen. For large systems, the most likely approach is either the installation of a pressure-swing absorption plant to generate the oxygen or pipeline oxygen.
- The low oxygen to ozone conversion: electric arcs convert around 10% of the oxygen to ozone. Only one-third of the ozone reacts; so effectively only 3% of the oxygen ends up as reactive ozone.
- High power requirements—approximately 5.5kW power is required/pound of ozone generated.
- A long residence time is required upstream of the scrubber for complete oxidation.
- Excess ozone slip must be avoided, as the purpose of the NO_x removal is ozone reduction. Ozone is only slightly soluble in water, but will react with any organic compounds in the water to be removed. Ozone will also react with the sulfites present in scrubbers used to remove SO_2, and will thus be destroyed in the scrubber.

GAS TURBINE NO_X REDUCTION[5]

The vent from gas turbines has a much higher percentage of O_2 than heater and boiler vents. The gas turbine vents have around 15% O_2 unless duct burners are installed. Duct burners can reduce the oxygen to about 8–10%. The NH_3 slip for gas turbines is typically specified at 15% O_2.

Common gas turbine NO_x reduction technologies include:

- Steam or water injection: This has been a standard NO_x control approach. This technology works by cooling the flame. Water is more effective than steam, but high purity water must be used to prevent the deposition of solids. Water or steam is added at a ratio to the fuel (water-to-fuel ratio or WFR) in ranges from 0.28 to 2.48 (natural gas fuel).
- Steam or water injection combined with LNB: This can provide a slight improvement over steam or water injection alone.
- Lean combustion and lean premix systems: This technology has been acceptable on new installations in many parts of the country but is not proven on retrofit applications.
- SCR: This technology has been applied in California for a number of years. Nitrogen oxide levels as low as 4 ppmvd, with 5 ppmvd NH_3 slip, have been demonstrated. This is the most expensive NO_x control option, but it can achieve much lower NO_x numbers than the other technologies.

In addition to the technologies listed here, there are a number of technologies under development:

- Catalytic combustion: This technology uses a catalyst to combust the air/fuel mixture at a lower temperature. One test has demonstrated a NO_x level of 5 ppmvd.
- The SCONOXTMGT catalytic reduction process developed by Goal Line Environmental Technologies, LLC:[6] This technology uses a catalyst for the simultaneous reduction in NO_x, VOCs, and CO.

Typical NO_x levels than can be achieved by the different technologies are:

Uncontrolled gas turbine NO_x	150 ppmvd
Water or steam injection	25–90
Lean combustion/lean premix	9–65 (new installations only)
Catalytic	3–5 (but is still experimental)
SCR	3

THERMAL OXIDIZER NO_X REDUCTION

Thermal oxidizers are historically high NO_x generators because the available pressure drop is too low for good mixing between the vent gas and any air and/or fuel. Thermal oxidizer NO_x levels have traditionally run in the 0.2–0.3 lb/MM Btu range. Lower numbers can be experienced if the organics are diluted in an inert, such as nitrogen, to form a low Btu fuel. Numbers can be much higher if the vent contains NH_3 or organic nitrogen, both of which tend to oxidize to NO_x.

The vent stream can be the fuel source or the air source. If the vent stream is dilute organics in nitrogen, then both fuel and air will need to be added.

Ways to control NO_x from thermal oxidizers include:

- Staged combustion: The first stage operates in a reducing mode. Additional air is added to complete the combustion in the second stage. This is the standard approach for vents containing NH_3 or organic nitrogen, because it prevents these compounds from forming NO_x. But it is more expensive because it requires two fireboxes and separate control systems.
- Staged introduction of waste gases: Gases are added at multiple points in the burner section. Staging can reduce peak flame temperatures and localized hot spots.
- Increase ID fan pressure drop and provide better mixing of the air and fuel. A better burner can be used if sufficient pressure drop is available.
- If both air and fuel must be added, it can be done so in a low NO_x burner. The vent stream could be added in a way that dilutes the flame and thus reduces NO_x.
- Water or steam injection into the burner: This has been used inadvertently when the thermal oxidizer also is used to destroy waste water streams.

CONCLUSIONS

Nitrogen oxides, or NO_x, are a combination of nitrogen oxide (NO) and nitrogen dioxide (NO_2). Nitrogen oxides can combine with VOCs to form ozone. For this reason, NO_x control has become the target of the environmental regulatory authorities. The minimization or reduction of NO_x may be required because of ever-tightening regulations and permitting requirements.

The emission control requirements of the existing as well as future regulations requires an understanding of the NO_x emitting sources, pollution prevention opportunities, emission reduction technologies, costs of controls, and impacts on existing operations and plant safety. This article discusses a number of aspects of NO_x control:

- Nitrogen oxides' reductions through process changes and/or pollution prevention activities
- Ultra low NO_x burners
- Burner-related NO_x reduction, such as FGR.
- Postcombustion NO_x control options such as: selective Noncatalytic reduction (SNCR), SCR, and catalytic oxidation/scrubbing.

When evaluating these technologies, one must remember that in many cases retrofitting the NO_x controls can have positive additional benefits. In many instances, the installation of NO_x controls can result in better energy efficiency and lower maintenance requirements.

Numerical Computations for Chemical Process Analysis and Design

David G. Retzloff
Department of Chemical Engineering, University of Missouri–Columbia, Columbia, Missouri, U.S.A.

INTRODUCTION

Chemical industries can be traced back to the Middle East as early as 700 B.C. The Phoenicians in the sixth century B.C. were already making soap, and by the tenth century A.D. the Chinese were producing gunpowder. The early origins of present day chemical manufacturing began in the 17th century A.D. and were dominated by the British in the early 1800s and later by the Germans in the late 1880s. However, it was not until the 19th century that large-scale chemical industries made their appearance. Chemistry as a science originated in the 18th century. Up until the 19th century, chemical plants consisted of pots and kettles in which the chemicals of the times were made. They were built using experience gained from a trial and error approach to chemical processing. A chemical process design based on numerical computations could not be made during this period as the concepts of stoichiometry, Avogadro's number, and the periodic table are required for mass balance. The periodic table first appeared in printed form in 1869. Avogadro's number was proposed in 1811 and the first experimental measurements of this number were done in 1827. Jeremias Richter enunciated the principles of stoichiometry in 1792. These principles were not in widespread use in the 1880s. In addition, one also needed the laws of thermodynamics to write the energy balance equation. To put this into historical perspective, Mikhail Vasilievitch Lomonossov first formulated the laws of conservation of energy and mass in 1748 in a letter to Euler. Antoine Lavoisier published a book entitled Elementary Treatise of Chemistry in 1789, which contained the first concise statement of the Law of Conservation of Mass. It would take the work of Thompson (1798), Carnot (1824), Kelvin (1824), Clausius (1857), Maxwell (1859), Boltzmann (1872), Gibbs (1873), and others to establish the foundations of thermodynamics that are required to formulate the energy balance on a chemical process. The science of chemistry began in the 1830s in Germany and England. It was not until 1888 that chemical engineering formally began as a profession when Professor Lewis Norton introduced *Course X* at the Massachusetts Institute of Technology, thus creating a formal degree in chemical engineering. Hence, it is very unlikely that process design calculations including mass and energy balances, as we currently understand them, were used before 1900. One of the first textbooks on plant design was by Vilbrandt in 1942.[1] The initial design of a chemical plant consisted of bringing together the concepts of the chemistry and mechanical equipment principles to design and build the early chemical plants. The chemical plant designer relied heavily on experience gained from building previous chemical plants and elementary calculations to account for the chemicals used and the chemistry that occurred. The empirical relationships between the equipment size and the quantity of material processed per unit time were being developed in this period. This was followed by the development of the concept of unit operations[2] that established the basics of a chemical plant design, as we know it today. The basic calculations that were done were algebraic in nature and consisted of the steady-state equations for mass and energy for the process equipment. The calculations were performed using a pencil, paper, and a slide rule. The formulation of the design equations frequently resulted in nonlinear algebraic equations, transcendental equations, or differential equations. However, to obtain a numerical solution, these equations are reduced to a system of linear equations of the form $Ax = B$ by appropriate linearization of the original design equations. Thus, the numerical solution of the design equations requires that one establish that the linearized equations converge in a well-defined mathematical sense to the original equations and then solve the linearized equations by using well-established numerical techniques. It is also common to encounter a ''trial-and-error'' approach to solving the design equations that can be reduced to solving a system of linear equations to obtain updated values of those quantities that were determined initially by guessing, combined with a criterion for terminating the calculations when the unknowns are determined with sufficient accuracy. The computations involved are ideally suited to modern computers. As a result, a number of chemical process simulators have become available and simulators are now routinely used to perform chemical process design calculations and evaluate design alternatives. For this reason, numerical methods in

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120026494

chemical process design are also discussed in the context of a process simulator. The process simulator is first discussed, followed by a review of the numerical methods employed and the assimilation of numerical algorithms into process simulators to represent process units that are not already available as library routines.

CHEMICAL PROCESS SIMULATORS

Chemical process design consists of five components. The first identifies the equipment components that will be used in each block of the generic process flow diagram shown in Fig. 1.

The second consists of writing the material, energy, momentum, and empirical equations to determine the composition, flow rates, and size of each piece of equipment needed to process the materials. The third involves solving the resulting equations to determine the specifications for each piece of equipment in the plant design. In the fourth, an economic analysis is made of the proposed plant. The fifth is the optimization of the chemical process design both economically and functionally. In the plant design, several alternative processing strategies are usually considered. The economic analysis normally determines which, if any, of the process alternatives will be implemented. From the point of view of numerical complexity, economic analysis is a straightforward process that involves applying reasonable cost-estimating procedures. However, it is not the focus of this article; emphasis is on the numerical methods used in chemical process design.

Process design has matured to the point that there currently exist a number of commercially available process simulators for chemical process design. For instance, AspenPlus, ChemCad, HySys, ICAS, and Sim42 are among the well-known simulator packages. These simulators have a number of similarities with regard to defining the design to be simulated. They begin with a simulation flow sheet somewhat similar to Fig. 1 in which specific process units are depicted for each of the generic blocks. Streams representing the flow of material from one unit to another connect the process units. The simulation flow sheet consists of a collection of icons to represent the mathematical models and subroutines that describe the entire chemical process. Each process unit is associated with a mathematical model that describes its physical behavior. This is in contrast to the process flow sheet that depicts the process units and their interconnection, and represents the material and energy flows in the chemical process. This simulation flow sheet also depicts the flow of information during the numerical calculations. Current simulators contain thermodynamic models and empirical equations that enable process units to be appropriately sized. Once the simulation flow sheet has been constructed, information on the required thermo-physical properties are supplied to the computational program usually via a graphical user interface (GUI) that allows the user to identify the relevant chemicals that occur so that the necessary thermo-physical data are available from the database for the simulation run. There are two types of simulations that are normally run in process design. The first is the steady-state simulation, which identifies the behavior of the process for a large portion of the plant operation. In this simulation, the flow rates, the composition of flow streams, the thermodynamic state of the material, and the size of each piece of process equipment is determined. The second is dynamic simulation. The object of dynamic simulation is to evaluate the response of process units and the overall process design to disturbances. The viability of control schemes can be examined in dynamic simulation. A simulation flow sheet is required to establish the order in which the equations or modules will be solved in the simulation process. Although the simulation flow sheet is not a numerical method, it is a part of the overall strategy for performing chemical process design

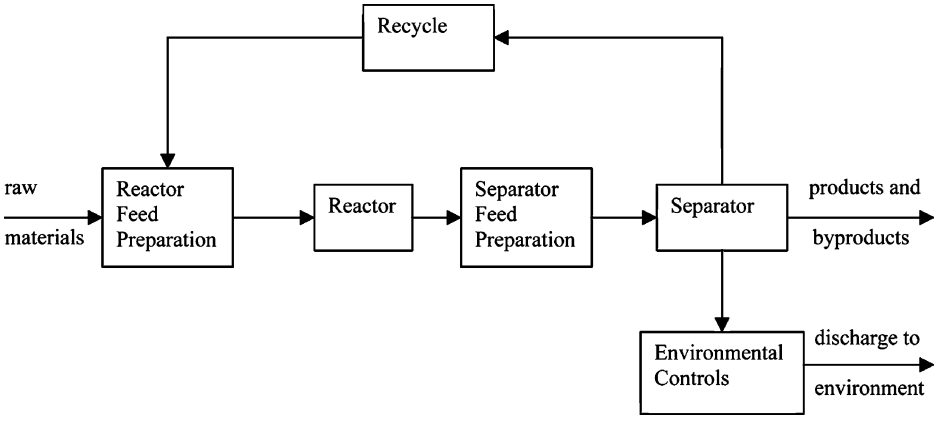

Fig. 1 A generic process flow diagram for chemical plant design.

evaluations. The procedure associated with determining a simulation flow sheet is presented next, followed by a discussion of the numerical methods employed in chemical process plant simulations.

GENERATION OF SIMULATION FLOW SHEETS

In chemical process plant simulations, one of the main considerations is the identification of all the feasible process flowsheets and the elimination of the nonoptimal ones. When only one reaction occurs to produce the required products and only one set of raw materials can be used, the problem of identifying the optimal flowsheets is relatively straightforward and can be accomplished by the application of common sense, heuristics, and analysis. However, when there are multiple reaction pathways to the products and multiple choices for the starting raw materials, the identification of the optimal flowsheets becomes a daunting task. Recently, two algorithmic approaches have been developed to determine the optimal flowsheets. The first approach developed by Friedler et al.[3] is based on graph theory and uses P-graphs to identify feasible flowsheets. Such flowsheets are optimized with respect to an objective function usually based on economic considerations. Optimal flowsheets are used to perform the process simulation. The second approach stems from the ideas of natural selection and genetics and is called a genetic algorithm. Laquerbe et al.[4] discuss the challenges in establishing a natural selection-like criteria for determining the possible flowsheets. The resulting flowsheets are then run on a process simulator to determine equipment sizes, processing conditions, and flow stream information. This information is obtained from computer programs that utilize the numerical methods to solve the mathematical equations that describe the process units that appear in the flowsheet. These numerical methods are the subject of the following section.

NUMERICAL METHODS FOR PROCESS SIMULATORS AND PROCESS DESIGN

Steady-State Simulations

For steady-state simulations, several solution methods have been used. The one most frequently used is the sequential approach. In this method, numerical modules are used that calculate the output stream of a process unit from the input streams coupled with any additional information that is required to uniquely define the performance of the process unit. The simulation treats one unit model at a time. For a simulation flow sheet consisting of interconnected units, the order in which the numerical modules are solved is determined by flow sheet decomposition methods based on process topology. When recycle is present, a tear-stream (guesses for the variables not uniquely determined by the equations describing the process unit) is used to provide an iterative calculation process to determine the tear variables. Convergence is obtained by using fixed-point iteration, Wegstein acceleration, or a quasi-Newton method.

A second solution method is based on an equation-oriented approach, which represents each process unit with a set of equations that are either part of the simulator model library or provided by the user. This method frequently uses an ordered set of equations. Procedures have been developed to automatically determine this information after the simulation flow sheet topology and the complete set of equations have been defined for the process simulation. The equations for all of the process units are solved simultaneously. The equations describing every process in the simulation flow sheet are solved by standard numerical methods that are discussed later. The methods for simulation flow sheet decomposition and equation ordering are covered in the work of Cameron and Hangos[5] and Westerberg et al.[6]

The procedures employed by a simulation package come directly from the approach that would be taken if the chemical process design were to be done by using a handheld calculator and process topology. This should not be surprising as the primary function of the computer is to perform calculations faster than is possible by an individual. The procedure is depicted in Fig. 2. The steady-state behavior of a process unit can be treated as a lumped parameter system. As such, it can be described mathematically in terms of its inputs and outputs. The distillation column and the constant flow stirred tank reactor are examples. In these cases, the equations describing the process equipment are algebraic in nature. If $\{x_1, \ldots, x_n\}$ represent the dependent variables of the problem such as concentration, temperature, and so on, then the equations representing the mass, energy, and momentum equations can be written as

$$\begin{aligned} f_1(x_1, \ldots, x_n) &= 0 \\ f_2(x_1, \ldots, x_n) &= 0 \\ f_3(x_1, \ldots, x_n) &= 0 \\ &\cdots\cdots\cdots\cdots \\ f_n(x_1, \ldots, x_n) &= 0 \end{aligned} \tag{1}$$

This set of equations must be augmented with additional equations to determine the size of the process equipment from empirical relationships. The

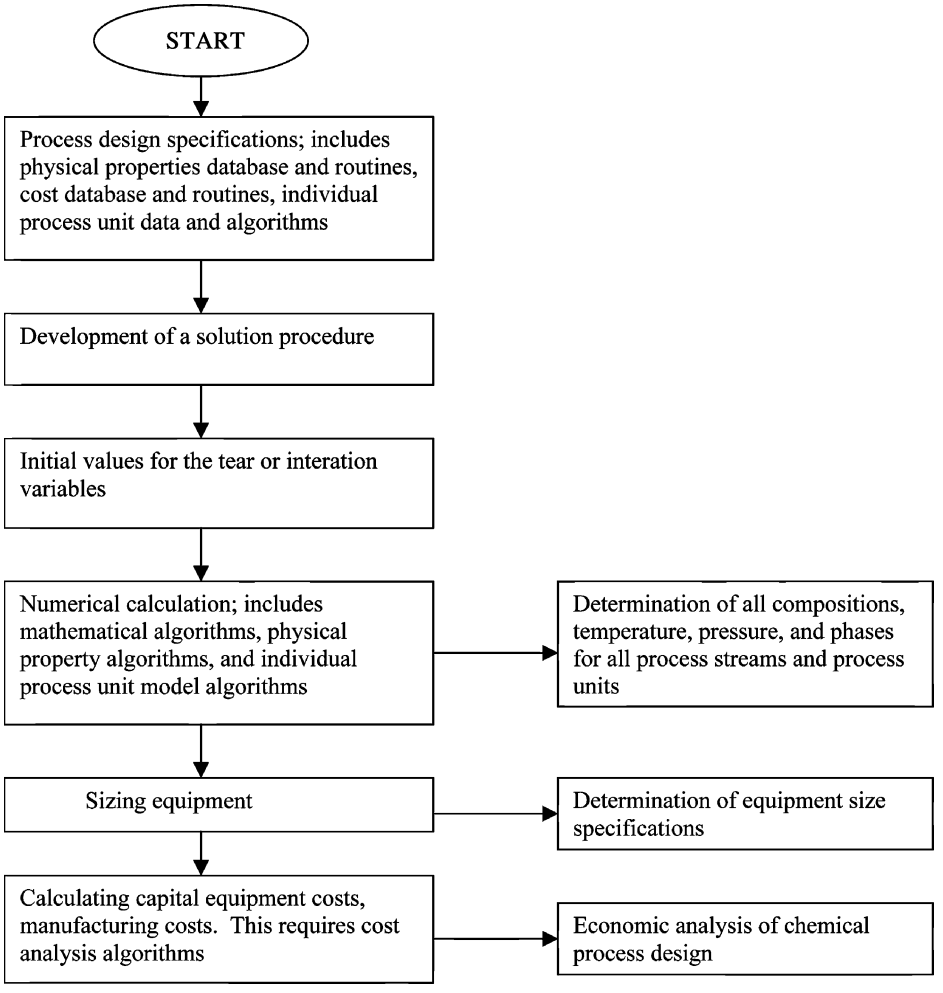

Fig. 2 General solution procedure for process design. This is implemented in process simulator packages.

conceptually simplest method to solve these equations is to rewrite them as

$$\begin{aligned} x_1 &= g_1(x_1, \ldots, x_n) \\ x_2 &= g_2(x_1, \ldots, x_n) \\ x_3 &= g_3(x_1, \ldots, x_n) \\ &\ldots\ldots\ldots\ldots\ldots \\ x_n &= g_n(x_1, \ldots, x_n) \end{aligned} \tag{2}$$

and use a fixed point iteration scheme. Essentially starting with an initial guess for $\{x_1, \ldots, x_n\}$ and substituting into the right-hand-side results in an updated estimate for $\{x_1, \ldots, x_n\}$. Intuitively what is required is that at each step of the iteration, the latest estimates for $\{x_1, \ldots, x_n\}$ are closer in norm to the solution than the previous values. This is called a contraction mapping and a sufficient condition for this to occur is that the equations satisfy a Lipshitz condition.

The conceptually simplest numerical approach to solving the equations is to linearize Eq. (1) about the unknown solution using a Taylor series expansion and rewrite the results to solve for the unknown solution. This yields the vector Newton's iterative method for solving the equations, which takes the form

$$\mathbf{J}^{(k)}\delta^{(k)} = -\mathbf{F}^{(k)} \tag{3}$$

where $\mathbf{J}^{(k)}$ is the Jacobian of Eq. (1) and the terms in Eq. (3) are defined as

$$\delta^{(k)} = \begin{vmatrix} x_1^{(k+1)} - x_1^{(k)} \\ x_2^{(k+1)} - x_2^{(k)} \\ \ldots\ldots\ldots\ldots \\ x_{n-1}^{(k+1)} - x_{n-1}^{(k)} \\ x_n^{(k+1)} - x_n^{(k)} \end{vmatrix}$$

$$\mathbf{J}^{(k)} = \left| \frac{\partial f_i^k}{\partial x_j} \right|$$

$$\mathbf{F}^{(k)} = \begin{vmatrix} f_1(x_1^{(k)}, \ldots, x_n^{(k)}) \\ f_2(x_1^{(k)}, \ldots, x_n^{(k)}) \\ \ldots\ldots\ldots\ldots\ldots \\ f_{n-1}(x_1^{(k)}, \ldots, x_n^{(k)}) \\ f_n(x_1^{(k)}, \ldots, x_n^{(k)}) \end{vmatrix} \tag{4}$$

This is a system of equations of the form $Ax = B$. There are several numeral algorithms to solve this equation including Gauss elimination, Gauss–Jacobi method, Cholesky method, and the LU decomposition method, which are direct methods to solve equations of this type. For a general matrix A, with no special properties such as symmetric, band diagonal, and the like, the LU decomposition is a well-established and frequently used algorithm.

The LU decomposition to solve $Ax = B$ given A and B, is developed in two steps. The two matrices L and U are determined from the equation $LU = A$ and the requirement that U be upper triangular and L be lower triangular with unit diagonal elements. Thus for A an $n \times n$ matrix, A, L, and U have the form

$$A = \begin{vmatrix} a_{11} & a_{12} & a_{13} & a_{14} & \cdots & a_{1N} \\ a_{21} & a_{22} & a_{23} & a_{24} & \cdots & a_{2N} \\ a_{31} & a_{32} & a_{33} & a_{34} & \cdots & a_{3N} \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots\cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ a_{N1} & a_{N2} & a_{N13} & a_{N4} & \cdots & a_{NN} \end{vmatrix}$$

$$L = \begin{vmatrix} 1 & 0 & 0 & 0 & \cdots & 0 \\ l_{21} & 1 & 0 & 0 & \cdots & 0 \\ l_{31} & l_{32} & 1 & 0 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots\cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ l_{N1} & l_{N2} & l_{N3} & l_{N4} & \cdots & 1 \end{vmatrix}$$

$$U = \begin{vmatrix} u_{11} & u_{12} & u_{13} & u_{14} & \cdots & u_{1N} \\ 0 & u_{22} & u_{23} & u_{24} & \cdots & u_{2N} \\ 0 & 0 & u_{33} & u_{34} & \cdots & u_{3N} \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots\cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & 0 & \cdots & u_{NN} \end{vmatrix} \tag{5}$$

The matrices L and U are found by solving $LU = A$. Once L and U are known, the problem $Ax = B$ is solved for x by first solving for y in the equation $Ly = B$ and then solving for x in the equation $Ux = y$. Solving the equation $Ly = B$ for y is known as forward substitution and solving the equation $Ux = y$ for x is called back substitution.

Then, the algorithm becomes

$$\begin{aligned} u_{1j} &= a_{1j} \quad j = 1, 2, \ldots, N; \\ l_{i1} &= a_{i1}/u_{11} \quad i = 2, \ldots, N \\ u_{ij} &= a_{ij} - \sum l_{ik}\, u_{kj}; \quad i = 2, \ldots, N; \\ &\qquad j = i + 1,\ i + 2, \ldots, N \\ l_{ij} &= (a_{ij} - \sum l_{ik}\, u_{kj})/u_{jj}; \\ &\qquad j = 2, 3, \ldots, N - 1; \\ &\qquad i = j + 1,\ j + 2, \ldots, N \end{aligned} \tag{6}$$

$$y_1 = b_1, \quad y_i = b_i - \sum l_{ij}\, y_j; \ i = 2, 3, 4, \ldots, N$$

and

$$x_N = y_N/u_{NN}, \quad x_i = (1/u_{ii})\left(y_i - \sum u_{ij}\, x_j\right); \quad i = N - 1, N - 2, \ldots, 1$$

To improve the accuracy of the calculation, partial pivoting obtained in the form of exchanging rows so that the largest diagonal element is in the row on which one is currently calculating is employed. The column containing the diagonal element of the row that is to be calculated is searched, starting below the diagonal element, for an element larger in magnitude. If such an element is found, the two rows are interchanged so that the largest possible element in magnitude will appear at the diagonal position. This is required to ensure stablity of the algorithm. If zero or a very small element appears at the diagonal position during this computation, then an error message is generated and the calculation terminated to prevent division by zero. To efficiently use the dynamic memory of the computer, the elements of the L and U matrices replace those of the A matrix as they are calculated. However, the diagonal elements of the L matrix that are 1s are not stored. Furthermore, the elements of the b vector are stored as an extra column of the A matrix, which is then called the augmented A matrix. As the elements of the solution vector y are determined, they are stored in the row of the augmented matrix A that originally held the b vector. The x vector is calculated from the elements of the final augmented A matrix. The x vector can be stored as the last column of the augmented A matrix if desired or can be calculated and written to a file. This algorithm is easily written as a parallel program that can be executed in a distributed computer cluster or a Beowulf cluster.

The main drawback of Newton's method is the evaluation of the derivatives of the functions in the expression for $\mathbf{J}^{(k)}$ in Eq. (6). This requirement involves either writing explicit equations for the derivatives and encoding these expressions into the simulator program or numerically computing the derivative. This is computationally intensive and must be iterated until $\|\delta^{(k)}\| < \epsilon$ at which point the solution is $\mathbf{x}^{(k+1)} = \{x_1^{(k+1)} x_2^{(k+1)} \cdots x_n^{(k+1)}\}^T$. Alternatively, one can replace $(\mathbf{J}^{(k)})^{-1}$ in Eq. (3) with an approximation $\mathbf{H}^{(k)}$ that is easy to compute and use iteration to solve the resulting equation

$$\mathbf{x}^{(k+1)} = \mathbf{x}^{(k)} - \mathbf{H}^{(k)}\mathbf{F}^{(k)} \tag{7}$$

Broyden's method and Wegstein's method are two examples of this approach that use different approximations for $(\mathbf{J}^{(k)})^{-1}$. In the former,[7] which is based on the Householder, theorem $\mathbf{H}^{(k)}$ is calculated recursively using the equation

$$\mathbf{H}^{(k+1)} = \mathbf{H}^{(k)} + [(\delta^{(k)} - \mathbf{H}^{(k)}\mathbf{F}^{(k)})(\delta^{(k)})^T\mathbf{H}^{(k)}]/ [(\delta^{(k)})^T\mathbf{H}^{(k)}\mathbf{F}^{(k)}] \tag{8}$$

The latter uses a secant approximation to the derivatives in $\mathbf{J}^{(k)}$. In this method, the functions in Eq. (1) are written as $f_i(\mathbf{x}^{(k)}) = x_i^{(k)} - g_i(\mathbf{x}^{(k)})$ and the method can be written for each component in $\mathbf{x}^{(k+1)}$ as

$$\begin{aligned} x_i^{(k+1)} &= (1 - \omega_i)x_i^{(k)} + \omega_i\, g_i(\mathbf{x}^{(k)}), \\ \omega_i &= 1/[1 - q_i], \\ q_i &= [g_i(\mathbf{x}^{(k)}) - g_i(\mathbf{x}^{(k-1)})]/[x_i^{(k)} - x_i^{(k-1)}] \end{aligned} \tag{9}$$

The Wegstein acceleration is a popular algorithm in chemical process simulators as it is easy to implement in a computer and well adapted to handle recycle calculation when recycle streams are present in the process flow diagram and tear variables are used to solve the recycle loops. However, the convergence of these numerical schemes can be a problem when recycle streams are present. The difficulty arises from the method employed to obtain new estimates of the assumed tear variables in the iteration procedure. If the method for determining successive estimates of the tear variables is equivalent to a fixed-point iteration scheme, then convergence is assured. However, establishing that this is the case is often difficult. These numerical methods are currently included in commercially available chemical process simulators. Thus to take advantage of these numerical procedures, a user has to supply only a mathematical description of any chemical process unit that is not already available in the process simulator. Most simulators are written using FORTRAN as the computer language and have incorporated a procedure for writing user-defined models of chemical processing units and producing object module files for these process units that can be used by the process simulator in connection with its simulation flow sheet and process topology sequencing of the order of solution of the process units.

We next consider the simulation of the unsteady-state behavior of chemical process units.

Dynamic Simulations

Dynamic simulations represent the temporal and the spatial behavior of a chemical process unit in the presence of perturbations or at process startup. There is a natural division in the types of numerical methods used to solve the equations describing the dynamic behavior of the process. In lumped parameter descriptions of the process units, the resulting equations are ordinary time evolution differential equations, whereas for distributed parameter descriptions of process units the resulting equations are parabolic partial differential equations. The numerical methods used to solve these equations are very different and necessitate a separate discussion. Numerical methods used to solve ordinary differential equations describing the dynamics are considered first followed by a discussion of the methods employed to solve evolution equations of the parabolic type.

Dynamics Described by Ordinary Differential Equations

Examples of chemical process units in this category include constant flow stirred tank reactors, separation processes such as distillation columns, liquid–liquid extractors, and other units that are described in terms of the thermodynamic equilibrium stage concept. To develop a numerical algorithm, time derivatives are replaced by finite differences. There are a number of numerical algorithms to solve the resulting equations. For differential equations that are not stiff (the dynamics do not exhibit multiple time scales, i.e., the dynamical behavior does not exhibit time intervals for which the dependent variables change very slowly and other time intervals in which the dependent variables change rapidly with time), the fourth-order Runge–Kutta algorithm is a viable algorithm. For stiff differential equations, either Gear's method or the implicit form of the modified mid-point method discussed by Bader and Deuflhard[8] provide efficient algorithms. The modified mid-point method is presented because the author's experience is that it works well with both stiff and nonstiff differential equations and systems of differential equations even though it

is weakly unstable and the truncation error is of order h^3. The presentation focus is on systems of differential equations, as there is negligible additional effort to formulate the method for more than one evolution differential equation.

Let $\mathbf{Y}$ denote the column vector of physical dependent variables (e.g., mass or mole concentration or temperature) and $\mathbf{Y}_n$ the value of $\mathbf{Y}$ at time $t_n = n\Delta t$, then the system of differential equations under consideration is written as

$$\frac{d\mathbf{Y}}{dt} = \mathbf{f}(\mathbf{Y}) \tag{10}$$

The finite difference algorithm is obtained by replacing the time derivatives by a forward difference, using an implicit rule to evaluate $\mathbf{F(Y)}$ at time t_n, and setting $h = \Delta t$. The result is

$$\mathbf{Y}_{n+1} - \mathbf{Y}_n = 2h\mathbf{f}([\mathbf{Y}_{n+1} + \mathbf{Y}_{n-1}]/2) \tag{11}$$

The numerical algorithm is obtained by linearizing $\mathbf{f}$ about $\mathbf{Y}_n$ and rewriting Eq. (11) as

$$\mathbf{Y}_{n+1} - \mathbf{Y}_n = \mathbf{Y}_n - \mathbf{Y}_{n-1} + 2[\mathbf{I} + \partial\mathbf{f}/\partial\mathbf{Y}]^{-1} \times [h\mathbf{f}(\mathbf{Y}_n) - (\mathbf{Y}_n - \mathbf{Y}_{n-1})] \tag{12}$$

By defining $\Delta_p = \mathbf{Y}_{p+1} - \mathbf{Y}_p$ the computational procedure can be written in the standard form

$$\begin{aligned} \Delta_p &= \Delta_{p-1} + 2[\mathbf{I} + \partial\mathbf{f}/\partial\mathbf{Y}]^{-1}[h\mathbf{f}(\mathbf{Y}_p) - \Delta_p]; \\ & \quad p = 1, \ldots, q-1 \\ \mathbf{Y}_{p+1} &= \mathbf{Y}_p + \Delta_p \end{aligned} \tag{13}$$

with t_q as the final time of the calculation. This is not a self-starting algorithm. To start the calculations, the semi-implicit Euler algorithm is used in the following form:

$$\begin{aligned} \Delta_0 &= [\mathbf{I} + \partial\mathbf{f}/\partial\mathbf{Y}]^{-1} h\mathbf{f}(\mathbf{Y}_0) \\ \mathbf{Y}_1 &= \mathbf{Y}_0 + \Delta_0 \end{aligned} \tag{14}$$

The matrix inversion $[\mathbf{I} + \partial\mathbf{f}/\partial\mathbf{Y}]^{-1}$ can be accomplished by using the LU-decomposition method discussed previously. The final value for $\mathbf{Y}$, i.e., $\mathbf{Y}_q$, can be calculated from Eq. (13), but it is frequently determined by the smoothing operation given by

$$\begin{aligned} \Delta_q &= [\mathbf{I} + \partial\mathbf{f}/\partial\mathbf{Y}]^{-1}[h\mathbf{f}(\mathbf{Y}_q) - \Delta_{q-1}] \\ \langle\mathbf{Y}_q\rangle &= (\mathbf{Y}_{q+1} + \mathbf{Y}_{q-1})/2 = \mathbf{Y}_q + \Delta_q \end{aligned} \tag{15}$$

The algorithm is applied by choosing an interval size that integer divides t_q and is suitable for representing the solution graphically. Then, Eqs. (13–15) are applied across the interval with an appropriately chosen step size, h, so that the desired accuracy is obtained. The process is repeated for each succeeding interval until $\mathbf{Y}_q$ is determined. In general, reducing the step size lessens the error in the approximation of the derivative by a finite difference. Step size halving, recomputing to the same end time, and comparing the values of $\mathbf{Y}$ for two successive time steps provide a measure of the accuracy of the calculation. This procedure for ascertaining the accuracy of the calculation can be computationally optimized by incorporating adaptive step size control and extrapolation to zero step size in the algorithm so that the largest step size possible is used to compute $\mathbf{Y}$ across the interval consistent with the specified error tolerance. Extrapolation to zero step size as the name implies takes the values of $\mathbf{Y}$ for all available step sizes across the interval and extrapolates to the value of $\mathbf{Y}$ at the end of the interval that corresponds to choosing a step size of zero. The extrapolation is done using polynomial functions or rational functions. A complete implementation of this algorithm in C with adaptive step size control and extrapolation to zero step size can be found in Ref.[9].

The presence of recycle streams increases the complexity. A recycle stream in this context is a stream that is returned to a unit. It appears earlier in the simulation flow diagram with no change in physical properties and chemical composition from its process unit of origin. The recycle streams introduce a time delay in the mathematical equations and change the mathematical description from a finite dimensional system of equations to an infinite dimensional system of equations. Discussion of these issues is beyond the scope of this entry.

One method to solve partial differential equations using the numerical schemes developed for solving time dependent ordinary differential methods is the method of lines.[10] In this method, the spatial derivatives at time t are replaced by discrete approximations such as finite differences or finite element methods such as collocation or Galerkin. The reason for this approach is the advanced stage of development of schemes to solve ordinary differential equations. The resulting numerical schemes are frequently similar to those developed directly for partial differential equations.

A frequent application of dynamic simulation is to investigate a proposed control strategy for a chemical plant. It is usually assumed that the plant is operating at steady-state initially. The objective is to investigate the response of the system including controllers to process disturbances and evaluate the performance obtained for different types of control action. What

is required is a map that transforms input (both control actions and upsets) changes into output responses. The method of lines is a good candidate for a numerical scheme to provide the required map.

Dynamics Described by Partial Differential Equations

Examples of chemical process units in this category include plug flow reactors, laminar flow reactors, turbulent flow reactors, plasma reactors, and separation units that are described in terms of the mass transfer concept. To develop a numerical algorithm, the time and spatial derivatives are replaced by finite difference approximations. In general, the time derivative is represented by a forward difference, whereas the second order spatial derivatives are approximated by central differences as follows for the dependent variable Y in Cartesian coordinates:

$$\begin{aligned}
\frac{\partial Y}{\partial t} &= \frac{Y^{n+1}_{jkl} - Y^{n}_{jkl}}{\Delta t},\\
\frac{\partial^2 Y}{\partial x^2} &= \frac{Y^{n}_{j+1kl} - 2Y^{n}_{jkl} + Y^{n}_{j=1kl}}{(\Delta x)^2},\\
\frac{\partial^2 Y}{\partial y^2} &= \frac{Y^{n}_{jk+1l} - 2Y^{n}_{jkl} + Y^{n}_{jk-1l}}{(\Delta y)^2}\\
\frac{\partial^2 Y}{\partial z^2} &= \frac{Y^{n}_{jkl+1} - 2Y^{n}_{jkl} + Y^{n}_{jkl-1}}{(\Delta z)^2},\\
Y^{n}_{jkl} &= Y(t = n\Delta t,\ x = j\Delta x, y = k\Delta y, z = l\Delta z)
\end{aligned} \tag{16}$$

There are a number of numerical algorithms to solve the difference equation representation of the partial differential equations. Implicit algorithms such as Crank–Nicolson scheme where the finite difference representations for the spatial derivatives are averaged over two successive times, $t = n\Delta t$ and $t = (n + 1)\Delta t$, are frequently used because they are usually unconditionally stable algorithms. Most conservation laws lead to equations of the form

$$\frac{\partial \mathbf{Y}}{\partial t} = \nu\Delta^2\mathbf{Y} + \mathbf{F}(t, \mathbf{x}, \mathbf{Y}) \tag{17}$$

which are parabolic equations.

The resulting numerical scheme for solving this system of differential equations can be written in the following general form:

$$\mathbf{Q}_1\mathbf{Y}^{n+1} = \mathbf{Q}_2\mathbf{Y}^{n} + \Delta t\mathbf{G} \tag{18}$$

The ordering for the dependent variables Y^{n}_{jkl} is

$$\begin{aligned}
\mathbf{Y}^{n} = [&Y^{n}{}_{111}, \ldots, Y^{n}{}_{\text{jmax}\,11}, Y^{n}{}_{121}, \ldots,\\
&Y^{n}{}_{\text{jmax}\,21}, \ldots Y^{n}{}_{\text{jmax kmax}\,11}, \ldots Y^{n}{}_{\text{jmax kmax lmax}}]^{\mathrm{T}}
\end{aligned} \tag{19}$$

The exact form of the matrices $\mathbf{Q}_1$ and $\mathbf{Q}_2$ depends on the type of partial differential equations that make up the system of equations describing the process units, i.e., parabolic, elliptic, or hyperbolic, as well as the type of applicable boundary conditions, i.e., Dirichlet, Neuman, or Robin boundary conditions. The matrix $\mathbf{G}$ contains the source terms as well as any nonlinear terms present in $\mathbf{F}$. It may or may not be averaged over two successive times corresponding to the indices n and $n + 1$. The numerical scheme solves for the unknown dependent variables at time $t = (n + 1)\Delta t$ and all spatial positions on the grid in terms of the values of the dependent variables at time $t = n\Delta t$ and all spatial positions. Boundary conditions of the Neuman or Robin type, which involve evaluation of the flux at the boundary, require additional consideration. The approximation of the derivative at the boundary by a finite difference introduces an error into the calculation at the boundary that propagates inward from the boundary as the computation steps forward in time. This requires a modification of the algorithm to compensate for this effect.

From an elementary point of view, Eq. (18) can be solved for $\mathbf{Y}^{n+1}$ by multiplying Eq. (18) by the matrix $\mathbf{Q}_1^{-1}$. From the computational point of view, this is not necessarily the most efficient approach. If $\mathbf{F}$ consists of only nonhomogenous terms, then the nonhomogenous alternating direction implicit schemes such as the Douglas–Gunn scheme[11] are computationally attractive. When $\mathbf{F}$ contains nonlinear terms in the dependent variables, a Newton-like scheme is employed. Similar methods are used when the partial differential equations are of the hyperbolic or the elliptic type. The key issues in developing a numerical scheme for solving these balance equations are stability, convergence, and the order of accuracy of the numerical scheme in the variables Δt, and the spatial step sizes. The numerical scheme must be both stable and convergent. In addition, all terms in the partial differential equations should be approximated consistently in the spatial and time step sizes. Multigrid methods that employ two distinct mesh sizes with the operations of prolongation and retraction as well as finite element methods have also been successfully used to obtain numerical solutions for the balance equations.

Recycle streams introduce time delays that appear in the boundary conditions. A discussion of the effects of

recycle streams on the stability and the convergence of the numerical scheme is beyond the scope of this entry.

COMPUTATIONAL CONSIDERATIONS

Solving chemical plant design problems involves developing a numerical scheme that is stable and convergent as well as implementing the resulting algorithm on a computer. The basic consideration is the time required for execution of the algorithm and printing out the results in appropriate format. A large number of design simulations and computations of moderate complexity can be handled by modern personal computers running at speeds in the gigahertz range. Beginning 1997, distributed computing clusters (frequently called Beowulf clusters) composed of off-the-shelf components capable of supercomputer speeds have made their debut and are now commonplace and commercially available. The underlying communication programs necessary for distributed computing are at a mature state of development and freely available as packages under the name of MPI (message passing interface) and PVM (parallel virtual machine). To realize the power of cluster computing, parallel programming is required. To date, there are a few commercial packages available that take a program written in serial format and translate it to a parallel program. However, the most efficient parallel programs are still written by skilled programmers. Most computational programs are not what is termed massively parallel but are rather composed of segments that can be run in parallel separated by sequential segments. At the moment, this requires the skills of an experienced programmer to write a time efficient parallel code. As a result, chemical process simulators have not yet been written to run on Beowulf-type clusters. This will undoubtedly change in the future as translators from serial to parallel computer code become more efficient and cluster computing becomes commonplace. These computer clusters can handle computationally intensive design simulations and have the advantage that they can be constructed using standard personal computers or standard personal computer parts making them economically attractive.

CONCLUSIONS

Models of the steady-state behavior of a chemical plant consist of a system of algebraic equations that can be solved by well-established algebraic numerical methods. These can be implemented on computer clusters, which can achieve supercomputing execution times. Recycle streams require the use of tear variables and an iterative numerical scheme to obtain a solution. The convergence of the numerical algorithm is an important consideration. Several numerical schemes can be used to obtain convergence including Newton's, Broyden's, and Wegstein's methods. Dynamic simulations are required to obtain the time-dependent behavior of the chemical plant. One of the primary objectives of dynamic simulations is the evaluation of proposed control systems and strategies. Chemical process units whose descriptions do not involve spatial dependence give rise to ordinary differential equations that can be numerically solved by finite difference methods such as the modified midpoint method, Gear's method, or the Runga–Kutta method. Gear's method and the modified midpoint method are required for units described by stiff differential equations. Recycle streams introduce time delays into the resulting differential equations, thereby increasing the complexity of the description. When the spatial dependence of the dynamic behavior of a chemical process unit must be considered, partial differential equations arise. Numerical schemes based on implicit finite difference approximations are used to obtain convergent stable algorithms. Convergence, stability, and consistency are important considerations when choosing a particular numerical scheme. The consistency requirement allows one to estimate the time- and spatial-step sizes needed to meet accuracy considerations. Numerical schemes for partial differential equations inevitably lead to systems of algebraic equations for the unknown process variables that are solved numerically by Newton-like methods or explicit matrix methods. When a computer is used in generating the numerical solution, a major consideration is the computational time required. Usually, iterative methods are faster, i.e., require less computational time, than explicit methods for a required numerical accuracy. Currently, computer clusters employing message passing can be used to reduce the computational time. To utilize the supercomputer power of a cluster, the numerical scheme must be written in parallel computer code for execution on the cluster. Computer software is available for converting serial computer code to parallel code. This reduces the effort required to obtain a parallel program. However, experienced programmers currently produce the most efficient (shortest execution time) parallel programs. This is because of the requirement that writing efficient parallel code requires that all parts of the program that can be executed in parallel by multiple CPU (central processing units) must be identified and the associated communication overhead among the CPUs be taken into account. As numerical libraries of efficient parallel code for specific numerical tasks such as matrix multiplication, matrix inversion, and the solution to differential equations become available, producing parallel

code will become a routine task and the use of computer clusters will be a standard practice.

INTRODUCTION

Chemicals provide enormous benefits to American society but impose well-recognized risks to the health and safety of plant workers. In addition, there are also risks to adjacent neighborhoods and those living and working near transportation routes linking chemical production, storage, and distribution facilities. All these risks can be managed through effective programs for onsite and offsite emergency preparedness (EP). This entry begins by addressing the demands chemical emergencies place on facility personnel and community emergency responders. It then turns to the processes of developing an emergency preparedness program, formulating an emergency operations plan, and establishing coordination among facility departments and with public sector organizations. This is followed by a discussion of methods for conducting hazard/vulnerability/risk analyses, emergency assessment analyses, expedient hazard mitigation analyses, personnel and population protection analyses, and incident management analyses. The entry concludes with a discussion of methods for developing plans and procedures; establishing emergency operation centers (EOCs); conducting and evaluating training, drills, and exercises; and disseminating risk information.

UNDERSTANDING EMERGENCY DEMANDS

Chemical incidents impose specific agent-generated and response-generated demands on emergency response organizations.[1] Agent-generated demands are caused by the hazard agent itself and threaten human health and safety, property, and the environment. By contrast, response-generated demands are caused by the need to coordinate the activities of the many individuals and organizations seeking to respond to the incident. Major disasters elicit a significant outpouring of assistance, frequently creating convergence at an incident scene. Moreover, when incident demands deviate from planners' expectations, emergency response organizations generally improvise adaptive responses within existing organizations and—in some cases—new organizations emerge to meet unforeseen needs.

Contrary to their expectations, emergency responders typically find households responding to disasters with rational information seeking and adaptive action. Indeed, panic, shock, passivity, disorientation, and antisocial activities such as looting are *extremely* rare.[2] Not only is household emergency response generally rational, it also is frequently prosocial. That is, many individuals, households, and larger organizations volunteer to help during emergencies. Unfortunately, the convergence of unexpected volunteers, the emergence of new organizations, and the improvisation of unplanned responses can hinder an orderly emergency response. Consequently, facility EP coordinators need to develop emergency programs in coordination with community emergency managers and also participate in community-wide emergency response planning, training, and exercising.

To address the demands of major incidents, emergency response organizations must perform four basic types of functions—emergency assessment, expedient hazard mitigation, personnel/population protection, and incident management.[3,4] Emergency assessment actions characterize the nature and the magnitude of an incident by evaluating conditions in the physical and social environment. Expedient hazard mitigation involves *preventive* and *corrective actions* that limit the magnitude of hazard impacts by controlling the source (e.g., plugging leaks in hazmat containers) or the spread (e.g., diking around spills) of hazards. Personnel population protection actions preserve safety and health; for example, by requiring emergency responders to wear respirators and implementing evacuations of community residents. Finally, incident management actions ensure that the emergency assessment, expedient hazard mitigation, and population protection actions are performed promptly and effectively. In addition, incident management actions ensure responders are

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120040387

supported by adequate emergency resources such as support staff, facilities, equipment, and materials.

DEVELOPING AN EP PROGRAM

A capability for prompt and effective emergency response is based on the quality of the facility's EP program, which must have clear support from the plant manager and any levels of management above that. In many instances, the responsibility for facility EP is assigned to the manager for health, safety, and environment. Whoever is assigned this responsibility, the EP coordinator must understand the duties of his or her position: specifically, who does the EP coordinator report to, who reports to him/her, what duties for the position are specifically listed in the job description, and what are the specific qualifications (education, training, and experience) that are listed in the job description.

Once the basic expectations of the job have been established, EP coordinators should develop EP program plans that systematically direct their efforts over the course of each year. The National Fire Protection Association's standard for emergency management programs, NFPA 1600, lists a set of criteria that can be used to guide this development effort.[5] In the public sector, the Federal Emergency Management Agency[6] has advised local emergency managers to set annual goals in each of the major programmatic areas for which they are responsible. The next step is to conduct organizational capability analyses that assign the tasks needed to perform the emergency response functions to organizations having the resources needed to perform those tasks. There is relatively little guidance on performing organizational capability analyses, but the best procedure is to contact subject matter experts (SMEs) for information about each emergency response function.[7] In the case of emergency public information, for example, this would include public safety and health officials and members of the local news media. Once the SMEs have been identified, they can be asked what specific tasks are needed to perform each function under different emergency scenarios (e.g., fire, explosion, toxic chemical release). For each task, they can then be asked to identify the personnel, facilities, equipment, and materials needed. Emergency planners should exercise caution when asking SMEs about performance of tasks under conditions they have not previously experienced. Fire brigade members, for example, might assume their experience in handling small-scale fires and chemical spills will generalize to large-scale incidents involving major conflagrations threatening to cause catastrophic failures of toxic chemical tanks. Thus, when the hazard/vulnerability/risk analysis identifies disaster conditions that might be significantly different from the facility's previous experience, the EP coordinator should seek outside expertise.

This capability assessment is likely to identify satisfactory levels of capability in some areas but not in others. Thus, the EP coordinator should document the capability shortfall and devise a multiyear development plan to reduce it. Emergency preparedness is often a low priority for most organizations; hence, the limited funds available for this activity make it likely that a multiyear (typically five year) development plan will be needed that sets specific annual milestones. Once the annual milestones have been set, facility EP coordinators should monitor their programs' achievement of these objectives.

ESTABLISHING COORDINATION WITH FACILITY DEPARTMENTS AND PUBLIC SECTOR ORGANIZATIONS

A facility EP coordinator can facilitate the development of EP program but cannot implement it alone. Ultimately, EP is the responsibility of the facility's operational departments; hence, the EP coordinator must staff the emergency response organization from the employees in these departments. In addition, the EP coordinator should work with the local fire department, local emergency management agency (LEMA), and local emergency planning committee (LEPC). Obviously, coordination with the local fire department is essential to ensure the adequacy of offsite support (e.g., number of personnel and apparatus) and compatibility of equipment (e.g., hose fittings and radio frequencies). However, there also is a need to ensure the compatibility in the structure of the onsite and offsite emergency response organizations. Moreover, coordination with the LEMA and LEPC is also important in achieving a realistic appraisal of the geographic areas at risk if there are incidents at the facility, the nature of the special facilities and populations that could be affected by these incidents, and the ability of community agencies to provide the emergency response resources needed to respond to these incidents.

CONDUCTING HAZARD/VULNERABILITY/ RISK ANALYSES

Incidents involving fires, explosions, or chemical releases can be initiated by internal (accident or sabotage) or external (geophysical, meteorological, or hydrological events; or terrorist attacks) causes. The types of hazards that can occur at a chemical facility, their initiating events, their consequences, and their likelihoods of occurrence are assessed using hazard analysis. This process begins by identifying dangerous

chemicals (i.e., those that are threats because of their flammability, reactivity, or toxicity), their locations, and the quantities at those locations. Once the chemical inventory has been developed, this information can be used to assess the threats these chemicals pose to the facility, its workers, its neighbors, and the environment. In the case of Extremely Hazardous Substances defined under SARA Title III, Vulnerable Zones (VZs) can be computed using data on the chemical's toxicity, its quantity available for release, the type of spill (liquid or gaseous), the postulated release duration (e.g., 10 min), assumed meteorological conditions (wind speed and atmospheric stability), and terrain (urban or rural). Available methods include manual computations,[8] *ALOHA*,[9] see information about *CAMEO* at www.epa.gov/ceppo/cameo], or *RMP*Comp* at ⟨yosemite.epa.gov/oswer/ceppoweb.nsf/content/rmp-comp.htm⟩.

Once the radii of the VZs for the different chemicals have been computed, these can be overlaid onto a map with the release point in the center of the circle and the radius drawn around it (see Fig. 1). Moreover, there will also be a rectangular VZ surrounding the transportation route to the facility. The facility and the transportation route VZs can then be examined to identify areas of residential, commercial, and industrial land use (see Ref.[10] for an analysis of hazardous waste transportation to an incinerator). In particular, special attention should be given to identifying the locations of special facilities whose inhabitants have limited ability to receive warnings or to take protective action (Table 1).

CONDUCTING EMERGENCY ASSESSMENT ANALYSES

The facility emergency response organization must be prepared to promptly and accurately assess the nature and magnitude of an emergency. As Table 2 indicates, this includes detecting a threatening situation promptly, safely conducting a reconnaissance to obtain critical information about the product and container, and monitoring environmental conditions that affect the direction and extent of any fires, explosions, or releases to air, water, soil, or groundwater.[4,12,13] Data from the reconnaissance and environmental monitoring should be integrated into an emergency classification system (e.g., Level I: Threat to a single building; Level II: Sitewide threat; Level III: Minor offsite threat; Level IV: Major offsite threat) that allows offsite emergency response organizations to anticipate the need for providing technical assistance to the facility or implementing population protective actions. An emergency classification system can be constructed using the information from the hazard/vulnerability/risk analysis by overlaying the radius of the VZ onto a site map. For example, a chemical whose VZ lies entirely within a single building on the facility site can produce only a Level I incident.

Emergency assessment also includes assessing any damage that might increase the severity of the threat, monitoring any fires or releases that occur, and projecting the potential impacts of these events to offsite locations.[4,12,13] These damage assessments should be communicated to offsite agencies so that they can be aware of the potential for any minor incidents (e.g., Level I or II) escalating to Level III or IV. The EP coordinator should ensure adequate personnel, facilities, and equipment to support the emergency assessment function—especially equipment for fire and chemical release detection and meteorological monitoring.

CONDUCTING EXPEDIENT HAZARD MITIGATION ANALYSES

The facility emergency response organization must be prepared to assess the need for, and implement, actions

to prevent fires, explosions, or releases. It must also be able to limit the severity of such events when they do occur and terminate them as soon as possible. As Table 2 indicates, there are four principal methods of expedient hazard mitigation—leak control, spill control, fire control, and container stabilization.[12] *Leak control* limits the rate at which chemical product escapes from containment to the environment. In turn, there are two types of leak controls: direct controls and indirect controls. Direct controls restore the integrity of a compromised container by patching, plugging, overpacking, or crimping; indirect controls include product shut-off, product transfer, and product displacement.

Spill control limits the rate at which a chemical disperses through the environment. Gaseous releases to the atmosphere can be controlled by ventilation, dissolution, dispersion, and diversion. Liquid releases to ground can be controlled by diking, retention, adsorption, and neutralization. Liquid releases to water can be controlled by damming, diverting, booming, and absorption. Solid releases to ground can be controlled by blanketing. By contrast, *fire control* involves extinguishment, exposure (adjacent structures) protection, and controlled burn.

Finally, *container stabilization* attempts to restore an unstable container to a stable physical location or orientation. Container stabilization is principally used in transportation incidents, but natural hazards, such as severe inland flooding and earthquakes, can displace stationary tanks from their foundations.[13] As in the case of emergency assessment analyses, the EP coordinator must ensure the availability of adequate personnel, facilities, equipment, and materials to support expedient hazard mitigation.

CONDUCTING PERSONNEL AND POPULATION PROTECTION ANALYSES

As Table 2 indicates, the facility emergency response organization and the offsite emergency response organization have many personnel and population protection tasks to perform in a chemical emergency. Onsite actions focus on protecting members of the onsite emergency response organization, whereas offsite actions focus on prompt initiation of protective actions for the population at risk. Protection of the onsite emergency response organization requires the use of personal protective equipment (PPE) and the implementation of procedures to ensure the safety of those attempting to assess the incident, fight fires, prevent explosions, and control releases. In addition, it is important for facility EP coordinators to recognize that many major emergencies require prompt and effective protective action by local residents and special facility populations near the facility. Indeed, facility

personnel might sometimes need to warn offsite populations at the same time as they notify local officials of an emergency. Consequently, EP coordinators must understand the process for offsite population protection. First, as Table 2 indicates, one or more protective action recommendations must be selected that generally involves a choice between evacuation and sheltering in-place. The most common protective action for environmental hazards, evacuation, appears deceptively simple: just warn everyone in the risk area to leave. Indeed, a rapid evacuation is relatively easy to achieve when the risk area population is small, all evacuating households are united and have their own vehicles, and the capacity of the evacuation route system is high.[3,14,15] However, evacuation can take many hours to clear the risk area when the population is large in relation to the capacity of the evacuation route system. Indeed, evacuation time estimates for some major urban areas around commercial nuclear power plants, where the VZs are 10 miles in radius, have been

estimated to exceed 30 hr.[16] By contrast, sheltering in-place is the most common protective action recommendation for some hazards (e.g., tornadoes), but the criteria for choosing between evacuation and sheltering in-place can be complex for chemical emergencies. For further discussion, see Ref.[3].

In addition, the risk area population must be warned about the hazard. The seven primary warning mechanisms are face-to-face warnings, mobile loudspeakers, sirens, commercial radio and television, tone alert radio, newspapers, and telephones.[3] These warning mechanisms differ in their precision of dissemination, penetration of normal activities, specificity of the message, susceptibility to message distortion, rate of dissemination over time, receiver requirements, sender requirements, and feedback (verification of receipt). EP coordinators should work with local emergency managers to select the most appropriate warning mechanisms based on the characteristics of the jurisdiction (e.g., population density and wealth) and the hazards to which it is exposed (especially speed of onset and scope of impact).

Unlike the other emergency response functions, population protection does not require the EP coordinator to ensure the availability of adequate personnel, facilities, equipment, and materials because this is the responsibility of the offsite emergency response organization. Nonetheless, facilities sometimes provide technical or financial support for the development of warning systems and implement these warning systems in rapidly escalating incidents.

CONDUCTING INCIDENT MANAGEMENT ANALYSES

As Table 2 indicates, incident management involves a series of tasks that are virtually identical for both the onsite and the offsite emergency organizations. The similarity in tasks for the two otherwise quite different organizations arises from the fact that incident management is the function that copes with the response-generated demands of the emergency. Although the requirements of most tasks listed in Table 2 are self-evident, it is important to distinguish internal direction and control from external coordination because the former refers to authority relations with teams inside the facility emergency response organization, whereas the latter refers to collaborative (nonhierarchical) relationships with offsite organizations. Similarly, it is important to understand that population warning disseminates information about the hazard, protective action recommendations, and sources of further information to those at risk. By contrast, public information is directed toward those segments of the population that are *not* at risk. As is the case with the other emergency response functions, the EP coordinator must ensure the availability of adequate personnel, facilities, equipment, and materials to support incident management.

DEVELOPING PLANS AND PROCEDURES

For many years, the chemical industry has provided technical guidance to support the development of facility emergency response plans. For example, the Chemical Manufacturers Association *CAER Program Handbook*[17] defined the planning standards for an emergency response plan as including: 1) assignment of organizational responsibilities; 2) risk evaluation; 3) notification procedures and communication systems; 4) emergency equipment and facilities; 5) assessment capabilities; 6) protective action procedures; 7) public education and information; 8) postemergency procedures; 9) training and drills; and 10) program maintenance. In this regard, the *CAER Program Handbook* complements federal government guidance that is oriented primarily toward local government agencies for the development of radiological emergency response plans,[18] chemical incident response plans,[7] or all-hazards emergency operations plans.[19]

More recent guidance has promoted the adoption of the incident command system/incident management system (ICS/IMS), which seeks to establish a universal command structure for emergency response under the authority of a single incident commander.[20] The incident commander (IC) can be supported by a unified command consisting of representatives from other response organizations (e.g., local fire chief, state environmental protection representative, and federal coordinating officer). The IC directs an emergency response organization consisting of five sections. Command consists of the IC and the information, safety, and liaison functions. The operations section, which is responsible for tactical operations, operates a staging area for mobilizing personnel reporting to the scene and can comprise divisions (defined geographical areas), functional groups (assigned to specific tasks such as leak control, evacuation management, and emergency medical services), or combinations of units in task forces and strike teams. The Planning section has a resources unit, situation unit, demobilization unit, and documentation unit. The Logistics section has a service branch and a support branch. The service branch contains a communications unit, a medical unit, and a food unit, whereas the support branch contains a supply unit, a facilities unit, and a ground support unit. Finally, there is a finance and administration section that has a time unit, a procurement unit, a compensation and claims unit, and a cost unit.

Incident command system/incident management system provides two important advantages—unified command and standardization of roles. Facility EP Coordinators should understand how their emergency response organizations will link with the local version of ICS/IMS adopted by local government agencies so that the onsite and the offsite organizations can work together effectively. For further discussion of ICS/IMS, see Refs.[21–23].

ESTABLISHING EOCs

Emergency Operations Centers are facilities that provide technical assistance to emergency responders at the scene of an incident. Emergency operations centers, which are permanently located in areas expected to be safe from hazard exposures, are important because the resources needed to respond to a major incident can be widely dispersed; hence, the EOC relieves the IC and his/her command staff of the need to locate them. Moreover, many organizations participate in the incident response and each organization must have a capability for obtaining and processing timely information about onsite and offsite aspects of the incident. This capability is established by collocation of senior decision makers with telecommunications and information processing equipment in the EOC. An EOC should be designed to provide enough space to house the emergency response functions taking place within it and allocate this space so that its staff are located close to the equipment, information, and materials they need. For further discussion of EOC design, see Ref.[24].

CONDUCTING AND EVALUATING TRAINING, DRILLS, AND EXERCISES

Training provides the means by which emergency responder skills are upgraded; hence, the facility emergency response plan should describe the content and the frequency of the emergency training to be provided for all response personnel—including members of the senior management team. Classroom instruction should include discussion of each individual's assigned tasks and a review of the procedures for which each individual is responsible. To promote flexibility in organizational response, all emergency personnel should receive an explanation of the nature of the hazard, measures they should take to ensure their own personal protection, and an overview of the emergency response plan and the rationale for its components.[25]

Once a training program has been implemented, it must be evaluated using drills, exercises, and (occasionally) responses to actual incidents. Drills and exercises involve the measurement of performance over varying degrees of scope. Drills usually involve the performance of a single individual or a small team over a period of minutes to hours, whereas exercises and incidents involve the performance larger organizations and multiorganizational networks over a period of hours to days.

In preparing for drills and exercises, the first task is to specify clearly what is to be tested.[26] Typically, drills and exercises are used to test people, facilities, and equipment on tasks that are difficult, critical, and are performed infrequently. Exercises are more comprehensive than drills because they are used to test people's ability to perform both taskwork and teamwork. While the former is obviously the ability to competently perform each separate aspect of the emergency response, the latter is the ability to allocate resources and schedule tasks to achieve a coordinated performance that is efficient, effective, and timely.[27]

Walk-through drills should be conducted to ensure procedures are current (e.g., testing notification procedures to verify telephone numbers are current), or determine the capabilities of individuals or small teams to perform their designated emergency duties. In tabletop exercises, agency heads and assistants gather informally to discuss solutions to very general emergency situations presented by the local emergency manager. Response actions are described but not actually implemented.

Functional exercises are conducted using the staff from a single department to perform a limited number of specific tasks in response to a more detailed scenario than is used in drills. By contrast, full-scale exercises involve staff from many departments performing a wide range emergency response functions. The scenario for a full-scale exercise might address initial detection, emergency classification, activation of emergency response organizations, continuing emergency assessment, communication and coordination with other responding organizations, protective response (including protective action decision making and implementation, and medical support), and termination of the emergency. The scenario for a full scale exercise is often very detailed and is usually constructed by a training committee or an external consultant. Functional exercises and full scale exercises can be announced in advance, but should be based on emergency scenarios whose contents are withheld from all responding personnel.

All three forms of exercises (tabletop, functional, and full-scale) and incident responses will benefit from an immediate oral and later written critique by the players, controllers, and evaluators.[26] The discussions should address whether the response was consistent with the emergency plan and procedures and, if it is an exercise critique, whether the exercise objectives

were met. If there were deviations from the emergency plan and procedures, the participants should discuss why this occurred. In some cases, the conclusion will be that the emergency plan or procedures need to be revised. In other cases, the solution will be to reassign personnel, improve personnel training, or upgrade facilities and equipment. The results of the critique should be documented in a written report that contains specific recommendations for action, assignment of responsibility for implementation, and a schedule for completion. More detailed guidance on this process can be found in Refs.[26,28].

DISSEMINATING RISK INFORMATION

Risk communication should be a process by which stakeholders share information about hazards affecting a community.[29] Stakeholders include businesses and households that are vulnerable to a specific hazard, as well as community and industry personnel who are responsible for managing a hazard in ways that reduce the risk to an acceptable level. Communication among stakeholders can be analyzed in terms of who (source) says what (message), via what medium (channel), to whom (receiver), and directed at what kind of change (effect). Sources (authorities, news media, and peers) are perceived primarily in terms of expertise and trustworthiness. Messages vary in their content—especially their information about a hazard, its characteristics (e.g., magnitude, location, and time of impact), alternative protective actions and their attributes (efficacy; cost; safety; and requirements for time and effort, knowledge and skill, tools and equipment; and cooperation from others).

The information channels available for use include print media such as newspapers, magazines, and brochures; electronic media such as television, radio, telephone, and the internet; and face-to-face interaction through personal conversations and public meetings. The distinctions among these information channels are important because they differ in the ways in which they accommodate the information processing activities of the receivers. For example, orally presented information is ephemeral and is easily lost unless otherwise recorded, whereas written information inherently provides a record that can be referred to at a later time.

Receivers differ in many respects, but the most important of these are psychological characteristics that have direct effects on the communication process. For example, receivers differ in their perceptions of source credibility, access to communication channels, prior beliefs about hazards and protective actions, ability to understand and remember message content, and access to resources needed to implement protective action. The effects of a message on a receiver include attention, comprehension, acceptance, retention, and action.

Finally, feedback is an important component of the communication model because some attempts are unidirectional, whereas others are interactive. Unidirectional communications appeal to many EP coordinators because they appear to be less time consuming and sometimes this actually is the case. Frequently, however, interactive communication is needed for receivers to indicate that they have not comprehended the message that was sent or that the message sent by the source did not satisfy their information needs.

It is important to recognize that risk information is transmitted through social networks.[2] Thus, a warning message is likely to be relayed from the original source (e.g., an authority) through an intermediary (e.g., a risk area resident) to an ultimate receiver (e.g., a peer such as a friend, relative, neighbor, or coworker) in addition to—or even instead of—being transmitted directly from the original source to the ultimate receiver. In addition, warning messages are often transmitted through peer networks and requests for confirmation or further information transmitted back to authorities and the news media.

There are six basic functions that should be addressed in a community risk communication program.[29] These are strategic analysis, operational analysis, resource mobilization, program development, program implementation for the continuing hazard phase, and program implementation for the escalating crisis and emergency response phases.[29] The first function, strategic analysis, involves four tasks. The first task is for facility EP coordinators to conduct hazard/vulnerability/risk analyses to identify the facility's hazards and the neighborhoods nearby that are at greatest risk. During the second task, EP coordinators should become aware of the community context to identify emergency response relevant variables such as the ethnic composition, communication channels, perceptions of authorities, and level of education in nearby neighborhoods. The third task is for EP coordinators to work with the LEPC to identify the community's prevailing perceptions of environmental hazards and hazard adjustments. During the fourth task, EP coordinators should set appropriate goals for the risk communication program, beginning with establishing a basic awareness of the hazards to which the facility exposes the community, continuing through explanations of alternative hazard adjustments, and concluding with development of active citizen support for the LEPC.

Operational analysis comprises five tasks, the first of which is to identify and assess feasible hazard adjustments for the community and its households/businesses. To accomplish this objective, EP coordinators

can access resources such as the American Red Cross web site at http://www.redcross.org/services/disaster/beprepared, where they can find information about recommended household adjustments for a wide range of hazards. During the second task, EP coordinators should work with the LEPC to identify ways to provide incentives, sanctions, and technological innovations for these hazard adjustments. During the third task, EP coordinators should work with the LEPC to identify the available risk communication sources in the community. In choosing among authorities (local, state, and federal government agencies; facility operators; and scientists), news media (especially newspapers, television, and radio), and peers (friends, relatives, neighbors, and coworkers), EP coordinators should recognize that official sources are generally the most credible and message recipients infer credibility from the source's credentials (e.g., job title and educational degrees), acceptance by other sources of established credibility, or previous history of job performance.[3] However, the degree of expertise attributed to different sources varies from one hazard to another and by gender, ethnicity, and other demographic characteristics.[30–32] During the fourth task, EP coordinators should work with the LEPC to identify the available risk communication channels in the community from electronic (radio, television, and, increasingly, web sites) and print (newspapers, magazines, brochures, posters, telephone book inserts, comic/coloring books, and reports) media. Additional communication channels include informal face-to-face conversations (drop-in hours at local libraries, newsletters, information booths at local events, and shopping malls) and formal meetings with or without audiovisual presentations such as computer simulations, slide shows, and films. During the fifth task, EP coordinators should work with the LEPC to identify the differences among audience segments in terms of their access to and preferences for different types of media (e.g., radio) and specific channels (e.g., specific radio stations) within each medium, and if there are any audience segments with language barriers.

There are five steps in *resource mobilization*. During the first task, EP coordinators should obtain the support of senior management by "selling" the importance of community hazard vulnerability and identifying hazard mitigation, emergency preparedness, emergency response, and disaster recovery as effective solutions. In the second task, EP coordinators should enlist the participation of other departments in their facilities and work with the LEPC to do the same with government agencies. EP coordinators should adopt a collaborative strategy to ensure all chemical facilities within a community are aware of any risk communication programs being planned and implemented by other organizations and to develop a coalition that pools their resources.[33–35] During the third task, EP Coordinators should work with the LEPC to enlist the participation of nongovernmental (nonprofit) and private sector organizations—many of which can identify geographic areas in which there is a high concentration of vulnerable households, and which can also assist these households to prepare for emergencies. The fourth task is for EP coordinators to work through the LEPC to develop active contact with reporters and editors who can provide access to channels citizens routinely use. The fifth task involves having EP coordinators work through the LEPC with neighborhood associations and service organizations to facilitate their organizational effectiveness and to provide them with opportunities to learn about environmental hazards and feasible adjustments to those hazards.

Program development for all phases involves five tasks. During the first task, EP Coordinators should staff, train, and exercise a crisis communications team. This team forms a critical link between technical experts and the population at risk; hence, its members should have skills in communicating with both groups. In addition, the crisis communications team should be represented by a spokesperson who is technically competent to explain emergency conditions clearly and will be perceived as credible because of relevant credentials (e.g., job title and educational degrees), acceptance by other sources of known credibility, or a demonstrated history of job performance that has enhanced credibility.[3,36] It will also be helpful if this spokesperson receives training from public relations experts.[37] The second task is for EP coordinators to establish procedures for maintaining an effective communication flow in an escalating crisis and in emergency response to ensure each organization receives all the information it needs as promptly as possible. In the third task, EP coordinators work with the LEPC to develop a comprehensive risk communication program that presents information about hazards and hazard adjustments in a form that attracts attention and is easily understood and retained. In addition, this information should be repeated over time and emphasize the personal consequences of environmental hazards, the need to accept personal responsibility for protective action, the efficacy of alternative hazard adjustments, and information about hazard adjustments' resource requirements. During the fourth task, EP coordinators should encourage the LEPC to use informal communication networks in the community. The fifth task is for EP coordinators to establish procedures for obtaining feedback from the news media and the public. Feedback is usually limited in public hearings; hence, many scholars recommend informal channels of communication such as advisory panels and meetings with neighborhood associations and civic organizations.[37–39]

During emerging crises, feedback can be obtained by reading copies of local newspapers, and monitoring radio and television broadcasts. In addition, EP coordinators can work with the LEPC to obtain feedback from citizens via rumor control centers with a telephone number or a web site address that has been publicized in advance.

There are five steps to *program implementation for the continuing hazard phase*. During the first task, EP coordinators should build source credibility by increasing perceptions of expertise and trustworthiness. Thus, members of the crisis communication team should ensure its procedures are coordinated with all relevant agencies' emergency operation plans, and emergency personnel from each facility or agency should develop a demonstrated history of effective job performance during minor incidents such as severe storms and minor floods. To enhance trustworthiness, messages must be perceived as accurate, objective, and complete[40,41] and the source is perceived as competent, open and honest, caring and concerned, and sympathetic.[42] These qualities can be enhanced when EP coordinators promote meaningful public involvement by working with the LEPC to involve the community in the continuing hazard phase, avoid secret meetings, explain constraints in risk communication procedures (especially what constraints on public participation are imposed by law and agency policy), and provide accurate information that is responsive to people's requests. The second task is for EP coordinators to use a variety of channels to disseminate hazard information because each channel can affect a different stage of information processing. For example, radio or television ''spots'' might have their greatest impact in establishing initial hazard awareness (i.e., attracting attention to the hazard) and maintaining its intrusiveness by means of frequent thought and discussion. By contrast, printed materials are most effective in providing the detailed information needed to establish a perception of threat and identifying suitable hazard adjustments. In the third task, EP coordinators describe community or facility hazard adjustments being planned or implemented. In particular, local residents should be informed of any hazard mitigation actions being taken so they will understand their risk is being reduced. In the fourth task, EP coordinators should work with the LEPC to describe feasible household hazard adjustments risk area residents can take to protect themselves. For example, households can prepare for airborne releases of toxic chemicals by reducing air infiltration in their homes,[3] or drinking bottled or boiled water if local wells are contaminated. The fifth task is for EP coordinators to evaluate program effectiveness by measuring the degree to which it has achieved its objectives.[43] Thus, they should determine how to measure the goals they have set, how to collect the data needed to measure performance, and how to analyze these data. This comparison process can then serve as the basis for determining whether changes need to be made in the risk communication program.

Program implementation for the escalating crisis and emergency response phases involves six activities. The first task is for EP Coordinators to work with their plant managers and public information managers to classify the situation in terms of its severity. To a great extent, ''perception is reality,'' so a crisis exists if facility operators, civil authorities, the news media, or a significant proportion of those in the community believe a situation is dangerous. Nonetheless, facility personnel can exert some control over other people's definition of the situation by establishing specific criteria in advance of an incident that systematically define elevated conditions of threat. To accomplish the second task, EP coordinators should activate the crisis communication team promptly so that its members can make all appropriate contacts and open all necessary communication links. This makes it possible for all organizations to be aware of the information being disseminated by other organizations, identify any disagreements, and prepare appropriate explanations before they are contacted by the news media. During the third task, facility personnel should determine the appropriate time to release sensitive information by developing procedures that define when information is to be released. This is a challenging task because even experts disagree on the rules for determining when to release information.[44] On the one hand, early releases of information are often characterized by a significant degree of uncertainty; hence, there is a possibility that crisis conditions might never materialize or that they will be less severe than initially expected. However, withholding information to avoid unnecessary disruption can be misinterpreted as a ''cover-up'' if the data are leaked.[37] The fourth task involves having facility personnel select the communication channels appropriate to the situation. The newsworthiness of an escalating crisis ensures there will be little difficulty in obtaining news media coverage, but facility personnel need to promote dialogue through two-way communication in small groups as well as in press conferences.[37] The fifth task is for EP coordinators to maintain source credibility with the news media and the public. If the available data are incomplete, facility personnel should be honest about what is and is not known. In addition, they should recognize that the news media have many other sources of information; hence, it is important to respond promptly to reporters facing imminent deadlines.[45] To accomplish the sixth task, facility personnel should provide timely and accurate information to the news media and the public. In particular, news releases should be no longer than two

pages with simple short sentences in plain English. They should contain a dateline (date and location of release), the organizational source (including point of contact) for the information, a summary lead that provides a one sentence abstract of the press release, the text of the press release, and a brief description of any attachments.[45] These should be supplemented by fact sheets containing basic background information that is appropriate to any incident. Facility personnel should state that they do not know the answer to a question when this is the case, but should make a commitment to answer the question at a later time. Last, they should evaluate performance through postincident critiques that permit all members of the crisis communication team to review the goals of the risk communication program, the event logs kept during the incident, and other available documentation to identify deficiencies in organizational performance. Each participant should be encouraged to address any deficiencies by recommending improvements in plans, procedures, training, facilities, equipment, or materials and supplies.

CONCLUSIONS

Chemical risks can be managed through effective programs for onsite and offsite emergency preparedness. Such programs begin by anticipating incident demands and developing an emergency preparedness program to meet these demands. Facility emergency coordinators should conduct hazard/vulnerability/risk analyses, emergency assessment analyses, expedient hazard mitigation analyses, personnel and population protection analyses, and incident management analyses to guide the development of their emergency response plans. In addition, they should use established methods for developing plans and procedures; establishing EOCs; conducting and evaluating training, drills, and exercises; and disseminating risk information.

Oriented Morphologies: Development in Polymer Processing

Mario A. Perez
3M Company, St. Paul, Minnesota, U.S.A.

INTRODUCTION

Most of the key findings in polymer morphology development and its connection to property enhancement took place during the latter half of the 20th century. Polymer morphology is still a very active area of research as there is a great need for understanding macrostructure obtained with new materials and processes. This entry is an overview of morphologies that can be obtained in polymeric materials and their connection to useful commercial properties. It is limited to semicrystalline homopolymers. Blends and copolymers were omitted, as they should be treated separately. Development of methods for property improvement through morphology creation or modification has focused on linear chain polymers or thermoplastic semicrystalline materials. This is because of the nature of amorphous and thermosetting polymers. The study of extended amorphous regions is already encompassed within the framework of semicrystalline thermoplastics.

Thermosetting materials, as the name implies, cannot be easily deformed to attain an oriented morphology once crosslinking has taken place. The notable and well documented exception being the deformation of crosslinked rubbers. Furthermore, in uncrosslinked thermosets, molecular length is often insufficient to form metastable oriented morphologies. Within linear polymers or semicrystalline thermoplastics, one can find those that form liquid crystalline phases, spherulitic structures, self-assembled layers, hard segmental sections, functional bonding, and strong intermolecular secondary forces.

Polymers are commercially available in various forms, such as pellets, powders, solutions, and dispersions. In the undissolved state, most thermoplastic semicrystalline polymers are shaped by processing beyond their melting point, followed by forming and cooling. Several choices are available for drawing, but two are of great practical importance: a) extension in the molten state and rapid quenching and b) cooling to or below crystallization followed by deformation, with the two techniques applicable being melt drawing and solid state drawing, respectively. An array of macrostructures can be obtained by these techniques.

MORPHOLOGY DEVELOPMENT

The deformation of long chain polymer molecules has always been of great industrial interest as more value can be placed on a material that has improved properties. Molecular extension, or alternatively molecular orientation, is of particular interest as it can enhance mechanical properties of an otherwise weak polymer. Oriented materials are inherently anisotropic. These anisotropic regions can be found directly in semicrystalline polymers where chains organize themselves into crystalline domains.

Quiescent Systems

Polymer chains aggregate and fold spontaneously upon cooling from a molten or a diluted state. Evidence of folding in polymer single crystals was first presented by Keller.[1] Molecules aggregate side by side to form lamellar crystallites where the chain backbone is preferentially aligned in a given direction. It is customary to label the chain axis direction within the crystallite, the *c*-axis direction. This is the direction perpendicular to the plane of the crystallite. Typical lamellar thicknesses ranges from 100 to 200 Å. Chain folds are present on two sides of this lamellar crystallite. Fig. 1 shows a sketch and a micrograph of a polymer single crystal grown from a dilute solution. The lozenge shape is characteristic of low concentration solutions and lower crystallization temperatures. More dendritic structures are observed as the concentration increases and the growth temperature is higher.

Intermolecular forces hold the crystallite together. These forces are overcome by increased molecular vibration when the melting point is approached. Alternatively, these crystallites can be cleaved, deformed, aligned, or rotated upon mechanical loading. The maximum property attainable with any polymer system is that of a fully aligned chain where covalent linkages bear the load. Even though the properties of perfect polymer crystals have been measured, they cannot be fully realized in practical commercial processes. Among the factors that preclude attainment of maximum properties through molecular extension are chain

entanglements (and other topological constraints), chain size distributions, chain slippage, tacticity defects, and kinetic constraints. The chemistry of linear polymers can also be tailored to provide inherent stiffness and strength.

Besides single crystals grown from solution, saturated polymer solutions and melts yield larger scale macrostructures under quiescent conditions. A very common macrostructure is spherulitic morphology. Spherulites are structures that grow radially from a single crystal or heterogeneity until their boundaries meet. Spherulite sizes vary a great deal; however, for most polymers typical sizes range from 1 to 20 μ. Semicrystalline thermoplastics like polyethylene and polypropylene readily form spherulitic structure upon cooling. More exotic polymers also form these structures. For example, spherulites of a crystalline diepoxide can be observed in Fig. 2. A maltese cross pattern, as shown in Fig. 2, is typical when spherulites are examined with a visible light microscope under cross polarization. A clover leaf pattern is formed instead with small angle light scattering.[2] The periodic nature of tangential polarizability from the center to the boundary of a spherulite is attributed to the helicoidal positioning of the crystalline lamellae around a radial axis, where the higher refractive index observed is the *c*-direction. In spherulites, the *c*-axis of lamellar regions is aligned tangentially to the radial direction in a spiral screw pitch staircase-like structure.

Besides those macrostructures obtained in the bulk, one can find oriented structures that originate at the boundaries from contact with other materials. This can happen during crystallization of a polymer against a steel surface, as in the case with the polymer processing practice of injection molding. It can also take place in composites where crystallization occurs near the fiber's boundary, or on a regular and crystalline face of another material. Such material may be a

Fig. 2 Visible light micrograph of spherulites from a crystalline diepoxide taken with a 5X lens and cross polarization. The observed maltese cross pattern arises from the spiral positioning of lamella along the radial growth direction. The high refractive index *c*-axis is tangential to the spherulite's radius.

mineral, an organic crystal, or a polymer. These morphologies originate from the difference in nucleation potential between the interface and the bulk. So, growth starts first at the interface and propagates into the bulk. In the case of contact with heterogeneous irregular or nonperiodic surfaces, the phenomenon is called transcrystallization. Transcrystalline behavior is widely known and has been reported for a variety of polymers and surfaces.[3,4] This phenomenon is of particular importance in fiber reinforced composites where the matrix polymer is semicrystalline. Spherulitic branches radiating away from the interface, coupled with an abundance of nucleation sites and tight packing, give rise to local oriented structures.

In cases where substrate surface periodicity influences the nature of the polymer crystalline structure obtained, the growth is called epitaxial. Polymer molecules are housed along the crystallographic plane of a given substrate providing an oriented morphology. For example, polyethylene can be crystallized in this manner using oriented polypropylene as the substrate. Polyethylene (1 0 0) planes align parallel to the (0 1 0) lattice plane of the oriented polypropylene monoclinic α-crystalline form.[5] The resulting structure of a high-density polyethylene crystallized on uniaxially oriented polypropylene is shown in Fig. 3. In this figure, the orientation direction of polypropylene is along the horizontal—polyethylene lamellae align at a 40° angle with the horizontal.[6] A related phenomenon, cross-hatching, is one where a bimodal lamellar orientation is observed with the same polymer and within the same spherulite.[7,8] Cross-hatching has been observed in the spherulitic structure of isotactic polypropylene that is generated by high temperature crystallization. In this case, orthogonal lathlike growths stemming from the radial structure are observed. It is implied from this discussion that a temperature gradient can either influence, or be the origin of an oriented morphology at an interface.

Within the boundaries of the quiescent methods discussed here, these oriented morphologies do not propagate far into the bulk, but typically only a few tenths of microns. So it has been of interest to develop methods to impart an oriented structure throughout the bulk as well. Usually, these methods involve polymer deformation or flow. The following sections cover a discussion of the most common situations where deformation provides oriented morphologies.

Deformation-Induced Morphologies

In semicrystalline polymers, crystallites and the macrostructures that they contribute to form, provide an added dimension to the consequences of imposed deformation.

Two events need to be managed during this deformation: chain extension (or unfolding) and chain relaxation. The ability to immobilize a chain after extension depends on several factors, such as drawing temperature in melts and polymer concentration in solutions. As mentioned earlier, random chains from melts and solutions minimize their energy by organizing themselves into chain-folded lamellae when

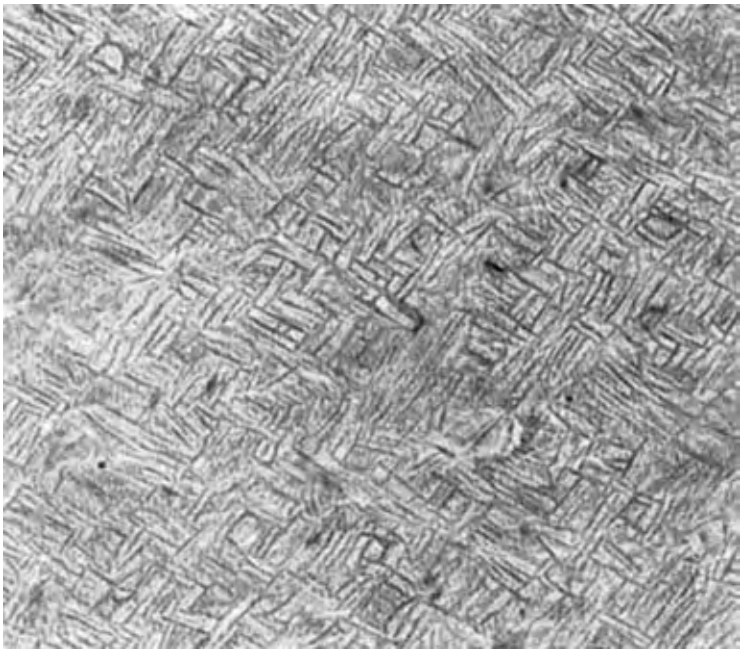

Fig. 3 Epitaxial growth of high-density polyethylene on oriented polypropylene. Polyethylene lamellae aligns at a 40° angle with the direction of orientation of the polypropylene. The orientation direction of polypropylene in the micrograph is along the horizontal. (From Ref.[6].)

conditions allow for good mobility. Chain-folded lamellae are observed in diluted polymer systems and molten polymers. The onset of lamellae formation depends on the concentration of the solution, molecular length, and cooling rate.

Flowing solutions

Fibrous crystals or crystalline bundles can be formed by the increasing alignment and proximity of chains undergoing macroscopic extension in solvent and melt systems. Studies of flow-induced morphologies in solvent systems date back to the mid-1960s and early 1970s. Beyond plain fibrillar structures, the first flow-induced polymeric structures with lamellar overgrowth resulted from experiments on cooling stirred dilute solutions.[9] These crystallized polymer structures obtained with nonquiescent solutions were termed ''shish-kebabs.'' In this composite structure, the ''shish'' are core fibril bundles and the ''kebabs'' are chain-folded lamellae that are formed periodically around the fibril core. An example of shish-kebab structure is shown in Fig. 4. The fibrillar core has been recognized to be composed of the longest molecules that precipitate from the solution first in this case. This fibrillar core then comprises elongated crystals that resemble a tight bundle. These bundles are connected with regions having a lower degree of order. The origin of the periodicity of the spacing between the lamellar kebabs is not clear, but it is probably dependent on the following factors: Strength of the flow field, frequency of the disordered tie regions in the fibrillar core, crystallization rate at the imposed temperature gradient, remaining unprecipitated molecular lengths, and chain stiffness. In some instances, the kebabs may not be connected to the fibrillar core. In addition, a distinction between regions within the main kebabs has been made, and macro- and microdomains have been reported.[10]

Melts

Studies of flow-induced morphologies in polymer solutions were crucial to the understanding of more complicated structures crystallized from flowing melts or deformed solids. Shish-kebab structures have been found to be present in melt drawn films.[11] Values of 20–35 nm were observed for the core fibrillar structures. Lamellar thicknesses in the range of 40–60 nm were obtained with scanning force microscopy. In addition to shish-kebabs, other structures can be prevalent in deformed melts such as needle crystal morphologies, oriented fringed micelles, and parallel stacked lamellae. Lamellar stacked and needle crystal morphologies are shown in Figs. 5[12] and 6.[13,14] In addition, another structure prevalent in polymer processing is the fringed micelle morphology.

A stacked lamellar morphology can be obtained by solid-state deformation of a crystallized polymer and also by freezing or capturing molecular orientation from the melt. In general, oriented fringed micelle structures can be obtained at deformation temperatures below or around the glass transition temperature and needle crystal morphologies through deformation of the polymer near its melting temperature.[13,14] As the chains between crystallites become taut and aligned, other phenomena can take place. For example, an apparent increase in overall crystallinity because of increased chain proximity and registry, and a departure from initial crystallite dimensions. Order is

increased further if these processes are followed by an annealing step.

Overall crystallinity increases observed in oriented morphologies are accompanied by melting point elevations. Elevated melting is detected for semicrystalline polymers that undergo processes that extend chains beyond their kinetically restricted coiled conformations. In thermodynamic terms, entropy is lowered upon chain extension. Chain extension leads to a shift in melting to higher temperatures and larger endotherm area. A larger endotherm area implies a higher degree of apparent crystallinity. This effect is shown in Fig. 7, which shows differential scanning calorimetry traces for polypropylene. Smaller crystallites melt first. Crystallites with higher dimensions along the chain direction are more resistant to melting, such as in the case of needle crystals.

METHODS

Uniaxial Extension

A common way to produce oriented morphologies or attain enhanced properties is to mechanically deform the polymer in one direction. This is uniaxial extension or draw. To attain molecular extension, imposed stress needs to transfer from the outer layers of the polymer sample or melt to the individual chains. This can happen through frictional contact among chains or between a chain and its surrounding medium. In the solid state, the contact is influenced by chain stiffness, functional groups, molecular length, charges, and aggregates (crystallites or heterogeneous particles). In the most basic of cases such as parallel plate flow, deformation of the fluid can come from simple shear by setting one of the plates in motion. Momentum transfers to the polymer's layers that are in contact with the moving plate as the fluid velocity at the wall is zero. If the channel is large enough, shear flow evolves in a flow with a strong rotational component. Therefore, polymer orientation through shear flow is not necessarily effective. An elongational flow field is the best way to extend a polymer molecule. Because of the nature of this elongational flow field, there is an inherent material acceleration, i.e., a chain can be extended more effectively as it proceeds downstream. In these flows, higher molecular weight chains—there is an upper limit to this—extend at lower strain rates, while lower molecular weight entities need to accelerate downstream in the flow field further to extend under high strain rates.

In uniaxial macroscopic deformation, the term draw ratio (DR) is customarily used to denote nominal draw (not molecular draw), or the change from the sample's initial dimension to its deformed state at each drawing step.[15] Even though this is by no means a rigorous definition, it applies to deformations induced during simple sample extension or during stretching by differential roll speed. DR assumes full extension efficiency.

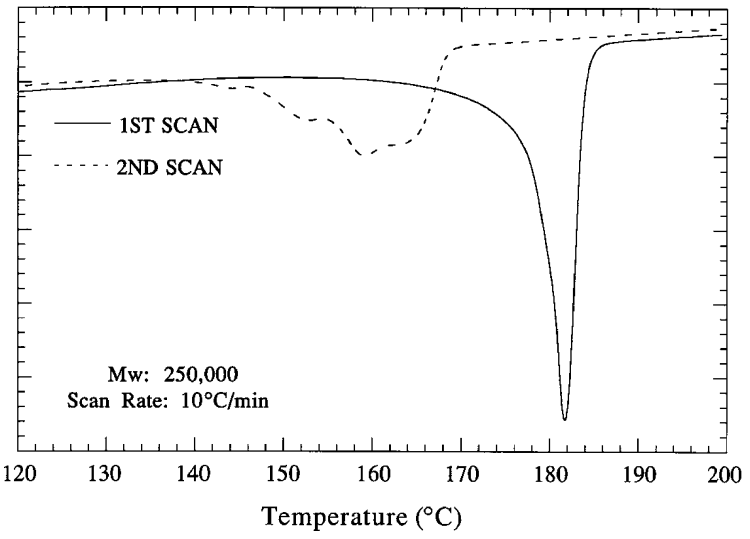

Fig. 7 Differential scanning calorimetry traces of an isotactic polypropylene. The first heating trace exhibits a sharp high melting transition with larger endotherm area and higher apparent crystallinity. Sample: Uniaxially oriented rod with high aspect ratio crystallites. The second heating trace shows the unioriented specimen's melting endotherm.

This is not necessarily the case at the molecular level where the efficiency of permanent chain extension can be influenced by factors like chain relaxation, topological restraints, chain size and distribution, dissipation of frictional heat, chain repeating structure, and chain slippage. An expression that accounts for chain slippage and provides a measure of true molecular extension has been proposed by Porter et al.:[16]

$$\text{MDR} = [(L_t - L_s)/L_o)] + 1$$

where L_t is the total length after full deformation; L_s the length of sample after shrinkage on heating beyond melting or glass transition; and L_o the length before deformation.

Affine deformation takes place when molecular draw ratio (MDR) = DR.[15] This is true in the absence of chain slippage. In a typical sample with a wide distribution of molecular lengths, this would be an average molecular DR. In practice, macroscopically uniform orientation properties are hard to obtain, because only sample surfaces and ends are in contact with rolls or clamping devices to effect extension. For example, during roll drawing, differences in oriented morphologies are produced when one side of the film is in contact with a heated roll and the other side is exposed to air or heat transfer medium. Nonuniformities in roll heating or surface finish differences may also affect final structure and property development.

Common uniaxial deformation methodologies

The most common type of uniaxial extension can take place during simple tensile drawing of cast polymeric sheets. In this case, the two ends are gripped and the material is pulled to extend, and then chain extension and crystallite rearrangement takes place.

Neck formation (sudden loss of nominal cross-sectional area) after a yield stress maximum is typical for room temperature deformation in several thermoplastic materials. Free radical generation has been detected during tensile deformation long before specimen fracture occurs.[17] This is because of the rupture of highly strained load bearing intercrystalline tie molecules. Lamellar planes do move and rotate toward the direction of tensile draw as well as suffer some shear-induced size modification. This size modification may produce populations of various lamellar aspect ratios that will in turn influence the breadth of the melting endotherm or may altogether form another melting maxima. Lamellar dimensions have a large effect on melting temperature. The Gibbs–Thompson equation[18] can be utilized to calculate this effect. This is shown in Fig. 8.

Another common processing operation that involves uniaxial orientation is fiber spinning. It is customary to extrude using a multiple orifice die (spinneret) and subsequently impose a draw step while quenching in a tank. In general, higher spinning speeds lead to higher levels of induced orientation and better load bearing properties. Because of geometry, important uniaxial texture information in samples made by fiber spinning can be extracted unequivocally with a few measurements. The same average structure should be observed as the sample is rotated to spin around the fiber axis. Wide-angle X-ray patterns can be utilized to determine the degree of orientation of crystallographic planes when the beam is perpendicular to the fiber axis. The span of the diffraction spot in the azimuthal direction provides a measurement of the degree of orientation of a particular diffraction plane with respect to the fiber axis. The breadth of the diffraction spots in the radial direction can be utilized to compute the average dimension of a crystallite in the direction perpendicular to the plane.

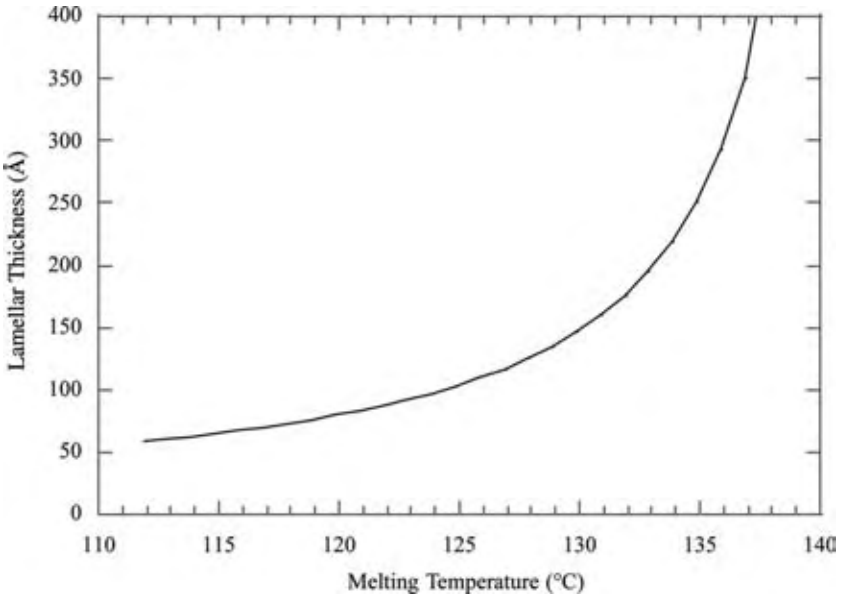

Fig. 8 Theoretical calculation of the effect of lamellar thickness on the melting point of a polymer crystallite using the Thompson–Gibbs equation. (From Ref.[18].) *(View this art in color at www.dekker.com.)*

Less information can be obtained if the beam is parallel to the fiber axis because crystalline plane orientation should have no bias. Fig. 9 shows a wide angle X-ray diffraction pattern of a uniaxially oriented polypropylene when the beam is perpendicular and parallel to the sample's fiber axis. No preferred orientation direction is seen when the beam is parallel to the fiber axis. Besides wide angle X-ray analysis, other popular techniques utilized for the characterization of orientation include small angle X-ray diffraction, optical microscopy, birefringence, infrared and Raman spectroscopy, nuclear magnetic resonance spectroscopy, and neutron scattering. Owing to increased availability of beam time in national laboratories, synchrotron high energy X-ray diffraction is being utilized more and has led to new findings on topics that have generated a great deal of debate in the past. Real time studies of rapidly occurring events and new collimation techniques to resolve submicron length scales have been reported with synchrotron X-ray sources.[19]

Ultraoriented structures

Beyond regular processing operations such as fiber spinning, film stretching, and molding, more exotic methods for obtaining oriented morphologies and ultimate properties have been proposed by both industry and academia. However, most of these methods suffer from line speeds that only amount to a few centimeters per minute. These methods have been reviewed in the literature.[20] A summary of some of these methodologies is provided in Fig. 10. Melt spinning is included for comparison. Most methods devised for obtaining ultraoriented structures are solid-state deformation methods. The only method, as listed in Fig. 10, capable of providing a high orientation directly from the melt is melt transformation extrusion and coextrusion.[21,22] In this process, a flowing melt is forced to flow through a converging cavity at very high pressures, and the orientation attained is frozen at a land section where a crystallization front is formed. Coextrusion is implemented to lubricate the converging and land section walls with a lower viscosity polymer. This allows for higher drawing speeds.

In solid-state extrusion, a solid material is processed without melting. A heated solid plug of a thermoplastic material below its crystallization temperature, or glass transition in amorphous materials, is forced through a conical cavity. There are several versions of this methodology: hydrostatic, where a solid billet forced through the orifice via pressurized fluid; coextrusion,[23] where the solid billet is housed between fluoropolymer sleeves; and ram or plug extrusion, where the billet is pushed by a piston. Successful hydrostatic extrusion trials in uniaxial and biaxial deformation modes have been reported.[24,25] Very high crystallinities and orientation functions can also be obtained by these methods.[26]

Solid-state extrusion has also yielded some of the highest properties for uniaxially oriented morphologies. Tensile moduli (210 GPa) nearing the theoretical value of a polyethylene single crystal have been attained.[27]

A similar technique, die drawing, is a solid-state extrusion method that is assisted by a tensile force to help overcome the high constraints and polymer strain rates at the die exit. Several methods were devised to address the problem of low lineal speeds because of the aforementioned constraints. These methods include solid state rolling,[28] roll drawing,[29,30] and roll trusion.[31]

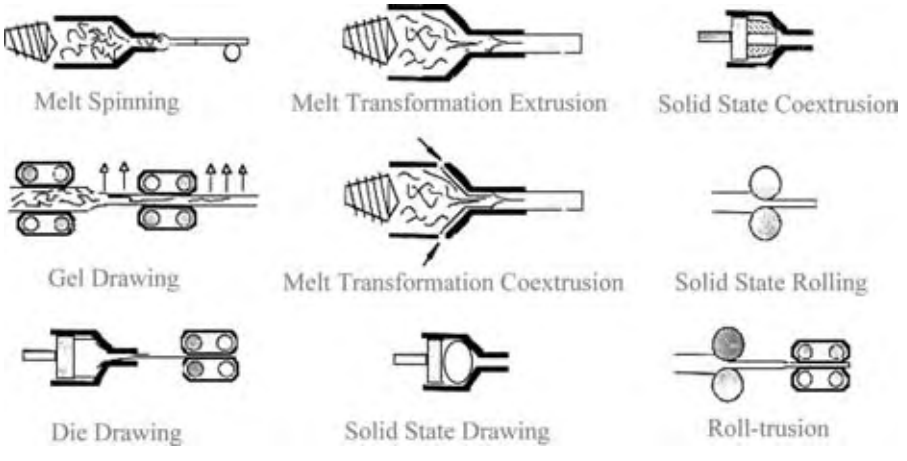

Fig. 10 Deformation methods to produce ultrahigh modulus materials. *(View this art in color at www.dekker.com.)*

Roll trusion suggests the delivery of a system where conditions can be manipulated to provide control of structure formation in two directions.

As done in some of the rolling processes mentioned earlier, it is often desirable to combine stretching with a pressure-induced orientation step during solid-state drawing. Such combinations may involve a hydrostatic extrusion or calendering steps. A higher degree of molecular orientation can be attained with processes that use a compression deformation step than tensile draw only at a given extension ratio.[32] The compressive deformation step induces crystallite cleaving. Crystalline planes shear and slip, thus changing the apparent crystallite size and getting the structure ready for the tensile drawing steps.[33] Unless these compressive steps are done using narrow channels, the nature of the deformation may no longer be uniaxial. Such is the case in calendering where a biaxial character can be obtained.

A tensile modulus comparison for various materials made using some of these ordering processes are shown in Table 1.[34] The reported moduli in this figure were for the direction of maximum level of extension or order. If density is factored into mechanical property comparisons, superior properties are obtained with these ordered polymers when compared to metals and glass.

From the processes shown in Fig. 10, only one is solvent based, i.e., gel spinning.[35] Here ultrahigh molecular weight polyethylene may be diluted to 95% in mixtures of decalin, paraffin oil, or xylene to enable processing and avoid topological restrictions. The solvent is evaporated upon drawing. Surface porosity may arise depending on solvent evaporation conditions. The manufacturing feasibility attained by this process results from a combination of high DR (70 : 1) and line speed (app. 25 m/min). Fibers made by this process are commercially available.

Table 1 Tensile modulus values of highly ordered polymers and reference materials

Material	Tensile modulus (Gpa)
Unoriented thermoplastics	0.1–4
Wood (fiber direction)	15
Glass	70
Highly oriented polyethylene fiber	100–150
Polyparaphenylene-terephthalamide fibers	80–130
Steel	200
Polyphenylenebenzobisoxazole fibers	180–280
Polydiimidazopyridynylene-dihydroxyphenylene fibers	300
Diamond	1200

(From Ref.[34].)

Order in Rodlike Polymers

Most rodlike high polymers are materials with rigid aromatic backbone structures that have very high or intractable melting points. Some of these are liquid crystalline materials. In lyotropic liquid crystalline systems, ordering takes places in solution, while in thermotropic, the oriented domains form in the molten state. Some of these highly ordered systems are made commercially by spinning from solutions. Structure development is dependent on how the solvent is evaporated effectively to yield the best properties. Most liquid crystalline polymers can be made to attain very high properties in tension. However, their compressive properties are very poor because of low shear properties where crystalline planes can be slip sheared. Among these aromatic rod polymers are polyphenyleneterephthalamide, polyphenylenebenzobisoxazole, polydiimidazopyridynylene-dihydroxyphenylene, and a series of thermotropic polyesters. A model of fibrillar hierarchy for highly oriented liquid crystalline polymers has been proposed to describe microfibril size, shape, and organization.[36] This model elucidates morphological causes for poor compression performance and high tensile properties.

Biaxial Orientation

In a biaxial texture, polymer chains are oriented with high bias in the deformation plane. Most biaxial operations with high DRs are done in sequence. After casting, the film is subjected to a machine direction or uniaxial deformation step. This step is followed by a tenter or transverse direction draw. In this latter step, the edges of the film are clamped to effect stretching. The film is still under tension in the forward or machine direction and moves at normal line speeds through the tenter oven. As in fiber spinning, the film may undergo an annealing or a tensilizing step to provide a stable temperature set or a desirable final property. The deformation mechanism during this tranverse orientation step can be dominant. The morphology that is formed during the initial uniaxial or machine direction orientation is intensely modified or destroyed during transverse drawing. Previously obtained crystallite sizes are reduced by this deformation perpendicular to the original draw direction.

Because of recent technological advances, high DR simultaneous biaxial orientation can be achieved continuously at industrial speeds. Ideally for the simultaneous case—at an equal stretch ratio in each direction—in-plane periodicity or other morphological

features should be homogeneous. In isotactic polypropylene, the order attained in the film plane is dependent on the deformation method utilized, sequential or simultaneous biaxial. Molecular orientation developed normal to the plane is independent of either method.[37] In the most industrially common biaxial orientation method, sequential drawing, the sample initial morphology is of extreme importance to the development of morphology during the deformation steps. In this process, a cast sheet is stretched uniaxially, followed by transverse stretching and annealing steps. Crystalline plane orientation is strongly dependent on the degree of crystallinity and crystallite dimensions obtained during previous steps. The temperature at which this transverse or restretching step takes place dictates the type of morphology that will be ultimately attained. For example, the morphology of polypropylene can be substantially changed if the restretching step is done above 130°C. Studies on biaxial orientation of polypropylene conclude that high temperature restretching (around 155°C) yields a smaller size crystallite population through lamellar breakage.[38] Formation of intermolecular crystallites in the direction of stretching was observed upon cooling.

In terms of macrostructure, studies on the deformation of spherulites during biaxial orientation elucidated that spherulitic break-up occurs not only at their boundaries, but also at their centers.[39] In either case and preferentially at higher temperatures, a fibrillar morphology was observed to develop at higher levels of stretching. Less data are available on direct methods to quantify the behavior of amorphous segments as they take part in these deformations.

Besides film tentering, hydrostatic extrusion offers methodologies for biaxially orienting thick sheets.[40] Good mechanical properties have been obtained in the plane of the film with this method, but void formation was reported to be extensive. Biaxial orientation of polyethylenes has also been attained through full compressive deformation.[41] Using this latter method, a modulus of 10 Giga Pascals was obtained in the plane of the sheet with ultrahigh molecular weight polyethylene. Dies with converging-diverging geometries in solid-state extrusion have been shown to enhance mechanical properties along the extrudate's width.[42]

Cyclic Processes

The most common cyclic process for thermoplastics is injection molding. Modern machinery is of the reciprocating screw type. In this process, the screw rotates and loads a metered dosage of polymer toward the tip. A ring valve at the tip of the screw prevents backflow during forward movement of the screw during the injection part of the cycle. The molten polymer flows into mold, which is held at lower temperatures. Depending on the complexity of the mold, different morphologies may be encountered. For example, those originating from the effects of flows near walls and pins, merging flows that form weld lines, and flows at gates and vents. Core or bulk morphologies differ from wall morphologies and depend a lot on the rate of cooling during the injection molding cycle. A strong shearing deformation is imposed on a polymer flowing near walls in a mold cavity. In general, skin layers tend to have a higher level of molecular orientation than the bulk. This is coupled with molecular extension caused by fountain flow or advancing flow fronts. Weld lines yield weak morphological boundaries as melt fronts flow around cold pins or other inserts.

Molecular relaxation in adjacent sections of a part with varying degrees of orientation can induce differential shrinkage that leads to warpage. Rapid cooling of these macrostructures, before and after part ejection, can give rise to a complex state of stress. Residual stress formation was found, at least for amorphous polymers, to be caused by contributions from frozen-in orientation as well as nonequilibrium shrinkage and viscoelastic behavior changes.[43] Residual stress commonly develops as the material undergoes inhomogeneous cooling through its glass transition temperature.

Studies of the orientation phenomena in injection molding have shown that irrespective of the molding conditions and type of thermoplastic, molecular orientation is higher near the walls and decreases toward the interior.[44] Low crystallinity and flow-induced structures have been observed near the walls for injection molded isotactic polypropylene parts.[45] High modulus materials have also been obtained with some injection molding techniques.[46]

CONCLUSIONS

A broad view of principal findings and processes utilized for the development of oriented polymer morphologies has been presented. New trends toward the advancement of this topic are being developed within the realm of multidisciplinary research. Studies of order development in polymers have—for a few years already—transcended beyond traditional disciplines in chemistry and engineering. Genetically engineered polymers, nanoparticles, self-assembled molecules, supercritical fluids, and hybrids are some of the few areas that are now an integral part of macromolecular structural property relationship studies.

ACKNOWLEDGMENT

My sincere appreciation goes to the 3M Company for kindly donating equipment time to develop a deeper

understanding of morphology development in oriented polymer systems.

Osmotic Distillation

Bob Johnson
School of Physical and Chemical Sciences, Queensland University of Technology, Brisbane, Queensland, Australia

INTRODUCTION

Osmotic distillation (OD) is a membrane separation process that is used primarily for the dewatering of liquid food products at mild (usually ambient) operating temperatures. It is similar to membrane distillation (MD) in its mode of operation. That is, water evaporates from the feed stream (solution being concentrated) and is then transferred in the vapor phase through the pores of a hydrophobic (liquid water repelling) membrane to the strip stream, where it recondenses. The only driving force for mass transfer is a water vapor pressure gradient. However, OD and MD differ in the method by which this gradient is maintained and it is this difference, which determines the applicability of each technique to particular processing applications. In MD, the water vapor pressure of the feed stream is increased, relative to that of the strip stream, by heating the feed stream. In OD, the water vapor pressure of the strip stream is lowered, relative to that of the feed stream, by using a concentrated aqueous solution of an osmotic agent (inorganic salt) as the strip solution.[1,2]

The mild operating temperature of OD is conductive to the concentration of solutions containing thermally labile components and those containing volatile solutes. Thermal degradation or a substantial loss of volatile solutes during concentrate production often detracts from the quality of the concentrate. The most thoroughly investigated applications of OD so far have been the concentration of fruit juices, in particular grape, orange, tomato, and passion fruit juices.[3–10] These solutions have traditionally been concentrated to their required levels (usually greater than 60 Brix) by multistage vacuum evaporation, with obvious quality deterioration. The same levels of concentration have been achieved using OD, with no detectable degradation and with minimal loss of volatile flavor and fragrance components.

This treatment of OD covers the fundamental principles and various practical aspects of the process. Since the first patent on the subject appeared in 1988,[1] OD has been transformed from a laboratory novelty into a commercially viable process in a range of niche applications. However, the wider commercialization of OD has been hampered by the lack of a suitable membrane–membrane module (housing) combination. The interest in OD has been driven by recognition of the numerous potential applications afforded by a process, which facilitates the concentration of aqueous solutions under conditions that maintain a high degree of product integrity.

PRINCIPLES OF OSMOTIC DISTILLATION

OD Membranes

Like MD, OD utilizes a microporous hydrophobic membrane (pore diameter 0.01–1.0 μ) to separate the feed stream from the strip stream. Both streams are pumped across their respective membrane surfaces in cross-flow mode (parallel to membrane surface), to minimize the effects of concentration polarization (see below). Microporous hydrophobic membranes allow the passage of water vapor through the pores, but aqueous solutions are excluded from entering under normal operating pressures. Feed and strip pressures are typically less than 150 kPa, with the feed pressure maintained at 20–40 kPa above that of the strip stream. The use of a higher feed pressure is a precaution against contamination of the feed by the strip solution in the event of membrane leakage. In most cases, this pressure gradient is well below the critical penetration pressure of the membrane, ΔP_c.

ΔP_c depends on the liquid surface tension, γ_l, the liquid–solid (membrane) contact angle, θ (greater than 90° for hydrophobic membranes), the membrane pore radius, r, and the pore geometry co-efficient, B, in accordance with the Laplace equation [Eq. (1)]. B has a value of 1 for cylindrical pores. The higher the liquid surface tension, the larger the contact angle, and the smaller the pore radius, the greater the pressure required for pore intrusion by the liquid.

$$\Delta P_c = \frac{-2B\gamma_l \cos\theta}{r} \quad (1)$$

Young's equation [Eq. (2)] shows that high contact angles are achieved when the solid (membrane) surface tension, γ_s, is low, and the interfacial solid–liquid tension, γ_{sl}, and liquid surface tension are both high. Accordingly, the most suitable membranes for use in

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120016181

OD applications are those fabricated from nonpolar polymers with low surface free energies. The most commonly used OD membrane materials are polyolefins, such as polyethylene and polypropylene, and fluoropolymers, such as polytetrafluoroethylene (PTFE) and polyvinylidine difluoride (PVDF).[11]

$$\cos\,\theta\;=\;\frac{\gamma_s\;-\;\gamma_{\mathrm{sl}}}{\gamma_l} \tag{2}$$

The surface tension of most concentrated aqueous solutions of inorganic salts, such as those employed in OD as strip solutions, is considerably greater than that of pure water. Intrusion of these solutions into microporous, hydrophobic membranes of the types used in OD is, therefore, unlikely under moderate operating pressures. However, some aqueous feeds contain amphiphilic components that may depress the liquid surface tension, and thereby reduce the critical penetration pressure. In such cases it may be necessary to use a membrane with a pore diameter of less than 0.1 μ, to prevent liquid intrusion. For most applications however, membranes with a nominal pore diameter of 0.2 μ have been found to be suitable.

Mass Transfer

The water flux, J, which is normally expressed as kg (or L) $m^{-2}\,h^{-1}$, is proportional to the water vapor pressure gradient, Δp_m, between the feed–membrane and strip–membrane interfaces, and the membrane mass transfer co-efficient K_m, [Eq. (3)]. The vapor pressure gradient between the two interfaces depends on the water activity, a_w, in the bulk feed and strip streams, and the extent to which concentration polarization reduces that activity at each interface. Whilst K_m can be estimated using established diffusional transport equations, it is more difficult to estimate values for the water vapor pressure at the membrane wall for use in Eq. (3). However, an overall approach using the vapor pressures of the bulk solutions and semi-empirical correlations that take account of the different conditions near the membrane wall can be used to estimate J.

$$J\;=\;K_m\Delta p_m \tag{3}$$

Maintenance of water vapor pressure gradient

The water vapor pressure of the strip stream is rendered lower than that of the feed stream by the use of a concentrated solution of a solute with high osmotic activity (high water solubility and low equivalent weight) as the strip stream. The strip solution requires periodic reconcentration to maintain the vapor pressure gradient at an effective level. Depending on the size of the plant, an evaporator that utilizes factory waste heat is usually adequate for this operation because of the relatively small fluxes of OD systems (1–3 $kg\,m^{-2}\,h^{-1}$). Typically, the evaporator is placed in a closed loop with the strip tank. Osmotic distillation feed streams contain solutes with low osmotic activity (sugars, polysaccharides, protein), and hence their water vapor pressure is relatively insensitive to concentration changes as OD proceeds.[11] For example, at 25°C a 10 wt% sucrose solution has a vapor pressure of about 25 mm Hg (3.3 kPa), whereas that of a 50 wt% solution is only slightly lower at about 23 mm Hg (3.1 kPa).

In addition to the requirement for high osmotic activity, there are several other factors to be considered when selecting an osmotic agent for use in OD. The agent should be thermally stable and nonvolatile, to withstand reconcentration for reuse. Also, it should preferably be nontoxic, noncorrosive, and of low cost. The agents most frequently used are the alkali and alkaline earth metal halides, particularly NaCl and $CaCl_2$. However, halide salts are quite corrosive to ferrous alloys and are, therefore, unsuitable for prolonged use in most applications. Also, NaCl has relatively low water solubility and $CaCl_2$ is sensitive to precipitation as $CaCO_3$ in the presence of carbon dioxide. Agents found to be most suitable, particularly for the concentration of liquid foods and pharmaceutical products, are the potassium salts of *ortho-* and pyrophosphoric acid. For example, a 50 wt% solution of K_2HPO_4 with a water vapor pressure of about 17 mm Hg (2.2 kPa) at 25°C has been found to be an effective strip solution. Phosphate salts have the added advantage of being present in many biological fluids and are, therefore, considered safe in the event of leakage through a faulty membrane.[11]

Membrane mass transfer

Three mechanisms have been invoked to describe the transfer of water vapor from the feed–membrane interface to the strip–membrane interface, namely Poiseuille flow, Knudsen diffusion, and Fickian (molecular) diffusion.[12] The operative mechanism in a particular system depends on the pore diameter and on whether or not the pores are filled with stationary air. The membrane mass transfer co-efficient (as $kg\,m^{-2}\,h^{-1}\,Pa^{-1}$) applicable to each of these mechanisms can be estimated using Eqs. (4), (5), and (6), respectively. Here, r is the pore radius, ε is the membrane porosity, M_w is the molar mass of water, p_m is the mean water vapor pressure in the pores, δ is the membrane thickness, χ is the pore tortuosity, η is the viscosity of water vapor, R is the gas constant, T is the absolute temperature, D_w is the diffusion co-efficient of water vapor in air, P_a

is the pressure due to stagnant gas (air) in the pores, and P is the total gas pressure in the pores.

Poiseuille flow:

$$K_m = r^2 \varepsilon M_w p_m / 8\delta\chi\eta RT \quad (4)$$

Knudsen diffusion:

$$K_m = (2/3)(r\varepsilon/\delta\chi)(8M_w/\pi RT)^{0.5} \quad (5)$$

Fickian diffusion:

$$K_m = (1/P_a)(\varepsilon/\delta\chi)(D_w P M_w/RT) \quad (6)$$

When air is absent in the pores and the pore diameter is substantially greater than the mean free path, λ, of the diffusing water molecules (distance traveled between collisions with other molecules), water molecules collide more frequently with each other than with the pore walls and the Poiseuille flow relationship applies. The mean free path can be calculated using Eq. (7), where k_b is the Boltzmann constant and σ is the collision diameter of the water molecule. However, for pore diameters in the range of membranes that are suitable for OD applications and for a gas-phase pressure attributable to water vapor alone at ambient temperature (approximately 20 mm Hg, 2.7 kPa), the mean free path is significantly greater than the pore diameter. This results in more frequent collisions of the water molecules with the pore walls than with each other, and Knudsen diffusion predominates.

$$\lambda = k_b T / P(2\pi\sigma^2)^{0.5} \quad (7)$$

In practice, both the feed and strip solutions are saturated with air at ambient temperature, and consequently, the membrane pores contain air at about atmospheric pressure. In some applications, the air may have a higher carbon dioxide or nitrogen content than usual, depending on whether the feed has been sparged with one of these gases to remove oxygen, and thereby prevent oxidative deterioration or microbial attack. Knudsen diffusion may occur in the presence of air when the pore diameter is sufficiently small, and in constricted regions within otherwise larger pores. However, in the presence of air, water vapor–air collisions usually predominate over water vapor–pore wall collisions, and mass transfer through the membrane is by simple Fickian diffusion. In this case, the rate of mass transfer is independent of pore diameter.

The most appropriate model for mass transfer through air-filled pores can be determined by reference to the Knudsen number, K_n, which is the ratio of the mean free path of the water molecule and the pore diameter [Eq. (8)]. A Knudsen number of 10 or greater is indicative of Knudsen diffusion, whereas a value of 0.01 or less is indicative of Fickian diffusion. Intermediate Knudsen numbers signify the coexistence of both mechanisms. Fickian diffusion is significantly slower than Knudsen diffusion at the same vapor pressure gradient. Experimental measurements of water flux in the presence and absence of air in the pores have shown a two to three-fold increase on degassing. Lowering the total gas pressure in the pores decreases the frequency of water vapor–air collisions, and thereby increases the mean free path of the water molecules. However, feed pretreatment by heating or exposure to a vacuum to remove air is often counterproductive to the preservation of product quality.

$$K_n = \frac{\lambda}{2r} \quad (8)$$

Feed and strip mass transfer

Mass transfer in the feed and strip solutions is limited by the extent of concentration polarization. On the feed side of the membrane, concentration polarization refers to an increase in the concentration of solutes at and near the feed–membrane interface because of evaporation of water into the membrane pores (Fig. 1). The resulting solute concentration gradient between the membrane–feed interface, where the concentration is greatest, and the bulk solution induces diffusive transport of rejected solutes back through the concentration polarization boundary layer into the bulk stream. Bulk solution is simultaneously transported to the membrane wall by convection. When equilibrium has been established under a given set of operating conditions (stream flow rate, temperature, fluid dynamics imposed by membrane module design), the rate of back diffusion is equal to the rate at which the solutes are carried to the membrane surface by convective flow.[13]

On the strip side of the membrane, concentration polarization refers to an increase in the water concentration at and near the strip–membrane interface because of condensation of permeate into the strip solution. At equilibrium, the solutes (osmotic agent) diffuse from the bulk stream towards the membrane wall at the same rate as their concentration is reduced by permeate condensation.[12] Water is transported away from the membrane by convection.

Feed-side and strip-side concentration polarization result in a reduction in the driving force for mass transfer. There is a decrease in water activity at the feed–membrane interface and an increase at the strip–membrane interface. This results in a reduction in the water vapor pressure gradient across the membrane. The feed side and strip side mass transfer co-efficients, K_f and K_s, respectively, can be expressed in terms of the solute diffusion co-efficient in the boundary layer, D_s,

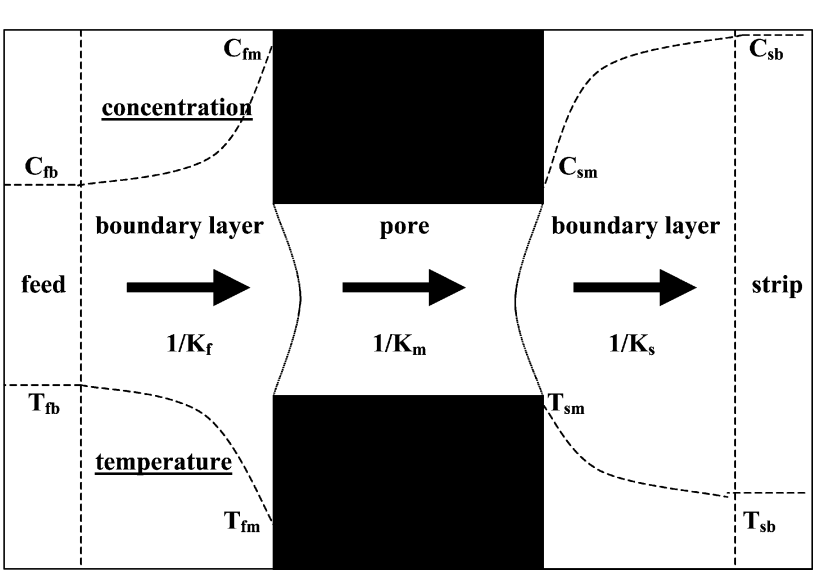

Fig. 1 Solute concentration profile, temperature profile, and mass transfer resistances in OD. The subscripts f, b, m, and s refer to the feed, bulk, membrane, and strip, respectively.

and the boundary layer thickness, z [Eq. (9)]. The magnitude of each mass transfer co-efficient is determined by the viscosity and density of the solution, on which D_s is dependent, and on the hydrodynamic properties of the system, on which z is dependent. However, it is difficult to estimate values for D_s and z and hence an overall approach that takes both the physical properties and hydrodynamics of the solutions into account is used in flux estimations.

$$K_f \text{ or } K_s = \frac{D_s}{z} \tag{9}$$

Overall mass transfer

The water flux achieved in OD can be described in terms of an overall mass transfer co-efficient, K, and the water vapor pressure gradient between the bulk feed and strip streams [Eq. (10)]. The total resistance to mass transfer, given by $1/K$, is the sum of three separate resistances in series [Eq. (11)]. Here, $1/K_f$, $1/K_m$ and $1/K_s$ are the resistances imposed by the feed-side boundary layer, the membrane, and the strip-side boundary layer respectively.

$$J = K\Delta p \tag{10}$$

$$\frac{1}{K} = \frac{1}{K_f} + \frac{1}{K_m} + \frac{1}{K_s} \tag{11}$$

K_m may be estimated using the equation applicable to either Knudsen or Fickian diffusion. K_f and K_s are estimated using empirical correlations of the dimensionless Sherwood, Sh, Reynolds, Re, and Schmidt, Sc, numbers.[11] Several such correlations have been proposed to describe flow through membrane-bound channels of various configurations. These include rectangular channels, such as those present in flat-sheet and spiral-wound modules, and hollow fibers. As an example, Eqs. (12) and (13) show the correlations for the calculation of the Sherwood number applicable to laminar (Re less than 2100) and turbulent flow (Re greater than 4000) through the lumen of a hollow fiber membrane. Having estimated the Sherwood number, the liquid (feed or strip solution) mass transfer co-efficient, K_l, can be calculated using Eq. (14). The Reynolds number and the Schmidt number are calculated using Eqs. (15) and (16), respectively. In these equations, d_h is the hydraulic diameter of the fiber, L is the fiber length, D_s is the diffusion co-efficient of the solute in water, v is the mean solution velocity, ρ is the solution density, and η is the dynamic viscosity of the solution. This approach allows the flux to be estimated by using the vapor pressures of the bulk feed and strip solutions [Eq. (10)].

$$\text{Sh} = 1.86, \text{Re}^{0.33}\ \text{Sc}^{0.33}\ (d_h/L)^{0.33} \tag{12}$$

$$\text{Sh} = 0.023\ \text{Re}^{0.8}\ \text{Sc}^{0.33} \tag{13}$$

$$\text{Sh} = K_l d_h / D_s \tag{14}$$

$$\text{Re} = v d_h \rho / \eta \tag{15}$$

$$\text{Sc} = \eta / \rho D_s \tag{16}$$

Viscous fingering is a complicating factor in the prediction of water flux using the above correlations.[11] This phenomenon, which is rarely encountered in other membrane concentration processes, can be quite

detrimental to process performance. Viscous fingering results from the anomalously high viscosities of feed solutions containing hydrophilic solutes, such as sugars, polysaccharides, and proteins, when concentrated to high levels at ambient temperature. As the feed solution passes through the membrane-bound channel, the solution near the membrane wall becomes increasingly concentrated. Upon reaching a critical concentration, the viscosity rises rapidly with further dehydration. Viscous transport of this layer through the channel becomes progressively slower because it is bounded by flowing liquid of lower viscosity and density. Stagnation of the boundary layer results and the incoming solution "fingers" through the center of the channel with increasing velocity.

The decrease in residence time in the channel, and the blockage of access of the incoming feed solution to the membrane, result in large decreases in the process performance. An example of the rapid increase in viscosity beyond a critical solute concentration is that associated with the concentration of grape juice. The production of grape juice concentrates has been the major commercial application of OD up to the present time.[3] The viscosity of Gordo grape juice increases slowly from about 2×10^{-3} Pa s at a solutes concentration of 18 Brix (single strength) to about 50×10^{-3} Pa s at 60 Brix. On further concentration to the standard concentrate level of 68 Brix, the viscosity increases rapidly to about 220×10^{-3} Pa s, with an accompanying rapid flux decline.[11]

Another complicating factor in the prediction of OD flux using the above correlations is temperature polarization.[13] This is an internally generated phenomenon resulting from mass transfer through the membrane. There is a reduction in temperature at the feed–membrane interface because of the latent heat requirement associated with water evaporation. Condensation of the vapor at the strip–membrane interface releases this latent heat with a consequent increase in temperature. The resulting temperature gradient across the membrane acts in opposition to the vapor pressure gradient generated by the osmotic agent (Fig. 1). The latent heat of evaporation is supplied by convection in the bulk feed stream, conduction across the feed-side boundary layer, and conduction of the heat released on permeate condensation back across the membrane. The net result is a reduction in feed temperature. Heat that is not returned to the feed side from the strip–membrane interface is lost to the strip stream by conduction across the boundary layer and convection in the bulk strip stream. This results in an increase in strip temperature.

To maximize the amount of heat that is returned to the feed side by conduction across the membrane, it is desirable to select a membrane with good thermal conductivity and minimum practical thickness. Membranes used for OD have generally been found to allow recovery of most of this energy. Consequently, the resulting temperature difference between the feed and strip streams seldom exceed 2°C.[9] Frictional heating in the process equipment usually compensates for the slight cooling of the feed stream. The temperature of the strip solution is usually maintained constant by refrigeration. Whilst most authors have considered the effect of temperature polarization on OD flux to be negligible,[14,15] others have suggested that neglecting the driving force decay can lead to over-predictions of the water flux by more than 20%.[13,16] The requirement for a membrane with good thermal conductivity is the opposite of that for MD. The latter process relies on the maintenance of a temperature gradient across the membrane to provide the water vapor pressure driving force, and hence a membrane of low thermal conductivity is preferred.

Effect of temperature on mass transfer

The water vapor flux increases exponentially as the mean temperature of the system increases in accordance with the Antoine equation [Eq. (17)]. Here, T is the absolute temperature and A, B, and C are constants. Temperature also affects water flux through the thermal sensitivity of solution viscosity, solute diffusivity, and the diffusion co-efficient of water vapor in air-filled membrane pores. Elevated temperatures tend to lower feed-side, membrane, and strip-side resistances to mass transfer. However, operation at such temperatures may lead to a loss of product integrity through thermal degradation or volatiles loss.

$$\mathrm{Ln}\, p = \frac{A - B}{T + C} \tag{17}$$

PRACTICAL ASPECTS OF OSMOTIC DISTILLATION

Product Integrity

Osmotic distillation is unique among concentration processes in that feeds containing thermally labile or shear-sensitive components, and those with appreciable volatility, can be concentrated with little or no loss of product integrity. This characteristic is particularly important for the concentration of fruit juices and other liquid foodstuffs, such as vegetable juices, and tea and coffee extracts. These feeds contain a complex mixture of essential volatile hydrophilic flavor, and fragrance components in very low concentrations. Substantial depletion of these components by direct destruction or evaporation may render the product

unacceptable to consumers. The evaporative loss of volatile solutes during multistage vacuum evaporation, which is the conventional method of concentrate production, can be offset to some degree by condensation of the vapor mixture, followed by rectification to recover the volatiles for reblending. However, this process increases the extent of thermal degradation and results in a significant incremental processing cost. Osmotic distillation concentrates that have been reconstituted to single-strength are organoleptically very similar to that of the fresh feeds.

Reverse osmosis (RO) is able to concentrate these feeds at ambient temperature but may damage the product as the result of shear stresses at the high operating pressures required. Also, RO is limited to concentration to 25–30 Brix in most applications because of the high osmotic pressure of the feed. The high feed-side pressure required in overcoming this osmotic pressure to effect further concentration renders RO both uneconomical and impracticable for concentration to high levels. However, RO is among the least costly means for water removal from dilute solutions and may, therefore, be used successfully as a preconcentration step in a hybrid process with OD. Although RO always results in a small leakage of low molar mass solutes through the membrane, concentrates of a quality comparable to that achieved by OD alone have been produced in this way, with a significant reduction in processing costs.[11] For example, grape juice has been concentrated from 18 Brix (single strength) to 30 Brix by RO, followed by concentration to 68 Brix by OD. In this case, RO removed one-half of the water originally present in the juice.

There are several factors that allow OD to effect the concentration of feeds with a minimal reduction of volatile flavor and fragrance components. In general, low temperature operation substantially depresses the vapor pressure of these components relative to that of water, thereby reducing the driving force for transmembrane transport of these solutes. Also, the solubilities of these lipophilic components are substantially lower in the concentrated strip solution than in the feed solution. Consequently, the vapor pressures of these components over the strip solution are higher than over the feed solution at the same concentration. Thus, the vapor pressure driving force for transfer of these solutes across the membrane is considerably lower than that in simple evaporation. Additionally, the molar masses of these components are considerably greater than that of water and consequently their diffusive permeabilities through the membrane are much lower.

Notwithstanding these factors, there is always a small loss of volatile solutes across the OD membrane. However, there is evidence to suggest that this loss can be controlled by the choice of membrane.[8] Membranes having relatively large pore diameters at the surface have been shown to provide better retention of volatile solutes per unit water removal than those with smaller pore openings. It has been suggested that pores with large diameters at the membrane surface allow greater intrusion of the meniscus of both the feed and strip streams into the pore openings. This provides an effective increase in the thickness of the boundary layers at the pore entrances with a resulting increase in the resistance to mass transfer through the aqueous medium. While larger pores are preferred on the basis of reduced volatiles loss, the choice of membrane is dictated by the commercial availability of modules that are most suitable for OD, in particular the four-port hollow fiber modules (see the following sections).

Membrane Modules

As in the case of all membrane separation processes, the choice of an appropriate module type is based on feed type (viscosity, suspended solids content, and particle size), required membrane packing density (based on flux, total throughput, and available floor space), good flow hydrodynamics (for minimization of concentration polarization, effective cleaning and sanitation), and module cost. The various types of membrane modules and their fabrication have been reviewed by Strathmann.[17] Hollow fiber modules, which have the highest membrane packing density of all module types, are the most suitable for use in OD because of the inherently low flux of this process. However, the membranes that have provided the best fluxes and volatiles retention because of their relatively large pore diameters and porosities, that is those fabricated from PTFE, have not yet become available in hollow fibers with an acceptably low wall thickness.

CONCLUSIONS

Osmotic distillation is a relatively new membrane separation process, which is used primarily for the dewatering of liquid food products. The majority of reported applications have involved the production of fruit juice concentrates. The main advantage of OD over vacuum distillation, which is the conventional method for concentrate production, is the preservation of product integrity. Osmotic distillation is operated at mild temperatures (typically ambient), and thereby produces concentrates that are free from the effects of thermal degradation. Also, the delicate volatile flavor and fragrance components that are essential to consumer acceptance of fruit juice concentrates are largely retained.

Osmotic distillation also has advantages over MD with respect to concentrate quality. Osmotic and

membrane distillation are similar in that both the processes utilize a water vapor pressure gradient across a microporous hydrophobic membrane as the driving force for water removal. However, the advantage of OD lies in the use of a concentrated osmotic agent as the strip solution to maintain the vapor pressure gradient, rather than subject the feed stream to heating with a consequent reduction in concentrate quality. Membrane distillation has the advantage of higher fluxes than OD. Osmotic distillation also has a major advantage over RO, a pressure-driven process, despite the high quality of RO concentrates. The high osmotic pressure of the feed at concentrations of 25–30 Brix prevents further concentration from occurring, whereas OD is unlimited by osmotic pressure in the degree of concentration achieved. However, there is potential for the use of the cost effective RO process as a preliminary concentration step in a hybrid process with OD.

While several niche applications for OD have been identified, the commercial acceptance of the technology has been hampered by the nonavailability of a suitable membrane–membrane module combination. Fluoropolymer membranes, such as PTFE and PVDF, have been shown to provide superior flux performance, but are still unavailable in hollow fiber form with a suitable thickness for use in OD applications. The inherently low flux of OD requires that membrane-packing density be maximized for effective operation, and hence the available flat-sheet form of perfluorocarbon membranes is unsuitable for commercial use. Four-port hollow fiber modules that provide excellent fluid dynamics are currently available, but only low-flux polypropylene membranes are utilized.

NOMENCLATURE

a_w	Water activity
B	Pore geometry co-efficient
Brix	Approximate measurement of % by weight of solutes, strictly applying to aqueous sucrose solutions only (% w/w)
C	Concentration ($mol\,m^{-3}$ or $mol\,L^{-1}$, subscripts: f, feed; b, bulk; s, strip; and m, membrane)
D_s	Diffusion co-efficient of solute in water ($m^2\,s^{-1}$)
D_w	Diffusion co-efficient of water vapor in air ($m^2\,s^{-1}$)
d_h	Hydraulic diameter (m)
J	Water flux ($kg\,m^{-2}\,s^{-1}$ or $kg\,m^{-2}\,h^{-1}$)
K	Overall mass transfer co-efficient ($kg\,m^{-2}\,s^{-1}\,Pa^{-1}$)
K_l	Liquid mass transfer co-efficient ($kg\,m^{-2}\,s^{-1}\,Pa^{-1}$)
K_f	Feed side mass transfer co-efficient ($kg\,m^{-2}\,s^{-1}\,Pa^{-1}$)
K_s	Strip side mass transfer co-efficient ($kg\,m^{-2}\,s^{-1}\,Pa^{-1}$)
K_m	Membrane mass transfer co-efficient ($kg\,m^{-2}\,s^{-1}\,Pa^{-1}$)
K_n	Knudsen number
k_b	Boltzmann co-efficient ($1.381 \times 10^{-23}\,J\,K^{-1}$)
M_w	Molar mass of water ($18.0\,g\,mol^{-1}$)
P	Total gas pressure in membrane pores (Pa)
P_a	Pressure because of stagnant gas (air) in membrane pores (Pa)
ΔP_c	Critical penetration pressure (Pa)
Δp_m	Water vapor pressure gradient across membrane (Pa)
p_m	Mean water vapor pressure in membrane pores (Pa)
r	Membrane pore radius (m)
R	Gas constant ($8.314\,J\,mol^{-1}\,K^{-1}$)
Re	Reynolds number
Sc	Schmidt number
Sh	Sherwood number
T	Absolute temperature (K, subscripts: f, feed; b, bulk; s, strip; and m, membrane).
v	Mean solution velocity ($m\,s^{-1}$)
z	Boundary layer thickness (m)
ρ	Density ($kg\,m^{-3}$)
θ	Contact angle (°)
η	Viscosity (Pa s)
χ	Pore tortuosity
ε	Membrane porosity
δ	Membrane thickness (m)
σ	Collision diameter (m)
λ	Mean free path of diffusing species (m)
γ_l	Liquid surface tension ($N\,m^{-1}$)
γ_s	Solid (membrane) surface tension ($N\,m^{-1}$)
γ_{sl}	Interfacial solid–liquid tension ($N\,m^{-1}$)

Ozone Treatment

Jiangning Wu
Department of Chemical Engineering, Ryerson University, Toronto, Ontario, Canada

INTRODUCTION

This entry introduces applications of ozone technology in various areas: water and wastewater treatment; control of the microbial safety of food; decontamination of soils; polymer surface modification; and bleaching paper pulps. For water and wastewater treatment, in addition to being used alone, ozone is increasingly used in combination with heterogenous catalysts, UV/H_2O_2 (advanced oxidation process), and biological treatment to enhance ozonation efficiency. The discussion that follows mainly introduces the applications of ozone in water and wastewater treatment because ozone has been both extensively and intensively used in this area; however, it does briefly describe other applications.

PROPERTIES OF OZONE

Ozone (O_3) is a very powerful oxidant (oxidation potential, $E^\circ = 2.07\,V$).[1] It can oxidize a wide spectrum of chemicals and oxidatively inactivate diverse microorganisms. Ozone's self-decomposition to oxygen makes it a residue-free technology. Mainly because of the strong oxidative capability and the unique residue-free characteristic, ozone has been used extensively in water and wastewater treatment.[2] Other applications of ozone include control of the microbial safety of food, decontamination of soils contaminated by polycyclic aromatic hydrocarbons (PAHs), modification of polymer surfaces to increase their biocompatibility, and bleaching paper pulps.[3–8] In addition to being used alone for water and wastewater treatment, ozone is increasingly used in combination with heterogenous catalysts, UV/H_2O_2 (advanced oxidation process), and biological treatment to enhance ozonation efficiency.[5,6,9]

Ozone is a metastable molecule produced from elemental oxygen.[2] It has a pungent, characteristic odor described as similar to "fresh air after a thunderstorm."[10] The solubility of ozone is 13 times that of oxygen at 0–30°C and ozone has a longer half-life in the gaseous state than in aqueous solution.[11] The major physical and chemical properties of ozone are listed in Table 1, and the oxidation potential of ozone together with several commonly used oxidizing agents is shown in Table 2.

GENERATION OF OZONE

Because of ozone's instability, it has to be generated on-site of applications. Ozone can be generated by electrical (corona discharge), photochemical, electrochemical, thermal, and chemonuclear methods.[3,13] Among these methods, corona discharge (CD) is the most widely used to produce large amounts of ozone.[2,3] The first industrial CD ozone generator was developed by von Siemens in 1857, and the CD ozone is generated by passing dried oxygen or air through a high-voltage electrical field.[2] The photochemical ozone generation, on the other hand, involves the formation of ozone from oxygen exposed to UV light below 200 nm. UV-generated ozone is mostly used for residential pool and spa treatment.[5]

OZONE TREATMENT OF WATER AND WASTEWATER

Ozone is residue-free in water due to its self-decomposition into oxygen. As described above, ozone has been extensively used in water and wastewater treatment since its first full-scale application in drinking water treatment at Oudshoorn, Netherlands, in 1893.[2] To date, ozone has been used full scale for disinfection and purification of ground and surface waters, treatment of municipal and industrial wastewater, and treatment of swimming pool and cooling tower waters.[2,4,5,14]

In water and wastewater treatment ozone is used for the following purposes: 1) disinfection; 2) oxidation of organic compounds, including removal of taste, odor, and color; and 3) oxidation of inorganic compounds.[2,13,15] Ozone is usually used as pre-, intermediate-, or posttreatment with other processes such as sedimentation, adsorption, filtration, etc.

Ozone treatment of water is relatively expensive when compared with chlorine. Regardless of the relatively higher cost, however, considering the overall health and environmental problems caused by chlorination, ozone sometimes cannot be replaced by chlorine. Moreover, continuing efforts on lowering the energy consumption of ozone generation and optimizing ozonation processes would result in considerable cost reduction and thus would enable

ozone treatment to be a more competitively economic technology.

Reaction Kinetics of Ozone with Solutes in Water

When ozone is dissolved in aqueous medium, it reacts with solutes in two mechanisms: the direct reaction and the indirect reaction.[16] The two reactions may occur simultaneously. The direct reaction involves molecular ozone reaction with solutes while the indirect reaction involves the reaction between the solute and the hydroxyl free radical ($OH^{\bullet}$), which is produced from the decomposition of ozone in water. Hydroxyl radical is an even stronger oxidant than molecular ozone (oxidation potential, $E^{\circ} = 3.06$ V). When in reaction with solutes, molecular ozone is selective whereas the hydroxyl free radical is nonselective.[16] The efficacy of the hydroxyl radical for water treatment mainly depends on the quality of the water because of its nonselective nature. It may be less effective for waters containing a high concentration of radical scavengers such as *tert*-butanol, bicarbonate, carbonate, and natural organic matter.[17] Fig. 1 shows the different pathways of ozone reacting with solutes.

Table 2 Oxidizing agents and their oxidation potential

Oxidizing agent	Oxidation potential (mV)
Fluorine	3.06
Ozone	2.07
Permanganate	1.67
Chlorine dioxide	1.50
Hypochlorus acid	1.49
Chlorine gas	1.36

(From Ref.[12].)

For direct reactions between ozone and the solute, the reaction is first order with respect to ozone and the solute, respectively. Overall, the reaction is second order:[2]

$$-\frac{d[O_3]}{dt} = k[O_3][M] \quad (1)$$

where k is the reaction rate constant and $[O_3]$ and [M] are concentrations of ozone and the solute, respectively.

For indirect reactions between the hydroxyl radical and the solute, the rate of reaction mainly depends on the rate of ozone decomposition, which in turn, significantly depends on the nature of solutes in water. Because the solutes vary from water to water, it is difficult to express the indirect reactions in a general rate law. Numerous researchers have conducted investigations on rate equations of ozone decomposition, and have derived the equations with different complexity and different orders (half-, first-, second-, or third-order reactions with respect to the ozone).[15] More details can be found in Ref.[15]. It has also been found that pH is a very important parameter for ozone decomposition. Generally, when pH <7, it has a small effect on the rate of ozone decomposition. However, at higher pH, the rate of ozone decomposition increases significantly with pH.[15,16]

Drinking Water Treatment

The ability of ozone to disinfect polluted water was recognized by de Meritens in 1886 and the number of ozone treatment facilities for drinking water grew rapidly prior to 1914, mainly located in Europe.[2] Later, the use of ozone was significantly slowed down because of the development of an inexpensive chlorine treatment method. However, in the late 1970s, it was discovered that some chlorine disinfection by-products (DBP), trihalomethanes (THMs), were carcinogens. In addition, chlorine was incapable of inactivating some parasitic organisms. Consequently, there was a renewed interest in the applications of ozone in drinking water treatment.[2,13] Till 1997, there were more than 1000 drinking water treatment plants in Europe and over 200 in the United States.[5,18] In the United States, ozone is applied to nearly all bottled waters to provide final disinfection.[5] In general, ozone is used in drinking water treatment for disinfection, removal of taste, odor, and color, and minimization of the formation of chlorination by-products (THMs).

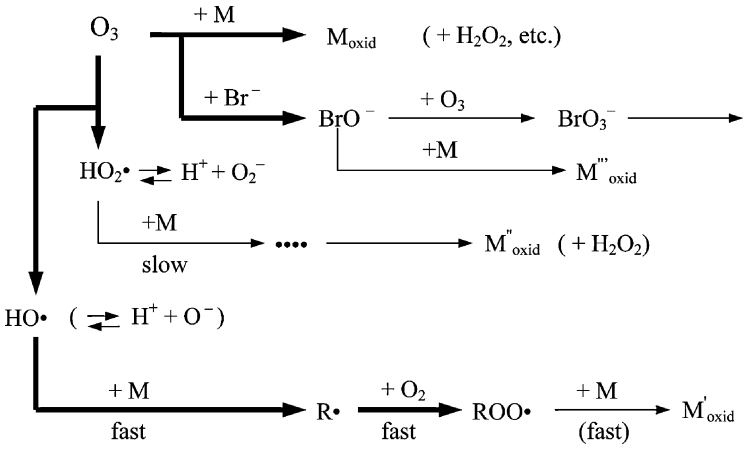

Fig. 1 This scheme shows the different pathways of the reactions of ozone with solutes (M) (including Br^-), and the formation of secondary oxidants, which also react with solutes M, but which produce different products from those formed on direct reaction with ozone. (From Ref.[16].)

Disinfection

Ozone has been found to be very effective on inactivating a wide range of microorganisms. It is generally accepted that molecular ozone is a more effective biocide than hydroxyl radicals, because the latter are very short-lived and nonselective. The resistance of microorganisms follows the increasing order: bacteria, viruses, and parasite cysts.[13,19]

The disinfection kinetics can be expressed by the law of Chick–Watson:[2]

$$\ln\left(\frac{N}{N_0}\right) = -AC^n t \qquad (2)$$

where N is the number of microorganisms surviving at time t; N_0 the initial number of microorganisms; C the concentration of disinfectant; t the contact time; A the specific coefficient of lethality, and n the coefficient of dilution.

Based on the Chick–Watson law, the concept of Ct has been adopted, where C is the dissolved disinfectant concentration (in mg/L) and t is the time (in min) the water is in contact with the disinfectant.[2,5,19] Because of ozone's powerful disinfecting capabilities, it has the minimum value of Ct compared with chlorine and other commonly used disinfectants as shown in Table 3.

Oxidation of organic compounds

Natural Organic Matter. Natural organic matter (NOM), the major component of total organic carbon (TOC) in raw drinking water, has been recognized as the principal precursor of chlorine DBPs.[20] The well-known DBPs are THMs that have already been identified as human carcinogens. The presence of NOM also causes other water quality problems such as color and odor. In addition, a water distribution system containing NOMs favors the bacterial regrowth.[13,19]

The main constituents of NOM in natural water are humic substances consisting of humic and fulvic acids.[2] Humic substances are the precursors of THMs. These must be degraded before chlorine disinfection because once THMs are formed they cannot be removed by chemical oxidation. Ozonation can degrade humic substances into low molecular weight compounds that are less reactive toward chlorine, and hence can minimize the formation of THMs.[19,21]

As mentioned above, humic substances may not be completely mineralized by ozonation alone. Instead,

Table 3 Ct values (mg · min/L) for 99% inactivation of microorganisms with disinfectants at 5°C

	Disinfectant			
Microorganism	**Free chlorine (pH 6–7)**	**Preformed chloramine (pH 8–9)**	**Chloride dioxide (pH 6–7)**	**Ozone (pH 6–7)**
E. *coli*	0.034–0.05	95–180	0.4–0.75	0.02
Polio I	1.1–2.5	770–3740	0.2–6.7	0.1–0.2
Rotavirus	0.01–0.05	3810–6480	0.2–2.1	0.006–0.06
Phage f2	0.08–0.18	—	—	—
G. lamblia cysts	47–>150	—	—	0.5–0.6
G. muris cysts	30–630	1400	7.2–18.5	1.8–2.0

(From Ref.[2].)

ozonation of humic substances usually leads to the formation of small molecules, mainly aldehydes and carboxylic acids. Therefore, the TOC is either reduced or kept unchanged. However, the low molecular weight aldehydes and carboxylic acids could be easily removed using a medium such as granular activated carbon (GAC) that allows the development of biological activity. In fact, combined ozone/GAC filtration proved to be efficient in reducing humic substances and dissolved organic carbon (DOC).[19,21]

Ozone is particularly effective in terms of color reduction. The removal of color and UV-absorbance is usually conducted in preozonation steps. The color removal results from the depolymerization and loss of aromaticity of humic substances.[14,19]

Ozone can sometimes solve taste and odor problems when the taste and odor are caused by unsaturated organic compounds. For example, unsaturated aldehydes, which are important taste and odor by-products of *Synura* species, are readily oxidizable by ozone.[2] Also, ozone is quite effective in removing 2-methylisoborneol (MIB), which causes the musty–earthy taste and odor and is rarely removed by conventional water treatment methods, from the natural water. However, if the taste- and odor-causing compounds are saturated, ozone treatment may have little effect.[2,22]

Synthetic Organic Micropollutants. Micropollutants that frequently presented in water include chlorobenzenes, PAHs, polychlorinated biphenyls (PCBs), and pesticides. Polycyclic aromatic hydrocarbons can be degraded effectively by ozone. But oxidation of chlorobenzenes and PCBs is slow by molecular ozone. However, they are more reactive with hydroxyl radicals. Therefore, it is recommended that either ozonation be conducted at high pH or advanced oxidation processes (AOP) be used. As for the pesticides, their removal by ozonation may be related to their water solubility. However, faster degradations are usually obtained with AOP.[19]

Oxidation of inorganic compounds

Inorganic compounds including manganese and iron usually are oxidized by preozonation to form insoluble species. Preozonation must be followed by a filtration or a coagulation–flocculation–decantation step to finally remove those inorganics.[19]

It should be noted that for water containing bromide, ozonation results in the formation of bromate, a potential carcinogen. Therefore, the presence of bromate has been regulated in water intended for human consumption. In Europe, bromate concentration cannot exceed 25 μg/L from December 25, 2003, and 10 μg/L after December 25, 2008.[18]

Wastewater Treatment

Ozone treatment of wastewater includes municipal and industrial wastewater treatment.

Municipal wastewater treatment

In municipal wastewater treatment, ozone has been used primarily for disinfection following primary or secondary treatment to meet microbiological standards of discharge. Although chlorine or chlorine compounds are most often used for disinfection, because of the potential DBP production as discussed in the drinking water treatment section, ozone is used to avoid those by-products. In the United States, ozone treatment of municipal wastewater for the purpose of disinfection is declining since 1976. The reason is that in 1976 the U.S. Environmental Protection Agency (USEPA) changed its disinfection policy. The USEPA required the sewage treatment plants to disinfect their effluents only when the receiving waters are to be used for 1) potable water intake; 2) agriculture; or 3) human contact with the waters.[5,14] In 1994, there were more than 40 municipal wastewater treatment plants in the United States that had ozonation facilities.[17]

In addition to disinfection, ozone has been used in municipal wastewater treatment to enhance biodegradability of recalcitrant organic chemicals, control odor, improve suspended solids removal, improve the performance of granular activated carbon, and condition sludge.[5,17]

Industrial wastewater treatment

The full-scale applications of ozone have been installed to treat wastewaters from marine aquaria, electronic chip manufacture, textile industry, petroleum refinery, and electroplating. Ozone has also been used to treat landfill leachates and meat processing wastewater. These applications of ozone are described below.

Treatment of Marine Aquaria Wastewaters. Wastewater from marine aquaria contains high levels of BOD_5 (5-day biological oxygen demand), NH_3, and microorganisms. Owing to restrictions against discharge of aquaria wastewater, the wastewater must be recycled for reuse. Ozone has been used to oxidize excess BOD_5, COD (chemical oxygen demand), and to disinfect pathogenic microorganisms. Sea World of Florida (Orlando) and at least 35 U.S. marine aquaria have installed ozonation facilities followed by biofiltration to treat their recirculating artificial brines. During biofiltration, additional BOD_5 is removed along with NH_3. These techniques allow 100% recycling of wastewater and permit the animals to thrive in a chlorine-free environment. Many U.S. zoos also have installed

ozonation facilities in various animal exhibits. In fact, the acceptance of ozone in aquaria and zoos is growing steadily.[4,5]

Treatment of Electronic Chip Manufacture Wastewater. Electronic chip manufactures need a large quantity of very high-purity water per day, because impurities cause lower electrical yields or even failures of the integrated circuits. Ozone is a recognized oxidizing/disinfecting agent for water purification purpose. It has been used for treatment of influent water to the plant and rinse wastewaters for recycling, and for the storage of high-purity process waters.[4,5] Integrated circuit manufacturers that use ozone technique for water treatment include Bell Telephone Laboratories and IBM Corporation. Bell uses ozone mainly for bacteria control. After ozonation 5–20 CFU (colony forming units) per milliliter can be achieved. On the other hand, IBM uses the combined ozone/H_2O_2 technique for the recycling of spent deionized water. This technique can oxidize trace organic materials (isopropyl alcohol, acetone, photographic stabilizers, and chlorinated organic solvents) and ammonia. When ozone treatment is followed by reverse osmosis and ion exchange, the quality of the treated water meets the standards of reuse.

Treatment of Textile Wastewater. Textile wastewater is characterized by heavy color and a large number of diversified auxiliary agents. Conventional treatment processes do not readily degrade dyes in textile wastewater because dyes are stable to light, oxidizing agents, and aerobic digestion.[23] The oxidation potential of ozone is 1.52 times that of chlorine, as shown in Table 2; ozone decolorization of textile effluents is, therefore, quite successful.[4,24,25] Ozone decolorization of the dyes can be explained by the oxidative cleavage of conjugated chains that shifts the absorption of light from the visible to the invisible portion of the spectrum.[26] During the decolorization processes, ozone may also oxidize many organic compounds to low molecular weight substances, resulting in an increase in the ratio of BOD_5 to COD for the wastewater, indicating an increase in biodegradability.[24] Because raw textile wastewater usually contains a large amount of oxidizable substances, which are ozone consuming, it is advisable to use ozone as a final treatment or at least following chemical coagulation.[27]

Full-scale ozone applications of textile wastewater treatment have been installed in Japan, the United Kingdom, Italy, Germany, etc.[4,13]

Treatment of Petroleum Refinery Wastewater. Ozone treatment of petroleum refinery wastewater has been used mainly to remove organic contaminants, especially phenols.[4] The combination of ozonation followed by GAC adsorption could lower the hydrocarbons and other organic contaminant levels to 0.1 mg/L. In addition, lifetime of the GAC adsorbent is extended 10–50%.

Treatment of Electroplating Wastewater. Toxic cyanide ions are the major pollutant in electroplating wastewater. They must be removed before discharge of the wastewater. As shown in Eqs. (3) and (4), ozone can oxidize free cyanide ion rapidly to less toxic cyanate ion, which then slowly hydrolyzes to nitrogen and ammonia. The reaction equations are as follows:[4]

$$CN^- + O_3 \Rightarrow CNO^- + O_2 \quad (3)$$

$$2CNO^- + 2H_2O \Rightarrow 2CO_2 + N_2 + 4H^+ \quad (4)$$

Boeing Aircraft plant in Wichita, KS, installed an ozone treatment system for its electroplating wastewaters in the 1950s. Later in the 1970s, to remove the ozone-stable iron–cyanide complex, full-scale ozone/UV systems were installed at the U.S. Tinker Air Force Base (Oklahoma). The hydroxyl free radicals generated can readily destroy the complexes. The Cadillac Motor Division at Detroit, MI, also installed a full-scale ozone cyanide remediation unit in the 1980s. So far, ozone application in the treatment of electroplating wastewater is not extensive. The main reason is that the less expensive alkaline chlorination can also oxidize cyanide ions to satisfy the wastewater discharge standards. However, alkaline chlorination cannot convert all of the toxic cyanide ions to cyanate ions. Therefore, the advantage of ozone application is to completely eliminate the cyanide ions so that the discharge of the wastewater and the subsequent sludge are cyanide-free.[4,5]

Treatment of Landfill Leachates. Landfill leachate contains large quantities of nonbiodegradable and toxic constituents.[28] Some heterogenous catalytic ozonation processes (Ecoclear or Catazone systems) can successfully treat landfill leachates.[4,13,28] In addition, ozone-based AOPs have also been successfully used to remove COD or TOC either as pretreatment or at the final stage of the treatment. Both heterogenous catalytic ozonation and the AOP processes are introduced below.

Treatment of Meat Processing Wastewater. Meat processors consume a large quantity of water and produce a significant amount of wastewater. Because of increasing water costs and environmental constraints, reuse of the processing water has become an attractive option for meat processors. Recycling of poultry chill water is permitted by the U.S. Department of Agriculture (USDA) regulations, provided that certain reconditioning criteria (microbial load, COD, light transmission, etc.)

can be satisfied.[29] Ozonation of poultry chiller water could decrease microbial load >2 logs and COD by ca. 33%. Ozonation could also increase light transmission (at 500 nm) of the poultry chiller water.[3,30] Also, ozone is effective on disinfection of red meat processing water.[31]

Treatment of Other Waters

Treatment of cooling tower water

Ozone has been used to replace chromium-containing chemicals to control biofouling for the cooling tower water. The U.S. cooling water market for ozone is in steady growth. Approximately 500 cooling towers have installed ozone.[5]

Treatment of swimming pool water

The major concern for the swimming pool water is the control of microorganisms. In the United States, more than 500,000 pools and spas have installed UV-generated ozone units. Only a few dozen use CD-generated ozone. Consequently, the objectionable odors of chlorine can be avoided.[5]

Some Typical Combined Use of Ozone with Catalysts or with Other Processes in Water Treatment

Heterogenous catalytic ozonation

Heterogenous catalytic ozonation used in water treatment usually implies the use of insoluble solid catalysts to enhance ozonation efficiency. The advantages of catalytic ozonation over regular ozonation are as follows: 1) accelerated degradation of pollutants; 2) considerably reduced ozone consumption and reaction time; and 3) higher degree of mineralization of the pollutants. The use of heterogenous catalysts also allows easy separation of the catalysts from the water for reuse or regeneration.[9,32]

Commonly used solid catalysts are metal oxides such as TiO_2, MnO_2, etc. Activated carbon is also a member of the heterogenous catalyst family.[17,32] Examples of industrial applications of heterogenous catalytic ozonation include CATAZONE and ECOCLEAR processes. CATAZONE process uses TiO_2 as catalyst and this process could almost mineralize oxalic acid completely. CATAZONE can also effectively remove halogenated pesticides such as aldrin, dieldrin, and hexachlorobenzene.[17] Unlike CATAZONE process, in which TiO_2 is used as catalyst, in ECOCLEAR process, ozone gas and wastewater flow cocurrently in a fixed-bed reactor in the presence of the activated carbons, which is used as the catalyst. The ECOCLEAR process has been successfully applied in full scale for the treatment of biologically pretreated landfill leachates since 1992.[13]

Ozone/biological treatment

Biological treatment of wastewater is usually the most cost-effective method. However, recalcitrant contaminants in wastewaters are the challenge for biological treatment because they are resistant to biodegradation. Because many recalcitrant contaminants can be oxidized by ozone to produce biodegradable derivatives, the combination of ozone and biological treatment (usually activated sludge treatment) is very useful for wastewaters containing such contaminants.[13,17]

Advanced oxidation processes

Advanced oxidation processes (AOP) have been defined as processes that involve the generation of hydroxyl radicals in sufficient quantity for effective water purification.[13] Ozone-based AOPs generally include the activation of free radicals by 1) hydrogen peroxide (O_3/H_2O_2); 2) UV (O_3/UV); and 3) hydrogen peroxide and UV ($O_3/H_2O_2/UV$).[17] Advanced oxidation processes improve ozonation efficacy, hence can achieve higher-degree mineralization of organic contaminants.[32]

Ozone-based AOPs are being used increasingly to treat landfill leachates.[4] They are also used for groundwater treatment to destroy trichloroethylene (TCE), tetrachloroethylene, and pentachlorophenol. In addition, they are used for groundwater remediation at Superfund sites in the United States to destroy volatile organic compounds and benzidines. Another application of ozone-based AOPs involves their use at U.S. ammunition plants to destroy explosives.[5]

In fact, heterogenous catalytic ozonation introduced above is a novel type of AOP, because a large amount of radicals are produced during the processes.[32]

OZONE APPLICATIONS IN THE FOOD INDUSTRY

Ozone's strong antimicrobial capability and its self-decomposition into nontoxic oxygen make it very useful in enhancing the microbiological safety and quality of food. However, in contrast to the fact that ozone has been used extensively for water treatment since the beginning of the 20th century, its applications in food industries have been limited in the United States. Only in 1982, the United States Food and Drug Administration (USFDA) granted generally recognized as safe (GRAS) status for use of ozone as a disinfectant

in bottled water.[3,10] In 1997, ozone was granted GRAS status by FDA for use as a disinfectant in foods and food processing. Finally, in June 2001, the FDA formally approved the use of ozone as an antimicrobial agent in the gas or liquid phases on food.[33] This approval enhanced ozone's applications in the food industry as an alternative sanitizer/disinfectant for chlorine in North America.

Ozone inactivates numerous bacteria as vegetative cells and as spores. In general, inactivation of spores is more difficult than that of vegetative cells. Ozone inactivates such gram-positive bacteria as *Listeria monocytogenes*, *Staphylococcus aureus*, *Bacillus cereus, Enterococcus faecalis*, and such gram-negative bacteria as *Pseudomonas aeruginosa, Salmonella typhimurium*, and *Yersinia enterocolitica*. Ozone is also an effective fungicidal agent. It inactivates such fungi as *Aspergillus* and *Penicillium*. As for virus inactivation, ozone is effective for a wide range of viruses including Venezuelan equine encephalomyelitis virus, hepatitis A, influenza A, vesicular stomatitis virus, and infectious bovine rhinotracheitis virus as well as several bacteriophage strains. Ozone can also inactivate such protozoa as *Cryptosporidium parvum, Naegleria gruberi, and Giardia lamblia*. Efficacy of ozone inactivation of microflora on food depends on the nature and composition of the food surface, the type of microbial contaminants, and the degree of attachment or association of microorganisms with food.[3,10]

When ozone is used for food protection, it can be used either in gas phase or after dissolving in water. Gaseous ozone is usually used for surface microflora control of beef; disinfection of hatchery, hatching eggs, recycled poultry chiller water, poultry carcass, and contaminated eggs; inactivation of bacteria and fungi associated with cereal grains, peas, beans, spices; mold control of cheese; removal of odor and color from fish flesh; increase of shelf life of fruits and vegetables; disinfection of slaughterhouse effluent.[3,31,34] On the other hand, water containing dissolved ozone is used for reduction of bacterial contamination of beef carcasses and fish, and for sanitation of meat transport vehicles and food plant equipment.

When ozone is used for the treatment of food, the applied dosage should be carefully optimized. Otherwise, at the same time pathogenic microorganisms are inactivated, the quality of food such as color and taste could deteriorate when the applied ozone dosage is over certain thresholds.

OZONE APPLICATIONS IN SOIL DECONTAMINATION

Soils contaminated by PAHs are widespread, mainly due to fuel oil spills. Biodegradation has been successfully used for soils contaminated with low molecular weight PAHs. However, the higher molecular weight PAHs are resistant to bioremediation.[6,35,36] Similarly, ozone alone has been found to be very efficient for the destruction of PAHs containing two and threebenzene rings in soils, but was not effective for those PAHs containing four and five rings.[35] However, the integrated ozonation and biodegradation processes are found to be more effective than either of them alone. The preozonation generates products that have a better solubility in water and thus a better bioavailability, which is of great importance for a successful bioremediation of the PAHs.[36] Therefore, the combination of ozonation and subsequent biological degradation may be a successful technology in the remediation of soils contaminated with PAHs.

The use of gaseous ozone for in situ chemical oxidation is more effective than aqueous-based systems for the treatment of contaminated soils, because the diffusivity of ozone gas is much greater than that for aqueous species. In addition, the concentration of ozone in the gas phase can be orders of magnitude higher than that obtainable in aqueous solutions, and ozone is more stable in the gas phase than in water.[6]

OZONE APPLICATIONS IN POLYMER SURFACE MODIFICATION

Polymers have been extensively used in the medical field for a large number of important implants and devices since the early 1950s. In spite of their extensive applications, to date the general biocompatibility problem of the polymer materials has not been completely solved. The natural inert surfaces of polymers hinder their applications as biomaterials, which require excellent wettablity. One approach to improve the biocompatibility of some polymers is the ozone-induced graft polymerization. In this approach, the polymer is oxidized by gaseous ozone to generate peroxide groups on the surface, and the peroxide groups are capable of initiating free radical graft copolymerization of various monomers with hydrophilic groups, resulting in modified surfaces with increased hydrophilicity and reduced protein adsorption.[7]

Surface ozone oxidation is applied in polymers because it has the following advantages: it introduces peroxides uniformly on the polymer surfaces; it is applicable to complex geometries; it can be handled easily; and it is relatively economical as compared with other techniques such as corona discharge, plasma treatment, flame treatment, irradiation with gamma rays.[7,8,37]

The common base polymers whose surfaces would be oxidatively modified by ozone include polyurethanes (PU), segmented polyether urethane (SPEU),

polypropylene (PP), polyethylene (PE), polymethylmethacrylate (PMMA). The common monomers used for graft include acrylamide (AAm), 2-hydroxyethyl methacrylate (HEMA), polyethylene oxide (PEO), *N, N′*-dimethyl-*N*-methacryloyloxyethyl-*N*-(3-sulfopropyl ammonium (DMMSA). The ozone-induced graft polymerization has been successfully applied for grafting HEMA monomer onto PP, grafting AAm onto PU film, grafting PEG onto PU, PE, and PMMA, and grafting DMMSA on to SPEU.[7,8,37,38]

OZONE APPLICATIONS IN BLEACHING PAPER PULPS

Ozone has been increasingly used to replace chlorine for bleaching paper pulps. Changing the bleaching agent from chlorine to ozone eliminates the production of AOX (adsorbable organic halides) compounds, which are very difficult to destroy by chemical oxidation once formed, hence they will remain in the paper mill effluents. Moreover, the chlorine-free bleaching could result in the recycle/reuse of a significant amount of process waters, or could even allow the paper mills to be effluent-free.[4,5]

The world's largest industrial ozonation system of 420 kg O_3/hr production capacity is in operation in a pulp bleaching process in Finland, and at least 10 commercial ozone pulp bleaching mills are in operation in various countries throughout the world.[5,13]

CONCLUSIONS

Ozone has been applied successfully and extensively for water and wastewater treatment. Ozone also has been used as a safe and effective antimicrobial agent in many food applications. Other applications of ozone include soil decontamination, polymer surface modification, and bleaching paper pulps. It is recognized that for water treatment, the combined use of ozone with either biological treatment, or heterogenous catalysts, or UV and/or H_2O_2 makes the whole process more efficient.

Packed Absorption Column Design

Karl B. Schnelle, Jr.
Department of Chemical Engineering, Vanderbilt University, Nashville, Tennessee, U.S.A.

Partha Dey
P.A. Consulting, Nashville, Tennessee, U.S.A.

INTRODUCTION

Absorption columns may be packed towers or plate towers. As the current process usage is leaning more toward packed towers and especially structured packing, this entry will concentrate on vertical packed tower design. There are two directions of flow in a vertical tower, countercurrent and cocurrent. This entry presents the methodology for vertical countercurrent and cocurrent packed absorption column design. In the basic sense, the design consists of determining the tower diameter and packing height. The tower diameter depends on the fluid dynamics of the flow. The tower height depends on the vapor–liquid equilibrium and mass transfer characteristics, which are also functions of the fluid dynamics. Cross-flow towers are also used in absorption. Here, the gas flows horizontally and the liquid is sprayed down on the gas flow. Design is more complicated for the cross-flow tower and will not be considered in this entry.

In countercurrent flow, the tower must be designed to prevent flooding, which occurs when the upward flow of the gas is of sufficient velocity, to prevent the liquid flow from coming down the column. The advantage of a cocurrent tower is that the fluids flow both in the same direction, usually downward, and flooding will not occur. High flow rates of both the liquid and gas may be used, which results in smaller column diameters. The disadvantage of cocurrent flow absorbers is that only one equilibrium stage is available. Therefore, the mass transfer may not be sufficient.

Tower height depends on vapor–liquid equilibrium and mass transfer. The driving force for mass transfer in absorption is the concentration difference of the solute between the gaseous and liquid phases. The driving force can be interpreted as the difference between the partial pressure of the soluble gas in the gas mixture and the vapor pressure of the solute gas in the liquid film in contact with the gas. If the driving is negative, desorption or stripping will occur, and the concentration of the gas being treated will increase.

THERMODYNAMIC EQUILIBRIUM RELATIONSHIPS FOR ABSORPTION COLUMNS

For an extensive discussion of phase equilibria, consult Smith, van Ness, and Abbott[1] for an introductory treatise, and Prausnitz, Lichtenthaler, and Gomes de Azevado[2] for a more advanced text.

Conditions for Equilibrium

The concept of fugacity was developed by Lewis.[3] Fugacity for a vapor can be defined by Eq. (1).

$$\frac{f_i^v}{y_i P} \rightarrow 1 \quad \text{as } P \rightarrow 0 \tag{1}$$

Here, y_i is the mole fraction of component i in the vapor. As $P \rightarrow 0$, the vapor approaches an ideal gas. Therefore, for an ideal gas, the fugacity is the partial pressure $y_i P$ as seen in Eq. (2).

$$f_i^v = y_i P \tag{2}$$

Equilibrium for a vapor and a liquid (VLE) is defined in Eq. (3).

$$f_i^v = f_i^l \tag{3}$$

Raoult's Law

Raoult's law is the simplest quantitative expression for vapor–liquid equilibrium. This law is based on the vapor phase being an ideal gas and the liquid phase being an ideal solution. Therefore, the vapor-phase fugacity is given by Eq. (2). The effect of pressure on the liquid phase is very small, and since the vapor is ideal, the liquid fugacity may be written as in Eq. (4). Here, P_i^{sat} is the vapor pressure of component i at the temperature of the solution.

$$f_i^l = x_i P^{sat} \tag{4}$$

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120041351

Substituting Eqs. (2) and (4) into Eq. (3) results in Eq. (5) known as Raoult's law.

$$y_i P = x_i P_i^{sat} \quad (5)$$

Note that this law was developed essentially for an ideal solution where the vapor is an ideal gas. Therefore, Raoult's law is very limited in its usefulness. Essentially, it is valid for solutions of chemically similar compounds at a pressure of up to 2 or 3 bars. Raoult's law can be applied only to systems where the component's vapor pressure is known. If the temperature of the system is above the critical temperature for any component, there is no vapor pressure for that component, and other means must be employed to determine compositions. This situation is described by Henry's law in the following section.

Henry's Law

In the case where the solute is at a temperature above its critical temperature, the liquid mixture cannot exist over the entire composition range. Assume that we are dealing with an ideal dilute solution where the solvent does not dissolve in the solute. We can write the fugacity for an ideal solution as in Eq. (6) where f_i is the fugacity of pure component i.

$$f_i^{id} = x_i f_i \quad (6)$$

As we have a dilute solution, we can assume that no solvent dissolves in the solute. Let subscript 1 refer to the solvent and subscript 2 to the solute. Then, as $x_2 \rightarrow 0$, Eq. (7) results in

$$\lim_{x_2 \rightarrow 0} \frac{f_1^{id}}{x_1} = f_1 \quad (7)$$

For component 2, the solute, we can define Henry's law constant by Eq. (8).

$$\lim_{x_2 \rightarrow 0} \frac{f_2^{id}}{x_2} = H_{2,1} \quad (8)$$

Henry's law for a dilute solution and for the situation where the pressure is low enough that the ideal gas can apply is given by Eq. (9) and this is very similar to Eq. (5),

$$y_2 P = x_2 H_{2,1} \quad (9)$$

Raoult's law, but now it is applied to dilute solutions. It is also apparent that Eq. (9) can be applied to the case where gases are only slightly soluble in a solvent. A classic case is to determine the saturation concentration of oxygen in natural waters and in waste treatment plant effluents.

The Case for Nonideal Liquid Solutions and Ideal Vapor Solutions

In the case of the ideal gas solution at a moderate pressure, Eq. (2) defines the fugacity for the vapor. The activity coefficient can be defined by Eq. (10), where f_i^* is the fugacity of

$$\gamma_i^l = \frac{f_i^l}{x_i f_i^*} \quad (10)$$

component i in the standard state. If we now assume that the pure component at the pressure and temperature of the solution becomes the standard state of the liquid, f_i^* becomes the vapor pressure of component i. The vapor–liquid equilibrium can now be written as Eq. (11).

$$y_i P = x_i \gamma_i^l P_i^{sat} \quad (11)$$

This formulation is Raoult's law extended by the inclusion of the activity coefficient and is not much more difficult to use and it has much greater utility and accuracy at moderate pressures than Raoult's law. It is especially useful when correlations are available for liquid-phase activity coefficients γ_i^l.

Correlations Representing VLE Data—Margules, van Laar, Wilson, and UNIQUAC

Wohl[4] proposed a general method for expressing excess Gibbs energies as a function of effective volume fractions. Liquid mole fractions can be related to the excess volume fractions. The advantage of Wohl's method is that a rough physical significance could be attached to the parameters of the equations. Prausnitz, Lichtenthaler, and Gomes de Azevado[2] give a detailed description of Wohl's method and the relation to equations representing the excess Gibbs energy. The Margules and van Laar equations are common relationships that can be derived from Wohl's work. Margules equations are best for molecules of similar size, and van Laar's equations are best for molecules of different sizes.

There are many other equations, which have been proposed, that do not result from Wohl's method. Two of the most popular equations are the Wilson[6] and the universal quasi-chemical theory (UNIQUAC) by Abrams and Prausnitz.[5] These equations are based on the concept of local composition models, which was proposed by Wilson[6] in his paper. It is presumed in a solution that there are local compositions that differ

from that of overall mixture. These local compositions result from differences in molecular size and intermolecular forces. The local compositions account for the short-range order and nonrandom molecular orientations.

Multicomponent Solutions

It is difficult to fit data with the local composition models due to their complex logarithmic forms. However, they are readily generalizable to multicomponent systems. Smith, van Ness, and Abbott[1] and Prausnitz, Lichtenthaler, and Gomes de Azevedo[2] present the Wilson and UNIQUAC models extended for multicomponent solutions. They both employ the constants from binary data. However, the constants are not unique in the sense that valid, but different constants may be obtained from different sets of data. Wilson's equations cannot be employed for immiscible solutions, but the UNIQUAC model may be used to describe such solutions. However, Wilson's equations are good for polar or associating compounds. A compilation of Wilson parameters can be found by Hirata, Ohe, and Nagahama.[7]

The UNIQUAC method of Abrams and Prausnitz[5] divides the excess Gibbs free energy into two parts, the combinatorial part and a part describing the intermolecular forces. The sizes and shapes of the molecule determine the combinatorial part and are thus dependent on the compositions and require only pure component data. As the residual part depends on the intermolecular forces, two adjustable binary parameters are used to better describe the intermolecular forces. The UNIQUAC equations are about as simple for multicomponent solutions as for binary solutions. Parameters for the UNIQUAC equations can be found by Gmehling, Onken, and Arlt.[8]

UNIFAC—A Group Contribution Method

When it is necessary to estimate activity coefficients where no data or very limited data are available, estimates may be made by using a group contribution method. In this case, a molecule is divided into functional groups, or subgroups of the molecule. These subgroups are assumed to act independently of the molecule in which they appear. Molecular interactions are accounted for by properly weighted sums of group interactions. Fredenslund, Jones, and Prausnitz[9] developed the method for UNIQUAC and named it as universal functional activity coefficient (UNIFAC). Smith, van Ness, and Abbott[1] report the equations for the activity coefficients of multicomponent solutions and their parameters. These equations are very similar to the equations for UNIQUAC. Recent sources for the group interaction parameters may be found by Hansen et al.[10] Gmehling, Li, and Schiller,[8] and Fredenslund and Sørensen.[9]

Dealing with the Nonideal Case

The fugacity of the vapor phase can be accurately represented in terms of a fugacity coefficient defined by Eq. (12). For an ideal gas, $\phi_i^v = 1.00$, and the vapor-phase fugacity can be

$$\phi_i^v = \frac{f_i^v}{y_i P} \tag{12}$$

represented by Eq. (2). A most exact representation for vapor–liquid equilibrium can then be written as Eq. (13). A liquid-phase fugacity can be calculated from Eq. (14).

$$y_i^v \phi_i^v P = x_i \gamma_i^l f_i^l \tag{13}$$

In Eq. (13), ϕ_i^v becomes the fugacity coefficient at saturation conditions.

$$f_i^c = \phi_i^{sat} P_i^{sat} \exp\left[\frac{v_i^c (P - P_i^{sat})}{RT}\right] \tag{14}$$

If it is assumed that the specific volume, v_i^c, of the phase is very nearly constant over a large pressure increase, then when the pressure difference in the exponential is small enough, the exponential will be nearly one. Thus, at moderate pressures the fugacity of a condensed phase is nearly equal to the vapor pressure. This approximation was used in Eq. (11) to write Raoult's Law. When the pressure is low enough that the fugacity coefficient is nearly 1.00, Eq. (13) reduces to Raoult's Law extended with the activity coefficient included or Eq. (11). The fugacity coefficient can be calculated from equations of state, and the activity coefficient can be found from various correlations as discussed earlier.

The Equilibrium *K* Value

A useful formulation for VLE in separation calculations is the equilibrium K value defined in Eq. (15).

$$K_i \equiv \frac{y_i}{x_i} = \frac{\gamma_i^l f_i^l}{\phi_i^v P} \tag{15}$$

Under conditions of low pressure when the fugacity coefficient for the vapor is nearly 1.00, then K becomes Eq. (16), which for the case of an ideal solution can

then be simplified to Eq. (17).

$$K_i = \frac{\gamma_i^l P_i^{sat}}{P} \tag{16}$$

$$K_i = \frac{P_i^{sat}}{P} \tag{17}$$

Originally there were charts prepared to make use of these definitions. The DePriester Charts[11] for the homologous series of light hydrocarbons can serve as a basis with approximate validity for simple calculations of VLE situations.

MASS TRANSFER

The Whitman Two-Film Theory

Mass transfer in real absorption equipment resembles a molecular diffusion process only in the basic idea of a concentration difference driving force. However, the two-film theory of Whitman[12] can be used to construct a model similar in many respects to molecular diffusion equations. Fig. 1 is a schematic representing the Whitman two-film theory:

The theory may be summarized as follows:

1. Visualize two films, the gas and liquid films, on either side of the interface.
2. Material is transferred in the bulk of the phases by convection currents. Concentration differences are negligible except in the vicinity of the interface.
3. On each side of the interface, convection currents die out and the two thin films form.
4. Both films offer resistance to the mass transfer. Transfer takes place through these films by a mechanism similar to molecular diffusion.
5. The interface is at equilibrium and offers no resistance to mass transfer.
6. There is uniform composition in the main stream.
7. At the interface, y_{Ai} and x_{Ai} are considered to be in equilibrium described by Henry's law, $y_{Ai} = m_i x_{Ai}$, where m_i is the Henry's law constant.

In a packed absorption column, the fluid is in turbulent motion. Mass transfer through the films is defined by k_y and k_x, which are now turbulent mass transfer coefficients. An equation similar to that for molecular diffusion can be used to describe the mass transfer. However, in this case, the concentration difference is expressed in terms of mole fractions at the interface. The molar mass transferred $\overline{N}_A$ can be found from Eq. (18).

$$\overline{N}_A = k_y(y_A - y_{Ai}) = k_x(x_{Ai} - x_A) \tag{18}$$

Overall Mass Transfer Coefficients

Mass transfer coefficients defined on the basis of interfacial mole fractions have little practical value because

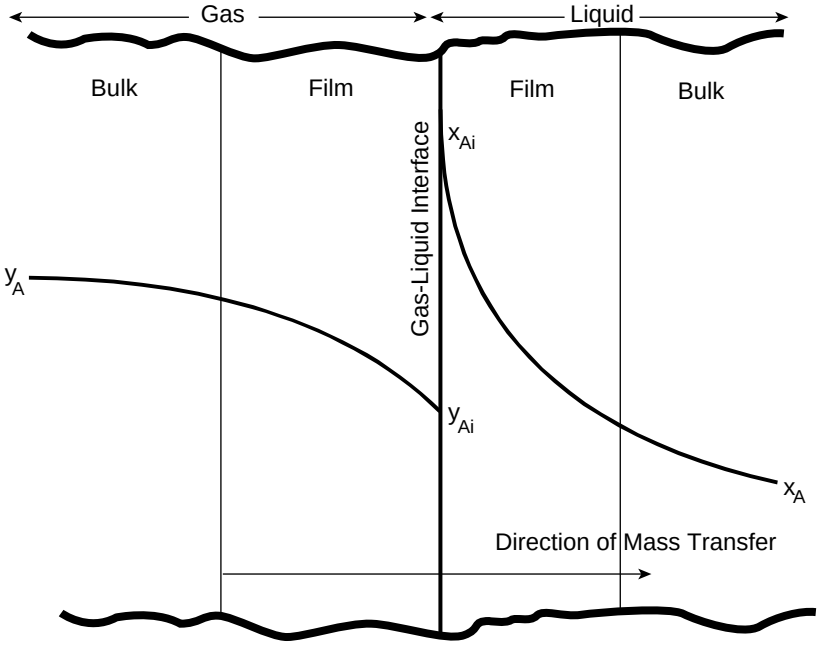

Fig. 1 Whitman two-film theory.

these mole fractions cannot be measured. A new mass transfer coefficient can be defined, which can be determined from measured data. Two new pseudo-mole fractions are defined as illustrated in the Fig. 2. Overall mass transfer coefficients K_y and K_x are defined based on these new pseudo-mole fractions defined below:

y_A^*, equilibrium mole fraction of the solute in the vapor corresponding to the mole fraction x_A in the liquid.

x_A^*, equilibrium mole fraction of the solute in the liquid corresponding to the mole fraction y_A in the vapor.

The mass transfer may now be written as

$$\overline{N}_A = K_y(y_A - y_A^*) = K_x(x_A^* - x_A) \tag{19}$$

The mass balance line or the operating line and the equilibrium curve are both plotted in Fig. 2. The construction in the figure illustrates how to determine y_A^* for any y_A, and x_A^* for any x_A. The overall coefficients can be related as follows to the individual phase coefficients making use of Henry's law constant m.

$$\frac{1}{K_y} = \frac{1}{k_y} + \frac{m}{k_x} \tag{20}$$

Volume-Based Mass Transfer Coefficients

Absorption towers are packed with plastic, metal, or ceramic pieces to provide a greater area for contact between the vapor and the liquid phases. Each of these packings has a characteristic area per unit volume of packing, which can be denoted by the quantity "a," where

$$a = \frac{\text{Interfacial area}}{\text{Unit volume}}$$

The flow rate of both phases, viscosity, density, surface tension, and size and shape of the packing determine the value of "a". These same factors affect the value of the mass transfer coefficients K_y and K_x. Therefore, it is expedient to include "a" in the mass transfer equation and define two new quantities $K_y a$ and $K_x a$. These quantities would then be correlated with the solution parameters as functions of various chemical systems. If A is the absorption tower cross-sectional area, and z the packing height, then Az is the tower packing volume. Defining A_i as the total interfacial area:

$$A_i = aAz \tag{21}$$

We can now rewrite Eq. (19) in terms of a differential rate of mass transfer dN_A, with units (moles/unit unit time) = (moles/unit time – interfacial area) × (interfacial area),

$$\begin{aligned} dN_A &= \overline{N}_A dA_i = K_y a(y_A - y_A^*) A dz \\ &= K_x a(x_A^* - x_A) A dz \end{aligned} \tag{22}$$

Eq. (22) defines the volumetric mass transfer coefficients $K_y a$ and $K_x a$, which have the typical unit moles/(hr m^3 mole fraction). Note also that the term Adz represents the differential packed tower volume. Therefore, Eq. (22) can serve as a model to determine packing height in a packed absorption tower.

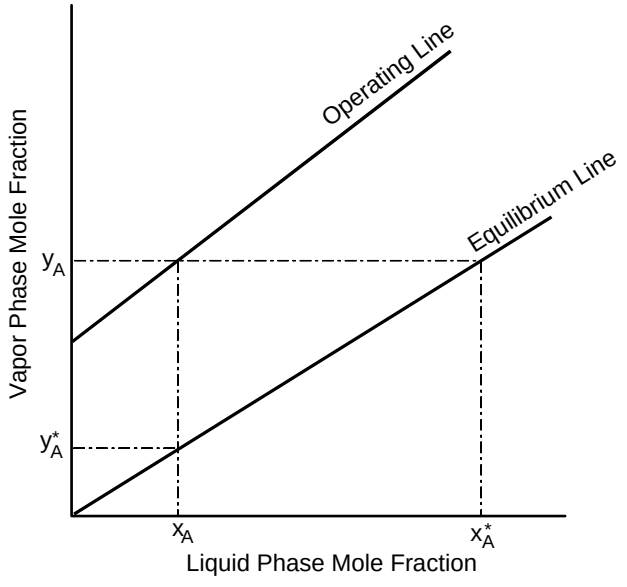

Fig. 2 Pseudo-mole fractions defined.

PACKED TOWER DESIGN

In a packed tower operating in countercurrent flow at a constant liquid rate, the pressure drop varies with the gas mass velocity. With liquid holdup in the packing, there is smaller void space in the column, and a higher pressure drop exists than with dry packing. When plotting gas flow rate vs. pressure drop at a constant liquid flow rate and lower gas flow rates, the liquid flow rate lines are nearly parallel to the dry line up to high liquid flow rates. However, there is a continually increasing pressure drop with gas flow at any liquid flow rate until the slope of the curves become infinite. The point at which the rate of change in pressure drop increases more rapidly than a constant value has been called the upper loading point. The liquid holdup now increases with the increasing gas rate.

Above the loading region, the column will approach the maximum hydraulic capacity at the point where the slope becomes infinite. This is the upper limit to the gas rate. The velocity corresponding to this upper limit is known as the flooding velocity. Flooding can be observed as a crowning of the packing that begins at the bottom and progresses to the top of the packing where a layer of liquid is visible above the packing. At gas rates greater than the flooding velocity, the column will act as a gas bubbler. The greater the liquid rate, the lower the gas velocity at which flooding occurs. Larger more open packings flood at high velocities than smaller, denser packings.

Liquid holdup is a function of liquid flow rate and column pressure drop. Two types of holdup have been defined. Static holdup is the volume of liquid per volume of packing that remains after gas and liquid flows are stopped and bed has drained. Static holdup depends on packing surface characteristics. The second type is operating holdup that is the volume of liquid per volume of packing that drains out of the bed after gas and liquid flows have been stopped. The gas flow rate has little effect on holdup below loading.

Packed towers may be operated above 90% of the flooding velocity when pressure controls are provided to maintain a fixed maximum pressure drop not to exceed the desired flooding velocity. Strigle[13] suggests the following operational characteristics for countercurrent towers.

- Pressure drop between 0.25 and 0.60 in H_2O per foot of packing.
- Air velocity between 5.0 and 8.0 ft/sec with modern high-capacity plastic packing.
- Liquid irrigation rates typically between 2 and 8 gpm/ft^2 of column cross-sectional area.

Choosing a Liquid–Gas Flow Ratio

Fig. 3 illustrates a packed absorption tower with countercurrent flow where flow rates are constant. Making a differential mass balance around the differential cross section in molar units results in Eq. (23). This equation can now be integrated from the top of the column down

$$\mathrm{d}(Gy_\mathrm{A}) = \mathrm{d}(Lx_\mathrm{A}) \tag{23}$$

to the tower cross section, producing Eq. (24), defined as the operating line. A common

$$y_\mathrm{A}G - y_{\mathrm{A}1}G_1 = x_\mathrm{A}L - x_{\mathrm{A}1}L_1 \tag{24}$$

equation for general use, especially when dilute solutions are not expected, is to rewrite the flow rates

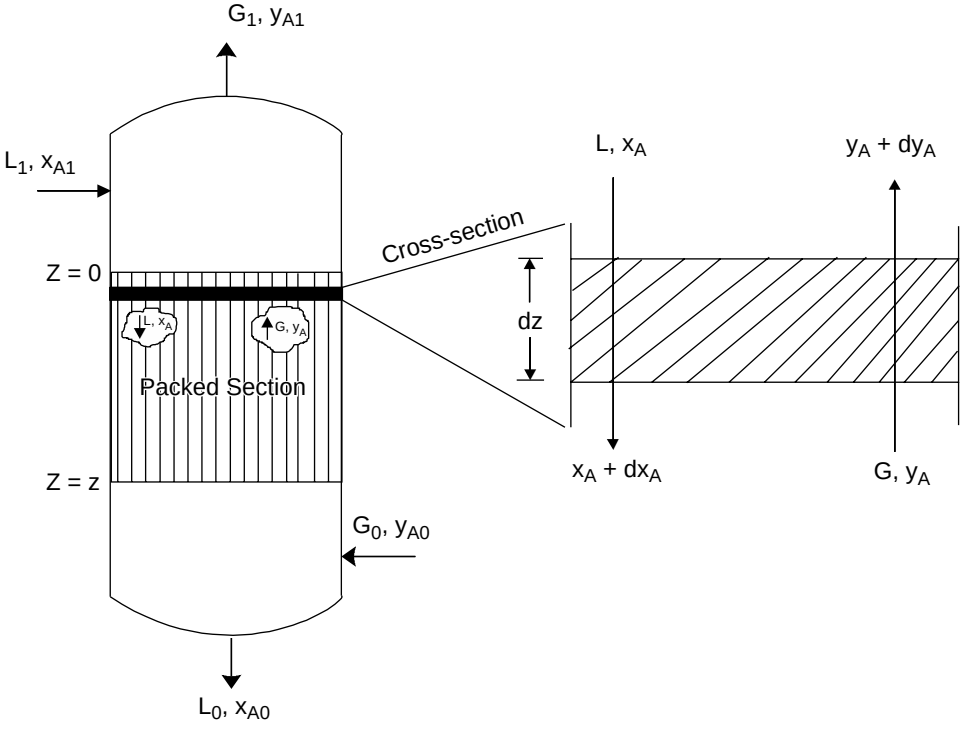

Fig. 3 Countercurrent flow-packed absorption tower.

on a solute-free basis. Eq. (25) uses these solute-free flow rates designated by the subscript B.

$$\left(\frac{y_A}{1 - y_A}\right)G_B + \left(\frac{x_{A1}}{1 - x_{A1}}\right)L_B = \left(\frac{x_A}{1 - x_A}\right)L_B + \left(\frac{y_{A1}}{1 - y_{A1}}\right)G_B \quad (25)$$

For dilute solutions, which might be found in most air pollution control conditions. Eq. (25) reduces to Eq. (24)—a general equation that can be used along with a general equilibrium relationship such as Eqs. (13) and (15). For this case of a dilute solution, Eq. (24) will be used along with Eq. (9), Henry's law. Then, both the equilibrium line and the operating line will plot as a straight line on an x–y plot.

Choosing a Liquid–Gas Flow Rate

When designing an absorption tower for removal of a component, usually the following variables will be known:

G, molar gas flow rate.

L, molar liquid flow rate.

y_{A0}, mole fraction of A, gas at inlet coming from process.

y_{A1}, mole fraction of A, gas at outlet (specified by control agency regulation if discharged to the atmosphere).

x_{A1}, mole fraction of A, liquid into tower, quite frequently is zero if solvent is used only once.

Eq. (24), the material balance up to the tower cross section, can be rearranged as follows.

$$y_{A0} = \left(\frac{L}{G}\right)(x_{A0} - x_{A1}) + y_{A1} \quad (26)$$

Thus, if L or (L/G) can be found, the entire material balance will be solved.

In absorption, on a plot of y_A vs. x_A, the equilibrium curve can be concave up or can be nearly a straight line, or the curve can be "S" shaped, having a concave downward portion. These situations are illustrated in the two equilibrium curves of Fig. 4 on which the operating line as specified by Eq. (26), the material balance, is also plotted. In the case of Fig. 4A with a concave equilibrium line, three possible operating lines are shown. Note that on these plots (L/G) is the slope of the operating line. As can be seen, the line furthest to the right with the smallest slope represents the limit to which the slope of the operating line can be drawn. Thus, this slope represents a minimum (L/G) ratio in which x_{A0} and y_{A0} are actually in equilibrium, and the line could not be drawn with a smaller slope because it would go through equilibrium. As true thermodynamic equilibrium can never be reached practically, this point represents a theoretical minimum (L/G) that never can be attained practically.

In practice, (L/G) ratios are usually set at 1.1–1.7 times this minimum rate. Thus, if G is known, (L/G) is determined and x_{A0} can be found. In the case of Fig. 4B, with an "S"-shaped equilibrium curve, the minimum value of (L/G) is reached at some point within the column where the operating and equilibrium lines are tangent and thermodynamic equilibrium would be "exceeded," if the (L/G) ratio were any smaller.

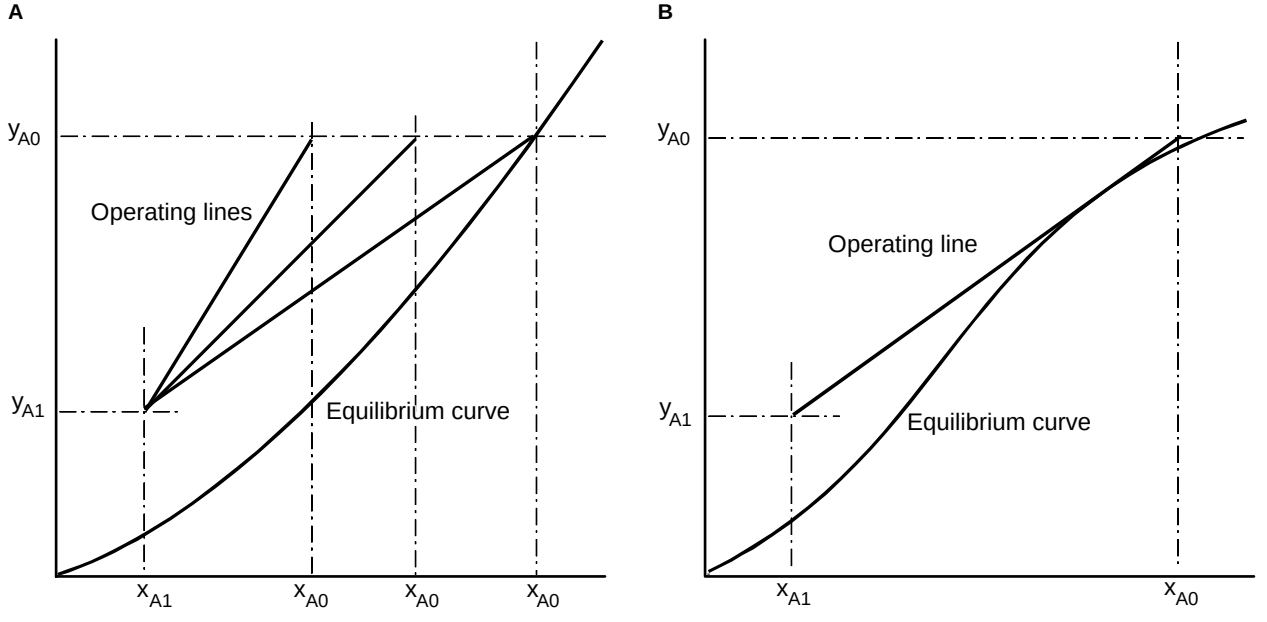

Fig. 4 Operating lines and equilibrium curve relationships.

Determining Tower Diameter—Random-Dumped Packing

From the (L/G) ratio and the overall material balance, having selected the type of packing and the pressure drop per foot of packing, the tower diameter can now be determined. Current accepted practice is to use a modified Sherwood, Shipley, and Holloway[14] flooding correlation to determine tower diameter. Strigle[13] presents such a correlation in Fig. 5 modified with the addition of Sherwood's flooding curve. This correlation uses a linear scale for the ordinate, which is expressed in terms of a capacity factor; C_S. Table 1 presents the definition of terms used in Fig. 5. It should be noted that the pressure-drop correlation ordinate contains a term defined as the packing factor. The packing factor is a characteristic of a particular packing size and shape. Originally it was defined as a^3/ε where a is the interfacial area per packed volume and ε is the void fraction. However, this definition for F did not adequately predict the packing hydraulic performance. Therefore, Table 2 from Strigle[13] presents packing factors that have been calculated from experimentally determined pressure drop.

Since (L/G) is known, we can calculate the value of the abscissa in Fig. 5, if the gas density ρ_G and the liquid density ρ_L are known. Although these densities may vary through the column, the variations will be small, especially in the dilute solution case, and an average of the top and bottom values from the column should be sufficiently accurate. If the entering gas is very dilute, the entering values of density could be used.

From the abscissa, the packing factor, and the required pressure drop per foot of packing, the ordinate of the curve can be read and the value of G^* in $\text{lbs}/\text{ft}^2\,\text{sec}$ calculated. The column cross-sectional area A_s is then:

$$A_s(\text{ft}^2) = \frac{G(\text{lbs/sec})}{G^*\left(\text{lbs}/\text{ft}^2\,\text{sec}\right)} \tag{27}$$

The column diameter can be found from:

$$D = \sqrt{\frac{4G}{\pi G^*}} \tag{28}$$

Determining Tower Diameter—Structured Packing

Parkinson and Ondrey[15] report that structured packing is becoming more frequently used in air separations. They also report that structured packings are being favored because they have a higher capacity than dumped packing, and the scale up is more predicable.

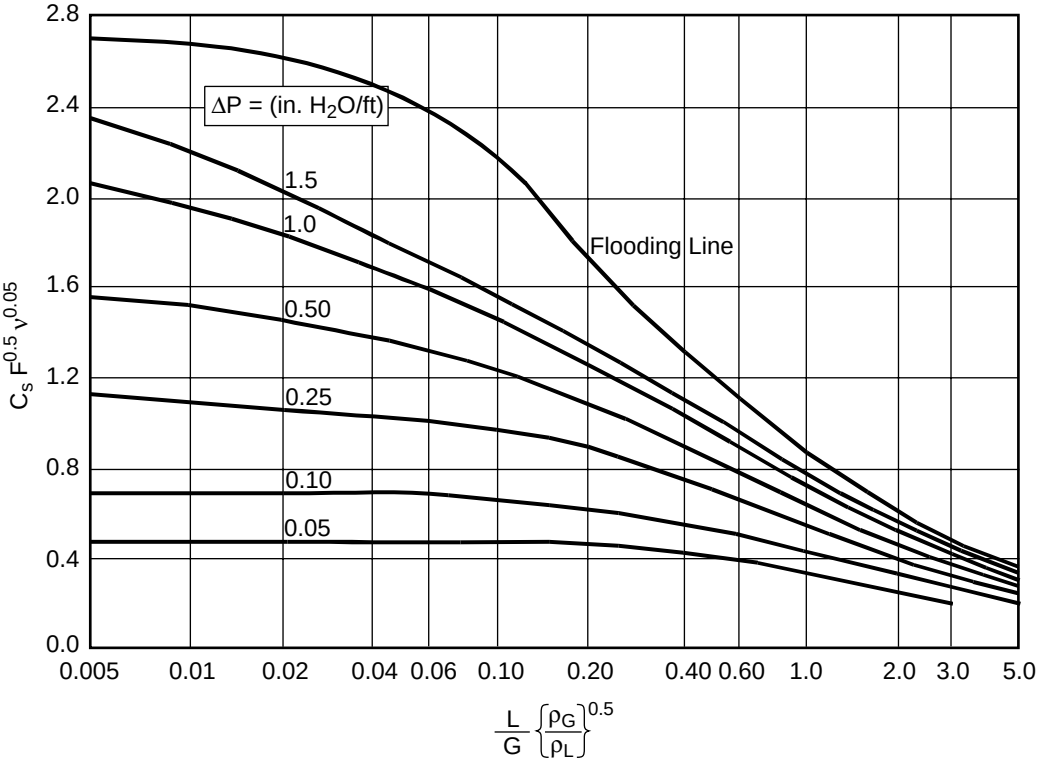

Fig. 5 Generalized pressure-drop correlation. (See Table 1.)

Table 1 Variable definitions and units for Fig. 5

$\overline{L}$	Superficial liquid mass velocity in lbs/ft^2 hr
L	Liquid mass flow rate in lbs/hr
$\overline{G}$	Superficial gas mass velocity in lbs/ft^2 hr
G	Gas mass flow rate in lbs/hr
G^*	Superficial gas mass velocity in lbs/ft^2 sec
ρ_G	Gas density in lb/ft^3
ρ_L	Liquid density in lb/ft^3
V	Kinematic liquid viscosity in cSt
F	Packing factor
$V = G^*/\rho_G$	Superficial velocity in ft/sec
$C_S = V\sqrt{\frac{\rho_G}{\rho_L - \rho_G}}$	Capacity factor in ft/sec

Correlations similar to Fig. 5 have been used to predict the pressure drop in structured packing. Bravo, Rocha, and Fair[16] developed a generalized method of predicting the pressure drop in structured packing. A review of the methods for prediction of the pressure drop in structured packing is presented by Fair and Bravo.[17] Bravo, Rocha, and Fair[16] present a new more comprehensive pressure drop model developed from distillation data. Because the pressure drop curves for random and structured packings are similar, Strigle[13] reports that the pressure drop for structured packing can be estimated from the generalized correlation of Fig. 5. However, in this case the operating pressure affects the packing factor.

Determining Height of Packing in the Tower: The HTU Method

The differential rate of mass transfer given by Eq. (22) is equal to the differential rate of change in mass within a phase, Eq. (23). For the gas phase, the differential rate of mass transfer of component A is equal to the differential rate of change in the mass of A in the incoming gas stream. It can be shown that the differential tower height, dz, is given by Eq. (29). A similar equation based on the liquid phase can be written, which would be useful in

$$\frac{G\mathrm{d}(y_A)}{(1 - y_A)} = K_y a\left(y_A - y_A^*\right) A\mathrm{d}(z) \tag{29}$$

stripping calculations. We now define a mass transfer coefficient, Eq. (30), based on the logarithmic mean concentration, Eq. (31). This mass transfer coefficient is independent of

$$K_y = \frac{K_y^0}{(1 - y_A)_{LM}} \tag{30}$$

$$(1 - y_A)_{LM} = \frac{(1 - y_A) - \left(1 - y_A^*\right)}{\ln\left[\frac{(1 - y_A)}{(1 - y_A^*)}\right]} \tag{31}$$

Table 2 Packing factors, F, for random-dumped packings

Normal packing size (in.)		1/2	5/8	3/4	1	1/4	1 1/2	2	3 or 3 1/2
IMTP packing (metal)		51		41		24	18	12	
Hy-pak packing (metal)					45		29	26	16
Super intalox saddles (ceramic)					60			30	
Super intalox saddles (plastic)					40			28	18
Pall rings (plastic)			95		55		40	26	17
Pall rings (metal)			81		56		40	27	18
Intalox saddles (ceramic)		200		145	92		52	40	22
Raschig rings (ceramic)	580	380	255	179	125	93	65	37	
Raschig rings (1/32-in. metal)		300	170	155	115				
Raschig rings (1/16-in. metal)		410	300	220	144	110	83	57	32
Berl saddles (ceramic)		240		170	110		65	45	

(From Ref.[13].)

flow rate through the column. Define the set of flow rates based on the tower cross section. This

$$\overline{G} = \frac{G}{A} \quad \text{and} \quad \overline{L} = \frac{L}{A} \tag{32}$$

equation can now be integrated down the column from $z = 0$ to $z = z$ to determine the tower height shown in Eq. (33). The ratio of flow rate to mass transfer coefficient has been designated

$$z = \left(\frac{\overline{G}}{K_y^0 a}\right) \int_{y_{A1}}^{y_{A0}} \frac{(1 - y_A)_{LM}}{(1 - y_A)(y_A - y_A^*)} dy_A \tag{33}$$

as the height of a transfer unit (HTU) or for the gas phase, H_{OG}. Therefore, H_{OG} has been

$$H_{OG} = \left(\frac{\overline{G}}{K_y^0 a}\right) \tag{34}$$

defined in such a way that it remains constant through the absorption column. The integral portion of Eq. (33) is designated as the number of overall mass transfer units (NTU) or for the gas phase N_{OG}. Thus

$$N_{OG} = \int_{y_{A1}}^{y_{A0}} \frac{(1 - y_A)_{LM}}{(1 - y_A)(y_A - y_A^*)} dy_A \tag{35}$$

The integral may be evaluated by graphical or numerical techniques. The height of the column may now be calculated from

$$z = H_{OG} N_{OG} \tag{36}$$

Dilute solution case

For dilute solutions, Henry's law is usually a good choice for an equilibrium relationship. In this case, $y_A^* = mx$, which is defined in relation to the overall mass transfer by Eq. (19). For a dilute solution

$$(1 - y_A) \approx (1 - y_A)_{LM} \approx 1.0 \tag{37}$$

and Eq. (35) reduces to

$$N_{OG} = \int_{y_{A1}}^{y_{A0}} \frac{dy_A}{(y_A - y_A^*)} \tag{38}$$

The operating line, Eq. (24), may now be rewritten as

$$y_A = \left(\frac{L}{G}\right)(x_A - x_{A1}) + y_{A1} \tag{39}$$

Note that the ratio $\frac{L}{G} = \frac{\overline{L}}{\overline{G}}$ and introducing Henry's law constant m, the absorption factor A can be defined as

$$A = \frac{L}{mG} = \frac{\overline{L}}{m\overline{G}} \tag{40}$$

Recall that $y_A^* = mx_A$ and solve Eq. (39) for y_A^* after multiplying and dividing by Henry's law constant m, and Eq. (41) results.

$$y_A^* = \left(\frac{y_A - y_{A1}}{A}\right) + mx_{A1} \tag{41}$$

Substituting Eq. (41) into Eq. (38) and integrating, we get:

$$N_{OG} = \frac{\ln\left[\left(\frac{y_{A0} - mx_{A1}}{y_{A1} - mx_{A1}}\right)\left(1 - \frac{1}{A}\right) + \left(\frac{1}{A}\right)\right]}{\left(1 - \frac{1}{A}\right)} \tag{42}$$

When a pure solvent such as water is used, $x_{A1} = 0.0$, and Eq. (42) reduces to

$$N_{OG} = \left(\frac{1}{1 - \frac{1}{A}}\right) \ln\left[\left(\frac{y_{A0}}{y_{A1}}\right)\left(1 - \frac{1}{A}\right) + \frac{1}{A}\right] \tag{43}$$

Colburn[18] put Eq. (43) into graphical form, which makes it easier to use. (See Ref.[19].)

Correlation for the effect of the L/G ratio on the NTU

Eq. (43) is based on Henry's law, which is a straight line on a y_A vs. x_A plot. On the same plot Eq. (39), the operating line, will intersect Henry's law line at the point where $y_{A0} = mx_{A0}$, which can be seen in Fig. 4. This represents the minimum L/G ratio, $(L/G)_{min}$. Eq. (43) can then be redefined as follows. Recall that Eq. (43) is based on $x_{A1} = 0.0$. Solve Eq. (39) for $(L/G)_{min}$, substitute the equilibrium value for x_{A0}, and rearrange the equation with the following result.

$$\left(\frac{L}{G}\right)_{min} = \left(1 - \frac{y_{A1}}{y_{A0}}\right) m \tag{44}$$

Define b as a multiple of $(L/G)_{min}$ to set the actual (L/G), then

$$\left(\frac{L}{G}\right) = b\left(\frac{L}{G}\right)_{min} \tag{45}$$

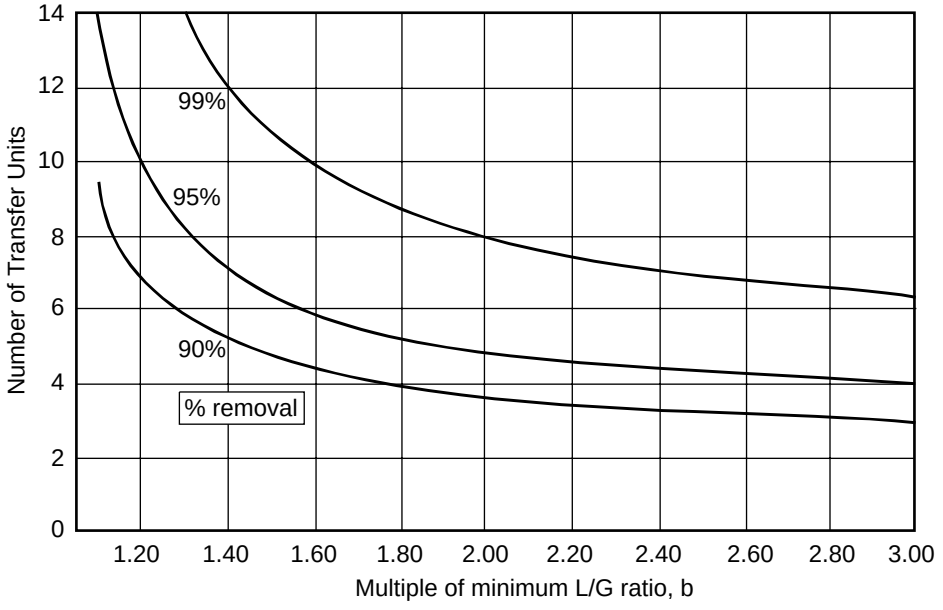

Fig. 6 Effect of the multiple of minimum L/G ratio on the number of transfer units.

and define Ab in the following equation

$$Ab = \frac{b(L/G)_{\min}}{m} = b(1 - y_{A1}/y_{A0}) \tag{46}$$

Under these conditions, the operating line may now be written as

$$y_A = \frac{y_A^*}{m}\left(\frac{L}{G}\right) + y_{A1} \tag{47}$$

which can be substituted into Eq. (38) and integrated with the following result.

$$N_{OG} = \left(\frac{1}{1 - \frac{1}{Ab}}\right) \ln\left[\left(\frac{y_{A0}}{y_{A1}}\right)\left(1 - \frac{1}{Ab}\right) + \frac{1}{Ab}\right] \tag{48}$$

This equation looks the same as Eq. (43) with Ab substituted for A. As Ab is a function of b, which is a multiple of $(L/G)_{\min}$, Fig. 6 is a plot of Eq. (48), N_{OG} vs. b, with (y_{A1}/y_{A0}) as the parameter fixed at 0.90, 0.95, and 0.99 and $x_{A0} = 0.0$. Note that this parameter is the fraction of material A removed from the inlet stream.

Knowing values for $\overline{G}$ and $K_y^0 a$, H_{OG} can be calculated from Eq. (34). For any given value of b, Fig. 6 can be used to determine N_{OG}, if the removal fraction required is between 0.95 and 0.99. Fig. 6 shows that, for dilute solutions, the number of transfer units cannot be materially reduced by increasing b, the multiple of $(L/G)_{\min}$ above 1.70.

COCURRENT TOWER DESIGN

Wankat[20] has a description of the design method for cocurrent packed towers. The procedure to determine the tower height using the HTU method follows that for countercurrent flow.

However, now both streams enter the column at the top. H_{OG} is based on Eq. (39), and N_{OG} is now written as follows.

$$N_{OG} = \int_{y_{A0}}^{y_{A1}} \frac{dy_A}{(y_A - y_A^*)} \tag{49}$$

Eq. (39), the operating line, now becomes

$$y_A = \left(\frac{L}{G}\right)(x_{A1} - x_A) + y_{A1} \tag{50}$$

With a straight operating line and a straight equilibrium line (Henry's Law for example), where the entering absorption liquid is pure, i.e., $x_{A0} = 1.0$, N_{OG} as shown in Eq. (48), it now becomes

$$N_{OG} = \left(\frac{1}{1 + \frac{1}{Ab}}\right) \ln\left[\left(\frac{y_{A1}}{y_{A0}}\right)\left(1 + \frac{1}{Ab}\right) + \frac{1}{Ab}\right] \tag{51}$$

HENRY'S LAW CONSTANTS AND MASS TRANSFER INFORMATION

Limited Henry's Law constants and mass transfer information can be found by Perry and Green.[19]

Yaws, Yang, and Pan[21] have published a listing of Henry's Law constants for 362 organic compounds in water. Strigle[13] also lists mass transfer coefficients for dumped packing. Mass transfer coefficients for structured packing are usually greater than in dumped packing. Manufacturers of structured packing should be consulted for available mass transfer data.

CONCLUSIONS

The methodology and models for packed column design were developed in this entry. The methods are valid for isothermal columns where heat generation from reactions would be negligible. Vapor–liquid equilibrium data are necessary to carry out the design; these data are frequently available in the literature. Mass transfer information is necessary as well to carry out the design. However, mass transfer data are much more difficult to come by. General information required for determining pressure drop is available in the literature. However, companies producing packing can supply data more accurately for their particular packings. Although random or dumped packing is still used, stacked packing is gaining much favor for use in columns. Stacked packing can usually be handled much easier and most usually is more efficient for mass transfer and provides lower pressure drop.

Plate Columns: Plate columns or equilibrium stage columns remain available for absorption operations. They are not as frequently used as the packed column. The design proceeds similar to that of a distillation plate column. As the distillation stage or plate column design began to evolve, it was recognized that the system of equations was very difficult to model. Sorel[22] developed the equilibrium model to solve this problem. In this model, it is assumed that the vapor and the liquid leaving stage are in equilibrium. It is then possible to use thermodynamic calculations to determine the phase equilibria and the energy balance. In carrying out design, it is assumed that the column is composed of equilibrium stages, and the number of equilibrium stages is calculated. These ideal stages are converted to actual stages by means of tray efficiencies. Then, the column diameter can be determined. A graphical solution to Sorel's method developed independently by Ponchon[23] and Savarit[24] solves both the mass and energy balance and phase equilibrium relationships simultaneously stage by stage. This same concept can be applied to absorption column design. Consult Wankat[20] for a discussion of the methodology.

Multicomponent Systems: According to Sherwood and Pigford,[25] in the recovery of natural gasoline and the treatment of refinery gases the problem of multicomponent solutions was of enormous importance in the petroleum industry. The gas to be treated usually consisted of mixtures of methane and several other lower hydrocarbons. The solvent used was usually a nonvolatile light hydrocarbon oil in which the hydrocarbons to be absorbed were highly soluble. In the petroleum industry, plate columns were used and the theoretical-plate concept was employed in the design calculations. Strigle[13] reports on a design technique that could be used for packed absorption tower design. A key component is selected and the absorption efficiency for that component is set. The depth of packing and solvent rate is determined for that component. Then, the effect on the other components is considered. The mass transfer coefficient and driving force will differ for the other components of the solution. Therefore, the economic effects of the removal of the other components need to be considered and the design changed, if necessary, to meet those requirements. Strigle[13] discusses several examples in detail.

Particle–Particle Interaction: Improvements in the Prediction of DLVO Forces

Anh V. Nguyen
Linh T. T. Tran
Discipline of Chemical Engineering, The University of Newcastle, Callaghan, New South Wales, Australia

Jan D. Miller
Department of Metallurgical Engineering, University of Utah, Salt Lake City, Utah, U.S.A.

INTRODUCTION

Particle–particle interaction is central to a wide range of engineering applications and processing industries. Examples include coagulation, flocculation, dispersion, emulsification, and froth flotation. In these applications, the particle size is small, and the overall particulate behavior is determined by forces associated with the surface properties rather than those related to mass or volume. The surface properties of a particle in a liquid medium are the result of a complex interaction between molecules, atoms, and ions at the particle surface and in the surrounding liquid. If a number of particles are present, interactions also take place between particles at short separation distances, and it is this interaction that is of most interest as it can determine the overall stability or instability of dispersions and/or suspensions.

It is customarily assumed that the overall particle–particle interaction can be quantified by a net surface force, which is the sum of a number of independent forces. The most often considered force components are those due to the electrodynamic or van der Waals interactions, the electrostatic double-layer interaction, and other non-DLVO interactions. The first two interactions form the basis of the celebrated Derjaguin–Landau–Verwey–Overbeek (DLVO) theory on colloid stability and coagulation. The non-DLVO forces are usually determined by subtracting the DLVO forces from the experimental data. Therefore, precise prediction of DLVO forces is also critical to the determination of the non-DLVO forces. The surface force apparatus and atomic force microscopy (AFM) have been used to successfully quantify these interaction forces and have revealed important information about the surface force components. This chapter focuses on improved predictions for DLVO forces between colloid and nano-sized particles. The force data obtained with AFM tips are used to illustrate limits of the renowned Derjaguin approximation when applied to surfaces with nano-sized radii of curvature.

This entry is organized in the following paragraphs: First, the advanced determination of van der Waals interaction between spherical particles is described. Second, the relevant approximate expressions and direct numerical solutions for the double-layer interaction between spherical surfaces are reviewed. Third, the experimental data obtained for AFM tips having nano-sized radii of curvature and the DLVO forces predicted by the Derjaguin approximation and improved predictions are compared. Finally, a summary of the review and recommended equations for determining the DLVO interaction force and energy between colloid and nano-sized particles is included.

VAN DER WAALS INTERACTIONS BETWEEN COLLOIDAL PARTICLES

There are essentially two approaches for the determination of the van der Waals interaction energy and forces. In the first, due largely to Hamaker,[1] the interaction between macroscopic bodies is calculated by a pairwise summation of all the relevant microscopic interactions, which are assumed to be nonretarded and additive. In reality, the microscopic interactions are retarded by the nearby atoms and molecules, which are included in the classical theories on retardation via the finite speed of light propagating in dispersed media.[2] The second, more rigorous, approach developed by Lifshitz[3] is based on quantum-mechanics theory and depends entirely on the macroscopic electrodynamic properties of the interacting particles and the media such as dielectric constants and refractive indices. The electric fields established by the fluctuating dipoles are considered to interact both constructively and destructively. The result of these fluctuating and many-body interactions is the formation of a standing wave between the bodies whereby only certain modes, or frequencies of electromagnetic radiation may pass through. The summation of all fluctuation modes in

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120030608

the electromagnetic field gives the van der Waals interaction energy.[4] The full theory is complicated, and this is probably the reason that the additive approach of Hamaker is still used by many scientists. In some cases, the results of the Hamaker theory are accurate when an experimentally determined Hamaker constant is used. For many practical systems of colloidal particles, the Hamaker constant is not known but the Hamaker prediction can be useful if the (effective) Hamaker constant (function) is determined from the Lifshitz continuum approach.

Hamaker Microscopic Approach

In the Hamaker approach, the energies of all the atoms in one body with all the atoms in the other one are summed, leading to an integral expression for the interaction energy, E, between the two macroscopic bodies: $E_{vdW} = -\oint\oint (C\rho_1\rho_2/r^6)\mathrm{d}v_1\mathrm{d}v_2$, where C is the coefficient of the appropriate interaction between elementary particles separated by distance r and $\mathrm{d}v_i$ ($i = 1, 2$) the volume elements of bodies 1 and 2 at distance r, and with densities of atoms or molecules of ρ_i. The problem appears simple since it only requires the calculation of a closed integral. However, the results in closed analytical forms are available only for some simple systems.[4] The Hamaker prediction for interaction energy splits into two terms: the Hamaker constant described by $A = \pi^2 C\rho_1\rho_2$ and the second term that represents the geometrical dependence of the van der Waals energy.

For the van der Waals energy per unit area, E^*_{vdW}, between two half-spaces separated by a distance h, the Hamaker theory gives

$$E^*_{vdW} = -\frac{A}{12\pi h^2} \tag{1}$$

The interaction force, F, is then determined by the first derivative of the energy with respect to the distance by $F(h) = -\mathrm{d}E/\mathrm{d}h$.

The Hamaker interaction energy for two spheres separated by the inter-surface shortest distance, h, is described by

$$E_{vdW} = -\frac{A}{6}\left\{\frac{2R_1R_2}{r^2 - (R_1+R_2)^2} + \frac{2R_1R_2}{r^2 - (R_1 - R_2)^2} + \ln\frac{r^2 - (R_1 + R_2)^2}{r^2 - (R_1 - R_2)^2}\right\} \tag{2}$$

where R_1 and R_2 are the radii of two spheres and r the inter-center distance, $r = R_1 + R_2 + h$. We will see later that Eqs. (1) and (2) are useful for combining the Hamaker microscopic and Lifshitz macroscopic theories.

Lifshitz Macroscopic Approach

The description of the van der Waals interaction based on the Lifshitz[3,5] approach is now sufficiently advanced to provide accurate predictions for the complete interaction energy. For the geometry of two half-spaces, the exact theory is available in a formulation suited for computational purposes.[4] In parallel with work on planar systems, there has been a focus on the interaction between spheres.[4,6–8] These developed theories have been used as the exact solutions in the validation of the approximate predictions using the Hamaker approach. The significant contribution of the continuum approach to our understanding of the van der Waals interaction lies in the reliable prediction of the Hamaker constant. The interaction energy for two half-spaces and two spheres is summarized below.

The van der Waals interaction energy, E^*_{132}, per unit area between two half-spaces 1, 2 immersed in a medium 3 as a function of the separation, h, is described by the Lifshitz macroscopic theory as follows:[4]

$$E^*_{132}(h) = \frac{k_BT}{8\pi h^2}{\sum_{N=0}^{\infty}}' \int_{x_N}^{\infty} x\ln[(1 - y_{13}y_{23}e^{-x}) \times (1 - z_{13}z_{23}e^{-x})]\mathrm{d}x \tag{3}$$

where $y_{a3} = \frac{x\varepsilon_a - s_a\varepsilon_3}{x\varepsilon_a + s_a\varepsilon_3}$, $z_{a3} = \frac{x - s_a}{x + s_a}$, $\xi_N = 2N\pi k_BT/\hbar$, $x_N = 2h\xi_N\sqrt{\varepsilon_3}/c$, $\varepsilon_a = \varepsilon_a(i\xi_N)$, and $s_a^2 = x^2 + x_N^2\{\varepsilon_a/\varepsilon_3 - 1\}$. In these equations, the subscript $a = 1$ to 3, $i = \sqrt{-1}$, c is the speed of light, k_B Boltzmann's constant, T the absolute temperature, $\hbar$ the Planck constant divided by 2π, and $i\xi_N$ are the discrete equally spaced imaginary frequencies. The prime on the summation symbol indicates that the zero-frequency term, which accounts for the contributions due to the orientation and induction interactions, is divided by 2. Eq. (3) shows that the interaction energy depends on electromagnetic fluctuations, via the relative permittivity, $\varepsilon(i\xi_N)$, of all three materials.

For two spheres separated by the (shortest) distance, h, the interaction energy is given by the Lifshitz macroscopic theory:[6,9]

$$E_{132}(h) = k_BT\sum_{N=0}^{\infty}\sum_{m,n=1}^{\infty}(2m+1)(2n+1)\Delta_m\Delta_n \times \sum_{\mu=-\mu_m}^{\mu_m} V^{\mu}_{mn}(K_3r)V^{-\mu}_{nm}(K_3r) \tag{4}$$

where

$$\Delta_m = \frac{\begin{array}{r}(x_3^2 - x_1^2)mi_m(x_3)i_m(x_1) + x_3x_1[x_1i_m(x_1)i_{m-1}(x_3) \\ - x_3i_m(x_3)i_{m-1}(x_1)]\end{array}}{\begin{array}{r}(x_3^2 - x_1^2)mk_m(x_3)i_m(x_1) - x_3x_1[x_1i_m(x_1)k_{m-1}(x_3) \\ + x_3k_m(x_3)i_{m-1}(x_1)]\end{array}}$$

$$V_{mn}^{\mu}(x) = U_{mn}^{\mu}(x) + \frac{n - \mu + 1}{(n + 1)(2n + 1)} xU_{mn+1}^{\mu}(x) - \frac{n + \mu}{n(2n + 1)} xU_{mn-1}^{\mu}(x),$$

$$U_{mn}^{\mu}(x) = \left(\frac{2}{x}\right)^{\mu} \sum_{v=0}^{v_m} S_{mn}^{\mu v} k_{m+n-\mu-2v}(x),$$

$$V_{mn}^{-\mu}(x) = \frac{(n - \mu)!(m - \mu)!}{(n + \mu)!(m + \mu)!} V_{mn+1}^{\mu}(x),$$

and

$$S_{mn}^{\mu v} = \frac{\begin{array}{r}\Gamma(m - v + 1/2)\Gamma(n - v + 1/2)\Gamma(m + v + 1/2) \\ \times (m + n - v)!(m + n - \mu - 2v + 1/2)\end{array}}{\begin{array}{r}\Gamma(m + n - \mu - v + 3/2)\Gamma(\mu + 1/2)\Gamma(1/2) \\ \times (m - \mu - v)!(n - \mu - v)!v!\end{array}}.$$

In these equations, $K_a = (\xi_N/c)\sqrt{\varepsilon_a(i\xi_N)}$ ($a = 1, 2, 3$), $x_a = K_aR, \varepsilon_a$ is the permittivity, $\mu_m = \min(m, n)$, $v_m = \min(m - \mu, n - \mu)$, r the inter-center distance, $r = R_1 + R_2 + h$, Γ the gamma function, and i_m and k_m are the modified spherical Bessel functions of the order m and of the first and second kind, respectively. The susceptibility function Δ_m is purposely used for particle 1 with radius $R = R_1$. The susceptibility function Δ_n is used for particle 2 and can be described similarly with x_1 replaced by x_2 and $R = R_2$. There is a typographic error in Δ_m given in:[9] the term in the brackets must be multiplied by the particle radius. The modified spherical Bessel functions are not uniquely defined in the literature. In this chapter, the functions are defined by the respective modified Bessel functions: $i_m(x) = \sqrt{\pi/(2x)}I_{m+1/2}(x)$ and $k_m(x) = \sqrt{2/(\pi x)}K_{m+1/2}(x)$. Because the definition of modified spherical Bessel functions of the third kind is not unique in the literature, the Bessel functions of the third kind are not used in the above equations.

The convergence of Langbein's solution described by Eq. (4) is slow. Pailthorpe and Russel[9] evaluated Eq. (4) by computing the difference between the retarded and nonretarded interactions, which converges much faster. They then evaluated the nonretarded interaction by using Love's prediction,[7] which is faster than evaluating Langbein's nonretarded expression, and added this to the difference. Fig. 1 shows the results of the calculation and comparison with different models.

The full spectra of permittivities are required in the calculation of the van der Waals interaction energy using Eqs. (3) and (4). For water and a few materials, the dependence of the permittivity, ε_a, on the sampling frequency, ξ_N, is available (see Fig. 2).[10–12] For highly polar liquids such as water, the relaxation in the microwave and infrared appears significant and the oscillator model for the spectrum of water permittivity has a number of terms as described by Eq. (5), and the model parameters are given in Table 1.

$$\varepsilon(i\xi) = 1 + \frac{d_m}{1 + \xi\tau_m} + \sum_j \frac{f_j}{\omega_j^2 + g_j\xi + \xi^2} \quad (5)$$

For other materials, the permittivity spectra can be approximately determined using the refractive index, $\sqrt{B}$, and the static dielectric constant, $\varepsilon(0)$, as follows:

$$\varepsilon(i\xi_N) = \begin{cases} \dfrac{B + (\xi_N/\omega)^2}{1 + (\xi_N/\omega)^2} & \text{for } N \geq 1 \\ \varepsilon(0) & \text{for } N = 0 \end{cases} \quad (6)$$

where ω is the characteristic relaxation frequency of the UV region, which is $\sim 2 \times 10^{16}$ rad/s.[14] The nonzero sampling frequency ξ_N ($N \geq 1$) begins at $\xi_1 = 2.4 \times 10^{14}$ rad/s and is closely spaced in the UV region; the relaxation in the UV dominates the portion of the dielectric spectra most important for the van der Waals interaction. For most nonmetallic materials with simple spectra, a single UV relaxation may be sufficient for the Hamaker constant calculation.[12] Thus, the simple oscillator model described by Eq. (6) is sufficient for determining the van der Waals energy. In this simplification, water presents an important exception: the permanent dipole contribution of water is only taken into account in the static dielectric constant but is ignored in calculating $\varepsilon(i\xi)$ at nonzero frequencies. The best fit with the available permittivity for water gives $B = 1.887$, which is slightly higher than the square of the refractive index of water. Parameters of Eq. (6) for some materials are given in Table 2. The simplified model given by Eq. (6) also allows simple equations for van der Waals energy to be developed.

Approximate and Simplified Equations for van der Waals Interaction Between Spheres

A number of approximate models have been developed for the calculation of the van der Waals interaction energy between two spherical particles. The

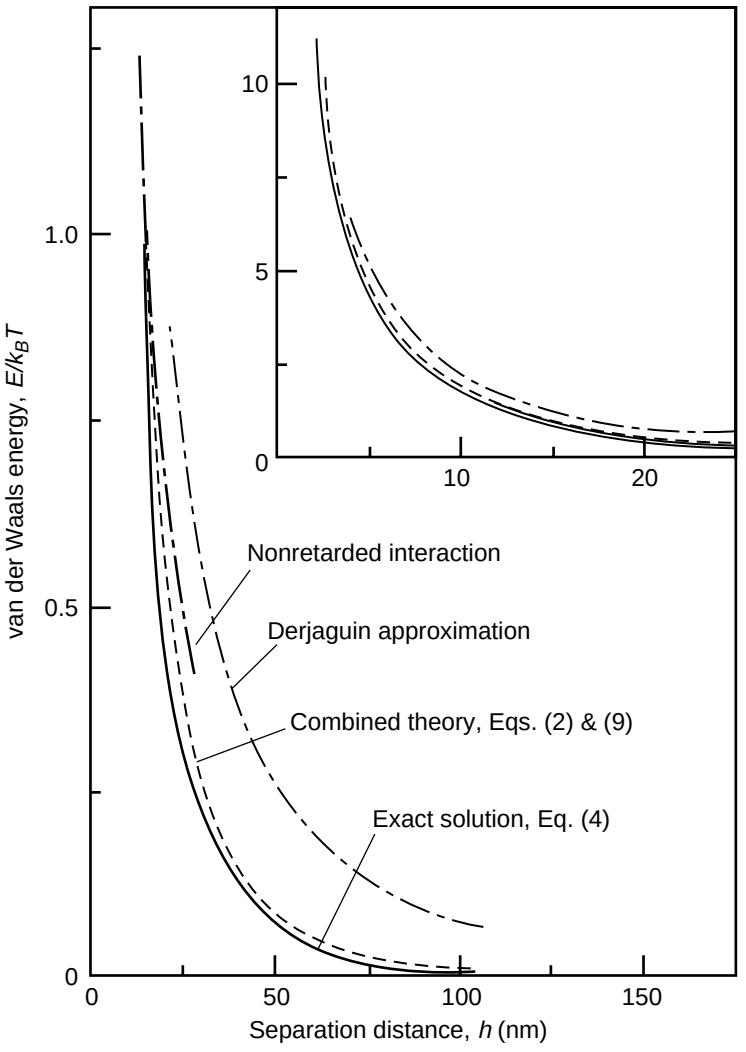

Fig. 1 Comparison between approximate models and the exact solution for the van der Waals energy for two polystyrene spheres of radius $R = 250$ nm in water. (From Ref.[10].)

most well-known approximation was provided by Derjaguin[15] who made the approximate estimation of the interaction energy or the force between two spherical particles or curved surfaces from the corresponding interaction energy per unit area between two infinite parallel flat plates. In terms of force, $F(h)$, between two spherical particles with radii R_1 and R_2, and energy per unit area between parallel flat plates,

$E^*(h)$, the Derjaguin approximation gives

$$F(h) = 2\pi \frac{R_1 R_2}{R_1 + R_2} E^*(h) \tag{7}$$

The interaction energy between the particles is then obtained by integrating Eq. (7) from infinity to the separation distance h. The Derjaguin approximation can be applied to van der Waals, double-layer, and many other interactions. For van der Waals interaction, either Eq. (1) or (3) for $E^*(h)$ can be substituted into Eq. (7) to determine the force between two spheres.

As long as the range of the interaction and the separation h is much less than the radius of curvature of the system, it is a valid approximation for interaction between surfaces quadratically curved in the vicinity of the point of closest approach. The condition makes curvature effects, higher than second order (via truncation of a Taylor series expansion), on the approximated energy significantly small.[16] However, the Derjaguin approximation should not be adequate for submicron-sized particles. Shown in Fig. 1 is the deviation of the Derjaguin approximation from Langbein's full macroscopic prediction described by Eq. (4) for van der Waals interaction between 250 nm radii particles. There are two important improvements of the Derjaguin approximation for submicron-sized particles.

Table 2 Parameters $\varepsilon(0)$, B, and ω in Eq. (6)

(From Refs.[10,12,14].)

The first improvement is based on the discovery that Eq. (2) of the Hamaker microscopic theory for spheres agrees with Eq. (4) of the continuum macroscopic theory when the Hamaker constant, A, in Eq. (2) is determined from Eq. (3) of the Lifshitz theory for parallel flat plates (Fig. 1). The combined Hamaker–Lifshitz function, $A(h)$, can be obtained by comparing the right-hand sides of Eqs. (1) and (3), giving

$$A_{132}(h) = -\frac{3k_BT}{2} \sum_{N=0}^{\infty}{}' \int_{x_N}^{\infty} x \ln[(1 - y_{13}y_{23}e^{-x}) \times (1 - z_{13}z_{23}e^{-x})]\mathrm{d}x \tag{8}$$

Eq. (8) can be simplified to provide an approximate prediction suitable for engineering calculations. Using Eq. (6), the simplification of Eq. (8) gives

$$A_{132}(h) = A^0_{132} + A^{\xi}_{132}(h) \tag{9}$$

The first and second terms on the right-hand side of Eq. (9) represent the zero-frequency (separation-independent) and the nonzero-frequency (dispersion) parts described by:[17]

$$A^0_{132} = \frac{3k_BT}{4} \sum_{m=1}^{\infty} \left\{ \frac{\varepsilon_1(0) - \varepsilon_3(0)}{\varepsilon_1(0) + \varepsilon_3(0)} \frac{\varepsilon_2(0) - \varepsilon_3(0)}{\varepsilon_2(0) + \varepsilon_3(0)} \right\}^m \Big/ m^3 \tag{10}$$

$$A^{\xi}_{132}(h) = \frac{3\hbar\omega}{8\sqrt{2}} \frac{(B_1 - B_3)(B_2 - B_3)}{(B_1 - B_2)} \times \left\{ \frac{I_2(h)}{\sqrt{B_2 + B_3}} - \frac{I_1(h)}{\sqrt{B_1 + B_3}} \right\} \quad (11)$$

Functions $I_1(h)$ and $I_2(h)$ in Eq. (11) describe the retardation effects and are defined by $I_j(h) = [1 + (h/\lambda_j)^q]^{-1/q}$, where $q = 1.185$. The characteristic wavelengths, λ_j, are measured in units of length by:$\lambda_j = \frac{c}{\pi^2\omega}\sqrt{\frac{2}{B_3(B_j + B_3)}}$, where c is the speed of light in vacuum. Unlike the London wavelength in the classical theories on retardation,[2] which is ~100 nm, λ_j is on the order of 5 nm, depending on the refractive index of the interacting materials. For two identical particles, Eq. (11) reduces to $A^{\xi}_{131}(h) = \frac{3\hbar\omega}{16\sqrt{2}} \frac{(B_1 - B_3)^2}{(B_1 + B_3)^{3/2}} \{1 + (h/\lambda)^q\}^{-1/q}$.

The van der Waals interaction energy in salt solutions is reduced.[4] In this case, Eq. (9) for the Hamaker–Lifshitz function is recast to give

$$A_{132}(\kappa, h) = A^0_{132}(1 + 2\kappa h)e^{-2\kappa h} + A^{\xi}_{132}(h) \quad (12)$$

where κ is the Debye constant. The zero-frequency term of the Hamaker–Lifshitz function is strongly influenced by salts whereas the dispersion (nonzero frequency) term remains unaffected, as the electrolyte ions do not respond to frequencies higher than 10^{14} rad/s. Therefore, the van der Waals forces across an electrolyte solution will effectively be determined solely by the London dispersion interaction.

ELECTROSTATIC DOUBLE-LAYER INTERACTION

Since particles in a polar solvent, like water, become electrically charged, electrostatic double-layer interaction (EDL) is important in determining particle–particle interactions. The Poisson–Boltzmann (PB) equation is used to describe the double-layer interaction. For $z : z$ valence salt solutions, the PB equation yields

$$\nabla^2\left(\frac{ez\psi}{k_BT}\right) = \kappa^2 \sinh\left(\frac{ez\psi}{k_BT}\right) \quad (13)$$

where ψ is the electrostatic potential in the solution and e is the charge of an electron. The Debye constant, κ, is defined by: $\kappa = \left\{\frac{2000cN_Ae^2z^2}{\varepsilon\varepsilon_0k_BT}\right\}^{1/2}$, where c is the salt concentration in mole/L, N_A the Avogadro number, ε_0 the permittivity of the vacuum, and ε is the dielectric constant (the relative permittivity) of the salt solution. The EDL force acting on a particle is determined by integrating the stress tensor, **T**, over the particle surface:[18]

$$\mathbf{F}_{edl} = \oint \mathbf{T} \cdot \mathrm{d}\boldsymbol{s} \quad (14)$$

where d$\boldsymbol{s}$ is the normal vector of the surface element. **T** is determined by the tensor of the hydrostatic (osmotic) pressure and the electric stress tensor by:

$$\mathbf{T} = \left[\varepsilon\varepsilon_0\kappa^2\left(\frac{k_BT}{ez}\right)^2 \sinh^2\left(\frac{ez_i\psi}{2k_BT}\right) + \frac{\varepsilon\varepsilon_0}{2}E^2\right]\mathbf{I} - \varepsilon\varepsilon_0\mathbf{EE} \quad (15)$$

where $\mathbf{E} = -\nabla\psi$ is the electric field, E the magnitude of **E**, **I** the unit tensor, and **EE** describes the dyadic product of the two vectors **E** and **E**. The integration of Eq. (14) gives the net force acting along the particle center-to-center line as by symmetry all components perpendicular to the centerline integrate to zero.

In Eq. (15), the electrostatic potential, ψ, is for the overlapping electric double layer of the interacting particles. Numerous models have been created to predict the overlapping field electrostatic potential between parallel plates. However, calculation of the EDL interaction for the common geometry of two spheres has not been satisfactorily resolved, due mainly to the nonlinear partial differential terms in Eq. (13) arising because of the three-dimensional geometry of the system. As a consequence, a number of approximate and numerical models have been developed for the calculation of the EDL interaction between two spheres. These models are briefly described below.

Approximate Models for EDL Interaction Between Two Spheres

The first approximate models are obtained by solving the linearized Eq. (13) for planar parallel surfaces and determining the EDL force and energy between spherical particles using the Derjaguin approximation. For low potential, the right-hand side of Eq. (13) can be linearized by $\sinh z = z + O(z^3)$. Eq. (13) reduces to a one-dimensional differential equation, which can be solved analytically using appropriate boundary conditions at the surfaces. The solution for ψ is then substituted into Eq. (15) to determine the pressure, which can be integrated to obtain the force and energy between spheres, using the Derjaguin approximation described by Eq. (7). The obtained models are summarized in Table 3.

Table 3 Results of Debye–Hückel linearization of Eq. (13) and Derjaguin approximation

Boundary conditions	Force and energy between spheres with radii R_1 and R_2
Constant surface potentials: $\psi(0) = \psi_1$ and $\psi(h) = \psi_2$ Hogg–Healy–Fuerstenau (HHF) model[19]	$F^{\psi} = \varepsilon\varepsilon_0\kappa\frac{2\pi R_1R_2}{R_1+R_2}\frac{2\psi_1\psi_2\exp(\kappa h) - \psi_1^2 - \psi_2^2}{\exp(2\kappa h) - 1}$ $E^{\psi} = \varepsilon\varepsilon_0\frac{\pi R_1R_2}{R_1 + R_2}[4\psi_1\psi_2\,\mathrm{a\,tanh}(e^{-\kappa h}) + (\psi_1^2 + \psi_2^2)\ln(1 - e^{-2\kappa h})]$ ψ_1 and ψ_2 are the particle surface potentials
Constant surface charges: $\left(\frac{d\psi}{dx}\right)_{x=0} = -\kappa\psi_{1\infty}$ $\left(\frac{d\psi}{dx}\right)_{x=h} = \kappa\psi_{2\infty}$	$F^{\sigma} = \varepsilon\varepsilon_0\kappa\frac{2\pi R_1R_2}{R_1 + R_2}\frac{2\psi_{1\infty}\psi_{2\infty}\exp(\kappa h) + \psi_{1\infty}^2 + \psi_{2\infty}^2}{\exp(2\kappa h) - 1}$ $E^{\sigma} = \varepsilon\varepsilon_0\frac{\pi R_1R_2}{R_1 + R_2}[4\psi_{1\infty}\psi_{2\infty}\mathrm{a\,tanh}(e^{-\kappa h}) - (\psi_{1\infty}^2 + \psi_{2\infty}^2)\ln(1 - e^{-2\kappa h})]$ $\psi_{1\infty}$ and $\psi_{2\infty}$ are the surface potential at infinite separation distance (of isolated particles)
Constant surface potential and charge: $\psi(0) = \psi_1$ $\left(\frac{d\psi}{dx}\right)_{x=h} = \kappa\psi_{2\infty}$	$F^{\sigma\psi} = \varepsilon\varepsilon_0\kappa\frac{2\pi R_1R_2}{R_1 + R_2}\frac{2\psi_1\psi_{2\infty}\exp(\kappa h) + \psi_1^2 - \psi_{2\infty}^2}{\exp(2\kappa h) + 1}$ $E^{\sigma\psi} = \varepsilon\varepsilon_0\frac{\pi R_1R_2}{R_1 + R_2}[4\psi_1\psi_{2\infty}\,\mathrm{a\,tan}\,(e^{-\kappa h}) + (\psi_1^2 - \psi_{2\infty}^2)\ln(1 + e^{-2\kappa h})]$

The second group of EDL models are obtained by solving the nonlinear PB Eq. (13) for planar parallel surfaces using elliptic functions and integrals,[20–22] and determining the EDL force and energy between spherical particles using the Derjaguin approximation.[15,20,22] While the models given in Table 3 are only applied to low surface potentials, the models with elliptic functions and integrals in this second group are not limited by the condition of low surface potentials. The interaction force and energy obtained for spherical particles are only restricted by the applicability of the Derjaguin approximation, i.e., the particle size must be significantly larger than the separation distance between the surfaces. This condition is not satisfied by submicron- and nano-sized particles because the range of double-layer interaction in water often exceeds a few 100 nm.

The third group of the approximate models includes various improvements of the Derjaguin approximation, linearization, and approximate solutions of PB Eq. (13) for spherical particles. The first improvement on the Derjaguin approximation for the interaction energy between identical spheres was probably obtained by the Debye–Hückel linearization and the superposition approximation,[23] given by:

$$E(h) = 4\pi\varepsilon\varepsilon_0 R\psi_s^2\frac{R + h}{2R + h} \times \ln\left[1 + \frac{R}{R + h}\exp(-\kappa h)\right] \quad (16)$$

For two spheres of different radii, R_1 and R_2, and at a constant surface charge interaction, the improved Derjaguin approximation in the framework of the Debye–Hückel linearization can be expressed as:[24]

$$E^{\psi}(h) = \varepsilon\varepsilon_0\frac{\pi R_1R_2}{R_1 + R_2 + h}[4\psi_1\psi_2\mathrm{a\,tanh}(e^{-\kappa h}) + (\psi_1^2 + \psi_2^2)\ln(1 - e^{-2\kappa h})] \quad (17)$$

Eq. (17) includes the separation distance in the sum of the particle radii. In the limit of large particles, namely, $R_1 + R_2 \gg h$, Eq. (17) reduces to the Hogg–Healy–Fuerstenau expression for $E^{\psi}(h)$, given in Table 3.

For the interaction between identical spheres at moderate surface potentials ($y_\infty \leq 4$), the improved Derjaguin approximation can be described by:

$$E^{\psi}(h) = \varepsilon\varepsilon_0\frac{64\pi R^2}{2R + h}\left(\frac{k_BT}{ez}\right)^2 \times \mathrm{a\,tanh}^2\left[e^{-\kappa h/2}\tanh\frac{y_\infty}{4}\right]e^{\kappa h}\ln(1 + e^{-\kappa h}) \quad (18)$$

Eq. (18) is claimed to be valid for all κh.[24] Note that in the limit of small surface potentials, Eq. (18) does not reduce exactly to Eq. (16), which was derived based on the superposition approximation typically used in the limit of large κh. However, if the particle radius is significantly larger than the range of the EDL interaction, Eqs. (16) and (18) in the limit of small potentials reduce to the expression:

$$E(h) = 2\pi\varepsilon\varepsilon_0 R\psi_s^2\ln[1 + \exp(-\kappa h)], \quad (19)$$

which was first derived for two identical spheres at the constant surface potential interaction using the Derjaguin approximation and the Debye–Hückel linearization by Derjaguin in 1939.[20]

There are two other developments in predicting electrostatic double-layer interactions between spheres. Firstly, an approximate expression for the correction to the Derjaguin approximation has been using a series expansion and the Debye–Hückel linearization.[25] Comparison with the exact numerical results has found that the derived expressions for the EDL interaction at constant surface potential are in good agreement with the exact numerical results. However, for constant surface charge a poorer approximation is obtained at small separation distances. This is most probably due to the inaccuracy of the Debye–Hückel linearization under the condition of the constant surface charge interaction. The study highlights the ongoing difficulty in improving the Derjaguin approximation for the EDL interaction at constant surface charge for particles in the colloidal size range. Secondly, the Derjaguin approximation is actually the zero-order approximation in terms of curvatures of the particle surfaces. Improvements to this model include the effect of curvature. For instance, in the case of interaction at constant surface potential, the additional corrections to the known HHF expression are the second and higher order terms of $1/(\kappa R)$.[26] However, the corrections often contain many terms and series expansions, approaching the complication of direct numerical computations.

Exact Numerical Solutions for EDL Interaction Between Two Spheres

The direct numerical solutions of PB equation for spheres have been reported by a number of researchers, including.[27] In the numerical computation, PB Eq. (13) is conveniently expressed and solved in the bispherical coordinates. Due to the rotational symmetry of the interaction along the centerline, Eq. (13) simplifies into

$$\frac{\partial}{\partial\xi}\left(\frac{\sin\eta}{\cosh\xi - \cos\eta}\frac{\partial\phi}{\partial\xi}\right) + \frac{\partial}{\partial\eta}\left(\frac{\sin\eta}{\cosh\xi - \cos\eta}\frac{\partial\phi}{\partial\eta}\right) = \frac{c^2\sin\eta}{(\cosh\xi - \cos\eta)^3}\sinh\phi \tag{20}$$

where the reduced potential, ϕ, is defined by $\phi = ez\psi/k_BT$. The bipolar coordinates (η, ξ) are directly related with the reduced cylindrical coordinates (r, z), where the z-axis is the particle inter-center line. One obtains: $r = \frac{c\sin\eta}{\cosh\xi - \cos\eta}$ and $z = \frac{c\sinh\xi}{\cosh\xi - \cos\eta}$. The origin of the cylindrical coordinates on the centerline is determined by the inter-center distance, $d = h + R_1 + R_2$, between the spheres and the distances, d_1 and d_2, of the center of each sphere to the origin. We have $d_1 = \frac{d^2 + R_1^2 - R_2^2}{2d}$ and $d_2 = -\frac{d^2 + R_2^2 - R_1^2}{2d}$, where R_1 and R_2 are the sphere radii, and $d_1 > 0$ and $d_2 < 0$. In the bipolar coordinates, the sphere surfaces are described by the constancy of the ξ-coordinate, i.e., by $\xi = \alpha_1$ for sphere 1 and $\xi = \alpha_2$ for sphere 2, where $\alpha_1 = \operatorname{acosh}\frac{d^2 + R_1^2 - R_2^2}{2dR_1}$ and $\alpha_2 = -\operatorname{acosh}\frac{d^2 + R_2^2 - R_1^2}{2dR_2}$. The length constant, c, in Eq. (20) is defined by $c = R_1\sinh\alpha_1 = -R_2\sinh\alpha_2$.

Eq. (20) can be discretized in the computational domain bounded by $\xi = \langle\alpha_2,\alpha_1\rangle$ and $\eta = \langle 0,\pi\rangle$. The discretization can be carried out using either the finite volume or finite difference scheme, producing a system of nonlinear equations for the reduced potential in the computational domain, which can be solved employing the Newton–Ralphson method or other relaxation techniques. The boundary conditions of constant surface potentials are described by $\phi = \phi_1$ at the surface of sphere 1 with $\xi = \alpha_1$ and $\eta = \langle 0, \pi\rangle$, and $\phi = \phi_2$ at the surface of sphere 2 with $\xi = \alpha_2$ and $\eta = \langle 0, \pi\rangle$. The boundary conditions of constant surface charge are described by $\left(\frac{\cosh\xi - \cos\eta}{c}\frac{\partial\phi}{\partial\xi}\right)_{\xi=\alpha_1,\alpha_2} = \pm\frac{\sigma_{1,2}ze}{\varepsilon\varepsilon_0\kappa k_BT}$ at the surface of spheres 1 and 2 with the surface charges, σ_1 and σ_2, respectively.

The general behavior of the numerical results of Eq. (20) for the potential distribution between the particle surfaces is shown in Fig. 3 for the constant surface potential interaction between two spherical particles with radii of 20 nm and surface potentials of 50 mV. The effect of the interaction is to distort the potential profiles around the particles. At a separation distance of about 10-particle radii (~200 nm), the potential profiles are almost identical to those around the isolated particles. However, the distortion of the potential profiles becomes stronger with decreasing the separation distance between the surfaces. The strong distortion of the potential profiles increases the repulsive interaction between the particles as shown below.

Once the potential field in the computational domain is available, the EDL force can be determined by integrating the stress over the sphere surface using Eqs. (14) and (15). In the bipolar coordinates, the normal vector of the surface element in Eq. (14) yields $\mathrm{d}s = -\mathbf{i}_\xi 2\pi\left(\frac{c}{\cosh\xi - \cos\eta}\right)^2\sin\eta\,\mathrm{d}\eta$, where the unit vector, $\mathbf{i}_\xi$, is pointed towards the surface of one of the spheres. The potential gradient is described by

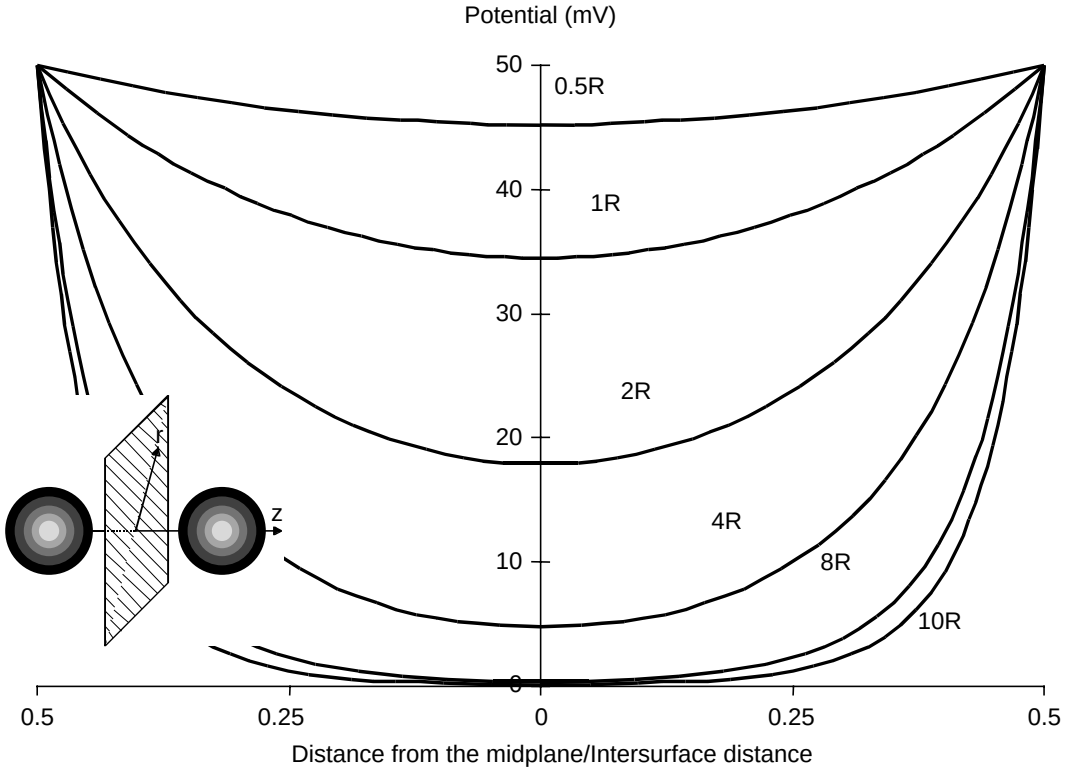

Fig. 3 Numerical results of Eq. (13) for the potential distribution on the inter-center line of two identical spherical particles with radii $R = 20$ nm and surface potentials of 50 mV, showing the distribution at the different inter-surface distances: 0.5, 1, 2, 4, 8, and 10R. The distance from the ($z = 0$) midplane is normalized by dividing by the inter-surface distance.

$\mathbf{E} = -\frac{\cosh\xi - \cos\eta}{c}\left(\frac{\partial\psi}{\partial\eta}\mathbf{i}_\eta + \frac{\partial\psi}{\partial\xi}\mathbf{i}_\xi\right)$, where $\mathbf{i}_\eta$ is another unit vector of the η-coordinate. Combining Eqs. (14) and (15) gives

$$\mathbf{F} = 2\pi\int_0^\pi \left[\left(\left\{\frac{c}{\cosh\xi - \cos\eta}\right\}^2 \Pi + \frac{1}{2}\varepsilon\varepsilon_0\left\{\left(\frac{\partial\psi}{\partial\xi}\right)^2 - \left(\frac{\partial\psi}{\partial\eta}\right)^2\right\}\right)\mathbf{i}_\xi + \varepsilon\varepsilon_0\frac{\partial\psi}{\partial\eta}\frac{\partial\psi}{\partial\xi}\mathbf{i}_\eta\right]\sin\eta\,\mathrm{d}\eta \tag{21}$$

where Π describes the first term (the osmotic pressure) in the brackets in Eq. (15). The net force acting on the inter-center line is obtained by multiplying Eq. (21) with the unit vector, $\mathbf{i}_z$, of the z-axis. Since $\mathbf{i}_\eta \cdot \mathbf{i}_z = \frac{\sin\eta\sinh\xi}{\cosh\xi - \cos\eta}$ and $\mathbf{i}_\xi \cdot \mathbf{i}_z = \frac{\cos\eta\cosh\xi - 1}{\cosh\xi - \cos\eta}$, Eq. (21) gives

$$F = 2\pi\int_0^\pi \left[\left(\left\{\frac{c}{\cosh\xi - \cos\eta}\right\}^2 \Pi + \frac{\varepsilon\varepsilon_0}{2}\left\{\left(\frac{\partial\psi}{\partial\eta}\right)^2 - \left(\frac{\partial\psi}{\partial\xi}\right)^2\right\}\right)\times\frac{1 - \cos\eta\cosh\xi}{\cosh\xi - \cos\eta} + \varepsilon\varepsilon_0\frac{\partial\psi}{\partial\eta}\frac{\partial\psi}{\partial\xi}\frac{\sin\eta\sinh\xi}{\cosh\xi - \cos\eta}\right]\sin\eta\,\mathrm{d}\eta \tag{22}$$

The integral in Eq. (22) is independent of the specific choice of the constant ξ-plane and, therefore, it can be numerically integrated along any surface that encloses one of the spheres and has a constant value for the ξ-coordinate. The surface $\xi = 0$ is particularly useful for the numerical integration because $\sinh\xi = 0$ at $\xi = 0$. For symmetrical interactions between two identical spheres, the surface of $\xi = 0$ is the plane of the symmetry, where the ξ-derivative of the potential is zero, and the numerical integration is significantly simplified.

Finally, knowing the force as a function of separation distance, the interaction energy, $E(h)$, can be determined by integrating the force with respect to the separation distance from infinity. The numerical integration can start at some cut-off distance as the available analytical solutions described by Eqs. (16)–(19) can be used when the particles are far apart and the interaction is weak.[20] In practice, the numerical

data for the interaction force versus separation distance are often limited and the integration for the interaction energy can be effectively carried out using the Gauss-Laguerre quadrature scheme. The same principle can be used to integrate Eq. (22) with moderate computing costs.

Exact numerical results are used to validate the available approximate models described by Eqs. (16)–(19). The comparison is shown in Fig. 4 for particles with scaled radii $R\kappa = 0.1$ and $R\kappa = 15$. The interaction energy was determined for two identical spheres in a $z:z$ electrolyte solution. The approximate solutions are given by Eqs. (16)–(19) and the equation for the HHF model given in Table 3. For the exact numerical solution, the full Poisson–Boltzmann equation was discretized and solved by the finite volume method. The results have been plotted for two particle sizes $\kappa R = 0.1$ (Fig. 4A) and $\kappa R = 15$ (Fig. 4B).

It can be seen that for both scaled particle sizes the predictions for $G(h)$ from Eqs. (16)–(18) match closely the exact numerical solution. For the result of the Derjaguin Eq. (19) and the HFF model given in Table 3, however, good agreement is obtained only for the $\kappa R = 15$ case. Further analysis (not shown here) indicates that the Derjaguin approximation should only be used for $\kappa R \geq 10$, which corresponds to spherical particles larger than a few microns in diameter. Although it can be seen from Fig. 4 that both Eqs. (16) and (17) provide very good approximations to the exact numerical solution, Eq. (17) is more widely applicable to double-layer interaction at constant and low surface potentials. It is also simpler in terms of the expressions involving separation. For these reasons, it is usually recommended to use the generalized HHF expression given by Eq. (17) for calculating the double-layer interaction energy between spheres.

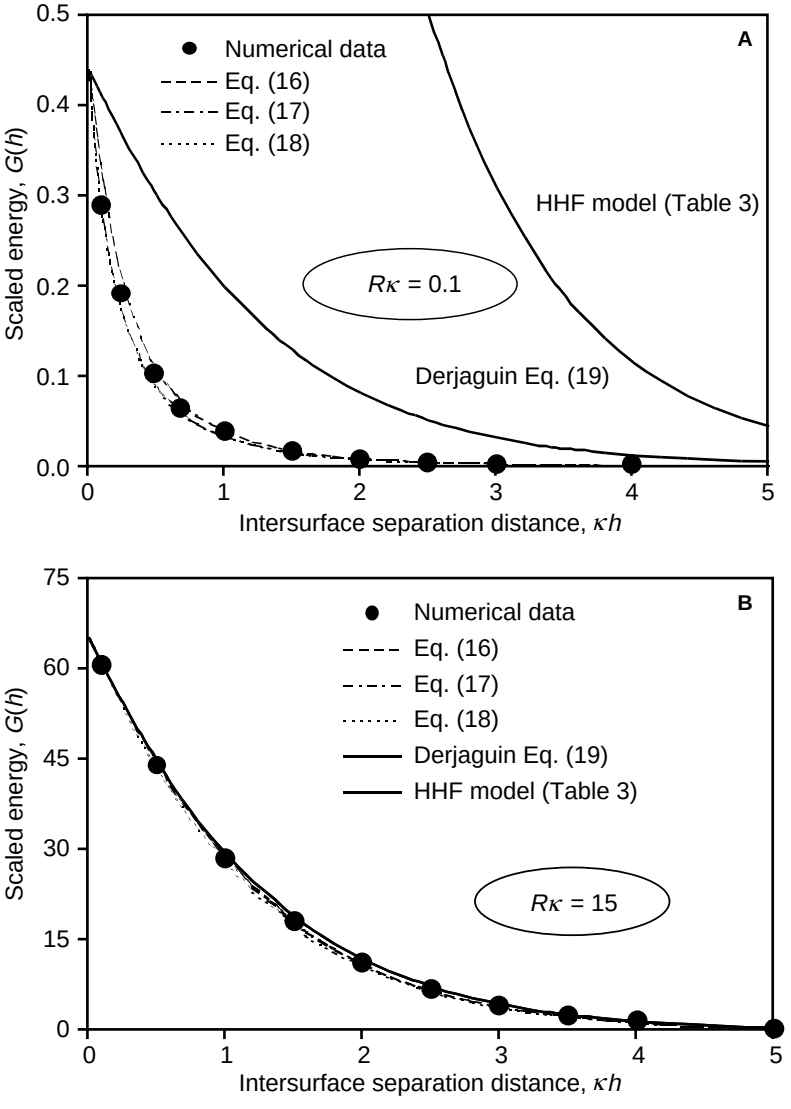

Fig. 4 Comparison of the model improvements on the Derjaguin approximation to the exact numerical computational results of the full Poisson–Boltzmann equation for two spheres with the scaled radius $R\kappa = 0.1$ and $R\kappa = 15$ and constant surface potential $\psi_s ez/(k_B T) = 1$. The scaled energy, $G(h)$, on the vertical axis is defined by $G(h) = E(h)/\left\{\frac{\varepsilon\varepsilon_0}{\kappa}\left(\frac{k_B T}{ez}\right)^2\right\}$.

LIMITS OF THE DERJAGUIN APPROXIMATION PROBED WITH AFM TIPS

The limits of the celebrated Derjaguin approximation for predicting forces between submicron-sized particles have been argued for some time. Now the approximation can be validated using the force data obtained for the interaction between the AFM tips on microfabricated cantilevers and the flat surfaces. The radius of curvature of the AFM tips is about 10 nm and provides the ideal geometry with small interaction forces. Fig. 5 shows an example for the forces measured with the graphite (HOPG) flat surfaces and the silicon nitride tips with the radius of curvature of about 7 nm in solution with different pH.

In Fig. 5, the interaction force between the tip and the HOPG surface, as predicted by the Derjaguin approximation, F_{DA}, is described by:[28]

$$F_{DA}(h) = 2\pi R E^*(h) \tag{23}$$

where R is the characteristic radius of the tip ($\sim$7 nm) and E^* is the interaction energy between flat surfaces per unit area. An EDL model and a hard-core repulsion model are used to describe the energy E^* by:[28]

$$E^*(h) = \frac{2\pi}{\varepsilon\varepsilon_0\kappa}(\sigma_1\sigma_2)\exp[-\kappa(h - h_0)] + \frac{const}{72\pi(h - h_0)^8} \tag{24}$$

where $\sigma_1\sigma_2$ is the product of the surface and tip charge densities, *const* a constant, and h_0 is an off-set separation distance due to the uncertainty of absolute zero separation distance in the force measurements with AFM.

The surface element integration (SEI) method provides an improvement on the interaction force between a spherical particle and a flat surface.[29] The SEI improves the Derjaguin approximation by replacing infinity in the integration of the Derjaguin approximation by a finite upper limit, leading to the following prediction for the interaction force, F_{SEI}, between the tip and the surface:

$$F_{SEI}(h) = 2\pi\int_0^R \frac{\partial}{\partial h}\{E^*(D_+) - E^*(D_-)\} r\,dr \tag{25}$$

where the energy E^* is given by Eq. (24) and $D_\pm = h + R \pm \sqrt{R^2 - r^2}$. The integration can be calculated numerically.

The solid lines in Fig. 5 show Eqs. (23) and (25) with the model parameters obtained by regression analysis. Despite the best-fit procedure employed, the Derjaguin approximation shows significant deviation from the experimental data at short separation distances. The Derjaguin approximation cannot model the interaction under the given conditions when the radius of the surface curvature is similar to the range of the double-layer forces ($1/\kappa = 9.6$ nm). In this case, the upper limit of the integration of the Derjaguin approximation cannot approach infinity and the SEI approximation, which considers the finite limit of the integration, agrees with the experimental data.

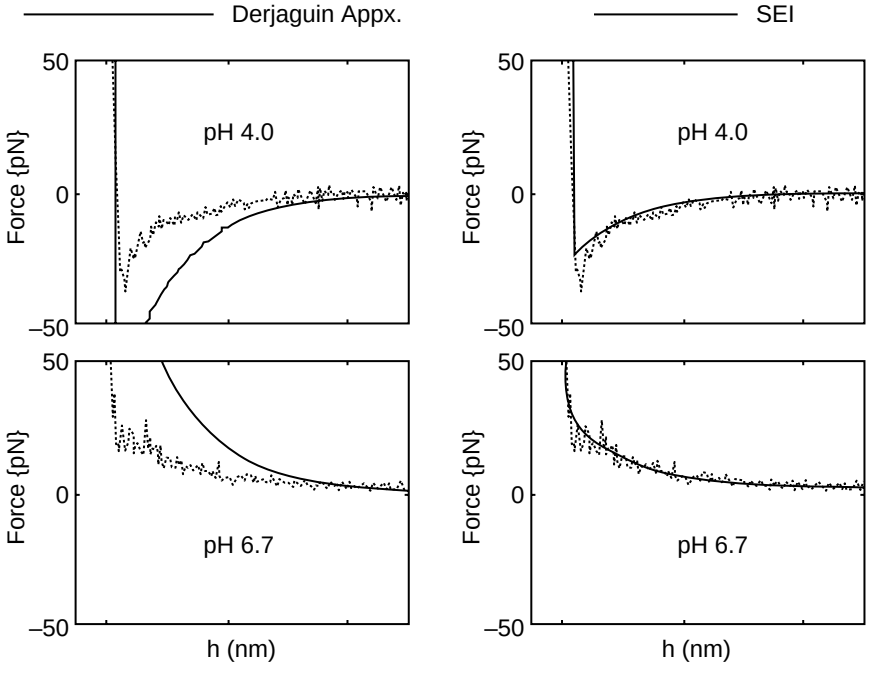

Fig. 5 Experimental data (dotted lines), and the Derjaguin approximation (solid lines on the left diagrams) and its SEI improved prediction (solid lines on the right diagrams) for the interaction force vs. separation distance between a silicon nitride AFM tip and an HOPG surface in 1 mM NaCl solutions ($1/\kappa = 9.6$ nm. (From Ref.[28].)

CONCLUSIONS

Improvements in the DLVO force predictions for the van der Waals and electrostatic double-layer interactions between small spherical particles have been critically reviewed. The van der Waals interaction energy between two spheres can be determined from the exact Langbein theory. The approximate equations for van der Waals interaction energy between two spheres can be obtained by combining the Hamaker microscopic and Lifshitz macroscopic theories. The Hamaker–Lifshitz function, $A_{132}(h)$, described by Eq. (12) depends on the separation distance (accounting for the retardation effects due to the finite speed of light) and salt concentration (accounting for the screening effects of electrolytes). The Hamaker–Lifshitz function is used in conjunction with Eq. (2) to determine the van der Waals interaction energy and force between small spherical particles.

It was shown in the analysis that the Poisson–Boltzmann Eq. (13) developed within the Gouy–Chapman theory provides a useful tool for predicting the EDL interaction between particles. Comparison with the numerical solution of the Poisson–Boltzmann equations and experimental data obtained with AFM tips shows that the Derjaguin approximation will fail to predict the double-layer interaction between nano-sized particles. The predictions using the approximate expressions described by Eqs. (16)–(18) for small particles were found to be an improvement over the Derjaguin approximation, when compared with the exact numerical data obtained by numerically solving the full Poisson–Boltzmann equation. It was also shown that the SEI technique provides significant improvement for predicting the force between a surface with nano-sized radius of curvature such as an AFM tip and a flat surface.

Pervaporation: Vapor Permeation

Nicholas Patrick Wynn
Sulzer Chemtech GmbH, Neunkirchen, Germany

INTRODUCTION

Pervaporation occupies a special niche in the chemical industry—it is the only membrane process primarily used to purify chemicals. At the start of 2000, about 100 pervaporation units were operating worldwide, most of them dehydrating solvents, such as ethanol and isopropanol. Now that pervaporation has been proven in these end-of-pipe applications, attention is being focused on large-scale separations that are closer to the chemical reaction step—to be more critical for production and to bring much greater benefits.

These developments result from the introduction of composite membranes, originally developed in the 1970s primarily, for desalination by reverse osmosis. Application of the same membrane fabrication techniques to pervaporation membranes radically improved their performance and spurred commercial utilization. Today, pervaporation and vapor permeation plants are widely used to dehydrate volatile organics and separate other mixtures, primarily in the pharmaceutical and fine chemical industries.

This shift in focus is accelerating the development of new, more robust membranes, with tailored performance, which can be used at higher temperatures. Over the next few years, pervaporation will be used increasingly in the CPI, HPI, and O&G industries, not just for dehydration, but also for organic–organic separations.

PERVAPORATION AND VAPOR PERMEATION PROCESSES

Pervaporation and vapor permeation (and gas permeation) are closely related processes and are characterized by generating a permeate in the vapor state. In this situation, the driving force for permeation of a particular component approximates very closely to the difference in partial vapor pressure of that component across the membrane. Because the pressure on the back-side of the membrane is low, almost all of the faster permeating component can be removed from the feed. The process purifies the feed by removing the faster permeating component. The product from the process is the retentate and the concentrated impurity is the permeate.

Contrast this with the more common pressure driven membrane processes, such as reverse osmosis, where liquid is present on both sides of the membrane. In this situation, the faster permeating component cannot be completely removed by permeation. The membrane acts like a strainer or filter, holding back the slower or non-permeating component. In this case, the product from the process is the pure permeate and the concentrated impurity is the retentate.

The best performing industrial membranes permeate water in preference to other components hence the pressure driven filtration and RO processes are used typically to purify water. In contrast, pervaporation and vapor permeation are commonly, but not exclusively, used to remove water from organics (Fig. 1).

Transport of a component through the membrane is best described by the so-called ''solution–diffusion model.'' This model is based on a component of the feed having a high affinity to the membrane being easily and preferentially adsorbed and dissolved in the dense membrane. Because of a concentration gradient, it migrates through the membrane by a diffusion process and is desorbed at the back-side of the membrane. Thus, the separation characteristic of the membrane is determined primarily by the different solubilities of components in the membrane material, and to a lesser extent by the different diffusivities (which may actually counteract the solubility differences).

Driving Force for Pervaporation

In pervaporation and vapor permeation processes the permeate leaves the membrane as a vapor, hence the driving force for permeation for a particular component is the difference in partial vapor pressure of that component across the membrane. The partial vapor pressures of the components at the feed side are fixed by the feed composition and temperature. Temperature can only be increased up to the operating limit of the membrane material, typically quite low for polymer membranes. Therefore, the driving force for the transport of matter through the membrane is applied principally by reducing the partial vapor pressure at the permeate side.

Different means have been proposed to effect this reduction of the permeate side partial vapor pressure:

1. The permeating vapor is condensed under vacuum, i.e., using a sufficiently low temperature.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120008111

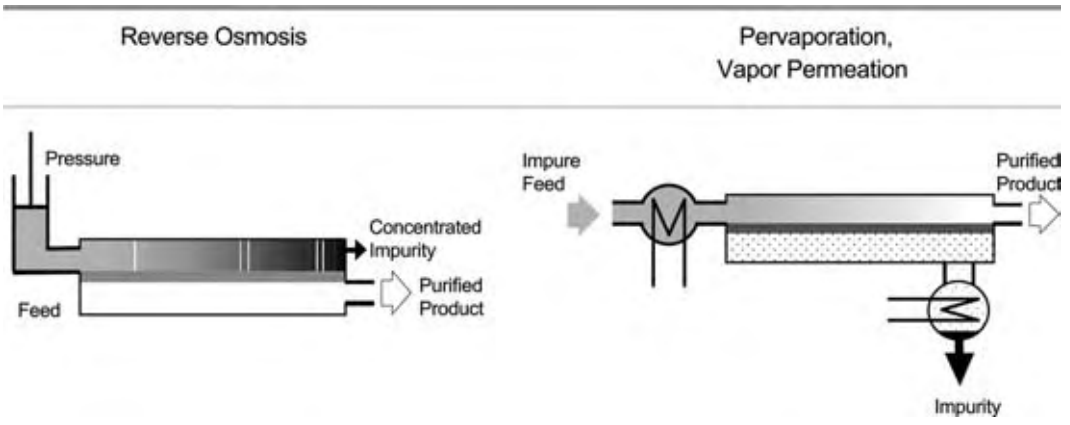

Fig. 1 Contrast pervaporation with reverse osmosis. *(View this art in color at www.dekker.com.)*

Only a small vacuum pump is then required to remove trace quantities of noncondensables.

2. All permeating vapor is removed by means of a vacuum pump. The vapor may be condensed after recompression at the pressure side of the pump.
3. The permeate side of the membrane is swept with an inert gas, to keep the partial vapor pressure of the faster permeating component sufficiently low. If the gas stream cannot be discarded, it has to be reconditioned and recycled.

In most industrial installations, the first option has been proven to be the most effective and economical process. However, it is preferable to pass all the permeate through a vacuum pump and condense them at atmospheric pressure, if the permeate quantity is low or if it contains a very volatile organic. Regarding the second option, sweep gas operation is rarely used, because sweeping right up into the pores of composite membranes is difficult.

Continuous Pervaporation Systems

Pervaporation is unusual amongst membrane processes because permeation through the membrane is coupled with a phase change from liquid to vapor. Thermodynamically, this is equivalent to a partial flash. If the membrane is operated adiabatically, this results in a cooling of the liquid on the pressure side of the membrane, which quickly reduces the driving force and permeation rate. This problem is overcome in older plants by splitting the total membrane area into a number of stages in series and installing interstage heaters. In more modern plants, steam heated tubular pervaporation modules that operate isothermally are more commonly used. Continuously operating pervaporation units run at steady state conditions (Fig. 2). Feed is passed continuously through the unit and the product leaves the unit at the desired water content. Wet feed is first heated in a recuperator, and fed to the membrane modules where it is further heated and dehydrated by pervaporation, and then it is cooled in the recuperator, depressurized and passed off the skid as product. Permeating water vapor is condensed in the permeate condenser, which is cooled by chilled water/glycol. A vacuum pump removes noncondensables from the system. Optionally, if the permeate flow is small, it can be passed through the vacuum pump and condensed at atmospheric pressure without using refrigeration.

Batch Pervaporation Systems

Pervaporation can also operate in batch mode, and this is done typically when testing membranes for small plants and for some larger multipurpose plants. Batch pervaporation systems are robust, well proven, and flexible in operation. The pumparound rate on batch systems is normally set high to give a low permeate quantity per pass. Pervaporative cooling effects are small, and such systems can be built with a single preheater and unheated modules (Fig. 3).

Hydrated solvent from a buffer tank is continuously circulated through the unit until the desired degree of dryness has been reached (Fig. 4). Such units are very flexible—different start and end water contents can be accommodated, and with multi-purpose membranes a range of solvents can be dehydrated. Note that batch pervaporation units are not suitable for feeds that may contain suspended solids or dissolved solids, which could precipitate as water is removed.

Vapor Permeation Systems

In vapor permeation, the feed is typically a saturated vapor mixture, or at least the permeating component

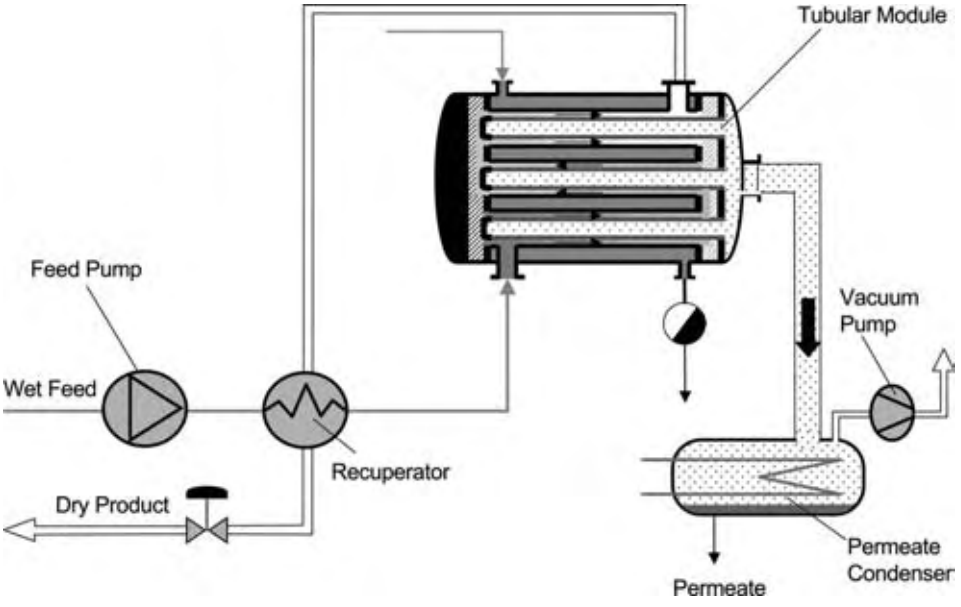

Fig. 2 Continuous pervaporation unit. *(View this art in color at www.dekker.com.)*

is close to saturation conditions. The temperature and pressure of the feed are linked by the vapor–liquid equilibrium. This process does not include a phase change, hence heating is unnecessary, and the membrane modules are simpler.

Vapor permeation is often a preferred technique to pervaporation, and liquid feeds are often evaporated, especially, to run the vapor permeation process. The evaporator is typically operated under pressure, giving a vapor feed at the maximum temperature and flux rate consistent with membrane stability. The advantages are a simpler plant and more reliable operation, because both dissolved and suspended solids are removed in the evaporator and cannot damage the membranes. The disadvantage is the extra energy required to evaporate the complete feed (Fig. 5).

Vapor Permeation Combined with Distillation

Vapor permeation is also used in combination with distillation feed of net overhead vapor from a distillation column directly to a vapor permeation plant is a very economical way of splitting azeotropes (Fig. 6). Typically, the column must be operated at pressure to provide a vapor overhead at the optimum temperature for permeation. Fig. 7 shows a vapor permeation plant for drying isopropanol directly coupled to a distillation column.

Process Selection

Selection of the optimum process is application specific, however, Table 1 gives some general guidelines (Fig. 8A–C).

PERVAPORATION AND VAPOR PERMEATION MEMBRANES

Composite Polymer Membranes

Developments in pervaporation were boosted by the improvements in membrane structure and membrane manufacture resulting from R&D expenditures on desalination membranes in the 1970s. Two different types of pervaporation membrane were developed in the beginning of the 1980s:

- Hydrophilic membranes, used mainly for the removal of water from organic solvents and solvent mixtures, especially azeotropic mixtures.
- Organophilic membranes, preferentially dissolving and permeating organics, used for the removal of volatile organic components from water and gas streams.

Both membrane types are of composite construction, with adequate mechanical, chemical, and thermal stability despite very thin high flux separation layers. Because of the composite structure, flat sheet configurations are preferred. The substructure of both types of pervaporation membranes consists of a porous support membrane with an asymmetric pore structure, cast onto a support layer consisting of a woven or nonwoven fabric. The result is similar to an ultrafiltration membrane. On the exposed side of this porous substructure the pores have diameters in the order of 20–50 nm. Pore width on the fabric side is closer to the micrometer range. Structural polymers like polyacrylonitrile, polyetherimide, polysulfone, polyethersulfone, and polyvinylidenfluoride are used to form the cast porous support. Polyester, polypropylene, and similar fibers are used for the fabric support.

A thin dense separating layer (in the range of 0.5–5 μ thick) is then coated on this substructure. Different coating techniques are in use, but most commonly a solution of polymer in an appropriate solvent is spread onto the porous substructure. The solvent is evaporated, followed by further treatment to crosslink the polymer.

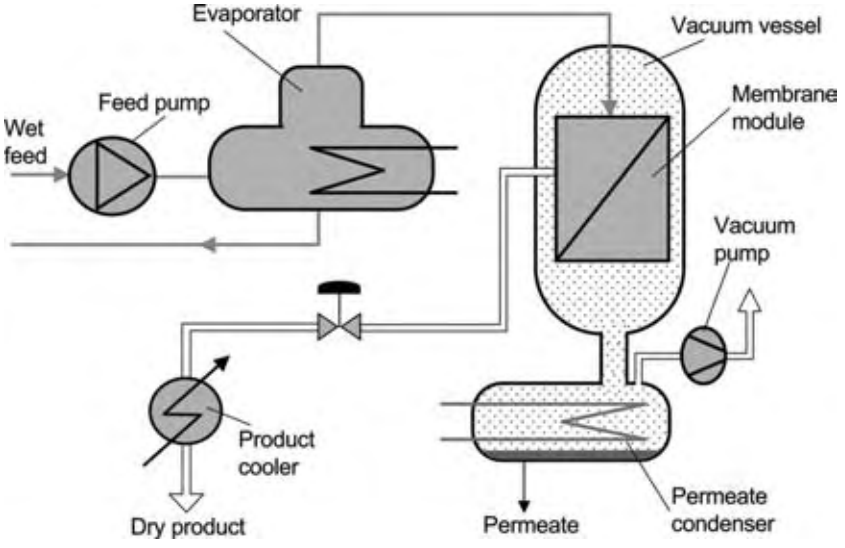

Fig. 5 Vapor permeation unit. *(View this art in color at www.dekker.com.)*

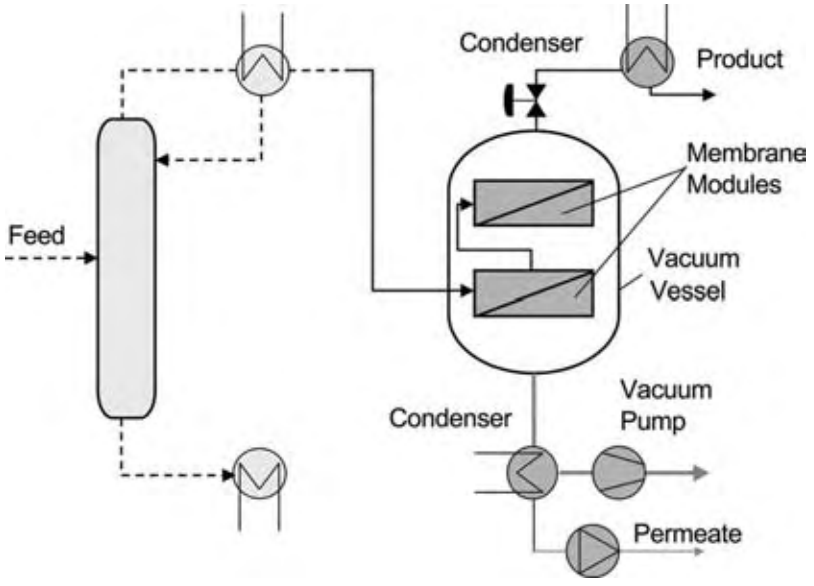

Fig. 6 Vapor permeation coupled with distillation.

In hydrophilic membranes the separating layer is most commonly made from crosslinked polyvinylalcohol (PVA), however, polyimides or natural polymers like chitosan or cellulose acetate (CA) are also used (Fig. 9).

In organophilic membranes the separation layer is typically formed from siloxanes like polydimethyl siloxane (PDMS) or polyoctylmethyl siloxane (POMS).

In recent years tailored polymeric membranes for organic–organic separations have been intensively developed. The large-scale separation of olefins from paraffins is of particular interest, e.g., propene from propane, also aromatics like benzene or toluene from aliphatic hydrocarbons or the separation of the xylene isomers. A number of smaller organic–organic separation plants are already operating, separating methanol from mixtures with hydrocarbons, ethers, and esters. The membranes used are actually of the hydrophilic type, through which the more polar methanol permeates quickly.

Ceramic Membranes

Ceramic membranes are now being used in pervaporation and promise higher operating temperatures and better chemical resistance than polymer membranes. The thermal, mechanical, and chemical stability of the cast porous substructure in polymeric membranes limits the operating range more than the stability of the actual separating layer. Ceramic substructures can be coated by crosslinked polymeric separating layers similar to those on polymeric substructures. In more recent developments inorganic separation layers are applied, either by coating the porous substructure with a layer of zeolite, or by reducing the size of the pore to molecular dimensions. The separation mechanism of these membranes is even more complex than that of polymeric separating layers, as molecular sieving effects, caused by shape and size of molecules, and molecule–surface interaction decide whether a component can pass through the membrane or will be retained. Flux rates can be considerably higher than with polymeric membranes. A number of ceramic membrane plants are already operating in dehydration applications (Fig. 10).

Modules for Pervaporation and Vapor Permeation

The basic module types originally used for ultrafiltration and reverse osmosis in water treatment have been adapted for pervaporation and vapor permeation.

In both processes the partial vapor pressure at the permeate side has to be reduced to fairly low values, especially when low final concentrations of permeating component have to be reached in the retentate. Large volumetric flows have to be accommodated on the permeate side with minimal pressure drop.

As any feed mixture will contain organic components at high concentration, mostly at elevated temperatures, chemical stability of all module components, such as spacer and potting material and glues is critical. So far two types of modules are most widely used.

Plate Modules

Plate modules are mainly used for dehydration applications, with stainless steel used as construction material for support plates for the membranes and for spacers. Gaskets are normally graphite based and

Fig. 7 Combination vapor permeation and distillation. *(View this art in color at www.dekker.com.)*

compatible with a wide range of organics. Permeate channels are open over the whole periphery of the modules, which are housed in a vacuum vessel directly piped to the permeate condenser. Alternative designs mimic plate heat exchangers, in which the supported membrane replaces the heat exchanger plates. Internal ducts channel feed, retentate, and permeate. The drawback with such modules is the risk of gasket failure releasing process fluids to the outside (Fig. 11).

Spiral Wound Modules

Spiral wound modules with stainless steel central tubes, but otherwise similar to those known for other membrane processes, are mainly used for removing small quantities of organics from water with organophilic membranes. Glues can more easily resist this environment because of the low organic content and low temperatures. Multiple spiral wound modules are housed inside pressure tubes and assembled in banks in conventional skids. In a special design, the sandwich structures of membranes, permeate and feed spacer is welded together and not spirally wrapped around the central tube, but are arranged as flat sheets on the central tube for the removal of the permeate (Fig. 12).

Tubular Modules

Tubular modules are now being introduced for pervaporation and vapor permeation with number of advantages. Ceramic membranes are preferably coated on tubular substrates; coating the outside of the tube allows high operating pressures on the feed side. The tube-in-tube design, with feed flowing in multiple passes through the annulus between external steel tubes and central ceramic tubes, combines high turbulence in the feed channels with low feed flows per unit membrane area (low loading). Steam heating the shell of such a module ensures isothermal operation and the low loading allows almost all the permeating component to be removed in a single module (Fig. 13).

Tubular pervaporation and vapor permeation modules are also under development to house polymer membranes and promise more predictable performance, easier membrane replacement, isothermal operation, and lower costs.

Table 1 General guidelines for process selection

	Continuous pervaporation	Batch pervaporation	Vapor permeation
Tolerance to dissolved or suspended solids	Poor—membranes damaged by solids	Poor—membranes damaged by solids	Blow down from evaporator or column avoid entrainment
Flexibility to change feed, operating conditions	Fair—feed rate cannot normally be increased	High—change batch start and end conditions, batch time	Low—operation also tied to pressure of vapor feed
Drying non-polar organics (high water activity)	Suitable because of high water partial pressure relative to concentration	Suitable because of high water partial pressure relative to concentration	Not suitable, large membrane areas required
Steam requirement	Low (Fig. 8A)	Low (Fig. 8B)	Moderate (Fig. 8C)

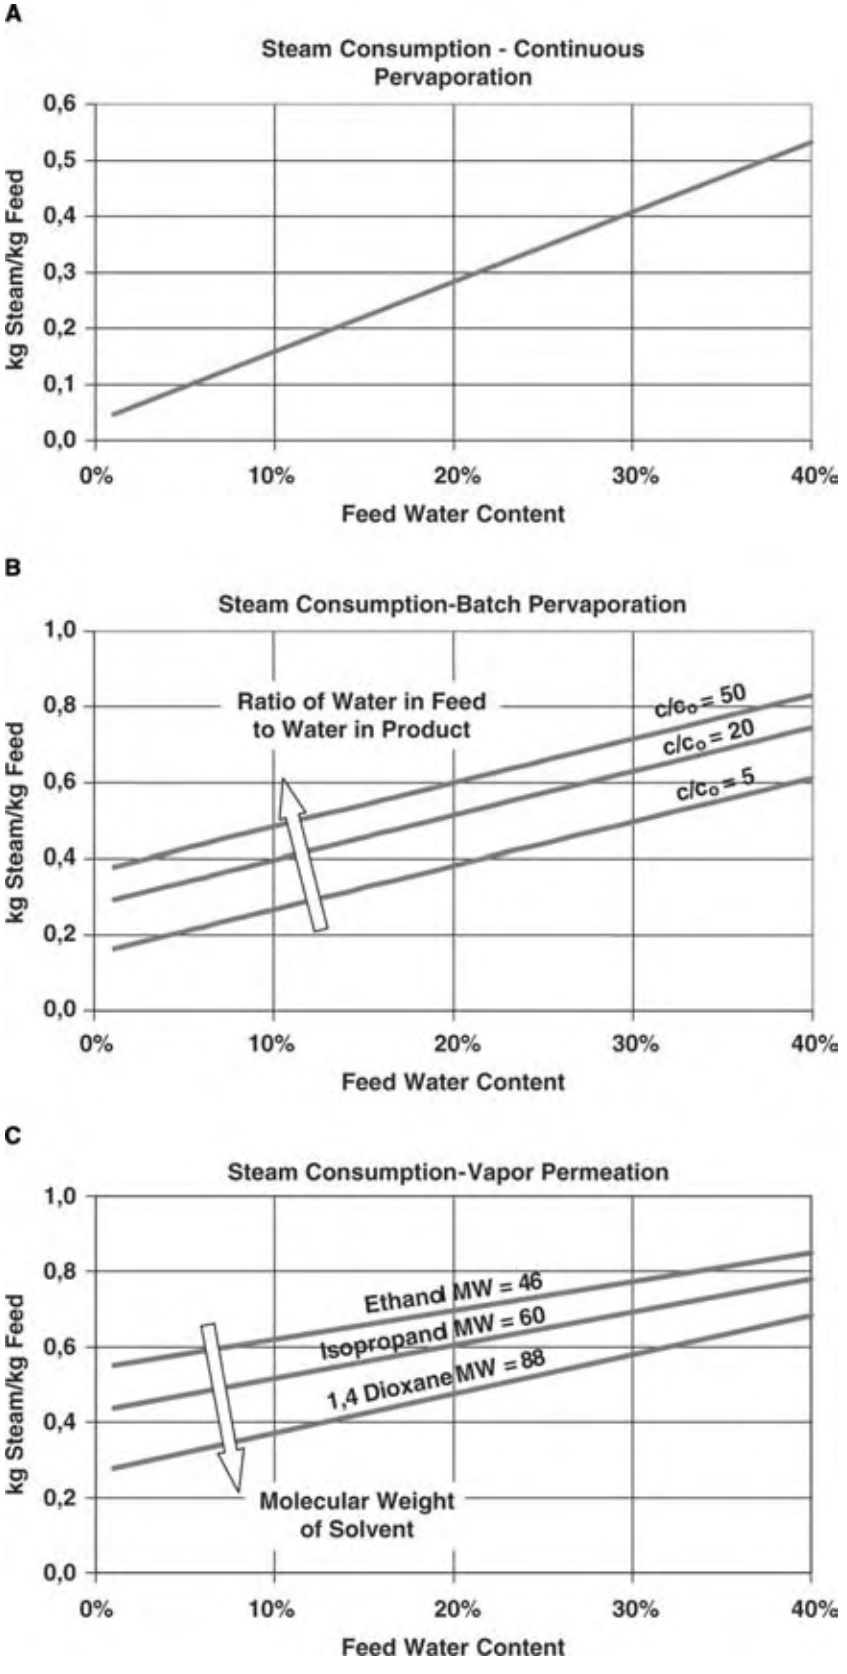

Fig. 8 Steam consumption. *(View this art in color at www.dekker.com.)*

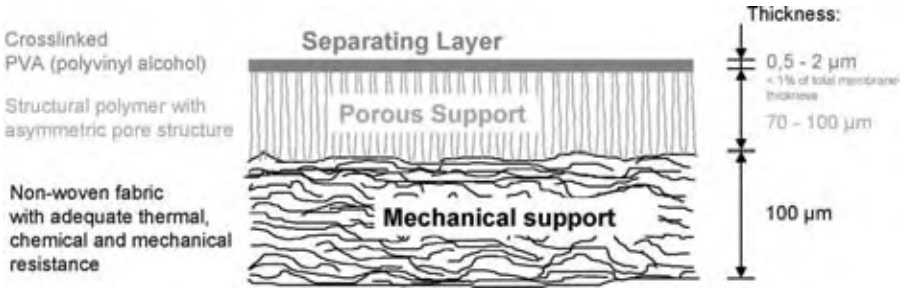

Fig. 9 Membrane structure. *(View this art in color at www.dekker.com.)*

Hollow fiber designs are only rarely used, generally with the feed flow inside the bore of the fiber. The more conventional arrangement with feed outside the fiber has the disadvantage of high permeate pressure loss.

MODELING PERVAPORATION

Membrane Testing and Data Correlation

Performance of a specific membrane with a particular feed is typically determined in a laboratory experiment. A heated quantity of feed is run over the membrane in a batch pervaporation test, and samples of feed and permeate are taken periodically and analyzed. Permeate rate is also measured. The temperature of the circulating liquid is thermostatically controlled and the permeate pressure is kept low, perhaps 5–10 mbar. Overall flux rates for permeating and nonpermeating components are determined by mass balance and plotted together with permeate composition against the feed composition.

From such results an Arrhenius temperature dependency can be correlated as follows:

$$\dot{n}_i'' = f(x_{iF}) \exp(-k/T_F)$$

Theory

In general, the flux of component i through a membrane is proportional to the membrane area and depends on the state of the feed (pressure and temperature), the composition of the feed, and the back pressure on the back-side of the membrane:

$$\dot{n}_i''/A = \dot{n}_i'' = f(P_F, T_F, \text{composition}_F, P_P)$$

In the case of pervaporation, because the feed is a liquid and the permeate is a vapor, the pressure of the feed is unimportant. The above equation can then be simplified to:

$$\dot{n}_i'' = f(T_F, \text{composition}_F, P_P)$$

For binary systems with low back pressures the equation can be further simplified to

$$\dot{n}_i'' = f(C_{iF}, T_F)$$

Corresponding to the data sets referred to above.

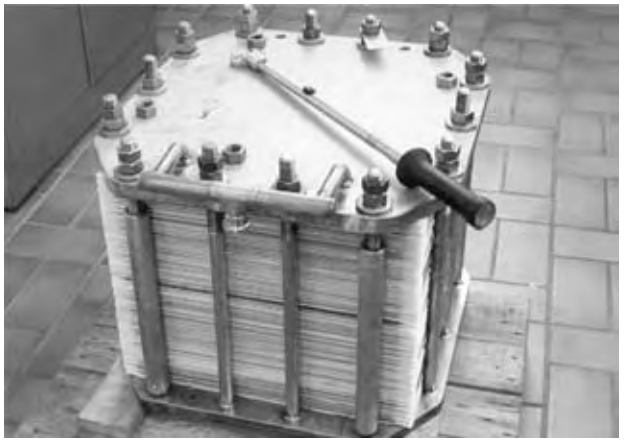

Fig. 11 Plate module. *(View this art in color at www.dekker.com.)*

Modeling for Process Simulators

With the advent of process simulation packages, modeling of pervaporation and vapor permeation processes in a user added subroutine allows these unit processes to be included in overall separation schemes right from the conceptual stage. This enables many different combinations of pervaporation, for example, distillation to be studied and the optimum operating parameters for the preferred configuration to be selected very quickly. Such parameters include membrane feed temperature, which strongly influences the flux rate and, therefore, the membrane area required and permeate pressure, which influences apparent selectivity, as well as permeate condensing temperature.

Most binary system/pervaporation membrane combinations are tested as above with low permeate pressures. The following relationship can be extracted from such results for both fast and slow permeating components:

$$\dot{n}_i'' = J_{oi}(x_{i,\mathrm{F}} p_i^o \gamma_{i,\mathrm{F}} - y_{i,\mathrm{P}} P_{\mathrm{P}})$$

Pervaporation membranes are commonly subject to swelling. This has the effect of increasing the permeance as the concentration of permeating component increases. In addition, permeance generally increases with temperature. Hence, J_{oi} is not a constant, but can be expressed as a function of temperature and of the partial vapor pressure of the permeating component, i.e.,

$$J_{oi} = f(T, p_i)$$

On inspection, it can be seen that this relationship is similar to the one developed above for membrane testing and data correlation. It is, however, easier and more useful when incorporated into generic simulation programs. Even when flux data is only available for the membrane in question with other feed mixtures, the thermodynamic data called up by the simulation

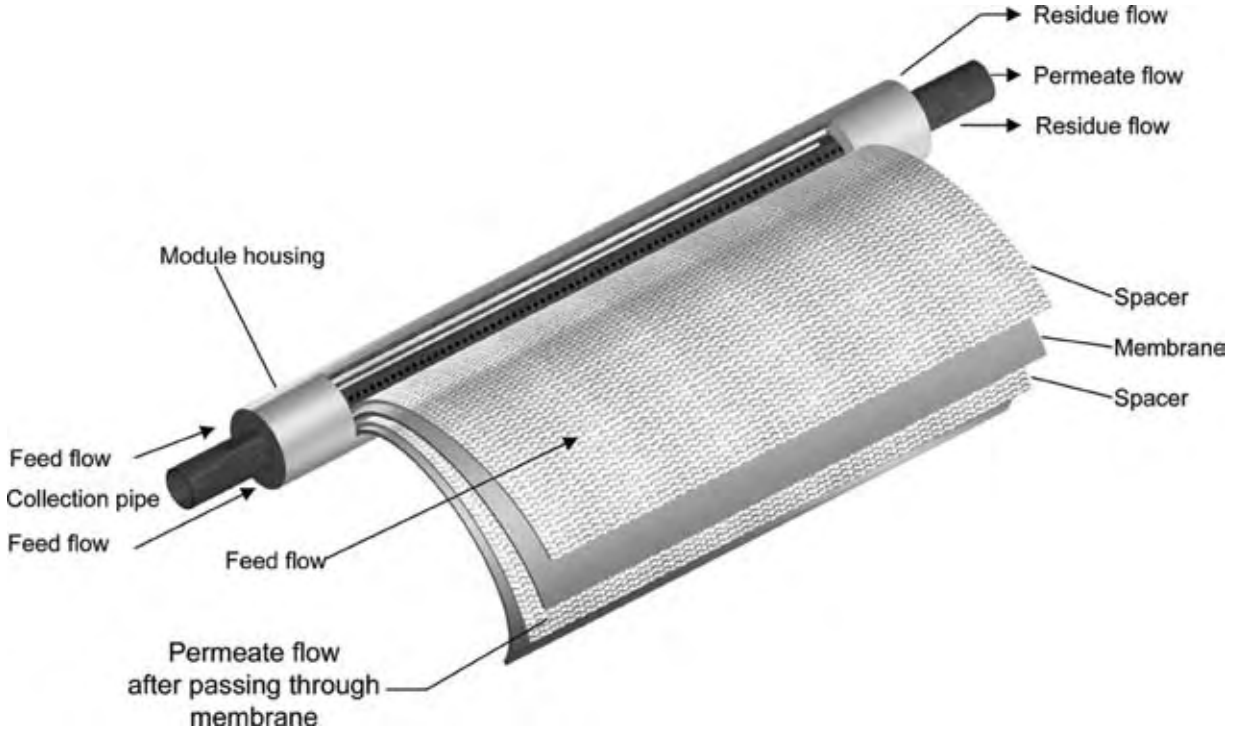

Fig. 12 Spiral wound module. *(View this art in color at www.dekker.com.)*

Fig. 13 High flux pervaporation module for silica membrane. *(View this art in color at www.dekker.com.)*

package (i.e., activity coefficients) allow a reasonable prediction to be made of expected flux rates.

APPLICATIONS OF PERVAPORATION AND VAPOR PERMEATION

Pervaporation is most competitive in situations where simple evaporation or distillation lacks separation power because of low volatility differences. It was first adopted for breaking azeotropes, primarily in solvent dehydration. These small-scale, end-of-pipe applications have served as a low risk, fast payback demonstration of a developing technology. The earliest plants were mainly continuous pervaporation for a dedicated service. Lately, multipurpose batch plants and continuous vapor permeation plants for impure feeds have also been built (Table 2).

Further applications with high growth potential listed above also serve to break azeotropes, or remove trace water. Removing water from condensation reactions can give multiple benefits in certain situations. The largest growth is now in separations that are integral to production in much larger plants. Accumulated experience, higher standards of reliability, and equipment development, which leverages economies of scale are now driving adoption of the technology in these situations.

Solvent Dehydration

Solvents are used for a variety of purposes in the pharmaceutical industry, e.g., for synthesis of pharmaceuticals, to precipitate materials from aqueous solutions, for cleaning purposes and for drying final products.

Spent solvents nearly always contain some water. Dehydration is an essential step in their recovery, but is difficult because most polar solvents form azeotropes with water. Final water removal by distillation is

Table 2 Applications of pervaporation and permeation

Application	Task	Processes	Membrane	Status
Solvent dehydration	Breaking azeotropes	Batch and continuous pervaporation, vapor permeation—often coupled with distillation	Hydrophilic, e.g., PVA polymer composite, ceramic	Well-established
Debottlenecking distillations	Breaking azeotropes	Continuous pervaporation and vapor permeation	Various	Growing
Water removal from condensation reactions	Breaking azeotropes, trace water removal	Batch and continuous pervaporation, vapor permeation—often coupled with distillation	Hydrophilic, e.g., PVA polymer composite	Growing
Methanol and ethanol removal	Breaking azeotropes	Batch and continuous pervaporation, vapor permeation—often coupled with distillation	Hydrophilic, e.g., PVA polymer composite	Growing
Organics removal from wastewater	Trace organic removal	Continuous pervaporation	Organophilic, e.g., PDMS, POMS polymer composite	Sporadic only
Separating hydrocarbons	Various	Continuous pervaporation	Various	Embryonic
Drying of reaction feed streams	Trace water removal	Continuous pervaporation	Hydrophilic, e.g., PVA polymer composite, ceramic	Embryonic

impossible or complicated. Entrainer use is not an option for pharmaceutical or fine chemical production, where stringent process certification rules out the introduction of potential sources of contamination.

Pervaporation dehydrates solvents without using any third substance or entrainer, simply, cheaply, and without problems and irrespective of vapor/liquid equilibria. On site solvent recovery by using pervaporation and vapor permeation is becoming standard practice in the pharmaceutical and chemical industries.

Solvents Commonly Dehydrated Using Pervaporation/Vapor Permeation

Isopropanol, ethanol: Standard applications for pervaporation, typically dehydrated from their azeotropes to fractions of a percent of water. Many continuous, batch and vapor permeation units are operating around the world.

Ethyl acetate, butyl acetate: Form azeotropes in the miscibility gap and were traditionally dehydrated by two distillation columns and a phase separator, however, with a massive recycle. Esters decompose in contact with zeolites. Pervaporation/vapor permeation is easily the best technique for dehydration.

THF: Easily dehydrated by pervaporation down to a few 100 ppm water. Traditional caustic washing is operationally messy, requiring a redistillation of the product. Pressure swing distillation requires high pressures and large recycles.

MEK: Pervaporation is again the preferred technique. Distillation is only possible with an entrainer because the azeotropic composition is nearly identical to the miscibility limit.

n-Butanol, n-propanol: Form azeotropes with high water content, hence the distillation/phase separation process involves massive recycle streams. Pervaporation plants are less costly to build and easier to operate.

Acetone: Does not azeotrope with water, but when distilled, a large reflux is required to get a half dry product. Pervaporation is ideal for final dehydration or for debottlenecking existing distillation systems. Very often pervaporation and vapor permeation plants are designed for operation with various solvents or with solvent mixtures.

Pervaporation and vapor permeation offer many benefits when dehydrating solvents:

- No introduction of additional chemicals—complete solvent dehydration by pervaporation membranes irrespective of azeotrope formation—no possibility of contamination.
- A choice of batch or continuous pervaporation systems, or continuous vapor permeation depending on the duty.
- Able to dehydrate esters without any decomposition.
- Low energy consumption.

Solvent Recovery from Mother Liquors

Spent solvents typically contain some water and are often saturated with dissolved material. Such mother liquors cannot be re-used without purification. Evaporation combined with vapor permeation is a powerful technique for purifying and dehydrating mother liquors.

The feed of spent solvent is evaporated and the resulting vapor is fed directly to a vapor permeation unit. Water vapor selectively permeates the membrane and is condensed under vacuum. The water free solvent vapor leaving the vapor permeation unit is condensed and is stored for reuse (product).

A blowdown is taken from the evaporator to prevent build-up of dissolved solids. This purge can be treated to recover valuable components.

Combining evaporation with vapor permeation gives the following benefits:

- Only vapor is fed to the membranes—no possibility of fouling and no possibility of solids carryover into the recovered solvent.
- Both evaporation and vapor permeation process steps are carried out in a single unit.

Debottlenecking Distillations

Debottlenecking pinched distillations

Distillation processes are driven by volatility differences. If these volatility differences are small, or become small under certain conditions, then columns need to operate with high reflux to achieve the desired separation. Because pervaporation/vapor permeation processes separate irrespective of volatility differences, they can be used very effectively to debottleneck pinched distillations.

Consider for example, the system acetone/water. Acetone is concentrated in the vapor phase at low concentrations, hence stripping of acetone from water is easy. At high concentrations this is not the case. Complete dehydration of acetone is difficult (Fig. 14).

Debottlenecking entrainer distillation systems

Existing entrainer distillation systems can also be effectively debottlenecked using pervaporation/vapor permeation (Fig. 15). Normally, the rectification column will be operating to give a product as close to the azeotrope as possible, running with a high reflux.

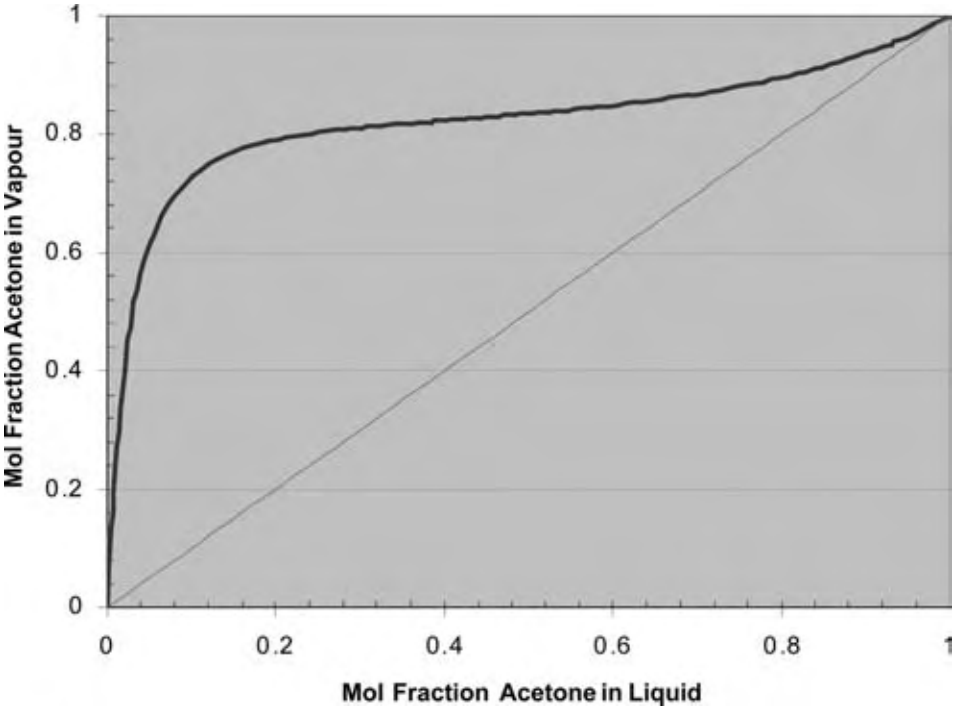

Fig. 14 Acetone/water distillation. *(View this art in color at www.dekker.com.)*

To debottleneck the system, reflux in the rectification column is reduced, giving more overhead product, but with a higher water content. The pervaporation unit is sized to remove enough water that the subsequent entrainer column is also unloaded. Both columns can then realize a significant capacity increase.

The pervaporation unit required for debottlenecking is relatively small, because the driving force for water permeation is high.

Adding a pervaporation/vapor permeation system to a pinched distillation can give the following benefits:

- Higher product capacity and reduced reflux.
- Significantly higher product purity.
- Reduced energy costs.

Recovery of tower side-draws

Trace components in distillation feeds can accumulate in the column if they form azeotropes with the other feed constituents, and if these azeotropes are intermediate boilers. This situation is alleviated by a side-draw at the tray with maximum concentration of

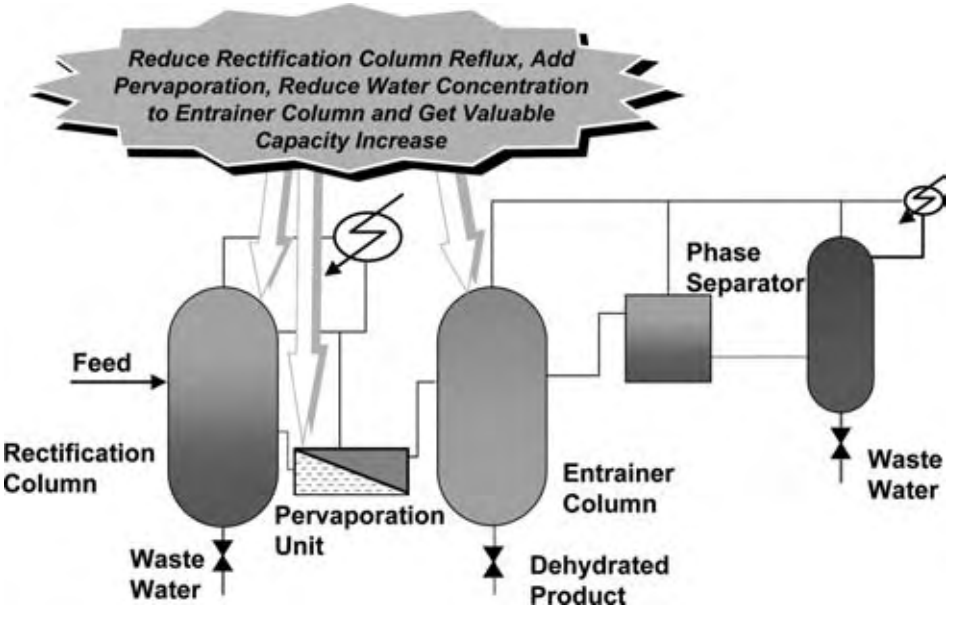

Fig. 15 Debottlenecking distillation systems. *(View this art in color at www.dekker.com.)*

azeotrope, leading to a loss of product, however. If these azeotropes can often be broken by pervaporation/vapor permeation, the product can be returned to the column, without the trace component. Yield is improved and column capacity can be increased as parasitic internal flows are reduced.

This technique has already been commercialized to debottleneck methanol distillation columns and has also been proposed for MTBE rectification (Fig. 16).

Water Removal from Condensation Reactions

Typical condensation reactions include:

Esterification:

$$R'\text{–}COOH + HO\text{–}R \rightleftharpoons R'COOR + H_2O$$

Acetalisation:

$$R'\text{–}CHO + 2HO\text{–}R \rightleftharpoons R'CH\text{–}(OR)_2 + H_2O$$

Ketalisation:

$$R'R''CO + 2HO\text{–}R \rightleftharpoons R'R''C(OR)_2 + H_2O$$

Condensation reactions are normally equilibrium limited, hence removal of co-product water reduces production costs in three ways:

- Purer products—less effort for product purification.
- Higher yield—lower reagent consumption.
- Faster reaction—greater reactor throughput.

Fig. 17 shows how on-line water removal shifts the equilibrium in a batch esterification.

The optimum scheme for water removal from these reactions depends on the relative volatilities of the reactants and products, and whether the units are operated batchwise or continuously. The examples below illustrate how pervaporation or vapor permeation can be used in particular situations.

Batch condensation reactions of ethyl and propyl alcohols

Unless producing volatile products, the typical procedure for these reactions is to dissolve the acid in an excess of alcohol, add catalyst, and then heat to drive off a water/alcohol mixture. This vapor is fed to a distillation column; the reaction water leaves as bottom product, and the alcohol/water azeotrope leaves as top product. At the beginning of the reaction, the azeotropic mixture is fed back to the reaction and the reaction still proceeds at a reasonable rate. As the reaction progresses, the concentration of product in the excess alcohol approaches an equlibrium because of the water in the reactor and the reaction slows. At this point, recycling of wet alcohol is discontinued and fresh dry alcohol is added instead. Gradually, co-product water is distilled away, correspondingly, more acid is reacted and a reasonably high yield is obtained, if sufficient time is available. The reaction product, excess alcohol, and unused acid are then separated and a further batch is started. Normally a batch is started with wet alcohol, generated at the end of the previous batch.

There are three ways in which pervaporation or vapor permeation can be used to enhance such reactions:

- *Offline pervaporation* (Fig. 18) is the simplest procedure and can be very effective. In this case, alcohol/water azeotrope from the top of the column is collected in a tank over the latter part of the

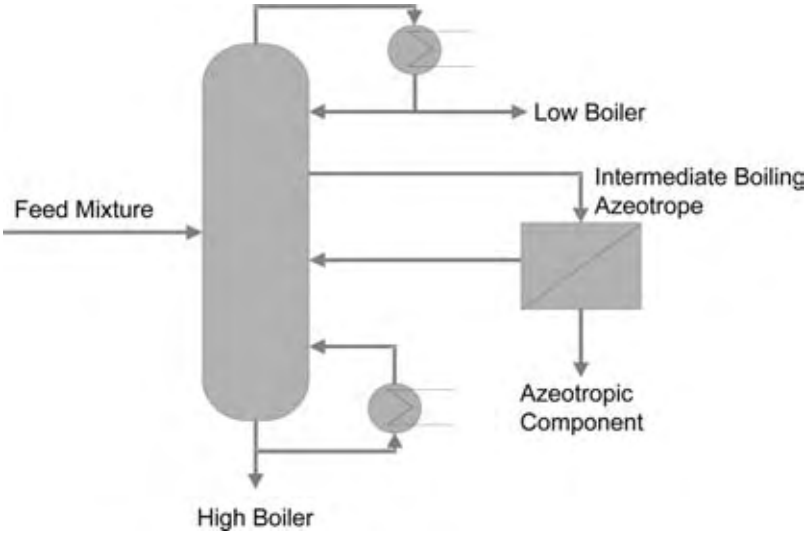

Fig. 16 Debottlenecking by splitting side-draw.

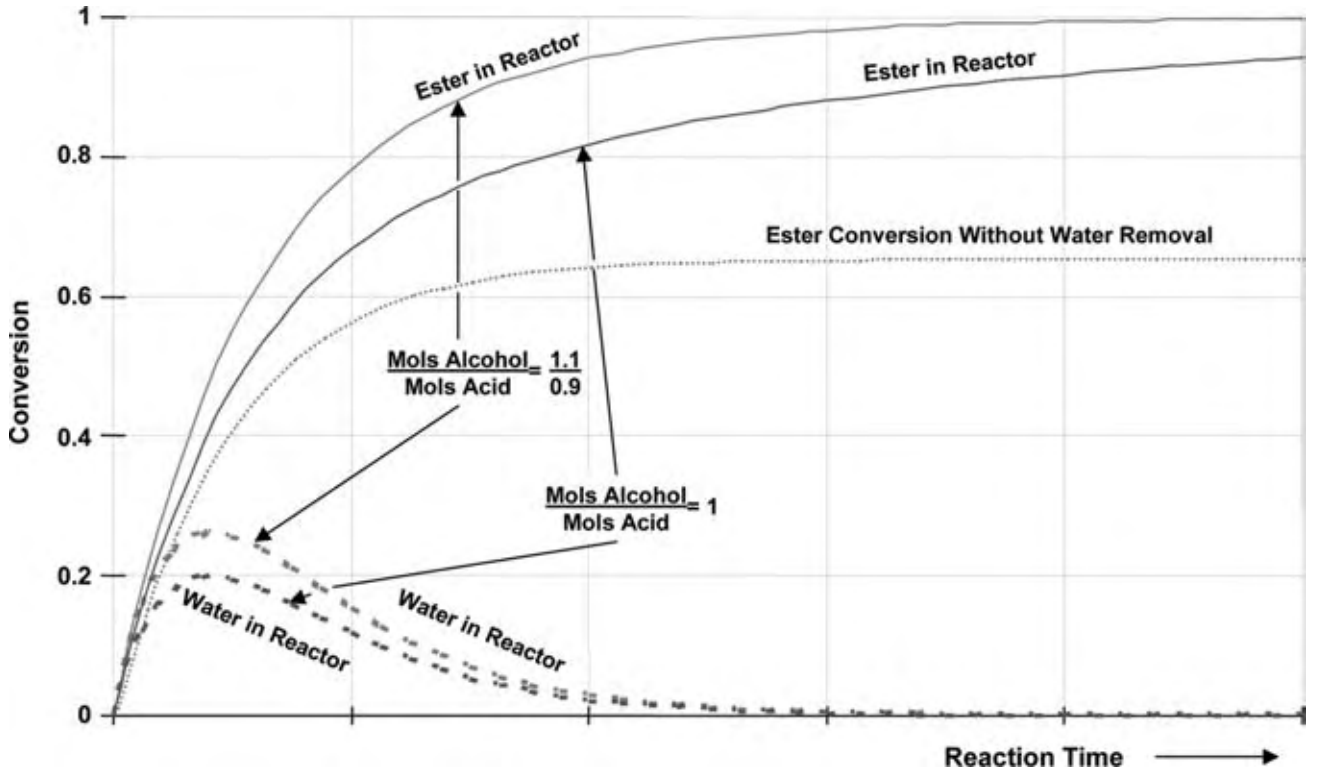

Fig. 17 Progression of a batch esterification (with equilibrium constant $K = 4$) with continuous water removal by pervaporation. *(View this art in color at www.dekker.com.)*

batch. The tank contents are continuously dehydrated by pervaporation and the resulting dry alcohol stored in a second tank. This material is fed to the process over the latter part of the batch.

- *Online vapor permeation* (Fig. 19) is used to remove water directly from the product of the distillation column. Dry alcohol is continuously fed back to the reaction.

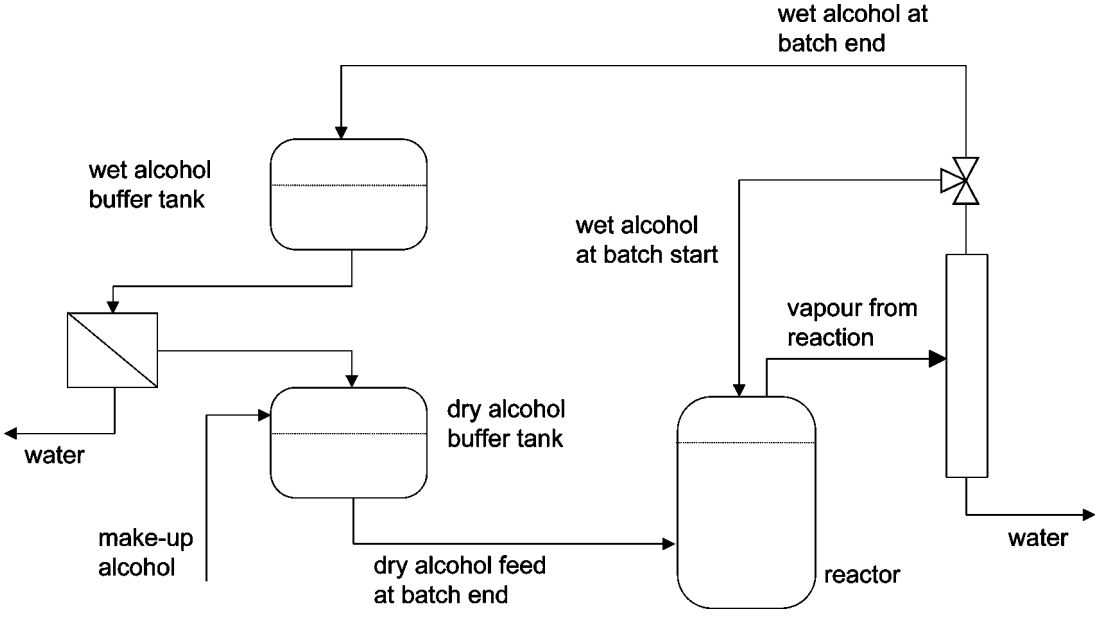

Fig. 18 Reaction water removal—offline pervaporation.

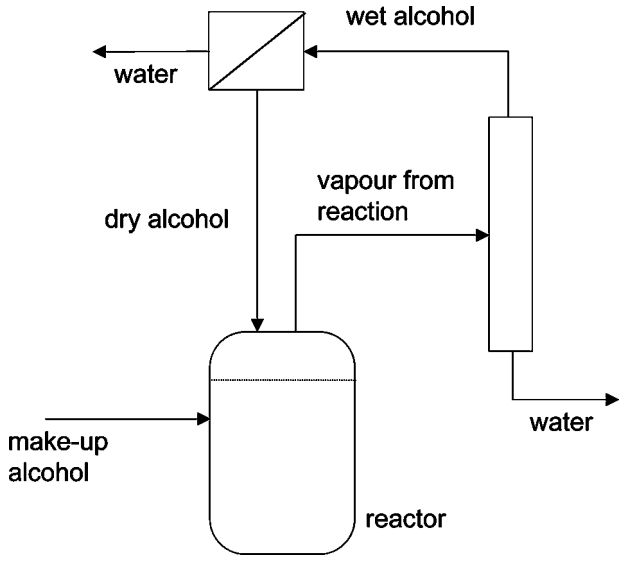

Fig. 19 Reaction water removal—online vapor permeation.

- *Online pervaporation* (Fig. 20) replaces the distillation column altogether. Reaction mixture is continuously pumped through the pervaporation unit at a high rate, and a drier stream is returned to the reactor.

In general, online pervaporation will give the most benefits, provided the membrane is able to handle the reaction mix. Such units are simple, and a high pump-around rate enables water to be removed very fast at the beginning of the batch, when it is being generated fastest. Although highly crosslinked, PVA membranes can cope with a few percent of sulfuric acid catalyst, and problems can arise with aggressive catalysts and with impurities in the feed. In addition, the pores in a composite membrane can become blocked, if the acid or product permeate the membrane faster than they can evaporate into the permeate vapor.

Online vapor permeation avoids these problems, but the unit is constrained to operate at the reaction pressure (normally atmospheric) and with the flowrate passing through the column. It is difficult to fully utilize such units throughout the cycle.

Offline pervaporation allows the membrane unit to be utilized at full capacity throughout the batch—in fact it can also be used when the reactor is not operating. In addition, such a unit is easily coupled to other reactors. Such units enhance the economy of a batch processing operation, while providing a high degree of flexibility.

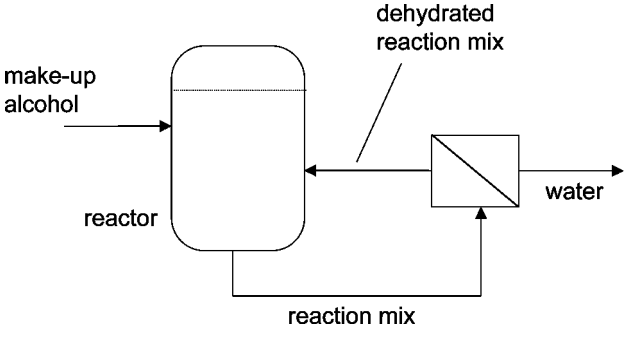

Fig. 20 Reaction water removal—online pervaporation.

Continuous production of ethyl and propyl esters of low volatility acids

The classical scheme for such a process is shown in Fig. 21. Acid is continuously fed into a reactor containing an excess of alcohol. A product mix is continuously drawn off from the reactor containing alcohol, water, ester, and some unreacted acid. Three columns are then used to remove product ester and co-product water. Unreacted alcohol is recycled back to the reaction.

In the first column, the least volatile component, unreacted acid, is taken out at the bottom and recycled back to the reaction. Alcohol, water, and ester pass overhead to the second column. Product ester is taken from the bottom of this column and water and alcohol taken overhead. The third column is used to remove water, again taken out at the bottom. The overhead product from this column is the alcohol/water azeotrope, which is recycled to the reactor.

This scheme has two major drawbacks:

- There is a high concentration of water in the reactor, requiring a large excess of alcohol to drive the reaction.
- The recovered ester is contaminated with trace quantities of water, which hydrolyse the product, decreasing its purity, quality, and usability in many situations.

Fig. 22 shows a reaction scheme enhanced by continuously removing water directly from the reactor. In this case, the water is removed from the vapor phase. A vapor stream is sparged from the reactor and circulated through a vapor permeation membrane module, where water is selectively permeated through the membranes. The membrane unit is sized, such that all the reaction water can be removed with the water/alcohol ratio just below the azeotropic composition.

Reaction mixture is similarly passed through the first column to remove excess acid. In the second column, ester is again taken out at the bottom. However, because relatively little water is in the feed to this column, the water is entrained out with the alcohol. The ester bottom product is contaminated with traces of alcohol instead of water, and hence will not hydrolyse.

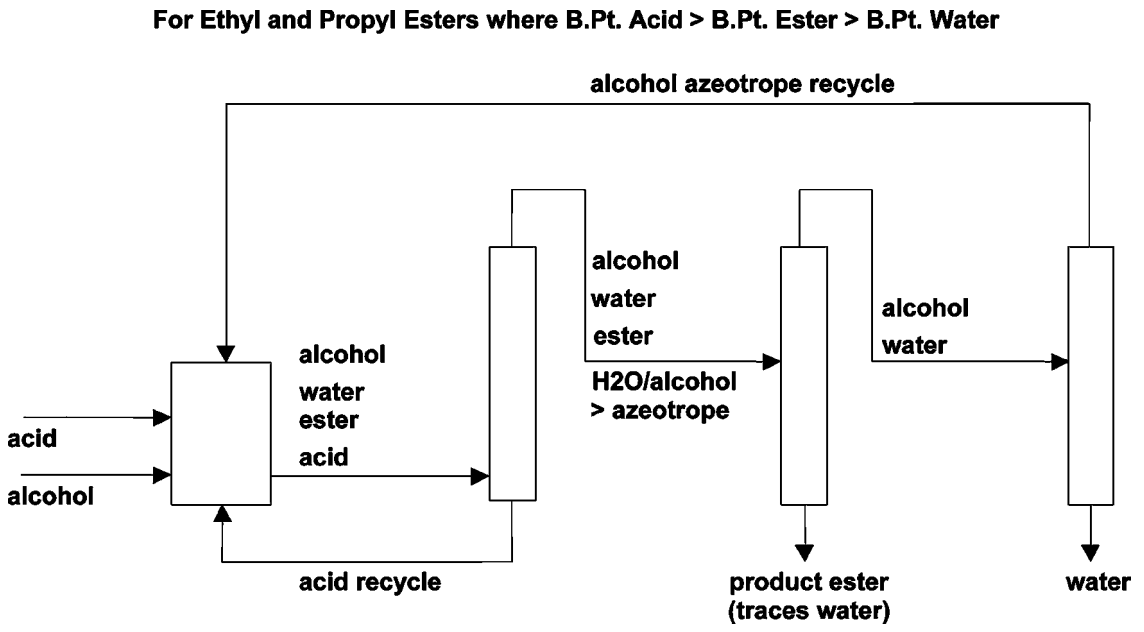

Fig. 21 Classical reaction/separation scheme.

Removing reaction water directly from the reactor improves reaction conditions—the reaction runs faster, lower residence times suffice, equipment costs are minimized, and side reactions are reduced. No third column is required and product quality is better.

Continuous esterification with heterogeneous catalysts

Some condensation reactions are carried out using heterogeneous catalysts. Continuously removing water from such systems brings concrete benefits, particularly in yield.

Fig. 23 shows a scheme for removing water from a continuous esterification process, which uses a heterogeneous catalyst. The process runs in four stages. Each stage includes a reactor, where the components are brought close to equilibrium over the catalyst. The mixture then flows through a pervaporation stage, where water generated in the reaction step is removed, shifting the reaction equilibrium. In the next reaction step, equilibrium is re-established and then again the reaction water is removed. In four such stages, the reaction will be pushed far over to the right and consume nearly all of the feed supplied. Such a procedure not only maximizes reagent usage, but also minimizes

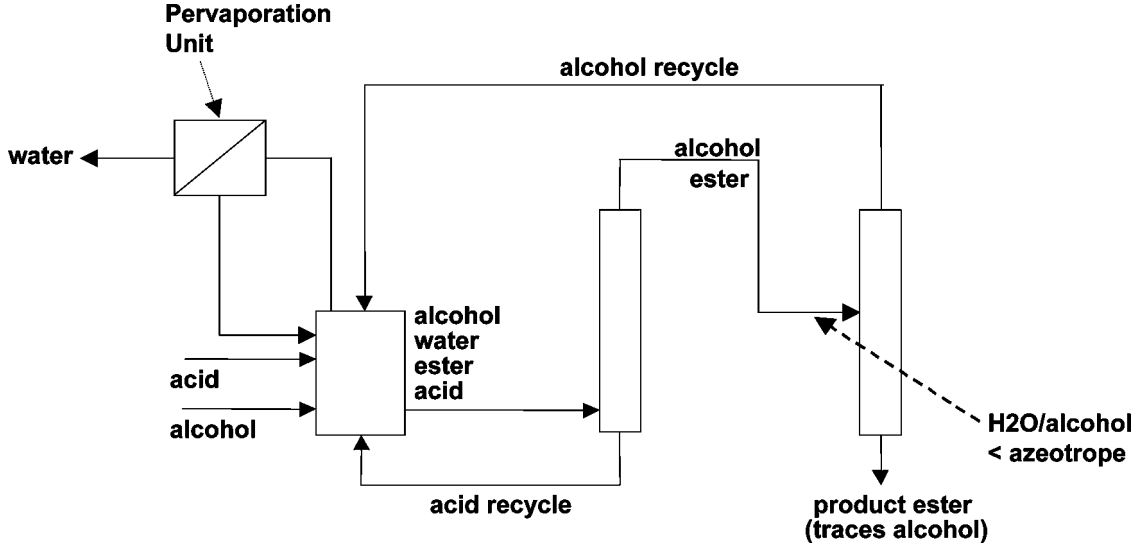

Fig. 22 Enhanced reaction/separation scheme.

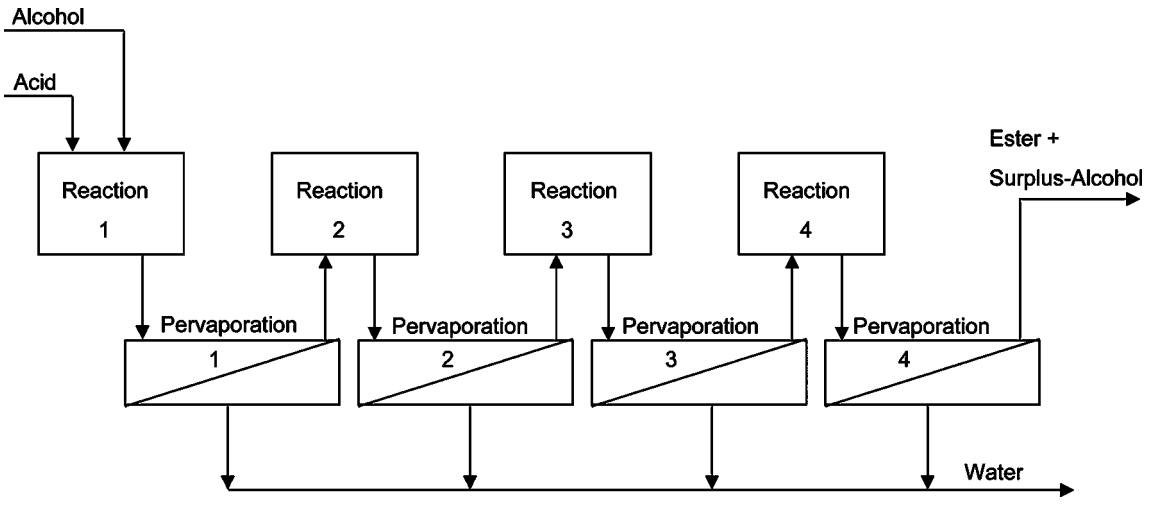

Fig. 23 Four stage reaction/pervaporation cascade.

the separation work required to purify the product. A number of plants of this type are operating.

Transesterifications using methyl esters

Many esters are made using transesterifications, because the milder conditions prevailing permit the reaction of components containing additional functional groups. In alcoholysis, a complex alcohol is reacted with a methyl ester, forming a complex ester and methanol. These reactions are all equilibrium limited, hence the reaction only proceeds if product or co-product is removed. Commonly the reaction mix is distilled to remove the methanol. However, methanol azeotropes react with many methyl esters, hence driving out the methanol also removes a reactant.

Separation of these azeotropic mixtures generated in such situations by traditional means is difficult. However, polymer membranes with a low degree of cross linking preferentially permeate methanol over less polar organics.

Fig. 24 shows a vapor permeation unit installed to remove methanol from the top of a column, treating the boil-off from a transesterification reactor. The column is operated to condense overhead product close to the azeotropic point. Condensed liquid is refluxed through the column. Net overhead vapor is passed through the vapor permeation unit, which is sized to

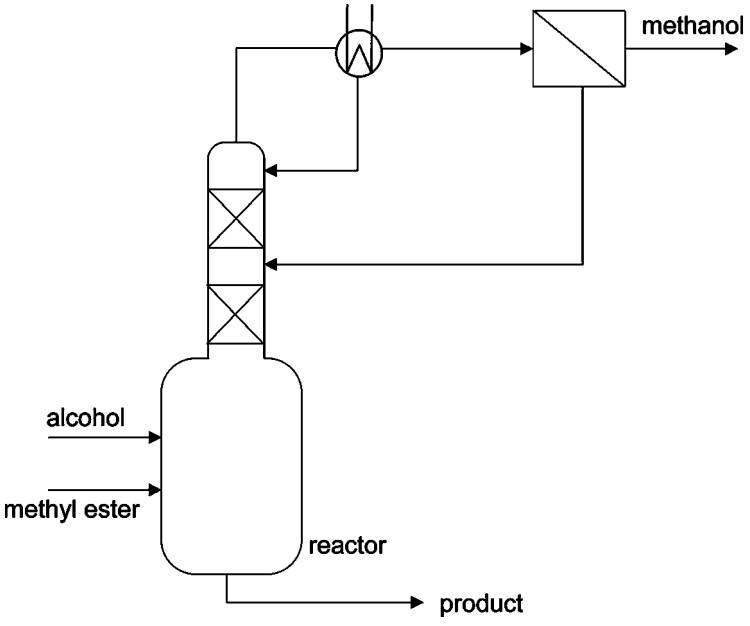

Fig. 24 Methanol removal from a transesterification.

Fig. 25 A pervaporation plant for methanol removal. *(View this art in color at www.dekker.com.)*

permeate methanol at the rate it is generated in the reaction. The recovered ester is recycled to the reaction. In the example shown, membrane area is saved by feeding ester, only partially depleted, in methanol back to the column. The remaining methanol is stripped from the stream as it passes down the column to the reactor.

Such enhancements directly impact the quantity of reagent required, and hence have a direct impact on the bottom line. Payback times for the separation equipment are typically extremely short.

Methanol and Ethanol Removal

Hydrophilic polymer membranes have also been developed, which will permeate methanol, ethanol, and to some extent isopropanol. These compounds can be removed from less polar organics, although membrane selectivity is not as high as when permeating water. Fig. 25 shows an industrial vapor permeation plant, which continuously removes methanol from a methyl ester/methanol azeotrope.

Methanol forms azeotropes with many substances, particularly esters, and often cannot be recovered from spent solvents or from reaction mixtures by simple distillation. Pervaporation provides a simple way to break these azeotropes. Used alone or in combination with distillation, such units provide an economical and reliable route to recover or remove methanol (Fig. 26).

A separation scheme for methanol removal from a methanol rich methanol/ethyl acetate mixture is shown below. The mixture is distilled to the azeotrope, taking out pure methanol as bottom product. The overhead stream is passed directly to a vapor permeation unit, which permeates a methanol rich stream. This stream is condensed and passed back to the methanol column, via the feed buffer (Fig. 27).

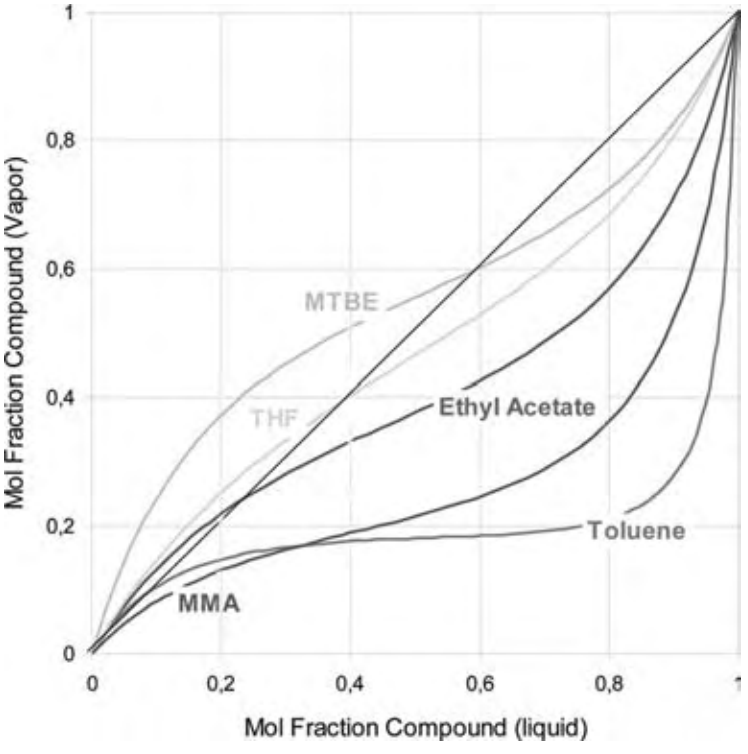

Fig. 26 Azeotrope splitting. *(View this art in color at www.dekker.com.)*

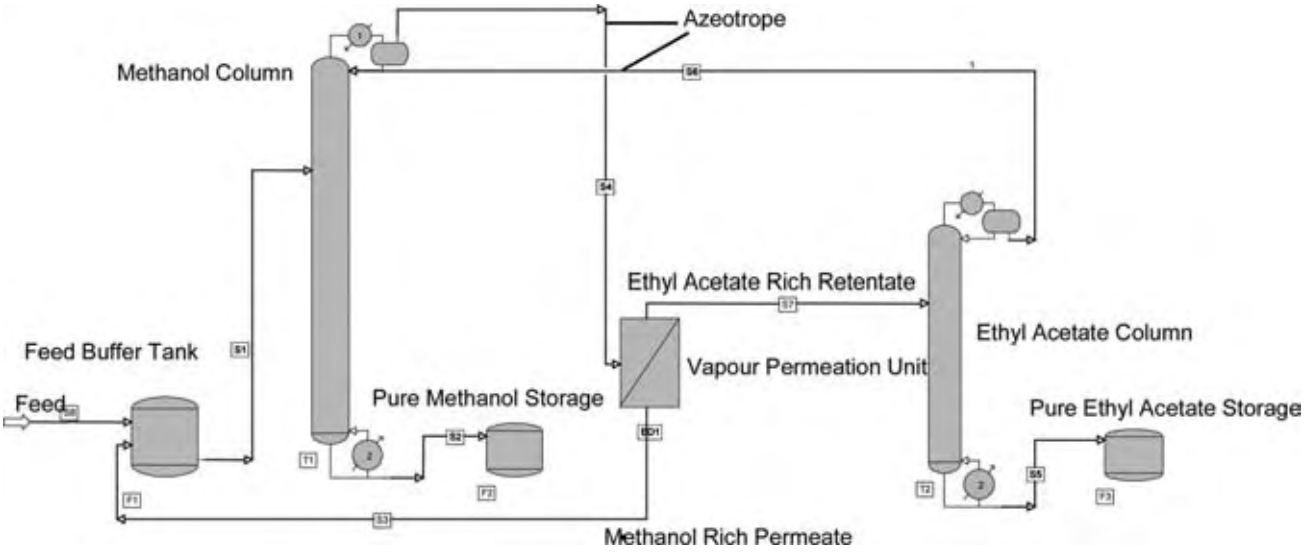

Fig. 27 Methanol recovery by azeotrope breaking—example methanol/ethyl acetate. *(View this art in color at www.dekker.com.)*

Retentate from the vapor permeation unit, strongly depleted in methanol, is fed directly to the ethyl acetate column. Pure ethyl acetate leaves this column as bottom product, while overhead azeotrope is sent to the vapor permeation unit.

Many solvent or ester/methanol mixtures can be separated using a similar scheme. If the feed is close to the azeotrope, then the methanol column can be dispensed with. If the capacity is small the purification column for the second component may not be required, depending on the desired purity. One of the most promising uses of this technology is removing methanol from the products of transesterifications.

Methanol removal from column side-draws

Institut Français du Pétrole (IFP) has developed a process, where pervaporation of methanol is used to debottleneck MTBE production. In the debutanizer columns used in MTBE processing, the MTBE/methanol azeotrope results in a concentration of methanol at a point midway between the feed tray and the

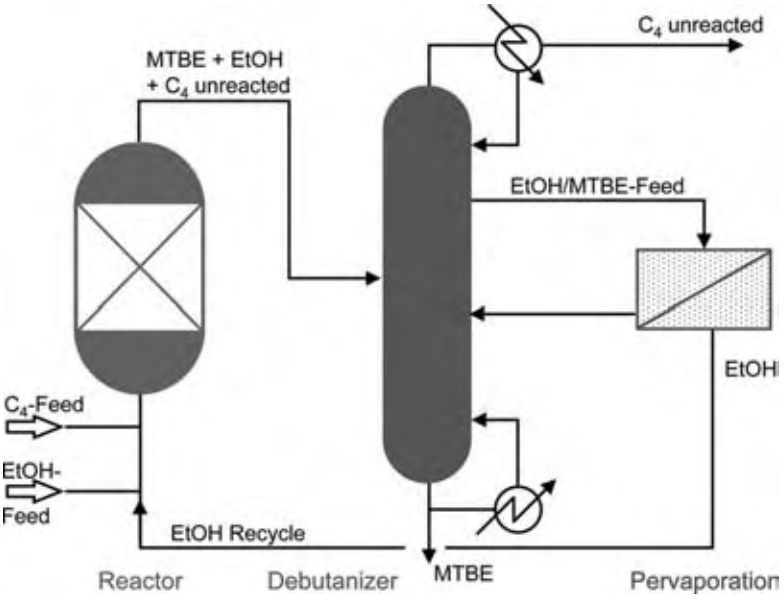

Fig. 28 MTBE-synthesis—optimized process with integrated pervaporation. *(View this art in color at www.dekker.com.)*

reboiler. Pervaporating methanol out of the process from a side-draw taken at this point results in methanol free MTBE as debutanizer bottom product (Fig. 28).

Separation systems, based on pervaporation/vapor permeation of methanol, offer the following benefits:

- Problem-free separation of methanol/organic mixtures irrespective of azeotrope formation.
- Avoids water wash for methanol removal.
- Low energy costs.

Organics Removal from Wastewater

Treatment of contaminated wastewater by pervaporation is superficially attractive, however, only a few commercial installations have been built. Phenol, which azeotropes with water at around 10 wt%, is typically recovered by extraction in large plants, where measures to eliminate extractant loss can be economically applied. Pervaporation is an attractive and cost competitive alternative for small plants. Organophilic membranes in spiral wound modules are used in these applications.

Separation of Hydrocarbons

A number of hydrocarbon separations have been intensely studied and piloted in recent years and commercialization is expected soon. Pervaporation is expected to be one of a number of proven options for sulfur and benzene removal from fuels and olefin/paraffin separations. These plants will use robust, specially engineered polymer membranes, installed in large-scale tubular modules.

Continuous Drying of Reaction Feed Streams

Mol sieves are routinely used for drying a number of reaction feeds to very low water levels. This is particularly important where expensive catalysts are susceptible to wet feed. Pervaporation has the advantage of continuous, steady operation, minimizing operational upsets, which can result from sieve regeneration. Simpler systems are especially attractive where toxic materials are involved.

CONCLUSIONS

The emerging applications outlined above use existing membranes with proven industrial performance. Development of new and better membranes, i.e., with higher fluxes, better selectivities, and broader chemical resistance is being pursued in a number of companies and institutions. These efforts will expand the areas where pervaporation is a viable option. Parallel developments in module design are also opening up new opportunities. In particular, tubular membranes allow the use of module geometries with superior heat and mass transfer characteristics.

These developments will have a wide impact. Reaction enhancement will be a major beneficiary, but a look at the simpler field of solvent dehydration shows that the innovation process is very application dependant. Pervaporation (with vapor permeation) is progressively displacing other techniques in solvent dehydration. Replacing entrainer distillation for drying ethanol and isopropanol, pervaporation at initial stages is always now preferred to techniques, where a third component must be added to shift equlibria. The handling of entrainers and/or calcium chloride or caustic with the attendant environmental risks and costs is no longer a viable option.

Pervaporation has also made inroads in drying solvents, where phase separation facilitates drying by distillation. Drying esters this way requires high reflux ratios, hence pervaporation is easily cost competitive. If the solvent mixes include alcohols, then the phases will not separate and distillation will not work at all.

The field of reaction enhancement is more complex and developments more difficult to predict. The ability of ceramic membranes to run at higher temperatures greatly increases the number of reactions, which can be the considered as enhancement candidates. These reactors can be further enhanced, for example, by using the ceramic tube to support a catalyst as well as a membrane. Equipment of this type is already under development.

NOMENCLATURE

i_i''	Membrane flux of component i per unit area (kmol/m^2/h)
$x_{i\mathrm{F}}$	Mol fraction of component i at a point on the feed side of the embrane
K	Constant for flux dependency on temperature (1/K)
T_{F}	Temperature at a point on the feed side of the membrane (K)
A	Membrane area (m^2)
P_{F}	Pressure at a point on the feed side of the membrane (bar)
P_{P}	Permeate pressure (bar)
J_{oi}	Flux coefficient for component i (kmol/m^2/h/bar)
p_i^o	Vapor pressure of the pure component i at temperature T_{F} (bar)
$\gamma_{i\mathrm{F}}$	Activity coefficient of component i

$y_{i,p}$ Mol fraction of component i in the permeate leaving the membrane at a specific point

p_j Vapor pressure of swelling component j at temperature T_F and mol fraction CiF (bar)

Petroleum Refinery Distillation

Stanley Marple
Chemical Engineering Department, University of Houston, Houston, Texas, U.S.A.

INTRODUCTION

Distillation in the petroleum refinery is different from most distillation operations in two principal ways:

1. Thousands of molecular species are present. The separations are roughly by molecular weight, thus yielding a differentiation of physical properties.
2. In many cases, the distillation feed contains species of high molecular weight, which cannot be readily boiled in shell-and-tube heat exchangers such as those used in most distillation processes.

The first problem makes it difficult to predict distillation separations because the large number of species would overload computational systems. The problem is solved by first analyzing feed stocks by precision batch analytical distillation or equivalent gas chromatography. The stocks are then divided (on paper) into groups of narrow boiling-point range. As volatility is represented fairly accurately by atmospheric boiling point, each boiling-point range, e.g. 200–225°F, can be represented as a single pseudocomponent at the fraction's mean boiling point. Of course, in the lower boiling-point ranges, individual chemical species can be analyzed and entered as such into the distillation model. Then the refinery distillation operation can be studied as a familiar multicomponent distilling calculational model.

The second problem, providing reboil heat for heavy (high molecular weight) stocks, is handled by using fired heaters with short thermal exposure time to preheat the feedstocks. The distilling column is then set up primarily as a rectifying column with side-stripped draw streams to separate the products. Usually superheated steam is used to strip volatiles from each side-draw stream and the bottom product. Less often the strippers may be reboiled. In some operations, the feed preheat may be supplied by a catalytic or thermal reactor. Product separation of the heaviest fractions can be carried further by reheating the bottoms from the first distillation and rectifying the distillate under vacuum. In the interest of concise presentation, this article will be primarily devoted to refinery distillation separations handled by the methods described above, with a brief discussion only of other separations that use mostly well-known general distillation processing methods.

CRUDE OIL AND CRACKED PRODUCT DISTILLATION

In most refineries, only two basic schemes are used for crude oil distillation: single-column and two-column arrangements. In the single-column arrangement, liquid crude oil is pumped at high velocity through a series of preheat exchangers and through the coils of a fired preheat furnace, where partial vaporization takes place. The exit temperature from the fired heater is often in the vicinity of 720°F or 382°C, limited by thermal degradation. The two-phase stream is introduced into the feed zone of the crude tower (Fig. 1). The unvaporized liquid portion of the feed flows by gravity over a section of stripping trays on which superheated steam vaporizes any volatile components.

The pressure in the preheat train is maintained high, perhaps 500 psi, to prevent vaporization, because the flow must distribute accurately among parallel piping as it passes through the preheat furnace.

If the crude oil contains a substantial amount of water and volatile hydrocarbons, it may be best to reduce preheat system pressure by removing water and volatiles upstream of the warmest preheat exchangers. This separation may be done in a primary distilling column or even in a preflash vessel. Fig. 2 represents the resulting two-column scheme.

In the usual two-column scheme, the primary column depends on recovered heat for vapor formation; a few refiners use a fired heater reboiler. The main crude column runs at low pressure compared to the single-column situation. The main column in two-column systems is often called the ''secondary column'' or the ''atmospheric column.''

Comparison of Single-Column vs. Two-Column Crude Distillation

The choice of single-column vs. two-column crude distillation may depend to some extent on the feedstocks to be handled and on the choice and costs of downstream processes.

The single-column scheme will produce less residue, because the inclusion of water and volatiles in the main-column feed reduces the partial pressure of heavy oil vapor fractions; thus more of the heavy oil can

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120017366

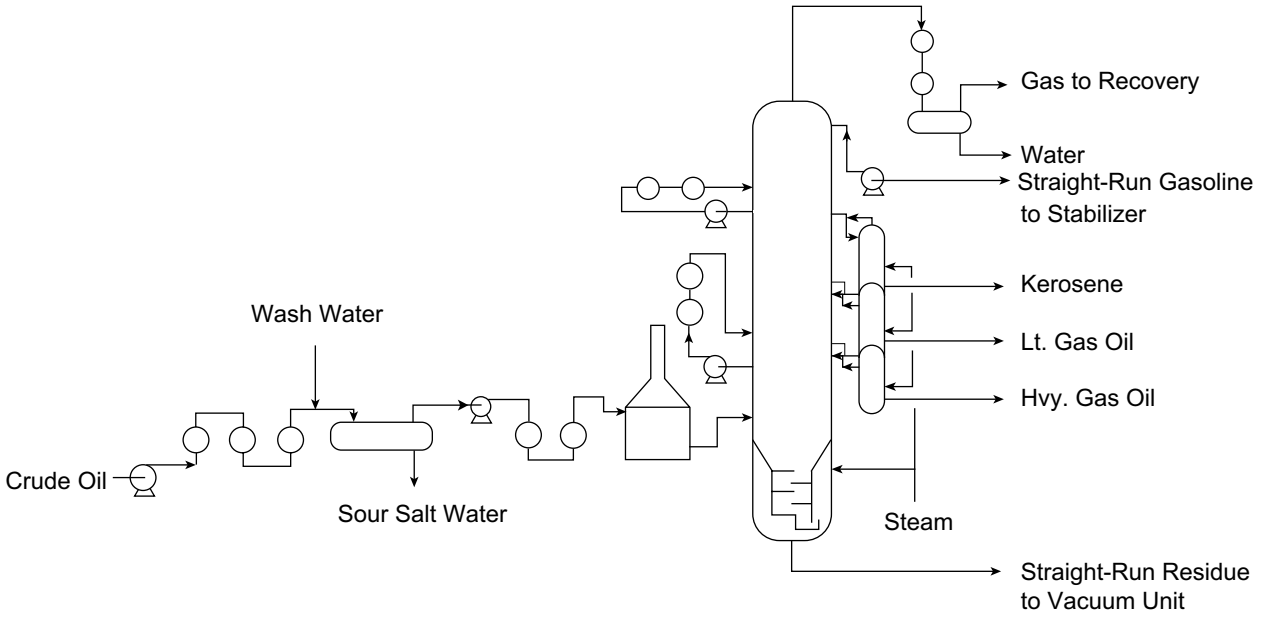

Fig. 1 Basic scheme of single-column crude distilling unit.

vaporize. This effect is similar to steam distillation in principle. The column temperatures for each scheme are the same, limited by thermal degradation.

Consider however the handling of gasoline and naphtha fractions. Most refiners split the naphtha into at least two streams: The lighter straight-run gasoline is often treated for sulfur removal (''sweetened'') by wet chemical processes, while the heavier stream may be hydro-desulfurized. In the two-column scheme, the straight-run gasoline may be an overhead product of the primary column. The heavy gasoline can go directly to hydrotreating as a top product of the main column.

However for the single-column scheme, both light and heavy naphtha fractions are fed to the main column. If they are taken together as overhead liquid product, there will need to be a downstream stabilizer and a naphtha splitter to produce the gasoline streams for treatment.

In the single-column scheme, some refiners take the heavy gasoline as a side draw off the upper main column. With this arrangement, there may be internal

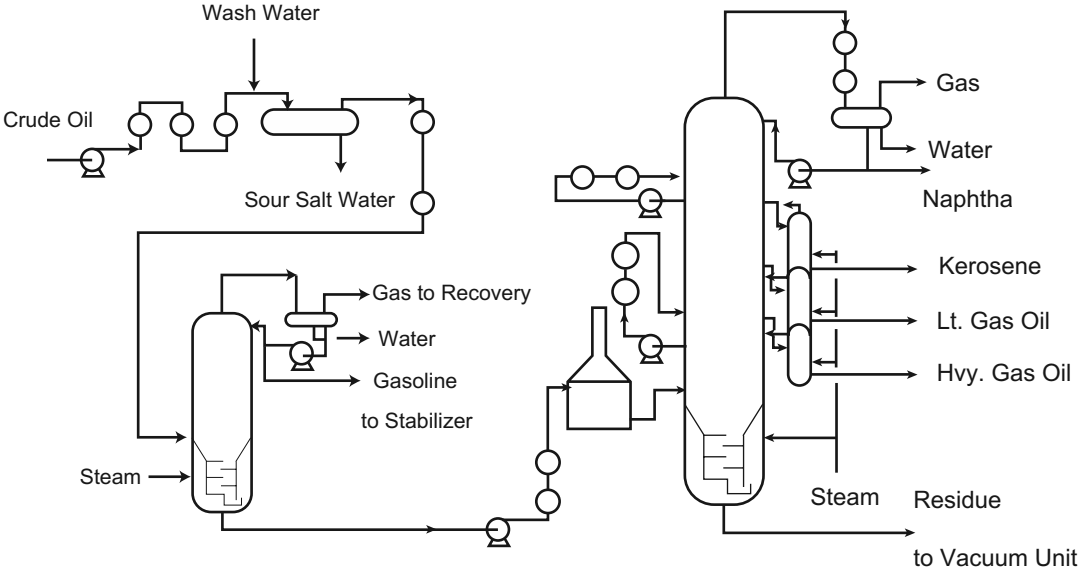

Fig. 2 Basic scheme of two-column crude distillation unit.

water condensation in the main column because of low tray temperatures in the upper column. Even though internal water condensation can be dealt with satisfactorily, it is a nuisance, which requires additional equipment cost.

The main column will be larger in the single-column units, hence somewhat more expensive.

Fuel cost will usually be higher for two-column operations, because more of the available heat from hot products must be used to provide vapor for the primary column. Less of this heat of vaporization is recoverable than in the single-column scheme because the overhead products are cooler in the two-column scheme.

It may be necessary to compare overall capital and operating costs to determine which type of crude scheme is best for a given situation. Occasionally a refiner will convert a single-column system to two columns as a means of expanding throughput.

When volatiles and water are removed in a flash vessel rather than by a primary column, it is sometimes expedient to direct the flash vessel overhead stream into the crude column. Unfortunately, the flashed stream is relatively cold and may contain color bodies from entrained crude residue. These characteristics favor the use of a primary distilling column rather than a flash vessel.

The preheat train

The warm product streams and pumparound heat removal streams from the main column are used to preheat the cold crude oil coming from storage. Obviously the heat recovery system is subject to optimization. If the crude stream is kept intact, there are two ways to optimize: 1) temperature approach on the cold end of each exchange service; and 2) order of the exchangers and number of breaks for the warm streams. This optimization may be done graphically as illustrated in Fig. 3 or mathematically.[1] Another degree of optimization is possible by splitting the crude stream into parallel trains of exchangers. Such splitting adds greatly to capital cost and increases the complexity of the operation.

Fig. 3 shows how the exchange train might be arranged in one typical case. Obviously any change made at the cold end of the train has an effect all the way along the system.

For example, if additional Btus are recovered at the cold end of the train, the crude oil temperature rise will hurt the heat recovery at the hot end of the train, so that the net heat saving might be only half as much as expected. Another complication is that the hot end of the train may require expensive metals to inhibit corrosion.

In operation, the crude oil preheat exchangers will gradually become fouled and lose effectiveness over a period of months. The piping of the exchange train needs to be arranged to permit cleaning on stream.

The crude oil desalter

The crude oil contains suspended droplets of salt water and silt, which must be removed. Demulsifying

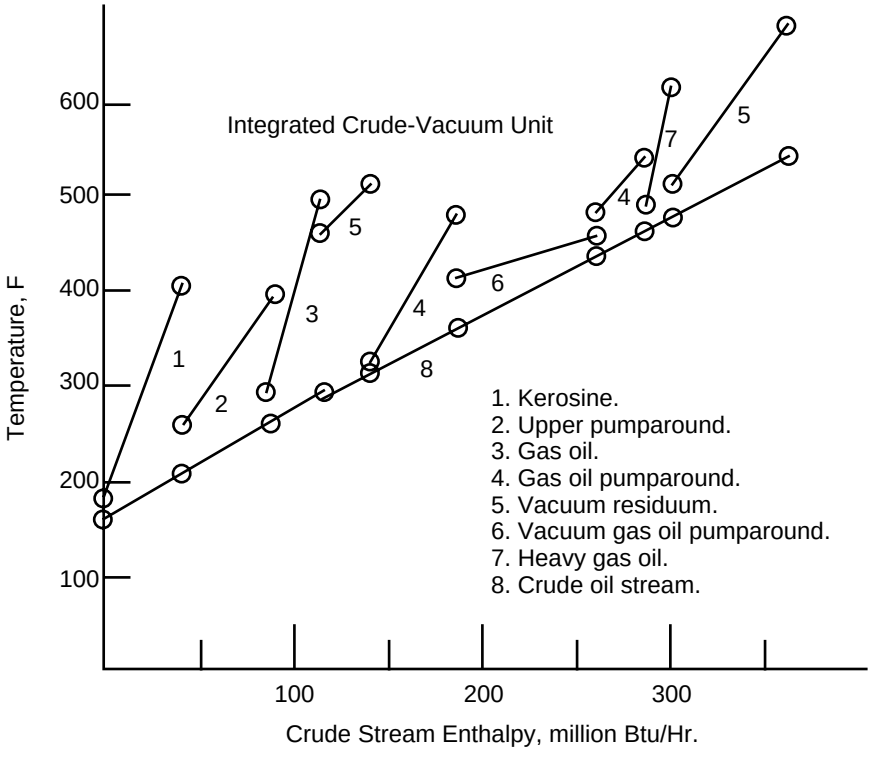

Fig. 3 Typical preheat train.

chemicals and wash water are mixed with the crude stream and it passes to a large horizontal cylinder, which may be equipped with an electrostatic separator, to remove the salt water. Sometimes a second stage of desalting is useful.

The fired crude heater

Design of the fired preheater is a complex subject and cannot be adequately described here. A few points are worth mentioning. Firstly, it is necessary to prevent vaporization before the flow control valves that divide the flow among parallel tube passes. Two-phase flow results in unreliable control; low flow is dangerous and high flow gives inadequate vaporization. Secondly, corrosion-resistant metallurgy is necessary and thirdly, the furnace must avoid hot spots on the tube walls.

And fourthly, it will be necessary to provide for periodic removal of solidified carbonaceous material on the inside walls of the tubes. This is done by controlled burning in the presence of steam; the coke tends to break up (spalling) and react with the oxygen and water vapor to produce CO, CO_2, and H_2O.

Sometimes the coke is too hard for chemical removal and must be drilled out. This decoking is required at intervals from several months to a year or more, depending on the composition of the crude oil and the temperature severity. The exit flow from the heater will normally contain liquid; care should be exercised to make sure that flow is in the mist-annular regime.

The crude column (Fig. 1)

The two-phase stream from the preheater flows into an enlarged feed zone, a vertical cylinder, which has the purpose of separating the liquid and vapor portions of the feed stream and providing well-distributed vapor flow to the trays above. The crude column will be constructed of carbon steel, but may require lining with high-chromium alloy, especially in the hot zones. The type of lining depends on the crude oil composition; naphthenic acidic or high-sulfur crudes are especially troublesome. The phase separation in the feed zone, usually called the flash zone, may be accomplished by gravity alone at low velocity or by centrifugal separation with tangential entry to the feed zone, or with curved internal vanes. If centrifugal flow is present, the swirl needs to be stopped by baffling in the flash zone so that an even vapor flow is presented to the wash trays just above.

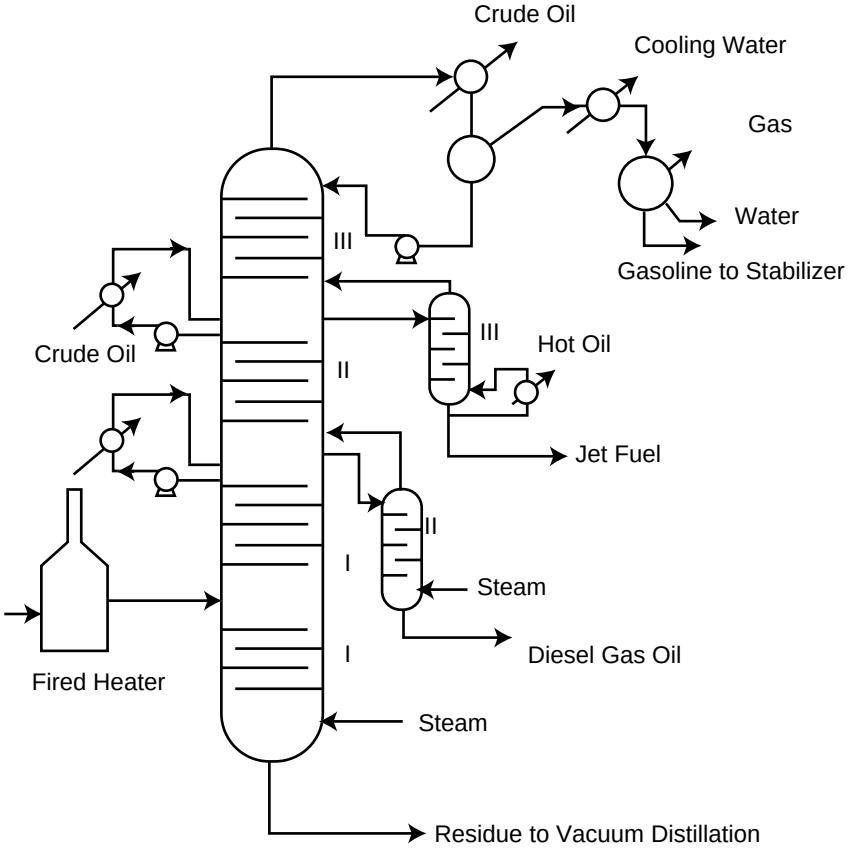

Fig. 4 A crude column as three two-product columns.

The side-product liquid streams shown in Figs. 1, 2 and 4 may be generated at each zone by liquid pumparounds, which also provide internal reflux for rectification. Of course, it would be possible to condense only at the top of the column, but the heat recovery would be greatly damaged because of the poor thermodynamic reversibility. Also, the hydraulic load in the upper column would be a problem.

The trays that carry the pumparound liquid are the heaviest loaded in the tower. Sometimes extra vertical spacing is provided at these trays, or high-capacity trays or packing may be used.

When heavy gasoline (e.g., 200°F to 400°F boiling range) is taken as a side-stream product, the upper trays may be in a water-condensing situation.

Sometimes internal water settling is provided; however, external settlers may be needed because the required settling time is often several minutes. The internal liquid water will be corrosive; tower and tray metallurgy must be corrosion-resistant when liquid water is present.

Side-product strippers (Fig. 1)

Each side-product liquid draw goes through a steam stripper, usually equipped with 5 or 10 trays, to prevent inclusion of more volatile hydrocarbons in the product. The side-product stripper may be reboiled for sharper separation. Optimum amounts of stripping steam will often be in the order of 2% or 3% w or more of each product rate. After stripping, the side products are cooled in the preheat train and cooled further in water or air coolers to safe storage temperatures. Heavy gas oil and residuum products often go to downstream cracking processes without cooling.

Upper crude column trays

As will be shown later, the trays in the main column are mostly rectifying sections for the side products; some of them are pumparound contact condensers. There is a wide variation in the industry of tray count between side draws, from 4 to 15, depending on the degree of rectification desired.

Two or three trays just above the flash zone are wash trays to prevent entrainment of dark color bodies into the heavy gas oil. The internal reflux flow on these trays should be limited to a few percent of the molal vapor rate, for good energy conservation and minimum residue handling. These trays are often equipped with anti-blowing baffles. The wash rate is sometimes controlled by using a total draw for the heaviest gas oil, then metering the wash oil rate.

Residue stripping trays

Five or ten trays at the bottom of the column are used for steam stripping the straight-run residue. Because this section is very hot, it is important to ensure that no liquid steam condensate ever enters this section during operation.

Top condensing sections

Overhead vapors may be cooled with cold crude oil, with cooling water or air coolers. When crude oil exchange is employed, extreme care is necessary to prevent leakage of crude oil into the hydrocarbon condensate. Filming or neutralizing amines or other chemicals may be added to the overhead vapor stream to prevent fouling and corrosion. If heat is recovered from the top condensing system, it is best to use two overhead liquid accumulators. The first would provide only warm top reflux for good heat economy.[2]

Another important factor is the size of the overhead product liquid accumulator. Ten minutes liquid residence time based on net product rate is common; however, aromatic gasoline fractions may require 5 to 8 min settling time for clarification because water vapor tends to condense in small droplets. The required accumulator size is also affected by the type of process equipment downstream.

Computer modeling

Computer modeling of the crude process is worthwhile for many reasons including: 1) initial design; 2) economic optimization of operation; and 3) control and adjustment of product compositions and operating costs. The first models were based on reducing the process to a combination of two-product distillation calculations because of the available computer power. More recently, the computer calculation is able to handle the crude tower as is; however, the two-product combinations are useful to guide technical supervision of the operation (Figs. 4 and 5).

The results of test runs or of computer modeling the separations in the crude tower system are represented as stream compositions in Fig. 6.

Each curve in Fig. 6 is analogous to a population distribution curve for the molecules in the crude feed and products. Each could also be represented as weight or volume distribution. The curves are constructed from the amounts of material with atmospheric boiling points in, for example, three-degree boiling range intervals in the precision distillation or gas chromatographic analyses.

It is apparent from the illustrations that the rectifying sections of each conceptual tower (I, II, or III) are

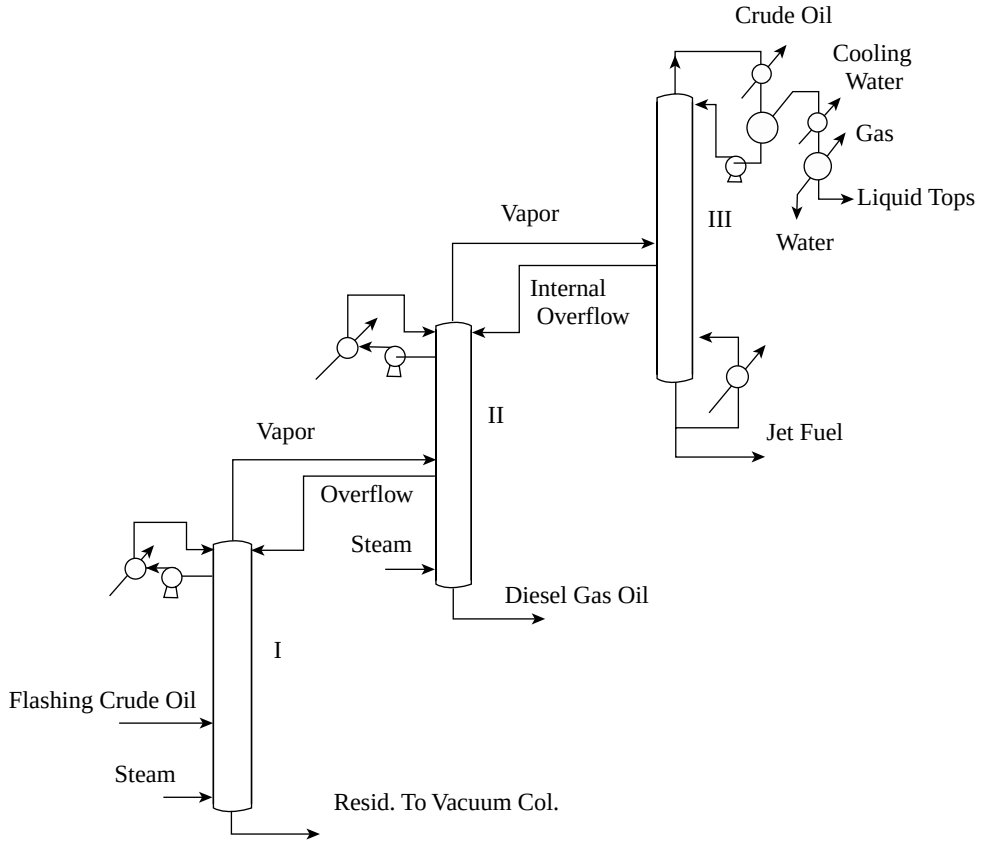

Fig. 5 A crude column as three two-product columns.

parts of the main column above the feed point. These sections are in rectification; i.e., each of them is the primary agent to tailor the back or high-boiling end of each side product leaving the system just above the rectifying trays in question. Similarly, it is apparent that the side-stripper trays have primary responsibility for the volatiles content of each product.

The modeling calculations are usually made with a commercial modeling calculation system, which includes calculation (from correlations) of physical properties and equilibrium stage separations. There are extensive empirical predictions of separations available[3–5] but many successful models are built on a direct use of semi-fundamental distillation calculations.

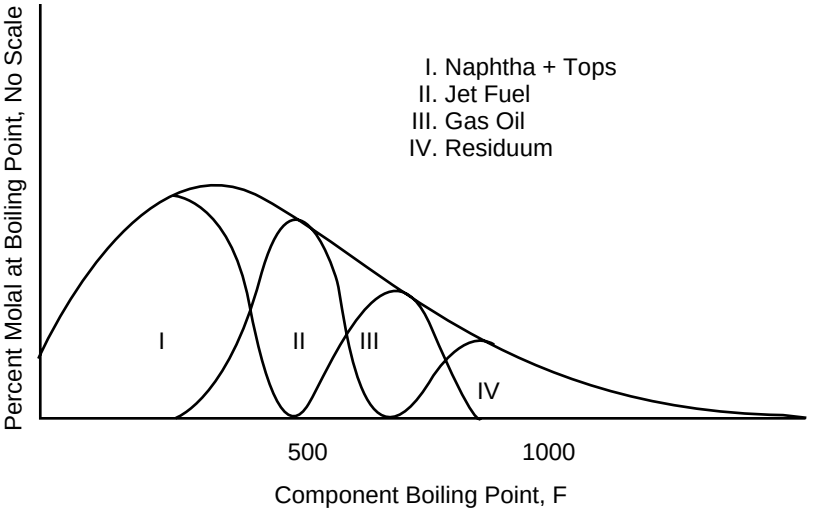

Fig. 6 Typical crude column cuts, molal distribution.

Regulation of crude tower operation

Three types of regulation may be identified as necessary for good operation:

Yield control is the primary control of product properties, accomplished by adjusting the product draw rates. These adjustments must be made in a fashion to maintain overall material balance, i.e., if operation is steady, at least two rates must be adjusted together to maintain steady state. The separation between side draws is sometimes defined as "cut point." This term has had several different definitions; a preferred definition is the atmospheric boiling point of the component equally divided between adjacent product draw streams.

Sharpness of separation can be adjusted by varying internal reflux to adjust removal of high-boiling components and stripping vapor rate to adjust removal of more volatile materials. Changing the side-product draw point has only a small effect on the boiling-point range of the side products. The major effect of tray count is on the degree of rectification of the side products.

As in material balance, heat balance must be maintained when internal reflux rates are being changed.

An example of the need for sharpness control might be the benefit of removing dicyclic hydrocarbons boiling at 400°F or above from the catalytic reforming feed, while maintaining naphtha yield. These dicyclics are known to foul platinum reforming catalysts with carbon.

Rectification of reformer feed can be improved by providing more internal reflux for the upper trays of the crude column, perhaps by using less pumparound heat removal above the jet fuel draw point.

Steadiness of operation is a complex subject. A steady operating pressure is important: when the column is making gas, back pressure control is the usual mode. Otherwise control of condensing rate is involved. Sometimes this is done by injecting non-condensible gas and controlling its removal rate. Smoothness of control requires defense against variation in vaporization rate; fuel composition may vary when refinery waste gas is being burned. Also, variation in condensing rate may require top tray temperature control.

A steady feed composition is important; sudden changes in crude type can be a challenge to operators.

Cracked Product Distillation

The distillation separation of products from cracking operations, whether catalytic or thermal, is similar in principle to the technology of main crude oil distillation columns. As the cracking reactors discharge a product at temperatures in the range of 700°F to 1200°F, no fired preheater is necessary. On the other hand, it is often necessary to add a desuperheating section to reduce the mostly vaporized feed mix to a temperature that will allow distillation without rapid coke formation.

Fig. 7 shows the feed zone of a typical catalytic cracking plant main fractionator. The reactor product is hot vapor; it is fed to the column through a large conduit, which may be several feet in diameter. The desuperheating is accomplished by direct contact in a zone equipped with simple baffle trays or large-size packing, against a recirculated liquid condensate stream, which is cooled by generating steam. There is a net make of heavy black slurry oil, which is drawn off, clarified by gravity or other settling, and sent to No. 6 fuel oil blending. It is necessary to maintain a substantial liquid rate on the desuperheating hardware to prevent carbon deposition.

Attempts to improve vapor distribution to the desuperheating packing or trays have usually been unsuccessful because of carbon laydown on the baffles.

The upper section of the cracking plant fractionator is very similar to the crude column arrangements previously discussed.

Sometimes when cracking throughput is expanded, it is expedient to add top condensing capacity to handle the additional condensing load. Unfortunately, heat recovery is thus wasted and column capacity may be challenged. Attention should be paid to expanding heat removal in the desuperheating and pumparound zones when cracking capacity is increased.

Since cracking processes make relatively more normally gaseous products than found in the usual crude distiller, there is usually a substantial gas compression section also. This gas compression section presents an opportunity to keep the column pressure low, perhaps only 5 or 10 psi gage, in turn allowing lower reactor and catalyst regenerator pressures, which in turn improve cracking yields and reduce regeneration air supply horsepower.

The compression often comprises two or more stages of centrifugal machines with interstage cooling and liquid separation. Discharge to the gas absorption plant will often be at pressures near 200 psi. The liquid interstage condensate may be added to the de-ethanizing absorber to reduce the need for recirculated absorption medium. Cracking plant overhead liquid accumulators are larger than in crude oil distillation, because the more aromatic cracked naphthas require more clarifying time to get rid of the entrained water.

The main column zone just above the slurry return has the primary duty of preventing catalyst particles from being entrained into the gas oil product via entrainment of slurry. Usually only two or three fractionating trays with a small liquid flow will be required below the heaviest gas oil draw tray.

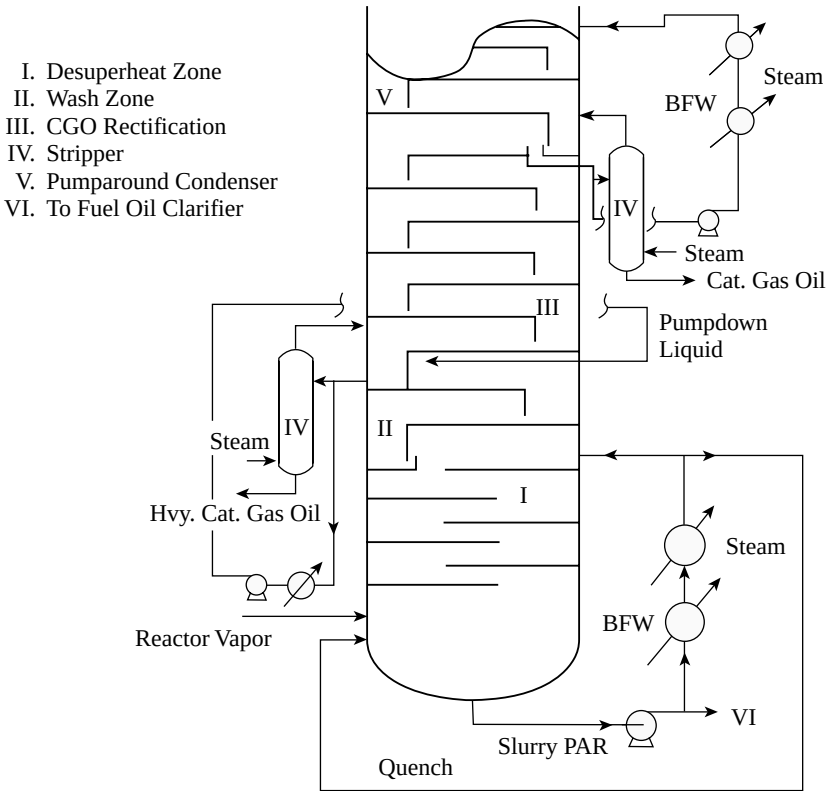

Fig. 7 Lower section of catalytic cracking main fractionator.

Operation of the desuperheating zone is particularly important. If the vapor leaving the zone is too hot, there will be carbon fouling of the fractionation trays. This temperature probably should not be above 700°F. The recirculated cooled slurry oil should not be too cool, however, because if it is as cool as 400°F, for example, the black oil will absorb some volatiles from the reactor product, leading to low flash points for the No. 6 fuel oil.

It is important to get adequate heat transfer in the zone; however, if the contact has too many theoretical stages, the liquid will leave the column too hot and may deposit solids in the downstream heat exchangers. One theoretical stage of contact for the entire zone is a feasible condition in most cases.

Many refiners use a direct injection of cooled slurry oil into the bottom of the column to prevent fouling the exit piping. However, if too much of the temperature moderation comes from this ''quench,'' the desuperheating trays or packing may be deprived of cooling and become plugged with coke. If possible, the temperature of the liquid leaving the bottom of the desuperheating zone should be measured directly. The exact limiting temperatures around the desuperheating zone will vary with different cracking conditions and feedstocks; however, it is well known that condensation reactions for heavy hydrocarbons accelerate above 700°F and usually cannot be tolerated at 800°F.

Coking process fractionators

In principle, contact coking process fractionators are similar to catalytic cracking process fractionators. However, sometimes the fractionator desuperheating zone is also used for preheating coke-drum feedstock. Contact coking fractionators are difficult to control because of the cyclic nature of the process. Also, thermally cracked heavy oil liquids are susceptible to further molecular condensation.

VACUUM DISTILLATION OF HIGH-BOILING OILS

Fuels-type Distillation

Fig. 8 is a schematic representation of a vacuum column, sometimes called a ''flasher,'' intended to produce asphaltene-free cracking feed and heavy black fuel oil. The fired preheat furnace is similar to the crude unit heater, except that tolerable tube skin temperatures are somewhat lower because of the absence of light hydrocarbons.

For lowest capital cost, the preheat furnace is usually a ''dry'' operation. Sometimes, however, two or three percent weight of superheated steam is added to the feed to give a higher internal velocity, thus reducing the rate of carbon laydown inside the tubes. This steam is termed ''velocity steam'' to differentiate

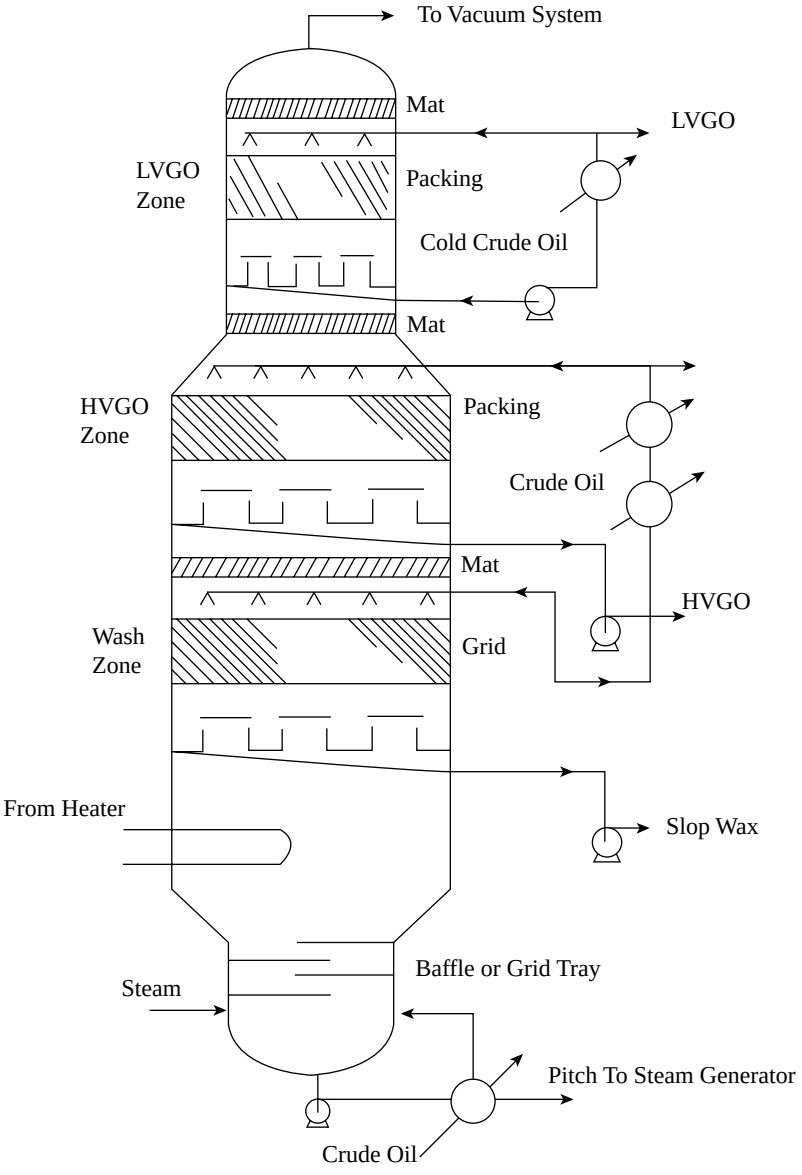

Fig. 8 Fuels-type vacuum column.

it from "dilution steam," which is sometimes introduced to reduce oil partial pressure.

The feed zone is intended to provide a primary separation of liquid residue droplets and vaporized gas oils. Some units utilize centrifugal action to throw the liquid against internal vanes or the vessel wall itself; other units rely on gravitational separation alone, usually at lower velocities than for the centrifugal units. It has been shown that at high velocities, approaching the velocity of sound in the two-phase mix, the liquid film on the surface of the feed piping assumes a wavy shape and that the vapor stream will strip off small droplets that are difficult to de-entrain. If velocities are kept far below the speed of sound, sometimes in the order of 400 ft/sec in this case, equipment sizes become very large.

If the feed zone is intended to be a centrifuge, the swirl should not impinge on the catch tray, because the Bernoulli effect at high vapor velocity can reverse flow through a chimney, thus causing maldistribution in the de-entrainment zone.

The de-entrainment zone is often composed of relatively open grid packing. It is intended more to catch tarry residue than to perform normal rectification. However, the temperatures are so high in this zone, often well over 700°F, that it is necessary to irrigate to prevent accumulation of coke. It is shown by the calculational models that much of the heavy vacuum gas oil usually used for irrigation will re-evaporate in the grid packing, so that the irrigation rate at the bottom part of the packing will be much less than the rate at the top. A minimum irrigation of around 0.3 gpm

per square foot of cross section at the bottom of the packing is sometimes recommended. However, the slop wax draw rate will often be much larger, because the liquid drawn includes the de-entrained vacuum residue, sometimes called ''pitch.'' The slop wax can be analyzed by high-temperature gas chromatography to establish what the real grid wash rate is. If insufficient wash is provided, the grid will eventually plug with coke.

Pumparound condensing zones

Frequently vacuum gas oils are condensed in packed sections. If several zones are used, there will be opportunity for better heat efficiency. Structured packing, sheet-metal type, has largely displaced trays for contact in vacuum pumparound zones because packing requires less pressure drop. Thus, flash zone pressures can be lower and less vacuum pitch can be produced. Flash zone pressures as low as 25 Torr (millimeters of mercury absolute) have become routine. For heat efficiency, a corrosion-resistant de-entrainment mesh pad is often installed above each pumparound packed zone.

The liquid reflux distributors above each packed zone are often arrays of solid-cone sprays; preferably the nozzles should be $\frac{1}{4}$ inch or larger in orifice, free passage, and pipe sizes. The spray liquid needs to be screened at all times. The sprays are not as good distributors as the drip-pan type, but they are economical and contribute to heat transfer without adding substantial pressure drop. The nozzles should be designed to operate at a flow rate that gives a good spray pattern without excessively small droplet sizes.

The vacuum at the top of the flash column is often produced by a sequence of three elevated steam-jet eductors with intermediate and final surface condensers to remove the steam. A liquid-ring compressor can be substituted for one or more eductors to conserve steam. Mechanical vacuum pumps are seldom used because of the corrosive nature of the off-gas. The noncondensible sour compressed gas and condensate are led away through a water seal for safety in case of steam system failure. The seal pot is equipped to skim off condensed oil continuously.

Lubricating Oil Vacuum Columns

These columns in principle are like crude columns, taking various lubricating oil stocks as side draws and using pumparound and water or air top condensing systems. The more recent installations use packing for internal condensing and rectification, for low pressure drop, and use in the order of 50 to 100 Torr as top column pressures. Vacuum systems are similar to those for fuels-type vacuum columns. Another feature is the reduced heat flux in the preheat furnace tubes, intended to reduce thermal degradation of products. Of course, cracking and color degradation can be corrected by hydrotreating. The distillates may be further treated by clay or acid treating, or by solvent extraction or hydrotreating to remove aromatic or asphaltic hydrocarbons. Normally the asphaltenes are found only in the vacuum bottom product. Wax is also removed by solvent crystallization and filtration, or by catalytic processes.

Usually, steam is added to the preheat system, either as velocity steam or after the preheater as dilution steam to get deeper volatilization. Each product is steam stripped as in crude oil distillation. In the case of naphthenic crude oils, the bottom product may be directed to asphalt specialties rather than being treated to make lubricating oil base stock.

RECOVERY AND PURIFICATION OF NORMALLY GASEOUS HYDROCARBONS

In the larger refineries, olefinic gas streams are recovered separately from paraffinic gases. The saturated gas plant collects its feed from crude oil distillation and from hydrogenation processes. The products might be hydrogen and methane, often fed to a hydrogen production reactor, ethane for ethylene plant feed, propane and butane for sale as fuel, and isobutane for alkylation plant feed to make high-octane gasoline.

The cracked gas plant, on the other hand, would likely produce a C_4 olefinic mixture for alkylation or chemical manufacture, a propylene product for the same purposes, a propane cut for fuel, and a C_2 fraction which is fed to chemical manufacture, or combined with hydrogen and methane used for hydrogen manufacture.

In a few modern plants, these separations are made by direct distillation, using refrigerated columns and condensers as used in ethylene plants. Most refiners, however, avoid deep refrigeration by absorbing the C_3^+ gases in naphtha or kerosene, using an arrangement such as that shown in Fig. 9. This arrangement is often seen in refineries designed by UOP. Operating pressures are fairly high, such as 200 psi, to assist absorption. The lean oil is sometimes refrigerated, but below about 50°F, hydrate plugging may occur.

The absorber and stripper shown in Fig. 9 can be combined into a single reboiled absorption column; however water condensed internally will cause bottom column corrosion and plugging, whereas in the scheme of Fig. 9, the water is removed at the feed drum. Tray efficiencies in absorption columns are much lower than in distillation columns because of the presence of noncondensible gases. Furthermore, there is a tendency to

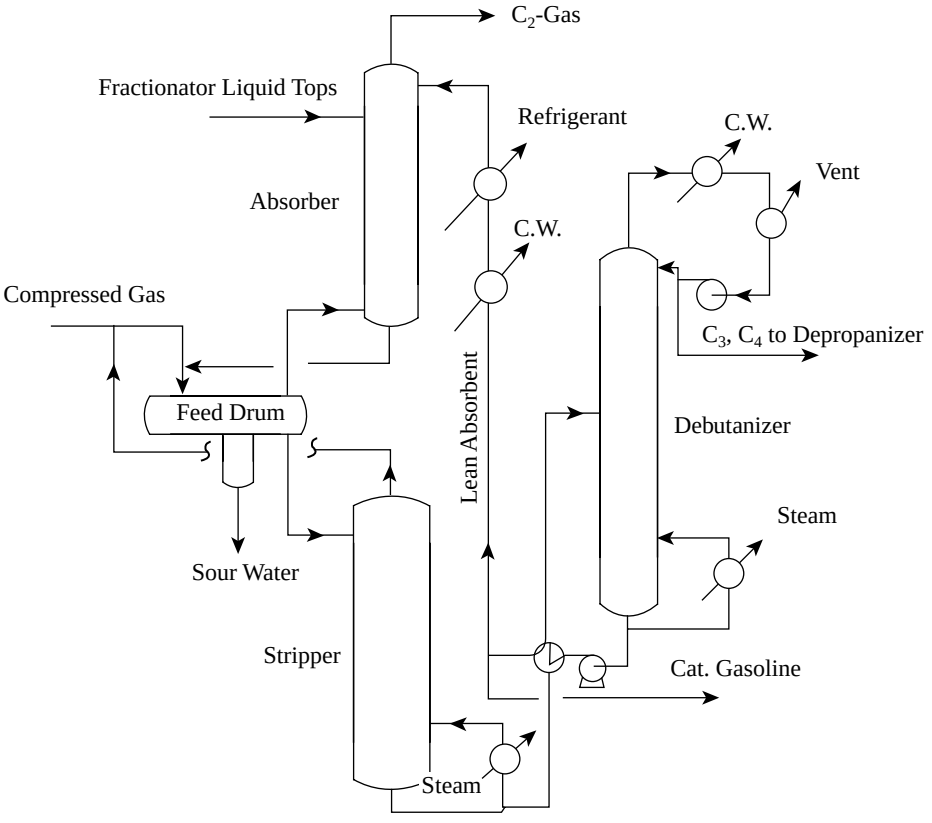

Fig. 9 Absorption-type de-ethanizing gas plant.

foaming in the upper part of the stripping section and in the absorber. System capacity factors as low as 0.6 or less should be expected.

In older refineries, high-pressure de-ethanizing distillation towers were often used, especially for straight-run crude oil distillation or thermal cracking plants.

Even at 500 psi plus, the critical properties of the ethane–ethylene and lighter top product made it difficult to maintain reflux without refrigeration. The advent of catalytic cracking and hydrocracking processes added large amounts of light gases, which made the absorption system of Fig. 9 more attractive.

HYDROPROCESS PRODUCT DISTILLATION

Most hydrotreating processes are equipped with reboiled product strippers to remove hydrogen and light ends produced in the reactions. These strippers are of normal design; however a few details may be noted. Because of the high bottom column temperatures required, fired-heater reboilers may be useful because they may allow vaporization with minimum exposure of bottom product to thermal degradation.

In the presence of hydrogen under pressure, the basic data systems such as SRK[6] and Peng-Robinson[7] fail to account properly for the presence of dissolved hydrogen in the liquid. Empirical systems based on Grayson–Streed[8] are often used for simulation.

Stripping columns may be equipped with a few rectifying trays and a small reflux flow to prevent loss of liquid product to the bulk hydrogen top gas. If the hydrotreater is upstream from a platinum-catalyst reforming unit, it may be advisable to reboil the stripper carefully to get a bone-dry feed to the catalytic reformer. In order to get good stripping and drying performance from the stripper, it may be advisable to preheat the stripper feed. In fact, preflashing the stripper feed is a method of increasing stripper capacity. Such flashing makes the rectifying trays particularly important.

SPECIAL SEPARATIONS

Solvents. Special boiling-range solvents are sometimes distilled from straight-run or other naphthas in the petroleum refinery. It may be tempting to prepare such solvents as part of the crude oil distillation process, but the small amounts usually required would be a costly nuisance to the very large crude oil distilling equipment. Hence smaller multi-plate columns are usually used. The design and modeling of these

columns is done using precision analytical distillation or gas chromatographic curves, splitting the curve into narrow boiling-point fractions similarly to the modeling of crude oil or cracked-product distillation.

Such solvents might be paint thinners, called Varnish Makers and Painters (V.M.&P.) naphthas or mineral spirits. There are many other specialty solvent fractions manufactured in petroleum refineries. The product specifications for these solvents as well as for many refinery products are often given in terms of the simple ASTM distillation boiling ranges. However, for best results in modeling, precision distillation analysis is used, with end-product correlation to compare with specifications. Such an approach is often used also for fuel fractions, even to the extent of controlling the operation with gas chromatographic precision distillation analysis.

Reforming and Isomerization Feedstocks. Some saturated fractions contain substantial amounts of low octane-number normal pentane or normal hexane. These chemical species can be isomerized for anti-knock performance enhancement. It is, however, useful to remove branched compounds from the feedstock by sharp distillation. A de-isohexanizer, for example, may need 60 or more actual valve plates and a high reflux ratio. The modeling of equipment for this purpose follows standard distillation design procedures, but because of the narrow relative volatilities, special care is needed with the basic data.

Alkylation-plant Feeds and Products. Separation between isobutane and normal butane for alkylation feed requires large plate counts, perhaps 60 or more, and high reflux ratios. Sometimes the butane splitter column is combined with the product stabilizer in a single large multi-product column.

Purification of Individual Molecular Species. The chemical process industries use large amounts of hydrocarbons, which can be individually recovered and purified from petroleum refinery fractions. Examples would include ethane, propene, butadiene, isoprene, benzene, toluene, and xylenes. Sometimes distillation must be supplemented with liquid–liquid extraction, as well as extractive and azeotropic distillation, to purify these materials. The technology of recovering individual chemical species will be dealt with in other parts of this encyclopedia.

BASIC DATA

The basic data used in modeling petroleum refinery distillations are usually obtained from proprietary systems of which many are marketed. For straight-run and paraffinic systems, Peng-Robinson[8] and Soave–Redlich–Kwong[7] systems are used to modify vapor–pressure and ideal system behavior. For the more aromatic cracked products, Chao–Seader[9] is often used. For species separations, a wealth of binary data and methods is available.

SAFETY

Injuries and damage are particularly to be guarded against. These occur in many ways; some of them are as follows:

1. When liquid water is mixed with hot oil, the resulting rapid evaporation may lead to violent vapor pressure surges. Such incidents with resulting equipment damage occur most frequently during shut-down or start-up procedures. The steam used for product stripping or for purging equipment may be the source of aqueous condensate, which may settle in unexpected places to cause trouble sooner or later. Extreme care is taken by refiners to avoid these incidents.
2. Combustible vapors allowed to mix with air may ignite violently. Prevention of these incidents is mostly obvious; however, undetected corrosion has sometimes led to vapor release with violent gas explosions. Vacuum distillation equipment must be protected against air intrusion, for example in case of steam supply failure.
3. Nitrogen or other inert gas, used for blanketing or purging, must be positively removed and equipment vented with air before personnel are allowed to enter equipment.
4. Warm vapors sometimes condense inside closed vessels; the resulting may collapse the vessel. Such incidents have occurred when a vessel was purged with steam, then closed in without venting. Similarly, a distillation column may go to vacuum if reboil fails but condensing continues.

CONCLUSIONS

Petroleum refinery distillation is like most chemical-plant distillation practice except for two differences: Firstly, the number of chemical species present is huge. Computer modeling of refinery distillation is often done by grouping components by boiling point to reduce the complexity of the calculation.

Secondly, the high-boiling hydrocarbons present in crude oil would make conventional reboilers subject to plugging with products from thermal degradation. To avoid this fouling, the feeds to distillation are often

partially prevaporized in fired heaters or other reactors at short residence time, followed by multi-product rectification towers.

Of course, the equipment sizes in refineries are very large.

The separation of C_1up to C_5 species is often done in complex absorption systems rather than by deep refrigeration.

Phase Behavior of Hydrocarbon Mixtures

X.-Y. Zou
Oilphase-DBR, Schlumberger, Edmonton, Alberta, Canada

J. M. Shaw
Department of Chemical and Materials Engineering, University of Alberta, Edmonton, Alberta, Canada

INTRODUCTION

This contribution provides an introduction to the key building blocks, terminologies, and presentation methods used for describing, modeling, and discussing the phase behavior of hydrocarbon mixtures. The mechanics related to interpreting and constructing phase diagrams and phase behavior projections are reviewed. Solidification of components and the impact of systematic variations in the constituents present on observed phase behaviors are addressed explicitly. Solidification adds to the complexity of phase diagrams as it can also interfere with critical phenomena and suppress multiphase behavior that would otherwise be present. A more detailed discussion of phase diagrams for single component and binary systems can be found elsewhere.[1] While simple hydrocarbon mixtures are the focus of this contribution, the concepts illustrated provide insights for understanding the phase behavior of industrial fluids such as waxy and asphaltene rich hydrocarbon mixtures that pose a host of challenges for the petroleum industry.

OBSERVED PHASE BEHAVIORS

In addition to vapor (V), high-density liquid (L_2), or low-density liquid (L_1) phase behavior, reservoir fluids, oils, and other organic fluids exhibit a variety of multiphase behaviors and critical phenomena as noted in Fig. 1. These include liquid–vapor (L_1V or L_2V), liquid–liquid (L_1L_2), and liquid–liquid–vapor (L_1L_2V) phase behavior and associated critical phenomena. The designations $L = V$ or $L_1 = L_2$ mean that the two phases in question are critically identical. They possess the same values for density, composition, molar volume, viscosity, and all other physical properties, and the boundary between the phases disappears (Fig. 1). Two phases can also become critically identical in the presence of a third phase, giving rise to the so-called K and L points. A K point arises when a low-density liquid (L_1) becomes critically identical to a vapor in the presence of a high-density liquid (L_2). This is designated as $L_1 = V + L_2$. An L point arises when a low-density liquid (L_1) and a high-density liquid (L_2) become critically identical in the presence of a vapor phase. An L point is designated as $L_1 = L_2 + V$. Tricritical points, where three phases in equilibrium are also critically identical, are designated as $L_1 = L_2 = V$. Such critical points, while present in phase diagrams and phase projections, are rarely observed in practice. At low temperatures, solid phases such as asphaltenes and wax can, and frequently do, coexist with the fluid phases noted here and are discussed in later sections.

THE PHASE RULE

The maximum possible number of phases present at equilibrium for a given number of components is governed by the phase rule. This rule, first derived in its simplest form by Gibbs over a century ago, has been augmented over time to allow for magnetic and other field effects that increase the number of degrees of freedom (where relevant) and critical phenomena that reduce the number of degrees of freedom. In petroleum science and engineering, constraints imposed by critical phenomena are important and the relevant phase rule has become:

$$F = N - \pi + 2 \quad \text{for } k = 0 \tag{1a}$$

$$F = N - \pi + 2 - (k - 1) \quad \text{for } k = 2, 3, \ldots \tag{1b}$$

where F is the number of degrees of freedom, N is the number of components, π is the number of phases, and k is the number of phases that are critically identical. Thus, for a binary system, two noncritical phases may coexist over a range of compositions and pressures at fixed temperature, or over a range of temperatures and compositions at fixed pressure. In contrast, a binary system may exhibit two critical phases at specific compositions along a curve in pressure–temperature space as there is only one degree of freedom, i.e., once

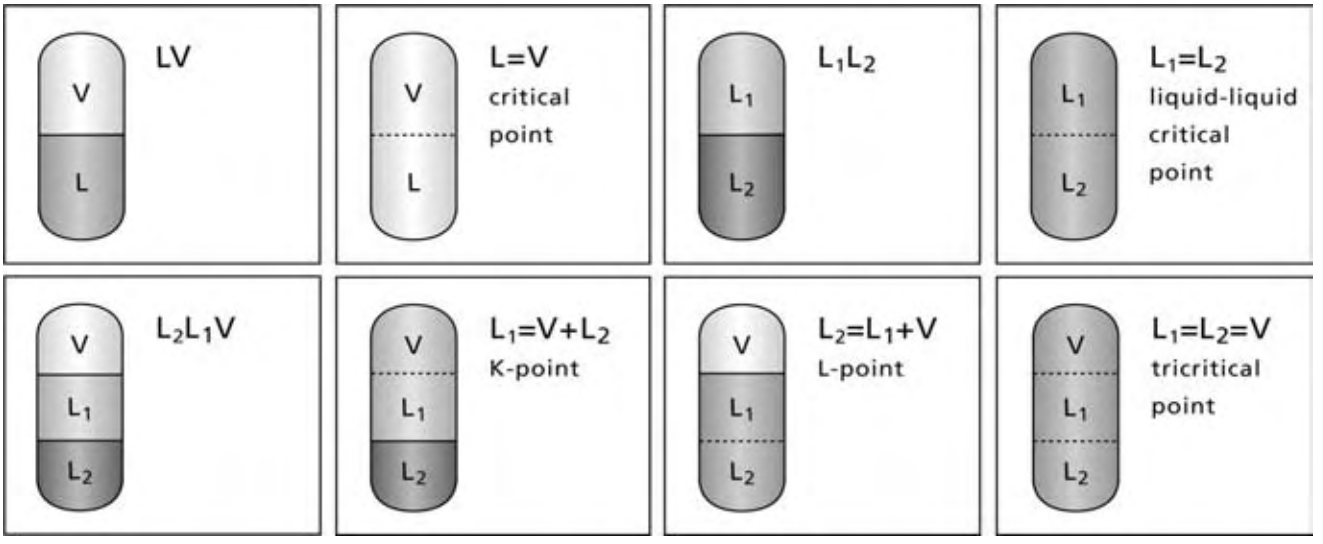

Fig. 1 Multiphase, fluid-only behaviors exhibited by hydrocarbon mixtures. Dashed phase boundaries indicate critically identical phases.

the composition is fixed the critical pressure and temperature are fixed as well. This curve is called a critical locus. Finally, binary mixtures may exhibit up to four noncritical phases in equilibrium, or up to three phases in equilibrium, when two of the phases are critically identical. Given the number and the diversity of components present in hydrocarbon mixtures, multiphase behavior is to be expected. For example, even the mixture methane + hexane exhibits L_1L_2V phase behavior.[2]

PROJECTIONS AND PHASE DIAGRAMS

Sets of observed phase behaviors are often presented as phase diagrams where pressure and composition are varied at fixed temperature (P–x diagrams), or temperature and composition are varied at fixed pressure (T–x diagrams), or pressure and temperature are varied at fixed composition (P–T diagrams). In order to present the phase behavior of binary mixtures, large numbers of these diagrams are required. Projections that capture key features of the phase behavior of a binary mixture, such as the vapor pressure curves of the pure components, critical phenomena, and multiphase behavior complement the more detailed diagrams regardless of composition, as one can sketch P–x and T–x phase diagrams from P–T projections. Two illustrative pressure–temperature projections, where the composition axis is collapsed into the pressure–temperature plane, are shown in Figs. 2 and 3 along with example P–x and T–x phase diagram constructions. The projection shown in Fig. 2, known as a Type I projection according to van Konynenburg and Scott[3] who proposed the first naming scheme for projections, is the simplest of the six possible binary projections. Mixtures such as methane + ethane or other pairs of similar compounds exhibit Type I phase behavior. The Type IV projection, shown in Fig. 3, captures key aspects of the complex phase behaviors exhibited by mixtures where substantial differences in molecular size, polarity, etc. result in only partial miscibility of the components—Type II through Type VI. For example, the carbon dioxide + tridecane binary exhibits Type IV phase behavior.[4]

HOW TO READ A P–T PHASE BEHAVIOR PROJECTION

In P–T projections, the composition axis is collapsed into the pressure–temperature plane. The vapor pressure curve for component A is labeled LV(A) and that for component B is labeled LV(B). These curves terminate at the component critical points (L = V) designated as hollow circles. In Fig. 2, dew pressure and bubble pressure curves for an intermediate composition "x" intersect at a point on the (L = V) critical locus where the liquid and vapor phases become critically identical. Normally, dew and bubble pressure curves are not shown in projections. They are shown here so that the construction of the related P–x at fixed T, and T–x at fixed P, phase diagrams is clearly illustrated. Each critical point on the critical locus corresponds to a fixed composition. Points close to the critical point of component A are critical points for mixtures with high concentrations of A, whereas points closer to the critical point of

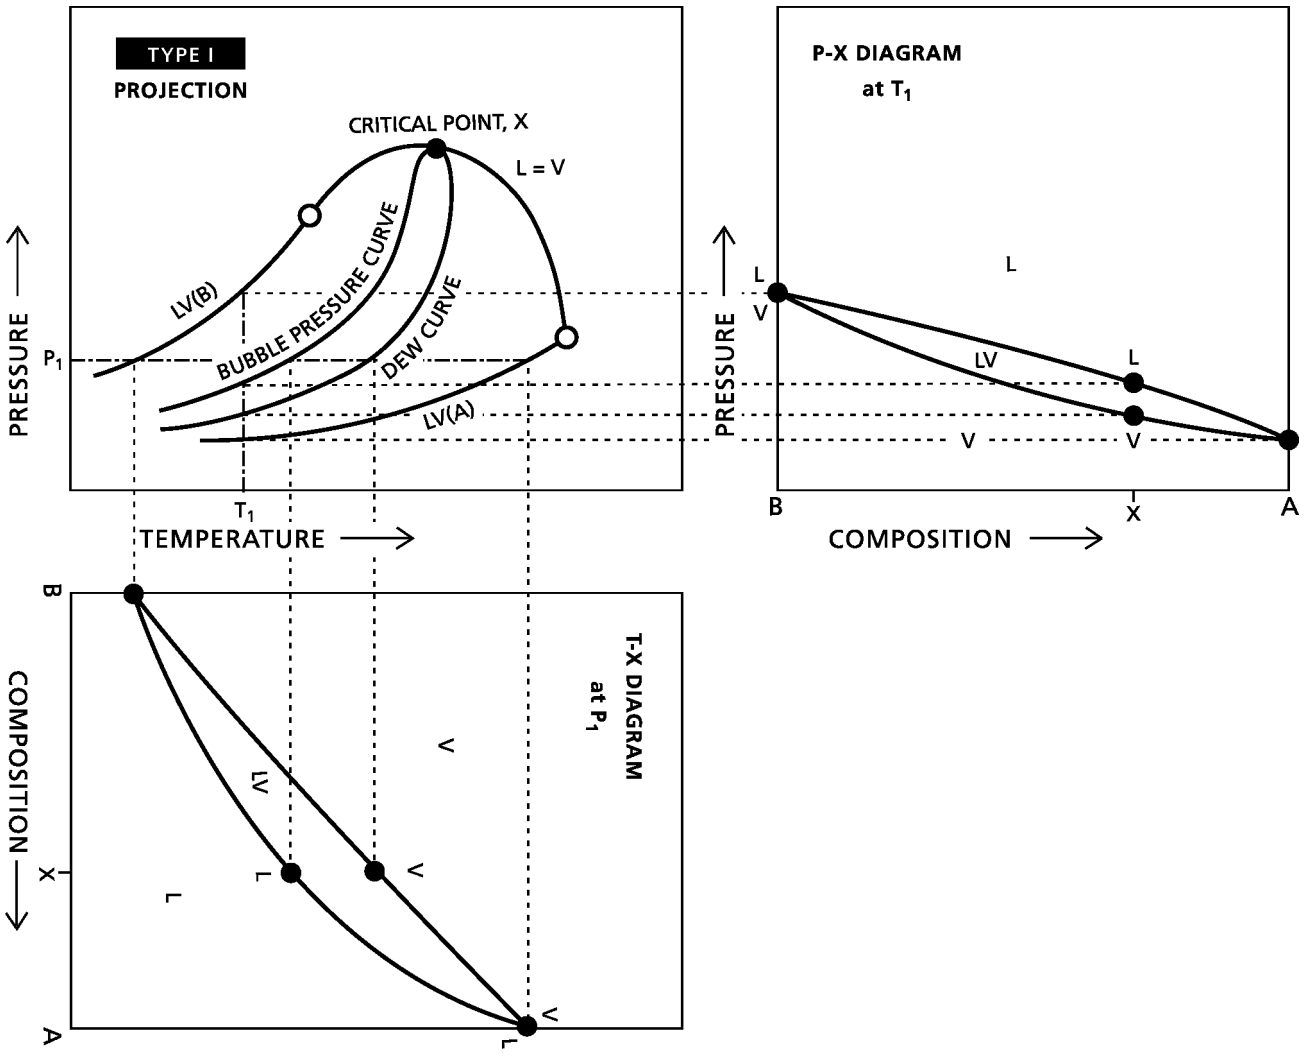

Fig. 2 Pressure–temperature phase projection and examples of pressure–composition and temperature–composition phase diagrams for a Type I binary mixture.

component B correspond to critical points for mixtures with high concentrations of B. Normally, the critical pressures for intermediate compositions are high relative to the component critical pressures.

CONSTRUCTION OF PHASE DIAGRAMS FROM PROJECTIONS AND EXPERIMENTAL OBSERVATIONS

With reference to the pressure–temperature projection in Fig. 2, we see that in order to construct a P–x diagram at T_1, a line parallel to the pressure axis passing from low pressure to high pressure is drawn and the points of intersection with features in the projection are noted. For the P–x at T_1 example, the construction line intersects the vapor pressure curve for pure A, the dew and bubble pressure curves for the mixture with composition x, and the vapor pressure curve for pure B. Each of these points is transcribed onto the P–x diagram and labeled accordingly. One then connects the dots! The points labeled V are connected one to the other sequentially in composition, as are the ones labeled L. As expected, all mixtures of A and B are a single-phase liquid, at high pressure, and a single-phase vapor at low pressure. A lens of liquid–vapor phase behavior arises at intermediate pressure. The boundary between the L and the LV regions is typically referred to as the bubble pressure curve, and the boundary between the LV and the V region is referred to as the dew pressure curve. A T–x at P_1 diagram is constructed in an analogous manner except that the line of construction is drawn parallel to the temperature axis.

In the Type IV pressure temperature projection illustrated in Fig. 3, the binary mixture exhibits partial miscibility at low temperature and near the critical

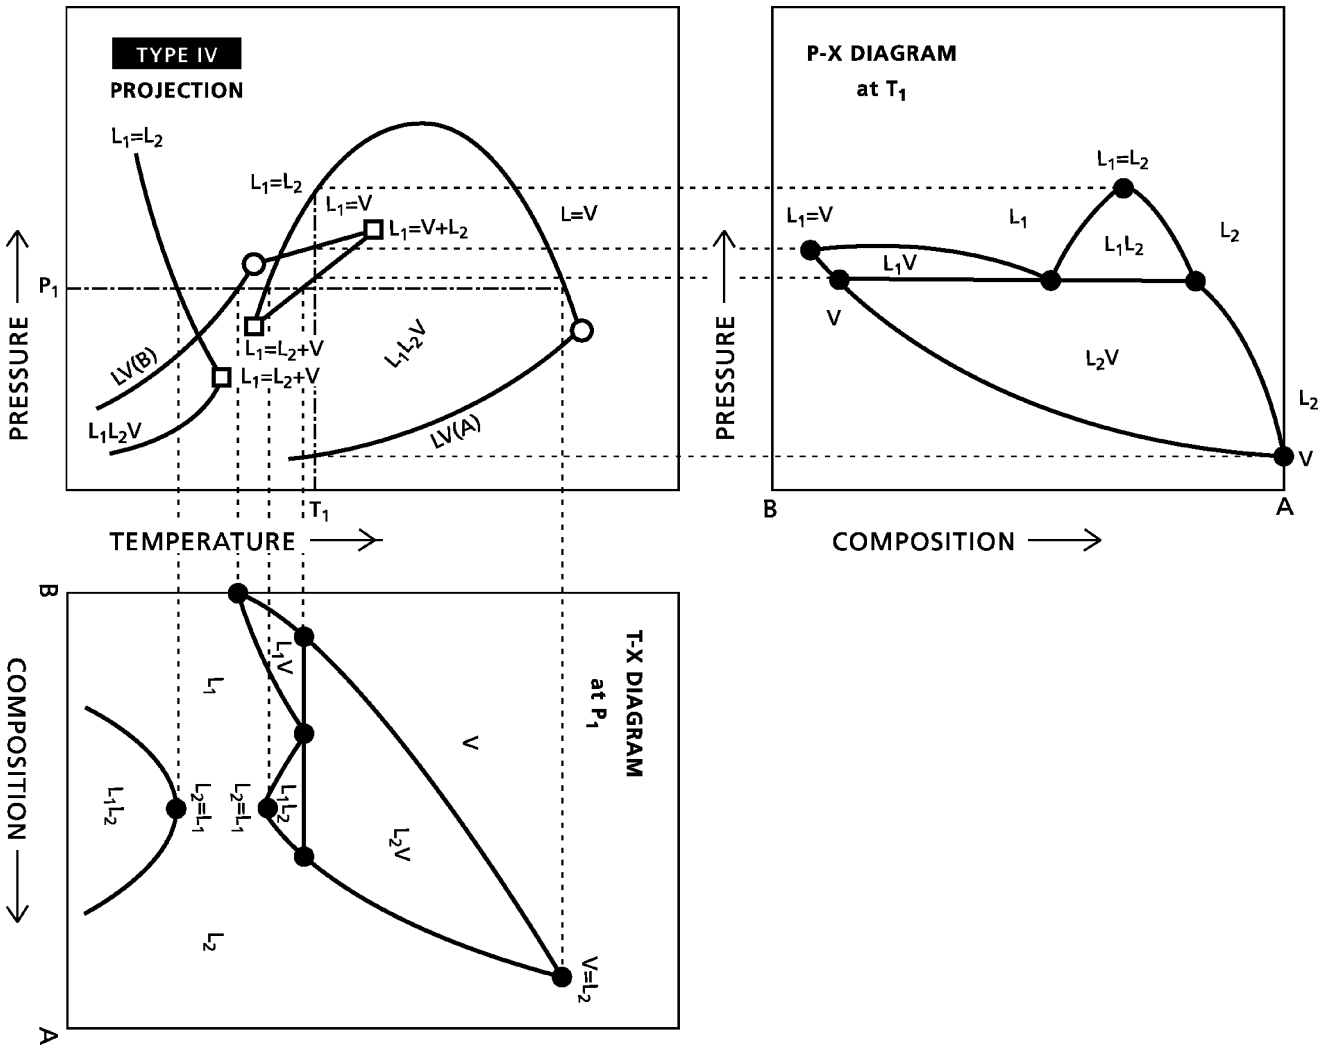

Fig. 3 Pressure–temperature phase projection and examples of pressure–composition and temperature–composition phase diagrams for a Type IV binary mixture.

region of component B. L_1L_2 and L_1L_2V phase behavior are observed in both regions in addition to the simpler V, L_2V, L_2, L_1, L_1V phase behaviors. The approach to P–x and T–x phase diagram construction is the same as for the Type I phase behavior case above. Let us construct the T–x diagram at P_1. The first curve encountered by the construction lines is an $L_1 = L_2$ critical locus. At temperatures below the point of intersection, the components A and B are not miscible. At higher temperatures they are mutually soluble. The vapor pressure curve for component B is encountered next followed by a second L_1L_2 critical locus that marks the beginning of the high temperature partial miscibility zone at P_1. The three-phase L_1L_2V line is then encountered. This is shown on the T–x diagram by the three dots for the compositions of V, L_1, and L_2 where the vapor comprises mostly B, the more volatile component, L_2 comprises mostly A, the least volatile component, and L_1 possesses an intermediate composition. The three dots are connected by a line to show that the three phases are in equilibrium, and to facilitate the construction of the phase diagram, as two and one phase behaviors surround the three-phase behavior. Finally, the $L = V$ locus is encountered at a temperature and a pressure close to the critical point of pure A. Again, the dots are connected sequentially in composition for the various phases and the T–x phase diagram emerges. Had other temperatures or pressures been chosen for the construction of the P–x and T–x phase diagrams, the phase behaviors encountered by varying temperature at fixed pressure or varying pressure at fixed temperature would have differed, as would the resulting phase diagrams, even though the underlying P–T projections are invariant.

Projections place phase diagrams or phase behavior observations in context and provide a clear basis for

the construction and verification of computational phase behavior models. For example, the set of observations obtained by heating a mixture comprising half A and half B at fixed pressure (P_1) in Fig. 3:

$$L_1L_2 \rightarrow L_2 \rightarrow L_1L_2 \rightarrow L_1L_2V \rightarrow L_2V \rightarrow V$$

is consistent with Type IV phase behavior and one would seek out critical phenomena [$L_1 = L_2$, $L_1 = V$, $L_2 = V$, $L_1 = L_2 + V$ (two points), $L_1 = V + L_2$], either computationally or experimentally, in order to define the phase behavior of the mixture. Other observation sets such as $L \rightarrow LV \rightarrow V$, obtained by heating an alternative composition (close to either pure "A" or pure "B") at the same fixed pressure (P_1), provide no cues for identifying the phase behavior of the mixture as a whole because they arise in all phase behavior types over ranges of compositions.

THE IMPACT OF SOLIDIFICATION ON OBSERVED PHASE BEHAVIORS (BINARY MIXTURES)

Generally, solid phases appear at temperatures below the melting temperature of one or both of the components. Solidification has a dramatic impact on the appearance of phase projections and diagrams.[4,10–12] For example, Figs. 4A and 4B illustrate the impact of solidification on the appearance of a Type I binary projection, i.e., the simplest binary case. In Fig. 4A, solid–liquid–vapor curves (S_ALV, S_BLV) emerge from the triple points of components A and B, respectively, and converge at a four-phase eutectic point where S_AS_BLV phase behavior arises. If the triple point of component A occurs at a temperature well above the critical temperature of component B, the S_ALV curve intersects the $L = V$ critical locus and the projection shown in Fig. 4B results. While the projections share a eutectic at low temperature, they are quite different at high temperature. For a Type IV binary, four projections, illustrated in Fig. 5A–D, arise depending on the respective values of the triple point temperatures and pressures of the components. In addition to four-phase eutectics (S_AS_BLV), four-phase ($S_AL_1L_2V$) points, referred to as Q points, also arise. L_1L_2V phase behavior, a characteristic of Type IV phase behavior, can be suppressed in whole or in part by solidification if the triple point temperature of component A is sufficiently high, a case that is treated elsewhere in detail.[11] The resulting projection, Fig. 5D, is identical to one of the possible projections for a Type I binary–Fig. 4B. Projections shown in Figs. 5C and 5D also correspond to those expected for a Type III binary, where in the absence of solidification L_1L_2V, phase behavior extends from the critical region of component B to low temperatures. It is frequently necessary to compare phase behavior observations for a homologous series of solvents (B_i) with fixed solute (A), or a homologous series of solutes (A_i) with fixed solute (B), in order to place observations in context.

THE IMPACT OF ASYMMETRY ON OBSERVED PHASE BEHAVIOR (BINARY MIXTURES)

The phase behavior exhibited by a mixture is related to the degree of asymmetry of the components, which is a measure of differences in size, structure, and polarity among components–the greater the differences, the greater the degree of asymmetry.[4,10,13] Raeissi et al.[13] highlight the role of asymmetry on the nature of the phase behavior exhibited by binary and pseudobinary mixtures of light gases (e.g., carbon dioxide, methane, propane) + members of various homologous series (alkyl-benzenes, *n*-alkanes, *n*-alcohols). Light gases tend to be miscible with the smallest members of homologous series (Type I). One observed sequence is that as the degree of asymmetry increases, the mixtures become only partially miscible at low temperatures where L_1L_2V curves appear in the pressure–temperature projections, but the mixtures remain miscible at elevated temperatures (Type II). As the degree of asymmetry is increased further, a second miscibility gap appears in the near critical region of the lighter component and one finds L_1L_2V phase behavior at both low and high temperatures. At intermediate temperatures, the mixtures remain miscible. This is referred to as Type IV phase behavior. If the degree of asymmetry is increased still further, the miscibility gaps at high and low temperature merge resulting in a single L_1L_2V curve stretching from low to high temperatures (Type III). For the carbon dioxide + *n*-alkanes series, the P–T projection for octane (C_8H_{16}) through dodecane ($C_{12}H_{26}$) is Type II, with tridecane ($C_{13}H_{28}$) Type IV (Fig. 5C), with tetradecane ($C_{14}H_{30}$) Type III (as in Fig. 5D). Other sequences of phase behavior transitions are observed for the other cases cited.

PHASE BEHAVIOR TRANSITIONS

Measurement and prediction of transitions from one type of phase behavior to another are key to our understanding of the physical properties of hydrocarbon mixtures. One can examine phase behavior type transitions for binary mixtures from the perspective of the solute or the solvent while varying the other. Both approaches are found in the literature. The solvent fixed approach is shown in Fig. 5 for carbon dioxide + *n*-alkane binary mixtures.[4] The anthracene

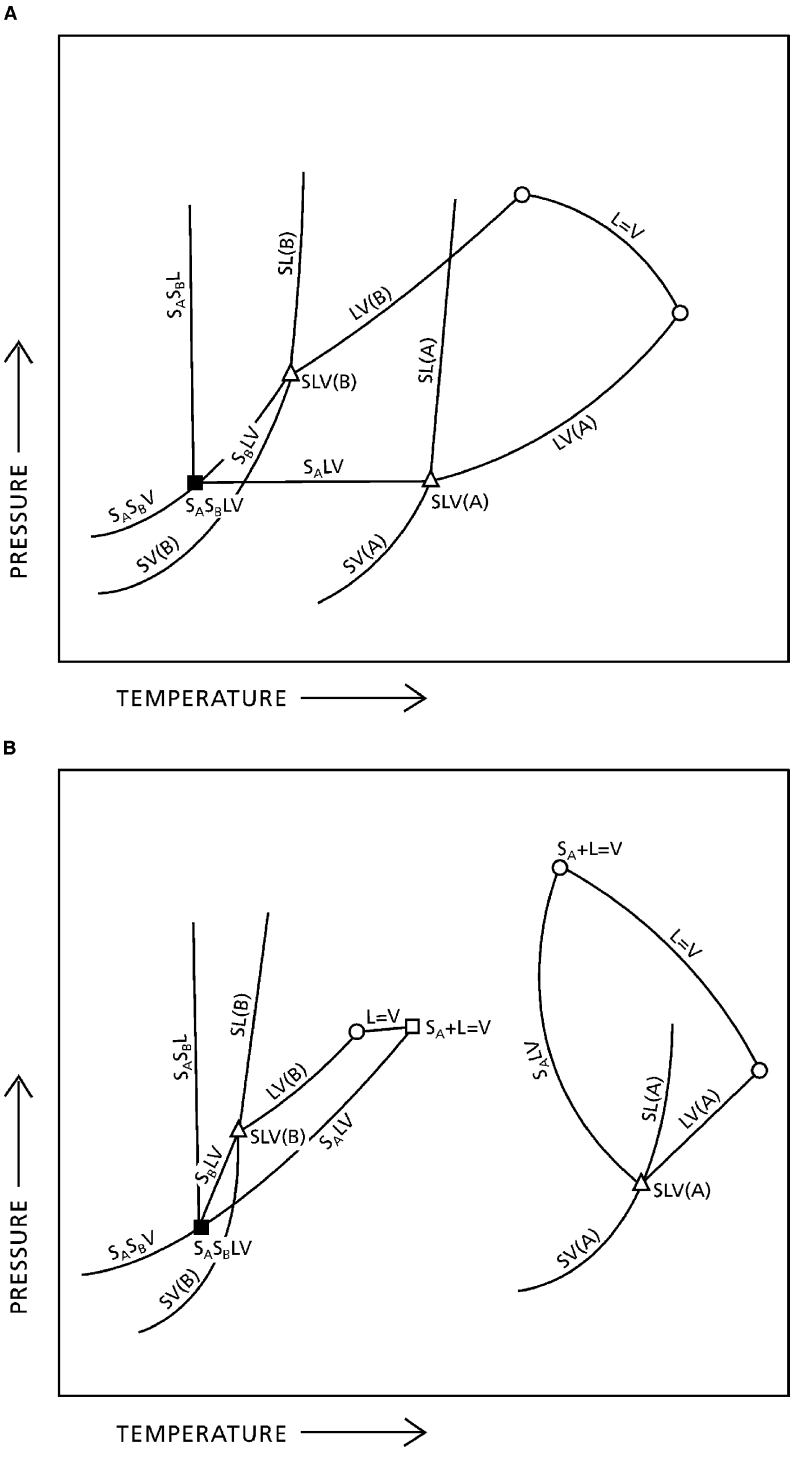

Fig. 4 Possible pressure–temperature projections for Type I binaries including solids.

(solute) + *n*-alkane (solvent) binary and pseudobinary case (Fig. 6) illustrates the latter approach.[9] Transitions from Type III (projection as in Figs. 4B and 5D) to Type IV (projection as in 5B) to Type V (Fig. 5C) to Type I (Fig. 4A) arise over the interval from anthracene + butane to anthracene + hexane.

Consequently, dramatic changes in phase behavior, with slight changes in either solvent or solute composition, arise commonly for hydrocarbon mixtures. Multiphase behavior can be introduced or suppressed as the examples illustrate. Such sharp transitions also pose a challenge for modeling as small errors in fluid phase behavior prediction, or the location of Q points, can yield phase behaviors and phase behavior transition sequences incompatible with experimental data.[9,11]

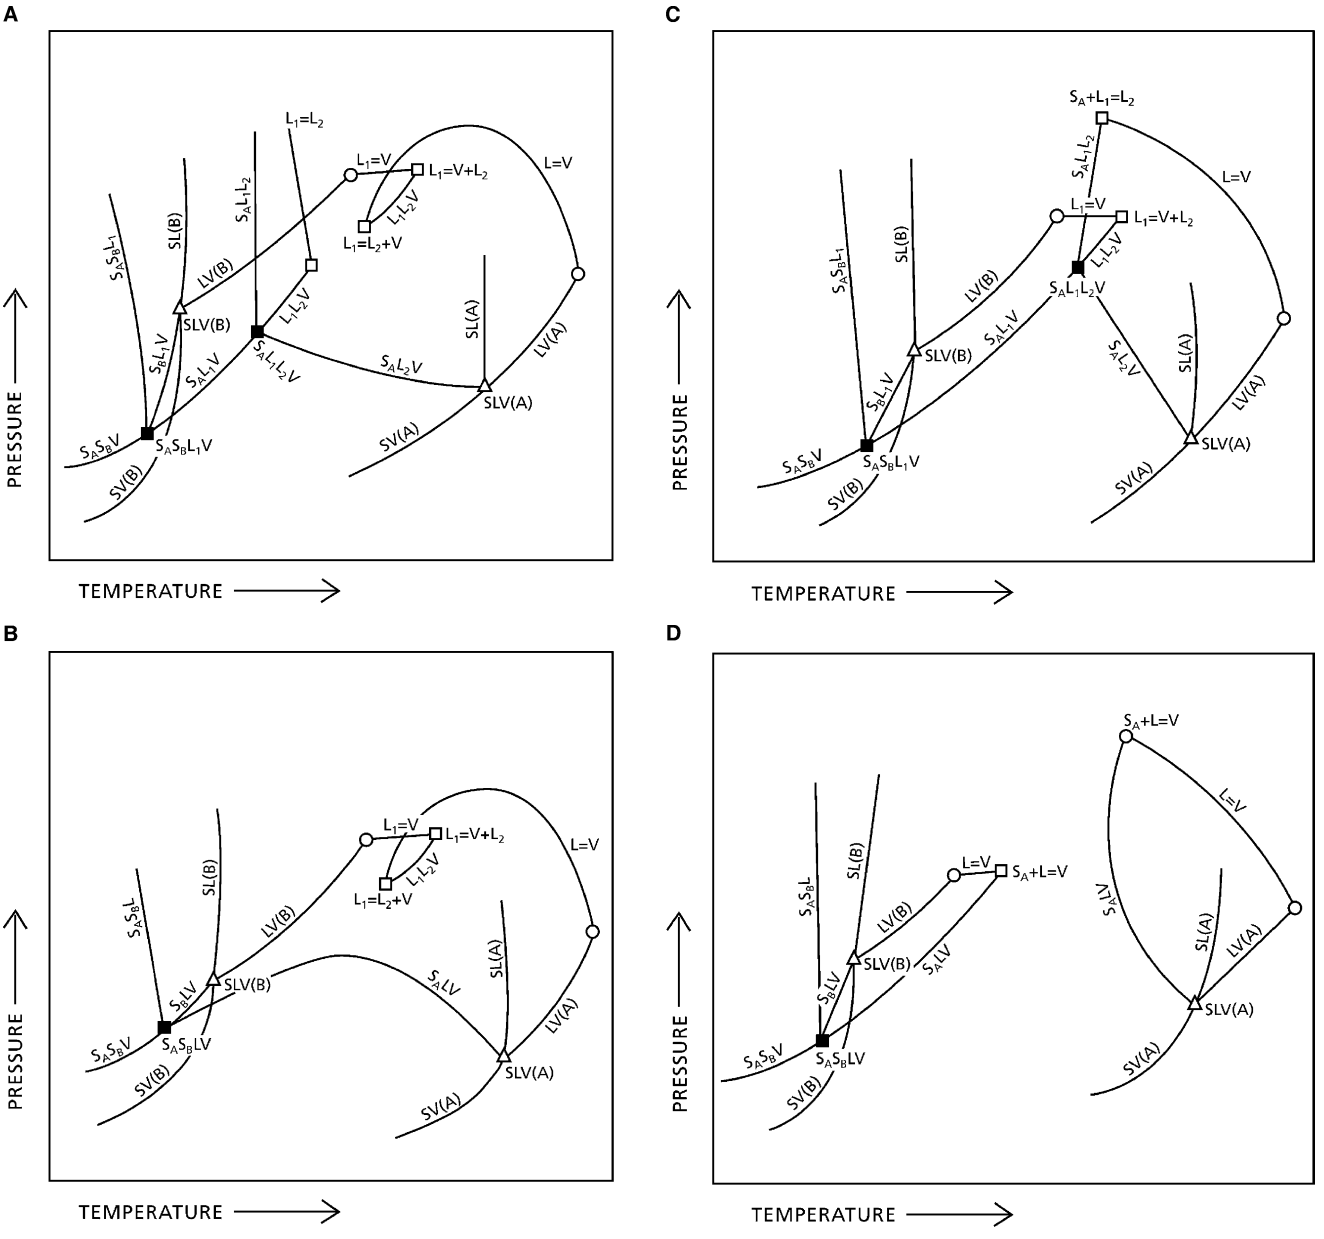

Fig. 5 Possible pressure–temperature projections for Type IV binaries including solids where the melting point of component A increases from A to D.

IMPLICATIONS FOR MULTICOMPONENT MIXTURES

Phase diagrams for multicomponent mixtures possess additional degrees of freedom and are inherently multidimensional. In practice, construction and interpretation of phase diagrams of multicomponent mixtures are similar to, and based on, those of binary mixtures.[14–17] The phase behavior of multicomponent mixtures can also be depicted as sections in PTx_1x_2-space, keeping one or more of the variables constant. A widely used section for ternary mixtures is an equilateral triangle composition diagram at fixed pressure and temperature (Fig. 7). Three vertexes (A, B, and C) represent the three pure components, respectively; a point on a side (AB, BC, or AC) represents a binary mixture (A + B, B + C, or A + C); a point within the triangle represents a ternary mixture (A + B + C). The region enclosed by triangle DEF (dash dot line) represents a three-phase zone. Points within the zone represent compositions of heterogeneous mixtures of three phases ($\alpha + \beta + \gamma$); the compositions of these three phases are fixed and represented by D, E, and F, respectively. The relative amounts of coexisting phases are determined from the component mass balances. As Fig. 7 illustrates, phase behaviors not present in binaries can arise within the body of the diagram

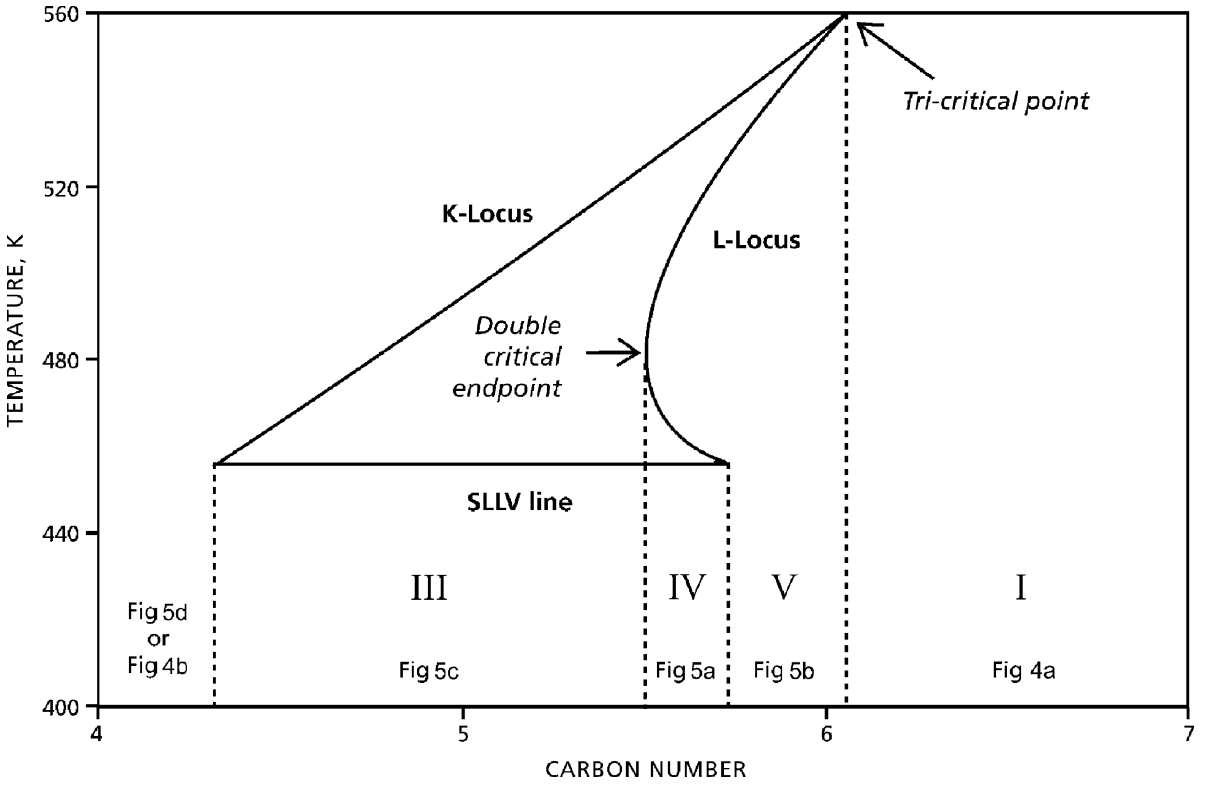

Fig. 6 Phase behavior transitions for the anthracene (solute) + *n*-alkane (solvent) system.

due to the additional degrees of freedom. For example, Heidemann and Abdel-Ghani[18] observed five co-existing phases (one vapor phase + four liquid phases) in phenol–water–hexane ternary mixtures whereas the constituent binaries exhibit a maximum of three phases in equilibrium! Stacks of triangular diagrams (prisms) are used to show the effect of pressure or temperature on the phase behavior of ternary mixtures.[19] Pyramids are used to describe the phase behavior of quaternary mixtures at fixed temperature and pressure where the vertices represent the four components; points on an edge represent binary mixtures; points on the triangular surfaces represent ternary mixtures; points within the pyramid represent quaternary mixtures.[20] Recently, Shaw[21] discussed the use of pyramid diagrams to describe the phase behavior of complex hydrocarbon mixtures.

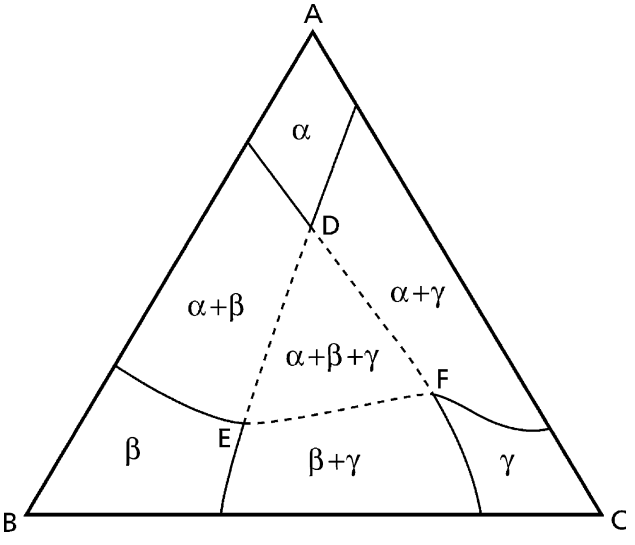

Fig. 7 An example of an equilateral triangle composition diagram for a ternary mixture at fixed pressure and temperature.

PHASE BEHAVIOR PREDICTION

The theory and conditions for phase equilibrium are well established. If more than one phase is present, then the chemical potential of a component is the same in all phases present. As chemical potential is linked functionally to the concepts of fugacity and activity, models for phase behavior prediction and correlation based on chemical potentials, fugacities, and activities have been developed. Historically, phase equilibrium calculations for hydrocarbon mixtures have been fragmented with liquid–vapor, liquid–liquid, and other phase equilibrium calculations, subject to separate and diverse treatments depending on the temperature, pressure, and component properties. Many of these methods and approaches arose to meet specific needs in the chemical process industries. Poling, Prausnitz,

O'Connell[24] provide an excellent survey of computation methods and restrictions.

From the 1980s onward, equation of state based models and cubic equation of state based computational methods in particular have come to dominate phase equilibrium calculations for hydrocarbon mixtures and are particularly useful for phase diagram and phase projection construction. van der Waals equation of state, for example, can be used to predict five of the six phase behavior types expected for binary mixtures including hydrocarbons.[3] The computations are intensive and involve minimizing Gibbs free energy for a mixture as a whole. Most algorithms employ Michelsen's tangent plane criterion[5,6] for this purpose. A large number of computational routines and options are now built into commercial process simulators. While these computations are frequently reliable for well-defined mixtures, one must be wary of the results obtained because, in general, errors can be substantial. This is particularly so at higher pressures where the number, nature, and composition of phases present at fixed composition can be predicted incorrectly,[7,8] or where the wrong phase behavior type can be predicted for a mixture as a whole.[9] Some equations of state also predict phase behaviors that do not arise in nature. Custom regression of interaction parameters based on (some) experimental data, and careful attention to the numerical methods employed, mitigate, but do not eliminate, these difficulties even for simple mixtures.

Pure solid + fluid phase equilibrium calculations are challenging but can, in principle, be modeled if the triple point of the pure solid and the enthalpy of fusion are known, the physical state of the solid does not change with temperature and pressure, and a chemical potential model (or equivalent), with known coefficients, for solid constituents is available. These conditions are rarely met even for simple mixtures and it is difficult to generalize multiphase behavior prediction results involving even well-defined solids.[23] The presence of polymorphs, solid–solid transitions, and solid compounds provide additional modeling challenges, for example, ice, gas hydrates, and solid hydrocarbons all have multiple forms.

IMPLICATIONS FOR HYDROCARBONS OF INDUSTRIAL INTEREST

Reservoir fluids and heavy oil + light hydrocarbon mixtures comprise numerous components from methane to asphaltenes and are often asymmetric in nature. These diverse constituents are difficult to identify at a molecular level[22] and are typically lumped into pseudocomponents. The reservoir fluid and heavy oil literatures diverge on how the lumping should be performed.[21] For reservoir fluids, the typical scheme is to treat low molar mass species individually, and intermediate hydrocarbons as pseudocomponents based on carbon number. For example, an ill-defined maltene fraction comprises one or more pseudocomponents and asphaltenes one or two others. For bitumen and heavy oil mixtures, the light components are typically ignored and one encounters pseudobinary, and more typically ternary, diagrams where the composition variables are asphaltenes, and one or two hydrocarbon fractions. Thus, the impact of the variability of the phase behavior of the high molar mass constituents on the phase behavior of reservoir fluids is largely ignored in one literature and the impact of low molar mass constituents on the phase behavior of heavy feedstocks is largely ignored in the other literature. The phase behavior of hydrocarbon mixtures is too sensitive for such an approach to be successful from a modeling perspective. As a consequence, the phase behavior of individual fluids must be identified primarily from experiments in order to obtain reliable information.

CONCLUSIONS

This contribution introduces phase behavior concepts, such as multiphase equilibria, critical phenomenon, and the phase rule that lay a foundation for understanding the phase behavior of hydrocarbon mixtures. The mechanics related to interpreting and constructing phase diagrams and projections are reviewed. The phase behavior of hydrocarbon mixtures is complex but falls within established qualitative frameworks that build on the work of van Konynenburg and Scott. Dramatic changes in phase behavior, with slight changes in either solvent or solute composition, characterize the phase behavior of asymmetric hydrocarbon mixtures. Solidification adds to the complexity of the phase behaviors exhibited through the introduction or the suppression of multiphase behavior. Regardless of their source, sharp phase behavior transitions pose challenges for process design and operation and hamper modeling efforts because small errors in fluid phase behavior prediction, or in the location of Q points, can yield phase behaviors and phase behavior transition sequences incompatible with experimental data, even for well-defined mixtures. Phase behaviors of multicomponent and ill-defined mixtures present additional challenges as phase behaviors not present in the constituent binary or ternary diagrams can arise. Composition variations within coarsely lumped fractions also influence phase behavior. The impact of such variations is not captured in existing databases and, as a consequence, the phase behavior of fluids of industrial interest is still approached primarily from experiment.

Phase Equilibria

Karl B. Schnelle, Jr.
Department of Chemical Engineering, Vanderbilt University, Nashville, Tennessee, U.S.A.

INTRODUCTION

Our lives are intrinsically linked with mixtures. As scientists and engineers involved with the chemical processing industry, we are well aware of the nature of air and gasoline as mixtures. We must deal with these mixtures in our daily activities and professionally in our work as scientists and engineers. We are also concerned with the transfer of components to and from these mixtures to other mixtures. Oxygen from the air will transfer to the waters of our rivers and lakes, dissolving in them and providing a healthy mixture with the water to support aquatic life. If this does not happen, the waters may be of such a composition so as not to support the aquatic life and become polluted. If we are not aware of the nature of the combustion of gasoline, it is also possible for carbon monoxide formed in the combustion and entering the air to be transferred and dissolved in our blood stream thereby causing a toxic reaction and even death. The important thing here is the composition of the two phases, i.e., the air–water and air–blood as gasses and liquids where material is transferred from the one phase to the other. The transfer process continues from the one phase to the other until each phase reaches a constant value, which is said to be the equilibrium condition. In this condition, the composition of the components in each phase may be very different in from each other. When we separate the components in these mixtures by the processing methods of absorption, adsorption, distillation, extraction, etc., we need to have this difference established.

Phase equilibrium is the science that allows us to determine the physical properties of the phases that exist at this equilibrium condition. In general, phase equilibria deals with all combinations of vapor, liquid, and solid phases. This chapter will present the basic concepts and models to allow for the determination of the equilibrium compositions of these phases in combinations with each other. In this chapter, we will be not consider chemical and nuclear reactions, surface and tensile effects, or the effect of a gravitational or electromagnetic fields.

There are two textbook sources for the details of the concepts and models of phase equilibria. Smith, Van Ness, and Abbott[1] present the basic material in a book that is the most widely distributed textbook in chemical engineering. Advanced and very thorough information may be found in the text by Prausnitz, Lichtenthaler, and Gomes de Azevedo.[2]

FOUNDATIONS OF PHASE EQUILIBRIA

Measures of Composition

In phase equilibrium, mole fraction in each of the phases is the most common way to express composition that goes along with mole balances around the system being studied. There is also the possibility to use mass fraction for defining composition. Mass balances around the system can then be made. For some situations, absorption column design, for example, the composition may be expressed as mass of solute per mass of solvent.

Solution Equilibrium

It was the work of Josiah Willard Gibbs[3] that introduced the concept of the thermodynamics of multicomponent systems and applied the ideas to the behavior of chemical systems. A homogenous system is one in which the system properties are uniform throughout. An open system is one in which mass may be transferred between phases. We can then write the fundamental equation defining the Gibbs free energy function, G, for this system.

$$\mathrm{d}G \equiv -S\,\mathrm{d}T + V\,\mathrm{d}P + \sum_i \mu_i\,\mathrm{d}n_i \tag{1}$$

In Eq. (1), T is the temperature, P is the pressure, S is the entropy, V is the volume, n_i is the mole number of component i, and μ_i is the chemical potential of component i. In this case, the chemical potential is defined by Eq. (2).

$$\mu_i \equiv \left(\frac{\partial G}{\partial n_i}\right)_{T,P,n_j} \tag{2}$$

Consider the closed heterogeneous system made of two or more phases that are open systems. Equilibrium

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007962

is achieved when in each phase the temperature and pressure are the same and the chemical potential of each component is the same in all phases. The equality of chemical potential in every phase will define equilibrium for each component. Thus for m components and π phases, there are m times π phase equilibrium equations that can be written. The final one is Eq. (3); however, only $(m - 1)$ π are independent equations.

$$\mu_m^{(1)} = \mu_m^{(2)} = \ldots \mu_m^{(\pi)} \tag{3}$$

The Phase Rule

Intensive variables are those that do not depend on the mass of the system. In the case of a homogenous system specified by Eq. (2), the temperature, pressure, and the $m - 1$ mole fractions are intensive variables. Note that if x_i is the mole fraction of component i in a liquid solution, then $\sum_i x_i = 1.00$. Therefore, for m components only $m - 1$ mole fractions are required to define the system. Degrees of freedom, F, are the number of variables that can be independently fixed. In this case with π equal to the number of phases, there are $2 + (m - 1)(\pi)$ phase rule variables. The degrees of freedom are the difference between these phase rule variables and the number of independent equations noted above.

$$F = 2 - \pi + m \tag{4}$$

(If we allow P to be the number of phases and C to be the number of components, then $P + F = C + 2$, or in a small town like Grinders Switch, TN, the Police Force is the Chief plus Two officers.) Knowing the number of components in a system and the number of phases, we can now use this rule as guidance for the number of intensive variables we need to determine equilibrium for the system.

Chemical Potential and Fugacity

The chemical potential provides the fundamental criteria for determining phase equilibria. Like many thermodynamic functions, there is no absolute value for chemical potential. The Gibbs free energy function is related to both the enthalpy and entropy for which there is no absolute value. Moreover, there are some other undesirable properties of the chemical potential that make it less than suitable for practical calculations of phase equilibria. Thus, G.N. Lewis[4] introduced the concept of fugacity, which can be related to the chemical potential and has a relationship closer to real world intensive properties. With Lewis's definition, there still remains the problem of absolute value for the function. Thus, arbitrary reference states or standard states must be established to allow calculation to proceed. Eq. (5) presents the relationship between chemical potential, fugacity, and standard states for an isothermal change in solid, liquid, or gas, pure or mixed, ideal or real systems.

$$\mu_i - \mu_i^* = RT \ln \frac{f_i}{f_i^*} \tag{5}$$

The fugacity of the component in the solution is f_i. Both μ_i^* and f_i^* are values chosen at the standard state. Either can be arbitrarily chosen setting the value of the other, but they both cannot be chosen independently.

Activity and Activity Coefficient

The ratio f_i/f_i^* was called activity by Lewis. Therefore, the activity a_i is defined by Eq. (6)

$$a_i \equiv \frac{f_i}{f_i^*} \tag{6}$$

Activity compares the chemical potential of the component to the chemical potential of the component in the standard state. The fugacity of the component is determined by the temperature, pressure, and composition. In defining the standard state and deriving Eq. (2), the system was assumed to be isothermal. Therefore, the temperature of the standard state must be the same as the temperature of the component under study. However, the pressure and composition of the standard state may be set to best serve the situation under study.

Excess properties and activity coefficient

Liquid solutions are most readily dealt with by excess properties, which are defined for extensive properties and in this case for the Gibbs free energy by the difference between the real solution property G and the ideal solution property G. Eq. (7) is the excess Gibbs free energy.

$$G^{\mathrm{E}} = G - G^{\mathrm{id}} \tag{7}$$

Refer to Eq. (2) where the chemical potential is given as a function G at constant T, P, and composition n_j. Here, the subscript j indicates that all compositions but n_i are to be held constant along with T and P. Thus, Eq. (2) defines the partial molar Gibbs free energy $\overline{G}$.

Then, Eq. (8) defines the partial molar excess Gibbs free energy.

$$\overline{G^{\mathrm{E}}} = G - \overline{G^{\mathrm{id}}} \tag{8}$$

Note also from Eq. (2) for component i, that the chemical potential is related to the excess Gibbs free energy by Eq. (9).

$$\mu_i = \overline{G_i} \tag{9}$$

The activity coefficient can be defined by Eq. (10).

$$\gamma_i \equiv \frac{a_i}{x_i} \tag{10}$$

It can be shown that $\ln \gamma$ is a partial molar property in relation to G^E/RT. Then according to the characteristics of partial molar properties, Eq. (11) can be written.

$$\frac{G^E}{RT} = \sum x_i \ln \gamma_i \tag{11}$$

Another useful relation Eq. (12) can be found from Eq. (11) by differentiation.

$$\sum_i x_i d \ln \gamma_i = 0 \tag{12}$$

VAPOR–LIQUID EQUILIBRIUM (VLE)

Qualitative Behavior—Binary System

Equilibrium of a two component, i.e., a binary system can be readily depicted on a two dimensional figure. With two components and two phases, the degrees of freedom according to Eq. (4) would be two. If we choose to study an isothermal system, the concentration of both phases would be fixed at any pressure in the range of condensation. Conversely if we choose an isobaric system, the concentration of both phases would be fixed for any given temperature. Because many chemical separations processes run at constant pressure, we have chosen isobaric systems to illustrate. The following three figures are isobaric, temperature, x–y diagrams where x is the mole fraction in the liquid and y is the mole fraction in the vapor. For isobaric plots of binary data, the upper curve is the dewpoint and the lower curve is the bubblepoint. The dewpoint may be described for isobaric data as the temperature at which the first drop of liquid forms when cooling a constant composition solution from above the line. Conversely, when heating a constant composition liquid from below the curve, the bubblepoint is the temperature at which the first bubble appears. Fig. 1 is isobaric data for a simple binary solution, benzene and toluene, which closely obeys Raoult's law (discussed below). Fig. 2 is a more complex isobaric system, acetone and chlorobenzene, that does not obey Raoult's law. One of the more nonideal solutions and perhaps one of the most well-known azeotrope is acetone and chloroform. Due to hydrogen bonding (see Pauling[5]) to the OH^- ion, this solution, as do most of the water–alcohol solutions, forms an azeoptrope. An azeoptrope is where both the liquid and vapor phases have the same composition at the azeotropic temperature. There may be an upper or a lower boiling azeoptrope. Acetone and chloroform, shown in Fig. 3, are an upper boiling azeoptrope.

Conditions for Equilibrium

Fugacity for a vapor can be more precisely defined by Eq. (13).

$$\frac{f_i^v}{y_i P} \to 1 \quad \text{as } P \to 0 \tag{13}$$

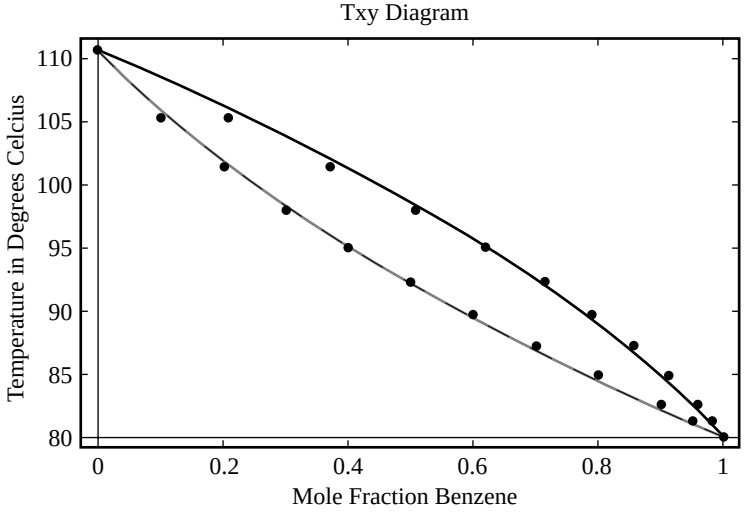

Fig. 1 Isobaric vapor–liquid equilibrium of benzene and toluene at 1.01325 Bars.

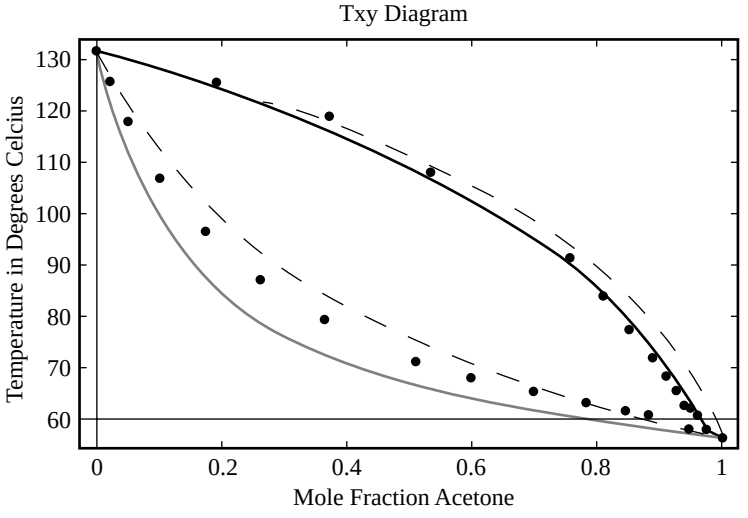

Fig. 2 Isobaric vapor–liquid equilibrium of acetone and chlorobenzene at 1.01325 Bars. Solid lines are calculated from Wilson's equation. Dashed lines are from Raoult's law.

Here, y_i is the mole fraction of component i in the vapor. As $P \rightarrow 0$ the vapor approaches an ideal gas. Therefore, for an ideal gas the fugacity is the partial pressure $y_i P$ as seen in Eq. (14).

$$f_i^v = y_i P \tag{14}$$

For phases, $\alpha,\beta,\ldots,\pi$, and component I, Eq. (5) leads to the fundamental equation of phase equilibria in terms of fugacity illustrated in Eq. (15).

$$f_i^\alpha = f_i^\beta = \cdots f_i^\pi \tag{15}$$

At equilibrium for a vapor and a liquid Eq. (16) expresses the equilibrium.

$$f_i^v = f_i^l \tag{16}$$

Raoult's Law

Raoult's law is the simplest quantitative expression for VLE. This law is based on the vapor phase being an ideal gas and the liquid phase being an ideal solution. Therefore, the vapor phase fugacity is given by Eq. (14). The effect of pressure on the liquid phase is very small, and since the vapor is ideal the liquid fugacity may be written as in Eq. (17). Here, P_i^{sat} is the

$$f_i^l = x_i P^{\text{sat}} \tag{17}$$

vapor pressure of component i at the temperature of the solution. Substituting Eqs. (14) and (17) into Eq. (16) results in Eq. (18) known as Raoult's law. Note that this law was

$$y_i P = x_i P_i^{\text{sat}} \tag{18}$$

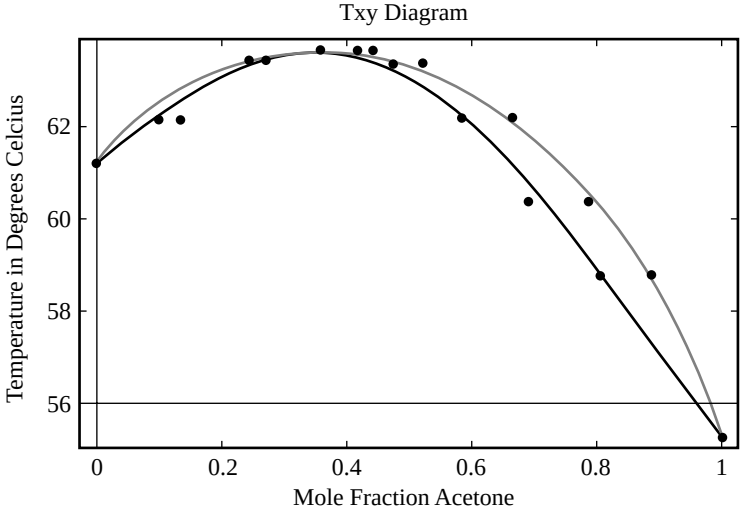

Fig. 3 Isobaric vapor–liquid equilibrium of acetone and chloroform at 0.9839 Bars. The solution is strongly hydrogen bonded, is non-ideal and does not obey Raoult's law. Solid lines are calculated from Wilson's equation.

developed essentially for an ideal solution where the vapor is an ideal gas. Therefore, Raoult's law is very limited in its usefulness. Essentially it is valid for solutions of chemically similar compounds at a pressure of up to 2 or 3 bars. As an example, see Fig. 1 above for benzene and toluene, which is a system that closely obeys Raoult's law. Raoult's law is insignificantly different than the actual data. In Fig. 2, the system is acetone and chlorobenzene, which does not obey Raoult's law. The system shown in Fig. 3 is acetone and chloroform, an azeoptrope, extremely nonideal, and cannot obey Raoult's law for the simple reason that there are three temperature points that must be satisfied where the vapor and liquid have the same composition, the two pure components and the azeoptrope. In the case of the two pure components, these temperature points are the boiling points at the pressure of this solution, 1.01325 bars.

Raoult's law can be applied only to systems where the components' vapor pressure is known. If the temperature of the system is above the critical temperature for any component, then there is no vapor pressure for that component and other means must be employed to determine compositions. This situation is described in the following section on Henry's law.

Henry's Law

In the case where the solute is at a temperature above its critical temperature, the liquid mixture cannot exist over the entire composition range. Assume that we are dealing with an ideal dilute solution where the solvent does not dissolve in the solute. We can write the fugacity for an ideal solution as in Eq. (19) where f_i is the fugacity of pure component i. Since we have a dilute

$$f_i^{id} = x_i f_i \tag{19}$$

solution, we can assume that no solvent dissolves in the solute. Let subscript 1 refer to the solvent and subscript 2 refer to the solute. Then as $x_2 \to 0$, Eq. (20) results in

$$\lim_{x_2 \to 0} \frac{f_1^{id}}{x_1} = f_1 \tag{20}$$

For component 2, the solute, we can define Henry's law constant by Eq. (21).

$$\lim_{x_2 \to 0} \frac{f_2^{id}}{x_2} = H_{2,1} \tag{21}$$

Henry's law for a dilute solution and for the situation of where the pressure is low enough that the ideal gas can apply is given by Eq. (22). Eq. (22) is very similar to Eq. (18),

$$y_2 P = x_2 H_{2,1} \tag{22}$$

Raoult's law, but now applied to dilute solutions. It is also apparent that Eq. (22) can be applied to the case where gases are only slightly soluble in a solvent. A classic case is to determine the saturation concentration of oxygen in natural waters and in waste treatment plant effluents.

The Case for Nonideal Liquid Solutions and Ideal Vapor Solutions

In the case of the ideal gas solution at moderate pressure, Eq. (16) defines the fugacity for the vapor. The activity was defined by Eq. (6), which can be combined with Eq. (10) and written as Eq. (23) for the liquid phase. If we now assume the pure component at the

$$\gamma_i^l = \frac{f_i^l}{x_i f_i^*} \tag{23}$$

pressure and temperature of the solution for the standard state of the liquid, f_i^* becomes the vapor pressure of component i. Vapor–liquid equilibrium can now be written as Eq. (26).

$$y_i P = x_i \gamma_i^l P_i^{\text{sat}} \tag{24}$$

This formulation is Raoult's law extended by the inclusion of the activity coefficient and is not much more difficult to use and it has much greater utility and accuracy at moderate pressures than Raoult's law. It is especially useful when correlations are available for liquid phase activity coefficients γ_i^l. Correlations for this purpose will be discussed in a later section. In the case of systems acetone–chlorobenzene and acetone and chloroform shown respectively in Figs. 2 and 3, the Wilson correlation equation was used to successfully fit the data. The Wilson correlation would also fit the data of benzene–toluene shown in Fig. 1; however, the fit would be no better than Raoult's law and is not illustrated in the figure.

Dealing with the Nonideal Case

The fugacity of the vapor phase can be accurately represented in terms of a fugacity coefficient defined by Eq. (25). For an ideal gas $\phi_{\text{i}} = 1.00$ and the vapor phase, fugacity can be

$$\phi_i^v = \frac{f_i^v}{y_i P} \tag{25}$$

represented by Eq. (16). A most exact representation for the vapor–liquid equilibrium can then be written as Eq. (26). A condensed phase such as a liquid phase

fugacity can be calculated

$$y_i^v \phi_i^v P = x_i \gamma_i^l f_i^l \tag{26}$$

from Eq. (27). Here, it is assumed that the specific volume, v_i^c, of the phase is very nearly

$$f_i^c = \phi_i^{\text{sat}} P_i^{\text{sat}} \exp\left[\frac{v_i^c (P - P_i^{\text{sat}})}{RT}\right] \tag{27}$$

constant over a large pressure increase. When the pressure difference in the exponential is small enough, the exponential will be nearly one. Thus at moderate pressures, the fugacity of a condensed phase is nearly equal to the vapor pressure. This approximation was used in Eq. (24) to write Raoult's law. Then when the pressure is low enough that the fugacity coefficient is nearly 1.00, Eq. (27) reduces to Raoult's law extended with the activity coefficient included.

The fugacity coefficient can be calculated from equations of state and the activity coefficient can be found from various correlations discussed in a later section.

The Equilibrium *K* Value

A useful formulation for VLE in separation calculations is the equilibrium K value defined in

$$K_i \equiv \frac{y_i}{x_i} = \frac{\gamma_i^l f_i^l}{\phi_i^v P} \tag{28}$$

Eq. (28). Under conditions of low pressure, K becomes Eq. (29), which for the case of

$$K_i = \frac{\gamma_i^l P_i^{\text{sat}}}{P} \tag{29}$$

an ideal solution can then be simplified to Eq. (30).

$$K_i = \frac{P_i^{\text{sat}}}{P} \tag{30}$$

Originally there were charts prepared to make use of these definitions. The DePriester Charts[6] for the homologous series of light hydrocarbons can serve as a basis with approximate validity for simple calculations of VLE situations.

Analyzing VLE Data to Determine Liquid Phase Properties

Extensive properties of solutions are those that depend upon the quantity of material in the system with which we are dealing. These properties can be readily handled by considering the contribution of each component separately using the concept of partial molar properties. A partial molar property of a particular component is that portion of the total extensive property of the solution. The partial molar Gibbs free energy can be written formally as in Eq. (31).

$$\overline{G} = \left[\frac{\partial(nG)}{\partial n_i}\right]_{T,P,n_{j\neq i}} \tag{31}$$

Based on Eq. (11), the partial molar excess Gibbs free energy will result in Eq. (32).

$$\frac{\overline{G^{\text{E}}}}{RT} = \left[\frac{\partial\left(\frac{nG^{\text{E}}}{RT}\right)}{\partial n_i}\right]_{T,P,n_{j\neq i}} = \ln \gamma_i \tag{32}$$

Therefore, if we can devise an equation for $\frac{G^{\text{E}}}{RT}$ as a function of the liquid mole fraction x_i, we can create an expression for the liquid activity coefficient, γ_i, as a function of the liquid mole fraction.

Representing VLE Data—Margules, van Laar, Wilson, and UNIQUAC

Wohl[7] proposed a general method for expressing excess Gibbs energies as a function of effective volume fractions. Liquid mole fractions can be related to the excess volume fractions. The advantage of Wohl's methods is that a rough physical significance could be attached to the parameters of the equations. Prausnitz[2] gives a detailed description of Wohl's method and the relation to equations representing the excess Gibbs energy. Common relationships resulting from Wohl are as follows:

Margules' equations are the best for molecules of similar size:

$$\frac{G^{\text{E}}}{x_1 x_2 RT} = A + (B - A)x_1 \tag{33}$$

$$\ln \lambda_1 = x_2^2[A + 2(B - A)x_1] \tag{34}$$

$$\ln \lambda_2 = x_1^2[A + 2(B - A)x_2] \tag{35}$$

Van Laar's equations are best for molecules of different sizes:

$$\frac{x_1 x_2 RT}{G^{\text{E}}} = \left(\frac{1}{A}\right) + \left(\frac{1}{B} - \frac{1}{A}\right)x_1 \tag{36}$$

$$\ln \gamma_1 = \frac{A x_2^2}{[x_2 + (A/B)x_1]^2} \tag{37}$$

$$\ln \gamma_2 = \frac{A x_1^2}{[x_1 + (A/B)x_2]^2} \tag{38}$$

Wilson and UNIQUAC Equations

There are many other equations, which have been proposed, that may or may not result from Wohl's method. Two of the most popular equations are the Wilson[8] and UNIQUAC by Abrams and Prausnitz.[9] These equations are based on the concept of local composition models, which was proposed by Wilson[8] in his paper. It is presumed in a solution that there are local compositions that differ from the overall mixture compositions. These local compositions result from differences in molecular size and intermolecular forces. The local compositions account for the short-range order and nonrandom molecular orientations.

Multicomponent Solutions

It is difficult to fit data with the local composition models due to their complex logarithmic forms. However, they are readily generalizable to multicomponent systems. Smith, Van Ness, and Abbott[1] and Prausnitz, Lichtenthaler, and Gomes de Azevedo[2] present the Wilson and UNIQUAC models extended for multicomponent solutions. They employ the constants from binary data. However, the constants are not unique in the sense that valid but different constants may be obtained from different sets of data. Again Wilson's equations cannot be employed for immiscible solutions, but the UNIQUAC model may be used to describe such solutions.

Wilson's equations: Good for polar or associating compounds

Wilson then derived Eq. (39) based on the local composition theory. Eqs. (40) and (41) for the activity coefficient result from Eq. (39).

$$\frac{G^{\mathrm{E}}}{RT} = -x_1 \ln(x_1 + x_2 G_{12}) - x_2 \ln(x_2 + x_1 G_{21}) \tag{39}$$

$$\ln \lambda_1 = -\ln(x_1 + x_2 G_{12}) + x_2 \left[\frac{G_{12}}{x_1 + x_2 G_{12}} - \frac{G_{21}}{x_2 + x_1 G_{21}} \right] \tag{40}$$

$$\ln \lambda_2 = -\ln(x_2 + x_1 G_{21}) + x_2 \left[\frac{G_{12}}{x_1 + x_2 G_{12}} - \frac{G_{21}}{x_2 + x_1 G_{21}} \right] \tag{41}$$

The parameters G_{12} and G_{21} are temperature dependant. A compilation of Wilson parameters can be found in Hirata, Ohe, and Nagahama.[10]

UNIQUAC Equations

The Universal Quasi-chemical Theory or UNIQUAC method of Abrams and Prausnitz[9] divides the excess Gibbs free energy into two parts. The dominant entropic contribution is described by a combinatorial part $\left(\frac{G^{\mathrm{E}}}{RT}\right)^{C}$. Intermolecular forces responsible for the enthalpy of mixing are described by a residual part $\left(\frac{G^{\mathrm{E}}}{RT}\right)^{R}$. The sizes and shapes of the molecule determine the combinatorial part, which is thus dependent on the compositions and requires only pure component data. Since the residual part depends on the intermolecular forces, two adjustable binary parameters are used to better describe the intermolecular forces. As the UNIQUAC equations are about as simple for multicomponent solutions as for binary solutions, the UNIQUAC equations for multicomponent solutions are given below. Species are identified by subscript i, subscript j is a dummy index. Here, q_i is a relative molecular surface area and r_i is a relative molecular volume. Both of these quantities are pure-species parameters.

$$\frac{G^{\mathrm{E}}}{RT} = \left(\frac{G^{\mathrm{E}}}{RT}\right)^{C} + \left(\frac{G^{\mathrm{E}}}{RT}\right)^{R} \tag{42}$$

$$\left(\frac{G^{\mathrm{E}}}{RT}\right)^{C} = \sum_i x_i \ln \frac{\phi_i}{x_i} + 5 \sum_i q_i x_i \ln \frac{\theta_i}{\phi_i} \tag{43}$$

$$\left(\frac{G^{\mathrm{E}}}{RT}\right)^{R} = -\sum_i q_i x_i \ln \left(\sum_j \theta_j \tau_{ji} \right) \tag{44}$$

$$\phi_i \equiv \frac{x_i r_i}{\sum_j x_j r_j} \tag{45}$$

$$\theta_i \equiv \frac{x_i q_i}{\sum_j x_j q_j} \tag{46}$$

In this case, $\tau_{ji} \neq \tau_{ij}$; however, when $j = i$, then $\tau_{ii} = \tau_{jj} = 1.0$. Temperature dependence enters into the equation through the parameter τ_{ji}. Gmehling, Onken, and Arlt[11] have found values

$$\tau_{ji} = \exp \frac{-(u_{ji} - u_{ii})}{RT} \tag{47}$$

for parameters $(u_{ij} - u_{ii})$ by regression of binary VLE data. The activity coefficients that follow can be found

from Eqs. (42), (43), and (44).

$$\ln \gamma_i = \ln \gamma_i^C + \ln \gamma_i^R \tag{48}$$

$$\ln \gamma_i^C = 1 \ln - J_i + J_i - 5q_i\left(1 - \frac{J_i}{L_i} + \ln \frac{J_i}{L_i}\right) \tag{49}$$

$$\ln \lambda_i^R = q_i\left(1 - \ln s_i - \sum_j \theta_j \frac{\tau_{ij}}{s_j}\right) \tag{50}$$

$$J_i = \frac{r_i}{\sum_j r_j x_j} \tag{51}$$

$$L_i = \frac{q_i}{\sum_j q_j x_j} \tag{52}$$

$$s_i = \sum_l \theta_l \tau_{li} \tag{53}$$

Parameters for the UNIQUAC equations can be found in Gmehling, Onken, and Arlt.[11]

UNIFAC—A Group Contribution Method

When it is necessary to estimate activity coefficients where no data or very limited data are, available, estimates may be made by using a group contribution method. In this case, a molecule is divided into functional groups, or subgroups of the molecule. These subgroups are assumed to act independently of the molecule in which they appear. Molecular interactions are accounted for by properly weighted sums of group interactions. Fredenslund, Jones, and Prausnitz[12] developed the method for UNIQUAC and named it Universal Functional Activity Coefficient or UNIFAC. Smith, Van Ness, and Abbott[1] reported the equations for the activity coefficients of multicomponent solutions and their parameters. These equations are very similar to the equations above for UNIQUAC. Recent sources for the group interaction parameters may be found in Hansen, Rasmussen, Fredenslund, Schiller, and Gmehling,[13] Gmehling, Li, and Schiller,[14] Fredenslund and Sørensen.[15]

Simplified Technique for Handling Binary Data

It is assumed that x, y, temperature, and pressure data are measured for a binary solution. The data can be either isothermal or isobaric. The measurements should be at a low enough pressure so that Eq. (54) will apply. The vapor–pressure relationship may be determined at the same time or found in the literature. The method is then to:

1. Calculate the activity coefficients from Eq. (24).

$$\gamma_1 = \frac{y_1 P}{x_1 P_1^{\text{sat}}} \qquad \gamma_2 = \frac{y_2 P}{x_2 P_2^{\text{sat}}} \tag{54}$$

2. Calculate the excess Gibbs energy function from Eq. (11).

$$\frac{G^{\text{E}}}{RT} = x_1 \ln \gamma_1 + x_2 \ln \gamma_2 \tag{55}$$

3. Plot $\frac{G^{\text{E}}}{x_1 x_2 RT}$ vs. x_1 to test Margules' equation and $\frac{x_1 x_2 RT}{G^{\text{E}}}$ vs. x_1 to test van Laar's equation.
4. Choose whichever plot offers the best fit to a straight line. Then, determine the parameters A and B of the activity coefficients from either Eq. (33) or (36).
5. Use Wilson's equation if neither plot produces a good fit to the data.

It would be best to examine a plot of the activity coefficients versus x_1 first. If these plots exhibit a maxima or a minima, neither van Laar's nor Wilson's equations are useful. Furthermore, Wilson's equations are not suitable for use in systems of limited solubility.

LIQUID–LIQUID EQUILIBRIUM (LLE)

Stability in Single Phase Systems

At a fixed temperature and pressure, the stable state of a system has a minimum Gibbs free energy, indicated in Eq. (56), which is the basic equation of equilibrium. A liquid mixture

$$(dG^t)_{T,P} = 0.0 \tag{56}$$

will split into two phases if it can lower this Gibbs energy. The Gibbs energy G^t is the total Gibbs energy. It can be related to the molar Gibbs energy, G, through Eq. (57). In this

$$G^t = nG < \sum_i n_i G_i \tag{57}$$

equation, the Gibbs energy G_i is for a pure component where n is the total moles in the solution.

At constant temperature and pressure, the Gibbs free energy, ΔG^{mix}, of mixing is then

$$\Delta G^{\text{mix}} = G - \sum_i x_i G_i < 0 \tag{58}$$

For a binary solution at constant temperature and pressure, a plot of ΔG^{mix} versus the mole fraction x_1 will result in a smooth curve concave downward where ΔG^{mix} is negative as long as the solution is stable. The condition for this concave curve to exist is given by Eq. (59).

$$\left(\frac{\partial^2 \Delta G^{\text{mix}}}{\partial x_1^2}\right)_{T,P} < 0 \tag{59}$$

If by decreasing the temperature the ΔG^{mix} becomes concave upward, the solution will split into two liquid phases. The composition of the phases may be determined from the plot.

Activity Coefficient Method Applied to LLE

In liquid–liquid equilibrium, equality of fugacity applies as it does in vapor–liquid equilibrium. Therefore, Eq. (15) applies to liquid–liquid equilibrium where α and β apply to the two liquid phases. Therefore,

$$f_i^{\alpha} = f_i^{\beta} \tag{60}$$

If the same standard state is chosen for both phases, Eq. (61) can be written as

$$x_i^{\alpha}\gamma_i^{\alpha} = x_i^{\beta}\gamma_i^{\beta} \tag{61}$$

The activity coefficients can be calculated from Wilson's equations or from UNIFAC if the parameters of the models are known. There are some parameters for UNIFAC in Magnussen, Rasmussen, and Fredenslund,[16] Gupte and Danner,[17] and Hooper, Michel, and Prausnitz.[18] These parameters are not as accurate as those for vapor–liquid equilibrium.

VAPOR–LIQUID–LIQUID EQUILIBRIUM (VLLE)

Under certain temperature and pressure conditions, it is possible for some binary solutions to form two liquid phases along with one vapor phase. Under these conditions, only one degree of freedom exits for the solution. Therefore, for a given pressure, the temperature and composition of all the phases are fixed. For a given temperature, the three phases will all occur in equilibrium. At a temperature greater than this, the system may be a single liquid; two phases, a vapor and liquid phase; or three phases, a vapor and two liquid phases. At low pressure, the composition of the three phase system may be calculated as shown in the following section.

Activity Coefficient Method Applied to VLLE

Eq. (24), modified Raoult's, can be applied to low pressure vapor–liquid–liquid equilibrium. For a given pressure, three phase pressure P, Eq. (24) can be rewritten for two components and for the phases α and β. The following four equations result.

$$x_1^{\alpha}\gamma_1^{\alpha}P_1^{\text{sat}} = y_1 P \tag{62}$$

$$x_1^{\beta}\gamma_1^{\beta}P_1^{\text{sat}} = y_1 P \tag{63}$$

$$x_2^{\alpha}\gamma_2^{\alpha}P_2^{\text{sat}} = y_2 P \tag{64}$$

$$x_2^{\beta}\gamma_2^{\beta}P_2^{\text{sat}} = y_2 P \tag{65}$$

When complete immiscibility occurs, Eqs. (63) and (64) can be added to give Eq. (66).

$$P = y_1 P + y_2 P = x_1^{\beta}\gamma_1^{\beta}P_1^{\text{sat}} + x_2^{\alpha}\gamma_2^{\alpha}P_2^{\text{sat}} \tag{66}$$

The vapor composition can be calculated from Eq. (66), which results in the following equation.

$$y_1 = \frac{x_1\gamma_1 P_1^{\text{sat}}}{P} \tag{67}$$

Thus with knowledge of the activity coefficients, all compositions of the three phases could be calculated.

SOLID–LIQUID EQUILIBRIUM (SLE)

Fugacity and Activity Coefficient Method Applied to SLE

In dealing with the solution of solids in liquids, the solubility or mole fraction of the solute in the solvent is the primary variable of interest. The solubility depends on the intermolecular forces between the solute and the solvent, which are represented by the activity coefficient. However, equally important in determining the solubility is the standard state to which the activity is referred and the fugacity of the pure solid. In writing the equilibrium equation, it is assumed that there is no solubility of the solvent in the solid. Then, Eq. (68) can be written.

$$f_{2(\text{pure solid})}^{s} = \gamma_2 x_2 f_2^{o} \tag{68}$$

The solubility is given by x_2, γ_2 is the activity coefficient of the liquid phase, and f_2^o is the standard state fugacity to which the activity coefficient is related. The solubility can then be found from Eq. (69), which illustrates the dependency of the solubility on the

ratio of the

$$x_2 = \frac{f_{2(\text{pure solid})}}{\gamma_2 f_2^o} \tag{69}$$

two fugacities.

Define the standard state as the pure sub-cooled liquid at the operating temperature. Then, f_2^o becomes the fugacity of the pure sub-cooled liquid, $f_{2(\text{pure, subcooled liquid})}$. Redefine the two fugacities as follows,

$$f^s_{2(\text{pure solid})} = f_2^s \quad \text{and} \quad f_{2(\text{pure sub-cooled liquid})} = f_2^{\text{SCL}}$$

By considering a path at the operating temperature where the solid passes through the triple point to a sub-cooled liquid, the ratio of the two fugacities in Eq. (69) can be written as follows.

$$\ln\frac{f_2^{SCL}}{f_2^s} = \frac{\Delta H_{fus}}{RT_t}\left(\frac{T_t}{T} - 1\right) - \frac{\Delta c_p}{R}\left(\frac{T_t}{T} - 1\right) + \frac{\Delta c_p}{R}\ln\frac{T_t}{T} \tag{70}$$

In Eq. (69), T_t is the triple point temperature, ΔH_{fus} the heat of fusion, and $\Delta c_{\text{p}} \equiv c_{\text{p(liquid)}} - c_{\text{p(solid)}}$ between T and T_t. Eq. (70) can be combined with Eq. (69) to find the solubility.

For an ideal solution $\gamma_2 = 1.0$ and in many cases, Δc_{p} can be neglected and the triple point temperature can be approximated by the melting point temperature T_{m}. Then, the solubility becomes Eq. (71).

$$\ln x_2 = -\frac{\Delta H_{fus}}{RT_m}\left(\frac{T_m}{T} - 1\right) \tag{71}$$

Prausnitz, Lichtenthaler, and Gomes de Azevedo[2] show several methods for determining the activity coefficient for SLE.

PHASE EQUILIBRIUM AT HIGH PRESSURE

Vapor–Liquid Equilibrium from Equations of State

Prausnitz, Lichtenthaler, and Gomes de Azevedo[2] suggest that the best way to approach high pressure vapor–liquid is through the fugacity and fugacity coefficient. Eq. (25) defines the fugacity coefficient for a vapor. In the same way, the fugacity coefficient can be defined for a liquid as follows,

$$\phi_i^L = \frac{f_i^L}{x_i P} \tag{72}$$

At equilibrium, the frugalities will be equal and the following equation will result.

$$\varphi_i^V y_i = \varphi_i^L x_i \tag{73}$$

It is then possible to calculate the fugacity coefficient from an equation of state applied to Eq. (74). In this equation, n_i is the moles of component i and n_T is the total number of

$$\ln\phi_{\text{i}}^{\text{V}} = \frac{1}{RT}\int_{V^V}^{\infty}\left[\left(\frac{\partial P}{\partial n_i}\right)_{T,P,n_{j\neq i}} - \frac{RT}{V}\right]dV - \ln\frac{PV^V}{n_T RT} \tag{74}$$

moles in the solution. A similar equation can be written for the liquid phase. The equation of state selected is applied to both the vapor and liquid fugacity coefficients. Since the calculation will involve at least binary mixtures and quite likely multicomponent mixtures, mixing rules for the equation of state parameters will need to be used. Smith, Van Ness, and Abbott[1] report this procedure for a cubic equation of state.

Solid–Vapor Equilibrium (SVE)—Supercritical Extraction

Important to many current processes is the ability of gasses at pressure above the critical to have increased solubility capability. A common example is the decaffeination of coffee beans by supercritical carbon dioxide. In this case, it is assumed that species 1 is the solute dissolved in species 2, which is therefore the solvent. It is assumed that the solvent is insoluble in the solute. Thus, the equilibrium can be written as follows,

$$f_1^{s(\text{pure})} = f_1^v \tag{75}$$

Then the solubility of the solute in the gas, y_1, can be written as in Eq. (76).

$$y_1 = \frac{P_1^{\text{sat}}\phi_1^{\text{sat}}}{P\varphi_1^{(\text{pure})}}\exp\left[\frac{V_1^s\left(P - P_1^{\text{sat}}\right)}{RT}\right] \tag{76}$$

The molar volume of the solid is V_1^s. The vapor phase nonidealities are reflected in the ratio of the fugacity coefficients $\frac{\phi_1^{\text{sat}}}{\phi_1^{(\text{pure})}}$. In most cases, the vapor pressure of the solute, P_1^{sat}, will be small enough to be neglected. An example of the use of this equation

to determine the solubility of naphthalene in carbon dioxide is given in Smith, Van Ness, and Abbott.[1]

SOME SPECIAL TOPICS

There are several areas of interest in chemical processing that should be reviewed in this chapter. These areas include retrograde condensation, polymers, and electrolytes. In each case, the material is more extensive than can be covered in any detail in this chapter. Reference should be made to Prausnitz, Lichtenthaler, and Gomes de Acevedo.[2] Furthermore, the principles covered in this chapter form the basis for viewing and calculating the phase equilibrium that applies. The subjects of polymers and electrolytes are so complex that they require a chapter by themselves. However, a brief statement follows describing retrograde condensation.

Retrograde Condensation

The vapor pressure curve forms the basis for the description of vapor–liquid equilibrium for a pure fluid. As the temperature increases, the vapor pressure curve for the vapor–liquid situation ends at the critical pressure. In the case of a binary or multicomponent solution, the critical point is not necessarily a maximum with respect to either temperature or pressure. It is then possible for a vapor or liquid to exist at temperature or pressures higher than the critical pressure of the mixture. At constant temperature, it is then possible for condensation to take place as the pressure is decreased. At constant pressure, condensation may take place as the temperature is increased. Vaporization can take place at constant temperature as the pressure is increased and decreased. This unusual behavior can be useful in some process situations, for example, in the recovery of natural gas from deep wells. If the conditions are right, liquefaction of the product stream is possible. At the same time, the heavier components of the mixture may be separated from the lighter components.

CONCLUSIONS

Phase equilibria are necessary components for any process that requires separation of materials to take place. Phase equilibria have always been necessary in the design of chemical and petroleum processing plants. They are also important in environmental situations like dissolved oxygen in natural waters and the design of air pollution control equipment. The subject is quite complicated and can only be briefly reviewed in this chapter. References provide the necessary information for a fuller understanding of the theories, correlations, and use of the methods of data handling.

ACKNOWLEDGMENTS

In preparation of the chapter, the author wants to acknowledge that his interest in phase equilibria was stimulated by Lawrence Nicholas Canjar. Professor Canjar was a great teacher, scholar, and a warm friend. He excelled especially in the field of chemical engineering thermodynamics. Through lectures and discussions, he opened the way for a lifelong interest of the author in teaching and using thermodynamics, especially Phase Equilibria. The author also wants to recognize Professor John Allen Tallmadge who preceded the author as an earlier student of Professor Canjar. It is their data that are presented in Fig. 3 of this chapter.

Phenolic Resins

Adriane G. Ludwick
Mohamed O. Abdalla
Department of Chemistry, Tuskegee University, Tuskegee, Alabama, U.S.A.

INTRODUCTION

This entry will provide an overview of the ''classical'' phenol–formaldehyde system. The fundamentals of this system will be described. The current applications of this classical system will be discussed. Resins prepared from structurally modified phenols will be examined and labeled as ''modified-classical'' phenol–formaldehyde systems. The effect of these modifications on the mechanical, thermal, and other properties will be examined. Finally, the considerable work on polymers that can be classified as ''nonclassical'' phenolic resins will be presented and the area of nanocomposites utilizing phenolic resins will be examined.

The aim of this entry is to present a balanced view of the current state of phenolic resins. The patent literature, refereed journals, and other general sources have been utilized to survey the classical and nonclassical phenolic resin systems as well as the nanocomposite systems. The article is pedagogical rather than comprehensive.

PHENOLICS CHEMISTRY

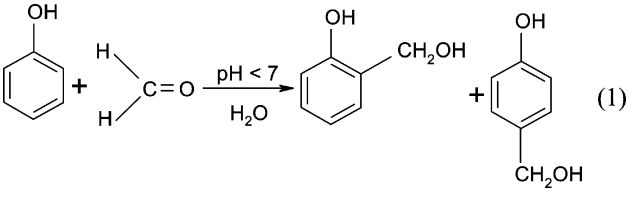
This section gives a brief overview of the chemistry of classical phenolics. Classical phenolics refer to the reaction of phenol and formaldehyde in water under basic or acidic conditions.

Phenol and Formaldehyde Reaction

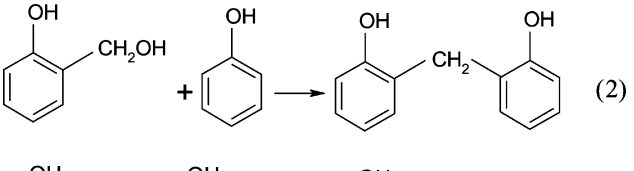
Phenol and formaldehyde react in water to give *ortho*- and *para*-substituted products (Scheme 1). The reaction mechanism is an electrophilic aromatic substitution.[1–3] The product depends on the molar ratio of phenol to formaldehyde, pH conditions, and temperature. The mechanism is essentially the same in acidic or basic aqueous solution, but the details of the reaction are different. The product in an acidic medium is known as a novolac and that in basic medium is known as a resol.

Novolac preparation and processing

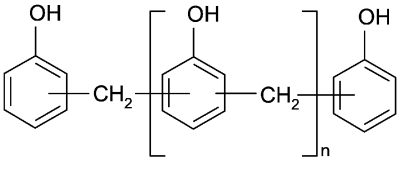
Typically, in the preparation of a novolac, the molar ratio of phenol and formaldehyde is greater than 1. Hence, the initial major product is a mono-substituted phenol [Eq. (1)]. Because the reaction is done under aqueous acidic conditions, the products shown in Eq. (1) are not isolated. Instead, a methylene bridge is formed between the phenyl rings [Eq. (2)]. In both Eqs. (1) and (2) the mechanism is an electrophilic aromatic substitution. Heating the system so as to promote removal of water and polymerization results in thermoplastic material known as novolac (**1**). This thermoplastic resin can be mixed with hexamethylenetetramine (formed from ammonia and formaldehyde) and stored until cure. Heating this system produces an excess of formaldehyde and ammonia. A cross-linked polymer results from the cure. The linkages are mostly methylene and amino groups.



(1)



(2)

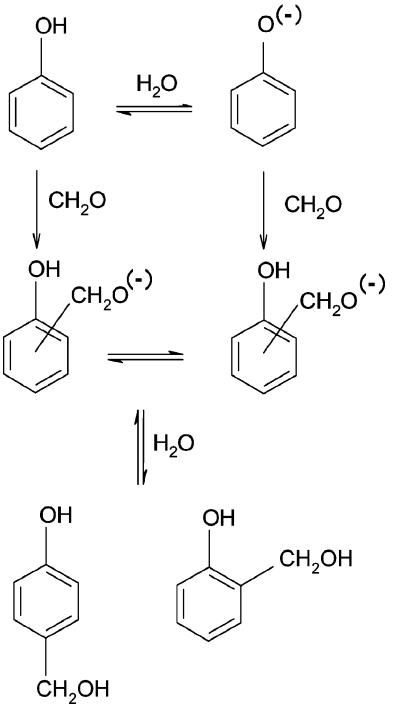


1

Resol preparation and processing

The chemistry of resol formation has many similarities to that of novolacs. However, because conditions utilize a phenol to formaldehyde ratio less than 1, mono-, di-, and tri-substitutions to the aromatic ring occur. Additionally, the aqueous medium is basic. Hence,

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120027016



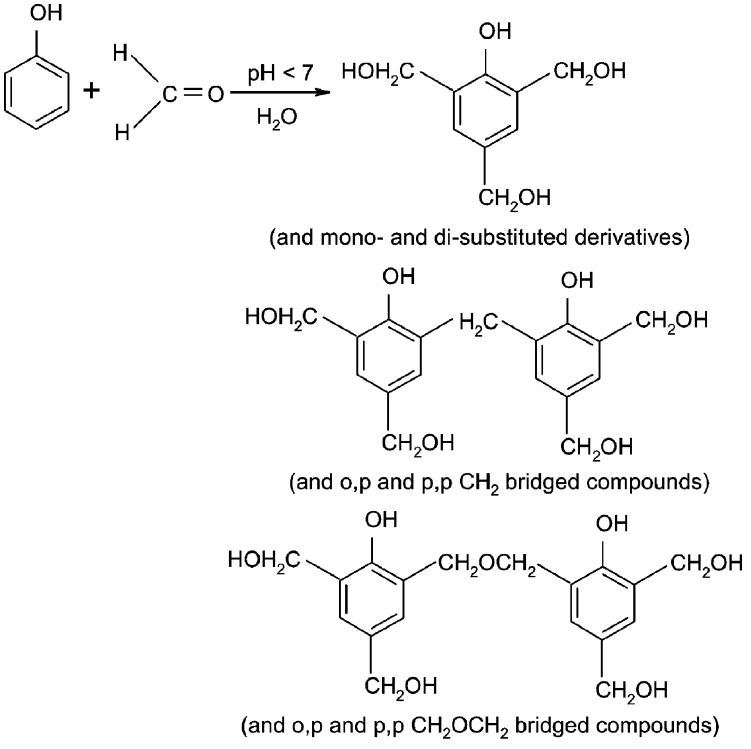
Scheme 1 General pattern for phenol–formaldehyde reaction.

these initial substitution products can be isolated (see Scheme 2). Cure of this system resulting in a cross-linked polymer occurs upon heating to temperatures above 100°C, typically 125–150°C.

Resol application

Using the classical resol chemistry, Asai and coworkers patented new molded materials.[4] Added to the resol phenolic resin are inorganic fiber, a silica powder, and a rubber component. The prepared phenolic resin composition was noted to have excellent resistance to abrasive wear and to heat shock, as well as excellent mechanical strength. As such, this material is very suitable for the fabrication of engine parts such as pulleys. These pulleys are currently fabricated from heavier and more expensive materials.

The resol phenolic resin is dimethylene-ether-based or methylol-based and either solid or liquid. The rubber component includes as possibilities: nitrile, acrylic, chloroprene, styrene–butadiene, or silicone. The inorganic fiber component includes glass, carbon, silicon carbide, or potassium titanate. The glass fiber may be preferably subjected to a surface treatment with a silane coupling agent to improve adhesion to the phenolic resin. Asai and coworkers optimized the amount of rubber in the resin composition to 1–15 parts by weight in 100 parts by weight of phenolic resin. Less than one part by weight of rubber detrimentally affected the elastic modulus of the product. More than 15 parts by weight of rubber resulted in a material with poor abrasive wear resistance. The inorganic fibers and silica powder composition were essential for the abrasive wear resistance properties of this phenolic resin mixture.



Scheme 2 General reaction for preparation of resol resins.

MODIFIED PHENOLIC RESINS

Phenol Derivatives

Modification of the phenol ring can affect both the kinetics and the properties of the phenol–formaldehyde system. Substitution at the *ortho* and/or *para* position of the phenol will limit the extent of cross-linking and hence the mechanical properties of the cured phenolic resin. A summary of current work on these modified-classical phenolic resins is given.

Bromine substitution

Including 4-bromophenol in the phenol–formaldehyde resol system impacts the cross-link density of the cured product. In a systematic study of this copolymer, a comparison was made among the polymers obtained using phenol only, a 9 : 1 mole ratio of phenol to 4-bromophenol and a 1 : 1 mole ratio of phenol to 4-bromophenol.[5] Comparisons included measurement of interlaminar shear strength and cone calorimetry tests of composites prepared using these phenolic resins and S2-glass fiber plain weave.

Table 1 demonstrates the effect on mechanical properties for the phenol–4-bromophenol systems. The substitution of bromine at the *para*-(4-) position on the phenol ring gives a significantly less brittle material than from the classical unsubstituted phenol. The cone calorimetry results (Table 2) indicate that the 1 : 1 phenol–4-bromophenol system has the best flammability properties. The 9 : 1 phenol–4-bromophenol and phenol systems give similar values. The hazard from the generation of hydrogen bromide upon burning a bromine-containing compound mitigates the usefulness of this material. However, this is a sound approach toward obtaining improved properties for phenolic systems.

The greater flexibility of the 1 : 1 phenol–4-bromophenol system indicated by these results is consistent with ^{13}C NMR observations. Analysis of the C–Br carbon absorptions confirmed that the phenol and 4-bromophenol rings are connected through primary bonds. Additionally, the 1 : 1 phenol–4-bromophenol resol contains the most ether linkages. The ether connections between the aromatic rings are more flexible than the methylene connections. Presumably, this situation persists in the cured system.

Table 1 Interlaminar shear strength properties of phenolic composites

Composite resin	Average maximum failure load (lb)	Average shear strength (psi)
P	73.7	951
9 : 1 P/4-BrP	90.8	1087
1 : 1 P/4-BrP	121.9	1443

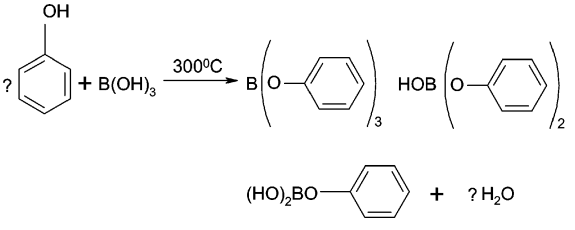
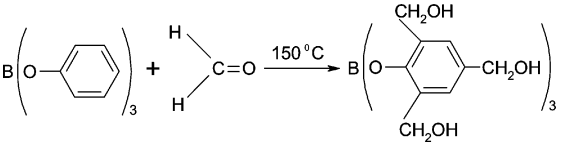
Boron-modified phenolic resin

Hirohata et al. reported a solid-state preparation of boron-modified phenolic resins (BPR).[6] A triphenyl borate ester (TPB) was prepared by reacting phenol with boric acid [Eq. (3)]. The TPB was then reacted with paraformaldehyde to produce the BPR [Eq. (4)]. The solid product was obtained by resinifying at 150°C. The resin produced by this method was difficult to process by conventional processing methods such as resin transfer molding. No structural characterization for the prepared TPB ester or resins was reported in Hirohata's study. However, thermal characterization of the hardened prepared resin showed the BPR to have superior resistance against thermo-oxidative degradation in comparison to the hardened regular and halogenated phenolic resins.



(3)



(4)

A more recent study by Abdalla, Ludwick, and Mitchell presented a different approach for the preparation for BPR.[7] The resin was prepared from the reaction of TPB and paraformaldehyde at three different resinifying temperatures, 130°C, 120°C, and 90°C. The BPR produced at 90°C melted upon reheating, which indicated promising processing applications for this resin. ^{1}H and ^{13}C NMR spectra of resins from the three resinifying temperatures had the same pattern of absorptions, similar to that of phenolic resins that did not contain boron. Comparison between the ^{1}H NMR spectra of the TPB and the BPR prepared at 120°C (see Fig. 1) showed that substitution of methylol groups occurred at the *ortho* and *para* positions of the ester phenyl rings (4.86–4.75 ppm). Aromatic, methylene and ether linkage protons were assigned at about 7.45–6.74 ppm, 4.93–3.36 ppm, and 5.30–4.91 ppm. The application of this system needs to be explored.

Table 2 Selected cone calorimetry results for phenolic composites

Composite resin	Time to ignition (sec)	Peak HRR (kW/m^2)	EHC (MJ/kg)	CO yield (g/g)
P	110	107	16.5	0.118
P/4-BrP 9 : 1	115	93	16.8	0.191
P/4-BrP 1 : 1	181.5	31	6.3	0.281

HRR, heat release rate; EHC, effective heat of combustion.

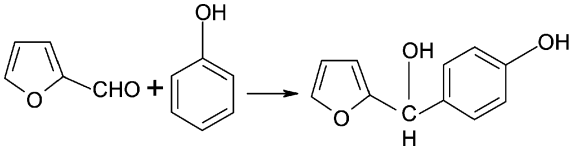
Carbonyl Derivatives

Furfural is the aldehyde most commonly used as a replacement for formaldehyde in the preparation of phenolic resins.[8] Furfural is obtained from natural sources. The naturally abundant pentosans, obtained from agricultural and forestry wastes, are hydrolyzed by dilute sulfuric acid to give furfural. The furfural is then isolated by steam distillation. The reaction of furfural under alkaline conditions is similar to that of formaldehyde, yielding *ortho*- and *para*-hydroxyphenyl furfuryl alcohol [Eq. (5)]. The polymerization of this furfural resol proceeds by a mechanism that is not fully understood. It is possible that the scission of the furan ring occurs and that this ring takes part in the polymerization reaction, leading to a complex mixture of products. The cleavage of the furan ring occurs more readily under acidic conditions, giving, however, the same complex product as in the alkaline medium.



(5)

Furfural has replaced formaldehyde in phenol–resorcinol–formaldehyde resins.[9] These formaldehyde-containing resins have been used as cold-set, exterior grade structural wood adhesives for almost half a century. The use of furfural to prepare these resins has several advantages. In addition to longer resin shelf life, when furfural is used, the emission of formaldehyde is lowered. To enhance the reaction rate when furfural is used, a small amount of formaldehyde is added to the furfural system. Hence, the furfural system is not formaldehyde-free, but nearly so. Finally, furfural has a higher molecular weight than formaldehyde. This results in a smaller amount of the expensive resorcinol being required in the system.

Modified phenolic resin applications

Phenolic resins have been used as binders for mineral wool insulation products. Typically, the phenol–formaldehyde resol used in binders for wool insulation products has large amounts of free formaldehyde. This is due to the high molar ratio between formaldehyde and phenol typically used for insulation resins. Bohumila et al. patented that the addition of a small amount of sodium tetraborate during the early stage of the formation of a phenolic resin enhances its properties. Lower molecular weight products are obtained and the resin stability appears to be improved.[10] The advantage of a stable prepolymer is that it will reduce formaldehyde emissions during transfer and storage from the manufacturing site to the user's site.

Chiu, Shelast, and Lam patented a fast curing spray-dried phenol–formaldehyde composition that contains 0.02–0.09 mol of highly reactive phenolic compounds as curing accelerators per 100 parts of the solids of the phenolic resin.[11] The curing accelerators may include resorcinol, alkyl resorcinol, *m*-aminophenol, and phloroglucinol. The curing accelerator in the powder resin functions as a cross-linking agent. This cross-linking agent reacts with the methylol groups of the resole resin under the heat and pressure experienced during the manufacture of wood composite products. The fast curing powder resin composition may be made by first preparing a resol liquid phenol–formaldehyde resin that contains the desired amount of methylol groups and of the desired molecular weight. The second step includes eliminating the residual free formaldehyde with a scavenging agent. Then, the prepared liquid resol resin is mixed with the highly reactive phenolic compound. The mixture is spray-dried to prepare a powder resin composition without realizing a chemical reaction between the highly reactive phenolic compound and the phenol–formaldehyde resin. The spray-drying process stabilizes the highly reactive phenolic compound in the phenol–formaldehyde resin composition. Besides being a fast-curing product, Chiu and coworkers named several other advantages of their formulated powder resol including good shelf life, which causes reduction in the cost of manufacturing wood composites.[11] Moreover, the powder has a high tolerance of wood moisture content, which improves the quality of the manufactured wood composites.

NONCLASSICAL PHENOLIC SYSTEMS

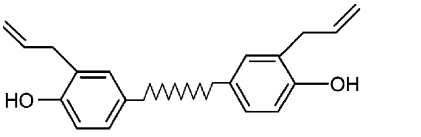
Addition-Cure Phenolic Resins

A recent review of addition-cure phenolic resins provides extensive information on the work in this area.[12] In this entry, parts of the review will be highlighted to provide a view of the importance of the work and its relationship to the classical and modified-classical phenolic resins.

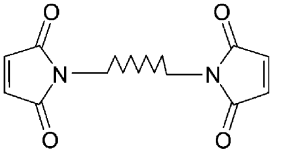
The cross-linked polymers obtained from the addition-cure approach are often a complex arrangement of atoms bonded in heterocyclic and carbocyclic rings. However, the objective in the preparation of these systems is not simplicity. It is to obtain systems with the desirable properties of phenolic resins retained and the undesirable properties improved or removed. Voids are an undesirable result in the synthesis of both resols and novolacs. Hence, addition-cure phenolic resins are designed to avoid this result. Ease and flexibility of processing are also sought in the addition-cure systems.

Diels–Alder systems

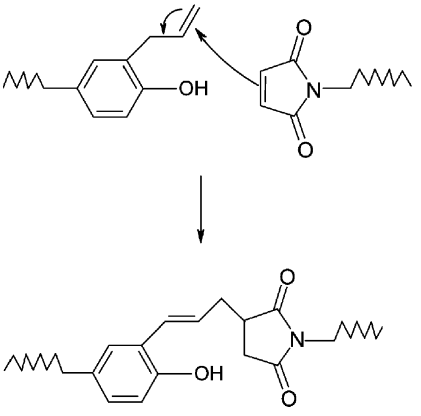
A well-studied addition-cure phenolic resin utilizes the Diels–Alder reaction for its preparation. The result is a complex polymer that originates from a diallyl phenol and a diimide (for example, see structures **2** and **3**, respectively). Initially, compounds **2** and **3** react across the double bond of the imide ring and the allylic group to generate a diene [see Eq. (6)]. Compound **2** then serves as the dienophile. The polymer forms from the reaction of the diene with **2**. The amount of **2** relative to the diene affects the properties of the resulting polymer, as does the cure temperature. Some of these properties will be summarized collectively, for all the addition-cure systems discussed in Table 3.



2



3



(6)

Rather than building the polymer through a succession of Diels–Alder reactions, the approach can be to utilize the hydroxyl groups on the backbone of a thermoplastic phenolic resin as the point of attachment for allylic groups. Heating rearranges the allylic attachment from the oxygen to the aromatic ring. Reaction of a diimide with this polymer produces the diene. The diene–dienophile reaction then proceeds to give the cross-linked addition-cure phenolic resin [see Eq. (7), formation of *O*-allyl derivative; Eq. (8), *C*-allyl

Table 3 Selected properties of addition cure polymers

	Bismaleimide/2,2′-diallyl bisphenol A[a]	Boron-containing alderenes[b]	Poly(bisoxazoline)/ Phenolic[c]	Phenolic/ epoxy[d]

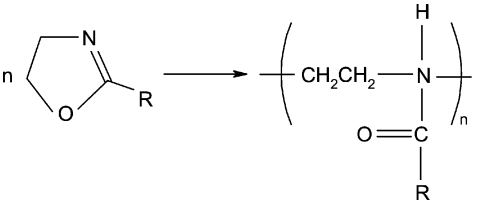
(9)

derivative formation; and Eq. (9), Diels–Alder reaction to give cross-linked polymer].

The thermoplastic phenolic resin in the above Eqs. (7)–(9) could be a novolac resin.[13,14] Similarly, the commercial polyparaalkyl phenol, Xylok, has been used in Diels–Alder reactions with diimides.[15,16] These systems have good processing properties, good mechanical properties, and superior thermal properties.

Oxazoline ring systems

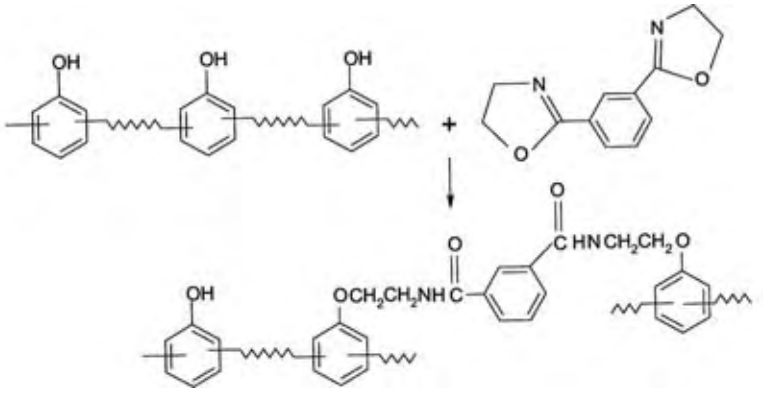
The versatile oxazoline ring has been utilized in reactions with novolacs. Oxazolines polymerize readily to give thermoplastics of various molecular weights [see Eq. (10)]. Reaction of a bisoxazoline with a novolac gives a cross-linked system that has properties dependent on the relative amounts of bisoxazoline to novolac [see below Eq. (11)]. This approach for an addition-cure phenolic resin has been commercialized.[17]



(10)

Epoxy systems

As an alternative to using hexamethylenetetramine as a cross-linking agent for novolacs, the hydroxyl group of the novolac can be reacted with epoxy reagents.[12,18,19] The variables to this approach are plentiful. The epoxy



(11)

reagent can include as possibilities classical Bisphenol-A-based, halogen-containing epoxy systems, or epoxy systems with stereochemical features. Additionally, the relative amounts of novolac and epoxy reagent can be varied. A relatively larger amount of novolac will result in a decrease in T_g and an increase in toughness for the resulting cross-linked polymer. Flammability can be controlled either through the traditional novolac or through appropriate substitutions on the epoxy reagent. A schematic for the cross-linking is shown in Scheme 3. Some properties of these systems are included in Table 3.

Enzymatically Synthesized Phenolic Polymers

This class of phenolic polymers opens a wealth of potential systems.[20–22] The preparation [Eq. (12)] involves a phenol, an oxidizing agent, and an enzyme. The polymer obtained consists of phenylene and oxyphenylene units. The attachment A is limited only by the kinetics and thermodynamics of the reaction. In a recent study, A was CH_2OH.[23] The monomer, 4-hydroxybenzyl alcohol, was polymerized using hydrogen peroxide as the oxidizing agent and horseradish peroxidase as the catalyst. The resulting polymer therefore had a CH_2OH primary alcohol pendant. The alcohol functional group was reacted with the carboxylic acid functional group of 4-(1-pyrenyl) butanoic acid to give a pendant sensitive to explosive materials (e.g., dinitrotoluene). The approach of these authors would lend itself to other applications in, for example, agriculture (herbicide and pesticide attachments) and in the pharmaceutical field.

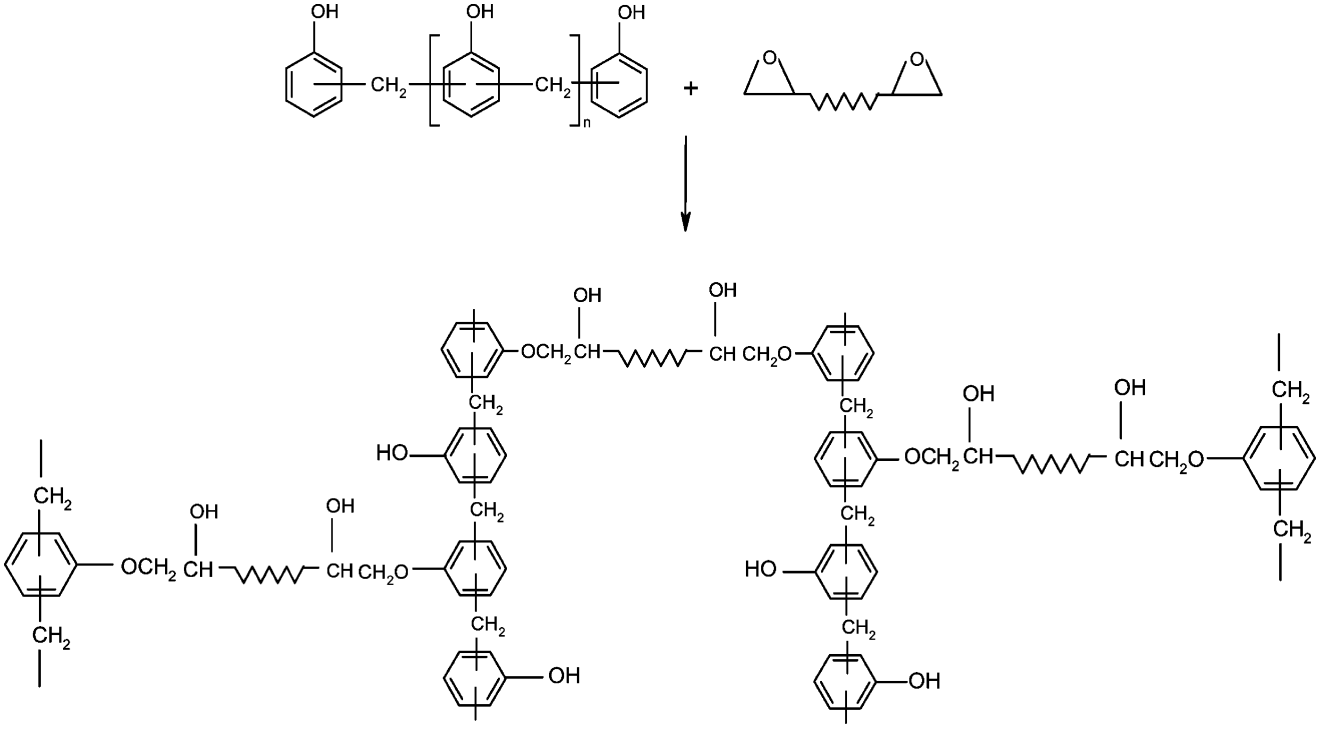
PHENOLIC RESIN NANOCOMPOSITES

General Background

The field of organic–inorganic hybrids or nanocomposites has attracted considerable attention as a method of enhancing polymer properties and extending the utility of polymers. The improvements occur through the use of molecular or nanoscale reinforcements rather than conventional particulate filled microcomposites. Among the organic–inorganic hybrids, researchers have focused mainly on the use of clay minerals as the polymer reinforcement. The clays are layered structures belonging to the general family of 2 : 1 layered silicate. The breakthrough for these materials occurred more than a decade ago when scientists from the



Scheme 3 Reaction of phenolic resins with epoxy.

Toyota Research Center reported unprecedented improvements in the mechanical properties of nylon–clay nanocomposites.[24] The Toyota Research group resolved the setback of the incompatibility of mixing between the hydrophilic-layered silicate and the organophilic polymers through chemical substitution on the surface of the clays. Typically, this is accomplished by exchanging the surface sodium cation with an organic cation, and thus producing organically modified layered silicate. As a result of the Toyota group's accomplishment, many studies on the preparation and characterization of various thermoplastic and thermoset polymer–layered silicate nanocomposites have been reported. All the nanocomposite systems reported showed new and improved properties when compared to their micro- and macro-composite counterparts and the neat polymers. The nanocomposites exhibit improved tensile strength and moduli, decreased thermal expansion coefficient, decreased gas permeability, enhanced ionic conductivity, and flammability.[24–29] Among phenolic resins, nanocomposite systems from novolacs have more reported successful results than resols.[30] One possible reason for this is that the novolac molecules have dimensions that fit easily between the silicate layers. Once the novolac molecules are in position between the silicate layers, this intercalated system can be reacted with a curing agent (e.g., hexamethylenetetramine) to give a cross-linked product. The control of exfoliation for this system is probably a function of the rate and extent of cure. For the resol system, the trisubstituted phenolic rings are larger than the phenolic rings of the novolac system. As a result, exfoliation of the silicate layers has probably begun before cure to a greater extent for the resol than for the novolac system. The distribution of the silicate layers in the resol system nanocomposite should be distinctly different from that for the novolac system nanocomposite. The control of exfoliation is also probably less for the resol system than for the novolac system. In other words, the resol system is probably more difficult to manage in the study of nanocomposites. Hence, the more easily managed novolac system has received more attention. Regardless, both systems should provide an interesting model for the molecular events in nanocomposite formation. The following two sections will present a summary of the studies that were done on phenolic resins reinforced with nanoparticles.

Novolac Nanocomposites

The earliest study cited for the preparation of novolac–layered silicate nanocomposites was reported by scientists from the Toyota Research Center.[31] Usuki et al. modified a sodium-type montmorillonite (MMT) clay with 4-aminophenol hydrochloride in water. The modified MMT was dispersed during the preparation of phenol and 37% formaldehyde solution in the presence of oxalic acid as catalyst. The prepared novolac–MMT nanocomposite was mixed with hexametylenetetramine as a curing agent and underwent press molding. The nanocomposite exhibited a heat distortion temperature of 210°C and a tensile modulus of 7.2 kg/m^2. These values were not specifically compared to those of other systems but the implication was that the nanosilicate improved the properties of the phenolic resin.

The thermoplastic nature of novolacs made it feasible to use melt intercalation to disperse nanoparticles into the polymer. The melt intercalation process involves heating the resin to a temperature just above its melting point, followed by dispersing the reinforcement in the molten resin by different mixing methods such as shear mixing. Lee and Giannelis were the first to report a preparation of a novolac–layered silicate nanocomposite via melt intercalation.[32] Choi, Chung, and Lee reported a more detailed study on preparation of novolac–layered silicate nanocomposites by melt intercalation.[30] They discussed the morphology and curing behaviors of these systems. They utilized two types of clays, natural MMT clay and synthetic fluorohectorite clay. The MMT clay was modified with dodecylammonium, octadecylammonium, and benzyldimethyloctadecylammonium salts and the fluorohectorite was modified with benzyldimethyloctadecylammonium salt. They also utilized the unmodified layered silicate for the purpose of comparison. From x-ray diffraction (XRD) data, they noted that the 12-carbon system widened the spacing between the silicate layers by 1.4 Å (12.2 Å for the pristine silicate layer spacing and 13.6 Å for the modified system spacing). The 18-carbon system widened this spacing by 6.1 Å (18.3 Å for this spacing). Attempts at melt intercalation by a novolac resin appeared very successful for the 18-carbon system. The spacing between the silicate layers increased by another 15.6 Å. Intercalation also appeared to have occurred for the pristine system (a further 3.3 Å increase in spacing). The 12-carbon system gave only a further 1.3 Å in spacing. The authors did not give any unifying rationale for these observations. However, it is possible that the micelle from the dodecylammonium salt distributes so as to occupy much of the space between the silicate layers. Hence, there is little room for the novolac resin. The octadecylammonium salt micelle may distribute so as to provide more open space for the resin. Upon cure with hexamethylenetetramine, the XRD data are interpreted to indicate that the spacing is maintained.

More recent work by Choi and coworkers involved study of octadecylammonium and the benzyldimethyloctadecylammonium salts of the previously discussed work and a bis(2-hydroxy ethyl)methyl tallow ammonium salt.[33] The tallow salt gave a slightly larger

increase in spacing between the silicate layers (19.4 Å) upon melt intercalation. The increase in spacing for the benzyl salt was approximately 18 Å in both studies. The authors examined the mechanical properties of these systems in comparison with the neat polymer. The octadecylammonium system showed no improvement up to 3 wt% of silicate, and then showed a decline in properties relative to the neat resin from 3–5 wt%. The other two modified systems showed significant improvement in mechanical properties relative to the neat polymer at all weight percents, but especially at 3 wt%. The tallow salt system gave the best mechanical properties.

Resol Nanocomposites

Byun, Choi, and Chung reported a method of preparation for resol–layered silicate nanocomposites by melt intercalation using unmodified Na-MMT and MMT modified with amino acids.[34] The amino acids utilized in Byun et al. study contained 3 carbons (β-alanine), 6 carbons (6-aminocaproic acid), and 12 carbons (12-aminododecanoic acid). Characterization by XRD and transmission electron microscopy (TEM) showed that all the prepared nanocomposites have partially exfoliated structures. Exfoliation of the layered silicate in the polymer is usually achieved through intercalation of the resin oligomers in the intergallery of the clay. Then, the intercalated oligomers undergo curing and the polymer molecules grow in size, which leads to complete disruption of the layered structures of the clay. However, in some polymer systems, including the one studied by Byun and coworkers, deintercalation of the polymer molecules from the intergallery of the layered silicate was observed to occur during the curing process. With the exception of the C6-MMT–resol system, Byun and coworkers observed deintercalation of the polymer to occur during the cure cycle for all the nanocomposite systems. Based on the findings about the degree of deintercalation, the C6-MMT was selected as the most compatible modified layered silicate with the resol polymer. The excellent compatibility between the C6-MMT and the resol prevented the deintercalation of the polymer from the intergallery of the layered silicate. At the initial stages of curing, the unmodified MMT–resol system showed a rapid expansion in the spacing between the silicate layers, which typically leads to exfoliation of these layered structures. This was attributed to the high compatibility between the hydrophilic unmodified MMT and the hydrophilic resol. However, at later stages of curing, this system showed the highest degree of deintercalation when compared to the other systems. This was attributed to the severe reduction in the compatibility between the resol and the unmodified MMT due to reduction of the methylol groups that are consumed during curing.

The mechanical properties of the C3, C6, and C12 nanocomposites were all significantly better than those of the neat phenolic resin, even if a very small amount of the silicate was used. Among the nanocomposites prepared, the organically modified MMT–resol systems showed better mechanical properties than those of the unmodified MMT–resol system. This improvement was attributed to the formation of an end-tethered structure due to the reaction of the carboxylic acid of the organic modifier with the methylol group of the phenolic resin. Thermogravimetric analysis reported by Byun and coworkers showed that the nanocomposite systems had similar thermal stability to that of the neat polymer.

Wang et al. reported preparation of resol nanocomposites by polymerizing phenol and formaldehyde in the presence of MMT modified with hydrochloric acid.[35] X-ray diffraction analysis for the acid-modified MMT–resol showed exfoliated structures for nanocomposites with low silicate contents (3 and 5 wt%) after 2.5 hr of curing time. However, in the XRD curve for the 10 wt% nanocomposite, a weak peak attributable to the (001) plane of MMT was observed. This suggested that complete exfoliation was not achieved in the 10 wt% nanocomposite. Both scanning electron microscopy and TEM analyses for the nanocomposite systems agreed with the XRD results. Wang et al. explained that exfoliation occurred in the acid-modified MMT–resol nanocomposites because of the presence of the protons in the intergallery of the MMT. The protons had a catalytic effect on the polymerization of the resol in the intergallery of the MMT, which resulted in the exfoliation of the layered structures. Dynamic mechanical analysis showed an approximately 60°C increase in the T_g of the nanocomposites in comparison to the neat resol. Similarly, a 53% improvement in the impact strength of the nanocomposites was reported.

CONCLUSIONS

Phenolic resins continue to be an important material at both the commercial and the research levels. These complex systems are fascinating not only because of their current usefulness, but also because of their potential to become even more useful materials of the future. The classical phenol–formaldehyde system is deceptively simple and lends itself to much variation depending on factors such as pH, molar ratio of reactants, preparation/cure temperature, and curing agents. The desire to enhance the properties of phenolic resins and expand the processing options has led to considerable work on modified-classical and nonclassical phenolic resins.

The modified-classical phenolic resins are particularly noteworthy for their effect on the mechanical and thermal properties of the cured resin. The processing of these systems is very similar to the classical systems. The nonclassical phenolic resins utilize phenol, but in many cases give a cured product with a chemical structure having little resemblance to the classical system. In future articles, it would be best to develop independent grouping for ''addition-cure phenolics resins.'' This redefinition of polymer types is not within the scope of this entry and instead, this interesting class of polymers has been viewed based on current designations.

The work on nanocomposites utilizing novolacs and resols can be considered preliminary and promising. The very subtle differences between novolacs and resols appear to have the potential to contribute to significantly different nanocomposite systems. The distinct separation of the silicate layers may provide the basis for the properties of nanocomposites prepared as novolacs or resols.

Photodegradation of Polymers

J. R. White
School of Chemical Engineering and Advanced Materials, University of Newcastle Upon Tyne, Newcastle Upon Tyne, U.K.

INTRODUCTION

Photodegradation of polymers is generally accepted as the main factor that limits their use in outdoor applications. It is caused by the ultraviolet (UV) component of solar radiation and is a serious problem in the sunniest climates. Artificial sources of UV also cause photodegradation and may disqualify polymers from use in certain applications. The sensitivity of polymers to artificial UV radiation has led to the development of accelerated aging laboratory equipment for assessing the weathering properties of polymers. Radiations such as γ-radiation that possesses greater energy than UV can also produce photodegradation and this may restrict the choice of materials used in certain nuclear installations. Photodegradation caused by γ-radiation is also of concern in medical implants such as acetabular cups used in hip prostheses because γ-radiation is an option for sterilization prior to inserting the implant. This is rather specialized, however, and the fundamental chemical and physical consequences of exposure to γ-radiation are not very different from those obtained with UV radiation; hence this entry concentrates exclusively on UV photodegradation. Most research into photodegradation has been conducted in atmospheric air because this relates to the majority of practical cases and is reflected on this entry. Although the weathering of polymers remains the focus of much research, the subject is well established, and for a balanced view of the scientific background and practical issues, the review provided by Davis and Sims in 1983 remains unsurpassed.[1]

The chemical mechanisms of degradation are dealt with first, followed by the physical consequences of the chemical changes. This leads to a consideration of the changes in engineering properties. Procedures for testing the photodegradability and weather resistance of polymers are then discussed. Much research has been directed into the development of photostabilizers that prolong the lifetime of polymers and this important and highly successful enterprise is dealt with next. Finally, some consideration is given to the recycling of photodegraded polymers.

CHEMICAL MECHANISMS OF PHOTODEGRADATION

Degradation Reactions

Polymer photodegradation proceeds by a radical chain process initiated either by dissociation caused by the collision of a UV photon with a polymer molecule or as the result of some impurity present, such as a polymerization catalyst.[2] Visible light photons and UV photons with wavelengths just less than the visible band are generally not energetic enough to cause the formation of radicals in polymers. The Earth's atmosphere scatters or absorbs all photons with wavelengths below about 290 nm, but photons with wavelengths in the range 290–340 nm are quite effective in forming radicals in many polymers. Lower wavelength (higher energy) photons may cause additional reactions but are not considered in this entry.

The chain reaction has four main stages:

1. *Initiation*, in which the long chain polymer molecule, PH, is converted into a radical:

$$PH + O_2 \rightarrow P^{\bullet} + HO_2^{\bullet} \quad (1)$$

There is a high probability that the radical will be located somewhere along the chain rather than at a terminal site.

2. *Propagation* also involves reaction with oxygen:

$$P^{\bullet} + O_2 \rightarrow POO^{\bullet} \quad (2)$$

$$POO^{\bullet} + PH \rightarrow POOH + P^{\bullet} \quad (3)$$

3. *Chain branching* involves hydroperoxides formed in reaction (2):

$$POOH \rightarrow PO^{\bullet} + HO^{\bullet} \quad (4)$$

$$2POOH \rightarrow POO^{\bullet} + PO^{\bullet} + H_2O \quad (5)$$

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007895

Radicals formed in (4) and (5) re-enter the propagation phase via the following reactions:

$$PO^{\bullet} + PH \rightarrow POH + P^{\bullet} \quad (6)$$

$$HO^{\bullet} + PH \rightarrow P^{\bullet} + H_2O \quad (7)$$

4. *Termination* involves the reaction of pairs of radicals:

$$P^{\bullet} + P^{\bullet} \rightarrow \text{inactive products} \quad (8)$$

$$P^{\bullet} + POO^{\bullet} \rightarrow \text{inactive products} \quad (9)$$

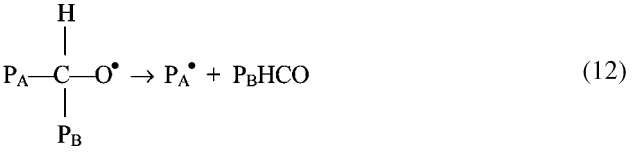
$$POO^{\bullet} + POO^{\bullet} \rightarrow \text{inactive products} \quad (10)$$

The reactions may be catalyzed by trace metal impurities such as polymerization catalyst residues or contaminants from processing machinery. The reaction scheme is similar to that in thermal oxidation, differing only in the method of initiation and in the relative reaction rates (which are likely to be quite different at the higher temperatures normally required for thermal initiation).

In solid polymers, the propagation and termination reactions are controlled by diffusion. Large macroradicals have very restricted motion in the solid phase, either because they are restrained by entanglements in the case of amorphous polymers, or are tethered by segments within the crystal phase in semicrystalline polymers. Spatial propagation of degradation can proceed by way of translational diffusion of low molecular weight radicals formed by the decomposition of peroxide or alkoxyl macroradicals. Decomposition of a peroxide radical, $POO^{\bullet}$, creates a small radical, $r^{\bullet}$, which then diffuses to a new site where it reacts with a hydroperoxide molecule to form a new macroradical in a radical exchange reaction:

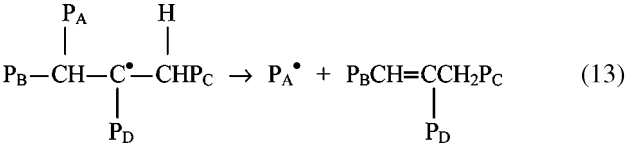
$$r^{\bullet} + POOH \rightarrow rH + POO^{\bullet} \quad (11)$$

Consequently, the peroxide radical effectively moves from the initiation site by a distance that depends on the diffusion rate of the small radical (and hence on the temperature, etc.) and on the reaction rate for reaction (11). In reactions (1)–(11), the long chain nature of the molecules is preserved almost unchanged. If the termination reaction (8) is by cross-linking rather than by disproportionation, then a significant change in the molecular size occurs and this will cause a significant change in the properties of the polymer. Analysis of photodegraded polymers usually shows that the predominant effect is chain scission, however, and this is not specifically covered by reactions (1)–(11). Scission releases chain entanglements in amorphous polymers and breaks tie molecules in semicrystalline polymers and, hence, has a very strong influence on the properties. Chain scission occurs through the decomposition of unstable species, especially hydroperoxides, and may be caused by UV radiation. Decomposition occurs by chain scission adjacent to the hydroperoxide group, at the position of the original site of the radical created in reaction (1). Hydroperoxides produced by reaction (3) or by other means can be decomposed by UV photons with wavelength below 360 nm giving a $PO^{\bullet}$ radical, as shown in reaction (4). β-Scission of the alkoxy radical produces two smaller molecules, one of which is a radical and may participate in further reactions of the kind shown earlier:



(12)

Alkyl radical decomposition produces a similar result:



(13)

Decomposition of hydroperoxides is a key feature in the degradation of polyolefins and may include reactions of the kind:

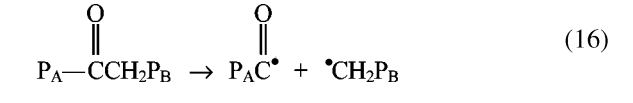
$$POOH \rightarrow P^{\bullet} + {}^{\bullet}OOH \quad (14)$$

$$POOH + PH \rightarrow PO^{\bullet} + P^{\bullet} + H_2O \quad (15)$$

These lead to chain scission through decomposition of radicals as in reactions (12) and (13).

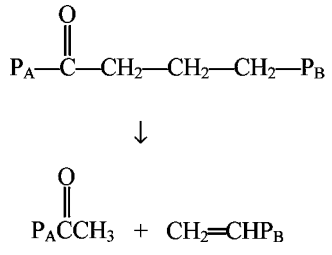
Carbonyl groups are frequently produced during polymer degradation making the material vulnerable to further deterioration because they are photolabile. Aldehyde and ketone carbonyl groups are common defects produced during polymer processing and may partake in photolytic decomposition reactions in the fabricated article, as in the following example for aliphatic ketones:

- *Norrish type I*:



(16)

- *Norrish type II*:



(17)

Kinetics of Polymer Photodegradation

The production of carbonyl groups can be used to determine the rate of oxidation caused by UV exposure. Fig. 1 shows the progressive increase in carbonyl group concentration measured using Fourier transform infrared (FTIR) in a series of polyethylene samples exposed to UV irradiation in the laboratory. It is frequently observed that there is an induction period during which there is no indication of change in many of the measures of degradation, including carbonyl group development. In Fig. 1, this is shown by the unpigmented polyethylene sample and also by the one containing the rutile form of TiO_2, a pigment that can provide some protection against UV irradiation. Both these samples also show evidence for autoacceleration whereby the rate of reaction increases progressively. This is hardly surprising in view of the role of reaction products in promoting further reactions, discussed in the earlier section. An alternative explanation for the acceleration in rate has been given by George et al.,[3] who proposed that infectious spreading of reaction is responsible. In their view, active species (e.g., free radicals) may migrate a finite distance before reacting and setting up a new zone of reaction. The third sample for which data are given in Fig. 1 is polyethylene pigmented with the anatase form of TiO_2. Anatase is a photocatalyst and is responsible for the different kinetic behavior. Finally, it is noted that carbonyl groups are both created and destroyed during photo-oxidation and that conclusions concerning the progress of degradation of the polymer should not be made based on carbonyl group accumulation alone.

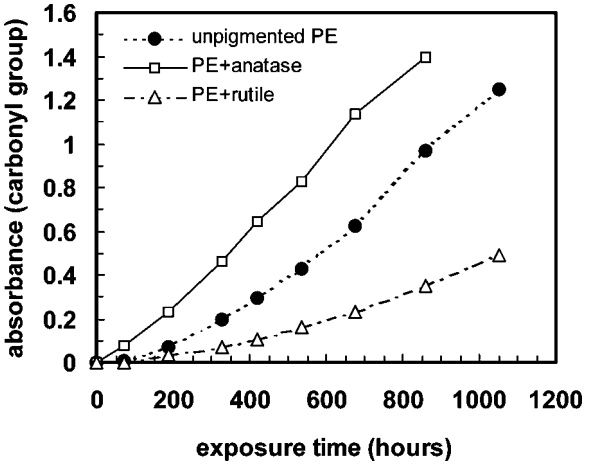


Fig. 1 Carbonyl group development in polymer samples exposed to UV illumination. The materials were an unpigmented polyethylene sample and similar samples pigmented with 5 phr TiO_2 pigment in the form of (i) anatase and (ii) rutile. (Data from Jin, C.Q. Ph.D. thesis, University of Newcastle upon Tyne, 2004. See also Jin, C.; Christensen, P.A.; Egerton, T.A.; White, J.R. Effect of anisotropy on photomechanical oxidation of polyethylene. Polymer **2003**, *44*, 5969–5981.)

A full kinetic analysis of photodegradation is very difficult because of the large number of reactions and reagents involved. Many of the reagents are both created and destroyed by reaction, and keeping track of their concentrations in a computed analysis is a formidable challenge. A similar problem is present in thermal degradation of polymers. Despite the difficulties, significant contributions have been made by Audouin et al.[4] and Gillen, Wise, and Cough.[5] This approach has been particularly valuable in the study of the depth profile of degradation that develops when reaction is oxygen diffusion limited, as discussed later.

Molecular Degradation Products

The feature most responsible for the special properties associated with polymers is their molecular weight. The molecular weight distribution (MWD) is an important characteristic to track the progress of photodegradation. Fig. 2 shows the MWD for a low-density polyethylene (LDPE) obtained using gel permeation chromatography (GPC) in the unexposed state and after laboratory UV exposure. The unexposed polymer had a fairly broad MWD. The MWD for the material at the exposed surface shifted very significantly to the left (lower molecular weight) showing that molecular chain scission was dominant. Smaller leftward shifts are shown for material deeper in from the exposed surface. In addition, a high molecular weight tail developed with a small but significant fraction of material having higher molecular mass than the largest molecular mass fraction in the unexposed sample. This is attributed to cross-linking.

Shyichuk has developed a Monte Carlo method of computer-aided simulation of the MWDs of degraded polymer derived from the MWD of the unexposed polymer and assuming scission and cross-linking are random events. The results of trial scission cross-linking concentrations are compared with measured MWDs for the exposed samples using the sum of the squares of the

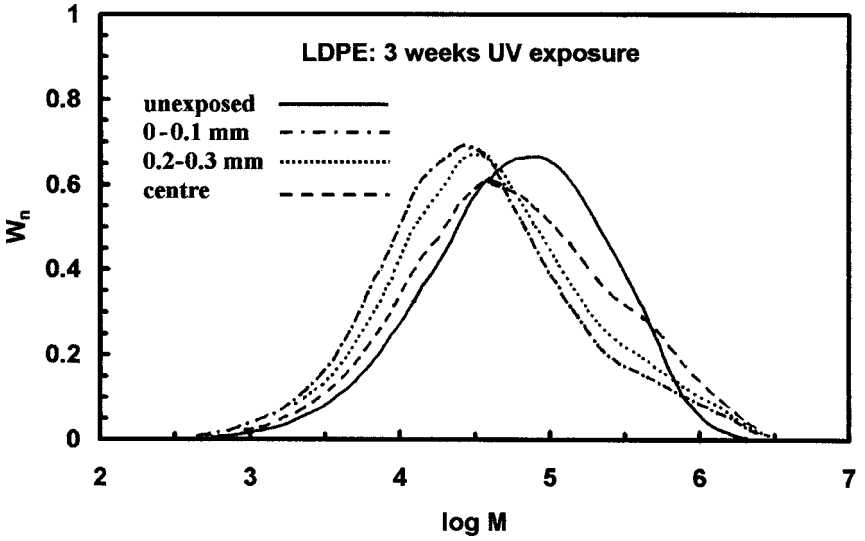

Fig. 2 Molecular weight distributions obtained from GPC analyses of layers of 0.1 mm thickness taken at different depths from the exposed surface of an LDPE bar after 3 weeks of UV exposure. The MWD for unexposed material is shown for comparison. (More details on the study from which these data are taken are given in Craig, I.H.; White, J.R.; Shyichuk, A.V.; Syrotynska, I. Photo-induced scission and cross-linking in LDPE, LLDPE, and HDPE. Polym. Eng. Sci. **2005**, *45*, 576–587.)

residuals at the data points to assess the closeness of fit and to determine the best values.[6] Fig. 3 shows results from this kind of analysis for polypropylene samples exposed in the laboratory for two different times. Samples were taken at different depths from the exposed surface of 3 mm thick bars. Scission dominated at all depths.

In addition to the macromolecular fragments, many small molecule species are formed during photodegradation. The smallest molecules migrate to the surface and are lost by a variety of mechanisms including volatilization. Although they no longer influence the properties of the material that remains behind, they can be used to monitor the progress of photodegradation in carefully controlled laboratory tests. Christensen, et al. have developed a method in which the sample under test is exposed to UV in a specially designed cell that allows simultaneous interrogation of the gaseous phase in an FTIR spectrometer.[7] Carbon dioxide evolved during photodegradation accumulates in the cell and the concentration is monitored continuously. This method was first applied to the study of paints[7] and its sensitivity can produce an assessment of the UV-oxidizability of a sample in a fraction of the time required using the carbonyl analysis method. This is shown by the results given in Fig. 4 for polyethylene samples. Figs. 1 and 4 are based on data obtained with the same

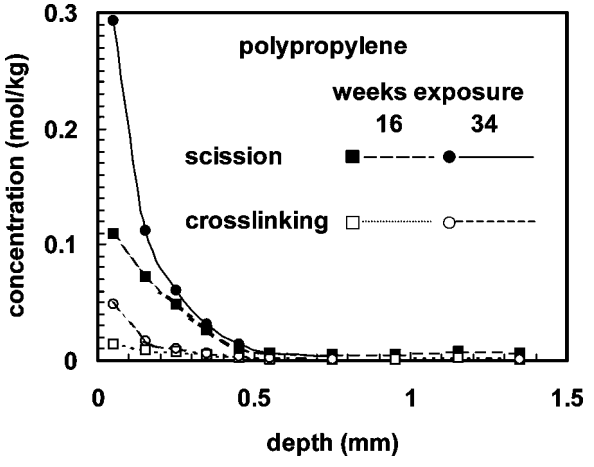

Fig. 3 Scission and crosslinking concentrations produced in polypropylene after 16 weeks and 34 weeks of UV exposure in the laboratory. Samples taken at different depths from the exposed surface. Each sample was 0.1 mm deep: the corresponding result is plotted at the midpoint of the layer. (More details in Shyichuk, A.V.; Turton, T.J.; White, J.R.; Syrotynska, I.D. Different degradability of two similar polypropylenes as revealed by macromolecule scission and crosslinking. Polym. Degrad. Stab. **2004**, *86,* 377–383.)

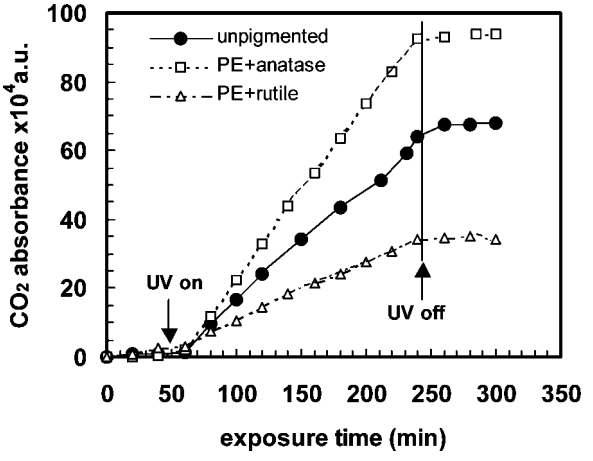

Fig. 4 Accumulated carbon dioxide emitted from polymer samples exposed to UV illumination from an unpigmented polyethylene sample and similar samples pigmented with 5 phr TiO_2 pigment in the form of (i) anatase and (ii) rutile. (Data from Jin, C.Q. Ph.D. thesis, University of Newcastle upon Tyne, 2004.)

materials and it is evident that the same ranking is obtained. Fig. 4 shows that a significant carbon dioxide signal was obtained almost as soon as the UV illumination was switched on: there was no apparent induction time. The rate of accumulation of CO_2 reduced almost to zero on switching off the illumination. The potential of this technique is not only for rapid assessment, it also permits convenient arrangement of experiments to test the effect of changing the atmosphere around the sample (especially by changing the oxygen concentration) or changing the spectral distribution in the illumination.

Environmental Effects

It is often observed that photodegradation of polymers occurs more rapidly in humid air than dry air. For this reason, tests should be conducted in controlled-humidity enclosures. Some popular commercial UV exposure cabinets include periodic water spray or temperature cycling that induces condensation of water onto the sample surface. The effects caused by this treatment are not confined to altering the reaction chemistry scheme and may include modifying the residual stress distribution because of chilling the surface. Pollutants, especially sulfur dioxide and oxides of nitrogen, may accelerate polymer degradation in the presence of UV. Ozone can attack polymers, especially if unsaturated. It is so aggressive toward rubber that perishing of rubber under tensile stress is often attributed to ozonation and the effect of photodegradation is disregarded as a possible cause. However, Maillo and White provided evidence for very significant photo-oxidation under these conditions.[8] They used a mask to partially cover the surface of rubber samples while being exposed to UV in the stretched state and showed that visible degradation was almost absent behind the mask, whereas in the illuminated zone immediately adjacent to the edge of the mask very substantial degradation occurred (Fig. 5).

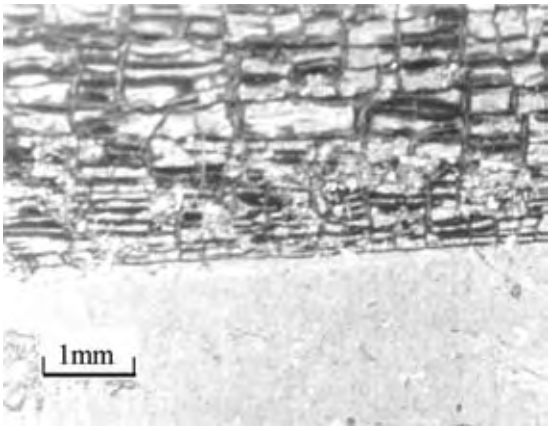

Fig. 5 Surface of blend of natural rubber and butadiene rubber (45 : 55) after UV exposure while under tensile stress (applied parallel to the vertical). The lower part of the sample was shielded from the UV illumination and suffered very much less visible degradation than the upper zone. (See also Ref.[8].)

PHYSICAL ASPECTS OF PHOTODEGRADATION

Oxygen Diffusion Limited Degradation: Depth Profiling

When many polymers are exposed to UV levels similar to those on a sunny day near to the equator, photodegradation reactions proceed very rapidly and the rate of oxygen consumption is very high. With some polymers, oxygen diffusing into the material from the exposed surface is consumed by reaction before it can penetrate very far. Therefore, under a period of sustained UV exposure, any oxygen that had accumulated in the interior of the sample prior to exposure is rapidly consumed and the reaction rate in the interior then becomes very slow because of oxygen starvation. Because of this, a strong degradation gradient develops, with the material at the surface becoming extensively degraded,[9] while that at depths of the order of 1 mm may be relatively unchanged. Examples of this can be seen in Figs. 2 and 3. If characterization measurements are conducted across the whole sample section,

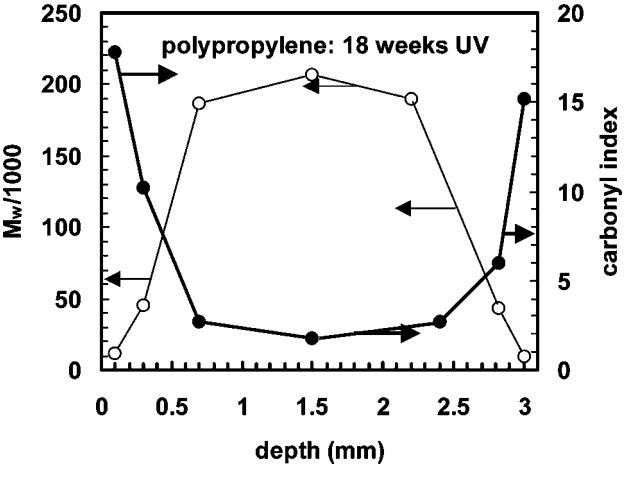

Fig. 6 Depth profiling in 3 mm thick polypropylene bar exposed to UV in the laboratory for 18 weeks. The exposed surface was at depth = 0. The steep gradients for both the carbonyl index and the weight average molecular weight at the back face indicate that oxygen starvation in the interior of the bar is the dominant factor rather than UV intensity. (Data from Rabello, M.S. Ph.D. thesis, University of Newcastle upon Tyne, 1996.)

through to the side that received no direct illumination (back face), it is sometimes observed that the degradation near to the back face is almost as advanced as that near to the exposed face (Fig. 6).[10–12] This can occur even when the UV levels in the interior and at the back face are very much less than those at the illuminated face because of absorption and scattering in the sample, a significant effect in polypropylene.[12] Attempts to take into account diffusion limited effects in models for the kinetics of photodegradation have reproduced the observed depth profiles fairly faithfully.[4,5,13]

Chemicrystallization

When a crystalline polymer is photodegraded, the oxidation occurs almost exclusively in the amorphous phase because oxygen can diffuse relatively freely through it but does not enter the crystal phase to a significant degree. When chain scission occurs, molecule segments that were previously relatively immobile because of entanglements or because of their attachment to a neighboring crystal become free to move. Some of them may rearrange and add to the growth faces of the crystals (or may even nucleate new crystals). Unless the photodegradation is very advanced, no damage accrues in the crystal phase and there is an increase in the crystallinity of the material. This is an example of chemicrystallization. An illustration of this phenomenon is given in Fig. 7, which shows data obtained for a linear low-density polyethylene in the form of 3 mm thick bars. Crystallinity measurements were made using differential scanning calorimetry on samples taken at different depths from the surface of an unirradiated bar and one exposed to UV in the laboratory for 6 weeks. Near the exposed surface the crystallinity in this material increased by up to 6%, a very substantial change, in view of the sensitivity of polymer properties to crystallinity. The change in the center of the 3 mm thick bar was very small, another example of oxygen diffusion-limited reaction. In Fig. 7, there appears to be a small drop in crystallinity after UV exposure but this is probably because of a small sample-to-sample variation and/or experimental error. The depth profile in crystallinity will contribute to the depth profile in other properties, such as density.

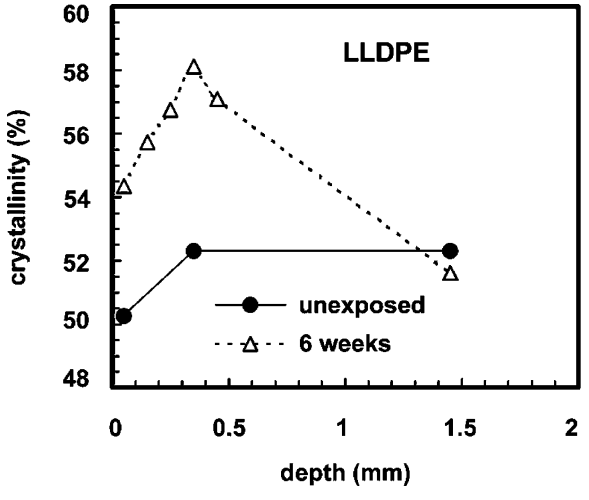

Fig. 7 Changes in crystallinity near to the surface of a linear lowdensity polyethylene bar exposed to UV in the laboratory for 6 weeks. Samples taken at different depths from the exposed surface. Each sample was 0.1 mm deep: the corresponding result is plotted at the midpoint of the layer. (More details in Craig, I.H.; White, J.R. Crystallization and chemicrystallization of recycled photo-degraded polyethylenes. Polym. Eng. Sci. **2005**, *45*, 588–595.)

ENGINEERING PROPERTIES—CONSEQUENCES OF PHOTODEGRADATION

Mechanical and Fracture Properties

The molecular changes that occur as a consequence of photodegradation almost always lead to a reduction in both strength and toughness of the polymer article. Entanglements in the amorphous phase of the polymer are essential for the mechanical integrity and obstruct the passage of a crack, and it is inevitable that their release by photoinduced chain scission will reduce the strength and the toughness of the material. It might be expected that photoinduced cross-linking would have the opposite effect, but it is generally observed that it also leads to embrittlement, presumably because it restricts molecular motion and reduces the range of deformation mechanisms available to produce toughening. The loss of toughness is sometimes very rapid and devastating. Polypropylene, normally a quite tough polymer, can effectively lose all toughness within a week of exposure to solar radiation in an equatorial region if it does not contain photostabilizers.

When the UV intensity is sufficient to produce depth profiling of the kind discussed earlier, it is the surface that becomes embrittled. Cracks nucleate and grow easily in the surface layer and rapidly reach the less degraded material in the interior (Fig. 8). If the embrittled zone is of sufficient depth, then the surface crack will constitute a critical stress-concentrating flaw and the crack will propagate into and through the rest of the section when sufficient stress is applied. This behavior follows closely the rules of fracture mechanics. After prolonged exposure, the surface may become so fragile that it forms multiple fractures (that may mutually unload) and/or it may have insufficient mechanical integrity to transmit stress into the underlying relatively undegraded material. At this point, it may

Fig. 8 Surface of polypropylene bar after 80 weeks of UV exposure followed by uniaxial tensile test. Bar axis is vertical. Cracks formed in degraded layer, perpendicular to stress axis. Degraded surface is very fragile and easily parted from underlying material that is less degraded. Degradation tends to be greatest nearer to the corner, possibly because oxygen can diffuse into the surface layers from two adjacent surfaces. (Courtesy of T.J. Turton. See also Refs.[16,24].)

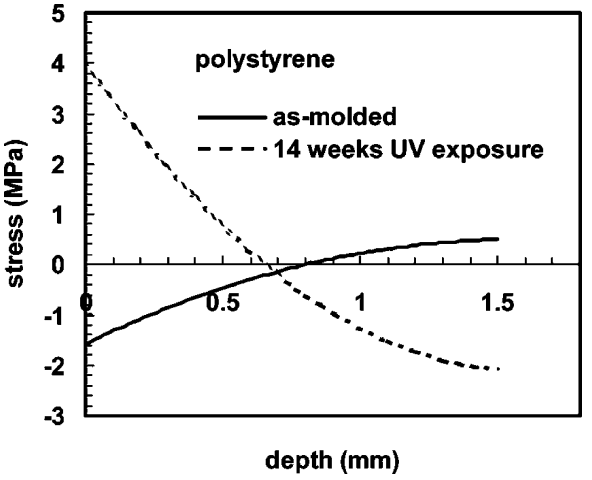

Fig. 9 Residual stress distributions in injection molded polystyrene bars in the as-molded state and after 14 weeks of ultraviolet (UV) exposure in the laboratory. The bars were approximately 3 mm thick and the distributions are shown as a function of depth from the (exposed) surface. (See Ref. [18])

be possible to observe some recovery of strength and toughness because the relatively undegraded material in the interior retains its strength and toughness, and supports the applied load.[14,15] Such recovery can be observed during a series of carefully controlled laboratory tests but is not of any practical value because, while in service, the component will fail as soon as it experiences a critical load and this is likely to happen when strength is near to the minimum and the component will not survive to reach the''recovered'' state.

Inspection of fracture surfaces of photodegraded polymers often reveals the presence of a smooth brittle zone near to the surface and a much more ductile fracture in the interior. The brittle zone depth often corresponds to that of the highly degraded depth obtained by FTIR or molecular mass measurements.[16]

Residual Stresses

Polymer articles made by injection molding, or any other molding operation in which a large temperature gradient exists while the material within the molding is solidifying, contain residual stresses.[17] When the molding is made from a hot melt that cools inside a cold mold, the stress in the interior is tensile because of thermal shrinkage of the core material as the molding cools; this is resisted by the previously solidified skin, which is then under compression. When photodegradation occurs, the material near the surface usually shrinks. In the case of a semicrystalline polymer, this is the result of chemicrystallization, the crystal density being significantly greater than the amorphous density in most polymers. A similar phenomenon has been observed to occur in polystyrene (Fig. 9 and Ref.[18]) and has been attributed to densification of the photodegraded material near to the surface caused by accelerated aging.[19] Similar changes in residual stresses have been observed in samples exposed to natural weathering.[20,21]

There are several reasons to be concerned by the changes in residual stress promoted by photodegradation. Flaws from which cracks grow and cause the ultimate failure of components (whatever material they are made from) are more likely to occur at the surface than in the interior. This is especially unfortunate because of the ease with which a critical strain can be applied at the surface while bending. The compressive stresses that are normally present at the surface in polymer moldings in the as-molded state discourage the formation and propagation of cracks and, therefore, toughen the material. Their loss is consequently detrimental and this is exacerbated if the stresses are reversed, becoming tensile at the surface, especially if the material at this position has become embrittled by photodegradation. If the changes in residual stress occur preferentially at one surface (e.g., the exposed surface), then the stresses through the section become imbalanced and the molding distorts; in some applications this will be unacceptable.

PHOTOSTABILIZATION

Most commercial polymers contain thermal stabilizers to protect against oxidation during processing at elevated

temperature, and many contain photostabilizers that can produce quite spectacular improvements in their lifetime in aggressive UV environments.[22] Protection against photo-oxidation can be provided by UV screening, UV absorption, excited state deactivation, free radical scavenging, and hydroperoxide decomposition.[22,23] UV screening may be provided by a reflective coating or by including pigments such as carbon black or TiO_2 (which are often present to provide other desirable properties).

Photodegradation is confined to the surface regions in the presence of such additives because UV penetration is restricted to very short distances. Some grades of TiO_2 photosensitize the material and must be used with caution. Ultraviolet absorption can be provided by additives such as hydroxybenzophenones, hydroxyphenylbenzotriazoles, hydroxyphenyltriazines, and derivatives of phenyl salicylates that are (almost 100%) transparent to visible light and do not alter the appearance of the product while having transmittance close to zero for all wavelengths below about 400 nm. The absorber must be able to dissipate the energy absorbed without damaging the neighboring polymer; as with screens, the presence of UV absorbers causes the UV intensity to drop rapidly as it penetrates into the material and degradation is concentrated even more sharply near the surface than is the case when no absorber is present. Excited state deactivation (or quenching) provides a method for the dissipation of energy absorbed by a polymer chromophore that would otherwise cause chain scission. As with UV absorbers, the quencher must be able to dissipate the acquired energy.

Radical scavengers limit photodegradation damage by breaking the oxidation chain. In the chain-breaking donor mechanism, a hydrogen atom is donated by (usually) a hindered phenol to an alkoxyperoxyl radical to form a hydroperoxide. Alkyl radicals are rendered ineffective by the chain-breaking acceptor mechanism for which suitable stabilizers include free radicals such as nitroxyls and phenoxyls that are relatively stable and do not themselves initiate reactions with the undamaged polymer. It is believed that some stabilizers, including the hindered amines, act via cyclic reaction paths so that they are regenerated and can be effective at lower concentrations or for longer periods of time than would otherwise be expected. This type of stabilizer can have a quite different effect on the depth profile to that produced by UV absorbers. The very much reduced reaction rate results in much slower oxygen consumption and there is ample opportunity for oxygen to diffuse into the interior of thick-walled articles. Therefore, oxidation is not diffusion-rate limited and proceeds at almost the same rate at all depths.[24] Thus, even though the reaction is slow, the rate of degradation at large depths from the surface is much greater than that in the absence of stabilizer.[24]

Hydroperoxides are potent photoinitiators and their decomposition into inactive products is an important method of stabilization in polyolefins for it prevents generation of radicals by reactions such as (4), (5), (14), and (15). Decomposition of hydroperoxides can be achieved by a reaction with phosphite esters or nickel chelates or by a catalytic action by a range of compounds including dithiocarbamates and mercaptobenzothiazoles. Decomposition of hydroperoxides formed during processing is important for the stabilization of PVC.

The distribution of stabilizers in a polymer article has a significant influence on their effectiveness. They have greatest influence when located at the surface. If they are lost by volatilization, surface migration, or consumed by reaction, it is an advantage if stabilizer can be replenished at the surface by diffusion from the interior, favoring low molecular mass stabilizers. Conversely, higher molecular mass molecules are less likely to be lost by volatilization or migration. The effect of stabilizer molecular mass has been studied by Gugumus.[25] Further immobilization of the stabilizer can be achieved by copolymerizing it with the polymer or by photografting to the polymer at a later stage. This has the additional advantage of ensuring that the stabilizer does not phase-separate from the polymer; solubility of stabilizers in polymers is often low, limiting the maximum useful concentration.

TESTING

Much of the testing of the photodegradation properties of polymers is conducted with the objective of determining their suitability for outdoor use, where solar radiation is usually the principal hazard. Natural exposure, even in an extreme climate, is too slow for many commercial requirements and suffers from the further objection that there are no simple ways to calibrate one climate against another. There are many strategies for accelerated artificial weathering in the laboratory, but it is difficult to calibrate one conditioning procedure—natural or artificial—against another. The purpose of testing is (i) to rank polymers according to their resistance to UV photodegradation; (ii) to determine whether additives, including stabilizers, have a beneficial or a detrimental effect; and (iii) to predict lifetime in service. The first two are relatively easy to achieve, though the ranking may differ (slightly) from one UV environment to another. The third one is extremely elusive and has been achieved only for very closely specified materials operating in very well defined environments.

The testing of photodegradation properties normally consists of a conditioning exposure of known characteristics followed by interrogation of the degraded sample by means of chemical analysis, structural/morphological characterization, and mechanical/engineering analysis.[26] Conditioning can be natural (usually in an extreme climate) or artificial. Acceleration of UV degradation can be achieved by using high intensities, though use of intensities higher than the maximum terrestrial UV levels may provoke degradation that is not only more rapid but different in kind to that obtained in service. Even less advisable is the use of UV sources with wavelengths lower than those in solar radiation as this may provoke chemical degradation pathways not found with higher wavelength radiation.[27] Popular chemical characterization techniques include FTIR, to determine the type and abundance of reaction species, and GPC to obtain the molecular mass distribution.

Morphological characterization can be conducted by light and electron microscope techniques and by X-ray diffraction and thermal analysis, often used to determine crystallinity. Standard mechanical tests can be used to determine strength, extension to break in tension, and toughness. Normally, a selection of characterization methods is used with samples exposed for selected periods. When mechanical tests are used, the exposure period increment must be fairly short, in case a recovery phenomenon is present (see the section ''Engineering Properties—Consequences of Photodegradation''). Other tests related to appearance, such as gloss or color, may be employed if relevant to the service application.

A departure from the conventional ''expose then test'' procedure in which these two activities are separated, has been described recently in which the carbon dioxide emitted as the result of photodegradation is collected and measured in a quasicontinuous manner while the exposure is in progress.[7]

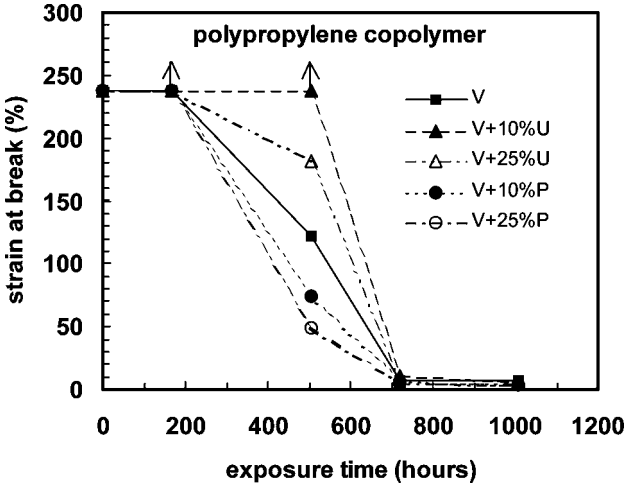

Fig. 10 Strain at break Vs. UV exposure time for polypropylene copolymer bars made from (a) virgin polymer (V); (b) virgin polymer + ''undegraded'' recyclate (U); (c) virgin polymer + photodegraded recyclate (P). Results for blends with recyclate contents of 10% and 25% are shown. (More details in Craig, I.H.; White, J.R. Mechanical properties of photo-degraded recycled photo-degraded polyolefins. J. Mater. Sci. **2006**, *in press*.)

RECYCLABILITY OF PHOTODEGRADED POLYMER

There is ever increasing pressure to recycle materials. Although thermoplastic polymers might be expected to be amenable to recycling, photodegraded polymers may present difficulties. Photodegradation creates active species that readily partake in further degradation reactions. Reprocessing may not destroy the activity. Even if the active species are lost by reaction during reprocessing (for example at elevated temperatures in mixing, extrusion, or molding), the reaction products will often be prodegradants and will be present to accelerate photodegradation of the recyclate during its new lifetime.[28,29] An example of prodegradation action is given in Fig. 10.

The addition of new stabilizer to recycled polymer (''restabilization'') is, therefore, required not only to replace the stabilizer consumed in the first life of the material, but also to attempt to combat the effect of the presence of prodegradants.[30]

CONCLUSIONS

Photodegradation of polymers is a complex process. Ultraviolet photo-oxidation creates free radicals that start a chain reaction, which can progress quite rapidly, causing rapid deterioration of mechanical properties. Degradation is often steeply graded from the exposed surface as the result of oxygen diffusion limited reaction. Photostabilizers are available and can produce spectacular improvements in polymer lifetime under UV exposure. The degradation products are often prodegradants and this places restrictions on the recyclability. Testing for photodegradability usually involves accelerated laboratory conditioning and this is difficult to calibrate against natural conditions to produce lifetime prediction.

Chemical Department, Nizhny Novgorod State University, Nizhny Novgorod, Russia

INTRODUCTION

Since the appearance of the integrated circuit, photolithography (or photoresist technology) has been the main locomotive of economic and technological progress in the manufacturing of microelectronics devices. The ability of production of numerous copies of a circuit on a single silicon wafer in the batch-like technology has enabled the industry's exponential growth and the paramount improvement of the circuits. Gordon E. Moore[1] has made an observation that circuit densities of semiconductors had doubled every year for the past three decades and would continue to do so. Later, he revised his annual rate of circuit density doubling upward and has stated that every 18 months density-doubling is more suitable rate.

Photolithography can be defined as a method for transferring a desired pattern into a photosensitive material called photoresist, which having been placed on the top of the device layer, is able to change its chemical properties under the UV light exposure. Usually a photoresist contains a solvent, photosensitive chemicals (PAC), and a polymer binder. By changing the chemical properties of the photoresist in the exposed areas (it becomes either less resistant in the case of a positive photoresist or more resistant in the case of a negative photoresist against an etching procedure called development), it becomes possible to provide a prerequisite for a photoresist mask formation. Finally, regions of the substrate unprotected by photoresist are etched away; when the remaining photoresist is stripped away, the device layer becomes patterned as desired. Over the past 50 years, chemists have been able to provide a wide variety of photoresists to meet the constantly growing needs of microelectronics. The choice of materials to be utilized as components of photoresists and determination of the optimal parameters of their use in photolithography assumes thorough knowledge of the corresponding chemical mechanisms of the relief formation process. The trend in microelectronics toward printing features 0.20 μm and below has motivated researches to find new principles of the photoresist formulating, or to repair the old ones to be involved in the lithography at the 193-nm wavelength of argon fluoride excimer lasers, or even further at 157 nm and below. The chemical amplification and top-surface imaging concepts seem to be the most productive among the principles that have recently been developed. It is believed that they will be the grounds for the future levels of the technology.

Chemical nature of photoresists, the chemistries involved in the photolithography, the properties of photoresists are briefly described. The discussion includes diazonaphthoquinone/novolac positive photoresists, polymer-aromatic diazide negative photoresists, photopolymerizable compositions, chalcogenide glass using systems, chemically amplified photoresists, and photoresists with an image formation in a thin layer.

GENERAL SCHEME OF PHOTOLITHOGRAPHY

The photolithography usually consists of the following obligatory steps (see Fig. 1):

- *Wafer surface priming*. A surface treatment with a primer drives off moisture and improves adhesion of a photoresist. Typically, a wafer is heated in the presence of chemical vapor of the primer. Hexamethyldisilazane seems to be one of the best primers.
- *Coating of the wafer with a photoresist*. A small amount of the photoresist is dropped onto the center of the wafer and then spun at high speed to produce a uniform thin film.
- *Prebaking of the photoresist layer*. After the photoresist being coated on the wafer, a solvent should be driven off by a prebake.
- *Exposure of the photosensitive article*. The exposure step photographically transfers a pattern from a reticle or photomask to the photoresist coated on the wafer surface. Photomasks are glass plates with patterns made of opaque and transparent areas. A photomask will typically have the pattern for a few dice and will be stepped across the wafer exposing the pattern after each step. In order to ease a task of a photomask fabrication and make the process less defect sensitive, photomask patterns are either 5× or 4×, the size of the desired feature on the wafer, and the photomask pattern is optically shrunk before reaching the wafer.

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120006819

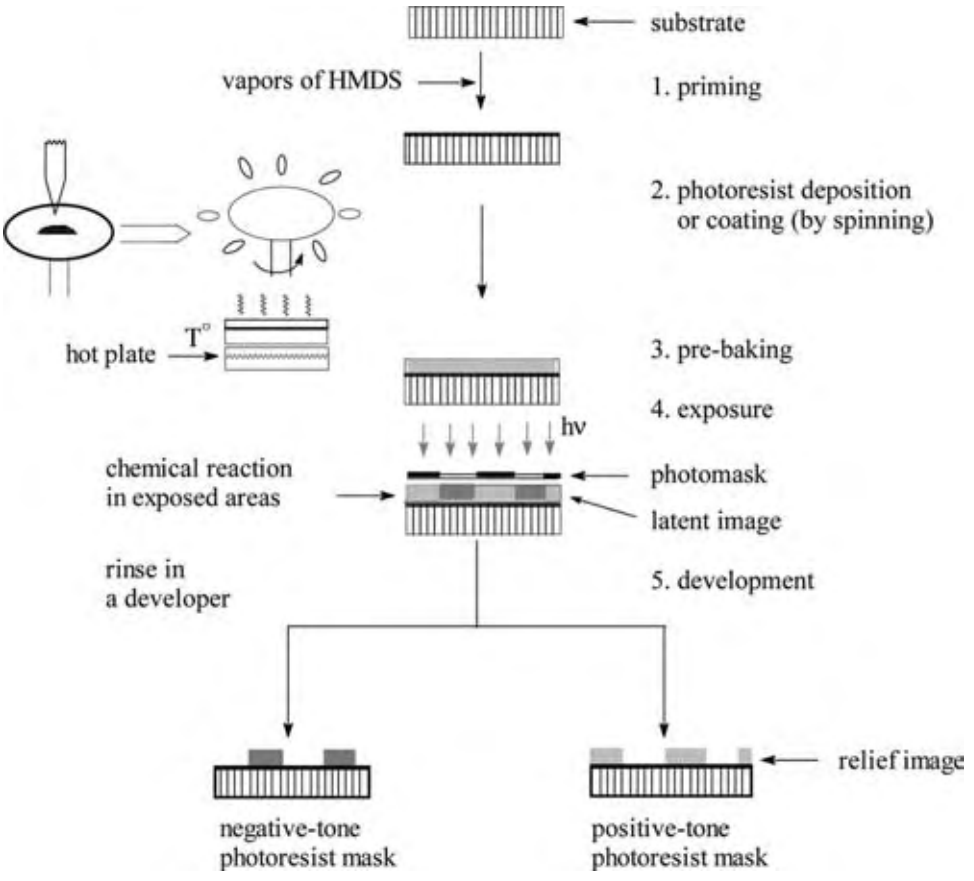

Fig. 1 Schematic presentation of a commonly used photolithography process. *(View this art in color at www.dekker.com.)*

- *Postexposure bake of the wafer*. A postexposure bake (PEB) improves contrast of the photoresist before its development. The PEB process causes three effects:[2] 1) diffusion of the PAC; 2) solvent evaporation; and 3) thermally induced chemical reactions. In general, the dissolution rate of a resist decreases as a function of a PEB temperature. PEB becomes more important for the photoresists with a chemical amplification (CA) feature. The photoresists need the PEB to complete chemical reactions initiated by exposure.
- *Development of a relief image in the photosensitive layer of a photoresist*. A development of a relief image in the photosensitive layer of the photoresist is the central step of a photolithography. The step suggests an implementation of physical and chemical procedures to use differences in properties of the exposed and unexposed parts of the photoresist for selective removal of only one type (i.e., either exposed or unexposed) of them and hence to produce a relief image in the photoresist. At the end of the development, the pattern from the reticle is replicated in the photoresist and a photoresist mask is formed.
- *Postbaking of a photoresist mask*. Postexposure high temperature bakes are used to stabilize the film prior to subsequent processing.

A photoresist mask formed by a photolithography is used to realize selective processing, for example, etching of a substrate through windows opened in the photoresist. After etching, the photoresist mask has to be stripped off and the wafer should be sent for further processing.

The most critical and expensive step of photolithography is an exposure. A typical exposure system consists of three main components: 1) a source of light at a particular wavelength; 2) a reticle photomask used as a master copy of the desired pattern through which the light is passed to transfer the pattern onto a photoresist-coated wafer sometimes by means of 3) projection optics. In early lithography systems, the photomask was placed directly on the wafer and illuminated by a lamp to expose the photoresist in a process known as contact printing. However, this process was not suitable for a batch production because the photomask gained distortions as a result of direct contact with the wafer. Later, the photomask was lifted just above

the wafer during exposure, in a method known as proximity printing. Proximity and contact printing transfer the photomask feature size to the wafer in a 1 : 1 fashion. In projection printing, the photomask pattern is demagnified as being transferred to the wafer. Projection optics is required to project a reduced image of the photomask onto the photoresist. Projection printing is the modern industry standard and promises to be the standard for at least in the nearest future.[3] Projection optics give rise to diffraction effects which in turn limit resolution, or minimum printable feature size of the lithography tool. Resolution obeys the Raleigh equation:

$$R = \frac{k_1 \lambda}{\mathrm{NA}} \tag{1}$$

where R is a resolution of projection optics used, λ the illumination wavelength, NA the numerical aperture of the final lens element, and k_1 a lithography level parameter, which effectively captures information about every other aspect of the lithography system. Usually k_1 belongs to the range 0.5–1.0. In the case of the standard process with a single-layer positive resist $k_1 = 0.8$; the use of modern techniques (such as multilayer resists, contrast-enhancing methods, top-imaging technologies, etc.) makes it possible to reach the limiting value of 0.5.

Next important characteristic of a projection lithography is the depth of focus (DOF) defined as a range over which the wafer can be moved along the optical axis in such a way that the image stays in focus:

$$\mathrm{DOF} = \frac{k_2 \lambda}{\mathrm{NA}^2} \tag{2}$$

where k_2 is a constant, which depends upon properties of projection optics, and has maximum value of 2 in the case of the idealized optics.

Usually, manufacturers of the projection optics for steppers destined for manufacturing of VLSI try to use the optics having minimal NA.

PHOTORESISTS, THEIR LITHOGRAPHIC PROPERTIES, CLASSIFICATION, AND MECHANISMS TO PRODUCE A RELIEF IMAGE

Lithography Properties of Photoresists

Photoresists can be characterized by several parameters such as sensitivity, resolution, contrast, etch resistance, etc.

Sensitivity

Sensitivity, S, to the UV radiation seems to be one of the most important properties of a photoresist. The value can be defined as dose (or exposure) of the UV light necessary to turn a photoresist into either insoluble (negative photoresist) or soluble (positive photoresist) compound.

The given definition is somewhat uncertain. Fig. 2 shows the dependence of thickness of a photoresist exposed by various UV light doses and developed by rinsing into a developer. There are three values that could characterize an exposure curve: $S_{\min}$, $S_{0.5}$, and $S_{1.0}$. These values of doses correspond, respectively, to the beginning of the relief image formation (frequently named as the critical or minimum dose), to obtaining of a photoresist mask with thickness being a half of that for a starting photoresist, and to reproducing thickness of the photoresist completely. They all are useful for photoresist characterization.

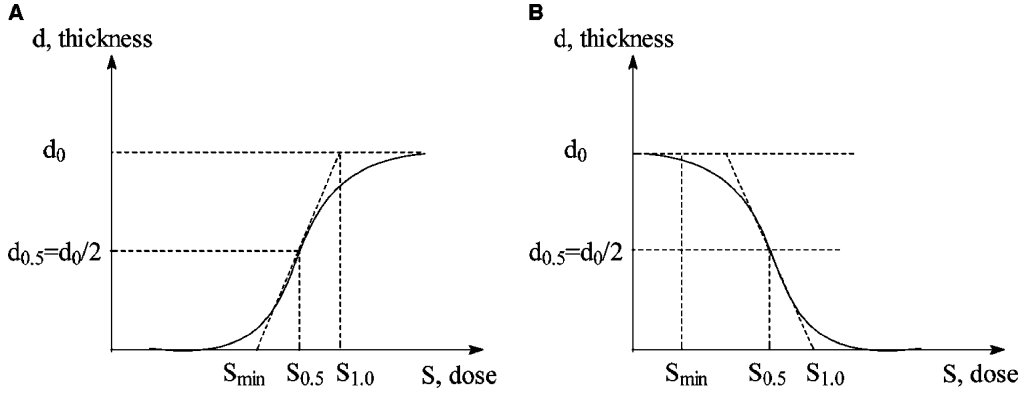

Fig. 2 Typical exposure or characteristical curves. d_0 is the maximum thickness of a resist layer: (A) a negative tone photoresist; (B) a positive tone photoresist.

Resolution

Resolution can be defined as the minimal or critical dimension (CD) of a photoresist mask element that is possible to develop. Sometimes resolution is considered to be a number of lines and intervals of equal width placed within an interval of 1 mm.

Contrast

Photoresist contrast, γ, is a measure of a resolving power of a photoresist. The photoresist should have high contrast to give high resolution, so that the UV light reflected from a substrate, or appeared because of diffraction effects during exposure should not influence upon a photoresist mask formation. The contrast correlates well with photoresist profile characteristics, but less so with CD reproduction.[4]

The measured contrast is a slope of a ''thickness obtained vs. dose exposed'' curve (characteristic curve). The theoretical value of contrast is the maximum slope of a plot of the logarithm of development rate vs. logarithm of exposure energy curve. Contrast can be determined as[5]

$$\gamma = \left| \log\left(\frac{S_{\min}}{S_{\max}}\right) \right|^{-1} \quad (3)$$

where $S_{\min}$ and $S_{\max}$ are doses corresponding to complete removal of the photoresist and to formation of areas with maximum thickness, respectively.

Etch resistance

A photoresist mask formed after development stage serves often as a mask for etching of a substrate. Resistance of the mask against the etchant of the substrate seems to be one of the main functional characteristics of the photoresist. The resistance can be measured as a time interval during which the photoresist mask withstands the etchant action, i.e., from the moment of the etching beginning up to the moment of appearance of such defects as partial destruction, undercutting, local point-like etching of the photoresist layer, etc. Etch-resistance can be written as

$$K = \frac{\nu_{\text{sub}}}{\nu_{\text{res}}} = \frac{h}{x} \quad (4)$$

where ν_{sub} and ν_{res} are rates of etching of a substrate and of a resist mask, respectively, and h is depth of the substrate etching, and x is width of side-etching of the resist mask.

Last two decades were period of a transition from a liquid toward dry etching. That is why plasma resistance is among the most important properties of a photoresist. In the case of fluorine-containing plasmas, etch resistance is defined as a ratio of the resist mask etching rate to the rate of SiO_2 etching. When a polymer substrate is to be etched, it is possible to use a ratio of the rate of the resist mask etching to the rate of polystyrene etching.

It is well known[6] that insertion of silicon-containing groups into a polymer enhances its plasma resistance greatly. The rate of a reactive ion etching in oxygen (RIE in O_2) in the stationary state, P, is proportional to the ratio of the silicon atom mass densities in the polymer, $\rho_{\text{pol.}}$, and in SiO_2, ρ_{oxide}:[7]

$$P = P_0 \frac{\rho_{\text{oxide}}}{\rho_{\text{polym.}}} \quad (5)$$

where P_0 is a rate of sputtering of SiO_2 being etched in RIE in O_2. Irrespective of the etch technology used, all polymers are etched with a constant rate after the starting transitional period. The difference between contents of silicon in the exposed and unexposed areas of the photoresist has to be not less than 10^{15}–10^{16} atoms per 1 cm^2 to ensure a successful RIE in O_2.[8]

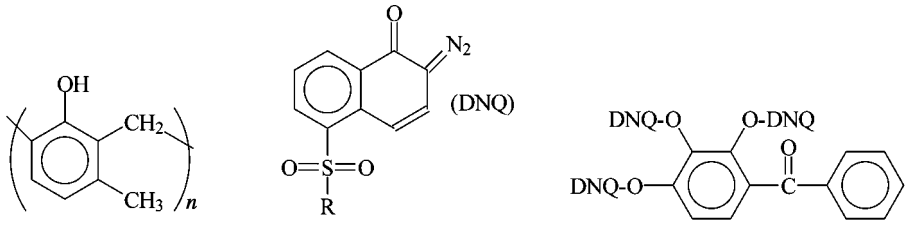
Many attempts have been made to find correlations between etch resistance of a polymer and its chemical nature. The thumb rule advices to use aromatic groups incorporated into a polymer to enhance etch resistance. However, about 20 years ago it was found[9] that aromatic rings were not strictly needed to improve polymer etch resistance. It was the carbon-to-hydrogen atoms ratio for a polymer that was related to its resistance in oxygen plasma. An increase in the ratio tends to produce a decreased rate of the RIE in O_2.

Application of a photoresist in a given technological process often imposes additional demands. It is extremely important to point out that choice of a photoresist should be dictated by a concrete technology.

Mechanisms of Relief Images Formation in Positive Photoresists

Diazidonaphthoquinone-containing photoresists

The diazido-*ortho*-naphthoquinone/novolac (DNQ/novolac) photoresists have been the workhorse for the semiconductor industry for over 30 years and still continue to be the most widely used photoresists today.[10] They may be utilized with different exposure wavelength technologies: I-line (365 nm), G-line (436 nm), and even 248 nm. Although productivity requirements for the technology with 248 nm exposure have demanded the transfer to photoresists with a chemical amplification, the DNQ–novolac resists still remain to be the most widely used and constantly finding new areas of implementation. The modern state-of-the-art in the microdevices technology gives an opportunity to use the DNQ–novolac resists to print features as small as 0.25 μm.[10] In addition, these photoresists in the form



1 **2** **3**

of thick film materials are used in the manufacture of thin film magnetic heads, micromachines, etc.

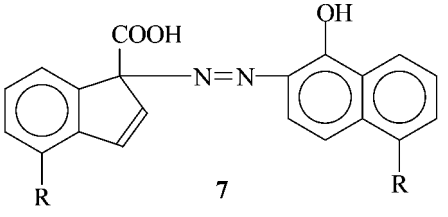
A DNQ–novolac photoresist usually consists of a novolac polymer and diazido-*ortho*-naphthoquinone [2-diazo-1(2H) -naphthalenone-5-sulfonate] derivative. Photoresist films are cast from solutions in organic solvents (such as propylene glycol monomethyl ether acetate). The polymer provides the desired physical characteristics of the material, such as good adhesion, film forming ability, and resistance to a plasma etching. Commercial photoresists contain a complex mixture of *meta*- and *para*-cresols having molecular weight of 960–2400 and 5–15 wt.% of DNQ.[11]

Pure novolac polymer **1** is dissolved in an aqueous base. An addition of DNQ **2** to the novolac leads to reduction of the dissolution rate of the polymer in the aqueous base, relative to the dissolution rate of the pure polymer. This difference can be of several orders of magnitude.[11] One of the reasons is that DNQ-fragment is hydrophobic by its nature. The second reason is that DNQ-fragments can and do form hydrogen bonds between nitrogen atoms of the diazo-group and hydrogen atoms of hydroxyl groups of the novolac molecules.[12,13] Although bond energies of the hydrogen bonds are not large and being of 10–12 kcal/mol, they are strong enough to inhibit a penetration of water molecules into the photoresist films. The hydrogen bonds formed between different novolac macromolecules serve as intermolecular physical cross-links.[12,13] Their importance to inhibit dissolution is supported by an observation that only use of PACs having not less than two DNQ groups (as it has place in the most frequently used DNQ-derivative **3**) makes it possible to inhibit the dissolution completely.[11]

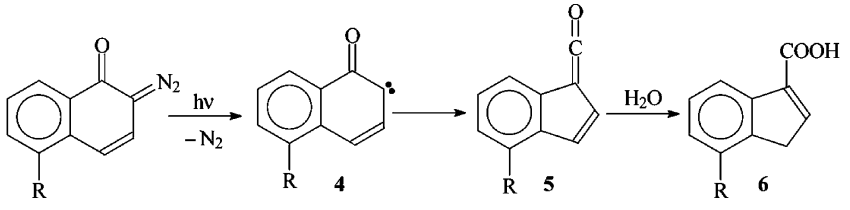
The UV light decomposes DNQ groups; the overall reaction scheme is shown here.[11,14]

Photolysis of the DNQ gives carbene **4** and molecular nitrogen; the carbene then rearranges into ketene **5**. The ketene is very reactive and interacts with trace amounts of water (constantly occurring in a novolac polymer) and produces indene carboxylic acid **6**. Besides, decomposition of DNQ leads to breaking of hydrogen bonds between DNQ and novolac macromolecules. In addition, gaseous nitrogen is evolved and produces microchannels in bulk photoresist. And at last, the acid formed is hydrophilic in contrast to the initial DNQ moieties being hydrophobic. All this promotes water molecules penetration into the exposed areas of the photoresist, and finally, the exposed areas become soluble in the aqueous base. It is this change in the dissolution rate of the photoresist, which allows for the formation of relief images in the positive photoresists, comprising of DNQ derivatives and novolac. Nowadays, aqueous solution of 0.26 N tetramethylammonium hydroxide is more frequently used as a developer.[11]

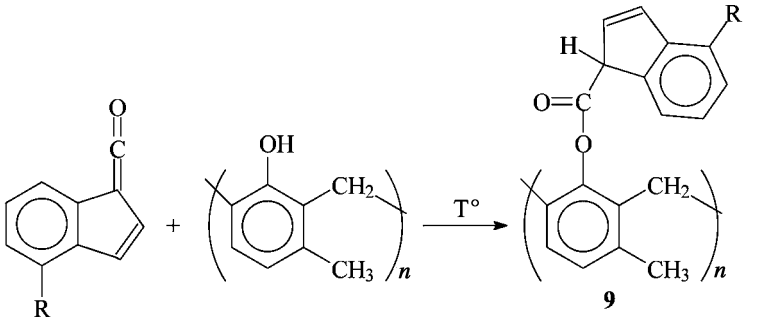
Ketene **5** can react not only with water but also take part in intermolecular dimerizations with unreacted DNQ derivatives, decarboxylation, and decarbonylation. In particular, coupling of DNQ and ketene or indene carboxylic acid gives rise to dye **7**.



7

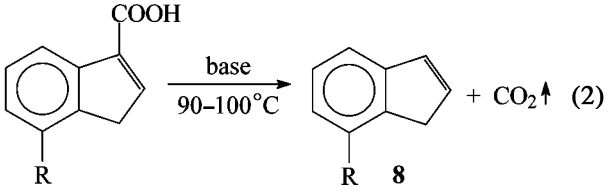


(1)



(3)

The presence of a base in the photoresist causes decarboxylation of the indene carboxylic acid.



(2)

Sometimes, the last reaction is used to obtain a negative-tone resist mask by means of the DNQ–novolac positive photoresist.[14] Imidazole, triethanol amine, and other bases can be used as tone-modifiers.

Ketene formed after exposure can react with novolac macromolecules, especially when water molecules are completely absent. The result of such interactions is crosslinking of novolac macromolecules.

Mechanisms of the Relief Images Formation in the Negative Photoresists

The most wide use in industry have been received by negative photoresists based upon 1) crosslinking of macromolecules by means of low molecular weight photosensitive bifunctional compounds; 2) photopolymerization; and 3) photochemically induced diffusion of metal atoms into chalcogenide glasses.

Negative photoresists possess very important advantages. They have

1. Large technological ranges of acceptable processing parameters; insensitivity to over development.
2. Good adhesion and wet etching resistance.
3. An ability to ''self-proximity corrections,'' i.e., unexposed areas can be ''recovered'' up to the desire dimensions, as a result of under etching in the course of subsequent isotropic wet etching.
4. A wider choice of components of the photoresist compositions and solvents to be used as developers.

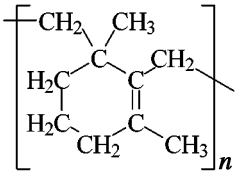
Unfortunately, the negative photoresists have some drawbacks:

1. Resolution is limited by the photoresist film thickness. A rule of thumb exists that typical CD of a photoresist mask obtained after development may be estimated as thrice of photoresist film thickness.
2. The relief formation in negative photoresists is very much inhibited by oxygen.
3. It is difficult to use them for the ''lift-off'' photolithography.

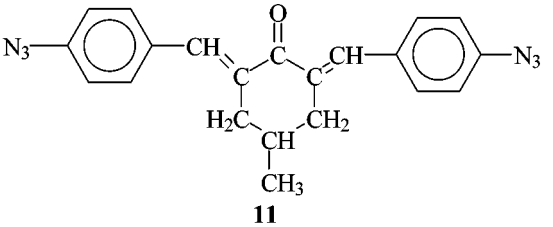
Crosslinking of polymers by diazides and related compounds

The most widespread photoresists of negative tone consist of organic polymers and aromatic diazides dissolved in an organic solvent. In 1970–1980, the photoresists were based on cyclized rubber **10** and 2,6-di (4′-azidobenzylidene) -4-methylcyclohexanone **11**.[14,15]

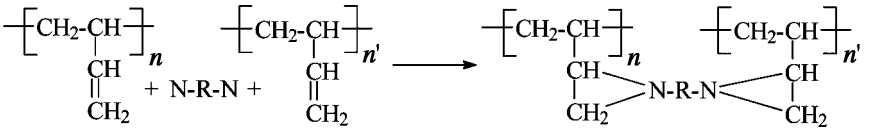
The relief formation in the photoresists can be presented by the following scheme. The diazide eliminates



10



11



(5)

nitrogen and turn into nitrene:

$$N_3\text{-R-}N_3 \xrightarrow[-2N_2]{h\nu} \bullet\dot{N}\text{-R-}\dot{N}\bullet \qquad (4)$$

The nitrene reacts with double bonds containing in polymer to produce ''diaziridine bridges'' or crosslinks.

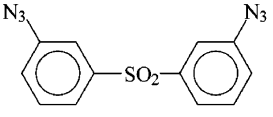
If there are no double bonds in polymer, then insertion of dinitrene into C–H bonds will have place.

Two crosslinks per macromolecule are needed to make a polymer insoluble. Quantum yield of a diazide photolysis is ca. 0.5, therefore, the critical dose of the photochemical polymer insolubilization should be about $50\,mJ/cm^2$.

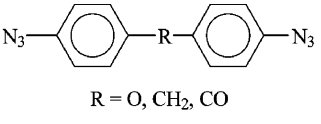
Oxygen usually inhibits the crosslink formation by trapping nitrene molecules to transform them into nitroso- or/and nitrocompounds.[14,16]

$$4N\text{-R-}N + 3O_2 \longrightarrow 2N\text{-R-NO} + 2N\text{-R-}NO_2 \qquad (7)$$

Photoresists, using cyclized rubber as a polymer and an aromatic diazide as a photoinitiator, swell strongly during development and have a very low contrast ($\gamma = 0.5$). Phenol- and cresolformaldehyde resins are frequently used as polymers and ''white azides'' as photosensitive components to avoid the last shortcoming. These azides **12** and **13** absorb at shorter wavelengths than the commonly used azide **11**.



12



R = O, CH_2, CO

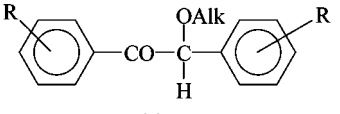
13

Absorbance of the photoresist is high (backscattering is absent), and a developer can underetch photoresist mask edges near a substrate. The latter gives a possibility to obtain the relief having high contrast and resolution. The underetching can produce images having a profile suitable for the ''lift-off'' lithography, but very rigorous control of the processing variable is desirable to produce such a profile.

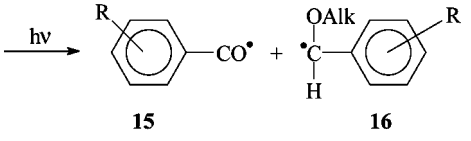
Photopolymerization

Photopolymerizable compositions have found their use in the production of thick (5–100 μm) relief images, especially in the field of printed plates and micromachinery. The compositions contain a monomer, matrix polymer (binder), and photoinitiator. The branched monomers are used most frequently. Many photosensitive compounds generating radical and ion centers upon UV irradiation are used as a part of the compositions. Polymethylmethacrylate and its derivatives are very often used as polymer binders.

The key component of a photopolymerizable composition is a photoinitiator. This compound can absorb UV radiation and then produce a pair of radicals, either by dissociation (a photoinitiator of the I type)[17]



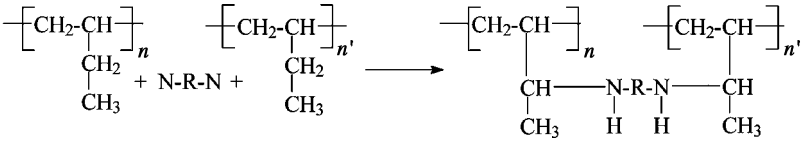
14



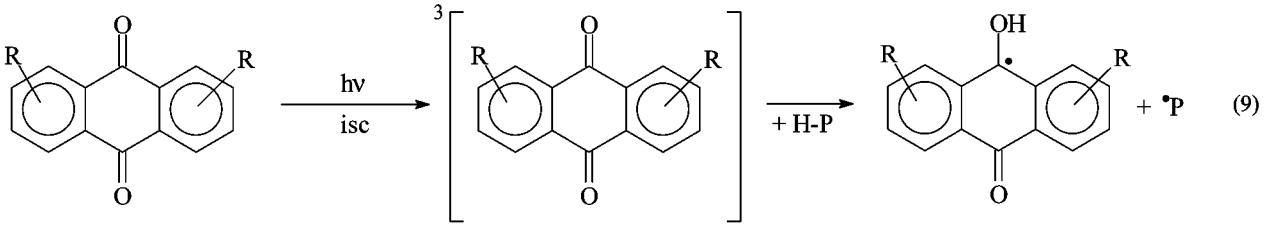
(8)

15 **16**

or by hydrogen atom abstraction (a photoinitiator of the II type).[17]



(6)



In the first case, the dissociation products **15** and **16** serve as centers initiating polymerization of monomers. In the second case, the II-type initiator absorbs the UV light and transfers into the singlet excited state and then, after intersystem crossing the molecule is converted into the triplet state **18**. The triplet molecule reacts with a hydrogen atom donor H–P to give ketyl radicals **19** and •P. The radicals initiate a polymerization process.

In general case

$$RM^{\bullet} + nM \longrightarrow R(M)_nM^{\bullet} \quad (11)$$

(the chain forming process)

$$R(M)_n^{\bullet} + R(M)_k^{\bullet} \longrightarrow R(M)_{n+k}R \quad (12)$$

(the terminating step)

The photopolymerizable composition can be used both as liquids to coat a substrate with light sensitive films and as dry photoresist films. In the latter case, the photoresist is a trilayer pie consisting of a top layer made of poly(ethylene terephthalate), a middle layer being the photopolymerizable composition, and an underlayer made of polyethylene. The underlayer is removed before exposure and the remained bilayer composite is laminated onto a clean substrate. The article is prebake to anneal a polymer layer and to enhance adhesion to the substrate. The selective exposure by the UV light through the top layer hardens the exposed areas of the photoresist. After exposure, the top layer is removed and the photoresist layer developed by rinsing into a developer solvent (trichloroethylene or the like).

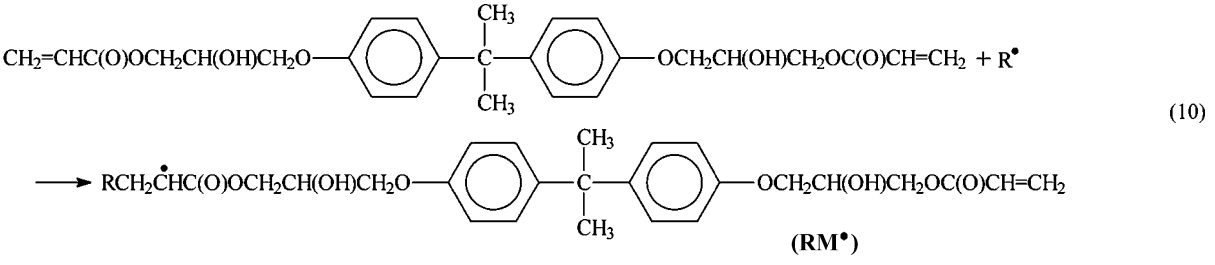
Among the most important advantages of the dry film photoresist are 1) easy coating; 2) convenience in processing; 3) processing stability; and 4) insensitivity to oxygen exposure. The dry film photoresist took their niche in the photoresist technologies of the electronics components not requiring high resolution.

Chalcogenide glasses

Inorganic photoresists constitute a new promising class of the photosensitive materials.[18–20]

The materials consist of an underlayer made of a chalcogenide glass such as As_2S_3, As_2Se_3, Ge–Se, etc. and a top thin layer of silver or its halogenide (AgCl). The UV light liberates silver atoms that diffuse into As_2S_3 layer (up to 10 nm depth) and produce alloys resistant to etching (this phenomenon is called as ''photodoping''). The UV light absorption is limited to a thin layer (because of very high absorbance of metal containing compositions), so high resolution may be obtained. Unfortunately, the UV light sensitivity of the resists is very low when liquid development is used. It can be enhanced tremendously (up to 50 mJ/cm^2) when etching in fluorine-containing plasmas is used.

For instance, Ge–Se composition deposited by CVD and doped by Ag has photosensitivity at wavelengths ranging from 200 to 450 nm. Upon exposure by the light Ag_2Se is formed as a result of photo initiated diffusion. Ag_2Se can be removed by treatment in an aqueous solution of KI. After the removal of the surplus



amount of silver the latent image is developed by plasma etching in SF_6 or freon gases.

The inorganic photoresists possesses some advantages:

1. They have very high contrast (up to 8) because of the contrast enhancement phenomena observed in the photoresists.[14,19,20]
2. The photoresists have very strong absorption even for thin films. The latter gives a possibility to use the photoresists as thin top layers in the bilayer photoresist systems.
3. The relief masks formed from the photoresists have very high resistance in oxygen plasma. This enables a use of the Ag/chalcogenide layer as a top layer in bilayer photoresists with high resolution and aspect ratio. The under layer of the photoresist is usually made of polymer such as polyimide.

The phenomenon of the contrast enhancement is caused by side-directed diffusion of silver atoms into the exposed areas because of the decrease of chemical potential in the areas. Silver atoms diffusion from the unexposed areas into the exposed ones compensates the influence of diffraction effects. As a result of diffusion, resolution may be considerably improved.

The use of inorganic photoresists should be advantageous for the technological processes because inorganic films can be deposited very homogeneously by a CVD procedure.

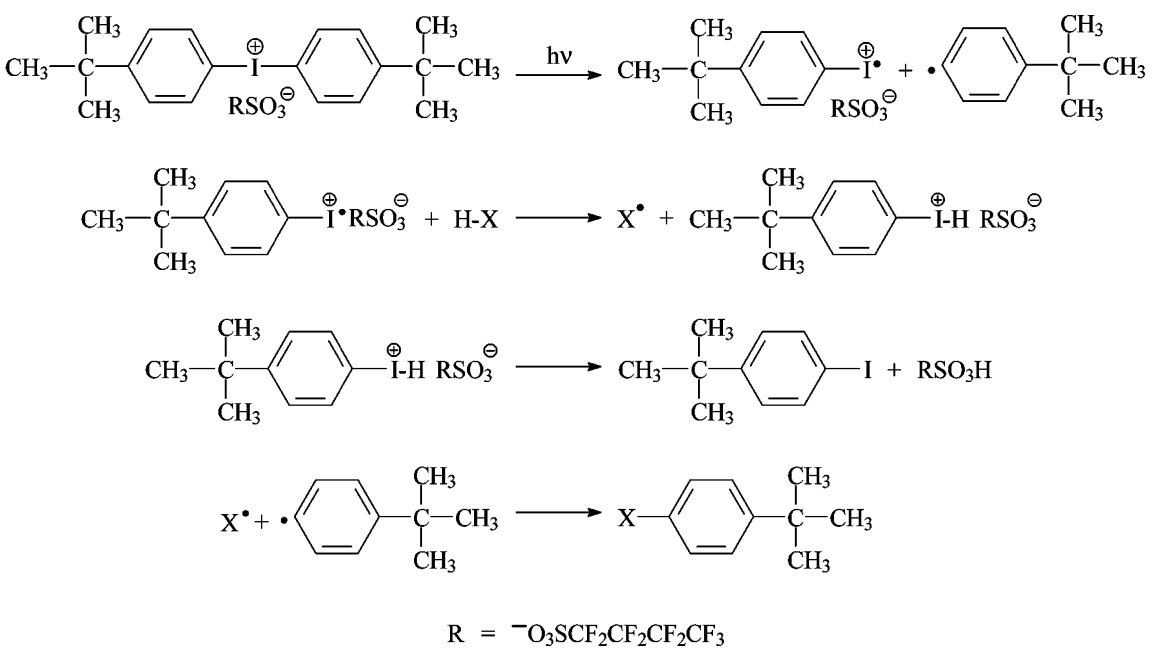
Chemically Amplified Photoresists

In 1979, Frechet and Willson put forward a very productive idea of a chemical amplification that was used in the development of a new generation of photoresists.[21] They decided to use a photoresist comprising of a photochemical acid generator (PAG) and a polymer that was able to switch from hydrophobic to hydrophilic in the course of acid catalyzed hydrolysis. The PAG reacts with light to produce an acid catalyst. During a subsequent postexposure bake, the catalyst diffuses and reacts with the polymer component, causing many reaction events in the polymer and recovers the acid catalyst. The acid molecules catalyze the deprotection reaction and provide a prerequisite for chemical amplification. The number of the reaction events initiated by single quantum absorption has been estimated to be of order of 100.[22]

The following reaction scheme can present a simplified mechanism occurring in the photoresists with chemical amplification chemistry.[21,23]

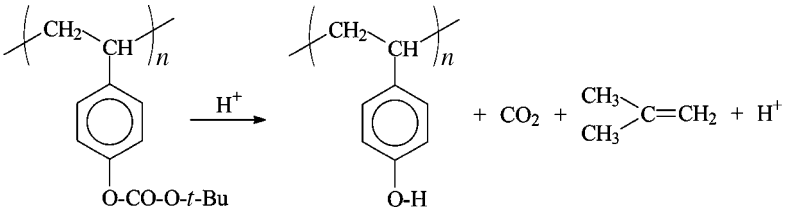
The photoresists are widely used in 248 and 193 nm photolithography and are generally considered as the most probable candidates for the next generation of photoresists with fine and ultra fine resolution.[21]

The problems met by chemically amplified photoresists are: a) poor stability to environmental contaminations such as airborne amines; b) sensitivity of lithographic parameters to PEB temperature variations; c) poor stability during storage both after coating and after exposure; d) side-directed diffusion



(13)

$R = {}^{-}O_3SCF_2CF_2CF_2CF_3$



(14)

of PAG causing broadening of formed lines; and e) formation of ''T'' shape profile.

The striking effect of airborne contaminations on the performance of the poly(4-*tert*-butoxycarbonyloxy styrene)/onium salt system has been demonstrated.[24] The effect can be observed when the coated wafers stand for 16 min in air containing only 15 ppb of an organic base. The cause of the effect is that the photogenerated acid can be neutralized by organic base.

Careful carbon filtration of the clean-room air has been used to remove airborne contamination effects.[24–26] To reduce the photolithographic performance parameters dependence upon the PEB temperature, it has been proposed[27] that the incorporating of the protecting hydrophility blocking groups having low activation energy for acid catalyzed hydrolysis (deblocking) should be used.

The most serious drawback of the chemically amplified resists is a considerable broadening of formed lines during PEB. Umbach et al. has shown that a thin (ca. 2 nm) electron beam exposure resulted in a ca. 40 nm feature with poly(4-*tert*-butoxycarbonyloxy styrene).[28] The high catalytic chain length also suggests that acid may migrate into areas that are unexposed. The side-directed acid diffusion is a reason of an image blur, line width altering, and so on. The problem can find its solving by using a base along with the polymer and PAG used. The base addition decreases side broadening, but it consumes some amount of the generated acid and the latter reduces both resolution and sensitivity of the photoresists.[29,30]

The chemical amplification idea appeared when it was necessary to develop photoresist material having high sensitivity, high resolution, and good plasma etch resistance. It was desirable primarily when the 248 nm exposure became the requirement of the industry. And the result of implementation of the idea was very good. Chemical amplification as a basic ideology of the photoresist creation partly worked at the 193 nm millstone.[21]

Photoresists with Thin Layer Imaging

The second productive idea useful in designing of modern photoresists is based upon ''thin film imaging'' (TFI).[31] The thin uppermost layer of a photoresist forms an image, which serves as a mask to transfer the pattern into the lower layers, to form an etch mask by means of the RIE in O_2. As thickness of the upper layer may be very low (of ca. 20–100 nm), the image in it can possess very high resolution. The RIE being anisotropic (i.e., the side etching is much slower than the in-depth one), permits to obtain high aspect ratio, and the pattern is transferred with high precision.

There are several realizations of the idea: bilayer lithographic processes, top-surface imaging through vapor phase silylation, digital top-surface imaging using vapor phase silylation, and imaging by means of selective graft-polymerization.

Bilayer lithographic processes

The TFI idea has found its application in developing of multilayer resists long ago. Later, the idea was used in the bilayer photoresists consisting of a thin silicon containing photosensitive imaging layer situated on the top of a crosslinked underlayer. After the UV exposure, and subsequent development the image formed in the upper layer is transferred (usually by means of RIE) into the underlayer. The remaining areas of the silicon-containing layer are oxidized by oxygen plasma to form plasma resistant oxide, which protects underlying material, while the unmasked areas of the underlayers are etched away. A simplified processing scheme of the processes using the bilayer photoresists is shown in Fig. 3 (the left-side scheme).

A modification of the bilayer photoresist processing is shown on the right side of Fig. 3. The scheme presents so-called ''Si-CARL'' (silicon chemical amplification of resist lines) process.[32] In the Si-CARL process, the upper layer is photosensitive, but does not contain silicon in its composition. In a typical process,[32] an anhydrade-containing photoresist thin imaging layer is selectively exposed by the UV light and then developed and exposed to a silylated agent. Silicon is incorporated into the remaining photoresist by use of amino-containing siloxanes, which react chemically with the anhidride functions and creates a silicon-containing skin on the surface of the image elements in the upper layer.

Disadvantage of both the processes shown in Fig. 3 lies in their complexity. Among their advantages are 1) good etch resistance of the photoresist masks

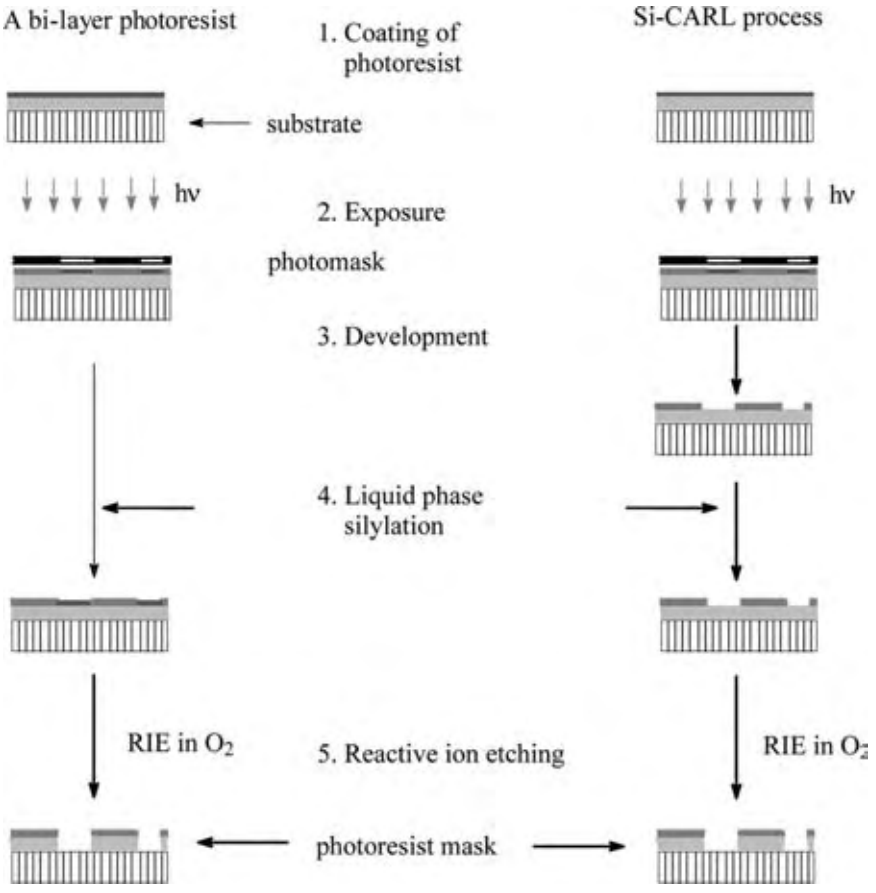


Fig. 3 Processing scheme of lithography with bilayer (left) and Si-CARL (right) photoresist. *(View this art in color at www.dekker.com.)*

coupled with high sensitivity of the upper photosensitive layer; 2) high aspect ratio of the masks formed; (3) the depth of focus for the photoresists is extremely large; and (4) the processes are simpler and cheaper than the trilayer photoresist technologies.

Top-surface imaging through vapor phase silylation

The complexity of the processes using the bilayer photoresists was reduced in single-layer photoresists working on the basis of the TFI idea. Diffusion enhanced silylated resist (DESIRE)-,[33,34] positive resist image by dry etching process (PRIME)-,[35,36] SUPER-,[37] and SAHR-technologies[38] use top-surface imaging of photoresists through their vapor phase silylation. Although the processes have been developed for the 365 or 248 nm lithography, there exist their modifications to work at shorter wavelengths.[39,40]

The DESIRE lithographic process is shown in Fig. 4. A DNQ/novolac photoresist is coated on a wafer (substrate). Exposure to the UV light causes the DNQ decomposition to give indene carboxylic acid. After the photoresist baked in vacuum at high temperature to form unstable ketene and the reaction of the ketene with phenolic group on the novolac resin, the unexposed regions of the photoresist become crosslinked. As a result, considerable difference in penetration of small molecules into the exposed and unexposed areas of the photoresist upper layer appears. The photoresist is then exposed to vapors of a reactive silylating agent (usually aminosilane). The compound permeates into the exposed regions of the upper layer (about 20–100 nm depth) of the photoresist, but not into the unexposed regions. The silylation agent reacts with free phenolic functions and transforms novolac macromolecules into silicon-containing ones. The silylated regions may then serve as etch masks in the course of subsequent RIE in O_2.

The most important advantages of the DESIRE photoresist technology are

- Greater simplicity of the process as compared to other TFI-technologies.
- Good compromise between high sensitivity of DNQ/novolac systems and high resolution obtained because of small thickness of the imaging layer and large anisotropy of RIE.
- Insensitivity to topology created on the substrate (absence of light scattering from a relief created on the substrate).
- Larger depth of focus.

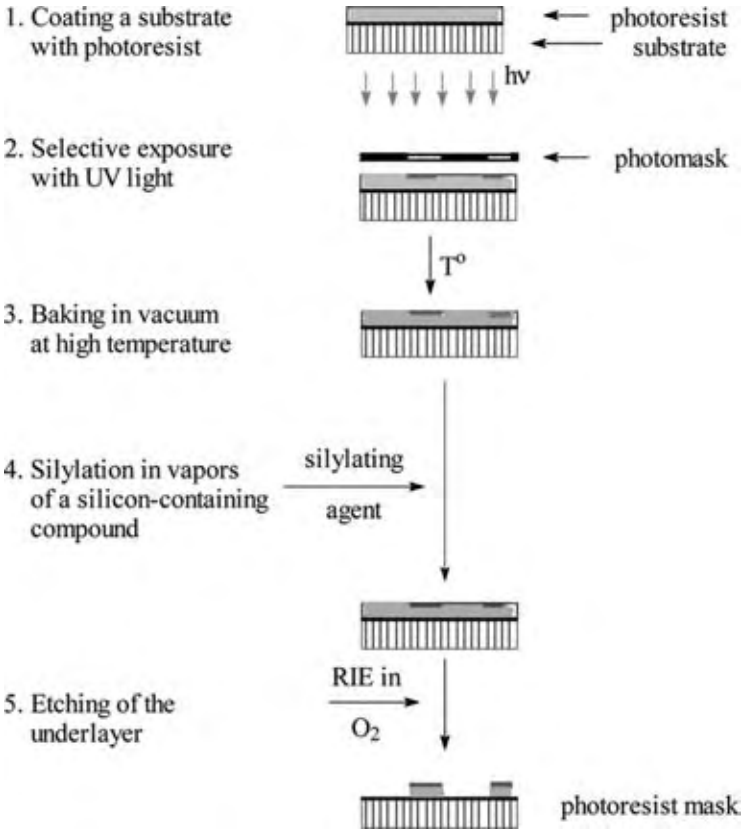

Fig. 4 Processing scheme for the DESIRE technology. *(View this art in color at www.dekker.com.)*

The main drawbacks of the DESIRE technology are the following points:

- "Skin" formation because of the silylating agent penetration not only into exposed, but unexposed regions.
- A "grass" formation (residues in open areas) caused by sputtering of silicon from silylated areas and transferring of it onto the open areas.
- Modified methods of cleanup and stripping of the photoresist mask is to be developed.
- The silylation should be controlled carefully because of cracking occurring when the content of silicon atoms incorporated into the photoresist is large enough and of not sufficient plasma resistance against RIE in O_2, when silylation process is stopped earlier than it should be.

It is possible to decrease the influence of "skin" or "grass" formation by etching away a top thin layer (ca. 20–30 nm), using halogen-containing plasma, just before the RIE in O_2.

A positive photoresist technology using polyvinylphenol layer as a photoresist and dimethylsilyldiamine as a silylating agent for 193 nm exposures has been developed.[39,41] The silicon atoms concentration in silylated regions with the said silylating agent in liquid phase is two times higher than that for the vapor phase silylation.[41] Resolution obtained by both methods is about 0.18 μm.[40,41] Diffusion rates correlate with the molar volume of the silylating agent, although the activation energy does not.[42]

The most frequently used silylation agents are hexamethyldisilazane, trimethylsilyldimethylamine, trimethylsilyldiethylamine, dimethylsilyldimethylamine, 1,1,4,4-tetramethyl-1,4-bis(*N*,*N*-dimethylamino)diethylene, and 1,1,3,3,5,5-hexamethylcyclotrisilazane.[29]

The PRIME technology being a variant of the DESIRE technology gives an opportunity to form openings down to 0.3 μm using the 248 nm exposure wavelength and hexamethyldisilazane as a silylating agent.[36]

Thus, the DESIRE technology gave a great impulse for penetration of the TFI idea into microdevice industry. It is not of large complexity, quite successful in implementation. The potential of the method does not seem to be used completely.

Digital top-surface imaging using a vapor phase silylation

A combination of the TFI and chemical amplification ideas leads to development of a new promising method

called ''digital top-surface imaging using a vapor phase silylation'' (DTSI).[43,44] The DTSI method was created to enhance the difference in reactivity toward a silylating agent between exposed and unexposed areas in the DESIRE technology. A photoresist in the DTSI technology contains poly(4-*tert*-butoxycarbonyloxystyrene) and PAG. After exposure by the UV light of the upper layer of the photoresist, a subsequent thermal treatment, exposure of the wafer to a silylating agent and RIE in O_2 good quality photoresist masks were formed.

The described photoresist technology is not greatly complicated when compared with the DESIRE technology, but it should and does possess a greater difference of the silicon atom components of exposed and unexposed areas of the photoresist, i.e., leads to better contrast and has improved production stability.

Both the DESIRE and DTSI processes might be good decisions for modern technology, but closely related with either DNQ/novolac or chemically amplified resists. The limited choice of materials to be used as the photoresist component and ''skin'' formation is the main drawbacks of the DTSI technology. The problems arisen could be party solved by the TFI approach realization in the form of the selective surface graft-polymerization.

Imaging by means of selective graft-polymerization

The idea being a basis for the method is simply to use a radical or ion latent image formed after selective exposure of a photosensitive layer to initiate graft-polymerization of monomers containing silicon and/or of improved plasma etch resistance.[45–52] The graft-polymerization has place on the interface between photoresist and silylating agent, or just nearby. Sometimes, the process is fast enough and produces a good conformal mask to etch the bulk photoresist by RIE in O_2. The processing scheme of the graft-polymerization lithography is shown in Fig. 5.

There exist several realizations of the graft-polymerization lithography (GPL).

Photolithography on the basis of the cationic graft-polymerization[46] uses an inert polymer film containing a PAQ coated onto a wafer. Exposing the photoresist to the UV radiation generates acid on its surface, to which a vapor-phase silicon-containing monomer is grafted. RIE in O_2 is used as a final step.[50,53,54]

One of the drawbacks of the method is inability to use metal-containing PAQ, such as $Ph_3S^+SbF_6^-$ or the like. There is no good substitution for the hexafluorometal-containing PAQ, but triphenylsulfonium-tris(trifluoromethylsulfonyl) methide. Most disadvantages caused by chemical amplification and postexposure heating have resulted in the widening of the large opening.

Another type of lithography uses a radical graft-polymerization.[55–58] In typical realization,[55] a negative resist structure can be created by applying a photoresist containing polyvinylacetate or poly(*iso*-butylene). A pattern-like exposure under the UV radiation creates radical centers. Exposure of the radical centers to oxygen converts them into peroxide or hydroperoxide groups. Subsequent thermally decomposing of the groups in presence of the silicon-containing

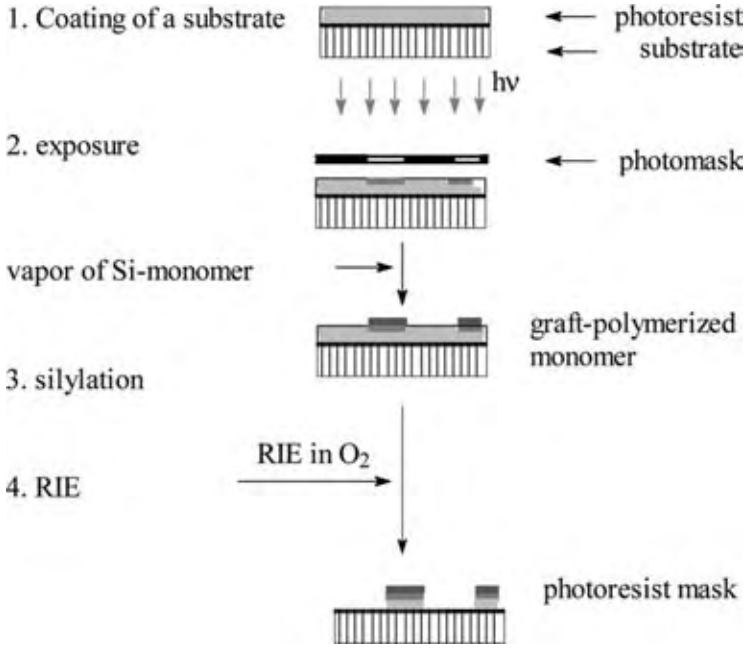

Fig. 5 Technology scheme of the photoresist technology using selective graft-polymerization. *(View this art in color at www.dekker.com.)*

monomer vapor and RIE in O_2, finishes the mask production process. The grafting monomer may be chosen from a wide class of silicon-containing monomers, such as vinyltrimethylsilane, γ-methacryloxyloxypropyltrimethoxysilane, etc.

The method described above serves as a prototype to create a universal imaging method, which will be in use to develop a new photoresist generation. Too high complexity of the method and not effective graft-polymerization of monomers from gas phase are among the main drawbacks of it.

To improve effectiveness of graft-polymerization and to decrease complexity of the lithography method, it is advantageous to use liquid or solid-phase polymerization strategies. One of the solving is to deposit a silicon-containing monomer onto a selectively exposed photoresist and then to heat it. The monomers will polymerize and an excess of them can be removed from the photoresist. The mask obtained can be used for the RIE in O_2.[52]

In conclusion, it should be stated that the TFI idea and the graft-polymerization imaging can be most desirable in the 193 and 157 nm technologies, and certainly will serve a prototype of a future photoresist.[59]

MODELING OR SIMULATING IN THE PHOTORESIST TECHNOLOGY

The photoresist technologies involve many steps; each can be characterized by many parameters. It is very difficult to optimize the processes. Previously used pilot experiments now proved to be very costly and difficult. It is not possible to optimize all parameters by performing large series of the lithography experiments, at all possible sets of the parameters. The problem may be simplified and sometimes completely solved by means of mathematical modeling and simulation.[60,61] Photoresist technology simulation provides the opportunity to perform experiments in a virtual environment that can be much faster and cheaper than the full-scale wafer experiments.

The process simulator PROLITH[62] is used to simulate a photolithography process and create a library of the input-technological parameters–profile relations. These profiles are then used to generate simulated diffraction responses, resulting in a library of diffraction-response-technological parameters–profile inter-relations.

There are some advantages provided by accurate simulation tools. They are not very expensive, not much time-consuming, and the ''experiments'' can be performed at more rich set of technological parameters, than the one usually being used for optimization, by means of the real experiments performing.

Today, software packages permitting to model an exposure step rigorously do exist, but the photochemical reaction steps and especially development step are still problems for theoretical description, and consequently a more primitive model must be used for their simulation. There seems to exist a good compromise suggesting strict descriptions of the exposure step (mainly by means of geometrical optics) and photochemical reactions (it is believed that the photochemical kinetics equations often permit to find their solutions or provide a ''constructive method'' of creating approximations in form of functional series[63]), and use semiempirical relations to describe development and plasma etching steps. The need for such an approach has been stated by the 2001 International Semiconductor Roadmap document that says ''there is a growing need to resist studies based on computational molecular modeling'' of the photoresist technologies.[3]

The further detail concerning the mathematical modeling of photoresist technologies may be found in literature.[64–68]

CONCLUSIONS

Photoresist technology is a novel technology of the 21st century. It finds more and more different applications in many fields of science and industry. The foremost of the technologies will be those using the thin film imaging idea.

The following textbooks and article can be useful for further reading on photoresists and their technology: Refs.[10,11,14,15,17,21,26,30,31,42,43,46,49,50,59].

Photovoltaic Materials

Richard Corkish
ARC Centre of Excellence for Advanced Silicon Photovoltaics and Photonics, University of New South Wales, Sydney, New South Wales, Australia

INTRODUCTION

Photovoltaic materials are photoconductive semiconductors able to absorb energy from photons (wave packets of light) to release electrons and holes (negative and positive charge carriers) from their host atoms and separate the different types of charge carriers. The energy quantum required to release an electron is termed the *bandgap* of the material and is in the range of 0.5–2 eV for commercially important solar cell materials. Freed electrons and the holes, which are essentially vacancies from which electrons have been excited, are mobile within the material and their motion is influenced by electric fields and diffusion. Photovoltaic cells contain some asymmetry that forces electrons and holes toward negative and positive contacts, respectively. That asymmetry is commonly a p–n junction, being the interface of p-type material that is doped with impurity atoms having a deficit of electrons relative to the host material and n-type material that is doped with atoms having an excess of electrons relative to the host. Hence, cells produce voltage and current (power) under illumination.

This entry gives a brief historical overview and discussion of relevant material properties, followed by a survey of the methods currently used to produce solar cell materials, with an emphasis on silicon.

HISTORY OF PHOTOVOLTAIC MATERIALS

A very large number of materials[1] have been discovered to be photovoltaically active since Alexandre–Edmond Becquerel noted the photoelectrochemical production of electricity from light.[2] Platinum, brass, or silver electrodes were inserted in a liquid electrolyte, one electrode was illuminated and current between the electrodes was observed with a galvanometer. The effect was (transiently) enhanced by coating the illuminated electrode with a semiconductor, such as copper oxide or silver halide. This discovery is generally acknowledged as the beginning of photovoltaics, although it would instead be termed photoelectrochemistry today. It was not until 1914 that a photoelectric, rather than entirely chemical, interpretation was made.

Selenium was discovered in 1876 to exhibit the photovoltaic effect in the solid state.[3] It was rediscovered more than once in Europe and in the United States until the 1930s and 1940s, by which time there were several companies manufacturing selenium photovoltaic cells as light sensors for photography and industrial applications. Selenium devices were then in competition with copper–cuprous oxide (Cu–Cu_2O) heterojunctions, in which the photovoltaic effect had been discovered in 1917.[1] The late 1920s and early 1930s was a time of intense activity and competition in the development of cuprous oxide rectifiers and photovoltaic cells. Commercial devices were produced from 1930 but were eventually surpassed by improved selenium devices in that decade.

Photovoltages have been identified in a range of other materials, including Ag_2S, MoS_2, Tl_2S, Ag_2S, Pb_2S, Ag_3AsS_3, Ag_5SbS_4, CdS, a range of BiI_3–PbI_2 alloys, and germanium.[1] However, these were unimportant, relative to selenium and cuprous oxide, and all were surpassed by the discovery of the effect in silicon in the 1940s.

Russel Ohl of Bell Laboratories discovered and filed patents in 1941 that were granted in 1946 and 1948[4] for the p–n junction photovoltaic effect in silicon. The early devices contained rectifying junctions that were accidentally formed by segregation of dopant impurities during cooling.

MATERIAL ISSUES FOR PHOTOVOLTAICS

Bandgap is a fundamental material property for photovoltaics. The bandgap restricts the range of wavelengths of light that can be absorbed by the material and limits the voltage it may produce. To a first approximation, only photons with energy in excess of the bandgap may be absorbed to produce electron–hole pairs, while the material is transparent to lower energy photons and each photon can produce only a single electron–hole pair, even those that carry much more than the bandgap energy. Hence, there is an optimization to maximize output power: A lower bandgap will allow the useful absorption of more photons and production of more current but the voltage will tend to be low. The optimum bandgap for reception of

Encyclopedia of Chemical Processing DOI: 10.1081/E-ECHP-120007896

the solar spectrum has been calculated to be in the range 1–1.5 eV.

Between the stages of initial creation of an electron–hole pair from absorption of a photon and eventual collection of the charge carriers at the contacts, the carriers are vulnerable to being lost through recombination. Recombination is encouraged by defects within the material, such as defects in crystal structure and impurities and by surfaces. Electrically active impurities and defects introduce allowed energy states into the otherwise forbidden bandgap energy range for charge carriers. Surfaces need to be passivated to reduce their impact on performance, for example, by thermally grown silicon dioxide on the surfaces of silicon cells.

Other important properties for photovoltaic materials are their refractive index, stability, brittleness, toxicity, crystal lattice constant, thermal expansion coefficient, temperatures required for processing into cells, energy investment for cell production, ability to be doped both types, level of technological knowledge and industrial maturity, cost, and abundance. Issues particular to passivation and the trapping of weakly absorbed light include the availability of compatible and affordable passivation and surface texturing methods.[5]

GROUP IV MATERIALS

Silicon is by far the most important semiconductor for electronics and photovoltaics since the 1960s and for the foreseeable future. It is used in many forms, with monocrystalline and multicrystalline (MC) self-supporting silicon wafers being dominant but also in the forms of deposited thin-films in amorphous or crystalline form. The structure of one commercially important crystalline silicon cell technology is shown in Fig. 1.

Metallurgical Grade Silicon

Silicon is produced in large quantities as metallurgical grade (MG) material for use in the metals and chemicals industries and some is further refined to produce ultrapure electronics grade (EG) silicon. MG silicon is made from lumps of quartz (10–100 mm) and carbon in the form of MG coal, woodchips, charcoal, or coke.[6] They are mixed and heated by an electric arc between carbon electrodes and the furnace body. The reduction of quartz to silicon proceeds according to the (principal) reaction,

$$SiO_2 + 2C \rightarrow Si\ (liquid) + 2CO\ (gas)$$

Additional, incidental reactions are discussed by Ceccaroli and Lohne.[6] The liquid crude silicon has 1–3% impurities, principally aluminum, calcium, iron, titanium, and carbon.

Features include surface texturing for light trapping, diffusions front and rear and the front current grid buried in laser grooves. (Courtesy of UNSW Centre for Photovoltaic Engineering Image Library.)

Oxidizing gas and slag-forming materials, such as silica (SiO_2) sand, lime (CaO), limestone ($CaCO_3$), dolomite (CaO–MgO), or calcium fluoride (CaF_2) are added to the still-molten raw silicon in a refinement step. Less noble elements than silicon are oxidized and dissolved in the slag, which is removed. To avoid excessive heat losses, some of the silica can be provided directly by oxidation of some of the silicon melt instead of sand. Carbon is removed from the melt in the form of SiC precipitates.

The silicon is solidified in a mold, forming MC blocks with impurities congregating at grain boundaries. The blocks are then crushed into pieces up to 100 mm in size and the ''fines,'' which are both inconvenient for most subsequent processes and contaminated by impurities, are removed. An alternative process is to use granulation in water to avoid casting and crushing.

Semiconductor Grade Polycrystalline Silicon

Aside from experimental and developing processes,[7] there are three competing commercial processes for further refining metallurgical silicon into semiconductor grade polycrystalline silicon (polysilicon):[6,8] Siemens, Union Carbide Chemicals, and Ethyl Corporation methods. This industry exists primarily to support the electronics industry.

In the energy intensive Siemens process (Fig. 2), MG silicon and hydrochloric acid are combined in a

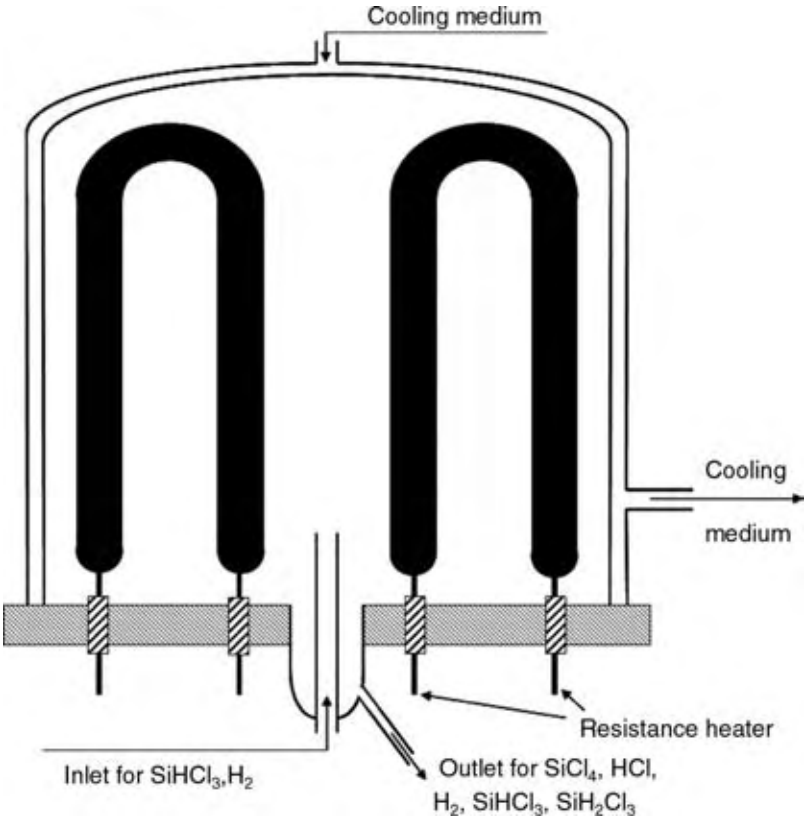

Fig. 2 Schematic of Siemens bell-jar reactor. (From Ref.[6].)

fluidized bed reactor to produce volatile trichlorosilane:

$$Si\ (solid) + 3HCl \rightarrow HSiCl_3 + H_2$$

Competing reactions result in other silanes, including $SiCl_4$, SiH_4, and SiH_2Cl_2, which are removed by fractional distillation in two stages.

The pure trichlorosilane is vaporized, mixed with hydrogen, decomposed into silicon seed rods, and heated to 1100°C. Deposition occurs on multiple inverted-U seed rods under steel bell jars (Fig. 2), cooled to avoid deposition on the inner surface. The main reactions are

$$2SiHCl_3 \rightarrow SiH_2Cl_2 + SiCl_4$$
$$SiH_2Cl_2 \rightarrow Si + 2HCl$$
$$H_2 + 2SiHCl_3 \rightarrow Si + 3HCl$$
$$HCl + SiHCl_3 \rightarrow SiCl_4 + H_2$$

Unfortunately, more of the source silicon results in $SiCl_4$ byproduct than in deposited polysilicon. The market for alternative uses for $SiCl_4$ has not kept up with polysilicon production rates, hence recycling into $SiHCl_3$ is now preferred.

One company is modifying the final polysilicon deposition step in the Siemens process.[7] The new method uses a graphite pipe heated to 1500°C, beyond the melting point of silicon. Liquid silicon precipitates from liquid trichlorosilane poured over the graphite and drips and hardens into granules. Another is reported to be trialing an alternative method to produce tiny polysilicon granules by blowing trichlorosilane into a fluidized bed reactor.[7]

The Union Carbide process for trichlorosilane production is an alternative. Tetrachlorosilane is hydrogenated through a bed of granular MG silicon, using one of the reactions commonly used for the recycling of the byproduct $SiCl_4$ in the Siemens process:

$$3SiCl_4 + 2H_2 + Si \rightarrow 4SiHCl_3$$

The trichlorosilane is separated by distillation from unreacted tetrachlorosilane, which is returned to the reactor. The trichlorosilane is then passed through quaternary ammonium ion exchange resins that catalyze the following two reactions,

$$2SiHCl_3 \rightarrow SiH_2Cl_2 + SiCl_4$$
$$3SiH_2Cl_2 \rightarrow SiH_4 + 2SiHCl_3$$

The monosilane, SiH_4, is distilled and pyrolyzed to deposit polysilicon on heated silicon seed rods in a metal bell jar,

$$SiH_4 \rightarrow 2H_2 + Si$$

and the $SiCl_4$ and $SiHCl_3$ are recycled to the earlier steps described above. The practices of recycling the byproducts and distilling each time results in a very high purity output and reduced input requirements, because the hydrogen and chlorine are both recycled.

The third commercial process for production of polysilicon was developed by the Ethyl Corporation. In this case, the raw material is not MG silicon but silicon fluoride, a waste product from fertilizer manufacture, which is reacted with lithium aluminum hydride or sodium aluminum hydride, with saleable byproduct of lithium aluminum fluoride or sodium aluminum fluoride,

$$SiF_4 + AlXH_4 \rightarrow SiH_4 + AlXF_4$$

where X is either Li or Na. The monosilane is pyrolized to polysilicon as above except that instead of a bell jar, the seed crystals are granules in a fluidized bed. A company is reported to be about to start production of granular polysilicon, especially for the photovoltaics market, from SiH_4 using fluidized bed reactors.[7] Another company instead, intends to precipitate silicon from silane onto hollow silicon cylinders at 800°C.

Other recent developments include one that avoids the conventional path of chemical purification of MG silicon, but uses a metallurgical refining step instead.[7] This process is claimed to be less reliant on capital and to reduce the energy requirement by 20% compared to the Siemens process. An experimental, two-stage carbothermic process is at the stage of pilot production and is under consideration.[7] Silicon carbide is made from quartz and carbon black powder in a plasma furnace. Then, the silicon carbide is converted to silicon in an electric arc furnace and the silicon is purified to remove residual carbon. The intention is to use high purity starting materials and thereby avoid one purification step altogether. Ceccaroli and Lohne[6] list a large number of alternative processes that have been or are being explored with the aim of increasing throughput, reducing energy demand, reducing costs, and facilitating continuous rather than batch operation, relative to the current commercial processes for production of polysilicon.

Crystalline Silicon

Until 1998, the silicon photovoltaics industry was able to rely on off-specification EG material, including rejects from polysilicon manufacture (material from aborted processes, faulty seeds, ends of seed rods close to the carbon contacts, fines and chips, dendritic growths, small granules, sawn sections of seed rods) and from crystal growth (heads and tails of monocrystalline boules, ingots from aborted processes, crucible leavings, pot scrap) that was effectively waste of the electronics industry. This amounted to 2000–3000 tons per year. However, the rapid growth of photovoltaics has resulted in demand exceeding that supply in recent years and shortages will occur until new capacity comes on line in 2006–2007.[7]

Purity requirements for silicon for solar cell manufacture are not as severe as for the electronics industry, with silicon with up to 4 ppm of carbon, 5 ppm of oxygen, 0.3 ppm of boron and 0.1 ppm of phosphorous, and metals having been used.[6] Carbon (Group IV) is an electrically neutral, substitutional impurity in silicon. It has smaller atoms and can be associated with species with larger lattice spacing, such as silicon dioxide. Oxygen, often originating from fused-quartz crucibles, is a common interstitial impurity. It is implicated in gradual degradation in silicon solar cells made from boron-doped (p-type) wafers.[9] The 3d transition metals, Sc, Ti, V, Cr, Mn, Fe, Co, Ni, and Cu are additional common interstitial impurities. They often form complexes at structural crystal defects.

We adopt Basore's nomenclature (Table 1) for different forms of crystalline silicon.[10]

Single Crystal Silicon

Single crystal silicon wafers currently satisfy a significant but declining fraction of the solar cell market (36.4% in 2002, 32.2% in 2003) although there are signs of a possible resurgence.[11] Relative to MC, monocrystalline wafers have the advantages that they were already produced for other markets and they allow higher efficiency cells. On the other hand, they require higher quality feedstock, tend to be more expensive, and are circular, leading to lower packing densities in photovoltaic modules unless they are cut into squares or pseudo-squares.

Wafers grown by the Czochralski process[12,13] dominate the monocrystalline fraction of the photovoltaic market. The process has a purifying effect with respect to several important metallic impurities, to the extent that even poor quality starting material can produce good solar cells. The polysilicon source material is melted in a crucible under vacuum or inert

Table 1 Nomenclature for crystalline silicon

Crystallinity	Symbol	Grain size range
Single crystal	sc-Si	>10 cm
Multicrystalline	mc-Si	1 mm–10 cm
Polycrystalline	pc-Si	1 μm–1 mm
Microcrystalline	μc-Si	<1 μm

(From Ref.[10].)

gas and a seed crystal is dipped into the melt and slowly withdrawn vertically and rotated so that the liquid crystallizes to the seed (Fig. 3). The melt temperature and pulling speed are controlled to ensure a constant diameter of the growing monocrystalline boule and low dislocation density. The normal crystal orientation is ⟨100⟩ because this allows dislocations, which propagate on oblique (111) planes, to rapidly ''grow out'' as the top neck is forming and permits the use of simple NaOH anisotropic etching methods on solar cells for surface texturing to aid light-trapping and reduce reflection.

Very pure, low-defect crystals are produced by the alternative float zone process[13] in which a cylindrical polysilicon rod has a seed crystal melted into its lower end with an encircling inductive heating coil. The heater is then raised along the rod length, entraining a molten zone and a monocrystalline solidified region below. Impurities have higher solubility in the molten silicon and are carried with it to the top. The process may be repeated to enhance the purity and crystallinity.

Multicrystalline Silicon

Multicrystalline silicon wafers, with crystal sizes in the range 1–100 mm,[10] are currently the main workhorse for the photovoltaics industry. Hydrogen passivation steps used in cell manufacture in recent years, particularly those involved in the deposition of silicon nitride layers on front surfaces, have reduced the impact of electrically active impurities and defects in MC-Si cells and reduced the performance deficit relative to monocrystalline cells.

Three main processes are in use to produce MC-Si ingots—tricrystalline growth, the Bridgeman, and block casting methods, with Bridgeman more common than the others.[14] The tricrystalline process[11] results in ingots consisting of just three grains with all boundaries perpendicular to the (110) plane meeting at the ingot axis. Growth is carried out similar to the Czochralski method described above but a tri-Si seed is used and faster growth is possible. The pulling axis is parallel to the ⟨110⟩ orientation of each grain, hence dislocations do not naturally grow out during the top neck formation. The resulting wafers have higher mechanical strength than other MC wafers, allowing thinner wafers to be used for a given yield.

The Bridgeman and block casting methods both produce ingots with weights 250–300 kg. In the Bridgeman process, a nitride-coated crucible containing the silicon source material is slowly moved downward through an inductive heating zone so that the silicon melts and then solidifies from the bottom. The upward vertical movement of the liquid–solid interface, known as directional solidification, results in large columnar grains. The purpose of the nitride crucible coating is to allow slippage of the silicon as it expands and contracts.

In the block casting process, source silicon is melted in a first quartz crucible and poured into a second, nitride-coated crucible. Heaters are used to control cooling to produce columnar grains. Relative to Bridgeman, faster solidification is possible but at the expense of smaller grains.

The detrimental effects of grain boundaries on cell performance depend on their density and on their electrical activity, which depends on their decoration

with impurities, particularly transition metals. Defects with more impurities facilitate additional recombination of charge carriers, which should be minimized for good cell performance. Keeping the liquid–solid interface planar has been shown to reduce grain boundary activity. Dislocations within crystal grains are also effective in reducing cell efficiency and these are reduced by limiting temperature inhomogeneities during cooling. Oxygen is incorporated into the ingot from the quartz crucible. Carbon from graphite heaters reacts with SiO to produce CO, which leads to carbon impurity incorporation in ingots, especially in the upper region. Excessive carbon can lead to SiC needles short circuiting the p–n junction in a cell. Crystallization is deliberately managed to segregate active metallic impurities into the top portion of an ingot, which is rejected.

Standard MC silicon is boron (p-type) doped to a concentration around $2 \times 10^{16}\,\mathrm{cm}^{-3}$, yielding electrical resistivity around 0.1–5 Ωcm. The doping is achieved by adding B_2O_3 to the raw silicon before melting. n-Type regions are produced during subsequent cell manufacture by diffusion of phosphorous, either by bubbling nitrogen carrier gas through $POCl_3$ and injecting into a quartz furnace or by phosphorous-containing pastes if a belt furnace is used.[14]
